8. Reconstruction of the pericardium should be considered to reduce adhesions in cases where a future redo sternotomy is likely and is important when there is a risk of cardiac herniation after an intrapericardial pneumonectomy.

INTRODUCTION

The pericardium supports and protects the heart. The smooth pericardial surface and the small amount of normal pericardial fluid provide a frictionless chamber improving cardiac efficiency as well as serving as a barrier to infection. The pericardium can be susceptible to a variety of disease processes including inflammation, infection, malignancy, and trauma. Changes in compliance and the accumulation of 1 pericardial fluid can impair cardiac function, and the prompt recognition and treatment of cardiac tamponade can be lifesaving.

HISTORY

Hippocrates first described the pericardium in 460 BC. Three hundred years later, Galen described a pericardial effusion and the inflammatory changes associated with pericarditis. Lower first reported pericardial tamponade in humans in 1669. Lancisi and Morgagni described constrictive pericarditis, and Laennec wrote of the "bread-and-butter" appearance of acute pericarditis in 1819.[1] Kussmaul described the hemodynamic changes known as pulsus parodoxus, and Beck and Griswald performed experimental studies in the 1930s leading to a better understanding of the pathophysiology of pericardial effusion.[2,3] Karaeneff first described relieving the symptoms of tamponade using pericardiocentesis in 1840.[4] Rehn reported methods to resect the pericardium in 1913.[5]

EMBRYOLOGY AND ANATOMY

The pleuropericardial membranes fuse during the fifth week of gestation dividing the thoracic cavity into pleural and pericardial spaces and forming the fibrous pericardium.[6] The serous pericardium is a single layer of mesothelial cells that produce and reabsorb pericardial fluid. The serous and fibrous pericardium form the parietal pericardium which is normally 2 mm in thickness. The visceral pericardium covers the heart and the intrapericardial great vessels. The phrenic nerves are contained in the parietal pericardium, and there is a risk of diaphragmatic paralysis with any operation on the pericardium. The pericardial folds form the oblique sinus, a blind cul-de-sac behind the left atrium, and the transverse sinus between the aorta and pulmonary artery superiorly and the left and right atrium inferiorly (**Fig. 84.1**). Lymphatic drainage is to the bronchial and tracheal lymph nodes and the thoracic duct. The pericardium normally produces 15 to 50 mL of serous fluid with a protein level lower than plasma.[7]

NORMAL PHYSIOLOGY

Although there are no significant consequences of the congenital absence or surgical resection of the pericardium as long as the defect does not lead to cardiac herniation, the pericardium has some function in the normal patient. The pericardium anchors the heart and prevents torsion and acute distension.[8] The pericardium contributes to the diastolic coupling of the ventricles along the Starling curve. Mechanoreceptors in the pericardium may also regulate blood pressure and heart rate. The pericardium stretches up to 20% with small changes in pressure but becomes abruptly stiff and resistant with larger volumes. Compliance depends on the rate of fluid accumulation, and the hemodynamic response is also partially dependent on intravascular volume status.

The normal pericardial pressure is less than the atmospheric pressure and is the same as the intrapleural pressure. With inspiration, right-sided venous return and preload increases. Blood pools in the lungs and decreases left-sided venous return and aortic blood flow. The arterial pressure normally decreases less than 10 mm Hg with inspiration. The normal jugular waveforms are shown in **Figure 84.2**. The a wave is the normal atrial contraction. The c wave reflects the bulging of the atrioventricular valve into the atrium during isovolumic ventricular systole. The v wave represents passive atrial filling from the vena cava. The x descent occurs with systolic collapse during ventricular systole and atrial relaxation. The y descent reflects diastolic collapse with opening of the atrioventricular valve and passive ventricular filling. Inspiration decreases intrathoracic pressure and leads to a lower x descent compared to the y descent.

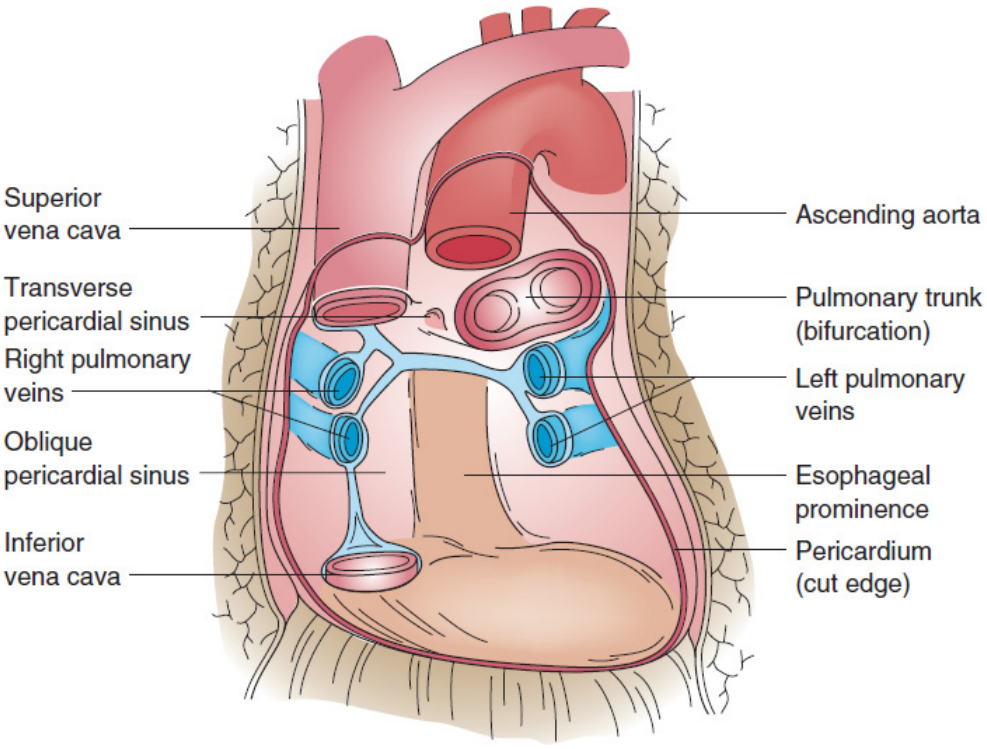

Figure 84.1 This drawing illustrates the pericardial attachments of the great vessels and pulmonary veins. The oblique sinus forms a blind cul-de-sac behind the left atrium, and the transverse sinus is a space between the aorta and pulmonary artery superiorly and the left and right atrium inferiorly.

DIAGNOSTIC STUDIES

While the electrocardiogram (EKG) is nonspecific, it can be helpful in suggesting the diagnosis. In acute pericarditis, the EKG classically shows diffuse ST elevations, and a low-voltage QRS is seen with a large pericardial effusion. The chest radiograph in a patient with a pericardial effusion shows an enlarged cardiac silhouette described as a water bottle. Pericardial calcification can be seen in chronic constrictive pericarditis secondary to tuberculosis.

2 The echocardiogram is the most useful noninvasive test in evaluating pericardial disease. The echocardiogram can identify an effusion, pericardial thickening, or masses. By using Doppler and assessing changes in chamber size, echocardiography is useful in assessing hemodynamics and can help differentiate tamponade, constriction, and restriction. It can also be used to help guide procedures like pericardiocentesis. Computed tomography (CT)

and magnetic resonance imaging (MRI) can identify pericardial masses and pericardial thickening or calcification.[9] Cardiac catheterization provides pressure tracings that help to distinguish cardiac tamponade, constriction, and restriction. Endomyocardial biopsy can also be useful in diagnosing restrictive cardiomyopathy.

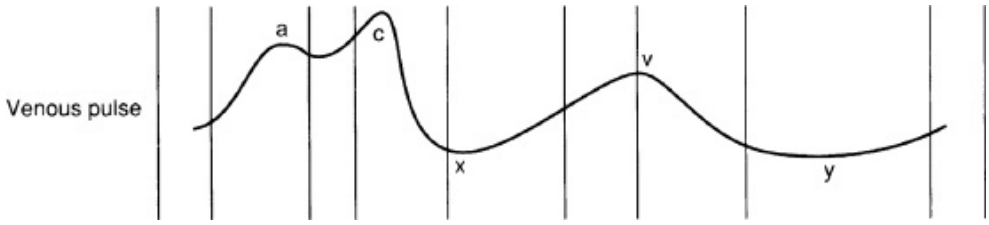

Figure 84.2 The jugular venous pulse waveform.

CONGENITAL ABNORMALITIES

Congenital absence of the pericardium is usually partial but can be complete. It is most common on the left side and is more frequent in males. Associated congenital cardiac defects include atrial septal defect, a bicuspid aortic valve, and pulmonary malformations. Defects on the right side can lead to cardiac herniation. Patients can present with chest pain, syncope, or death. The EKG can show a right bundle branch block. The pericardial defect can be appreciated on CT or MRI. The treatment of a partial defect is total pericardiectomy or patch closure with PTFE or bovine pericardium. Total pericardial absence is usually asymptomatic and is found incidentally.

Pericardial cysts are rare benign cysts that generally measure 1 to 15 cm in size. They are most commonly found at the right cardiophrenic angle and are asymptomatic. Patients may present with mediastinal compression and respiratory symptoms. The differential diagnosis includes a Morgagni hernia, lipoma, mediastinal tumor, or bronchogenic cyst. CT scans are used to confirm the location and relationship to surrounding structures. The cyst is excised if the patient is symptomatic, or the diagnosis is unclear.

ACUTE PERICARDITIS

Acute pericarditis is an inflammatory process that has involved the pericardium for less than 2 weeks (**Table 84.1**). Patients often present with a 3- to 7-day prodrome of low-grade fevers, malaise, and muscle aches. Acute pericarditis occurs in 5% of those who present to the emergency department with nonischemic chest pain[10] and in 1% of those with ST elevation.[11] It is important to distinguish pericarditis from the chest pain of an acute myocardial infarction. Acute pericarditis usually causes sharp, pleuritic pain that can last several days. The pain most commonly radiates to the trapezius ridge and is improved by leaning forward. Patients can present with shortness of breath, a nonproductive cough, and clear lung fields. The differential diagnosis also includes aortic dissection and pneumothorax. On physical examination, a friction rub may be heard and is sometimes intermittent. The classic friction rub has three components during systole, early diastolic filling, and atrial contraction.

3 The EKG is important in the diagnosis and classically shows diffuse ST elevations without Q waves or T-wave inversion. PR depression can also be seen. There is a four-stage progression in the changes seen on EKG with diffuse ST elevations followed by normalization of ST segments with flattening of T waves. The EKG then evolves with T-wave inversions prior to normalization of the EKG. Pericarditis and associated myocarditis can cause elevations in creatinine kinase and troponin I.[12] The minimal workup should include an EKG, complete blood count, cultures, chemistry profile, C-reactive protein, and antibody titers for collagen diseases.

ETIOLOGY

Table 84.1 Causes of Pericarditis
Idiopathic
Infectious
Neoplastic
Hemopericardium Blunt and penetrating trauma Postcardiac surgery Aortic dissection
Autoimmune and inflammatory Connective tissue disorders Postmyocardial infarction Medication induced
Miscellaneous Radiation induced Hypothyroidism Uremic

Idiopathic and Viral Pericarditis

Idiopathic causes of pericarditis are the second most common after neoplastic disease. The majority are likely viral although routine testing is not usually performed. A virus is only identified in 15% to 20% of cases with the most common being Coxsackievirus, echovirus, adenovirus, influenza, and cytomegalovirus. Patients present with chest pain, malaise, and fever, and often have an elevated erythrocyte sedimentation rate. The episode is self-limited in 70% to 90% of cases.[10] A systematic review of 30 studies showed that fever, a large effusion or tamponade, failure of nonsteroidal anti-inflammatory drugs (NSAIDs), and a subacute course were associated with a worse prognosis and the need for hospital admission.[13]

Initial treatment was traditionally NSAIDs with a 15% to 30% relapse rate.[10] However, a multicenter randomized trial showed that the addition of colchicine during initial treatment reduced the rate of persistent or recurrent pericarditis by approximately 50%.[14] Colchicine is now included as a class I recommendation in the European Society of Cardiology Guidelines for the diagnosis and management of pericardial diseases as first-line therapy for acute pericarditis combined with NSAIDs.[15] Recurrent pericarditis can be treated with a repeat course of NSAIDs, colchicine, or steroids, and specific causes such as autoimmune disorders should be investigated. There is also growing evidence including the randomized controlled Anakinra-Treatment of Recurrent Idiopathic Pericarditis, or AIRTRIP, trial supporting the use of IL-1 blockade in the treatment of recurrent pericarditis.[16] Pericardiectomy is recommended if the patient is unresponsive to medical treatment or constriction develops.

Acquired Immunodeficiency Syndrome

A pericardial effusion develops in up to 20% of patients with HIV and is usually a poor prognostic sign.[17] This may be partly due to a generalized capillary leak syndrome as well as increased cytokine expression seen in the more advanced stages of HIV. Other contributing factors include tubercular and mycobacterial infections, lymphoma, Kaposi's, or congestive heart failure. The majority are idiopathic and do not require further therapy if asymptomatic. Symptomatic effusions are drained.

Tuberculous Pericarditis

Tuberculous pericarditis occurs in 1% to 8% of patients.[18] In immunocompromised patients, infection by *Mycobacterium avium* or *Mycobacterium intracellulare* can lead to pericarditis. The incidence of tuberculous pericarditis has decreased although it continues to be a significant issue in immunocompromised patients, particularly HIV patients in Africa. Patients present with fever, night sweats, cough, dyspnea, and weight loss. While infection usually results from hematogenous spread, it can also extend directly from lymph nodes or through lymphatics. Pericardial changes occur in four stages including fibrinous, effusive, fibrous, and

constrictive fibrous stages. Making the diagnosis from pericardial fluid alone is rare. Pericardial biopsy with acid-fast staining provides the diagnosis 80% to 90% of the time. Treatment includes multidrug antitubercular therapy and pericardiocentesis. Steroids have not been shown to be beneficial for mortality or progression to constriction but leads to a faster resolution of symptoms and reaccumulation.[19] If patients present with late constriction, pericardiectomy may be required.

Purulent Pericarditis

Bacteria can be introduced into the pericardial space by direct injury, pneumonia, extension from head and neck infections, or hematogenous and lymphatic spread. Patients present with chest pain, fever, and leukocytosis. The most common organisms in adults are staphylococcus, pneumococcus, and streptococcus. Purulent pericarditis can evolve rapidly into tamponade and can be confused with septic shock. Fungal infections are less common, but immunocompromised patients and drug addicts are at greater risk. Pericardial fluid in purulent pericarditis has low glucose, high protein, and elevated LDH and neutrophils. An air–fluid level may be seen on chest radiograph with gas-producing organisms. Treatment includes antibiotics and drainage. Surgical drainage may be needed for thick fluid or refractory effusions. The prognosis for purulent pericarditis is poor with a survival of 30%.[10,20]

Uremic Pericarditis

Fifty percent of patients with untreated renal disease develop pericarditis. The incidence is decreased to approximately 20% in patients on hemodialysis. The exact cause is unknown but is not directly related to the BUN or creatinine. Other possible etiologies include hypercalcemia, viral infection, and autoimmune disease. Chest pain is usually less common, and the large effusions accumulate gradually. Treatment includes more intensive dialysis, NSAIDs, and steroids. The fluid is generally bloody and care should be taken in heparinizing these patients for dialysis. If patients develop tamponade or the effusion is unresponsive, pericardiocentesis or surgical drainage is performed.

Vasculitis, Connective Tissue Disease, and Drugs

Pericarditis can result from a variety of vasculitic and connective tissue diseases including rheumatoid arthritis, Wegener's granulomatosis, rheumatic fever, lupus, scleroderma, Reiter's syndrome, Behçet's disease, dermatomyositis, polyarteritis nodosa, dermatomyositis, sarcoidosis, and amyloidosis. Treatment includes management of the underlying disease process and NSAIDs. Pericardiocentesis is performed if necessary. Several medications can also lead to pericarditis including warfarin, hydralazine, isoniazid, procainamide, phenytoin, dantrolene, cromolyn, and methysergide.

Dressler and Postpericardiotomy Syndrome

Pericarditis can occur following acute myocardial infarction in 3% to 5% of patients.[21] Pericarditis can develop early in the first 1 to 3 days particularly with transmural infarction. Forty percent of large Q-wave infarctions cause pericardial inflammation although the incidence is decreasing with the use of thrombolytics and early revascularization. Patients are usually asymptomatic and are found to have a pericardial rub on examination although they can present with pleuritic chest pain. Treatment is usually with NSAIDs. Steroids can prevent conversion of infarcted myocardium to scar leading to greater thinning and risk of rupture.[22]

Patients can also present with pericarditis 1 week to a few months after a myocardial infarction with a friction rub, typical EKG changes, and chest pain although the incidence has decreased with increased revascularization. Pericardial inflammation is thought to be from an autoimmune reaction to myocardial cells. Similar symptoms can also occur after cardiac surgery, blunt trauma, and pacemaker placement. Patients can develop a pericardial effusion and even tamponade. Treatment includes NSAIDs and colchicine for 2 to 3 weeks and occasionally steroids. The syndrome is usually self-limited.

Radiation-Induced Pericarditis

Pericarditis can result from mediastinal and thoracic radiation for cancer including lymphoma and breast carcinoma, and is related to the dosage

delivered. With modern techniques, the incidence is 2% but can be as high as 20% if the entire pericardium is treated. Patients may develop chest pain and fever.[15] Symptoms are usually self-limited, and tamponade is rare. Delayed symptoms can develop years later and can result in pericardial constriction. Due to the history of malignancy, the etiology can be confused with a malignant effusion. If pericardial constriction develops, the treatment is pericardiectomy although the mortality is higher than for other etiologies.

PERICARDIAL EFFUSION AND TAMPONADE

Any of the etiologies mentioned above for pericarditis can also lead to a pericardial effusion. Other causes include blunt or penetrating trauma, retrograde bleeding from an aortic dissection, and a transudative effusion from congestive heart failure. Effusions due to a bacterial or fungal infection, HIV, or malignancy have a higher incidence of progressing to tamponade. Twenty percent of large symptomatic effusions of unknown cause are due to an undiagnosed cancer.[23]

Normally there is only a small reserve volume before pericardial fluid causes significant cardiac compression and prevents adequate 4 cardiac filling. The hemodynamic significance of a pericardial effusion depends on the volume and the rate of accumulation. The compensatory adrenergic response to a pericardial effusion leads to tachycardia and increased contractility, and patients on beta blockers are less likely to compensate. Tamponade usually occurs when filling pressures reach 15 to 20 mm Hg although tamponade can occur at lower pressures in conditions where blood volume is reduced including dialysis, with diuretic therapy, and bleeding. Cardiac pressures become elevated and are most closely equalized during inspiration. Tamponade generally affects right heart filling first which then leads to underfilling of the left heart.[24]

Patients may present with dyspnea, tachycardia, and diaphoresis. The three classic signs of Beck's triad are hypotension, jugular venous distension, and muffled heart sounds although each may be absent in patients with tamponade.[25] Symptoms can be confused with right heart failure and pulmonary embolus. The jugular waveform changes characteristically with loss of the y descent.[26] Since the total heart volume is fixed in tamponade,

blood only enters the heart when blood leaves. The y descent represents opening of the tricuspid valve and is lost since no blood is ejected from the heart. Pulsus paradoxus is also noted with a fall in the systolic blood pressure of greater than 10 mm Hg with inspiration. Pulsus paradoxus is absent in left ventricular dysfunction, atrial septal defect, positive-pressure ventilation, aortic insufficiency, and regional tamponade. The EKG shows variation in the morphology of every other QRS complex, or electrical alternans, due to swinging of the heart in the pericardial effusion (**Fig. 84.3**). Chest radiograph shows an enlarged, rounded cardiac silhouette, and the pericardial fat pad sign is seen when the pericardial fat is separated from the heart by the effusion.

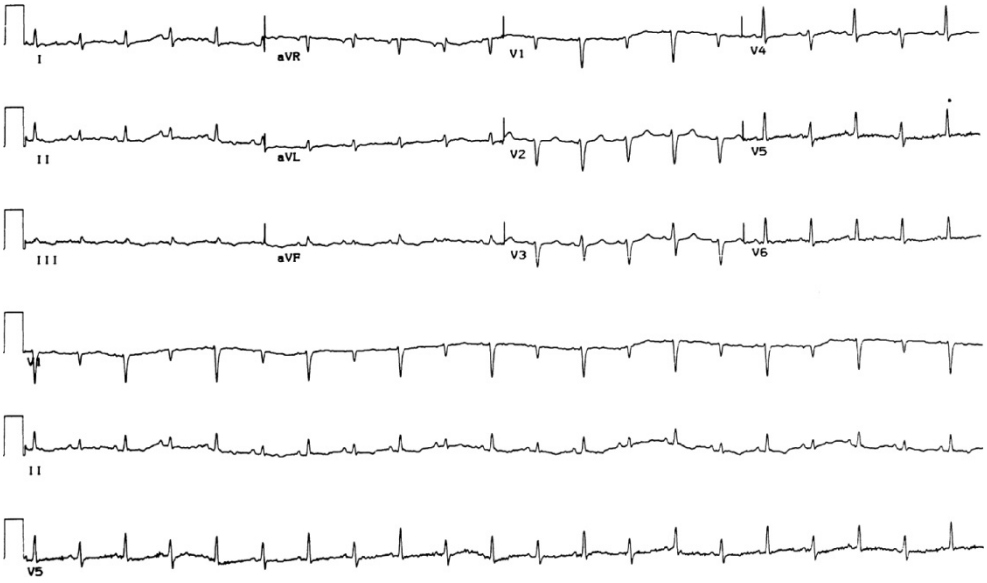

Figure 84.3 The 12-lead EKG shows electrical alternans with variation in the morphology of every other QRS complex in a patient with a large pericardial effusion. (From Joffe II, Jacobs LE, Kotler MN. Pericardial tamponade. *Circulation* 1996;94:2667, with permission.)

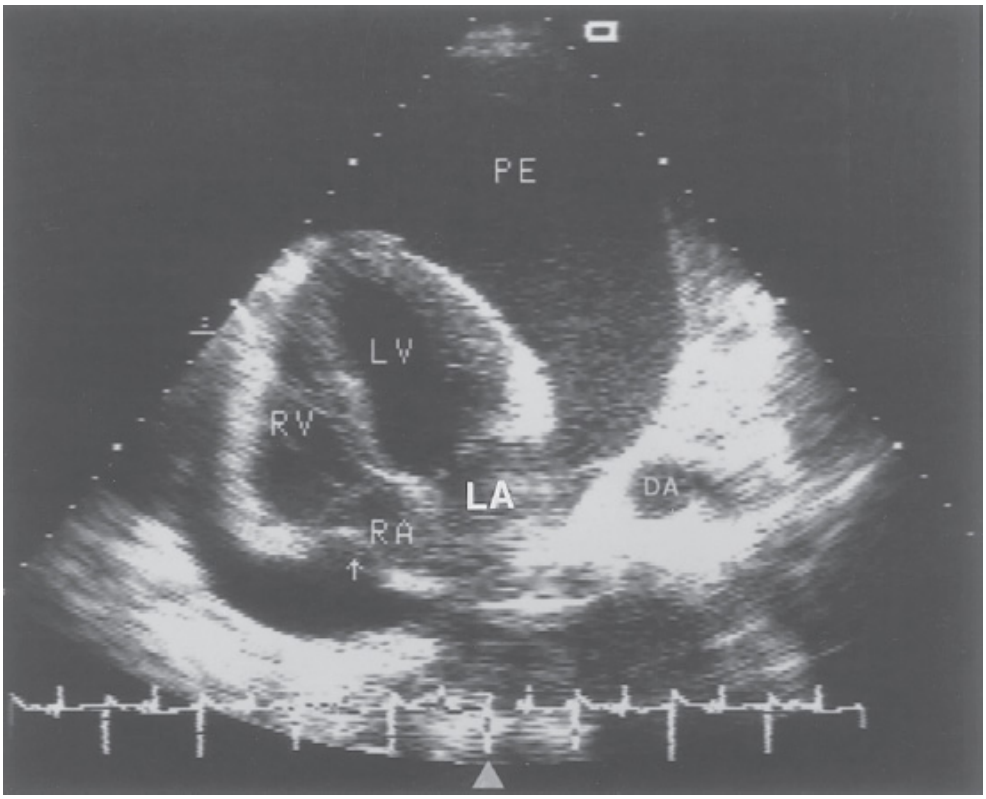

Figure 84.4 The echocardiogram shows a large pericardial effusion with diastolic right atrial collapse (*arrow*). (From Joffe II, Jacobs LE, Kotler MN. Pericardial tamponade. *Circulation* 1996;94:2667, with permission.)

Echocardiography is the most useful test in diagnosing pericardial effusion and tamponade. Signs of tamponade include early diastolic right ventricular and right atrial collapse (**Fig. 84.4**) and distension of the cava that does not diminish with inspiration. Doppler is useful in evaluating blood flow and shows exaggerated respiratory variation with an increase with inspiration on the right and decrease on the left side of the heart. Echocardiography is also useful in identifying localized atrial compression which can lead to tamponade with the other changes described above.

If there are significant hemodynamic changes, emergent pericardiocentesis should be performed. Intravenous fluid and inotropes can temporize the hypotension but should not delay pericardiocentesis. If the effusion is loculated or contains blood clots, open drainage may be necessary. There should be a higher suspicion for tamponade in situations involving bleeding, bacterial or tuberculous pericarditis, or an acute or increasing moderate-to-

large effusion. The approach to a patient with a large pericardial effusion is outlined in **Algorithm 84.1**.

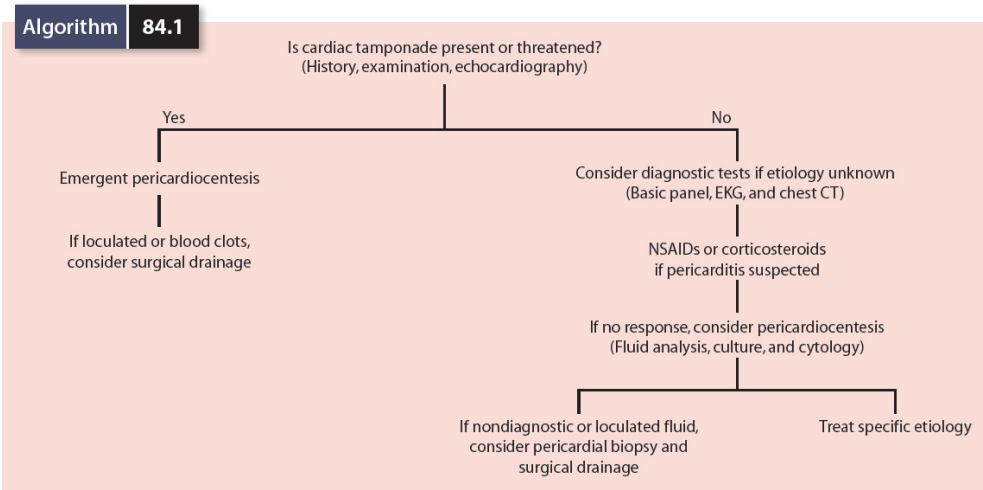
Postoperative Cardiac Tamponade

5 Postoperative tamponade should always be in the differential diagnosis with low cardiac output after cardiac surgery. Patients may have rising filling pressures, hypotension, and decreased urine and cardiac output. Mediastinal chest tube output may increase or abruptly stop. Hypovolemia during the postoperative period can limit the increase in filling pressures. Pulsus paradoxus may also be masked by positive-pressure ventilation. On chest radiograph, the cardiac silhouette is enlarged. In the postoperative cardiac patient, the epicardial pacing wires may move farther from the pericardium with increasing tamponade on chest films. Tamponade can result from relatively small amounts of blood with localized atrial compression from blood clots. There should be a low threshold for reexploration which also provides a definitive diagnosis. Patients can also present with delayed tamponade after being started on anticoagulants.

PERICARDIAL CONSTRICTION

Constriction develops when the heart becomes constrained by a fibrotic pericardium. The process can progress over years, and the most common causes in the developed world are radiation treatment, postsurgical changes, and idiopathic. Tuberculosis was the most common cause before antitubercular drug therapy. Other causes include amyloidosis, scleroderma, sarcoidosis, hemochromatosis, and malignant disease. Patients develop signs and symptoms of right heart failure due to obstruction of the right ventricular outflow tract including hepatomegaly, ascites, and peripheral edema. Patients can also have dyspnea, pleural effusions, fatigue, and weight loss. On physical examination, a pericardial knock, or a loud third heart sound, can be heard which corresponds to the abrupt cessation of diastolic filling. Kussmaul's sign is increased jugular venous distension with inspiration. Atrial fibrillation or flutter is present in up to 25% of patients, and tricuspid regurgitation is also common.

Pericardial calcification is pathognomonic but is only seen in 40% of cases. Thickened pericardium can be seen on CT or MRI (**Fig. 84.5**) although the pericardium was normal in thickness in 18% of patients in one series.[27] The normal pericardial thickness is 2 mm on CT and 4 mm on MRI. Echocardiography shows a thickened pericardium and a septal bounce due to the abrupt displacement of the septum during early diastole. The ventricles are small with good function. Ventricular filling halts abruptly in diastole due to the limits of the stiff, fibrotic pericardium. There are signs of systemic venous congestion with a distended inferior vena cava. In contrast to tamponade, there is no decrease in early diastolic filling but a sudden decrease in late diastole (**Table 84.2**).[26] When the myocardium is involved by fibrosis, ventricular dysfunction is present which is associated with a poorer response to pericardiectomy.



Algorithm 84.1 The algorithm outlines the initial approach to a patient with a large pericardial effusion.

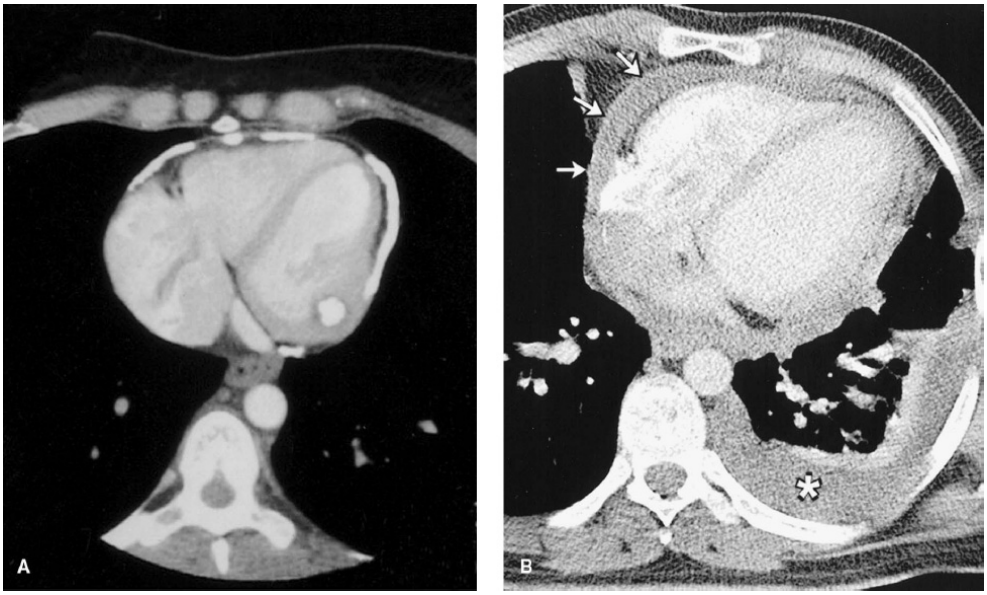


Figure 84.5 **A:** Chest CT shows extensive pericardial calcification. (From Cavendish JJ, Linz PE. Constrictive pericarditis from a severely calcified pericardium. Circulation 2005;112(11):e137–e139, with permission.) **B:** Chest CT shows thickening of the pericardium in a patient with constrictive pericarditis. (From Tom CW, Oh JK. Images in cardiovascular medicine. A case of transient constrictive pericarditis. *Circulation* 2005;111:e364, with permission.)

On right heart catheterization, the y descent is deeper and more rapid than normal. The right atrial waveform is M or W shaped. The right ventricular tracing is described as the square root sign with an early diastolic decrease with a rapid increase and plateau (**Fig. 84.6**). Pulmonary artery and right ventricular pressures can be moderately elevated, but more severe pulmonary hypertension suggests a different disease process. In addition, hypovolemia can mask these findings, and patients may need to be volume-challenged to see the diagnostic changes.[28]

6 Distinguishing constrictive pericarditis from restrictive cardiomyopathy can be difficult but is important since the treatment is significantly different (**Table 84.3**). In restrictive cardiomyopathy, there is no pericardial thickening. Decreased systolic function, mitral regurgitation, and left heart pressures greater than right are more common in restrictive cardiomyopathy. Early diastolic filling is slower. In addition, left and right ventricular pressures move in the same direction on inspiration rather than opposite directions.[29]

Constrictive pericarditis is generally progressive although it can be transient after cardiac surgery and should be observed for several months. Diuretics with fluid and salt restriction may help initially. Pericardial enhancement on cardiac MRI may be able to identify early forms of reversible constrictive pericarditis, and a trial of anti-inflammatory medical therapy may be beneficial.[30] However, pericardiectomy is the definitive treatment when symptoms progress. Tachycardia is a compensatory response, and beta and calcium channel blockers should be avoided.

NEOPLASTIC PERICARDIAL DISEASE

Primary tumors of the pericardium are rare and include benign fibromas, hemangiomas, lipomas, lymphangiomas, leiomyomas, and neurofibromas. Malignant pleural tumors include mesothelioma, teratoma, and fibrosarcoma. Surgical resection is therapeutic and diagnostic.

Table 84.2 Distinguishing Cardiac Tamponade and Constrictive Pericarditis

	Tamponade	Constriction
Pulsus paradoxus	Usually present	Present in one-third of cases
Jugular venous waveform	Absent y descent	Prominent y descent (M or W)
Inspiratory changes in venous pressure	Decrease	Increase (Kussmaul's sign)
Equal right and left pressures	Present	Present
"Square root" sign ventricular pressure	Absent	Present

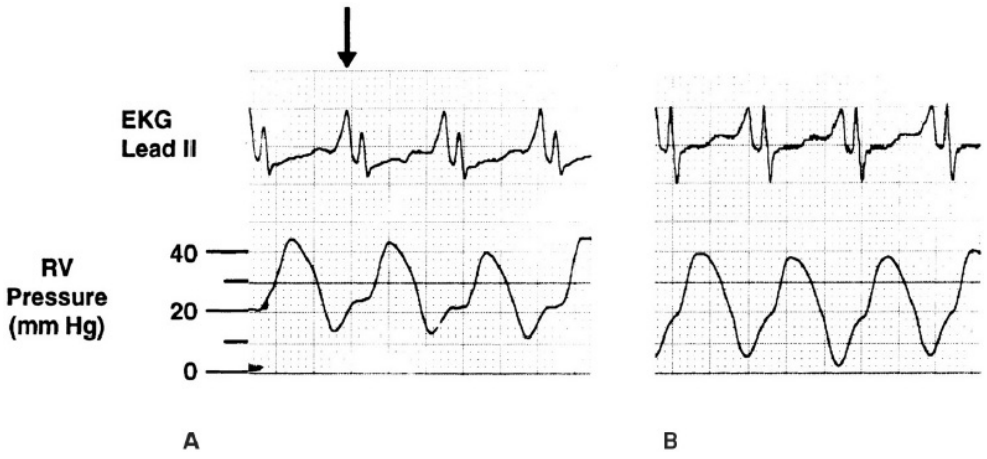

Figure 84.6 Pericardial constriction. **A:** The right ventricular (RV) pressure tracing shows elevated RV diastolic pressure with the dip-and-plateau waveform known as the "square root sign." The EKG tracing shows a large P wave indicative of atrial enlargement. **B:** The postoperative RV tracing shows normalization of the RV waveform. (From Correa SD, Amsterdam EA. Constrictive pericarditis. *Circulation* 1998;97:806, with permission.)

Malignancies can also extend directly from the mediastinum, esophagus [7], and lung. Metastatic disease is the most common cause of pericardial effusion. Cardiac involvement is found in 5% to 10% of patients dying of cancer with 85% of those having pericardial involvement. The most common cancers are lung and breast carcinoma, lymphoma, melanoma, and leukemia. Patients often present with tamponade. The diagnosis is made on echocardiography or CT. Cytology of pericardial fluid is negative in 20% to 50% of cases, and pericardial biopsy may be helpful. Palliation includes sclerosing agents such as tetracycline, radiotherapy, intrapericardial chemotherapy, catheter drainage, and pericardial window.

Table 84.3 Distinguishing Constrictive Pericarditis from Restrictive Cardiomyopathy

	Restriction	Constriction
Pericardial knock	Absent	Present
Pulsus paradoxus	Absent	Present in one-third of cases
Thickened pericardium	Absent	Present
Atrial enlargement	Severe biatrial	Possibly left atrial
Septal bounce	Absent	Present
Equal right and left pressures	Left 3–5 mm Hg > Right	Present
Filling pressures >25 mm Hg	Present	Uncommon
Pulmonary artery SBP >60 mm Hg	Present	Absent
"Square root" sign ventricular pressure	Variable	Present
Prominent y descent	Variable	Present

SBP, systolic blood pressure.

PERICARDIOCENTESIS

Pericardiocentesis can be diagnostic and therapeutic. Ideally, it should be performed in the catheterization laboratory so the hemodynamic response can be monitored. Normal pericardial fluid is an ultrafiltrate with an LDH 2.4

times serum and protein 0.6 times.[31] Uremic fluid is bloody. Rheumatic effusions are high in protein and leukocytes and low in glucose. Cholesterol crystals are seen with myxedema, tuberculosis, and rheumatoid arthritis.

Generally, a 16- to 22-gauge needle is inserted to the left of the xiphoid. The needle is angled at a 45-degree angle toward the left shoulder (**Fig. 84.7**). An EKG lead may also be attached to the needle to monitor for an injury current although echocardiography is more commonly used for guidance. There is a 97% success rate with a complication rate of 4.7% (**Table 84.4**).[32] If the effusion is anterior, a parasternal approach is used 1 to 2 cm to the left of the sternum in the fourth or fifth intercostal space. The removal of even a small amount of fluid can lead to significant hemodynamic improvement. For longer-term drainage, a catheter can be placed over a guidewire. Pericardiocentesis may not be effective for purulent or bloody effusions that may require open drainage.

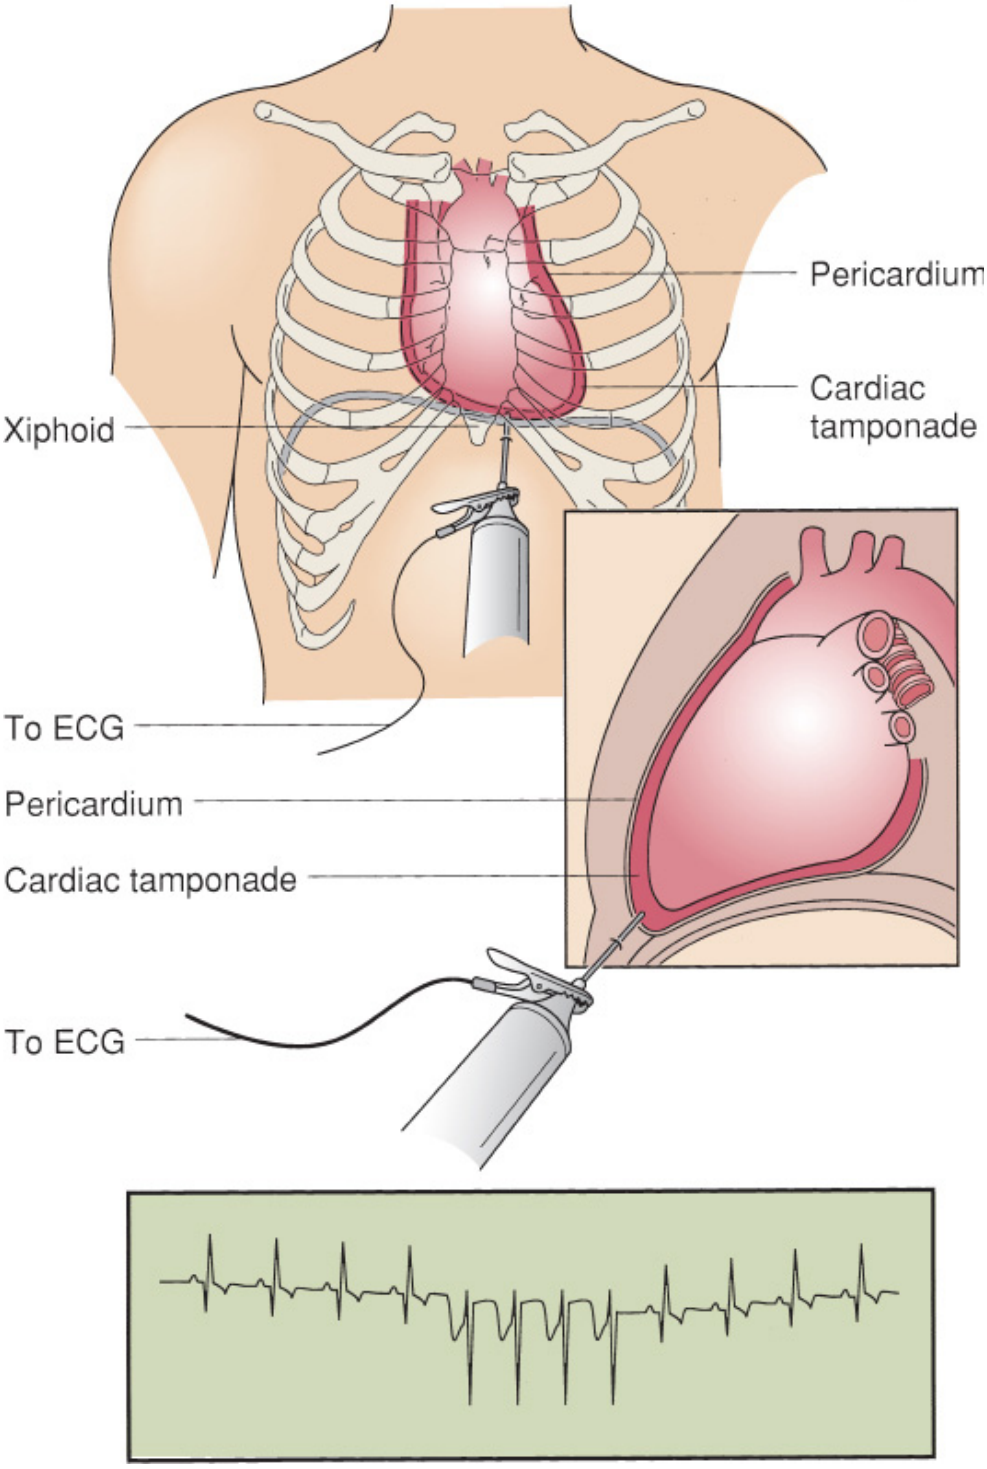

Figure 84.7 Pericardiocentesis is performed by inserting a needle to the left of the xiphoid and toward the left shoulder at a 45-degree angle. An EKG lead may be attached to the needle to monitor for Q waves indicating contact with the epicardium.

COMPLICATIONS

Table 84.4 Potential Complications from Pericardiocentesis
Injury to surrounding organs Liver laceration Lung (pneumothorax) Coronary arteries Myocardium
Arrhythmias
Pulmonary edema from acute left ventricular failure
Recurrence

PERICARDIAL BIOPSY AND SURGICAL DRAINAGE

Pericardial biopsy is useful when pericardiocentesis is nondiagnostic, which is not uncommon in neoplastic and tubercular effusions. This can be approached through a subxiphoid incision, anterior thoracotomy, or thoracoscopically (**Fig. 84.8**). Open drainage may be useful if the fluid is viscous, including bloody or purulent effusions, or in patients who have recurrent effusions. Loculated effusions may also require open drainage. The subxiphoid approach is better for purulent effusions to prevent contamination of the pleural space. Chronic or malignant effusions can be drained through a pericardial window into the left pleura. Preinduction pericardiocentesis or intravenous fluids may be necessary for patients to tolerate general anesthesia.

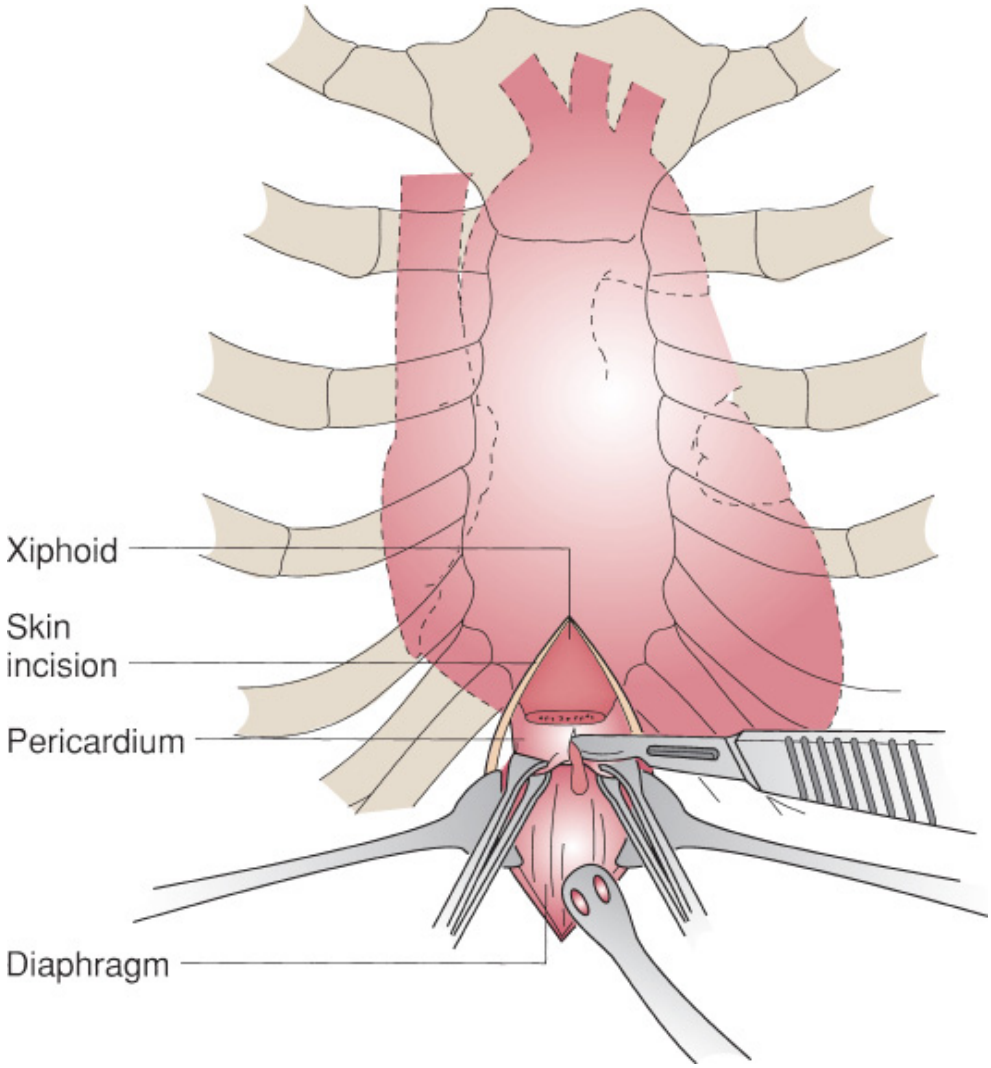

Figure 84.8 Open pericardial biopsy or drainage is performed through an upper midline incision. The xiphoid is retracted or removed providing exposure to the pericardium.

RECONSTRUCTION OF THE PERICARDIUM

Generally, the pericardium does not need to be reconstructed after routine opening of the pericardium during cardiac surgery or when resecting portions of the pericardium for adjacent tumors such as a thymoma. Primary pericardial closure is often avoided due to concerns for hemodynamic compromise and perioperative tamponade. Dantas et al. found a temporary, but clinically insignificant, decrease in hemodynamics in a study of 48 patients with primary closure of the pericardium after open heart surgery.[33]

Reconstruction 8 of the pericardium should be considered in cases where a future redo sternotomy is likely such as a bioprosthetic valve that will need to be replaced or a left ventricular assist device that will be removed at the time of transplant. To prevent hemodynamic compromise, the closure should be performed without tension. A biologic mesh implant made of porcine extracellular matrix has been used to prevent adhesions and protect the right ventricle, aorta, and coronary bypass grafts. Reconstruction of the pericardium was also reported in a retrospective study of 222 patients to decrease the incidence of atrial fibrillation.[34] The results of a randomized trial evaluating new-onset postoperative atrial fibrillation after pericardial reconstruction using extracellular matrix (NCT01247974) have not been published, but the rate of serious adverse events listed on clinicaltrials.gov was higher in the extracellular matrix group (36.54% vs. 24.55%), and the rate of atrial fibrillation was similar (5.77% vs. 5.00%).

Reconstruction of the pericardium is important when there is a risk of cardiac herniation. When resection of the pericardium is required during pneumonectomy due to a central lung tumor or an extrapleural pneumonectomy for mesothelioma, the pericardium should be reconstructed to prevent herniation into the empty hemithorax.[35] Cardiac herniation must be quickly recognized if the patient becomes hypotensive postoperatively. The pericardial defect is reconstructed with a 0.1-mm Gore-Tex mesh. The mesh should be fenestrated with small incisions to allow fluid to escape decreasing the risk of tamponade. Reconstruction of the pericardium may also help to prevent inflammatory epicarditis which can lead to constrictive physiology after extrapleural pneumonectomy.[36]

PERICARDIECTOMY

Pericardiectomy is most commonly performed for constrictive pericarditis. It can be performed through a median sternotomy or a left anterior thoracotomy in the fifth intercostal space. Anterior thoracotomy allows removal of the pericardium over the left ventricle with minimal manipulation. Median sternotomy is the most common approach (**Fig. 84.9**). Cardiopulmonary bypass increases the risk of bleeding and is used when significant cardiac manipulation is needed or the dissection is difficult. Femoral cannulation is

used if bypass is necessary. The pericardium over the left ventricle is resected first to avoid pulmonary edema from the right ventricle ejecting against a constricted left ventricle. The pericardium is removed from phrenic nerve to phrenic nerve. Some patients have an immediate improvement in hemodynamics and symptoms while others do not improve until weeks or months later. A delayed or partial response is thought to be due to incomplete resection of the visceral pericardium or myocardial atrophy and fibrosis. Left ventricular function returns to normal in 40% of patients.

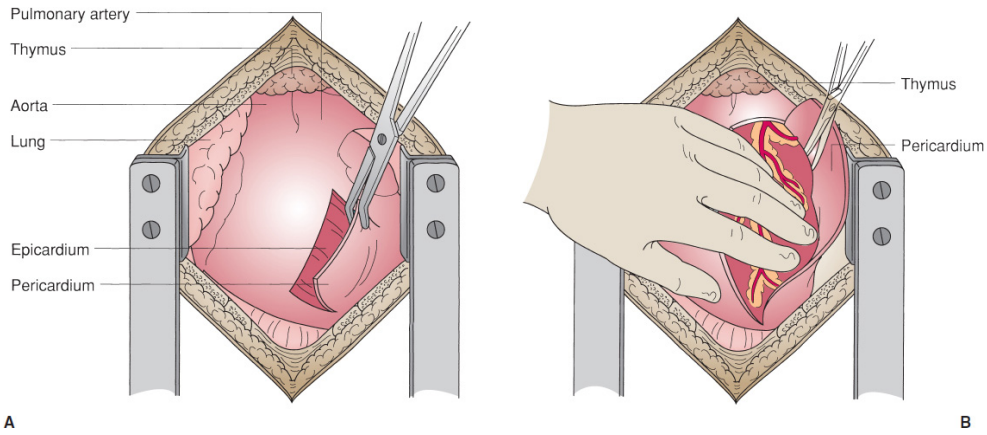

Figure 84.9 Pericardiectomy is most commonly approached through a median sternotomy. **A:** The pericardium is incised, and the fibrous pericardium dissected from the left ventricle. **B:** The heart is retracted to the right so that the pericardium can be resected from phrenic nerve to phrenic nerve.

Perioperative mortality has been reported between 5% and 15% and is due to low cardiac output, sepsis, bleeding, and renal or respiratory failure.[37] Seventy percent of mortality is due to low cardiac output. Mortality is directly related to the patient's preoperative status[38] and is 1% for New York Heart Association class I to II, 10% for class III, and 46% for class IV.[39] Five-year survival is 84%, and 99% of late survivors were class I or II. Patients with constriction due to radiotherapy have a higher mortality which may be due to radiation-induced myocardial injury. Other poor prognostic factors are renal failure, advanced age, pulmonary hypertension, hyponatremia, and reduced cardiac output.[37,40]

Vascular Diagnostics: The Noninvasive Vascular Laboratory

Gregory L. Moneta

Key Points

1 Duplex ultrasound consists of a combination of grayscale imaging and pulse Doppler. Because the speed of sound is relatively constant in tissue, with a pulse Doppler it can be determined when an echo is generated and when it is received. This provides range resolution enabling the operator of the duplex machine to precisely sample and interrogate blood flow at a known location.

2 When a sound wave encounters moving reflectors, such as red blood cells, the frequency of the reflected wave changes from that of the original wave generated by the transducer. This relationship is reflected in the Doppler equation: $f_r - f_o = [(2f_o v)/c] \cos \theta$, where f_r is the received frequency, f_o is the originating frequency, v is the velocity of the reflector, c is the speed of sound in tissue, and θ is the angle of the incident sound beam with the moving reflectors, the so-called Doppler angle.

3 Arterial Doppler waveforms reflect the resistance of the circulation supplied by the artery being examined. Low-resistance circulations such as cerebral and renal circulations have relatively high amounts of diastolic flow whereas high-resistance circulations, such as extremity arteries have little flow at the end of diastole.

4 Carotid stenosis is determined primarily from measurement of peak systolic velocity (PSV) and end-diastolic velocity (EDV) from pulse Doppler waveforms using criteria agreed upon in a national consensus conference.

5 Air plethysmography (APG) can be used to display pulse volume waveforms. Pulse volume recordings (PVRs) are obtained with partially inflated blood pressure cuffs that detect volume changes sequentially down a limb. Volume changes beneath the cuffs resulting from the pulse wave result in small pressure changes within the cuffs. These changes are displayed as arterial waveforms with the use of appropriate transducers and provide an overall measure of the arterial circulation in an extremity.

6 The ankle brachial index (ABI) is determined by dividing the higher ipsilateral dorsal pedal or posterior tibial artery pressure by the higher of the two brachial artery systolic pressures and is highly sensitive and specific for documenting the presence or absence of lower extremity arterial occlusive disease.

7 Measurement of ankle pressures after exercise can be used to confirm arterial disease as an etiology for exercise-associated leg pain. Failure of the ankle pressure to drop with exercise along with failure of the ABI to decrease 20% with exercise, combined with a normal resting ABI, substantially rules out arterial insufficiency as an etiology of exercise-induced complaints of leg pain.

8 Duplex ultrasound can detect hemodynamically significant stenosis in abdominal arteries: a PSV in the superior mesenteric artery (SMA) of 275 cm/s or more indicates a ≥70% SMA stenosis, a celiac artery PSV of ≥200 cm/s indicates a ≥70% celiac artery stenosis whereas a ratio of the PSV in a renal artery to that in the aorta (renal–aortic ratio, RAR) of ≥3.5 indicates a ≥60% diameter-reducing renal artery stenosis.

9 The primary ultrasound diagnostic criterion for diagnosis of venous thrombosis is failure of the vein to collapse with application of pressure with the ultrasound probe.

10 In the upright position, venous reflux stimulated by cuff deflation that lasts >0.5 to 1 second is indicative of pathologic venous reflux.

INTRODUCTION

The noninvasive vascular laboratory provides accurate, safe, and objective evidence of the presence and physiologic significance of vascular disease throughout the body. Two broad categories of testing are available in the noninvasive vascular laboratory; those based on plethysmographic techniques, and those based on ultrasound-based techniques.

PLETHYSMOGRAPHY

Plethysmographic techniques detect volume changes in limbs that occur in response to arterial and venous disease. The technology can be modified to determine digital pressures and produce pulse waveforms. Examples of plethysmographic techniques include mercury strain gauge plethysmography, air plethysmography (APG) (pulse volume recordings [PVRs]), and photoplethysmography (PPG).

ULTRASOUND

Ultrasound techniques, in particular duplex ultrasound-based technique, have largely eclipsed plethysmographic techniques. Duplex ultrasound, introduced in 1974, was first applied to carotid arteries. The technique combines information from ultrasound-generated images (B-mode) and Doppler analysis of blood flow direction and velocity, hence the term "duplex." Duplex ultrasound is currently extensively employed for evaluation of carotid arteries, intra-abdominal arteries and veins, and upper and lower extremity arteries and veins. Since inception duplex ultrasound has advanced through: (1) improved B-mode imaging, (2) better low-frequency scan heads permitting deeper penetration of the ultrasound beam from the skin surface, (3) improvements in online computer-based microprocessor software, and (4) perhaps, most importantly, the addition of color flow to the B-mode image.

Color flow superimposes a real-time color image of blood flow onto a standard gray-scale B-mode picture. Returning echoes from stationary tissues generate the B-mode image, whereas those interacting with moving substances (blood) generate a significant enough phase shift that they can be processed separately and color coded by operator selection to give information on direction and velocity of blood flow according to the magnitude and direction of the Doppler frequency shift. It is color flow, combined with the ability of the current generation of duplex scanners to detect very low blood flow velocities (<5 cm/s), which makes duplex scanning practical on a routine basis throughout the body. Color flow permits

more rapid identification of vessels to be examined and is essential for duplex examination of some vessels such as tibial arteries and veins.

BASICS OF DUPLEX ULTRASOUND

An ultrasonic wave is produced in tissue by placing a vibrating source in contact with the tissue. In medical ultrasound the vibrating source is the ultrasound *transducer* contained within the ultrasound *scan head.* The scan head steers and focuses the sound beam arising from the transducer, functions crucial in deriving an ultrasound image from returning echoes.

Ultrasound transducers convert electrical energy into vibrational energy and, conversely, turn vibrational energy of returning echoes into electrical signals that can be analyzed by the software of the duplex machine. The design of the transducer determines the frequency of the vibrations which in turn determines the wavelength of the sound wave produced. The relationship between frequency and wavelength is expressed mathematically as follows:

$$\lambda = c/f \qquad (85.1)$$

where λ is the wavelength, c is the speed of sound in tissue and f is the incident frequency.

The speed of sound in soft tissues averages 1,540 m/s and varies only minimally from this average in soft tissues insonated in clinical applications of duplex ultrasound. The wavelength of the sound beam is the primary determinant of how well the ultrasound beam penetrates the tissue. Because the speed of sound within the tissue is, for all practical purposes, constant (1,540 m/s), the ability of ultrasound to penetrate tissue depends on the frequency of the vibrating source (transducer). As noted above, transducer frequency is determined by the design of the transducer and is thus controlled by the manufacturer of the duplex device. For examination of the carotid artery, transducer frequencies of 5 to 7.5 MHz provide optimal tissue penetration for clinical purposes.

As noted above the term duplex refers to the combination of Doppler and B-mode ("B" stands for "brightness") ultrasound in the same device. Both types of ultrasound require analysis of reflected echoes of the original sound beam initially created by placing the ultrasound transducer in contact with the

tissue. The B-mode component of the duplex machine analyzes the *strength* (intensity) and *origin* of the reflected echo. The Doppler component analyzes *shifts* in frequency of the original sound wave produced by the transducer that result when the ultrasonic wave encounters moving reflectors.

B-Mode Ultrasound

As a sound wave passes through tissue, its strength moving away from the transducer depends upon the degree to which the beam is attenuated, scattered, and reflected. The strength of the reflected echo depends in part, upon relative differences in acoustic impedance between two different media. Major differences in acoustic impedance result in reflection of a large proportion of the sound beam back to the transducer, whereas small differences result in comparatively little reflection and continued propagation of the beam through the tissue.

In B-mode ultrasound, the strength of the returning echo is reflected in the brightness of the individual pixels comprising the ultrasound image. This is the ultrasound *grayscale* and the resulting image is termed a *grayscale image*. (As we will in the chapter, the primary purpose of the grayscale image in duplex ultrasonography is to aid in properly positioning the Doppler sample volume.)

Very bright pixels represent sites of large differences in acoustic impedance between media, whereas less dramatic differences are represented by proportionally less bright pixels on the B-mode image. Thus gallstones, which differ dramatically in acoustic properties from soft tissue, result in strong echoes and proportionally brighter pixels on an ultrasound image, whereas blood, which differs little from soft tissue in acoustic characteristics, frequently cannot be distinguished from soft tissue in a grayscale image.

The strength of the reflected echo will also be dependent upon the strength of the sound beam at the point of its reflection. Grayscale images do not show the percentage of the beam reflected, but rather represent the absolute strength of the reflected echo arriving back at the transducer. Thus if the sound beam is very weak at the site of its reflection, even areas of significant differences in acoustic impedance will not result in a bright pixel on the ultrasound image.

The strength of the ultrasound beam at any point also depends on the degree to which the beam has been attenuated as it passes through the tissue. Attenuation of a sound wave as it traverses tissue weakens the wave and depends upon the tissue traversed and the frequency of the wave. The frequency of the wave depends upon the frequency of the transducer used to generate the wave (see discussion above and Equation 85.1). Sound waves resulting from higher-frequency transducers are attenuated more rapidly than those produced with lower-frequency transducers. Higher-frequency transducers therefore provide relatively weak echoes to be reflected from a deep structure and thus a comparatively poor B-mode image compared to a lower frequency transducer.

The linear resolution of an ultrasound image depends upon the ability to focus the beam. Sound beams emanating from high-frequency transducers can be more precisely focused than those from low-frequency transducers and thus provide clearer B-mode images of more superficial structures. Because the carotid artery is superficial, higher-frequency transducers can be used to provide much clearer B-mode images than is possible with deeper vessels such as the aorta, renal, or iliac arteries.

Doppler Ultrasound

In a continuous wave Doppler, a transducer continually emits vibrations into the tissue. Echoes are therefore continually reflected back to the transducer. A transducer cannot, however, simultaneously generate and receive an echo. Continuous wave Doppler therefore must have separate transmitters and receivers to both generate and receive echoes.

Duplex 1 devices utilize pulse Doppler. A pulse Doppler uses the same transducer to generate and receive echoes. Because the speed of sound is relatively constant in tissue, with a pulse Doppler it can be determined when an echo is generated and when it is received and therefore it is possible to calculate the depth in the tissue where a reflected echo originated. The *sample volume* of the duplex device is thus determined by specifying from what depth one wishes the pulse Doppler to receive reflected echoes.

The transducer is *gated,* based on the total time from original sound-wave generation to arrival of the reflected echo back at the transducer, to only receive echoes from the specified depth of the sample volume. The desired

"position" of the sample volume is determined by the operator of the duplex device from the B-mode image, and in duplex examination of arterial and venous flow corresponds to particular points within the lumen of the vessel examined. Because B-mode images and Doppler waveforms cannot be generated simultaneously, the technologist must continually update the B-mode image during the course of the examination to insure proper placement of the sample volume.

2 When a sound wave encounters moving reflectors, such as red blood cells, so-called Rayleigh scatters, within the lumen of an artery or vein, the frequency of the reflected wave changes from that of the original wave generated by the transducer. Velocity is a vector with both speed and direction therefore, the magnitude of the frequency shift depends upon the velocity of the moving reflectors and their angle with the incident sound beam. Because the frequency of the original sound wave is known, and the frequency of the received echo can be determined by the software of the duplex machine, the velocity of the moving reflectors (red blood cells) can be calculated provided the angle of the incident sound beam with the moving reflectors is also known. This relationship is reflected in the *Doppler equation:*

$$f_r - f_o = [2f_o v/c] \cos \theta \qquad (85.2)$$

where f_r is the received frequency, f_o is the originating frequency, v is the velocity of the reflector, c is the speed of sound in tissue, and θ is the angle of the incident sound beam with the moving reflectors, the so-called *Doppler angle.*

A Doppler angle of 0 degrees is ideal for velocity calculations as the cosine of 0 is 1 and measured reflected velocity changes are therefore 100% of what actually occurred. However 0-degree Doppler angles are difficult to obtain as it is not generally possible to look directly down the lumen of a vessel from a percutaneous approach. Therefore to solve the Doppler equation for the velocity of the moving reflectors, the Doppler angle must be known. To standardize the results of duplex scanning, it has been traditionally recommended that examinations be conducted as close as possible to a Doppler angle of 60 degrees. The cosine of 60 is 0.5, therefore at this angle the measured reflected velocity is half the actual reflected

velocity. Errors in velocity calculations secondary to misreading of the Doppler angle are small as a percentage of the true velocity at ≤60 degrees as cosine vary comparatively little with incremental changes in angle below 60 degrees. When the Doppler angle approaches 70 degrees, changes in the cosine of the angle become more pronounced with incremental increases in angle, and errors in velocity calculations secondary to improper angle measurement become much more significant. Small errors in determining the Doppler angle when the angle of insonation is <60 degrees have little overall impact on the calculation of the velocity of the moving red cells. Indeed, Doppler angles from 45 to 60 degrees are acceptable for most clinical studies. Most often an angle of 60 degrees can be easily obtained in carotid artery and extremity artery duplex examinations and, in line with traditional teaching, 60 degrees is chosen whenever possible as the Doppler angle in such studies. In examination of intra-abdominal vessels it may be much more difficult to adhere to a 60-degree angle.

As noted above, pulse Doppler both transmits and receives echoes with the same transducer. This dual function places limits on the frequencies that can be displayed in the spectral waveform. The maximum frequency that can be displayed is half the pulse-transmitting frequency or pulse-repetition frequency (PRF), and is known as the *Nyquist limit*. If frequencies are encountered that exceed the Nyquist limit, they are flipped and appear on the reverse-flow side of the spectrum. This is termed *aliasing*. If aliasing is encountered, the PRF should be increased to increase the Nyquist limit. The PRF can be adjusted by changing the scale displayed on the right side of the spectral waveform or by adjusting the baseline. If aliasing still occurs, the operator should consider switching to a lower frequency transducer or to the use of a continuous-wave Doppler. A continuous-wave Doppler is not affected by aliasing.

Color Flow

A color flow image is produced by assigning color to Doppler shifts. Returning echoes that are not Doppler shifted are shown in grayscale. The net result is what appears to be color pasted or superimposed on a grayscale image. This pasting process can in effect obscure the edges of the grayscale image resulting in obfuscation of the true lumen of the grayscale image

limiting somewhat the accuracy of color images to define stenosis. The hue and intensity of the color are determined by the direction and magnitude of the Doppler shifts. The technologist can adjust the color settings as desired. Varying shades of red and blue are generally used to distinguish flow toward or away from the transducer. By convention, red is most often assigned to arterial flow and blue to venous flow.

When the Doppler angle is 90 degrees, there is no Doppler shift. When this occurs, the assigned color is black and corresponds to the horizontal black bar serving as the baseline on the color scale that appears on the right side of a color flow image (Fig. 85.1). Aliasing can be readily recognized on a color flow image as a mosaic pattern or as a transition from red-to-blue or blue-to-red without an intervening black line. In areas of actual reverse flow, the blue and red colors are separated by a black border. Just as with pulsed Doppler, color aliasing can be reduced by increasing the PRF. This is often quite important, as an extensive mosaic pattern can obscure clear visualization of a stenotic site.

Power Doppler is a variant of color Doppler. Power Doppler, however, assigns no direction of flow to the color image and velocity information is not calculated. Any detected Doppler shift is colorized without consideration of the direction of the Doppler shift or the magnitude of the Doppler shift. It is therefore not subject to aliasing or affected by Doppler angle. Its principal utility lies in the ability to detect blood moving at very low velocity and in outlining the course of tortuous vessels. It can be quite useful in detecting flow in small distal veins and flow in arteries distal to a very high-grade stenosis.

It is tempting to try a direct estimate of the severity of a stenosis from the color flow image. However as discussed above such estimates are probably less accurate than measurements of stenosis derived from spectral analysis. Color serves primarily as a guide in locating the vessels and selecting specific sites for examination with the pulse Doppler. The absence of color can indicate extensive mural calcification and difficulty in obtaining a pulse Doppler waveform.

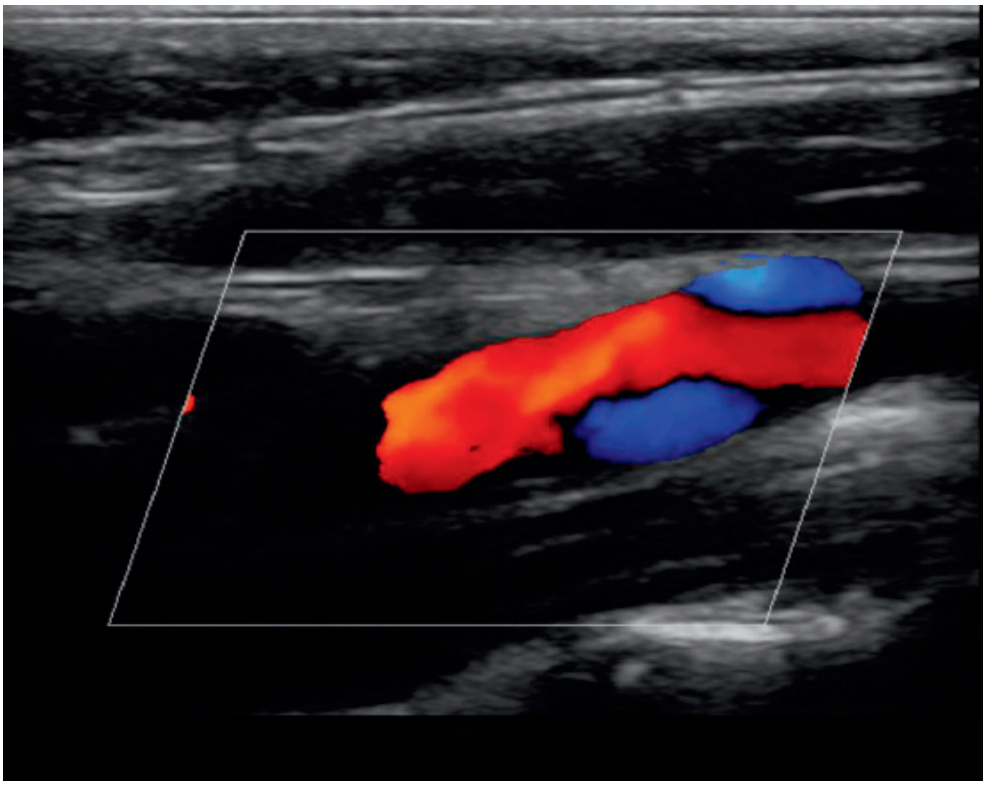

Figure 85.1 Flow separation with reverse flow along the wall of the carotid bulb as indicated by direct transition from *blue* to *red* with an intervening black line is a normal finding and indicates an artery without significant plaque.

Carotid and Vertebral Arteries

The vascular laboratory began with assessing internal carotid artery (ICA) stenosis. Doppler diagnosis of ICA stenosis, and arterial stenosis in general is based on duplex ultrasound and focuses on three areas, the prestenotic region, the stenosis itself, and the poststenotic region. Detecting carotid stenosis involves a combination of spectral analysis, color and grayscale imaging and, in selected cases, power Doppler. The primary interest is in the detection of increased flow velocities within the area of suspected stenosis and therefore in most cases spectral analysis dominates in the detection of carotid stenosis. The exception is in distinguishing ICA occlusion from a very high-grade stenosis where color flow or power Doppler flow can identify very low flow in the area of the stenosis or distal to the stenosis that may not be detected by pulse Doppler.

In all cases, the pulsed Doppler and color flow findings should be crosschecked for concordance. If there is disagreement between the

impression obtained with color and pulsed Doppler examinations (i.e., color Doppler suggests high-grade stenosis but velocities are only moderately elevated), the findings of both should be reviewed to resolve the discrepancy.

Common Carotid Artery Waveforms

In the majority of cases, carotid stenosis or occlusion occurs in the proximal ICA at or just beyond the carotid bifurcation. A normal ICA waveform reflects the low resistance of the cerebral circulation with high flow at the end of the diastolic component of the waveform. In the presence of a distal ICA occlusion resistance to flow increases and there is decreased flow in diastole (Fig. 85.2**A,B**). The external carotid artery (ECA) supplies the relatively higher-resistance circulation of the scalp and face and therefore has a low-end diastolic flow component (Fig. 85.2**C**). The common carotid artery (CCA) waveform reflects the fact that normally 80% of CCA flow is directed to the ICA. CCA end-diastolic flow is therefore generally well above baseline and exceeds ECA diastolic flow (Fig. 85.2**D**). In the presence of a very high-grade ICA stenosis or ICA occlusion, outflow is primarily through the higher-resistance external carotid 3 circulation. The CCA waveform then takes on the high-flow resistance characteristics of an ECA, with flow to zero, or nearly zero, in end diastole (Fig. 85.3).[1] In addition, the PSV and the overall flow velocity may be substantially lower than normal because of reduced carotid artery flow. By observing these changes in the CCA, one can reliably predict the presence of high-grade stenosis or occlusion of the ICA.

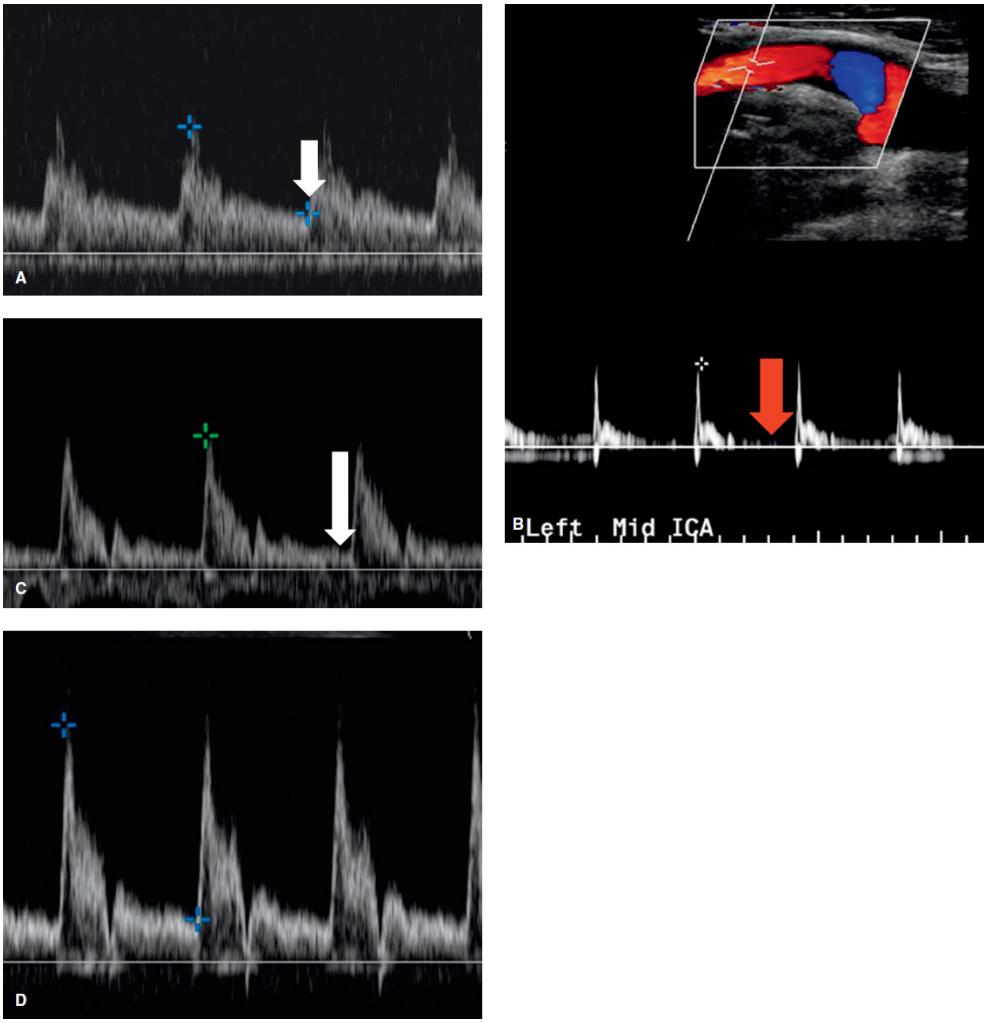

Figure 85.2 **A:** A normal internal carotid artery (ICA) waveform with high diastolic flow (*white arrow*) reflecting the low resistance of the cerebral circulation. **B:** Absence of ICA diastolic flow (*red arrow*) indicates more distal occlusion or severe stenosis of the extracranial or intracranial ICA. **C:** Normal external carotid artery waveform. The external carotid artery has low diastolic flow reflecting the high-resistance circulation of the scalp and face. **D:** Normal common carotid artery waveform. The common carotid artery waveform has diastolic flow well above the baseline as the majority of flow is directed to the low-resistance internal carotid artery circulation.

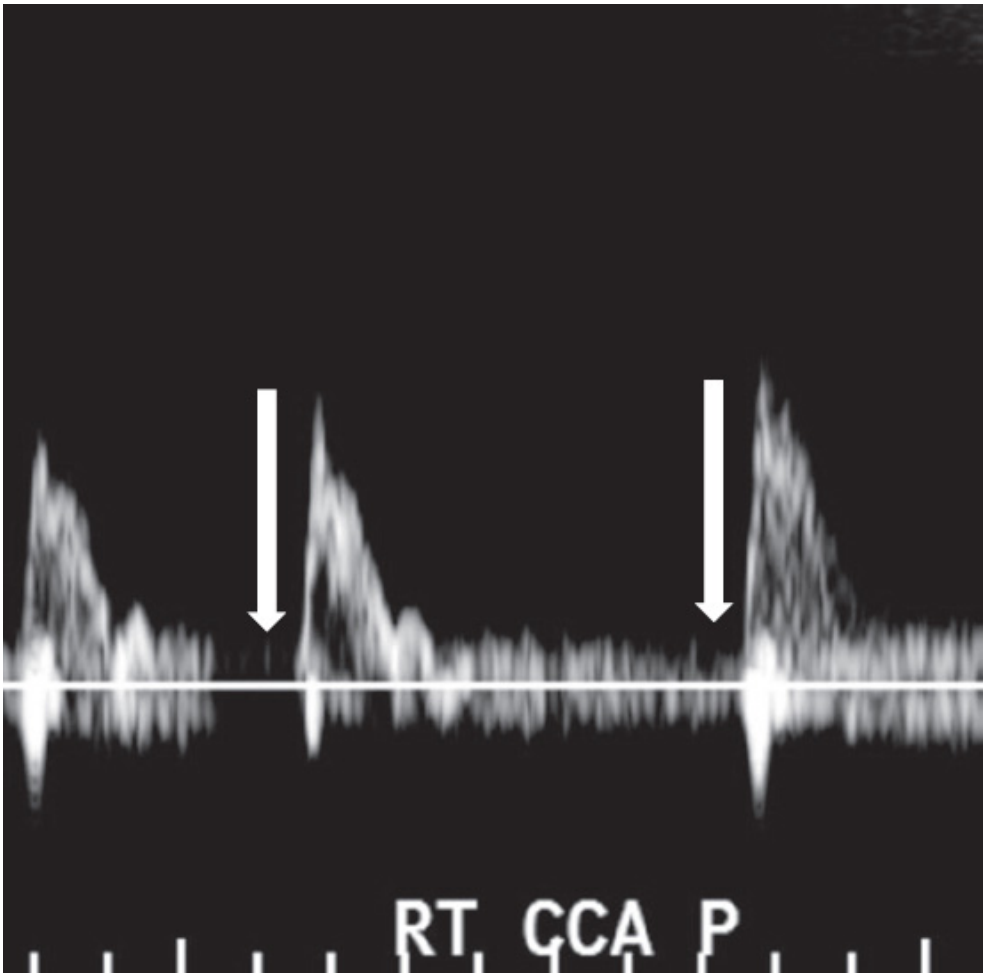

Figure 85.3 In a patient with internal carotid occlusion common carotid artery (CCA) diastolic flow approaches 0 (*arrows*) as CCA flow is now routed to the high-resistance external carotid circulation.

The CCA *contralateral* to an ICA stenosis or occlusion may demonstrate an increased flow velocity with particular elevation of the velocity at the end of diastole; the so-called end-diastolic velocity (EDV). These changes represent a compensatory increase in blood flow volume in the nonobstructed ICA in response to reduced contribution to cerebral perfusion from the opposite high-grade stenotic or occluded ICA. This compensatory hemodynamic change can be substantial and flow velocities may be artificially elevated on the side with compensatory high-volume flow giving a false impression of the presence of a stenosis or a higher degree of stenosis than is actually present.[2]

In the presence of a significant stenosis at the origin of a CCA or the innominate artery, the ipsilateral CCA waveform may be dampened, with

low overall peak systolic velocities (PSVs) and EDVs and a slower rise to peak systole when compared with the contralateral CCA waveform and potentially reverse flow in the ICA (Fig. 85.4**A,B**). The CCA flow changes seen with proximal stenosis are also important in the diagnosis of ICA stenosis because the overall reduction in flow velocity may artificially lower velocities in an ipsilateral ICA stenosis, leading to underestimation of the severity of ICA stenosis. In some cases of proximal CCA or innominate artery stenosis, the stenotic lesion may not be accessible to direct insonation by the duplex scanner. In such cases, a stenotic lesion can be suspected as the ipsilateral CCA waveform will often exhibit poststenotic turbulence low in the neck, reflecting disturbed flow distal to the more proximal stenosis.

ICA Waveforms

As noted above, the normal ICA spectral waveform is indicative of high flow in a low-resistant circulation. The systolic upstroke is rapid, PSV is <125 cm/s, and flow is maintained throughout diastole (Fig. 85.2**A**).[3] In the absence of plaque there is generally a clear spectral window under the outline of the spectral waveform as there is little turbulent flow. The presence of color shifts, indicating high-velocity flow, and color mosaics, indicating poststenotic turbulence, aids in selecting potential areas for examination with the pulsed Doppler.

Hemodynamic quantification of the severity of ICA stenosis is primarily achieved by analysis of Doppler spectral waveforms and measurements of peak systolic and EDV or comparison of PSVs in the ICA to those in the CCA just proximal to the carotid bifurcation, ICA/CCA ratio. As a stenosis develops, the PSV first becomes elevated. PSV is the primary measure of stenosis severity. EDV lags behind, relatively speaking, as stenosis severity progresses but rises rapidly as the stenosis becomes severe (diameter reductions of ≥60%). Thus, elevation of EDV is a good marker for high-grade stenosis (Fig. 85.5).[4] The ICA/CCA ratio is also a very important measure of stenosis severity.[5] Because it is a ratio, it compensates for abnormally high- and low-flow states that may skew the PSV and EDV upward or downward.

To accurately measure flow velocity, the sample volume must be placed within the area of greatest stenosis. Color flow imaging has demonstrated

that the orientation of the stenotic jet within a stenosis is frequently not along the longitudinal axis of the vessel. This finding has resulted in controversy with regard to the proper technique of obtaining velocity waveforms at sites of stenosis. In areas of mild to moderate stenosis, use of a Doppler angle of 60 degrees to the long axis of the vessel is recommended. However, in areas of more severe stenosis and/or wall abnormalities, the Doppler angle of 60 degrees should be defined by the long axis of the stenotic flow jet, as demonstrated by color flow.

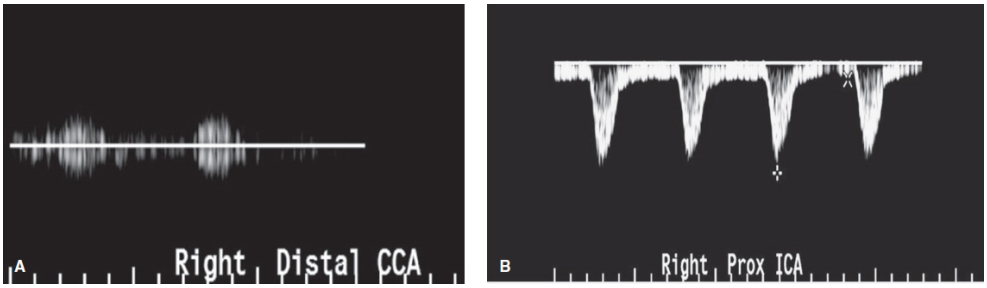

Figure 85.4 **A and B:** In the presence of innominate artery very high–grade stenosis or occlusion the common carotid artery (CCA) waveform will be blunted with a decreased amplitude and slowed upstroke **(A),** and there can be actually reverse flow **(B)** in the ipsilateral internal carotid artery (ICA).

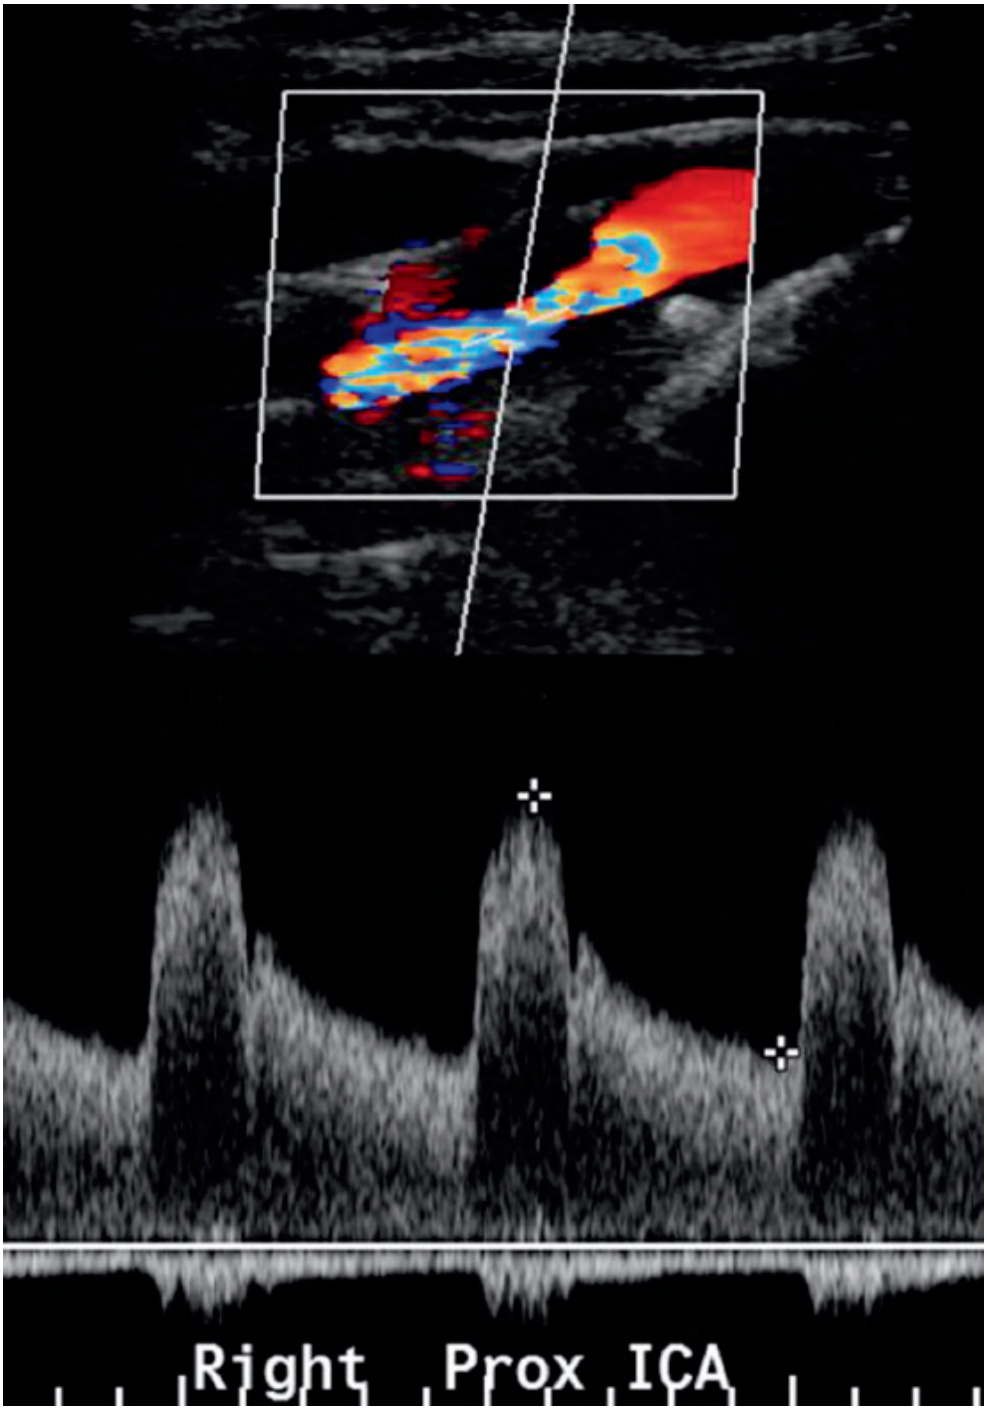

Figure 85.5 Internal carotid artery (ICA) waveform from the site of a >80% ICA stenosis. Both peak systolic and end-diastolic velocities are very elevated.

The sample volume size should be kept as small as possible, usually 1.5 mm, to detect discrete changes in flow velocity. This is important as the highest velocities may be localized to a small area in the flow stream that

emanates from the stenosis. A large sample volume that incorporates flow from many points within the vessel in the generation of the spectral waveform may give the false impression of disturbed flow, potentially leading to the misdiagnosis of moderate disease in an otherwise normal vessel. In practice, the sonographer, having identified the stenosis, gently moves a small sample volume around until the point of highest velocity is found.

Damping of spectral Doppler waveforms may be seen in the region distal to the carotid stenosis when the lesion is severe enough to be flow reducing. The most common abnormality seen distal to a carotid stenosis is spectral broadening caused by disturbed blood flow or turbulence. At best, poststenotic flow disturbance is a qualitative measure of arterial stenosis; nevertheless, its detection is important. With proper gain settings, "fill-in" of the Doppler spectral waveform generally indicates the presence of carotid stenosis with diameter reduction of at least 50%. However, this level of disturbed flow occasionally can be seen with nonstenotic disease. Diagnostically, the most significant poststenotic flow disturbance produces a simultaneous forward and reverse spectral Doppler signal, accompanied by poor definition of the upper spectral border. Such disturbed flow implies the presence of severe carotid stenosis. Severely disturbed flow distal to a highly calcified plaque may be the only substantial evidence for the presence of clinically significant stenosis if calcification prevents direct insonation of the stenosis.

Vertebral Artery

On rare occasions, a stenosis may be found in the cervical portion of the vertebral artery associated with cervical osteoarthritis. However, the origin of the vertebral artery from the subclavian artery is by far the most common site of disease in the vertebral artery. The vertebral artery origin lies deep in the base of the neck and may be difficult to access with ultrasound. Mean vertebral artery diameter is about 4 mm but the vertebral arteries are frequently asymmetric in size with one, most commonly the left, being larger than the right.

The vertebral artery is most commonly interrogated with ultrasound further distally in the neck, from an anteroposterior window, as it threads through the

transverse processes of the cervical spine. The vertebral bodies serve as a reference to insure the vertebral artery is actually under examination (Fig. 85.6). The artery is usually seen deeper but adjacent to the vertebral vein. Color Doppler is helpful to locate the vessel. A spectral waveform from the vertebral artery in the mid-neck provides information about direction of flow, waveform shape, and velocity but does not rule out disease at the origin. The normal vertebral artery waveform is similar to that of the ICA with normal PSVs reported to be 20 to 40 cm/s.[6] Velocities up to 80 cm/s are, however, frequently seen without apparent clinical importance and may represent collateral flow through a dominant vertebral artery, or a small but disease-free, vertebral artery. Evaluation of disturbed flow distally may help determine which elevated velocities are associated with a vertebral artery stenosis and which are not. Velocity patterns are usually similar in the two vertebral arteries but systolic and diastolic velocities may differ if vertebral artery diameters are asymmetric. For this reason if there is concern for stenosis based on an elevated peak systolic velocity (PSV) in a vertebral artery, recording of vertebral artery diameters is important.

Flow in the vertebral artery is normally antegrade with a rapid upstroke and continuous diastolic flow. In cases of anatomic subclavian steal, color flow provides an important initial clue to the diagnosis as flow in the artery will be retrograde in the same direction as the vein. Spectral Doppler must still be used to verify arterial flow and will demonstrate reverse or bidirectional flow in cases of subclavian steal. Depending on the degree of subclavian stenosis the vertebral artery flow may be reversed or biphasic, with flow above and below the baseline (Fig. 85.7**A,B**). End-diastolic flow will be zero or near zero reflecting the high resistance of the peripheral arm circulation rather than low-resistance cerebral circulation. High-resistance vertebral artery flow may also be seen with antegrade flow and like the situation for the ICA may represent distal stenosis or occlusion of the vertebral artery or an atretic or hypoplastic distal vessel.

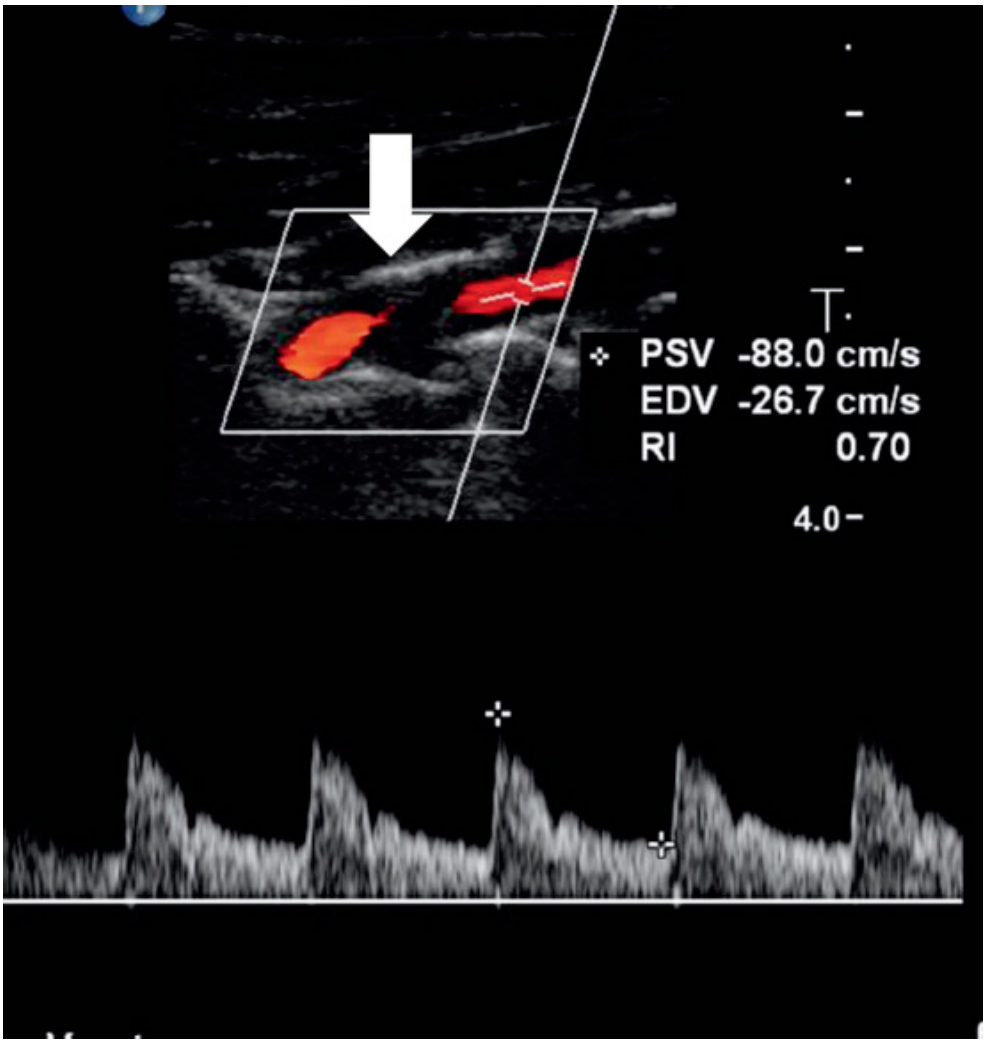

Figure 85.6 Bony landmarks of the vertebral bodies (*arrow*) mark the course of the vertebral artery.

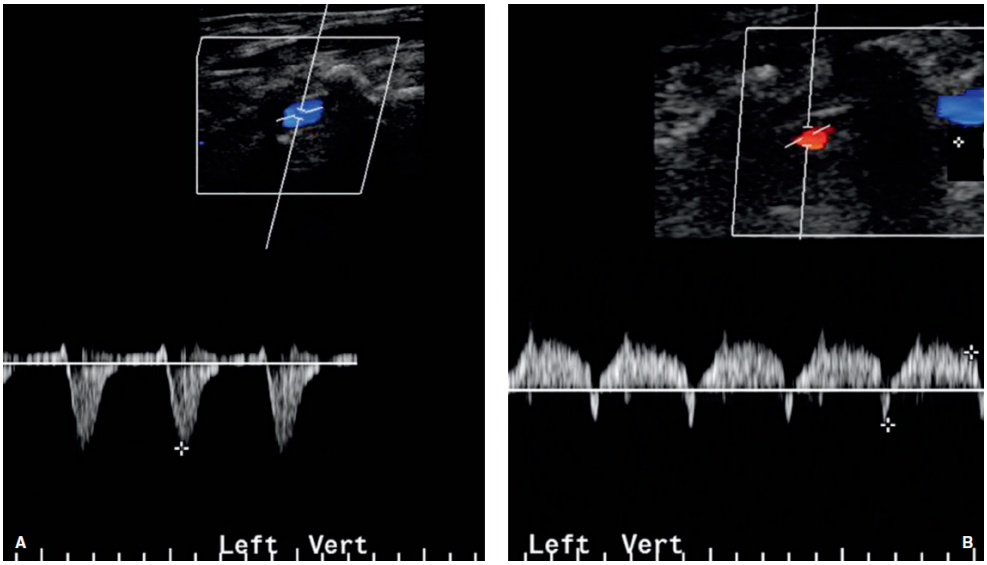

Figure 85.7 **A and B:** Both reverse vertebral artery flow **(A),** and vertebral flow both above and below the baseline **(B)** indicate a proximal innominate or subclavian artery stenosis.

External Carotid Artery

The ECA is smaller in diameter than the ICA at the level of the carotid bulb but similar in diameter beyond the bulb. It has little clinical significance in most cases but can serve as an important source of collateral flow to the brain in cases of ICA very high-grade stenosis, or occlusion. The ECA may also serve in such cases as a conduit for emboli to the brain; the so-called carotid stump syndrome.[7]

The ECA waveform has a sharp upstroke, a prominent dichroitic wave in late systole or early diastole, and velocity that is near or at the zero base line in end-diastole. The PSV of the ECA is normally higher than the ICA. The ECA may adopt the characteristics of the ICA in end-diastole as the resistance in the face and scalp decreases with temperature change and/or in the presence of disease. In cases of common carotid occlusion with preservation of patency of the carotid bulb, reverse flow in the ECA can provide antegrade flow in the ICA maintaining patency of the ICA even with CCA occlusion.

Classifying Carotid Stenosis

Duplex criteria for quantifying carotid artery stenosis were developed by comparing duplex-derived spectral waveforms and contrast arteriograms. Duplex-derived *categories* of stenosis are relatively broad. Sensitivities and specificities for spectral analysis of duplex-derived waveforms for detecting an ICA stenosis of >50% to 99% are between 90% and 95%. There are numerous spectral criteria for classifying ICA stenosis. Some focus on *categories* of stenosis, whereas others focus on *threshold levels* of stenosis.

One of the most widely accepted classification schemes for categories for ICA stenosis was developed at the University of Washington under the direction of Dr. Eugene Strandness. These criteria were useful in the study of the natural history of carotid atherosclerosis and in clinical practice. In the University of Washington system, velocity waveform analysis and spectral criteria were used to classify ICA angiographic stenosis as normal, 1% to 15%, 16% to 49%, 50% to 79%, and 80% to 99% stenosis and occlusion. Prospective validation of these criteria has demonstrated an overall agreement of 82% with contrast angiography. The ability of the criteria to detect carotid disease is 99% sensitive and the ability of the criteria to recognize normal arteries is 84% specific.[3]

Criteria for detecting carotid artery stenosis scanning have undergone reevaluation to remain relevant to current clinical practice. This reevaluation was stimulated by the randomized trials testing the efficacy of carotid endarterectomy (CEA) that took place over the last two decades (Table 85.1).[8–12] The trials had a profound impact on validating the indications for CEA in patients with carotid bifurcation atherosclerosis. The trials identified significant benefit, in terms of stroke reduction, for CEA in patients with specific levels of ICA stenosis. In particular, patients with symptomatic ICA stenosis >70% to 99% had dramatic benefit from CEA, whereas patients with symptomatic ICA stenosis between 50% and 69% and patients with asymptomatic ICA stenosis between 60% and 99% also benefited, albeit to a lesser extent, from CEA.

In the North American trials of CEA, ICA stenosis was calculated from arteriograms by comparing the diameter of the minimal residual lumen to the diameter of the distal cervical ICA.[13] The University of Washington duplex criteria for categories of stenosis pre-dated the endarterectomy trials. These criteria compared the diameter of the residual ICA lumen at its narrowest point with an estimate of the ICA bulb diameter assuming it free of

atherosclerotic plaque. Because the bulb has a greater diameter than the distal ICA, the two methods of measurement do not give the same calculated percentage of angiographic stenosis for the same lesion. Calculations of angiographic stenosis using the distal ICA as the reference vessel result in lower calculated stenosis percentages than calculations using the bulb as the reference site. This effect is particularly striking for modest lesions.

Table 85.1 Major Randomized Trials Assessing Efficacy of Carotid Endarterectomy

Symptomatic Stenosis

VA Cooperative Study # 309[10]
Asymptomatic Stenosis
Asymptomatic Carotid Atherosclerosis Study (ACAS)[11]
Asymptomatic Carotid Surgery Trial (ACST)[12]

In a review of 1,001 internal carotid angiograms, 34% of the ICAs were classified as stenosis of 70% to 99% using the ICA bulb as the reference vessel. In contrast, when the distal cervical ICA was used as the reference site, only 16% of the ICAs were classified as 70% to 99% stenosis.[14] More than 99% of the distal ICA-based calculations of stenosis were less than bulb-based calculations. Thus, the duplex stenosis criteria using the bulb as the reference vessel are not and were not directly applicable to the results of the clinical trials.

Current Criteria for ICA Stenosis

Since the randomized CEA trials were completed, additional duplex criteria were developed comparing duplex scans to angiographic ICA stenosis using the distal ICA as the reference vessel in calculating angiographic stenosis. Such criteria are considered more useful by many in selection of patients for carotid intervention because they are directly applicable to the threshold levels of carotid stenosis addressed in the CEA trials.

The initial studies addressing the issue of duplex criteria relevant to the CEA trials were performed at the Oregon Health & Science University (OHSU)[5,15] with subsequent publications from many different institutions, with many different proposed criteria for identification of clinically relevant threshold levels of ICA stenosis.[16–21]

Recognizing that duplex criteria from different centers differed for the threshold levels of angiographic stenosis determined by the CEA trials, a panel of authorities from a variety of medical specialties assembled to review the carotid ultrasound literature. The panel developed a consensus regarding the key components of the carotid ultrasound examination and reasonable criteria for stratification of ICA stenosis.[22]

The consensus committee recommended that all carotid examinations be performed with grayscale imaging, color Doppler, and spectral Doppler. Examinations should be performed by a credentialed vascular technologist in accordance with the standards of an accrediting body. Doppler waveforms should be measured with an insonation angle as close to 60 degrees as possible but not exceeding 60 degrees, and the sample volumes should be placed within the area of maximal stenosis. The panelists recommended the consistent use of relatively broad diagnostic strata to estimate the degree of ICA stenosis. The panel also concluded that Doppler is relatively inaccurate for subcategorizing ICA stenosis <50%, and recommended that these lesions be reported under a single category as <50% stenosis, and that subcategories for minor degrees of stenosis not be used.

Table 85.2 Consensus Panel Recommendations for Classification of Internal Carotid Artery Stenosis[22]

Normal	The ICA PSV is less than 125 cm/s and there is no visible plaque or intimal thickening. Normal arteries should also have an ICA/CCA ratio of less than 2.0 and ICA EDV of less than 40 cm/s.
ICA stenosis <50%	is present when the ICA PSV is less than 125 cm/s and there is visible plaque or intimal thickening. Such arteries should also have an ICA/CCA PSV ratio of less than 2.0 and an ICA EDV of less than 40 cm/s.
ICA stenosis of 50–69%	is present when the ICA PSV is 125 cm/s to 230 cm/s and there is visible plaque. Such arteries should also have an ICA/CCA PSV ratio of 2.0 to 4.0 and an ICA EDV of 40 cm/s to 100 cm/s.
ICA stenosis ≥70–99%	but less than near occlusion is present when the ICA PSV is more than 230 cm/s and there is visible plaque with lumen narrowing on grayscale and color Doppler imaging. The higher the PSV, the more likely (higher positive predictive value) it is to have severe disease. Such stenosis should also have an ICA/CCA ratio of more than 4.0 and an ICA EDV of more than 100 cm/s.
Near occlusion of the ICA	The velocity parameters may not apply. "Preocclusive" lesions may be associated with high, low, or undetectable velocity measurements. The diagnosis of near occlusion is therefore established primarily by demonstration of a markedly narrowed lumen with color Doppler. In some near occlusive lesions, color Doppler can distinguish between near occlusion and occlusion by demonstrating a thin wisp of color traversing the lesion.
Occlusion	There is no detectable patent lumen on grayscale imaging and no flow with spectral, color, and power Doppler. Near occlusive lesions may be misdiagnosed as occlusions when only grayscale ultrasound and spectral Doppler are used.

ICA, internal carotid artery; PSV, peak systolic velocity; EDV, end diastolic velocity; CCA, common carotid artery.

The consensus panel noted that PSV is easy to obtain. However, data suggest reproducibility of PSV, even among experienced vascular

technologists, has sufficient problems that PSVs should not be used as a continuous variable in clinical carotid duplex scanning. Even so, the degree of stenosis estimated by ICA PSV and the degree of narrowing of the ICA lumen seen on grayscale and color Doppler should correlate with PSV as the primary parameters for determining ICA stenosis. Additional parameters such as ICA/CCA PSV ratio and ICA EDV are secondary parameters and should be employed as internal checks. They are especially useful when ICA PSV may not be representative of the extent of disease. After their discussions the consensus panel recommended criteria, stratifying ICA stenosis into specific categories relevant to the 4 CEA trials (Table 85.2). These criteria have not been subjected to widespread retrospective or prospective evaluation and do not represent the results of any one laboratory or study. They are not meant to serve as a substitute for continuous quality assurance in individual laboratories.

BILATERAL HIGH-GRADE ICA STENOSIS

Doppler-derived flow velocities from the ICA opposite an ICA occlusion or high-grade stenosis may suggest a higher degree of narrowing than is observed angiographically.[2] This likely is because of compensatory flow. Duplex scan overestimation of stenosis is more common in less-severe categories of stenosis than in higher-severity categories.[23]

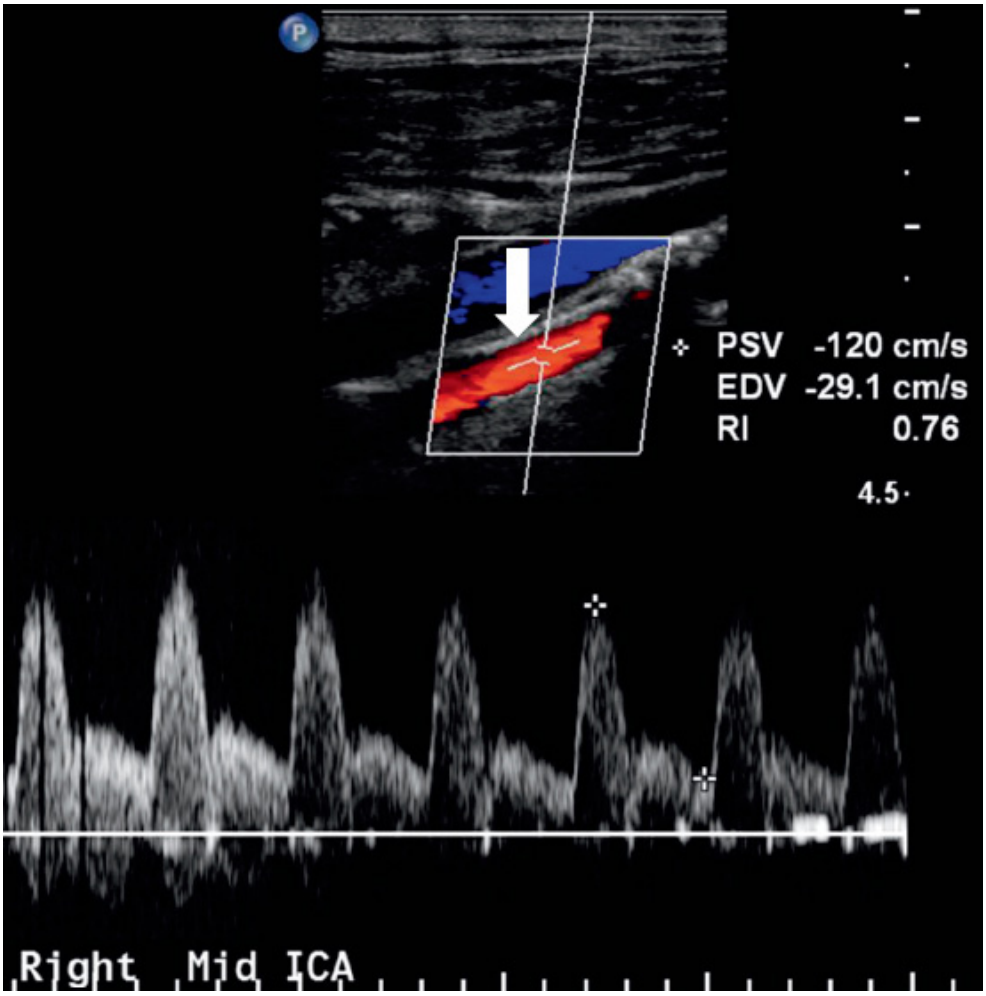

Figure 85.8 Color flow image and velocity waveforms from a stented internal carotid artery. A peak systolic velocity of 120 cm/s indicates the stent is widely patent. The stent itself is easily recognized as a hyperechoic stripe (*arrow*) parallel to the vessel wall.

Stented Carotid Arteries

Carotid artery stenosis may be selectively treated with an intraluminal stent. However, ultrasound criteria developed for native ICAs are likely not applicable to stented carotid arteries, especially to more modest lesions in the stented arteries. With rare exceptions the number of patients in studies of stented carotid arteries that have actually had severe in-stent restenosis is small. No study has correlated the degree of stenosis or increase in ICA velocities within a stented carotid artery with clinical symptoms or outcomes. Studies have also not evaluated the effect of the stented carotid

artery on the opposite nonstented artery. It is generally agreed that PSVs >125 cm/s, will be needed to identify a >50% stenosis in a stented ICA. Criteria to detect high-grade stenosis in native ICAs still work reasonably well to identify high-grade stenosis in stented ICAs (Fig. 85.8).[24,25]

CCA and ECA Stenosis

Criteria used for classifying disease in the ICA have not been prospectively tested for application to the ECA or the CCA. However, as with the ICA, relative degrees of stenosis may be determined by the presence of plaque with B-mode imaging, aberration in color flow on duplex examination, spectral broadening, and increases in PSV. Greater than 50% stenosis can be inferred by the presence of a focally increased PSV followed by poststenotic turbulence. As noted above, the CCA waveform normally has attributes of the ICA and ECA. The CCA will take on the quality of the "normal" vessel (ICA or ECA) when the other is occluded. If there is a proximal CCA (or innominate artery) high-grade stenosis or occlusion, the ipsilateral CCA Doppler flow quality will be dampened with low PSVs and delayed upstroke of the waveform compared with the nonstenotic contralateral side. Poststenotic turbulence also may be seen. There are no widely employed validated criteria to give a diameter reduction for stenosis in the CCA or ECA. Greater than 50% stenosis in the ECA is often inferred by PSV >125 cm/s associated with poststenotic turbulence whereas a PSV >200 cm/s may be an appropriate threshold for >50% stenosis in the CCA.[26]

LOWER EXTREMITY ARTERIAL DISEASE

The noninvasive vascular laboratory, in combination with the history and physical examination, has a critical role in providing objective diagnosis of lower extremity arterial occlusive disease in asymptomatic patients, those with intermittent claudication (IC), and in those with critical arterial insufficiency. Both plethysmographic and ultrasound techniques are used in the evaluation of peripheral arterial disease (PAD).

In many patients the clinical history and physical examination are all that is necessary to establish a diagnosis of IC. Almost all patients with IC have

diminished or absent lower extremity pulses. However, palpation of pulses is subjective and poorly reproducible. Therefore, the pulse examination in a patient suspected of having arterial disease should be supplemented with objective testing in the noninvasive vascular laboratory. On occasion a patient will give a history suggesting IC, yet have what appear to be normal resting lower extremity pulses. In such cases, exercise testing with postexercise Doppler-measured ankle pressures and ankle–brachial systolic blood pressure ratios is crucial to confirm the diagnosis of IC secondary to arterial stenosis or occlusion.

Many patients with PAD have atypical leg symptoms or are asymptomatic. Such patients have a similar increased risk of cardiovascular death as patients with typical IC symptoms, leading some to advocate for screening for PAD in patients with atypical leg symptoms or atherosclerotic risk factors.

Patients with exercise-induced lower extremity and/or buttock pain should be asked about the location of their pain, its relationship to walking, severity and duration of symptoms, and symptom progression over time. Only exercise-induced muscular pain of the calf, thigh, or buttock, relieved within a few minutes of rest and reproduced by additional walking, can be predictably improved by lower extremity arterial revascularization. There are no data on the response of atypical leg symptoms to revascularization in patients with evidence of PAD.

Ischemic pain at rest is a clinical diagnosis. It is suspected when a patient complains of pain and/or numbness in the forefoot, toes, or instep at rest. In such patients the vascular laboratory can objectively confirm and quantify the magnitude of arterial insufficiency. Ischemic pain is generally associated with an ankle pressure <50 mm Hg and an ankle brachial index (ABI) ≤0.4.

PLETHYSMOGRAPHIC TECHNIQUES

Volume Flow

Calf or foot blood flow can be recorded with a mercury-in-silastic strain gauge. Electrical resistance of the mercury column depends on the length of the column. Changes in electrical resistance, reflect changes in the volume of

the extremity, and are based on detection of minute changes in the length of the column. However, neither calf nor foot blood flow at rest differ between normal subjects and patients with even rather severe IC.[27] Hyperemic volume flow is often lower in patients with occlusive disease but such testing can be quite painful for the patient. Measurements of volume flow therefore are not very useful in the evaluation of lower extremity ischemia.

Pulse Volume Recordings

5 APG can be used to display pulse volume waveforms. PVRs are obtained with partially inflated blood pressure cuffs that detect volume changes sequentially down a limb. Volume changes beneath the cuffs resulting from the pulse wave result in small pressure changes within the cuffs. These changes are displayed as arterial waveforms with the use of appropriate transducers. A normal pulse volume waveform has a sharp systolic upstroke and peak, as well as a prominent dichroic notch on the downward portion of the curve. With increasing proximal arterial occlusion, the dichroitic notch is lost and the waveform bows out on the down portion of the systolic portion of the curve. The peak of the pulse wave also becomes rounded and there is loss of amplitude of the wave as disease is more severe. With even more severe disease there are nearly equal upstroke and downstroke times and in very severe proximal disease the pulse wave is absent (Fig. 85.9).[28,29] An absence of quantitative data limits the utility of PVRs. More quantitative data for the evaluation of lower extremity arterial disease are available using ultrasound-based techniques.

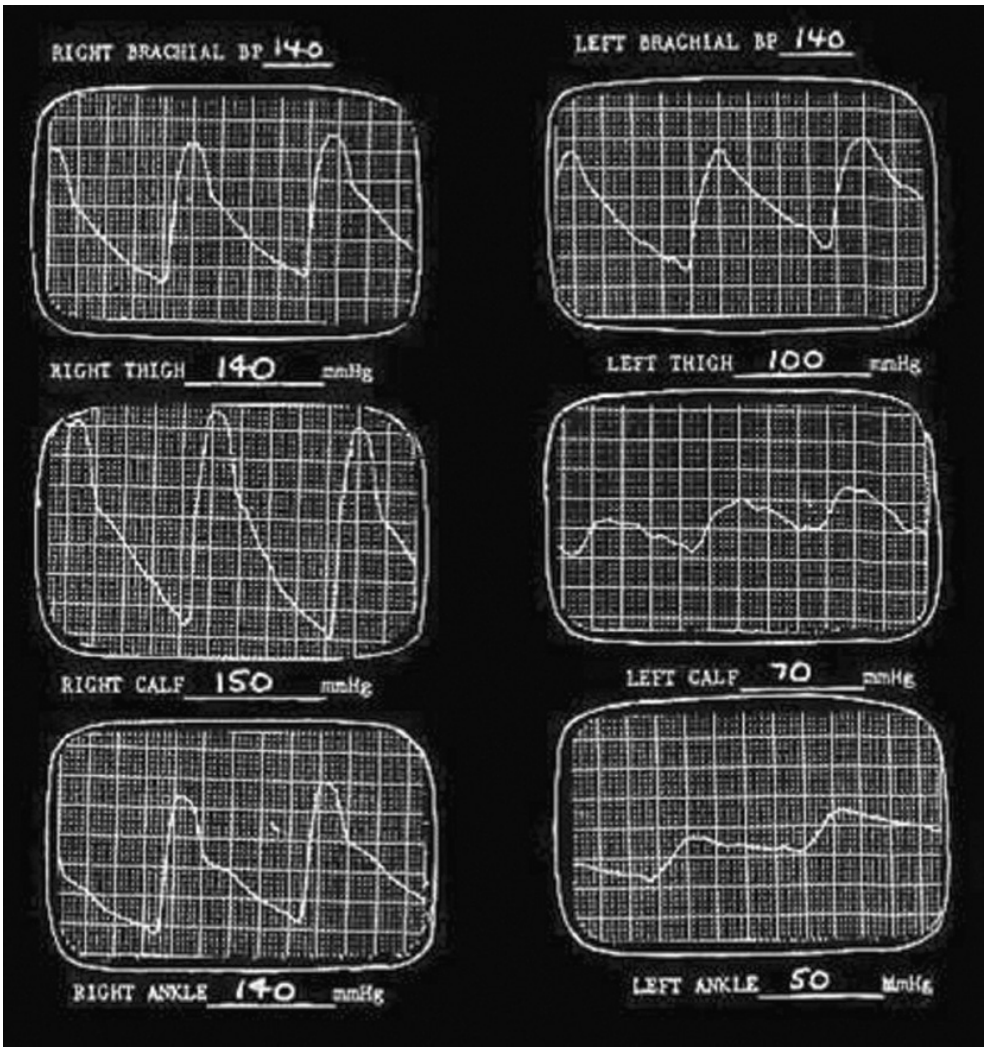

Figure 85.9 Pulse volume recordings. The plethysmographic waveforms are normal on the right and severely abnormal in the left leg with loss of amplitude of the waveform, slowing of the upstroke of the waveform, and outward bowing of the downstroke of the waveform.

ULTRASOUND TECHNIQUES

Ankle–Brachial Index

6 ABI is a very useful measure of overall lower extremity perfusion. The test is performed with the patient supine and having rested for a few minutes. A pneumatic pressure cuff is placed just above the ankle and inflated to supra systolic levels. A continuous wave Doppler probe is positioned over the posterior tibial or dorsalis pedal artery distal to the cuff. The cuff is deflated

and the pressure reading when the Doppler signal returns is recorded. The sequence is repeated for the other ankle artery and the values compared with the highest brachial artery systolic pressure also obtained with the Doppler. For clinical purposes, the higher ipsilateral dorsal pedal or posterior tibial pressure is divided by the higher brachial artery systolic pressure, yielding an ABI for that lower extremity. The use of a ratio makes the test relatively independent of day-to-day variations in arterial blood pressure.

A normal ABI is 1.0 to 1.2, with progressively lower values corresponding to worsening arterial disease (Table 85.3). ABIs below normal indicate relative lower extremity arterial insufficiency and increased risk of cardiovascular death with the risk increasing with the magnitude of depression of the ABI. This test has several limitations. Significant bilateral subclavian or axillary artery occlusive disease results in a falsely elevated ABI. Calcified tibial arteries that can frequently occur with diabetes or renal failure may be inadequately compressed by the pressure cuff. This also results in a falsely elevated (suprasystolic) ankle pressure. An ABI >1.4 should therefore also be considered abnormal. Such patients often have severe arterial disease and are also at increased risk of cardiovascular death. When the ABI may be falsely elevated, qualitative analysis of Doppler-derived analog or plethysmographic waveforms or measurement of digital systolic pressures is a more appropriate indicator of the arterial status of the lower extremity. Other problems with ABI include confusion with venous signals when the ankle arterial pressure is low or unmeasurable and relative insensitivity to certain patterns of progression of arterial disease. A tibial artery can occlude without a change in ABI if the remaining tibial vessels remain patent. High-grade stenosis may also progress to occlusion without a change in ABI.

Table 85.3 Correlation between Ankle Brachial Index (ABI) and Clinical Severity of Lower Extremity Arterial Ischemia

ABI	Clinical Status
>1.3	Abnormal, significant arterial wall calcification
1.1 ± 0.1	Normal
0.6 ± 0.2	Intermittent claudication
0.3 ± 0.1	Ischemic rest pain
0.1 ± 0.1	Impending tissue necrosis

Segmental Limb Pressures

Multiple pneumatic cuffs may be used along the lower extremity to determine the arterial blood pressure at specified levels. These "segmental leg pressures" are compared with the higher brachial artery systolic pressure, with other locations in the ipsilateral leg and with the corresponding levels in the contralateral extremity. Three or four cuffs may be used. In the four-cuff technique cuffs are placed: (1) as far proximal on the thigh as possible; (2) immediately above the knee; (3) just below the knee; and (4) just proximal to the ankle. Each cuff width should be 20% greater than the diameter of the limb at the point of application to avoid falsely elevated pressure readings induced by too narrow a cuff.[30] For the thigh, this generally necessitates a single, wide, thigh cuff. Use of two cuffs above the knee, however, can permit assessment of inflow at or proximal to the common femoral artery with the proximal cuff, and permit evaluation for the presence of superficial femoral artery disease by the distal thigh cuff. With two thigh cuffs the most proximal thigh cuff is often too narrow. An artificially elevated pressure in the proximal thigh is then expected. Therefore the high-thigh index, comparing the proximal thigh pressure to the brachial pressure, is normally about 1.4 with the four-cuff technique and 1.0 to 1.1 with the three-cuff technique (Fig. 85.10).

A hand-held Doppler is used to detect the most prominent Doppler signal at the ankle. Examination proceeds proximal to distal. First the high-thigh

cuff is inflated until the ankle Doppler signal is no longer audible. The cuff is then deflated and the pressure where there is return of the Doppler signal at the ankle is the high-thigh pressure. The above-knee, below-knee, and ankle pressures are similarly determined. If there is no audible ankle Doppler signal, the popliteal artery is insonated with the Doppler to determine high-thigh and above-knee pressures. Comparison of the pressures measured at each location permits an estimation of the location of occlusive lesions (Fig. 85.11).

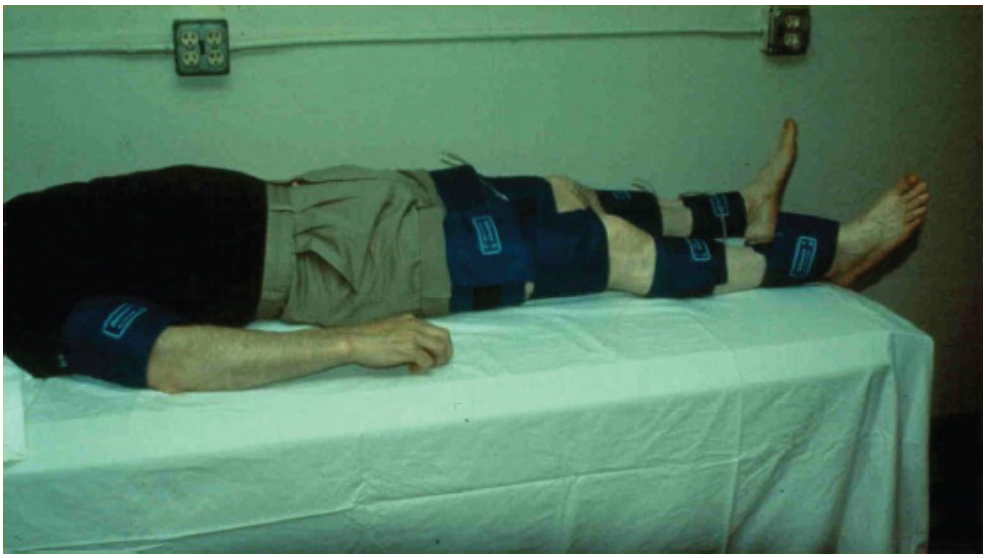

Figure 85.10 Segmental pressures multiple pneumatic cuffs may be used along the lower extremity to determine the arterial blood pressure at each level. Comparison of the pressures measured at each location permits an estimation of the location of occlusive lesions. Use of two cuffs above the knee can permit assessment of inflow at or proximal to the common femoral artery with the proximal cuff, and permit evaluation for the presence of superficial femoral artery disease by the distal thigh cuff. In many patients, however, the high-thigh cuff is relatively narrow compared to the diameter of the thigh resulting in an artificial elevation of the high-thigh pressure so that with use of four cuffs the high-thigh pressure will be 30 to 40 mm Hg higher than the highest brachial pressure.

There are multiple limitations in the interpretation of segmental limb pressures. The high-thigh pressure is subject to particular interpretation difficulties. A diminished high-thigh pressure can reflect an occlusive lesion anywhere at or proximal to the common femoral artery bifurcation. Low high-thigh pressures therefore may reflect a pressure-reducing stenosis in the ipsilateral common or external iliac artery, a common femoral artery lesion

or tandem pressure-reducing lesions in the profunda femoris, and the proximal superficial femoral artery or any combination of such lesions. The accuracy of segmental pressures may be affected by mural calcification resulting in artificially elevated pressures. Diminished proximal pressures may also mask gradients that exist further down the leg. Segmental pressures also do not allow differentiation between short- and long-segment occlusions, or between occluded and patent, but highly stenotic arteries.

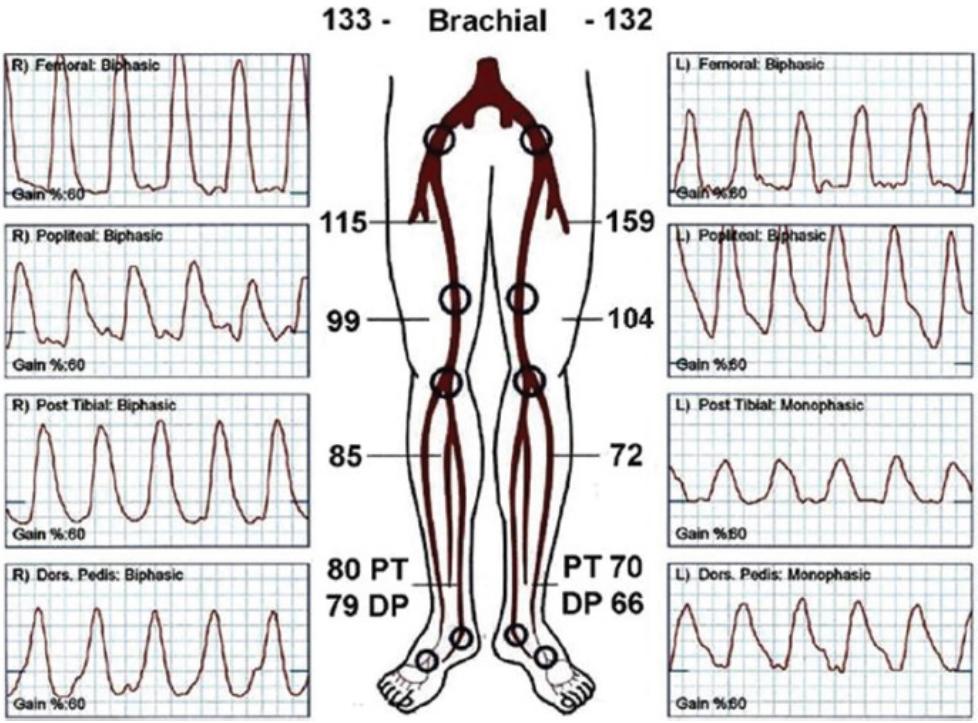

Figure 85.11 Segmental pressure examination with use of thigh, calf, and ankle cuffs. A drop in pressure of 30 mm Hg between levels indicates a hemodynamically significant stenosis between the two adjacent cuffs. This study therefore indicates a flow-reducing lesion somewhere at or proximal to the common femoral artery bifurcation on the *right side* and likely superficial femoral artery/popliteal artery occlusive disease on the *left*.

Exercise Testing

Doppler-determined pressures can be combined with treadmill exercise testing in patients without a contraindication to exercise. After determination of resting supine ankle pressures and ABIs, the patient walks on a treadmill with a predetermined incline at a predetermined rate. The test continues for 5 minutes or until the patient is forced to stop. The type, time-to-onset, and

location of symptoms are recorded. At completion of the test, the patient is immediately placed supine and absolute ankle pressures and ABIs determined.

In most patients exercise testing serves only to confirm a diagnosis of claudication. It is not required in a patient with classic symptoms of claudication, absent peripheral pulses and a diminished ABI. In some cases exercise testing can document a physiologic response to revascularization or provide an objective assessment of the potential postoperative physiologic benefit.

Exercise testing is particularly useful in the infrequent patient with symptoms of claudication and who has palpable pedal pulses and/or a normal ABI. Patients with exercise-induced leg pain occurring on the basis of arterial insufficiency will show a decrease in the postexercise ankle pressures and ABI. Exercise testing can also be used to document an ischemic response to exercise in a patient with PAD and other conditions that may limit their ability to walk. Patients with COPD, arthritis, venous disease, and PAD are often more limited in their walking ability by these coexisting conditions than by their PAD. If the patients cannot complete a treadmill examination, and no ischemic pressure response to exercise occurs, it is highly unlikely their walking ability would be improved by a revascularization procedure.

The precise endpoints and techniques of exercise testing are controversial. Some laboratories exercise patients at low speeds with no inclination of the treadmill whereas others utilize various inclines and graded increases in treadmill speed. Both initial and absolute claudication distances can be determined. Initial claudication distance is the point where the patient initially experiences claudication-type pain. The absolute claudication distance is where the patient can no longer continue to walk on the treadmill.

Criteria for a positive exercise test include a decrease in the ankle pressure of 20 mm Hg or 20%, a decrease in the ABI of 0.2 in the symptomatic extremity, or failure of the ankle pressure to return to baseline within 3 minutes of completing the treadmill portion of the examination. Because systemic pressure and therefore arm pressures, depending on work load, will increase with exercise, use of the ABI alone to indicate a positive exercise test is incorrect. The ABI decrease should be accompanied by an absolute pressure drop at the ankle.

7 Failure of the ankle pressure to drop with exercise along with failure of the ABI to decrease 20% with exercise, combined with a normal resting ABI, substantially rules out arterial insufficiency as the etiology of the patient's exercise-induced complaints of leg pain. An exception is the rare patient with buttock claudication secondary to isolated internal iliac disease.

Neurogenic claudication may be confused with arterial ischemia. Patients present with symptoms of exercise-induced leg or calf pain. Careful questioning, however, reveals atypical characteristics for vascular-induced exercise-associated pain. Such characteristics include occurrence of pain with standing, pain relief when leaning forward, worsening with coughing, and prolonged time for pain to resolve following exercise. These patients often have normal ankle pressures at rest that do not decrease with exercise despite onset of symptoms. Failure of the ankle pressures to decrease with exercise may also be a clue to the presence of other uncommon conditions, such as venous claudication and chronic exercise-induced compartment syndromes.

Doppler Analog Waveform Analysis

Similar to plethysmographic waveforms, continuous-wave Doppler waveforms may also be analyzed qualitatively. Normal lower extremity Doppler waveforms are described as triphasic with a sharp systolic upstroke, an end-systolic reverse flow component followed by low forward flow through diastole. The shape of the waveform changes with increasing severity of proximal obstruction. Initially, the reverse-flow component is lost. As proximal stenosis increases, the rate of rise of the systolic upstroke is decreased, the amplitude of the waveform is diminished, and diastolic flow increases relative to systolic flow.

Continuous-wave Doppler waveforms are generally used in conjunction with measurement of segmental Doppler pressures similar to the use of PVRs. Doppler waveform analysis can also be used to assess iliac artery inflow to the common femoral artery. An attenuated common femoral artery waveform indicates proximal disease.

Peripheral Artery Duplex Scanning

Arterial duplex scanning provides detailed anatomic and hemodynamic information from the infrarenal aorta to the distal tibial vessels that cannot be determined by indirect testing. Arterial duplex scanning has been prospectively compared with angiography to establish standard criteria for normal and diseased arteries.[31] Sensitivity of duplex examination for detecting the presence of a hemodynamically important lesion (>50%) ranges from 89% at the iliac artery to 68% at the popliteal artery. Overall sensitivities for predicting interruption of patency are 90% for the anterior and posterior tibial arteries and 82% for the peroneal artery. The technique is versatile and does not appear to be significantly influenced by the presence of previous operations or multilevel disease (Fig. 85.12**A,B**).

Velocity Patterns and Classification of Percent Stenosis

In the absence of arterial stenosis or occlusion triphasic waveforms are maintained throughout the length of the lower extremity but PSV decreases from the iliac to the tibial vessels. There are no significant differences in velocity measurements among the three tibial arteries in normal subjects.

Important changes in the velocity waveforms that signify disease include the absence of an end-systolic reverse flow component and elevation of the PSV. A 50% reduction in arterial luminal diameter (equivalent to a cross-sectional surface area reduction of 75%) is associated with a pressure drop across the lesion. The University of Washington criteria for classification of peripheral arterial stenosis are shown in Table 85.4.[32]

A PSV ratio, comparing the velocity within the stenosis to the velocity just proximal to the stenosis, is also useful for grading degree of stenosis. PSV ratios are independent of changes in blood pressure, cardiac output, and vascular compliance. Grading stenosis using the PSV ratio has been found to be highly reproducible.[33,34] Fifty percent stenosis in lower extremity arteries correlates with a PSV ratio from 1.4 to 3.0.[31,35–38] A velocity ratio of 2.0 is a reasonable compromise and is used by many vascular laboratories as indicative of a 50% peripheral arterial stenosis.

Lower extremity duplex scanning can serve as an alternative to contrast arteriography in the preoperative assessment of candidates for arterial intervention. In selected centers, successful lower extremity

revascularization either by open arterial bypass grafting or with catheter-based techniques has been reported using only arterial duplex in a high percentage of cases.[39–41] The limiting factor with preoperative arterial duplex is the ability to accurately identify the best site for the distal anastomosis of a bypass graft, especially when the distal anastomotic site is below the knee.[42]

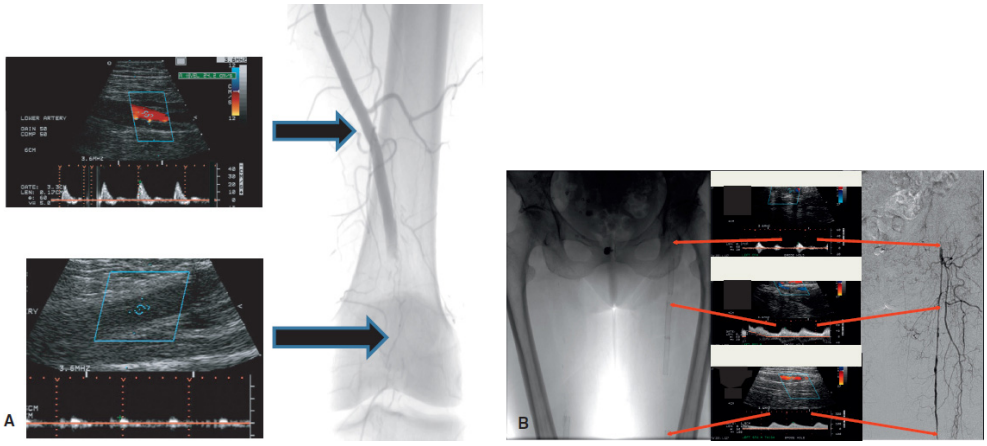

Figure 85.12 **A:** Duplex images/waveforms and corresponding angiogram of an abrupt popliteal artery occlusion. **B:** Duplex waveforms and angiographic images in a patient with severe in-stent stenosis of superficial femoral artery stents.

The role of duplex ultrasound scanning in the surveillance of lower extremity vein grafts has been well documented (Fig. 85.13**A,B**). Detection and repair of a graft-threatening stenosis detected by duplex scanning appears to improve secondary graft patency.[43–46] Twenty percent to 30% of vein grafts will develop a severe enough stenosis that revision is recommended.[47] Approximately 80% of these graft stenotic lesions develop in the first postoperative year. However, graft-threatening lesions can develop at any time. Surveillance is therefore generally recommended for the life of the graft. A widely utilized protocol for vein graft duplex surveillance is every 3 months for the first year and every 6 months to yearly thereafter. The examination involves point-to-point insonation of the proximal inflow artery, proximal anastomosis, midgraft, distal anastomosis, and the distal outflow artery. A PSV ratio of 4, or a PSV above 300 cm/s, indicates a critical graft stenosis, and repair of the lesion by open or catheter-based techniques should be considered.[48] If the PSV ratio is between 2 and 4, the patient should be evaluated again in 3 months with a duplex examination.

Table 85.4 University of Washington Duplex Criteria for Classification of Lower Extremity Arterial Stenosis

Disease Severity	Spectral Waveform Features
Normal	Triphasic waveform No spectral broadening
1–19% Diameter Reduction	Triphasic waveform with minimal spectral broadening PSVs increased <30% relative to the adjacent proximal segment Proximal and distal waveforms remain normal
20–49% Diameter Reduction	Triphasic waveform usually maintained (although reverse flow component may be diminished) Spectral broadening is prominent, with filling-in of the clear area under the systolic peak PSV is increased from 30% to 100% relative to the adjacent proximal segment Proximal and distal waveforms remain normal
50–99% Diameter Reduction	Monophasic waveform with loss of the reverse flow component and forward flow throughout the cardiac cycle Extensive spectral broadening PSV is increased >100% relative to the adjacent proximal segment Distal waveform is monophasic with reduced systolic velocity
Occlusion	No flow detected within the imaged arterial segment Preocclusive “thump” may be heard just proximal to the site of occlusion Distal (collateral) waveforms are monophasic with reduced systolic

velocities

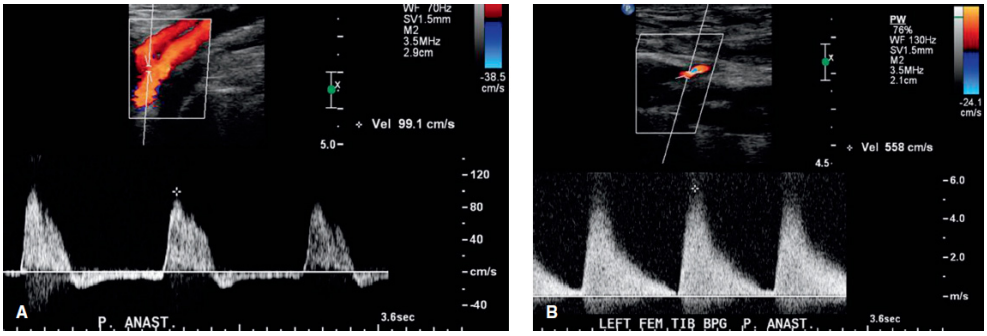

Figure 85.13 **A and B:** Duplex ultrasound images and velocity waveforms of normal **(A)** and stenotic **(B)** proximal anastomoses of femoral tibial bypass grafts. The abnormal study has a severe elevation in flow velocity of 558 cm/s indicating a high-grade stenosis.

Aneurysms and pseudoaneurysms of lower extremity arteries are also readily identified and characterized with duplex scanning with particular attention to the diameter of the aneurysm and the presence or absence of intraluminal thrombosis (Fig. 85.14**A,B**).

Upper Extremity Arterial Evaluation

Upper extremity arterial disease is a small but important component of vascular surgical practice. Both ultrasound and plethysmographic techniques are important in the evaluation of upper extremity arterial disease.

SEGMENTAL ARM PRESSURES

Upper extremity segmental pressures are obtained by measuring blood pressure with pneumatic cuffs above the elbow, below the elbow, and above the wrist while insonating the radial or ulnar artery at the wrist using a continuous wave Doppler. Doppler-derived or plethysmographic waveforms can also be recorded at the different levels. Abnormal waveforms or pressures will help diagnose arterial disease proximal to the wrist.

A 12-cm blood pressure cuff is usually sufficient for measuring the brachial artery pressure, whereas a 10-cm blood pressure cuff is used at the wrist to measure the systolic pressure from the radial and ulnar arteries. A systolic pressure measurement is taken from the upper arm (brachial artery) and at the wrist (radial and ulnar arteries). Normally, there is not a recordable gradient between any of these sites and a normal wrist/brachial blood pressure ratio is 1.0. If there is a blood pressure difference between the two arms of more than 15 mm Hg, it is likely that there is a stenosis or occlusion somewhere on the side of the lower pressure. Abnormal waveforms and decreased pressures at the above-elbow cuff site indicate axillary, subclavian, or brachiocephalic arterial occlusive disease. Similarly, abnormalities at the below-elbow and above-wrist sites indicate brachial and proximal ulnar/radial arterial occlusive disease, respectively. If there is a blood pressure difference between levels, or between the radial and ulnar arteries, of more than 15 mm Hg it is likely caused by a stenosis or occlusion (Fig. 85.15).

DIGITAL PRESSURES AND PLETHYSMOGRAPHY

Digital pressure measurements and digital plethysmography are extremely useful in the diagnosis of upper extremity arterial disease and can be as accurate as arteriography in assessing patients with hand ischemia.[49] Photo plethysmography (PPG) or strain-gauge plethysmography can be used to measure digital blood pressure and to obtain pulse waveforms. PPG is preferred because the equipment is easier to use and more durable. An additional advantage of PPG is that it is possible to record the volume pulses from the tips of the digits. This may also be useful in documenting obstruction within the digit arteries themselves.

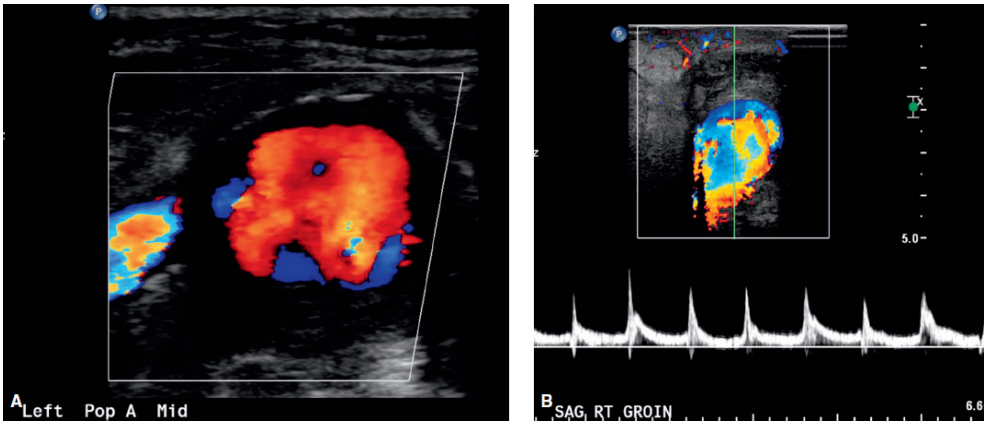

Figure 85.14 **A:** Native popliteal artery aneurysm with intraluminal thrombus. **B**: Large pseudoaneurysm of the right common femoral artery resulting from arterial infection from intra-arterial injection of street drugs.

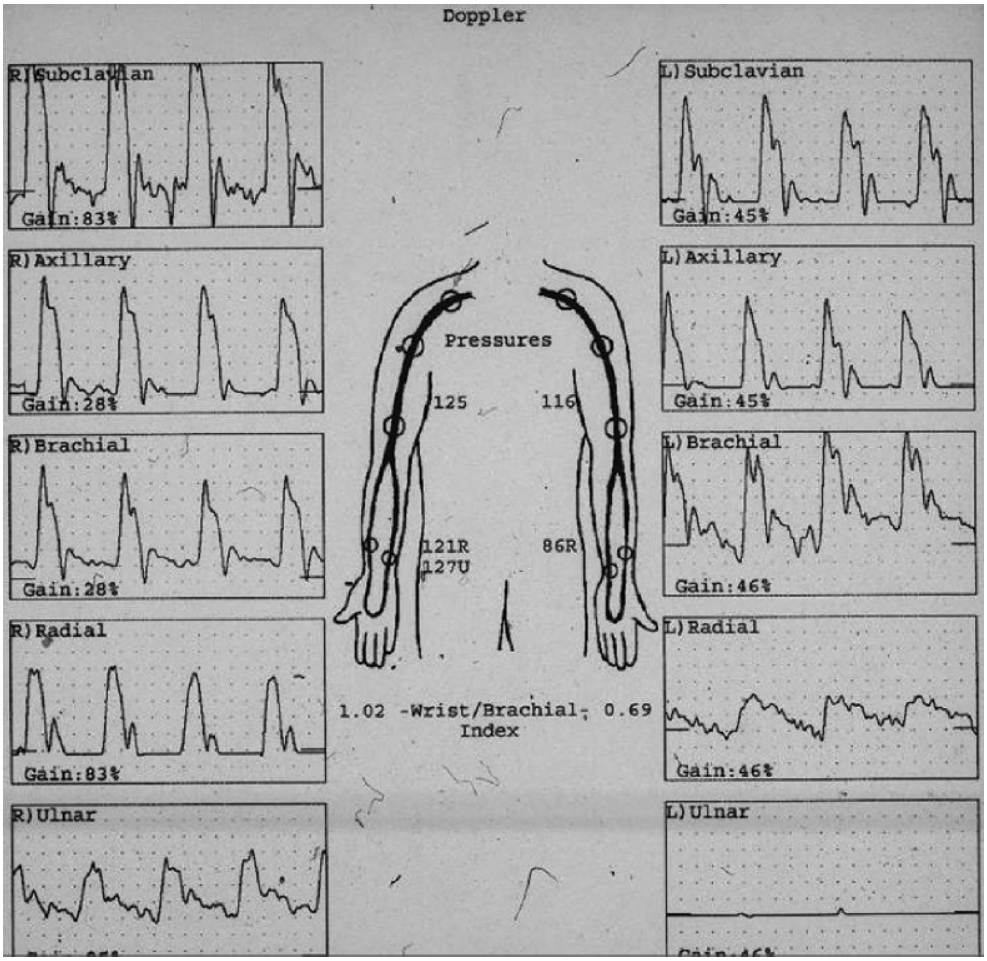

Figure 85.15 Upper-extremity segmental pressures and Doppler waveforms. The findings are normal on the **right** and suggest radial and ulnar artery or distal brachial artery occlusive disease on the **left**.

The photo cell is attached to the fingertip pulp with double-sided tape or small strain gauges are placed around the fingertip. One-inch (2.5 cm) blood pressure cuffs are placed around the proximal phalanx. Waveforms are recorded using pulse tracings obtained at high speed to evaluate the shape of the waveform. Waveforms are normal if the upstroke time is less than 0.2 seconds (Fig. 85.16**A**). They may or may not have a dichotic notch. An abnormal obstructive waveform will have a rounded peak, as opposed to the normal notched peak. Upstroke time is prolonged. The amplitude of the waveform is not important. Finger PPG waveforms are not quantitative. The amplitude of the waveform is primarily dependent on the gain setting, not blood flow.

Patients with vasospasm will often have an abnormally shaped waveform termed a "peaked pulse," which is thought to represent abnormal elasticity and rebound of the palmar and digital vessels (Fig. 85.16**B**).

Finger blood pressures are measured by inflating the cuffs placed at the base of the fingers. At reduced chart recorder speed the pulsations are recorded while the blood pressure cuffs are inflated. When digit pulsations are obliterated, the cuff is slowly deflated until the pulsation returns. The pressure reading at this point is recorded and represents the digital artery pressure.

It is extremely important to measure and record finger temperature before performing digital plethysmography and obtaining finger blood pressures. If the finger temperature is less than 28° to 30°C false-positive results may be obtained secondary to cold-induced vasospasm. It is recommend that hand and/or whole-body warming be performed in patients with low finger temperatures.

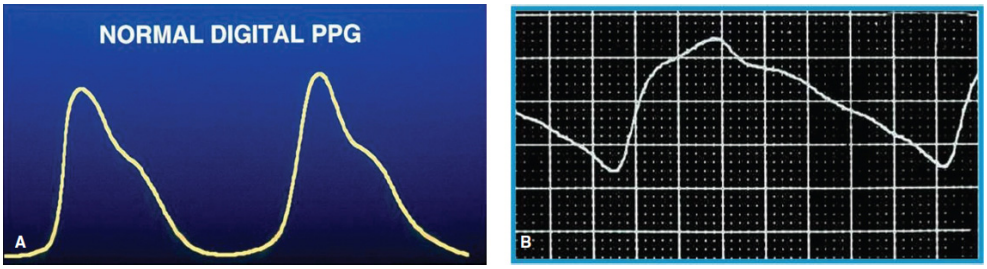

Figure 85.16 A and B: Normal **(A)** and "peaked pulse" **(B)** digital photoplethysmographic (PPG) waveforms. A normal waveform has a rapid upstroke and a sharp apex whereas an obstructive waveform would demonstrate a delayed upstroke and rounded apex. In a peaked pulse, waveform suggestive of vasospasm, the dichroitic notch slides to high on the systolic downslope of the waveform.

Digital blood pressure is normally within 20 to 30 mm Hg of brachial pressure. A ratio of finger systolic pressure to brachial systolic pressure of greater than 0.80 is normal but does not necessarily rule out digital artery occlusive disease. It is important to remember that there are occasional patients with very distal digital artery occlusive disease with normal finger pressures since the digital cuff is around the proximal phalanx. Also, occlusive disease in a single digital artery can be missed if the other digital artery in that finger is normally patent.

COLD CHALLENGE TESTING

The simplest cold intolerance test is to measure the digital temperature recovery time after immersion of the hand in ice water for a short time period. Preimmersion digital temperatures must be above 30°C. Hand and body warming may be required prior to immersion.

Using a thermistor probe to measure finger temperatures, the patient's hand is immersed in a container of ice water for 30 to 60 seconds. After the hand is dried, the fingertip pulp temperatures are measured every 5 minutes for 45 minutes, or until the temperature returns to preimmersion levels. Normal individuals will have a recovery time to preimmersion levels of less than 10 minutes. This test is very sensitive for detecting cold-induced vasospasm but is nonspecific, with approximately one-half of patients with a positive test having no clinical symptoms of cold sensitivity.[50] Cold immersion testing is

also uncomfortable and poorly tolerated by patients with significant Raynaud syndrome symptoms. Pressures often fall to unrecordable levels in such patients.

A better, but infrequently utilized, test for cold sensitivity is the digital hypothermic challenge test as described by Nielsen and Lassen (Fig. 85.17).[51] This test involves placing a finger cuff around the proximal phalanx on the test finger and perfusing the cuff with progressively cooler fluid. The pressure in the test finger is then compared with that in a reference finger that is not cooled. The Nielsen test is interpreted as positive for abnormal cold-induced vasospasm if the test finger pressure is reduced by more than 17% compared with the reference finger.

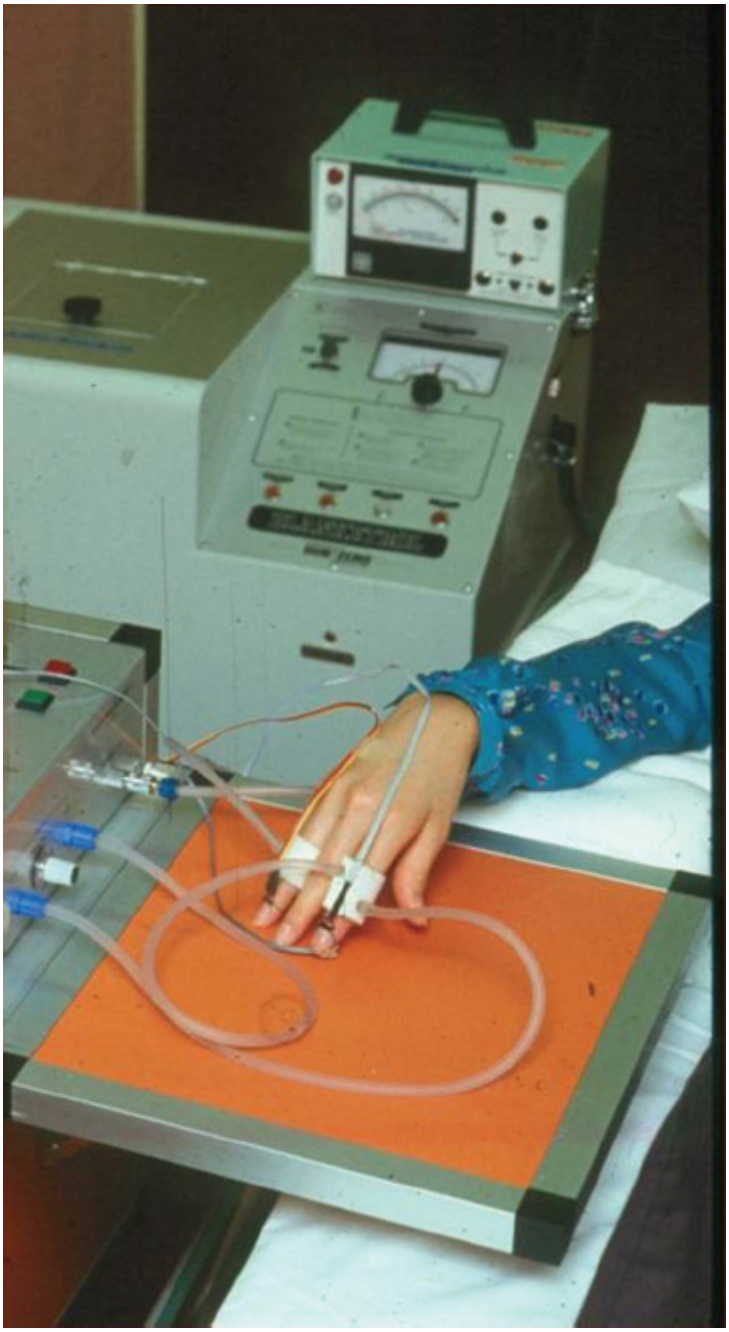

Figure 85.17 Device for performance of digital hypothermic challenge or Nielsen test. The cuff on the second finger is used to cool the test finger and measure digital pressure. This allows controlled application of cold to induce a vasospastic response. The fourth finger is the reference finger. Strain gauges on the finger tips are used to measure the digital pressures. See text.

Other tests for cold-induced vasospasm include thermal entrainment, digital laser Doppler response to cold, thermography, venous occlusion

plethysmography, and digital artery caliber measurement. None are widely accepted or employed.[52–54]

UPPER EXTREMITY DUPLEX SCANNING

Duplex scanning of the upper extremity is carried out in a manner similar to arterial examination elsewhere. The origins of the brachial cephalic vessels can be difficult to visualize with duplex scanning. For examination of the origin of the subclavian artery a 3- or 5-MHz transducer with a small footprint probe using the sternal notch as a window generally gives the best images. One study found 48 of 50 right subclavian artery origins (96%) and 25 (50%) of 50 left subclavian artery origins could be visualized by color duplex scanning.[55]

Criteria for stenosis at the origins of brachial cephalic arteries are slightly different than those used elsewhere. A PSV ratio of ≥2 indicates stenosis at the origin of a brachial cephalic artery. Stenosis can also be implied by monophasic flow without actual visualization of a high-velocity jet and by reverse flow in a vertebral artery. Such additional criteria are necessary to assess the origins of the brachiocephalic vessels. If only PSV ratios are utilized there would be higher numbers of both false-positive and false-negative results.[55]

More distally the upper extremity arteries are relatively superficial and fairly constant in location. They are best scanned with a higher-frequency probe such as a 7.5- or 10-MHz probe. Either a sector or linear scan head may be used, but in either case a standoff or mound of acoustical gel is helpful to visualize the vessel clearly and to assess the flow pattern within it. Color facilitates identification of the vessels, and tortuosity of the upper extremity arteries may be more easily seen with color flow imaging. Stenosis, occlusions, and aneurysms of upper extremity arteries are all readily identified with ultrasound (Fig. 85.18**A–C**).

The interpretation of duplex findings in the upper extremity beyond the origins of the vessels is similar to the interpretation of B-mode images and Doppler signals gathered in other arterial systems.[56] Normal waveforms in the upper extremity arteries are usually triphasic. As elsewhere in the arterial system, stenosis will produce high-velocity jets, poststenotic turbulence, and

dampened distal waveforms. There are, however, at present no specific frequency or velocity criteria with which to gauge the severity of stenosis in the upper extremity arteries. Some general guidelines are listed in Table 85.5. The diagnosis of arterial occlusion is made by imaging the artery and using the pulsed Doppler to show that there is no flow within the lumen.

For patients with unilateral symptoms who may have a surgically correctable lesion such as a subclavian artery aneurysm or stenosis, duplex scanning is quite useful.[57] The duplex evaluation of aneurysms is based upon the B-mode image appearance, with the most important feature being the size of the enlarged artery and the presence of intraluminal thrombus that may serve as a source of distal embolization. Presence or absence of flow within the aneurysm can be determined by the Doppler component.

Duplex scanning may be of use in patients with suspected embolization to identify proximal aneurysms, but the evaluation should also include echocardiography to look for mural thrombi and valvular lesions. While duplex scanning alone cannot be used to make the diagnosis of Takayasu arteritis, it can be a helpful adjunct in following the progression or regression of arterial involvement in response to treatment.[58]

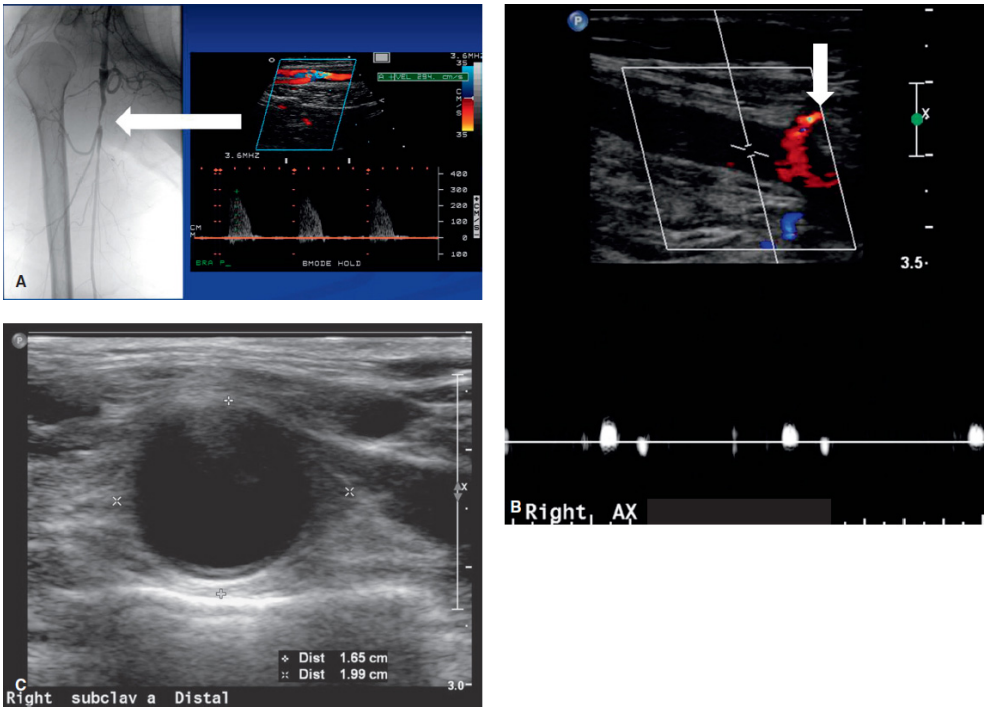

Figure 85.18 **A:** Duplex color flow image and velocity waveform with corresponding angiogram in a patient with brachial artery stenosis (*arrow*) and symptomatic arm ischemia secondary to a crutch injury. Note the loss of the end-systolic reverse flow component of the arterial waveform. **B:** Duplex image of a right axillary artery occlusion secondary to embolism. Note the occlusive waveform and reconstitution of the artery via a distal branch vessel (*arrow*). **C:** Grayscale image of a small subclavian artery aneurysm.

VISCERAL ARTERIES

Mesenteric Arteries

Duplex ultrasonography can serve as a valuable noninvasive screening test for splanchnic artery stenosis in patients with possible chronic mesenteric ischemia and for follow-up of mesenteric artery reconstructions. Aneurysms and dissections of the visceral arteries can also be identified (Fig. 85.19). Despite the accuracy of duplex detection of mesenteric artery stenosis, angiographic confirmation of high-grade stenosis or occlusion of the splanchnic vessels, and appropriate history and physical examination are still required for the diagnosis of chronic mesenteric ischemia. The examination is technically difficult and is best performed by vascular

technologists with extensive experience in intra-abdominal ultrasound techniques.

Table 85.5 Duplex Ultrasound Criteria for Evaluation of Upper Extremity Arterial Stenosis

Condition	Characteristics
Normal	Uniform waveforms; biphasic or triphasic waveforms; clear window beneath systolic peak
<50% diameter reduction	Focal velocity increase; spectral broadening; possibly triphasic or biphasic flow
>50% diameter reduction	Focal velocity increase; loss of triphasic or biphasic velocity waveform; poststenotic flow (color bruit)
Occlusion	No flow detected

Interpretation of Mesenteric Duplex Ultrasound Studies

In healthy individuals, fasting arterial waveforms differ in the SMA versus the CA. The arterial waveforms reflect end-organ vascular resistance. The liver and spleen have relatively high constant metabolic requirements and are therefore low-resistance organs. As a result, CA waveforms are generally biphasic, with a peak systolic component, no reversal of end-systolic flow, and a relatively high EDV. The normal fasting SMA velocity waveform is triphasic, reflecting the high vascular resistance of the intestinal tract at rest. There is a peak systolic component, often an end-systolic reverse flow component, and a minimal diastolic flow component (Fig. 85.20**A**).[59]

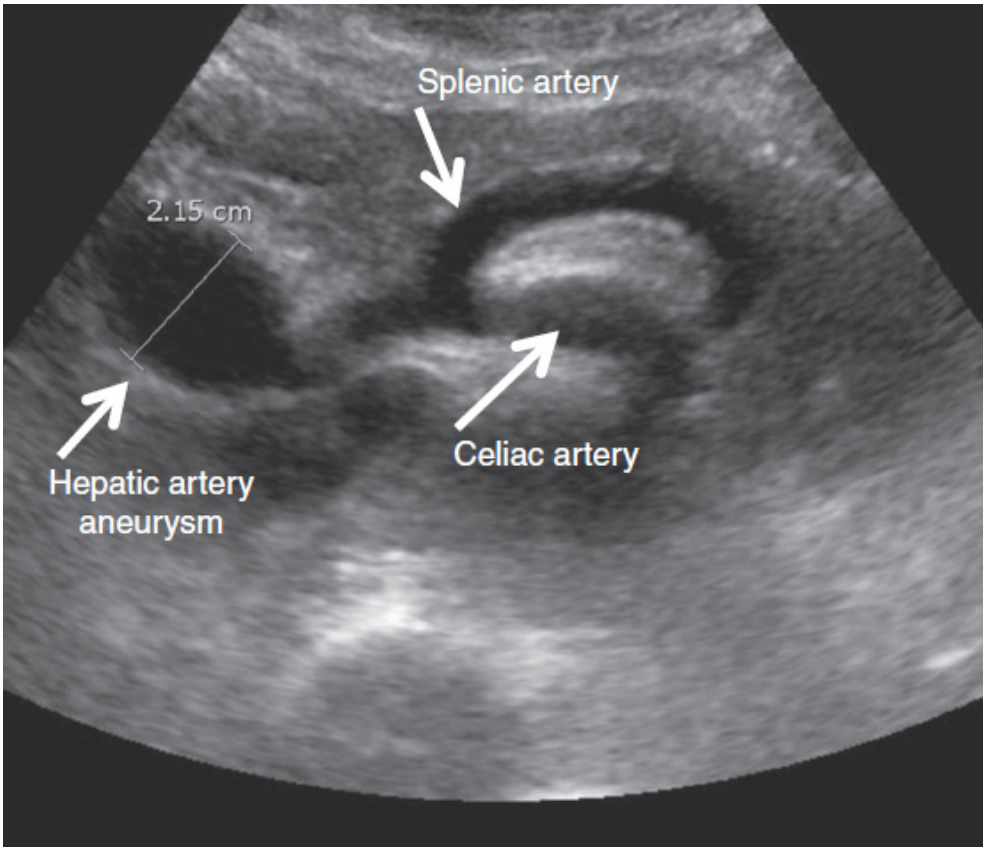

Figure 85.19 Grayscale image of a 2.15-cm hepatic artery aneurysm.

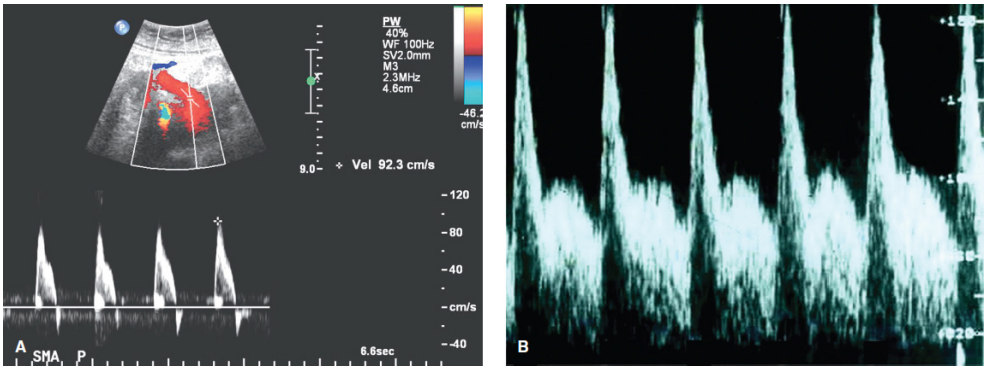

Figure 85.20 **A:** A normal fasting superior mesenteric artery (SMA) waveform may exhibit reverse flow at the end of systole and relatively low end-diastolic velocity reflecting relatively high resistance of the intestinal circulation in the fasting state. **B:** Postprandial SMA waveform. There has been, in comparison to **A,** loss of end-systolic reverse flow and an increase in end-diastolic flow as resistance in the intestinal arterial circulation falls following feeding.

Changes in Doppler-derived arterial waveforms in response to feeding are also different in the CA and SMA. Because the liver and spleen have

basically fixed metabolic demands, there is no significant change in CA velocity waveform after eating. Blood flow in the SMA, however, increases markedly after a meal, reflecting a marked decrease in intestinal arterial resistance. The postprandial waveform changes in the SMA include a near doubling of systolic velocity, tripling of the EDV, and loss of end-systolic reversal of blood flow (**Fig. 85.20B**).[60]

Postprandial changes are maximal at 45 minutes after ingestion of a test meal and depend on the composition of the meal ingested. Mixed nutrient composition meals produce the greatest flow increase in the SMA when compared with equal caloric meals composed solely of fat, glucose, or protein.[61]

Detection of Mesenteric Arterial Stenosis

8 Duplex ultrasound can detect hemodynamically significant stenosis in splanchnic vessels. In a blinded prospective study of 100 patients who underwent mesenteric artery duplex scanning and lateral aortography, a PSV in the SMA of 275 cm/s or more indicated a ≥70% SMA stenosis with a sensitivity of 92%, a specificity of 96%, a positive predictive value of 80%, a negative predictive value of 99%, and an accuracy of 96% (Fig. 85.21). In the same study, a PSV of ≥200 cm/s identified a ≥70% angiographic celiac artery stenosis with a sensitivity of 87%, a specificity of 80%, a positive predictive value of 63%, a negative predictive value of 94%, and an accuracy of 82%.[62]

Other duplex criteria for mesenteric artery stenosis are also in use. An SMA EDV greater than 45 cm/s correlates with a ≥50% SMA stenosis with a specificity of 92% and a sensitivity of 100%, whereas a CA EDV of 55 cm/s or greater predicts a ≥50% CA stenosis with a sensitivity of 93%, specificity of 100%, and accuracy of 95%.[63]

Surgical revascularization of the mesenteric arteries is a standard treatment for chronic mesenteric ischemia. Most often bypass grafts are constructed to the superior mesenteric and/or celiac arteries. Mesenteric artery bypass grafts can be followed postoperatively with mesenteric artery duplex scanning. Flow velocities within mesenteric artery bypass grafts vary little with the origin of the graft (supraceliac or infrarenal aorta or a common iliac artery) and remain stable over time. Serially increasing velocities over

time in a mesenteric bypass likely suggest the development of a graft or anastomotic stenosis.[64]

Placement of an intraluminal stent is a viable alternative in many cases to surgical bypass, for the treatment of mesenteric artery stenosis. Similar to the carotid artery, there is reason to suspect duplex criteria developed for stenosis in native mesenteric arteries may not be applicable without modification to stented superior mesenteric arteries. Mesenteric duplex scans pre- and postplacement of a superior mesenteric artery (SMA) stent have been compared and correlated with pressure gradients measured at the time of angiography. The data indicate that SMA stenting provides good anatomic results and significantly reduces angiographically measured pressure gradients. Duplex measured SMA PSVs are reduced post stent placement but, despite good angiographic results, remain in most cases above criteria predicting high-grade native artery SMA stenosis.[65]

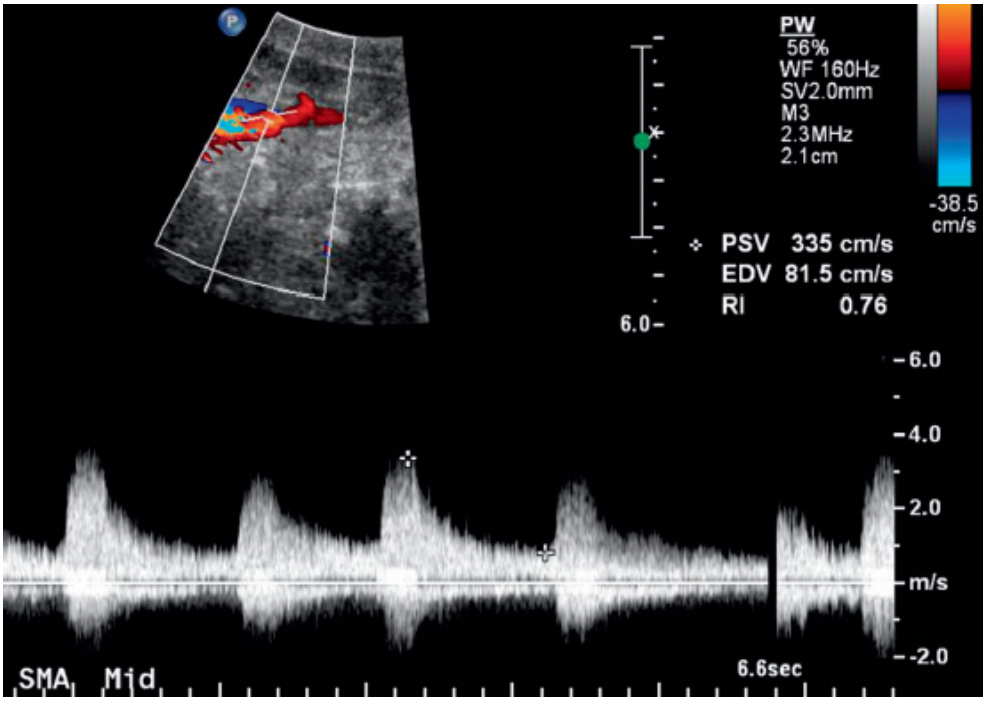

Figure 85.21 Color flow image and duplex-derived SMA waveform in a patient with possible chronic mesenteric ischemia. A peak systolic velocity of >330 cm/s indicates a high-grade SMA stenosis and is compatible with a clinical picture of chronic mesenteric ischemia.

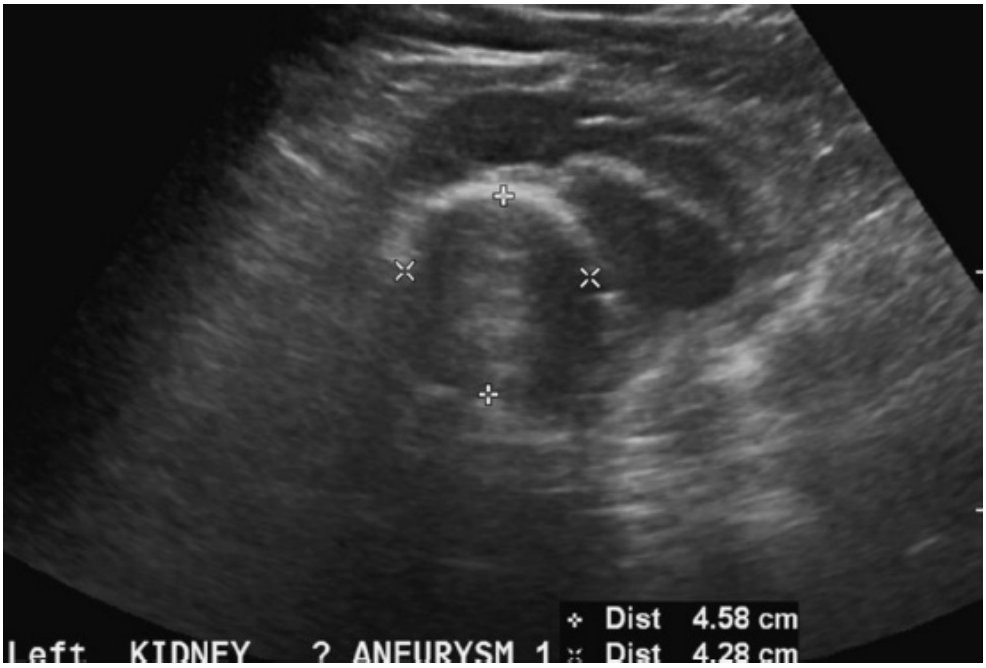

Figure 85.22 Grayscale image of a large renal artery aneurysm in the hilum of the kidney.

RENAL ARTERIES

Duplex scanning of the renal arteries is useful in evaluating for renal artery stenosis in patients with possible renal vascular hypertension and can also be used to detect renal artery aneurysms (Fig. 85.22), as well as provide a measure of the health of the renal parenchyma.

Indirect Assessment of Renal Artery Stenosis

Indirect methods to assess renal artery stenosis evaluate interlobar arteries. Decreased acceleration times and/or presence of tardus/parvus waveforms (waveforms with delayed or slowed upstrokes) may suggest the presence of a main renal artery stenosis. These techniques are quicker and easier to perform than direct examination of the main renal artery but have been not widely validated. Improved visualization of main renal arteries with modern duplex scanners has made indirect methods of assessing the main renal artery essentially obsolete. These techniques are even less accurate in patients with

bilateral stenosis and are not applicable in patients with a single patent renal artery.

Direct Assessment of Renal Artery Stenosis

Normal renal arteries have a PSV less than 180 cm/s and low-resistance waveforms reflecting the high metabolic demands of the kidney. A ratio of the PSV in the renal artery to that in the aorta (renal–aortic ratio, RAR) of ≥3.5 indicates a ≥60% diameter-reducing renal artery stenosis (84% to 88% sensitivity, 97% to 99% specificity, 94% to 98% positive predictive value) (Fig. 85.23).[66] A PSV of ≥200 cm/s has also been suggested to indicate a ≥60% renal artery stenosis whereas a velocity in the renal artery of >185 cm/s has been suggested to indicate a less than 60% renal artery stenosis. Therefore a renal artery can be considered normal when PSV is <180 cm/s and the RAR is <3.5. With a PSV >180 cm/s and a RAR <3.5, the renal artery can be considered to have a <60% stenosis. RARs of >3.5 indicate >60% renal artery stenosis regardless if the renal artery PSV is less than or more than 180 cm/s.[67] When the EDV exceeds 150 cm/s, data suggest a >80% renal artery stenosis.[68] The same criteria have been used to evaluate the patency of renal arterial reconstructions, but similar to stented carotid and mesenteric arteries may need modification for stented renal arteries.[69]

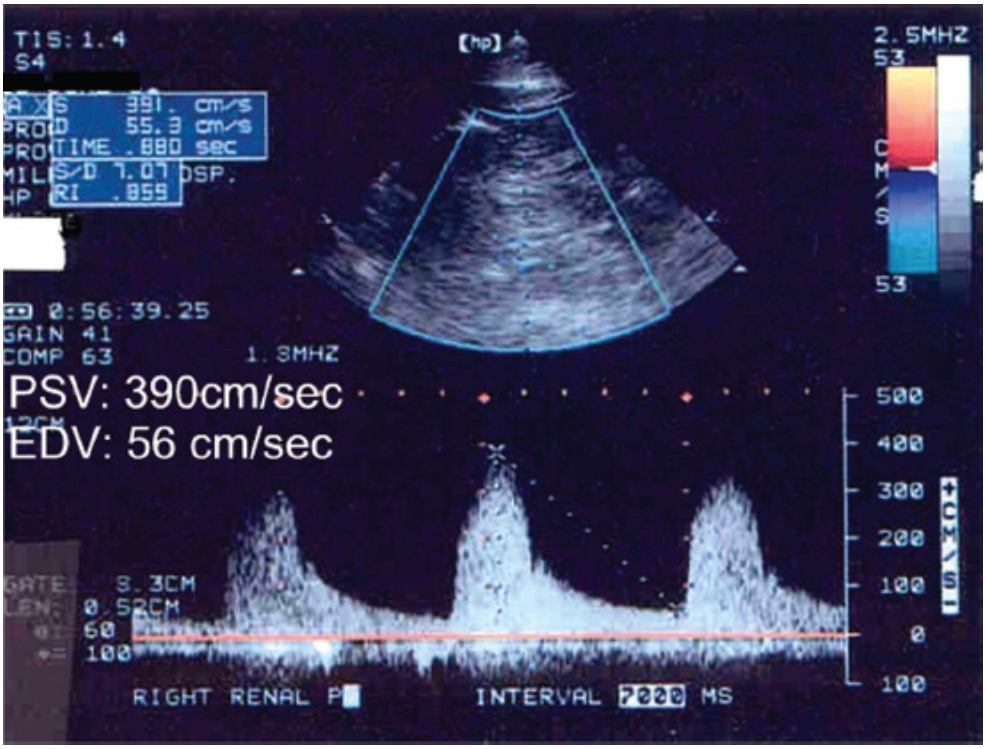

Figure 85.23 Renal artery waveform in a patient with severe hypertension. The high peak systolic velocity is compatible with a high-grade renal artery stenosis.

Predicting Success of Renal Artery Interventions

EDVs tend to be lower in patients with renal insufficiency, indicating decreased diastolic flow and suggesting increased parenchymal resistance to blood flow. Decreased parenchymal diastolic velocities may therefore suggest renal parenchymal disease (Fig. 85.24). Many patients, 20% to 40%, treated with renal artery angioplasty and stenting or open surgical reconstructions do not have postprocedure blood pressure or renal function improvement. An estimate of resistance to flow within the renal parenchyma can be made by comparisons of EDV and PSVs of renal artery waveforms obtained from renal parenchymal arteries. The so-called resistive index (RI) is calculated as follows:

$$RI = [1 - (EDV/PSV)] \times 100 \qquad (85.3)$$

In effect a high RI, >0.7 is bad, suggesting renal parenchymal disease whereas a low RI is good, indicating healthy renal parenchymal tissues.

Evaluation of parenchymal resistance has been suggested as a possible preprocedure predictor of clinical success of renal artery interventions.[70] Abnormal parenchymal resistance may also be a marker of renal allograft dysfunction or rejection (Fig. 85.25).

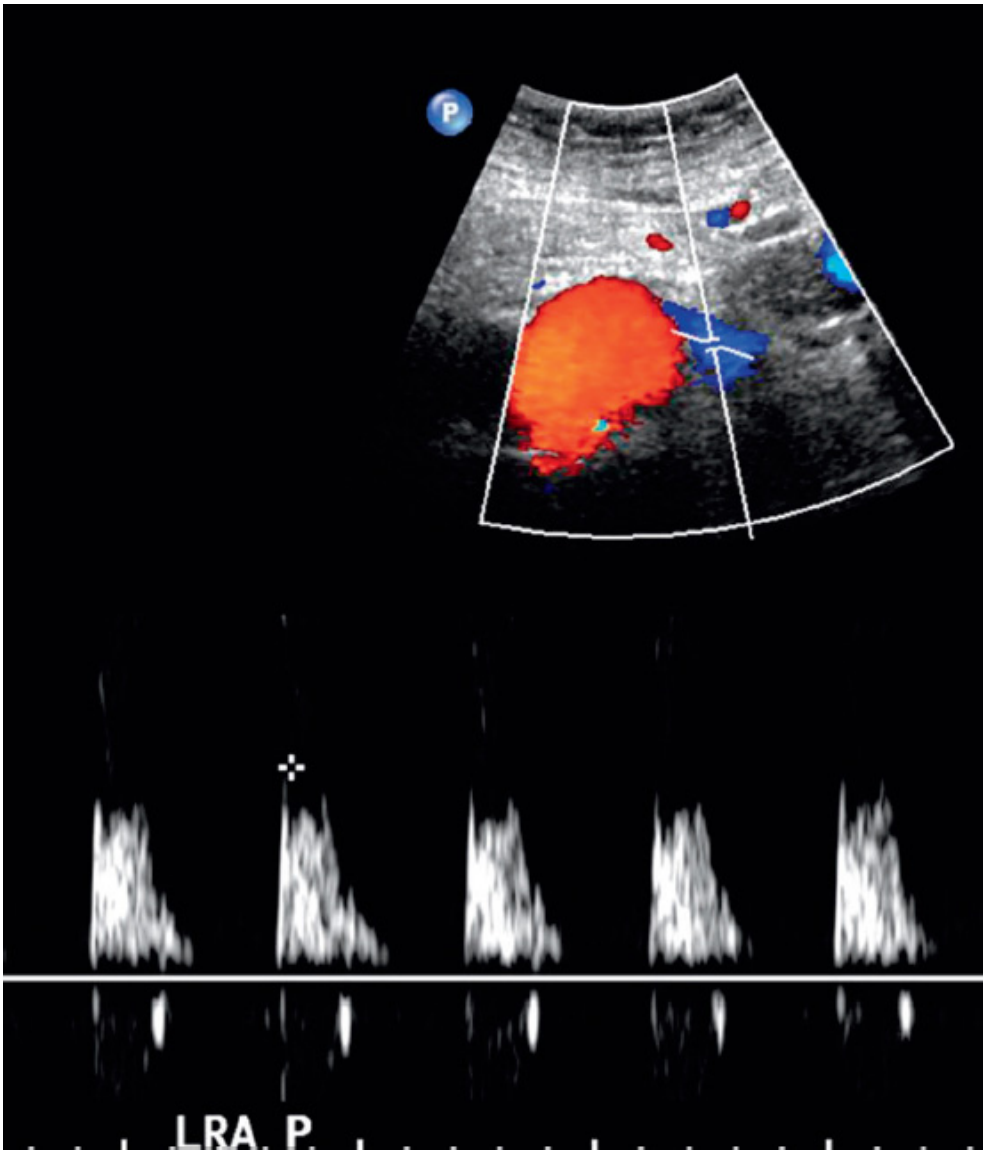

Figure 85.24 The absence of end-diastolic flow in the left renal artery indicates severe parenchymal disease of the left kidney.

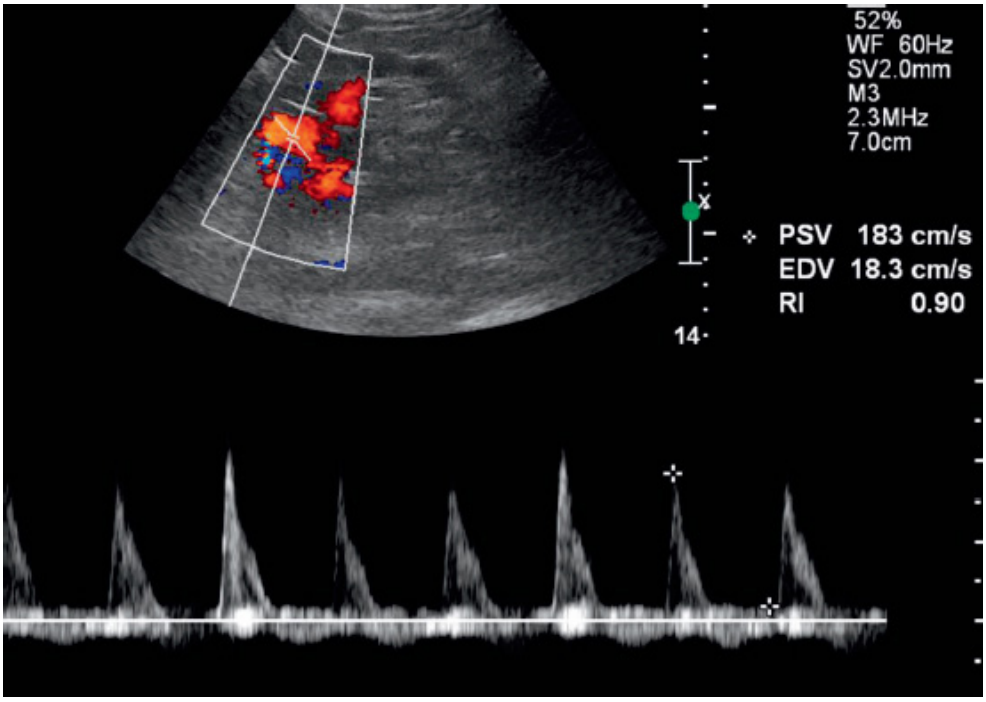

Figure 85.25 There is very little diastolic flow in the renal artery of the transplanted kidney consistent with rejection or primary allograft dysfunction.

VENOUS DISEASE

Acute Deep Venous Thrombosis

Physical examination is not sensitive or specific for the detection of acute deep venous thrombosis (DVT).[71] Prior to the acceptance and widespread use of venous duplex scanning, impedance plethysmography (IPG) was employed as the initial noninvasive test for patients with suspected acute lower extremity DVT. IPG is a reasonably sensitive (87%) and specific (up to 100%) test for proximal (above-knee) lower extremity DVT in symptomatic patients.[72–74] However, lower sensitivities for proximal DVT (65%) have been reported in studies that exclude clinical outcomes and only report in comparison to venography. IPG may not detect nonocclusive proximal DVT, occlusive proximal DVT present in parallel venous systems, such as duplicated femoral or popliteal veins, and cannot detect DVT isolated to the calf veins.[75,76] While IPG is still sometimes used for clinical situations felt to require serial evaluations of the proximal veins, the limitations noted above make it a substandard examination for routine

clinical assessment of lower extremity DVT.[77] Currently, color flow duplex scanning performed by skilled operators provides the most practical and cost-effective method for assessment of DVT of the lower and upper extremity veins as well as for detection of thrombosis in superficial veins.

At a minimum, vascular laboratory duplex ultrasound evaluation for lower extremity DVT should include examination of the common femoral, profunda femoris, femoral, and popliteal veins. Venous waveforms from the right and left common femoral veins should always be compared. A normal lower extremity examination will show patency of the veins on color flow imaging, collapsing of the veins with application of pressure by the ultrasound probe, and venous flow patterns in the common femoral and femoral veins that decrease with inspiration and increase with expiration. Flow within a patent vein should also increase with application of compression distal to the site of examination (Fig. 85.26).

9 The primary ultrasound diagnostic criteria for diagnosis of venous thrombosis is failure of the vein to collapse with application of pressure with the ultrasound probe (Fig. 85.27**A,B**). A continuous flow pattern in one common femoral vein and not the other suggests ipsilateral iliac vein thrombosis or external compression of the ipsilateral iliac vein. Bilateral pulsatile common femoral waveforms suggest volume overload, tricuspid regurgitation, or heart failure.

Not all venous ultrasound examinations for DVT are the same. Some vascular laboratories do not include evaluation of the calf veins as part of their routine evaluation for lower extremity DVT, even in symptomatic patients. This results from outdated perceptions of inaccuracy of calf vein ultrasound evaluation for DVT. Failure to perform a complete initial examination necessitates serial ultrasound examinations or alternative strategies to detect possible extension of venous thrombi initially isolated to the calf veins. Such strategies are inefficient, ineffective for noncompliant patients, and not cost-effective compared to a single stand-alone color flow duplex study of the proximal and calf veins in patients with suspected lower extremity DVT.

Limited ultrasound studies for acute DVT may include compression ultrasound (B-mode imaging only), duplex ultrasound (B-mode imaging and Doppler waveform analysis), and color Doppler alone. The sensitivities and specificities for detecting acute DVT differ among the examinations, and

different examinations are appropriate for different veins. Compression ultrasound is typically performed for evaluation of proximal deep veins, specifically the common femoral, femoral, and popliteal veins. A combination of duplex ultrasound and color Doppler is more often used for calf and iliac veins. Color flow alone may be used to assess patency of the calf veins as they are difficult to reliably compress in subjects with larger legs.

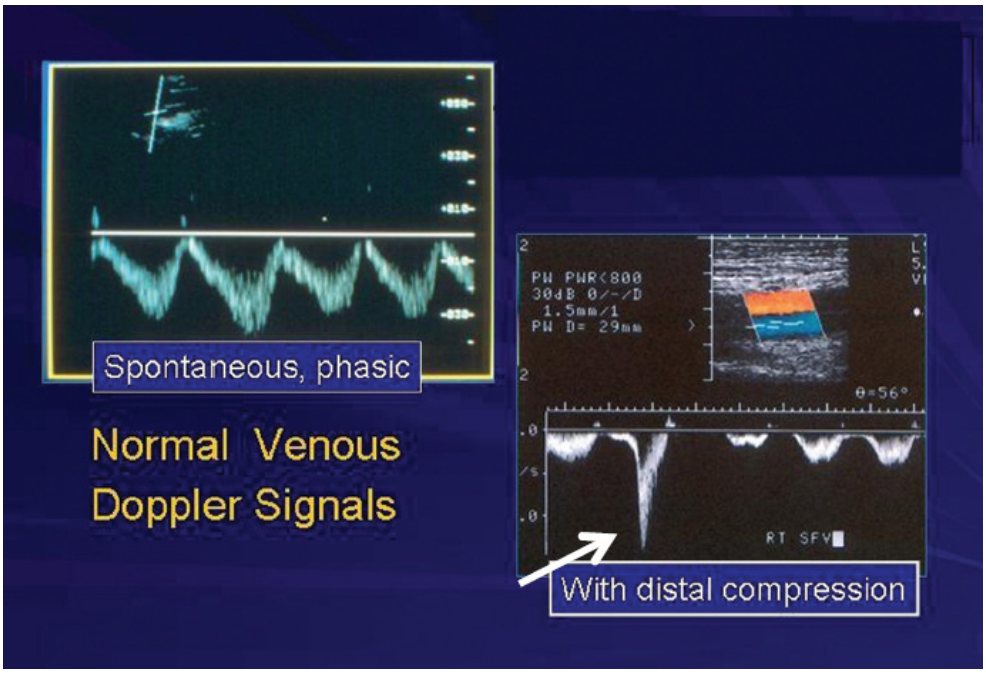

Figure 85.26 Venous flow is typically depicted below the baseline. Venous flow in the proximal lower-extremity veins should be spontaneous, vary with respiration, and augment with distal compression.

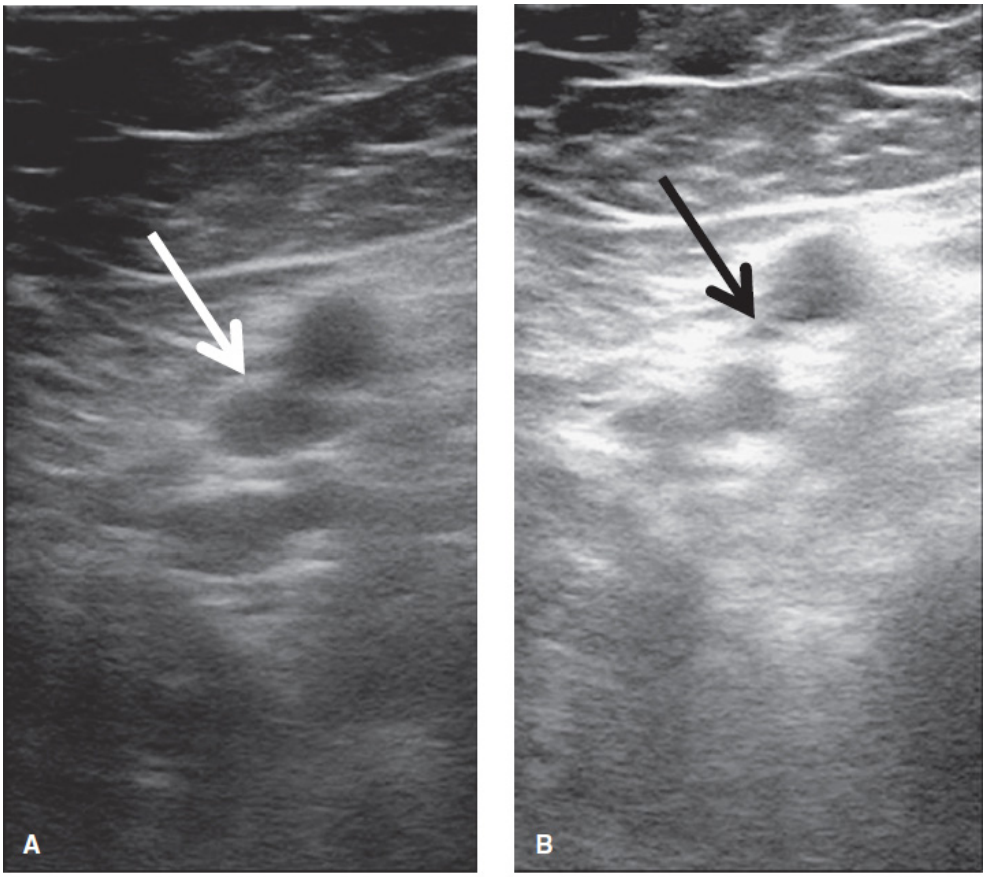

Figure 85.27 **A:** Without compression with the ultrasound probe the femoral vein is easily visible (*white arrow*). **B:** With compression the vein collapses and is no longer visible (*black arrow*). Failure of the vein to collapse with probe pressure would indicate the presence of thrombus within the vein.

Many factors will influence which venous segments can be evaluated in an individual examination. These include the presence of morbid obesity, lower extremity edema or tenderness, or the presence of immobilization devices and bandages. Overall, a complete color and Doppler examination has become the standard of care for assessment of lower extremity DVT. It is recommended that whenever possible, a venous duplex examination to exclude the presence of DVT consist of an evaluation of both the proximal and calf veins.

A well-trained technologist can interrogate calf veins in 80% to 98% of cases using a combination of B-mode, Doppler waveform analysis, and color Doppler.[78,79] Overall accuracy of venous ultrasonography in comparison to venography has been well established. The weighted mean sensitivity and

specificity of venous ultrasonography (including all types) for the diagnosis of symptomatic proximal DVT are 97% and 94%, respectively.[77] As suggested above, in technically adequate studies, the sensitivity and specificity of color Doppler to identify isolated calf vein thrombosis exceeds 90%.[79] The high specificity of venous ultrasonography allows treatment for DVT to be initiated without further confirmatory tests, and the high sensitivity in diagnosing proximal DVT makes it possible to withhold treatment if the examination is negative.

Some ultrasound examinations are limited by practical constraints. Inability of the patient to fully cooperate with regard to positioning for the examination and/or intolerance of the pressure of the ultrasound scan head on the skin, or inability of the examiner to obtain a complete examination secondary to bandages, casts, or extremity wounds, may lead to a requirement for serial examinations. An alternative diagnostic procedure, such as catheter-based contrast, MR, or CT venography may be indicated when a complete ultrasound examination is not possible or if the patient cannot or is unlikely to return for a follow-up examination. Currently, repeat or serial venous ultrasound examinations are advisable in follow-up for a limited negative examination in symptomatic patients highly suspicious for DVT in whom an alternative form of imaging is unavailable or contraindicated.

The diagnosis of pulmonary embolism (PE), like that for DVT, also cannot be established without objective testing. Several studies have evaluated lower extremity venous ultrasound examinations in patients suspected of PE. These studies, often employing ultrasound of only the proximal veins and nuclear medicine-based ventilation perfusion (V/Q) scanning, unfortunately have little relevance to modern practice where complete proximal and distal vein ultrasound examinations are usually routine, and where CT pulmonary angiography (CTPA) or MR pulmonary angiography (MRPA) have largely supplanted V/Q scanning.

The rationale for venous ultrasonography in patients who present with symptoms of PE is that a diagnosis of DVT may indirectly suggest a diagnosis of PE, making additional investigation to exclude PE unnecessary in some clinical settings. However, ultrasound cannot make a definitive diagnosis of PE. Patients can have DVT and pulmonary symptoms or hemodynamic instability from causes other than PE.

Normal bilateral proximal venous ultrasound scans do not rule out PE. When PE is definitively present, DVT of the proximal lower extremity veins is detectable by compression ultrasound in only 50% of patients.[80] When a PE is objectively diagnosed with no evidence of lower extremity DVT, the PE may have originated from pelvic veins, arm veins, or possibly embolized completely from a lower extremity vein. An objective diagnostic test for PE is therefore indicated in most cases. Currently, in most centers this would be a CT pulmonary angiogram.

Chronic Venous Insufficiency

The presence of venous insufficiency can also be evaluated with either air or PPG and with duplex scanning.[81] In theory, APG can provide an analysis of overall venous hemodynamics including evaluation of the individual components of venous function; reflux and the efficacy of the calf muscle pump. A flexible chamber is placed on the calf and volume changes then induced by a series of positional and exercise maneuvers. Measurements derived from these maneuvers are then used to calculate measures of venous reflux (venous filling index [VFI]), calf muscle pump function (ejection fraction [EF]) as well as a measure of overall venous function termed the residual volume fraction. Of these values VFI has the potential for being the most important. A VFI of >2 mL/s indicates abnormal reflux with values >10 mL/s indicating increased risk of cutaneous changes associated with chronic venous insufficiency (CVI). APG, however, while theoretically interesting, is used only infrequently in clinical practice.

Figure 85.28 Placement of PPG probes for assessment of venous reflux.

PPG is a variant of plethysmography techniques to assess venous reflux. It detects changes in the blood content of the skin that theoretically reflect venous volume. It consists of a light emitting diode and a photo sensor. The diode transmits light into subcutaneous tissues. Blood attenuates light in proportion to its content in tissue. The PPG machine amplifies the difference between the transmitted and reflected signal and converts it into a waveform. To assess for venous reflux the sensor is typically applied to the medial ankle area (Fig. 85.28). The patient performs a series of plantar and dorsal flexion maneuvers of the foot decreasing the venous volume of the extremity. The time for the waveform to return to baseline is termed the venous recovery time (VRT). A normal PPG VRT is 20 seconds or greater. Shorter

times indicate the presence of venous reflux. If the VRT returns to normal with the application of a superficial venous tourniquet then the reflux is confined to the superficial venous system (Fig. 85.29). If the VRT does not correct with a superficial venous tourniquet deep venous reflux is present. Neither, APG or PPG can provide information about the specific venous segments that are abnormal. That information can be provided by duplex ultrasound.

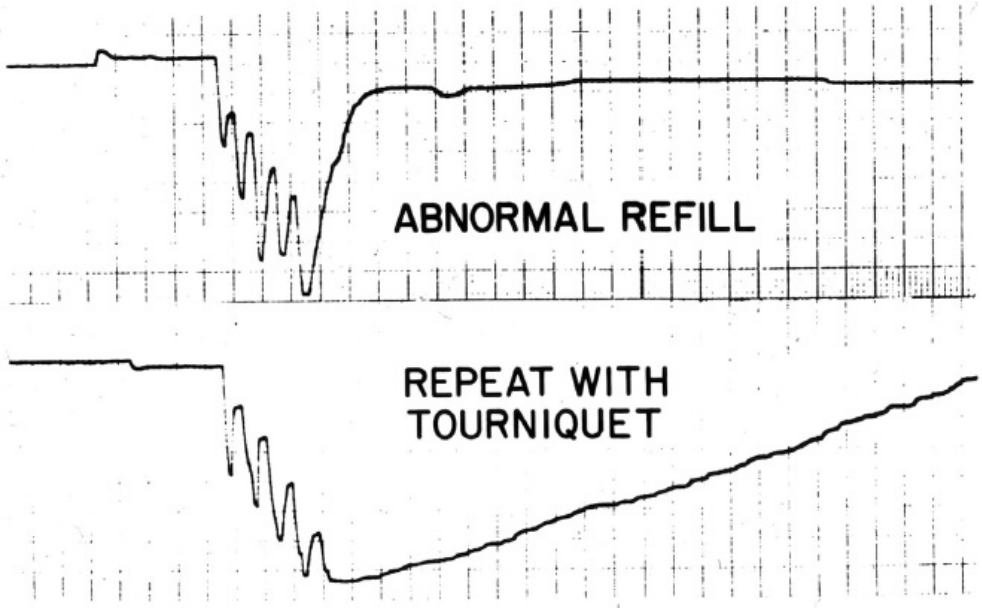

Figure 85.29 Venous PPG waveforms in a patient with superficial venous reflux. The patient is asked to perform 10 dorsal and plantar flexions of the ankle resulting in emptying the leg of venous blood. In the **top panel** the veins refill very rapidly indicating the presence of venous reflux. Refill slows with application of a tourniquet to occlude the superficial veins indicating this patient likely has only reflux in the superficial venous system and no deep venous reflux.

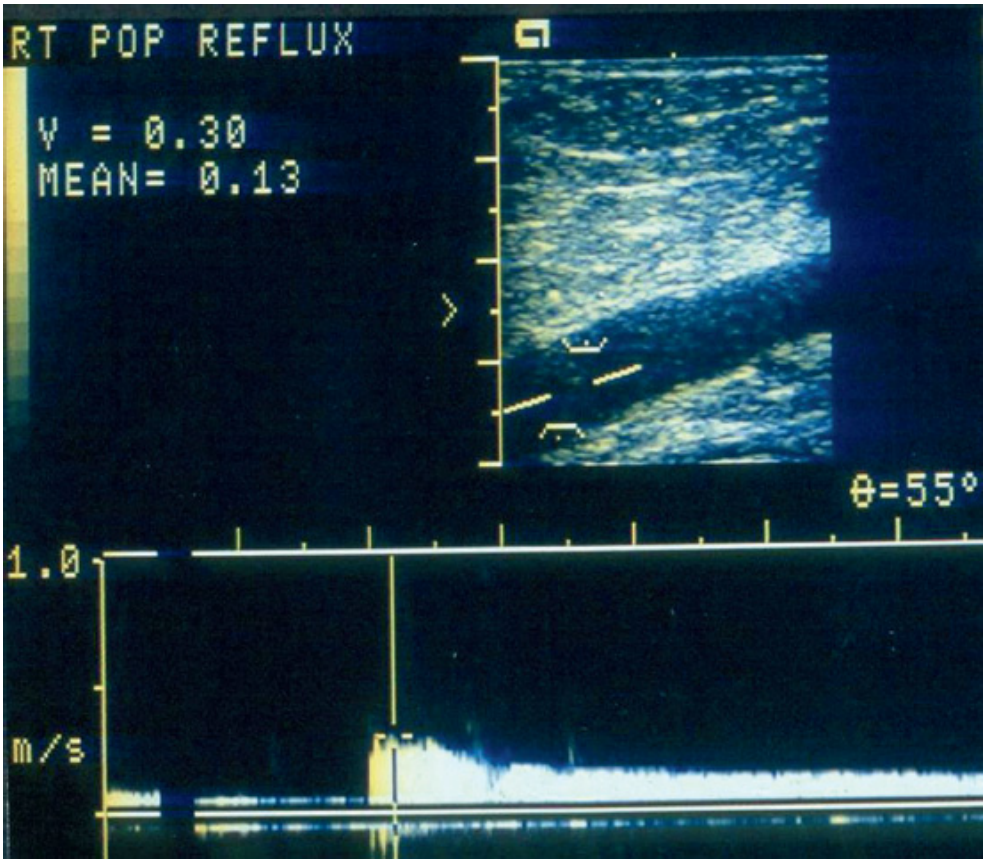

Figure 85.30 Popliteal venous waveform with cuff deflation for duplex assessment and localization of venous reflux. Reflux lasting >0.5 to 1 second is abnormal.

Duplex ultrasound can provide important physiologic and anatomic information in patients with possible CVI. Both sites of reflux and of venous obstruction can be determined in deep, superficial, and perforating veins. In patients with valve incompetence, reflux can be stimulated and then detected with duplex using a Valsalva maneuver, manual compression proximal to the transducer, or release of compression distal to the transducer. The examination has been standardized with the patient upright and using deflation of a series of pneumatic cuffs at specific sites on the leg with the leg under examination 10 not bearing weight. In the upright position, reflux stimulated by cuff deflation that lasts more than 0.5 second is indicative of pathologic reflux.[82] The technique allows localization of reflux to specific venous segments and can serve as a valuable preoperative planning tool to target specific venous segments for removal or reconstruction (Fig. 85.30). It has a sensitivity of 82% and specificity of 100% for the identification of

competent and incompetent perforating veins. Duplex determination of reflux sites and sites of venous occlusion as a means of assessing overall venous hemodynamics is not established. Currently duplex assessment of venous reflux provides the basis of planning for the large majority of venous procedures designed to treat the manifestations of superficial venous reflux.

SELECTED MISCELLANEOUS EXAMINATIONS

Evaluation for Abdominal Aortic Aneurysm

Vascular laboratory ultrasound screening for abdominal aortic aneurysm (AAA) in males >65 years with a history of cigarette smoking has been shown to be effective in preventing aneurysm-related deaths in this cohort.[83] Ultrasound is highly accurate and reproducible in measuring the diameter of infrarenal AAAs (Fig. 85.31). Typically patients with AAA diameters below

accepted threshold levels for repair are followed with serial ultrasound examinations to monitor for enlargement of the aneurysm to a diameter where repair is indicated.

Evaluation of Aortic Endografts

Placement of endoluminal stent grafts is now standard therapy for most patients with AAA. With stent grafting of an AAA the aneurysm is left in situ and blood flow diverted through the stent graft. Some stent grafts eventually leak at proximal or distal attachment sites. AAAs with these so-called type I endoleaks are at increased risk of rupture. In addition, AAAs treated with stent grafts may also occasionally enlarge because of back pressure in the aneurysm sac from patent lumbar vessels; type II endoleak. Patients whose AAAs enlarge in association with type II endoleaks after endografting are also considered at risk for aneurysm rupture.

Standard monitoring of endoluminal stent grafts is with serial CT scans to detect endoleak and changing aneurysm sac diameter. However, there are increasing concerns about repeated doses of contrast and radiation exposure associated with serial CT scans. It now appears many stent grafts can be followed with serial duplex ultrasound examinations. Duplex ultrasound is capable of measuring sac diameter (Fig. 85.32) and detecting both type I and II endoleaks. Even if an endoleak cannot be detected by ultrasound an increase in sac diameter following stent grafting should prompt further investigation. In some centers duplex ultrasound has replaced CT scanning as the preferred method of follow-up of AAA stent grafts.[84,85]

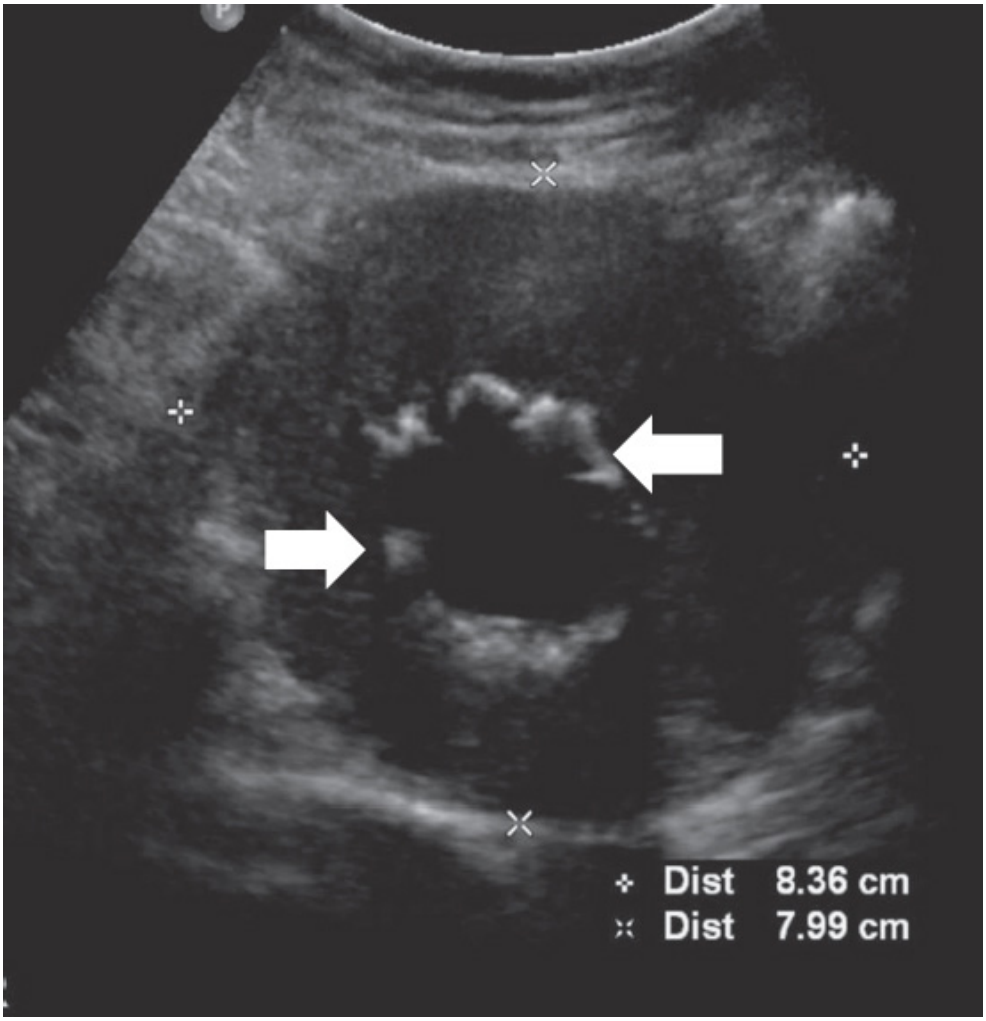

Figure 85.32 Ultrasound examination of an aortic stent graft. The aortic stent graft (*arrows*) is visible within the lumen of the residual aneurysm sac measuring 8.36 cm × 7.99 cm.

Evaluation and Treatment of Groin Pseudoaneurysms

Pseudoaneurysms can occur as a complication of an arterial puncture in the groin performed for diagnostic or therapeutic angiography. Groin pseudoaneurysms are readily detected with duplex ultrasound (Fig. 85.33). Color flow demonstrates a typical collection of flowing blood usually anterior to the artery from which the psuedoaneurysm originates. The native artery and the pseudoaneurysm are connected by a so-called "neck." To-and-

fro flow within the neck of the pseudoaneurysm is characteristic and pathognomonic of a pseudoaneurysm arising from an arterial puncture.

Treatment of pseudoaneurysms may be with direct surgical repair or, utilizing the vascular laboratory, direct compression of the pseudoaneurysm until it clots using the ultrasound scan head to both locate the pseudoaneurysm and apply pressure. Alternatively, the pseudoaneurysm is visualized with the ultrasound scan head and a needle introduced into the body of the pseudoaneurysm for injection of small amounts of thrombin to induce thrombosis of the pseudoaneurysm.[86] All techniques are effective but currently direct thrombin injection is favored in most cases as it is relatively noninvasive and less painful and more effective than prolonged compression alone.[87,88]

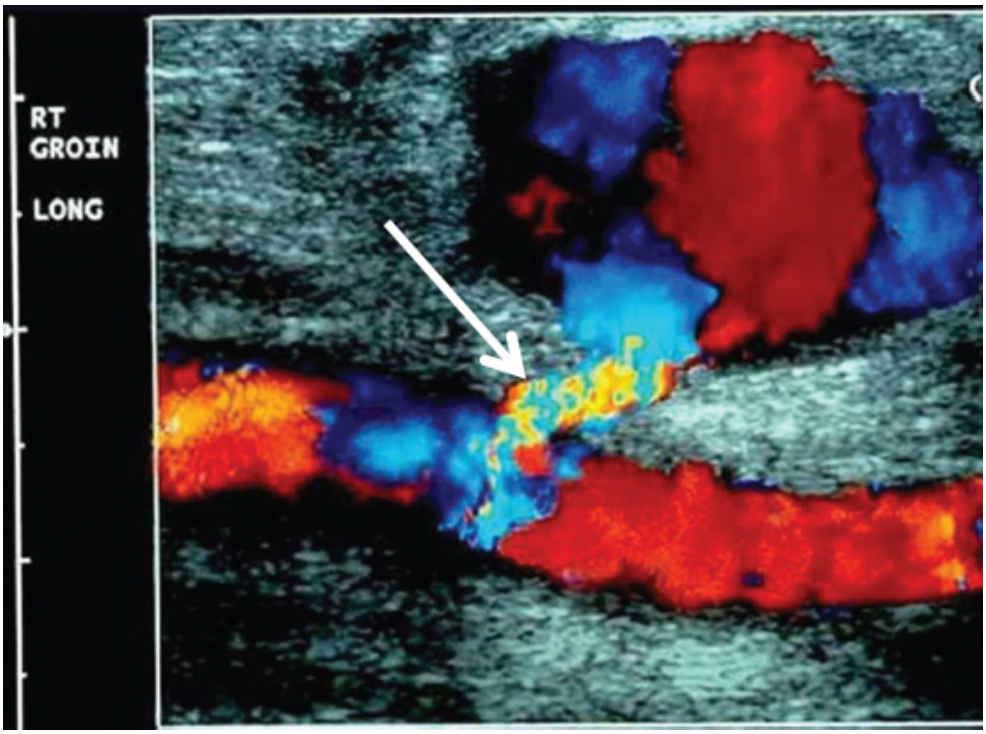

Figure 85.33 A pseudoaneurysm of the superficial femoral artery following arterial cannulation. The so-called neck of the aneurysm (*arrow*) is readily visible.

Figure 85.34 A transcutaneous oxygen probe. $TCpO_2$ measurements can serve as an aid in determining healing potential of pedal wounds or ulcers.

Transcutaneous Oxygen Measurements

Measurements of transcutaneous oxygen ($TCpO_2$) can be performed as an aid in predicting healing of pedal lesions or healing of an amputation at the site where the measurement is taken (Fig. 85.34). In general, a $TCpO_2$ >30 mm Hg indicates healing is likely, measurements between 20 and 30 mm Hg are equivocal for healing and measurements below 20 mm Hg indicate healing is unlikely.[89] Measurements are not influenced by the presence of diabetes but it has been suggested the level for predicting healing be increased to 40 mm Hg in patients with diabetes. The test is less accurate in the presence of edema, cellulitis, hyperkeratosis, and in older patients.

Vascular Infection

Courtney E. Morgan and John E. Rectenwald

Key Points

1 The pathogenesis of infected aneurysms involves seeding of a pre-existing aneurysm by bacteremia.

2 The pathogenesis of microbial arteritis involves hematogenous seeding of an atherosclerotic plaque.

3 The pathogenesis of infected aortitis involves direct spread of infection to the aorta by contiguous septic structures, such as vertebral osteomyelitis.

4 The pathogenesis of arterial graft infections involves seeding of the graft from intraoperative contamination, erosion of adjacent structures, or hematogenous seeding from a distant source.

5 Characteristics of a prosthetic graft that predispose to graft infection include surface irregularity that permits bacterial attachment, abrogation of local defense against infection, creation of the bacterial biofilm that protects microbes from host defenses and antibiotics, all of which lowers the bacterial bioburden required to cause a graft infection.

6 The most common organisms causing arterial graft infections are skin flora, especially *Staphylococcus aureus* and *Staphylococcus epidermidis*.

7 Diagnosis of vascular infections requires a high index of suspicion as patients often present with nonspecific symptoms. This requires a thorough query of recent sources or risk factors for infection, evaluation of culture data and inflammatory markers, and understanding the pros and cons of various imaging techniques in detecting vascular infections.

8 Surgical treatment of arterial infections requires appropriate resuscitation, preoperative planning, resection of all infected material and tissue, and revascularization. No single approach is suitable for all patients, but understanding the algorithm and tailoring this to local surgical expertise is critical in caring for these patients.

9 Antibiotic therapy is imperative in treatment of arterial infections. Initial treatment involves broad-spectrum antibiotics followed by culture-driven therapy when possible, although up to 40% of patients are culture negative. While there are no guidelines directing the type, dose, duration, or route of therapy, most patients are treated with an initial

multiweek course of antibiotics with consideration for long-term suppression if not all graft material is excised.

10 Each method of aortic reconstruction after aortic graft excision has varied outcomes. Extraanatomic bypass with aortic ligation risks aortic stump blowout and poor graft patency. Reconstruction with in situ cryopreserved allograft has high cost, varied availability, and can demonstrate pseudoaneurysm degeneration. In situ reconstruction with rifampin-soaked Dacron has excellent patency, but has higher reinfection rates. In situ autogenous vein reconstruction is time consuming, but is resistant to infection and has excellent patency.

INTRODUCTION

Vascular infections are among the most daunting conditions that a surgeon may encounter in clinical practice. Vascular infections may afflict native arteries and veins or vascular prostheses. Primary arterial infections of native arteries are rare, but highly lethal conditions.[1] Secondary infections of prosthetic vascular grafts, albeit rare, are seen more frequently and are often more challenging because of the adhesions, scarring, and inflammation in the redo operative field.[2] These infections commonly occur in a compromised patient population with significant chronic medical conditions and relative immune deficiency. The clinical presentations for vascular infections range from indolent infections detected incidentally to overt sepsis or hemorrhage.[1] The management of vascular infections is individualized, based on the clinical presentation, anatomic location of the vascular infection, and the medical condition of the patient. In recent years, newer therapeutic adjuncts, such as covered stents and improved cryopreserved grafts offer additional options to surgeons managing and treating arterial graft infections. However, the basic tenets of timely diagnosis, antibiotic administration, resuscitation, operative planning, surgical resection, and revascularization remain the mainstays of therapy in most cases.

DEFINITIONS AND PATHOGENESIS

Pathogenesis of Primary Arterial Infections

1 Arterial infections commonly result in aneurysms, or more correctly pseudoaneurysms since there is disruption of the arterial wall in many infected aneurysms. Aneurysms or pseudoaneurysms related to infection are often loosely termed "mycotic aneurysms." However, the term mycotic aneurysm was initially coined to describe an arterial aneurysm or pseudoaneurysm caused by a septic embolus from the heart that lodges in a distal artery to create a septic focus that injures the adjacent artery.[3] "Mycotic aneurysm" is a misnomer as the vast majority of these are of bacterial origin, not fungal. Pre-existing aneurysms that are subsequently seeded by bacteremia 2 are "infected aneurysms." Arteries in which an atherosclerotic plaque becomes seeded develop "microbial arteritis." "Traumatic 3 infected aneurysms" describe those infected aneurysms or pseudoaneurysms that develop secondary to complications of iatrogenic or other trauma. "Infected aortitis" occurs when the aorta becomes infected by contiguous septic structures, such as vertebral osteomyelitis.[3] For simplicity, we will utilize the term "primary arterial infection" to refer to all infected arterial infections that occur in the absence of prosthetic graft or stent material.

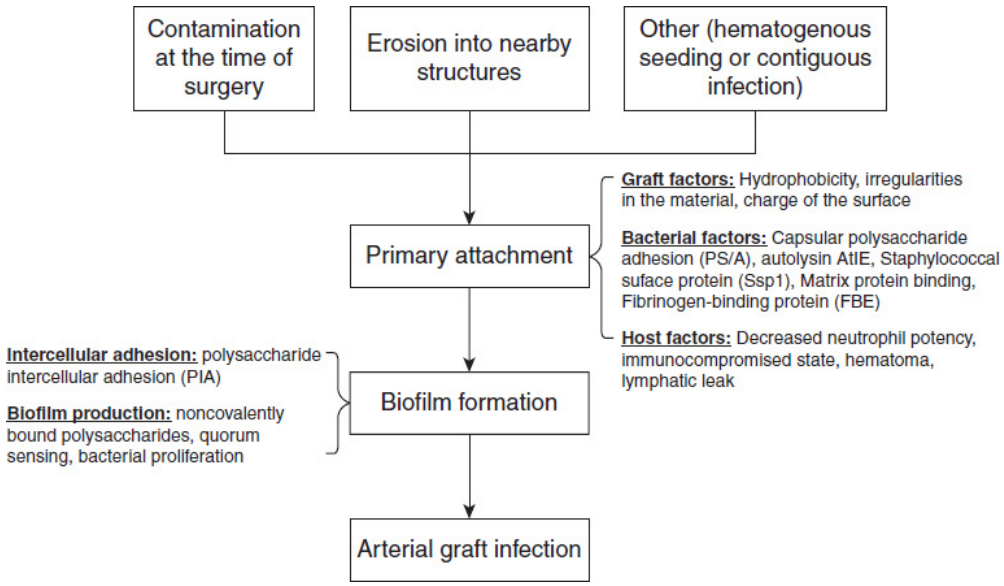

Figure 86.1 Proposed mechanism of *Staphylococcus epidermidis*–mediated graft infection.

Infective endocarditis is no longer the major source of primary arterial infections. Arterial trauma, due to iatrogenic trauma, or intravenous drug use, appears to be the most prevalent cause.[1,4] Risk factors for primary arterial infections include trauma to the arterial wall, atherosclerosis, and pre-existing aneurysmal degeneration. In an autopsy study, Miller reaffirmed that many of

infected aneurysms arise after pre-existing atherosclerotic lesions are seeded due to an episode of bacteremia, since 75% of the infected arteries had evidence of atherosclerosis in the resected specimen.[5] In Miller's study, 42% of arterial infections were located in the infrarenal aorta; the descending thoracic aorta was the next most common site of infection.[5] Immune compromise by systemic conditions or medications, such as chronic steroid use, malignancy, human immunodeficiency virus syndrome, chronic hepatitis, or malnutrition, is a common theme among patients with primary arterial infections. Predisposing conditions have been identified in nearly 70% of patients with mycotic aneurysms.[5–8]

Pathogenesis of Arterial Graft Infections

4 Prosthetic grafts are foreign bodies that are either seeded at the time of the operation, or become infected secondarily due to hematogenous seeding or contiguous infection. The incidence of aortic graft infection is about 1% with one study suggesting similar numbers for open prosthetic graft repair (1.4%) versus endograft (0.9%). This did not differ between thoracic and abdominal aortic aneurysms.[9] No particular endograft design or fabric appears to alter the risk of graft infection, but presences of infection at the time of the initial hospitalization occurs in 34% of patients.[10]

Lower extremity prosthetic grafts are at the highest risk of infection, which probably relates to the abundance of skin flora in the groin and the proximity of the graft to the incision. Infections of grafts originating from or terminating at the femoral artery complicate 4% to 6% of cases.[11,12] By comparison, carotid patches rarely become infected, with Mann reporting a single-center incidence of 0.8% over 20 years.[13] Polytetrafluoroethylene (PTFE) may be somewhat more resistant to infection than Dacron, as it has less porosity to sequester microbes.[14] Peripheral bare metal stents appear to be highly resistant to infection, with a presumed incidence of less than 0.1% based on isolated case reports.[15]

5 Prosthetic material is at risk for becoming infected for several reasons. First, a 10,000-fold lower bacterial bioburden is required to cause a graft infection, relative to healthy tissue.[16] Irregularly surfaced materials are also more likely to harbor microbes, as these surfaces create small pockets where shear stress is decreased to allow bacterial attachment.[14,17] Also, the local inflammatory response to implants abrogates the local defense against infection. Instead of being inert, the prosthetic material acts as a potent activator of host

defenses, which subsequently renders them less capable of defending the graft from infection. Multiple studies have shown contact with implants causes neutrophils to lose their ability to produce superoxide and reactive oxygen species, which are critical to their bactericidal activity.[18,19] Finally, communities of bacteria form slime to create biofilms, protecting microbes from host defenses and antibiotics.[14,17,20] Quorum-sensing is prevalent in biofilms, which decreases the virulence of microorganisms and makes them more difficult to eradicate by host defenses as the bacteria proliferate.[21] This is a critical step in the pathogenesis of prosthetic graft infections caused by *Staphylococcus epidermidis* (Fig. 86.1).[14,16,21]

MICROBIOLOGY

Primary Arterial Infections

For infected aortic aneurysms, blood cultures are negative in approximately one-fourth of subjects.[5] Intraoperative cultures are more reliable, although intraoperative cultures may be negative in many cases due to improper culture techniques or preoperative antibiotic administration that precludes isolation of 6 organisms.[5–8] In other series, up to 40% of infected aneurysms had negative blood and/or tissue culture.[6,10] The most frequent causative organisms vary by country. Hsu et al. found that 76% of primary aortic infections in Taiwan were due to *Salmonella* strains.[8] Reports from the United States show that *Staphylococcal* species (*S. aureus* or *S. epidermidis*) are most prevalent, followed by *Escherichia coli, Streptococcal* species, and *Salmonella.* Anaerobic, mycobacterial, and fungal infections represent rare causes of arterial infections.[5,7] European series are similar to the American experience, as Muller reported that 30% of infections in his series were related to *S. aureus* and *S. epidermidis*.[6] In Muller's series, *Salmonella* was the next most frequent isolate, followed by *Aspergillus, Enterococcus, Streptococcus,* and *E. coli*.[6] The causative organisms also appear to vary based on the artery involved. Infected femoral artery aneurysms are rarely true aneurysms, but are infected pseudoaneurysms related to prior catheterizations or intravenous drug use. Skin flora, such as *S. aureus* or *Streptococcal* species, are the predominant organisms isolated from infected femoral artery pseudoaneurysms.[22,23]

Arterial Graft Infections

The most common causal organisms for prosthetic grafts are *Staphylococcus* and *Streptococcus* except in the case of aortoenteric fistula (AEF) where *E. coli* is the most common organism. Up to 30% are polymicrobial, an equal number have negative intraoperative cultures.[10,24]

Prosthetic grafts infections involving the femoral artery are most often related to *Staphylococcal* species, which comprised 68% of the infections in one series.[11,12] *Enterococcal* and polymicrobial infections were less frequent among femoral artery grafts.[11,12] Endograft infections are predominantly caused by *Staphylococcal* species and other minor skin flora, such as *Propionibacterium*.[25] Similarly, *Staphylococcal* species predominate in peripheral arterial stent infections, with over 85% of the case reports attributed to *Staphylococcal* species.[15] In a report on carotid artery prosthetic patch infections, Mann found that 58% were related to *Staphylococcal* infection, one-third had an unidentified source due to negative cultures, and the remainder had gram-negative infections, with one beta-hemolytic *Streptococcal* infection.[13]

CLASSIFICATION OF ARTERIAL GRAFT INFECTIONS

Early graft infections are defined as those occurring less than 4 months after graft implantation. The Szilagyi classification system classified early surgical site infections[26] which was modified by Samson to further distinguish between different types of vascular infections.[27] Bundt's classification, developed in 1983, describes prosthetic graft infections according to the anatomic segment of the graft that is involved,[28] while the Management of Aortic Graft Collaboration was developed in 2016 in collaboration with vascular surgeons, infectious disease specialists, and radiologists to better define precise criteria for defining aortic graft infection.[29] These criteria are summarized in Table 86.1. Clinical management often varies significantly based on the extent of infection, according to these classification systems.

DIAGNOSIS

The diagnosis of primary arterial infection or prosthetic graft infection may be difficult due to the significant overlap of symptoms with other pathologies. While a thorough history and physical examination are essential, a high index of suspicion is critical to the diagnosis. Delays in diagnosis may have devastating consequences for the patient. Understanding some of the more common presentations of arterial infections can facilitate a timely diagnosis.

Common Clinical Presentations

7 Patients with vascular infections often present with nonspecific symptoms of malaise, fever, and pain in the region of the infected artery or graft, which may be accompanied by elevations in erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP).[7,10] These symptoms are most commonly associated with arterial infections caused by more virulent organisms, such as *S. aureus, Pseudomonas aeruginosa, E. coli,* or polymicrobial infections. Arterial infections caused by lower virulence organisms, such as *S. epidermidis* or *Enterococcus,* are often even more indolent and may not be associated with local or systemic signs and symptoms.[12] Peripheral arterial infections (primary or graft infections) may exhibit local symptoms, such as erythema, swelling, tenderness, or a sinus tract with purulent drainage.[12] In contrast, local signs and symptoms are unlikely with infections of cavitary arteries or grafts.

Table 86.1 Classification of Arterial Graft Infections

Szylagi Classification[26]	Grade I: Cellulitis involving wound Grade II: Infection involving subcutaneous tissue Grade III: Infection involving native arteries or vascular graft		
Samson Classification[27]	Group 1: Infection does not extend beyond dermis Group 2: Infection involves subcutaneous tissue but does not contact graft Group 3: Infection involves body of graft, but not anastomosis Group 4: Infection involves the anastomosis, without anastomotic bleeding or bacteremia Group 5: Infection involves a graft to artery anastomosis and associated with septicemia bleeding at the time of presentation		
Bundt Classification[28]	P0: Infection of a cavitary graft P1: Infection of a graft whose entire anatomical course is noncavitary P2: Infection of the extracavitary portion of a graft whose origin is cavitary Graft-enteric erosion Graft-enteric fistula Aortic stump sepsis after excision of an infected graft		
MAGIC Criteria[29]	**Clinical/Surgical**	**Radiology**	**Laboratory**
Major	Pus around graft or in aneurysm sac Open wound with exposed graft or communicating sinus Fistula development (aortoenteric	Perigraft fluid on CT scan >3 mo after insertion Perigraft gas on CT >7 weeks after insertion Increase in perigraft gas volume demonstrated on serial imaging	Organisms recovered from implanted graft Organisms recovered from operative specimen organisms

	or aortobronchial) Graft insertion in an infected site		recovered percutaneous, radiologic aspirate of perigraft fluid
Minor	Localized clinical features of graft infection Fever >38°C as most likely cause	Other (e.g.) suspicious perigraft gas/fluid, soft issue inflammation, aneurysm expansion, pseudoaneurysm formation, focal bowel wall thickening, osteomyelitis, suspicious metabolic activity on FDG-PET/CT, radiolabeled leukocyte uptake	Blood cultures positive without apparent source except graft abnormally elevated inflammatory markers with graft infection as likely cause

If a primary arterial infection is suspected, the patient should be queried for potential sources of infection. Many patients with arterial or graft infections have a history of an antecedent infection, such as pneumonia or a urinary tract infection.[7] A recent gastrointestinal illness may be a source of exposure to *Salmonella*.[8] Other potential clues include a history or clinical stigmata of intravenous drug use or a recent invasive procedure, which could provide a mechanism for seeding of a native artery or graft.

Associated medical conditions may be cofactors in the pathogenesis of vascular infections. Any condition that produces relative immune compromise may predispose to primary arterial or graft infection. Examples include

malignancy, human immunodeficiency virus syndrome, chronic hepatitis, malnutrition, and conditions that require immunosuppressive medications. Predisposing conditions have been identified in up to 70% of patients with mycotic aneurysms.[5–8] Malignancy is especially relevant due to the association between *Clostridium septicum* arterial infections and malignancy.[30] Symptomatic atherosclerosis is important to note since atherosclerotic plaques may become seeded by episodic bacteremia to create a primary arterial infection.

For patients with a history of a prior bypass involving the femoral artery, occult infections frequently present with an anastomotic pseudoaneurysm in the groin. Over 60% of femoral pseudoaneurysms are ultimately found to harbor an occult infection.[31] Mertens found that 74% of patients with infected infrainguinal bypass grafts presented with a draining wound or sinus.[32] Infections with low virulence organisms, such as *S. epidermidis,* are less likely to be present with a draining sinus because the virulence of the organisms is insufficient to incite a vigorous inflammatory response to produce the sinus tract.[12]

Graft thrombosis is another underappreciated clinical presentation for an occult graft infection. Graft thrombosis is believed to predispose to subsequent graft infection.[33] The coagulated blood within a thrombosed prosthetic graft provides a rich media for the microorganisms to proliferate.[33] In addition, prosthetic materials are fomites that may harbor microorganisms. Some authors advocate removing occluded grafts when performing subsequent revascularization operations or amputations to prevent contiguous spread from the prior occluded grafts.[34]

AEF with gastrointestinal hemorrhage is a rare, but life-threatening presentation for graft infection that must be diagnosed expeditiously. Any patient presenting with gastrointestinal hemorrhage that has a history of prior aortic surgery, especially those with vascular prostheses, must have a rapid evaluation for an AEF. AEFs often present initially with a “herald bleed,” or a relatively small amount of gastrointestinal bleeding that temporarily abates prior to a full on fatal exsanguination several hours or days later.[35–39] The mortality rate for AEFs is 30% to 77%. Delay in diagnosis is frequently a contributing factor among patients who die from this condition. Approximately 75% of AEFs result from a communication between the aorta and the third or fourth portion of the duodenum.[35] The vast majority of AEFs occur in the setting of prior surgical or endovascular aortic reconstruction. Rarely AEFs occur as a complication of a primary aortic infection.[38] If a portion of the graft erodes through the adjacent

bowel without suture line involvement, gastrointestinal bleeding results from intestinal mucosal irritation. This phenomenon is termed "graft-enteric erosion."[39] Graft-enteric erosions are often discovered incidentally during surgery to excise an infected aortic graft.

Ureteral obstruction can occur due to a mechanical complication during the tunneling of an aortofemoral limb or as a consequence of the inflammatory reaction associated with an infected aortofemoral limb. Ureterohydronephrosis is strongly associated with aortic graft infections. Wright et al. found that the presence of a urologic complication after aortoiliac arterial reconstructions was associated with a fourfold increase in the risk of graft complications, including pseudoaneurysms, limb thrombosis, AEFs, and overt graft infections.[40] Ureteral complications are typically asymptomatic, so ureterohydronephrosis is often discovered incidentally during imaging studies for other indications and should alert the physician to the possibility of a graft infection.

Imaging for Vascular Infection

The history, physical examination, and laboratory findings for primary arterial infection or graft infections are often nonspecific, so imaging plays a pivotal role in establishing a diagnosis. Although advances in imaging techniques have improved the sensitivity and specificity significantly, no single modality is perfect. Confirming a physician's suspicion of occult infection with a low-virulence organism remains a challenge in many cases. Understanding the advantages and disadvantages of each imaging modality will allow the surgeon to choose the most appropriate examination, or combination of imaging studies, to optimize the diagnostic yield.

Computed Tomography (CT) and Computed Tomographic Angiography (CTA)

CT and CTA are the preferred imaging modalities for suspected aortic graft infections in most centers. CT is readily available in most hospitals, and standard protocols enable most centers to duplicate the diagnostic sensitivity achieved at centers of expertise. Contrast allergy, contrast-induced nephropathy, metal artifact, and radiation exposure are shortcomings of CT, but the benefit outweighs the risk in most cases. The addition of oral contrast agents can help to define the association with enteric structures if an AEF is suspected. Findings suggestive of graft infection on CT or CTA include inflammatory changes in the

soft tissues surrounding the graft (**Fig. 86.2**), thickening of the bowel adjacent to vascular structures, loss of tissue planes around the artery or graft, perigraft or periarterial air or fluid, or erosion into surrounding structures (**Figs. 86.3** and **86.4**).[41,42] The sensitivity and specificity of CT for the diagnosis of aortic graft infections may be as high as 95% and 88%, respectively,[42] although the diagnostic accuracy varies depending upon the organism and severity of the infection. The sensitivity and specificity for low-grade, indolent infections may be as low as 55% and 100%, respectively.[43,44] The presence of either fluid or air significantly enhances both the sensitivity and specificity of CT scans for detecting late graft infections (>4 months postimplantation).[41,42] Early graft infections (<4 months postimplantation) present a particular challenge for diagnosis. Perigraft air is a normal finding in the periaortic tissues for 2 months after open aortic reconstruction and should not be considered indicative of an aortic graft infection.[45] Similarly, a small amount of perigraft fluid is normal for 3 months after arterial reconstruction.[41] After endovascular aortic aneurysm repair, Sawhney found that air was visualized in the aneurysm sac, surrounding the endograft, in 58% of patients on early postoperative CTA.[46] The air is introduced during endograft deployment and dissipates over a period of weeks after surgery.

Figure 86.2 CT scan demonstrating thickened inflammatory wall around the aorta.

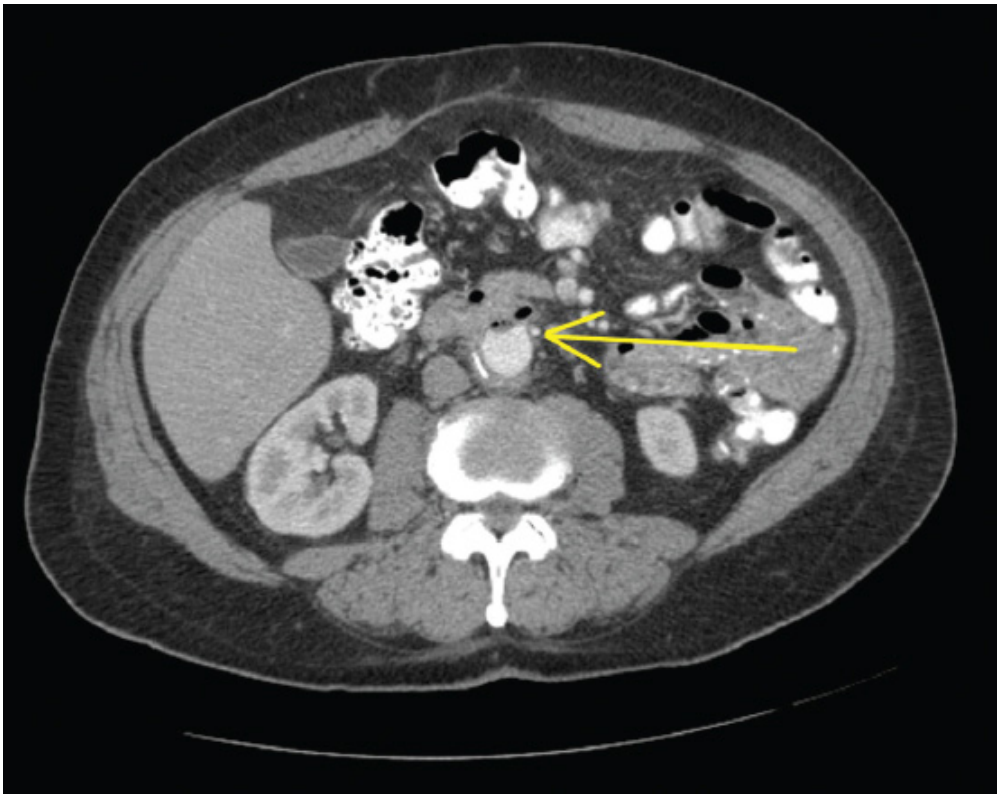

Figure 86.3 CT scan demonstrating loss of tissue planes around the aorta with foci of air as a sign of infection.

Duplex Ultrasonography

Duplex ultrasound offers a relatively safe and inexpensive tool for evaluating native arteries and bypass grafts for signs of infection. Ultrasound circumvents the risks of contrast allergy, contrast-induced nephropathy, and radiation associated with CT. The main limitations of ultrasound are the lack of availability in some centers of skilled ultrasound technicians capable of arterial imaging. Overlying structures, particularly bowel gas and the lungs, and body habitus can also obscure visualization and limit the efficacy of ultrasound evaluations within the chest or abdomen.[41] Findings on duplex ultrasound that are suggestive of infection include the presence of a pseudoaneurysm, hematoma, soft tissue masses, and perigraft gas and fluid collections. A "halo sign" surrounding an infected aortofemoral limb is a hypoacoustic shadow surrounding the graft that is indicative of perigraft fluid consistent with graft infection.[41]

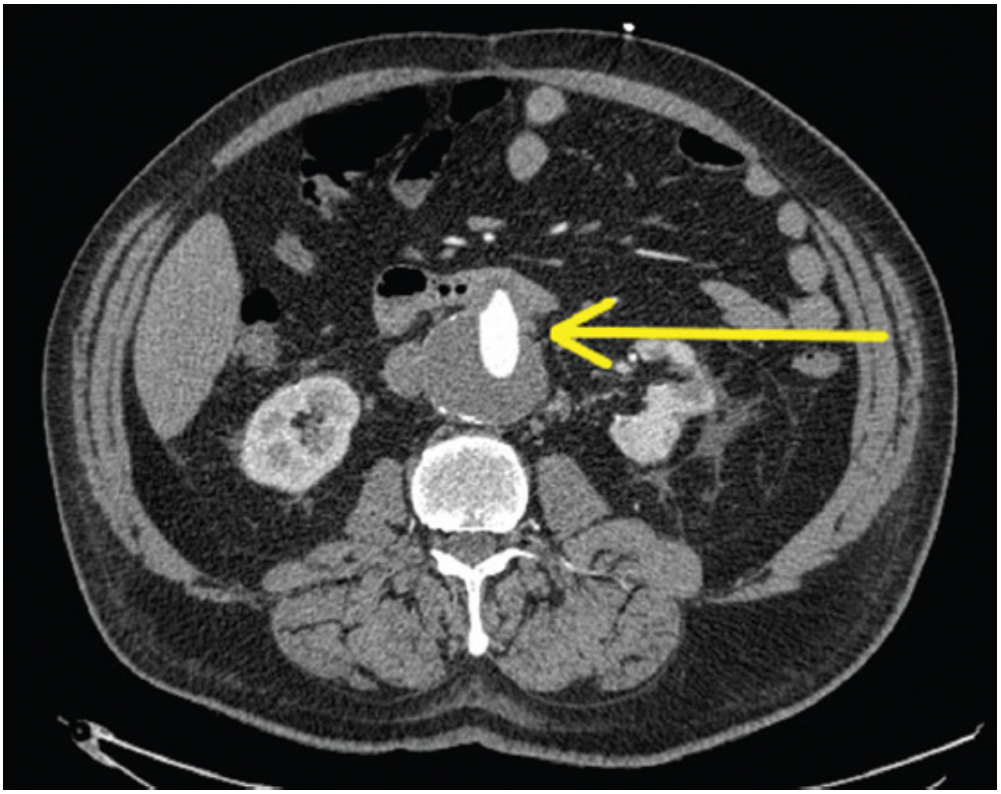

Figure 86.4 CT scan demonstrating erosion from the aorta into the overlying bowel consistent with an aortoenteric fistula.

Magnetic Resonance Imaging (MRI)

MRI offers some theoretical advantages over CTA for the diagnosis of vascular infections, including the avoidance of radiation and contrast-induced nephropathy. There are also clear disadvantages to MRI that have limited its utility in diagnosing graft infections. MRI studies for graft infection are time consuming, and MRI is contraindicated for patients with certain metal implants.[45] The sensitivity and specificity for graft infection is highly variable between institutions. MRI may be as useful as CT scan in the diagnosis of arterial infections at centers with expertise with MRI for arterial infections. In a study of 40 patients with suspected arterial graft infections, Shahidi found that the sensitivity, specificity, positive predictive value, and negative predictive value of MRI were 68%, 97%, 95%, and 80%, respectively.[47] MRI may detect small collections of biofilms, the hallmark of *S. epidermidis* infections, which are notoriously difficult to diagnose.[45] MRI creates a low-intensity "halo" around infected grafts on T_1 imaging, while also creating a hyperintense signal on T_2-weighted images.[45,48] Since gadolinium is not required, MRI may be useful in patients with chronic renal insufficiency. MRI is plagued by some of the same

limitations as CT in detecting early graft infections since air and fluid are normal findings on MRI for 2 to 3 months after graft implantation.[49]

Leukocyte Scintigraphy

Leukocyte scintigraphy may be performed using either ^{111}Indium- or ^{99m}Technetium-labeled leukocytes to localize infection within the arterial wall or graft. A theoretical advantage of leukocyte scintigraphy is the diagnosis of indolent infections with low-virulence organisms for which the symptoms are most ambiguous. Unfortunately there are numerous pitfalls to this modality. Leukocyte scintigraphy is time-consuming, labor-intensive, and prone to false-positive results due to undesired cross-labeling of platelets that may bind to grafts.[50,51] Uptake of the radionuclide-labeled white blood cells requires intact chemotaxis and a minimum total white blood cell count of 2,000/μL.[50] The net effect of these issues is that the sensitivity and specificity for tagged white blood cell scanning is highly variable between institutions, with sensitivity and specificity both ranging between 50% and 100%,[47,50] but notable false negatives have also been demonstrated.[51]

Single-Photon Emission Tomography (SPECT) Scanning

SPECT scanning, when combined with CT scanning, may enhance the specificity of leukocyte scintigraphy in the detection of vascular infections.[52] While there are limited data available at this time, the early results appear promising. In one study of SPECT–CT in 55 subjects with suspected vascular graft infections, SPECT–CT reduced the number of false positives by 37%, compared to CT alone. The sensitivity and specificity of SPECT–CT was 100%, which was superior to SPECT or CT alone.[52]

Fluorodeoxyglucose Positron-Emitting Tomography (FDG-PET)

FDG-PET utilizes glucose labeled with ^{18}fluoride, which is utilized by cells proportional to their metabolic activity. Initially, this technique was utilized to detect occult metastases in oncology patients. The protocols have been adapted for the detection of occult arterial infections.[53,54] FDG-PET can be advantageous in diagnosing endograft or peripheral stent infections since the images are less prone to metal artifact. Compared with leukocyte scintigraphy, FDG-PET offers the advantages of shorter examination times, less radiation exposure, higher

resolution, and improved interobserver agreement.[55] Unfortunately there is a high false-positive rate for diagnosing arterial graft infections because of the inflammatory response associated with prosthetic grafts, which is most prominent in the first 4 weeks postoperatively.[55] Poor uptake of the FDG-glucose can also yield nonspecific results, which is a limitation of using this test in diagnosing low-virulence infections, or after the administration of antibiotics. In addition, there is variability in both quantitative and qualitative parameters used among studies. In a meta-analysis by Rojoa, SUV_{max} and focal uptake had the best sensitivity and specificity (0.98 and 0.8 for SUV_{max} and 0.93 and 0.78 for focal uptake).[55] While the sensitivity and specificity of FDG-PET alone are inferior to CT scan alone, combining FDG-PET with CT scanning markedly improves the localization of infection and the sensitivity and specificity of the examination. Drawbacks of the fusion technology include longer study times and increased radiation exposure. Furthermore, expertise with FDG-PET-CT techniques and interpretation remains variable. Despite these limitations, the combined modality timed appropriately before antibiotic administration is a promising diagnostic option.[55]

Adjunctive Diagnostic Modalities

Arteriography, endoscopy, and image-guided biopsy should be viewed as adjunctive diagnostic modalities that have a limited role in diagnosing graft infections. Arteriography may be useful in planning reconstruction. Rarely, an occult AEF can be discovered with angiography by filling of the enteric structure. Esophagogastroduodenoscopy (EGD) is typically performed to exclude other sources of upper gastrointestinal hemorrhage in a patient with a suspected AEF. EGD was successful in diagnosing AEF in approximately 25% cases in one small series of primary AEFs (Fig. 86.5).[37] In spite of the low diagnostic yield, the authors recommended endoscopy in hemodynamically stable patients with a suspected AEF because of the devastating consequences of a missed diagnosis. Image-guided biopsy of the fluid or rind surrounding the affected vascular structure has been described when the diagnosis of graft infection is equivocal.[56] This approach could potentially distinguish between patients with benign early postoperative perigraft gas versus an early graft infection, however, sufficient sampling is difficult to achieve in all cases, as the tissue is often fibrotic and in close proximity to other major vascular structures and bowel.[56] Further study is needed to clarify if this modality has a role in the evaluation of arterial infections.

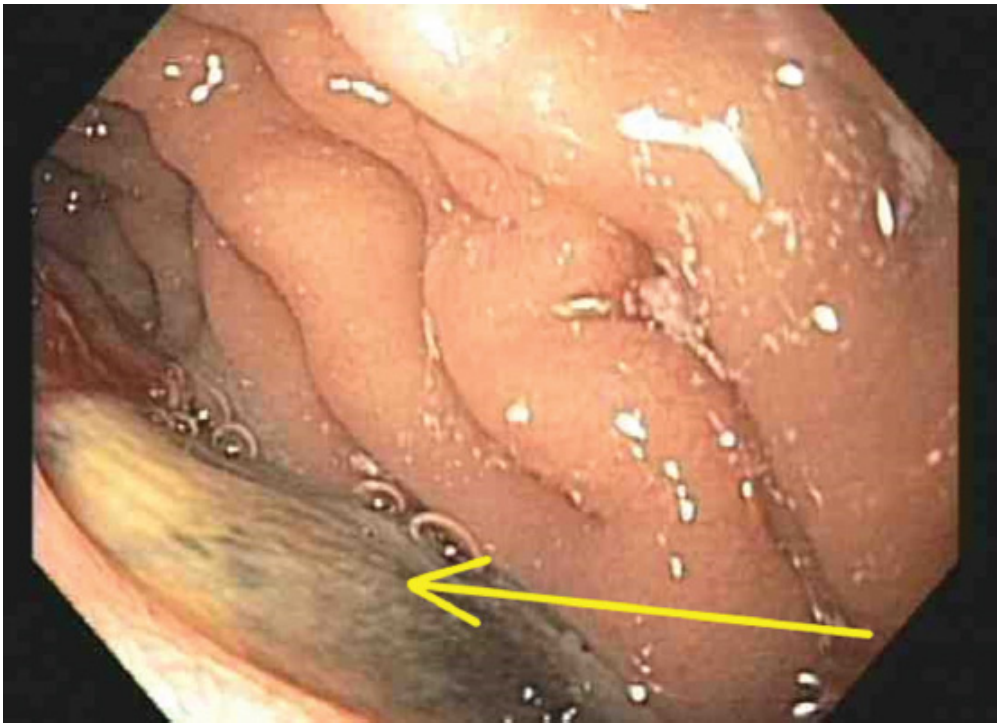

Figure 86.5 EGD demonstrating graft material visible in the bowel lumen consistent with graft-enteric fistula.

CONSERVATIVE MANAGEMENT

Primary Arterial Infections

Hsu et al. provided insight on the outcome of conservative management of subjects with primary aortic infections.[57] Hsu examined 22 subjects with infected aortic aneurysms with perceived contraindications to surgery. The predominant organism in the cohort was *Salmonella,* with two-thirds of subjects having infections of the abdominal aorta. All subjects received culture-specific intravenous antibiotics for at least 6 to 8 weeks, or until normalization of white blood cell count, daily temperatures, and CRP levels. After the acute phase treatment, oral antibiotics were continued indefinitely. In Hsu's series, the in-hospital mortality was 50% due to rupture or sepsis. The 1-year survival rate was 32%. Patients with *Salmonella* infections had a lower aneurysm-related mortality rate than patients with non-*Salmonella* infections.

Arterial Graft Infections

Calligaro advocated for complete or partial prosthetic bypass preservation in subjects with severe comorbidities precluding surgical repair.[58] Over a 20-year period, 51 extracavitary grafts (aortofemoral limbs or lower extremity bypasses) were treated with graft preservation and aggressive wound management without surgical graft resection. When wounds were present, aggressive debridement of all necrotic tissue and exudate surrounding the artery was performed. Nine cases utilized adjunctive muscle flaps to aid healing. Povidone–iodine 1% or antibiotic-soaked dressing changes were performed three times a day. With this regimen, 2 of 51 patients (4%) experienced major hemorrhage from the infected graft at 3 and 12 months after presentation. Eleven of the patients (22%) failed the treatment regimen, with nonhealing wounds or recurrent infections requiring total graft excision. Thirty-two subjects (63%) were ultimately treated successfully. Calligaro concluded that conservative management of extracavitary grafts is an acceptable option in the absence of sepsis or hemorrhage, especially when graft excision and revascularization is not feasible due to patient comorbidities. *Pseudomonas* infections, however, were particularly prone to failure with this regimen.

Building on the early reports of graft preservation therapy, subsequent reports have emerged utilizing vacuum-assisted negative pressure therapy with antibiotics and wound debridement to preserve extracavitary grafts with Szilagyi III wounds.[59,60] Wound healing with these regimens have ranged between 82% and 91% with excellent graft preservation rates.[59,60] Episodes of hemorrhage remain an issue with this approach,[59] and the failures have been associated with *Pseudomonas*.[59,60] Based on these reports, it appears that carefully selected patients with early infections involving extracavitary grafts may be treated without surgical graft excision with acceptable results.

Calligaro et al. used a nonoperative approach in six patients with intracavitary graft infections with a hostile abdomen or severe medical comorbidities.[61] All subjects underwent either open or percutaneous placement of drains along the graft with instillation of 10 mL of 1% povidone–iodine in 100 mL of normal saline or antibiotics (neomycin or a cephalosporin) three times a day. All subjects were treated concurrently with culture-directed intravenous antibiotic therapy for 6 weeks, followed by 6 months of oral antibiotic therapy. Of these six subjects, only one died due to sepsis. One patient ultimately required total graft excision and survived. The remaining patients (66%) were alive at last follow-up. These authors showed that in highly selected patients, conservative management can have reasonable outcomes. Stone et al. described the use of

antibioitic-loaded polymethylmethacrylate beads in treatment of prosthetic graft infection in 32 patients. This resulted in 87% wound sterilization, 50% rate of graft preservation, and reinfection rates of 12%.[62]

SURGICAL MANAGEMENT OF AORTIC ARTERIAL AND GRAFT INFECTIONS

Surgical treatment is based upon the central tenets of appropriate resuscitation, preoperative planning, resection of all infected material and tissue, and arterial revascularization. The optimal method of arterial reconstruction remains unresolved, as few direct comparisons between approaches have been published. Based on our extensive institutional experience with a variety of techniques, we have concluded that no single approach is suitable for all patients. We advocate tailoring the treatment algorithm based on each patient's clinical presentation and the local surgical expertise.

Aortic Infections Presenting with Hemorrhage or Sepsis

A minority of patients present with septic or hemorrhagic shock. For these patients, rapid intravenous access and resuscitation are essential prior to emergent surgery. In the authors' experience, the complexity of the operations required to manage these patients mandates a rapid CTA to obtain essential anatomic information. It is recognized that some of these patients will have either acute kidney injury or chronic kidney disease, but managing the life-threatening complications of the aortic graft infection outweighs the risk of contrast-induced nephropathy. Ideally, blood and wound cultures are obtained prior to the administration of broad-spectrum gram-positive and gram-negative antibiotic therapy. The surgical approach to managing patients presenting with hemorrhage or sepsis should be individualized based on the patient's anatomy and the expertise of the surgeons.

Endografting as Bridge Therapy

Endografts are being used with increasing frequency as a method to temporize hemorrhage in patients with aortoenteric or aortobronchial fistulas.[36,37,63–65] When the anatomy permits, endografting may temporarily prevent exsanguination

and allow time for resuscitation, medical stabilization, and further investigations to plan definitive surgery.[63] While earlier studies suggest that endografting should not be viewed as definitive therapy since recurrent hemorrhage occurs in majority of cases without further surgical treatment, often within 2 weeks,[36,64] additional studies suggest that in association with long-term antibiotics, this can be a definitive therapy in patients with short life expectancy (<6 months), while further surgical intervention should be planned for patients with longer life expectancy.[65] Some studies suggest endograft as definitive therapy. Sorelius et al. described 132 patients with mycotic abdominal aortic aneurysms, 77 of which were treated with endografts. They demonstrated improved short-term survival and 1-year survival for EVAR compared to open repair (96% vs. 74% and 84% vs. 73%). There were similar rates of infectious-related complications (24% vs. 18%) and reoperation (24% vs. 21%).[66] Patel et al. described TEVAR in conjunction with long-term antibiotics for infected thoracic aortic pathology in 27 high-risk patients. The short-term mortality was 11.5%, and 3-year survival was 57%.[67] These options expand our treatment options for aortic infection, especially in patients with high operative risk.

Definitive Surgery for AEF

Definitive surgery for an AEF involves resection of the infected graft, repair of the enteric defect, and revascularization of the lower extremities. The most appropriate surgical approach to achieve these goals has been the focus of considerable debate. For decades, the most common approach to AEFs was total graft excision with "triple" ligation of the infrarenal aortic stump and extraanatomic bypass.[68–69] In recent years, a variety of groups have touted the merits of in situ reconstruction of the aorta after graft excision, using a variety of conduits. The advantages, disadvantages, and technical details of these approaches are discussed later in the chapter (see "Aortic Infections in the Stable Patient").

Aortic Ligation and Extraanatomic Bypass for AEFs

In stable patients with a small herald bleed caused by an AEF, Reilly et al. at the University of California-San Francisco advocated staging of the two component operations at an interval of several days to minimize the physiologic impact on the patient.[69] The first stage of this approach consists of performing an axillobifemoral bypass or bilateral axillary–popliteal bypasses (depending on the configuration of the infected graft), followed several days later by resection

of the infected graft with aortic stump closure. In the patient with ongoing bleeding or hemodynamic instability, a staged approach is not feasible. Reilly reported a 26% mortality rate with the staged approach, compared to 43% for the traditional, nonstaged.[69] A subsequent study by Seeger reported a 19% treatment-related mortality rate.[70] In addition to a high mortality rate, this approach is plagued by a significant risk of aortic stump blowout (9%), reinfection of the extraanatomic bypass graft (16%), and major amputation (16%).[69]

In Situ Aortic Reconstruction for AEFs

In response to the sobering results associated with the traditional approach, in situ aortic reconstruction has been touted as a relatively simple and effective alternative.[71–75] Oderich et al. from the Mayo Clinic reported their results using in situ rifampin-soaked grafts with spiraled omental graft coverage in 54 patients with aortic graft-enteric erosions or fistulae.[71] In their series, operative mortality was 9%, and graft reinfection occurred in 4%. A subsequent multicenter study of 37 patients with AEFs treated with either in situ prosthetic grafts (n = 9), extraanatomic bypass (n = 25), or endografting (n = 3), reported a 30-day mortality rate of 43% for in situ reconstructions.[73] In that series, 3 of 11 (27%) long-term survivors with in situ grafts developed reinfection of the in situ graft, which was universally fatal.

Alternative conduits for in situ reconstruction for AEFs include cryopreserved aortoiliac allograft and creation of a neoaortoiliac system (NAIS) with femoral vein. Harlander-Locke et al. published a multicenter experience with 220 patients with aortic graft infections treated with in situ cryopreserved aortoiliac allograft, which included 33 patients with AEFs.[74] The reinfection rate in patients presenting with AEFs was 12%. In situ repair with autogenous femoral vein is not appropriate in the unstable patient due to the time required for femoral vein harvest, but may be reasonable in the stable patient with a herald bleed due to an AEF. Valentine reported a 42% mortality rate in 24 patients treated with in situ femoral vein for AEFs and graft-enteric erosions, so femoral vein may not offer any advantage over the alternative conduits for AEFs.[75]

Aortic Infection with Sepsis

Sepsis caused by an aortic infection poses a challenge because temporizing with an endograft is not an option since the septic focus is not eliminated. In unstable patients, CT-guided percutaneous drainage may be a reasonable option for

source control if there is a large perigraft fluid collection. In a series of 23 patients with graft infections, Belair et al. found that percutaneous drainage was associated with improved perioperative mortality, compared to surgery alone.[76] In the absence of a large perigraft fluid collection for percutaneous drainage, graft excision with extraanatomic bypass is the most reasonable approach.

Aortic Infections in the Stable Patient

Preoperative Evaluation

The incidence of coronary artery disease is high in surgical series of arterial infections, especially in subjects with infected endografts.[2,6] Thus, a thorough cardiovascular history, physical examination, 12-lead electrocardiogram, and echocardiogram should be obtained to evaluate for heart failure, valvular dysfunction, and pulmonary hypertension. These investigations may reveal a history of active cardiac conditions that may modify the type of operation selected or preclude surgery. Only rarely is stress testing or coronary arteriography indicated since coronary revascularization is usually contraindicated in the context of an active infection. However, this information may alter the surgical plan, provide valuable information for the anesthesiologists, and guide discussions with the patient or family regarding the expected outcomes. Pulmonary evaluations are rarely undertaken, as this information seldom alters the management of the patient. Only those patients with the most severe pulmonary insufficiency may benefit from formal testing to guide perioperative management.[77]

8 Operative planning is greatly facilitated by a preoperative CTA to define the arterial anatomy. Angiography of the lower extremities is reserved for cases when a concurrent infrainguinal bypass is considered likely. Noninvasive measurements of distal perfusion and lower extremity vein mapping should be performed. Ankle–brachial indices (ABIs) may forewarn the surgeon of the potential for infrainguinal revascularization after graft excision and aortoiliac reconstruction. Mapping of the bilateral greater saphenous veins and femoral–popliteal veins is essential if an autogenous conduit is contemplated. Femoral–popliteal veins with a diameter of less than 6 mm or evidence of vein wall sclerosis are inadequate for aortoiliac reconstruction.[2]

Anesthetic Considerations

Operations to excise infected aortic grafts are technically challenging, lengthy, and prone to a large volume of blood loss. The importance of a quality anesthesia team in managing these challenges cannot be overstated. Hypothermia, hypovolemia, and intraoperative anemia must be assiduously avoided with the use of warming blankets, warmed resuscitative fluids, warm ambient operating room temperature, and a low threshold for blood and crystalloid replacement. The blood bank should be prepared to provide fresh-frozen plasma, cryoprecipitate, or platelets on short notice if coagulopathy develops. Culture data are often not available at the time of operation, so broad-spectrum antibiotic coverage for gram-positive, gram-negative, and anaerobic organisms should be redosed throughout the operation.

Aortic Ligation and Extraanatomic Bypass versus In Situ Reconstruction

A major advantage of graft excision with extraanatomic bypass is the removal of all prosthetic graft material from the infected operative field. This approach also obviates the need to procure an aortoiliac allograft. Finally, use of an extraanatomic bypass circumvents any reticence a surgeon may have with harvesting femoral veins since some surgeons are not familiar with the technique. The obvious pitfalls of this approach are the risk of aortic stump blowout, reinfection of the extraanatomic bypass graft, and poor long-term patency of the extraanatomic reconstruction. In situ reconstruction is appealing because it avoids the risk of aortic stump blowout and the poor long-term patency of extraanatomic bypasses. For patients with insufficient infrarenal aorta for a secure three-layer closure, in situ may be the only reasonable option. Reinfection of new graft is the obvious risk of this approach. In the following sections, we will offer technical suggestions for performing these complex operations and summarize the published results for each approach.

Aortic Graft Excision

Common to each of the described surgical approaches to aortic graft infection is the need for complete graft excision. This is summarized in Table 86.2. For graft excision, aortic exposure can be performed via a transperitoneal or retroperitoneal approach. Proximal control of the infrarenal aorta can be challenging in a redo operative field, so the surgeon should be prepared to obtain proximal control of the aorta at the suprarenal or supraceliac level, or consider balloon occlusion as an adjunct. When treating an AEF, proximal control should

be obtained prior to mobilizing the duodenum since there may be uncontrolled hemorrhage in the absence of proximal aortic control. The left renal vein may be densely adherent to the graft or the native aorta, which may necessitate its division to gain access to the aorta near the renal arteries. Once proximal control is obtained, distal control of the bilateral common iliac arteries should ensue, unless these arteries are occluded. When excising an aortofemoral graft, the femoral limbs should be controlled in the abdomen to facilitate their removal. Removal of aortofemoral grafts requires considerable dissection in the groins for control of the prosthetic graft limbs and native common femoral, superficial femoral, and profunda femoris arteries. Femoral exposure may be performed through an incision directly over the femoral limb or incisions lateral to the sartorius muscle. The lateral incision avoids some of the prior scarring and may preserve soft tissue for arterial coverage. Systemic heparin is administered prior to cross-clamping, and the graft is removed in its entirety. Any arterial tissue that appears to be abnormally friable is probably infected and should be debrided. Remnants of graft and arterial tissue should be sent for Gram stain, culture, and sensitivity testing. A critical adjunct is wide debridement of the retroperitoneum, which is believed to decrease the residual bacterial bioburden that will predispose to recurrent infection. After completing graft excision and debridement, closure of the aortic stump or in situ aortoiliac reconstruction may ensue. The primary options for reconstruction include extraanatomic bypass or in situ repair using a variety of conduits including cryopreserved allograft artery, rifampin-soaked or silver-impregnated Dacron, or autogenous femoral vein. The results of these techniques are compared in Table 86.3.

Table 86.2 Excision of Aortic Graft Operative Steps

Step
Transperitoneal or retroperitoneal incision
Exposure for proximal control ▪ May require division of left renal vein ▪ Consider balloon control as adjunct
Distal exposure ▪ Control aortofemoral bypass limbs in the abdomen ▪ Consider lateral approach to femoral artery to avoid scarred field
Heparinize and cross clamp
Remove graft in entirety ▪ Send graft for culture
Wide debridement of the retroperitoneum ▪ Send tissue for culture
Aortic stump closure or in situ reconstruction ▪ Double layer running nonabsorbable polypropylene suture horizontal mattress followed by baseball stitch ▪ Omental wrap secured with sutures

Extraanatomic Bypass

For stable patients, staging of the extraanatomic bypass and graft excision should be considered, as proposed by Reilly.[69] The first stage of this approach consists of performing an axillobifemoral bypass or bilateral axillary–popliteal bypasses, meticulously avoiding any infected or contaminated planes when tunneling the new grafts. The second stage consists of aortic graft excision, retroperitoneal debridement, and aortic stump closure. Aortic stump closure requires a meticulous three-layer closure or "triple ligation" of the aorta. The first two layers consist of nonabsorbable polypropylene suture; a vertical mattress suture, followed by running "baseball" suture. The final layer is an omental wrap secured with sutures.[69] When staging the extraanatomic bypass and graft excision, the optimal time interval between the two operations has not been defined. It has been our experience, however, that the presence of both an

aortobifemoral bypass and an extraanatomic bypass creates competitive flow between the grafts that often results in thrombosis of the extraanatomic bypass graft. To minimize the risk of interval graft thrombosis, patients are anticoagulated with intravenous unfractionated heparin between operations, and a short (1 to 3 days) time interval (usually 1 to 2 days) between the two operations is planned. If the two operations are performed at the same operative setting, the clean portion of the procedure (the extraanatomic bypass) is performed prior to the infected portion of the case (graft excision) whenever feasible to minimize the risk of bacterial inoculation of the new graft.

Table 86.3 Complications Associated with Different Methods of Aortic Reconstruction after Aortic Graft Excision, Based on Selected Publications

Method of Aortic Reconstruction	Mortality	Graft Occlusion	Amputation	Reinfection (Stump Blowout)	Pros (+)/Cons (–)
Extraanatomic bypass with aortic ligation[72,73,78,79]	Early 11–45% Late 40%	27–34%	0–27%	3–27% (9–27%)	(+) reduced morbidity with staging (–) decreased patency, stump blowout, amputation rate, and reinfection
In situ autogenous vein[25,80]	Early 9% Late 40–55%	3%	6–7%	0–4%	(+) resistant to infection, excellent long term durability and limb salvage (–) time consuming, fasciotomy in up to 25%
In Situ Allograft[24,74]	Early 2.8–9% Late 3–48%	4–7%	1–2%	3–4%	(+) resistant to reinfection, excellent long-term durability and limb salvage (–) rupture and pseudoaneurymsal degeneration, cost, persistent infection
Rifampin soaked[68,73,78]	Early 8–31% Late 16–40%	0–9%	0%	0–12%	(+) excellent patency, convenience (–) higher reinfection rates
In situ silver-impregnated graft[81,82]	Early 16–18% Late 16–27%	0–8%	0–4%	9–13%	(+) excellent patency, convenience (–) highest reinfection rates

In Situ Reconstruction with Cryopreserved Arterial Allografts

Experience with allograft replacement of primary or secondary arterial infections began with Alexis Carrel more than a century ago.[83] Difficulties with procurement and preservation resulted in poor-quality control. Allografts were largely abandoned until their resurrection for the treatment of infectious pathologies of the ascending aorta in the 1980s.[84] Initial positive experience resulted in more widespread use, including the treatment of infected infrarenal aortic graft infections.[85] Initially, local tissue banks were responsible for procuring, preserving, and allocating allografts for clinical use. This resulted in

considerable variability in the processes of preparing and storing the product, which may have impacted the quality of the product. Currently, these processes have been centralized in both North America and Europe with primary suppliers of the cryopreserved allografts.

The primary advantage of cryopreserved allografts is its resistance to infection, while major disadvantages include cost (approximately $18,000 per aortoiliac segment), and that the grafts are not readily available at most centers or immediate use in urgent circumstances.

In Situ Reconstruction with Rifampin-Soaked and Silver-Impregnated Grafts

Rifampin shows unique activity against *S. epidermidis* biofilms, making it an excellent choice for prosthetic graft infections. Rifampin-soaked Dacron grafts (600-mg rifampin in 250 mL of normal saline, soaked for 30 minutes) with omental wrapping has been shown to have variable resistance to recurrent infection, ranging between 4% and 11.5%.[71,72] Recurrent infections have been fewer when treating AEFs, compared to prosthetic graft infections. Primary patency and limb salvage are also excellent. Circumferential omental wrapping of the grafts is a critical technical adjunct to decrease the risk of reinfection.[71]

Silver-impregnation relies upon the ability of silver to adsorb gram-positive and gram-negative bacterial membranes, resulting in disruption of the membrane and cell lysis. There has been no reported bacterial resistance to silver.[86] It is theorized that silver-impregnated grafts would have activity against *E. coli* and methicillin-resistant *S. aureus,* which would be an improvement over rifampin-soaked grafts, however limited clinical data suggest that silver-impregnated grafts are not equivalent to rifampin-soaked grafts based on higher reinfection rates.[81,87]

In Situ Reconstruction with Autogenous Femoral Vein

Autogenous femoral vein was proposed as an alternative conduit for in situ reconstruction for infected aortic grafts in the early 1990s.[88] Clagett described creating a “neoaortoiliac system” or NAIS using femoral veins harvested from both legs. The proposed advantages of femoral vein include an innate resistance to infection and excellent long-term patency. The major pitfall of using femoral vein for in situ reconstruction is the time required to harvest the veins. Although many surgeons have not had formal training in the technique for harvesting femoral veins, it is well within the capability of any vascular surgeon. The

technique is described in detail elsewhere, and summarized in Table 86.4.[89] Among clinicians who are not familiar with using femoral vein for aortoiliac reconstruction, there appears to be reluctance based on concerns with any venous morbidity associated with harvesting the femoral vein. Modrall et al. described their intial experience as requiring up fasciotomy of up to 17% of patients.[90] However, the need for fasciotomy in recent data is rare due to an increased tolerance leg swelling by the surgeons before performing fasciotomy.[91] Two preoperative predictors of a higher probability of fasciotomy were identified: concurrent harvesting of the greater saphenous vein in the same limb and a low ABI (<0.55) in the harvested limb. Prior harvest of the ipsilateral greater saphenous vein was not a risk factor for requiring a fasciotomy. Venous collaterals develop over time to normalize venous physiology in most patients, so long-term venous morbidity is minimal. One-third of patients experience mild chronic leg swelling, and the remainder are asymptomatic.[91] To our knowledge, no limbs have developed venous ulceration as a consequence of femoral vein harvest.

Table 86.4 Operative Steps for Femoral Vein Harvest

Step
Incision is extended along the lateral edge of the sartorius from the anterior superior iliac spine to the medial femoral condyle
Sartorius is reflected medially to preserve blood supply
Avoid saphenous nerve
Double ligate side branches >3 mm over suture ligation to avoid tearing vein wall
Expose entire length from the confluence with the profunda vein to the knee joint
Divide the vein flush with the profunda vein to prevent blind stump thrombus
Evert the intima for valve excision
Distend under pressure and repair defects with 6-0 or 7-0 polypropylene
Use in nonreversed orientation to improve mismatch

NONAORTIC ARTERIAL AND GRAFT INFECTIONS

Lower Extremity Arterial Infections

Lower Extremity Graft Infections

The nonoperative management of Szilagyi III wounds was described previously. Older studies show that lower extremity bypass graft infections carry a postoperative major amputation and mortality rate of nearly 50% due to the underlying atherosclerotic disease burden.[92] These patients often do not have other conduit suitable for bypass, which is a major impetus for graft preservation strategies for infected extremity bypass grafts. The use of local debridement with adjunctive vacuum-assisted closure and muscle flaps has yielded promising results. Siracuse cited an estimated 1-year limb salvage rate of 71%, which was attributed to the graft preservation techniques described above.[12]

Cryopreserved human allograft veins have been touted as an alternative if a prosthetic bypass graft must be removed for infection. Unfortunately, human allograft veins have yielded relatively poor results. In a series of bypasses for critical limb ischemia using cryopreserved greater saphenous vein, primary patency at 1 and 3 years was 27% and 17%, respectively.[93] Amputation-free survival at 1 and 3 years was 43% and 23%, respectively. Better results have been reported using cryopreserved human allograft arteries, especially when covered with muscle flaps. One series reported good long-term results with only 15% late conduit-related graft complications.[94] Cadaveric grafts are expensive, on the order of $5000–$10,000. In view of the outcomes and cost, the use of cryopreserved conduit must be weighed against the outcomes of graft preservation techniques on a case-by-case basis.

Extraanatomic bypass is an alternative to avoid inguinal infections. Obturator bypass yields reasonable results with 60% to 83% survival with healed wounds beyond 3 years, and 70% to 80% 3-year patency.[95,96] Lateral femoral bypass also yielded good results with 95% survival and wound healing, 83% 2-year patency, and 93% limb salvage.[97]

Infected Common Femoral Artery Pseudoaneurysms

The management of infected common femoral artery pseudoaneurysms diverges from the management of infected pseudoaneurysms in other anatomic locations.

The most frequent clinical scenarios involve infection after a history of recent arterial catheterization or intravenous drug abuse. The incidence of infection after cardiac catheterization is less than 1%, although the use of arterial closure device increases the risk due to the presence of a foreign body. Aggressive debridement, removal of the closure device, and revascularization remains the mainstays of therapy. In situ repair with autogenous greater saphenous or femoral vein is preferred if arterial replacement is necessary.[23] A rotational muscle flap may be necessary for graft coverage in some cases. Occasionally, in situ repair may not be advisable due to the quality of the arteries or the surrounding tissue. Ligation of the native arteries in the groin and an extraanatomic bypass, such as an obturator bypass or lateral tunneling may be preferable.[96,97] Ligation of the common femoral artery without reconstruction is utilized as a last resort and is less likely to threaten the limb if the femoral bifurcation remains intact.[23]

Conversely, infected common femoral artery pseudoaneurysms secondary to intravenous drug abuse should be preferentially managed with aggressive arterial and soft tissue debridement and ligation of all of the involved arteries. Immune suppression due to malnutrition and human immune deficiency virus infections, delayed presentation, and patient recidivism make arterial reconstruction hazardous in this setting. Reddy showed that ligation of the common, superficial, and profunda femoral arteries is associated with a 33% major amputation rate.[98] Rates of major amputation are very low in other series, with some authors reporting 0% to 1% amputation rates in their series.[23,99,100] Claudication is common, however one group reported only 11% early claudication all of which resolved over time.[23]

Arterial Infections in Other Sites

Carotid patch infection is a rare, but dreaded occurrence. Management entails removal of the patch, wide debridement, and primary closure of the artery versus vein patch closure. Interposition grafting with autogenous vein is often necessary after the artery is debrided adequately. Occasionally ligation of a bleeding, infected artery is necessary as a life-saving intervention.[13] In a series of carotid patch infections, the stroke rate after debridement and reconstruction was 8.1% and increased to 14% when carotid ligation was necessary.[13] Endografting is an acceptable option to control hemorrhage and permit stabilization and evaluation for definitive surgery.[101]

Case reports and small case series of infected pseudoaneurysms of the superior mesenteric, celiac, and splenic arteries have been reported.[102–104] Treatment is individualized by the patient's comorbidities and anatomy. Infected visceral artery aneurysms are prone to rapid growth and rupture.[102–104] The most common pathogens are streptococcus followed by staphylococcus.[101–104] Arteriography is often helpful to delineate the anatomic relationship of the aneurysms to nearby branch vessels and to define the quality of the collateral circulation. Excision, debridement, and arterial reconstruction with autogenous conduit remain the gold standard for infected pseudoaneurysms of main arterial trunks. Cryopreserved artery has also been described in the absence of autogenous conduit.[94] Resection and arterial ligation may be an option in some cases, depending on the anatomic location due the abundant collateral circulation between the mesenteric arteries and branches.[104] Coil embolization and long-term antibiotic therapy should be reserved for surgically inaccessible aneurysms, such as intrahepatic mycotic pseudoaneurysms, since coils may become infected.[105]

ANTIBIOTIC THERAPY

9 Unfortunately, there are no guidelines directing the type, dose, duration, or route of administration of antibiotics in treating arterial infections. This reflects the wide spectrum of causal organisms that are found in arterial graft infections, with approximately one-third of subjects having polymicrobial infections. Moreover, physician preference and patient tolerance of antibiotic regimens vary considerably. In addition, culture-directed therapy is not always possible since nearly 40% of patients have negative cultures, presumably due to preoperative broad-spectrum antibiotic therapy.[5] Finally, the consequences of a reinfection are dire, so there is a tendency among physicians to overprescribe antibiotics.

Initial broad-spectrum antibiotics should include agents with activity against gram-positive bacilli, gram-negative rods, and anaerobes, as these are the most prevalent organisms in graft infections. Currently our preferred combination therapy is vancomycin, piperacillin/tazobactam, and metronidazole. Blood cultures and graft and tissue cultures should be obtained to direct therapy. Recommendations for the duration of antibiotics vary widely, ranging from 2 weeks to 6 months after graft excision. If a graft or stent is not fully excised, indefinite antibiotic therapy should be considered. Fungal infections are

particularly difficult to eradicate and may require the use of micafungin (FK463) due to the increasing incidence of resistance to fluconazole and its related molecules.[106]

PREVENTION OF SECONDARY ARTERIAL INFECTIONS

Meticulous surgical technique is critical to minimizing arterial graft infections. Judging from the microbial flora associated with graft infections, intraoperative contamination and surgical site infections are the most likely sources of contaminations that result in arterial graft infections. Adherence to all perioperative guidelines for reducing surgical site infections is important, but the use of prophylactic systemic antibiotics appears to be critically important. A recent meta-analysis and systematic review performed by Stewart concluded that prophylactic systemic antibiotics decreased the risk of wound and early graft infection for peripheral arterial reconstruction.[107] No benefit was seen in continuing antibiotics for greater than 24 hours, prophylactic rifampin bonding to the grafts, suction groin wound drainage, or preoperative bathing with or without antiseptic agents. Using guidelines for prosthetic heart valves, some authors suggest similar antibiotic prophylaxis in patients with aortic graft undergoing dental procedures.[108]

CONCLUSIONS

10 Primary and secondary arterial infections constitute a myriad of some of the most technically, intellectually, and emotionally challenging cases that vascular surgeons may encounter in clinical practice. For aortic arterial infections, there is no consensus regarding the optimal method of in situ reconstruction. Autogenous vein reconstruction may be the most resistant to recurrent infection and most cost effective, but requires an additional, lengthy procedure for vein harvest. Reconstruction with either antibiotic- or silver-impregnated grafts may also be a reasonable alternative, but appears to have a higher rate of reinfection compared to the alternatives. Cryopreserved allografts have improved since their initial development, but are still hampered by a minority of hemorrhagic complications and pseudoaneurysmal degeneration. Moreover, cryopreserved

allografts are considerably more expensive than the other alternatives. Extraanatomic bypass remains a viable alternative for patients unable to undergo a more extensive operation. Endovascular stent grafts are excellent tools to stabilize patients with hemorrhagic complications of arterial infections prior to definitive surgery. Arterial infections in other locations utilize the same principles of wide excision and debridement, arterial reconstruction, and appropriate antibiotic coverage whenever technically feasible.

Cerebrovascular Disease

Omar Al-Nouri and Mahmoud B. Malas

Key Points

1. Stroke is the fifth leading cause of death in the United States, worldwide stroke continues to be one of the most common causes of death and disability.
2. Stroke remains the leading cause of disability in the United States and costs an estimated $34 billion each year.
3. Duplex ultrasonography remains an invaluable tool in the diagnosis of significant carotid artery atherosclerotic disease.
4. The preferred management of symptomatic and severe asymptomatic carotid artery disease is surgical intervention over medical therapy alone.
5. Aggressive risk factor modification is imperative in all patients with atherosclerotic cerebrovascular disease.
6. Transcarotid artery revascularization (TCAR), with its CEA-like protective qualities, should be preferred over transfemoral carotid artery stenting in select patients not candidates for CEA.
7. Endovascular management of proximal vertebral artery atherosclerotic lesions has been shown to be safe and effective in small nonrandomized trials, but further studies are needed to sufficiently assess its efficacy.
8. Open surgical correction of brachiocephalic occlusive atherosclerotic disease should be preferred over endovascular management.

INTRODUCTION

Stroke continues to be a common cause of disability and death, accounting for the fifth leading cause of death in the United States.[1] Stroke disability can be debilitating, even more so than that of a myocardial infarction (MI). Quality-of-life sub-analysis of the Carotid Revascularization Endarterectomy versus Stenting Trial (CREST)[2] among 1-year survivors indicates that stroke

has greater adverse effect on a broad range of health-status domains than did an MI. Permanent disability from a stroke can lead to blindness, weakness, paralysis, or aphasia. Transient ischemic attacks (TIAs) have symptoms last <24 hours and manifest similarly, albeit without long-term sequelae. These sequelae have long-lasting social and financial burdens not only on patients and families, but on the healthcare system as well.

There are a multitude of etiologies leading to stroke with many modifiable risk factors. Some of the most common risk factors include hypertension, diabetes, hypercholesterolemia, obesity, genetics, and smoking. Eighty-five percent of all strokes are thought to be ischemic, whereas only 15% are embolic. Atherosclerotic plaque is the most common and important underlying pathology leading to ischemic strokes.[3] Since the first successful carotid endarterectomy (CEA) in 1953 by Michael DeBakey, carotid revascularization has been shown in multiple randomized clinical trials to decrease the risk of ipsilateral ischemic strokes. Minimally invasive endovascular techniques such as transfemoral carotid artery stenting (TFCAS) and transcarotid artery revascularization (TCAR) have been introduced as alternative options in patients who are high risk for CEA. However, CEA remains the gold standard option for symptomatic carotid artery stenosis. Ongoing randomized trials comparing surgical, endovascular and medical management of asymptomatic carotid artery occlusive disease are highly anticipated.

Vertebrobasilar insufficiency (VBI) can be a much more difficult diagnosis to obtain as compared to atherosclerotic carotid artery disease. Symptoms are often vague and are easily confused with other diagnoses. These symptoms are more likely posterior circulation symptoms that include diplopia, vertigo, drop attacks, and headaches. Traditional treatment for true VBI was open surgical treatment of the ostial vertebral artery atherosclerotic occlusive disease. Endovascular repair with balloon angioplasty and/or stenting is an attractive option, however, outcomes have not been extensively evaluated.

Atherosclerotic brachiocephalic occlusive disease typically involves the origins of the great vessels. Symptoms may be similar to atherosclerotic carotid stenosis including amaurosis, TIA, and stroke, but also can include arm fatigue and weakness. Again, traditional treatment has been open surgical repair with transthoracic repair versus extra-anatomic bypass.

Endovascular management with angioplasty and stenting has also been advocated for this disease entity, but experience is limited.

This chapter provides a comprehensive review of the epidemiology, pathophysiology, diagnosis, treatment, and controversies in management of atherosclerotic and nonatherosclerotic carotid artery disease, as well as VBI and brachiocephalic occlusive disease.

ATHEROSCLEROTIC CAROTID ARTERY DISEASE

Epidemiology

1 Worldwide, stroke continues to be one of the most common cause of mortality and disability. One in six people worldwide will have a stroke in their lifetime. Fifteen million people worldwide suffer a stroke each year and 5.8 million people die from it.[4] Despite the decreasing incidence in the United States, annual incidence of new or recurrent stroke is 795,000, of which 610,000 are first or new strokes.[5] Stroke prevalence is linked to patients' age, as older Americans over the age of 65 have a much higher prevalence as compared to Americans aged 18 to 44 years (8.4% vs. 0.7%).[6] Race also seems to play a role in stroke, as whites have a lower incidence of stroke when compared to blacks and Hispanics.[7] Stroke rates also vary by region in the United States, with the southeastern United States with higher incidence of stroke hospitalization rates as compared to the western United States. Stroke deaths, however, have been on the decline in the United States over the past few decades. Stroke is now the fifth leading causing of death, killing about 140,000 Americans each year.[8] This decrease in stroke mortality can be attributed to improvement in acute stroke care with the advent of intra-arterial thrombolysis and endovascular mechanical thrombectomy.[9] Improved recognition of the importance of medical management with statin and antiplatelet agents certainly has played a role as well. Despite the decreasing mortality and the earlier recognition of acute stroke symptoms and the timely use of acute stroke therapies, stroke remains the leading cause 2 of disability in the United States and costs an estimated

$34 billion each year. Care for stroke survivors cost an estimated $18.8 billion during 2008 and lost productivity and premature mortality cost an additional $15.5 billion.[10] The risk factors for stroke include age over 55, male sex, hypertension, family history, atrial fibrillation, hypercholesterolemia, renal insufficiency, obesity, diet, diabetes, smoking, and alcohol use. Of those, the five most significant factors that lead to stroke are: hypertension, smoking, obesity, diet, and physical inactivity.[11]

Pathogenesis of Stroke

Cerebrovascular accidents (CVAs) in the United States are overwhelmingly related to ischemia (87%), whereas intracerebral and subarachnoid hemorrhage account for 10% and 3%, respectively.[12] Carotid atherosclerotic disease may cause a stroke in a variety of ways. Most commonly, unstable plaque embolization to the middle or anterior cerebral artery will cause TIA or stroke. Rarely, reduced flow through a highly stenotic extracranial carotid artery may cause cerebral hypoperfusion in patients with poor cerebral collaterals, resulting in stroke. Additionally, acute thrombosis causing in situ obstruction from atherosclerosis, dissection, or fibromuscular dysplasia (FMD) is also a possible etiology for CVA.

Patients at highest risk for TIA or stroke are those with greater than 80% carotid artery stenosis secondary to soft, echolucent plaque or those whose plaque progresses from less than 80% to greater than 80% during a follow-up period.[13] These fibrous plaques will continue to have infiltration of lipids into the arterial wall leading to inflammation and infiltration of macrophages, which leads to lysis of proteolytic enzymes resulting in necrotic debris.[14] This can result in an unstable plaque that leads to intraplaque hemorrhage and rupture of the fibrous cap causing immediate embolization (**Fig. 87.1**). Once this embolization event occurs, the resulting ulcer will act as a nidus for the accumulation of platelet aggregates and other thrombotic debris, thereby putting the patient at risk for further embolization. This can be best illustrated by viewing photomicrographic images of an ulcerated plaque containing loosely adherent thrombotic debris prone to embolization (**Fig. 87.2**). Stroke from carotid vessel etiology has the highest recurrence rate at 30 days if not surgically treated.[15]

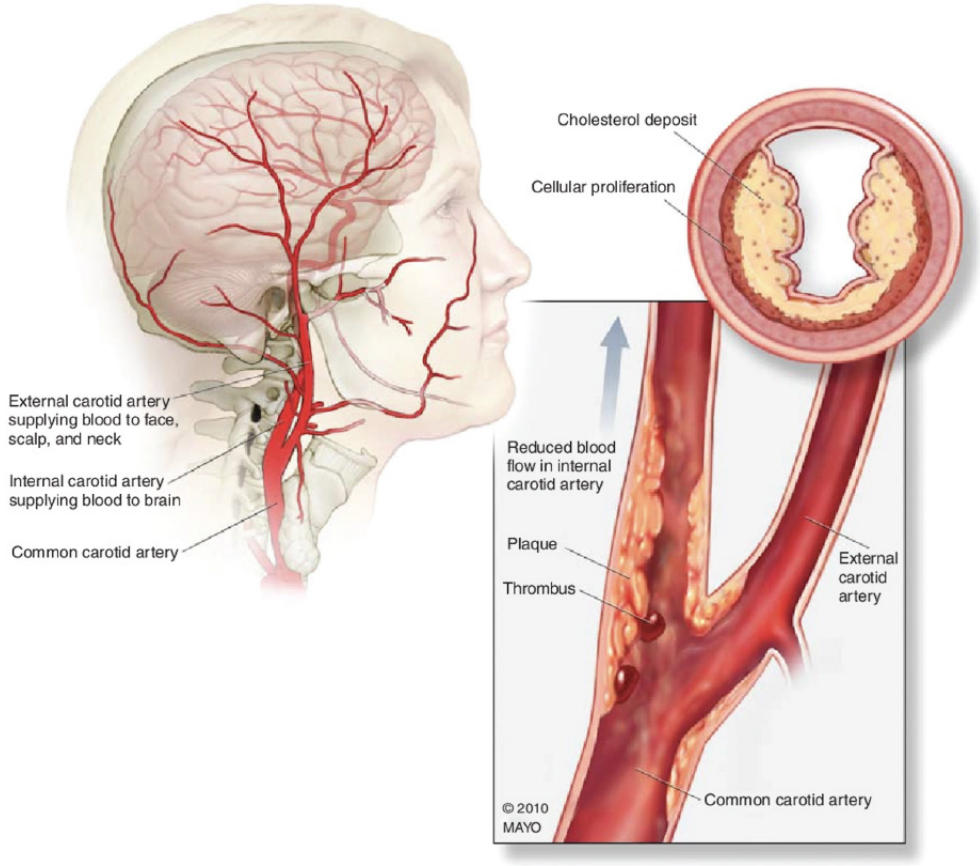

Figure 87.1 Stroke caused by carotid atherosclerotic disease is usually caused by atheroemboli from the internal carotid artery. As shown the majority of the anterior cerebral circulation comes from the internal carotid artery. As increasing carotid stenosis occurs, flow becomes more turbulent and carotid plaque can become more unstable, increasing the risk of atheroembolization.

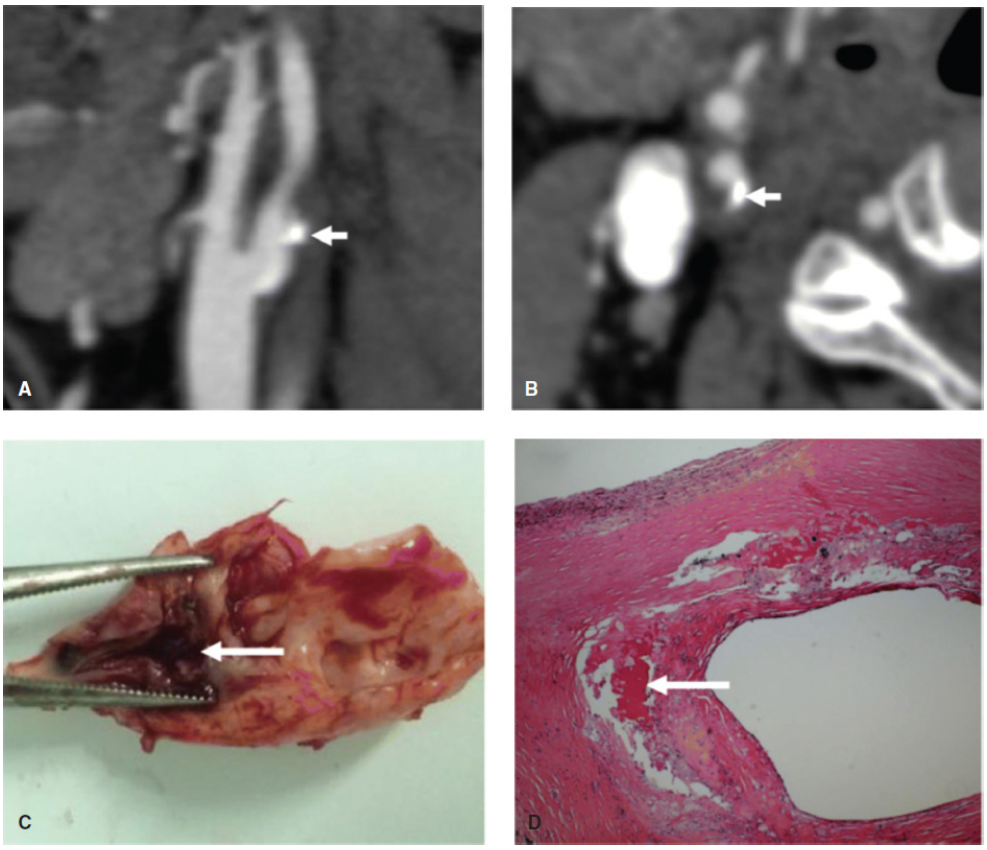

Figure 87.2 Panel showing unstable atherosclerotic plaque from CTA in figure **A** and **B** to endarterectomy specimen in **C**. **D:** (arrows) Photomicrograph of this ulcerated plaque demonstrates thrombus loosely adherent to the wall of the plaque, showing why embolization is very much a certainty in these cases.

The carotid bifurcation is especially susceptible to atherosclerotic plaque formation. The separation of flow between the high-resistance external carotid artery (ECA) and the low-resistance internal carotid artery (ICA), creates a low-flow and shear stress area, where turbulent flow is a set up for plaque formation on the walls opposite from the flow divider (**Fig. 87.3**). Constant nonlaminar flow at the carotid bifurcation with an inciting event, such as intimal injury, is the perfect storm that leads to platelet deposition, smooth muscle proliferation, macrophage infiltration and loss of luminal diameter. Reduced luminal size will thus lead to increasing velocities and more turbulent flow leading to increased risk of atheroemboli. As stated above, atheroemboli are more common when a thin fibrous cap ruptures as opposed to a thicker fibrous cap, which may be more stable (**Fig. 87.4**).

Clinical Syndromes

The clinical manifestations of symptomatic carotid atherosclerotic disease include TIA, stroke, and amaurosis fugax. TIAs are defined as neurologic events that are sudden in onset without a preceding aura and last less than 24 hours in duration. Patients return to their baseline neurologic function, which usually occurs within minutes of the inciting event. These are considered a precursor to a more serious neurologic event with a large number that will progress to stroke. Stroke symptoms can be broken down into motor and sensory changes. These include dysarthria, dysphasia, aphasia, monoparesis, hemiparesis, hemiplegia, monocular blindness, numbness, or paresthesias. When related to carotid stenosis, these symptoms occur on the contralateral side of the lesion due to ipsilateral cerebral embolization. Amaurosis fugax is temporary monocular blindness from cholesterol embolization to the retinal artery via the ophthalmic artery. An important, but often less recognized association with critical ipsilateral carotid stenosis is a severe chronic monocular visual deterioration known as chronic ocular ischemic syndrome.[16] Patients with chronic ocular ischemic syndrome may suffer from transient visual loss, gradual loss of visual acuity, and eye pain. Equally important is to recognize what symptoms are not likely related to carotid atherosclerotic disease. Dizziness, syncope, vertigo, seizures, migraines, bowl or bladder incontinence, and scintillating scotomas are not related to carotid atherosclerotic occlusive disease and other causes should be sought out. Once the symptoms progress pass 24 hours, the TIA has become a full stroke. It often will take weeks for the full severity of the stroke to manifest as the ischemic penumbra will either recover or it won't. The severity of stroke is graded by using a variety of severity scales. The most commonly used scale is that formulated by the National Institute of Neurologic Disease and Stroke (NINDS) of the National Institutes of Health (NIH). The NIH stroke scale yields a numeric score of 0 to 42 and can be used at the initial neurologic event and then throughout the evolution of the stroke to help map out the patient's clinical course (**Fig. 87.5**). A score of 5 or lower is considered a mild stroke; a score of 6 to 20, moderate stroke; and a score higher than 20 represents a severe stroke.

Initial Diagnostic Evaluation

Carotid atherosclerotic disease may be a difficult clinical diagnosis to obtain prior to the onset of neurologic symptoms. Physical examination in asymptomatic carotid atherosclerotic disease is limited to auscultation of a carotid bruit. Auscultation of a carotid bruit was once considered a part of the standard cardiovascular examination. Even though the auscultation may be an effective method for selecting further diagnostic tests, studies have shown that the sensitivity and positive predictive value are low for a carotid bruit detecting severe carotid stenosis.[17] The primary diagnostic tool for detection of hemodynamically significant carotid stenosis is duplex 3 ultrasonography (DUS). The benefits of DUS include excellent sensitivity and specificity (especially for high-grade carotid stenosis),[18] low cost, rapid availability, and ease of evaluation and avoidance of radiation. Decisions on carotid intervention are often solely based on information provided by the DUS. The severity of carotid stenosis is determined by measuring the peak systolic velocity (PSV), end-diastolic velocity (EDV), and the ratio of the PSV of the ICA to common carotid artery (ICA/CCA) (**Fig. 87.6**). There are two major DUS criteria for determination of carotid stenosis, modified University of Washington (UW) criteria (**Table 87.1**) and the Carotid Consensus Panel duplex Criteria (CCPC) (**Table 87.2**). Recent studies have shown that the CCPC criteria demonstrate a higher corroboration rate with measurements taken from computed tomography angiography (CTA), and may be more sensitive in classifying clinically significant stenosis and preventing unnecessary extra surveillance.[19] DUS can also give information regarding plaque morphology and aid surgeons in deciding which carotid atherosclerotic plaques may be at higher risk for embolization and thus benefit from carotid intervention. Despite the many benefits for initial use of DUS, there are few limitations related to operator experience, inability to visualize high carotid bifurcations, dampened waveforms due to proximal CCA lesions, excessive calcification causing acoustic shadowing, and inability to accurately measuring velocities.

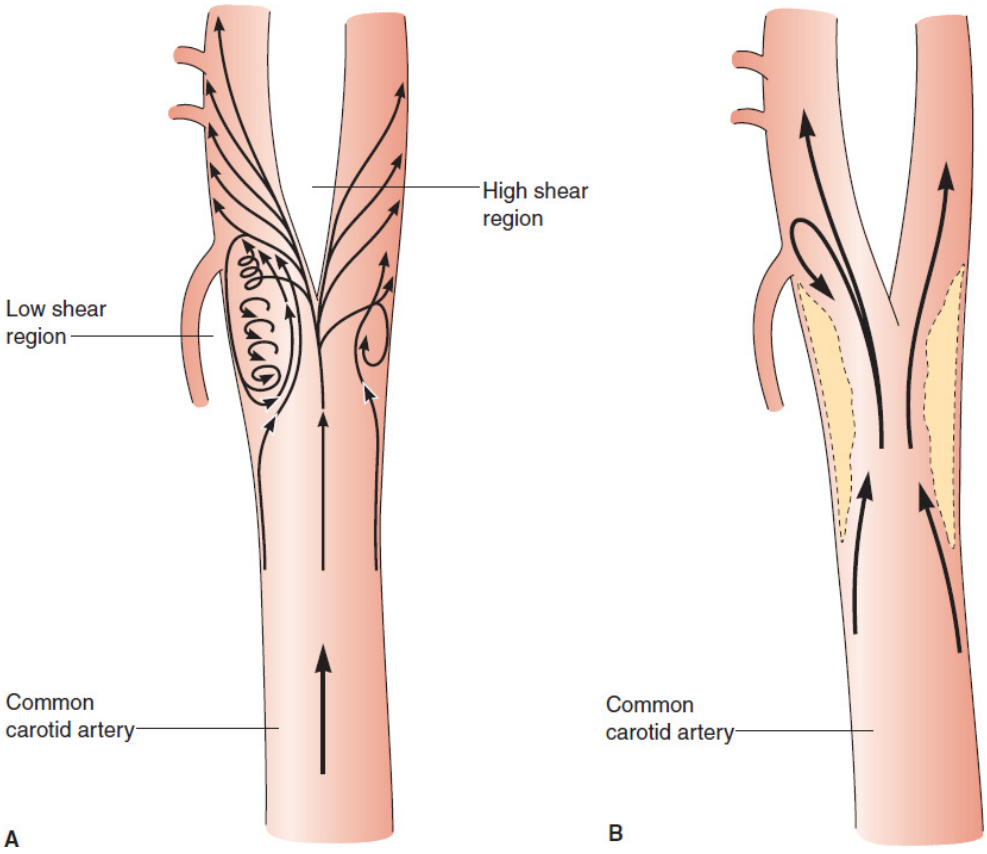

Figure 87.3 **A:** Carotid bifurcation represents an area of low-flow velocity and shear stress. As blood circulates this is a separation of flow between the low-resistance internal carotid artery and the high-resistance external carotid artery. **B:** Atherosclerotic plaque typically forms in the outer wall opposite the flow divider due in part to the low shear stress.

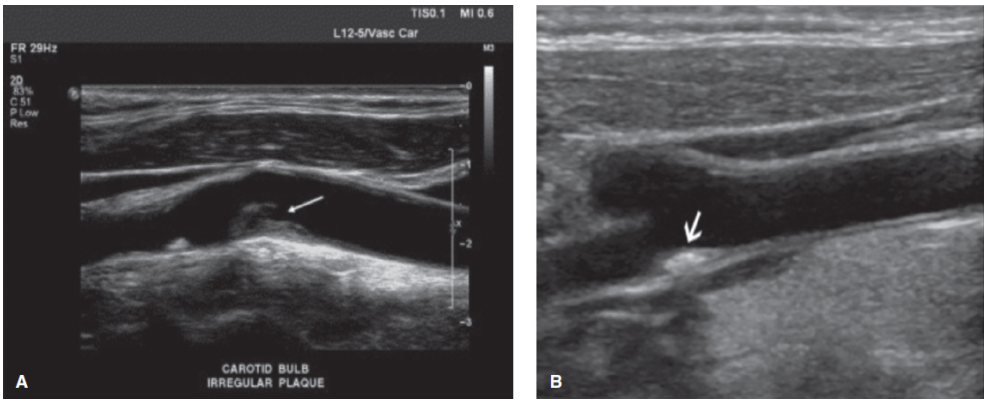

Figure 87.4 **A:** Duplex ultrasound showing unstable, hypoechoic plaque that is at high-risk for embolization. **B:** Duplex ultrasound showing stable plaque with thickened cap less likely to cause atheroemboli.

National Institutes of Health Stroke Scale score	
1a. Level of consciousness	0 = Alert; keenly responsive 1 = Not alert, but arousable by minor stimulation 2 = Not alert; requires repeated stimulation 3 = Unresponsive or responds only with reflex
1b. Level of consciousness questions: What is the month? What is your age?	0 = Answers two questions correctly 1 = Answers one question correctly 2 = Answers neither questions correctly
1c. Level of consciousness commands: Open and close your eyes. Grip and release your hand.	0 = Performs both tasks correctly 1 = Performs one tasks correctly 2 = Performs one tasks correctly
2. Best gaze	0 = Normal 1 = Partial gaze palsy 2 = Forced deviation
3. Visual	0 = No visual loss 1 = Partial hemianopia 2 = Complete hemianopia 3 = Bilateral hemianopia
4. Ficial palsy	0 = Normal symmetric movements 1 = Minor paralysis 2 = Partial paralysis 3 = Complete paralysis of one or both sides
5. Motor arm 5a. Left arm 5b. Right arm	0 = No drift 1 = Drift 2 = Some effort against gravity 3 = No effort against gravity; limb falls 4 = No movement
6. Motor leg 6a. Left leg 6b. Right leg	0 = No drift 1 = Drift 2 = Some effort against gravity 3 = No effort against gravity 4 = No movement
7. Limb ataxia	0 = Absent 1 = Present in one limb 2 = Present in two limbs
8. Sensory	0 = Normal; no sensory loss 1 = Mild-to-moderate sensory loss 2 = Severe to total sensory loss
9. Best language	0 = No aphasia; normal 1 = Mild to moderate aphasia 2 = Severe aphasia 3 = Mute, global aphasia
10. Dysarthria	0 = Normal 1 = Mild to moderate dysarthria 2 = Severe dysarthria
11. Extinction and inattention	0 = No abnormality 1 = Visual, tactile, auditory, spatial, or personal inattention 2 = Profound hemi-inattention or extinction
Total score = 0–42.	

Figure 87.5 NIH stroke scale scoring from zero (no deficit) to 42 (most severe deficits in all areas).

The need for corroborative imaging is sometimes necessary for initial diagnosis and to help plan possible operative intervention. Improvements in

technology and acquisition times have made magnetic resonance angiography (MRA) and CTA attractive options for diagnosis of carotid atherosclerotic disease. These modalities can give information regarding the aortic arch, tortuosity, any anomalous anatomy, presence of brachiocephalic disease or proximal CCA disease, location of carotid bifurcation, and information regarding intracerebral collateral circulation (**Fig. 87.7**). The gold standard remains carotid angiography for definitive diagnosis in carotid atherosclerotic disease (**Fig. 87.8**). Major stroke has been reported in 1% of carotid angiography cases, with majority of these due to aggressive injection of contrast and introduction of air. Similar to transfemoral carotid stenting, microemboli do occur during carotid angiography. These microemboli can be seen postprocedure on diffusion-weighted MRI and may contribute to possible stroke or further neurologic derangements. With that being said, these microemboli also may be clinically silent and have not led to new changes on follow-up cerebral MRI.[20] Transcranial Doppler (TCD) is less used for initial diagnostic evaluation for atherosclerotic carotid disease, but TCD can give useful information regarding the significance of a carotid stenosis and how it alters intracerebral hemodynamics. TCD can be helpful identifying high-risk asymptomatic carotid lesions if silent emboli are detected during the study.

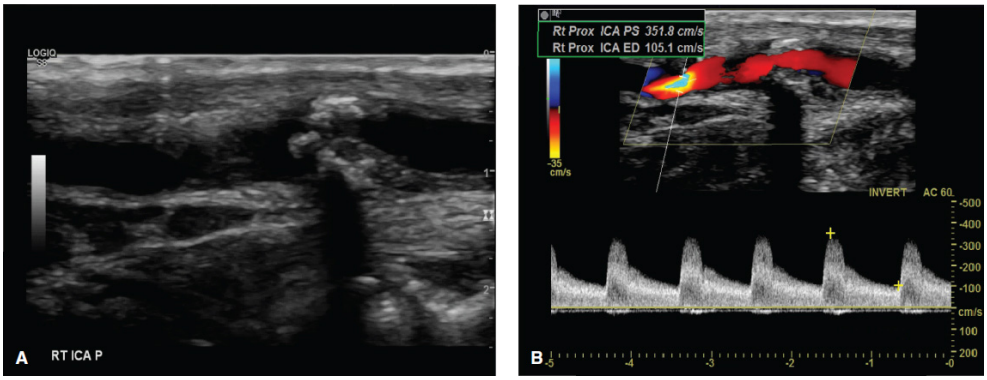

Figure 87.6 **A:** B-mode DUS showing severe calcified plaque and narrowing at proximal right ICA. **B:** Color flow Doppler showing PSV of 351 and EDV of 105 correlating to a >70% stenosis.

Treatment of Atherosclerotic Carotid Artery Disease

Atherosclerotic carotid artery disease can be broken down into asymptomatic and symptomatic carotid stenosis. A recent (<6 months) TIA, stroke, and amaurosis fugax are considered to be symptoms of atherosclerotic carotid occlusive disease. The benefit of carotid intervention in patients with recent ipsilateral carotid territory symptoms and moderate to severe carotid stenosis is much greater than the benefit of carotid intervention in asymptomatic patients. In patients with TIA, up to 15% will go on to CVA, 10% occur within 90 days.[10] Several landmark studies have examined the risk reduction of stroke with medical versus surgical management.

Symptomatic

Patients with symptomatic carotid lesions are at the highest risk of ipsilateral stroke. The degree of stenosis also corresponds with increased risk of ipsilateral stroke if not treated. Multiple landmark trials have validated the benefit of carotid intervention, namely CEA, over medical therapy for symptomatic carotid stenosis. The North American Symptomatic Carotid Endarterectomy Trial (NASCET) study and The European Carotid Surgery Trial (ECST) both showed that degree of stenosis does correlate to risk of ipsilateral stroke. In patients with >50% ipsilateral carotid stenosis, those treated with medical therapy alone were more likely to progress to ipsilateral stroke when compared to those treated with surgical intervention. Benefit was highest among patients with the highest degree of carotid stenosis (70% to 99%). In the NASCET study, symptomatic patients were randomized to medical therapy (which at the time primarily consistent of aspirin therapy) or CEA for those found to have >50% ipsilateral carotid stenosis. After 2 years, in patients with severe >70% symptomatic carotid stenosis, CEA conferred a 6.7% absolute risk reduction for death or major disabling stroke over medical therapy. NASCET 4 also found benefit of CEA over medical therapy in patients with “mild to moderate,” 50% to 69% carotid artery stenosis, with a 5-year absolute risk reduction of 4.7%.[21] The ECST corroborated NASCET findings with regard to severe >70% carotid stenosis, however, no benefit was found for surgery over medical therapy in mild to moderate 50% to 69% carotid stenosis.[22] There have been significant advances in medical therapy for the treatment of carotid atherosclerotic

disease. HMG-CoA reductase inhibitors have significantly improved the ability to medically treat carotid atherosclerotic disease. Statin therapy has been shown to help stabilize atherosclerotic plaque and reduce stroke by some 30% in patients with atherosclerotic carotid disease.[23] Statins have also been shown 5 to independently reduce the risk of all-cause mortality and recurrent stroke in younger patients who have suffered an ischemic stroke.[24]

Table 87.1 Modified UW (Strandness) Criteria for Carotid Stenosis

Stenosis Severity (%)	ICA PSV (cm/s)	ICA EDV (cm/s)	Spectral Broadening
1–14	<125	N/A	None
15–49	<125	N/A	Present and minimal
50–79	>125	<140	Present
80–99	>125	>140	Diffuse and marked
Occluded	0	0	N/A

ICA, internal carotid artery; PSV, peak systolic velocity; EDV, end-diastolic velocity.

Table 87.2 Carotid Consensus Panel Duplex Criteria (CCPC) Duplex Ultrasound Criteria for Carotid Artery Stenosis

Degree of Stenosis (%)	ICA PSV (cm/s)	ICA EDV (cm/s)	ICA/CCA Ratio	Carotid Plaque (%)
Normal	<125	<40	<2.0	None
<50	<125	<40	<2.0	<50
50–69	125–230	40–100	2.0–4.0	>50
70–99	>230	>100	>4.0	>70

ICA, internal carotid artery; PSV, peak systolic velocity; EDV, end-diastolic velocity; CCA, common carotid artery.

Figure 87.7 CTA with 3D reconstruction showing intracerebral collateral flow and intact circle of Willis.

Figure 87.8 Diagnostic carotid angiography showing severe mid ICA stenosis at the level of C2.

Clearly, carotid intervention has been shown to be beneficial over medical therapy for patients with symptomatic carotid stenosis. What is less clear is the timing of intervention. Traditionally, surgeons have waited >6 weeks prior to intervention to allow of any ischemic penumbra to resolve. However, 30-day recurrent ipsilateral stroke rates have been well established in recent studies in patients with symptomatic >50% carotid stenosis.[25] Early (<48 hours), aggressive intervention was suggested as the

most optimal time to intervene, given the aforementioned risk of recurrent stroke. However, performing carotid intervention, namely CEA, <48 hours after onset of symptoms has been shown to increase the risk of postoperative stroke, death, and other complications.[26] In patients with mild to moderate TIA/stroke that have returned to baseline from their symptoms, current practice is to perform carotid intervention in the delayed phase (i.e., between 2 and 14 days). Urgent revascularization is still warranted in patients with crescendo TIA and evolving stroke in order to prevent a larger stroke, despite the known increase risk of perioperative complications.[27]

Asymptomatic

There is a clear body of evidence supporting carotid intervention for symptomatic carotid artery stenosis. What is less evident is the ideal treatment for asymptomatic carotid artery stenosis. One of the first and most important trials that has driven how the management of asymptomatic carotid stenosis is in the United States over the past 30 years is the Asymptomatic Carotid Atherosclerosis Study (ACAS) trial.[28] In ACAS, asymptomatic patients with >60% stenosis were randomly assigned to either medical management or CEA. At 5 years, best medical therapy (BMT) was found to be inferior to surgery in regard to ipsilateral CVA (11% for BMT vs. 5.1% for CEA). These findings were also corroborated in the European Asymptomatic Carotid Surgery Trial (ACST), with a benefit in patients undergoing surgery over BMT with >60% carotid stenosis.[29] Both trials showed a significant relative risk reduction of stroke when undergoing CEA (ACAS 53% and ACST 46%). The findings of these trials in the mid-90s led to an explosion in the number of CEA being performed for carotid artery atherosclerotic disease and have guided management of severe >80% carotid artery stenosis in the asymptomatic patient. BMT during these trials primarily comprised of aspirin therapy. Medical therapy has evolved since the initiation of these trials, with the use of statin therapy as well dual antiplatelet therapy (DAPT) for atherosclerotic carotid disease. This is coupled with significant improvement in glycemic control and smoking cessation leading to dramatic decrease in annual rates of ipsilateral or any territory stroke since the early 1980s. These rates have been purported to be at or below those seen in stroke prevention with carotid intervention.[30] The

upcoming CREST-2 randomized trial between current best BMT and carotid interventions (CEA or CAS) will hopefully shed more light on the most optimal management of asymptomatic, severe >80% carotid artery stenosis.

CAROTID ENDARTERECTOMY

Technique

The first carotid surgery is credited to be performed by Eastcott, Pickering, and Rob in 1954 in a woman with recurrent TIAs.[31] The carotid surgery involved the excision of the carotid bifurcation, ligation of the ECA, and reconstruction with direct anastomosis of the CCA to the ICA. The first CEA was actually performed the year prior by Dr. Debakey, but he did not publish his findings until 1959. Since the advent of the CEA in the 1950s, it has become one of the most common surgery performed by vascular surgeons in the United States. Numerous trials, previously mentioned in this chapter, have validated the safety and efficacy of CEA especially in patients with symptomatic carotid artery disease. A fundamental consideration prior to performing a CEA is deciding the type of anesthetic method. CEA may be performed under general anesthesia (GA), regional anesthesia (RA) with a deep or superficial cervical block and under local anesthesia (LA). Several studies have shown the benefit of RA with reduction in the risk of postoperative complications such as MI.[32] Second fundamental choice regarding CEA is choice of intraoperative cerebral monitoring. Choice of monitoring is dependent on the choice of anesthesia. Patients who undergo GA, typically have a multitude of cerebral monitoring devices that include: electroencephalogram (EEG) with somatosensory-evoked potentials (SSEPs), TCD, stump pressure measurement, and cerebral pulse oximetry (near infrared spectroscopy). If the patient has the surgery under LA/RA, their ability to respond to commands and monitor neurologic status dictates the adequacy of collateral flow. Cerebral monitoring devices aid the surgeon in deciding if a shunt is necessary for those patients deemed to have poor collateral flow. EEG is the most widely used cerebral monitoring tool and measures brain activity with 10 to 16 leads. A significant finding is a drop of

fast background activity of 50% indicating possible cerebral ischemia. TCD evaluates the middle cerebral artery (MCA) for changes in flow with clamping. Stump pressure requires clamping the CCA and ECA while maintaining the ICA open and using a transducer to measure the back pressure. A mean pressure less than 40 mm Hg has been adopted as the standard threshold to indicate intolerability of clamping. All these measures are used to guide the surgeon to place an intraoperative shunt to decrease the time of cerebral ischemia. Shunting continues to be a controversial topic with some studies showing decreased stroke risk, while others showing no benefit in shunting.[33] Routine shunting allows for a consistent endarterectomy technique with less anxiety as the shunt completely relieves intracerebral ischemia if done correctly. Routine shunters maintain excellent results with low perioperative stroke risk.[34] In a recent study, we have shown an interaction between anesthesia types and shunting (with LA/RA) putting patients at increased risk of postoperative stroke and death when intraoperative shunting is performed.[35]

Careful patient positioning is paramount to performing a successful CEA, especially for high lesions at or above the level of C2. The patient is placed supine on the operating room table with a roll placed behind the scapulae to allow for hyperextension of the neck. The neck is turned away from the operative side and the patient is usually placed in a “beach chair” position, this allows for optimal exposure to the neck and the slight reverse Trendelenburg with decreased jugular venous pressure. A longitudinal skin incision is made along the anterior border of the sternocleidomastoid (SCM) (**Fig. 87.9**). Smaller skin incisions (~4 cm) can be made with adequate exposure. To facilitate this, use of ultrasound intraoperatively will help locate the carotid bifurcation, allowing the surgeon to center a smaller incision over the carotid bifurcation. The incision is deepened through the platysma layer and the SCM is identified and its medial border is retracted laterally exposing the internal jugular vein. The facial vein is an important landmark and usually signifies the location of the carotid bifurcation. This is carefully double ligated and divided. The dissection can be carried inferiorly to the superior belly of the omohyoid muscle. The CCA is located inferior and medial to the internal jugular in the carotid sheath. Care must be taken when dissecting the CCA in the carotid sheath in order to avoid injury to the vagus nerve. Circumferential control of the CCA is then performed in the

base of the neck incision, ensuring adequate CCA exposure if carotid shunting is to occur. Next, the ECA and the superior thyroid artery are identified and controlled. Dissection at the carotid bifurcation may result in bradycardia due to stimulation of the carotid body. This can be alleviated by administration of less than 0.5 cc of 1% lidocaine into the adventia and directly into the carotid body. Great care must be taken when dissecting out the proximal ICA to avoid excessive manipulation to avoid distal embolization of the underlying lesion. Moving more superiorly and identifying the hypoglossal nerve is of the utmost importance and can allow for dissection of the mid portion of the ICA in an area above the carotid atherosclerotic lesion. If there is a high carotid lesion above the level of C2, several maneuvers can assist in exposing the distal ICA which include: division of the posterior belly of the digastric (care must be taken to not injure the underlying glossopharyngeal nerve), subluxation of the mandible, removal of the styloid process, and finally nasotracheal intubation.

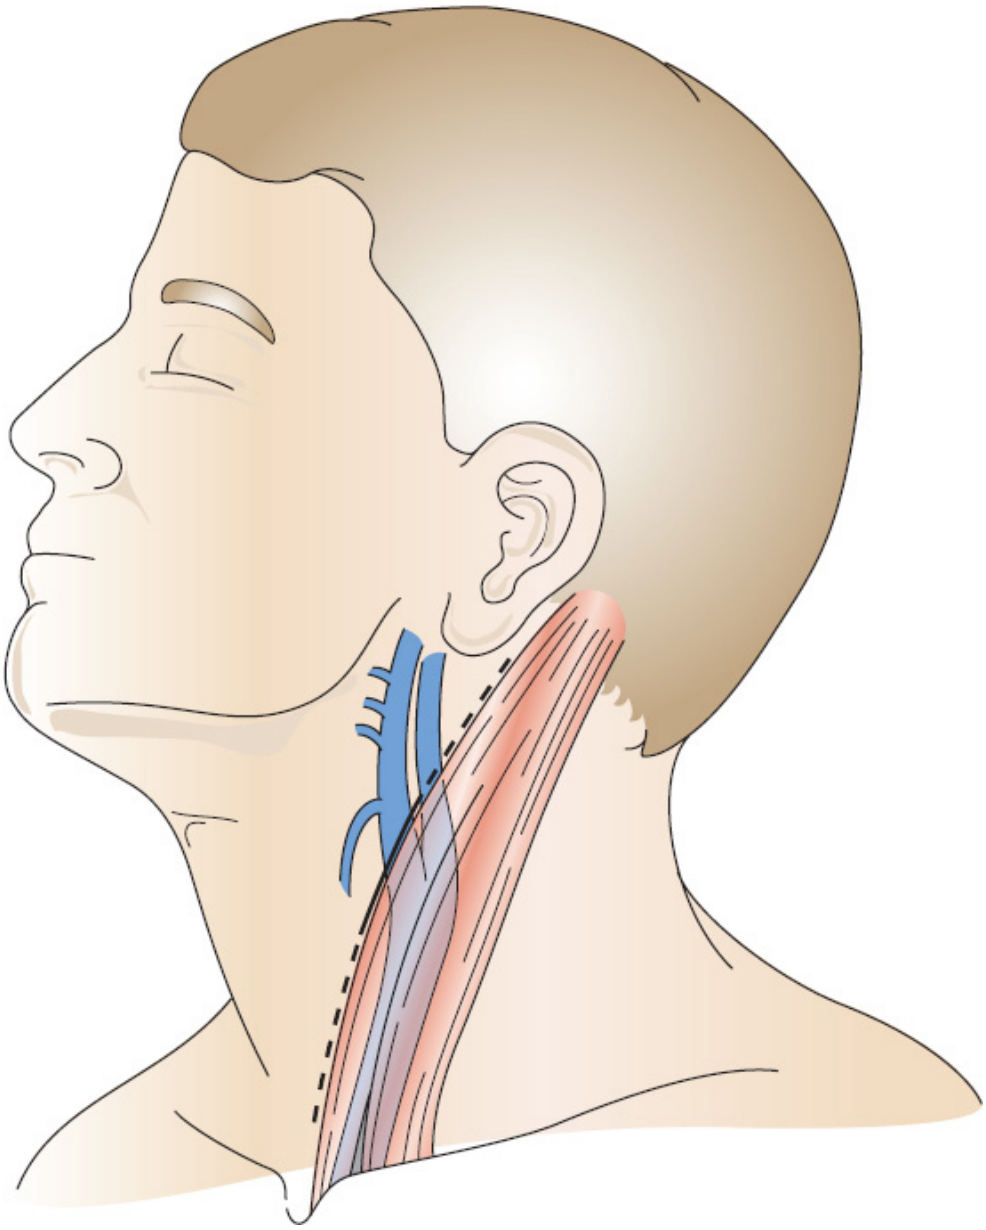

Figure 87.9 The patient's neck is slightly hyperextended and turned away from the ipsilateral side. An incision is made at the anterior border of the sternocleidomastoid muscle overlying the carotid bifurcation.

After complete vascular control of the CCA, ECA, and ICA, intravenous heparin (80 units/kg) is allowed to circulate for 3 to 5 minutes prior to clamping (**Fig. 87.10**). The ICA is clamped first in a safe area distal to the carotid plaque, in order to prevent embolization to the cerebral circulation. Next, the ECA and CCA are clamped. As discussed earlier, cerebral monitoring and use of carotid shunting is up to the discretion of the surgeon.

Endarterectomies of the carotid artery can be performed with a standard endarterectomy or an eversion endarterectomy. The standard endarterectomy consists of a longitudinal arteriotomy that is created on the distal CCA and extended onto the ICA. The arteriotomy should be extended just beyond the area of plaque in an area of normal ICA. At this point, if shunt is used it should be placed from the CCA into the ICA to maintain antegrade ipsilateral cerebral flow (**Fig. 87.11**). Endarterectomy is accomplished by teasing off the atherosclerotic plaque from the intimal layer. This can be done with a blunt elevator or sharply with a beaver blade (**Fig. 87.12**). In order to adequately endarterectomize the carotid artery, the plaque extending into the ECA is removed using an eversion technique (Fig. 87.13). Great care must be taken to ensure a nice stable feathered out endpoint of the endarterectomy plane on the ICA. The endarterectomized plane is then evaluated and any small flaps or debris are removed. Not uncommonly, the area of the distal endpoint on the ICA has soft intimal flap that should be tacked down with a 7-0 Prolene to avoid flaps being raised, causing dissection when antegrade flow is resumed. If not done appropriately, patients are at risk for acute carotid occlusion following CEA, which may have devastating consequences.

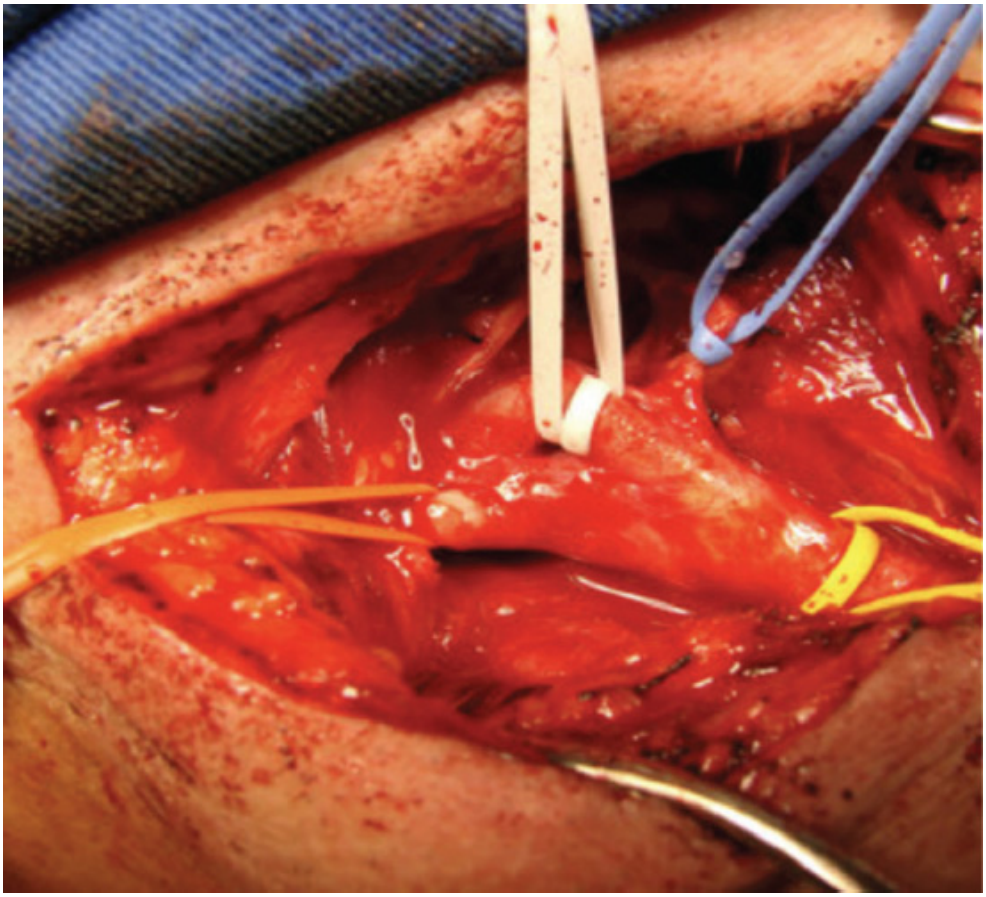

Figure 87.10 Circumferential vascular control surrounding CCA (*yellow loop*), ICA (*orange loop*), ECA (*white loop*), and superior thyroid artery (*blue loop*).

Repair of the arteriotomy should be accomplished with use of a patch angioplasty. Multiple studies[36–38] have shown the benefit of closing the arteriotomy with a patch versus primary closure to prevent late ipsilateral stroke and recurrent stenosis. Different patch materials include: Dacron, bovine pericardium, or autogenous materials. No difference has been shown to what type of patch material used and decision is up to surgeon preference. If shunt is used, patch should be almost completely closed prior to removal of shunt and resumption of clamping (Fig. 87.14). Prior to complete patch closure, it is necessary to appropriately back bleed and flush out any debris that may have accumulated within the endarterectomy site. Once patch is completed, allow reperfusion to the ECA first while keeping the ICA clamped to ensure any remaining debris of thrombus does not proceed into the anterior cerebral circulation. Meticulous hemostasis is obtained in the surgical bed and if needed heparin can be reversed with protamine. The

SCM is then reapproximated in the field and a surgical drain may be placed at the discretion of the surgeon in the subplatysmal layer. The platysma layer is then closed with absorbable suture followed by the skin. A full neurologic examination should be performed prior to extubation or while still in the operating room to ensure no neurologic deficits.

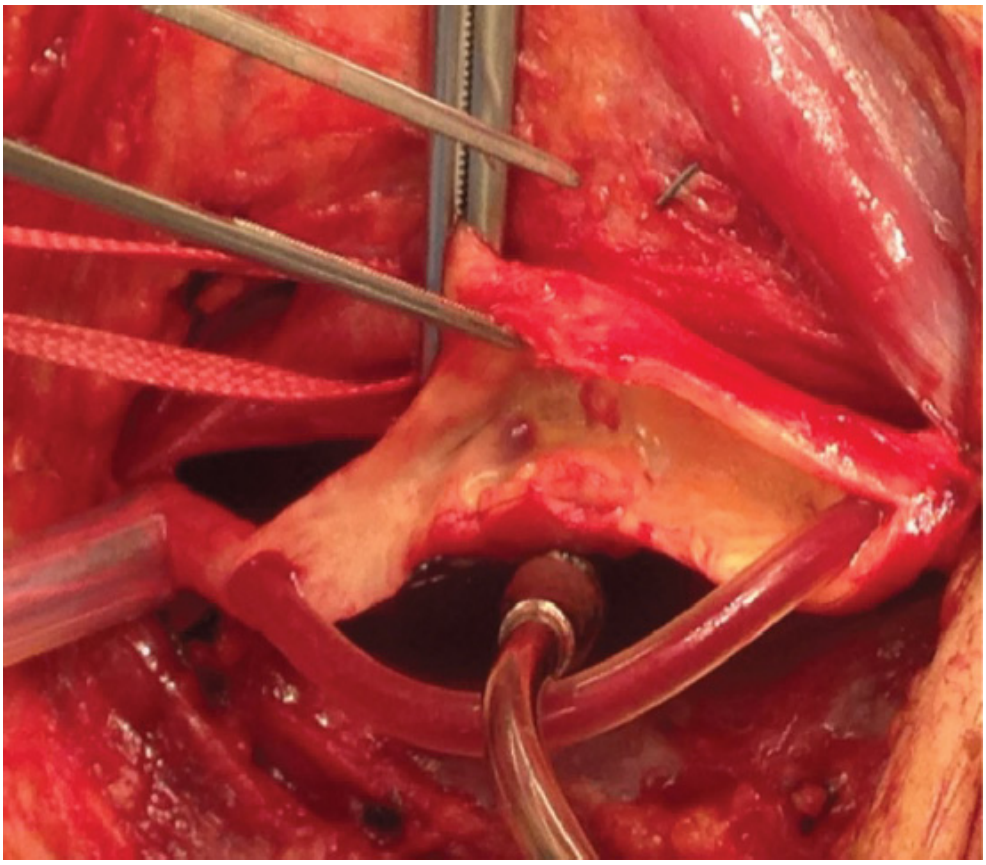

Figure 87.11 Intraluminal shunt placement from CCA to ICA.

Eversion endarterectomy (Fig. 87.15) is another CEA technique that has been employed and has the benefit of not requiring any prosthetic material for arteriotomy closure. Approach for eversion CEA is similar to standard CEA; similar incision is made and exposure of the carotid bifurcation occurs using similar standard techniques. The ICA is then transected obliquely at the carotid bulb including a small portion of the CCA. The edges of the ICA are the everted and peeled back performing an endarterectomy cleaving in between the intimal and medial layers. The atherosclerotic plaque plane is then removed as it proceeds distally until a clean portion is encountered. Several downsides to this technique are the difficulty of placing an

intraluminal shunt, if it is needed, and inability to easily use distal tacking sutures. Closure is accomplished primarily by anastomosing the ICA onto the CCA without compromising the lumen of the ICA. Eversion CEA has been shown to be safe, effective, and durable in long-term follow-up with similar results as seen with standard CEA.[39] In a recent study of over 95,000 CEA performed in the United States, we have shown no difference in outcomes between eversion CEA and CEA with patch angioplasty, however, eversion CEA was superior to CEA with primary closure with 30% reduction in the risk of stroke and death at 30 days.[40]

The avoidance of perioperative stroke during and immediately after CEA is of the utmost importance, especially when performing CEA for high-grade asymptomatic carotid stenosis. To minimize this risk, several intraoperative completion studies are available to aid the surgeon in ensuring a technically sound repair. These include use of intraoperative continuous-wave form Doppler, intraoperative duplex, and intraoperative angiogram. Continuous-wave Doppler is an inexpensive and readily available tool that is available in almost every operating room. It can confirm patency of the carotid vessels and indicate if there are potential issues based on the resistance heard or a high-pitch Doppler sound indicating a possible stenosis. An experienced operator can detect these subtle sounds; however, continuous-wave Doppler is insensitive at detecting small intimal flaps or more subtle stenoses. Duplex ultrasound, on the other hand, is a much more sensitive tool and can give detailed anatomic imaging regarding the existence of a possible intimal flap or high-grade stenosis. Like any duplex ultrasound, quality can be variable and is operator dependent. The "gold standard" continues to be intraoperative completion angiogram with injection of contrast directly into the common carotid. Completion studies are not uniform practice and have mixed results in the identification of clinically relevant defects. Furthermore, small questionable defects that are revised may do little to improve outcomes and may be predictive of possible perioperative stroke.[41]

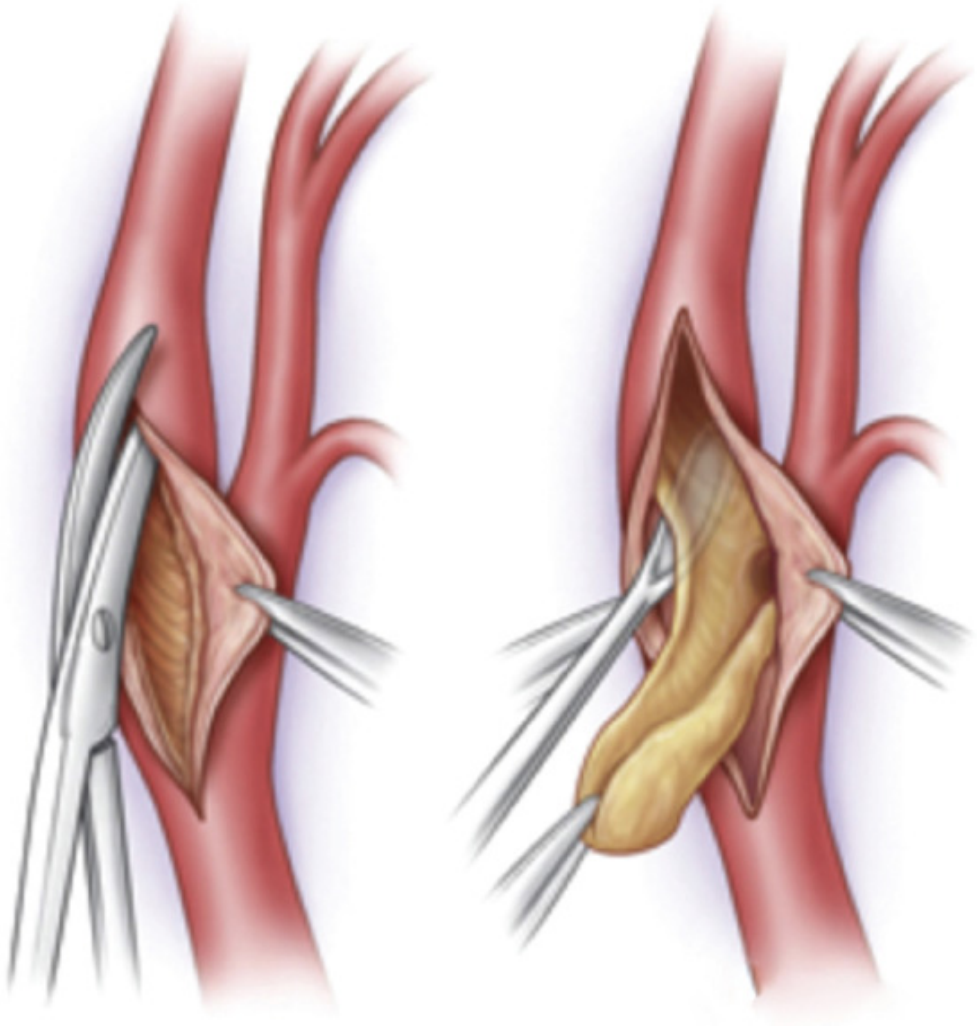

Figure 87.13 Conventional endarterectomy by removing plaque with blunt dissection and everting atherosclerotic plaque from ECA.

Complications

CEA can be safely done in the vast majority of cases and is well tolerated with most patients being discharged after 24 hours. However, a wide array of complications exists, from mild wound issue to life-threatening issues. The single biggest contributor to perioperative death continues to be MI. MI is responsible for 25% to 50% of all perioperative deaths after CEA and more late deaths are seen from MI than from stroke or other causes.[42] Significant advances have been made in the past two decades that have led to a significantly low rate of cardiac events during and immediately after CEA. One of the most feared complications, especially in treating asymptomatic

patients, is perioperative ipsilateral stroke. There are multiple etiologies for immediate postoperative stroke including embolization, hyperperfusion, and rarely acute occlusion. Embolization can occur from shunt placement, from the clamp site, thrombus forming during CEA, or inadequate flushing prior to arteriotomy closure. With manipulation of the carotid sinus, hypertension and hyperperfusion may ensue postoperatively and can lead to ipsilateral ischemic stroke if hypertension not controlled. This phenomenon usually occurs 24 to 72 hours after CEA and adequate postoperative blood pressure control is mandated prior to discharge home. Acute patch occlusion is rare but may be related to an intimal flap, platelet adhesion from the patch, dissection, or anastomotic stricture. This is why it is of the utmost importance to document a normal neurologic examination prior to extubation or prior to leaving the operating room. Intraoperative imaging is another important method to ensure normal flow prior to closing the wound. During CEA, cerebral ischemia can occur due to hypoperfusion of watershed cerebral area. This is related to inadequate collateral flow through the contralateral carotid artery and posterior circulation, which relies on a patent circle of Willis. Ipsilateral perioperative stroke rates continue to decline. Thirty-day stroke and death rate after CEA in CREST was 3.2% in symptomatic patients and 1.2% in asymptomatic patients. Additionally, for symptomatic patients, 30-day risk of MI was 2.2% and death rates were 1.1%; for asymptomatic patients, 30-day risk of MI was 2% and death rates were 1.1%. Overall, with CEA CREST showed a periprocedural risk of death at 0.3%, CVA of 2.3%, and MI of 2.3%.[2] Cranial nerve injury (**Table 87.3**) is the most common neurologic complication following CEA and one of the most problematic for patients. Incidence of postoperative cranial nerve injury ranges from 5% to 20% with the vast majority of these resolving at 6 months.[43]

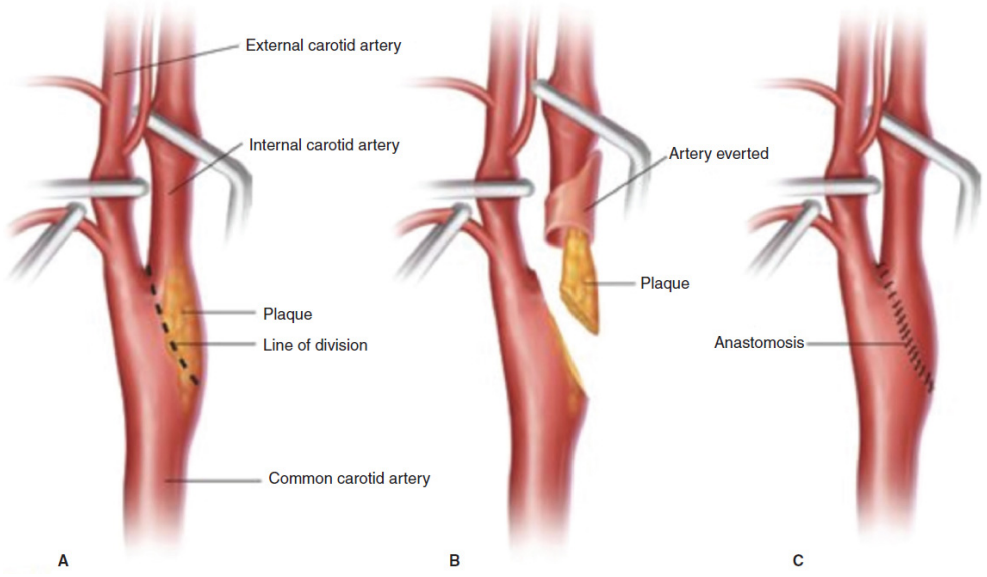

Figure 87.15 **A:** The ICA is divided from the CCA in an oblique plane. **B:** The divided ICA is everted and endarterectomy occurs until plaque endpoint, and is removed from the ICA. **C:** The ICA is then reattached to the CCA primarily.

Transfemoral Carotid Artery stenting

Technique

TFCAS with distal embolic protection device (EPD) has gained popularity since its advent in the early 90s. Since the Food and Drug Administration (FDA) approved TFCAS in 2004, there has been a proliferation of technology and expansion of its use for symptomatic and asymptomatic carotid artery stenoses. Similar to indications for CEA, TFCAS should be considered a viable carotid revascularization option in patients with symptomatic >50% stenosis and asymptomatic >80% stenosis. Most vascular surgeons believe CAS should be reserved for patients who are deemed high risk (surgical or medical) for CEA (**Table 87.4**). Currently, the Center for Medicare and Medicaid Services (CMS) will only reimburse for high-risk patients with symptomatic >70% carotid artery stenosis, limiting the use of TFCAS to these patients.

In order to obtain procedural success with low periprocedural complication rate, identification and examination of preoperative imaging is a must. Prior to planned TFCAS, axial imaging should be carefully reviewed. Typically, MRA or CTA with thin-cuts are performed with imaging including the aortic arch and the circle of Willis. Careful preoperative imaging examination will identify diseased arch and difficult tortuous anatomy for tracking wires and catheters into the carotid artery. Possible stroke can occur with excessive manipulation of the aortic arch and inability to recognize ostial disease. Arch types based on tortuosity are recognized on preoperative imaging (Fig. 87.16). In general, type III arches are now considered contraindication for TFCAS with mounting evidence of increased intraprocedure embolization. Preoperative imaging also can identify other high-risk lesion and anatomic criteria for TFCAS and potential contraindications for CAS (**Table 87.5**). Prior to TFCAS procedure, all patients should be on DAPT with 7 days of aspirin (typically 325 mg) therapy and 5 days of clopidogrel therapy (receiving a total of 450 mg of clopidogrel). Patients should also receive statin therapy prior to procedure, as we have shown a significant reduction in the risk of death following operative stroke or MI in patients on statin prior to TFCAS.[44] The procedure should be done in an angiographic suite or in a hybrid operating room with appropriate imaging quality. Preoperative arterial line placement is preferred for close blood pressure and HR monitoring. Alternatively, an arterial line can be hooked up to the arterial access sheath, however, during stent placement, the arterial line will be lost. TFCAS procedures should be done

under local only in order to adequately and frequently assess neurologic function. Performing this procedure under GA also increase the risk of cardiac complications including MI and arrhythmias.[45] The patient is placed in a supine position with bilateral groins prepped. Standard retrograde femoral access with US-guided micropuncture technique is obtained. The patient is systemically heparinized in order to maintain activated clotting time (ACT) between 250 and 300 seconds. If careful preoperative imaging evaluation was performed, then rarely should an arch aortogram be performed. Selective catheterization of the carotid artery is then obtained and catheter is placed just proximal to the carotid bifurcation. Multiple catheter types (**Fig. 87.17**) are available for use (e.g., H1, JB1, JB2, Vert, VTK, SIM, etc.). Angiogram is now performed to confirm carotid artery stenosis location and severity, assess ECA patency and evaluate distal carotid artery flow, and evaluate ipsilateral intracerebral circulation.

Table 87.3 Cranial Nerve Dysfunction and Incidence Following CEA

Cranial Nerve Injury	Clinical Sequelae	Incidence (%)
Vagus nerve (recurrent laryngeal nerve)	Unilateral—Hoarseness (rarely seen) Bilateral—Vocal cord paralysis	1.5–15
Superior laryngeal nerve	Fatigability of voice, difficulty with voice modulation	1.8–4.5
Hypoglossal nerve	Unilateral—Ipsilateral tongue deviation Bilateral—Difficult swallowing and articulation	4.4–17.5
Glossopharyngeal nerve	Aspiration, dysphagia	0.2–1.5
Marginal mandibular nerve	Drooping ipsilateral lip	1.1–3.1
Spinal accessory nerve	Shoulder droop, scapular winging	<1.0

Incidence data from Forssell C, Takolander R, Bergqvist D, et al. Cranial nerve injuries associated with carotid endarterectomy. A prospective study. *Acta Chir Scand* 1985;151:595–598

Table 87.4 High-Risk Medical and Surgical Patients for CEA

Clinical Criteria	Anatomic Criteria
Unstable angina	High lesion above C2
NYHA class III or IV CHF	CEA restenosis
LVEF <35%	Prior neck irradiation
MI <6 wk	Cervical immobility
Severe pulmonary disease	Tracheostomy
Contralateral recurrent laryngeal nerve injury	Previous neck surgery

NYHA, New York Heart Association; CHF, congestive heart failure; LVEF, left ventricular ejection fraction.

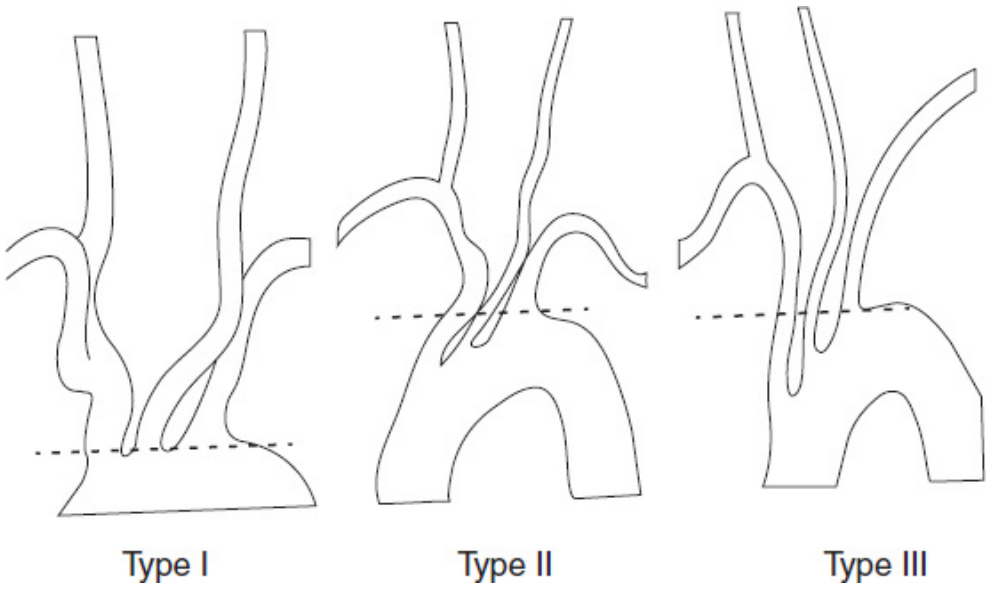

Figure 87.16 Arch types based on tortuosity.

Table 87.5 Contraindications and High-Risk Features for Carotid Artery Stenting

Carotid Artery Stenting Contraindications
Severe ICA kinking
Unstable plaque
Fresh thrombus
Brachiocephalic vessel tortuosity
Brachiocephalic vessel severe stenosis or occlusion
Acute aortic arch angle or anomalous aortic arch (type III arch)
Significant aortic arch plaque or thrombus
Circumferential calcification
Poor arterial access

Appropriate sheath (6-Fr shuttle select) is telescoped over the catheter and wire into the mid CCA, once decision is made to proceed with carotid artery stenting. Great care must be taken to avoid inadvertently manipulating the lesion and risk embolizing distally into the ICA. Alternatively, in difficult access anatomy, the ECA can be cannulated and stiff wire placed with advancement of the sheath into the CCA in a nontelescoped manner. Angiogram through the sheath is then performed to map out ICA anatomy to aid in cannulating the ICA for placement of EPD (Fig. 87.18). It is ideal to open and flush the appropriate size predilation balloon, carotid stent, and EPD so that minimal time is taken from predilation to completion stenting. Next, EPD is placed into the distal ICA in a straight area of the artery in order to minimize distal embolization and CVA during balloon angioplasty and stent placement. Depending on the type of carotid stent used, different EPDs are available for placement (Fig. 87.19). Filter placement requires wire manipulation and crossing of the lesion to access the distal ICA. Some filters are attached to the wire, while others can be advanced over the 0.014 wire into the distal ICA and deployed. The remainder of the stenting

procedure is performed over the EPD wire via a rapid exchange platform. Gentle predilation of the lesion is typically accomplished with an undersized 3- to 4-mm balloon at low atmospheric pressure. Bradycardia and hypotension can occur even with gentle ballooning of the carotid lesion, thus it's advisable to prophylactically administer or be ready to administer glycopyrrolate to minimize the risk or treat bradycardia and hypotension. Additionally, having available dopamine or phenylephrine infusions is wise in order to quickly treat prolonged or severe hypotension. Next, the predetermined stent size and length are advanced and carefully deployed encompassing the entire carotid lesion into the proximal portion of carotid stent into the CCA in order to stabilize carotid plaque. Stent size typically depends on the size of the ICA and CCA and comes in straight and tapered configurations. Type of carotid stent use is up to the discretion of the interventionalist. The stents are self-expanding and have either an open- or closed-cell stent design (Fig. 87.20). Flexibility of the stent depends on the number of connections between the cells of the stent. The less the amount of connections (open-cell design), the more flexible the stent will be and may be better used in tortuous ICA lesions. The more connections, the stiffer the stent will be (closed-cell design). Closed-cell stents may be better used in symptomatic patients to lessen embolization or extrusion of carotid plaque through the stent. However, the evidence is conflicting on the benefit of closed- versus open-cell design.[46] Postdilation of the stent should be carefully considered as studies suggest worse outcomes with higher stroke and death rates and more hemodynamic depression,[47,48] when routine postdilation is undertaken. Significant vasospasm in the distal ICA may occur with placement and removal of filter. Once EPD is removed, completion angiogram is performed (**Fig. 87.21**). Femoral access sheath is removed with closure device. Similar to CEA patients, close neurologic and hemodynamic assessments are made throughout the postprocedure period. Most patients are discharged home 24 hours after TFCAS and continue 1 month of clopidogrel and lifelong aspirin.

Complications

The most serious and important complication following TFCAS is periprocedural stroke. While cardiac events are less frequently seen, CREST found periprocedural MI rates to be lower in TFCAS patients versus CEA (1.1% vs. 2.3%, $p = 0.03$). Neurologic events following TFCAS can have devastating consequences and prompt recognition and treatment is needed. Potential causes of periprocedural stroke include: distal embolization from manipulation of the lesion, thrombosed EPD, acute stent thrombosis, kinking

after carotid stenting, carotid artery dissection, and hyperperfusion. Acute stent thrombosis may be related to failure of adequate expansion of carotid stent in densely calcified atherosclerotic plaque. This typically requires immediate stent explantation and conversion to CEA. Carotid dissection may require additional stenting versus antiplatelet therapy. Despite the necessity of using filter protection during transfemoral CAS, EPD can cause issues with placement. Distal filters may dissect or become full of thrombus/plaque causing thrombosis of the filter. Additionally, filter placement may cause severe vasospasm in the distal ICA that potentially could cause thrombosis of the vessel. Immediate EPD retrieval is performed when these complications occur. Distal embolization may require neurorescue techniques, such as: aspiration thrombectomy, catheter-directed thrombolysis, or stent retrieval. Access site complications can occur with or without use of a closure device. Such complications include hematoma, pseudoaneurysm formation, AV fistula, thrombosis, and possible infection.

Results

In its early phase, TFCAS was reserved for only high-risk, elderly patients who were deemed to be too high risk for CEA. Multiple randomized controlled trials (RCTs) have shown early efficacy in treatment of high-risk patients with TFCAS. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial examined TFCAS versus CEA for high-risk patients (medical comorbidities and anatomical features). The trial was designed to show noninferiority of TFCAS compared to CEA in patients with >50% symptomatic stenosis and/or >80% asymptomatic stenosis. There was no significant difference in 30-day major adverse events (stroke, death, and MI) between the two procedures, while TFCAS was associated with a lower risk of major events at 1 year, with a greater advantage in asymptomatic patients.[49] The Stent-Supported Percutaneous Angioplasty of the Carotid Artery versus Endarterectomy (SPACE) trial randomized patients with >70% symptomatic stenosis to TFCAS versus CEA. This study failed to prove noninferiority of TFCAS.[50] The endarterectomy versus angioplasty in patients with symptomatic severe carotid stenosis (EVA-3S) was a European randomized trial in symptomatic patients with >60% carotid stenosis. This trial was

stopped prematurely due to a 2.5-fold higher risk for 30-day stroke and death in the TFCAS group.[51] Routine use of EPD was not required, which was a major drawback in the TFCAS group. Most recently, the CREST compared TFCAS to CEA in standard-risk symptomatic and asymptomatic patients. Long-term follow-up out to 10 years did not show a difference between CAS and CEA with regard to stroke and death.[52] With that being said, 30-day outcomes did show a significantly higher risk of stroke for TFCAS versus CEA (4.1% vs. 2.3%, $p = 0.01$).

TRANSCAROTID ARTERY REVASCULARIZATION

Technique

TCAR is an innovative hybrid procedure that combines CEA like neuroprotective effects by clamping of the carotid artery with a minimally invasive approach to treat carotid stenosis by direct placement of carotid artery stent avoiding the arch. The procedure is done under novel flow reversal in the carotid and ipsilateral cerebrum. Like with any carotid revascularization procedure, careful patient selection is paramount to have success with TCAR. Currently, TCAR is approved for high-risk patients with >50% symptomatic carotid stenosis or >80% asymptomatic stenosis. Participating hospitals must be involved in the Vascular Quality Initiative (VQI) Carotid Artery Stent Registry for the Society for Vascular Surgery (SVS). As compared to previous high-risk criteria used for standard TFCAS, TCAR has a wider high-risk inclusion criteria (**Table 87.6**). TCAR approach and set up is similar to that for CEA. Patients prior to TCAR procedure need to be on 5 days of DAPT and statins. Successful TCAR procedure relies on certain anatomic criteria which include: ≥6-mm diameter CCA, CCA puncture site at base of neck free of calcified plaque, ≥5 cm clavicle to carotid bifurcation distance, and ICA diameter of 4 to 9 mm. The patient is brought in to the operating room or a hybrid operating suite. Choice of anesthesia is up to the discretion of the surgeon with similar options to CEA: GA, RA, or LA. It is recommended that the first few TCARs performed be

under GA until the surgeon is comfortable with the procedure. A radial arterial line is placed for continuous blood pressure monitoring. Patients are positioned similar to CEA, supine on the operating room table with a shoulder roll and the neck turned to the contralateral side. Duplex ultrasound should routinely be performed to confirm adequate clavicle to carotid bifurcation distance and the CCA is free of significant atherosclerotic disease as well confirm patency of the ICA. A small incision is made at the base of the neck (either transverse or longitudinal) in order to isolate the CCA in between the two heads of the SCM muscle (Fig. 87.22). A 3- to 4-cm segment of CCA is circumferentially controlled and an umbilical tape with a Rummel tourniquet is placed as proximally as possible under direct vision. A purse string 5-0 Prolene suture is placed on the anterior advential surface the CCA to facilitate arterial closure at completion of TCAR. Attention is then paid to obtaining femoral venous access in order to perform flow reversal. Standard femoral venous access is obtained (typically in the contralateral side from the TCAR site) under ultrasound guidance and an 8-Fr sheath is inserted.[53]

Table 87.6 High-Risk Medical and Anatomic Inclusion Criteria for TCAR

Clinical Criteria	Anatomic Criteria
Patient >75 yrs of age	Contralateral carotid artery occlusion
Patient with >2-vessel CAD and history of angina	Tandem stenosis >70%
History of unstable angina	High cervical carotid artery stenosis
NYHA functional class III or IV	Restenosis after CEA
LVEF <30%	Bilateral carotid artery stenosis
MI >72 hrs and <6 wk prior to procedure	Hostile neck but amenable to transcarotid access
Severe COPD w/ FEV1 <50% predicted	
Permanent contralateral cranial nerve injury	
Chronic renal insufficiency (>2.5 mg/dL)	

NYHA, New York Heart Association; LVEF, left ventricular ejection fraction.

Figure 87.23 Silk Road ENROUTE sheath with angled tip.

The patient is then systemically heparinized, similarly to a CEA, with 80 units/kg of heparin with goal ACT >250 seconds. Access is then obtained in the CCA with micro needle, wire and sheath is advanced to just proximal to the carotid bifurcation. Angiogram is then performed to map out the carotid bifurcation. It is preferable to engage the ECA when patent with the microwire and sheath. A stiff wire is then placed into the ECA and the ENROUTE 8-Fr sheath (Silk Road Medical, Sunnyvale, CA) is advanced into the CCA and sutured in place (Fig. 87.23). Passive flow reversal is then activated by connecting the arterial to the venous sheath via the dynamic flow controller and integrated 200 μ filter (Silk Road Medical, Sunnyvale, CA) (Fig. 87.24). TCAR time out is then performed ensuring adequate anticoagulation with ACT, prophylactic administration of glycopyrrolate,

adequate mean arterial pressure (to allow for the significant delta between the arterial and venous pressure for flow reversal), and finally ensuring that the wire, balloon, and stent are open and flushed ready for use. Active flow reversal is initiated by clamping the CCA. Debris that may accumulate during carotid intervention is then reversed out of the carotid into the circuit and caught in the filter, while the blood returns to the venous system. The ICA lesion is then crossed with a 0.014-in wire. Standard predilation of the carotid lesion with a 3- or 4-mm by 20-mm balloon is then performed. Some have suggested more aggressive balloon dilation of the carotid lesion with a 5- or 6-mm diameter balloon, as the flow reversal is more protective for atheroembolic lesions occurring during prestent dilation. Next, the selected sized ENROUTE stent is then delivered and deployed using standard technique. Completion angiogram is then performed to confirm adequate treatment of the carotid lesion (Fig. 87.24). Poststent balloon dilation is reserved for severe residual stenosis, as the trend has been to move away from routine poststent balloon dilation due to severe hemodynamic issues with persistent poststent hypotension. Next, the flow reversal is left on for 1 or 2 minutes after stenting to ensure no further debris accumulates. The CCA is unclamped and the flow reversal is then stopped and the carotid sheath is removed while the purse string is sutured down. The venous sheath is then removed. The filter chamber can then be checked to evaluate for debris accumulation (Fig. 87.25). Meticulous hemostasis is obtained in the wound base and if need be a drain is left behind (Fig. 87.26). The layers are then closed in the standard fashion and like CEA, it is crucial to ensure no new neurologic symptoms prior to leaving the operating room. Patients are monitored closely for hemodynamic or neurologic issues post-TCAR procedure. Patients are usually discharged home 24 hours after procedure with 1 month of clopidogrel and lifelong aspirin therapy.

Complications

Early results from the pivotal TCAR trial showed similar perioperative stroke rates as compared to CEA in what is deemed "high-risk" patients. At 30 days, in the pivotal TCAR group, all-stroke rate was 1.4% (2 of 141) and stroke and death rate was 2.8% (4 of 141).[54] MI rates in patients undergoing TCAR have been shown to be similar or slightly lower than those seen with traditional CEA. Postoperative cranial nerve injury is also much lower than in patients undergoing CEA. This is presumably due to the limited dissection of the carotid artery in the base of the neck, away from the cranial nerves. Initial ROADSTER results showed a 0.7% cranial nerve injury rate, with

that being one patient suffering from hoarseness from a potential cranial nerve X injury. This completely resolved at the 6-month postoperative visit. Other associated complications include wound complications and postoperative hematoma.

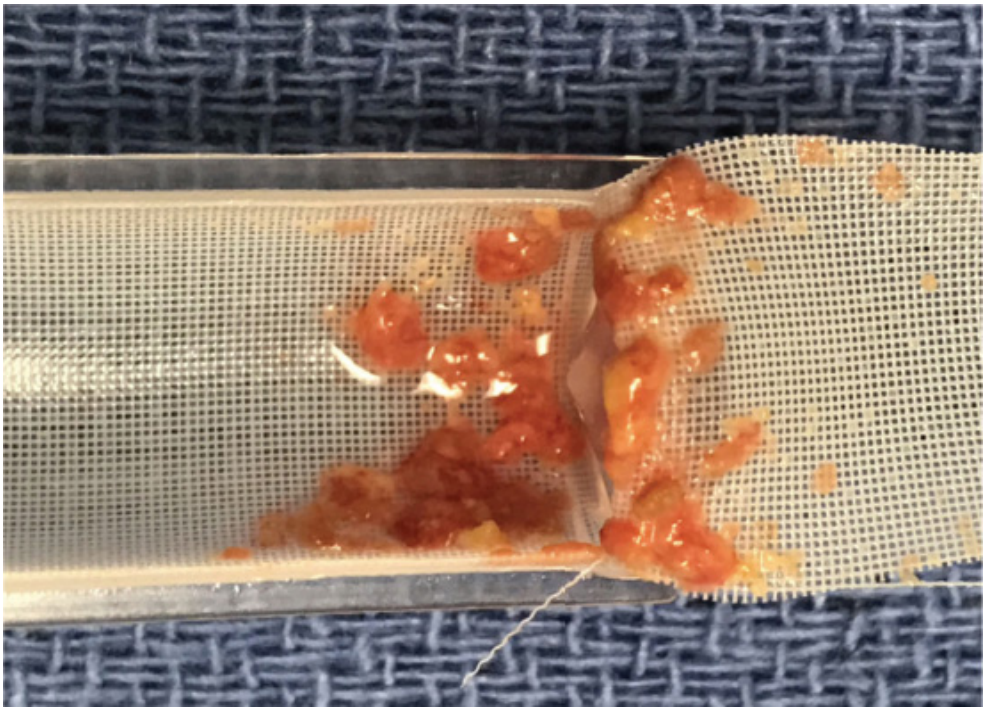

Figure 87.26 Post-TCAR stenting with flow reversal filtering system showing significant debris accumulated during procedure.

Results

TCAR provides an alternative to TFCAS in patients with carotid artery disease that are considered to be high risk for CEA, either anatomic or medical. The initial pivotal TCAR trial showed that at 30 days, TCAR was safe and effective. A further analysis was performed that included the initial ROADSTER patient and extended to analyze 1-year outcomes in terms of durability of TCAR with dynamic flow reversal. A total of 165 patients were examined, with majority of patients being male and asymptomatic. One-year ipsilateral stroke occurred in one patient (0.6%) from the pivotal cohort. One-year mortality rate was 4.2% following TCAR (no deaths were deemed neurologic in origin).[55] 30-day combined stroke, death, and MI rates were previously shown to be acceptably low (3.7% in ROADSTER 1) and with

further analysis of the effectiveness of TCAR, in the post approval study ROADSTER 2 showed a 1.7% combined stroke, death, and MI rate. Furthermore, ROADSTER 2 continued to show acceptable 30-day outcomes in terms of stroke/death rate (0.8% in ROADSTER 2 compared to 1.4% in pivotal ROADSTER 1).[56]

CAROTID ENDARTERECTOMY VERSUS TRANSFEMORAL CAROTID STENTING VERSUS TRANSCAROTID REVASCULARIZATION

Carotid interventions for patients with symptomatic (>50%) and asymptomatic (>80%) carotid artery stenosis is widely accepted. The choice of treatment modality is the next decision and is debatable and most certainly patient specific. CEA continues to remain the gold standard for treatment of atherosclerotic carotid artery disease. Higher-risk patients are now afforded multiple treatment types that are minimally invasive. Multiple previous clinical trials have examined the use of TFCAS versus CEA in high-risk patients. In every RCT, TFCAS failed to show similar outcomes to CEA as far as stroke and death.[49–51] Despite these results, TFCAS continues to have a role in treating patients with carotid artery disease who are not candidates for CEA.

With the recent advent of TCAR, multiple studies have compared treatment of carotid artery disease now with three treatment modalities: TFCAS, TCAR, and CEA. A multi-institutional analysis of TCAR compared to CEA showed similar 30-day and 1-year stroke rates (1.0% vs. 1.1%; 2.8% vs. 3.05%, respectively). These results were in spite of TCAR patients having higher rates of diabetes, hyperlipidemia, CAD, and renal insufficiency. TCAR was associated with a decreased rate of cranial nerve injury (0.3% vs. 3.8%; $p = 0.01$).[57] It has been previously shown that increasing age correlates with a higher embolic risk and thus higher ipsilateral stroke when performing TFCAS in elderly patients. However, at older ages, risk for stroke after CEA remains relatively constant across the age spectrum.[58,59] A comparative analysis was performed to evaluate the association between age

and outcomes after TCAR, TFCAS, and CEA. Rates of in-hospital stroke/death after TCAR were 1.4% in patients 70 years or younger, 1.9% in those 71 to 79 years, and 1.5% in those 80 years and older ($p = 0.55$). A comparison of TCAR with CEA across different age groups showed no significant differences in outcomes. When compared to 6 TFCAS, no differences were noted between TCAR and TFCAS in patients less than 80 years of age. However, in patients 80 years and older, TCAR was associated with a 72% risk reduction in stroke risk (4.7% vs. 1.0%; OR, 0.28; 95% CI, 0.12–0.065; $p < 0.01$), a 65% reduction in risk of stroke/death (4.6% vs. 1.5%; OR, 0.35; 95% CI, 0.20–0.62; $p < 0.001$), and 76% reduction in the risk of stroke/death/MI (5.3% vs. 2.5%; OR, 0.24; 95% CI, 0.12–0.47; $p < 0.001$) compared with TFCAS.[60] Finally, when comparing TCAR versus TFCAS, recently TCAR was shown to have lower rates of in-hospital stroke and death (1.6% vs. 3.1%) with no statistically significant differences in rates of perioperative MI (0.2% vs. 0.3%). At 1 year, TCAR was associated with lower rate of stroke or death as compared to TFCAS (5.1% vs. 9.6%). TCAR was associated with higher rates of access site complications resulting in interventional treatment (1.3% vs. 0.8%).[61,62]

NONATHEROSCLEROTIC CAROTID ARTERY DISEASE

Carotid Artery Dissection

Carotid artery dissection can either occur spontaneously or secondary to precipitating mechanical event (traumatic or iatrogenic). As in any arterial dissection, carotid dissection involves disruption or cleaving of the intima, which allows blood to extravasate in between layers of the vessel wall. The resulting hematoma usually extends distally and can lead to a high-degree distal ICA stenosis or occlusion (Fig. 87.27). Spontaneous dissections are more common in the carotid and vertebral arteries due to their mobility and proximity to bony structures. Even though carotid artery dissections account for a small number of overall strokes, up to 20% of stroke occurring in young patients are due to carotid artery dissection.[63] The classic triad of clinical

symptoms include ipsilateral headache or neck pain, ipsilateral Horner syndrome, and cerebral ischemia. It is quite rare to have all three clinical syndromes occur simultaneously. Headache appears to be the most common symptom and occurs in ipsilateral frontotemporal location. Even though largely asymptomatic, patient can also develop TIA, CVA, amaurosis fugax, cranial nerve palsies, and nausea. Similar to atherosclerotic carotid artery disease, multiple imaging modalities exist including: CTA, MRA, DUS; but the gold standard still remains angiography.

Figure 87.27 Digital subtraction carotid angiogram showing dissection starting in the proximal right ICA with classic appearing "flame" shape (*arrow*) resulting in distal occlusion.

Treatment options for asymptomatic carotid artery dissection begin with anticoagulation versus antiplatelet therapy. No studies have shown a difference with regard to mortality or stroke rate at 3 or 6 months when patients are treated with anticoagulation versus antiplatelet.[64] The only RCT, the Cervical Artery Dissection in Stroke Study (CADISS) trial, did have one major intracranial hemorrhage in the anticoagulation group versus none in the

antiplatelet group. These findings are similar to other nonrandomized studies.[65] Most common treatment continues to be IV heparin followed by anticoagulation for 3 months. Indication for acute surgical intervention include: inability to anticoagulate, worsening symptoms, symptoms refractory to anticoagulation, aneurysm formation, or severe neurologic symptoms with severe flow limitation. Options for open surgical repair include surgical bypass, patch angioplasty, or carotid ligation. Endovascular stenting for carotid dissection has had promising early results.[66]

Carotid Artery Fibromuscular Dysplasia

FMD involving medium-sized arteries is a rare clinical entity affecting up to 7% of the population.[67] This noninflammatory, nonatherosclerotic arteriopathy is most commonly seen in women, constituting 60% to 90% of patients with FMD.[68] The incidence of carotid FMD is even more rare, with an incidence of only 0.42% in 3,600 patients undergoing cerebral angiographic examination.[69] The exact etiology of FMD is unknown. Four subtypes of FMD exist, with the most common being the medial fibroplasia type, followed by perimedial fibroplasia, intimal fibroplasia, and medial hyperplasia. This type gives off the classic appearance of a "string of beads" (**Fig. 87.28**). This angiographic appearance is caused by segmental encroachment of the arterial lumen and poststenotic dilatation and can be a nidus for hypoperfusion and embolization. As seen in the previous figure, FMD typically occurs in the mid to distal ICA and avoids the carotid bifurcation. Duplex ultrasound imaging can be used to identify carotid FMD lesions, however, elevated velocities and the classic FMD appearance may not be well appreciated. CTA and MRA have largely replaced the need for angiography and are able to clearly show the "string of beads" appearance associated with classic FMD. With that being said, gold standard still remains carotid angiogram. The advantage of CTA or MRA is the ability to identify intracerebral aneurysms; which can occur in up to 50% of carotid FMD patients.[70]

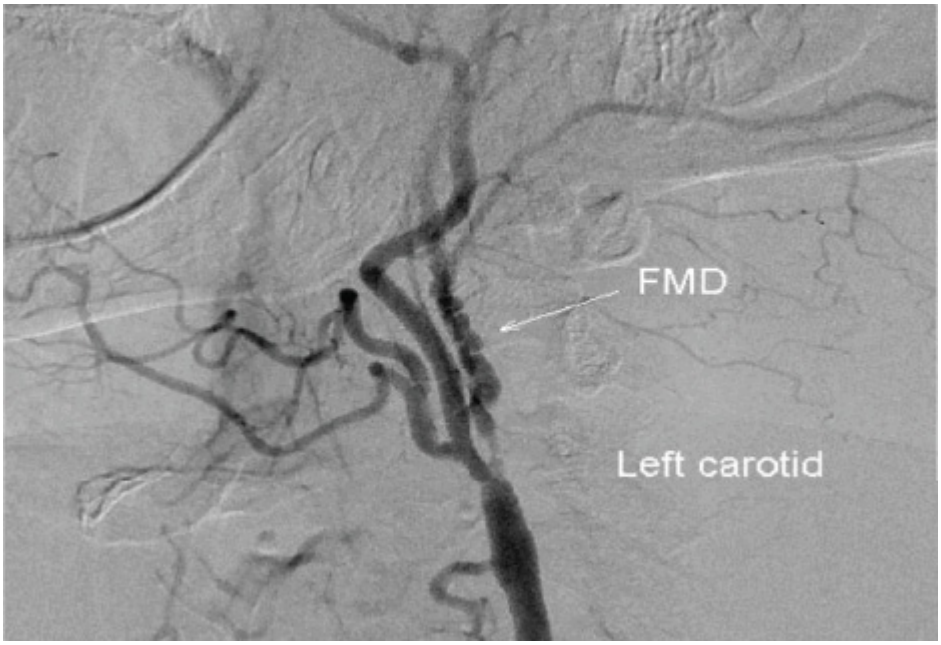

Figure 87.28 Carotid angiogram showing concomitant atherosclerotic carotid bifurcation disease and classic appearing mid ICA FMD.

The natural history of FMD is not well established, with few lesions progressing to the point of narrowing of the arterial lumen causing reduced perfusion, formation of thrombus leading to distal embolization, and dissection or rupture. However, the majority of lesions remain clinically silent for years and only require antiplatelet therapy.[71] Symptomatic patients should undergo repair, focusing on breaking the webs associated with FMD. This can be done with either open or endovascular means. In an open repair, serial rigid dilation occurs via a common carotid arteriotomy. This technique allows for back bleeding and removing of debris, however, stroke may occur from debris not washed out after breaking of the webs. Transfemoral angioplasty has been used as an alternative minimally invasive option. Stenting usually is not required. The anatomy of FMD prevents the use of EPD due to the increased risk of embolization. An attractive alternative is the use of TCAR and its novel flow reversal for angioplasty of FMD lesions.

Carotid Artery Aneurysms

Extracranial carotid artery aneurysms are rare and can occur as a result of atherosclerotic degeneration, traumatic injury, dissection or local infection,

or as a complication after CEA. True degenerative carotid artery aneurysms are quite rare, with an occurrence of 1% (Fig. 87.29). Pulsatile mass is the most common presenting symptom. A high index of suspicion is needed with bruit or pulsatile mass after traumatic head and neck injury. Other presenting symptoms may include cranial nerve dysfunction, Horner syndrome, neurologic complication, such as TIA or stroke. Rarely, carotid artery aneurysms become so large that they can cause dysphagia or present with hemorrhage or rupture. The natural history of carotid artery aneurysms is not well established, due to its rare incidence. Thus, almost all carotid artery aneurysms are referred for surgical repair. Open surgical repair may include ligation, interposition bypass with vein conduit, or primary end-to-end repair. Endovascular options include exclusion with covered stent graft placement. TCAR might be a reasonable option providing neuroprotection with flow reversal while placing the covered stent. This might be crucial in symptomatic distal carotid aneurysms with unstable thrombus where placement of EPD is difficult as with traditional TFCAS.[72]

Figure 87.29 3D reconstruction CTA showing degenerative extracranial carotid aneurysm emanating off of the ICA.

Carotid Body Tumors

Tumors arising from the carotid body are neural crest tumors and include paragangliomas, glomus tumors, or chemodectomas. The carotid body includes chemoreceptors located at the bifurcation of the CCA in the posterior and medial adventitia. Carotid body tumors (CBTs) are quite rare without a true known incidence. Risk factors for the development of CBT include hypoxemia, which can be the result of chronic obstructive pulmonary disease or living at high altitudes. These chronic hypoxic states can result in hyperplasia and/or neoplasia of the carotid body, leading to CBT.[73] The vast majority of these tumors are benign and malignant transformation can occur

in only about 5% of cases. A familial pattern has been recognized in about 20% of cases.[74] Since these masses arise at the carotid bifurcation, they can envelope the internal and external carotid arteries and the surrounding cranial nerves. CBTs are slow-growing tumors that typically present as asymptomatic lateral neck masses that may be associated with a thrill or bruit. Because these tumors are fixed to the carotid bifurcation, they are horizontally mobile but not vertically (Fontaine sign). With increasing size, associated symptoms such as neck pain, dysphonia, hoarseness, stridor, dysphagia, jaw stiffness, or sore throat may be present. DUS is a useful initial imaging modality to confirm the presence of CBT. A characteristic splaying of the internal and external carotid arteries is usually seen. Needle biopsy is not recommended due to the hypervascular nature of CBT. Confirmatory CTA of the neck will help delineate the extent of CBT invasion. Shamblin classification has been used to help with the extent of involvement and the degree of difficulty of possible resection. Three types have been described: type I are localized and easily resected; type II are adherent to or partially surrounding vessels; type III are intimately surrounded or encases in the vessels or nerves (**Fig. 87.30**). Treatment involves resection, with larger masses (i.e., >4 cm) may benefit from preoperative embolization.[75] Exposure for surgical resection involves a similar exposure to a CEA with careful dissection of the tumor off of the underlying arteries and nerves. Occasionally, in Shamblin type III cases, excision of the underlying artery is necessary and requires a bypass. Unlike CEA, there is a high incidence of cranial nerve injury at approximately 10%.[76]

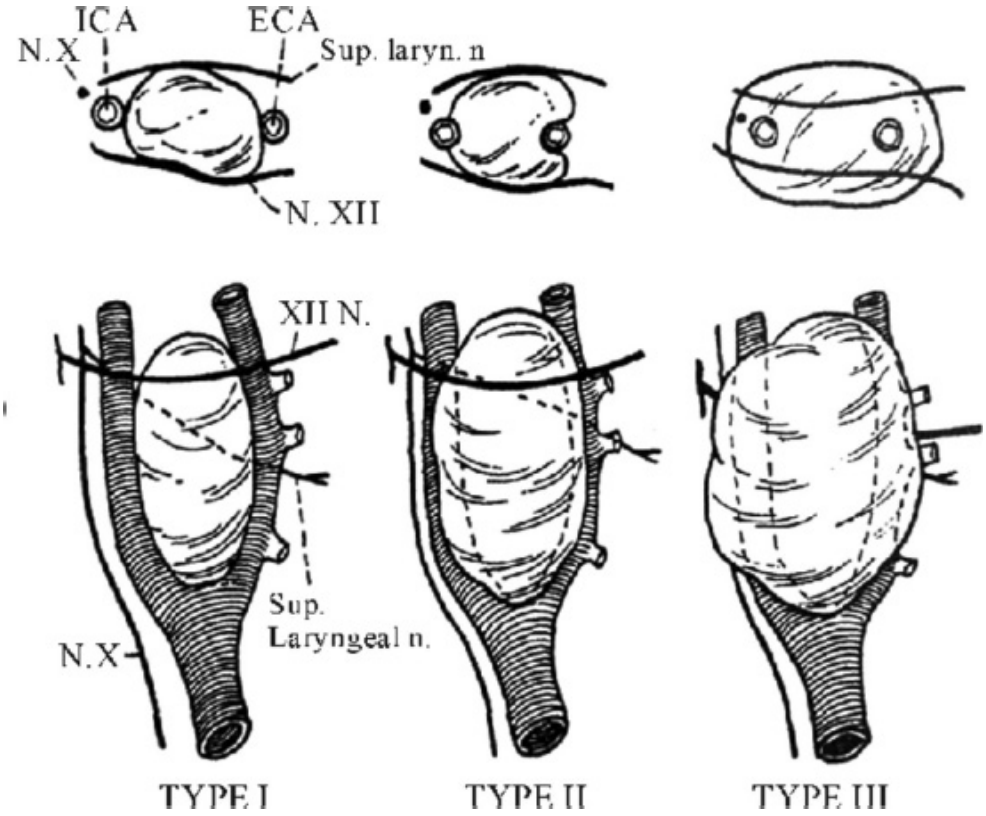

Figure 87.30 Shamblin classification for extent of carotid body tumors.

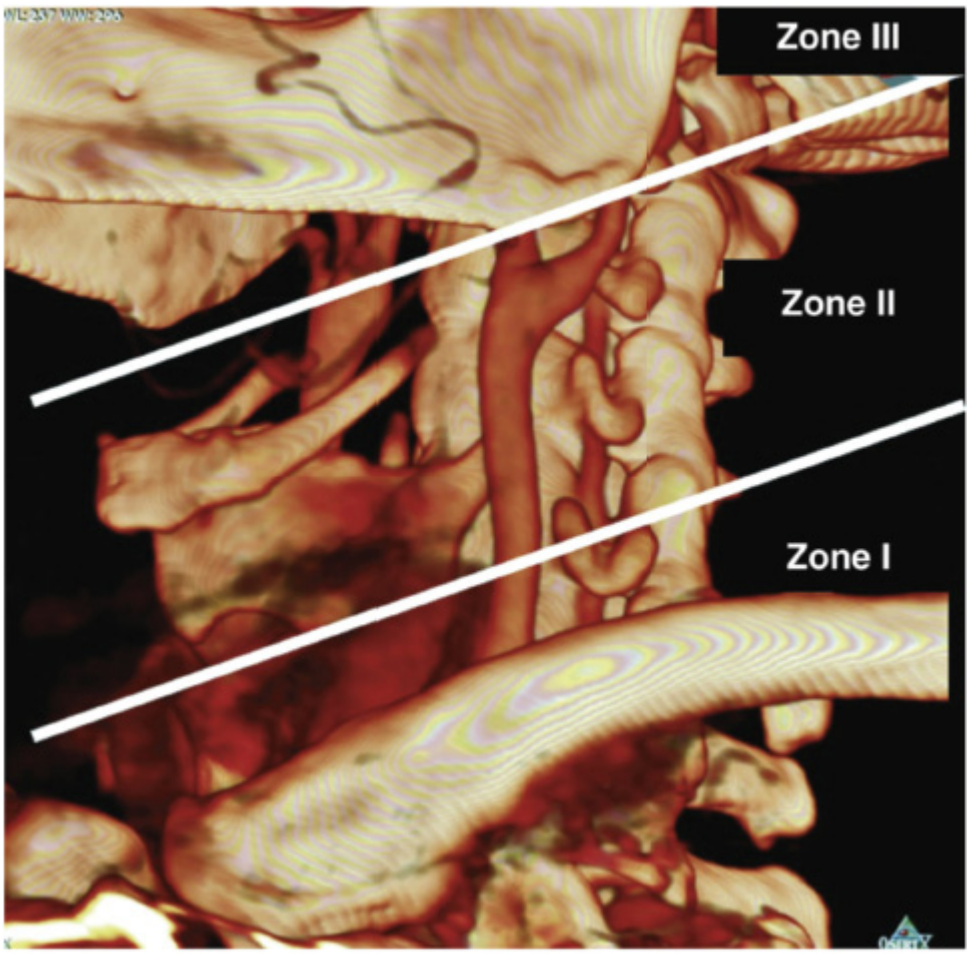

Figure 87.31 Anatomic zones of the neck for penetrating cervical injuries.

Carotid Trauma

Blunt or penetrating cervical trauma can involve the extracranial carotid artery, resulting in intimal disruption, dissection, thrombosis, pseudoaneurysm formation, or transection. Penetrating cervical trauma with injury to the carotid artery can account for a 7% to 27% stroke rate and a 7% to 50% mortality rate.[77] Penetrating cervical trauma with concern for major arterial injury should undergo evaluation and treatment based on location. The neck has classically been divided into three zones: zone I, below the cricoid cartilage; zone II, between the cricoid cartilage and the angle of the mandible; zone III, above the angle of the mandible (Fig. 87.31). Carotid artery injuries are most common in zone II (47%), followed by zone III (19%) and zone I (18%).[78] Injury to zones I and III require diagnostic work

up to determine if any vascular injury has occurred. Zone I injuries will require a median sternotomy for control, whereas zone III will require maneuvers similar to high exposure for an endarterectomy or the use of endovascular coil embolization or exclusion with covered stent graft placement. Traditionally, all zone II injuries should undergo immediate surgical exploration and repair if carotid artery injury is identified. This can include primary repair, bypass, or ligation. The diagnostic modality of choice is CTA for identification of carotid injury. CT scans can be rapidly obtained in the trauma bay or ED and leads to expeditious identification of possible carotid artery injuries that may require surgical intervention. Medical management can be undertaken in certain cases of asymptomatic carotid dissection with either anticoagulation or antiplatelet therapy. Close observation in asymptomatic traumatic carotid dissections are required to ensure that these injuries don't blossom into pseudoaneurysm formation or carotid thrombosis, necessitating either open or endovascular stent placement. Any patient with evidence of cerebral ischemia should undergo prompt carotid revascularization.

VERTEBROBASILAR INSUFFICIENCY

Introduction

Ischemic strokes in the vertebrobasilar territory can account for 25% of all ischemic strokes. The posterior cerebral circulation (i.e., vertebrobasilar system) supplies blood to the brainstem, cerebellum, and occipital lobes via paired vertebral arteries arising from the subclavian arteries. Anatomic variants can occur, the most common being a direct origin of the left vertebral artery arising from the aortic arch. The vertebral artery is composed of four segments: V1 is the origin of the vessel up to the level of C6, V2 is the segment that runs within the vertebral foramina to the level of C2, V3 is the next segment above C2 before it enters the base of the skull, and V4 is the intracranial portion of the artery before it joins with the contralateral side forming the basilar artery. VBI is less common than carotid artery ischemia, but it requires prompt diagnostic evaluation for possible

surgically correctable atherosclerotic lesions. Mortality associated with a posterior circulation stroke is 20% to 30%, significantly higher than those seen in anterior circulation strokes.[79]

Clinical Findings

VBI is a commonly misdiagnosed clinical syndrome, mostly due to the more subtle and broad symptoms associated with this entity in comparison to the anterior circulation. Unlike the anterior circulation, many times severe ipsilateral atherosclerotic vertebral artery stenosis may go unnoticed due to significant collateral filling due to sufficient collateral flow through a patent circle of Willis. Associated VBI symptoms are largely bilateral and include diplopia, headache, vertigo, drop attacks, ataxia, disequilibrium, and paresthesias.

Pathogenesis

The pathogenesis of vertebrobasilar disease can be broken down into ischemic low-flow mechanism versus embolic. The predominate cause of symptomatic VBI are due to low flow. Embolic issues are difficult to recognize and are most commonly originating from the heart, aorta, or brachiocephalic vessels. As previously mentioned, posterior circulation events are more likely to lead to irreversible ischemia and infarction, and thus far more debilitating. These infarctions are most likely the result of embolic events. Up to a third of vertebrobasilar ischemic episodes are cause by distal embolization from plaque or mural lesions of the subclavian, vertebral, or basilar arteries.[80]

Initial Diagnostic Evaluation

The diagnosis of true VBI can sometimes be difficult, given the vagueness of symptoms. Its subtle symptomatology can lend to a variety of other organ systems that can mimic these symptoms. Oftentimes, syncope or presyncope can be confused for vertebrobasilar symptoms. This can be due to a multitude of causes such as vasovagal, cardiac arrhythmias, neurologic, psychiatric, or idiopathic. Moreover, even though the vast majority of VBI is due to

atherosclerosis, other etiologies include dissection, trauma, FMD, aneurysms, and Takayasu disease. Patients with visual changes (i.e., diplopia) can be mistaken for myopia or presbyopia, cataracts, floaters, and amaurosis fugax. Vertigo type symptoms can be caused by many etiologies and can be confused for postural instability, hearing loss or nystagmus.

DUS can be a very useful initial study to help identify proximal vertebral artery atherosclerotic disease. With that being said, it is a more difficult examination than extracranial carotid arteries, and sometimes severe vertebral artery stenosis may be missed. Duplex can identify reversal of flow in the vertebral artery, which may indicate more proximal disease in the subclavian or innominate arteries. Evaluation of the vertebral artery between C2 and C6 is difficult with DUS. CTA and MRA allow for a complete and careful examination of the entire vertebral artery, this allows for identification of disease and illuminate collateral circulation. Additionally, MRI can help identify if embolic lesions and posterior cerebral infarctions have occurred. The "gold standard" remains angiography. Selective vertebral angiography will allow for a complete interrogation of the vertebral artery to identify proximal or distal stenosis. Collateral circulation can also be shown via contralateral and anterior circulation.

Treatment

Treatment of symptomatic VBI is based on the location of the offending vertebral lesion. The majority of lesions involve the proximal V1 segment of the vertebral artery. The prevalence of such lesions is approximately 20% to 40% in patients with cerebrovascular disease.[80] The most common pathology of the V2 segment is extrinsic compression of the vertebral artery by osteophytes. V3 segment lesions are mostly related to trauma and arterial dissection. The V4 segment is largely unaffected by atherosclerotic disease and given its intracranial location, it is more susceptible to direct trauma and stretch injuries as well as formation of AV fistulas or pseudoaneurysms. Proximal (i.e., ostial) V1 atherosclerotic lesions are the most common open operation for VBI. Vertebral artery transposition of the proximal vertebral artery on the adjacent carotid artery is the most common reconstruction. Less likely to be performed, bypass from the common carotid or subclavian artery (SCA) to the vertebral artery distal to the disease with a vein graft is a

viable option. The most common reason for open surgical repair of V2 lesions is hemorrhage and this typically requires proximal and distal ligation. Options for the V3 segment include bypass with greater saphenous or lesser saphenous vein, usually to the C1–2 segment. Other reported open surgical revascularizations for the V3 segment include use of ECA or radial artery. For more distal reconstructions (into the V4 segment) suboccipital exposure of the vertebral artery usually requires resection of the C1 transverse process. Vertebral artery transposition or other V1 segment operations are the most studied surgical operations for VBI. Stroke and death rates for these operations have been reported to be <1%.[81] Other complication includes nerve injury (vagus, recurrent, laryngeal), Horner syndrome and lymphatic leak. Vertebral artery transpositions experience excellent 5- and 10-year patency rates at 95% and 91%, respectively. More than 80% of patients will have relief of their symptoms after proximal surgical reconstruction.[82]

Endovascular 7 management of proximal vertebral artery atherosclerotic lesions has been shown to be safe and effective in a small amount of nonrandomized studies.[83,84] The relative ease in which angioplasty and stenting of a proximal vertebral lesion as compared to the open operation, has driven this increase in endovascular management (**Fig. 87.32**). As with carotid artery stenting, risk of embolization, stroke, thrombosis, dissection, or restenosis can occur. Use of EPD can reduce the risk of distal embolization and should be recommended when treating atherosclerotic proximal vertebral artery lesions. Stent placement has not been widely shown to be effective for the treatment of V2 or V3 traumatic dissections, given the location in the vertebral foramina. Similar to open ligation, endovascular management of vertebral artery transection or hemorrhage involves embolization to control bleeding.

ATHEROSCLEROTIC BRACHIOCEPHALIC DISEASE

Introduction

The great vessels arise from the aortic arch to give off (from proximal to distal) the innominate artery, the left CCA, and the left SCA. These arteries supply the upper extremities and brain and thus are commonly referred to as the brachiocephalic vessels. Anatomic variants do exist with regard to the origins of these vessels. Most commonly, the innominate and left CCA come of the arch in one common ostia, referred to as a "bovine arch" (**Fig. 87.33**). This variant is found in 8% to 25% of Americans, with higher incidence seen in African American patients.[85] Another common variant is the presence of the left vertebral artery directly emanating from the aorta between the left CCA and SCA. This occurs in about 6% of the patient population. Additionally, an aberrant right SCA can be seen with its origin coming the aorta distal to the left SCA and coursing posteriorly behind the arch. This variant is the rarest, occurring in 0.5% to 1% of the time.[86] The most common etiology of brachiocephalic disease continues to be atherosclerotic disease. Commonly, multivessel atherosclerotic disease can be present and is more often accompanied by symptoms of VBI from generalized low-flow. However, embolic phenomenon can be seen as well-exhibiting single-vessel symptoms, when multivessel disease is present. Other diseases affecting the brachiocephalic arteries include aneurysmal degeneration, dissection, vasculitis (e.g., Takayasu disease and giant cell arteritis), infection, and radiation arteritis.

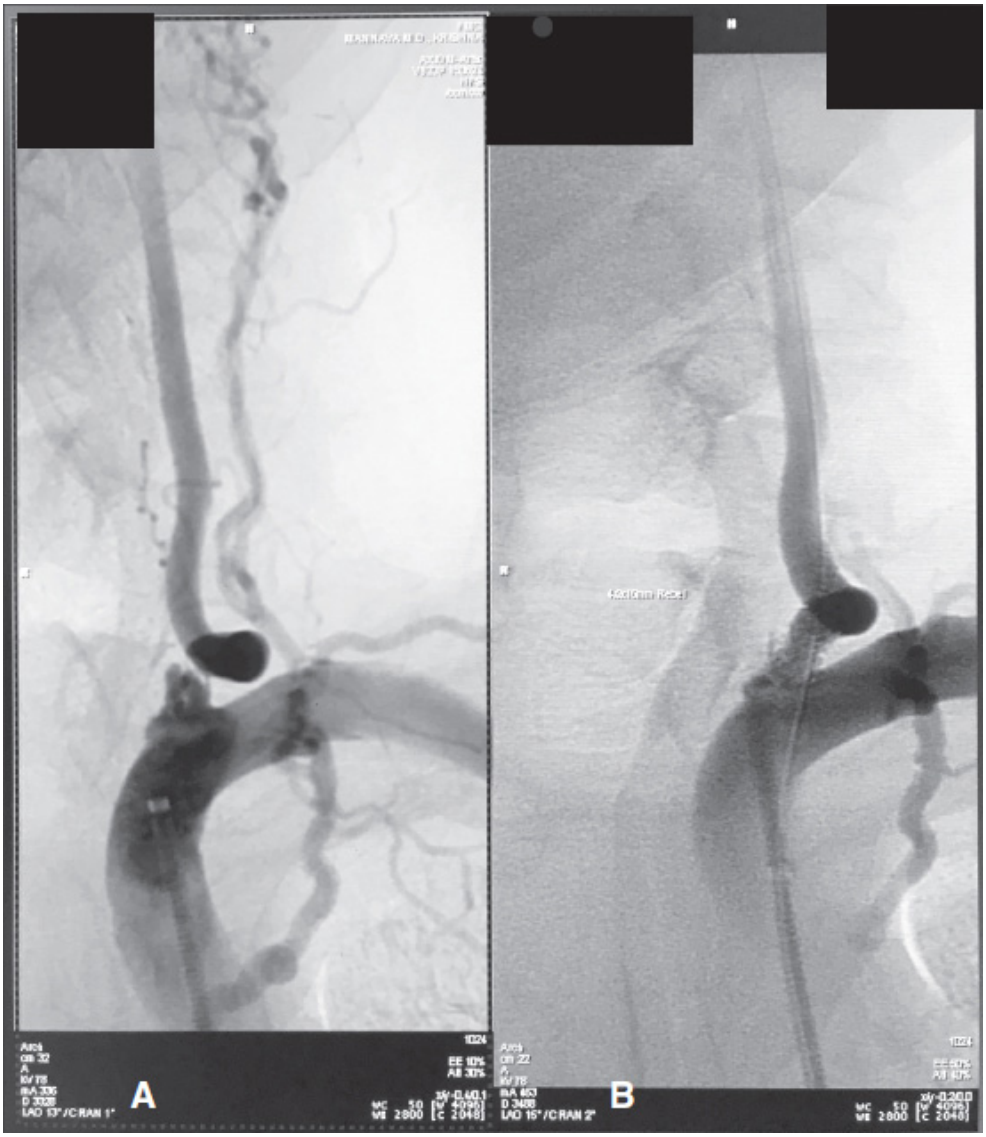

Figure 87.32 **A:** Angiogram showing severe proximal V1 vertebral artery stenosis in a patient with a posterior circulation stroke. **B:** Completion angiogram after successful balloon angioplasty and stenting.

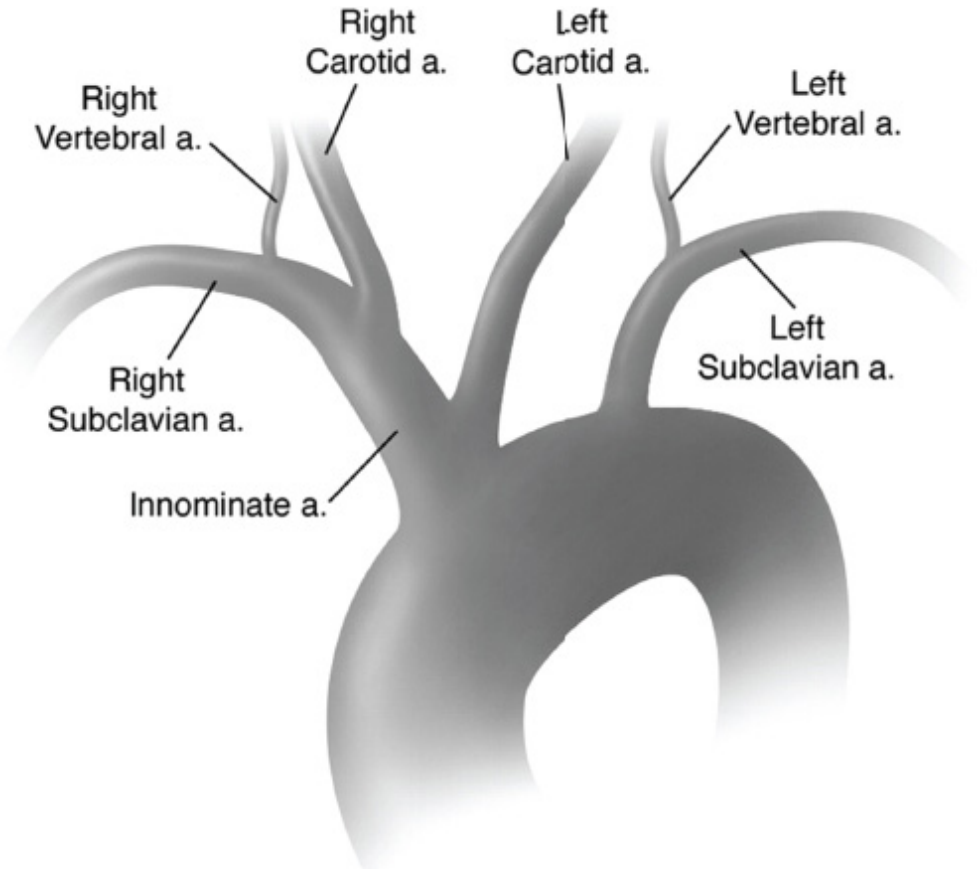

Figure 87.33 Most common aortic arch branch variants in humans with a common trunk for the innominate and left common carotid artery. (From Layton KF, Kallmes DF, Cloft HJ, et al. Bovine aortic arch variant in humans: Clarification of a common misnomer. *Am J Neuroradiol*. 2006;27(7):1541–1542; used with permission of Mayo Foundation for Medical Education and Research, all rights reserved.)

Clinical Findings

As mentioned above, atherosclerosis is the most common disease that affects the brachiocephalic vessels. Clinical findings are dependent on location of the disease and how many vessels are involved. Up to 40% of the time, multivessel disease is encountered.[87] Single-vessel atherosclerotic occlusive disease typically causes symptoms as a result of hemispheric or upper extremity emboli, but low-flow states are also seen. When the innominate artery is involved, patient may suffer from stroke (anterior or posterior circulation), TIA, or upper extremity ischemia. Isolated CCA disease is typically manifested as stroke or TIA. Single-vessel proximal SCA occlusive disease can cause arm ischemia, as evidenced by limiting arm claudication,

with very rare instance of digital ischemia and gangrene. Subclavian steal syndrome can be seen in single-vessel occlusive disease, which can manifest as VBI or subclavian-coronary steal. When patient has a functioning LIMA coronary bypass, recurrent episodes of angina can be seen in instances when severe proximal SCA stenosis is present.

Diagnostic Evaluation

The mainstay for screening for brachiocephalic arterial disease continues to be a prudent physical examination. Careful assessment of the upper extremity pulses, individual upper extremity blood pressure measurements, and auscultation of carotid and SCA bruits are effective tools that allow the practitioner to suspect significant pathology. Blood pressure measurements in individual arms in patients with brachiocephalic disease can show a 20 mm Hg or greater difference between sides. Typically, the initial diagnostic study that is performed is a DUS. There are limitations in using DUS for evaluation of brachiocephalic atherosclerotic disease. Overlying bony structures make identification of aortic arch and proximal great vessels difficult. DUS can be useful in identifying reversal of flow in the vertebral artery, indicating a significant proximal stenosis, as well as rule out significant disease in the extracranial carotid arteries. A decrease in the waveform amplitude and slope (tardus–parvus waveform) can signify significant proximal CCA disease.

CTA and MRA provide excellent imaging of the aorta and brachiocephalic branches. The use of 3D reconstruction, can help facilitate planning of surgical interventions without the need of performing a diagnostic angiogram. Gated CT in coordination with electrocardiogram allows for more careful identification of the mobile ascending aorta and arch, and decreases the amount of motion artifact. Furthermore, CTA and MRA (Fig. 87.34) allow for a complete evaluation of arterial flow from the arch to the brain, as well as evaluation of collateral circulation, which is necessary for surgical planning. Angiography remains the “gold standard,” but does have associated risk of stroke, embolization (albeit very low), and arterial injury. Also, with advanced CTA and MRA techniques, this is quickly surpassing routine diagnostic angiography for routine identification of brachiocephalic disease.

Finally, transesophageal echo (TEE) can be used to evaluate for ascending and descending aortic pathology.

Indications for Repair

Any symptomatic brachiocephalic stenosis should be treated with either open or endovascular techniques. Asymptomatic disease can safely be monitored for progression of disease, as well as medically managing risk factors. Stroke and TIA should be promptly evaluated and underlying lesion should be repaired, due to the fear of ongoing embolization or continued symptoms from a low-flow state. Severe upper extremity ischemia, as evident by severe claudication, rest pain or tissue loss should undergo prompt repair. Also, a low threshold for repair should be given to those with a patent LIMA coronary bypass and proximal subclavian disease. Patients with a functional hemodialysis access and evidence of SCA disease, should also be considered for repair if ongoing low-flow issues are occurring within the dialysis access or signs of steal are apparent.

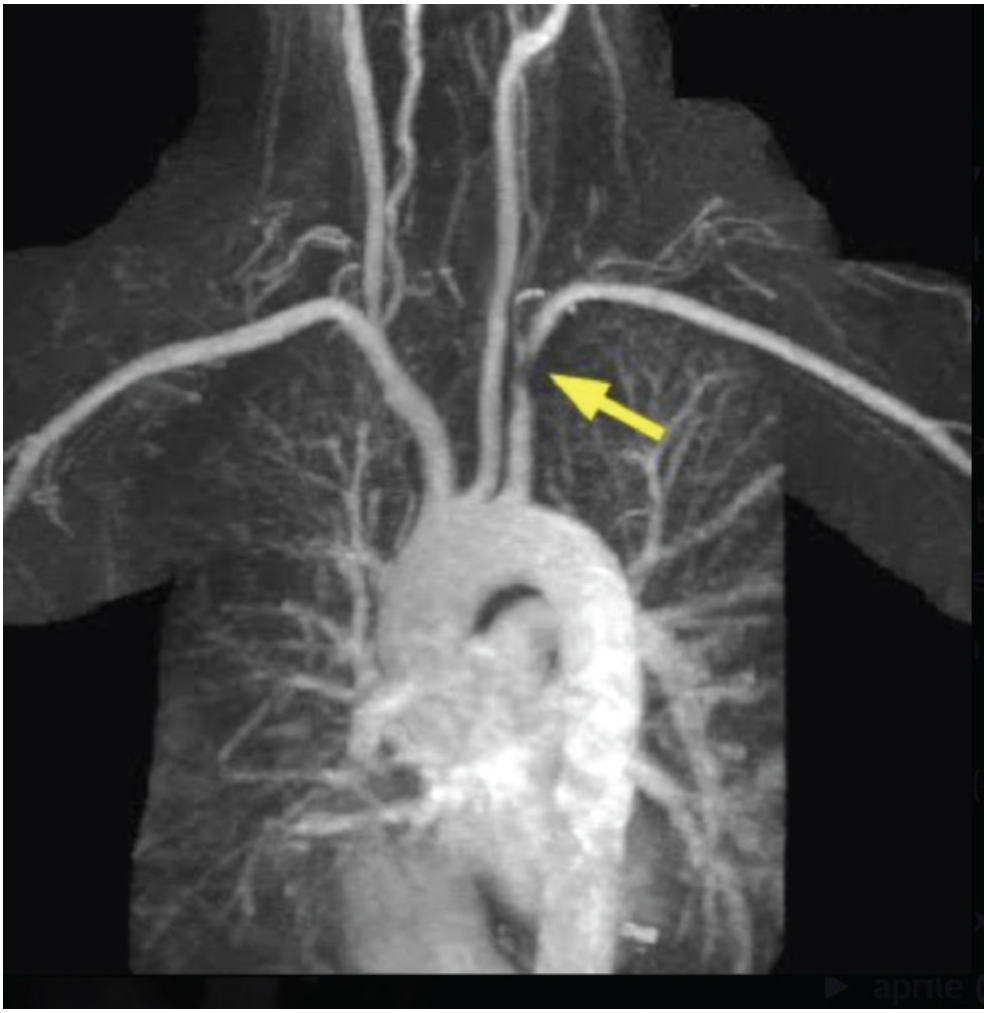

Figure 87.34 3D MIP reconstruction of a contrast-enhanced MRA demonstrating a focal left subclavian artery stenosis.

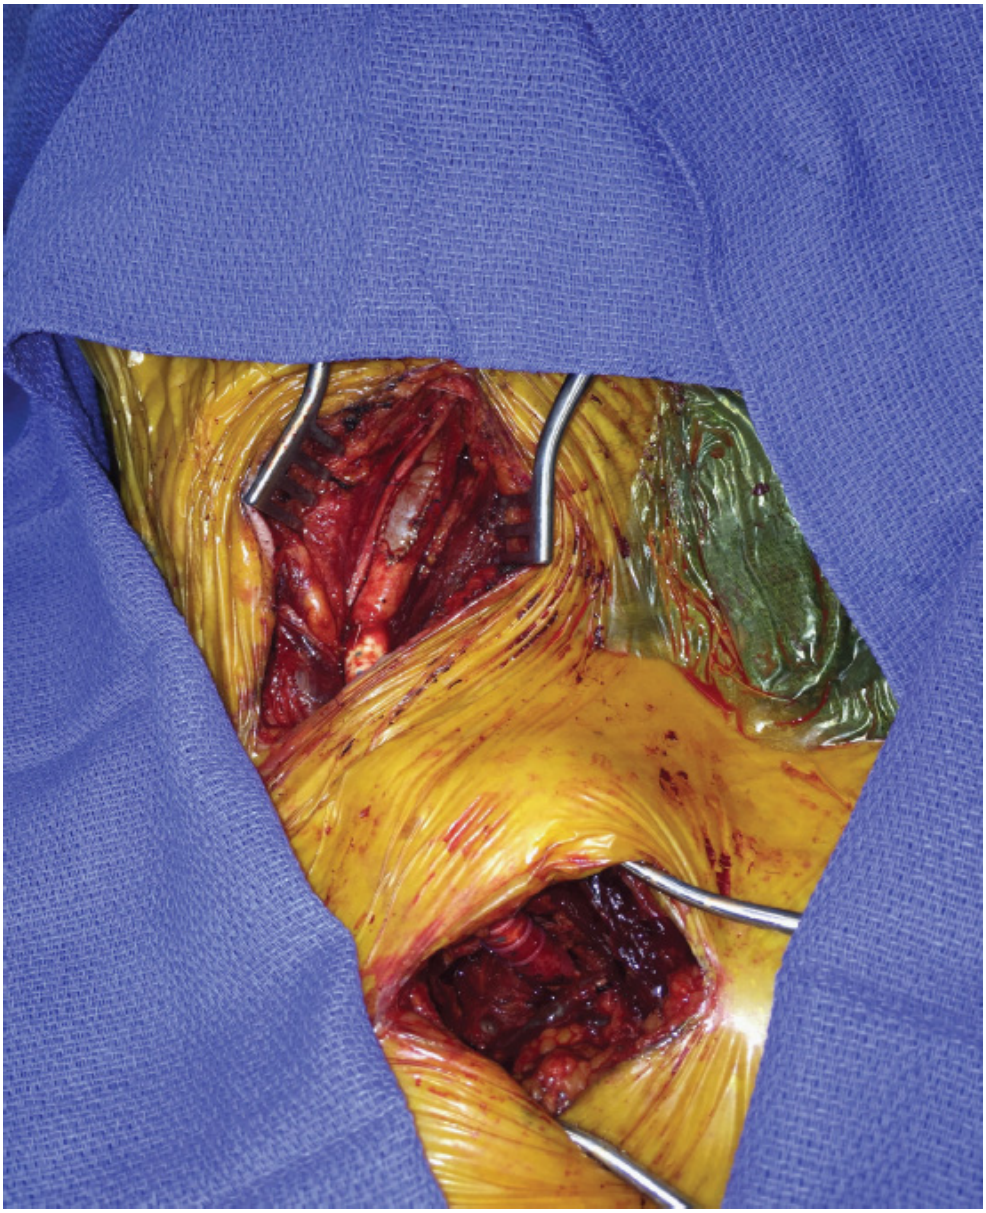

Figure 87.35 Patient with concomitant severe left ICA stenosis and symptomatic proximal and mid left SCA stenosis who underwent a left CEA with a left carotid-axillary artery bypass.

Surgical Treatment

Two main approaches are taken for the open surgical treatment of brachiocephalic disease: transthoracic and extra-anatomic revascularization. Transthoracic repair requires a median sternotomy and revascularization, with either direct arterial reconstruction or bypass from the ascending aorta to the involved brachiocephalic arteries. This approach is ideal for low-risk

patients and those with multivessel disease. When treating patients with multivessel disease, such as Takayasu arteritis, transthoracic repair with debranching off the ascending aorta to healthy vessels avoids diseased arterial segments and is the ideal repair. In appropriately selected patients, this approach can have excellent results with acceptable morbidity. Complications include mortality and stroke rates of 3% to 8% and MI rates of 1.5% to 3%. Excellent 10-year patency of approximately 90% can be achieved with direct transthoracic reconstruction.[88,89]

For single-vessel brachiocephalic disease and for higher-risk patients, extra-anatomic revascularization may be more suitable. This technique can also be used in hybrid approaches when treating patients with open surgical and endovascular techniques. Options for repair include a carotid–carotid bypass, axilloaxillary bypass, carotid–subclavian bypass, or carotid–subclavian transposition. The vast majority of extra-anatomic bypasses are done for single-vessel severe SCA stenosis. Transposition is technically more difficult than a carotid–subclavian bypass, but has the advantage of avoiding prosthetic material. Mortality and stroke rates are far less than those that undergo transthoracic repair.[90] Results are also excellent for carotid–subclavian bypass or subclavian transposition, with 5-year patency of 95% and 100%, respectively. Carotid–subclavian bypasses are one of the few bypasses that favor the use of prosthetic graft over autogenous vein graft, 5-year patency of 94% versus 58.3% ($p < 0.01$).[91] When considering carotid–subclavian bypass, if patients have concomitant, severe carotid stenosis, it is feasible to perform a CEA, followed by a carotid–subclavian bypass in order to prevent a low-flow state to the ipsilateral anterior circulation (Fig. 87.35).

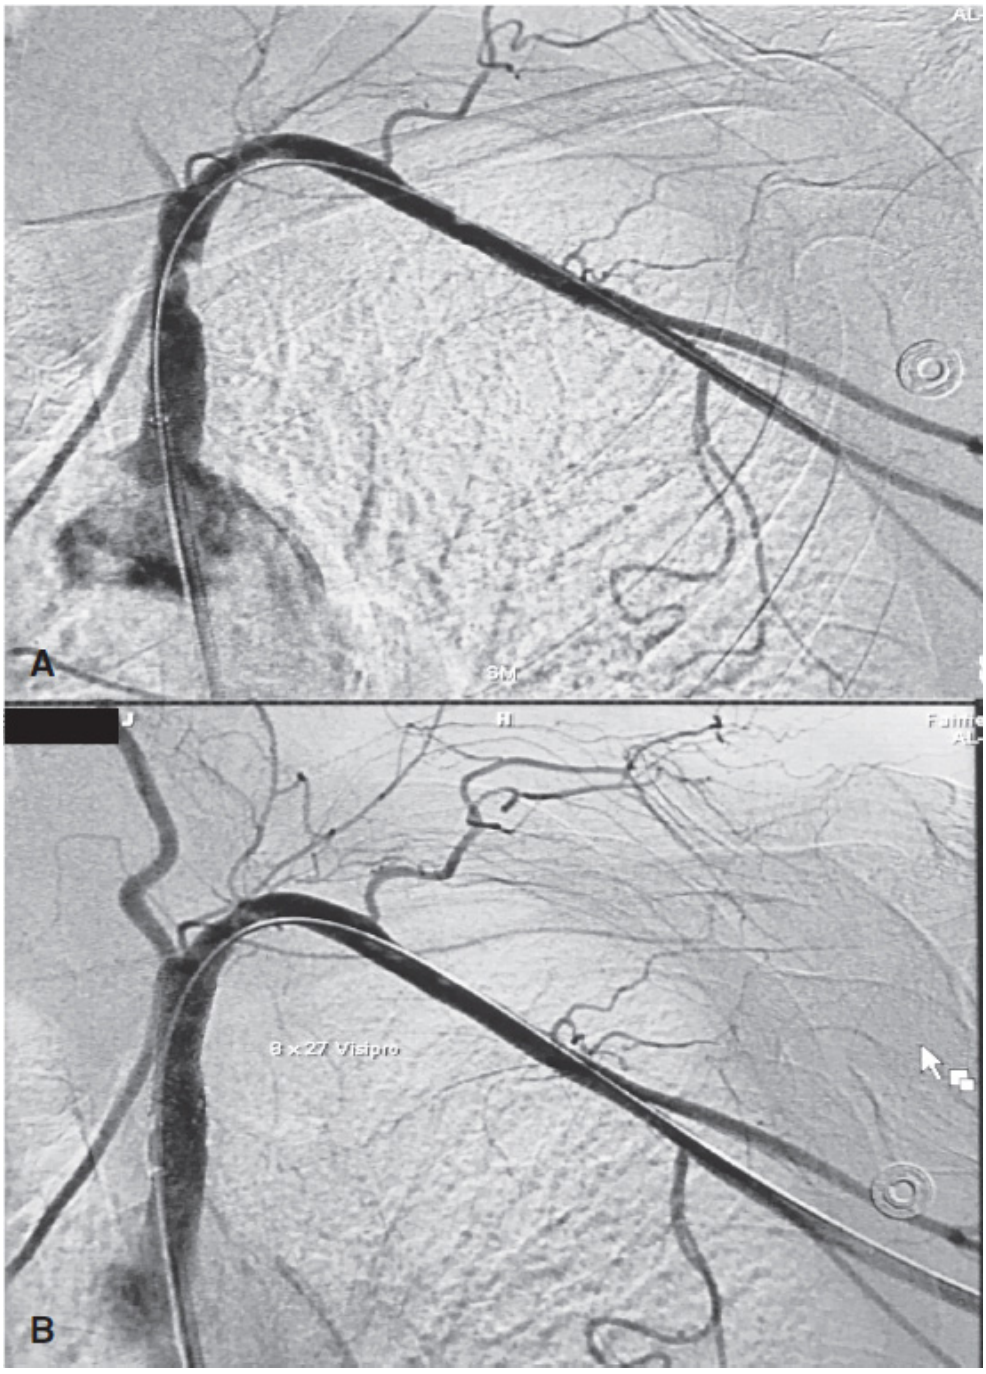

Figure 87.36 **A:** Prestent angiogram revealing high-grade left subclavian artery stenosis with ulcerated plaque. **B:** Poststent angiogram with stenting showing excellent flow throughout the subclavian artery with increased filling of the left vertebral artery.

Endovascular management of brachiocephalic lesions has gained wide popularity over the past 20 years. Single-vessel brachiocephalic stenosis is better suited for endovascular management, however, in a certain subset of

patients that are too ill to undergo an open repair, aggressive endovascular treatment in multivessel brachiocephalic stenosis can also be performed. As with carotid stenting, endovascular treatment of brachiocephalic lesions depends on aortic anatomy, anatomical variants, baseline renal function, arch type, lesion characteristics, and proximity to branch vessels. Endovascular management consists of angioplasty and stenting (Fig. 87.36). Similar to cervical carotid artery stenting, use of intraprocedural heparin and dual antiplatelet therapy afterward is a must. EPD can be used to minimize the risk of embolization when treating innominate or proximal 8 CCA stenosis. Endovascular results do not appear to compare favorably with open repair. One-year patency appears to be close to 90%, however, at 5-year patency drops to 77% to 89%.[92] Alternatively, retrograde approach through a cut down on the CCA allows for better protection with clamping. However, the risk of stroke is higher when concomitant CEA is performed.[93] When intervening on proximal SCA stenosis, great care must be used to avoid encroachment on or embolization to the vertebral artery. Similarly, great attention must be paid to avoiding embolization to the cervical ICA when treating innominate or proximal thoracic CCA stenoses. Sometime, alternate access (brachial) is needed to help facilitate protection of the vertebral or carotid artery during stenting of proximal brachiocephalic lesions.

Upper Extremity Arterial Disease

Heron E. Rodriguez and Courtney Furlough

Key Points

1. Presentation includes arm claudication, distal embolism, finger necrosis, and vasomotor changes described as Raynaud phenomenon.
2. Given the multiple potential etiologies of upper extremity ischemia, a thorough occupational and social history is necessary.
3. Unilateral hand ischemia points toward an isolated anatomic lesion whereas bilateral hand ischemia is more often related to systemic diseases.
4. A variety of noninvasive tests are available for the initial investigation of arm ischemia while detailed, bilateral arterial imaging is mandatory for treatment planning.
5. Although endovascular revascularization is an excellent option for many causes of upper extremity ischemia, open surgical revascularization is required for some of the diseases causing arm ischemia (i.e., thoracic outlet syndrome [TOS], hypothenar hammer syndrome, etc.)

INTRODUCTION

1 Compared to arterial occlusive lesions in the lower extremity, occlusive disease of the arteries of the upper extremity is often better tolerated and less frequently presents with severe ischemic symptoms. This not only can be attributed to the presence of an extensive collateral network, but also to the very different physiologic requirements of the upper extremities when compared to the legs. Another major difference between arterial disease in the arms compared to that of the legs is their etiologies. Whereas in the lower extremities, atherosclerosis is responsible for the overwhelming majority of cases of critical limb ischemia, in addition to atherosclerosis, numerous anatomic, occupational, and iatrogenic etiologies are responsible for occlusive disease in the arms.

PRESENTATION

Patients suffering from upper extremity arterial insufficiency can present with a variety of symptoms. Arm claudication (pain during exercise) is rare and often points to a proximal lesion (innominate, subclavian, or axillary arteries). More commonly, patients present with skin changes affecting the hands or fingers. Splinter hemorrhages of the bed of the nail, livedo reticularis, cyanosis of segments of the fingers, and gangrene are signs of embolism or ischemia affecting the arteries of the hand (Fig. 88.1).[1] Raynaud phenomenon indicates an episodic series of skin changes affecting the fingers or the hands triggered by changes in temperature or emotional stress. The classic presentation is a sequential appearance of first pallor, then cyanosis, and finally erythema. These correspond to (in order) vasospasm (pallor), desaturation of hemoglobin (cyanosis), and finally compensatory vasodilation, also known as reactive hyperemia (erythema).

Raynaud phenomenon (also called secondary Raynaud syndrome) can be the manifestation of occlusive disease or, more commonly, is associated with autoimmune conditions (scleroderma, Sjögren syndrome, rheumatoid arthritis, lupus).[1] In contrast, the term *Raynaud disease* (or primary Raynaud syndrome) is used to describe a condition of unknown etiology that occurs in patients without occlusive lesions or autoimmune disease. These patients can

experience vasomotor symptoms in both arms, and sometimes even the legs.[1,2]

ETIOLOGY

2 A myriad of conditions can cause upper extremity occlusive disease (Table 88.1). Atherosclerosis typically affects the origins of the supra-aortic trunks with ostial lesions at the origin of the subclavian artery being most common. The innominate artery and distal arteries can also be affected. Involvement of multiple segments of the upper extremity circulation is possible and is often asymptomatic even in the presence of total occlusion. Patients with renal failure typically have normal proximal vessels with severe disease in the blood vessels of the forearm and hand (Fig. 88.2). In this patient population, hand ischemia tends to occur at a younger age and is frequently associated with calciphylaxis.[3]

Inflammatory conditions like Takayasu arteritis or giant cell arteritis (GCA) can also affect the great vessels.[4] Takayasu arteritis is a rare, inflammatory vasculitis that affects the aorta and its major branches. Sometimes called "pulseless disease" from difficulty in obtaining peripheral pulses, this disease typically occurs in women in the second or third decades of life. An initial acute inflammatory phase of causes vessel thickening and is followed by a late chronic phase where long segments of stenosis occur in the vessels (Fig. 88.3). These lesions have low embolic potential generally present with end-organ ischemic symptoms secondary to high-grade stenosis (Table 88.2).[5] In chronic cases, revascularization of affected organs is attempted by either endovascular or surgical treatment. GCA, in contrast, is another more common inflammatory vascular disease. GCA typically affects older patients (more than 50 years old) and involves medium to large blood vessels. The typical pattern of disease is that of areas of normal luminal diameter alternated with dilated or stenotic lesions. The most common symptoms are headaches and visual changes related to involvement of the extracranial carotid arteries. Lastly, Buerger disease is an obliterative vasculitis that typically affects medium and small caliber arteries. It affects the lower extremities more commonly than the upper limbs and occurs more frequently in males than females.

Figure 88.1 Manifestations of upper extremity ischemia. Splinter hemorrhages in the nails arising from a proximal embolic source (**A**). Gangrene affecting the tip of the third finger (**B**). Advanced, severe gangrene in the radial artery distribution secondary to complications related to an arterial line (**C**).

Aneurysms of the upper extremity

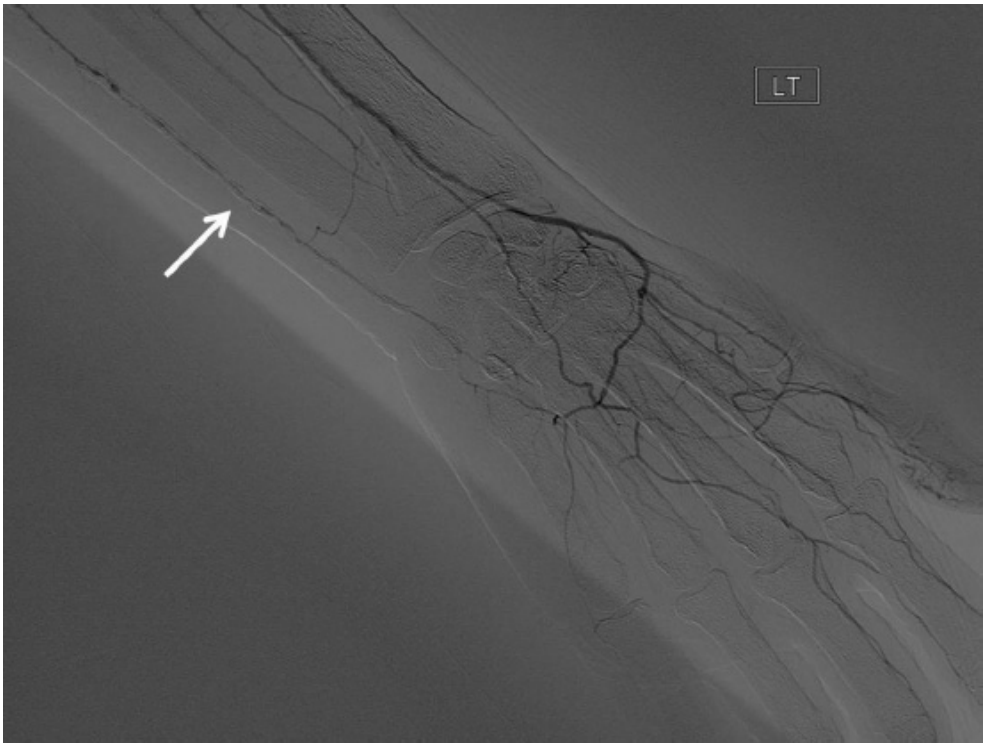

Figure 88.2 Selective left-hand angiogram in a patient with chronic renal insufficiency. There is severe, diffuse disease affecting a heavily calcified ulnar artery (*arrow*). In addition, there is lack of contrast opacification in several of the digital arteries.

Ergotamine is a substance that narrows vasculature. Ergot-induced vasospasm can create ischemia of the hands and the feet. Historically, epidemics occurred in Europe during the Middle Ages caused by the ingestion of rye contaminated by alkaloid-producing fungi. Today, most cases of ergotism are due to antimigraine drugs or recreational substance abuse.[6]

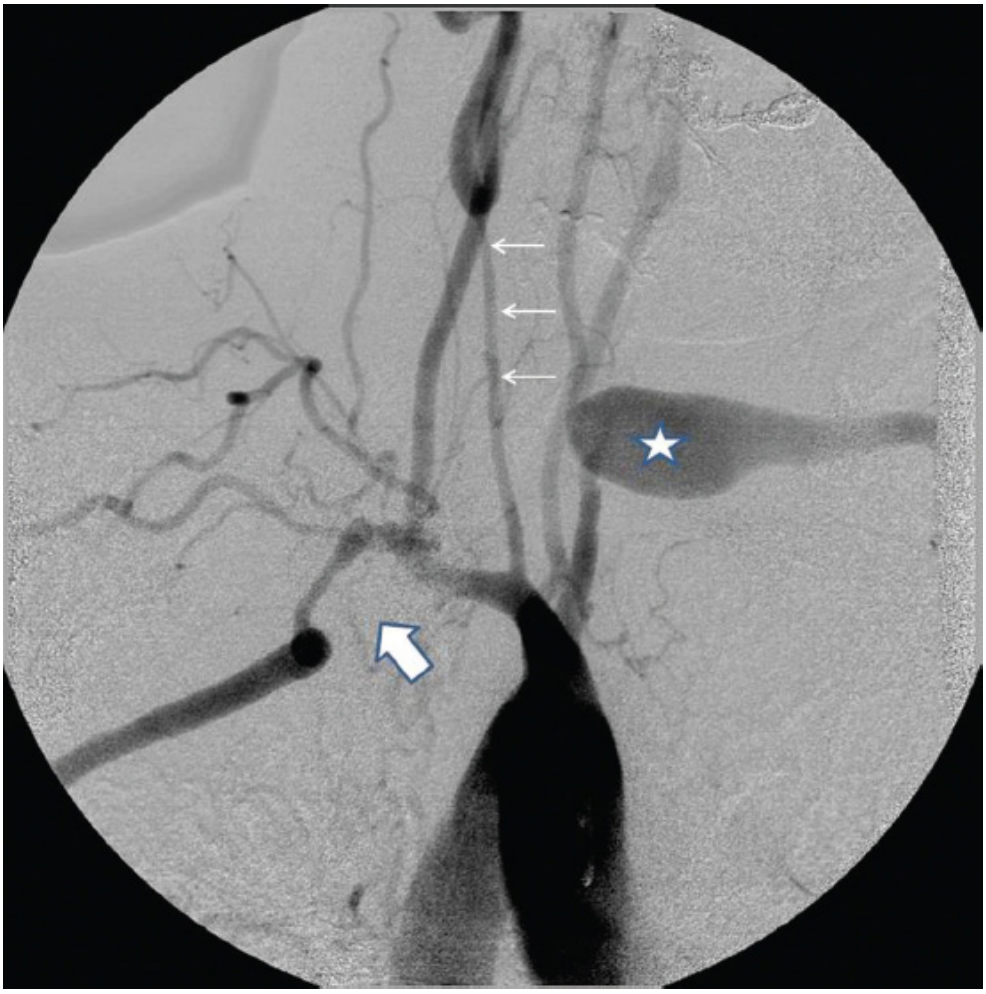

Figure 88.3 Aortogram in the right oblique projection of a patient with Takayasu arteritis. Long-segment right common carotid stenosis (*small arrows*) leading into a normal-appearing carotid bifurcation. Segmental occlusion of the right subclavian artery (*block arrow*) just distal to the origin of the right vertebral. There is distal reconstitution via a large collateral. There is also an aneurysm (*star*) of a previous bypass in the left subclavian artery.

Table 88.2 Takayasu Arteritis
Headache, often related to high blood pressure and kidney failure
Exertional chest pain
Fatigue and shortness of breath
Transient ischemic attacks, dizziness, vision changes, or fainting
Nausea, vomiting, and abdominal pain, generally from poor mesenteric blood flow
Exertional muscle pain in arms or legs

Connective tissue disorders are a common cause of upper extremity ischemia. Lesions typically affect the distal vasculature and are more common in scleroderma, rheumatoid arthritis, CREST syndrome, mixed connective tissue disorders, and lupus. Raynaud phenomenon is often the manifestation in early stages whereas digital gangrene occurs in late stages of the disease.

Thoracic outlet syndrome (TOS) is a term encompassing a group of signs and symptoms related to compression of the brachial plexus, subclavian vessels as they pass from the thorax into the axilla. There are three types: neurogenic, arterial, and venous. Only 1% of all TOS cases are arterial in etiology.[7] Although TOS is often asymptomatic, patients may present with a range of signs and symptoms, from fatigue or pain in the affected arm upon exertion and Raynaud phenomenon to critical ischemia of the upper extremity due to emboli. These emboli arise from a chronically injured artery or from a mural thrombus in a poststenotic aneurysm sac and can result in irreversible digital or hand ischemia.[8] Aneurysms can also form because of repetitive trauma in branches of the subclavian artery. The artery is compressed as it passes through the thoracic outlet into the axilla. This is a narrow outlet formed by the clavicle superiorly, the first rib inferiorly and the subclavius muscle anteriorly and superiorly, as well as the scalene muscles posteriorly (Fig. 88.4). Bony anomalies, such as a cervical rib or an abnormal first thoracic rib, are often structural contributors to arterial TOS. Pectoralis minor syndrome is a similar condition that causes compression of the

subclavian artery but this time by the pectoralis minor as it inserts on the coracoid process (Fig. 88.4).

Ischemia caused by flow disruption in the axillary, brachial, radial, and ulnar arteries is often the result of iatrogenesis. One of the most common causes of ischemia seen in our practice is due to hemodialysis access. Hand ischemia due to steal phenomenon is common and ischemia from intra-arterial catheters also occurs frequently.

Examples of occupational injuries to the hand arteries of the hand are thenar or hypothenar hammer syndromes. The ulnar artery is vulnerable to injury at the hypothenar eminence, just distal to the wrist where the ulnar artery passes through Guyon canal bound by the pisiform and hamate bones. Here, the ulnar artery is cushioned only by skin, subcutaneous tissue, and the thin palmaris brevis muscle. Repetitive use of the palm of the hand as a "hammer" compresses the unprotected ulnar artery against the nearby hook of the hamate bone. Both aneurysm formation and occlusive disease can result (Fig. 88.5).[9]

HISTORY AND PHYSICAL EXAMINATION

3 Given the frequent association of upper extremity ischemia with systemic and occupational disorders, a thorough medical and social history is mandatory. Interrogation should include history of tobacco and/or drug use. Antimigraine medications, HIV antivirals, and most commonly recreational drugs, like cocaine and other alkaloids, can cause ergotism. Occupational history is of particular importance when evaluating upper extremity vascular issues. TOS occurs in athletes who perform repetitive overhead shoulder motion (swimmers, baseball pitchers, weight lifters, etc.). Repetitive trauma to the palmar eminences (thenar and hypothenar) is typically observed in manual laborers (machinists, carpenters, and construction workers) but has also been described in athletes, musicians, and even computer workers who may have repetitive palmar injury due to the nature of their work.

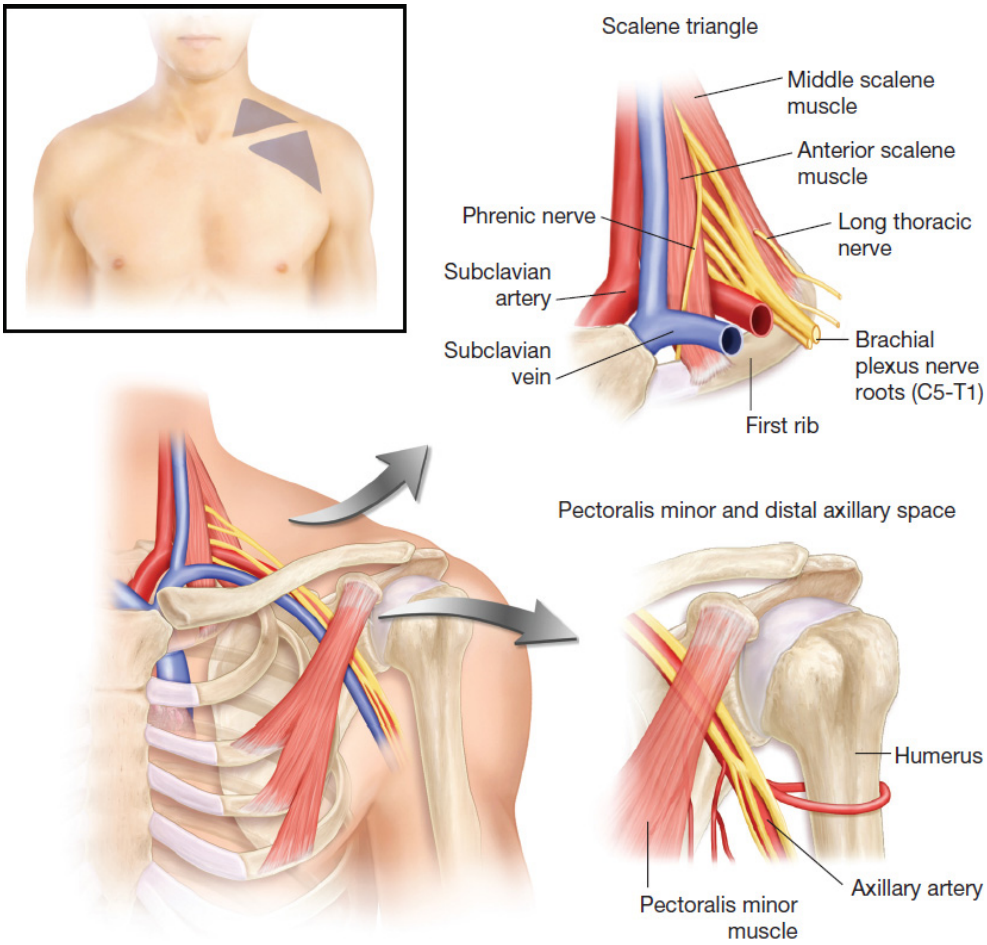

Figure 88.4 Compressive zones of the thoracic outlet. The subclavian structures can be compressed at the costoclavicular space, the scalene triangle, or distally at the border of the pectoralis minor muscle.

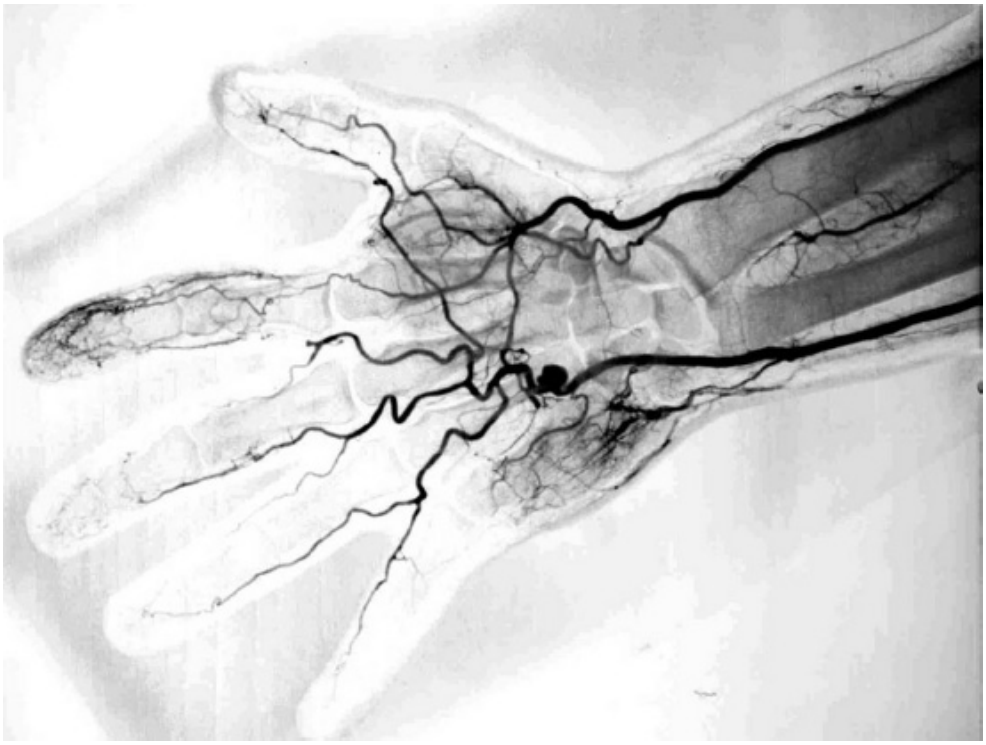

Figure 88.5 Ulnar artery aneurysm resulting from repetitive trauma in a construction worker.

The presence of atherosclerotic disease in the heart or other vascular beds should also be investigated given the potential for involvement of the origins of the great vessels. History of connective tissue disorders or their symptoms (dysphagia, arthritis, telangiectasia, and other skin abnormalities) cannot be obviated during the evaluation of upper extremity ischemia. Changes in the appearance of the skin of the hands suggestive of Raynaud's should be explicitly investigated.

It is necessary to obtain clear documentation of any prior intervention in the arm such as hemodialysis access, biopsies, and brachial or axillary access for cardiac catheterizations. Additionally any prior trauma (clavicular or rib fractures, humeral, shoulder, or elbow injuries) (Fig. 88.6) should be reviewed and documented.

A complete physical examination needs to include a systemic evaluation looking for signs of atherosclerotic, inflammatory, or autoimmune disease. Meticulous inspection, auscultation and palpation of both sides of the neck, periclavicular areas, shoulders, arms and hands should be done in the resting, neutral position, and also while abducting the arm. A bruit or a thrill

in the periclavicular area would suggest the presence of stenosis or poststenotic dilation arising from TOS and a prominent pulse should point to an aneurysm in the subclavian artery. Comparison between the two upper extremities is of crucial importance as bilaterality can point to a systemic disorder. A careful hand examination includes inspecting for splinter hemorrhages under the beds of the nails, skin evidence of embolism or gangrene, or skin color changes related to vasospasm and signs of trauma in the hand. Careful palpation of the radial, ulnar, snuffbox, and even digital pulses should be done. An Allen test should also be performed. In this test, digital pressure is applied to the ulnar and radial arteries in the wrist. After the patient opens and closes his or her hand, pressure is removed from one of the wrist arteries and inspection of the color of the hand and palpation of the distal pulses is repeated. The test is normal if the entire hand recovers its color and capillary refill. If a portion of the hand fails to normalize, then it is likely that the palmar vascular collateral circulation (palmar arch) is incomplete. Lastly to complete the physical examination, bilateral blood pressure measurements should be obtained and compared (brachiobrachial index).

Figure 88.6 Old clavicular fracture treated with a metallic prosthesis. Notice the luminal abnormality in the subclavian artery as it crosses the clavicle. This lesion was caused by periosteal scarring and caused distal embolism in the hand.

LABORATORY AND NONINVASIVE TESTING

4 A series of serologic tests is typically obtained if autoimmune disease is suspected (Table 88.3). A variety of tests are available from the blood flow laboratory to aid in the management of upper extremity occlusive disease.[10] All patients should be subjected to segmental arterial pressure measurement and waveform analysis, at the minimum. In the upper extremities, this test usually includes photoplethysmography (PPG) of the digital vessels. The absence of triphasic flow and the presence of "blunted" PPG tracing in the affected arteries and digits, respectively, help to localize obstructive lesions. If intermittent occlusion is suspected due to TOS, noninvasive testing can be performed along with the use of provocative maneuvers (Fig. 88.7). Historically, the cold challenge test has been used to assess patients with symptoms suggestive of vasomotor disorders (cold intolerance, skin color changes, etc.). In this test, the hands are immersed in iced water and digital temperatures are measured every 5 minutes. For a normal response, temperatures should normalize within 1°C of pre-immersion measurements. Cold intolerance is confirmed with failure to restore digital temperature in 20 minutes. Several variations of this test exist.[11]

Rheumatoid factor
Antinuclear antibody
Immunoglobulin electrophoresis
Cryoglobulins
Cold agglutinins
VDRL (Venereal Disease Research Laboratory) test
Complement (C3, C4)
Anticardiolipin antibody
Blood cell counts

A more sophisticated version of the Adson test can also be obtained in most blood flow facilities by adding the analysis of waveforms obtained before and after ulnar and/or radial artery occlusion at the wrist. Duplex ultrasound is useful when an obstructive lesion is localized by physical examination, waveform analysis, or segmental pressure recordings. B-mode imaging and color Doppler can further define the characteristics of the lesion and its hemodynamic severity. Finally, measurement of digital PPG tracings can be obtained with and without manual pressure causing temporary occlusion of hemodialysis grafts and fistulae when evaluating arterial steal in patients with renal failure.

ANGIOGRAPHY

Accurate imaging of the arterial anatomy of both arms, from the aortic arch to the digital arteries is mandatory when obstructive lesions are suspected on clinical evaluation or noninvasive testing. Although conventional angiography remains the gold standard, modern computed tomography angiography (CTA) and magnetic resonance angiography (MRA) have

essentially replaced this modality (Fig. 88.8). For comparison, both upper extremities should be imaged. If TOS is suspected, provocative maneuvers should be done while obtaining arterial images (Fig. 88.9). Of particular importance is obtaining clear images of the hand circulation to assess collateral circulatory pathways. Typically, the deep palmar arch arises from the terminal part of the radial artery and the superficial arch by the ulnar artery. Nevertheless, several variations exist (Fig. 88.10).

MANAGEMENT

5 The specific mode for revascularization used to treat upper extremity ischemia depends on the location of the lesion, its etiology, and the available local resources and expertise. Atherosclerotic lesions affecting the origin of the subclavian or innominate arteries are most frequently treated with percutaneous transluminal angioplasty and stenting. This is usually achieved via a femoral approach but can also be performed using a retrograde radial, brachial or even a carotid approach. A percutaneous approach is popular due to being minimally invasive, well tolerated by patients, and widely available to multiple disciplines. Immediate angiographic results that are usually excellent as well, however, several disadvantages should be considered when choosing this form of therapy. Deployment of intravascular devices across the origin of a vertebral artery, an internal mammary previously used as a coronary bypass, or under the clavicle should be avoided due to the obvious possibility of catastrophic results. Second, the long-term durability of intravascular stents in the ostia of the aortic arch is not clearly established. And finally, we have seen an elevated rate of stent fractures in this position.[12] This is likely due to the extreme motion of the aortic arch and the supra-aortic trunks around the cardiac cycle. Alternatively, open surgical bypasses and transpositions can be performed via small incisions in the neck with excellent long-term results. For example, the subclavian artery can be transposed to the common carotid artery using a small transverse neck incision. This procedure allows for preservation of the vertebral artery and its long-term patency rate is nearly 100%.[13] A short carotid to subclavian bypass using prosthetic material can also be used with excellent long-term results (Fig. 88.11). Finally, in some patients the best option resides in single

or multiple-branched bypasses arising from the aortic arch. A ministernotomy is used to expose the ascending arch and the bypass can be anastomosed to the aorta using a side-biting clamp thus obviating the need for cardiopulmonary bypass (Fig. 88.12).

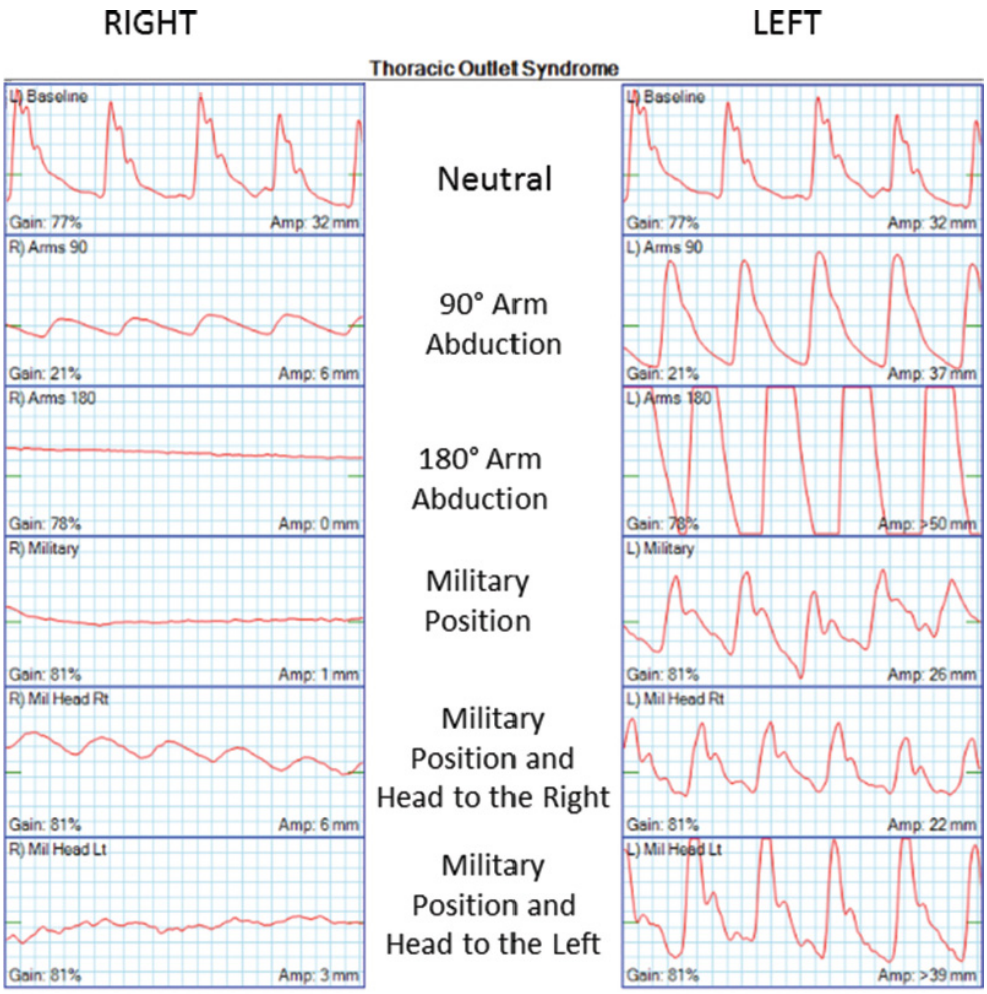

Figure 88.7 Noninvasive blood flow study in a major league baseball pitcher showing loss of normal signals during proactive maneuvers.

Intervention during the acute inflammatory phase of Takayasu arteritis should be avoided. The mainstay of treatment during the active phase is with corticosteroids. Patients with more severe disease may require additional immunosuppressant drugs (e.g., methotrexate or azathioprine). Any intervention should be delayed until the acute, active phase of the disease undergoes remission.[14] This is often indicated by normalization of serologic inflammatory markers, most commonly erythrocyte sedimentation rate (ESR)

and C-reactive protein (CRP). Antiplatelet therapies may lower the frequency of ischemic events. During the chronic phase, reconstruction is carried out using similar techniques as those used for the management of atherosclerotic occlusion (Fig. 88.13).

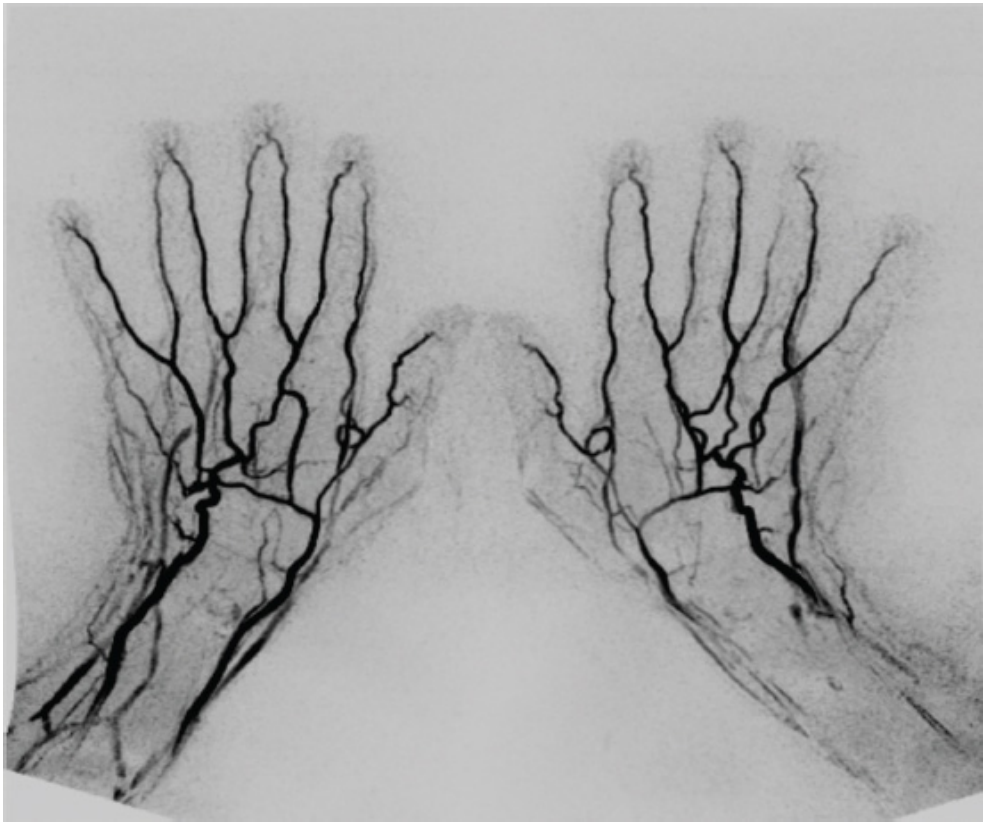

Figure 88.8 Focused magnetic resonance angiogram of the hands.

There is little controversy about the management of patients with arterial TOS. Untreated arterial injury due to repetitive torsion and compression leads to stenosis, poststenotic aneurysmal dilation, and distal embolism. In the majority of cases, evidence of distal embolism with compromise of the arteries of the hand is already present by the time of presentation. Thus, thoracic outlet decompression often with arterial reconstruction is mandatory. The subclavian artery can be compressed at any point from the root of the neck to the pectoralis minor tendon, therefore the decompressive approach depends on the specific anatomy of the patient. The surgical plan depends on the details obtained by imaging studies and the experience of the surgeon. In the absence of anatomic anomalies and with compression

demonstrated only during arm abduction and elevation, first rib resection via the supraclavicular approach appears to be the best choice. If chronic compression has caused arterial damage, arterial reconstruction is necessary. Interposition grafts from the ipsilateral common carotid to the axillary artery are commonly used. This can best be achieved by a combination of supra- and infraclavicular exposure. Eight-millimeter prosthetic grafts tunneled underneath the clavicle or subcutaneously have excellent patency rates. If present, cervical ribs are resected whereas full thoracic outlet decompression with scalenectomy is only necessary if concomitant neurogenic TOS exists.[15]

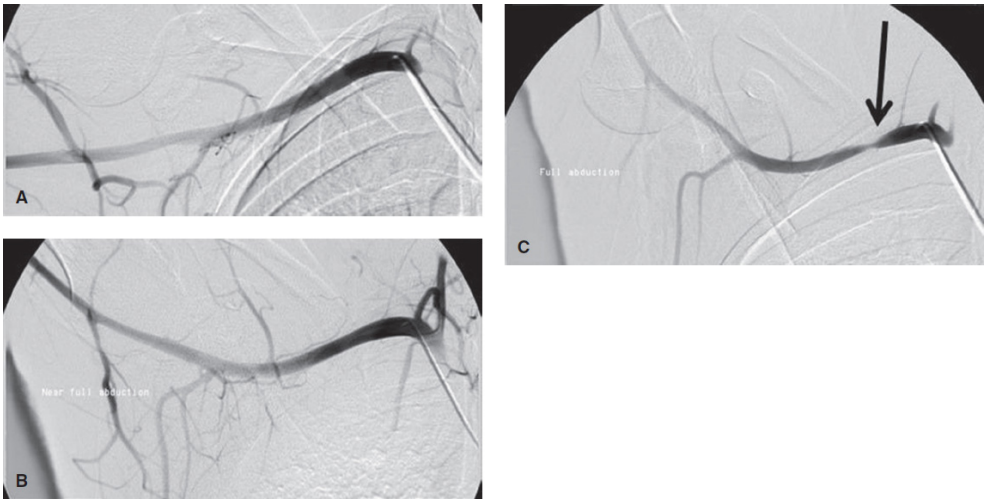

Figure 88.9 Selective digital subtraction angiography of the right arm in a patient with suspected arterial thoracic outlet syndrome. Subclavian artery stenosis is not seen when injecting contrast with the arm in neutral (**A**) and moderate abduction (**B**), but is evident when the arm is hyperabducted (*arrow*) (**C**).

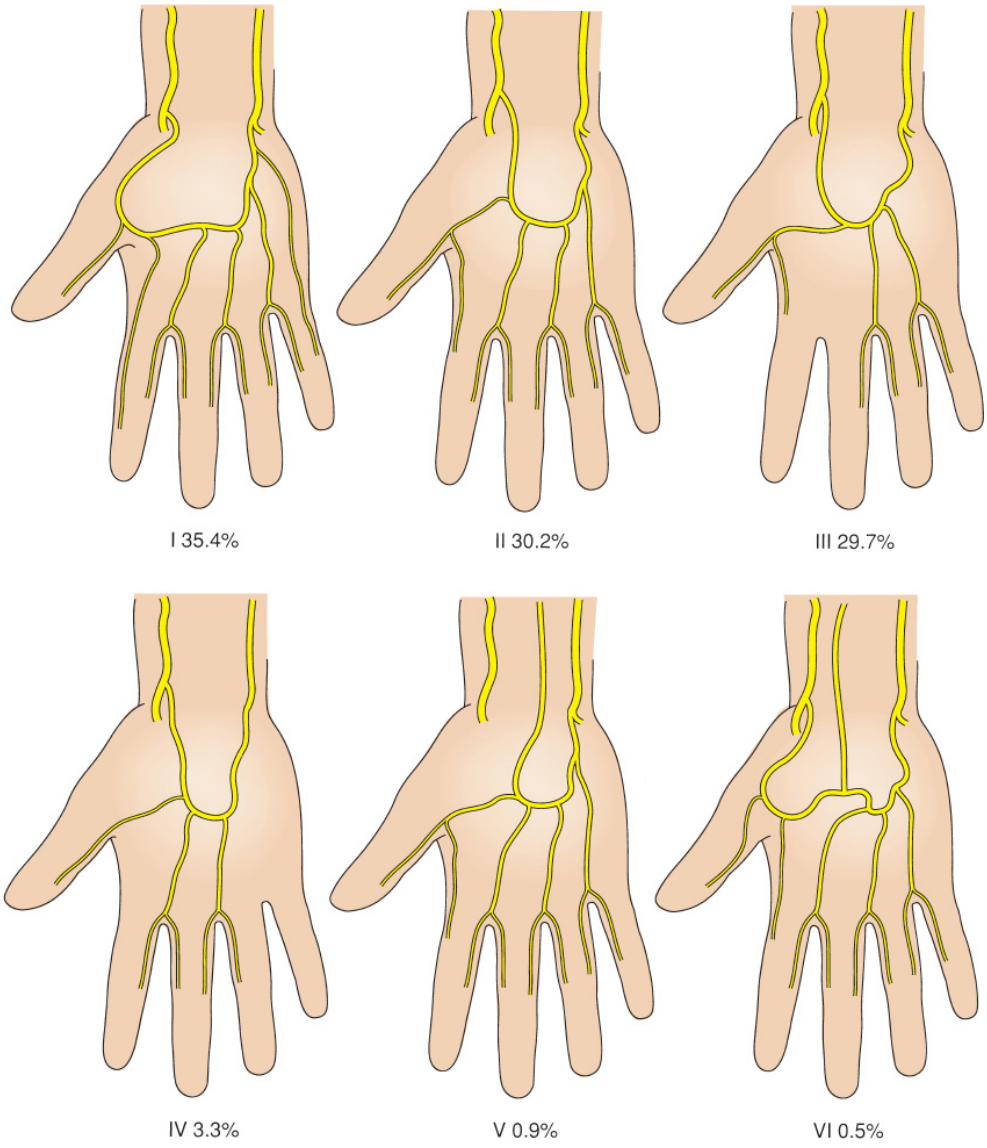

Figure 88.10 Different types of complex superficial palmar arch found on 500 hand arteriograms.

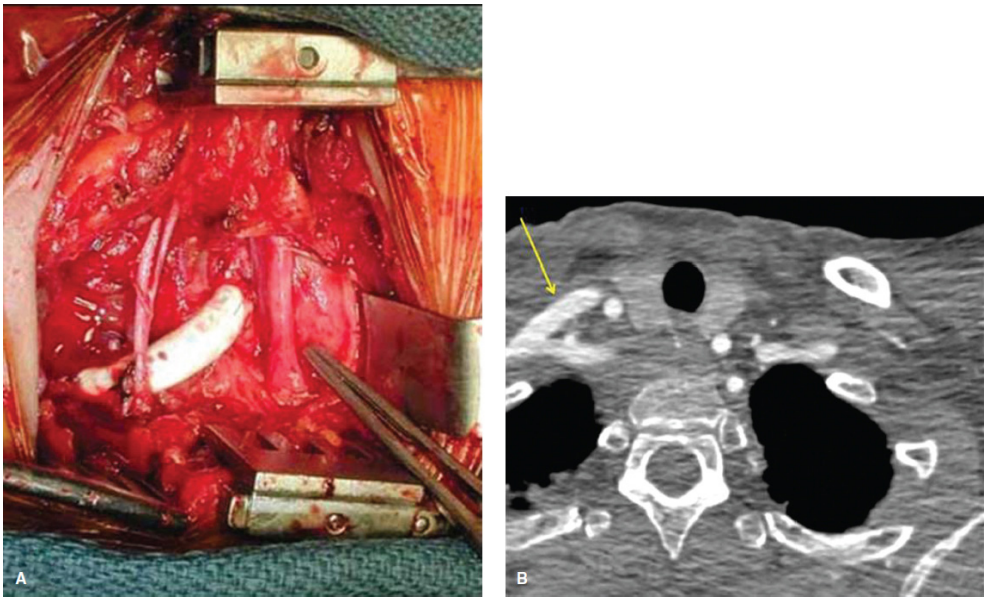

Figure 88.11 **A:** Right carotid to subclavian bypass performed via a supraclavicular incision using a prosthetic 10-mm conduit. **B:** CT scan showing patency of the bypass (*arrow*).

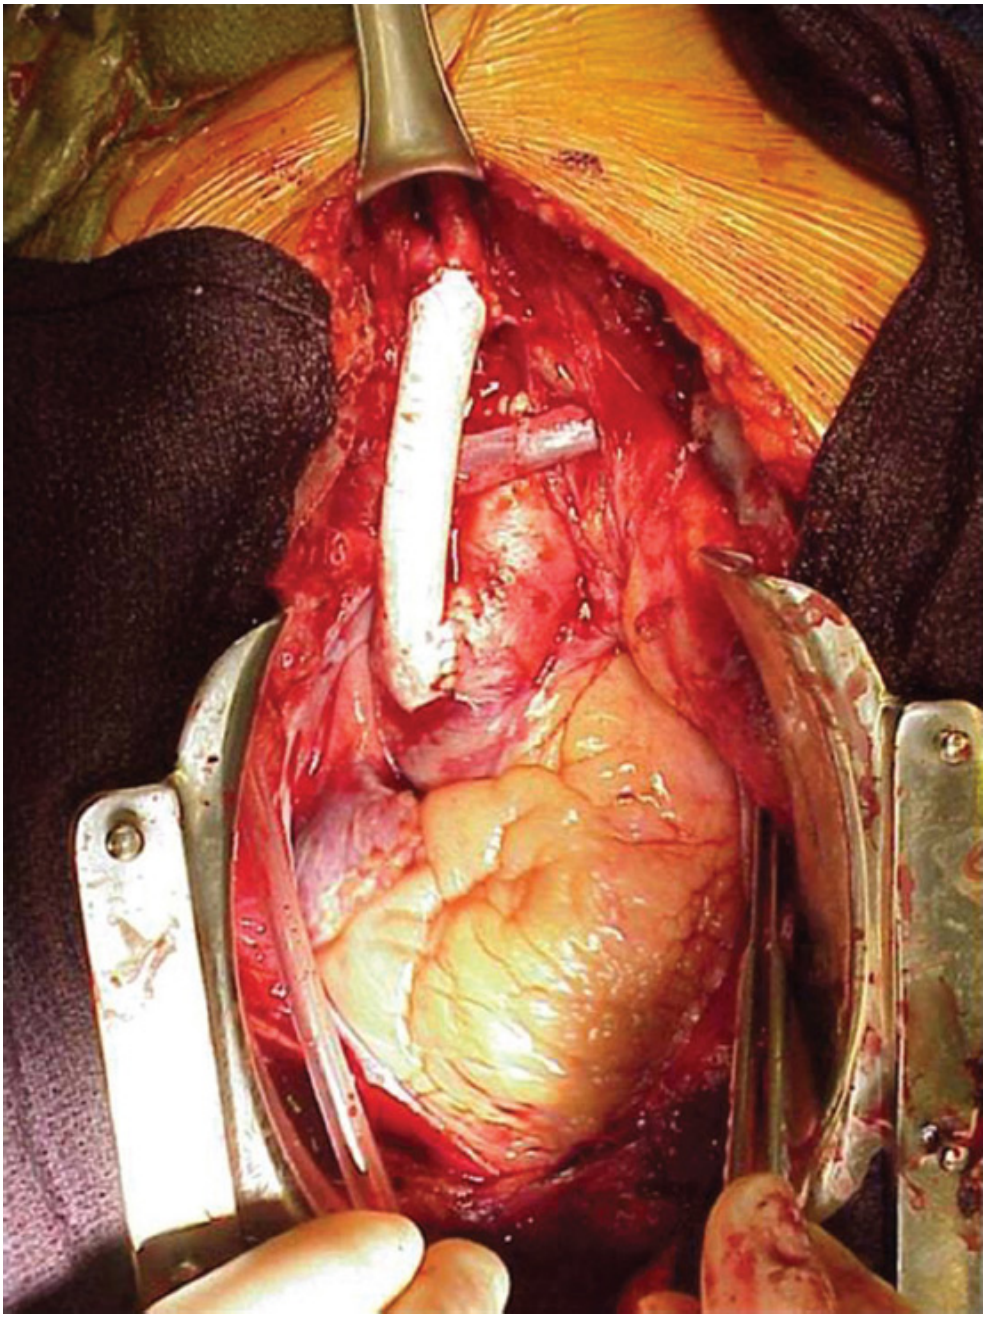

Figure 88.12 Aorto to inominate bypass. A ministernotomy is done and a side-biting clamp is used for creation of the proximal anastomosis in the ascending aorta. The distal anastomosis is created at the bifurcation of the innominate artery.

Other occlusive lesions of the subclavian, axillary, and brachial arteries are best treated with surgical revascularization. Due to potential compression at the costoclavicular space, the high mobility of the shoulder joint, and the caliber of the brachial artery, endovascular approaches are rarely indicated in this segment of the circulation. Many different bypass

configurations are available. The supraclavicular subclavian artery can be exposed by an incision at the base of the neck and used as inflow for bypasses tunneled subcutaneously over the clavicle and into the brachial artery. Alternatively, an excellent source of inflow is the common carotid artery. The outflow anastomosis can be created in the distal brachial artery, the radial or ulnar arteries in the proximal forearm (Fig. 88.14), or at the wrist and even in the arteries of the hand (Fig. 88.15).

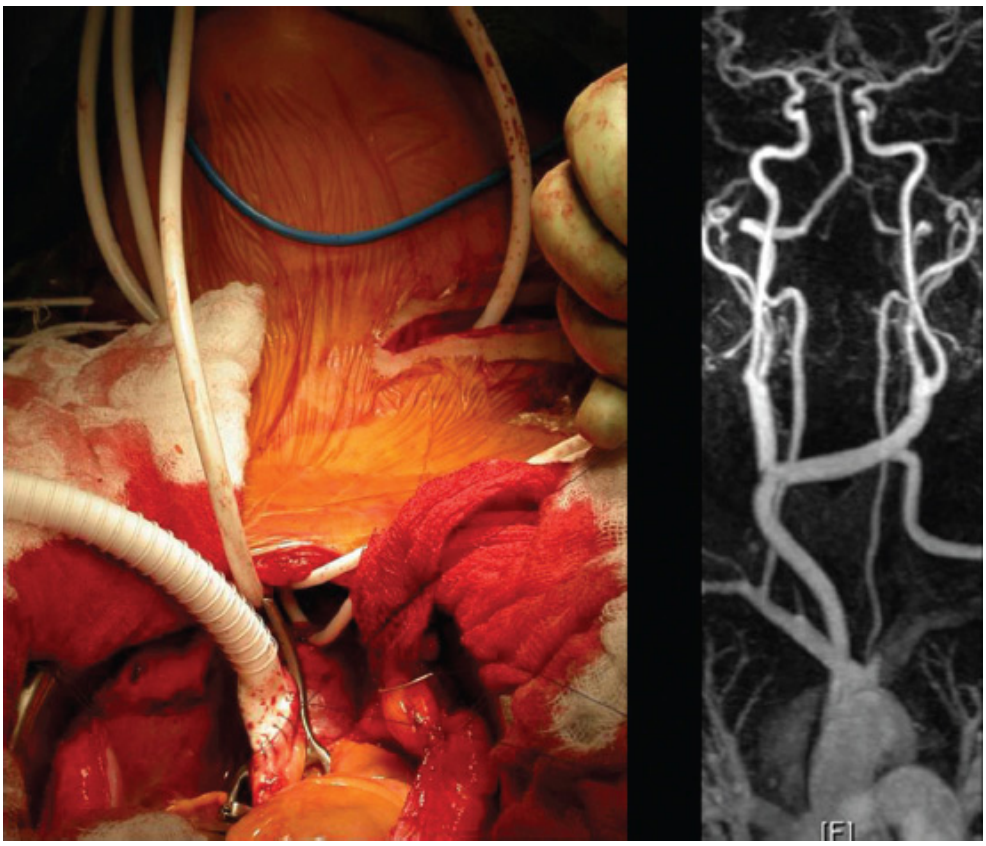

Figure 88.13 Arterial reconstruction on the patient with Takayasu arteritis shown in Figure 88.3. A median sternotomy with bilateral neck incisions was used. The proximal anastomosis was done in the ascending aorta. One branch was anastomosed in an end-to-end fashion to the right subclavian. A second branch was anastomosed to the right carotid (side-to-end) and then tunneled via the prevertebral space and anastomosed end-to-end to the left carotid bifurcation. Finally, a side arm was used to revascularize the left subclavian artery.

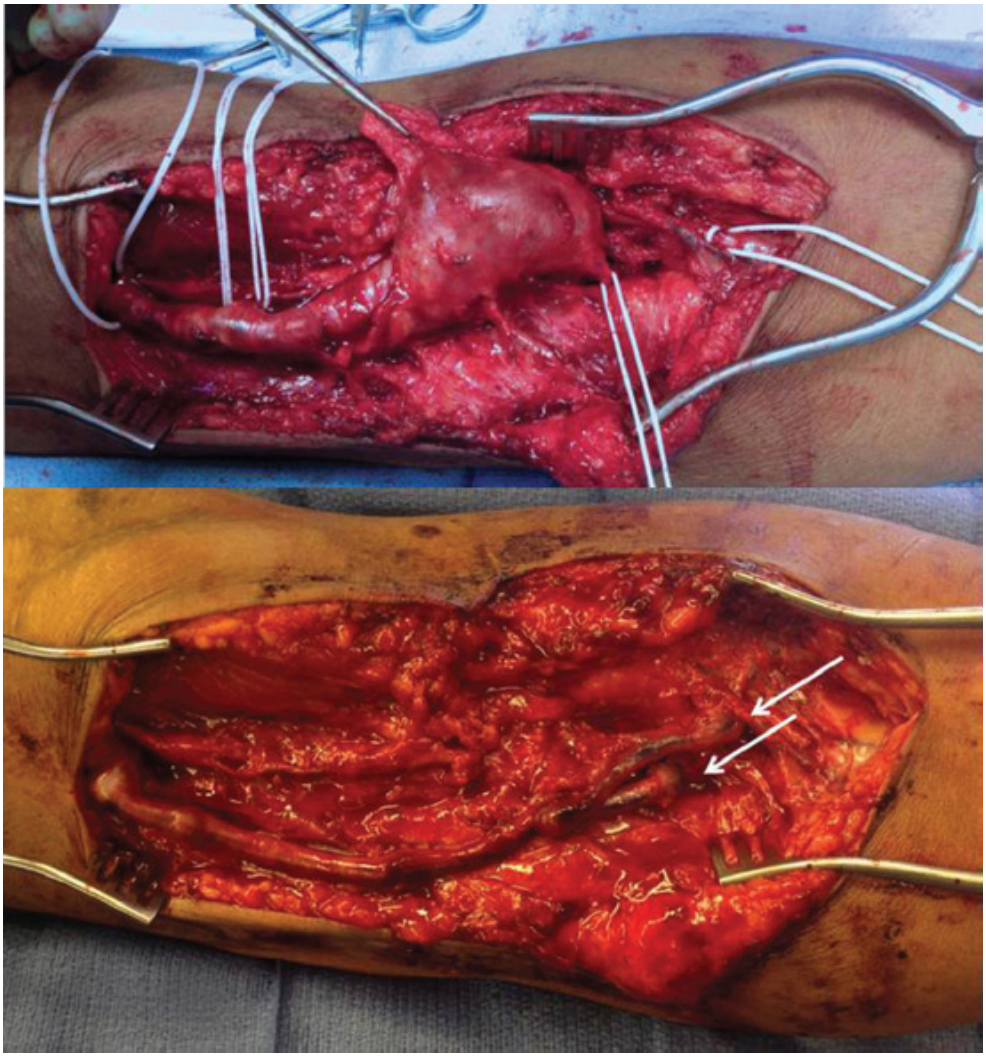

Figure 88.14 Large aneurysm of the distal brachial artery treated with a bifurcated bypass created with great saphenous vein. The distal anastomosis (*arrows*) were created into the radial and ulnar arteries just distal to the elbow.

Patients suffering from hypothenar hammer syndrome with mild symptoms and no aneurysm can be treated nonoperatively. Padded hand protection, avoidance of further repetitive trauma, tobacco cessation (if applicable), and the use of calcium channel blockers, antiplatelet agents, and/or anticoagulation all have been tried with some degree of success. Surgical intervention can include simple ligation of the aneurysm if there is adequate collateral circulation; typically resection of the affected segment with reconstruction is required (Fig. 88.16).

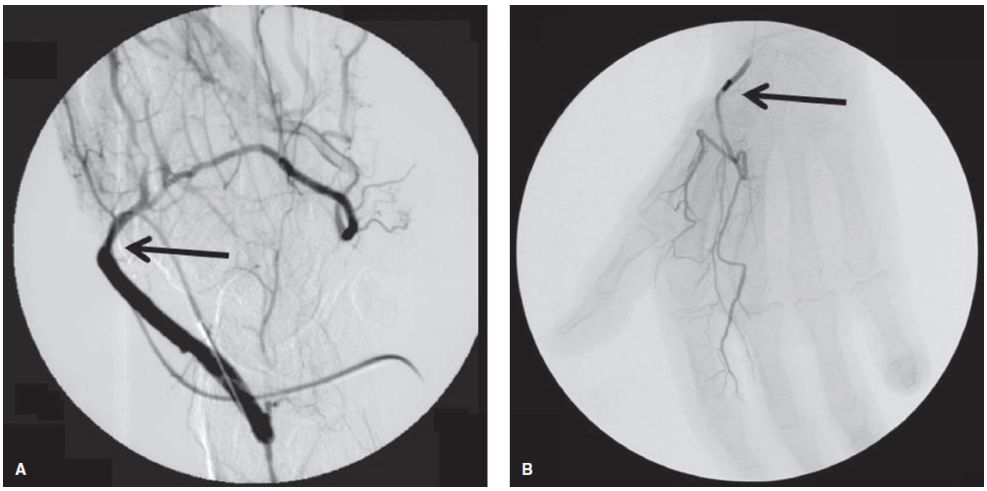

Figure 88.15 Completion angiograms of two different saphenous vein bypasses with distal anastomosis (*arrows*) to the palmar arch (**A**) and radial artery at the snuffbox segment (**B**).

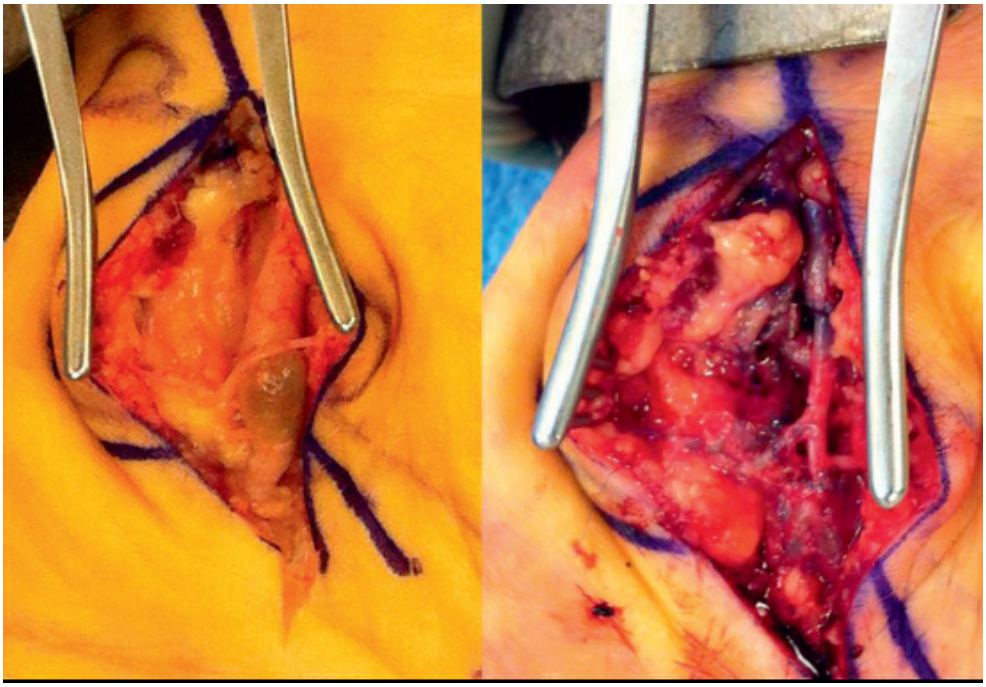

Figure 88.16 Ulnar artery aneurysm treated with arterial conduit (profunda femoris branch harvested from the thigh) in a patient with hypothenar hammer syndrome.

The management of Raynaud syndrome consists of the use of calcium channel blockers and vasodilators.[15]

CONCLUSIONS

Although atherosclerosis is still the most common cause of upper extremity arterial disease, a myriad of conditions associated with occupational, autoimmune, and social risk factors are often the cause of arm and hand ischemia. A complete history and physical examination often discloses a potential etiology and usually points to the anatomic location of the culprit lesion. Bilateral hand ischemia is often associated with systemic conditions, whereas unilaterality more commonly occurs with obstructive lesions. Accurate delineation of the anatomy by the use of imaging modalities is necessary in order to plan revascularization. Multiple endovascular and open surgical options are available for the management of upper extremity arterial disorders.

Renal and Splanchnic Vascular Disease

Dawn M. Coleman, John E. Rectenwald, and Gilbert R. Upchurch Jr

Key Points

1 Splanchnic vascular disease is uncommon across the spectrum of vascular surgery practice, but remains central to the specialty.

2 Intestinal ischemia may result from pre-splanchnic conditions that decrease total mesenteric blood flow (i.e., heart failure and hypovolemia), splanchnic conditions that decrease regional blood flow through the mesenteric circulation (i.e., thromboembolism) or post-splanchnic venous congestion (i.e., mesenteric vein thrombosis and cirrhosis).

3 The most common causes of acute mesenteric ischemia (AMI) include: embolization (40% to 50%), arterial thrombosis (25% to 30%), nonocclusive mesenteric ischemia (15% to 20%), and mesenteric venous thrombosis (5% to 15%).

4 Patients with AMI warrant immediate medical management that includes the establishment of adequate intravenous access and hemodynamic monitoring, systemic anticoagulation with heparin, fluid resuscitation, correction of electrolyte abnormalities, and administration of broad-spectrum antibiotics.

5 The progression from minor symptoms to AMI and intestinal infarction is unpredictable; almost half of patients presenting with AMI describe previous symptoms of chronic mesenteric ischemia (CMI).

6 Distribution of splanchnic artery aneurysms is as follows: Splenic artery (60%) > hepatic arteries (20%) > superior mesenteric artery (5.5%) > celiac artery (4%) and gastric and gastroepiploic arteries (4%) > ileocolic arteries (3%) > pancreaticoduodenal arteries (2%) > gastroduodenal artery (1.5%) > inferior mesenteric artery (<1%).

7 Renal artery occlusive disease is the most common cause of correctable hypertension (HTN) in adults and the third most common cause of HTN in children and should be considered in the clinical context of: (1) childhood HTN, (2) severe HTN in women <45 years of age, (3) acute and rapid escalation of mild HTN in older patients (>50 years), (4) initial diastolic BP >115 mm Hg, and (5) rapid deterioration in renal function following the administration of antihypertensive therapy (especially with ACE inhibition).

8 Medical therapy remains the mainstay of treatment for renovascular hypertension (RVH) with comprehensive goals of care that should encompass glycemic control, cholesterol reduction, smoking cessation, blood pressure reduction, and antiplatelet therapy with aspirin for primary prevention. ACC/AHA guidelines support the use of Angiotensin converting enzyme inhibitors (ACE-I), angiotensin receptor blockers (ARBs), calcium channel blockers, and beta blockers with a class I indication.

9 Several recent clinical trials comparing renal artery stenting to best medical management for renal artery stenosis have failed to demonstrate a conclusive clinical benefit to the endovascular treatment of renal artery stenosis.

SPLANCHNIC VASCULAR OCCLUSIVE AND ANEURYSMAL DISEASE

Introduction

1 Spl anchnic vascular disease is uncommon across the spectrum of vascular surgery practice, but remains central to the specialty. Patients often seek medical attention from alternative specialists, emphasizing the

importance of cross-disciplinary awareness. Acute mesenteric ischemia (AMI) remains associated with delayed diagnosis and dismal mortality despite notable progress in the diagnosis and treatment of patients with vascular disease. This section elaborates on the current treatment standards for both splanchnic vascular occlusive disease and aneurysms.

Anatomy and Physiology

Three branches of the abdominal aorta perfuse the gastrointestinal tract. The celiac artery originates at the level of T12 and branches into the left gastric, common hepatic and splenic arteries in a classic pattern in 65% to 75% of cases.[1] Variations are noted in Table 89.1 and may include a true trifurcation of these vessels (25% of the population), replaced and accessory hepatic vasculature, a common celiacomesenteric trunk (<1% of the population), and a persistent ventral anastomosis between the proper hepatic, and a replaced right hepatic artery (off the SMA) denoted as an "arch of Buhler" (<4% of the population). Additionally, the splenic artery can be found to originate directly off the aorta, SMA, left gastric or hepatic arteries. The celiac axis supplies primarily the stomach, duodenum, spleen, liver, and pancreas. The SMA originates approximately 1 to 2 cm caudad to the celiac artery and branches into the inferior pancreaticoduodenal artery, 4 to 6 jejunal and 9 to 13 ileal branches, the middle colic artery, the right colic artery, and terminates as the iliocolic artery. The SMA supplies primarily the lower portion of the pancreas gland, jejunum, ileum, ascending colon, and the proximal half of the transverse colon. The inferior mesenteric artery (IMA) originates off the terminal aorta at the level of L3 and divides into the left colic artery, sigmoid branches and continues as the superior hemorrhoidal artery.[1] This small and most distal mesenteric branch artery supplies primarily the large bowel from the level of the mid-transverse colon to the rectum.

Table 89.1 Normal and Variant Mesenteric Arterial Anatomy

Vessel	Incidence (%)
Celiac	
▪ Classic (3 branches)	65–75
▪ Four branches (including dorsal pancreatic artery)	5–10
▪ Celiacomesenteric trunk	<1
Hepatic	
▪ CHA from celiac artery	75
▪ CHA from SMA	2.5
▪ Replaced RHA	15–18
▪ From left gastric	11–12
▪ From SMA	2.5
▪ Accessory RHA	7–8
▪ Accessory LHA	2.5
Gastric	
▪ Left gastric artery	
▪ From celiac artery	90
▪ From aorta	3
▪ Accessory branches from or to left hepatic artery	23
▪ Right gastric artery	
▪ From proper hepatic artery	40
▪ From left or middle hepatic artery	40
▪ From RHA	10
▪ From GDA	8

CHA, common hepatic artery; SMA, superior mesenteric artery; RHA, right hepatic artery; LHA, left hepatic artery; GDA, gastroduodenal artery.
Adapted from Rosenblum JD, Boyle CM, Schwartz LB. The mesenteric circulation: anatomy and physiology. *Surg Clin North Am* 1997;77:289–306.

Collateralization is a crucial concept when considering the mesenteric circulation. On the grounds of redundancy, given multiple potential sources of collateral flow, at least two of the three major branch vessels must be occluded or have a critical stenosis for mesenteric ischemia to manifest. While arterial collaterals may be small in the physiologic circulation, they have the potential to hypertrophy dramatically when increased flow is required. Figure 89.1 demonstrates several important collateral pathways. The gastroduodenal artery (GDA) and pancreaticoduodenal arcade make up the primary potential pathway for collateral flow between the celiac axis and the SMA. In addition to the aforementioned arc of Buhler, the

arc of Barkow consists of arteries in the omentum (SMA branches) that connects to the right and left gastroepiploic arteries (celiac branches). The marginal artery of Drummond is the major collateral route between the SMA and IMA; it lies within the colon mesentery giving rise to the vasa recta. The arc of Riolan lies within a more central portion of the mesentery connecting the middle and left colic arteries. Finally, the IMA may also receive collateral flow from lumbar branches of the aorta, hemorrhoidal branches of the internal iliac artery, and the middle sacral artery.

Splanchnic venous anatomy parallels the arterial system to drain into the portal venous system. The splenic and superior mesenteric veins join to form the portal vein. Hepatic venous blood is drained by the right, middle, and left hepatic veins. Portal–systemic connections are multiple and important when considering portal hypertension.

Physiologic intestinal function relies on adequate perfusion and oxygenation of the microvascular splanchnic circulation. Splanchnic blood flow is estimated as 300 to 1,200 mL/min, or about 10% to 35% of the cardiac output, with approximately 70% of this blood flow supplying the mucosa and submucosa.[1,2] Various intrinsic and extrinsic autoregulatory mechanisms including tissue metabolites, myogenic mechanisms, and the autonomic nervous system ensure adequate gut circulation through both vasoconstriction and relaxation of arterial smooth muscle. The degree of visceral artery dilation and constriction determines the relatively large fluctuations in splanchnic blood flow during fasting and postprandial states.

Duplex ultrasound demonstrates moderate to high arterial resistance in the SMA, with low diastolic flow and slight flow reversal during fasting states. Figure 89.2 demonstrates duplex ultrasonography of normal aorta and SMA. Vessel diameter, flow velocity, calculated volumetric blood flow, spectral analysis, and response to physiologic stimuli allow for precise assessment of the visceral circulation. In the postprandial period (30 to 90 minutes), low-resistance signals are noted throughout systole and diastole, indicative of dilated splanchnic arteriolar beds. Flow reversal does not occur. In contrast, low arterial resistance signals are noted in the celiac artery circulation regardless of feeding, likely due to the influence of the low-resistance hepatic vascular bed.

2 Intestinal ischemia may result from presplanchnic conditions that decrease total mesenteric blood flow (i.e., heart failure and hypovolemia), splanchnic conditions that decrease regional blood flow through the mesenteric circulation (i.e., thromboembolism) or postsplanchnic venous congestion (i.e., mesenteric vein thrombosis [MVT] and cirrhosis). Regardless of the mechanism, impaired perfusion of the intestine results in hypoxia-associated sequelae that include cytokine release, free radial production, microcirculatory damage, and bacterial translocation. Mucosal barrier function is compromised secondary to physical disruption of the mucosa, a change in normal intestinal microflora resulting from treatment with broad-spectrum antibiotics, and impairment of host immune defenses.[3] Intestinal ischemia may rapidly progress to tissue necrosis causing severe metabolic derangements and ultimately multiple organ dysfunction and death. In addition to ischemia-related bowel injury, splanchnic reperfusion exaggerates injury patterns. Reperfusion injury is associated with increased microvascular permeability, increased epithelial permeability with leaking of fluid and molecules into the bowel lumen, and decreased intestinal blood flow.

Acute Mesenteric Ischemia

> *"Occlusion of the mesenteric vessels is apt to be regarded as one of those conditions of which . . . the diagnosis is impossible, the prognosis hopeless and the treatment almost useless."*[4]

AMI remains an uncommon event but carries catastrophic potential as illustrated by AJ Cokkinis' statement above from 1926. Klass is credited with the first successful restoration of arterial blood supply in an attempt to salvage AMI in 1951 by SMA embolectomy.[5,6] While clear medical and technologic progress has been made in the interim, delayed diagnosis and treatment continues to impede improvements in contemporary patient morbidity and mortality rates that approach 80%.[6,7]

AMI accounts for <1 in every 1,000 hospital admissions, presents most commonly during the seventh and eighth decades of life, and epidemiologic study suggests that women are affected with three times the frequency of males, at least in part attributed to relative female longevity.[6] A Swedish epidemiologic study cites an AMI incidence of 12.9/100,000 people years (as diagnosed by autopsy or operation).[8]

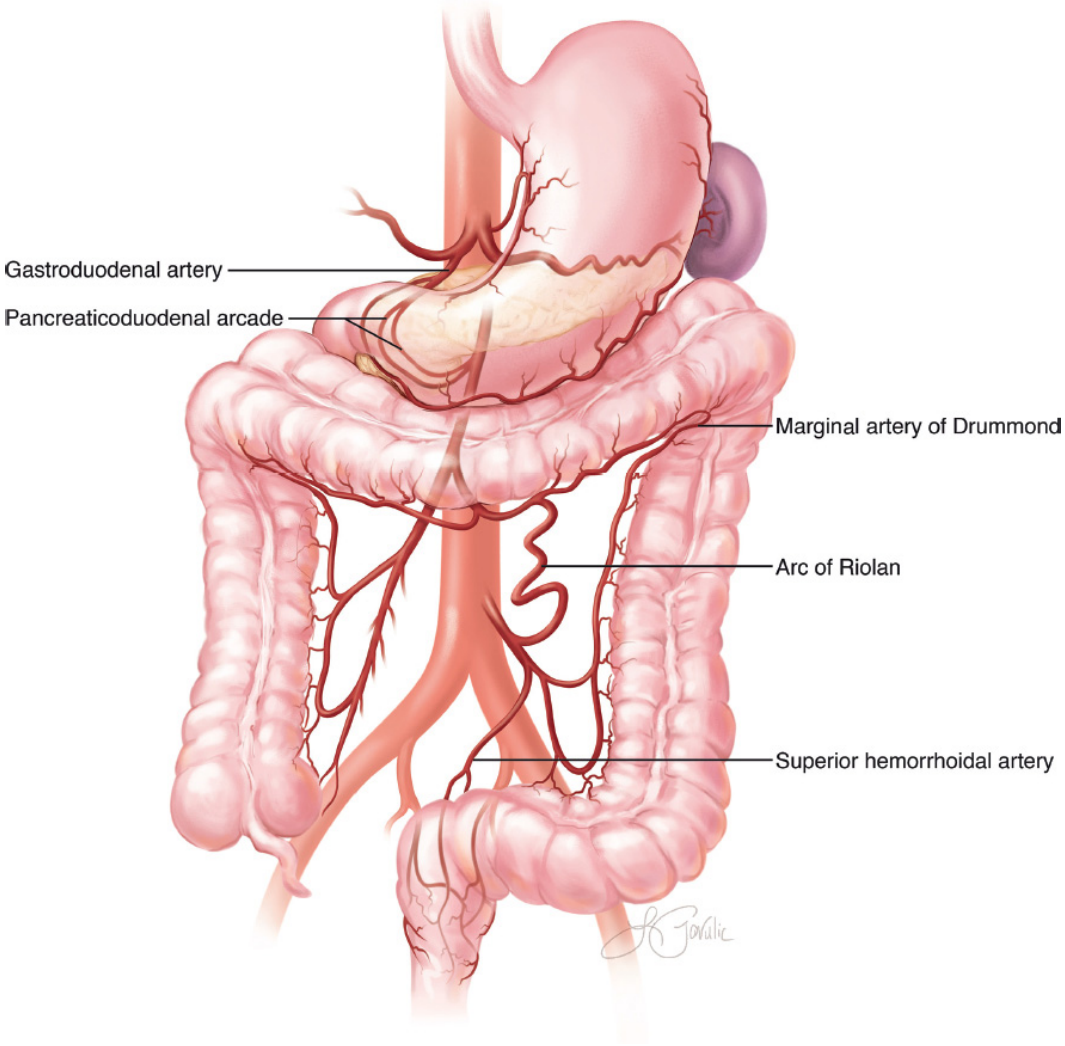

Figure 89.1 Mesenteric collateral circulation.

3 The most common causes of AMI are referenced above and include: embolization (40% to 50%), arterial thrombosis (25% to 30%), nonocclusive mesenteric ischemia (NOMI) (15% to 20%), and mesenteric venous thrombosis (5% to 15%).[6,8] Additional causes may include visceral malperfusion associated with aortic dissection, mesenteric arterial dissection, and trauma. Historic mortality rates for AMI are as high as 93%, although more contemporary series suggest in-hospital mortality rates of 17% to 62% and a systematic review of 45 observational studies cites a mean mortality rate of 71.6% for 3,692 patients with AMI.[8–13] While there is no validated prediction model for mortality in this clinical setting, authors have shown with logistic regression models that age, duration of symptoms, age-adjusted comorbidity, specific EKG markers, and shock index may be associated with higher mortality.[12,14,15]

Patients with AMI complain predominantly of abdominal pain followed by nausea, vomiting, and diarrhea. Pain is often described as "out of proportion" to the clinical examination as tenderness to palpation may be minimal until transmural necrosis of the intestine develops. Patients can be tachycardic

and demonstrate melena or heme-positive stools. Fever, guarding, and rebound are typically late findings associated with bowel infarction.

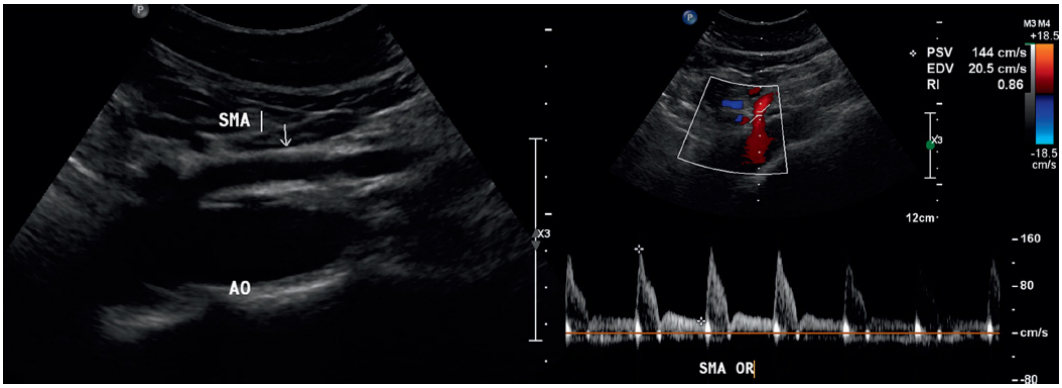

Figure 89.2 Mesenteric duplex ultrasound of a normal aorta and SMA that demonstrates moderate to high arterial resistance in the SMA, with low diastolic flow and slight flow reversal during fasting states. AO, aorta; SMA, superior mesenteric artery; PSV, peak systolic velocity; EDV, end-diastolic velocity; RI, resistive index; OR, origin.

Laboratory abnormalities may include hemoconcentration, leukocytosis, lactic acidosis, and elevated anion gap, amylase, aspartate aminotransferase, and lactate dehydrogenase. While a reliable biomarker for AMI remains elusive, D-dimer offers 96% to 100% sensitivity as an exclusionary test for early AMI with low specificity.[16,17] Intestinal fatty acid binding globulin (I-FABP), α-glutathione S-transferase, and D-lactate are currently promising plasma markers.[16,18] I-FABP and α-glutathione S-transferase are located in the small bowel mucosa while D-lactate originates from bacteria in the intestinal lumen as a normal product of bacterial fermentation. These markers leak into the blood stream during early ischemia from damaged enterocytes and may offer increased specificity for small bowel ischemia.

Diagnostic work-up often starts with a plain abdominal radiograph which may reveal ileus and vascular calcifications; bowel wall edema (i.e., thumbprinting), pneumatosis (Fig. 89.3), pneumobilia, and pneumoperitoneum may become evident with advanced ischemia and infarction, respectively. High-quality computed tomography angiography (CTA) has become the gold standard for imaging AMI given near-universal availability and its ability to assess for bowel perfusion while excluding alternate sources of abdominal pain. Additionally, "biphasic" CT offers arterial and delayed phase imaging that permits visualization of the portal venous system in addition to arterial stenosis, occlusions, and bowel wall features that support the diagnosis of AMI with a negative and positive predictive value reported up to 96% and 100%, respectively.[19,20] Duplex ultrasonography, magnetic resonance angiography (MRA), and diagnostic laparoscopy may serve as adjuncts for diagnosis but secondary to intrinsic limitations should not be considered first line. Finally, the role for arteriography remains important and will be described further as it allows for simultaneous therapeutic measures.

Mesenteric emboli most commonly affect the SMA given its oblique orientation off the aorta. Most emboli are cardiac in origin; less common embolic sources may include proximal aortic aneurysm, atrial myxoma, and paradoxical embolus secondary to venous thromboembolism with cardiac shunting. Patient history will likely reveal atrial fibrillation, myocardial infarction, congestive heart failure or cardiomyopathy, rheumatic heart disease or ventricular aneurysm. Most emboli will spare the SMA origin and lodge distal to the middle colic artery and early jejunal branches. This pattern of ischemia, in the absence of well-formed collaterals, results in a classic pattern of ischemia that compromises the bulk of small bowel and ascending colon while sparing the proximal jejunum and distal transverse colon (Fig. 89.4).

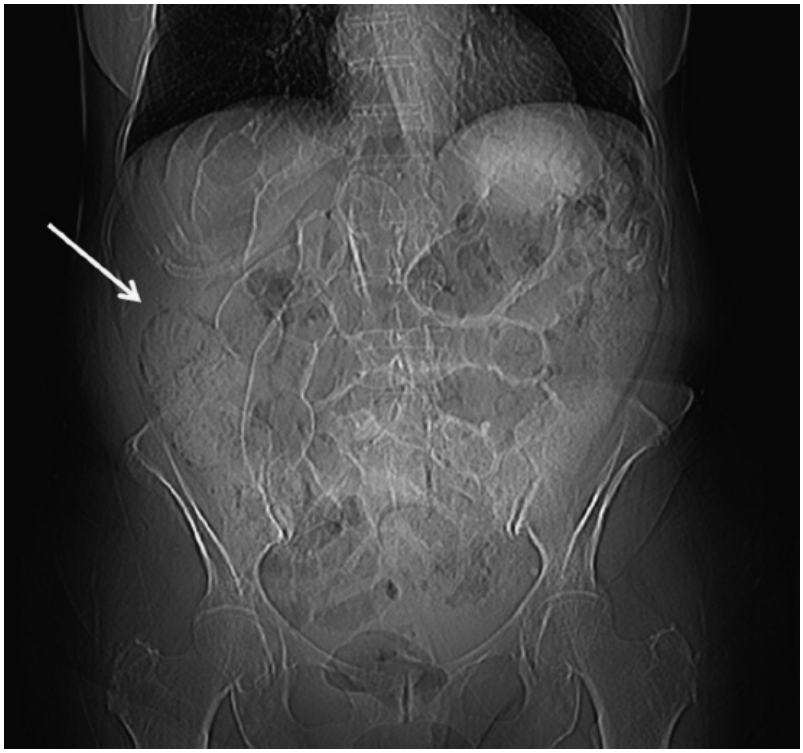

Figure 89.3 Abdominal radiograph demonstrating diffuse ileus and intestinal pneumatosis (*arrow*) in a patient with acute mesenteric ischemia.

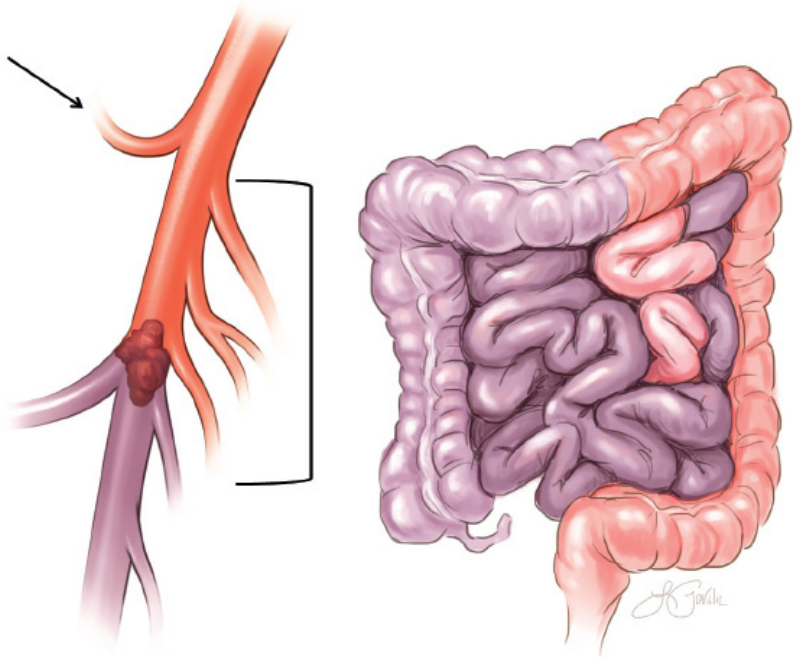

Figure 89.4 Pattern of embolic mesenteric ischemia—SMA emboli typically spare the middle colic artery (*arrow*) and proximal jejunal branches (*bracket*) resulting in an ischemic pattern that spares the jejunum and distal transverse colon.

Acute in situ arterial thrombosis typically coincides with pre-existing atherosclerotic disease. Up to 20% to 50% of patients will describe antecedent postprandial abdominal pain and weight loss consistent with CMI.[2,6,9] Clinical presentation may be more subacute given the presence of preformed collaterals that are

typically absent in cases of embolic AMI. Patient history will likely reveal common cardiovascular risk factors. Figure 89.5 demonstrates the highly calcified aorta of a patient presenting with AMI and chronic celiac artery occlusion, SMA thrombosis (encircled), and IMA occlusion.

Management of AMI

4 Patients with AMI warrant immediate medical management that includes the establishment of adequate intravenous (IV) access and hemodynamic monitoring, systemic anticoagulation with heparin, fluid resuscitation, correction of electrolyte abnormalities, and administration of broad-spectrum IV antibiotics. Further vasoconstrictive insult with vasopressors should be avoided if possible. Patients with AMI and evidence of threatened bowel viability warrant immediate surgical exploration. Frankly necrotic or perforated bowel should be resected and left in discontinuity to limit contamination while definitive intestinal management should never delay revascularization.

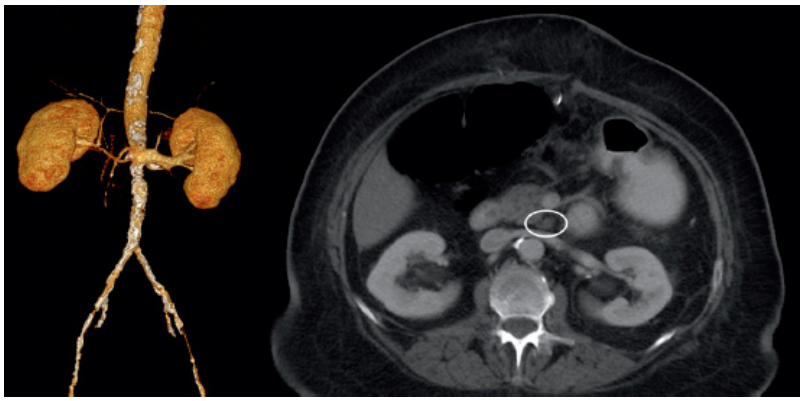

Figure 89.5 CT imaging demonstrating in situ SMA thrombosis in the setting of highly calcified aortoiliac occlusive disease and chronic celiac and IMA occlusions presenting as acute mesenteric ischemia.

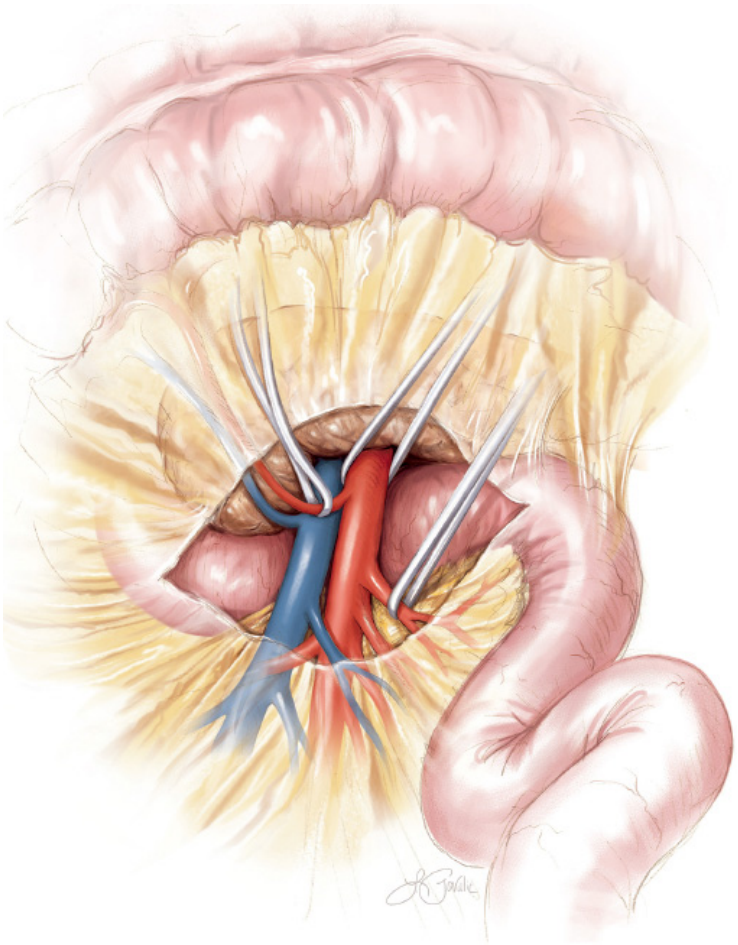

Figure 89.6 SMA exposure at the base of the colonic mesentery (*SMA encircled proximal to the middle colic artery*).

SMA thromboembolectomy is the standard technique for embolic disease. Figure 89.6 illustrates anterior exposure of the SMA at the base of the colonic mesentery. Typically, venous tributaries, small lymphatics, and autonomic nerve fibers require ligation to facilitate arterial exposure. The inferior pancreatic border may require mobilization for more proximal SMA exposure. The SMA is exposed and controlled proximal to the middle colic artery; the middle colic artery and jejunal branches are similarly controlled. After a therapeutic level of systemic anticoagulation is confirmed a transverse arteriotomy is created sharply (Fig. 89.7). The proximal SMA is vented; in the absence of robust and pulsatile antegrade flow a balloon thromboembolectomy should be performed with a 3-Fr or 4-Fr catheter. Distal vasculature is fragile and thromboembolectomy is best accomplished with a smaller catheter (i.e., 2 Fr or 3 Fr). During balloon thromboembolectomy the balloon should be inflated with heparinized saline (not air) as the catheter is withdrawn. The same person should control the balloon inflation that is controlling catheter removal. Finally, consider flushing regional heparin or thrombolytic agent directly into the distal SMA and branches. Balloon thromboembolectomy should be repeated until the balloon is withdrawn free of thrombus burden. Following the successful clearance of all macroscopic thrombus the arteriotomy can be repaired primarily with simple sutures of 5-0 or 6-0 monofilament suture placed in an interrupted fashion. Vein patch angioplasty should be considered over primary repair for diminutive vessels.

In cases of SMA occlusive disease with in situ thrombosis, bypass is typically required for successful revascularization. In cases of such acuity, typically single-vessel reconstruction (SMA) is all that is required. While there are multiple options for graft orientation and conduit, a retrograde bypass off the right common iliac artery oriented in a “lazy-C” configuration is most often favored (Fig. 89.8). The lateral

portion of SMA is exposed cephalad to the fourth portion of the duodenum. This exposure requires opening of the peritoneum adjacent to the duodenum with full exposure of the terminal aorta and iliac arteries. Synthetic graft (i.e., 6- or 8-mm externally supported polytetrafluoroethylene) is typically favored over autogenous conduit given its favorable size match, ready availability, and resistance to kinking. Saphenous vein graft may be considered for cases of gross enteric contamination. The terminal aorta or left common iliac artery may also be used for inflow. Antegrade bypass off the supraceliac aorta may be considered in cases of prohibitive anatomy. While this exposure adds additional technical complexity and operative time combined with the physiologic stress of aortic cross-clamping, contemporary data supports a lower risk of reintervention with an antegrade configuration.[21]

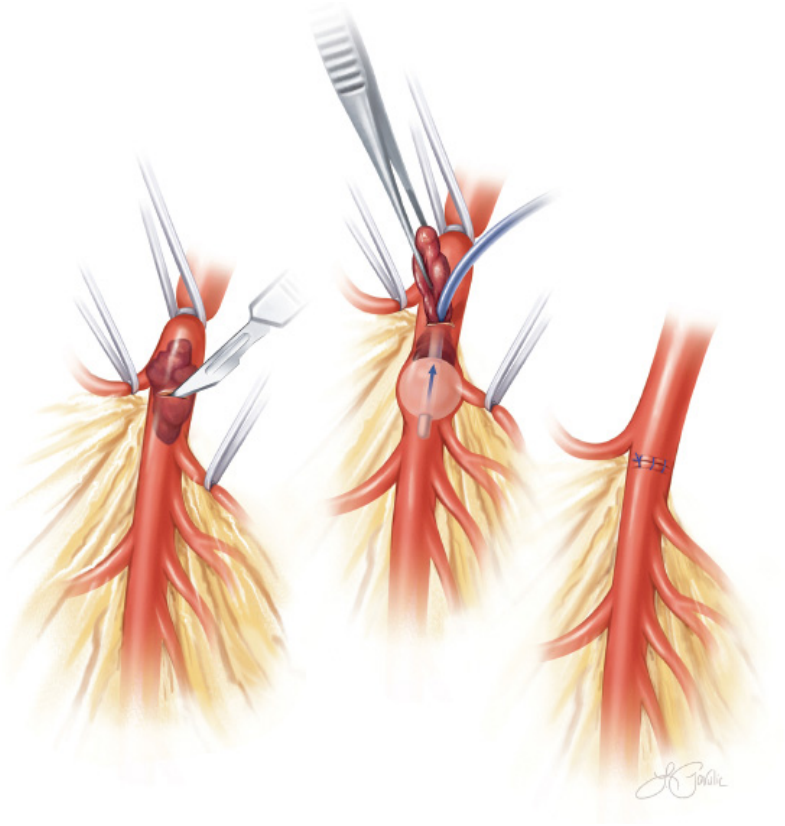

Figure 89.7 Illustration of balloon SMA thromboembolectomy through a transverse arteriotomy.

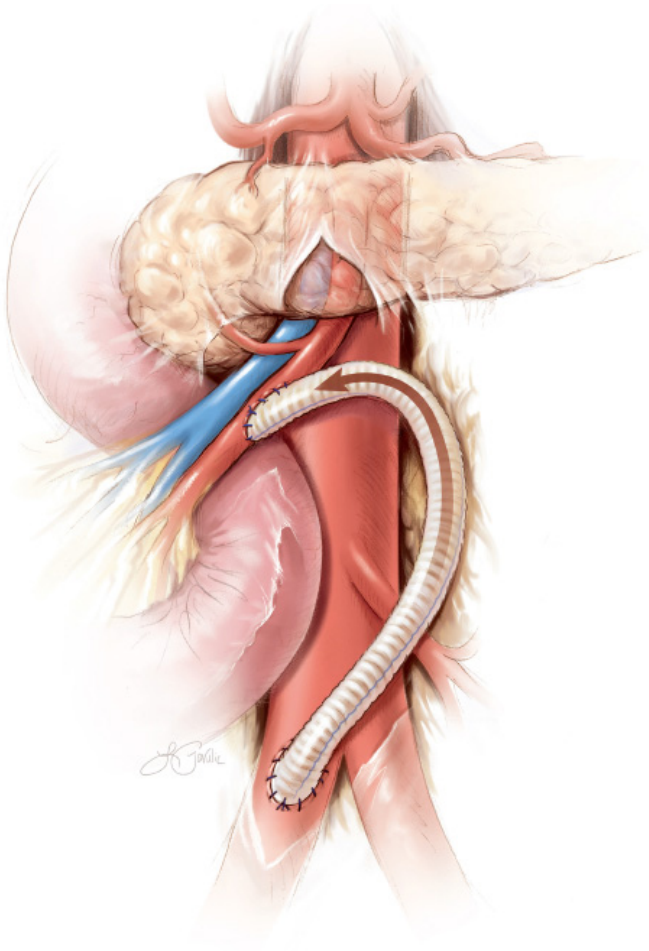

Figure 89.8 Retrograde bypass off the right common iliac artery oriented in a "lazy-C" configuration.

While surgery has remained the standard of care for AMI over previous decades, a hybrid procedure for SMA thrombosis has become widely embraced for its efficiency and decreased invasiveness for mesenteric revascularization. This approach negates the need for aortic cross-clamping, prosthetic conduit, and difficulty with arterial quality. Retrograde open mesenteric stenting (ROMS) was first described by Milner et al. in 2006 and further popularized by Wyers et al. in a 2007 case series.[22,23] The infracolic SMA is exposed at the base of the transverse colonic mesentery as previously described for retrograde cannulation following local patch angioplasty with vein or bovine pericardium. This hybrid approach allows for simultaneous assessment and treatment of nonviable intestine with mesenteric revascularization by way of SMA stenting. Contemporary series on ROMS report technical success rates of 93% and primary-assisted patency rates of 91% at 12 months with similar complication and reintervention rates when compared to mesenteric bypass with significantly reduced operative times.[24,25]

Regardless of the approach to successful revascularization, intestinal viability must be assessed; this decision is typically deferred for 20 to 30 minutes following reperfusion and aided by Doppler interrogation of the mesenteric arcade, observation of serosal color, and the presence of peristalsis. Adjuncts also include the use of fluorescein with a modified Wood's lamp or perfusion fluorometer.[6] Nonviable bowel is resected and in cases of unclear viability the intestine may be left in discontinuity, the abdomen left open, and plans for a second-look laparotomy at 24 to 48 hours secured for definitive intestinal management. Postoperative complications and mortality rates are high following open revascularization for AMI. Thirty-day mortality rates approximate 30%, with morbidity rates as high as 70%.[26,27]

Exclusive endovascular treatments for AMI are increasingly reported despite historic concerns that this approach increases time to revascularization, prohibits assessment of bowel viability, and that endovascular failure might delay traditional revascularization thereby worsening patient outcomes. Successful cases of percutaneous mechanical thrombectomy, aspiration thrombectomy, and intra-arterial thrombolysis, with or without adjuvant angioplasty and stenting, have been reported in patients without evidence of advanced bowel ischemia.[28–33] The largest single center experience with endovascular therapy for AMI reported a success rate of 87%, with failures most often requiring surgical embolectomy.[34] These authors compared outcomes following open and endovascular therapies for AMI and identified a reduction in need for laparotomy, length of bowel resected, and morbidity including acute renal failure and pulmonary failure in the endovascular group. Additionally, successful endovascular therapy was associated with improved mortality (36% vs. 50%) and those endovascular failures succumbed to similar mortality rates as the open surgical group. Most recently a National Inpatient Sample (NIS) review identified a significant increase in the utilization of endovascular therapy for AMI and reported that mortality, hospital length of stay, need for bowel resection, and need for postoperative parenteral nutrition were reduced in those patients receiving endovascular therapy in comparison to traditional open surgical revascularization.[35]

Nonatherosclerotic Mesenteric Arterial Occlusive Disease

Intestinal ischemia may result from iatrogenic injury (i.e., arterial dissection or thromboembolism during endovascular techniques), aortic dissection resulting in visceral malperfusion, trauma, inflammatory arteritides, and fibromuscular dysplasia (FMD). Indeed, these patients warrant an individualized approach to treatment. In cases of aortic dissection branch revascularization or aortic fenestration is essential. Traumatic injuries often require urgent surgical repair or revascularization. Inflammatory arteritides are typically managed medically (i.e., immunosuppression) with surgical bowel resection reserved for nonviability.

Mesenteric Vein Thrombosis

Splanchnic vein thrombosis is defined by thrombosis of the portal venous system which includes the superior mesenteric, inferior mesenteric, splenic, and portal veins. The sequelae of such may include bowel or splenic infarction and chronic portal hypertension. MVT is a less common form of intestinal ischemia that may present in a more subacute fashion. While AMI symptoms are similar to those aforementioned, patients with MVT may also complain of days to weeks of a prodrome that includes crampy abdominal pain, distension, nausea, and malaise. Whether thrombosis originates in the small or large splanchnic veins, intestinal infarction requires the involvement of venous arcades and vasa recta resulting in occlusion of venous return, venous engorgement of the bowel wall, cyanosis, and mucosal ischemia that can progress to transmural infarction.[36] Idiopathic MVT represents a minority of cases as more than 50% of patients have at least one predisposing risk factor. Risk factors for MVT include heritable and acquired thrombophilia, hypercoagulable states resulting from systemic disorders (including malignancy and heparin-induced thrombocytopenia), and local intra-abdominal processes (i.e., pancreatitis or trauma). A high index of suspicion is necessary for diagnosis given the nonspecific nature of presenting symptoms, signs, and laboratory studies.[36] CT imaging with portal phase venous contrast (CT venogram) is the imaging modality of choice. Findings suggestive of MVT include a sharply defined, enhancing venous wall with central low attenuation.[36,37] MRA, angiography, and laparoscopy are useful adjuncts. Emergent laparotomy should be considered for signs of advanced intestinal ischemia; intraoperatively blood-tinged ascites is likely to be encountered and the bowel will appear dusky, thick, and rubbery. Systemic anticoagulation is the mainstay of treatment as it reduces mortality, decreases recurrent thrombosis rates from approximately 30% to <5%, and decreases mortality associated with recurrent thrombosis.[36,38–41] Additionally, with anticoagulation most patients will demonstrate partial or complete venous recanalization with time. In the absence of a defined risk factor, patients with MVT should undergo a work-up for thrombophilia. A finite duration of anticoagulation is recommended for those with a reversible provoking risk factor with cessation of anticoagulation encouraged after 3 months; remaining cases of idiopathic MVT or persistent risk warrant indefinite anticoagulation.[42] Historically open venous thrombectomy was employed for advanced cases of

MVT at the time of laparotomy. More recently various systemic and percutaneous thrombolytic techniques have been applied to cases of large vessel disease; however, no large or well-controlled trials exist to guide recommendations for such over anticoagulation alone.[36,43–46]

Nonocclusive Mesenteric Ischemia

NOMI results from diffuse mesenteric vasospasm. This rare form of intestinal ischemia most often affects critically ill patients with hemodynamic instability. Risk factors include decreased cardiac output (i.e., heart failure or arrhythmia), hemodialysis, shock, vasoactive medications (i.e., vasopressors or digitalis), and drug abuse (i.e., cocaine). Angiography is required for diagnosis and will demonstrate diffuse vasoconstriction and nonopacification of branch vessels (Fig. 89.9). Treatment centers on improving mesenteric perfusion by optimizing volume status, limiting vasoactive medications and correcting contributing comorbidities. Intra-arterial infusion of vasodilators (i.e., papaverine or nitroglycerin) or IV infusion of glucagon or prostaglandin E2, which selectively increases splanchnic blood flow, have been advocated in treating this form of intestinal ischemia without robust, large, or well-controlled trials to support treatment guidelines.[47–49]

Figure 89.9 Nonocclusive mesenteric ischemia—mesenteric arteriogram revealing diffuse vasoconstriction and nonopacification of SMA branch vessels.

Chronic Mesenteric Ischemia

Symptoms of CMI are often referred to as "intestinal angina." Ostial stenosis secondary to arteriosclerosis is the most common etiology and patients typically share risk factors of overt atherosclerosis and long-standing tobacco abuse. Additional causes of CMI may include arterial FMD, vasculitis, aortic coarctation, and connective tissue disorders. In light of aforementioned mesenteric collaterals, the responsible anatomic lesions of CMI typically affect at least two of three splanchnic arteries, although isolated lesions of the SMA distal to the middle colic branch may yield intestinal angina by excluding collateralization.[2] Patients classically present with postprandial abdominal pain that occurs within 30 minutes of eating and may last up to 4 hours postprandial. Consistent postprandial symptoms typically result in the modification of eating habits that may range from the consumption of smaller meals to "food phobia" that subsequently results in weight loss and malnutrition. There is an increasing incidence of overweight patients presenting with CMI. These patients have been reported to undergo significantly more diagnostic testing to confirm the diagnosis of CMI, possibly delaying diagnosis.[50] Additionally, BMI ≥25 has been associated with poorer long-term survival following mesenteric revascularization for CMI in comparison to nonobese patients.[51]

5 The progression from minor symptoms to AMI and intestinal infarction is unpredictable; almost half of patients presenting with AMI describe previous symptoms of CMI.[52] The incidence of CMI also remains unclear. Population studies suggest that up to 18% of individuals over 65 years of age have asymptomatic radiographic mesenteric stenosis.[53] Duplex ultrasonography should be considered the first-line diagnostic modality for CMI. Specifically, high-grade stenosis of the SMA and celiac artery in a fasting state are suggested by a peak systolic velocity of >275 cm/s and 200 cm/s, respectively.[54] CTA and MRA support the diagnosis of CMI while offering additional vascular anatomic evaluation such as the presence of aneurysm, calcific burden, dissection, wall features suggesting vasculitis and venous anomalies that may impact open reconstruction. An additional advantage of MRI is the opportunity to perform blood flow measurements (i.e., measurements of flow profiles, stroke volumes, peak velocities).[55] Importantly, mesenteric blood flow will increase after a meal in healthy controls, while significantly less increase in postprandial blood flow of the SMV in patients with CMI can be shown with MR flow technique.[56] Aortography with anteroposterior and lateral views has been commonly cited as the gold standard for diagnosis and allows for simultaneous mesenteric arteriography, manometry, provocative measures (i.e., vasodilator infusion), and intervention (i.e., angioplasty and stenting) as appropriate. This modality is often favored over cross-sectional imaging when an endovascular approach for treatment is being considered over open revascularization. Growing data suggest there may be a role for additional work-up, especially in those patients with single-vessel mesenteric stenosis, to guide the decision to perform revascularization. Pressure measurements may help define a clinically relevant CA or SMA stenosis, with a pressure distal [Pd]/pressure aorta [Pa] ratio of 0.8 following vasodilator administration supporting clinically significant mesenteric stenosis.[57] Functional work-up to assess gastrointestinal mucosal perfusion may include PCO_2 tonometry and visual light spectroscopy. Often patients will present having undergone extensive gastrointestinal work-up (i.e., contrast motility studies, endoscopy) before the diagnosis of CMI is considered.

Management of CMI

Treatment goals in the management of CMI include symptomatic relief, restoration of normal weight, and the prevention of bowel infarction. Mesenteric revascularization provides immediate symptom relief in most patients. Classically, open surgical revascularization options consider patient cardiopulmonary reserve to tolerate aortic cross-clamping and aortic and arterial calcific burden to dictate vascular sites for clamping and sewing. Elective revascularization in the lower-risk patient favors two-vessel (i.e., celiac and SMA) antegrade reconstruction when anatomically feasible. Contingent on vessel calcification, the supraceliac aorta through a transperitoneal approach serves as a preferential target for inflow. After entering the lesser sac, division of the left triangular ligament allows for retraction of the left hepatic lobe. With the esophagus retracted toward the patient's left (confirmed by palpation of the existing nasogastric tube), transection of

the diaphragmatic crura exposes the supraceliac aorta. The celiac trunk, common hepatic artery, and splenic artery are exposed at this time. Subsequently with retraction of the transverse mesocolon cephalad, the SMA is exposed as described above at the root of the mesentery. A retropancreatic tunnel is created that courses anterior to the renal vein. The patient is systemically anticoagulated with heparin and the proximal anastomosis can be constructed with partial aortic occlusion. Most often a knitted polyester synthetic graft is utilized for conduit. There are multiple acceptable variations that include the use of two separate aortomesenteric bypass grafts (**Fig. 89.10**) or the use of a bifurcated graft. It is conventional to utilize a prefabricated bifurcated graft (e.g., 14 × 7 mm) for reconstruction. In this case a short main body is beveled to create the proximal end-to-side aortic anastomosis; the left limb is tunneled through the retropancreatic tunnel and an end-to-side distal anastomosis created next to the SMA; the right limb is subsequently cut to size and beveled to create an end-to-end anastomosis to the celiac artery directly or an end-to-side anastomosis with the common hepatic artery. These authors favor the approach presented in Figure 89.11. A limb of a bifurcated knitted polyester graft is transected off the main body in such a way that there is a phalange created. This limb is specifically utilized for creation of the aorto-SMA bypass, with the phalange incorporated into the proximal aortic anastomosis as shown. The remaining limb is cut to size and beveled accordingly; the proximal anastomosis is constructed end-to-side off the aorto-SMA bypass graft and the distal anastomosis constructed end-to-side to the common hepatic artery. This facilitates a very short celiac limb with a natural lie that may reduce the risk of limb kinking or torsion. Finally, the descending thoracic aorta may serve as an alternative source for inflow when supraceliac aortic anatomy is prohibitive or has previously been utilized for revascularization (Fig. 89.12). For those patients with comorbidity or anatomy (i.e., calcification) that precludes aortic clamping, a retrograde ilio-SMA bypass is favored as described above (Fig. 89.9).

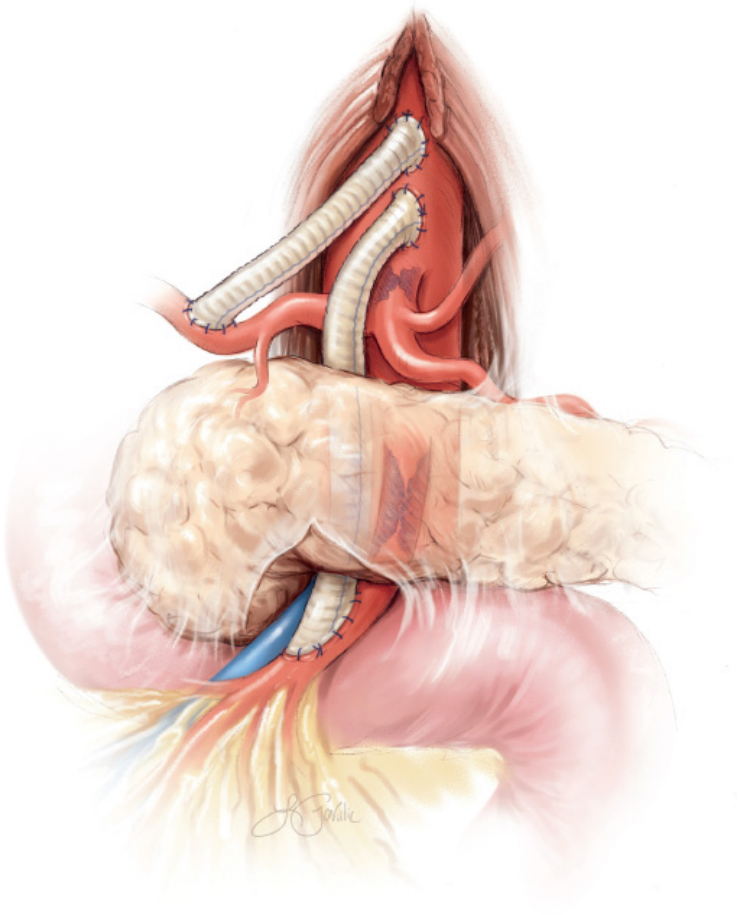

Figure 89.10 Two-vessel antegrade aortomesenteric bypass.

Transaortic endarterectomy is less often utilized in contemporary practice, but may be applicable for those patients with bowel perforation or contamination, hostile abdominal conditions (extensive adhesive disease or abdominal wall hernia), and bulky coral reef aortomesenteric plaque with lower-extremity ischemia. A retroperitoneal approach to the perivisceral aorta through a thoracoabdominal incision permits a longitudinal or trapdoor aortotomy, endarterectomy and repair with primary closure or patch aortoplasty as illustrated in Figure 89.13.

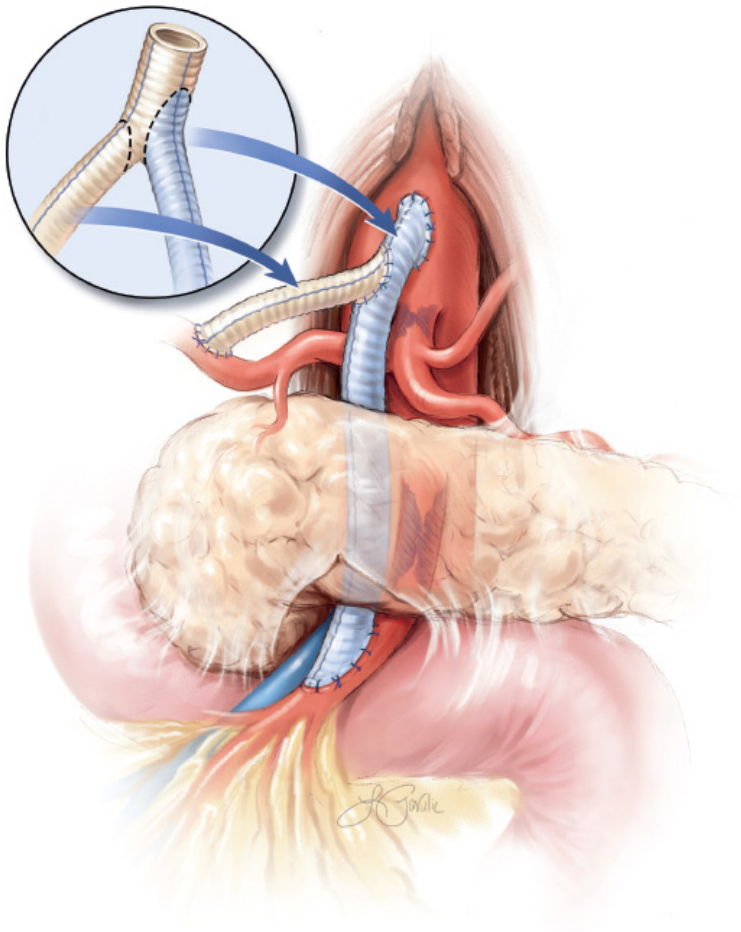

Figure 89.11 Two-vessel antegrade aortomesenteric bypass based off the supraceliac aorta using a presewn bifurcated graft.

While historically criticized for high mortality rates (up to 15%), contemporary outcomes following open mesenteric bypass at high-volume centers support mortality rates <4%, likely secondary to technical refinements, improved patient selection and advances in medical, anesthetic, and critical care management.[58–65] Open mesenteric revascularization boasts excellent symptom improvement (77% to 100%) with low recurrence rates at 3 to 5 years (0% to 32%) and perioperative morbidity rates approximating 35% to 40%.[65,66]

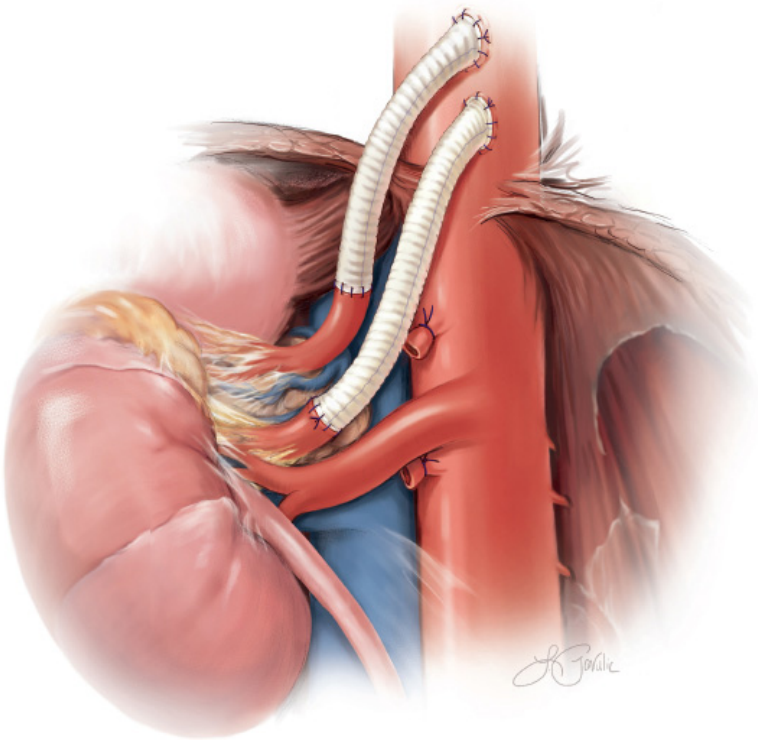

Figure 89.12 Two-vessel antegrade aortomesenteric bypass based off the supraceliac aorta using two separate grafts.

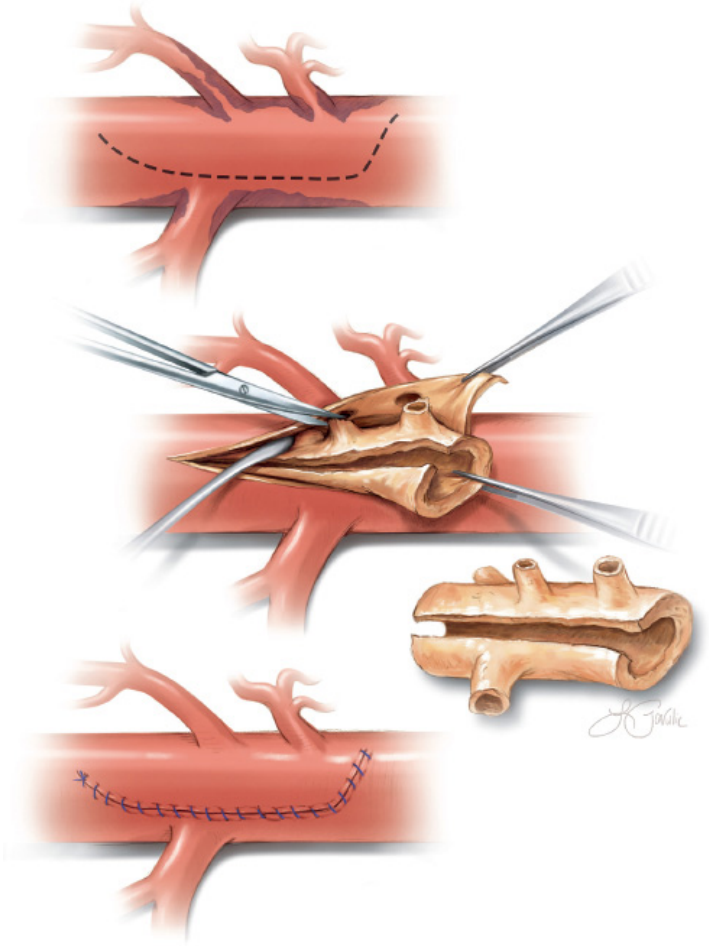

Figure 89.13 Endarterectomy of the aorta, celiac and superior mesenteric arteries through a longitudinal trapdoor aortotomy with primary closure.

Endovascular mesenteric revascularization has increasingly become utilized for chronic mesenteric ischemia. Stenting of the mesenteric vessels is recommended over angioplasty alone for favorable anatomy that excludes long-segment occlusion (i.e., >2 cm), small-diameter vessels, heavily calcified stenosis/occlusion and extrinsic compression (i.e., arcuate ligament compression of the celiac artery).[67–70] Endovascular revascularization offers success rates approaching 100% with immediate symptom relief. While perioperative morbidity is notably lower in comparison to open surgical revascularization, endovascular interventions are more likely to result in restenosis, recurrent symptoms (within 3 years), and require reintervention.[62,71–74] Primary and secondary patency rates approximate 40% and 88%, respectively at 5 years (in comparison to 88% and 97% following open revascularization) emphasizing the importance of patient counseling preoperatively and close surveillance postprocedure.[65] There is no significant difference in 3-year survival between open surgical and endovascular revascularization.[74] Two-vessel (celiac and SMA) stenting does not appear to reduce the risk of recurrent symptoms or reintervention when compared to single-vessel (SMA) stenting and moreover, isolated celiac artery stenting carries a higher risk of recurrence.[75] Covered stents may be associated with less restenosis, recurrence, and reintervention in comparison to bare metal stents.[76,77] Complications (average rates) may include symptomatic embolization (2.5%), thrombotic mesenteric arterial occlusion (1%), iatrogenic dissection (2%), stent dislodgement (2%) and access site–related complication (9%).[69]

A large review of mesenteric revascularization from the Nationwide Inpatient Sample between 1988 and 2006 demonstrated increased overall revascularization procedures for CMI.[78] Additionally, these authors

noted that mesenteric angioplasty and stenting not only surpassed open revascularization procedures for CMI in 2002, endovascular interventions more than doubled open procedures by 2005. An updated sampling of the same database between 2007 and 2014 supported decreased mortality, shorter hospital length of stay, reduced costs and decreased perioperative morbidity when compared to surgery.[79] These data are clouded by both the expansion of treatment indications and the fact that a greater risk of restenosis and recurrent symptoms may increase overall interventions. Moreover, these reinterventions for recurrence likely carry a variable risk for in-hospital morbidity and mortality. Regardless, mesenteric stenting has become the first-line therapy for most patients with atherosclerotic CMI and maintains an important role as a temporizing measure to facilitate weight gain in the high-risk malnourished patients (as a bridge to open revascularization) and for those patients with medical comorbidities that would further complicate or prohibit open surgical revascularization. Open mesenteric bypass surgery is recommended for low-risk patients with unfavorable mesenteric occlusive disease anatomy, failed prior endovascular revascularization, or multiple recurrences of in-stent stenosis/occlusion.

Median Arcuate Ligament Syndrome

Median arcuate ligament syndrome (MALS) remains a controversial diagnosis, first described in the 1960s.[80] Chronic abdominal pain is associated with radiographic evidence of celiac artery compression by the overlying fibrous arch of the median arcuate ligament (MAL) and adjacent celiac ganglion. The pathophysiology remains poorly understood and evidence suggests both ischemic and neurogenic etiologies for pain.[81] Gastric tonometry has documented evidence of mucosal ischemia in patients prior to treatment.[82] The 7% to 21% incidence of celiac artery compression in asymptomatic patients combined with the typical robust mesenteric collaterals and widely patent superior and inferior mesenteric arteries present in these younger individuals favor a neurogenic etiology.[83,84] Specifically, compression of the celiac plexus somatic nerves by the MAL may produce abdominal pain that is improved with a celiac ganglionectomy that accompanies ligament release or percutaneous celiac plexus block.

Patients with MALS are typically females in their third decade of life. Symptoms most commonly include postprandial pain, weight loss, and less commonly nausea and diarrhea. Diagnosis is supported by duplex ultrasonography that demonstrates elevated peak systolic velocities through the celiac artery on expiration that normalize or improve with inspiration and reverse flow through the hepatic artery.[85] Cross-sectional imaging like CTA and MRA can support the diagnosis as well, and may reveal poststenotic dilation of the celiac artery. Angiography demonstrating dynamic compression or occlusion during peak expiration remains the gold standard for the diagnosis of MALS (Fig. 89.14). Additionally, as MALS remains a diagnosis of exclusion, some authors favor gastric exercise tonometry test and celiac ganglion block to support patient selection.[86]

Release of the MAL should include complete dissection and skeletonization of both the MAL and surrounding nerve ganglion. This can be accomplished through an open approach whereby the aortic hiatus and celiac artery are exposed through the lesser sac. Additionally, laparoscopic and more recently robotic techniques have been described. The most contemporary literature review and large series suggest immediate postoperative symptoms relief in approximately 80% to 90% of patients.[81,82,87–92] Adjunctive procedures for celiac artery revascularization are utilized in a minority of cases and may include celiac angioplasty, celiac artery patch angioplasty, and celiac artery bypass (i.e., aortoceliac bypass). Late symptom recurrence approximates 6% and only Reilly and colleagues have demonstrated a reduction in recurrence following MAL release with celiac artery revascularization in comparison to MAL release alone (24% vs. 44%).[81,93] Multiple authors have highlighted the importance of patient selection for treatment suggesting that specific patient criteria may correlate with successful outcomes including: consistent postprandial abdominal pain, young age, female gender, weight loss >20 lb and anatomic features of poststenotic dilation or increased collateral flow.[93–95] Psychiatric diagnoses are common in adults with MALS, and may predict worse patient-reported quality of life outcomes following surgery.[96] A reasonable approach may reserve adjunctive revascularization for those patients with objective angiographic pressure

or ultrasound velocity gradients following open surgical MAL decompression or those with persistent symptoms following laparoscopic or robotic release.

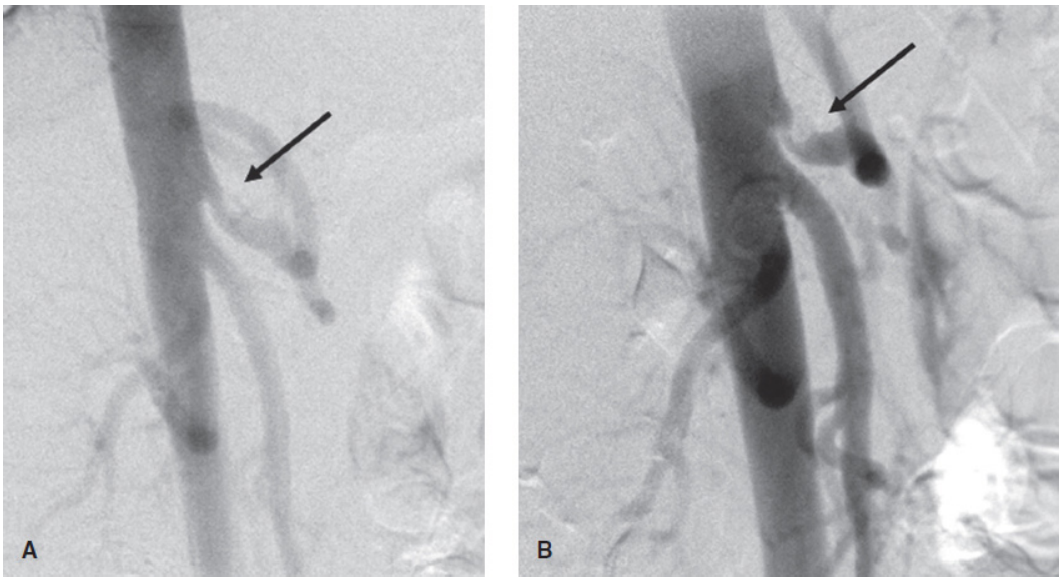

Figure 89.14 Lateral aortography demonstrating (**A**) external compression (*arrow*) of the celiac artery on peak inspiration that (**B**) worsens dynamically (*arrow*) during peak expiration.

Laparoscopic release of the MAL is increasingly employed for MALS.[81,87,91,92] While no procedure-related mortality has been reported for open or laparoscopic ligament release, there is a 9.1% incidence across series of open conversion for hemorrhage that follows laparoscopic release, which heightens morbidity and mortality risk.[81] Certainly independent operator learning curve, institutional technical enhancements, and patient selection may strongly affect this result. More recently, safe and effective robotic-assisted MAL release has been reported to offer benefits over laparoscopic release in light of improved visualization, extra degree of motion provided by robotic arms with "wrist movement" and scaled operator movements (including tremor elimination).[97] A contemporary study recently proposed a predictive model for MALS patients that uses preoperative data (age, baseline celiac artery expiratory velocity) to predict symptom improvement following release.[98] These same authors were the first to show a significant improvement in all eight AF-36 categories, and particularly bodily pain. While surgical intervention may treat this controversial but debilitating condition, long-term (>5 year) follow-up data remain lacking, as is a consensus as to the optimal surgical approach.[99]

Splanchnic Artery Aneurysms

Splanchnic artery aneurysms are historically cited as rare and mainly asymptomatic. In the past, most were syphilitic or mycotic, while contemporary visceral aneurysms are largely true aneurysms caused by atherosclerosis or medial degeneration.[100] True aneurysms are defined by the involvement of all three arterial wall layers (intima, media, and adventitia) while false aneurysms, or pseudoaneurysms, represent a collection of extravasating blood outside of the artery that remains confined next to the vessel by surrounding tissue. The incidence of splanchnic artery aneurysms is estimated at 0.1% to 2% and autopsy series suggest a prevalence that may approach 10%.[101,102] A minority of aneurysms present with life-threatening rupture and while historic-associated mortality rates approached 25% to 70%; more contemporary series suggest mortality rates of 15%, possibly reflecting improvements in perioperative management and the increasing use of endovascular techniques.[103] Most splanchnic aneurysms are asymptomatic however, and diagnosed as incidental findings by cross-sectional imaging.[104] False

aneurysms may carry a higher rate of rupture in comparison to true aneurysms (76% vs. 3% in once series).[105]

The natural history of these aneurysms remains elusive in light of their rarity and anecdotal, mainly institutional and retrospective, evidence to date. Indications for intervention remain conservative, especially as no significant difference has been identified between the diameters of ruptured and nonruptured aneurysms.[105] Additionally, aneurysm calcification and intraluminal thrombus are not associated with rupture risk. Historically, treatment had been recommended for symptoms and size >2 cm or aneurysm diameter three times greater than the respective normal artery, although contemporary guidelines support evidence-based guidelines for size threshold for repair by phenotype.[106] Patients with splanchnic aneurysms generally have 10-year survival rates >80% and open surgical treatment provides excellent, durable long-term results with low perioperative mortality and morbidity following elective surgery.[103,107,108] While surgical repair has remained the mainstay of treatment, minimally invasive endovascular techniques continue to evolve and are increasingly applied for both elective treatment and that of rupture. Endovascular intervention with local anesthesia offers excellent technical success, negligible morbidity and mortality in elective cases, and brief hospital stays.[103,105,108–112] Transcatheter embolization of visceral artery aneurysms offers additional advantages that include precise aneurysm localization, assessment of collateral flow, and negate the need for certain (i.e., intrahepatic) difficult arterial exposures.[100] Notably, embolization has become the standard of care for splanchnic artery pseudoaneurysm.[110,113] Additionally, endovascular therapy may offer decreased postoperative morbidity and mortality rates in cases of rupture when compared to open surgery (2.7% to 7% vs. 24% to 29%, respectively).[103,109]

6 Distribution of splanchnic artery aneurysms is as follows: Splenic artery (60%) > hepatic arteries (20%) > superior mesenteric artery (SMA) (5.5%) > celiac artery (4%) and gastric and gastroepiploic arteries (4%) > ileocolic arteries (3%) > pancreaticoduodenal arteries (2%) > GDA (1.5%) > IMA (<1%).[101,104] Most patients present in the sixth decade of life.[104,105] Symptomatic patients will present with abdominal pain and frank hemorrhagic shock with rupture. Rupture may be intra-abdominal, although erosion into a gastrointestinal lumen may result in sporadic gastrointestinal bleeding (i.e., herald bleed) and erosion into adjacent mesenteric veins results in arteriovenous fistulae. The asymptomatic patient inconsistently reveals a bruit on auscultation and rarely a palpable mass on examination. Each splanchnic aneurysm warrants individual consideration.

Splenic Artery Aneurysm

Splenic artery aneurysms account for 60% of all splanchnic artery aneurysms and are the third most common intra-abdominal arterial aneurysm. Their prevalence in the general population is very low approximating 0.16% to 0.8%.[114] These aneurysms occur two to four times more frequently in women than men and are associated with multiparity.[100,104,108,114,115] Hormonal and local hemodynamic events likely contribute to the evolution of splenic aneurysms. An etiologic classification system has previously been proposed by *Stanley and Fry* that implicates arterial dysplasia, portal hypertension, local inflammation, and hormonal and hemodynamic events in the pathogenesis of these aneurysms.[114] Hypertension is a common comorbidity affecting 50% to 60% of patients with splenic aneurysm, and up to 20% of patients will demonstrate concurrent aneurysms affecting alternate arterial beds.[112,113,116] Additional etiologic risk factors for true aneurysms may include dissection, septic emboli, polyarteritis nodosa, systemic lupus erythematosus, and connective tissue disorders like Ehlers–Danlos syndrome, while splenic pseudoaneurysms are typically attributed to chronic pancreatitis and trauma.[104] Splenic aneurysms most often arise at branch points off the mid- and distal main splenic artery. Tortuosity of the main splenic artery is common (Fig. 89.15). The majority (80%) of splenic aneurysms are solitary and saccular, although 90% of patients with portal hypertension will demonstrate multiple splenic aneurysms. Those aneurysms measuring >5 cm are often described as “giant lesions” and appear to be more common in older males.[117]

Splenic aneurysms typically rupture into the lesser sac with limited self-containment. Later hemorrhage into the peritoneal cavity results in cardiovascular collapse and the so-called “double rupture.” The

incidence of splenic aneurysm rupture approximates 2% to 5% and is not associated with calcification, blood pressure, or age.[101,104,113,114] Increased levels of aneurysmal peripheral calcification are associated with smaller aneurysm size at the time of diagnosis, but appear to have no impact on aneurysm growth.[113] Growth rates among surveyed aneurysms (out to 3.1 years) have been calculated as 0.2 mm/yr.[113] Rupture-associated mortality is dramatically increased in the peripartum patient (68% to 75% vs. 25%), and associated fetal mortality approaches 100%.[114,116,118] Rupture in this setting occurs most commonly during the last trimester.[100] While historically a strong association between pregnancy and splenic aneurysm rupture was reported, a contemporary series reporting on >67,000 consecutive live births over 5 years identified no cases of splenic artery aneurysm rupture.[116] There is no apparent role for routine screening for splenic aneurysm in the pregnant patient.[119] Rupture risk is increased twofold by liver transplantation, the mortality following which is 50%.[120,121]

Contemporary data have supported an indolent natural history of surveyed splenic aneurysms, of null to slow growth (0.02 to 0.06 cm/yr) without rupture or aneurysm-related complications.[113,122] As such, accepted indications for treatment include rupture, symptoms, asymptomatic aneurysms measuring 3.0 cm, and any size asymptomatic aneurysm at the time of liver transplantation or in women of childbearing age.[104,106,113,123,124] Historically, the open surgical treatment of splenic artery aneurysms included aneurysm resection or splenectomy. Recognizing the immunologic benefits of splenic preservation, arterial ligation, and aneurysm excision is preferred when possible; however, those patients with multiple and perihilar aneurysms may still require splenectomy. Laparoscopic and robotic techniques at ligation, aneurysm resection and splenectomy have become common-place offering negligible risk of open conversion, need for reoperation and mortality.[125–127] Splenic vaccinations and education regarding the need for booster vaccinations at regular 5-year intervals should be provided. Perioperative morbidity and mortality are estimated as 9% to 25% and 1% to 5%, respectively, across series.[113,114,128–130]

Endovascular therapy has been utilized with increasing frequency for both elective and ruptured cases boasting decreased early morbidity, mortality, and hospital length of stay. While only 2% of all splenic aneurysms were managed with endovascular therapies in 1999, this proportion increased to 70% between the years 2010 and 2013.[130] Embolization with coils, gelfoam, glue, thrombin, and vascular plugs has been advocated for saccular aneurysms with narrow necks (Fig. 89.16). Larger vessels with complex wide-neck aneurysms may be better approached with covered stents or stent-assisted coil embolization.[131] Technical success for endovascular treatment is 93% to 98%, limited primarily by vessel tortuosity that may be overcome with newer, steerable catheters.[113,130,132,133] Conversion to open surgery is rarely necessary (<2%) to accomplish successful aneurysm exclusion.[130] Postembolization syndrome (PES) complicates 10% to 30% of cases across series and may include left upper quadrant pain, fever, ileus, platelet dysfunction, leukocytosis, and pancreatitis following embolization with and without radiographic evidence of splenic infarction.[113,130,133,134] Up to 21% of patients will demonstrate major splenic infarct and may require reintervention for splenic abscess by way of percutaneous drainage or splenectomy.[113,132] Portal hypertension appears to increase dramatically the risk of major splenic infarction.[132] With late follow-up, endovascular repair is associated with an average regression in aneurysm size of 1.5 mm/yr.[113] Late complications may arise at an average rate of 3.7% per year, and there is a 3.2% rate of reintervention per year following endovascular repair.[130]

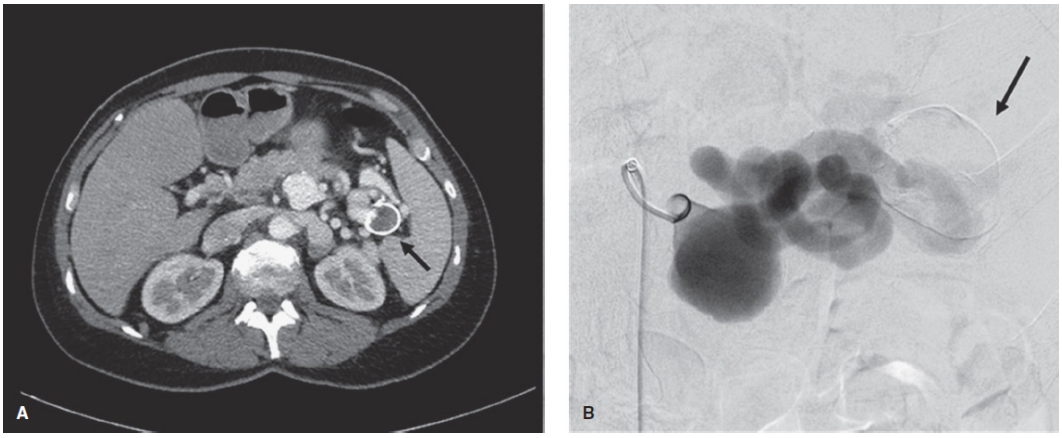

Figure 89.15 (**A**) CT angiogram and (**B**) splenic arteriogram revealing a tortuous splenic artery with two large aneurysms affecting the main splenic artery; the distal aneurysm (*arrow*) has extensive calcification and mural thrombus.

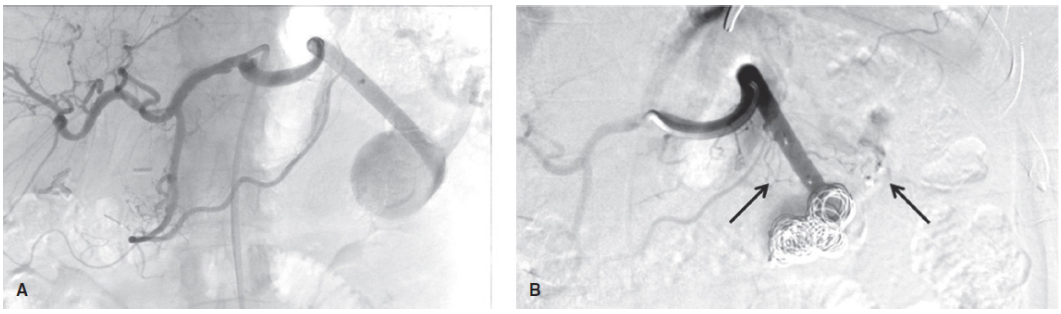

Figure 89.16 (**A**) Celiac arteriogram of a 78-year-old woman with a 4-cm splenic artery aneurysm; (**B**) Splenic arteriogram demonstrating a catheter in the proximal splenic artery. Vascular occlusion devices (*arrows*) have been positioned in the main splenic artery outflow (distal to the aneurysm) and inflow (proximal to the aneurysm) with multiple vascular coils embedded within the aneurysm sac.

Patients with splenic aneurysms have long-term survival rates that approach 90% at 10 years following aneurysm-directed treatments; cause of death is typically unrelated to aneurysm.[113] The most recent meta-analysis of splenic aneurysm therapies identifies significantly greater technical success balanced with greater 30-day mortality following open repair in comparison to significantly higher rates of acute minor complications, late complications, and reinterventions following endovascular repair.[130] Moreover, a recent decision analysis investigating the cost-effectiveness of open repair, conservative management, and endovascular repair for splenic aneurysm identified endovascular therapy as the most cost-effective treatment independent of gender and risk profile of the patient.[135]

Hepatic Artery Aneurysm

Hepatic artery aneurysms (Fig. 89.17) account for 20% of all splanchnic artery aneurysms, affecting men twice as often as women.[100,101,136] These aneurysms are mainly solitary and while small hepatic artery aneurysms (<2 cm) are typically fusiform, larger aneurysms will more often appear saccular.[136] The vast majority of these aneurysms are extrahepatic with the common hepatic artery and right hepatic artery most often affected; 20% to 30% of hepatic aneurysms however, are intrahepatic.[101,115,136] Hepatic artery pseudoaneurysms are increasingly frequent and account for approximately 50% of hepatic artery aneurysms.[104,115] Pseudoaneurysms may result from diagnostic and therapeutic interventions that require liver penetration (e.g., biliary stents), liver transplantation, and trauma; their incidence appears to be increasing secondary to the more frequent and regular use of CT imaging following blunt liver trauma and hepatobiliary intervention.[105,115] True aneurysms present most often during the sixth decade of life and proposed etiologic mechanisms include mainly atherosclerosis and acquired medial degeneration.

Polyarteritis nodosa, cystic medial necrosis, portal hypertension, infection, arterial fibrodysplasia, neurofibromatosis, and other arteriopathies are less commonly implicated.[104,136]

As with most splanchnic artery aneurysms, hepatic artery aneurysms rarely cause symptoms. Symptomatic patients will most commonly describe right upper quadrant or epigastric abdominal pain that may radiate to the back, while those patients with rapidly expanding aneurysms may describe abdominal complaints that mimic pancreatitis. Large aneurysms may erode into the stomach or duodenum resulting in gastrointestinal hemorrhage or they may obstruct the biliary tract resulting in biliary colic, hemobilia, and obstructive jaundice.[104] Additional physical examination findings like a palpable pulsatile mass and bruit are uncommon. Diagnosis is often made incidentally by cross-sectional CT/MRI, ultrasound or arteriography performed for a nonvascular indication.

Rupture appears to complicate a minority of hepatic artery aneurysms (20% to 30%) and results in an equal distribution of hemorrhage into the peritoneum and the biliary tract.[101,104] Rupture into the biliary tract results in hematobilia, hematemesis, and cholangitis; rarely is there melena and chronic anemia. Rupture-related mortality approximates 35% to 40%.[136] The relationship of rupture risk to aneurysm size remains unclear and a small series of 22 patients with a mean hepatic artery diameter of 2.3 cm (range 1.5 to 5 cm) were followed for a mean of 68.4 months without complication.[104,136] The presence of multiple aneurysms and nonatherosclerotic etiology are proposed risk factors for rupture.[136] While historically treatment was recommended for all asymptomatic aneurysms >2 cm in size, some authors have proposed elective intervention for all and any-size nonatherosclerotic aneurysms and for those patients with multiple hepatic artery aneurysms while reserving a more conservative approach for those atherosclerotic hepatic artery aneurysms measuring 2 to 5 cm in size.[136] Contemporary guidelines support elective repair in asymptomatic at a size threshold of >2 cm in patients without significant comorbidity at a size >2 cm (Grade 1A), or if the aneurysm enlarges >0.5 cm/yr (Grade 1C), at a size threshold of >5 cm in patients with significant comorbidity (Grade 1B), and at any size in those patient with vasculopathy or vasculitis (Grade 1C).[106]

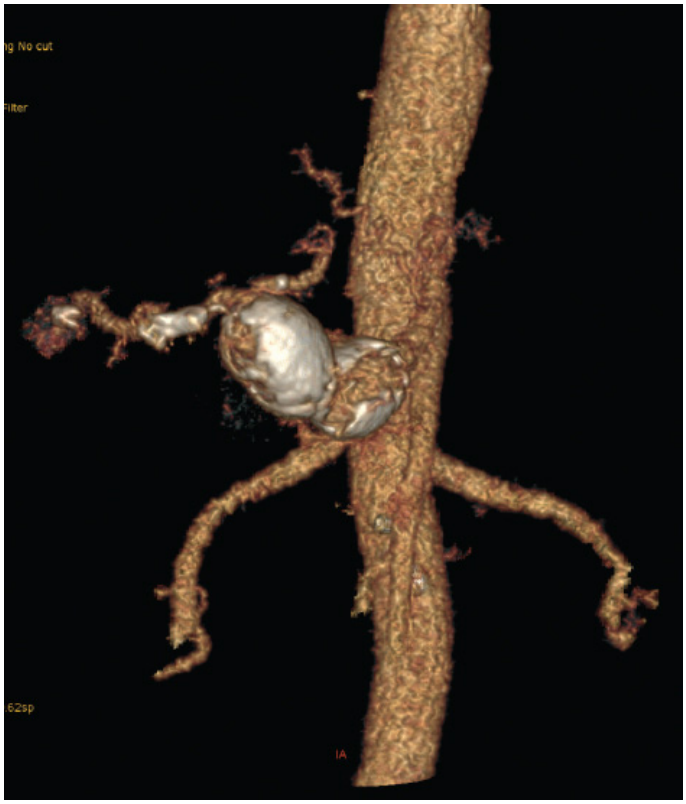

Figure 89.17 Reformatted CT angiogram demonstrating a bilobed and calcified hepatic artery aneurysm.

Open reconstruction has been favored for aneurysms of the extrahepatic artery by way of aneurysmectomy or exclusion, although current guidelines support an endovascular-first approach to all hepatic artery aneurysms (Grade 1A).[106] Often revascularization is not required in light of extensive foregut collaterals from the GDA and right gastric artery that preserve hepatic perfusion. When necessary, options for reconstruction may include primary or patch angioplastic closure of the common hepatic artery, aortorenal bypass, and splenohepatic bypass. Proper hepatic artery aneurysms may be treated by aneurysmectomy requiring reconstruction using a saphenous vein interposition graft or simple aneurysmorrhaphy. Distal or intraparenchymal lesions may require resection of the involved liver parenchyma, and lobectomy is advised for patients with large intrahepatic aneurysms to avoid significant liver necrosis.[106,107] Elective open surgical repair is associated with approximately 30% morbidity and negligible mortality.[108,110,136] Additional options include transcatheter embolization, which may be an especially useful adjunct for intrahepatic arterial aneurysms obviating the need for hepatic lobectomy, and stent graft exclusion for high-risk patients.[100,104,108,110,112,137] Technical and clinical success rates with transcatheter embolization approach 100% and 79%, respectively and offers efficient control of hemorrhage, shorter hospital length of stay and lower transfusion requirements in cases of rupture specifically.[138] Transient success and recanalization is well described however, mandating thoughtful postembolization surveillance.

Superior Mesenteric Artery Aneurysm

Superior artery aneurysms account for up to 7% to 14% of all splanchnic aneurysms, depending on the series.[101,103,105,108,109] These aneurysms affect men more frequently than women in their sixth decade of life and are mainly solitary.[101,139,140] SMA aneurysms may result from infection (i.e., nonhemolytic streptococci in bacterial endocarditis), dissection (Fig. 89.18), medial degeneration, atherosclerosis, FMD, vasculitis, connective tissue disorder, and trauma.[101,105] Additionally, false aneurysms may occur in the setting of pancreatitis and complicated peptic ulcer disease.[139] Concomitant hypertension is common, affecting >20% of patients with SMA aneurysm, as are associated aortic and peripheral/splanchnic aneurysms.[108,112,140,141]

In contrast to other splanchnic aneurysms up to 70% to 90% of SMA aneurysms may present with symptoms at diagnosis. While most patients with SMA aneurysm are asymptomatic, abdominal pain is the most common symptom followed by nausea, emesis, GI bleeding, and fever in cases of mycotic aneurysm.[139–141] Clinical examination may reveal a pulsatile mass in up to one-third of patients. Diagnosis is most commonly established by CT imaging, although these aneurysms can be appreciated by ultrasound, MRI, and angiography. Complications may include AMI resulting from thromboembolism and rupture. The natural history of SMA aneurysms appears to be that of expansion and rupture with 38% to 50% presenting with rupture.[105,139] Rupture risk has historically been considered rare and while rupture-associated mortality has historically approached 50%, more contemporary series cite 30-day mortality rates as low as 12.5% to 38%.[101,109,140] No comorbidities or aneurysm characteristics have been found to predict rupture risk.[140] Contemporary guidelines support repair of all SMA aneurysms at diagnosis, regardless of size (Grade 1A).[106]

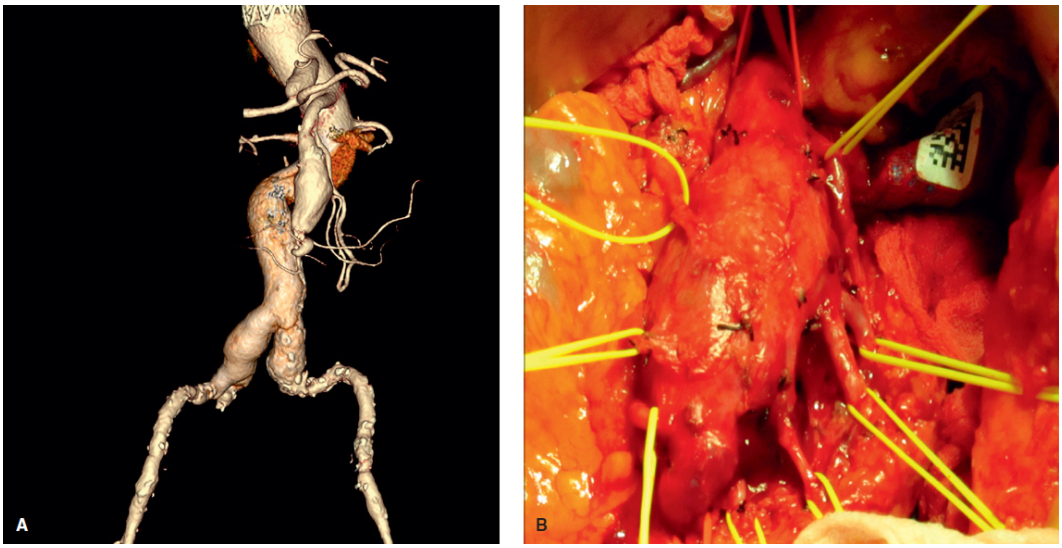

Figure 89.18 (**A**) CT angiogram and (**B**) intraoperative photo of a large 3.6-cm asymptomatic SMA aneurysm associated with extensive thoracoabdominal aortic and SMA dissection. The aneurysm was repaired by way of an SMA interposition bypass graft using nonreversed great saphenous vein; additionally the proximal SMA dissection flap was sharply fenestrated.

Surgical management of SMA aneurysm most often requires aneurysm excision (or exclusion) with revascularization, most often by way of aortomesenteric bypass.[108] Both autologous and prosthetic conduits have been described. Autologous conduit is favored in cases of mycotic aneurysm and frank contamination complicating intestinal ischemia while reinforced prosthetic conduit resists compression/kinking and future dilation.[112] Aneurysmorrhaphy and simple ligation of inflow and outflow vessels (in those patients with appropriate collateralization) have also been described with success.[101,112,139] Contemporary elective surgical results boast negligible morbidity and mortality.[112] Endovascular SMA aneurysm exclusion with a stent graft and embolization have been described and increasingly employed for patients with severe cardiopulmonary disease; these therapies remain limited by thromboembolic risks to the collateral circulation, endoleak, and limited long-term follow-up.[108,140–144] Aneurysms with a small neck distal to the SMA origin may be conducive to transcatheter embolization provided angiographic determination of collateral flow is determined as adequate.[140]

Celiac Artery Aneurysm

Celiac artery aneurysms account for approximately 4% of all splanchnic aneurysms affecting men more frequently than women in their sixth decade of life.[145,146] The incidence in the general population is unknown. Historically celiac artery aneurysms were primarily associated with infection like syphilis or tuberculosis and primarily diagnosed postmortem.[145] Contemporary etiologic risk factors include primarily atherosclerosis, developmental risk factors such as common celiacomesenteric trunk, arterial dysplasia with medial degeneration, collagen vascular disorder, trauma, and dissection.[145,146] Concomitant hypertension (20%), aortic aneurysm (18% to 40%), and alternate splanchnic aneurysms (38%) are common in patients with celiac artery aneurysm.[145,146]

As with most splanchnic artery aneurysms, celiac artery aneurysms rarely cause symptoms.[146] Symptoms may include abdominal pain, primarily epigastric in location with radiation to the back.[145] Less common associated symptoms may include nausea, emesis, dysphagia, anorexia, weight loss, and GI bleeding. Abdominal mass and bruit may be appreciated on physical examination. Diagnosis is most commonly established by CT imaging, although these aneurysms can be appreciated by ultrasound, MRI, and angiography.[146] Historically, rupture complicated approximately 70% of celiac artery aneurysms, resulting in near-certain mortality.[145] More contemporary estimates suggest rupture rates of 13% with associated 50% mortality.[145] Hypertension, aneurysm calcification, presence of thrombus, gender, and aneurysm

etiology do not appear to influence risk of rupture, which has been described in aneurysms ranging in size from 2 to 6 cm.[145,146]

Treatment should be individualized for cases of rupture and elective cases for patient symptoms and aneurysm size >2 cm. Aneurysm ligation and resection, without reconstruction, has previously been endorsed for those patients with adequate foregut collateral circulation. Simple ligation and transcatheter embolization may be considered as lifesaving in cases of rupture, but both offer substantial risk of perioperative hepatic and intestinal ischemia, necrosis, and patient mortality.[145–147] Aneurysmectomy with arterial reconstruction remains the preferred treatment of celiac artery aneurysms. Surgical revascularization may be accomplished by primary arterial–arterial anastomosis following aneurysm resection, direct aortic reimplantation of the celiac artery or its branches, or aortoceliac bypass. Prosthetic conduit may offer superior patency rates in comparison to autogenous reversed saphenous vein, which tends to kink.[146] Elective surgical repair offers patients symptomatic relief with a 0% to 5% risk of perioperative mortality.[146,147] Endovascular options for aneurysm treatment are increasingly described including celiac artery stent grafting.[148]

Gastric and Gastroepiploic Artery Aneurysm

Gastric and gastroepiploic artery aneurysms account for approximately 4% to 5% of all splanchnic aneurysms affecting men three times more frequently than women (Fig. 89.19).[101] Etiologic risk factors include primarily arterial dysplasia with segmental arterial mediolysis and periarterial inflammation like pancreatitis and vasculitis; atherosclerosis when present is felt to be a secondary process.[100,101,149] Gastric artery aneurysms are 10 times more common than gastroepiploic artery aneurysms. While patients may present with abdominal pain, up to 90% of patients have historically presented acutely ruptured with evidence of GI bleeding more common than intraperitoneal rupture.[100,101]

Treatment is recommended for all gastric and gastroepiploic arterial aneurysms, regardless the size. Arteriogram is invaluable for aneurysm identification preoperatively and operative planning. Surgical management has historically relied on simple arterial ligation or excision without reconstruction while intramural aneurysms required a wedge excision of involved gastric wall.[101,107] Contemporary literature would suggest that catheter-based embolization of these arteries is the new standard for care with multiple case reports and small series documenting successful aneurysm occlusion with coils and thrombin injection.[103,150,151]

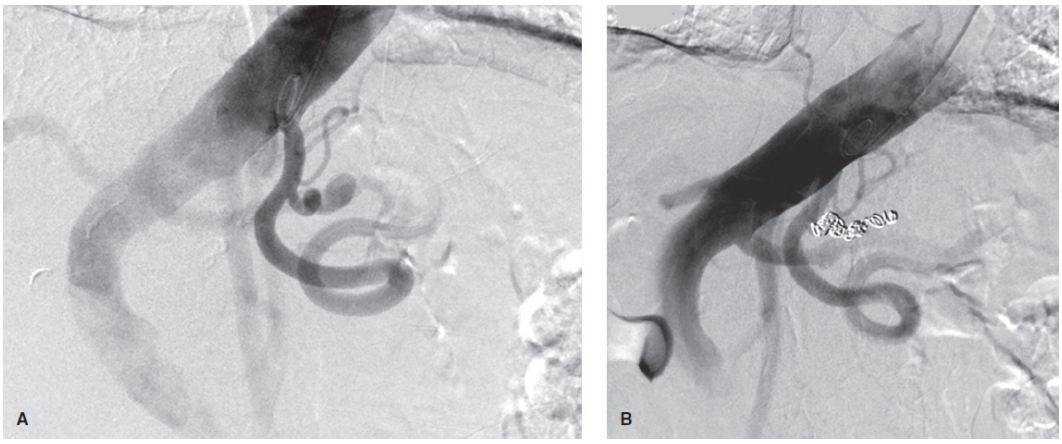

Figure 89.19 **A:** Diagnostic aortogram of an 82-year-old woman with a highly tortuous abdominal aorta, aberrant hepatic arterial anatomy, and two sequential gastric artery aneurysms measuring 10 mm in maximum diameter. **B:** Completion arteriogram following endovascular embolization.

Jejunal, Ileal, and Colic Artery Aneurysm

Aneurysms of the jejunal, ileal, and colic arteries account for <3% of all splanchnic aneurysms, affecting men and women equally beyond the sixth decade of life.[101] These aneurysms are associated with medial

degeneration, infection, connective tissue disorder, and polyarteritis nodosa with multiple aneurysms identified in approximately 10% of cases.[101,149,152] Atherosclerosis, when present, is felt to be a secondary process. While patients may present with abdominal pain, most have no symptoms. Rupture may complicate up to 30% of cases resulting in gastrointestinal bleeding and mortality rates that approach 20%.

Treatment is recommended for all mesenteric branch aneurysms, regardless of the size. Arteriogram is invaluable for aneurysm identification preoperatively and operative planning. Surgical management has historically relied on simple arterial ligation or excision without reconstruction.[101] Intramural aneurysms and those associated with bowel necrosis required resection of the involved intestine at the time of aneurysm exclusion. Transcatheter embolization has been increasingly utilized, and supported by contemporary guidelines, especially for cases of acute rupture and GI bleeding with intestinal necrosis, perforation, and late stricture potential complications.[153–155] Medical management is recommended for nonruptured asymptomatic ileal, jejunal and colic artery aneurysms associated with polyarteritis nodosa.[106]

Gastroduodenal and Pancreaticoduodenal Artery Aneurysm

Gastroduodenal and pancreaticoduodenal artery aneurysms account for <2% of all splanchnic aneurysm.[101] Men are affected four times more often than women during the sixth decade of life.[101] Periarterial inflammation resulting from pancreatitis with vascular necrosis or vessel erosion by pseudocyst reflects the most common etiology, while additional causes include arteriosclerosis, congenital medial degeneration, and trauma.[101] Concomitant celiac artery stenosis and occlusion are common in noninflammatory aneurysms and GDA and pancreaticoduodenal aneurysms are suggested to represent the effect of inordinately high-volume blood flow on branchings of the collateral circulation (Fig. 89.20).[156–158] Symptoms of abdominal pain are common; additional symptoms may include gastric outlet obstruction and compressive symptoms like nausea and emesis.[139,159] Rupture is also common, complicating up to 75% of inflammatory and 50% of noninflammatory aneurysms resulting most often in gastrointestinal bleeding and less commonly bleeding into the biliary or pancreatic ductal systems, peritoneum or retroperitoneum.[158] Rupture-associated mortality approximates 20% to 50%.[158,160] While it remains unclear if aneurysm size is a risk factor for rupture, rupture has been described at a small median size of 12 mm.[109,157,161]

Open surgical repair remains appropriate for most patients. These aneurysms are most often amenable to simple ligation, aneurysm resection, or aneurysmorrhaphy without revascularization.[103,108,112,139,158,162,163] Celiac artery revascularization should be considered in select noninflammatory cases. Pancreatitis-associated inflammatory aneurysms may require arterial branch ligation from within the aneurysm sac or pancreatic resection in severe cases. Transcatheter embolization with coils, glue, thrombin, and electrocoagulation has been successfully reported, especially for high-risk patients and those presenting with rupture.[108,137,158,160,164,165]

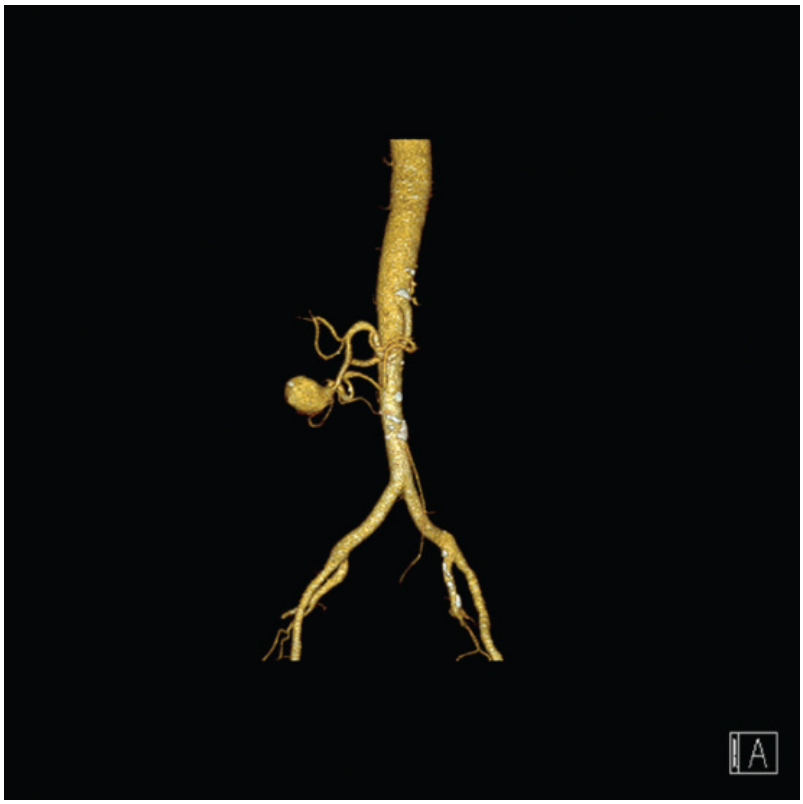

Figure 89.20 CT angiogram of an 87-year-old woman with a large 3.4-cm gastroduodenal artery aneurysm associated with celiac artery occlusion.

Inferior Mesenteric Artery Aneurysm

IMA aneurysms account for <1% of all splanchnic aneurysms. Our understanding of these aneurysms is limited to case reports. Men appear to be most commonly affected.[139] Atherosclerosis is the most common etiologic factor with additional risk factors including infection, polyarteritis nodosa, inflammatory arteritides, segmental arterial mediolysis, Behçet disease, and neurofibromatosis.[166] Concomitant celiac and SMA occlusion is common; it has been hypothesized that turbulent blood flow through tortuous marginal arteries originating from the IMA results in a high-flow state, or "jet disorder phenomenon," and subsequent dilation of the IMA and small collaterals which can lead to weakness of the arterial wall and aneurysmal disease.[166–169] Patients rarely have symptoms. Incidence of rupture approximates 20% with rupture-related mortality approaching 40%.[166]

Surgical management in cases of chronic celiac and SMA occlusion requires revascularization of at least one vessel (most commonly the SMA) to minimize intestinal ischemia during IMA aneurysm exclusion and theoretically decrease the risk of recurrent IMA aneurysm postoperatively. IMA aneurysm ligation and/or excision may be sufficient for treatment in certain cases of robust collateral intestinal circulation; in contrast certain cases will dictate IMA revascularization.[169] The role for endovascular therapy remains poorly defined.

RENAL ARTERY OCCLUSIVE AND ANEURYSMAL DISEASE

Introduction

Renovascular hypertension (RVH) is a well-defined form of secondary hypertension (HTN) that results from renal arterial insufficiency at some level. The pathophysiology of such ischemia is broad, and with both an increasing prevalence of atherosclerotic renal artery occlusive disease and ongoing clinical trials, treatment standards remain in flux.

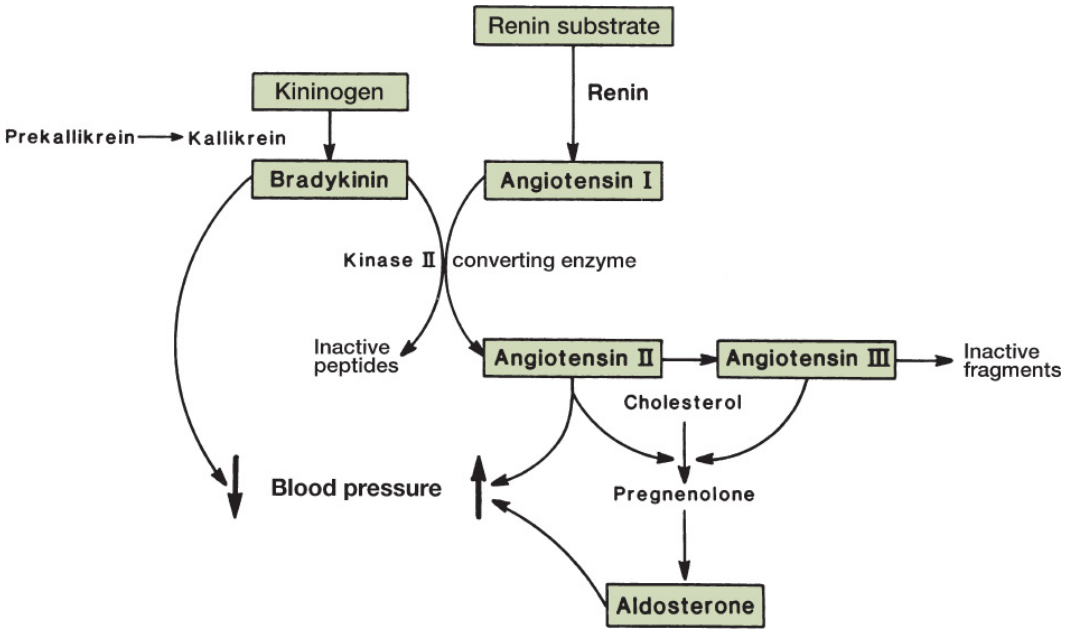

Figure 89.21 Renin–angiotensin system interrelation with aldosterone and bradykinin in blood pressure regulation. (Adapted from Stanley JC, Graham LM, Whitehouse WM Jr. Renovascular hypertension. In: Miller TA, Rowland BJ, eds. *Physiologic Basis of Modern Surgical Care*. St. Louis, MO: CV Mosby; 1988:734.)

Pathophysiology of Renovascular Hypertension

Renal artery stenosis resulting in a decrease in mean renal artery perfusion pressure by 10% to 15% stimulates renin release from the kidney. Renin is a proteolytic enzyme produced by the juxtaglomerular apparatus of the kidney that cleaves angiotensinogen to form angiotensin I. Angiotensin I is further processed to angiotensin II by angiotensin-converting enzyme (ACE), which is produced in the lung endothelium and vasculature (Fig. 89.21). Angiotensin II stimulates hepatic production of renin, while providing a continuous negative feedback on the renal release of renin.[170] Angiotensin II is a potent vasopressor that increases arterial blood pressure by a variety of mechanisms (Fig. 89.22). Glomerular filtration rate (GFR) is increased via vasoconstriction of the efferent arteriole. Additionally, antidiuretic hormone (ADH) is released from the posterior pituitary gland, causing water conservation. Release of aldosterone from the adrenal glands enhances exchange of sodium in the nephron-promoting volume retention. Finally, angiotensin increases sympathetic tone. All of these mechanisms coalesce to increase arterial pressure by way of arteriolar constriction, enhanced cardiac output, and the retention of sodium and water. Renin has a half-life of 20 to 30 minutes and is primarily cleared by the liver.[171] Normal physiology and sodium balance support a “steady state” of renin activity that is approximately 50% greater in the bilateral renal veins than that in the infrarenal inferior vena cava or peripheral circulation. In cases of unilateral renal artery stenosis, HTN is characterized by renin hypersecretion from the affected kidney and suppression of renin production in the contralateral kidney.[172,173] Additionally, angiotensin-mediated vasoconstriction causes pressure diuresis of the unaffected kidney. In cases of chronic bilateral or unilateral RVH in those patients with solitary kidney, sodium retention accounts for late reductions in renin secretion.

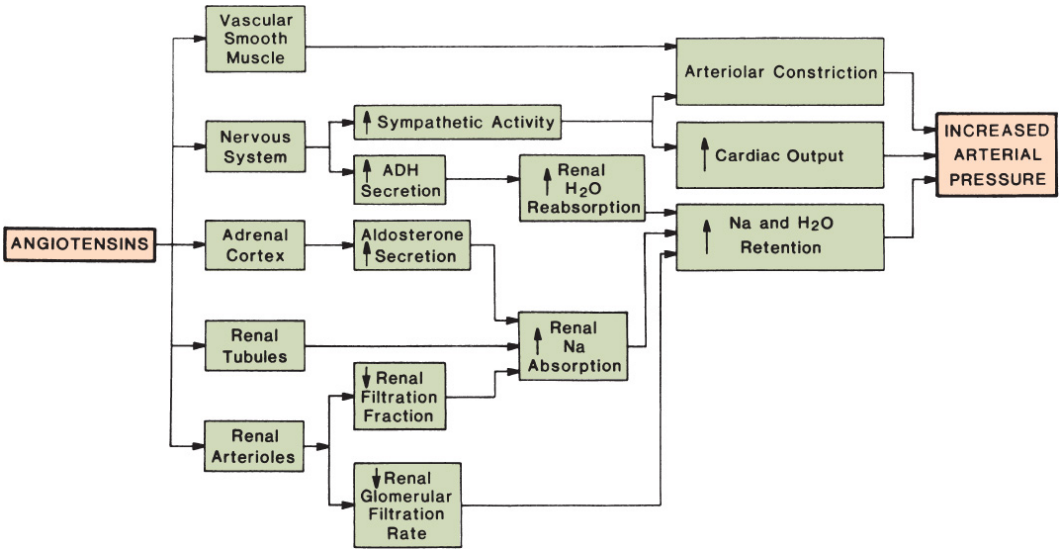

Figure 89.22 Effects of angiotensins contributing to increased arterial pressure. (Adapted from Stanley JC, Graham LM. Renovascular hypertension. In: Miller TA, ed. *Physiologic Basis of Modern Surgical Care*. 2nd ed. St. Louis, MO: Quality Medical Publishing; 1998:918.)

Renal Artery Occlusive Disease

7 Renal artery occlusive disease is the most common cause of correctable HTN in adults and the third most common cause of HTN in children and should be considered in the clinical context of: (1) childhood HTN, (2) severe HTN in women <45 years of age, (3) acute and rapid escalation of mild HTN in older patients (>50 years), (4) initial diastolic BP >115 mm Hg, and (5) rapid deterioration in renal function following the administration of antihypertensive therapy (especially with ACE inhibition). Renovascular HTN can be notoriously resistant to traditional medical management. Clinical examination may reveal an upper abdominal bruit during systole and diastole.

Diagnostic work-up should begin with serologies to assess renal function (BUN, creatinine) and electrolyte levels. Additional blood hormone levels may help differentiate the diagnosis as high plasma renin activity supports RVH while altered aldosterone, thyroid, and catecholamine levels may indicate endocrine dysfunction. Urinalysis may reveal hematuria or azotemia concerning for intrinsic renal disease. Ultrasonography is the first-line imaging modality for screening patients with RVH. While a high-quality duplex ultrasound examination in an experienced center is extremely accurate for the diagnosis of main renal artery and ostial stenosis or occlusion, sensitivity is compromised when surveying branch or parenchymal renal arteries and technically challenging in obese patients or in the presence of abdominal gas.[174] An elevated peak systolic velocity (>180 or >200 cm/s) or elevated renal aortic ratio >3.5 (calculated by dividing the peak systolic velocity of the renal artery by the peak systolic velocity of the adjacent aorta) detects renal artery stenosis with sensitivity and specificity of 84% and 97%, respectively.[175] Ultrasonography additionally facilitates a determination of renal length and symmetry, the presence of main renal artery aneurysm (RAA), visualization of adjacent structures (i.e., obstruction, masses, aortic aneurysm), and the assessment of intrinsic vessel renovascular disease by way of the resistive index.

Axial imaging with CTA and MRA are both useful adjunctive imaging modalities that better evaluate stenosis, aneurysms, renal infarcts, dissections, and adjacent structures. These imaging modalities have collectively received a class I indication (level B evidence) as screening tests to establish the diagnosis of renal artery stenosis from the American College of Cardiology (ACC) and American Heart Association (AHA).[176] CTA offers excellent spatial resolution and generated three-dimensional multiplanar images which can be very helpful in treatment planning. CTA, however, is limited by the risk of contrast-induced

nephropathy and in detecting subtle FMD lesions and branch vessel involvement. Multidetector CTA offers sensitivity and specificity ranging from 86% to 93% and 90% to 100%, respectively.[177] MRA is often favored in younger patients as it offers diagnostic sensitivity and specificity of 97% and 93% without the associated risks of irradiation.[178] Gadolinium is less nephrotoxic than iodinated contrast and while it may be advantageous for those patients with mild renal insufficiency, the risk of nephrogenic systemic fibrosis prohibits the use of gadolinium contrast in those patients with a GFR ≤30 mL/min/1.73 m^2. MRA offers the additional benefit of estimating renal perfusion and GFR via calculations of gadolinium clearance.

Catheter-based arteriography remains the gold standard imaging modality for the diagnosis of renal artery stenosis given its unmatched spatial resolution and capacity to detect reliably branch vessel and parenchymal involvement. Additionally, pressure gradients can be measured across a stenosis (a systolic pressure gradient <10 mm Hg is considered normal); intravascular ultrasound may be used to further characterize the renal artery; and any clinically indicated therapeutic interventions can be performed in the same clinical setting.

In cases of complex and equivocal disease, renal vein renin assessments may be used to calculate the renal vein ratio. This ratio reflects a renin comparison between peripheral and renal venous blood. With unilateral renal artery stenosis, the renal vein renin ratio (RVRR) is calculated by dividing the renin activity in venous blood from the affected kidney by that from the (normal) contralateral kidney. A ratio >1.48 supports a functionally relevant renal artery stenosis.[172,173] In patients with bilateral renal artery stenosis, a renal:systemic renin index (RSRI) is calculated by subtracting systemic renin activity from individual renal vein renin activity and dividing the remainder by systemic renin activity; this index reflects individual kidney renin release.[172] As aforementioned, there is a steady state of normal renal renin release; normal renal vein renin activity from each kidney is approximately 24% higher than systemic activity (with the total of both kidneys being then 48% higher than systemic activity). Documentation of renin hypersecretion (RSRI >0.48) associated with contralateral kidney renin suppression (RSRI 0 to 0.24) provides a method to differentiate those patients that will be cured or improved of RVH following renal revascularization or nephrectomy.[172,179]

Captopril scintigraphy (also known as isotopic or captopril renography) and hypertensive urography have fallen out of favor and are no longer recommended as diagnostic studies for the diagnosis of renal artery stenosis.

Arteriosclerosis

Arteriosclerosis is the most frequent cause of RVH affecting men twice as often as women, most commonly in the sixth decade of life.[180] Ostial stenosis is most common representing “spillover” of diffuse aortic atherosclerosis, which is present in approximately 80% of patients. Arteriosclerotic renal artery stenosis affects primarily the proximal third of the vessel, with more severe distal extrarenal disease limited mainly to black patients.[181] A contemporary prospective, multicenter, population-based study of cardiovascular health has estimated the incidence of renovascular disease in men and women aged >65 years as 6% to 7%.[180,182] Although early angiographic- and image-based studies in selected patients with arteriosclerotic RVH have suggested radiographic progression in approximately a third of renal artery lesions with 10% progressing to occlusion, this longitudinal cohort study reported anatomic progression to hemodynamically significant disease in only 4% of participants with an annualized progression rate of 0.5% per year and no disease progression to arterial occlusion. Importantly, renovascular disease has consistently been associated with cardiovascular disease across coronary, cerebrovascular, mesenteric, and peripheral vascular beds with a significant and independent relationship noted with prevalent coronary manifestations.[183–187]

Fibromuscular Dysplasia

FMD is thought to account for approximately 5% to 10% of RVH.[188,189] FMD is a nonatherosclerotic, noninflammatory vascular disease that may result in arterial stenosis, occlusion, aneurysm or dissection that affects primarily younger women.[190] The prevalence of FMD in the general population is unknown, although renal involvement is the most common phenotype comprising 58% to 75% of all FMD cases.[191,192] FMD

until recently has been described by histopathologic classification.[193,194] By this classification *medial fibroplasia* is the most common variant accounting for 60% to 90% of FMD cases. Deposition in the media of loose collagen in zones of degenerating elastic fibrils results in the generation of fibromuscular ridges with resultant arterial stenoses alternating with areas of smooth muscle loss with consequent arterial dilation producing a classic "string of beads" appearance angiographically (Fig. 89.23).[191] The distal two-thirds of the main renal artery and its branches are most commonly affected and bilateral disease is common. *Intimal fibroplasia* accounts for approximately 2% to 5% of all dysplastic renal artery stenoses and presents as a smooth, focal stenosis of the distal main renal artery. This histologic variant is notable for the accumulation of fibrous tissue within the intima with a moderately cellular component with mainly intact or partially fragmented elastic lamina (Fig. 89.24). *Perimedial fibroplasia* and *medial hyperplasia* are uncommon variants.

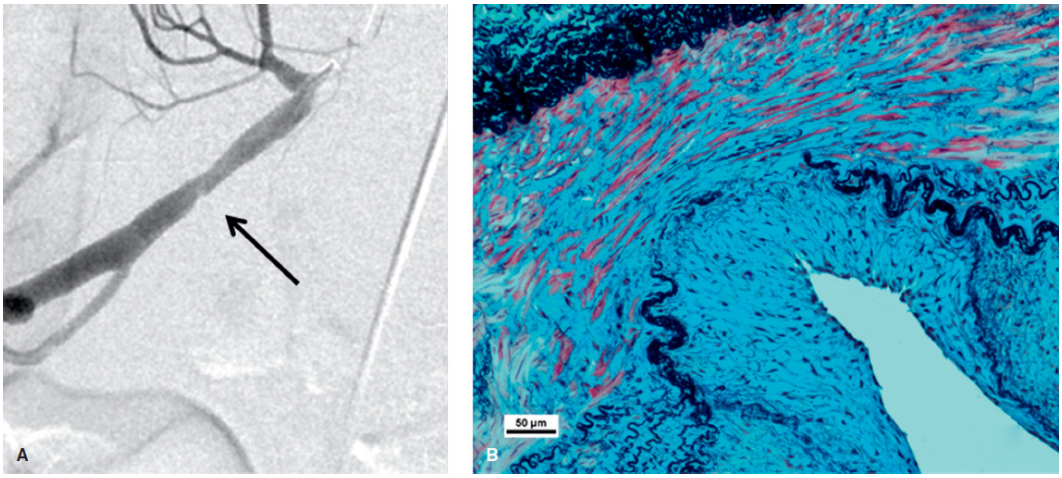

Figure 89.23 **A:** Right renal arteriogram demonstrating a radiographically subtle focal midartery stenosis (*arrow*); manometry across this lesion revealed a significant pressure gradient. **B:** Intimal fibroplasia as represented by pronounced intimal proliferation and partial fragmentation of the elastic lamina (*Movat stain, 20×*).

Medical Management of Renovascular Hypertension

8 Medical therapy remains the mainstay of treatment for RVH with comprehensive goals of care that should encompass glycemic control, cholesterol reduction, smoking cessation, blood pressure reduction, and antiplatelet therapy with aspirin for primary prevention. ACC/AHA guidelines support the use of ACE inhibitors (ACE-I), angiotensin receptor blockers (ARBs), calcium channel blockers, and beta blockers with a class I indication.[176] While beta blockers are often utilized first line, ACE-Is and ARBs are a mainstay of treatment for most antihypertensive regimens offering 86% to 92% efficacy.[189] Renal function monitoring is essential with the initiation of these agents as the resulting modulation of the renin–angiotensin system with renal artery stenosis affecting a solitary functioning kidney, severe bilateral RAS or advanced chronic kidney disease may result in acute renal failure.

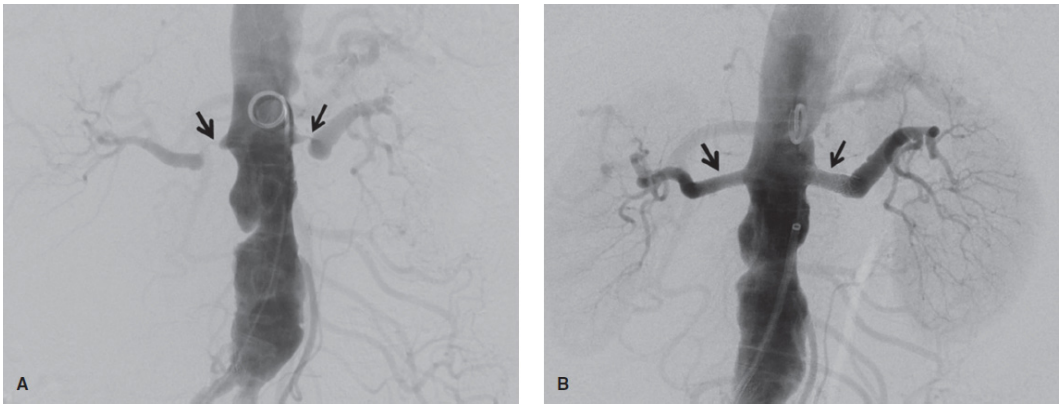

Figure 89.24 Aortogram demonstrating a highly irregular perirenal aorta with (**A**) high-grade bilateral renal artery stenosis (*arrows*) successfully treated with (**B**) bilateral renal artery stents (*arrows*). The stents are positioned with appropriate overlap into the aorta and are ballooned proximally such that they "flower" into the aorta.

Surgical and Endovascular Management of Renal Artery Occlusive Disease

As RAS may progress with concomitant renal atrophy, renal revascularization should be considered in select cases. Current ACC/AHA guidelines support renal revascularization for hemodynamically significant RAS in several clinical scenarios (Table 89.2).

Arterial Reconstructive Surgery for Renal Artery Occlusive Disease

Historically open revascularization procedures represented the standard of care in the treatment of RVH. The most common option for open renal revascularization remains aortorenal bypass with either autogenous reversed saphenous vein or prosthetic conduit. Alternatives may include (1) nonanatomic renal bypass based off the hepatic, splenic, or iliac arteries, (2) ex vivo renal artery reconstruction, and (3) aortorenal endarterectomy. Nonanatomic (or extra-anatomic) renal artery bypass may benefit those patients with medical comorbidities or aortic anatomy that prohibit aortic cross-clamping and aortorenal bypass.[196–200] The hepatic artery is used for a right-sided renal reconstruction, the splenic artery for a left-sided reconstruction. Ex vivo renal artery reconstruction may be considered selectively for those patients with complex, distal segmental arterial occlusive disease when balanced with the risk of prolonged operative time, disruption of pre-existing collaterals, and the need for renal cooling.[201,202] Transaortic and direct renal artery endarterectomy is particularly useful for those patients with bilateral disease, or when arteriosclerotic renal artery occlusive disease affects multiple (i.e., accessory) renal arteries.[203–205]

Open surgical revascularization offers significant blood pressure and renal function improvement in 85% and 50% of patients, respectively across high-volume centers with mortality rates of 2% to 5%.[188,206–209] While to date there has been no definitive trial comparing open surgical revascularization directly to endovascular therapy, angioplasty, and stenting appears to offer similar effectiveness with lower morbidity and mortality. As such, endovascular measures have replaced surgery as first-line therapy for RVH.[209,210] Contemporary open surgical renal reconstructions most commonly accompany hybrid endovascular interventions for aortic aneurysmal disease and may be considered for failed endovascular renal revascularization.

Endovascular Renal Revascularization

Since its introduction in 1978, percutaneous renal artery angioplasty (PTA), with or without stent placement, has virtually replaced open surgical reconstruction of arteriosclerotic renal artery stenosis. This technique has exploded in use and for over a decade has been utilized at times perhaps inappropriately as "prophylactic" therapy to treat clinically irrelevant renal artery stenoses.[211,212] Renal artery angioplasty alone risks arterial dissection from lesion/vessel recoil and early restenosis. Technical success rates of PTA may be as low as 30% to 50% in patients with significant aortic "spill over" lesions. PTA with

stenting offers improved success and very reasonable long-term patency with 5-year secondary patency rates >90%.[213,214]

9 Several recent clinical trials comparing renal artery stenting (RAS) to best medical management for renal artery stenosis have failed to demonstrate a conclusive clinical benefit to the endovascular treatment of renal artery stenosis (Table 89.3).[215–219] Moreover, RAS is associated with a 1.5% to 8% risk of major morbidity that can include infected hematoma, atheroemboli, renal failure requiring dialysis, and lower-extremity limb loss. Significant limitations apply to all of these studies, including design flaws and selection bias.

The appropriate patient for revascularization remains elusive, resulting from significant design flaws in existing trials. Most would suggest that those patients with refractory hypertension despite an appropriate medical regimen that includes a combination of ACE inhibition or angiotensin receptor blockade + diuretic + amlodipine with both a hemodynamically significant stenosis by manometric pressure gradient and overall preserved renal mass should still be considered for therapy.[220] Notably, evolving data have identified several promising predictors for clinical improvement following renal revascularization including bilateral RAS, mean arterial pressure >110 mm Hg, elevated baseline brain natriuretic peptide, elevated pulse pressure, and renal perfusion as measured by "renal frame count" during angiography (defined as the number of frames required for dye to pass through the renal parenchyma).[220–224] A contemporary study recently validated three preoperative markers of blood response to RAS from a single institution series with data from the CORAL trial.[225,226] These data supported (1) the requirement for ≥4 medications, (2) preoperative diastolic blood pressure >90 mm Hg, and (3) preoperative Clonidine use as predictors of hypertension improvement. Ongoing study remains necessary to identify consistent indications for RAS and reliable clinical predictors of successful outcomes following renal revascularization.

Table 89.2 Indications for Renal Revascularization for Hemodynamically Significant Renal Artery Stenosis[a]

Indication	Class Recommendation	Level of Evidence
Resistant HTN[b] and bilateral or or solitary severe RAS	2A	B
Accelerated HTN, resistant HTN, malignant HTN, HTN with unexplained unilateral small kidney, and HTN with intolerance to medication	2A	B
Stage IV chronic kidney disease with bilateral RAS (kidney size >7 cm pole-to-pole length)	2A	B
Stage IV chronic kidney disease and global renal ischemia (unilateral severe RAS with a solitary kidney or bilateral severe RAS) without another explanation	2B	B
Cardiac disturbance syndrome (i.e., Recurrent unexplained congestive heart failure, flash pulmonary edema, unstable angina)	1	B
Recurrent congestive heart failure with hemodynamically significant RAS		

[a]Hemodynamically significant renal artery stenosis defined as a resting translesional mean gradient of ≥10 mm Hg.

[b]Resistant hypertension defined as uncontrolled hypertension having failed maximally tolerated doses of at least three antihypertensive agents, one of which is a diuretic agent.

HTN, hypertension; RAS, renal artery stenosis.

Adapted from the 2005 Practice Guidelines for the management of patients with peripheral arterial disease and 2019 Prince et al. State of the Art Review.[176,195]

Table 89.3 Contemporary Clinical Trials Comparing the Effectiveness of Endovascular Renal Artery Revascularization to Medical Therapy

Trial	Number of Patients	Degree Stenosis	Indications for Renal Artery Revascularization	F/U (yrs)	BP Response	Renal Function Improvement or Stabilization
DRASTIC Trial[216] (PTA)	106	≥50%	Resistant HTN	1	No difference	N/A
STAR Trial[215] (RAS)	140	>50%	Renal impairment (GFR <80 mL/min)	2	No difference	No difference
ASTRAL[217] (RAS)	806	Variable	Refractory HTN or unexplained renal dysfunction with RAS suggested by imaging	5	No difference (systolic)[a]	Decreased progression of renal impairment and lower mean Cr level following revascularization
CORAL[218] (RAS)	931	≥60% + 20 mm Hg systolic pressure gradient -or- ≥80%	Systolic HTN ≥155 mm Hg despite at least two antihypertensives	43 mo	2.3 mm Hg reduction following RAS (vs. medical therapy) ($p = 0.03$)	No difference[b]

[a]The decrease in diastolic BP was smaller in the revascularization group.

[b]Composite end point included death from cardiovascular or renal causes, myocardial infarction, stroke, hospitalization for congestive heart failure, progressive renal insufficiency, or the need for renal-replacement therapy.

HTN, hypertension; PTA, angioplasty alone; RAS, renal artery stent; BP, blood pressure; Cr, creatinine.

Although randomized, controlled trials assessing renal revascularization for renal artery FMD are lacking, current guidelines support the following indications for renal revascularization in this patient cohort: (1) resistant HTN despite an appropriate three-drug regimen, (2) HTN of short duration with the goal being a cure of hypertension, (3) renal artery dissection, (4) RAA, and (5) preservation of renal function in patients with severe stenosis.[191,227] PTA of the renal artery is the procedure of choice for patients with renal artery stenosis secondary to FMD offering cure rates that approach 50%, with up to 86% of patients improved following PTA, a 20% risk of reintervention, and low risk of minor complications.[191] Hemodynamic significance must be documented by manometry prior to any intervention in these patients and success should be defined by resolution of this gradient postangioplasty. Stenting should be utilized selectively.

Developmental Dysplasia

Renovascular HTN secondary to renal artery stenosis and abdominal aortic coarctation remain an important cause of pediatric HTN, the natural history of which risks failure to thrive, heart failure, hypertensive encephalopathy, impaired mental development, hemorrhagic stroke, and early mortality.[228] It is estimated that 5% to 10% of pediatric HTN may be explained by renovascular disease, following thoracic aortic coarctation and parenchymal renal disease in incidence.[228,229] The pathophysiology of pediatric

renovascular disease remains ill defined, as are the mechanisms by which pediatric renovascular disease occur. FMD and neurofibromatosis type 1 (NF1) are reported as the most common causes of pediatric renal artery stenosis in the western world.[230] While the intimal FMD variant described above is uncommon in adults, it is the most common form identified in children with renal artery stenosis. Furthermore, histopathologic review of operative renal artery samples excised from patient with developmental arterial stenosis reveal mainly consistent findings of intimal hyperplasia, medial thinning, and disruption of the elastic lamina (Fig. 89.21).

Open surgical revascularization of renal artery stenosis remains the gold standard for children with developmental lesions.[228] Aortorenal reimplantation with spatulation of the renal artery and interrupted suture lines is favored. Alternatively, aortorenal bypass using hypogastric artery as conduit is favored over autogenous venous conduit, which can dilate over time to become aneurysmal. Approximately one-third of children will demonstrate associated aortic coarctation and require concomitant patch aortoplasty or aortoaortic bypass. The University of Michigan experience recently reported the largest single-center experience with surgical revascularization of 169 children with RVH supporting a sustainable hypertension benefit in 90% of children, including those with abdominal aortic coarctation, with no mortality or renal insufficiency requiring dialysis.[231] The authors noted that interventions in the very young and in those with concurrent abdominal aortic coarctation significantly increased the likelihood of reoperation, and those children undergoing remedial surgery after prior revascularization failures were less likely to be cured of HTN.

There may be a role for angioplasty for selected cases of pediatric renal artery stenosis. Certainly this procedure has gained substantial momentum in the past decade. The most robust U.S. experience includes the treatment of 19 hypertensive children aged 2 to 18 years that underwent PTA for renal artery stenosis, of which 7 patients carried the diagnosis of NF.[232] While immediate technical success was reported as 91%, only 39% of patients achieved a cure in HTN and an additional 17% of children demonstrated improvement. In total there was a 44% rate of clinical failure and these authors conclude that despite a high rate of technical success, PTA provides a clinical benefit in a smaller majority of children. This is consistent with improvement or cure rates that mainly average 50% to 60% across larger series of pediatric renal artery stenosis treated with PTA.[233–235] Notably, renal PTA for the treatment of pediatric RVH due to ostial disease may be complicated by failures requiring remedial operations that are made more complicated by such or nephrectomy.[236] Moreover, HTN cure is less likely following remedial operation (24% in comparison to 70% as referenced above).

Renal Artery Aneurysm

RAAs are rare with an incidence of 0.1% in the general population.[237–240] The natural history of RAAs appears to be that of slow to null growth with contemporary series estimating a median annualized growth rate of 0.06 to 0.6 mm.[241–243] Aneurysm growth rate does not seem to be affected by aneurysm morphology or calcification.[242] While historic series describe rupture rates as high as 14% to 30% with associated mortality of 80%, contemporary rupture rates are estimated at 3% to 5% with nongestational mortality <10%.[237,240,244–247] Most ruptures are diagnosed at the time of presentation and several authors have supported no rupture during the surveillance of nonoperative RAAs.[248]

Similar to other splanchnic artery aneurysms, RAAs typically present in the sixth decade with women more commonly affected than men.[237,244] Most patients will describe no symptoms, although flank pain and hematuria are most common when symptoms do arise. Clinical examination may reveal HTN, renal bruit or a palpable abdominal mass. Aneurysms are typically solitary, saccular, located at arterial bifurcations, and affect the right renal artery more often than the left.[248] Almost 70% of RAA may be associated with FMD and up to 30% of patients will have an alternate arterial aneurysm.[237,248,249] These aneurysms are commonly identified as an incidental finding by axial imaging; CT is the most common contemporary diagnostic modality, followed by magnetic resonance imaging, ultrasonography, and catheter-based arteriography.[242]

Conventional preoperative arteriography is warranted given the frequency of multiple aneurysms and arterial dysplasia affecting distal branches that may be missed on conventional cross-sectional imaging.

Historically accepted indications for RAA intervention included size >2 cm, female gender within childbearing age, symptoms like pain and hematuria, medically refractory HTN including that associated with functionally important renal artery stenosis, thromboembolism, dissection and rupture. Given the low risk of rupture, slow to null rate of growth, and improved survival following rupture some authors have suggested that a size threshold alone of 2 cm may be antiquated and too aggressive for surgical indication.[241,242] In fact, recently published contemporary guidelines support elective repair in patients with noncomplicated RAA of acceptable operative risk at a size >3 cm (Grade 2C), and at any size in those patient of childbearing potential (2B) or medically refractory HTN and functionally important RAS (2C).[106] The potential for gestational rupture remains a valid indication for repair in women of childbearing age as rupture during pregnancy has been described in aneurysms as small as 1 cm and historic reports suggest maternal and fetal mortality rates that approach 92% and 100%, respectively.[250,251] Pregnancy has previously been associated with a higher rate of RAA rupture, thought to result from increased vascular flow and hormonal changes resulting in weakening of the vessel wall elastic tissue, no large scale studies report the true incidence.[238,248] Gestational RAA ruptures occur mainly in the third trimester with only a few case reports of rupture postdelivery.[252] Notably, contemporary outcomes for both mother and fetus may be improving, as there are recent case reports of gestational rupture resulting in both maternal and fetal survival.

Approximately 70% of patients with RAA have HTN, with up to 100% affected in some series.[237,241,243,247,249,251] Hypotheses for the mechanism of HTN include (1) coexistent renal artery occlusive disease, (2) distal parenchymal embolization, (3) compression or kinking of associated renal artery branches, and (4) hemodynamic changes from turbulent blood flow within the aneurysm results in decreased distal renal artery perfusion.[237,247] Most series suggest improvement or cure in the majority of hypertensive patients undergoing RAA reconstruction, with postoperative improvement more likely when RVH or renal artery stenosis is identified preoperatively.[244,248,251]

Open surgical repair remains the gold standard for RAA management as these procedures performed in the elective setting offer low morbidity, negligible mortality, and durable patency.[241,242,244–247,249,253,254] Options for conventional in situ reconstruction may include aneurysm resection with (1) primary angioplastic closure with or without branch reimplantation, (2) patch angioplasty, (3) primary reanastomosis, (4) interposition bypass, (5) aortorenal bypass, (6) splanchnorenal bypass, and (7) plication of small aneurysms. While complex distal branch lesions were historically treated with nephrectomy, they may rather best be approached with ex vivo repair and autotransplantation which offers excellent technical success without major morbidity or mortality.[202,255] Most recently, robotic techniques have been introduced that may become more prevalent in future practices.[256,257] Most authors advocate completion imaging before hospital discharge and long-term follow-up with surveillance imaging.

While traditional endovascular therapies for RAA have utilized coil embolization for distal and parenchymal aneurysms and stent graft exclusion for main renal artery lesions, the indications for endovascular repair have broadened with the introduction of three-dimensional detachable coils, nonadhesive liquid embolic agents (i.e., Onyx), remodeling techniques (which include balloon- and stent-assisted coiling), and flow diverter stents (i.e., the Cardiatis multilayer stent).[248,258–260] Technical success is suggested as 73% to 100% across series with highly variable rates of morbidity (13% to 60%) that include primarily radiographic evidence of end-organ malperfusion from thromboembolism and subsequent postembolization syndrome, negligible evidence of arterial dissections or renal compromise, and low rates of recanalization requiring reintervention (4% to 13%).[254,261–263] Although prospective data are lacking, limited comparisons of open surgical and endovascular procedures have reported no significant difference in mortality, perioperative morbidity, freedom from reintervention, decline in renal function, or length of stay.[242,254,264]

Aortoiliac Occlusive Disease

Loay S. Kabbani, Mitchell R. Weaver, and Alexander D. Shepard

Key Points

1. Aortoiliac occlusive disease is mainly the result of atherosclerosis.
2. Claudication is the most common presenting symptom of patients with significant isolated aortoiliac occlusive disease. Some patients may complain of erectile dysfunction.
3. Physical examination typically reveals diminished or absent femoral pulses.
4. Medical treatment of atherosclerotic aortoiliac occlusive disease is key to long-term success. This includes risk factor modification (smoking cessation, control of hypertension, lipid abnormalities, and diabetes mellitus), supervised walking programs and pharmacotherapy.
5. Smoking is the most important reversible risk factor for the development of lower extremity atherosclerotic occlusive disease.
6. Endovascular approaches are favored for most candidates with aortoiliac disease requiring intervention.

INTRODUCTION

1 Peripheral a rterial disease (PAD) is usually a manifestation of systemic atherosclerosis. It affects 3% of the general population older than 40 years and 15% of those older than 70 years, with approximately 50% of patients with PAD being asymptomatic.[1,2] Atherosclerotic occlusive disease of the aorta and iliac arteries alone, or in combination with femoropopliteal or tibial occlusive disease, is the most frequent cause of chronic lower extremity arterial insufficiency.

The wide availability of computed tomographic angiography (CTA) and magnetic resonance angiography (MRA) has facilitated diagnosis, anatomic definition, and subsequent intervention for aortoiliac occlusive disease (AIOD). Selection of a patient-specific treatment from an increasing array of treatment alternatives, although challenging, will usually alleviate symptoms and reduce the risk of disease progression. Endovascular and open reconstructive procedures for AIOD have become routine, with low perioperative morbidity and mortality and excellent early and long-term outcomes.

ETIOLOGY

Atherosclerosis is a systemic disease. The earliest lesions tend to occur at arterial bifurcations and in areas of relative fixation, where disruption of normal laminar flow is greatest, and where eddy currents result in areas of low arterial wall shear stress. Arteriopathies other than atherosclerosis, such as Takayasu disease and radiation arteritis, can also involve the aortoiliac system. Smoking is the most important reversible risk factor for the development of lower extremity atherosclerotic occlusive disease. Other risk factors include hypertension, lipid abnormalities, diabetes mellitus, male sex, older age, and genetic predisposition.

Anatomy and Pathophysiology

The arteries supplying blood to the lower extremities are frequently divided into abdominal, or “inflow,” arteries (the aorta and iliac arteries) and

infrainguinal, or "outflow," arteries (the femoropopliteal and tibial arteries).

In slowly developing aortoiliac occlusive lesions, hemodynamic alterations lead to the enlargement of a network of collateral channels around the involved segments; this collateral network is usually sufficient to provide enough blood flow to meet the resting metabolic needs of the lower extremities (**Figs. 90.1** and **90.2**). These channels, however, do not have the capacity to increase blood flow to the level necessary to meet exercise demands of the lower extremity musculature.

PRESENTATION

Patients with symptoms of AIOD usually present in their 50s and 60s, whereas patients with infrainguinal disease or multilevel disease (AIOD plus infrainguinal) generally present in their 70s.[3]

- 2 Claudication (Latin *claudicare* = "to limp") is the term used to denote the characteristic exercise-induced, cramping pain in the muscles of the lower extremity that results from demand ischemia.[4] Claudication is the most common presenting symptom of patients with significant aortoiliac disease. Induced by ambulation and quickly relieved by rest, claudication is usually described as a cramping pain or easy fatigability of the involved muscle groups. Although patients with aortoiliac disease classically present with claudication of the thighs, hips, and buttocks, a significant number complain of calf claudication or have significant overlap. Erectile dysfunction in men secondary to reduced hypogastric perfusion is another common complaint and may be reported in as many as 30% to 50% of men with AIOD. 3 The combination of bilateral lower extremity claudication, atrophy of the lower extremity musculature, impotence, and diminished or absent femoral pulses is known as Leriche syndrome, after the French physician René Leriche who first described this constellation of findings in 1940.[5]
- Chronic limb-threatening ischemia (CLTI)[6] symptoms manifest in the lower leg or foot as ischemic rest pain, nonhealing wounds, or gangrene. Such symptoms may be a manifestation of AIOD alone but almost always occur in combination with more distal femoropopliteal/tibial disease which is known as multilevel arterial occlusive disease. In the absence of

infrainguinal disease, aortoiliac collaterals are usually capable of maintaining adequate resting distal tissue perfusion.

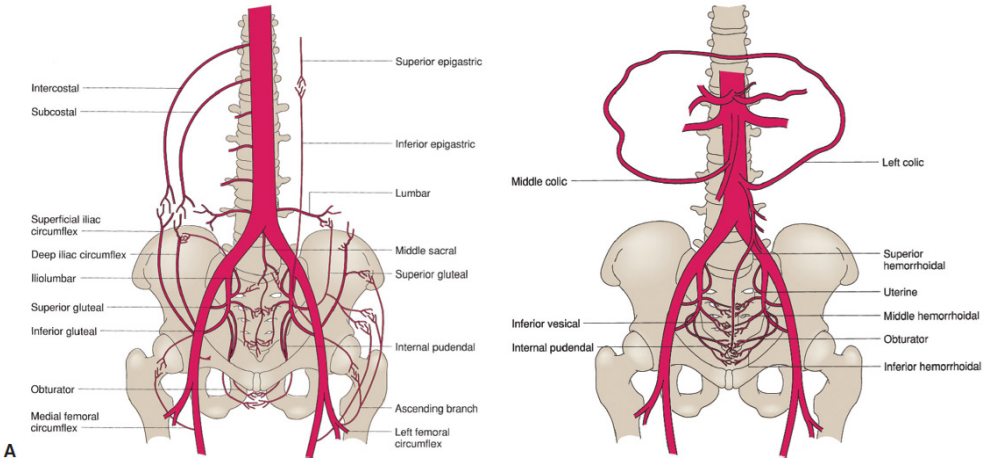

Figure 90.1 **A, B:** Major visceral and parietal collateral networks that may become prominent with aortoiliac occlusive disease.

- Acute arterial occlusions from emboli lodging at the aortic, iliac, or femoral bifurcations do not allow time for collateral pathways to mature and compensate for the sudden loss of blood supply. This situation leads to the acute onset of symptoms, with the resulting five “Ps” of acute ischemia: pain, pallor, pulselessness, paresthesia, and paresis/paralysis.

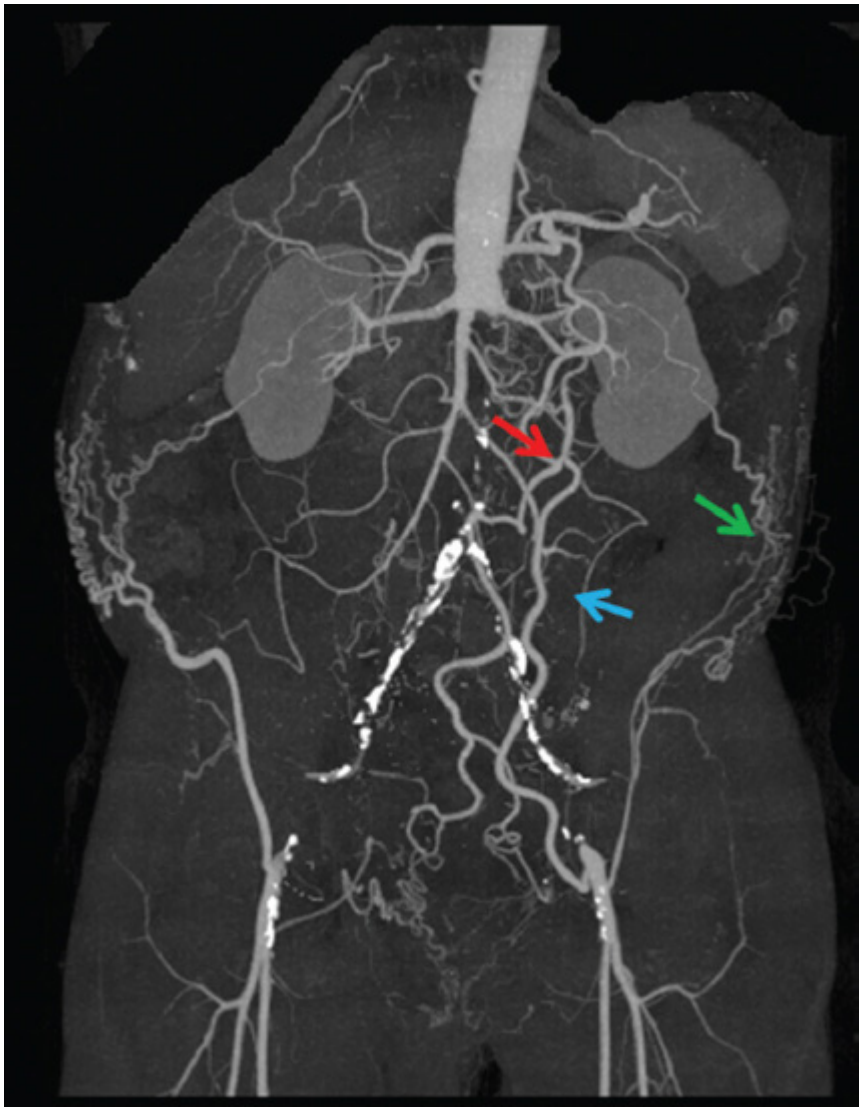

Figure 90.2 CTA with 3D reconstruction demonstrating severe aortoiliac occlusive disease with juxtarenal aortic occlusion. Note the extensive collateral networks reconstituting the inferior mesenteric artery (*red arrow:* marginal artery) and femoral arterial segments (*blue arrow:* inferior epigastric artery) (*green arrow:* subcostal arteries and superficial iliac circumflex artery collaterals).

Downstream embolism of debris from proximal atherosclerotic disease into the microcirculation of the lower extremities ("trash foot") can produce dermal discoloration in a characteristic reticular pattern (livedo reticularis), digital ischemia, or even gangrene (**Fig. 90.3**). Such patients may have palpable pedal pulses. Embolic events can occur spontaneously or can be induced by interventions, such as guidewire manipulation (e.g., during

angiographic procedures or placement of an intra-aortic balloon pump) or clamping an artery with unstable plaque during open vascular surgery.

Physical examination typically reveals diminished or absent femoral pulses. A bruit auscultated over the groins or lower abdomen is not specific for critical stenosis. Severely diseased, calcified femoral arteries may be palpable as firm, tubular structures in the groins. Normal femoral and distal pulses may be palpable, even in the presence of hemodynamically significant aortoiliac stenosis. These pulses, however, rapidly disappear following ambulation, as the increased flow demands of the exercising leg muscles lead to lowered peripheral vascular resistance and reduced distal arterial pressure. Patients with longstanding aortoiliac atherosclerosis may have disuse atrophy of the lower extremity musculature. Other common signs of lower extremity arterial occlusive disease include trophic changes, such as hair loss on the legs or toes, and thin, shiny skin on the feet; patients with severe reductions in pedal blood flow may display pedal rubor with limb dependency, coupled with pallor on elevation.

Figure 90.3 Digital atheroembolization progressed to gangrene.

Table 90.1 TASC II Classification

Type A: Limited stenoses (<3 cm) of the common or external iliac arteries	
Type B: Short stenoses of the infrarenal aorta and short stenoses or occlusion of the iliac arteries	Type C: Longer stenoses and/or occlusions of the iliac arteries, especially when calcified	
Type D: Infrarenal aortic occlusion sometimes with multiple iliac occlusions and stenoses or associated aneurysm disease	
Clinical Pathologic Types of Aortoiliac Disease

The Trans-Atlantic Inter-Society Consensus for the Management of PAD (TASC II) has classified AIOD into four types, A through D (**Table 90.1**).[7] Patients with focal disease (TASC II types A, B) requiring intervention can usually be treated with endovascular means, while those with more advanced

disease (TASC II C, D) are more challenging and may require more complex endovascular, hybrid surgical, or open surgical approaches.

Aortoiliac hypoplasia also known as *small aortic syndrome* or *hypoplastic aortic syndrome* is encountered in young to middle-aged women who smoke cigarettes. The infrarenal aorta and iliac arteries are unusually small in caliber and hence prone to significant narrowing, even with modest disease. Operative treatment of such patients can be particularly challenging.[8]

DIAGNOSIS

In most cases, diagnosing significant AIOD and its severity can be made on the basis of history and physical examination alone. A clinical diagnosis, however, should always be supplemented by noninvasive vascular testing. Such tests provide valuable information by confirming the presence of disease, assessing the degree of ischemia, objectively documenting the arterial segment(s) involved, and establishing a baseline from which the patient can be followed and appropriate interventions planned. Treatment results can be assessed by repeated testing. Formal imaging studies (CTA, MRA, and arteriography) are usually reserved for those patients considered for intervention.

Noninvasive Vascular Testing

Segmental Doppler-derived pressure measurements or pulse volume recordings are useful for demonstrating the physiologic significance of disease and can help localize hemodynamically significant lesions. Measurement of systolic arterial pressures at different levels of the lower extremity with a continuous wave Doppler flow probe is the simplest and most useful noninvasive method to assess arterial occlusive disease. The ratio of the ankle systolic pressure (measured at either the dorsalis pedis or the posterior tibial artery) to the brachial systolic pressure (using the higher of the two brachial pressures) is the ankle-brachial index (ABI), or pressure ratio, and is a good measure of the degree of ischemia present.[9] Normal ABIs are generally equal to or slightly greater than 1.0 (**Fig. 90.4**). PAD is

designated when the ABI is ≤0.90. Patients with claudication usually have ABIs ranging from 0.50 to 0.90, whereas patients with rest pain, tissue loss, or gangrene usually have ABIs of <0.50 (**Table 90.2**).[9]

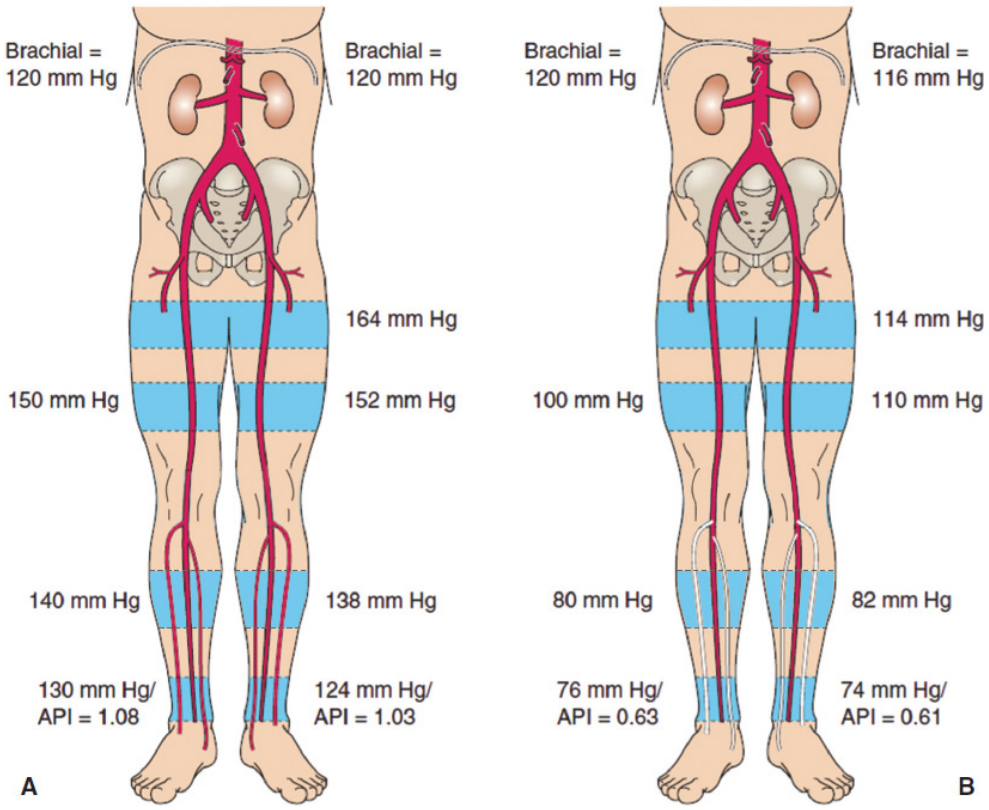

Figure 90.4 Segmental pressure measurements typical of normal results (**A**) and aortoiliac occlusive disease (**B**).

Determination of limb systolic pressures at different locations (with the "four-cuff" technique, where pressures are measured at the upper thigh, lower thigh, calf, and ankle) provides information concerning which arterial segments are involved with occlusive disease (**Fig. 90.4**) and helps define the presence of inflow artery disease, outflow (runoff artery) disease, or a combination of the two.[10] A pressure drop of more than 20 mm Hg between adjacent levels indicates significant disease within the intervening arterial segment. A reduced upper thigh pressure signifies occlusive disease in the aortoiliac or common femoral segments.

In patients with extensive calcification in the walls of the tibial arteries (as is frequently seen in diabetes mellitus or end-stage renal disease), may have incompressible arteries and have falsely elevated ABIs. In this

situation, the pressure in the digital arteries of the great toe can be measured, since small vessels are generally spared calcification. A toe pressure of less than 30 mm Hg indicates severe ischemia. Inspection of the Doppler-derived arterial waveforms can provide additional information.

Patients with claudication occasionally have normal or nearly normal ABIs. In such cases the arterial stenosis is not severe enough to cause a pressure drop in the limb at rest but does produce a significant hemodynamic change under conditions of higher flow rates when the distal vasculature dilates, as occurs with exercise. When the distal pressure drops because of vascular dilation, the stenosis prevents increased blood flow into the extremity so that a significant distal pressure drop results. The classic treadmill test involves walking on a treadmill at 1.5 miles per hour at a 14% incline for as long as the patient can go, up to 5 minutes. ABIs are measured before and after the treadmill exercise; a drop of 15% or more in the ABIs following exercise is indicative of a hemodynamically significant stenosis.[9]

Duplex scanning of the aorta and iliac arteries has been advocated by some as a noninvasive diagnostic tool. Accurate imaging of the abdominal arteries, however, can be difficult because of their deep retroperitoneal and pelvic locations, which can be further degraded by body habitus and overlying bowel gas. These drawbacks have limited the widespread use of this modality.[11] Arteriography, CTA, and MRA may be used for diagnosis, but are usually performed when interventional therapy is contemplated, and are, therefore, discussed later.

Table 90.2 Ankle-Brachial Indices

Ankle Brachial Indices (ABI) and Toe Brachial Indices (TBI)			
ABI Value	**TBI Value**	**Doppler Waveform**	**Disease**
> 1.2			Heavily calcified (incompressible) vessels
0.95–1.2	>0.63	Biphasic or triphasic	Normal
0.8–0.95	0.4–0.62	Biphasic or monophasic	Mild
0.5–0.8	0.2–0.39	Biphasic or monophasic	Moderate
<0.5	<0.2	Monophasic	Severe

Table 90.3 Differential Diagnosis of Claudication

The Differential Diagnosis for Intermittent Claudication (IC)

Condition	Location	Prevalence	Characteristic	Effect of Exercise	Effect of Rest	Effect of Position	Other Characteristics
Calf IC	Calf muscles	Common	Cramping, aching, discomfort	Reproducible onset	Quickly relieved	None	
Thigh and buttock IC	Buttocks, hip, thigh	Rare	Cramping, aching discomfort	Reproducible onset	Quickly relieved	None	Impotence. May have normal pedal pulses with isolated iliac artery disease
Venous claudication	Entire leg, worse in calf	Rare	Tight, bursting pain	After walking	Subsides slowly	Relief faster with elevation	History of deep vein thrombosis
Nerve root compression	Radiates down leg	Common	Sharp lancinating pain	Induced by sitting, standing, or walking	Often present at rest	Improved by change in position	History of back problems. Present with sitting, standing, or walking
Spinal stenosis	Often bilateral buttocks, posterior leg	Common	Pain and weakness	Induced by standing, or walking	Variable relief but can take a long time to recover	Relief by lumbar spine flexion	Worse with standing and extending spine
Symptomatic Baker cyst	Behind knee, down calf	Common	Swelling, tenderness	With exercise	Present at rest	None	
Hip arthritis	Lateral hip, thigh	Common	Aching discomfort	After variable degree of exercise	Not quickly relieved	Improved when not weight bearing	History of degenerative arthritis
Chronic compartment syndrome	Calf muscles	Rare	Tight, bursting pain	After much exercise (jogging)	Subsides very slowly	Relief with elevation	Usually athletes

Differential Diagnosis

The diagnosis of AIOD is usually straightforward, but occasional diagnostic difficulty may arise when other causes of lower extremity pain are present (**Table 90.3**). Irritation of lumbosacral nerve roots by spinal stenosis or intervertebral disc herniation may cause buttock and leg pain that is associated with activity. Such symptoms (neurogenic claudication), however, usually cannot be reproduced at the same level of activity, frequently occur when the patient is standing, and are relieved only by sitting or lying down. In addition, the pain is usually in a classic sciatic distribution.

Degenerative arthritis of the hip joints may produce similar buttock, hip, and referred thigh pain. There is usually a history of morning stiffness that progressively improves over the course of the day. Physical examination typically reveals tenderness directly over the hip joint that is exacerbated by moving the joint.

Peripheral neuropathy, particularly that associated with diabetes mellitus, may masquerade as ischemic rest pain.

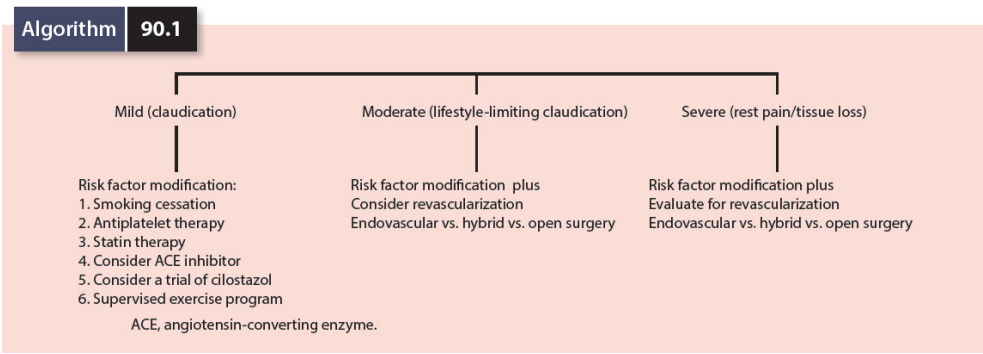
In all these situations, segmental limb pressure measurements, with or without stress testing, can be helpful in determining the contribution of arterial occlusive disease to the patient's symptoms.

TREATMENT

The aims of therapy in AIOD are to relieve symptoms and, in cases of CLTI, to prevent limb loss (**Algorithm 90.1**). Medical therapy should be instituted in all patients with atherosclerotic disease but is insufficient as sole therapy in patients with limb-threatening ischemia.

4 Medical Therapy (Table 90.4)[12]

Atherosclerosis is a systemic disease. Medical therapy is, therefore, key to reducing the risk associated with cardiovascular morbidity and death in these patients. Risk factor modification, including management of diabetes mellitus, control of hypertension, treatment of hyperlipidemia, and finally modification of lifestyle including smoking cessation, appropriate diet, and exercise, are perhaps the most important components of the care of patients with atherosclerotic disease.[12,13] Although risk factor control will not reverse the atherosclerotic process, it can limit disease progression; furthermore, some data indicate that smoking cessation lessens the severity of symptoms in many patients.[14]



Algorithm 90.1 Patient with symptomatic aortoiliac occlusive disease.

5 Smoking Cessation

Smoking is associated with a subclinical inflammatory reaction. The degree of damage caused by smoking is directly related to the amount of tobacco consumed.[15] All patients who are smokers or former smokers should be asked about the status of tobacco use at every visit. All patients should be strongly advised to stop smoking by their physicians. All patients should be offered pharmacotherapy, behavior modification, referral to a smoking cessation program, and counseling.[16] Smoking cessation alters the progression of the atherosclerotic process and may even reduce the severity of claudication.[17] Furthermore, it is an important step to reducing postprocedure complications in patients undergoing intervention.[18]

Exercise

Supervised exercise programs have been consistently demonstrated to improve walking time and walking distance, and in some studies supervised exercise has been as effective as revascularization.[18,19] Home- and community-based therapy are effective for improving walking tolerance but are less effective than formal supervised exercise programs and are associated with a high dropout rate, underscoring the need for ongoing psychological support.[20] Outcomes of supervised exercise programs have been shown to be similar and longer lasting than those of endovascular interventions for mild claudication. Patients are usually advised to walk until the onset of pain, rest until the pain subsides, and repeat the cycle, for a total of 30 minutes a day, three to five times per week. A 3- to 6-month trial of

exercise should be initiated before revascularization is considered in patients with intermittent claudication.

Table 90.4 AHA Guidelines for Medical Therapy of Patients with PAD

	Recommendations
Smoking cessation	Quit smoking
Weight reduction	Counseling to reduce weight if BMI >25
Hyperlipidemia	LDL <100 mg/dL for all patients or <70 mg/dL if diabetes or other vascular disease
Hypertension	BP <140/90 or <130/80 in patients with diabetes or renal failure
Diabetes	Hemoglobin A1c goal <7.0% or as close to 6% as possible
Antiplatelet therapy	ASA for all patients with symptomatic PAD. Clopidogrel may be an effective alternative to ASA

Diet

A well-balanced diet with low salt, low fat, and moderate amounts of added sugar intake, as per the American Heart Association Guidelines, reduces the risk of chronic diseases in general, and cardiovascular disease in particular, and should be followed.[13]

Glycemic Control

American Heart Association Guidelines recommend aggressive blood glucose control, with a target A1C goal of <7.0%, and as close to 6.0% as possible.[13]

Antiplatelet Therapy

Some form of platelet inhibition should be considered for all atherosclerotic patients in order to reduce the risk of myocardial infarction, stroke, and death.[13] Aspirin is the agent of choice, but clopidogrel may be used if aspirin is not tolerated. The effectiveness of antiplatelet therapy in reducing symptoms of claudication is not established; however, the risk of PAD progression requiring revascularization is significantly reduced by antiplatelet therapy, compared with placebo. Adding aspirin to clopidogrel does not reduce major vascular events, but does increase the risk of major life-threatening bleeding.[21]

Low-Dose Anticoagulation

The combination of a vitamin K antagonist (warfarin) and aspirin in patients with PAD resulted in a higher rate of bleeding without reducing the rate of cardiovascular events. There is some evidence that low-dose Rivaroxaban may decrease the incidence of cardiovascular death, stroke, and/or myocardial infarction in PAD patients but further study is needed.[22]

Antihypertensive Therapy

Antihypertensive therapy reduces mortality from atherosclerotic cardiovascular disease, with a goal blood pressure of less than 130/80 mm Hg. Antihypertensive therapy is, therefore, recommended despite the lack of data substantiating that it alters the progression of PAD.[7]

Lipid-Lowering Therapy

Lipid-lowering therapy with at least a moderate dose of a statin medication is recommended for all patients with atherosclerotic cardiovascular disease, irrespective of the baseline low-density lipoprotein cholesterol. Lipid-lowering therapy reduces disease progression (as measured by arteriography), helps alleviate symptoms, and improves total walking times, pain-free walking distance, and amputations.[23,24]

Other Pharmacologic Therapy

Cilostazol and naftidrofuryl can be valuable adjuncts in selected patients with severe lifestyle-limiting claudication.[25] A therapeutic trial (3 to 6 months) may be tried. Although the mechanisms of action of these agents are

unclear, a modest but significant reduction in claudication symptoms has been shown in controlled trials. Benefit has not been firmly established for other agents.

Indications for Revascularization

Revascularization is clearly indicated in patients with CLTI; without intervention, these patients can progress to limb loss in a fairly short period of time. At 1 year following onset of CLTI symptoms, it is estimated that 25% of patients will lose their limb, 25% will suffer a cardiovascular death. One to 2% of patients with claudication will progress to CLTI per year.[26]

Patients with significant or repetitive atheroembolism from an aortoiliac source represent a group that clearly benefits from early operative intervention. Removal or bypass of the culprit lesion(s) eliminates the risk for further macro- and microembolism.

The treatment of patients with claudication secondary to AIOD remains controversial and must be individualized. Patients with mild to moderate symptoms can usually be treated medically with satisfactory results, while patients with severe, disabling, and lifestyle-limiting symptoms of claudication can benefit from revascularization therapy.

Preintervention Imaging Studies

Once a decision has been made to proceed with revascularization, imaging studies are paramount for developing a treatment strategy.

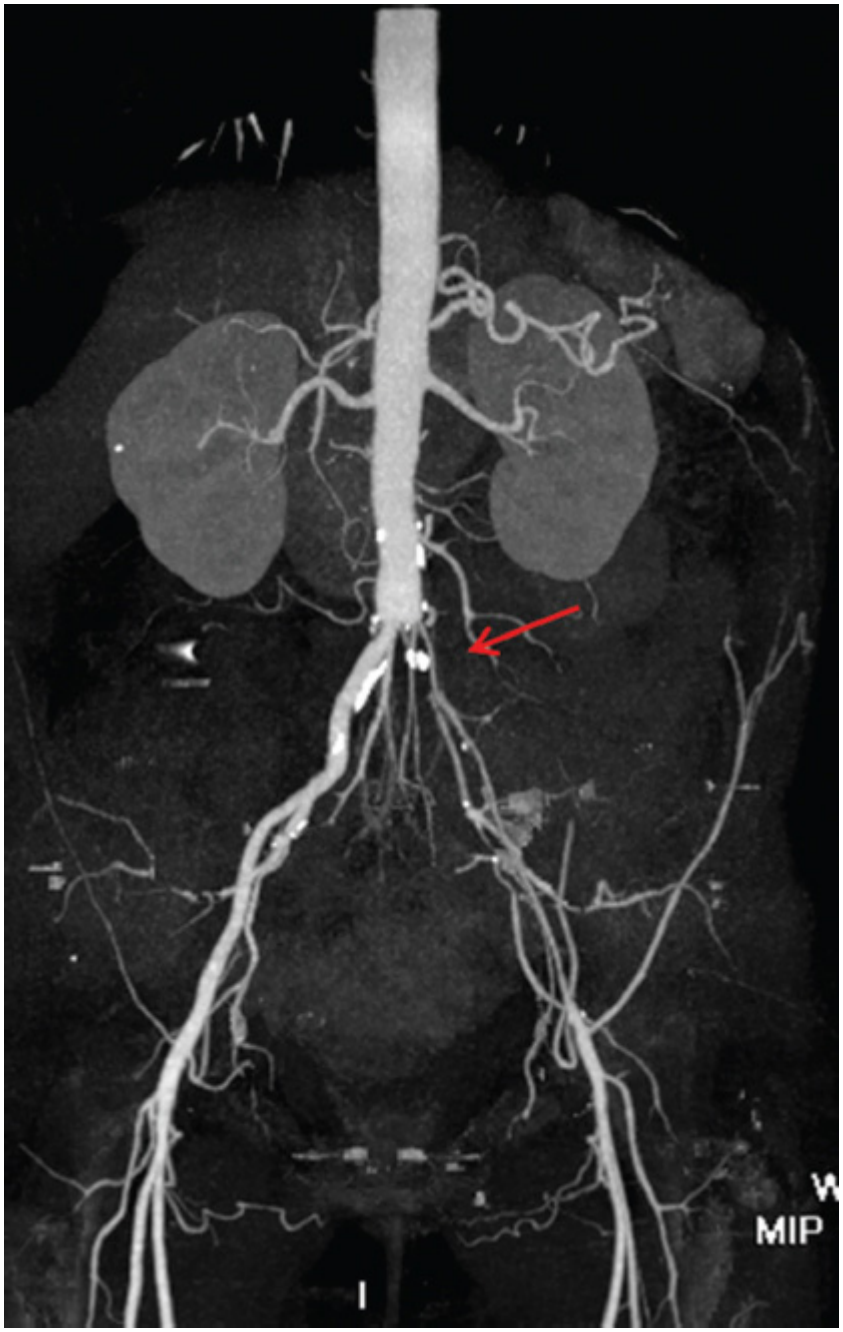


Figure 90.5 CTA 3D reconstruction showing left iliac artery chronic total occlusion (*red arrow*).

Computed Tomographic Angiography

CTA with reformatting requires the intravenous administration of iodinated contrast material, followed by a timed CT scan of the pertinent anatomy. The images are then processed into axial, coronal, and sagittal imaging planes and three-dimensional images (**Figs. 90.2**, **90.5** to **90.7**). For most patients,

120 mL of iodinated contrast is used (300 to 370 mg of iodine per liter of contrast). Sensitivity and specificity are greater than 92% and 93%, respectively, for detecting >50% stenosis. The main drawbacks of CTA are the ionizing radiation and the use of iodinated contrast, which can cause allergic reactions in addition to contrast-induced nephropathy.[27]

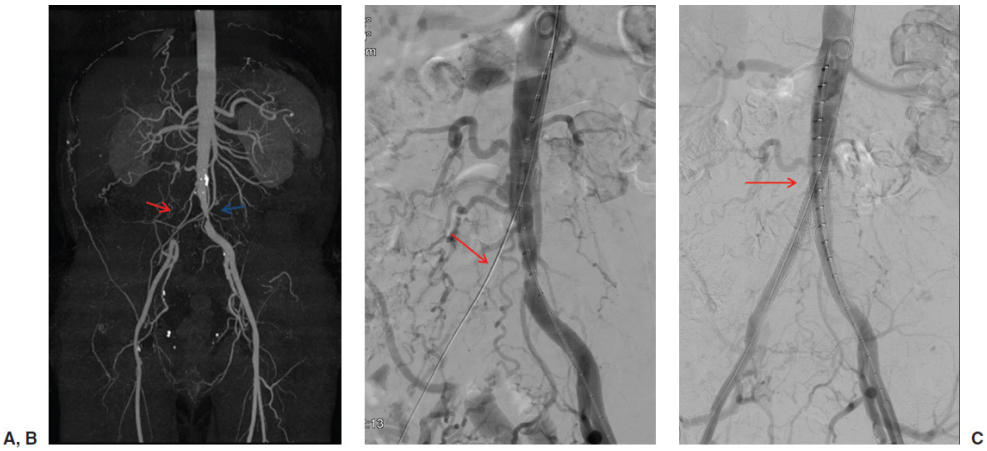

Figure 90.6 **A:** CTA 3D reconstruction demonstrating right common iliac artery chronic total occlusion (*red arrow*) and severe left common iliac artery stenosis (*blue arrow*). **B:** Abdominal aortogram redemonstrating right common iliac artery chronic total occlusion and left common iliac artery stenosis. Note successful wire traversal of the right common iliac artery occlusion (*red arrow*). **C:** Abdominal aortogram demonstrating successful endoluminal bilateral common iliac artery revascularization following percutaneous balloon angioplasty and stent placement. Note the "kissing" stents in the distal aorta (*red arrow*).

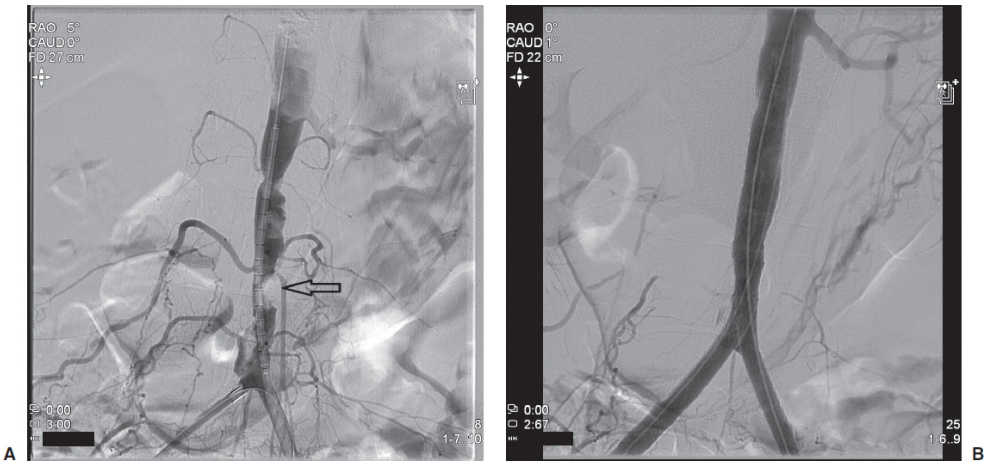

Figure 90.7 CERAB (covered endovascular reconstruction of aortic bifurcation). **A:** Infrarenal aortic stenosis (*arrow*). **B:** Post deployment of bifurcated stent graft.

Magnetic Resonance Angiography

Contrast-enhanced MRA uses intravenous administration of paramagnetic gadolinium-based agents. With good technique, contrast-enhanced MRA has a sensitivity of 80% to 97%, and a specificity of 73% to 96% (**Fig. 90.8**).[28] The disadvantage of MRA is that it cannot be used in patients with metallic implants such as pacemakers and patients with claustrophobia. Furthermore, in patients with moderately severe renal dysfunction (glomerular filtration rate of <60 mL/min/1.72 m^2), concerns for nephrogenic systemic fibrosis secondary to gadolinium limit the use of this technology.[29]

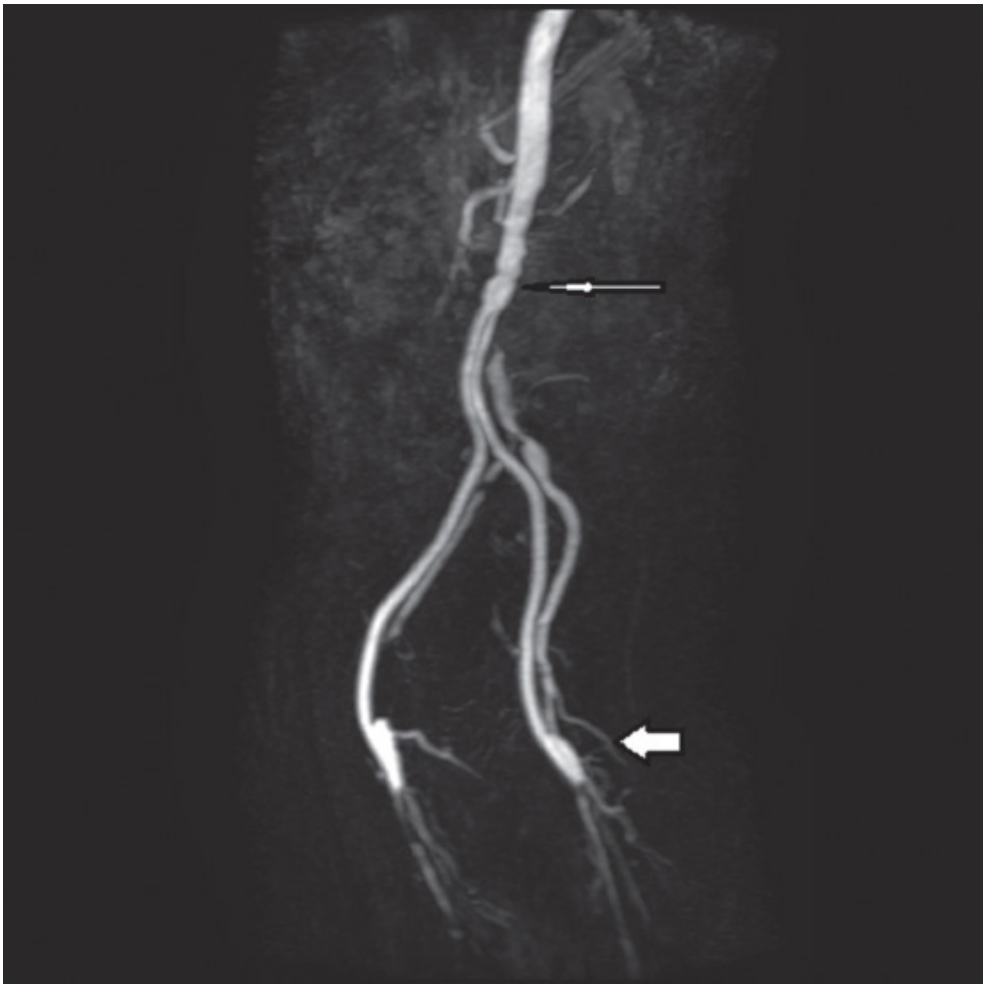

Figure 90.8 MRA of a patient who had an aortobifemoral bypass. Note the proximal anastomosis (*thin arrow*) and the distal anastomosis (*thick arrows*). Also note the retrograde flow into the iliac arteries.

Digital Subtraction Arteriography

Abdominal aortography, with or without demonstration of the arterial tree below the inguinal ligament ("runoff"), is performed after a full workup is completed and may be coupled with a therapeutic intervention. This procedure is most commonly performed via the femoral artery with the better pulse by means of a retrograde Seldinger technique. When neither femoral artery is suitable for puncture, an upper extremity approach may provide the necessary access. Hemorrhage, local hematoma, pseudoaneurysm, arterial thrombosis, or distal embolism of thrombus or atheromatous debris can occur in up to 0.2% of diagnostic procedures and in up to 3% of therapeutic procedures.[30] Anteroposterior views of the aortoiliofemoral segments demonstrate the extent of the occlusive process and the pattern of collateral formation. Oblique views of the iliac and femoral arteries are necessary to document posterior wall plaques and stenoses at the origins of the hypogastric and deep femoral arteries. Views of the "runoff" arteries to at least the midcalf level are required to assess the degree of associated infrainguinal occlusive disease. In cases of CLTI, visualization of the pedal circulation is also necessary. In patients with borderline kidney function, carbon dioxide may be utilized as a contrast agent.

Occasionally, the hemodynamic effect of a stenosis or series of stenoses along an iliac arterial segment may be difficult to determine, even with oblique views. When the significance of a stenosis remains in question, pressures proximal and distal to the lesion(s) can be measured. A systolic pressure gradient of more than 10 mm Hg (or a 5 mm Hg mean gradient) across the stenosis is indicative of a hemodynamically significant lesion.[31] For borderline cases, distal pressure measurements can be obtained before and after interarterial injection of a vasodilator (e.g., 100- to 200-µg nitroglycerin or 25-mg papaverine) to simulate the hyperemic hemodynamics of exercise. A pressure drop of more than 15% systolic pressure (or around 20 mm Hg) during hyperdynamic flow simulation is considered indicative of a hemodynamically significant stenosis.

The information supplied by CTA, MRA, or arteriography is crucial to the success of a revascularization procedure. In addition to providing a detailed "road map" of the exact arterial segments involved, such imaging identifies associated anatomic variations (e.g., accessory renal arteries) and aortic wall characteristics (e.g., extensive calcification and ulcerated plaque), which may alter the operative approach and the conduct of the procedure.

During an open revascularization procedure, a surgeon who knows that the aortic wall just below the renal arteries is heavily diseased with ulcerated plaque may, for example, opt to control the aorta at a more proximal level rather than risk dislodging atheromatous debris with standard infrarenal aortic clamping. Similarly, documented occlusive lesions in the visceral or renal arteries (e.g., a patent inferior mesenteric artery with a large "meandering mesenteric artery") may best be addressed at the time of aortic reconstruction, or require particular attention to avoid complications.

Preoperative Evaluation

Evaluation of patients for whom aortoiliac revascularization is being considered should include a careful assessment of overall operative risk. Age per se is not a contraindication to an open aortic reconstruction, if it is required. A less invasive procedure of more limited durability, however, may provide a similarly excellent outcome in a patient with reduced life expectancy. Patients with significant AIOD may have atherosclerotic occlusive disease in other vascular territories (e.g., coronary and cerebral) that can increase their operative risk. The detection and treatment of significant coronary artery disease is particularly important, because myocardial infarction is the leading cause of both perioperative and late mortality. In patients with significant aortoiliac disease, more than 50% have clinical or electrocardiographic evidence of coronary disease.[32] In the Coronary Artery Revascularization Prophylaxis (CARP) trial, patients undergoing elective, open, abdominal aortic surgery for aortoiliac occlusive or aneurysmal disease at Veterans Administration hospitals were assessed for cardiac risk.[33] With optimal medical management, there was no difference in outcome between those who underwent coronary revascularization prior to aortic surgery and those who did not. Only selected patients, therefore, require cardiac catheterization and occasional coronary angioplasty or bypass grafting before undergoing open aortic reconstruction, and these patients need to be stratified according to risk guidelines.[34]

Respiratory complications occur in 10% to 15% of patients after open aortoiliac repair, and pulmonary function should be assessed preoperatively only if clinical evaluation cannot determine that the patient is at his/her best

achievable baseline pulmonary function and that airway obstruction has not been optimally treated. There is otherwise no indication for routine preoperative pulmonary function testing, as the American College of Physicians Guidelines state that routine preoperative spirometry is not useful for predicting the risk of postoperative pulmonary complications.[35] Smokers who quit more than 4 weeks before surgery have a significantly lower risk of respiratory complications and improved wound healing.

Choice of Revascularization Technique

A variety of surgical procedures, both endovascular and open, are available for revascularization in the patient with AIOD. Selection depends on a number of factors, including the pattern of the occlusive process, patient risk, surgeon experience, and patient preference.

Commonly used techniques include (a) catheter-based balloon dilation (angioplasty) with or without luminal stenting, (b) arterial reconstruction with an anatomically placed bypass prosthesis (aortofemoral or iliofemoral bypass), (c) arterial reconstruction with a remote (or extra-anatomically placed) bypass prosthesis (axillofemoral or bifemoral, femorofemoral, thoracofemoral bypass), (d) aortoiliac endarterectomy, and (e) a hybrid approach encompassing a combination of endovascular and open procedures.

Catheter-based techniques are best suited for localized lesions of the common iliac arteries. However, this approach is currently being used as the main therapeutic modality for the majority of patients; it has essentially replaced endarterectomy procedures in patients with focal AIOD, and even more complex lesions. Prosthetic aortofemoral bypass is the procedure of choice for most patients with advanced, extensive aortoiliac atherosclerosis. Femorofemoral bypass can be chosen in poor-risk patients with diffuse unilateral iliac disease. Axillofemoral or axillobifemoral bypass is reserved for the subset of patients in whom standard aortic reconstruction is considered too risky, either for medical reasons (usually severe pulmonary or cardiac disease) or for technical reasons (e.g., aortic reoperations, multiple prior abdominal procedures with dense adhesions, prior abdominal irradiation, and prosthetic graft infection).

Percutaneous transluminal angioplasty (PTA) with or without stenting has become the most commonly performed and, in many cases, the preferred therapy for iliac artery occlusive disease. Like open operative reconstruction, PTA, when properly selected, has a high rate of success owing to the large caliber and high rates of flow in the aortoiliac segment. The pattern of the occlusive process and patient comorbidities are primary considerations in selecting PTA as the mode of therapy. The best results are obtained with short, focal, stenotic lesions in the common iliac arteries. Patients with severe atherosclerotic lesions, complicated stenoses, and occlusions may also benefit from complex endovascular approaches, with many series documenting excellent short and intermediate-term success. Atheromatous embolism (blue toe syndrome) from an ulcerative plaque may be treated with placement of a stent to trap the debris, relieve the stenosis, and prevent recurrent embolism.

Description of Technique

Preprocedure planning sets the stage for a successful endovascular intervention. Although not absolutely necessary, CTA or MRA can delineate the location, extent, and degree of stenosis and associated calcification (**Fig. 90.6A**). Other considerations include the possible need for a concomitant femoral endarterectomy. When there is significant common femoral artery disease (>50% stenosis) along with iliac occlusive disease, a femoral endarterectomy with patch angioplasty is performed. The endarterectomy should extend as high as possible under the inguinal ligament into the external iliac artery to facilitate stent deployment into the proximal endarterectomized segment but avoid its placement into the common femoral artery itself. A hydrophilic wire with an angled tip, and a straight or angled catheter for support are utilized to cross the stenosis or occlusion. Common iliac artery disease is treated through an ipsilateral retrograde approach if the external iliac is open. If the common iliac artery is occluded, bilateral punctures of the femoral arteries will be necessary to perform aortography to delineate the extent of obstruction (**Fig. 90.6B**). In the absence of significant ipsilateral common femoral artery disease, external iliac disease is usually approached antegrade through a contralateral femoral puncture and “up and over” the aortic bifurcation. Crossing total occlusions may be challenging, and reentry into the true lumen from the subintimal space can be difficult. If

crossing an occlusion cannot be achieved from the chosen point of vascular access (e.g., the ipsilateral common femoral), an attempt should be made from a new access site (e.g., contralateral common femoral or brachial). For more challenging cases, reentry devices such as the OUTBACK (Cordis Corp., Bridgewater, NJ) or Pioneer (Medtronic, Fridley, MN) catheters may be used. Once the lesion is successfully crossed with a wire, the mode of intervention should then be considered. The typical balloon size used for common iliac arteries is 8 to 10 mm in diameter, and for external iliac arteries 7 to 8 mm in diameter. The principal cause of balloon angioplasty failure is recoil of the atherosclerotic artery or a flow-limiting dissection. Stents serve as support to oppose the elastic recoil of the media and adventitia of the artery after angioplasty. They are also highly effective in sealing dissection planes within the atherosclerotic plaque resulting from the angioplasty procedure. Stents are also indicated for residual postballoon stenosis (>30%), persistent gradients (>10 mm Hg), ulcerative plaques that have a high risk of showering debris, and after recanalization of an occluded artery. Most vascular interventionalist stent iliac lesions primarily, rather than ballooning first to see if there is an issue requiring stenting (e.g., a residual dissection). Primary stenting for complex aortoiliac disease is thought to decrease complications and reduce overall long-term failure.[36,37]

Self-expanding stents come precovered with a sheath and can be introduced into the lesion directly. Pulling back the sheath allows the compressed stent to assume its expanded form. Self-expanding stents may be more flexible and less likely to get crushed in the event they are deployed close to or past the inguinal ligament into the common femoral artery and are, therefore, used more frequently in the external iliac artery. With self-expanding stents, postdeployment balloon angioplasty is usually needed to achieve full expansion. These stents are usually chosen 10% to 15% larger than the intended lumen diameter; undersizing must be avoided as self-expanding stents cannot be dilated past their nominal diameter.

Balloon expandable stents are sometimes preferred to self-expanding stents in the common iliac artery, owing to their ease and precision of deployment, their better visibility under fluoroscopy, and the increased radial force of their design. These stents are usually introduced through a long sheath passed through the lesion to prevent dislodgment of the stent as it traverses the lesion. The sheath is pulled back once the stent is in satisfactory

position, and the stent is deployed under fluoroscopic guidance. Balloon expandable stents are usually sized to the diameter of the normal adjacent artery. Slight undersizing of the stent can be easily managed by further dilating the stent, using a larger balloon. Covered balloon-expandable and self-expanding stents have been introduced and are purported to offer a longer patency rate by controlling neointimal hyperplasia that may grow through the interstices of a noncovered stent.[38] Covered stents may also be useful for ulcerated plaques, because they reduce the chance of distal atheromatous embolism and for heavily calcified or tortuous iliac arteries that are more prone to rupture with balloon inflation.

Lesions just above the aortic bifurcation are usually complex, exophytic, and calcific, and commonly involve both common iliac arteries. Safe and effective intervention in this situation typically requires the use of two stents, one in each iliac artery, that partially project into the aorta so that they "kiss" in the distal aorta (**Fig. 90.6C**). Theoretically, treating only one common iliac artery orifice can result in plaque shifting during the angioplasty, causing a new obstruction of the contralateral lumen. Treating both sides simultaneously ("kissing stents") avoids this complication. Endovascular stent grafts, similar to those used in the treatment of abdominal aortic aneurysms, have been evaluated for the treatment of AIOD; this is known as covered endovascular reconstruction of the aortic bifurcation (CERAB) (**Fig. 90.7**). Flow dynamics seem better with CERAB[39] and covered stents are associated with the purported advantages outlined previously. In one CERAB series, the 3-year primary and secondary patency rates were 82% and 97%, respectively.[40] Although these rates are inferior to conventional open reconstruction, they suggest that endovascular reconstruction affords a reasonable alternative when open procedures are high risk or contraindicated.

Table 90.5 Complications of Endovascular Therapy

Complication	
Access site hematoma	5%
Pseudoaneurysm	1.60%
Distal embolization	1.10%
Rupture	0.50%
Thrombosis	0.60%

Complications of Endovascular Interventions

The overall procedure-related complication rate has decreased over the years. It is cited to be around 10% of cases, while the rate of major complications is 5% with access site complications being the most common (**Table 90.5**).[41,42] The incidence of contrast-induced nephropathy is low but is troubling in patients with pre-existing renal insufficiency. Depending on the risk factors and amount of contrast used, the risk of any renal dysfunction ranges from 5% in low-risk patients to >50% in the high-risk groups.[43] Low-osmolality or iso-osmolality agents should be used in patients with moderate renal insufficiency. Volume expansion should be considered in the periprocedural period. The most serious intraoperative complication is arterial rupture during angioplasty (0.5% to 3%). This is seen as active extravasation on the postintervention angiogram and can be heralded by abdominal pain and hypotension. Treatment is quick passage and reinflation of the balloon to occlude the rupture site to maintain hemodynamic control and then either deployment of a covered stent across the rupture site or open repair in the operating room.

Outcome of Endovascular Interventions (*Table 90.6*)

Initial technical success is quite high (>90%).[41] The most common reasons for technical failure are inability to cross an occluded arterial segment, thrombosis after intervention, or arterial rupture. Surveillance with ABIs and possible duplex ultrasound play a major role in maintaining patency in these patients. The primary patency of iliac artery stenting is 60% to 80% at 5

years, but this can improve to >90% with close surveillance and reintervention as necessary.[41,42,44]

Table 90.6 Results of Endovascular Interventions for AIOD

Procedure	Technical Success	5-y Primary Patency	5-y Secondary Patency	Mortality
Iliac angioplasty and stenting	85–100% Technical success	60–80% 3-y primary patency	80–98% 3-y secondary patency	1–6%
CERAB[a]	97%	86%	97%	N/A

[a]CERAB, covered endovascular reconstruction of aortic bifurcation.

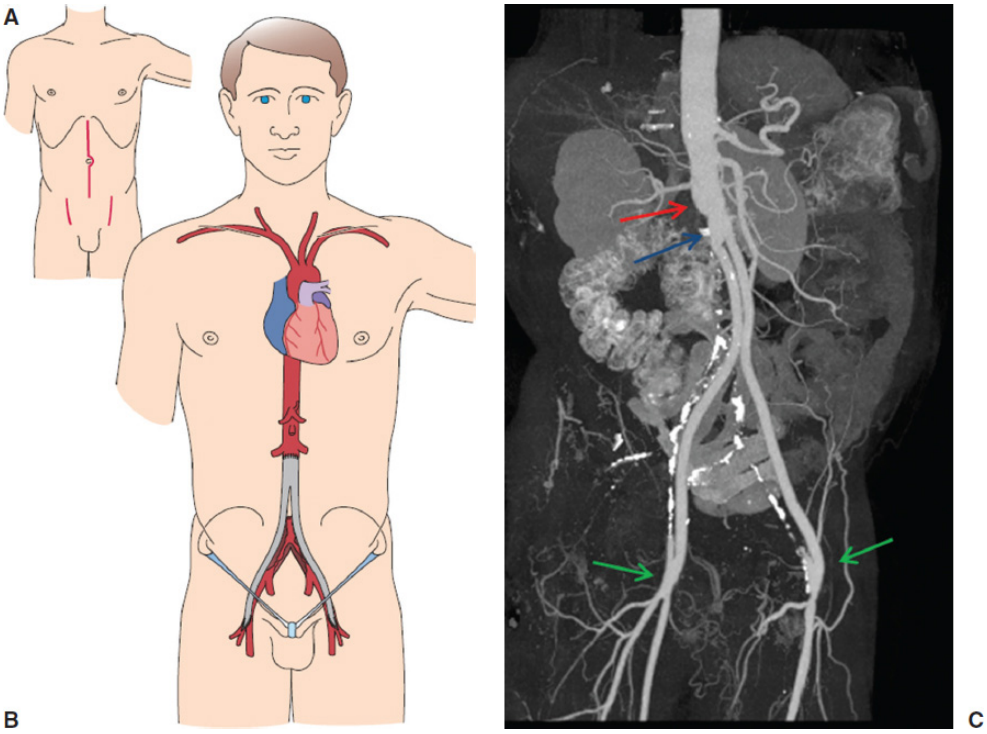

Figure 90.9 **A:** A midline abdominal incision and bilateral groin incisions overlying the common femoral arteries offer exposure for performance of aortobifemoral bypass. **B:** This image demonstrates an end-to-end proximal aortic to graft reconstruction with the respective graft limbs anastomosed end to side to the common femoral arteries. **C:** Computed tomographic angiographic postprocessed and reformatted image demonstrating open aortobifemoral arterial reconstruction of juxtarenal aortic occlusion (see **Fig. 90.2**, preoperative image) with prosthetic bifurcated graft. Note endarterectomy of aorta immediately distal to renal arteries (*red arrow*), followed by proximal end-to-end anastomosis between graft and aorta (*blue arrow*). Distal anastomosis to femoral arteries is performed in end-to-side fashion (*green arrows*).

Open Surgical Management

Aortobifemoral (AF2) bypass has been the gold standard open surgical procedure for treating AIOD for decades. Five-year patency rates are in excess of 95%, which is unmatched by any endovascular procedure.[45,46] However, direct revascularization of the aortoiliac segment is currently reserved for patients with advanced occlusive disease, for whom the risk of surgery is acceptable and a durable long-term result is required.

Description of Aortofemoral Bypass (Fig. 90.9)[46]

The operation begins with bilateral groin incisions to expose the common, superficial, and deep femoral arteries as needed. Starting the operation in the groins minimizes the duration of time the abdomen is open; this limits fluid loss and hypothermia, and decreases the risk of graft infection. If the femoral arteries are severely atherosclerotic, the external iliac just above the inguinal ligament is often a soft, disease-free segment that is amenable to safe clamping. The profunda femoris (deep femoral) artery is a critical collateral pathway for the entire lower extremity. If disease is present at its origin, exposure of the profunda femoris beyond its take off is required for a complete endarterectomy.

The abdominal aorta is usually exposed via a midline, transperitoneal, inframesocolic approach. The transverse colon is retracted cephalad, the ligament of Treitz taken down, and the duodenum (third and fourth portions) mobilized to the right. The left renal vein is identified in the retroperitoneum and serves as the most cephalad limit of exposure in most cases (0.5% to 3% of patients have a retroaortic left renal vein). The anterior surface of the aorta is then exposed from the lower border of the left renal vein to just below the inframesenteric artery (IMA). Numerous lymphatics are usually encountered in the para-aortic retroperitoneal space particularly at the level of the left renal vein. These should be ligated to decrease the chances of a chyle leak. The left renal vein is mobilized if more proximal aortic control is needed; this is performed by ligating and dividing its adrenal, gonadal, and lumbar branches. It is generally unnecessary to divide the renal vein. Distal control of the aorta is dictated by the extent of disease. When exposing sites for distal control, the location of the hypogastric plexus and the presacral nerves, which course anterior to the aorta and travel caudally over the aortic bifurcation and origin of the left common iliac artery, needs to be kept in mind. Injury to the sympathetic nerves can cause retrograde ejaculation in

males. Retroperitoneal tunnels are then developed between the exposed infrarenal aorta and the groins by means of blunt finger dissection. The tunnels are directed posterior to the ureters to avoid postoperative obstructive uropathy from entrapment of the ureter between the graft limb and the native iliac artery. A retroperitoneal approach to the aorta via a left flank incision is an accepted alternative, especially in those patients with "hostile" abdomen; however, it makes creation of the tunnel for the right limb of the bypass graft slightly more challenging.[47]

A bifurcated vascular prosthesis of appropriate size is selected, typically a presealed knitted Dacron or a polytetrafluoroethylene graft, and the patient is heparinized. With an occluding clamp below the renal arteries and another just above the IMA, the proximal anastomosis between the graft and the aorta is performed in either an end-to-end or end-to-side fashion. Though most vascular surgeons prefer an end-to-end anastomosis for technical simplicity, the end-to-side technique has been found to be just as good, depending on the pattern of occlusive lesions and need to maintain flow to patent hypogastric arteries.[48] The proximal anastomosis is placed as close to the renal arteries as practical to prevent future compromise of the bypass resulting from progression of atherosclerosis in the remaining infrarenal cuff. The limbs of the prosthesis are then delivered through the retroperitoneal tunnels into the groins. The distal anastomoses are performed to the common femoral arteries and should be carried onto the profunda femoral arteries if there is any disease at the femoral bifurcation (**Fig. 90.8**). Common femoral and profunda femoris origin endarterectomy may be needed and should be carried out prior to the anastomosis. Maintaining good outflow through the profunda femoris is very important as many of these patients have concomitant superficial femoral arterial disease, which may compromise long-term graft patency. In the rare patient with tissue loss secondary to multilevel disease (AIOD associated with an occluded superficial femoral artery and compromised deep femoral collaterals), a concomitant distal bypass (femoropopliteal–tibial) may also be required.

Endarterectomy

Endarterectomy was more commonly performed in the era before reliable vascular prosthetic conduits were available. The high success rates of

angioplasty and stenting for the more limited disease patterns amenable to endarterectomy have rendered aortoiliac endarterectomy essentially obsolete in most current practices.

Extra-Anatomic Bypass

Patients who are at high risk for open aortic surgery due to either physiologic or anatomic constraints and are not endovascular candidates may be better served with extra-anatomic reconstruction. Although these operations are less risky, they have a documented lower patency rate and are, therefore, reserved for patients with CLI and generally not performed for intermittent claudication.

Axillofemoral extra-anatomic reconstruction has been used for revascularization in poor-risk patients and in those with a "hostile" abdomen and has been reported to be an acceptable alternative to aortofemoral bypass (**Fig. 90.10**).[49] The axillary artery supplying the arm with the higher brachial blood pressure is chosen as the inflow vessel, usually the right side. The operative sequence starts with exposure of the first portion of the axillary artery through an infraclavicular, pectoralis major muscle-splitting incision. The common, superficial, and deep femoral arteries are then dissected through bilateral groin incisions. An externally supported polytetrafluoroethylene graft is then passed between the pectoralis major and minor muscles and through a subcutaneous tunnel in the anterior axillary line, connecting the axillary incision with the ipsilateral groin incision. Next, a cross-femoral limb of the graft is delivered through a subcutaneous suprapubic tunnel connecting the two groins. An anastomosis between the proximal axillary artery and the prosthesis is then constructed in an end-graft–to–side-of-artery fashion. The distal anastomoses are performed end to side to the common femoral arteries and may be carried over or onto the deep femoral arteries to ensure adequate graft outflow. Providing flow through both femoral arteries (axillobifemoral bypass) rather than one ipsilateral femoral artery (axillounifemoral) has been shown to increase flow velocities within the long main shaft of the graft and improve long-term patency of the bypass.[49] The lower patency of the axillofemoral bypass limits its application to patients with advanced aortoiliac disease who are poor surgical risks with a reduced life expectancy or those with a "hostile"

abdomen. For high-risk patients with diffuse advanced disease limited to one iliac artery, cross-femoral (or femoral artery–to–femoral artery) bypass or an iliofemoral bypass is an option.

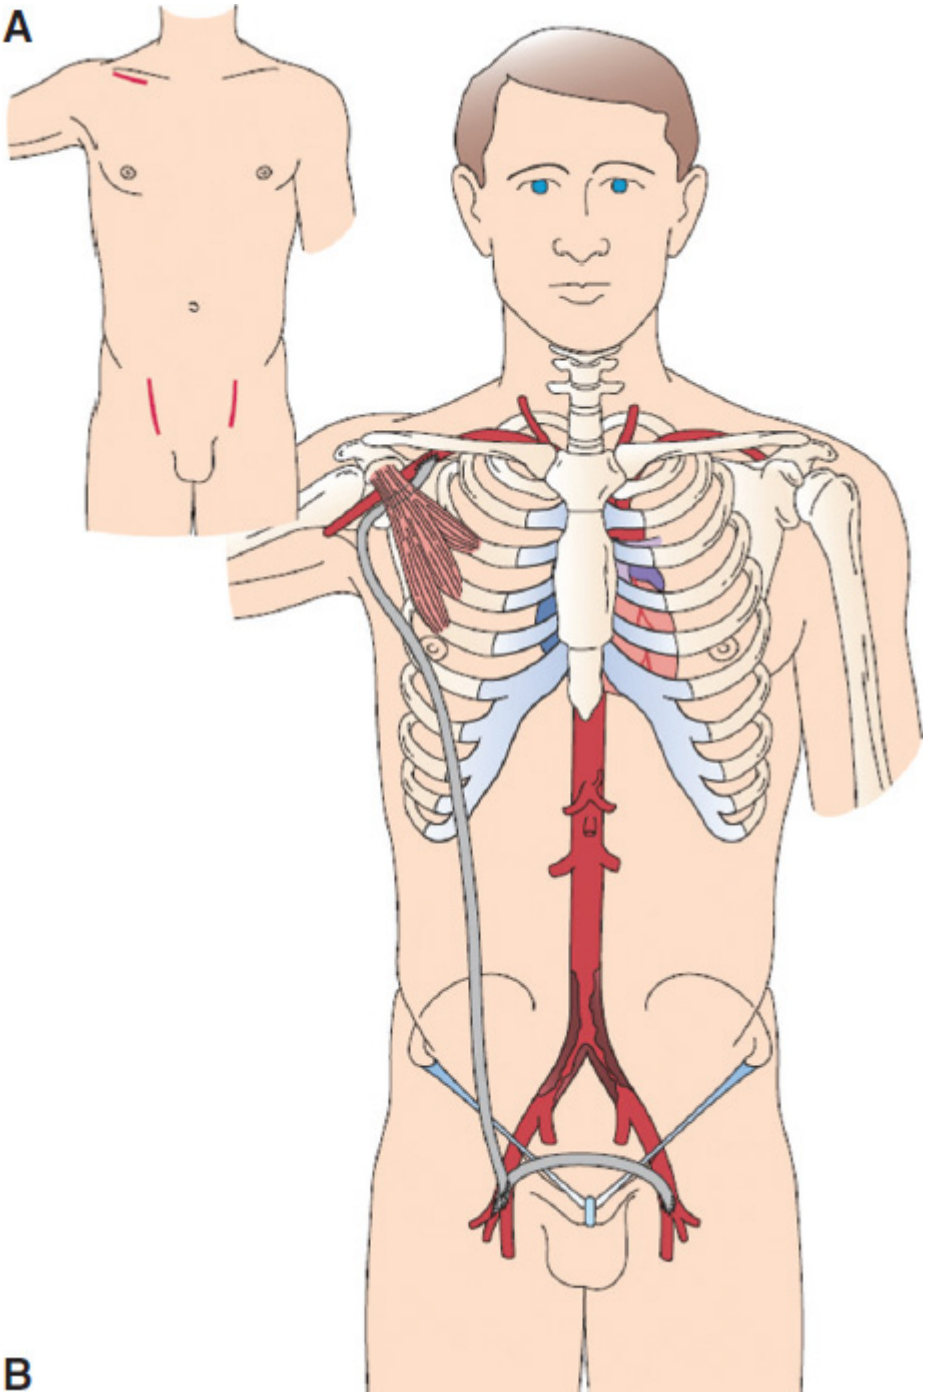

Figure 90.10 **A:** Ipsilateral infraclavicular incision and bilateral femoral incision locations for extra-anatomic axillary to bifemoral artery bypass. **B:** Image demonstrates unilateral axillary to ipsilateral femoral artery bypass graft with cross-femoral to femoral artery bypass graft.

Outcomes

The excellent durability of aortofemoral bypass is related to the large caliber and high flow rates of the vessels involved. Results of direct surgical revascularization are listed in **Table 90.7**. Aortofemoral bypass has excellent primary graft patency rates of approximately 85% to 95% at 5 years and 75% to 88% at 10 years. Factors associated with lower long-term patency of these reconstructions include female sex (in part due to smaller vessel size), multilevel arterial occlusive disease (poor run-off), and younger age (<50 years) where premature and aggressive atherosclerosis and/or hypercoaguability are usually present.[50,51] The most common cause of failure of surgical reconstructions is the progression of atherosclerosis proximal and/or distal to the graft or the development of anastomotic neointimal hyperplasia.[52]

Complications

Due to advances in anesthesia and surgical critical care, aortofemoral bypass can be performed with perioperative mortality and morbidity below 5%.[53] The perioperative morbidity and mortality for axillofemoral bypass is similar but is performed, in general, on a much higher-risk population of patients.

Early Complications

- Postoperative cardiac events have decreased to less than 5%. This is due to diligent preoperative screening and following the excellent perioperative guidelines promoted by numerous professional societies including the use of aspirin, statins, and perioperative beta blockers.

Table 90.7 Results of Direct Surgical Revascularization

Procedure	5-y Patency (%)	Operative Mortality (%)
Aortofemoral bypass	80–95	2–4
Femorofemoral bypass	50–60	1–3
Axillobifemoral bypass	30–50	1–4

- Pulmonary complications are not infrequent, occurring in up to 7% of patients. Adequate pain control with epidural anesthesia to facilitate pulmonary toilet and avoiding volume overload can help reduce these complications.
- Atheroemboli can occur during the procedure, manifesting as end-organ ischemia of the skin, pelvis, spinal cord, and bowel. Attention to detail during arterial clamping and flushing out the graft before unclamping can minimize this complication.
- Ischemic colitis and pelvic ischemia are rare and can be minimized by planning a procedure that maintains pelvic perfusion and blood flow to the IMA when collateral flow is insufficient to maintain left colon viability. Selective reimplantation of the IMA can be performed when poor IMA perfusion is anticipated or demonstrated. Ischemic colitis may require colectomy for treatment, but this is associated with a 50% mortality.
- Acute kidney injury can result from either atheroembolism from aortic clamping close to the renal arteries or from corticomedullary renal shunting induced by the acute increase in afterload with aortic clamping.
- Other possible complications include wound complications, particularly in the groin (lymphocele, lymphocutaneous fistula, wound infection), postoperative hemorrhage, erectile dysfunction in men, bowel injury, pancreatitis from retraction injury, and very rarely spinal cord ischemia. Groin wound complications can be particularly troublesome for axillofemoral and femorofemoral bypasses because of the subcutaneous location of these prosthetic grafts.

Late Complications

- Graft thrombosis is largely due to progression of native atherosclerotic disease either proximal or distal to the graft, or to anastomotic neointimal hyperplasia.
- Pseudoaneurysms from material fatigue, suture fracture, artery wall degeneration, or occult infection.
- Graft infection. A graft enteric fistula (most frequently to the third/fourth portions of the overlying duodenum) may present as a gastrointestinal bleed. Every gastrointestinal bleed in a patient with a history of aortofemoral bypass or other aortic reconstruction should be considered to be an aortoenteric fistula until proven otherwise.

QUIZ

1. A 60-year-old man with severe aortoiliac occlusive disease can walk half a block before he needs to stop due to severe lifestyle-limiting claudication. Before offering any interventional therapy, maximal medical therapy includes:
   - **a.** Aspirin and Plavix (dual antiplatelet therapy) is indicated in most patients with severe aortoiliac disease.
   - **b.** Statin therapy is not needed if the patient's LDL is <100 mg/dL.
   - **c.** Smoking cessation alters the progression of the atherosclerotic process and may even reduce the severity of claudication.
   - **d.** Cilostazol has shown modest but significant reduction in claudication symptoms in all patients.

Discussion: Medical therapy is key to treating any patient with aortoiliac occlusive disease. Risk factor modification includes management of diabetes mellitus, control of hypertension, treatment of hyperlipidemia (starting a statin regardless of LDL level because of its pleiotropic effects on the vascular wall), smoking cessation, appropriate diet, and exercise. Antiplatelet agents are beneficial in all patients with atherosclerotic disease but there is no benefit to dual antiplatelet therapy in the average patient. Cilostazol improves claudication symptoms in >50% of patients, but by no means all.

Correct answer—c.

2. The previous patient has attempted medical therapy for 6 months with no significant improvement. He has TASC D aortoiliac occlusive disease based on CTA with no aneurysm. He had a cardiac stress test 6 months ago that was negative. Which of the following is correct?
   - **a.** With appropriate medical therapy progression to critical limb ischemia is around 20% per year.

b. Endovascular repair may be a good treatment option with periprocedural mortality of 2% and a 5-year primary patency rate of 95%.
c. Open repair (with an aortobifemoral bypass) is the gold standard for operative revascularization with a periprocedural mortality of approximately 5% and a 5-year patency >90%.
d. There is no other revascularization option if he is not an operative candidate and has failed endovascular therapy.

Discussion: With medical therapy progression of disease is around 2% per year. Endovascular therapy has a low mortality (around 1% to 2%) but the need for further intervention is high. Open repair with an aortobifemoral bypass has the best long-term patency. Extra-anatomic bypasses are an option for sicker patients who cannot tolerate a standard aortobifemoral bypass.

Correct answer—c.

Peripheral Arterial Disease

Bryan A. Ehlert and William P. Robinson III

Key Points

1. Chronic obliterative atherosclerosis of the infrainguinal vessels is the most prevalent manifestation of peripheral arterial disease (PAD) encountered by the vascular surgeon.
2. The major risk factors for the development of PAD include smoking, diabetes, advanced age, male gender, hypertension, dyslipidemia, and chronic kidney disease.
3. PAD is a powerful risk factor for cardiovascular morbidity and mortality.
4. The most common lesion seen below the inguinal ligament is that of a short-segment total occlusion of the superficial femoral artery.
5. The diagnosis of infrainguinal occlusive disease is generally made based on patient symptomatology, physical examination, and noninvasive tests, such as ankle–brachial index (ABI), segmental pressure measurements, and pulse volume recordings.
6. A novel Wound, Ischemia, and foot Infection (WIfI) classification system allows for staging of limb-threat severity and guides initial management as well as additional adjunctive operative procedures for salvage of the foot and limb.
7. Percutaneous endovascular therapy is often applied as first-line therapy, particularly in patients with more limited extent of anatomic disease and/or high operative risk.
8. Open surgical revascularization remains the gold standard for those patients with disabling claudication, ischemic rest pain, and ischemic ulceration or gangrene.
9. Infrainguinal arterial bypass surgery remains the signature operation distinguishing vascular surgeons from other specialists involved in the treatment of peripheral vascular disease.
10. Infrainguinal bypass surgery is best performed with autogenous vein conduit, preferably the ipsilateral greater saphenous vein if available.

INTRODUCTION AND EPIDEMIOLOGY

The term "Peripheral Arterial Disease (PAD)" broadly denotes stenotic, occlusive, and aneurysmal diseases of the aorta and its branch arteries, exclusive of the coronary arteries. In common clinical usage, PAD, which is defined as an ankle–brachial index (ABI) <0.9, denotes atherosclerotic stenosis or occlusion of the arteries supplying the lower extremities.[1] Atherosclerotic occlusive disease of the aorta and iliac arteries is covered in Chapter 108. This chapter will cover PAD located in the femoropopliteal and tibial (infrainguinal) arteries. PAD affects 12% of the U.S. adult population and almost 20% of U.S. adults older than age 70 years.[1–3] PAD involving the lower extremities is the third leading overall cause of atherosclerotic morbidity worldwide after coronary artery disease and stroke.[4] With the aging of the American population, the prevalence of lower extremity occlusive disease has steadily 1 increased in recent decades. Symptomatic PAD in the form of claudication affects more than 10 million Americans including 1% to 2% of those aged <50, 5% of those aged 50 to 70, and 10% of those aged >70. Of those aged >50 with PAD, 1% to 3% will have chronic limb-threatening ischemia (CLTI) in the form of rest pain or gangrene.[5,6] The incidence of CLTI ranges from 220 to 1,000 new cases per year in a European or American population of 1 million people.[7] Not surprisingly, therefore, the clinical manifestations and complications of atherosclerosis are the most common therapeutic challenges encountered and treated by vascular surgeons.

The tendency for atherosclerotic lesions to develop at specific anatomic sites and follow recognizable patterns of progression was first appreciated in the late 1700s by the British anatomist and surgeon John Hunter. Considered one of the forefathers of vascular surgery, his dissections of atherosclerotic aortic bifurcations are preserved at the Hunterian museum in London and presage the disease process that Leriche would give his name to 150 years later.[8] The modern era of surgical reconstruction for complex atherosclerotic occlusive disease began in earnest in 1947, when the Portuguese surgeon J. Cid dos Santos successfully endarterectomized a heavily diseased common femoral artery.[9] Four years later, building on the pioneering work of Alexis Carrel, Kunlin would report the first long-segment vein bypass in the lower extremity.[10,11] It would be another 10 years before

the initial efforts to extend vein grafting to the tibial level were described by McCaughan.[12] The last three decades have seen tremendous advances in both the understanding of atherosclerosis biology and refinement in the techniques of infrainguinal surgical revascularization that have greatly improved surgeons ability to preserve limbs and improve quality of life in patients with femoropopliteal and tibial occlusive disease. Moreover, in the last two decades, advances in percutaneous treatment have revolutionized the treatment of infrainguinal occlusive disease. The concept of intravascular intervention was pioneered in the late 1960s by the radiologist Charles Dotter, and advanced greatly with the advent of the angioplasty balloon by Gruntzig in the early 1970s.[13,14] Nevertheless, endovascular intervention for infrainguinal disease was not utilized significantly until the 1990s. The technology remains in rapid development and surrounded by ongoing controversy as to its proper role.

Although a diverse range of technical skill is required of the contemporary vascular and endovascular surgeon, it is worth noting that infrainguinal arterial bypass surgery remains the signature operation distinguishing vascular surgeons from other specialists involved in the treatment of PAD. This distinction stems primarily from the fact that the outcome of infrainguinal reconstruction is highly dependent on the judgment and technical skill of the surgeon, with the end result often being either successful limb salvage or major limb amputation. This chapter reviews the surgical and endovascular management of femoropopliteal and tibial arterial occlusive disease and details standard and advanced techniques underlying successful infrainguinal operative revascularization. Endovascular intervention is introduced, though a comprehensive review of endovascular techniques used to treat femoropopliteal and tibial occlusive disease is beyond the scope of this chapter.

INFRAINGUINAL ARTERIAL OCCLUSIVE DISEASE

Risk Factors

2 The risk factors for infrainguinal occlusive disease are the same as those for the development of atherosclerosis in general and include age, male gender, hypertension, diabetes mellitus (DM), smoking, dyslipidemia, family history, and homocysteinemia. Smoking and diabetes are the most powerful risk factors. Smokers are at four times the risk of symptomatic PAD than nonsmokers while diabetics are more than three times more likely to develop symptomatic PAD in comparison to nondiabetics.[7] The propensity for heavy smokers to develop superficial femoral artery disease and for diabetics to develop tibial disease should be noted. More recent evidence indicates that nonwhite ethnicity, inflammatory markers such as C-reactive protein, and perhaps chronic renal insufficiency (CRI) are also associated with an increased risk of PAD.[15–17]

Presentation and Natural History

Chronic obliterative atherosclerosis of the infrainguinal vessels is the most prevalent manifestation of PAD encountered by the vascular surgeon. Patients are classified into two broad categories depending upon their symptomatology: claudicants and those with CLTI. Claudication, the reproducible ischemic muscle pain resulting from inadequate oxygen delivery during exercise, is the cardinal presenting symptom. Natural history studies indicate patients with claudication have increased rates of cardiovascular mortality, but an overall low risk of limb loss.[18,19] Seventy percent to 80% of patients with claudication demonstrate a stable pattern of disease throughout their lifetime or have improvement in their symptoms as a result of risk factor modification, whereas 20% to 30% undergo operation within 5 years as a result of disease progression. Claudication will progress to CLTI in 3 only 5% to 10% of patients over their lifetime. However, PAD leading to claudication is a marker of severe systemic atherosclerotic burden and increased cardiovascular morbidity and mortality. Twenty percent of claudicants experience a nonfatal myocardial infarction or stroke and 10% to 15% died of cardiovascular-related mortality at 5 years.[6] The annual rates of mortality and limb loss in patients with claudication are approximately 2% to 5% and 1%, respectively.[6,20]

4 The most common atherosclerotic disease pattern encountered distal to the inguinal ligament is that of a short-segment total occlusion of the

superficial femoral artery. Isolated disease of this nature typically presents as calf muscle claudication. It is not uncommon, however, for patients with significant single-level lesions, even those with long-segment arterial occlusions, in the superficial femoral artery or more distal arterial beds to be only minimally symptomatic or even asymptomatic. While this can sometimes be the result of exercise limitations imposed by concomitant coronary arterial disease or other physiologic impairments such as lung disease or arthritis, it is more often a result of compensatory collateral flow. Collateral perfusion from the profunda femoral artery around a heavily diseased or occluded superficial femoral artery frequently reconstitutes the distal superficial femoral artery or popliteal artery with enough well-perfused arterial blood to ensure adequate resting tissue perfusion. Similarly, the rich network of geniculate collaterals can sometimes compensate for a diseased popliteal arterial segment to a sufficient degree to prevent rest pain or overt tissue loss but will usually prove insufficient to meet the increased metabolic demands of ambulation and forestall claudication.

CLTI, which must be differentiated from acute limb ischemia, is the most severe form of PAD and refers to the presence of either rest pain or tissue loss in the lower limb. Rest pain occurs when blood flow is inadequate to meet resting metabolic requirements. In the lower extremity, ischemic rest pain is localized to the foot, frequently in the metatarsals or the instep, and should be easily distinguishable from benign muscle cramps in the calf commonly seen in older patients. Patients with rest pain are often awakened by severe discomfort in the forefoot and hang the affected extremity over the edge of the bed for temporary symptomatic relief. Trophic changes, such as muscle wasting, thinning of skin, thickening of nails, and hair loss are frequently also seen in the distal affected limb. Rest pain is an ominous symptom and usually requires revascularization given the tendency for progression to tissue loss. Ischemic ulcerations usually begin as small, dry ulcers of the toes or heel area, and progress to frankly gangrenous changes of the forefoot or heel with greater degrees of arterial insufficiency (**Fig. 91.1**). Patients with diabetes or renal failure are more susceptible to the development of ischemic pedal ulcers. Disease progression can be very rapid, as up to 50% of patients with CLTI are asymptomatic 6 months before onset of pain or ulceration.[21] Such progressive disease, affecting multiple

levels of the peripheral vasculature tree, is more frequently encountered in the elderly.

The natural history of CLTI is dismal as these patients are generally of advanced age and possess significant comorbidities contributing to their advanced limb ischemia. Overall, approximately 25% of patients with CLTI will die at 1 year, 30% will undergo major amputation, and 45% will be alive with two limbs.[6,7] The rate of amputation is 10 times higher in diabetics than nondiabetics and 5- and 10-year mortality in patients with CLTI have been reported to be 60% and 85%, respectively.[21] CLTI mandates revascularization for limb salvage when feasible, as limb salvage with medical therapy and wound care is virtually futile; success rates for rest pain and tissue loss have been reported to be as low as 27% and 5%, respectively.[21]

Several identifiable patterns of infrainguinal PAD are well recognized. It is important to note that symptoms and signs of ischemia generally involve the limb one level distal to the level of hemodynamically significant disease. Patients with an extensive history of cigarette smoking typically have lesions limited to the superficial femoral artery and corresponding symptoms of calf claudication (**Fig. 91.2**). Patients with rest pain or ischemic tissue loss typically manifest more extensive involvement of the femoral, popliteal, or tibial arteries than patients with claudication. Those with tissue loss also more commonly have multilevel disease involving the femoropopliteal system in combination with occlusive disease of the aortoiliac vessels or the infrageniculate runoff.[22] Diabetes often targets the tibial vessels, and patients may present with frank tissue necrosis in the presence of a palpable popliteal pulse and no prior history of claudication.

Diagnosis

5 The diagnosis of infrainguinal occlusive disease is generally based on patient symptomatology, physical examination, and noninvasive tests, such as the ABI, segmental pressure measurements, and pulse volume recordings. Accurate history-taking and physical examination are crucial to clarifying the diagnosis and guiding management aimed at maximizing symptom relief and limb preservation. Intermittent claudication (IC) indicative of infrainguinal occlusive disease is typically a cramping, aching discomfort consistently

reproducible at a given distance and relieved soon after cessation of ambulation. This must be differentiated from lower extremity pain secondary to nerve root compression or spinal stenosis which, in contradistinction to vasculogenic pain, often develops when patients maintain a stationary standing posture. Vasculogenic claudication must also be distinguished from venous claudication, hip and ankle arthritis, symptomatic Baker cyst, and chronic compartment syndrome. IC patients with isolated infrainguinal disease will likely have palpable femoral pulses but diminished popliteal and/or pedal pulses.

Figure 91.1 **A–C:** Examples of digital ischemic ulcerations resulting from progressive arterial insufficiency.

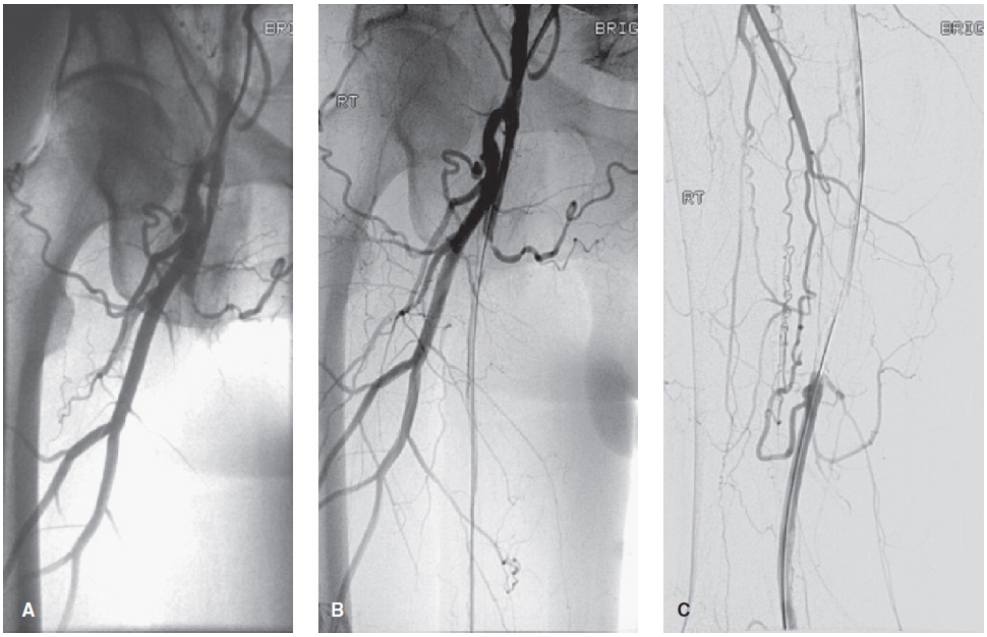

Figure 91.2 Long-segment total occlusion of superficial femoral artery (sfa) in a patient with a long history of cigarette smoking and severe claudication. Proximal sfa occlusion is demonstrated (**A**), followed by wire traversal of the occlusion (**B**), which will allow endovascular treatment of the occluded segment of the sfa proximal to reconstitution of the above-knee popliteal artery (**C**).

As is true with claudication, ischemic rest pain must be carefully distinguished from other sources of pain in the elderly population, most commonly arthralgia and neuropathy. Although tissue necrosis and gangrene are usually self-evident when caused by critical ischemia, similar lesions associated with venous stasis, severe anemia, decubitus ulcers, and diabetic neuropathy must be excluded.

Noninvasive physiologic arterial testing allows confirmation of infrainguinal occlusive disease when it is suspected based upon history and physical examination. Measurement of the ABI is the most useful diagnostic adjunct. A properly performed ABI in a claudicant without significant evidence for vascular calcification would be expected to be between 0.5 and 0.9. Ischemic rest pain generally occurs at ABI 0.4 to 0.5, whereas an ABI less than 0.4 is generally associated with tissue loss. Segmental pressure measurements at the level of the upper thigh, lower thigh, upper calf, ankle, and metatarsal level also aid in localizing the level of hemodynamically significant disease. A decrease in pressure greater than 20 mm Hg between levels indicates a hemodynamically significant stenosis in the intervening

arterial vasculature. In patients with DM or CRI leading to extensive vascular calcification, the ABI will often be erroneously elevated due to medial calcinosis and subsequent noncompressibility of the vessels. In such circumstances, pulse volume recordings, which ascertain the volume of blood flowing into segment of the limb, remain a reliable indicator of perfusion to the various levels of the lower extremity. Measurement of toe pressures also effectively quantitates distal perfusion as the digital arteries are generally spared of calcium which inhibits compressibility. A toe–brachial index less than 0.7 is considered abnormal. Absolute toe pressure less than 30 to 50 mm Hg generally indicates severe lower extremity occlusive disease with inadequate perfusion to heal tissue loss, particularly in diabetics.[7]

Further anatomic mapping is warranted only after the diagnosis of hemodynamically significant infrainguinal disease has been made based upon physical examination and noninvasive testing and the decision to pursue intervention has been made. The goal of anatomic imaging is to determine if adequate revascularization is anatomically feasible and to delineate the options for both endovascular therapy and open surgical revascularization. Duplex ultrasonography, magnetic resonance angiography (MRA), and computed tomographic angiography (CTA) are increasingly being utilized as first-line modalities in planning the optimal revascularization approach, and have supplanted contrast angiography as the initial imaging study of choice in many centers.[23] Nevertheless, due to inherent limitations with each of these techniques, digital subtraction angiography remains the gold-standard technique for imaging of the vascular tree prior to intervention.[24]

Although a growing literature supports the use of duplex scanning as a stand-alone preoperative mapping modality,[25] this use requires a highly dedicated vascular laboratory and to date has not gained wide acceptance. CTA is increasingly being utilized as a preoperative road-mapping technique in institutions able to provide high-quality three-dimensional reconstructions. MRA is also particularly useful as a noninvasive screening test to determine the suitability for percutaneous therapy, as advances have solved many of the technical limitations of earlier studies (**Fig. 91.3**). Should a lesion amenable to percutaneous therapy be identified, angiography is then pursued. Alternatively, in some instances of femoropopliteal reconstruction, operative planning may be based solely on MRA scanning if high-quality time of flight

and gadolinium-enhanced images are obtained.[26–28] In many cases, however, surgeons are reluctant to proceed to surgery without the confirmation of anatomy afforded by standard contrast angiography. This reluctance is particularly true if the distal target is at the tibial or pedal level, where anatomic detail provided by CTA and MRA remains more limited.[29]

When digital subtraction angiography is undertaken for preoperative planning, a retrograde femoral approach is typically utilized from the contralateral limb. In general, a catheter is placed in the infrarenal aorta to perform aortography and iliac angiography. If there is no aortoiliac disease which precludes catheter traversal, the wire and catheter are utilized to go "up and over" the aortic bifurcation to place the catheter in the common femoral artery of the affected limb. Lower extremity digital subtraction angiography is then carried out. Selective catheterization of the affected limb via "up and over" approach allows contrast volume to be minimized. It also allows the surgeon or interventionalist to proceed immediately with infrainguinal endovascular intervention through a single vascular access should endovascular therapy be the preferred treatment based on the patient's presentation and infrainguinal anatomy defined in the angiogram.[24] In patients in whom noninvasive imaging indicates a widely patent common femoral and proximal superficial femoral artery and body habitus is not prohibitive, an antegrade approach can serve as useful alternative. In ambiguous lesions or when iodinated contrast must be minimized, pull-back pressure measurements, both before and after the administration of a systemic vasodilator such as papaverine or nitroglycerine or the application of a tourniquet to induce reactive hyperemia, can be useful in documenting the hemodynamic significance of a particular stenotic zone.[30] The utilization of gadolinium or carbon dioxide as contrast agents in patients with compromised renal function, although perhaps less effective in the periphery than in the aortoiliac vasculature, can minimize or eliminate the nephrotoxic effects associated with standard iodinated contrast medium.[31,32]

Medical Treatment

Risk factor modification remains a cornerstone of the management of lower extremity occlusive disease. Smoking cessation has been shown to reduce the risk of disease progression, amputation, cardiovascular mortality, and may

lead to symptom relief in some patients. Smoking cessation has been best achieved with repeated physician assistance, group counseling, nicotine replacement or nicotinic receptor agonists, and antidepressant drug therapy in some patients. Weight and blood pressure reduction and aggressive efforts at lipid control should be addressed with every patient with atherosclerotic disease. Lipid-lowering therapy involves dietary modifications first and utilization of hydroxymethylglutaryl–coenzyme A–reductase inhibitors ("statins") to lower LDL cholesterol and fibrates or niacin to raise HDL cholesterol. Patients with lower extremity occlusive disease should have a goal LDL cholesterol of <70 mg/dL.[6] Statin therapy also has benefits in patients with PAD which are independent of their effect on lipid reduction. Stains stabilize atherosclerotic plaque and reduce vascular inflammation. Statin therapy has been shown to reduce cardiovascular events in patients with PAD.[33,34] In addition, statin therapy is associated with improved 1-year survival in patients undergoing lower extremity bypass for CLTI.[25] Patients with diabetes should have aggressive control of blood glucose toward a goal hemoglobin A1c of <7%. Antiplatelet therapy in the form of either aspirin or clopidogrel is a critically important element of the treatment of established occlusive disease, given its documented ability to prevent thrombosis and embolization and possibly even to arrest the progression of atherosclerosis.[35] Aspirin and clopidogrel have both been shown to reduce cardiovascular morbidity and mortality in patients with PAD.[36,37] A sub-analysis of patients with PAD from the COMPASS trial demonstrated a decreased incidence of major adverse limb events (MALE) and its complications in patients treated with combination therapy of daily aspirin and rivaroxaban 2.5 mg twice daily.[38] When evaluating this same treatment strategy in patients following lower extremity revascularization, the Voyager PAD investigators found significantly lower incidences of acute limb ischemia, major amputation, myocardial infarction, ischemic strokes, and death.[39]

Strong evidence exists supporting the benefit of a supervised, structured walking program in increasing the walking distance of patients with claudication.[40] The benefit of walking outside of a structured regimen with close follow-up is more debatable.[41] Nevertheless, patients should be encouraged to "walk through" the onset of lower extremity pain, resting intermittently as required. Overall, pharmacotherapy has not had a significant impact on relieving symptoms of infrainguinal occlusive disease. There is some evidence to suggest cilostazol, a phosphodiesterase inhibitor, improves walking distance and quality of life.[42,43] While early studies showed that pentoxifylline, a rheologic agent, had beneficial effects on walking distance, later studies have questioned its clinical benefit.[44,45] Similarly, although older studies suggested that prostanoids improved healing of ischemic ulcers, the current evidence does not support the utility of any systemic drug for the relief of ischemic rest pain or the treatment of ischemic ulcerations.[46–48]

Indications for Revascularization

The two major indications for the intervention of infrainguinal arterial occlusive disease are lifestyle-limiting claudication and CLTI. Although there are certainly cases in which primary amputation represents the safest and most advisable solution in the face of irreversible ischemia, particularly in nonambulatory patients or in cases in which extensive infection or tissue necrosis is present, an attempt at revascularization is generally indicated when a limb is threatened by severe ischemia. However, given the morbidity and mortality associated with CLTI, it is paramount to tailor therapy to an individual's overall medical condition and life expectancy as well as the patient's goals of therapy. In the often frail CLTI population, postoperative outcomes are most strongly impacted by patients' preoperative medical condition and functional status.[49] Nevertheless, improvements in endovascular technology and techniques as well as perioperative management and surgical technique have allowed progressively more distal revascularizations to be successfully completed in an older, sicker, and

challenging patient population. In general, high limb salvage (80% to 90%) rates may be anticipated for patients with critical ischemia at institutions devoted to peripheral bypass surgery.[50–52] In addition, occlusive disease of the tibial vessels is increasingly being treated percutaneously.[53] Though the long-term durability of various endovascular revascularization approaches is limited, similar rates of limb salvage from 1 to 3 years have been demonstrated.[53–55] 6 CLTI, and limb threat in particular, has been recognized as a more broad disease spectrum that incorporates limb perfusion, presence and extent of a wound, and the presence and severity of infection. The Society for Vascular Surgery sought to create a novel classification system that better reflects these important considerations impacting the threatened lower extremity. The Wound, Ischemia, and foot Infection (WIfI) classification system provides a grade for each component; and, based on the patient's overall score, their amputation risk and revascularization benefit can be stratified.[56] The WIfI classification system has been found to correlate with need for revascularization and patient-centered outcomes, including wound healing and risk for major amputation, while also reinforcing the necessity of treatment of additional components of limb threat beyond ischemia.[57–60] The importance of WIfI restaging following revascularization to assess risk of limb loss and adequacy of the revascularization has also been acknowledged.[61]

Claudication is a relative indication for intervention given the natural history of the disease, and it remains a subjective assessment on the part of both patient and surgeon as to the relative degree of disability a particular level of claudication pain represents. For example, two-block claudication in a younger patient whose livelihood depends on walking tolerance constitutes a more significant disability than the same degree of claudication in an older, retired individual able to attend to his or her daily affairs without significant consequence. Thus, proximal above-knee surgical reconstruction in a patient with disabling claudication and a patent popliteal artery with intact runoff may be justified in view of its minimal operative mortality, excellent long-term palliation, and absence of added risk of limb loss beyond that expected from the natural history of the disease process. Classically, it has been thought that the benign natural history of claudication does not warrant aggressive femorotibial reconstruction in patients with diffuse superficial femoropopliteal and tibioperoneal disease, though reconstruction will often

provide symptomatic benefit and can be considered in a good-risk patient.[62,63]

In recent years, the low morbidity of endovascular revascularization in combination with patient desire for intervention seems to have lowered the threshold for offering catheter-based revascularization for claudication. Patients once considered most appropriate for risk factor modification, exercise therapy, and medical treatment are now increasingly being offered percutaneous revascularization.[64,65] Nevertheless, endovascular revascularization is not without risk and is at present of limited durability. It is therefore prudent to follow the classical surgical axiom that because most patients with claudication remain stable for years, it is important to allow sufficient time for collaterals to develop and enlarge; some patients may improve to such an extent that intervention proves unnecessary.[19]

Approach to Revascularization

The last two decades have seen increasing utilization of endovascular revascularization of infrainguinal occlusive disease.[65] In this light, it cannot be overemphasized that symptom status and not anatomic findings should serve as the basis for revascularization. Once the decision to intervene has been made, a variety of factors should be considered in choosing whether to proceed with an endovascular, surgical, or combined (hybrid) approach. The goals and outcomes of revascularization should be considered in the context of the individual patient's comorbidities, operative risk and overall life expectancy, the extent of the occlusive disease present, and the expected durability of the procedure.

Anatomic variables appear to be the key determinant of the success and durability of endovascular therapy. With the promulgation of endovascular therapy has arisen, the need to classify the anatomic severity of disease in order to guide potential therapy and compare outcomes between various modes of revascularization. The Trans-Atlantic Intersociety Consensus Document on Management of Peripheral Arterial Disease (TASC) was published as the result of a multidisciplinary collaboration between key medical and surgical vascular societies in 2000 and an abbreviated update was published in 2007.[7,66] This document classified infrainguinal occlusive lesions into classes A, B, C, and D based upon the location of the lesion and

the number, length, and severity of the stenoses and/or occlusions present. Their recommendations, which reflect current practice to a variable extent, include initial endovascular treatment for TASC A lesions, primary surgical treatment for TASC D lesions, and individualized tailoring of treatment for TASC B and C lesions depending upon endovascular suitability and surgical risk. While a complete description of this classification schema is beyond the scope of this chapter, a few general principles are worth noting. The patency of endovascular revascularization decreases the more distal the disease and is less in patients with stenoses that are multiple, longer, and more severe.[7,53,67] On the other hand, the success of open bypass surgery is largely dependent on the quality conduit.[68,69] Sustained hemodynamic improvement in the affected limb is the measure of effective revascularization and the goal of therapy. Neither "endovascular first" nor "bypass first" approach can be applied to all patients and they are often complementary strategies.[70,71] A recognized limitation to the TASC document is its emphasis on anatomic lesions. A more recent collaboration, the Global Vascular Guidelines (GVG) on the Management of Chronic Limb-Threatening Ischemia, published in 2019 stress a "whole-limb" approach. The GVG endorse the utilization of the WIfI classification described above to stage the severity of limb threat. They also outline evidence-based revascularization strategies relying on patient risk, limb severity, and anatomic complexity. A proposed Global Anatomic Staging System (GLASS) focuses on defining a preferred target artery path to estimate limb-based patency. The GVG incorporate patient risk, anatomic data, severity of limb threat, and conduit availability to guide selection of optimal revascularization strategy.[72] The complexity of decision making emphasizes the importance not only of interventional expertise, but of thorough training in vascular disease and comprehensive experience in the care of vascular patients.[73]

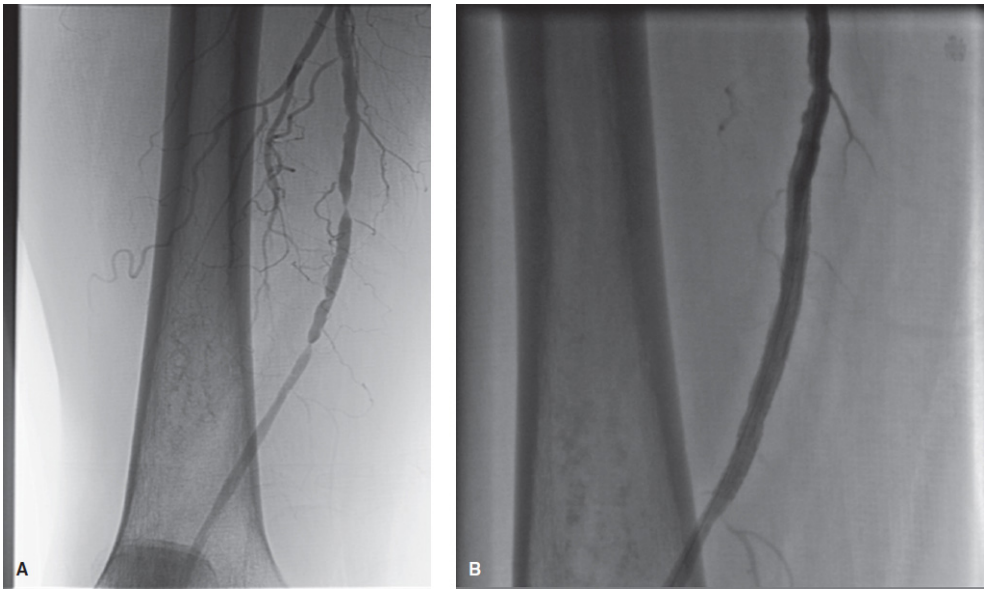

Figure 91.4 Angiogram of the right superficial femoral artery demonstrating short-segment occlusion and more diffuse stenosis in Hunter canal (**A**), which was treated with angioplasty and self-expanding bare metal stent placement (**B**).

Endovascular Therapy

A marked increase in the number and versatility of available balloons, stents, and other devices has helped to fuel the increasing application of percutaneous technology. While a complete description of endovascular treatment options and outcomes is beyond the scope of this chapter, a brief introduction is necessary. Percutaneous vascular intervention is generally performed under local anesthesia with minimal intravenous sedation as either a day surgical procedure or involving an overnight admission. Percutaneous vascular intervention first involves wires traversal of hemodynamically significant stenosis or occlusions in the arterial tree. Dilatation of the lesion with percutaneous transluminal angioplasty (PTA), with or without stenting, or obliteration of the lesion via atherectomy or other modalities is utilized to reestablish blood flow through the diseased segment (**Fig. 91.4**). For interventions on the femoropopliteal and tibial arteries, retrograde contralateral femoral access allows angiography of the affected limb and establishment of a stable treatment platform via an "up and over" approach across the aortic bifurcation. Ipsilateral antegrade femoral access can also be utilized. More recently, retrograde ipsilateral pedal and tibial access has

been described to allow wire traversal and endovascular treatment of disease not amenable to the standard antegrade approach.[74]

Periprocedural outcomes with endovascular therapy are excellent. Technical success, which is generally defined as the presence of antegrade flow through the tree to lesion with less than 30% residual stenosis at the conclusion of the procedure, is reported at 80% to 95% for both femoropopliteal and infrapopliteal procedures.[53,75,76] Associated overall morbidity in recent reports ranges between 8% and 17% while mortality is low at approximately 0.2%. Contrast-induced nephropathy remains a common complication. With the development of hypoosmolar and isoosmolar contrast agents; the overall incidence is approximately 8%, whereas the rate of acute renal failure requiring dialysis is less than 1%.[76–78] Higher rates are found in patients with pre-existing renal failure and diabetes.[79,80]

Substantial morbidity can result from access-site complications, predominantly pseudoaneurysms, groin hematomas, and arteriovenous fistulas (AVFs), which occur in 1% to 4% of patients.[76,81] Stable pseudoaneurysms in patients without coagulopathy can also be managed with ultrasound-guided compression therapy or ultrasound-guided thrombin injection into the pseudoaneurysm sac to induce thrombosis.[82] Maldeployment of these devices can lead to embolic or thrombotic sequelae causing compromise of distal flow.[83]

Reports indicate that endovascular therapy has good short-term efficacy for femoropopliteal disease (**Table 91.1**). In claudicants, PTA for femoropopliteal lesions has generally yielded 1-year patency of approximately 77% and 65% for stenoses and occlusions, respectively.[67,84] In patients with CLTI, PTA for femoropopliteal lesions has yielded 1-year primary patency of 60% and 40% for stenoses and occlusions, respectively.[84] Review of the literature does not provide compelling evidence that stent placement improves the results of all femoropopliteal PTA.[54] Many practitioners thus utilize stents selectively for failure of PTA (defined as greater than 30% residual stenosis or flow-limiting dissection) in femoropopliteal lesions. However, there is strong evidence, including two randomized trials, that primary self-expanding stent placement yields higher short-term patency than PTA and/or provisional stenting for more advanced femoropopliteal lesions.[84–86] Primary self-expanding stent placement is therefore preferred over angioplasty alone for femoropopliteal occlusions

and long-segment lesions by most surgeons and interventionalists. Infrapopliteal disease appears less amenable to endovascular therapy (**Fig. 91.5**). Primary patency is generally reported at 45% to 55% at 1 year.[53,87] Patency does not appear to be improved by stenting in the infrapopliteal segment.[88,89]

Table 91.1 Patency of Femoropopliteal Angioplasty and Stenting[a]

	1-Year % Patency (Range)	3-Year % Patency (Range)	5-Year % Patency (Range)
PTA: stenosis	77 (78–80)	61 (55–68)	55 (52–62)
PTA: occlusion	65 (55–71)	48 (40–55)	42 (33–51)
PTA+stent: stenosis	75 (73–79)	66 (64–70)	
PTA+stent: occlusion	73 (69–75)	64 (59–67)

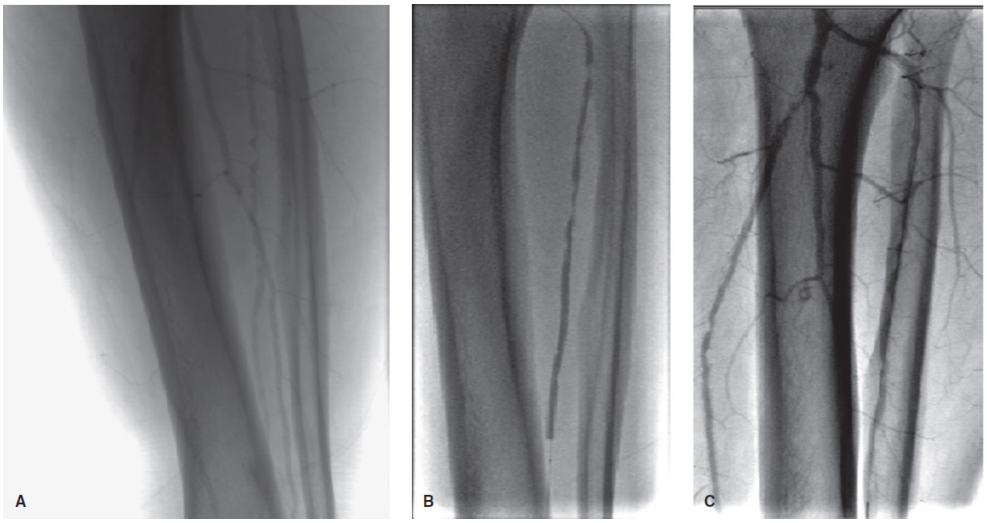

Figure 91.5 Angiogram of the tibial arteries showing diffuse anterior tibial artery high-grade stenosis (**A**) which was treated with long-segment balloon angioplasty, (**B**) completion angiogram showed patent anterior tibial artery with no significant residual stenosis (**C**).

Lack of durability has been the Achilles heel of infrainguinal endovascular intervention. Three-year patency after PTA has generally been reported to be 43% to 61% and 30% to 48% for femoropopliteal stenoses and occlusions, respectively.[84] Five-year patency data are seldom reported but have been generally reported to be between 26% and 45% after PTA for femoropopliteal lesions.[7]

There is a scarcity of high-level data comparing PTA and bypass surgery for infrainguinal occlusive disease. Heterogeneous study populations and the lack of standardized methodology and endpoints have limited the ability to compare the effectiveness of endovascular surgical therapy.[90] In addition, there have been only four randomized trials comparing angioplasty and lower extremity bypass surgery and these have included a heterogeneous group of patients, measured different outcomes, and generally included limited anatomic detail.[91–94] Pooled analysis of these trials demonstrates that surgical bypass generally had superior patency to PTA at 1 year, but there were no differences in progression to amputation. The BASIL (bypass vs. angioplasty in severe leg ischemia) trial which randomized 452 patients with "severe limb ischemia" to a "bypass first" or "balloon angioplasty" first strategy is the most widely cited trial. There was no difference in the primary endpoint of amputation-free survival at 6 months, although a "surgery-first"

strategy was associated with greater cost and morbidity.[91] It is necessary to note that the endovascular arm of this trial did not include adjunctive procedures such as stenting which are now frequently utilized in current day practice. Upon long-term follow-up of at least 3 years and more than 5 years in the majority of patients, bypass was associated with improved overall survival and a strong trend toward improved amputation-free survival in patients who survived at least 2 years. In addition, most balloon angioplasty patients ultimately required bypass surgery. Bypass after failed balloon angioplasty had significantly worse patency than that of primary bypass.[95] This finding corroborated other reports demonstrating that surgical bypass after failed endovascular treatment is inferior to primary bypass, indicating that a universal "endovascular first" approach may not be appropriate as failed endovascular intervention may "burn bridges" for surgical revascularization. Careful consideration must be given to the best initial therapy for infrainguinal occlusive disease.[96]

7 For patients with favorable anatomy and significant operative risk, and for the treatment of claudication in general, percutaneous therapy has assumed a primary initial role. When medical therapy or percutaneous treatment has proven 8 inadequate, open surgical revascularization remains the gold standard for those patients with disabling claudication. Furthermore, until the efficacy and durability of infrainguinal percutaneous intervention is better defined, surgical revascularization remains the gold standard for any patient with CLTI, especially those with extensive tissue loss. The relative roles of surgical and percutaneous intervention are actively being refined. It nevertheless appears that the rising popularity and success of femoral and tibial wire-based interventions may be reducing the volume, or ultimately just delaying the timing of, subsequent infrainguinal reconstructive surgery. Furthermore, many patients are best treated with a combination of percutaneous and open surgical therapy, often in a single procedure (hybrid procedure). In many instances, endovascular and open surgical revascularization are thus complementary modes of therapy.

Operative Management

9 Successful infrainguinal arterial bypass requires sound planning as well as technical expertise. As such, it remains the signature operation which

distinguishes vascular surgeons from other specialists involved in the treatment of PAD. Successful infrainguinal bypass grafting requires adequate arterial inflow. While aortobifemoral, femorofemoral, and axillofemoral bypass grafting remain routinely performed inflow procedures, aortoiliac angioplasty and stenting are increasingly becoming the preliminary procedures performed to attain sufficient inflow prior to construction of a more distal bypass graft. At times, the necessity of improving the inflow to support an infrainguinal graft is determined intraoperatively, either by direct visual assessment of the arterial flow at the desired donor site or by comparison of a transduced pressure tracing from the donor site with that of a systemic pressure tracing, typically obtained from a radial arterial line. Of equal importance to the outcome of any infrainguinal graft is target vessel selection. In general, the target vessel should be the least diseased artery that is the dominant supply to the foot. If tissue necrosis is present, restoration of pulsatile flow to the foot is often required to obtain full and sustained wound healing.

Infrainguinal surgical bypass can be performed under general anesthesia, or in the appropriate patient, under regional, spinal, or epidural anesthesia. In cases involving multiple sites of dissection, such as those necessitating more tedious arm vein or lesser saphenous vein harvesting, the procedures are particularly amenable to a two-team approach, with the time saved having direct benefit in minimizing the total anesthetic load and physiologic insult. For patients with superficial femoral artery disease, the initial dissection is most commonly at the level of the common femoral artery. This vessel is exposed through a longitudinal or oblique incision centered directly over the femoral pulse. Lymphatic tissue overlying the femoral vessels is best ligated and divided to prevent the postoperative development of lymph fistulas or lymphoceles. The severity of any concomitant common femoral and profunda femoral disease and the level of reconstruction planned dictate the extent of exposure of the femoral vessels. In most instances, the dissection extends from the inguinal ligament to the common femoral artery bifurcation, where the origins of the superficial and profunda femoral arteries are individually isolated.

If a profundaplasty is required, the dissection is extended distally along a sufficient length of the profunda femoral artery to attain an endpoint suitable for clamping and sewing (**Fig. 91.6**). Similarly, the inguinal ligament can be

partially divided to facilitate access to the distal external iliac artery in cases in which a more extensive proximal endarterectomy is necessary. In these circumstances, it is customary to close the endarterectomized bed with a vein, bovine pericardial or Dacron patch, onto which the proximal anastomosis can subsequently be attached.[97] In patients with a hostile groin crease from prior surgery or radiation therapy or in obese, diabetic patients with an intertriginous rash at the inguinal crease, meticulous skin preparation, close attention to draping, careful surgical technique, and judicious use of a short course of intravenous antibiotic therapy help minimize the chances of a postoperative wound or graft infection.

If all or part of the superficial femoral artery is spared of significant atherosclerotic involvement, the proximal anastomosis can be moved distally as dictated by the particular anatomic pattern of disease, and a so-called "distal origin graft" can be fashioned (**Fig. 91.7**).[98] This situation is particularly applicable to the diabetic population, in whom infrapopliteal disease is the rule and sparing of the superficial femoral and popliteal arteries is not uncommon. It is also utilized in situations in which conduit is sparse, and a moderately diseased proximal vessel is accepted as an inflow source for a more distal origin bypass graft in the interests of performing a fully autologous vein graft rather than utilizing prosthetic material. An increasingly popular approach when only limited conduit is available is to combine, either concurrently in the operating room or as a staged preoperative procedure, catheter-based treatment of the superficial femoral or popliteal artery inflow with more distal bypass.[99]

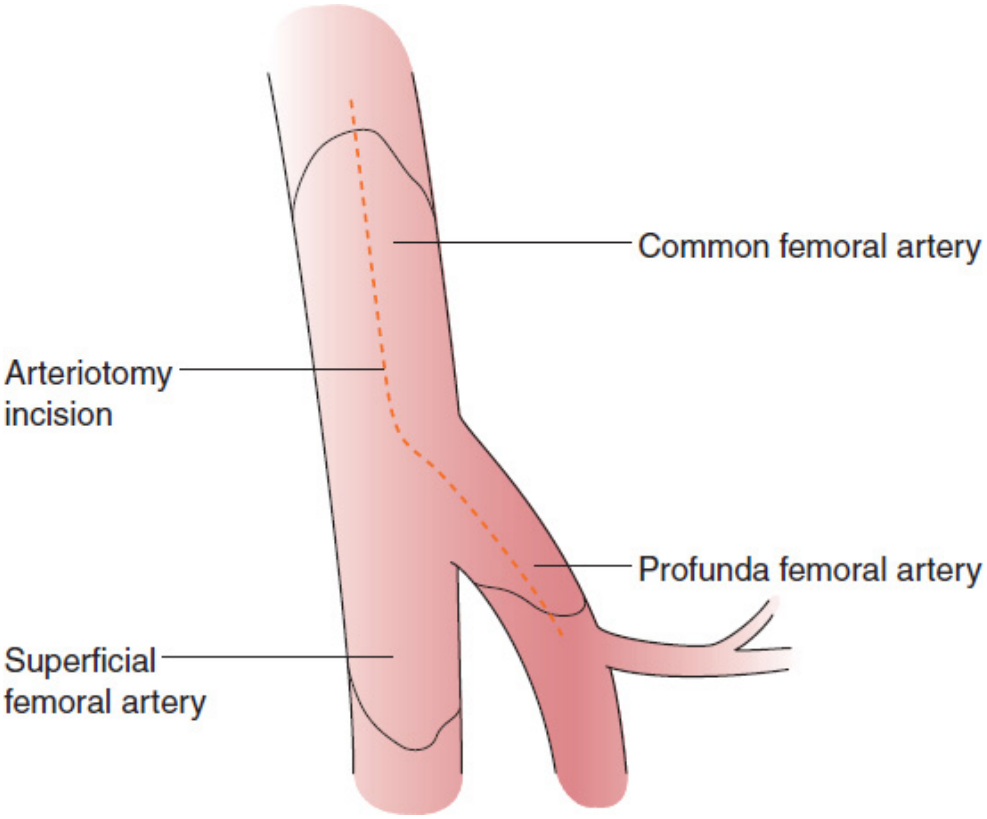

Figure 91.6 In the setting of orificial profunda femoral artery disease, extending the common femoral arteriotomy into the origin of the profunda and performing a profundaplasty will maximize profunda flow in the event of graft thrombosis.

The above-knee popliteal vessel is easily exposed through a medial thigh incision, with subsequent posterolateral retraction of the sartorius muscle. The popliteal artery with its accompanying vein and nerve is found just posterior to the femur. The vessel is palpated to determine the presence of atherosclerotic plaque, which will guide the extent of dissection and the optimal bypass target site. The below-knee popliteal artery is also exposed through a medial incision in the proximal calf (**Fig. 91.8**). If the saphenous vein is to be harvested, the incision is made directly over the vein to minimize the creation of devascularized skin flaps. With the exposed vein carefully protected, the incision is carried through the deep muscular fascia and the medial head of the gastrocnemius is reflected posterolaterally to expose the below-knee popliteal fossa. The distal popliteal artery is then dissected free from the adjacent tibial nerve posteriorly and popliteal vein medially. If the distal target is the tibioperoneal trunk, the dissection is

continued along the anteromedial surface of the distal popliteal artery after dividing the origin of the soleus muscle from the tibia (**Fig. 91.9**).

Although exposure of the proximal posterior tibial and peroneal vessels can be gained by extending the tibioperoneal trunk dissection distally, more distal exposure of these vessels is best gained through targeted medial incisions. The posterior tibial artery is found beneath the divided musculotendinous origin of the soleus muscle, and the peroneal artery is deeper and more lateral. The posterior tibial artery at the level of the ankle is a relatively easier target given the proximity of the vessel to the skin surface. The initial incision is made just posterior to the medial malleolus, and the artery exposed by division of the overlying retinaculum. Further distal dissection allows access to the bifurcation and medial and lateral plantar branches.[74] The more distal peroneal artery may be approached laterally via an incision placed over the distal fibula. Excision of a short segment of fibula will expose the underlying artery.

The anterior tibial artery is typically approached from the anterolateral aspect of the calf (**Fig. 91.9**) and is found deep within the anterior compartment with the adjacent deep peroneal nerve and anterior tibial veins. It is best identified by developing the intermuscular plane between the tibialis anterior muscle belly medially and the extensor digitorum longus laterally. The dorsalis pedis artery is easily exposed through an axial incision on the dorsum of the foot just lateral to the extensor hallucis longus tendon (**Fig. 91.9**). The artery lies just deep to the extensor retinaculum.

Figure 91.7 Arteriogram indicating preservation of the superficial femoral artery and popliteal arteries (**A–C**) with mid-calf occlusions of all three infrageniculate vessels (**D**), with reconstitution of the dorsalis pedis artery in the foot (**E**). This anatomic pattern of disease is amenable to "distal origin" vein grafting from the below-knee popliteal or proximal posterior tibial artery to the dorsalis pedis artery.

Autogenous Vein Bypass

10 Infrainguinal bypass surgery is best performed with autogenous vein conduit, preferably the ipsilateral greater saphenous vein if available.[100] This preference is particularly true for grafts extending below the knee, where prosthetic conduits of Dacron or polytetrafluoroethylene have significantly poorer patency rates. Given the orientation of the vein valves, the vein can be reversed such that the distal end of the vein is sewn to the proximal inflow artery and the larger proximal end of the vein is sewn to the distal outflow artery. However, it is our general practice to utilize the greater saphenous vein in the nonreversed orientation as will be discussed shortly. The vein is harvested through a long incision overlying the course of the vein or by more tedious but less invasive sequential skip incisions with intervening cutaneous skin bridges (**Fig. 91.7**). All side branches are ligated and after harvest, the vein is cannulated and gently dilated with a solution containing heparin and papaverine to assess its suitability. Veins with chronic fibrosis or that fail to dilate to a diameter of 3 mm or greater will likely have poor long-term function.

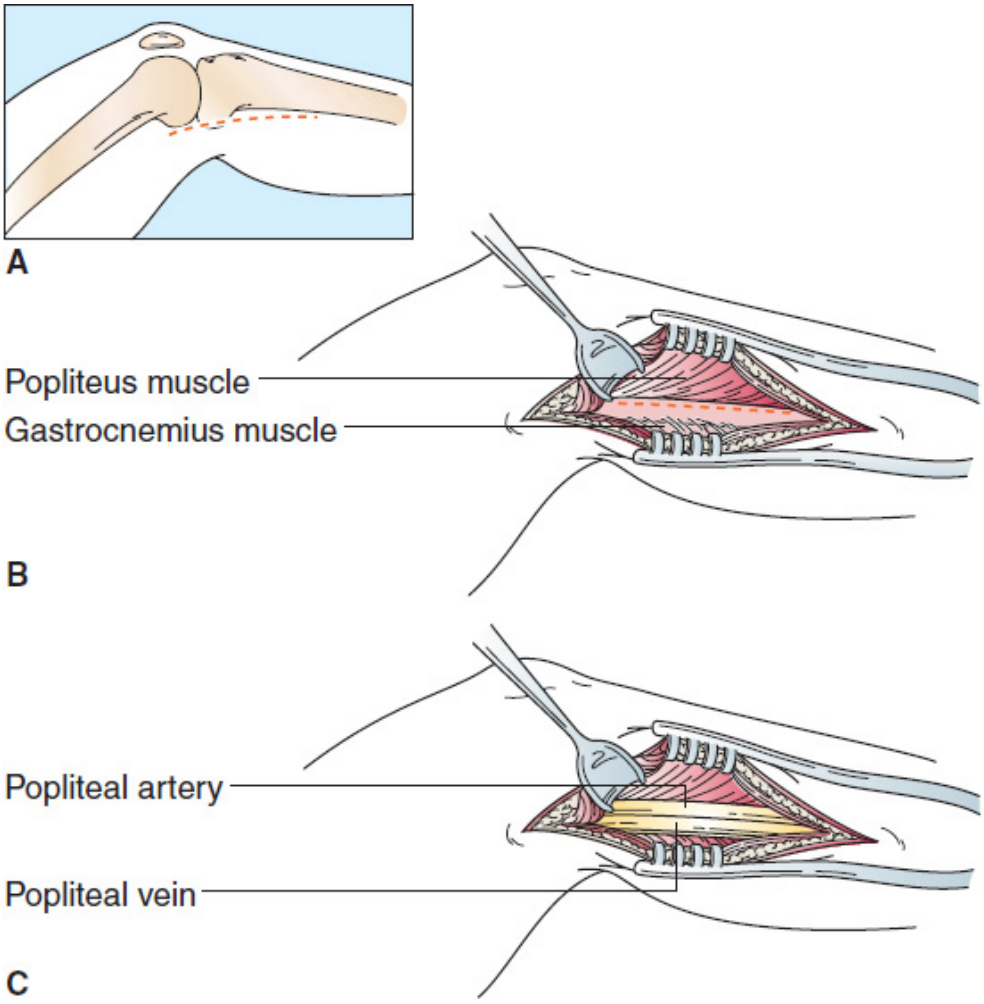

Figure 91.8 Exposure of the popliteal artery below the knee. The medial incision is made directly overlying the course of the greater saphenous vein (**A**), with posterior retraction of the gastrocnemius muscle (**B**), to reveal the popliteal vessels in the popliteal fossa (**C**).

An alternative and less invasive approach to saphenous vein harvest involves the use of endoscopic technology. In the case of harvesting of the greater saphenous vein, small skin incisions are made over the saphenofemoral junction and the distal vein, and guided by a videoscope inserted distally and advanced proximally, the side branches of the vein are serially identified and either cauterized or clip-ligated. Advocates of this method cite a significant reduction in wound complication rates and reduced rates of hospital stay, although patency rates may be compromised.[101,102]

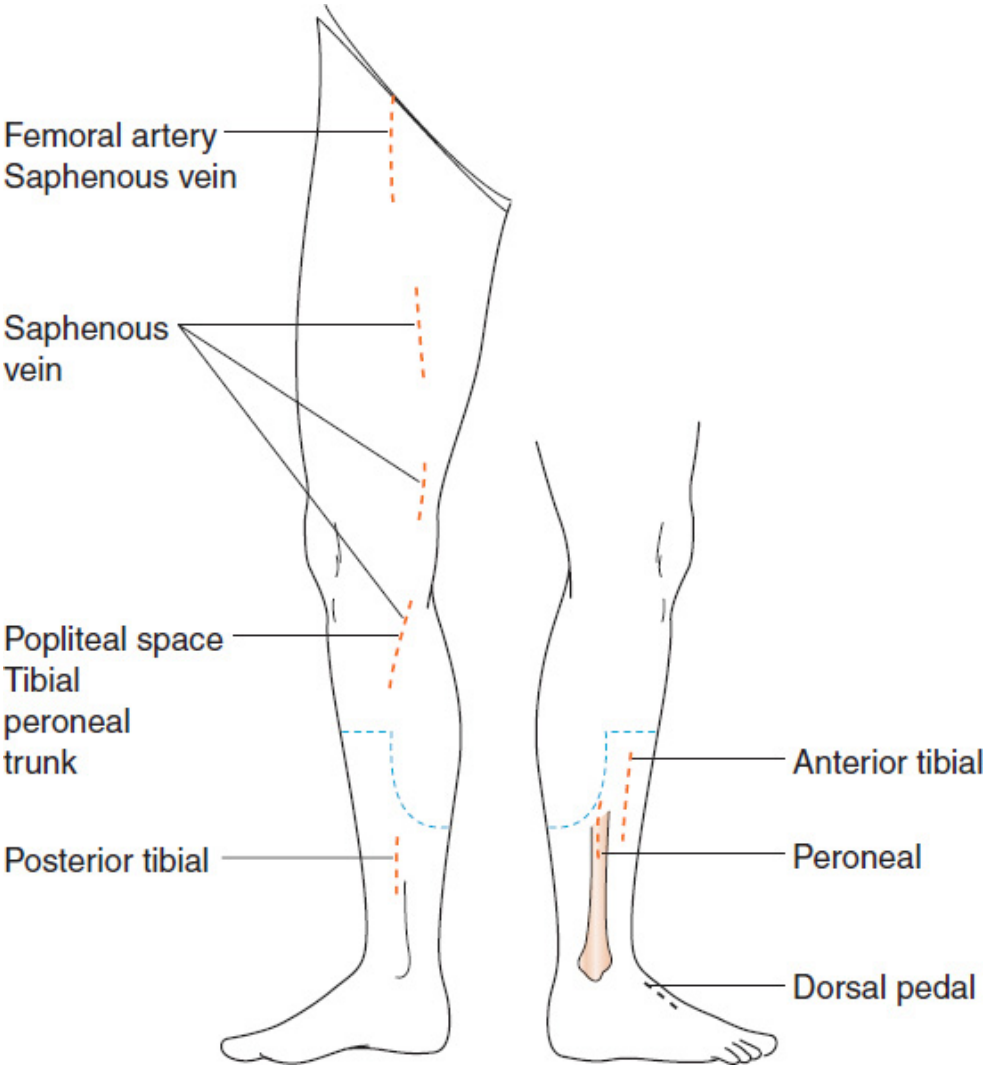

Figure 91.9 Placement of incisions for femoropopliteal and femorotibial bypass and for greater saphenous vein harvest. These should avoid the incision lines for a below-knee amputation.

For prosthetic grafts, a tunnel is usually fashioned through the subsartorial plane between the groin incision and the above-knee popliteal space in the interests of protecting the graft from subsequent infection. For vein conduits, it remains the surgeon's preference as to whether the graft is tunneled deeply or in a superficial location in the subcutaneous space. The more superficial configuration greatly facilitates ongoing clinical examination and ultrasonographic surveillance as well as later surgical revision, but carries a risk of graft exposure should there be wound-healing problems. Occlusion from trauma to grafts placed superficially has been of theoretical, but not a practical concern.

It is our practice to perform the proximal anastomosis prior to the distal anastomosis. First, this allows confirmation of adequate inflow before the bypass is performed. Second, performance of the proximal anastomosis first allows the graft to be tunneled and tailored to appropriate length under arterial pressure. This is of critical importance to prevent kinking along the length of the graft. An additional benefit of performing the proximal anastomosis first is that adequacy of flow through the graft can be assessed, both before and after tunneling, with brief release of the clamp.

Prior to occluding the inflow vessel, the patient is systemically anticoagulated with 5,000 to 10,000 units of heparin. Additional heparin is given throughout the procedure to maintain the activated clotting time near the target range of 250 to 300 seconds. After allowing sufficient time for the heparin to circulate, atraumatic vascular clamps are placed proximally and distally, and the artery is incised. The vein is then spatulated and a beveled anastomosis carried out. Typically a 5-0 monofilament suture of polypropylene is used for the femoral anastomosis, a 6-0 is used at the popliteal level, and a very fine 7-0 suture used at the tibial or pedal level. If the target tibial vessel is deep within the calf and visibility is challenging, a technique of "parachuting" the heel of the distal anastomosis is often employed. After completing the proximal anastomosis, the graft is carefully tunneled under arterial pressure. Occasionally, such extensive calcification of the target vessel is encountered that the risk of a significant injury from clamping, even with the minimally traumatic clamps in use today, is prohibitively high. In such cases, proximal inflow and distal artery back-bleeding can be controlled by occlusion balloons placed intraluminally. For distal anastomoses at the knee or more distal level, another alternative technique is the use of a proximally placed sterile pneumatic tourniquet. This technique is particularly advantageous when sewing to diminutive distal tibial or pedal targets, where the impact of a crush injury or plaque dislodgment on graft function could be considerable. Removing the need for clamps by using the tourniquet has two further advantages. First, it improves the operative visibility. Second, and more importantly, given that less longitudinal and circumferential dissection is needed, the degree of vessel spasm and venous bleeding that frequently accompanies vessel exposure at this level is kept to a minimum.

Flow through the graft and the outflow arteries are assessed following completion of the bypass with a continuous-wave Doppler. Ideally, a contrast angiogram is also performed after directly cannulating the proximal graft (**Fig. 91.10**); this allows for immediate repair of any technical defects that are identified, such as intraluminal thrombus, twisting or kinking of the graft, or retained valve cusps.[77] Intraoperative completion duplex ultrasonography is an additional sensitive screen for hemodynamically significant abnormalities within the graft, and its use further serves to prevent early graft loss caused by correctable technical problems.[103,104]

Current reports of the 5-year results of reversed saphenous vein graft using modern techniques have been excellent, with primary and secondary patency rates of up to 75% and 80%, respectively and limb salvage rates greater than 90% (**Table 91.2**).[73,105–107]

In Situ Grafting

There has been ongoing enthusiasm in some circles for in situ vein bypass grafting, whereby except for its proximal and distal extent, the greater saphenous vein is left undisturbed in its native bed. This technique was first described in 1962, but was later popularized by Leather and Karmody in the late 1970s.[108,109] Recent reports of in situ saphenous vein grafting have indicated 5-year graft patency rates of up to 80% and limb salvage rates of 84% to 95% (**Table 91.1**).[51,106,110–112]

The in situ approach minimizes trauma to the vein during excision and handling and in theory enhances preservation of the vasovasorum and endothelium. It further lowers the considerable risk of wound-healing complications seen with traditional vein harvesting, increases vein utilization, and facilitates the creation of more technically precise anastomoses because the proximal and distal vein diameters are more closely matched to those of the inflow and outflow target vessels (**Fig. 91.11**). The extent of the proximal vein mobilization is dictated by the location of the saphenofemoral junction relative to the proposed site of the proximal anastomosis. It may at times be necessary to perform an endarterectomy of the superficial femoral artery if the length of proximal vein is insufficient. Lysis of the valve cusps is obligatory given the nonreversed configuration, and is facilitated by newer, less traumatic valvulotomes that

function safely through the blinded segments of undissected graft. Critics of this technique argue that the advantages listed above have not translated into improved graft function or patency. They further argue that the time required and dissection involved in finding and ligating substantial side branches that can develop into physiologically important AVFs that “steal” distal flow obviates the stated benefits of this approach.

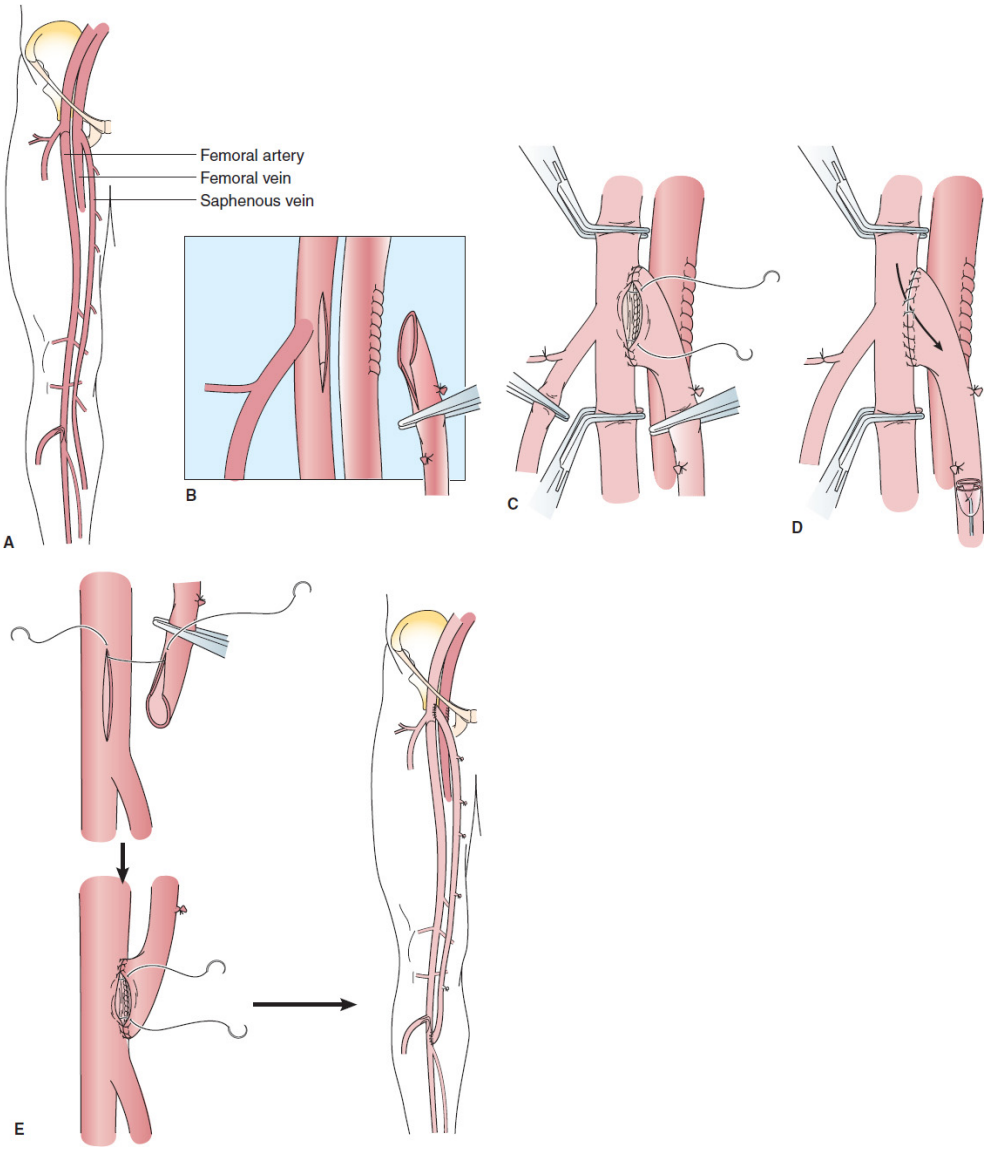

Figure 91.11 **A:** In the in situ method of infrainguinal reconstruction, the saphenous vein is left undisturbed in its native bed except for at the proximal and distal anastomotic sites, in this case, the common femoral artery and the tibioperoneal trunk, respectively. **B:** The saphenofemoral junction is transected in the groin, the venotomy in the femoral vein is oversewn and the proximal end of the saphenous vein spatulated is prepared for anastomosis. **C:** After the first venous valve is excised under direct vision, the graft is anastomosed end-to-side to the femoral artery. Flow is then restored through the vein graft and the valvulotome passed from the distal end to lyse the residual valves (**D**), before the distal anastomosis is performed (**E**).

Angioscopic-assisted valve lysis has been employed for over a decade, but has not gained widespread favor. Although there is a significant learning curve with this technology and operative times, at least initially, are

significantly prolonged, advocates cite fewer wound complications, shorter hospital stays, and decreased recuperative periods as potential benefits.

Nonreversed Saphenous Vein Grafts

Recognizing the many practical advantages inherent to the in situ technique, some surgeons have modified the approach to infrainguinal bypass grafting with venous conduit to incorporate several of the same principles.[50] In particular, if the harvested vein is tapered to any significant extent, it is used in a nonreversed fashion. By optimizing the size matching between the artery and vein at both the proximal and distal anastomosis sites as discussed previously, one can often accept for use, smaller veins than would be unsuitable for reversed vein grafting. The nonreversed configuration also allows preservation of the saphenous vein hood, which both extends the available conduit length and is especially beneficial when the femoral artery is thick walled and diseased.

The vein is harvested and dilated in a similar fashion to reversed vein grafts and the cusps of the proximal valve of the greater saphenous vein are excised under direct vision with fine Potts scissors. There are currently two main types of valvulotomes available. The modified Mills valvulotome is a short, metal, hockey stick-shaped cutter that can be introduced through the distal end of the vein or through the side branches. After the proximal anastomosis is performed, and with the perfused conduit on gentle stretch, the valves are carefully lysed in a sequential fashion by pulling the valvulotome inferiorly. An alternative, recently designed self-centering valvulotome allows lysis of all valves in a single pass and is thought by some to be less traumatic. Once acceptable pulsatile flow is ensured, the distal anastomosis is performed in the standard fashion.

It is important to note that similar patency rates have consistently been demonstrated regardless of which technique is applied, and so surgeon preference and comfort level is an acceptable reason for choosing one method over another.[111,112]

Prosthetic Bypass

It is recommended that infrainguinal bypass surgery be performed with saphenous vein or an autologous substitute whenever feasible given the clearly demonstrated enhanced patency rates.[45,113] Some institutions more frequently rely on prosthetic grafts. When the distal target is the above-knee popliteal artery and the tibial outflow is relatively well preserved, this is an acceptable approach, as patency rates in this situation approach those of vein grafts.[114] A variety of surgical adjunctive procedures, from patching the distal anastomotic target vessel to the creation of a distal AVF or various autogenous vein cuffs interposed between the distal prosthetic and the target artery, have all been attempted as a means of improving the patency rates of grafts extending below the knee.[115] Polyester (Dacron) and polytetrafluoroethylene (Teflon) grafts are the two main types of prosthetic available and, as in other anatomic positions, available data show generally equal results with either choice. The entire procedure is carried out through two small proximal and distal incisions between which the graft is tunneled anatomically. The selection of a 6-, 7-, or 8-mm graft is dictated by the size of the native vessels.

Reoperative Bypass Surgery

As the patient population treated by vascular surgeons has increased in age, and more and more challenging cases are accepted for primary treatment, there has been a corresponding increase in the incidence of reoperative bypass surgery performed for infrainguinal arterial occlusive disease. Such reoperative procedures are particularly challenging, both because of the scarring present at the inflow and outflow target sites and because there is typically a lack of ipsilateral greater saphenous vein. Whenever possible, the first problem is addressed by choosing anastomotic sites just above or below the previous touchdown points, thereby avoiding dissection through often densely scarred tissue planes. When ipsilateral greater saphenous vein is absent because of prior infrainguinal or coronary artery bypass surgery or prior saphenous vein stripping, there are a number of alternative conduit sites available. Investigators examining the consequence of using the contralateral greater saphenous vein in these situations found it to be the optimal conduit; despite the presumably high incidence of contralateral lower extremity as

well as coronary occlusive disease in this population, the short- and long-term impact was found to be minimal.[94]

In the absence of any greater saphenous vein, preoperative venous duplex ultrasonography is employed to evaluate the cephalic and basilic veins of the arms and the lesser saphenous veins of the legs in an effort to determine the best conduit available. Often the veins distal to the antecubital crease are scarred and of small caliber, but their more proximal counterparts are often of excellent size and quality. The use of arm veins in general can be technically challenging and for that reason has not been universally adopted. The dissection of the basilic vein can be particularly tedious as it has multiple side branches and lies adjacent to several important nerves. As arm veins are often relatively short, a venovenostomy is often required to create composite grafts long enough to complete the arterial reconstruction (**Fig. 91.12**). This is performed with generous spatulation of each vein hood to create a widely patent vein-to-vein anastomosis. Given their thin-walled nature, arm vein grafts are also quite prone to twisting and kinking, and special care must to taken during the tunneling process to avoid these problems. The more proximal arm veins can be relatively large, and it is often advantageous to use one or more of the segments in a nonreversed fashion to better match the graft to the inflow vessel size.

Not surprisingly, the results of reoperative infrainguinal bypass surgery do not match those of primary reconstruction. With autogenous vein, 5-year patency rates of 60% and limb salvage rates of 70% to 80% have been reported.[116] Anticoagulation is often used postoperatively in patients with compromised outflow or in whom the conduit was of marginal quality and has been associated with improved long-term patency.[117]

Postreconstruction Management

Unless otherwise contraindicated, all patients are maintained indefinitely on an antiplatelet regimen with either aspirin or clopidogrel following surgical bypass. As stated previously, in cases in which a graft is at increased risk of failure, such as in the setting of reoperation or in cases in which compromised outflow or a marginal conduit was accepted, the antiplatelet agent may be supplemented with heparin and then warfarin.[117] Patients with distal calf or pedal incisions should have consistent leg elevation in the early

postoperative period to minimize leg swelling and wound-healing complications. Thereafter, aggressive rehabilitation maximizes the chances of, and shortens the time to a return to full function after extensive reconstructive surgery.

Graft Failure and Surveillance

Postoperative graft failures are typically classified according to the time interval from surgery as early, intermediate, or late. Graft thrombosis occurring within 30 days, the so-called “early graft failures” are generally thought to be a result of technical or judgment errors by the surgeon. Included in this list would be such technical errors as twists, kinks, incompletely lysed valves, or anastomotic defects, as well as judgment errors in using a poor quality vein or targeting an outflow vessel with inadequate runoff to support the graft. Intermediate graft failures include those between 30 days and 2 years and are generally attributed to the proliferation of intimal hyperplasia at the anastomoses or prior valve sites within the graft (**Fig. 91.13**). Late graft failures occurring beyond 2 years are typically a result of the progression of atherosclerotic occlusive disease within the inflow or outflow arteries.

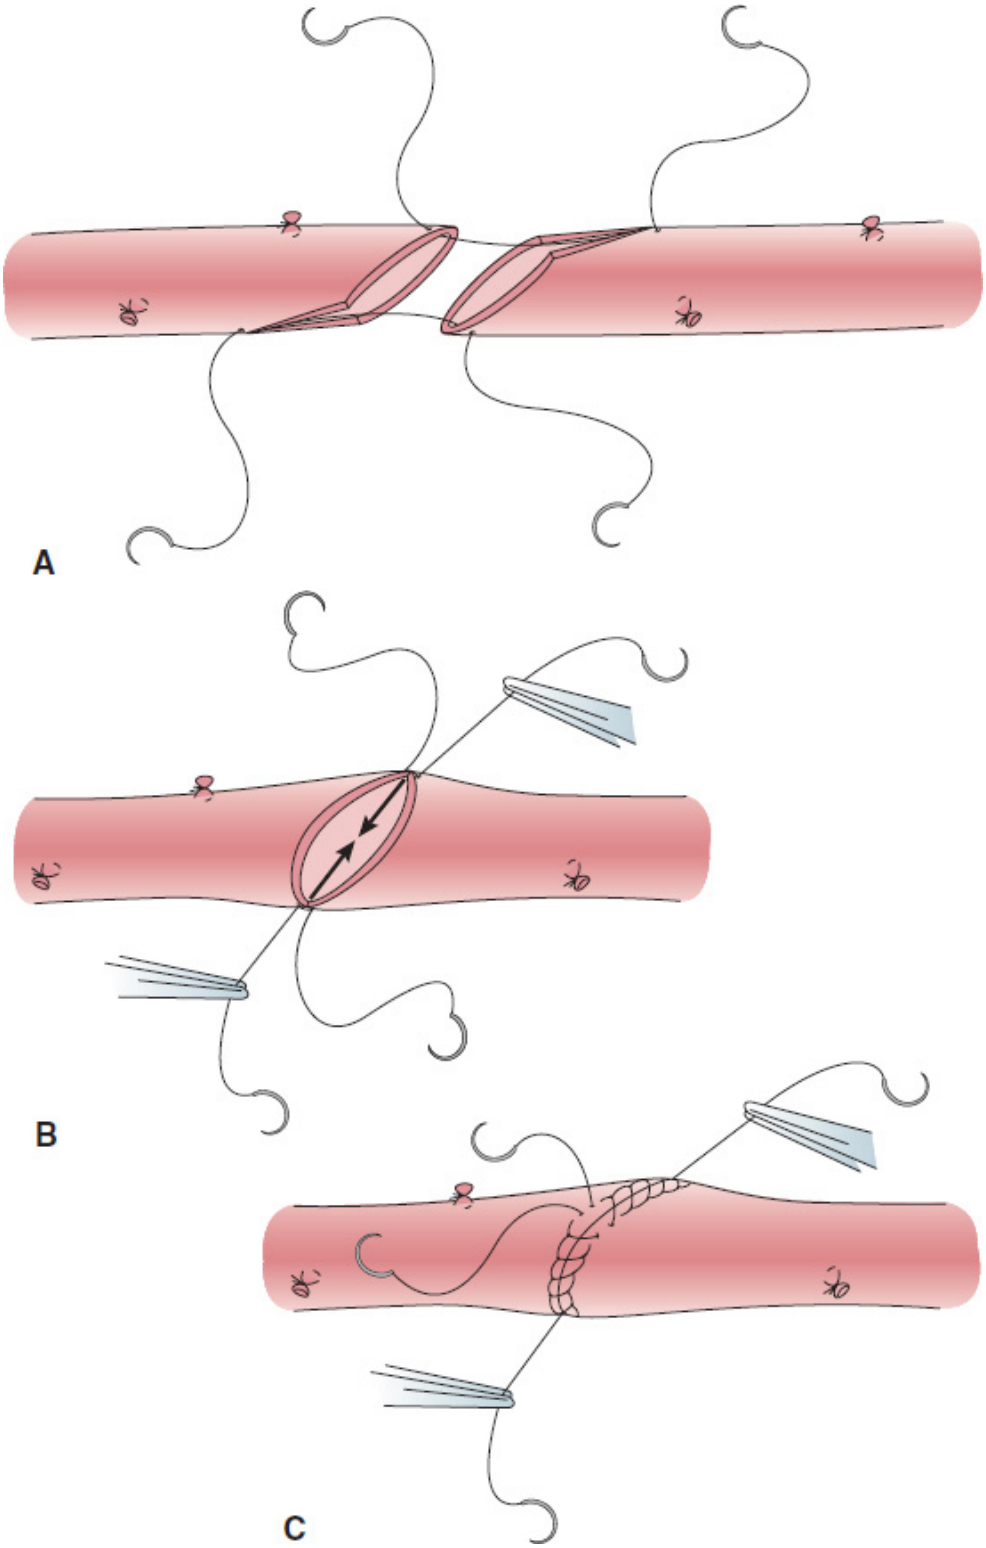

Figure 91.12 Creation of a composite graft from two or more segments of arm vein or lesser saphenous vein (**A**) is sometimes necessary to obtain the desired length of fully autogenous conduit for infrainguinal bypass. A widely spatulated venovenostomy (**B and C**) is optimal.

Given the known incidence of graft failure and the potentially dire consequence in terms of limb salvage or preservation of limb function in a patient with limited options for secondary or tertiary bypass, the ability to maintain graft patency through early identification and prompt correction of graft stenosis is of paramount importance.[118] Serial postoperative surveillance scanning with duplex ultrasound has proven an excellent means of accurately identifying hemodynamically significant stenosis within the vein graft that threaten the graft patency.[119] Velocity criteria have been developed for high-grade lesions that may warrant either more intensive surveillance or prophylactic intervention. Absolute velocities less than 40 cm/s or greater than 300 cm/s or a threefold increase in velocity in one segment compared with that of an adjacent segment are all indicative of impending graft failure. Confirmation by angiography and expeditious treatment by percutaneous cutting balloon angioplasty, surgical patch angioplasty, or interposition grafting of such significant lesions minimizes the risk of graft thrombosis and ensures optimal long-term graft patency.

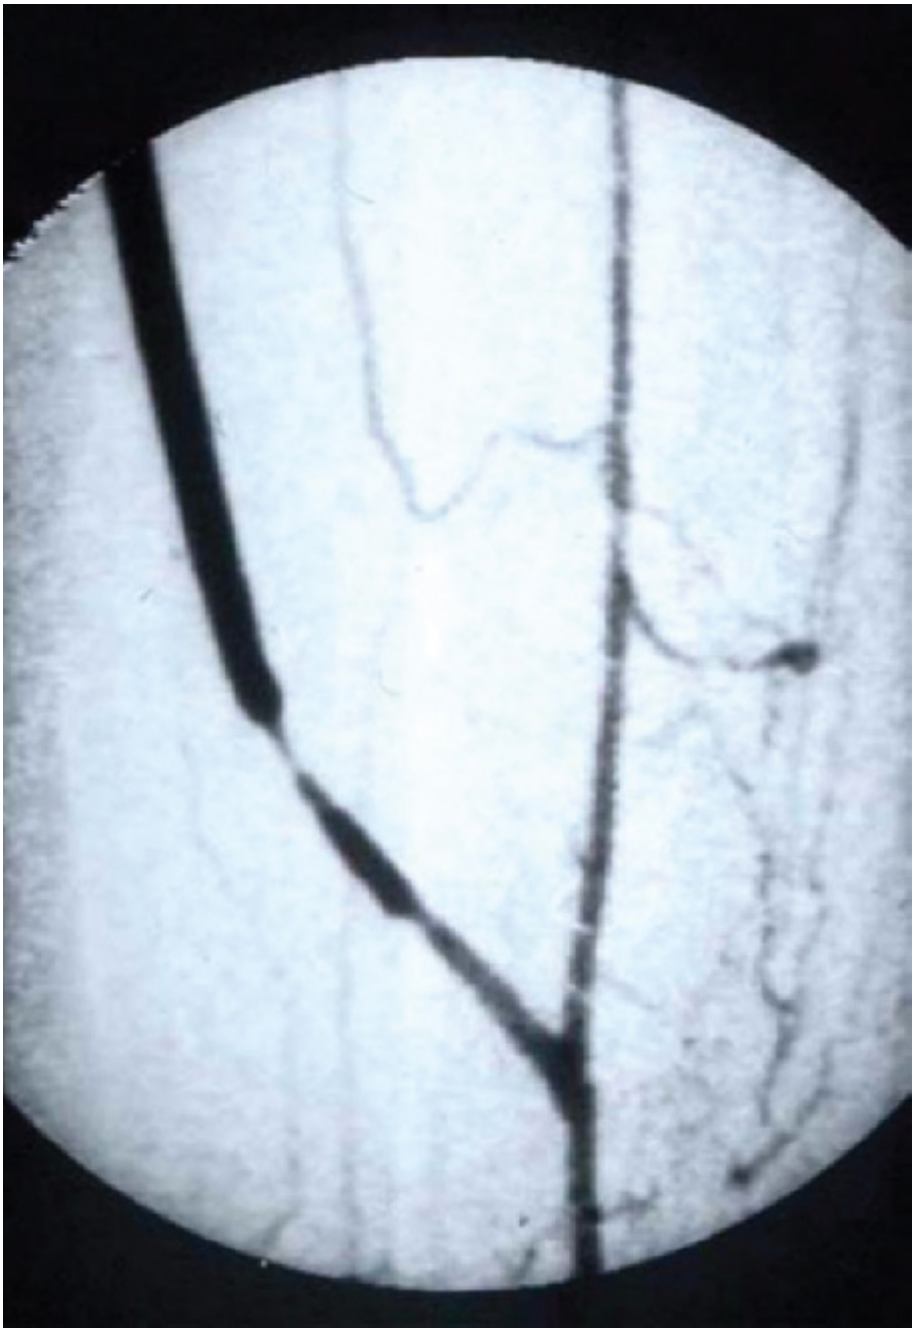

Figure 91.13 Arteriogram demonstrating severe stenosis of distal graft from intimal hyperplasia, likely at prior valve site.

Complications

The most commonly seen major complications of infrainguinal bypass surgery are cardiac in nature, and include myocardial infarction, congestive heart failure, and arrhythmias. In a recent review spanning 20 years and

involving more than 1,600 procedures, the perioperative myocardial infarction rate was 3%, and the rate of cerebrovascular accident was 1%.[105] Patients with diabetes mellitus or preoperative renal insufficiency are at particular risk for developing postoperative renal failure (defined as an elevation of serum creatinine >3 mg/dL, doubling of the serum creatinine or the need for hemodialysis), which is seen in up to 2% of patients overall. Patients undergoing lower extremity revascularization are also prone to wound complications, given the length of incisions and the prolonged operating times often required. Overall wound complications, including cellulitis and abscess formation, wound dehiscence, and skin flap necrosis, can occur in up to 40% of patients and can best be avoided by gentle handling of the tissue and the use of skin bridges and careful avoidance of skin flaps during vein harvesting.[120] Postoperative hematomas, usually caused by slow capillary or venous oozing, or seromas are seen in 5% of patients; and less commonly encountered hemorrhage, typically a result of either a slipped vein branch ligature or anastomotic disruption, is seen in less than 1% of cases.

ACKNOWLEDGMENT

This chapter is based on the previous version from the 6th edition entitled *Peripheral Arterial Disease* by William P. Robinson III.

Lower Extremity Amputation

Matthew J. Sideman, Kevin E. Taubman, and Bradley D. Beasley

Key Points

1. The annual incidence of major amputations has decreased over the past two decades.
2. The vast majority of lower extremity amputations are performed for complications of diabetes or arterial insufficiency.
3. Emergent amputation is indicated in the face of uncontrolled or ascending infection.
4. Primary amputation is occasionally indicated in cases of treatment for lower extremity trauma.
5. Revascularization is often performed in conjunction with a minor amputation, either simultaneously or as a staged procedure.
6. The choice of amputation level depends on the indication for the procedure, the condition of the patient, and the rehabilitation potential of the patient.
7. The energy required to ambulate following a lower extremity amputation increases with ascending level of amputation.

INTRODUCTION

1 Surgeons are often involved in treating patients requiring lower extremity amputation. Increasing incidence of diabetes, peripheral arterial disease, and the aging population has put more patients at risk for amputation. The explosion of endovascular interventions over the past decade has resulted in decreasing numbers of major amputations performed annually.[1] A review of the Nation Hospital Discharge Survey and Medicare claims data confirms this trend.[2] Clinical judgment is critical to a successful outcome. Factors to consider are primary amputation, revascularization, repeat revascularization, level of amputation, and timing of amputation. The surgeon must remember that the goal is to maintain maximal function of the patient not necessarily maximal length of the limb. Consequently, experience of the surgeon has been shown to be key to a successful outcome.[3]

INDICATIONS

2 Most lower extremity amputations are performed for complications of diabetes or arterial insufficiency (**Table 92.1**). Chronic infection and trauma account for less than 10% of the total number of amputations. Other indications include neuroma, frostbite, malignancy, chronic pain, arterial embolization, venous insufficiency, and cryoglobulinemia.[4]

Elective lower extremity amputation in diabetic and vascular patients is indicated for gangrene (dry gangrene), gangrene with infection (wet gangrene), unremitting and unreconstructable rest pain, and nonhealing ulcers. The goal of the operation is to remove all nonviable tissue, relieve ischemic rest pain, ensure primary wound healing, and facilitate rehabilitation. Elective amputation should only be performed following an evaluation for revascularization procedure by a surgeon capable of performing such procedures. Veith et al.[5] reported that 96% of patients who underwent lower extremity arteriography for limb-threatening infrainguinal arteriosclerosis were candidates for arterial reconstruction. Advances in percutaneous management have expanded treatment options to patients who were not otherwise operative candidates. Not all patients are candidates for arteriography, including those with chronic renal insufficiency, organic brain

syndrome, nonfunctional limbs, fixed joint contractures, insensate feet, and those with extensive gangrene.

Spinal cord stimulation (SCS) may offer a chance for limb salvage for patients with chronic ischemia in whom reconstruction is not an option. Based on Melzack and Wall theory for the treatment of chronic pain,[6] the mechanism of pain relief and increased blood flow in end-stage peripheral vascular disease is unclear. Despite this, there is peripheral vasodilatation on the microvascular level which leads to pain relief,[7] increased claudication distance,[8] ulcer healing,[9] and possible limb salvage.[7,10,11] The 1-year foot salvage rate is 60% to 70% on average, according to a review of the literature.[12] SCS is only appropriate when surgery for revascularization is no longer possible. Furthermore, SCS only dilates microvasculature and does nothing for the underlying, progressive peripheral vascular disease that is causing the ischemia. SCS, therefore, is only a temporizing measure, but can potentially give an extended functional period with a procedure that is well tolerated and relatively simple to perform.[12] Recently, Gersbach et al. have shown that the benefits of SCS persist longer than initially thought.[13]

Table 92.1 Indications for Lower Extremity Amputation

Indication	Percentage (%)
Complications of diabetes mellitus	60–80
Nondiabetic infection with ischemia	15–25
Ischemia without infection	5–10
Chronic osteomyelitis	3–5
Trauma	2–5
Miscellaneous (neuroma, frostbite, tumor, pain, and nonhealing wound)	5–10

From Malone JM. Lower extremity amputation. In: Moore WS, ed. *Vascular Surgery: A Comprehensive Review*. Philadelphia, PA: WB Saunders; 1993:810.

3 Emergent amputation is indicated in the face of uncontrolled or ascending infection. In the case of uncontrolled sepsis, it can even be a

lifesaving maneuver. A diabetic patient with a foot abscess is a surgical emergency. Frequently, incision and drainage with or without a toe or a combined toe and metatarsal resection is sufficient to control the acute problem. The wounds should be left open in the setting of acute infection. If the process extends beyond the foot, a staged amputation should be performed proximal enough to control the infection. This can include an ankle disarticulation, a guillotine below-knee amputation (BKA), a knee disarticulation, or a guillotine above-knee amputation (AKA). Disarticulations have the advantage of preserving limb length and avoiding an open bone in the incision. After the infection is controlled, the appropriate amputation can be completed. A one-stage primary AKA can be considered in patients who are nonambulatory, have infection involving the entire lower leg, have a fixed knee contracture, or those with a nonfunctional limb. Patients who are too unstable for surgery can be temporized with a cryoamputation.[14]

4 Primary amputation is occasionally indicated as treatment for severe lower extremity trauma. Both penetrating and blunt injuries of the lower extremities are frequently associated with vascular, nerve, bone, and extensive soft tissue injuries. Several treatment guidelines have been developed for lower extremity trauma. Lange[15] recommended primary amputation for open tibial fractures with associated vascular injuries if the posterior tibial nerve was disrupted in an adult or if the duration of warm ischemia was greater than 6 hours in a crush injury. In addition, he suggested that primary amputation was relatively indicated in patients with polytrauma, severe ipsilateral foot injuries, and in those with an expected protracted postoperative course. These suggestions are supported in work by Bosse et al.[16] demonstrating, in the case of high-energy lower extremity trauma, amputation and reconstruction have equal functional outcomes at 2 years. Additional guidelines have been provided by Johansen et al.[17] who devised a Mangled Extremity Severity Score to predict the need for amputation based on the extent of skeletal or soft tissue damage, limb ischemia, shock, and age. Unfortunately, none of these guidelines are predictive of functional recovery in patients who undergo limb salvage.[18] Therefore, treatment with primary amputation is an extremely difficult decision and requires extensive clinical judgment as well as multidisciplinary input. Contributing factors include the

severity of the injury, the overall clinical status, and the ultimate rehabilitation potential of the patient.

EVALUATION FOR REVASCULARIZATION

Modern vascular surgery techniques allow successful limb salvage in situations not previously possible. All patients who present for possible lower extremity amputation, including minor amputations, should have their peripheral vascular circulation evaluated preoperatively. Any patient with absent pedal pulses or abnormal ankle–brachial indices should be evaluated by a vascular surgeon skilled in both open and endovascular revascularization techniques. The evaluation may require only a thorough history and physical examination if there is an obvious contraindication to revascularization (e.g., nonfunctional limb, severe organic brain syndrome). Noninvasive vascular laboratory examinations are a mandatory minimum for patients with abnormal vascular examinations. Additional imaging with either computed tomographic angiography (CTA), magnetic resonance angiography (MRA), or contrast angiography can be done based upon the patient's initial evaluation and vascular lab results. The information obtained from these tests is heavily dependent on the quality of the machinery, the skill of the technologist, and the knowledge of the interpreting physician. All of these factors must be taken into account when deciding which test to order. Contrast angiography with selective lower extremity injections may be necessary to fully define the patient's anatomy and suitability for reconstruction; however, it is generally preferred to perform this invasive procedure for preoperative planning or for planned percutaneous intervention. Contrast arteriography should not be considered a *diagnostic* examination.

Exponential advances in endovascular techniques have occurred over the past two decades. These have found their way into the peripheral circulation and have applicability in limb salvage. Percutaneous techniques include balloon angioplasty (including conventional, cutting, and drug-coated balloons), stenting (including balloon expandable, self-expanding, drug eluting, and covered stents), intravascular lithotripsy, and percutaneous atherectomy (including laser, directional, orbital and rotational). The BASIL

trial showed no significant difference in amputation-free survival among patients with critical limb ischemia when randomized to open or percutaneous revascularization.[19]

In terms of surgical reconstruction, upper extremity[20] and cryopreserved cadaver vein[21] have increased the options for conduit in limb salvage situations. Prosthetic grafts with vein cuffs[22,23] provide other alternatives when appropriate autogenous conduit is not available. Heparin-bonded prosthetic grafts have been shown to be effective as well.[24–26] An operation for limb salvage should never be denied *only* for lack of conduit.

5 Revascularization is often performed in conjunction with a minor amputation, either simultaneously or as a staged procedure. This allows management of the acute problem of sepsis and the underlying chronic ischemia. Caution must be taken if there is active infection and the only available conduit is prosthetic for fear of infecting the graft. Amputation with control of infection followed by revascularization is the more prudent course. In extreme cases, a limited amputation can be combined with revascularization and a tissue transfer (free or rotational flap) to achieve limb salvage.[27,28]

CHOICE OF AMPUTATION LEVEL

General

6 The choice of amputation level depends on the indication for the procedure, the condition of the patient, and the rehabilitation potential of the patient. The most common amputation levels are illustrated in **Figure 92.1**. Because most amputations are performed for complications of diabetes or arterial insufficiency, the selected level must remove all nonviable, painful tissue, allow primary healing, and maximize rehabilitation potential. Selection of the amputation level for malignant disease is dependent on the biologic characteristics of the neoplasm and will not be discussed further.

The general medical condition and the rehabilitation potential of the patient are important factors in deciding to proceed with amputation and in selecting the appropriate level. If a patient is ambulatory and independent preoperatively, the level with the greatest likelihood of maintaining function

should be selected. If the patient is not ambulatory or has significant comorbid conditions, the primary wound-healing rate should be the determining factor.

Specific Situations

Aggressive attempts to salvage a distal amputation level are not indicated for patients who are unlikely to ambulate with a prosthesis.[29] For example, patients with fixed joint contractures greater than 15 degrees at the knee or 10 degrees at the hip are unlikely to ambulate with a prosthesis. BKAs are relatively contraindicated in patients with paraplegia because flexion contractures at the knee can lead to stump ulceration.

Mid thigh
Supracondylar
Knee disarticulation
Below knee

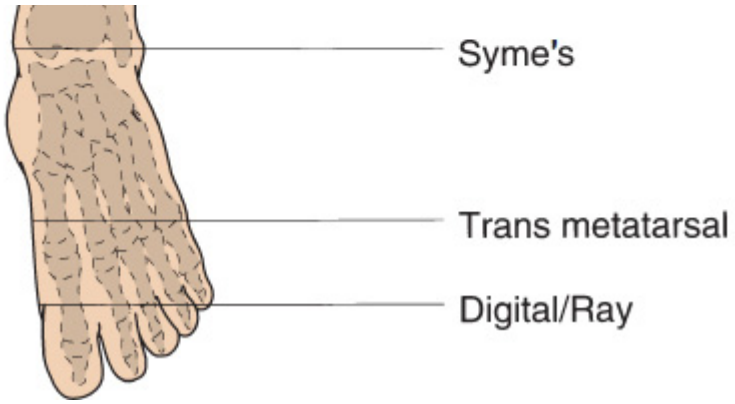

Figure 92.1 Common amputation levels for the lower extremity.

Energy Requirement

7 The energy required to ambulate following a lower extremity amputation increases with ascending level of amputation. The more proximal the amputation, the less likely a patient will be able to ambulate postoperatively. **Table 92.2** illustrates the increased energy cost of the common lower extremity amputations. In clinical practice, the most significant increase is between a BKA and an AKA. Ambulation on an above-knee prosthesis requires the use of muscle groups poorly suited for that purpose. These increased energy costs are minor issues for young trauma or cancer patients; however, they represent a considerable obstacle for the older diabetic or vascular patient.

Clinical Assessment

The primary preoperative consideration for wound healing is the status of the skin and muscle blood flow. Operative technique, the patient's nutritional status, and the presence of infection also affect wound healing. Clinical judgment by an experienced surgeon accurately predicts healing of a BKA in approximately 80% of cases.[30] A palpable pulse at the level immediately proximal to the proposed amputation essentially ensures healing[31]; however, the converse is not true. Noninvasive arterial testing is the most common adjunctive test used to predict healing of a specific amputation level. Its usefulness is limited when medial sclerosis prevents vessel compression, a condition common in diabetic patients. Because the digital vessels are often

spared from this process, digital pressure readings may be helpful in this setting. Transcutaneous oxygen measurement has been shown to predict primary healing although it is less able to predict failure to heal.[32,33] It has become more widely available and has supplanted previous less reliable tests that were more limited in availability. **Tables 92.3** to **92.6** summarize the results of various preoperative tests to predict wound healing for toe, foot and forefoot, below-knee, and above-knee amputations, respectively. The Society for Vascular Surgery WIfI (Wound, Ischemia, and foot Infection) classification system has more recently been shown to be very helpful in predicting the risk of amputation and benefit of/requirement for revascularization.[34–38]

Table 92.2 Rehabilitation Energy Cost of Amputation at Various Levels

Amputation Level	Energy Cost
Digital or ray	Minimal (except first ray)
Transmetatarsal	Minimal during normal walking
Below knee	30–60% increase in energy required for ambulation
Above knee	60–100% increase in energy required for ambulation
Hip disarticulation	100–110% increase in energy required for ambulation

Table 92.3 Preoperative Level Selection: Toe Amputation

Selection Criteria	Successful Healing, Primary and Secondary per Total
Empiric	86/115 (75%)
Presence of pedal pulses	357/365 (98%)
Doppler toe pressure >30 mm Hg	47/60 (78%)
Doppler ankle pressure >35 mm Hg	44/46 (96%)
Photoplethysmographic digit or TMA pressure >20 mm Hg	20/20 (100%)

OPERATIVE TECHNIQUE

General Considerations

Diabetic patients who present septic require adequate fluid resuscitation, broad-spectrum antibiotics (including anaerobic coverage), and an emergent operation. Whereas maintenance of limb length and function is admirable, control of sepsis and wide debridement of all nonviable tissue are essential and potentially lifesaving. All patients require atraumatic tissue handling. Avoid forceps on the skin edge. Excessive skin flaps and dead space are also not desired. Amputations done in the face of active infection are kept open and treated with dressing changes. Consider delayed primary closure in cases where perfusion is intact.

Postoperatively, the limb is elevated to minimize tissue edema and promote healing. Weight bearing on the amputation is delayed until healing is assured. This patient population requires effective prophylaxis against deep venous thrombosis and venous thromboembolism.

Digital and Ray Amputations

Digital amputations are indicated for some severe and irreducible deformities as well as gangrene or osteomyelitis localized distal to the base of the proximal phalanx. A technique for partial digital amputation is illustrated in **Figure 92.2A**. The circumferential or racquet-shaped skin incision is made over the distal end of the proximal phalanx and carried down to bone. Nerves and tendons are transected under tension and allowed to retract. The proximal phalanx is divided with bone shears or power saw and the transected end smoothed with a rongeur. Soft tissue coverage can be performed with either medial/lateral flaps or dorsal/plantar flaps depending

on skin tension and viability. The wound is closed with simple interrupted skin sutures. Judicious use of subcutaneous sutures is advised due to danger of vascular compromise to the small remaining flaps. Non–weight-bearing restrictions or protected weight bearing on the heel only in a rigid soled postoperative shoe or walking boot until the wound heals is recommended.

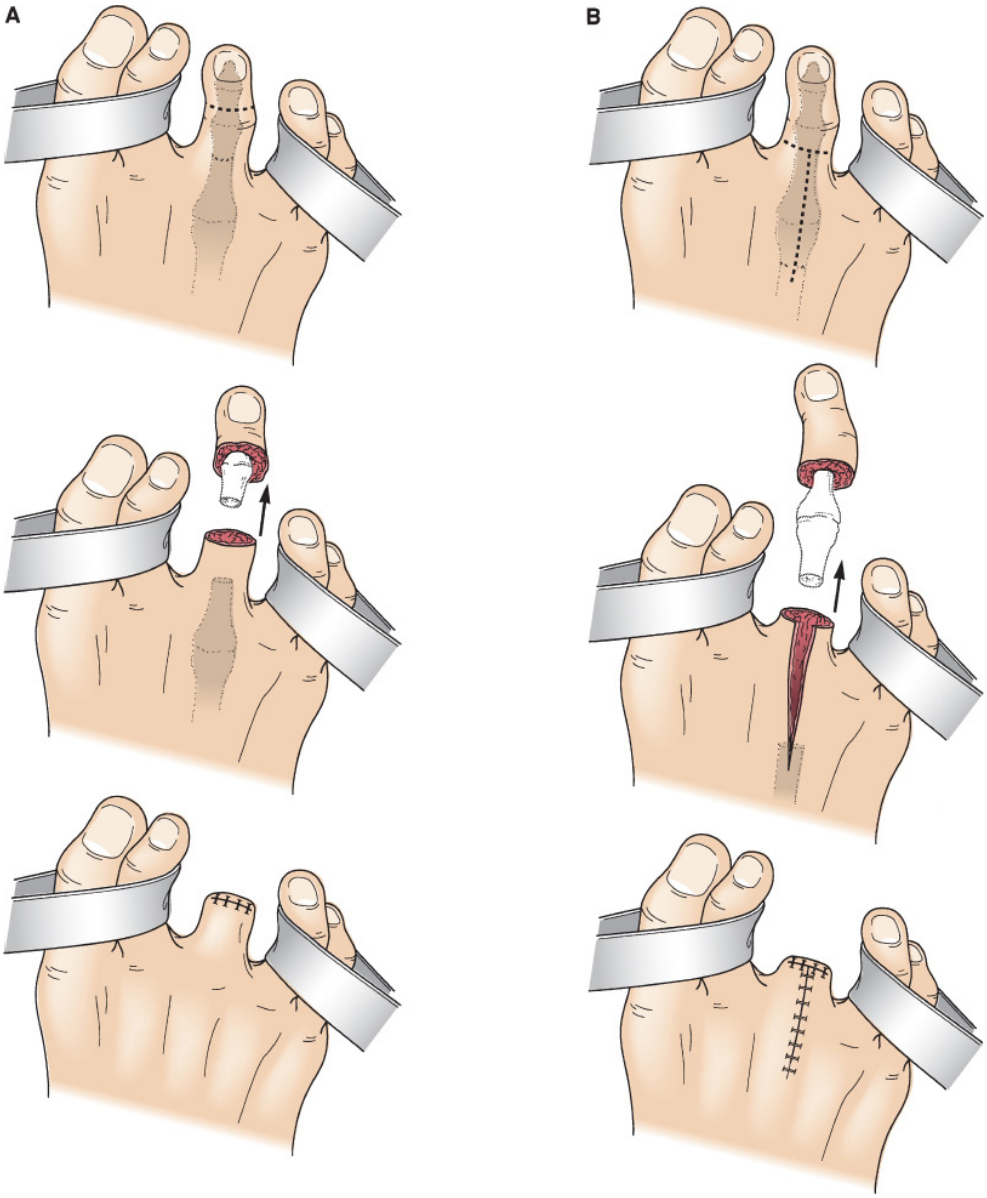

Figure 92.2 **A:** Digital amputation. A circumferential skin incision is made proximal to the gangrenous process. The proximal phalanx is transected and the soft tissue approximated. **B:** Metatarsal head resection (ray amputation). A racquet-shaped skin incision is made with the circular component extending circumferentially around the digit and the longitudinal component extending proximal to the metatarsal head. The metatarsal is transected proximal to the head and the soft tissue approximated.

A ray amputation is indicated when the disease process extends to the metatarsal phalangeal joint. The technique is similar to a digital amputation and is illustrated in **Figure 92.2B**. A circumferential incision is made at the base of the involved toe and extended proximally on the dorsum of the foot

over the metatarsal. The incision is extended to bone. The periosteum is cleared circumferentially and the bone is transected using a power saw at a level that will allow tension-free closure of the wound. In the case of the first or fifth toe, the incision is extended on the medial or lateral aspect of the foot, respectively. Care should be taken to bevel the distal metatarsal stump to minimize any prominence that may lead to skin breakdown with weight-bearing or shoe gear wear. Typically, the first metatarsal is beveled from proximal medial to distal lateral and proximal planter to distal dorsal. Metatarsals 2, 3, and 4 should be beveled from proximal plantar to distal dorsal. The 5th metatarsal is beveled from proximal lateral to distal medial and proximal plantar to distal dorsal.

In selected cases of neuropathic ulcers, the metatarsal head can be resected leaving the toe intact. A dorsal longitudinal incision is made over the metatarsal bone and the metatarsal head is resected with a power saw. Pulsed lavage and careful soft tissue inspection will help guide appropriate care for the plantar wound (i.e., packing, negative-pressure therapy, or ellipse of wound with closure). The dorsal wound is typically closed unless severe infection is encountered.

Transmetatarsal Amputation

Transmetatarsal amputation (TMA) is a useful procedure that maintains a patient's ability to ambulate without the aid of a prosthesis. It is indicated when the gangrenous or infectious process involves multiple digits or a portion of the forefoot. Care must be taken to plan for the appropriate soft tissue coverage if primary closure is desired. Maximizing the plantar flap is most common, but coverage can also be gained from medial or laterally based flaps and even filleted toe flaps. If adequate soft tissue coverage is not available and a more proximal foot amputation (i.e., Chopart joint amputation) is not desired then an open amputation through the metatarsal bones can be performed. The wound is allowed to close secondarily or covered with a skin graft. Skin grafts in this position, however, are susceptible to breakdown secondary to the pressure related to ambulation.

The technique is demonstrated in **Figure 92.3**. A skin incision is made on the dorsum of the foot immediately proximal to the metatarsal heads and extended medially and laterally to a point midway between the plantar and

dorsal surfaces. The plantar incision is made along the digital crease and extended diagonally medially and laterally to connect to the dorsal incision. The dorsal incision is deepened to the periosteum, which is cleared with a small periosteal elevator. The metatarsal bones are transected 0.5 to 1.0 cm proximal to the dorsal skin incision. The plantar flap is fashioned by continuing the dissection just superficial to the metatarsal heads. Care is taken to maintain plantar flap thickness. The nerves and tendons are transected sharply under tension and allowed to retract. The plantar flap is rotated anteriorly and assessed for length. Excess tissue is excised sharply and the deep tissue is approximated with absorbable suture. The skin is closed without tension using monofilament suture or skin staples.

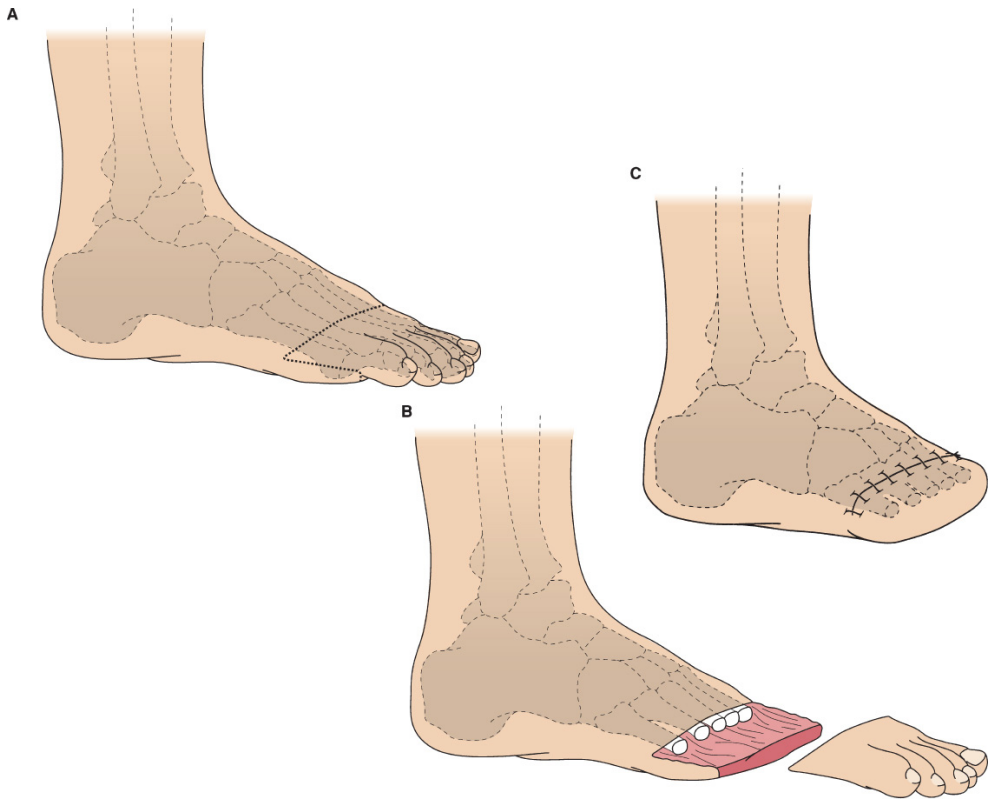

Figure 92.3 **A:** The skin incision for the transmetatarsal amputation is made on the dorsum of the foot immediately proximal to the metatarsal heads and on the plantar surface within the digital crease. **B:** The metatarsal heads are transected proximal to the skin incision and separated from the plantar soft tissue flap along a plane adjacent to the bone. **C:** The plantar soft tissue flap is rotated anteriorly and approximated.

Weight bearing is delayed for 1 month to allow adherence of the plantar flap. Either a soft dressing or a short leg cast can be used for a postoperative dressing.

Staging a tendo-Achilles lengthening (TAL) is important to consider following (or at the same time if no infection is present) a partial foot amputation. Ulcer formation at the TMA stump site is often related to equinus formation due to the ensuing flexion/extension imbalance that occurs after resection of the forefoot. A simple triple-hemisection percutaneous TAL can effectively lengthen the Achilles and reduce future pressures at the stump site.[39] Other tendon-balancing procedures may be needed to control varus and valgus contraction deformities that can develop.

Syme Amputation

The Syme amputation is a foot amputation that preserves limb length and the epiphyseal growth plates and allows occasional ambulation without a prosthesis. It is indicated in cases of extensive foot trauma or other nonviable tissue conditions distal to the hindfoot. The Syme amputation is contraindicated if a supple intact heel pad and a well-vascularized hindfoot tissue flap are not available.

The procedure can be performed in one or two stages, as illustrated in **Figure 92.4**. The initial steps for both procedures are identical, except that the skin incision for the two-stage procedure is located 1.5 cm more distally. The skin incision for the one-stage procedure extends from the medial to the lateral malleolus in the horizontal and vertical planes. The dorsal incision is extended to the bone, and the tendons are transected under tension. The anterior tibial artery is identified, divided, and suture ligated. The dissection is carried into the tibiotalar joint space as the foot is forcibly plantar flexed. The ligaments are transected and the talus is dislocated. The plantar aspect of the incision is deepened to the calcaneus, and the calcaneus is sharply dissected from the plantar fascia. The plantar fascia is densely adherent and care must be taken to prevent damage to the heel pad, especially at the level of the Achilles tendon. The posterior tibial artery must be preserved because it perfuses the heel pad. The foot is then removed. The two procedures differ from this point forward.

In the one-stage procedure, the medial and lateral malleoli are transected flush with the tibiotalar joint space, and the heel pad is rotated over the ends of the tibia and fibula. The deep fascial layers are approximated with absorbable suture and the skin is closed with monofilament suture or skin staples. Securing the distal end of the remaining plantar fascia to a small drill hole in the distal anterior tibia will help anchor the plantar flap and reduce posterior migration. In the two-stage procedure, the heel pad is similarly positioned and the wound is closed without further bone transection. In 6 weeks, elliptical incisions are made over the medial and lateral malleoli and the distal ends of the tibia and fibula are transected flush with the ankle joint. In addition, the distal flares of the tibia and fibula are transected, creating the rectangular stump of the two-stage procedure. The wound is closed in a similar fashion. For both procedures, weight bearing is delayed for at least 4 weeks to allow heel pad fixation. A soft dressing or a short leg cast can be used.

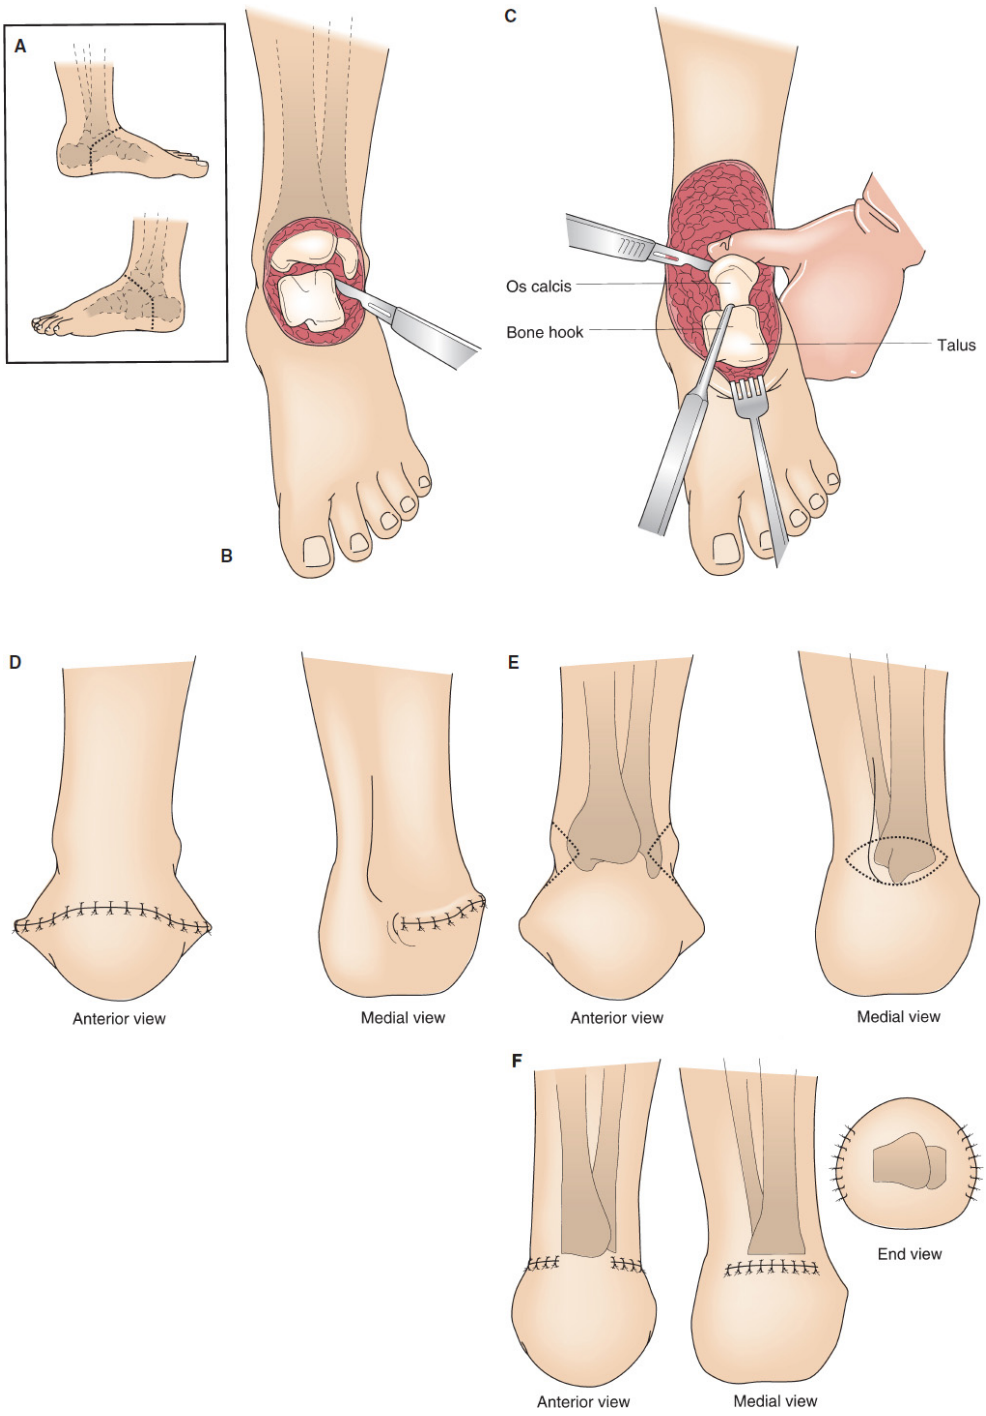

Figure 92.4 **A:** The skin incision for the one-stage Syme amputation connects the medial and lateral malleoli in both the horizontal and vertical planes. The skin incision for the two-stage procedure is located approximately 1.5 cm further distally. **B:** The incision is extended into the tibial—talar joint space, and the foot is placed in forced plantar flexion. **C:** The calcaneus is sharply dissected from the adherent plantar fascia along a plane adjacent to the bone. **D:** The heel pad is rotated anteriorly and approximated after the calcaneal dissection in the two-stage procedure and after the additional transection of the medial and lateral malleoli in

the one-stage procedure. **E:** Elliptic incisions are made over the medial and lateral malleoli during a second operation for the staged procedure. The medial and lateral malleoli are transected flush with the ankle joint, and the distal flares of the tibia and fibula are removed. **F:** The two-stage procedure results in a less bulbous, more cosmetically acceptable residual limb.

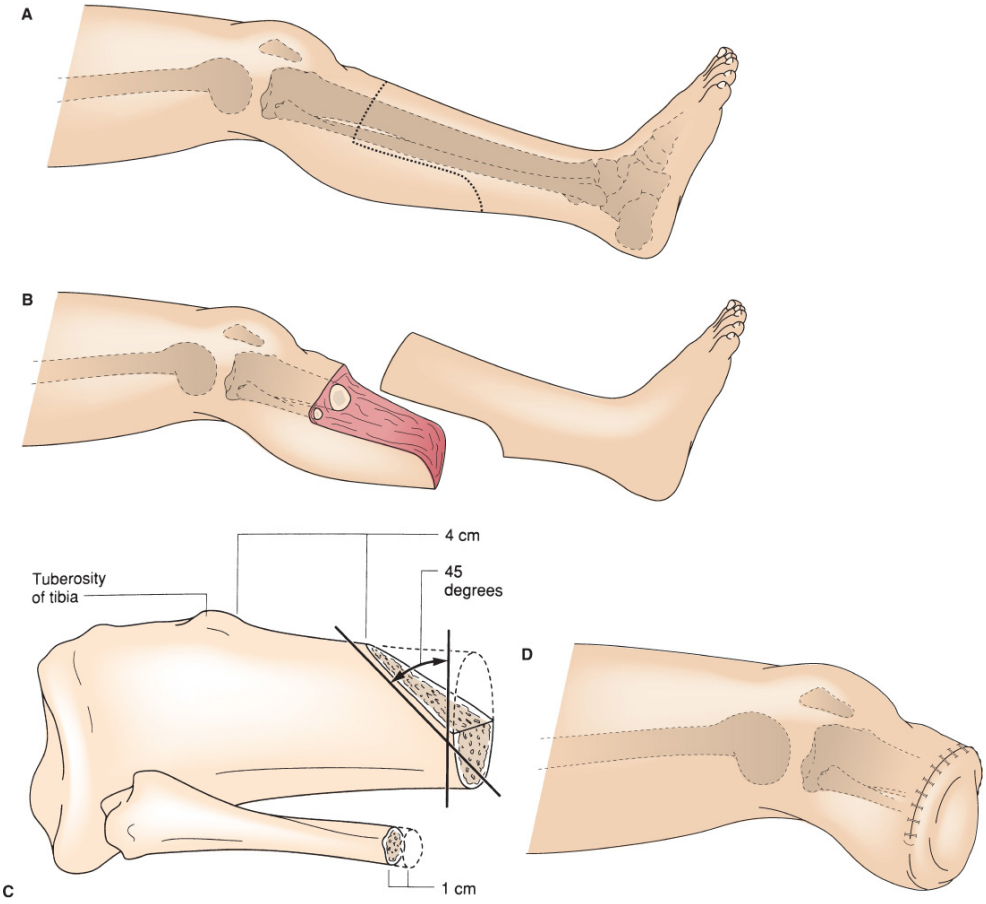

Figure 92.5 A: The skin incision for a below-knee amputation based on a posterior flap is made 11 cm distal to the tibial tuberosity and extended medially and laterally to the midpoint of the calf. The length of the posterior flap is about 2 cm longer than the diameter of the calf at the point of the proximal incision. **B:** The tibia is transected 1 cm proximal to the skin incision. The fibula is transected an additional 1 cm proximal to the level of the tibial transection, and the posterior calf muscles are incised along the plane of the skin incision. **C:** The anterior aspect of the tibia is beveled at an angle of about 45 degrees, and the bone edges are filed. **D:** The posterior flap is rotated anteriorly and approximated.

Below-Knee Amputation

The complications of diabetes and arterial insufficiency constitute most of the indications for BKAs. **Tables 92.5** and **92.6** outline the criteria used to

decide between a BKA and an AKA in this setting.

The most common technique, using a long posterior flap, is illustrated in **Figure 92.5**. When gangrene, wounds, or incisions preclude the use of a posterior flap, equal anteroposterior or sagittal flaps can be used; however, the posterior flap is associated with the highest incidence of primary healing and is thus preferred whenever possible. This higher rate of healing reflects the fact that the posteriorly located gastrocnemius and soleus muscles are supplied by the sural arteries that originate proximal to the knee.

The proposed skin incision is drawn on the leg with a marker. The tibia should be transected 10 cm distal to the tibial tuberosity and the anterior aspect of the skin incision should be 1 cm distal to the site selected for the tibial transection. The anterior incision is extended medially and laterally. The length of the anterior incision should equal two-thirds of the circumference of the leg at the proposed level of the tibial transection. The incision is then extended longitudinally along the medial and lateral aspects of the leg. The length of the longitudinal incisions should equal one-third of circumference of the leg at the level of the tibial transection. It is prudent to err on the side of making the posterior flap too long and trim excess length at the time of closure. The medial and lateral incisions are connected posteriorly. Curving the transitions of the incision prevents the accumulation of redundant tissue at the medial and lateral aspects of the completed amputation. The skin incisions should be down to the fascia to allow separation of the skin edges. This step decreases the chance of inadvertent injury to the posterior flap later in the procedure; however, the greater and lesser saphenous veins need to be ligated and transected.

The anterior aspect of the incision is deepened through the periosteum of the tibia. The muscles of the anterior compartment are divided at the level of the skin incision and the anterior tibial neurovascular bundle is identified and suture ligated. The proximal tibia is circumferentially cleared of periosteum and transected one fingerbreadth proximal to the skin incision. The anterior aspect of the tibia is cut on a 45-degree angle. The fibula is cleared and transected 2 cm proximal to the transected tibia. The bones are divided with either a power-driven reciprocating saw, or a manual saw. Regardless, care must be taken to avoid trauma to the anterior skin flap.

The posterior tibial and peroneal neurovascular bundles are identified and suture ligated. The tibia is retracted anteriorly and the posterior musculature

is divided along the plane of the longitudinal skin incisions using an amputation knife or Bovie electrocautery. Extreme caution must be taken to avoid injury to the skin edges of the posterior flap during this step. Often a scalpel is needed to complete the division of the gastrocnemius tendon distally. The specimen is removed and manual compression achieves temporary hemostasis while the remaining vascular structures are identified and ligated. The posterior tibial nerve is retracted distally, ligated, transected sharply, and allowed to retract. The posterior flap is rotated anteriorly to assess thickness and length. Frequently, the musculature needs to be debulked to allow a tension-free closure. Rough edges of the bones are filed smooth and the wound is irrigated. Bone wax is not used. A closed-system drain may be placed to prevent a hematoma. The end of the tibia is covered and stabilized with the deep posterior musculature using absorbable sutures. The gastrocnemius fascia is approximated to the anterior fascia using absorbable suture. The subcutaneous tissue is closed with absorbable suture to minimize tension on the skin edges and the skin is closed with monofilament suture or staples.

The length of the BKA may be shortened if required by the infectious or gangrenous process. Although not ideal, a short BKA is functionally superior to an AKA. In the extreme case, the tibia can be transected at the level of the tibial tuberosity and the stump can still be fit with a prosthesis. If a BKA is necessary at this level, the biceps tendon and collateral ligament should be sutured to the tibia, the common peroneal nerve should be transected above the knee, and the fibula should be removed.

A variation of the BKA is the osteomyoplastic transtibial amputation also known as the Ertl amputation. This technique has been well described[40] and involves creating a bone bridge between the tibia and the fibula using a piece of the amputated fibula. Proposed advantages of this technique include a more stable end bearing of the stump and prevention of fibular instability.

In the face of extensive foot infection, an open (guillotine) amputation should be performed as the first part of a staged procedure. A circumferential incision is made in the distal leg just proximal to the malleoli. The fascia is divided, and the tibia and fibula are dissected free. The bones are divided at the level of the skin incision. All major neurovascular bundles are suture ligated and the remaining soft tissue is divided to complete the amputation. Several sutures are placed through the skin and underlying fascia to prevent

retraction. The wound is left open and dressed. A negative-pressure dressing may be used and simplifies wound care. A definitive BKA is delayed until the infectious process has resolved which typically occurs within a week. Ankle disarticulation is an alternative to a guillotine BKA. An incision is made at the level of the ankle joint. Vascular structures are suture ligated. The tendons are divided sharply entering the ankle joint. The capsule is circumferentially incised removing the foot from the leg. The wound is packed open or with a negative-pressure dressing.

Above-Knee Amputation

An AKA is indicated for patients requiring an amputation with a fixed-knee contracture, a nonfunctional limb, or insufficient circulation to heal a BKA. Typically, a transverse fish-mouth incision is made in the lower thigh. The initial skin incision should be carried through the subcutaneous tissue to allow the edges to separate. This step will decrease the likelihood of inadvertent injury to the posterior skin flap during transection of the posterior muscle groups. The greater saphenous vein needs to be identified and ligated. The dissection is carried down to the femur that is cleared using a periosteal elevator to a level 2 to 3 cm proximal to the skin incision. The superficial femoral artery is dissected free and suture ligated. The bone is transected with a reciprocating or manual saw, and the posterior muscle flap is divided with an amputation knife or Bovie electrocautery. Manual compression with a laparotomy pad on the newly divided stump will easily control hemorrhage while vessels are identified and ligated or electrocoagulated. The sciatic nerve is identified and placed on gentle traction. It is then highly ligated, sharply divided, and allowed to retract into the wound. The flaps should be irrigated and hemostasis assured. The fascia is then closed with absorbable suture. The subcutaneous tissue is closed with absorbable suture to minimize tension on the skin edges and the skin is closed with monofilament suture or staples. Alternative incisions can be made to accommodate surgical wounds. Most AKA wounds will heal even when the femoral pulse is nonpalpable. More proximal thigh amputations are performed when arterial perfusion is in question.

Hip Disarticulation

Lower extremity amputation at the level of the hip is an uncommon operation. The indications include malignancy, trauma, infection, and, rarely arterial insufficiency. Hip disarticulation performed for an ischemic AKA is often associated with complications in the absence of revascularization.[41] This technique is well described.

Cryoamputation

Rarely, a patient may require an emergent amputation yet have overwhelming medical problems that preclude any operative intervention. In this situation, a temporizing cryoamputation (aka, medical or physiologic amputation) is indicated.[14] A tourniquet is placed proximal to the infectious or gangrenous process and the extremity is packed in dry ice. This prevents the systemic release of muscle degradation products and allows the required procedure to be delayed while the patient's condition can be stabilized. This technique can be performed at any level on the extremity. Consideration of the level of tourniquet application is extremely important to preserve as much viable tissue as possible and avoid higher levels of limb loss. The dry ice should be placed about 3 in below the tourniquet to reduce the chance of the "freeze line" extending proximal to the tourniquet. Adequate pain management should always be employed.

It should be noted that the use of cryoamputation constitutes a commitment to eventual surgical amputation (primary or staged). Once initiated, maintenance of the physiologic amputation is vital until definitive surgical removal is possible. As the frozen tissues thaw, a systemic inflammatory response syndrome (SIRS) or sepsis with hemodynamic instability may occur as inflammatory mediators are liberated back into the circulatory system. The ideal timing to proceed to the operating room would be as soon as reasonably possible. However, the literature describes the successful maintenance of this technique over many days if necessary.[14,42,43]

Other Lower Extremity Amputations

Three additional partial-foot amputations have been well described. A Lisfranc amputation is performed at the tarsometatarsal joint level and may be an option if there is inadequate soft tissue coverage for a TMA.[44] A Chopart amputation is performed at the level of the calcaneocuboid–talonavicular bones. Consideration of adding a percutaneous heel-cord lengthening with these amputations has been recommended.[45] A partial calcanectomy hindfoot amputation has shown good utility for chronic posterior heel wounds and calcaneal osteomyelitis.[46,47] This amputation involves removal of the posterior body of the calcaneus behind the posterior facet of the subtalar joint. Primary closure is typically possible, and patients can ambulate following this procedure using a custom orthotic with a heel filler.

Knee disarticulation is a useful amputation for patients with immature growth plates. It is superior to an AKA and allows end-weight bearing, improved proprioception, and improved prosthetic control. The required prosthesis is bulky and less cosmetically appealing than that used for a BKA. The technique is well described.[48] Rotationplasty is an uncommon procedure performed primarily for treatment of osteogenic sarcoma of the thigh.[49] It involves nerve-sparing resection of the femur and knee, 180-degree rotation of the leg, and reattachment of the leg. This results in a functional, sensate foot that can easily be fit with a prosthesis.

Wound Dressings

An important consideration after amputation is the type of wound dressings applied to the stump. Two important factors in the success of an amputation are time to rehabilitation and complete wound healing, both of which are influenced by postoperative wound care.[50] With transtibial amputations, there are a number of options, such as soft gauze dressings with elastic wrap, rigid plaster dressings without immediate prosthesis, rigid plaster with immediate postoperative prosthesis, and prefabricated pneumatic postoperative prosthesis. Several studies have compared two or more of these options. Endpoints are not standardized, however, and most studies are not randomized and prospective, making comparisons and meta-analysis difficult.[50]

Benefits and drawbacks are found for each postoperative option.[50] Gauze dressings with elastic wrap are simple and low cost and provide good accessibility to evaluate wound healing. On the other hand, they may lead to higher rates of joint contraction, increased time to ambulation, and risk pressure ischemia from poorly placed elastic wrap. Despite these drawbacks, no convincing data show that soft gauze dressings are inferior to other options.[50,51] A removable knee immobilizer may be used in conjunction with gauze dressings to minimize the risk of joint contracture.

Rigid plaster casts help with joint contracture and protect the wound from trauma. With addition of a temporary prosthesis, the rigid plaster also promotes early ambulation. The plaster, however, does not provide easy access to evaluate and care for the wound and if not fitted properly will result in sheer stress and thereby break down the wound. Consequently, a level of skill in plaster placement is required of the surgical team to make appropriate and often frequent plaster changes.[50]

Finally, a prefabricated pneumatic postoperative prosthesis allows early ambulation and weight bearing, easy wound access for examination, prevention of joint contracture, and wound protection. The prosthesis, however, is bulky and upfront is more expensive than the simple gauze. Prospective studies have demonstrated statistically fewer postoperative complications with the pneumatic prosthesis and statistically fewer limbs requiring higher revisions.[52]

Table 92.7 Amputation Mortality

Category	Percentage	Number
Below knee	2	25/1,200
Above knee	9	54/609
Diabetic vs. nondiabetic	No difference	
After amputation revision	5.5	12/218

Complications

Morbidity and Mortality

Operative mortality depends on the indication and the level. Mortality rates for major lower extremity amputations in vascular and diabetic patients have been reported to be between 0% and 35%.[53] Combined mortality rates from multiple series are shown in **Table 92.7**.[54] Cardiovascular causes account for two-thirds of these deaths, with myocardial infarction responsible for one-third.[54] These review data are further supported by recent studies by Sandnes et al.[55] and Aulivola et al.[56]

Long-term survival following major amputation in the vascular population is shown in **Table 92.8**. The 5-year survival rate is only 37% compared with 85% for age-matched controls.[57]

Deep Venous Thrombosis and Pulmonary Embolism

The incidence of deep venous thrombosis following lower extremity amputation ranges from 4% to 38%.[58–60] Prophylactic measures including subcutaneous heparin, low–molecular-weight heparins, early mobilization, and pneumatic compression devices should be used as indicated.

Stump Complications

Stump complications include nonhealing, infection, hematoma, contractures, ulceration, phantom pain, and trauma. Although most amputations heal primarily, a small percentage do not. Amputation at a more proximal level usually is successful. Postoperative infections complicate 12% to 28% of all amputations with the percentage higher in cases performed for infection.[61] Infected wounds should undergo incision and drainage with debridement of all nonviable tissue. The wound should then be treated with local wound care using gauze or negative-pressure dressings, depending on the appearance of the wound and surgeon preference. Broad-spectrum systemic antibiotics should be instituted and then tailored based on wound cultures. Wound hematomas are best treated with prevention. Meticulous hemostasis and avoidance of subcutaneous cavities decrease their incidence. Hematomas should be treated in the operating room with evacuation, irrigation, and closure of the wound.

Table 92.8 Survival after Amputation for Ischemia

Time (yrs)	Survival Rate (%)
1	75
2	60
3	50
4	45
5	37

From Frang RD, Taylor LM, Porter JM. Amputations. In: Porter JM, Taylor LM, eds. *Basic Data Underlying Clinical Decision Making in Vascular Surgery*. St. Louis, MO: Quality Medical; 1994:115, with permission.

Joint contractures complicate 1% to 3% of all amputations.[57,61] These contractures can occur rapidly postoperatively and are best treated by prevention. Rehabilitation specialists and physical therapists should evaluate patients preoperatively. Active and passive range of motion should be initiated immediately postoperatively. Adequate pain medication, ideally

with patient-controlled or epidural anesthesia,[62,63] is crucial. Pillows and bed positions that result in hip or knee flexion are to be strictly avoided.

Ulcers tend to develop over bony prominences. Poorly fitting prostheses or shoes are the most common causes. Diabetic patients with peripheral neuropathy are especially susceptible to the development of ulcers following toe and limited foot amputations. They can also form on the anterior aspect of AKAs secondary to the disproportional contraction of the hip flexors relative to the hip extensors. Local wound care and bedrest usually lead to healing if the ulcer is superficial. Deep skin ulcers with involvement of the soft tissue and the underlying bone are more complicated. They often suggest borderline perfusion of the stump and require formal revision to a higher level to treat definitively.

Another option in complicated wound closure is negative-pressure wound dressing, which has been used for a wide range of difficult-to-heal lesions. Studies indicate that this dressing technique decreases wound volume, whereas traditional moist gauze dressings do not.[64] The dressings result in granulation tissue and healing in otherwise difficult tissue beds, such as diabetic foot ulcers[65] and decubitus pressure ulcers.[66] In addition to helping contract the size of the wound, negative-pressure dressings also decrease the number and frequency of dressing changes drastically when compared with wet-to-dry dressings.

Neuromas are regenerative nerve tissues that form in response to transection. They can lead to pain if trapped in the fibrous scar or if irritated by a prosthesis. Proximal nerve division under tension during the original operation decreases the incidence of this complication. Symptomatic neuromas should be treated with proximal resection of the nerve because local excision of the neuroma is rarely adequate.

Some element of phantom extremity pain occurs in nearly all amputations,[67] although these complaints are not always directed to the treating surgeon. It is necessary to describe these common symptoms to the patient and specifically inquire about their presence. The pain is disabling in 5% to 30%[68] of patients surveyed. Currently, pain is felt to be a component of a central pain syndrome and unrelated to either a neuroma or the perception of an intact extremity. Although there is no universally effective treatment, Malone[53] has reported a low incidence with an aggressive rehabilitation program, including immediate prosthetic fitting.

Trauma to a limb following an amputation can convert a healed amputation to a nonhealing wound requiring a more proximal amputation. Perioperatively, patients with a BKA must be observed closely to prevent attempted ambulation. Diabetic patients with retinopathy should not walk barefoot following toe and foot amputations secondary to the risk that minor trauma may lead to a major wound healing problem.

Additional Amputation

The incidence of future amputation in vascular patients is not insignificant. Snyder et al. evaluated outcomes after forefoot amputations and found that 26% underwent a subsequent forefoot amputation and 37% had a more proximal amputation over 2 years.[69] Cruz et al. demonstrated 17% contralateral amputation in their series.[70] These dismal figures reflect the systemic nature of the underlying diseases and emphasize the importance of appropriate foot care, patient education, close follow-up, and early intervention.[71] A concerted multidisciplinary approach can dramatically decrease the incidence of initial and subsequent lower extremity amputation.[72]

Special Situations

In selected cases, hyperbaric oxygen (HBO) therapy can provide benefit in treating nonhealing amputation sites. Patients require thorough evaluation of their cardiopulmonary status before initiating such treatment. In addition, the treating vascular surgeon must determine that revascularization is completed or is not indicated. Patients may benefit from treatment if there is a substantial increase in transcutaneous oxygen pressure ($TcPO_2$) near the wound with administration of 100% oxygen. Daily treatments are typically continued for 30 days. Platelet-derived growth factor (becaplermin [Regranex]) is approved for use in the United States and has been effective in the management of diabetic foot ulcers and following open foot amputations or debridements. The wound must be clear of all necrotic tissue before initiating therapy.

REHABILITATION AND PROSTHETIC MANAGEMENT

General Considerations

Rehabilitation must be individualized. For some patients, successful rehabilitation means ambulation on a prosthesis and resumption of an independent lifestyle. For others, success may mean being able to pivot on the contralateral limb to be able to assist with transfer. Ambulating with a prosthesis depends on the physiologic status of the patient. **Table 92.2** illustrates the dramatic increase in energy requirement with increasing level of the amputation. As expected, the chance of ambulating on a prosthesis decreases with ascending amputation level. The percentages of diabetic and vascular patients who can ambulate with amputations at various levels are shown in **Table 92.9**. The likelihood of ambulating postoperatively is inversely related to the patient's age and the length of the rehabilitation process.[73] Consideration should be given to inpatient rehab immediately after the acute care of the amputation is complete. Not only does this allow strengthening of the upper extremities and improved transfers, but it has been shown to reduce 1-year mortality in amputees as well.[74]

Table 92.9 Ambulation after Lower Extremity Amputation for Diabetes or Occlusive Disease

Amputation Level	Postoperative Ambulation (%)
Digit or ray	100
Transmetatarsal	100
Syme amputation	90–100
Below knee	75
Above knee	39
Hip disarticulation	<100

Specific Considerations

Digital and Ray Amputations

All patients who were ambulatory preoperatively should be able to achieve their preoperative functional status following a digital or ray amputation. The first digit and metatarsal head are important for weight bearing and for power. A shoe orthosis should effectively compensate for these functions when the patient has some training.

The most important component of postoperative rehabilitation for patients following a digital or ray amputation is education. The rate of repeat amputation (other toe, more proximal level, and contralateral limb) is extremely high. Several studies have indicated that the rate of repeat amputation is diminished with a coordinated education program.[75,76]

Transmetatarsal Amputation

A TMA minimally increases the energy requirement of ambulation; therefore, postoperative ambulation is expected following successful healing. The absence of the toes and metatarsal heads results in the loss of some forward

thrust during the push-off phase of ambulation. This deficit can be overcome with either a steel-shank or a rigid, roller-soled shoe. The void in the distal shoe is filled with an insert.

Syme Amputation

The prognosis for return to bipedal ambulation following a Syme amputation is excellent. The required energy expenditure is only 10% more than baseline.[77] A significant advantage of this amputation is the ability to ambulate on the stump with only a cup slipper. Even though this activity is permitted on only a limited basis in the home, it is much more convenient for the patient, especially when arising at night. For routine activity, the patient uses a prosthesis composed of a nonmotion foot attached to a leg shaft. The shaft has a cutout on the medial aspect to allow passage of the flared distal end of the stump. The configuration of the distal end of the stump results in a bulbous ankle, which is less aesthetically pleasing than the typical below-knee prosthesis.

Below-Knee Amputation

The rehabilitation potential following a BKA is very good. Even when the indication for amputation is arterial insufficiency, approximately 75% of patients are able to ambulate with a prosthesis.[54] Multiple design options are available; however, the patellar tendon and the medial and lateral tibial flares are the weight-bearing surfaces for most prostheses. A variety of foot designs are possible to permit extension, flexion, rotation, and energy storage.

Above-Knee Amputation

Ambulation on an above-knee prosthesis is achieved by less than 40% of patients with arterial insufficiency.[54] In this patient population, the rate of ambulation on bilateral above-knee prostheses is less than 10%.[78] Most above-knee prostheses use the ischial tuberosity as the primary weight-bearing surface and are secured either by a belt or a suction socket. For younger patients, a suction socket works well. Patients with groin scars from previous revascularization attempts may benefit from a belt mechanism. The knee design depends on the patient's general condition and thigh strength. A

knee that engages during the stance phase of gait is more stable and is frequently used in older patients.

Thoracic and Thoracoabdominal Aorta: Aneurysm and Dissection

George J. Arnaoutakis and Eric Y. Pruitt

Key Points

1. There have been vast improvements in surgical outcomes for the management thoracoabdominal aortic aneurysms.
2. Improved preoperative care, surgical technique, and implementation of surgical adjuncts such as distal aortic perfusion and cerebrospinal fluid drainage have played pivotal roles in this improvement.
3. Neurologic outcomes have seen the most improvement with neurologic deficit seen in less than 2% of patients.
4. Endovascular repair of these aneurysms is not without risk and continued research and device development is needed for this complex disease.

BACKGROUND

In 1955, Ethridge reported the first repair of a thoracoabdominal aortic aneurysm (TAAA) using a homograft with DeBakey performing the first

descending and infrarenal aortic replacement using a Dacron graft just 1 year later.[1,2] This was soon followed by the establishment of the "clamp-and-go" technique by Crawford; introducing the three main tenets of aortic surgery: the inclusion technique, the use of Dacron tube graft conduit, and reimplantation of the visceral and renal arteries.[3] During this time, few adjuncts were available and cross-clamp time was the single biggest predictor of adverse outcome. As adjuncts have emerged, organ protection and outcomes have improved. Regardless of the advancements, the morbidity and mortality associated with emergent operations for TAAA are quite high, but surgery remains the only chance to save patient lives. Moreover, elective repair remains the only way to prevent the risk of TAAA rupture (**Fig. 93.1**). In this chapter, we will discuss a comprehensive approach to the diagnosis and management of TAAA and recent surgical results and advances in organ protection.

EPIDEMIOLOGY

Aortic aneurysm disease remains a significant cause of death in developed countries and its prevalence appears to be increasing. While part of this increase may be due to improved imaging techniques, increasing mean population age and overall heightened awareness of this disease, there is no doubt that this disease continues to be a serious issue.[4] The estimated prevalence of abdominal aortic aneurysms ranges from 2.3% to 10.7%, while the prevalence of TAAA is estimated to be much lower at 10.4 cases per 100,000 person-years.[5] Of the 51,000 aneurysms repaired each year, only 1,000 are TAAAs. The disease predominately affects males at 2 to 4 males to 1 female with an average age of 59 to 69 years old.[6]

Rupture is the leading cause of death in this population with 60% of affected patients rupturing at 5 years.[3,6–8] Rupture rates rapidly increase when the aortic size rises above 6 cm and the rate of rupture increases rapidly as size increases beyond 7 cm.[7,9] The median size at which TAAAs rupture is 7 cm with an 80% risk of rupture within 1 year as aneurysms approach 8 cm.[7,10] The lifetime risk of rupture is 75% to 80%, but how long it takes to reach the point of rupture is not easily determined. The median growth rates for TAAAs tend to be somewhat lower (0.20 to 0.34 cm per

year) than those of abdominal aortic aneurysms, but TAAAs tend to present at a larger diameter.[11]

PATHOGENESIS

As the aorta dilates beyond 50% of its normal diameter it is considered aneurysmal regardless of whether the dilation is focal or diffuse. Aneurysms are the result of degenerative changes within the aortic wall in a process that is similar to that seen in abdominal aortic aneurysm development. Arteriosclerosis has long been noted to be associated with aneurysm development, but these two processes are histologically distinct. Arteriosclerosis is the result of intimal changes leading to occlusive disease. Aneurysm disease is the result of thinning of the media with destruction of smooth muscle cells and elastin, infiltration of inflammatory cells, neovascularization and compensatory collagen deposition.[12–15] Inflammatory cells are predominately macrophages which secrete proteases and elastase that cause degradation of the aortic wall. The degradation byproducts serve as chemokines that promote further inflammatory cell recruitment.[12] Matrix metalloproteinases (MMPs) are peptidases that are highly prevalent in aneurysm development, particularly MMP9, MMP2, and MMP12.[12,16–19]

There is clearly a genetic role in aneurysm development with 20% of patients with thoracic aneurysm disease having a first-degree relative with the disease as well and this is regardless of the presence of connective tissue disorders.[20,21] Marfan syndrome is a connective tissue disorder that is the most common cause of inherited aneurysm disease and is also associated with ocular, skeletal, and cardiovascular abnormalities. It affects males and females of all races equally and affects 1 in 5,000 to 10,000 individuals. The aortic dilation is due to a mutation in *FBN1* which codes for fibrillin 1. Additional associated connective tissue disorders are Elhers–Danlos, Loeys–Dietz syndrome, and Turner syndrome.[22–24] Previously, autosomal dominant polycystic kidney disease was associated with aortic aneurysm development, but this linkage has failed to be replicated aside from the isolated ascending aneurysm disease.[25] There are familial cases of TAAA with an autosomal dominant inheritance pattern. Patients in these families develop aneurysms earlier and have aneurysms that expand more rapidly, but

penetrance is variable.[26] As TAAA is a complex disease with both environmental and genetic factors at play, identifying a true genetic cause of the disease is challenging, but the most strongly associated mutation is in *ACTA2* which codes for α-actin in smooth muscle and is estimated to account for 15% of familial aneurysm cases. Other genes that have been replicated are *MYH11*, *TGFBR1*, *TGFRB2,* and *SMAD2*.[27–31]

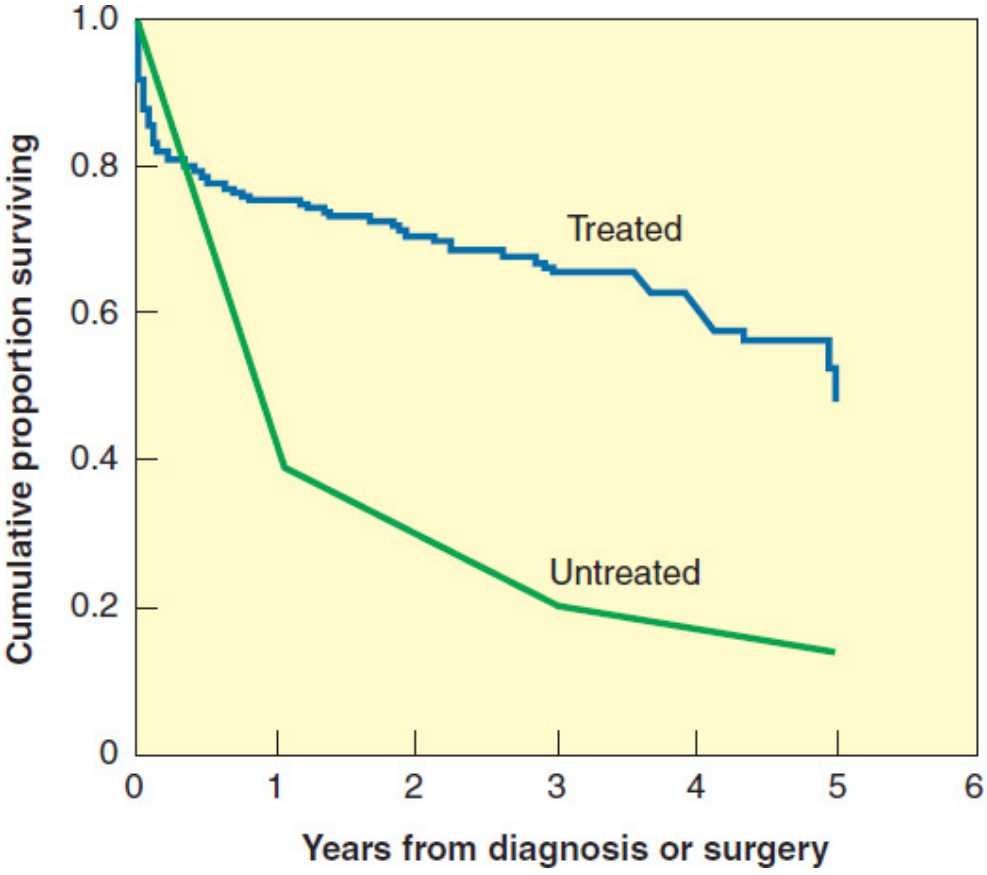

Figure 93.1 Thoracoabdominal aortic aneurysm: comparison of survival rates in untreated patients versus surgically treated patients.

Mycotic aneurysms are infectious in nature and are caused by bacterial or septic emboli seeding an atherosclerotic aorta or by spread from empyema or adjacent infected lymph node. These account for only 0.6% to 2% of aneurysms in developed countries. The most common organisms are *Salmonella* species, *Staphylococcal* species, *Streptococcus* species, or *Escherichia coli*.[32] Morphologically these aneurysms tend to be more saccular and are more prone to rupture. Trauma can also lead to a pseudoaneurysm of the aorta which can be unrecognized initially, but chronic

pseudoaneurysms are prone to rupture and should be repaired at the time of diagnosis.

An aortic dissection will often degenerate and form aneurysms with 40% of those who present with type B aortic dissections managed medically requiring surgical intervention for aneurysm degeneration.[33] There are several factors that appear to increase the risk of degeneration which include: entry tear size >10 mm, initial aortic diameter >40 mm, free-floating true lumen and false lumen patency.[33,34] Chronic dissection and patent false lumen are not linked to a higher risk of aortic rupture.[35]

It is common for an aneurysm to occur in more than one segment of the aorta which occurs in 20% of cases. In rare circumstances, the aneurysm can extend from the ascending aorta, through the arch and down through the abdominal aorta creating a "mega" aorta. This rare entity is frequently associated with Marfan syndrome and chronic aortic dissection.

CLINICAL MANIFESTATIONS

The symptoms of TAAA are frequently ill defined, but include back pain with flank, chest, and/or epigastric pain. A description of worsening pain is concerning as it can be a sign of pending rupture. Rarely, hoarseness can occur due to proximal descending thoracic aortic aneurysms causing compression of the left recurrent laryngeal nerve or vagus nerve. Shortness of breath can result from compression of the tracheobronchial tree. The aneurysm can also erode into the GI tract causing massive hematemesis or melena or can erode into the tracheobronchial tree causing massive hemoptysis. This bleeding can sometimes be intermittent and the diagnosis of aortoenteric or aortotracheal fistula should be considered even when patients describe episodic bleeding, but present without signs of overt bleeding. Compression of the intercostal arteries or spinal cord is rare, but can cause paraplegia. Paraplegia is more frequently a sign of malperfusion in acute aortic dissection. Embolization to the renal, mesenteric, or lower extremities from mural thrombus is very rare.

The initial presentation for many TAAA patients is rupture, which is seen in an estimated 10% to 20% of patients (**Fig. 93.2**). If a patient presents in shock with acute onset of chest, abdominal, or back pain, ruptured aneurysm

should be high on the differential. The thoracic cage frequently prevents the frequently described pulsatile mass on examination. Rupture is nearly universally fatal without operative intervention, but in rare instances the vessel wall may seal for several hours to days before there is free rupture. Most patients with free rupture are dead prior to arrival to the hospital.

DIAGNOSTIC IMAGING

The mainstay of imaging for TAAA diagnosis is computed tomography angiography (CTA) which is useful in defining extent of the TAAA as defined by the modified Crawford Classification (**Fig. 93.3**). It is also useful in identification of true and false lumens when dissection is also present and in allowing for measurement of the entire aorta as well as the presence of inflammation or thrombus. Fluid around the aneurysm can signal free or contained ruptures. CTA aids in surgical planning as patent intercostal or spinal arteries can be identified on high-resolution imaging. Coronal and sagittal views can also be useful in characterizing proximity to surrounding organs. In patients with renal insufficiency or contrast allergy, contrast can be omitted but this is less desirable.

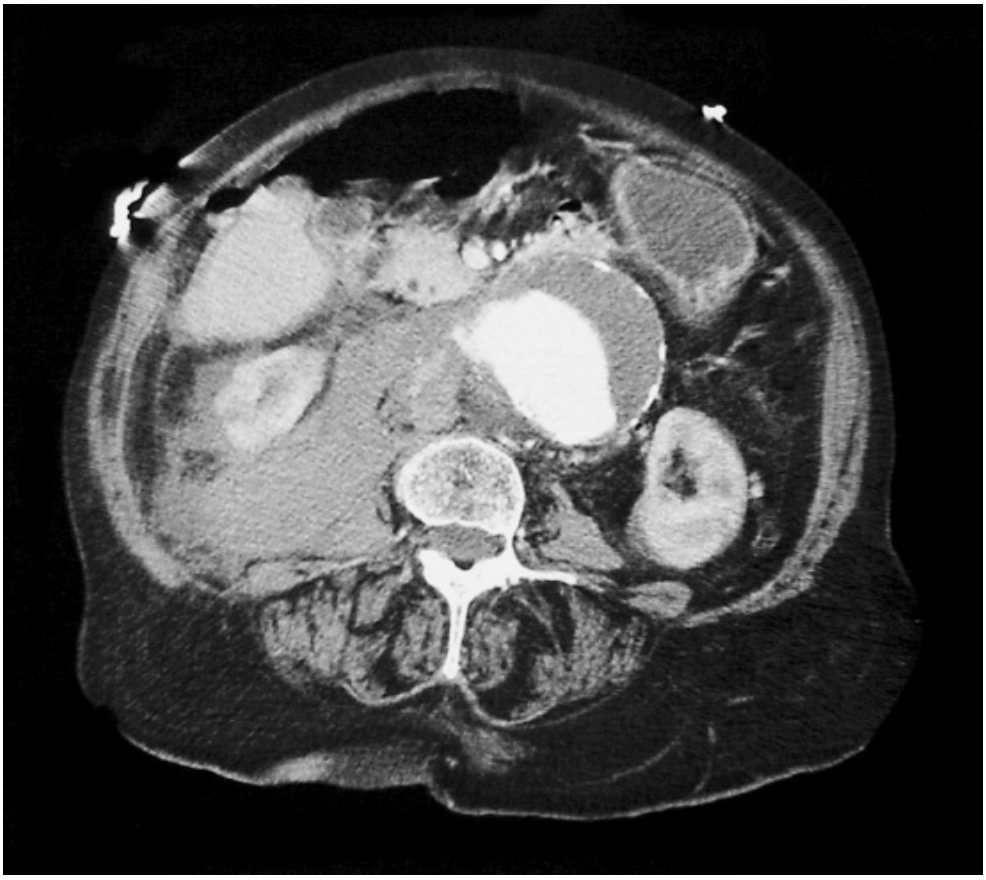

Figure 93.2 Computed tomography scan of a ruptured thoracoabdominal aortic aneurysm. Note stranding in the retroperitoneum denoting extravasation of blood.

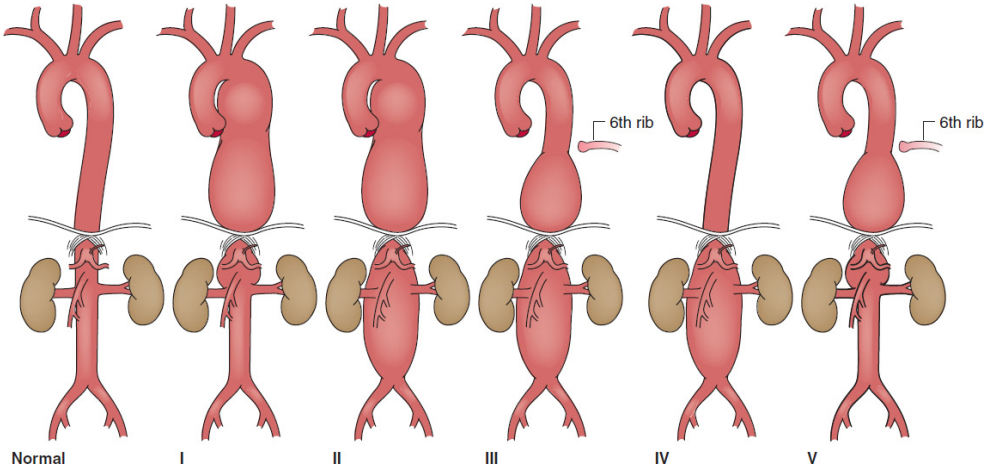

Figure 93.3 Thoracoabdominal aortic aneurysm classification. Extent I, distal to the left subclavian artery to above the renal arteries. Extent II, distal to the left subclavian artery to below the renal arteries. Extent III, from the sixth intercostal space to below the renal arteries. Extent IV, the 12th intercostal space to the iliac bifurcation (total abdominal aortic aneurysm). Extent V, below the sixth intercostal space to just above the renal arteries.

Magnetic resonance arteriography (MRA) has emerged as an alternative screening test for aortic disease and its branches. Advantages are the lack of contrast or radiation exposure in those undergoing surveillance, but it lacks the same degree of spatial resolution seen with CTA. Additionally, CTA is better at identifying intramural thrombus and calcifications. Other limitations are cost, duration, contraindication in patients with metallic implants, and claustrophobia.

Transesophageal echocardiography (TEE) provides excellent imaging of the ascending and descending thoracic aorta, provides real-time imaging and can be performed intraoperatively or at bedside. It is particularly useful when patients are too unstable to transport to the CT scanner. It can show aortic wall disease, differentiating plaque from intimal tear. It can also help identify optimal cross-clamping sites and to assess ventricular and valvular function. Imaging of the abdominal aorta is limited past the GE junction due to loss of contact with the aorta. TEE is invasive and should only be performed by those with experience due to risk of injuring the esophagus.

Intravascular ultrasound (IVUS) is also useful as it allows for characterization of intramural relationships which is particularly useful in aortic dissection. It requires access through a femoral sheath, but is very important in planning during endovascular repairs, particularly in dissection. Epiaortic ultrasound can also be used to allow better characterization of the thoracic aorta for cannulation and clamping.

PREOPERATIVE EVALUATION

As there are few signs or symptoms related to the aneurysm itself, a thorough history and physical examination are important to identify comorbidities. Aneurysm extent is determined via preoperative imaging. Risk stratification frequently must be determined via consultation with cardiologists, pulmonologists, and nephrologists. Pulmonary evaluation is frequently needed due to the need for single-lung ventilation and left lung surface trauma during open repair.

The risk-factor profile of those with TAAA overlaps with ischemic heart disease. As a result, these conditions frequently coexist. In patients with TAAA, ischemic heart disease is the most common cause of death. If

possible, coronary revascularization via coronary artery bypass grafting or via percutaneous coronary intervention (PCI) (stenting or balloon angioplasty) should be performed prior to TAAA repair to minimize risk of an ischemic event. However, the timing of repair should be balanced with the risk of rupture if TAAA repair is delayed. If bypass grafting is pursued before TAAA repair, the use of the left internal mammary artery is typically avoided in the event the aortic cross-clamp needs to be proximal to the left subclavian artery. Additionally, this vessel may provide collateral blood supply to the spinal cord and chest wall. Percutaneous coronary intervention is an option in many patients, but the use of bare metal stents is preferred as they do not require long-term antiplatelet therapy. It is very rare to require simultaneous coronary artery bypass grafting and TAAA repair in the same operation.

OPERATIVE TECHNIQUES

Prior to repair, a spinal drain is placed in the third or fourth lumbar space by the anesthesia team. The patient is brought to the operating room and placed in the supine position. Continuous arterial pressure monitoring is provided by cannulation of the right radial artery. For open repairs, a dual-lumen endotracheal tube is placed for single-lung ventilation after induction of general anesthesia. A bronchial blocker can alternatively be used. This maneuver avoids the need for tube exchange at the conclusion of the procedure, but requires careful positioning by the anesthesiologists and may not afford optional lung isolation. Continuous pulmonary artery pressure monitoring is provided by a balloon-tipped pulmonary artery catheter placed through central venous access via the internal jugular vein. Large-bore central and peripheral access is needed. Core body temperature is monitored via esophageal and Foley catheter temperature probes. If transesophageal echo (TEE) is to be used, it is inserted. A right femoral arterial catheter is useful for monitoring distal perfusion. The patient is then placed in the right lateral decubitus position and all pressure points are padded. If continuous electroencephalograph is used, monitors are placed on the scalp and along the spine for motor and somatosensory monitoring (MEP and SSEP). The spinal drain is then attached to the spinal cord pressure monitor and the drain

is set to maintain CSF pressure at 10 mm Hg or less. The field is then prepped and draped.

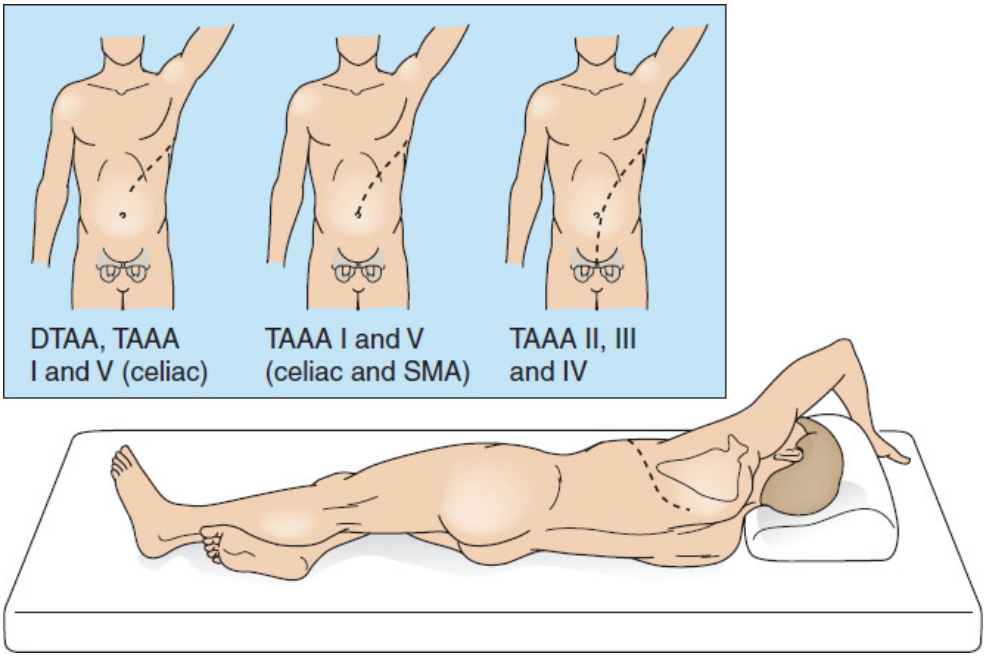

Figure 93.4 Tailoring of thoracoabdominal incisions for aneurysm extent. DTAA, descending thoracic aortic aneurysms; TAAA, thoracoabdominal aortic aneurysm; SMA, superior mesenteric artery.

An incision is made to fit the extent of the aneurysm (**Fig. 93.4**). A standard incision starts between the tip of the scapula and the spinous process. It curves along the sixth intercostal space to the costal cartilage and then obliquely to the umbilicus. The insertion of the serratus anterior muscle is mobilized after the latissimus dorsi is divided. The left chest is entered after the lung is deflated. For extent II, III, and IV TAAA, the full incision is typically needed. The incision can be shortened or lengthened as needed depending on the extent (**Fig. 93.4**). The use of a self-retaining retractor allows optimum visualization of the thoracic and abdominal aorta.

Dissection begins at the level of the hilum of the lung cephalad to the proximal thoracic descending aorta. Transection of the ligamentum arteriosum is performed with care to avoid the recurrent laryngeal nerve. The muscular portion of the diaphragm is incised with care taken to avoid the phrenic nerve (**Fig. 93.5**). Division of the diaphragm may be performed with electrocautery or with vascular stapler device and marking sutures placed along the diaphragm are often useful to aid with later reapproximation. A

retroperitoneal plane is established and a medial visceral rotation is performed, mobilizing the spleen, bowel, and left kidney to the right of the aorta. After dissection, mobilization and achieving hemostasis, 0.5 to 1 mg/kg of heparin is administered in preparation for distal aortic perfusion (**Fig. 93.6**). Different activated coagulation time (ACT) targets may be achieved based on institutional preference but we favor ACT >480 seconds. Posterior to the left phrenic nerve, the pericardium is opened to allow direct visualization of the pulmonary veins and left atrium. The left inferior pulmonary vein is cannulated. The arterial inflow is established through the left common femoral artery via a Dacron graft sutured to the artery in an end-to-side fashion. If the common femoral artery cannot be accessed, the descending thoracic aorta can be accessed. The circuit is run through a centrifugal cardiopulmonary pump with an inline heat exchanger. At this point, distal aortic perfusion is initiated. An alternative cannulation strategy is to cannulate both left common femoral artery and vein to establish full cardiopulmonary bypass. Constant communication between anesthesiologist and perfusionist is mandatory to achieve appropriate perfusion pressures.

A site is chosen just distal to the left subclavian and padded clamps are applied with additional clamps placed in the mid thoracic aorta. If the proximal extent of the aneurysm is too close to the left subclavian, a site is chosen between the left common carotid and the left subclavian arteries and the left subclavian artery is clamped separately. An alternative approach if no clamping site is available is to perform deep hypothermic circulatory arrest, with systemic cooling to 18°C. This approach is very effective for difficult proximal anatomy in the aortic arch; however, requires careful assessment of aortic valve competence and left ventricular venting as necessary to avoid ventricular distention during the period of myocardial fibrillation.

As there is risk for developing a graft–esophageal fistula, the inclusion technique is not used and instead the aorta is transected to separate it from the underlying esophagus (**Fig. 93.7A**). A woven Dacron graft is used for replacement. The graft is sutured to the descending thoracic aorta proximally in an end-to-end fashion with a running 2-0 or 3-0 monofilament polypropylene suture. Pledgeted polypropylene sutures are placed as needed for reinforcement at the anastomosis. After completing the proximal anastomosis, the midthoracic aortic clamp is moved distally onto the

abdominal aorta at the celiac axis in preparation for intercostal reattachment. Patent lower intercostal arteries from T8 to T12 are reimplanted whenever possible. Exceptions to reimplantation of the intercostals include occluded arteries, heavily calcified aorta, acute aortic dissection, or as guided by neuromonitoring (MEPs and SSEPs). If no change is noted in the MEP or SSEP signal without reattachment of the intercostals, they can be safely ligated with less concern for spinal cord ischemia. For patients with connective tissue disorders or who are over the age of 60 years old, a loop graft has replaced the island patch for reattachment of the intercostal arteries. If reattachment is performed, the proximal clamp is moved distal to the intercostal artery patch to restore pulsatile flow to the reattached intercostal arteries (**Fig. 93.7B**). At this point, the distal clamp is moved to the infrarenal aorta and the abdominal aorta is opened with the graft passed into the abdominal cavity. Celiac, superior mesenteric, and renal arteries are identified and can be perfused via 9- or 12-Fr balloon-tipped catheters based off the ostia (**Fig. 93.7C**). Cold perfusate (4°C) delivery to the viscera is dependent upon proximal aortic pressure (maintained between 300 and 600 mL/min). Reattachment of the visceral vessels is typically performed via an island patch. Typically, this island patch accommodates the reattachment of the visceral and renal arteries, but if the left or right renal artery is located too great a distance from the other arteries a separate interposition bypass graft may be necessary. Visceral patches are not recommended in patients with connective tissue disorders and in patients under the age of 60 years old due to the risk of recurrent patch aneurysm. In these scenarios, a commercially available Dacron graft with 10- and 12-mm side arms is used to provide separate attachments of the celiac, superior mesenteric, and renal arteries. A straight Dacron graft can be modified with openings made by the surgeon to sew on 10-mm limbs in a customized fashion. Regardless of the technique used, once the anastomosis is completed, the proximal clamp is moved distal to the renal arteries to restore pulsatile flow to the viscera and kidneys. The final anastomosis is then performed at the aortic bifurcation, or into the common iliac arteries if disease extends to the terminal aorta. A Wylie vascular clamp can be useful to obtain distal clamping of the right common iliac artery.

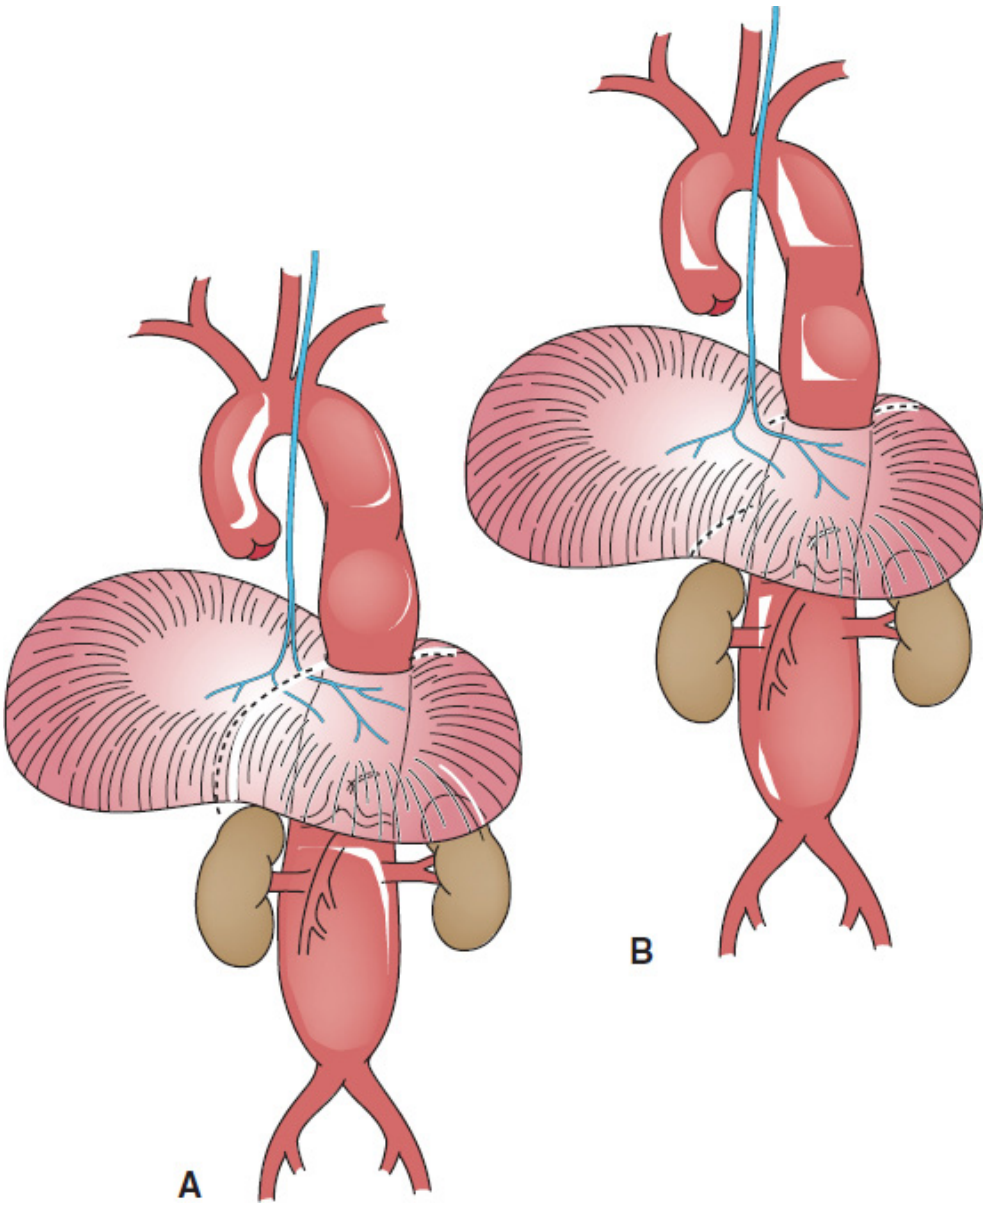

Figure 93.5 In previous surgical practice, the diaphragm was divided (**A**); currently, only the muscular portion of the diaphragm is cut (**B**).

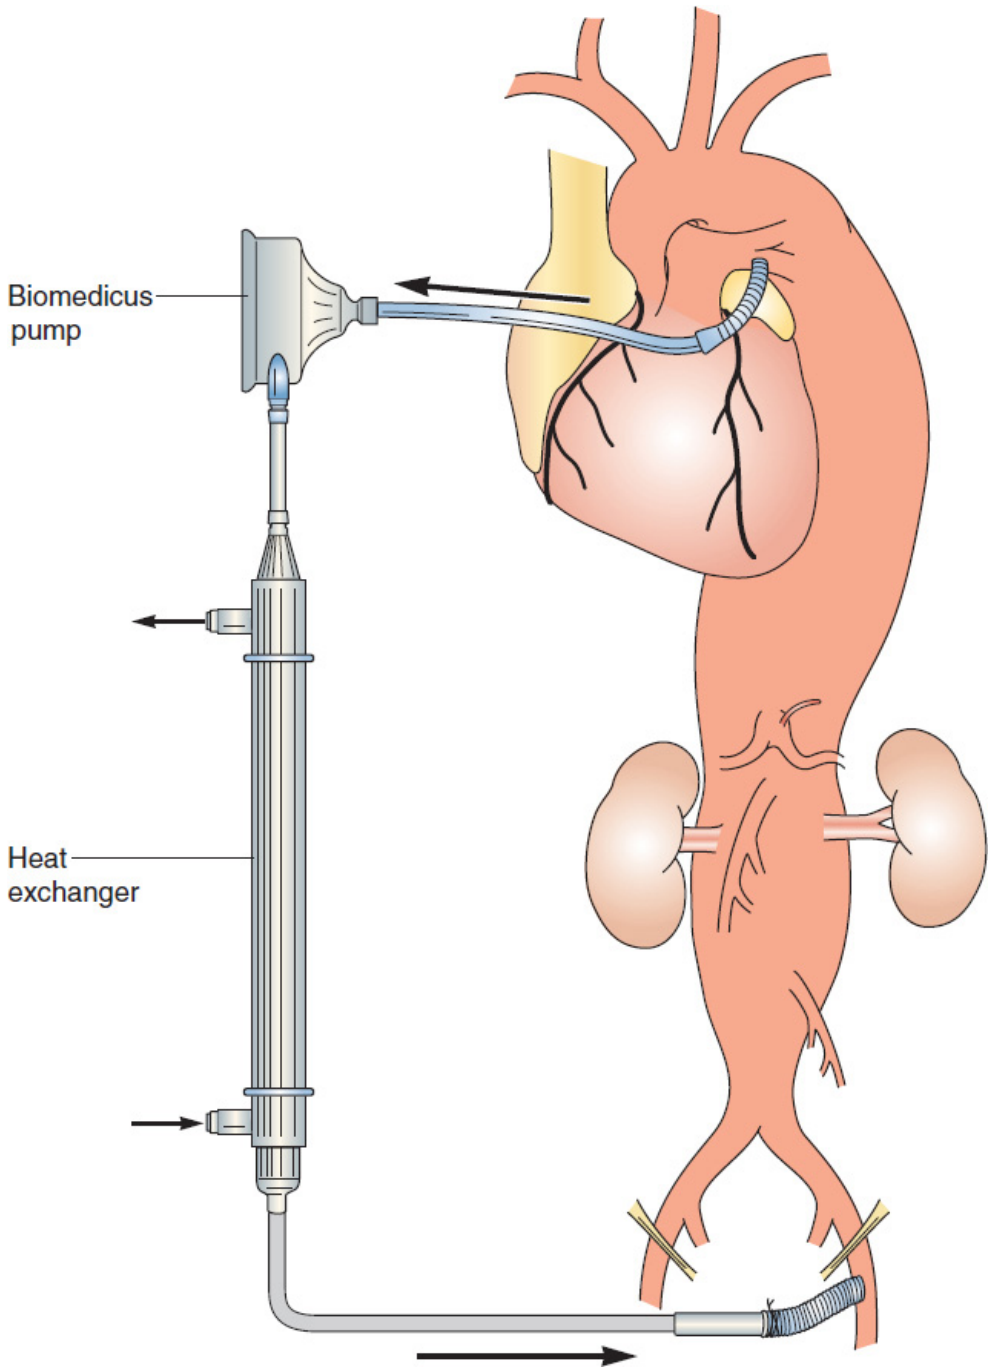

Figure 93.6 Distal aortic perfusion from the left inferior pulmonary vein to the left common femoral artery.

Once the core body or nasopharyngeal temperature returns to 36°C, the patient is weaned from bypass, protamine is administered (1 mg protamine per 10 IU of heparin) and the cannulas are removed. After hemostasis is achieved, two or three chest tubes are placed in the pleural space for

drainage. The diaphragm is reapproximated with running 1-0 polypropylene suture. The left lung is reinflated and the incision is closed in standard fashion. The patient is then returned to the supine position, the dual-lumen endotracheal tube is changed to a single-lumen tube and the patient is transported to the ICU.

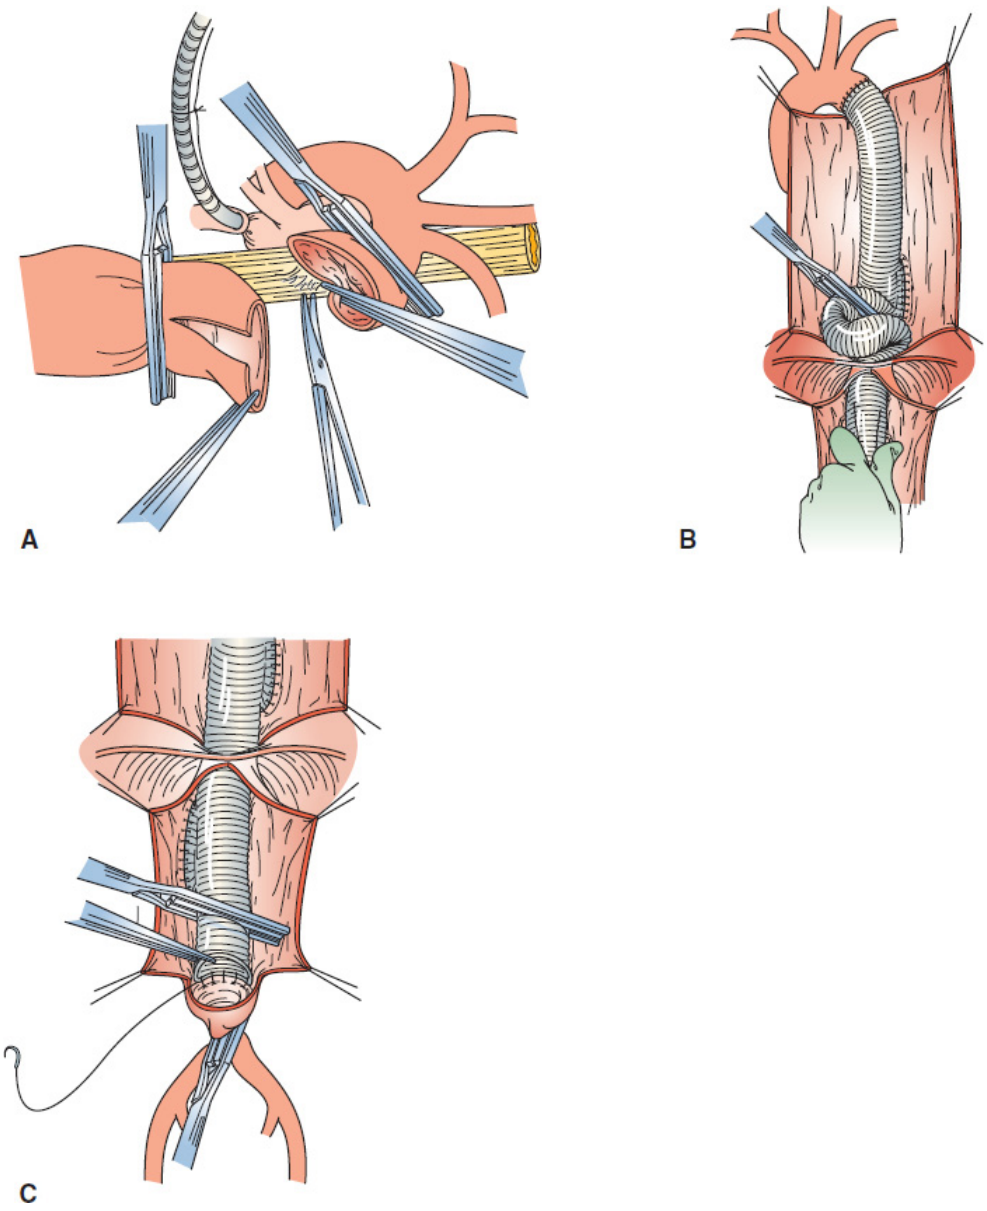

Figure 93.7 Sequential clamping and graft replacement. Padded clamps are placed on the proximal and mid-distal descending thoracic aorta. **A:** The proximal part of the aneurysm is opened. The aortic neck is completely transected and separated from the esophagus. The proximal anastomosis is fashioned. Subsequently, the patent lower intercostal arteries are reattached via an elliptical hole in the graft. **B:** The proximal clamp is then moved onto the graft to restore pulsatile flow to the intercostal arteries, and the graft is pulled through the hiatus into the abdomen. The distal clamp is reapplied onto the infrarenal aorta. The remainder of the aneurysm is opened. Balloon-tipped catheters are inserted into the celiac, superior mesenteric, and renal arteries to permit perfusion. **C:** An elliptical hole is made in the graft for reimplantation of the visceral and renal arteries.

Elephant Trunk Technique for Extensive Aortic Aneurysms

Extensive aneurysms involving the ascending, arch, and thoracoabdominal aorta can be repaired in a single stage, but not without significantly increased risk. Increased risk is secondary to prolonged operative times, multiple incisions, need for multiple surgical adjuncts, protracted clamp times and considerable blood loss. As such, staged repairs offer at least a partial solution to this elevated risk. The development of the elephant trunk technique by Borst in 1983 has greatly facilitated staged repair of extensive thoracic aortic aneurysms involving the entire thoracic and thoracoabdominal aorta.[36] Prior to this, staged repairs were plagued by complications, particularly bleeding from the pulmonary artery and thoracic aorta in the second stage repair of the thoracic or thoracoabdominal aorta. The elephant trunk technique avoids the issue of cross-clamping the native proximal descending aorta during the second stage and may simplify high dissection in the aortic arch via left thoracotomy.

The first stage of the operation is performed similarly to standard ascending and transverse arch surgery aside from the use of either an inverted distal graft or a commercially available collared graft inserted distally (**Fig. 93.8A**). An anastomosis is made between the folded edge or the collared portion of the elephant trunk and the aorta just distal to the left subclavian artery. Once this is performed, the inner portion of the graft is retrieved and the side limbs allow for reimplantation of the aortic arch vessels. The proximal anastomosis to the ascending aorta is then performed while the distal portion of the graft (the elephant trunk) is left floating in the proximal descending aorta. During this stage, cardiopulmonary bypass, profound hypothermia, circulatory arrest, and adjunctive antegrade cerebral perfusion protect the brain against hypoxia and stroke.

The second stage of the repair is performed in a similar fashion to the traditional TAAA repair using distal aortic perfusion and CSF drainage. After initiation of bypass, the distal clamp is applied to the mid descending thoracic aorta and the proximal descending aorta can be clamped between carotid and left subclavian or distal to the left subclavian artery. An alternative technique is to open the proximal aorta without a proximal clamp

being applied, but this risks significant bleeding unless performed under hypothermic circulatory arrest. The elephant trunk placed in stage 1 of the operation can be identified and clamped (**Fig. 93.8B** and **C**). The elephant trunk serves as the site for the proximal anastomosis for the remaining aneurysm to be replaced.

The frozen elephant trunk procedure is a newer strategy in patients with thoracic aortic aneurysm or dissection involving ascending, arch, and descending thoracoabdominal aorta. This concept combines endovascular technology with the advantages of conventional elephant trunk repair. Via median sternotomy for ascending or arch replacement, this technique involves antegrade deployment of an endograft device under direct vision into the descending aorta. The distal aortic suture line incorporates the endograft fabric material for added hemostasis. In staged fashion, at the time of thoracotomy for TAAA repair, the distal end of the endograft may be the site of the proximal anastomosis.

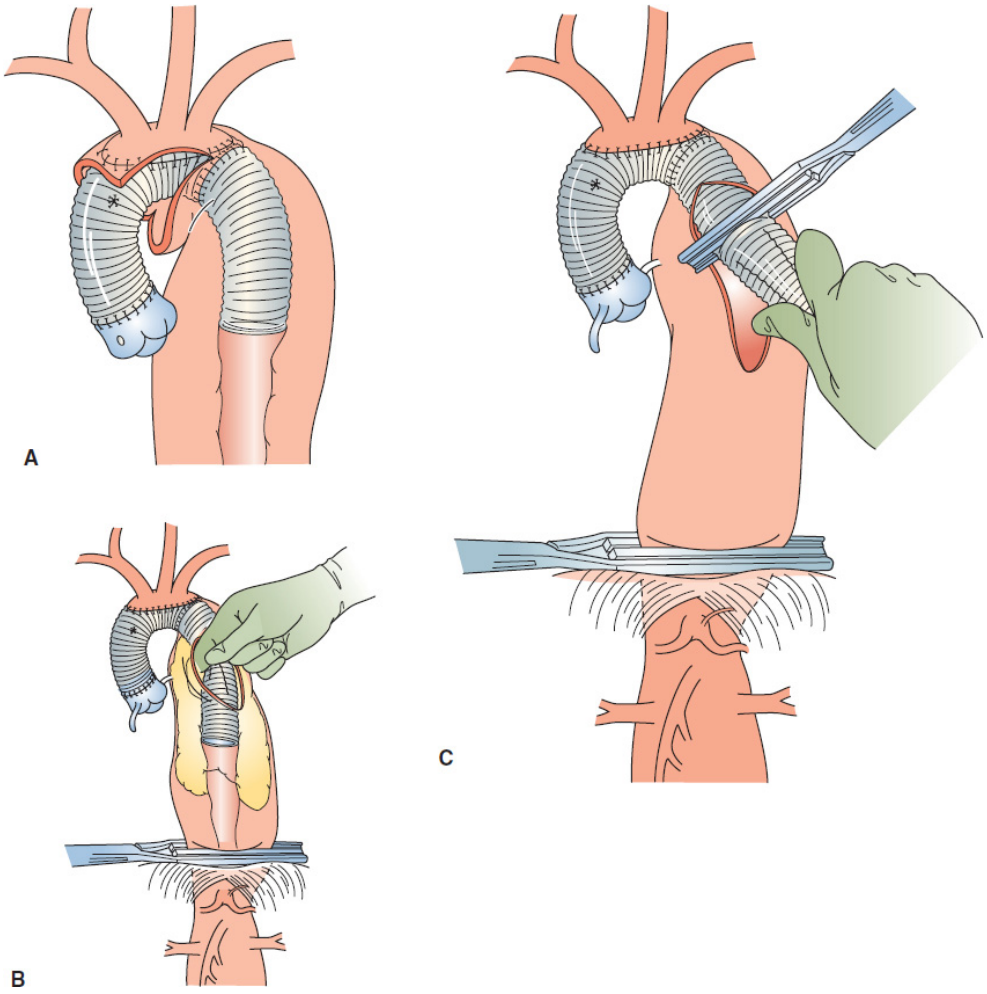

Figure 93.8 Elephant trunk technique. Illustration of completed stage 1 elephant trunk (**A**). In stage 2, the proximal aneurysm is opened and the existing graft is quickly grasped (**B**) and clamped (**C**). The remainder of the surgery follows the standard technique for thoracoabdominal aortic aneurysm.

POSTOPERATIVE MANAGEMENT

The patient is admitted to the ICU postoperatively for close hemodynamic monitoring and awakened as early as deemed safe in order to evaluate neurologic status, with particular emphasis on lower extremity motor function. Early extubation is appropriate when deemed hemodynamically stable. Mean arterial pressures (MAPs) are maintained between 80 and 90 mm Hg as hypotension (even brief) can be devastating for spinal cord perfusion and should be avoided. CSF pressures are continuously monitored and pressure is maintained at 10 mm Hg or less. Oral diet can be resumed

when the patient is extubated and can be advanced as tolerated. Ileus is not uncommon after surgery and diet should not be advanced until resolved.

Frequent neurologic checks after extubation should be performed in order to evaluate for delayed neurologic deficit (DND). While the strongest predictors of DND are low MAP and CSF drain complications, other risk factors for the development of DND are hypoxemia and low hemoglobin.[37] In the absence of DND, the CSF drain is generally removed POD 2 prior to transfer to the ward with telemetry. Typical ICU length of stay is 3 to 4 days depending on neurologic and pulmonary status.[38] Physical therapy should work with patients throughout their hospitalization.

Follow-up after repair consists of yearly CT scans or MRA if indicated to detect graft-related pseudoaneurysms or new aneurysms. The frequency of follow-up may change in circumstances such as Marfan syndrome, unoperated dissection, concurrent aneurysm, or family history of aneurysms.

SURGICAL OUTCOMES

Mortality rates for patients undergoing TAAA and descending thoracic aortic aneurysms repair range between 5% and 21% and vary with aneurysm extent.[39] Overall 70% of patients recover without significant postoperative complications.

Neurologic Outcomes

Neurologic deficit remains one of the most devastating complications following TAAA. This results from spinal cord ischemia from cross-clamping the descending thoracic aorta which also causes increased CSF pressure. Historically, under the "cross-clamp–and go" era, cross-clamp time was the single biggest predictor of neurologic deficit. With the current adjuncts of distal aortic perfusion and spinal drains for CSF pressure reduction, longer cross-clamp time appears to be tolerable. Keeping CSF pressure below 10 mm Hg has been shown to improve spinal cord perfusion in both animal and human studies.[40] Meta-analysis of CSF drainage in TAAA repairs has shown an absolute risk reduction of 10%.[40] The use of such adjuncts should be limited to centers with experience with TAAA. Distal

aortic perfusion and CSF drainage consistently show a significant decrease in risk of acute neurologic deficit.[41–43] Previously, cross-clamp time was a significant predictor of neurologic deficit, but with the use of adjuncts this appears to be less of a risk.[41] The highest incidence of neurologic deficits occurs in extensive (extent II) TAAA. Prior to the use of adjuncts, the rates of deficit were reported as high as 30% to 40%.[44] With the use of adjuncts, this has been reduced to a rate of 7.2% (**Fig. 93.9**).[43] In addition to extent, age, emergency presentation, renal dysfunction, active smoking and cerebrovascular disease have also been shown to be predictive of neurologic deficit.[41] The use of intraoperative distal aortic perfusion and perioperative CSF drainage should be considered in all elective cases as they prevent 1 neurologic deficit in 20 for all patients and 1 in 5 for extent II TAAA.[43]

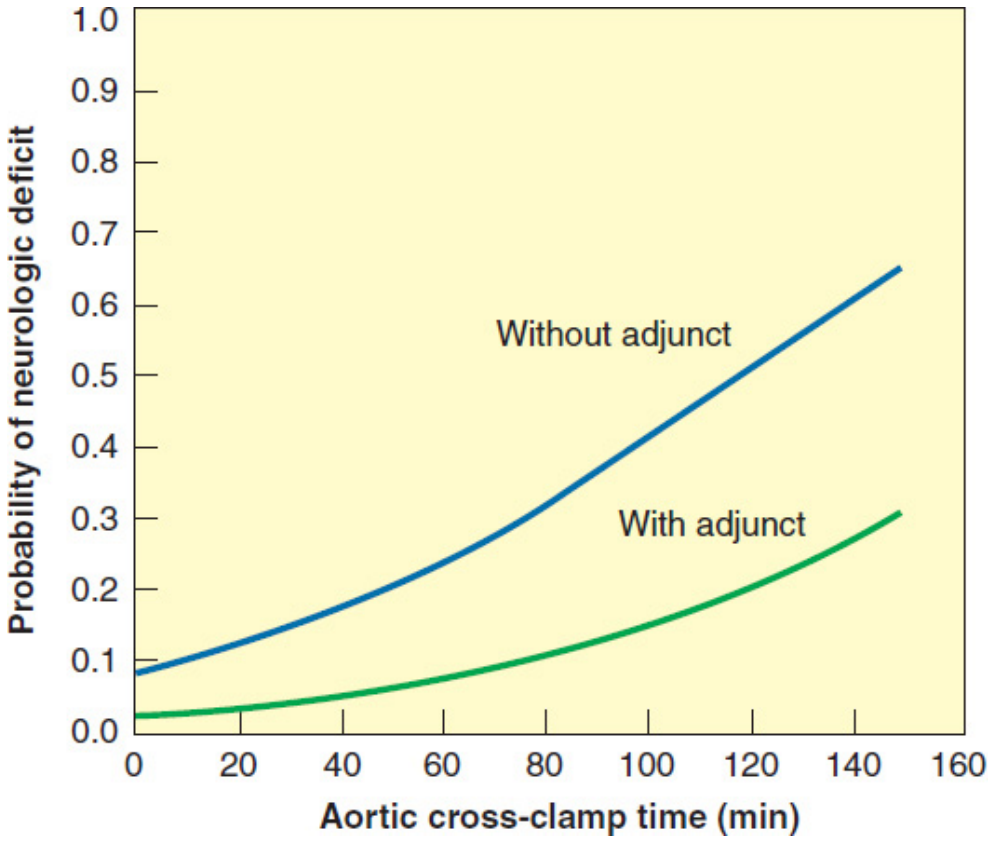

Figure 93.9 The probability of neurologic deficit increases with clamp time and is markedly higher in patients undergoing thoracoabdominal aortic aneurysm surgery without adjuncts.

In addition to CSF drainage and distal perfusion, reimplantation of the intercostal arteries has been shown to decrease risk of spinal cord ischemia.

The major blood supply to the anterior spinal artery of the spinal cord is thought to be the anterior radicular artery—*artery of Adamkiewicz* and while the origin is variable, it commonly branches from one of the lower intercostal arteries with or without additional collateral branches. It has been shown that ligation of intercostal arteries from T9 to T12 increases the risk of neurologic deficit and is believed to be due to decreased flow to the anterior radicular artery.[43] As such, these intercostals should be reimplanted when patent and feasible. This can be performed as one large patch to the graft, as separate buttons or with interposition grafts when the vessels are too far apart. If these lower arteries are occluded, it is important to reimplant the upper arteries as they likely assume a more important role in supplying the spinal cord.

Adequate spinal cord perfusion pressure should always be maintained with avoidance of hypotension during and after surgery as even brief episodes of hypotension can lead to neurologic deficit. Nitroprusside should not be used as an antihypertensive agent intraoperatively or postoperatively as it can potentially increase CSF pressures in addition to causing systemic hypotension.[45] Maintenance of adequate systemic arterial pressure cannot be overemphasized and should be achieved with judicious use of blood products as needed in addition to vasopressors.

Many institutions rely on intraoperative motor-evoked potentials (MEPs) and somatosensory-evoked potentials (SSEPs). For SSEP, monitoring is performed by placing probes on bilateral malleoli (stimulating posterior tibial nerve) and recordings are performed on the popliteal fossa, C5, and the vertex with positive finding defined as a drop in amplitude by 50% and/or a change in latency by 10%. For MEP, the precentral gyrus is stimulated and recording is measured at three sites: abductor digiti minimi, tibialis anterior, and abductor hallucis muscle (**Fig. 93.10**). Compound muscle action potential is monitored and results are binary with loss of potential being a positive finding. SSEP and MEP monitoring have been shown to be highly correlated with irreversible neurologic deficit, but have not been shown to correlate with reversible deficit. While MEP is more complex, the detection rate of irreversible injury is identical to SSEP. Both forms of monitoring have strong negative predictive value in that it is highly unlikely to have neurologic deficit immediately following surgery if there was no loss of signal intraoperatively.[46,47] If there are signal changes, rescue procedures

should be performed including increasing the MAP to >80 mm Hg, increasing distal aortic perfusion pressure to >60 mm Hg, lowering the CSF pressure, increasing the hemoglobin level, and attaching more intercostal arteries. Even with these adjuncts, the rate of deficit remains 3.1%.[46]

Delayed Neurologic Deficits

DND is normal defined as paraplegia or paraparesis after a period of observed neurologic function. When first described in 1988, this condition was irreversible.[48] CSF drainage has been shown to provide improvement in neurologic outcomes in select cases of DND.[49] DND can present nearly immediately after surgery or up to 2 weeks postoperatively (median 3 days) in 2.7% of patients.[50] There is no single predictor of delayed deficit, but rather a combination of risks leading to the development of DND. MAP less than 60 mm Hg and drain complications are the highest predictors of delayed deficit.[37]

The exact mechanism for the development of DND are not fully understood, but are hypothesized to be related to the "second hit" phenomenon in that adjuncts can clearly protect the spinal cord intraoperatively and reduce risk of neurologic deficit immediately postoperatively, but the spinal cord remains vulnerable postoperatively. During this time frame a "second hit" in the form of hypotension or drain malfunction can lead to DND. Any rise in CSF pressure during the early postoperative period can lead to increased compartment pressure and decreased perfusion, as such any sign of DND should be initially treated with free drainage of CSF to relieve the compartment pressure. Many institutions also routinely implement naloxone infusions and administration of steroids in the initial postoperative period as some studies have shown decreased incidence of DND with its use,[51–54] however strong evidence for its effect is lacking.

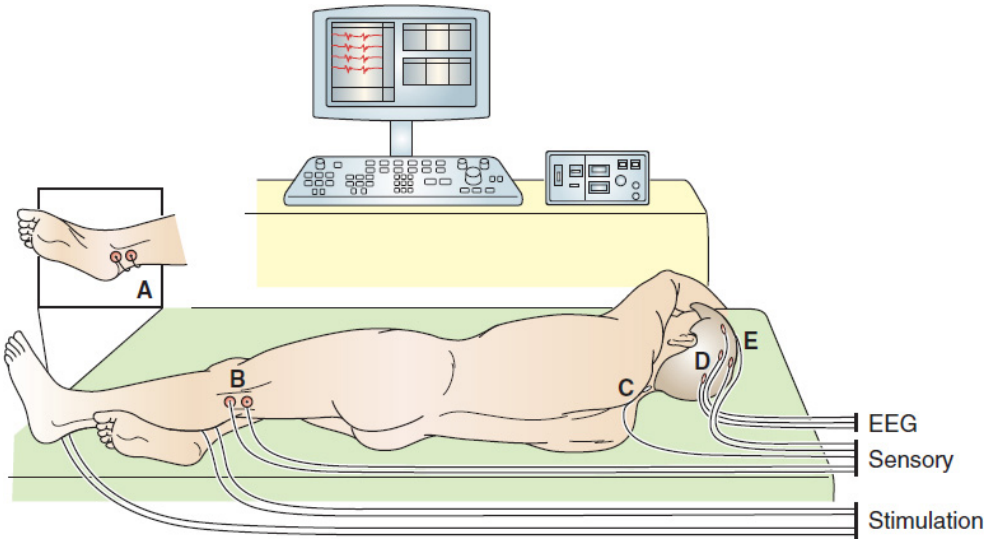

Figure 93.10 Somatosensory- and motor-evoked potentials are recorded at three sites: the popliteal fossa (**A**, **B**), C5 (**C**), and the vertex (**D**, **E**).

To optimize spinal cord perfusion in the early postoperative period the MAP is maintained between 90 and 100 mm Hg, hemoglobin greater than 10 mg/dL, and cardiac index greater than 2.0 L/min. Rescue protocols are initiated if any signs of DND emerge. These include laying the patient flat, checking the drain for malfunction, reinsertion of the drain if it was removed, free drainage of the CSF until the pressure is <10 mm Hg, increasing the MAP, liberalization of blood transfusion protocols, and increasing oxygen saturation. CSF drainage is continued for at least 72 hours after onset of DND. Using this multimodal approach, improvement in neurologic function has reportedly been improved in 57% of patients suffering from DND.[50]

Renal Failure

Acute postoperative kidney injury (AKI) is defined according to modern consensus Kidney Disease: Improving Global Outcomes (KDIGO) or Acute Kidney Injury Network (AKIN) criteria. These criteria define acute kidney injury as an increase in serum creatinine by ≥0.3 mg/dL (≥26.5 micromol/L) within 48 hours; increase in serum creatinine to ≥1.5 times baseline, which is known or presumed to have occurred within the prior 7 days; or urine volume <0.5 mL/kg/hr for 6 hours. AKI is a known independent predictor of postoperative morbidity and mortality with associated mortality reported as high as 70%.[55,56] The reported rate of postoperative AKI falls within the

range of 5% to 40% with dialysis-dependent renal failure reported in 1.5% to 10.7% for elective repairs.[57] Additionally, these patients are more likely to experience nonrenal complications such as respiratory failure, central nervous system dysfunction, sepsis, and gastrointestinal hemorrhage. For those who develop AKI, continuous venovenous hemodialysis or daily intermittent hemodialysis is initiated. In a large series, patients requiring permanent hemodialysis were low at 7%.[58] Preoperative renal dysfunction and emergency surgery are known predictors of postoperative AKI, but age, previous aortic surgery, return to operating room, and surgical blood loss have also been shown to be predictors of AKI.[57]

Perioperative renal protection remains a concern and general management strategies include maintaining adequate renal oxygen delivery, reducing renal oxygen utilization, and direct renal tubular injury. The advantages of metabolic suppression via cold temperatures are well known and there is some evidence that local cooling of the kidneys may be protective. Cold renal perfusion with 4°C solution has shown promising outcomes for renal protection but needs further investigation.[57]

Renal insufficiency is a known predictor of 30-day postoperative mortality. Estimated glomerular filtration rate (eGFR) has been shown to be superior to serum creatinine in prediction of 30-day mortality following TAAA repair. In those with normal eGFR mortality has been reported at 5%, while mortality was reported as 10%, 18%, and 28% for mild, moderate, and severe renal insufficiency, respectively. Five-year survival was 77% in those with normal eGFR yet was less than 25% for the severe renal insufficiency patients (**Table 93.1**).[59]

Table 93.1 Complications of Open TAAA Repair

Complication	Results
Early mortality	4–21%
Immediate neurologic deficit	2–33%
Delayed neurologic deficit	2–10%
Acute renal failure–need for dialysis	2–13%
Acute renal insufficiency	6–40%
Bleeding–reoperation for bleeding	5–10%
Vocal cord paralysis/paresis and hoarseness	10%
Cardiac complication–MI, CHF	5–15%
Pulmonary insufficiency (prolonged ventilation >48 h)	10–41%
Stroke or transient ischemic attack (reversible)	2–6%
Gastrointestinal complications (pancreatitis, ischemic colitis, small bowel, cholecystitis, hepatic insufficiency)	7–10%
Chylothorax	<1%
Hospital length of stay	10–22 days
Survival	1 y = 60–80% 5 y = 65–80% 10 y = 40%

CHF, chronic heart failure; MI, myocardial infarction.

COMPLICATIONS

A summary of complications is shown in **Table 93.1**. These have been compiled from a series of sources.[60–70]

Elephant Trunk Technique

Two-staged elephant trunk technique for the repair of extensive aortic aneurysms involving the ascending, transverse arch and thoracoabdominal aorta has proven to be a durable, but challenging approach to a complex problem. Complication rates have improved as advancements in surgical adjuncts have been made. In a large series of 348 patients who underwent a two-stage TAAA repair using the elephant trunk technique, mortality rates after the first stage ranged from 5% to 10% after stage 1 and 5% to 15% after stage 2 depending on renal function. A 5% mortality was reported in both stages for patients with normal GFR. In the interim between the two stages, mortality ranged from 4% to 17% (mean of 6.5%) depending on why the second stage was not completed. In their series 32% of patients failed to follow up after 5 years due to death. Stroke rates for the first stage were low at 2% and no neurologic deficits were noted after the second stage. While timing of the second stage of the repair is challenging, it is recommended that the second stage be performed after 4 to 6 weeks due to the risk of rupture.[71]

IMPACT OF AORTIC DISSECTION

Historically, aortic dissection was reported as a risk for developing neurologic deficits, but these reports are from the "clamp-and-go" era. In a series of 729 patients no difference in neurologic outcome was reported between those with chronic dissection and those without. The rate of paraplegia was 3.6% for those with dissection and 4.7% for those without.[72,73] These improved outcomes are likely the result of the adjuncts (mainly distal aortic perfusion and CSF drainage) as described previously.

The same is not true for acute aortic dissections requiring graft replacement as these patients have a neurologic deficit rate of 32%.[74] These patients are undergoing surgery urgently and are typically critically ill and typically the methods for spinal cord protection are suboptimal. In particular, reimplantation of the intercostal arteries is ill advised due to the friable dissected tissue and the risk for hemorrhage. Additionally, the addition of distal aortic perfusion and CSF drainage may not be possible due to hemodynamic instability.

ENDOVASCULAR REPAIR

Since the first thoracic stent graft repair in 1994, there has been a rapid evolution in endovascular management of thoracic aortic disease with multiple new devices entering the market. Endovascular repair of TAAA was initially purported to have the benefit of improved morbidity and mortality however meta-analysis regarding this has mixed results, but may slightly favor endovascular repair.[75] Regardless, further outcomes research in this area is needed. These procedures were initially developed to accommodate those deemed poor open surgical candidates, but are now frequently preferentially used in select patients.[76] There are currently four different methods for endovascular repair of TAAA: hybrid repair, use of parallel "chimney" grafts and custom-made branched fenestrated devices, as well as investigational endograft used inside of clinical trials or investigator-initiated device trials.

Hybrid Repair

The hybrid approach requires open debranching of the aorta with subsequent endovascular coverage of the aneurysmal segment.[77] Debranching is achieved via a retroperitoneal or transperitoneal approach for extra-anatomical bypass of the visceral and renal arteries via either iliac artery. The patient is allowed to recover and then the aneurysmal segment is covered with a stent graft. Advantages of this approach are the avoidance of a thoracotomy, single-lung ventilation, or aortic cross-clamping. Despite these advantages, the morbidity and mortality using this approach is comparable to that of an open repair.[76,78,79] As such, this method is likely only suited for those who will not tolerate an open repair and are not candidates for other endovascular repair techniques.

Parallel Grafts

This technique involves the use of parallel grafts (chimneys, periscopes or snorkels, commonly referred to as CHIMPS) to preserve blood flow to branch vessels. This was initially described in 78 patients in Brazil (15 patients had TAAA).[80] At 17 months, the primary patency rate was 96.7%

and early mortality was 5.1% (later 1.3%). This technique is advantageous in that off-the-shelf, modular grafts can be tailor fit to any anatomy.[81] This is beneficial in patients with small and tortuous vessels, history of dissection or significant thrombus burden in the paravisceral aorta. Endoleaks from the "gutters" are the main disadvantage and endoleak rates have been reported as high as 18.5%.[82] Meta-analysis of this technique showed 98.9% early success rate and perioperative mortality of 4%.[82,83]

Total Endovascular Repair

This method is performed via custom-made branched and/or fenestrated devices. The largest experience reported is by Greenberg et al. using this method in 406 patients with perioperative mortality of 2.3% for extent IV, 5.2% for extent II and III, and 12.5% for extent I aneurysms.[84] Estimated 24-month survival was 82%, 74%, and 70%, respectively. A multicenter prospective study of 268 patients reported 30-day mortality of 6.7%, in-hospital mortality of 10.1%, and severe complications of 22%.[85] These high rates of mortality prompted the authors to encourage investigation of new strategies. Despite this high mortality, our institution found this method to have the lowest mortality (4%) in extent II and III TAAA and has adopted this as our first-line treatment in those with favorable anatomy.[76] Regardless of the progress that has been made, the field needs to continue to evolve to allow for safer procedures and provide off-the-shelf devices that can be tailored to a variety of circumstances.

Abdominal Aortic Aneurysms

Dean J. Arnaoutakis, Gilbert R. Upchurch Jr, and Thomas S. Huber

Key Points

1. An aneurysm is defined as a permanent, focal dilation of an artery that exceeds 1.5 times the normal, expected diameter.
2. Risk factors for abdominal aortic aneurysm (AAA) include age, male gender, smoking, family history, hypertension, chronic obstructive pulmonary disease (COPD), and the presence of other aortoiliac or peripheral aneurysms.
3. The diameter of an aneurysm is the greatest predictor of rupture as estimated by the tangential stress of the vessel wall.
4. AAAs increase in size over time with a mean growth rate of 0.4 cm/yr.
5. Computed tomography (CT) arteriography is both the diagnostic study of choice and the sole imaging study required for operative planning.
6. The treatment of AAA represents a balance between the risk of rupture and the operative morbidity and mortality rate.
7. Infrarenal AAAs should be repaired in men when their diameter reaches 5.5 cm and in women when the diameter reaches 5 cm provided they are of reasonable operative risk.
8. Endovascular repair has supplanted open repair as the preferred choice by both patients and providers in the United States.
9. Endovascular aneurysm repair (EVAR) mandates long-term follow-up with serial imaging to confirm the integrity of the device and repair.

INTRODUCTION

Abdominal aortic aneurysms (AAAs) are a common problem in developed countries and represent a significant public health concern globally. Operative repair is the only means to reduce the risk of rupture and the associated mortality. The treatment algorithm represents a balance between

the risk of repair and the operative morbidity and mortality rate. Open surgical repair has been the traditional approach since its description by Dubost et al. in the early 1950s.[1] However, a catheter-based endovascular approach has emerged as the preferred treatment since its commercial release at the turn of the 21st century and has truly revolutionized the care of patients with AAAs.

DEFINITIONS AND CLASSIFICATIONS

1 An aneurysm is defined as a permanent, focal dilation of an artery that exceeds 1.5 times the normal, expected diameter.[2] The diameter of a normal abdominal aorta in an adult male is approximately 2 cm (range, 1.4 to 3 cm). The abdominal aorta is consistently larger in men than in women and increases slightly with age for both genders. AAAs should be differentiated from other conditions in which the size of the aorta is increased, including ectasia and arteriomegaly. In aortic *ectasia,* the diameter is increased by less than 1.5 times of the normal, expected diameter. *Arteriomegaly* refers to a diffuse (nonfocal) enlargement of several arterial segments with increases in diameter greater than 50% of the normal expected diameter. Arterial segments in patients with arteriomegaly may be considered aneurysmal if the diameter of a segment is increased by more than 50% of the diameter of an adjacent segment.

AAAs are classified primarily according to how far they extend cephalad (**Fig. 94.1**).[3] More than 85% of all AAAs are classified as infrarenal. These aneurysms are located sufficiently below the renal arteries such that there is adequate healthy aorta for an infrarenal cross-clamp position. Juxtarenal aneurysms refer to those that encroach upon the origin of the renal arteries such that a suprarenal cross-clamp position is necessary with a planned infrarenal proximal anastomosis. Suprarenal AAAs extend above the renal orifices to the level of the superior mesenteric artery (SMA) and typically require a supraceliac cross-clamp position. Aneurysms involving the thoracic and abdominal aorta are designated as thoracoabdominal aortic aneurysms and are classified according to how far they extend both cephalad and caudal (extent 1 through 5). Aneurysms that extend above the renal arteries complicate both endovascular and open repair and are associated

with greater morbidity. Newer techniques and endograft design have expanded the indications for endovascular repair to include select juxtarenal and thoracoabdominal aneurysms.[4,5]

Concomitant iliac artery aneurysms are present in approximately 10% to 20% of all AAAs.[6] Iliac artery involvement, which usually affects the common and internal iliac vessels but preserves the external iliac, may complicate both open and endovascular aneurysm repair (EVAR).

MAGNITUDE OF THE PROBLEM

AAAs are common in developed countries. The incidence of AAAs in the United States ranges from 1.5% in autopsy series to 3.2% among unselected adult patients screened with ultrasonography.[7] Predictably, the incidence increases among patients with risk factors for AAAs and approaches 50% in patients with either femoral or popliteal artery aneurysms.[7] Interestingly, the incidence of AAAs increased through the end of the 20th century, then plateaued, and has even started to decline more recently.[8,9] These changes may be reflective of smoking trends in the United States.[9] A total of 9,928 deaths were caused by AAAs and/or dissections during 2017 and this corresponded to death rate of 3/100,000 as reported by the Centers for Disease Control and Prevention.[10] These numbers may be an underestimate due to sudden deaths in the elderly, which may be secondary to undiagnosed ruptured aneurysms. Of note, since the introduction and rise of endovascular aortic aneurysm repair (EVAR), the 30-day abdominal aneurysm-related mortality (elective repair, rupture repair, and death due to rupture without repair) has decreased by 50%.[11]

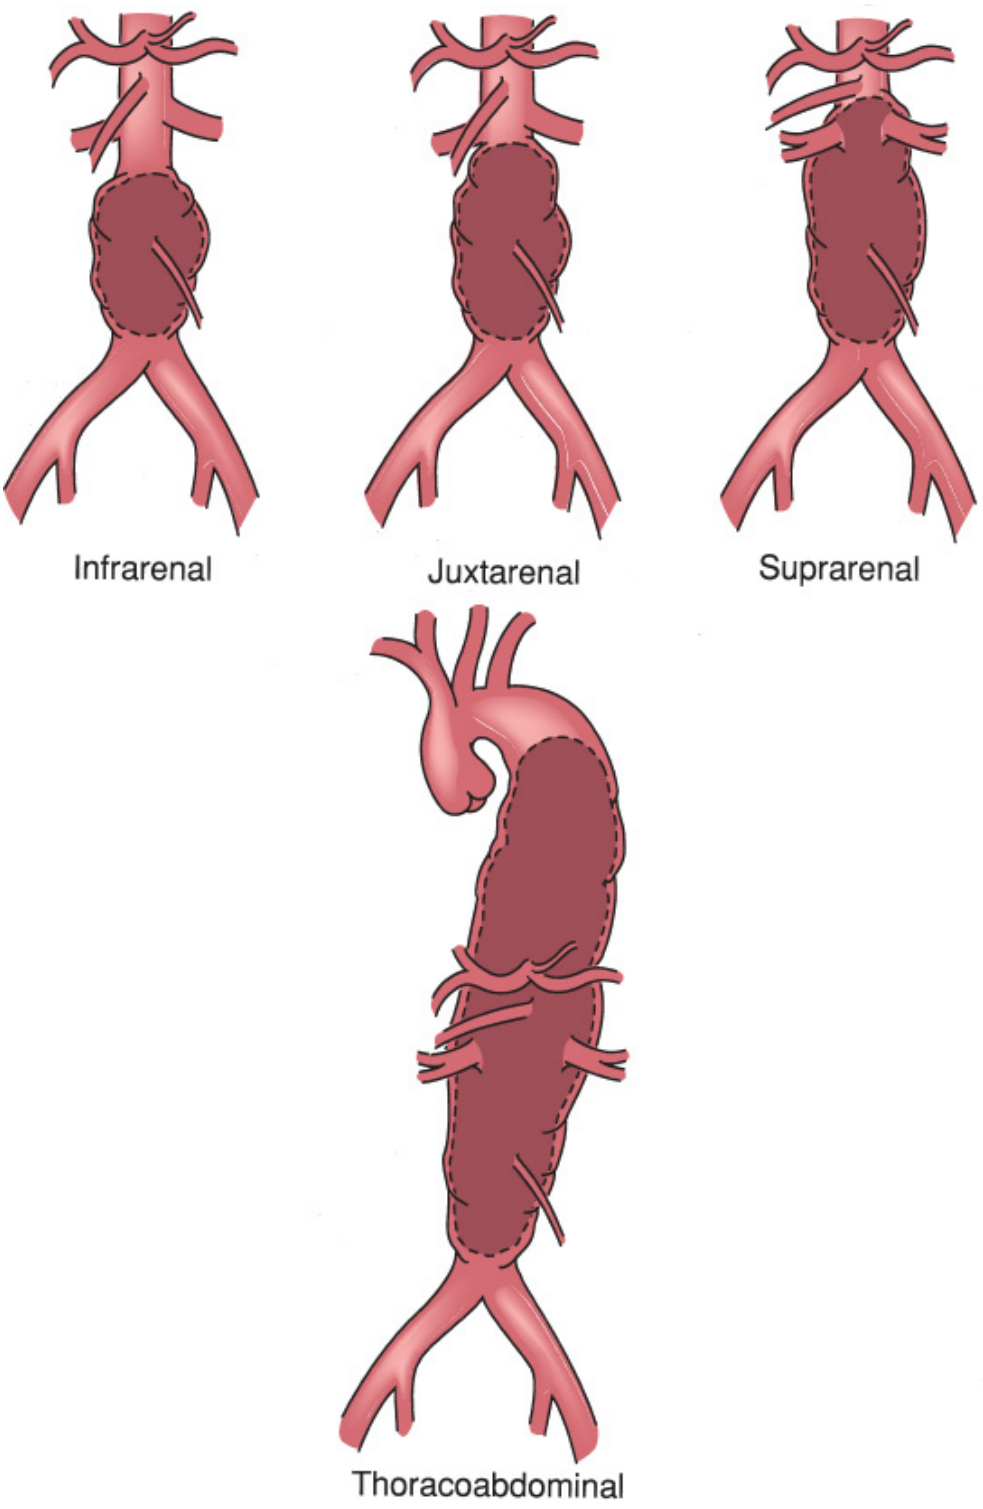

Figure 94.1 Classification of abdominal aortic aneurysms. More than 85% of all abdominal aortic aneurysms are infrarenal. Juxtarenal aneurysms extend to the level of the renal arteries, and suprarenal aneurysms to the level of the superior mesenteric. Aneurysms extending above the superior mesenteric artery and above are designated as thoracoabdominal aneurysms and are classified (Crawford extent I–V) according to how far they extend cephalad and caudal.

PATHOGENESIS AND RISK FACTORS

The pathogenesis of AAAs remains unresolved, although it is an intense area of investigation. Multiple etiologic factors have been implicated including atherosclerosis,[12] hemodynamics,[13] collagen,[14] collagenase,[15] elastin,[16] elastase,[17] metalloproteinases,[18] protease inhibitors,[19] programmed cell death (apoptosis),[20] neutrophils,[21] and inflammatory mediators.[22] The etiology is likely multifactorial with interaction between both environmental and genetic factors. Unfortunately, investigation into the potential mechanisms has not resulted in any effective biologic therapies. Elucidation of the pathogenesis has been complicated by the older age of patients at presentation and the absence of suitable animal models.

2 Multiple risk factors have been identified for the development of AAAs, including age, sex, race, smoking, hypertension, hyperlipidemia, peripheral vascular disease, myocardial infarction, and family history.[23] Identification of these risk factors is important to facilitate screening high-risk patient populations. AAAs typically affect the elderly and are rare among persons less than 50 years of age. Indeed, the mean age among patients undergoing repair across the country was 75.5 years in a Medicare population study.[11] A meta-analysis of the population-based screening studies for AAAs reported that male sex had the strongest association (odds ratio, 5.69).[24] The death rate from AAAs for men of 60 to 64 years of age is 11-fold higher than that for women of the same age, but it is only 3-fold higher for men between 85 and 90. Furthermore, men account for approximately 80% of all AAA repairs performed nationally.[11] The Aneurysm Detection and Management Veterans Affairs Cooperative Study Group (ADAM) reported that smoking was the strongest modifiable risk factor associated with AAAs >4 cm (odds ratio, 5.57) among the 73,451 veterans screened.[25] Darling et al.[26] prospectively analyzed patients undergoing repair of AAAs and reported that 15.1% had a first-degree relative with an aneurysm, in contrast to only 1.8% in the control group. Interestingly, the presence of a female family member with an aneurysm correlated with an increased risk for rupture. It is notable that the risk factors for AAA are similar to those associated with the development of atherosclerosis except for diabetes

mellitus.[27] Furthermore, atherosclerotic changes are found almost universally within degenerative aneurysms at the time of repair suggesting that the two disease processes are likely related, but it is unclear how.

The presence of an aneurysm in the aorta, iliac, femoral, or popliteal arteries increases the risk for a new or additional AAA. The incidence of aortoiliac aneurysms in patients with concomitant popliteal or femoral artery aneurysms is approximately 50%.[7] Importantly, all patients found to have one of these peripheral artery aneurysms should undergo a computed tomography (CT) scan of the entire aorta from thorax to the iliac vessels to exclude a synchronous aneurysm in addition to being screened for other peripheral aneurysms. In contrast, less than 15% of patients with AAA have a concomitant popliteal artery aneurysm and thus evaluation with proper physical examination and/or ultrasonography is typically adequate.[28]

The incidence of AAAs is increased among patients with an aortic dissection. Despite appropriate medical therapy, 20% to 40% of type B aortic dissection (TBAD) patients develop false lumen degeneration with aneurysm formation[29] and up to ~45% eventually undergo aortic-related intervention.[30]

Interestingly, the prevalence of AAAs and the rate of expansion are both increased among heart and abdominal organ transplant patients.[31,32] The responsible mechanisms remain unclear, but the obligatory chronic immunosuppression may contribute.

PRINCIPLES OF MANAGEMENT

The treatment goals for patients with AAAs are to prolong meaningful life, relieve symptoms, and reduce aortic-related mortality by preventing rupture. Because surgical treatment is the only effective means to achieve these goals, the crucial question that must be answered is whether the patient merits repair. The decision algorithm is relatively straightforward for patients with ruptured or symptomatic aneurysms, but more difficult for patients with asymptomatic, intact aneurysms. Prophylactic intervention in the elective setting is contingent on the balance between the risk of the procedure and that of expectant, nonoperative management within the context of the patient's wishes and life expectancy. Appropriate assessment of these risks requires

an understanding of the size-associated risk for rupture, the interval growth rate, and the morbidity and mortality associated with repair, as well as the natural history of a patient with the risk factors that led to aneurysm disease.

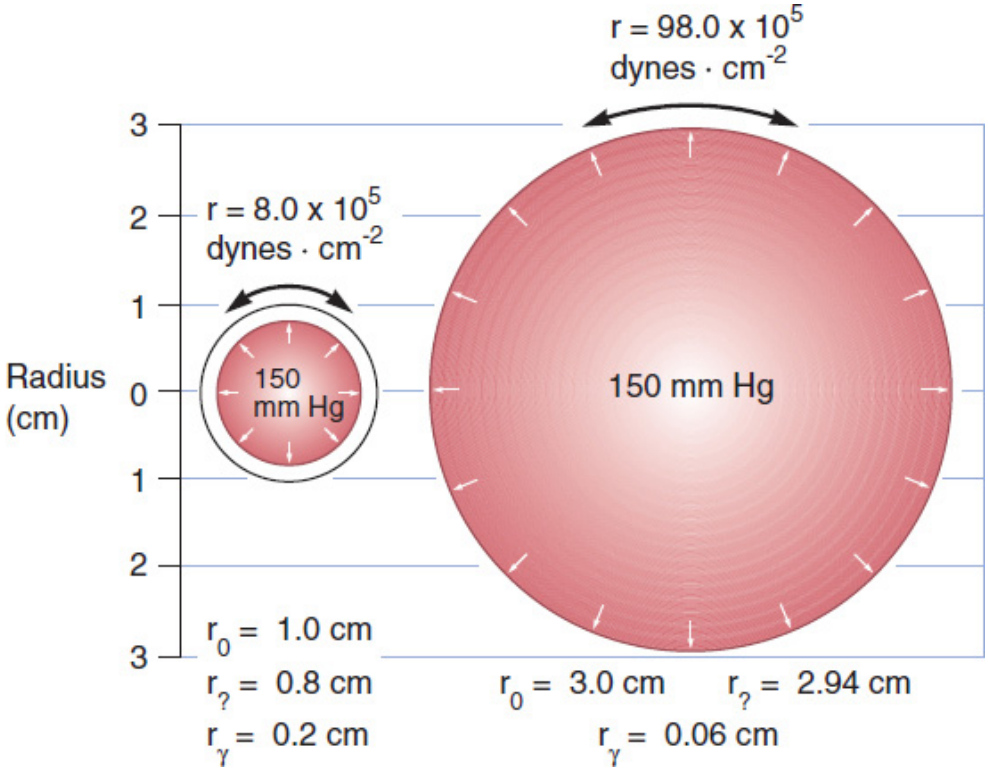

Figure 94.2 Cross-sectional view of a 2-cm-diameter cylinder that expands to a diameter of 6 cm while wall cross-sectional area remains constant. t, wall stress; d, wall thickness; r_i, inside radius; r_0, outside radius. Expansion of a 1-cm-diameter cylinder to a diameter of 3 cm with no change in wall cross-sectional area increases wall tensile stress 12-fold.

Understanding the natural history of untreated AAA requires knowledge of the physics associated with the vessel wall. The tangential stress (t) of a fluid-filled cylindrical tube is determined by the following equation:

$$t = Pr/d$$

where P is the pressure exerted by the blood (dyne/cm^2), r is the internal radius (cm), and d is the thickness (cm) of the arterial wall.[33] The tangential stress of a cylinder 0.2 cm thick with an internal radius of 0.8 cm and a fluid pressure of 150 mm Hg is 8×10^5 dyne/cm^2 (**Fig. 94.2**). An increase in the internal radius (diameter) of the cylinder to 2.94 cm and a concomitant

decrease in the wall thickness, as might occur with an aneurysm, would increase the tangential stress to 98×10^5 dyne/cm^2. Thus, a 3-fold increase in diameter would result in a 12-fold increase in the tangential stress. Aneurysms rupture when the tangential stress exceeds the tensile strength of the vessel wall. It should be emphasized that the tangential stress varies directly with the radius of the cylinder (vessel), but is independent of its length.

3 The diameter of an AAA is the greatest predictor of rupture as estimated by the tangential stress of the vessel wall. The diameter of an aneurysm is determined by measuring its greatest diameter from outer wall to outer wall, preferably using an orthogonal image, throughout the extent of the aneurysm. Orthogonal refers to a cross-sectional measurement perpendicular to the long axis, along the centerline of flow to avoid overestimation due to tortuosity of the aorta. The collective annual rupture risks per aneurysm diameter are shown (**Table 94.1**).[33] Although there is some variability in the data, it is agreed upon that the rupture risk for aneurysms less than 5 cm in diameter is very small, but increases considerably for those greater than 5.5 cm in men and 5 cm in women. These data may be simplified by using the rule of thumb that the annual rupture risk is ≤5% for a 5-cm aneurysm, ~5% for a 5.5-cm aneurysm, 10% for a 6-cm aneurysm, and 20% for a 7-cm aneurysm. These numbers correspond to an estimated 5-year rupture risk of 50% for 6-cm aneurysms and 100% for those of 7 cm. Notably, both the ADAM[25] and UK Small Aneurysm Trial[34] that randomized patients with small aneurysms (4 to 5.5 cm) to open repair or surveillance reported that the rupture risk for surveillance was ≤1%/yr.

Table 94.1 Estimated Annual Rupture Risk

AAA Diameter (cm)	Rupture Risk (%/yr)
<4	0
4–5	0.5–5
5–6	3–15
6–7	10–20
7–8	20–40
>8	30–50

Reproduced with permission from Brewster DC, Cronenwett JL, Hallett JW Jr, et al. Guidelines for the treatment of abdominal aortic aneurysms. Report of a subcommittee of the Joint Council of the American Association for Vascular Surgery and Society for Vascular Surgery? *J Vasc Surg* 2003;37(5):1106–1117.

A variety of other factors have also been reported to increase the risk of aneurysm rupture including female gender, chronic obstructive pulmonary disease (COPD), smoking, hypertension, family history, and wall stress.[34–36] The impact of the aneurysm growth rate on rupture risk remains unclear and has been difficult to separate from aneurysm diameter alone. However, an aneurysm expansion of ≥1 cm/yr is generally considered worrisome.

4 The natural history of AAAs is to grow in size over time. The reported mean rate of growth has varied from 0.2 to 0.4 cm/yr.[37] The rate of growth can be impacted by several factors including female gender, current smoking, and larger original diameter. Interestingly, coenzyme A reductase inhibitors (i.e., statins) may inhibit growth of small AAAs.[38] The growth curve may be somewhat erratic or "staccato" with no growth detected during consecutive 6-month intervals followed by a period of growth hence the need for persistent surveillance.[39]

The mortality rate associated with repair of an AAA depends on the status of the aneurysm (intact/asymptomatic, intact/symptomatic, ruptured), the physiologic state of the patient (age and medical comorbidities), and the method of repair (open vs. endovascular). Population studies from Medicare and the Nationwide Inpatient Sample (NIS) have reported that operative

mortality rates for *open repair of intact* aneurysms in the United States range from 4.2% to 5.4%.[40] Predictably, the operative mortality rate increases with age, ranging from 2.2% among persons of 50 to 59 years of age to 9.2% among those >80. Interestingly, operative mortality rate has been shown to be significantly higher among women (6.1% vs. 3.7%). The mortality rate for open repair in the randomized trials (UK Small Aneurysm Trial—5.8%, ADAM—2.7%, DREAM—4.6%, EVAR Trial—4.6%)[25,34,41,42] are within the range of nationwide series.

The operative mortality rate for *endovascular repair of intact* AAAs has been consistently lower than an open approach. Schermerhorn et al. reported that the operative mortality after EVAR was 1.2% among Medicare beneficiaries during 2001 to 2004 while mortality within the NIS through 2005 was 1.3%.[43] Results from the Dutch Randomized Endovascular Aneurysm Management (DREAM) Trial[41] and the Endovascular Aneurysm (EVAR) Trial[42] comparing open and endovascular repair have reported that the perioperative mortality rate is lower for endovascular repair and within the same range (DREAM—2% vs. 4.6%; EVAR Trial—1.7% vs. 4.7%).

The operative mortality rate for *open repair of intact/symptomatic* aneurysms among patients undergoing emergent repair exceeds that for elective repair and has ranged from 9% to 19%.[7,44] However, in more recent data, De Martino et al.[45] reported from the Vascular Study Group of Northern New England a perioperative mortality of 2.1% and 0% for open and endovascular repair for intact/symptomatic aneurysms, respectively. However, late mortality and inhospital adverse events were still higher comparable to the asymptomatic cohort. Various explanations have been proposed for this increased mortality rate relative to that for intact/asymptomatic aneurysms, including failure to maximize preoperative medical conditions and increased incidence of inadvertent venous injuries. Presumably surgeon experience would lend itself to improved outcomes in nonelective cases; however, Arnaoutakis et al. showed that more experienced surgeons had similar major complication rates as well as 1-year survival compared to early career surgeons with respect to nonelective open AAA repair.[46]

The actual mortality rate for ruptured AAAs is somewhat difficult to determine because a significant number of sudden deaths in elderly patients are likely secondary to ruptured aortic aneurysms. It has been estimated that

50% of all patients with ruptured AAAs die outside the hospital.[7] For those patients who do make it to the hospital, a meta-analysis spanning 50 years reported that the operative mortality rate for the *open repair of ruptured* aneurysms was 48%.[47] These figures correspond to an overall mortality rate of approximately 80% although this may be an underestimate. It is remarkable that the optimization of prehospital and emergency room care including a reduction in the mean transfer time from the emergency department to the operating room to 12 minutes did not appear to result in a decrease of the mortality rate of ruptured aneurysms.[48]

The mortality rate for the *endovascular repair of ruptured* AAAs is lower than the open approach, although data may be significantly skewed by selection bias.[49] Multiple meta-analyses have reported a perioperative mortality rate of 24% to 27% with improved overall outcomes compared to open repair.[50,51] The potential to treat ruptured AAAs with the endovascular approach may represent the greatest contribution or benefit of the technology. However, further validation is necessary since some reports likely reflect patient selection bias. In population data, Giles et al.[52] reported that the annual number of deaths across the country from both intact and ruptured aneurysms has decreased significantly since the introduction of EVAR.

CLINICAL PRESENTATION AND DIAGNOSIS

The overwhelming majority of AAAs are asymptomatic at the time of discovery. Most aneurysms are detected by abdominal or pelvic imaging studies, such as ultrasonography and CT, performed for other indications (e.g., chronic back pain, renal cysts) rather than on physical examination. It is difficult to palpate an AAA on physical examination because of its anatomic location in the posterior abdomen in conjunction with the national obesity epidemic. A literature review examining the accuracy of physical examination reported that the sensitivity ranged from 33% to 100%, the specificity ranged from 75% to 100%, and the positive predictive value ranged from 14% to 100%.[53] Intact abdominal aortic and iliac artery aneurysms may present with symptoms that lead to further investigation and the correct diagnosis although this is the exception rather than the rule. Rarely, enlargement of the aneurysm may cause vertebral erosion and chronic

back pain. In addition, thrombosis of an AAA may cause acute ischemia in the lower torso, and aneurysms may be a source of arterial macroemboli or microemboli leading to acute ischemia of a lower extremity or digit, respectively.

Patients with intact/symptomatic or ruptured aneurysms present with abdominal or back pain related to the aneurysm itself. The character of the pain is variable and ranges from dull to sharp. The pain is usually acute in onset and persistent. It may be superimposed on more chronic abdominal or back pain, but the presentation is usually not subtle, and the pain can be differentiated from more chronic complaints. In addition, the pain may radiate from the abdomen to the back, flank, inguinal region, or genitalia. Approximately 10% of patients with ruptured AAAs present with signs and symptoms similar to those of ureteral colic or other acute urologic problems.

Patients with a ruptured AAA may present anywhere along the spectrum from hemodynamically normal to profound shock. Their status depends on the ability of the tissues adjacent to the aorta to tamponade the bleeding. If the rupture is contained, the patient may present hemodynamically stable. However, it should be emphasized that this is usually temporary, and health care providers should not be lulled into a false sense of security. A ruptured AAA is a true medical emergency that requires immediate operative repair regardless of the patient's hemodynamic status. Furthermore, vital signs may be misleading because patients can lose up to 15% of their blood volume without any appreciable change in their pulse rate or blood pressure. If the aneurysm initially ruptures freely into the peritoneal space, patients usually exsanguinate before they can seek medical attention.

Patients with a ruptured AAA may also present with either an aortoenteric or an aortocaval fistula, although both are relatively rare. Patients with an aortoenteric fistula may present with massive intestinal bleeding, but often present with a "sentinel" bleed that is small volume. The aorta may rupture through any portion of the bowel, although the duodenum and proximal small bowel are the most common sites. The overwhelming majority of aortoenteric fistulae result from the erosion of a prosthetic graft into the adjacent bowel (secondary aortoenteric fistula) rather than from an unrepaired aneurysm (primary aortoenteric fistula). The diagnosis of an aortoenteric fistula must be ruled out in all patients with gastrointestinal bleeding who have either an AAA or a previous infrarenal aortic repair.

Patients with an aortocaval fistula generally present with high-output congestive heart failure, a continuous abdominal bruit, and edema of the lower extremities.

Several imaging studies are available to establish or confirm the diagnosis of an AAA. Indeed, the introduction of endovascular techniques for aneurysm repair has resulted in an evolution of these modalities. The generic imaging goals for patients with an AAA are to establish the diagnosis and determine the presence of rupture, the cephalad/caudal extent of the aneurysm, the feasibility of endovascular repair, the presence of other visceral pathology or anatomic variants that would complicate operative repair, such as a left-sided vena cava and/or a horseshoe kidney. Although no imaging study satisfies every objective, ultrasound has emerged as the ideal *screening* study with CT arteriography being the definitive *diagnostic* study and the preferred modality for operative planning.

Abdominal ultrasound is a safe, simple, and readily available method of detecting AAAs (**Fig. 94.3**). It is relatively inexpensive and does not require the use of ionizing radiation or intravenous contrast. The sensitivity of ultrasound for detecting AAAs is acceptable, and the technique is reproducible within 0.3 cm in experienced hands.[54] However, the technique is quite operator dependent and potentially confounded by the presence of bowel gas or extreme obesity. Ultrasound can accurately image the infrarenal aorta to its bifurcation but is less reliable for imaging the portions of the aorta proximal to the renal arteries and distal to the common iliac vessels. Furthermore, it is not as reliable as CT for differentiating a ruptured from an intact aneurysm. Further, it is a useful technique to follow patients with small aneurysms (<4 cm) when the exact measurement is not crucial.

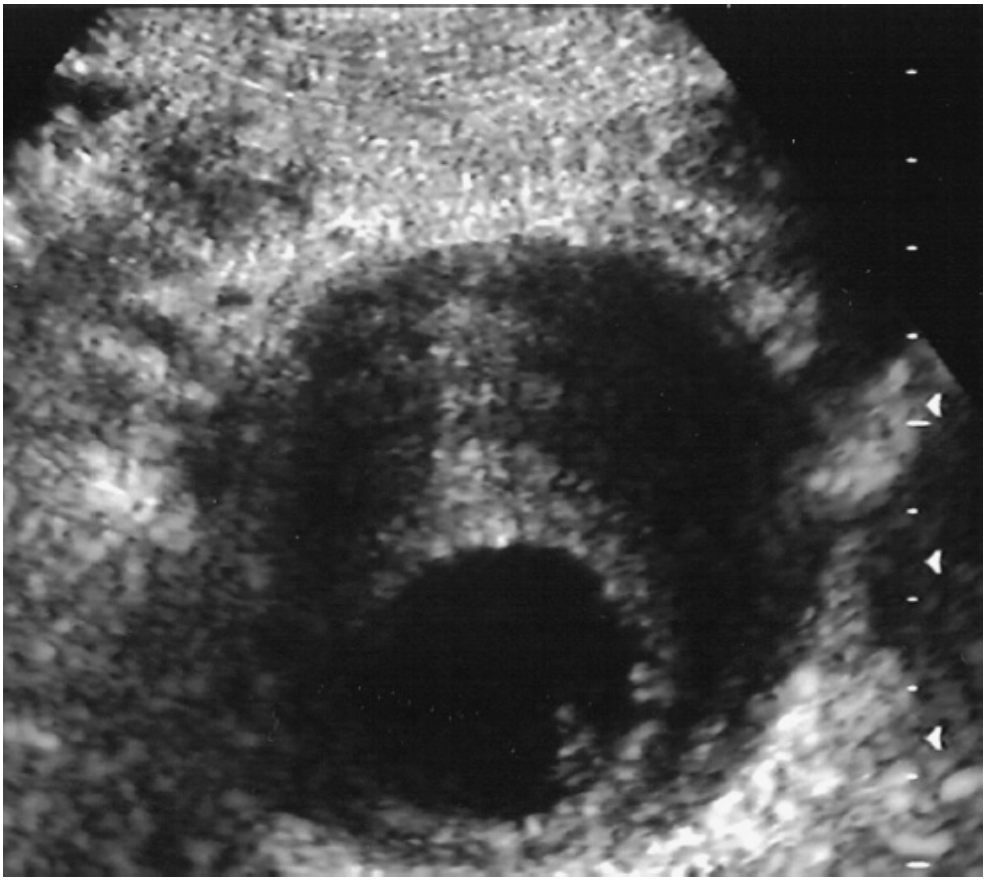

Figure 94.3 B-mode ultrasound image showing a transverse view of an infrarenal abdominal aortic aneurysm. Note the vessel wall and the large quantity of intraluminal clot surrounding the smaller, blood-filled center (*dark circle*).

5 CT arteriography overcomes many of the limitations of ultrasound and represents the current "gold standard" for imaging patients with AAAs (**Fig. 94.4**). The downside of CT is the greater expense and the potential harm that may be caused by ionizing radiation and intravenous contrast. Indeed, the evolution of EVAR and the required follow-up imaging studies have focused increased attention on the magnitude of long-term radiation injury. It is worth noting that the radiation dose associated with an abdominopelvic CT scan is 10 to 20 mGy while that for a routine chest radiograph is only 0.5 mGy. The incidence of allergic reactions to the contrast may be reduced by a steroid preparation while concerns regarding intravenous contrast-induced nephropathy remain debatable.[55] Of course, the renal risks can be avoided altogether by not using contrast. However, the quality of the noncontrast images is generally not useful for determining eligibility for endovascular repair. CT is very sensitive for detecting both

intact and ruptured aneurysms, and the images are reproducible within 0.2 cm.[56] The quality of the CT images has continued to improve with each new generation of scanners, and the image acquisition times have decreased. Given the quality and ease of imaging, CT arteriograms have essentially replaced traditional catheter-based diagnostic arteriograms for evaluation of aneurysms. Using axial CT images and 3D imaging software, a 3D image of the aorta can be obtained that allows measurements along the centerline of blood flow (**Fig. 94.5**), and dramatically improve the accuracy and consistency of sizing for EVAR.[57] CT is also helpful for detecting other intra-abdominal pathology or anatomic variants that may impact the operative approach. Specific concerns include the location of the left renal vein and other associated venous anomalies, the location and size of the kidneys, and the characteristics of the aneurysm wall. In addition, CT is the serial imaging study of choice when aneurysms exceed 4 cm and approach the threshold for intervention.

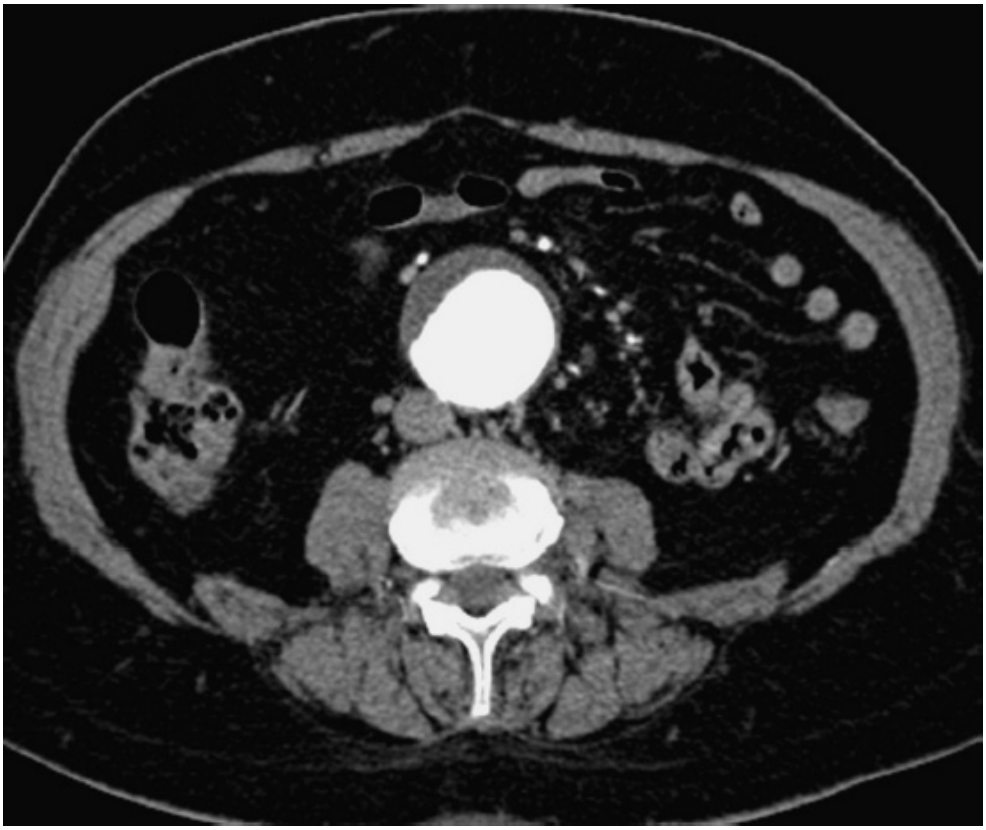

Figure 94.4 CT scan demonstrates a large abdominal aortic aneurysm. Note that the majority of the lumen is filled with contrast.

Figure 94.5 3D CT of the aorta and the iliac, femoral, and visceral arteries is shown. Note the infrarenal abdominal aortic aneurysm that extends to the aortic bifurcation.

Both magnetic resonance imaging (MRI) and catheter-based arteriography have been used as diagnostic imaging studies for patients with AAAs. The image quality and overall sensitivity of MRI is comparable to CT, but the technology is not as widely available and most surgeons are less familiar

with interpreting the images. Furthermore, the technique is relatively contraindicated for patients with ferromagnetic devices (e.g., pacemakers, joints) or renal insufficiency. Imaging of critically ill patients is also cumbersome, if not prohibitive.

Importantly, aneurysms are frequently diagnosed during catheter-based arteriography performed for other purposes, but this should not be viewed as a diagnostic test of choice for AAAs. An arteriogram only delineates the lumen of the vessels (i.e., aorta, iliac and femoral arteries), and thus gives no indication of aneurysm extent or diameter. AAAs are often filled with laminated thrombus and may have a relatively normal-appearing lumen. The "lumenogram" produced by the contrast reflects the patent lumen rather than the actual cross-sectional diameter of the aneurysm.

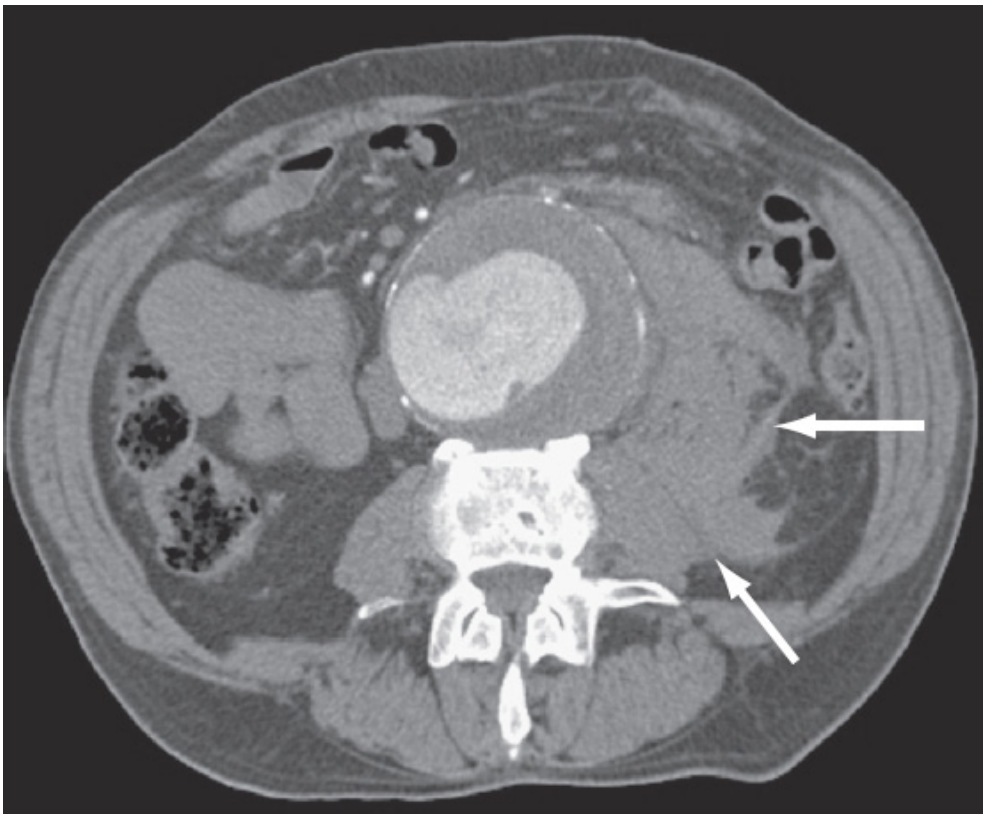

Figure 94.6 Contrast CT demonstrates a ruptured abdominal aortic aneurysm. Note the large retroperitoneal hematoma and the loss of the normal fat plane anterior and lateral to the left psoas muscle.

The diagnostic approach and initial treatment for patients with a potential ruptured aneurysm merit further comment. Because of the high attendant

mortality rate, prompt diagnosis and repair are necessary. In a study from the Cleveland Clinic Vascular Registry, the operative mortality rate associated with ruptured AAAs increased from 35% when the initial diagnosis was correct to 75% when incorrect.[58] A natural history study of patients with ruptured AAAs not offered operative repair reported that <15% of the patients died within 2 hours of hospital admission.[59] Based upon these findings, the authors concluded that most patients with ruptured aneurysms are sufficiently stable to undergo a CT scan and this opinion has been supported by improved mortality results of EVAR for ruptured aneurysms.

Several findings on CT are suggestive of a ruptured AAA including disruption of the calcium ring within the aortic wall, disruption of the aortic margins, retroperitoneal hematomas, mass lesions in the psoas region, displacement of the kidneys, abnormal soft tissues posterior to the aorta, effacement of the normal fat planes between the aorta and adjacent viscera, and abnormal retroperitoneal fluid collections (**Fig. 94.6**). Patients undergoing an emergent CT arteriogram to rule out a ruptured AAA should not receive oral contrast because of the delay associated with its administration and the confounding effects on the imaging of the vessels, especially if proceeding with an endovascular repair in short order.

The diagnosis of a ruptured AAA should be considered in elderly patients that present to the emergency room hemodynamically *stable* with abdominal or back pain. Admittedly, the differential diagnosis for abdominal or back pain in this patient population is extensive, and the incidence of a ruptured AAA is small. An expeditious history and physical examination can usually determine the cause of the pain. A pulsatile abdominal aortic mass, an unexplained low hematocrit, or hemodynamic instability before presentation are particularly worrisome and increase the level of suspicion. If ultrasound confirms the diagnosis of an aneurysm, further evaluation with CT should be obtained to rule out rupture. Alternatively, a CT may be obtained as the sole imaging study. Any findings consistent with a ruptured aneurysm on CT mandate direct transfer to the operating room for immediate repair. Aggressive fluid resuscitation should be avoided and mild hypotension (i.e., systolic pressure >80 mm Hg) tolerated in conscious patients due to the theoretical potential to cause the aneurysm to rupture into the peritoneal cavity and/or release the tamponade effect of the retroperitoneal tissue. If an intact aneurysm is found on CT without any suggestion of rupture, the next

logical question is whether the aneurysm is the source of the pain. Symptomatic aneurysms are likely associated with an increased risk of rupture although the natural history remains poorly defined. Patients with symptomatic/intact aneurysms ≥5 cm in diameter should be admitted to a monitored setting and scheduled for urgent operative repair provided no alternative causes for the pain are identified. Additional sources of the abdominal pain should be sought in patients with aneurysms smaller than 4 cm in light of the small rupture risk. The appropriate treatment for patients with aneurysms 4 to 5 cm is less clear. These aneurysms have the potential to rupture although the risk is very small. It is recommended that these patients be admitted and the source of their pain further investigated.

The role of screening for AAAs in asymptomatic patients is somewhat controversial given that screening in select populations has been shown to decrease aneurysm-related mortality yet increase the number of invasive procedures exposing patients to additional risks.[54] The United States Preventative Task Force has issued a position statement advocating a single screening ultrasound in males 65 to 75 years of age who have a smoking history and selective screening for males without smoking history.[54] These recommendations were based upon the results of a best-evidence systematic review of 50 studies, 17 of which were randomized controlled trials. Notably, the Preventative Task Force stated that the literature did not substantiate screening for women who have never smoked and have no family history of AAA and the literature was insufficient to make a recommendation for women aged 65 to 75 years who have smoked or have a family history of AAA. The American Heart Association and American College of Cardiology do not recommend screening in women[60]; however, the Society for Vascular Surgery advocates for screening in women older than 65 years who have tobacco history or family history of AAA.[61] Medicare currently pays for a single screening ultrasound as part of the Welcome to Medicare physical examination for men who have smoked sometime during their life and for both men and women with a family history of AAAs.

OPERATIVE INDICATIONS

All patients with symptomatic or ruptured AAAs should undergo operative repair unless they have an underlying medical condition that precludes long-term survival or their quality of life is not sufficient to justify the intervention. The latter situation entails a difficult decision, but not offering operative repair should be considered in certain cases (e.g., a debilitated, demented patient in a nursing home) after discussion with the patient and/or family.

6 The operative decision-making process for intact/asymptomatic AAAs is a complex one that needs to be tailored to the individual patient. Indeed, there is no single parameter that merits repair. The operative indications are contingent upon the size of the aneurysm, life expectancy, comorbidities, preference, and anatomic configuration. It is important to remember that the repair of an intact/asymptomatic AAA is a prophylactic operation that represents a balance between the operative risk and the future risk of rupture with the ultimate treatment goals to prolong life, relieve symptoms, and prevent rupture.

7 The diameter of the AAA is the best predictor of rupture as stated above and has been used as the most common indication for repair. The Joint Council of the American Association for Vascular Surgery and the Society for Vascular Surgery have released updated guidelines for the treatment of patients with AAAs.[61] They recommend that a diameter of 5.5 cm is an appropriate threshold for repair in the "average patient" with an intact infrarenal aneurysm, but emphasize the importance of individualizing each case. They state that rapid aneurysm expansion (>1 cm/yr), symptoms related to the aneurysm, and female gender merit repair at a smaller diameter, while consideration should be given to earlier repair in young patients provided that the operative mortality rate is acceptable. Furthermore, they recommend that a larger diameter threshold is appropriate in higher-risk patients and emphasize that there does not appear to be any justification to alter the operative threshold for the endovascular approach.

There is some controversy regarding the management of patients with aneurysms that are 4 to 5.5 cm. Both the UK Small Aneurysm Trial[34] and the ADAM Trial[25] concluded that it was safe to follow patients with 4 to 5.5 cm aneurysms and that early operation did not confer any long-term survival benefit. As noted above, the rupture risk for patients in the surveillance group was <1%/yr. It is important to note that more than 60% of the patients in both

studies ultimately underwent operative repair despite their initial randomization. A longer-term follow-up study from the UK Small Aneurysm Trial extending to 12 years did not demonstrate a survival benefit for the patients assigned to early surgery.[62] However, it is important to note that almost all of the patients that survived ultimately required repair since their aneurysms continued to grow and exceed the 5.5-cm threshold. Indeed, the relevant question may not be whether patients with small aneurysm need to be repaired, but rather when they need to be repaired. The proponents of smaller diameter-based thresholds for repair (i.e., <5.5 cm) have justified their approach stating that even small aneurysms rupture, aneurysms continue to increase in diameter and will likely need to be repaired, the patients' medical conditions will likely deteriorate with age, and the operative mortality/morbidity rate for small aneurysms may be less. In addition, the significant decrease in the perioperative mortality rate after EVAR have also challenged the threshold diameter for operative repair. However, Finlayson et al.[63] used a decision analysis model to determine the optimal diameter for open repair and EVAR and concluded that the endovascular approach lowers the operative threshold only for older patients in poor health. Although the level 1 evidence does not support this lower threshold, it is important to note that the size discrepancy between a 5.2-cm and a 5.5-cm aneurysm is very small and likely within the resolution of the imaging study.

The presence of medical comorbidities predictably impacts the perioperative mortality rate and threshold for repair. Steyerberg et al.[64] identified several independent risk factors for operative mortality during open repair, including renal insufficiency (creatinine >1.8 mg/dL, congestive heart failure, ECG ischemia, pulmonary dysfunction, older age, and female gender) and these have remained consistent throughout the literature. Similarly, Beck et al.[65] developed a predictive model for both open and endovascular repair using a prospective registry from the Vascular Study Group of New England. They reported that COPD, suprarenal aortic clamp, renal insufficiency, and advanced age (≥70) were predictive of mortality at 1 year after open repair with the mortality ranging from 1% to 67% depending upon the number of risk factors. Congestive heart failure and larger aneurysm diameter (≥6.5 cm) were the only predictive factors after endovascular repair with the mortality ranging from 4% to 23%. The consistent, dramatic impact of renal insufficiency was further emphasized by a national series that

reported a nine-fold increase in mortality. Notably, the estimated glomerular filtration rate may be a better index of renal function than serum creatinine and, therefore, likely a better predictor of adverse outcome. Life expectancy is inseparable from comorbidities, but it should be noted that the average life expectancy for a 60-year-old and an 85-year-old man in the United States is 18 and 5 years, respectively.

Patient preference should also be factored into the operative decision process. Patients may not be willing to accept the small, finite risk of rupture from a <5.5-cm aneurysm and thus desire to have their aneurysm repaired at a lower threshold. Indeed, patients often echo the justification for early repair proposed by surgeons.

The anatomic configuration of the aneurysm and/or the associated structures should factor into the operative decision process as well. Any technical factors that complicate the repair likely increase the perioperative mortality/morbidity including the need for suprarenal clamp application with subsequent renal/visceral ischemia, venous anomalies (e.g., left-sided vena cava), renal anomalies (e.g., horseshoe kidney), and inflammatory aneurysms. Admittedly, many of these technical concerns are relevant only to the open approach and can be overcome/avoided by endovascular repair provided that it is an option from an anatomic standpoint. Anatomic concerns relevant to endovascular repair include continued aneurysm degeneration of the aortic neck or iliac arteries that may make standard infrarenal endograft repair more difficult or impossible unless early repair is undertaken.

Patients that do not meet the threshold for operative repair should be followed closely. It is important to educate the patients about their underlying disease process and emphasize the importance of long-term follow-up. Notably, Valentine et al.[66] reported that 32% of patients with small aneurysms managed by “watchful waiting” were noncompliant with their follow-up plan. Furthermore, it is important to counsel patients about the presence of symptoms associated with rupture and the importance of seeking urgent medical attention. Guidelines have suggested that patients with aneurysms <3 cm in diameter should be reimaged at 5 years while those with between 3 and 3.4 cm should be reimaged at 3 years and those between 3.5 and 4.4 cm should be reimaged at 1 year. Aneurysms >4.5 cm should be reimaged every 6 months.[67] It is important to note that up to 50% of the patients deemed a prohibitive operative risk and not offered elective repair

will ultimately die from a ruptured aneurysm.[68] The patients who are not candidates for elective repair should not be offered emergent repair in the event that their aneurysm ruptures or becomes symptomatic and must be counseled on this matter preemptively.

CHOICE OF OPEN OR ENDOVASCULAR REPAIR

After the decision to recommend operative repair has been made, the technique for repair needs to be determined. Admittedly, these decisions are somewhat interrelated since the decision to recommend operative repair in certain subsets of patients is oftentimes contingent upon whether they are candidates for an endovascular approach. The past several decades have witnessed a rapid evolution of the endovascular technique, and, indeed, this evolution has helped define our discipline. It has been clearly demonstrated that the technical success rates for endovascular graft repair are excellent and the need for intraoperative conversion to open repair negligible. The perioperative events and long-term outcomes have been defined by level-1 evidence. Many of the technical limitations inherent to the earlier endovascular devices and anatomic limitations have been overcome. Despite a lack of long-term overall survival advantage compared to open repair, the endovascular approach for treatment of AAAs has been widely 8 applied.[69] Indeed, the endovascular approach eclipsed open repair in the United States in 2005 and data shows that more than 75% of aneurysms are repaired in this manner.[70] The choice of open or endovascular repair is complicated and contingent upon several factors including feasibility, outcome, comorbidities, compliance, cost, and preference. It is imperative that these issues, including their respective advantages/disadvantages, be addressed with patients preoperatively to ensure proper informed consent.

The initial determinant of the approach is the anatomic configuration of the aorta, the aneurysm, and the access vessels. The commercially available endovascular devices come in a finite range of sizes and, thus, are suitable only if specific anatomic conditions are satisfied. Although the number of available devices and their specific characteristics are constantly evolving,

the “generic” endograft consists of a fabric graft (i.e., polyester or ePTFE) and a metallic endo/exoskeleton (i.e., stainless steel or nitinol) that facilitates proximal/distal fixation by the radial force of the stent (**Fig. 94.7**). In some devices, proximal fixation is augmented by the presence of suprarenal hooks. The “generic” devices are modular and consist of either two (main body and contralateral iliac limb) or three (main body, contralateral iliac limb, ipsilateral iliac limb) components with a variety of additional ancillary pieces that allow proximal or distal extensions at the aortic and iliac ends, respectively. The current strategy is to seat the proximal component of the bifurcated system as close to the lowest renal artery as possible and the distal components as close to the iliac bifurcation as possible to improve immediate seal and fixation and decrease the potential for later aneurysm degeneration at or adjacent to seal sites.

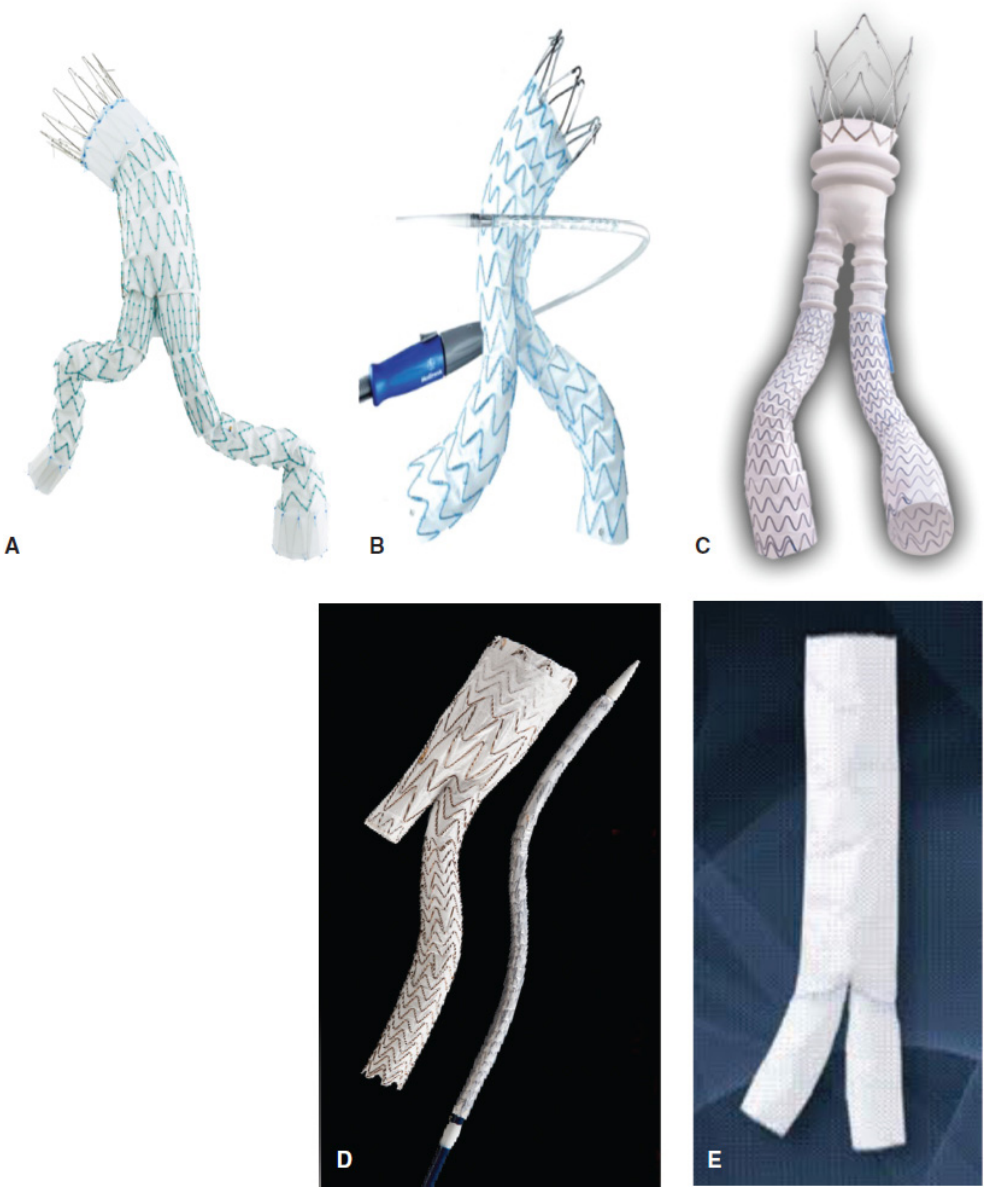

Figure 94.7 Some of the current commercially available infrarenal endografts in the United States are shown: Cook Zenith (**A**); Medtronic Endurant (**B**); Trivascular Ovation (**C**); Gore Excluder (**D**); Endologix AFX (**E**). These are modular devices consisting of a main body, iliac limbs/extensions, and main body extensions. Note the common theme of bilateral iliac limbs and a main body. There are many differences between these endografts, which make them each uniquely suited for some patients. Some devices (**A–C**) utilize a bare suprarenal stent construct to facilitate proximal fixation. Other devices do not have a suprarenal stent component but rather utilize active fixation with hooks (**D**) or anatomic fixation at the aortic bifurcation (**E**).

Although there is some variability among the commercially available devices in terms of their specific sizes and anatomic constraints, the general

anatomic requirements are somewhat similar. The infrarenal abdominal aorta must have a suitable, nonaneurysmal landing zone for the endograft that measures ≥10 to 15 mm in length and ≥17 mm but ≤32 mm in diameter (ranges reflect differences between the commercial devices). Furthermore, the proximal neck angle should be ≤60 degrees for most devices (≤75 to 90 for some newer devices), as measured by the intersection of the centerline of the infrarenal aorta at the landing zone site and the centerline of the aneurysm through the aortic bifurcation. Newer devices do allow for more neck angulation, but the operating surgeon should keep in mind that more infrarenal neck may be required in more severely angulated necks to allow for appropriate seal and fixation of the device. The infrarenal neck should be relatively free of thrombus and calcification to facilitate a seal at the implantation site. In general, a longer the infrarenal neck length equates to longer device seal zone and improved durability. The iliac artery should have a suitable landing zone ≥20 mm with an associated diameter between 7 and 20 mm to facilitate both anchoring the graft and passing the main device into the aorta. The distal landing zone for the iliac limbs is usually in the common iliac artery although the anatomic constraints with regard to the size of the access vessels and the introduction of the devices are relevant for both the common and external iliac vessels.

A variety of techniques have been described to overcome the anatomic limitations of the endovascular approach, thereby extending its feasibility. Indeed, some modification has been described to overcome almost every anatomic contraindication. Unfortunately, extending the indications for endovascular repair beyond those recommended by the manufacturers (i.e., instructions for use [IFU]) has been associated with an increase in the incidence of adverse events and a higher need for reintervention.[71] For those with short (≥4-mm) infrarenal necks, fenestrated endografts have been commercially available since 2012 with excellent midterm results.[72] Details regarding this technique/device are discussed later in the juxtarenal section of this chapter. EndoAnchor systems have been employed in those with short necks (≥4 mm and <10 mm) although long-term data using this technique is lacking.[73] Stenosis within the access vessels can be overcome by dilation (i.e., balloon angioplasty, serial dilators) or by the use of an open prosthetic conduit or endovascular stent graft conduit.[74] The open prosthetic conduit is usually anastomosed to the bifurcation of the common iliac artery and then

tunneled through the retroperitoneal space below the inguinal ligament. Alternatively, an aorto-uni-iliac endograft can be configured and a femoral–femoral bypass performed.

Aneurysm degeneration of the common iliac artery can be overcome by a variety of techniques including simply using larger-diameter graft limbs, occluding/embolizing the internal iliac artery, and seating the iliac limb in the external iliac artery, bypassing the internal iliac artery (and seating the iliac limb in the external iliac artery), or with an iliac branch endoprosthesis. Although relatively simple to perform, internal iliac artery embolization has been associated with a moderate incidence of complications including buttock/thigh claudication (30% to 40%), sexual dysfunction, neurologic deficit/paraplegia, pelvic ischemia, and gluteal compartment syndrome.[75] The claudication improves with time in the majority of patients, but can be quite debilitating. Many of the other complications, although somewhat rare, can be catastrophic. Because of these concerns, concomitant bilateral internal iliac artery occlusion/embolization should be avoided when possible. Iliac branch endoprostheses have been commercially available since 2016 and have demonstrated excellent midterm outcomes in preserving internal iliac artery flow yet providing aneurysm sac exclusion by extension into the external iliac artery.[76] Their main limitation remains somewhat stringent anatomic requirements for their application.[77] Nonetheless, this technology advancement has certainly changed the manner with which aneurysmal disease involving the common iliac artery is managed.

Consideration of the perioperative and long-term outcomes after EVAR requires introduction of the concepts of endoleak and endotension. Simply, endoleak is the perfusion of the aneurysm sac outside the lumen of the endograft while endotension is the persistent pressurization within the excluded aneurysm sac. Approximately 10% to 20% of patients develop an endoleak during the first year after endovascular repair.[78] Admittedly, not all of these require remediation. Endoleaks have been classified as types 1 through 4 based on the mechanism of the leak (**Fig. 94.8**). Type 1 leaks originate at either the proximal or distal attachment sites. Type 2 leaks come from branch vessels, such as the lumbar or inferior mesenteric arteries. Type 3 leaks are caused by fabric tears or problems at the graft interfaces of the modular devices, whereas type 4 leaks are usually transient (<24-hour) transgraft extravasations that result from the porosity of the graft and needle

holes. It should be emphasized that the entire concept of an endoleak is predicated on the ability to detect contrast or blood flow outside the lumen of the endograft and is, therefore, contingent on the sensitivity and specificity of the various imaging techniques. The major concern about both endoleaks and endotension is that the pressure transmitted to the aneurysm wall may cause the aneurysm to expand and/or rupture. The clinical significance of the various endoleak types is quite different. Both type 1 and 3 endoleaks are considered major adverse outcomes associated with an increased risk of rupture, and they merit reintervention.[79] Type 2 endoleaks are generally considered less worrisome in terms of their rupture risk although they are associated with an increased risk for reintervention. They can generally be followed with serial imaging studies, but merit evaluation/intervention if the aneurysm sac continues to enlarge. Type 4 endoleaks are self-limited and benign. The clinical significance of endotension is likewise unresolved. Indeed, the concept itself is somewhat ambiguous given the limitations of actually measuring the pressure within the aneurysm sac. It should be noted that freedom from endoleak does not necessarily mean freedom from endotension given the observation that aneurysms can continue to enlarge in the absence of an identifiable endoleak. Aneurysm-related reinterventions occurred in 3.7% of patients per year after EVAR from 2001 to 2004 in the Medicare population.[80] The majority of these remedial procedures are minor endovascular procedures, however with a risk of major open procedures of 0.4%/yr.[81] In contrast, open aneurysm repair is associated with a less than 1%/yr incidence of aneurysm-related complications that require remedial procedures in long-term follow-up. Graft-related deaths have been reported in 2% of patients at 15 years.[82]

Perioperative complication rates appear to be lower after endovascular repair. As noted above, the randomized, controlled DREAM and EVAR Trials reported a significant decrease in the perioperative mortality rate (DREAM—1.2% vs. 4.6%; EVAR Trial—1.7% vs. 4.7%).[41,42] The EVAR Trial also reported a trend toward a decrease in the combined operative mortality/*severe* complication rate (9.8% vs. 4.7%, $p = 0.10$). Multiple clinical trials have reported that the overall major complication rates after both endovascular and open repair are approximately 15% although the magnitude of the complications is less for the endovascular approach and primarily includes vascular access complications (e.g., hematoma, femoral

artery injury). These clinical trials have likewise demonstrated that the total hospital length of stay, intensive care unit length of stay, operative blood loss, and time necessary to resume normal activities are all less for the endovascular approach. Interestingly, the impact on sexual function remains unresolved. A survey of the DREAM participants demonstrated that sexual dysfunction was common after both endovascular and open repair, but returned to the baseline state at 3 months for both groups.[83] In contrast, Xenos et al. reported significantly less orgasmic and erectile dysfunction after endovascular repair.[84]

The long-term results after the EVAR and DREAM Trials have failed to document any significant benefit for the endovascular approach in terms of almost every outcome measure analyzed.[69] In the DREAM Trial, there was no difference in all-cause mortality at 12 years (survival, open—42.2%, EVAR—38.5%).[85] More concerning, the EVAR Trial showed worse overall and aneurysm-related mortality beyond 8 years for those undergoing EVAR (overall mortality: EVAR—53% vs. Open—46%; aneurysm-related mortality: EVAR—5% vs. open—1%).[86] These outcomes were presumably driven by secondary aneurysm rupture and increase cancer-related mortality in the EVAR group.

In the EVAR Trial, costs (EVAR—£13,257, open—£9,926) were significantly greater for the endovascular approach while there were negligible differences in the quality of life assessments.[87] However, the OVER Trial showed no difference in total healthcare costs between open and endovascular repair after 2 years.[88] The cost savings from a shorter length of stay and lower incidence of major perioperative complications with an endovascular approach are offset by the device costs. In fact, device costs reflect about 40% of initial hospitalization costs after endovascular repair.[89] It is important to note that most of the analyses have focused on the hospital and device-related costs, but have failed to include the associated professional fees and the costs associated with long-term follow-up and reintervention, all of which may be substantial.

These long-term results from the DREAM and EVAR Trials are somewhat sobering. It is clear that the endovascular approach is not as secure a repair as the traditional, open alternative. The endovascular repair is associated with ongoing rupture risk that likely approaches 1%/yr.[81,90] The rupture risk has been associated with poor patient selection, operator error,

unrecognized/untreated endoleaks, large aneurysms, and device migration.[81] Interestingly, the mortality rate associated with rupture after endovascular repair may be less than for de novo ruptures.[90]

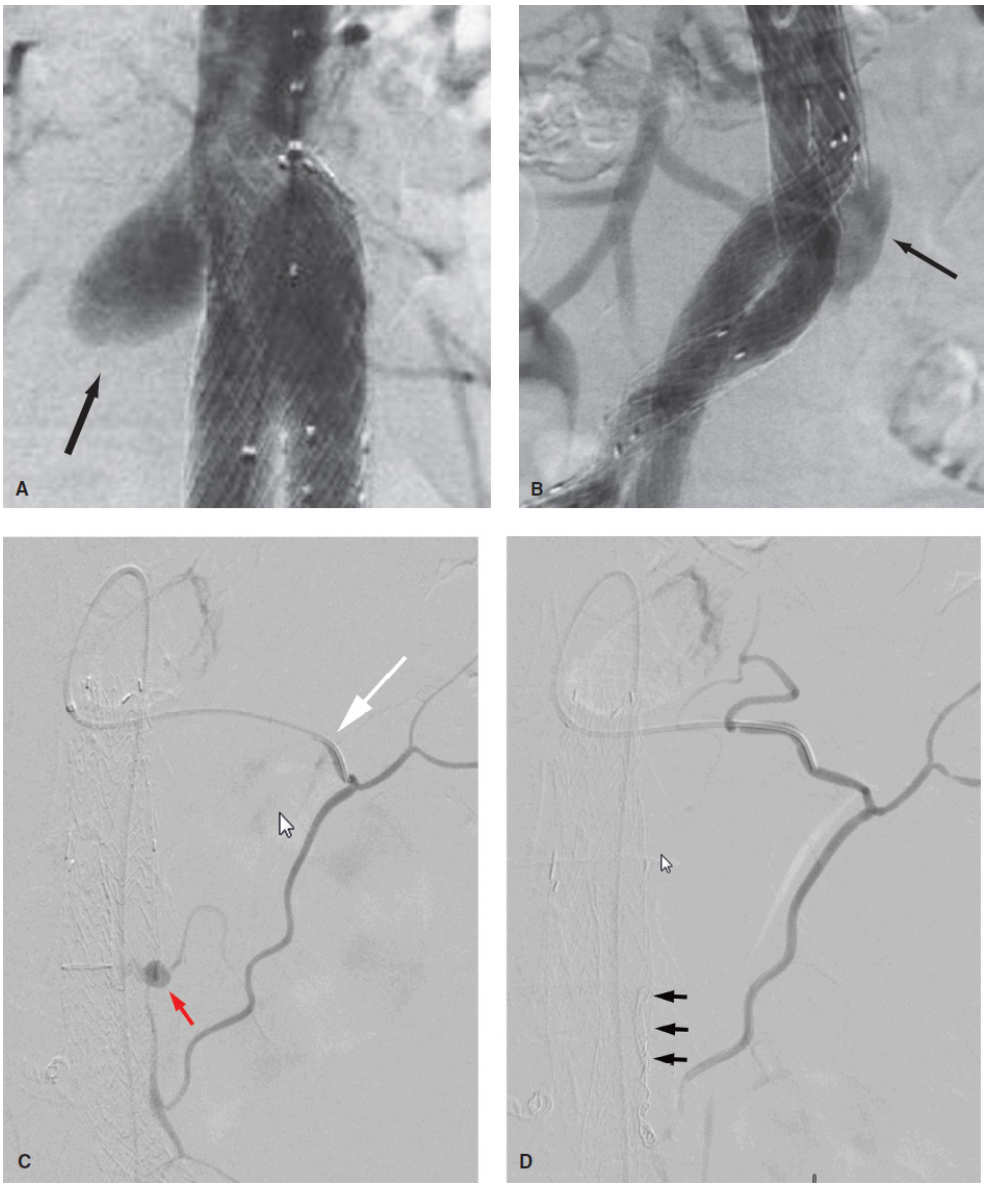

Figure 94.8 Type 1 to 4 Endoleaks. Type I and III represent the most dangerous forms of endoleaks, and represent what is essentially an unrepaired aneurysm. **A:** Type I leaks originate at either the proximal (Ia) or distal (Ib) attachment sites. Note the large blush of contrast outside of the graft lumen at the proximal fixation site, demonstrating a type Ia endoleak. **B:** Type 3 endoleaks are caused by fabric tears or problems at the graft interfaces of the modular devices. Note the contrast blush outside of the lumen of the graft at the modular interface. Type II endoleaks generally have a more benign natural history, but can cause aneurysmal growth and rupture. **C:** Demonstrates an inferior mesenteric arteriogram from a catheter (*white arrow*) in the meandering mesenteric artery. Filling of the aneurysm sac through a patent inferior mesenteric artery (*red arrow*) is evident. **D:** Demonstrates successful embolization of the IMA with coils demonstrated by *black arrows*. Note no further filling of the aneurysm sac.

The presence of significant comorbidities and advanced age favors the endovascular approach. Chronic renal insufficiency is not an absolute contraindication to endovascular repair as the procedure can be performed without contrast by using intravascular ultrasound (IVUS) or CO_2 as the contrast agent. Of note, both open and endovascular repair are associated with a long-term decrement in renal function.[91] In general, the endovascular approach may allow a subset of patients not considered suitable candidates for an open operation to have their aneurysms repaired. The EVAR Trial 2 randomized patients not fit for open repair to expectant management or endovascular repair and demonstrated no difference in aneurysm-related mortality, all-cause mortality, or quality of life.[92] Notably, the patients were truly "high risk" with a perioperative mortality rate of 9% and a 4-year mortality rate of almost 40%.

The known device-related complications and the uncertainty about the long-term outcome after endovascular repair mandate indefinite surveillance, although the intervals and type of imaging for surveillance remain controversial. Patients must agree to comply with the prescribed protocol and their ability to fulfill these expectations should be factored into the specific choice of procedure. It is important to note that although the incidence of complications declines with the number of negative postoperative CT scans, new endoleaks have been discovered many years after device implantation. Similarly, it is imperative that all surgeons that offer EVAR provide conscientious, long-term follow-up.

Despite the various advantages and disadvantages of the approaches outlined above, patients and providers seem to prefer the endovascular approach and these preferences appear to be one of the driving forces for the widespread application of the technique. Indeed, it is uncommon for patients that are candidates for either approach to elect open repair. Notably, Williamson et al. reported that 18% of all patients undergoing open repair would not undergo the procedure again.[93] The potential to perform the endovascular repair completely percutaneously (i.e., no femoral artery exposure) clearly adds to the appeal of the approach.

The proverbial "bottom line" for the open versus endovascular debate remains somewhat unresolved, but the discussion is merely academic at this point. EVAR, when anatomically possible, has essentially become the

standard of care in most practices despite all the aforementioned data suggesting equivocal results. The trend toward dominance of EVAR over open repair has increased to a point where many vascular training programs are having difficulty with finding enough open aneurysm cases to sufficiently educate their trainees.[94]

OPERATIVE REPAIR

Preoperative Evaluation

The preoperative evaluation of patients undergoing elective AAA repair is similar to that of patients undergoing any major general or vascular surgical procedure. Patients undergoing endovascular repair should likely undergo the same preoperative work-up despite the perception that associated perioperative stresses are less. All patients should receive a complete history and a physical examination, electrocardiogram, and a chest radiograph. Routine preoperative laboratory studies should be obtained and the appropriate quantity of blood products cross-matched. A thorough peripheral pulse examination should be included in the physical examination and validated with formal ankle–brachial indices. In addition, patients should be started on an aspirin and a statin (HMG Co-A reductase inhibitors). The perioperative use of beta-blockers in patients undergoing noncardiac surgery has been controversial. The most updated recommendations from the ACC/AHA in 2014 state that beta-blockers should be continued in patients who have been on these agents chronically.[95] The initiation of the beta-blockers should be *considered* in those patients who have ≥three cardiac risk factors (diabetes, heart failure, CAD, renal insufficiency, prior stroke), but these agents should *not* be started on the day of surgery as this is associated with increased adverse events. Beta-blockers have uncertain benefit in those without significant cardiac risk factors.[95]

All active medical problems should be controlled as well as possible before elective aneurysm repair. However, extensive diagnostic testing is probably unnecessary. Routine pulmonary function tests and measurement of arterial blood gases are not indicated, although they may be beneficial in selected patients with advanced COPD. The presence of COPD often

complicates postoperative ventilator management, but it is unusual for a patient's pulmonary disease to be sufficiently severe to preclude operation.[96]

The appropriate cardiac work-up before AAA repair is evolving and is somewhat institution dependent. This controversy has been further complicated by the publication of the CARP Trial that examined the role of coronary artery revascularization before major vascular surgery among patients with significant coronary artery disease.[97] Notably, the study reported that preoperative coronary artery revascularization did not reduce the incidence of either perioperative myocardial infarction or long-term mortality. It is important to emphasize that the overall objective of the preoperative cardiac work-up is to optimize the cardiovascular system and thereby reduce both the perioperative and long-term risk of myocardial infarction and death. Admittedly, the prevalence of coronary artery disease among patients undergoing AAA repair is quite high. Hertzer et al., in a landmark publication, reported that 25% of 1,000 patients undergoing evaluation for peripheral vascular surgery (cerebral vascular occlusive disease, lower extremity arterial occlusive disease, AAA) had severe, surgically correctable lesions detected during cardiac catheterization; 6% had severe, uncorrectable disease, and only 8% had no evidence of disease. Interestingly, the incidence of surgically correctable disease was highest among patients undergoing evaluation for AAA.[98] The ACC/AHA Guidelines have simplified the preoperative evaluation before elective vascular procedures for patients with risk factors for stable coronary disease.[95] Briefly, a patient's estimated perioperative risk of major adverse cardiac event should be calculated using combined clinical and surgical risk factors. The American College of Surgeons NSQIP risk calculator (https://riskcalculator.facs.org/RiskCalculator/) can be used. If elevated risk, the patient's functional capacity then determines the need for additional cardiac testing. More specifically, patients who can generate at least four metabolic equivalents (METS) can proceed without additional testing. Those patients with poor (<4 METs) or unknown functional capacity should undergo pharmacologic stress testing with coronary catheterization/revascularization as indicated before surgery. Notably, there is insufficient evidence to support a reduced cardiac work-up for patients undergoing endovascular repair.[99] It is important to emphasize that although

the cardiac risk of endovascular repair may be less, the subset of patients undergoing the procedure are often older and sicker.

Open Repair of Intact Abdominal Aortic Aneurysms

Technique

A significant amount of preparation is required in the operating room before making the incision. Adjunctive epidural anesthesia has been associated with improved survival along with reduced immediate postoperative events although the direct explanatory mechanism for this finding remains unclear.[100] Adequate intravenous access should be established to facilitate resuscitation. Central venous access is usually obtained although not necessary. Electrocardiographic leads, an arterial catheter, and a Foley catheter should be placed for continuous monitoring of the electrocardiogram, arterial pressure, and urine output, respectively. In addition, a nasogastric tube should be inserted. A Swan–Ganz pulmonary artery catheter or a transesophageal echocardiogram probe should be inserted in patients with heart failure. Peripheral arterial pulses should be interrogated with either palpation or continuous-wave Doppler ultrasound and marked to facilitate confirmation after restoration of lower extremity perfusion. Strategies to maintain core body temperature should be initiated. Bush et al. reported that hypothermia (<34.5°C) during AAA repair was associated with multiple physiologic derangements and adverse outcomes.[101] Of note, this does not pertain to thoracoabdominal aortic surgery where hypothermia has shown some benefits in spinal cord ischemia reduction.[102]

Use of an intraoperative autologous transfusion device should be considered. However, a meta-analysis reported that there is insufficient evidence to recommend its use during vascular surgery including aortic surgery.[103] These devices should likely be used when a significant amount of blood loss is anticipated, such as during suprarenal or thoracoabdominal aortic aneurysm repairs. Furthermore, they can be helpful in patients who object to blood transfusions on religious principles. A first-generation cephalosporin or vancomycin should be administered prior to the incision.

AAAs may be repaired through several different incisions or approaches including midline, retroperitoneal, or transverse/bilateral subcostal. The incisions or approaches must be viewed as complementary since neither is perfect for every clinical scenario. Indeed, surgeons should be familiar with the various approaches and select the optimal one for the clinical setting. The determinants of the incision include the cephalad/caudal extent of the aneurysm, body habitus, presence of prior abdominal incisions, presence of abdominal wall stomas, comorbidities, additional intraoperative pathology, inflammatory aneurysms, renal anomalies, requirements for concomitant procedures, urgency of aortic control, and surgeon preference. The midline approach is preferable for patients with ruptured infrarenal AAAs because aortic control at the level of the diaphragm can be obtained rapidly. The bilateral subcostal approach provides the best exposure and is the incision of choice for obese patients, those with extensive iliac artery aneurysms, those patients requiring concomitant renal artery revascularization, and those patients with juxtarenal aneurysms that require suprarenal aortic control. The retroperitoneal approach is optimal for patients with multiple previous abdominal incisions ("hostile abdomen"), abdominal wall stomas, suprarenal aneurysms, inflammatory aneurysms, and horseshoe kidneys. However, the retroperitoneal approach provides limited exposure to the right renal artery and right iliac vessels. It was previously contended that the retroperitoneal approach posed less of a physiologic insult than the transperitoneal approach and, therefore, was ideal for patients with advanced pulmonary or cardiac disease. However, this has not been supported by a prospective, randomized trial.[104] A detailed description of the retroperitoneal approach is beyond the context of this chapter, but is available in most standard vascular surgical texts.

The sequence of steps used to repair an intact, infrarenal AAA through a transperitoneal approach can be summarized (**Fig. 94.9**). The abdomen is explored after the peritoneal cavity is entered, and both the gallbladder and colon carefully examined. The small bowel is manually retracted laterally to the right, and the duodenum is mobilized by incising the ligament of Treitz. The inferior mesenteric vein may be suture ligated at this juncture to facilitate exposure. The tissue adjacent to the inferior mesenteric vein should be palpated to rule out a large, meandering mesenteric artery. This artery is an important visceral collateral and should be preserved. The

retroperitoneum over the aorta is incised with the electrocautery, and the left renal vein is exposed. Self-retaining retractors (e.g., Bookwalter, Omni retractors) are then placed to facilitate further exposure. The small bowel is retracted laterally to the right with the aid of malleable self-retaining retractors. The transverse colon and superior abdominal wall are retracted cephalad while the lower abdominal wall is further retracted caudal. The aorta immediately inferior to the renal arteries is exposed and both renal arteries visualized. The infrarenal aorta at this location is dissected to facilitate placement of an aortic clamp. It is important to identify the course of the renal vein and any venous anomalies on the preoperative CT scan to prevent inadvertently injuring these structures at this stage of the procedure. In the presence of a retroaortic renal vein or circumaortic collar, the aortic neck should not be dissected circumferentially and vascular control should be obtained with a vertical clamp. The retroperitoneum over the aorta is then incised further caudally and the incision extended along the course of the right common iliac artery. The extent of the caudal dissection depends on the anatomic configuration of the aneurysm. If the aneurysm extends to the aortic bifurcation, it is sufficient to dissect only the common iliac arteries provided a suitable site for clamp application is identified. If the aneurysm extends to the distal common iliac arteries, both the internal and external iliac vessels should be dissected free. This may be facilitated on the left side by mobilizing the sigmoid colon along its peritoneal reflection and reflecting it medially. The inferior mesenteric artery is then dissected free and vascular control obtained with a vessel loop. Patients are administered 100 units/kg of intravenous heparin, and the activated clotting time is confirmed to be twice the baseline value. Supplemental doses of heparin are administered throughout the procedure as dictated by the activated clotting time.

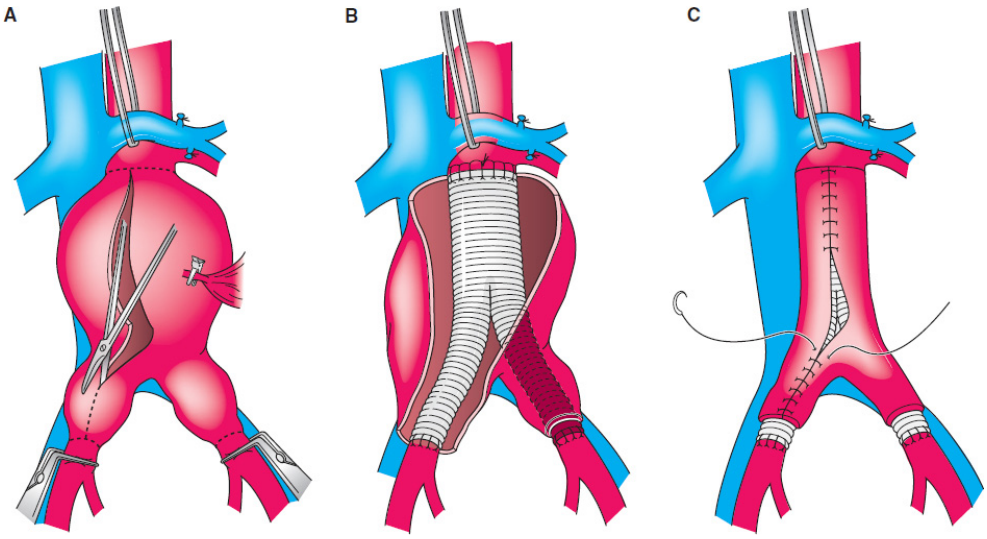

Figure 94.9 Steps involved in the standard repair of an infrarenal abdominal aortic aneurysm extending into the proximal common iliac arteries. **A:** The proximal duodenum is mobilized and the retroperitoneum overlying the aorta incised. The infrarenal aorta immediately below the renal vein is dissected. The iliac bifurcations are exposed, and vascular clamps are applied to the infrarenal aorta and distal common iliac arteries after adequate heparinization. A longitudinal arteriotomy is extended from the infrarenal aorta onto the right common iliac artery. **B:** Back bleeding from the lumbar arteries is controlled with "figure-of-eight" sutures. The proximal anastomosis is performed in an end-to-end configuration below the renal arteries. The distal anastomoses are performed at the common iliac bifurcation beyond the aneurysmal segments. The left limb of the graft is tunneled through the intact left common iliac aneurysm shell. **C:** The residual aneurysm shell is closed over the prosthetic graft, and the retroperitoneum is reapproximated to prevent erosion of the graft into the overlying bowel.

The appropriately sized prosthetic graft is selected. The graft diameter is sized according to the infrarenal aortic neck by visual inspection or with the calibrated graft rulers (i.e., "sizers"). The general "rule of thumb" is that the smaller graft should be selected when the aorta is between two graft sizes because the aorta always appears smaller after it is transected and redundant graft material at the proximal anastomosis is more difficult to correct than the opposite problem. A variety of vascular prostheses are available. Despite the contentions of the various manufacturers, there is no clear advantage for an individual graft and the choice should be determined by surgeon preference as dictated by ease of handling, cost, and availability.

The distal vascular clamps are applied to the external, internal, or common iliac vessels as indicated. Occasionally, the iliac vessels are so

calcified that they cannot be safely occluded with a clamp. Vascular control may be obtained intraluminally with the use of a balloon thromboembolectomy catheter after the aneurysm has been incised. The configuration of the aortic reconstruction (aortoaortic, aortoiliac, aortofemoral) depends on the extent of aneurysmal involvement and the degree of occlusive disease. Despite the fact that a patient may be a candidate for an aortic tube graft, it is often easier to perform an aorto-bi-iliac graft because the terminal aorta is often very calcified. Aorto-bi-femoral bypass grafts should be reserved for the small subset of patients who truly have concomitant aneurysms and severe occlusive disease since the risks of wound complications and graft infections are greater.

The proximal aortic clamp is then applied after the distal clamps. The clamp is applied immediately below the renal arteries to facilitate an anastomosis to the proximal infrarenal aorta. The length of the infrarenal aorta should be sufficient to permit a safe anastomosis. However, a long infrarenal cuff should be avoided because it may become aneurysmal over time. Either a vertical or horizontal aortic clamp may be used. The aorta is then incised longitudinally, and the incision is extended to the distal aorta and into the iliac arteries if the distal anastomosis will be to the iliac vessels. Attempts should be made to preserve the autonomic nerves overlying the distal aorta and proximal left common iliac artery in men. This can usually be achieved by incising the left common iliac artery transversely beyond the aneurysmal portion and tunneling the limb of the graft through the residual shell. The intraluminal thrombus and debris are removed from within the aorta, and all back bleeding from the lumbar arteries is controlled with suture ligatures. The atheromatous debris within the aorta has been reported to be culture positive in approximately 25% of cases although this has not been associated with long-term graft infections.[105] The infrarenal aorta at the level of the planned proximal anastomosis may be completely transected, or the back wall may be left intact. Completely transecting the aorta makes the proximal anastomoses slightly easier although leaving the back wall intact reinforces the anastomosis and provides the equivalent of an autogenous pledget. The proximal anastomosis is performed in an end–end configuration with a running 3-0 Prolene suture. All leaks in the suture line are repaired with Prolene sutures and felt pledgets as necessary. The distal anastomosis or anastomoses are performed to the aortic bifurcation, common iliac

arteries, or iliac bifurcation as dictated by the anatomy of the aneurysm. A 3-0 Prolene suture is used for anastomoses at the aortic bifurcation, and a similar 4-0 suture is used for the common iliac arteries.

All anastomoses are flushed to remove any intraluminal debris before flow is restored. Blood flow is restored to the pelvis and lower extremities in sequence. Attempts should be made to flush initially into the internal iliac circulation to prevent embolization to the lower extremities. This can be facilitated by manually compressing the common femoral arteries for tube graft configurations. The lower torso should be reperfused gradually (i.e., one extremity at a time) to prevent hypotension. It is imperative that the patient is resuscitated prior to reperfusion and it is frequently necessary to delay this process to allow the anesthesiologists, time to achieve this objective. Reperfusion of the ischemic tissue causes the release of acid, potassium, and a variety of inflammatory mediators and reactive oxygen species into the systemic circulation, all of which are potentially detrimental.

The inferior mesenteric artery may be reimplanted into either the body of the graft or the iliac limbs if it is patent. Alternatively, if there is robust back-bleeding from the inferior mesenteric artery, it is typically ligated. The colon and lower extremities should be interrogated with the Doppler ultrasound after reperfusion, and the heparin reversed with intravenous protamine sulfate after confirmation of adequate lower extremity signals. The protamine dose is estimated based on the effectiveness of protamine (1 mg of protamine/100 units of heparin). The protamine should be administered slowly to prevent any untoward hemodynamic events. The aneurysm sac and the overlying retroperitoneum are both closed with absorbable suture to provide a biologic tissue layer between the graft and the viscera. The retractors are then removed, the viscera are returned to their anatomic positions after inspecting their viability, and the abdominal wall fascia is closed with standard technique.

Patients are transferred directly from the operating room to the intensive care unit. Most of the patients are extubated in the operating room or shortly after arrival to the intensive care unit. The intensive care unit length of stay is usually 1 to 2 days, and the median total length of stay is 8 days.[40] Patients are encouraged to get out of bed and begin ambulating in the early postoperative period (i.e., 24 to 48 hours). Nasogastric decompression is continued until bowel function returns. Oral feedings are initiated after

removal of the nasogastric tube and advanced as tolerated. Patients are discharged when they are ambulatory, can tolerate a regular diet, have normal bowel function, and are sufficiently able to care for themselves. A subset of people requires transfer to rehabilitation or extended care facility. Patients are usually seen in the clinic 2 weeks after discharge and then at 6 months thereafter. Additional clinic appointments may be necessary as dictated by any ongoing postoperative problems. Furthermore, patients are discouraged from lifting heavy objects for the first 3 to 6 months to reduce the incidence of incisional hernias.

Complications and Outcome

Open repair of intact AAAs is associated with significant mortality and morbidity. The attendant mortality rates have been discussed extensively in the preceding sections. Briefly, the contemporary mortality rate across the country has consistently been 3% to 5%.[106,107] The overall morbidity rate remains about 30% in patients undergoing repair of intact AAAs across the United States.

Intraoperative complications can result from injury to the intra-abdominal structures during dissection although these technical complications are not specific to the aneurysm repair. The small bowel, colon, ureter, and major venous structures (inferior vena cava, iliac veins, left renal vein) are particularly susceptible. Iatrogenic bowel injury at the time of AAA repair is particularly problematic due to the potential to infect the prosthetic graft. If the colon is injured before the aneurysm repair, the defect in the colon should be fixed and the aneurysm repair should be aborted. If the small bowel is injured before the aneurysm repair, the same course should likely be followed although this decision requires a modicum of clinical judgment. The infectious concerns must be balanced by the fact that the small bowel contents are assumed sterile, a second procedure will be required to repair the aneurysm, and the small risk of aneurysm rupture during the intervening delay. Injury to the bowel during or after implantation of the aortic graft should be treated with repair of the defect, extensive irrigation, and prolonged antibiotics. Admittedly, these approaches are very conservative and it is noteworthy that clinical series have attested to the safety of simultaneous aortic and gastrointestinal/urologic procedures.[108] The ureter is

susceptible to injury at the point where it crosses over the iliac bifurcation. Injury can be avoided by a heightened awareness of this anatomic location and dissection in the tissue plane immediately on top of the common iliac vessels. Inadvertent venous injury can be associated with significant bleeding. This can usually be controlled by direct pressure using sponge sticks and suture repair. The left renal vein may be transected if necessary. It should be transected near its juncture with the vena cava, and the gonadal, adrenal, and lumbar branches should be preserved to maintain venous outflow from the kidney. Interestingly, division of the left renal vein does not appear to affect renal function after AAA repair.[109,136] Transecting the common iliac artery or infrarenal aorta may facilitate exposure of the common iliac or retroaortic renal veins, respectively.

Excessive intraoperative bleeding may be encountered occasionally. Patients with significant bleeding and platelet counts below 50,000/mL should receive a platelet transfusion, and it should be considered for coagulopathic bleeding and counts below 100,000/mL or for those on preoperative clopidogrel or other equivalent antiplatelet medications. Transfusions of fresh frozen plasma are indicated for both patients with either significant bleeding in conjunction with prolonged coagulation studies (>1.5 times control value) and those with coagulopathic bleeding.

Ischemia of the lower extremities has been reported to occur approximately 2% of the time after open repair.[110] The causes are multiple and include distal embolization, thrombosis, clamp injury, and technical errors. The lumen of the aneurysm is frequently filled with both thrombus and atheromatous debris that may serve as a source for both macro- and microembolization. Thrombosis may result from inadequate heparinization, hypercoagulable conditions, or poor arterial runoff. Further intervention is mandatory if the lower extremities are found to be ischemic. Anastomotic defects should be corrected. This may simply require dissembling and redoing the anastomosis, but often requires placing the anastomosis further distal on the outflow artery. If no problems are identified at the distal anastomosis, the femoral vessels should be explored and an intraluminal thrombus removed with a balloon embolectomy catheter. A transverse arteriotomy may be created in the common femoral artery if it is anticipated that only a thrombectomy will be required; a longitudinal incision should be created if a bypass (inflow or outflow) procedure is anticipated. A bypass

from the aortic graft to the femoral vessels is required if adequate inflow cannot be restored with thrombectomy alone. The popliteal artery below the knee should be explored and a thrombectomy performed if the extremity is still ischemic. This may be facilitated by creating a longitudinal arteriotomy on the below-knee popliteal artery that extends to the tibioperoneal trunk. This allows the passage of the balloon embolectomy catheter into all three tibial vessels under direct vision. A below-knee popliteal or tibial artery bypass is required if adequate perfusion to the distal extremity is not restored after patch closure of the popliteal arteriotomy. Predictably, a complex lower extremity revascularization in conjunction with an aortic reconstruction is associated with a significant degree of morbidity and dramatically increases the mortality rate.[110]

Many of the systemic complications that follow open aneurysm repair are not surprising, given the magnitude of the operation and the age/comorbidities of the patients. Cardiac complications (ischemia, infarction, arrhythmias, congestive heart failure) occur in up to 25%[111] and are the leading cause of death after open aneurysm repair in many series. Pulmonary complications (pneumonia, ventilator dependence >48 hours, acute respiratory distress syndrome) are also quite common and approximately 10% of the patients require prolonged ventilation.[111] Deterioration of renal function, defined by an increase in serum creatinine or blood urea nitrogen, occurs in approximately 5% of cases although acute renal failure requiring dialysis is rare (i.e., <1%).[111]

Ischemic colitis has been reported to occur in approximately 4% of cases after open aneurysm repair.[112] The reported incidence may vary, however, depending on the diagnostic modality (routine sigmoidoscopy vs. selective sigmoidoscopy) and is dramatically increased after ruptured aneurysm repair. Indeed, the incidence of colonic ischemia after ruptured aneurysm repair in patients undergoing routine colonoscopy is approximately 25% to 40%.[113,114] Multivariable analysis of patients undergoing both open and endovascular repair demonstrated that the duration of the procedure and preoperative renal insufficiency were also predictors of colon ischemia.[112] The sigmoid colon is affected most frequently and is usually due to inadequate resuscitation, disruption of collaterals, and/or failure to revascularize a hemodynamically significant inferior mesenteric artery. Patients usually present with bloody diarrhea in the early postoperative

period. However, the diagnosis should be considered in the absence of bloody diarrhea in patients with thrombocytopenia, multiple-organ dysfunction, increasing abdominal pain/peritonitis, and generalized "failure to thrive." The diagnosis may be confirmed by endoscopy. Treatment depends on the endoscopic findings and clinical setting. The endoscopic findings range from mucosal ischemia to transmural necrosis. In the absence of peritonitis, patients with mucosal ischemia alone can be treated with bowel rest, broad-spectrum antibiotics, total parenteral nutrition, and serial endoscopic examinations. Many of these lesions resolve spontaneously without long-term sequelae although colonic strictures may develop in a subset of patients. Patients with transmural colonic necrosis should undergo laparotomy with resection of the involved segment, a proximal diverting colostomy, and a distal Hartmann pouch. After laparotomy, they should be maintained on broad-spectrum antibiotics. The reported mortality rate in patients with transmural necrosis may range up to 85%.[112]

Several other gastrointestinal complications are common after standard infrarenal AAA repair.[115] A postoperative ileus develops in essentially all patients with bowel function usually returning within 3 to 5 days. Nasogastric decompression should be continued, narcotics minimized, electrolytes normalized, and ambulation encouraged. Either calculous or acalculous cholecystitis may develop after aneurysm repair. The mortality rates reported historically for postoperative cholecystitis were significant and served as the catalyst for simultaneous cholecystectomy and aneurysm repair. Although this approach has been found to be safe and not associated with an increased risk for graft infections, it is usually reserved for patients with small stones or evidence of chronic cholecystitis. Pancreatitis may develop after AAA repair although the incidence is surprisingly low in light of the obligatory manipulation of the pancreas during repair.

Sexual dysfunction is quite common after open AAA repair ranging from 7% to 80% depending on the series.[116] The responsible mechanisms include interruption of the pelvic perfusion and injury to the autonomic nerves that overlie the distal aorta/proximal common iliac arteries. Injury to these autonomic nerves disrupts the internal sphincter mechanism of the bladder and results in retrograde ejaculation. Care should be used during aneurysm repair to maintain pelvic perfusion and avoid nerve injury to prevent these

untoward complications. It is imperative that these potential complications be discussed with patients preoperatively.

Paraplegia after open infrarenal AAA repair occurs with an incidence of 0.25%.[117] The potential mechanisms for this devastating complication include embolization, thrombosis of the spinal artery, and disruption of the spinal blood supply. Paraplegia after aneurysm repair is usually an irreversible injury. Maintaining adequate antegrade pelvic perfusion through the internal iliac arteries may minimize this complication.

The long-term outcome after open repair is generally favorable with survival rates of approximately 80% beyond 4 years.[118] Cardiovascular events account for the leading cause of death.[119] This underscores the importance of long-term medical follow-up and the AHA/ACC Guidelines for preventing myocardial infarction and death. Prosthetic aortic grafts are associated with long-term complications with a reported incidence of approximately 10% to 15% at 15 years.[120] The long-term graft-related complications include infection, aortoenteric fistula, thrombosis, and pseudoaneurysm formation. Additional aneurysms of a sufficient size to merit intervention develop in approximately 5% to 15% of patients in either the iliac vessels or the aorta above the prosthetic graft. As such, the Society for Vascular Surgery recommends that patients undergo CT of the complete aorta and iliac vessels every 5 years postoperatively to screen for additional aneurysm disease.[61]

Endovascular Repair of Intact Abdominal Aortic Aneurysms

Technique

The preoperative preparation before endovascular AAA repair is more complicated than for the open approach. The various imaging studies must be reviewed before it can be determined whether the endovascular approach is even feasible. Appropriate measurements must be taken and the necessary devices/components selected. An operative plan must be generated including specific modifications of the standard approach to overcome the patient's anatomic limitations and, thereby, extend the feasibility of the technique.

Indeed, “preoperative planning” has facetiously been identified as the most important component of a successful repair.

CT arteriography with 3D reconstructions has emerged as the optimal approach to determine feasibility of EVAR. It is important to emphasize that no imaging technique is perfect and, consequently, a certain degree of flexibility is necessary for the operative plan. Measurements obtained from the 3D CT tend to overestimate the actual renal artery–internal iliac artery length assumed by the graft when deployed in vivo.

The various devices/components should be selected using the underlying principles that the main body of the device should sit as close to the orifices of the renal arteries as possible while the iliac limbs should extend to the orifices of the internal iliac arteries. This methodology not only provides exclusion of abnormal tissue, but also extends the length of seal and fixation of the endograft, and may provide additional column strength. Furthermore, the manufacturers’ recommendations (IFU) for sizing and device selection should be followed. The endograft is sized according to the anatomic configuration of the aneurysm and adjacent arteries, and this must be performed in advance of the procedure to ensure that the appropriate devices are available. The diameter and length of the infrarenal cuff, aneurysm, and iliac vessels must be measured precisely. In addition, the distance from the lowest renal artery to the aortic bifurcation and both renal bifurcations needs to be determined. The diameter of the proximal graft is chosen to oversize the aortic cuff and iliac arteries by approximately 10% to 20%. Oversizing the graft diameter beyond that recommended has been associated with both graft migration and aneurysm reexpansion.[121] Additional devices should be ordered for each case including two iliac limbs and an aortic extension cuff to allow for any discrepancy between the preoperative plan and the actual course of the graft in vivo. Each endograft procedure and device configuration is “custom fit” for an individual patient. Furthermore, physicians typically are required to complete a training course comprised of sizing exercises and monitored deployments.

The choice of the specific endovascular device is contingent upon the anatomic constraints of the aneurysm, device-associated outcome, and surgeon preference. There are specific differences between the various grafts that lend themselves to different clinical scenarios. The specific considerations include neck diameter, neck length/angulation, renal–internal

iliac artery distance, common iliac artery diameter, and access vessel diameter. For example, a graft with suprarenal fixation may be more suitable for a shorter neck while a lower profile system (i.e., smaller outer diameter of the delivery sheath) may be most appropriate for patients with smaller access vessels (i.e., common femoral and external iliac arteries). Despite the initial concerns about compromising renal function, suprarenal fixation has been consistently shown to be safe.[122] Deployment of the various endografts is reasonably involved from a technical standpoint; thus, it is not particularly surprising that most surgeons choose to concentrate their proficiency with one or two devices. However, a working knowledge and comfort level with all devices on the market is advised given the benefits that each graft may have over the others in certain scenarios. This permits use of a graft that best meets the individual patient's needs.

The need for adjunctive procedures to facilitate the endovascular repair is usually determined by the preoperative imaging and should be factored into the overall plan. The major concerns include stenotic access vessels and the absence of a suitable common iliac artery landing zone due to aneurysm enlargement. The remedial procedures for small access vessels or significant occlusive disease include serial dilation or a retroperitoneal prosthetic iliac conduit, as previously discussed. Repeated attempts to pass the device through a diseased native artery should be avoided as it can cause vessel rupture. Aneurysm degeneration of the common iliac artery can be overcome by extending the iliac endoprosthesis into the external iliac artery. This necessitates either embolization of the ipsilateral internal iliac artery or more preferably preserving internal iliac perfusion with the use of an iliac branch device, which has a precannulated internal iliac gate for ease of use. These devices have demonstrated satisfactory midterm results and their application to preserve internal iliac flow is strongly recommended by the Society for Vascular Surgery.[61,76]

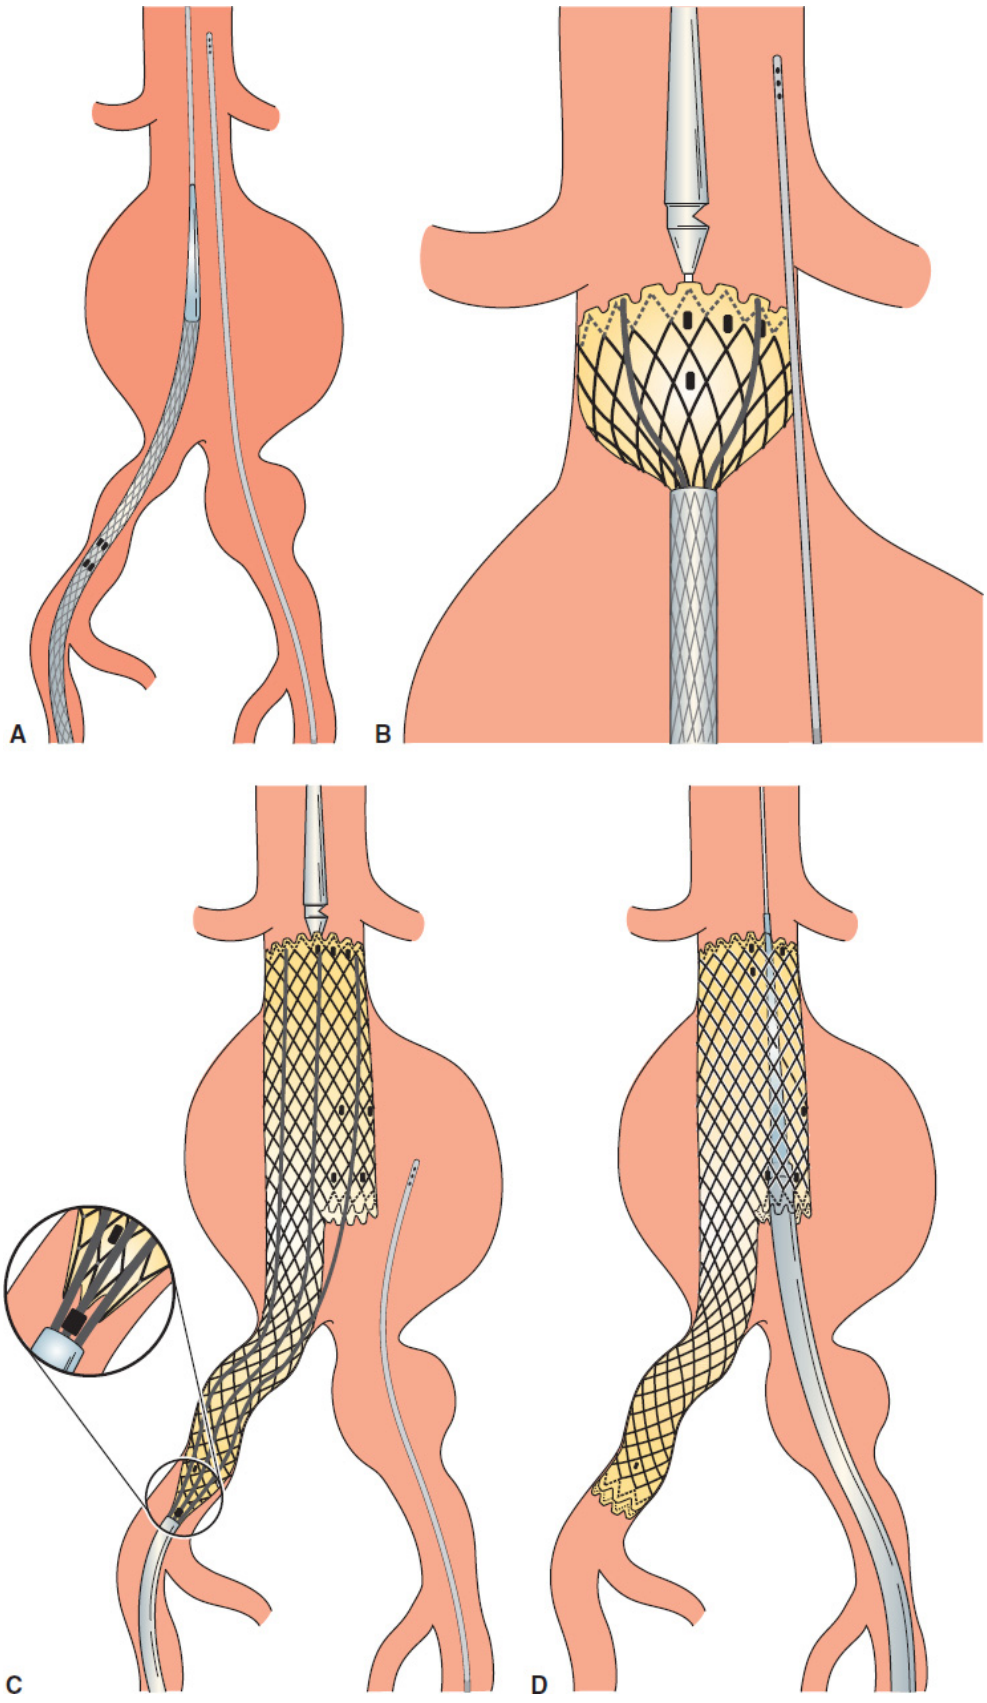
Intraoperative preparation for endovascular repair is similar to that for the open approach although there are several significant differences. The appropriate imaging equipment is mandatory. Ideally, this would entail a complete endovascular suite with a fixed fluoroscopic unit although a portable unit with the appropriate vascular software and an imaging table is adequate. General endotracheal anesthesia, local, and regional anesthesia can all be used for endovascular repair, depending on the individual patient,

the clinical scenario, the planned length/complexity of the procedure, and the comfort level of the surgeon and anesthesiologist. Indeed, the endovascular approach is well suited for these less-invasive alternatives particularly considering the feasibility of a completely percutaneous approach. For a straightforward endovascular repair, intraoperative autologous transfusion devices and a nasogastric tube are unnecessary. In the current era, it is quite rare to convert to an open repair at the time of the initial implantation. However, it should be emphasized that EVAR is a surgical procedure and most would agree that the procedure should be performed in an operating room with strict aseptic technique.

Percutaneous access to the common femoral arteries has become standard for many physicians using a "preclose" methodology that involves placing a suture-based closure system that is deployed prior to delivery of the device and closed at the conclusion of the procedure.[123] If the surgeon is uncomfortable with that approach, or the femoral artery anatomy precludes use of closure devices, an open exposure works well and can be done through transverse, longitudinal, or oblique incisions. Although the technique for implanting the various endografts is somewhat specific to the individual device, the basic steps for deploying a "generic" modular bifurcated device using an open femoral artery exposure is illustrated (**Fig. 94.10**).

Briefly, the common femoral arteries are exposed and an umbilical tape or vessel loop is wrapped circumferentially around the vessels at the level of the inguinal ligament to facilitate vascular control. Approximately 2 cm of the common femoral artery is dissected free. The common femoral artery on the side chosen to introduce the main body of the device (ipsilateral groin) is punctured using an angiographic needle and a 0.035-in standard working wire (e.g., Bentsen) is passed into the abdominal aorta using fluoroscopic guidance. A 5-Fr introducer sheath is advanced over the guidewire using a Seldinger technique and vessel entry is confirmed by manual contrast injection. The working wire is further advanced into the thoracic aorta and exchanged for a longer 0.035-in stiffened guidewire (e.g., Lunderquist, Meier) using a catheter. Attention is then directed to the contralateral groin and in a similar manner a guidewire is advanced into the aorta and an appropriate-sized introducer sheath is inserted over the guidewire into the body of the aneurysm at approximately the L3 vertebral space. An angiographic catheter is advanced to the L1 vertebral body through the

contralateral sheath and the catheter connected to the power injector. The patient is then anticoagulated with heparin using a standard protocol (100 units/kg) and therapeutic anticoagulation (ACT twice baseline) is maintained throughout the procedure. The main body delivery catheter is introduced over the stiff wire through the ipsilateral groin and the upper limit of the main body positioned between the L1–L2 vertebral bodies. Devices that do not have an integral sheath as part of their delivery system require an 18- to 22-Fr sheath to be inserted prior to introduction of the actual delivery catheter. Radiopaque markers on the graft facilitate the positioning and orientation of the main body.



A

C
D

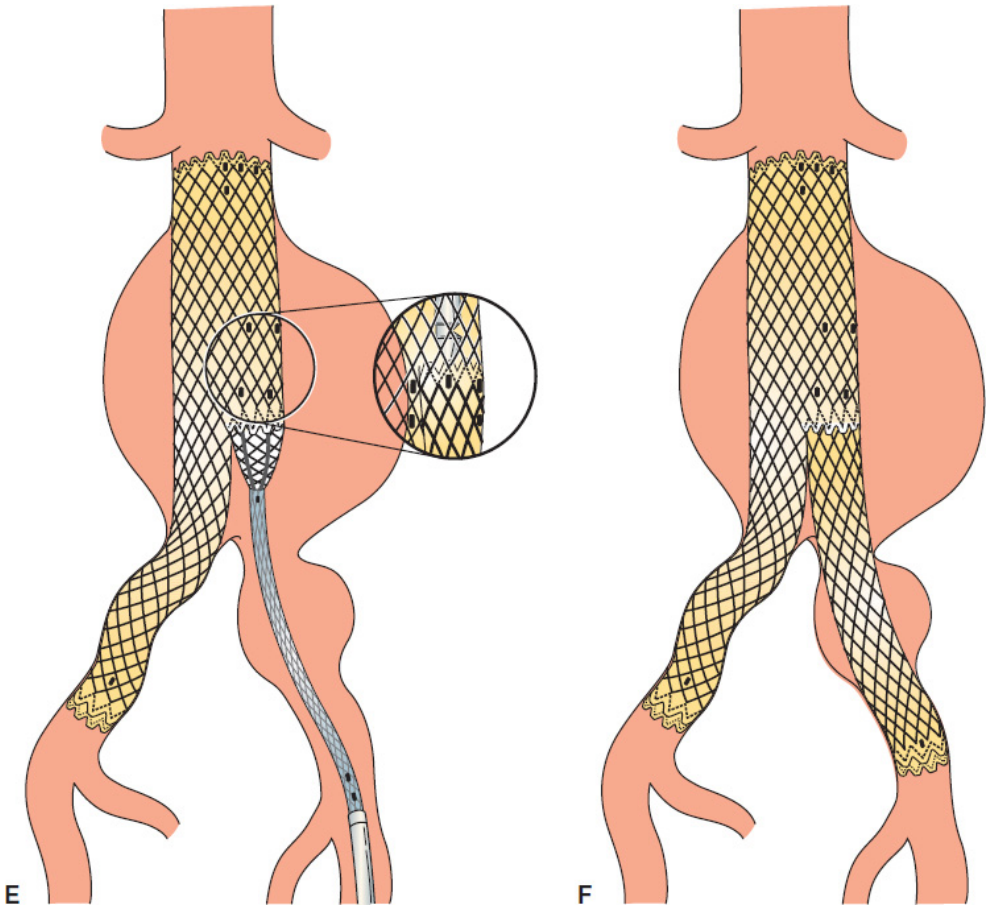

Figure 94.10 General steps involved in the endovascular repair of an abdominal aortic aneurysm. The common femoral arteries are exposed bilaterally (alternatively, and more commonly, percutaneous access is achieved and "preclose" sutures are placed) and stiff wires are introduced into the thoracic aorta under fluoroscopic guidance. An appropriate-sized large diameter introducer sheath is inserted over the stiff wire into the body of the aneurysm at approximately the L3 vertebral space on the side contralateral to the one chosen for the main device. If the device is contained within its own deployment system, a sheath may not be required. **A:** The main body delivery catheter is introduced over the stiff wire through the ipsilateral groin and the upper limit of the main body positioned between the L1 and L2 vertebral bodies. An aortogram is obtained and the location of the renal arteries identified. The location of the renal arteries is marked on the imaging screen and the position of the main body finely adjusted. **B, C:** The main body is deployed exposing the opening of the contralateral docking limb. The contralateral docking limb is cannulated and a stiff wire advanced into the thoracic aorta. After confirming successful cannulation of the docking limb, deployment of the contralateral limb is deployed after marking the origin of the hypogastric artery. The hypogastric origin can be identified by using intravascular ultrasound or by obtaining a retrograde arteriogram through the sheath in the opposite oblique projection to identify the orifice of the internal iliac artery. **D–F:** The location of the orifice is marked on the imaging screen; the contralateral limb is then introduced over the stiff wire, appropriately positioned, and deployed. A compliant aortic occlusion

balloon is advanced over the stiff wire and inflated in the region of the infrarenal neck to mold the proximal and distal attachment sites, and is used to ensure the overlapping devices are well sealed.

As imaging has improved, multiple techniques allow for determining the proper location of endograft deployment. This may involve the use of IVUS or 3D overlay imaging, both of which can decrease the use of contrast and the radiation exposure to both the patient and practitioner. In the absence of these advanced imaging techniques, an aortogram can be obtained after delivery of the endograft to the location of the renal arteries and the renal arteries marked for device deployment. A 5- to 10-degree cranial angulation is usually sufficient to account for the anterior angulation of the infrarenal neck caused by the natural lumbar lordosis of the spine and the posterior bulging of the aneurysm sac. However, the optimal angulation or orientation should be estimated based upon the preoperative 3D CT images. The location of the renal arteries is marked on the imaging screen and the position of the main body adjusted. The main body is now deployed exposing the opening of the contralateral docking limb ("gate"). Using a combination of a hydrophilic wire and a curved catheter, the contralateral docking limb is cannulated. Various maneuvers including different fluoroscopic projections, different-shaped catheters, and proper orientation of the contralateral docking limb prior to deployment of the main body device can facilitate this step. It is imperative to confirm that the cannulating guidewire is actually within the body of the main endograft. There are a number of methods to confirm entry into the main aortic graft. The most definitive way is to use IVUS. A common method is to place a reverse curve catheter, such as a SOS, or a pigtail catheter into the main body at the level of the neck and then spin the catheter. If the catheter spins freely, this confirms that it is inside the endograft and not trapped between the aortic wall and endograft. Another option is to insert a compliant aortic occlusion balloon (which will be used later in the procedure) partially into the gate and *gently* inflate giving the balloon an upside-down mushroom appearance. Alternatively, an arteriogram can be performed using a catheter within the main body, confirming that dye fills the aortic graft, but not the aneurysm on initial injection. Once the wire is confirmed to be within the endograft, the contralateral wire is advanced

into the proximal descending thoracic aorta under fluoroscopic guidance and exchanged for a stiff wire using a catheter.

Next, the contralateral internal iliac artery origin must be identified in order to select the appropriate length iliac endoprosthesis. This can be accomplished with an IVUS catheter. Alternatively, retrograde angiography can be performed through the sheath in order to visualize and mark the internal iliac artery. The optimal fluoroscopic angle to visualize this artery can be variable and is best determined using preoperative 3D imaging. However, the typical angle is in the opposite obliquity about 30 degrees from the side of the vessel (i.e., right anterior oblique for the left internal iliac artery). The location of the orifice is marked on the imaging screen and a marker catheter is used to measure the distance from the contralateral docking limb to confirm the iliac device selection. The contralateral limb is then introduced over the stiff wire, appropriately positioned relative to the docking limb and the orifice of the internal iliac artery, and then deployed.

After deployment of all the devices, a compliant aortic occlusion balloon is advanced over the ipsilateral stiff wire and inflated in the region of the infrarenal neck to mold the proximal attachment sites. The aortic balloon is then withdrawn and gently expanded at the main body/iliac limb overlap zone and both distal iliac artery fixation sites. A completion arteriogram is then obtained using an angiographic catheter placed through one of the introducer sheaths (**Fig. 94.11**). The arteriogram should adequately evaluate the proximal/distal fixation sites, the graft/graft overlap zones, and the orifices of the renal/internal iliac arteries. In addition, it should include delayed imaging to help identify any endoleaks. Problems identified on the completion study should be corrected, if possible. The potential remedial procedures include balloon dilation or aortic/iliac extension cuffs.

Figure 94.11 Completion arteriogram after an endovascular aneurysm repair is shown. The *arrow* marks the caudal extent of the stent graft. Note that the iliac limbs have been intentionally crossed to facilitate the cannulation of the contralateral gate.

All sheaths, catheters, and wires are removed after the completion of the arteriogram if using an open femoral approach and the arteriotomy is closed using purse-string suture placed at the time of the initial exposure or primary suture repair. In the case of percutaneous approach, the wire is left in during initial Perclose use to allow placement of additional closure devices as necessary. Doppler signals should be confirmed in the pedal vessels prior to removal of the wire and completion of arterial closure. Heparin is then reversed with protamine (1 mg protamine/100 units of heparin). The groin wounds are closed in layers with absorbable suture and the final skin later is closed with a subcuticular technique.

The immediate postoperative course is typically uneventful. Patients are transferred to the general care ward after recovery in the postanesthesia care unit. Patients are started on an appropriate diet the evening of the procedure and encouraged to get out of bed. However, patients should be kept supine for 4 to 6 hours after the operation when a percutaneous technique is used to ensure successful hemostasis. Most infrarenal EVAR patients are discharged home on postoperative day 1, and then seen in the outpatient clinic at 1 month with an abdominal/pelvic CT scan. It is important to note that mild fever and the finding of air around the graft on CT are common occurrences immediately after endograft repair and have not been associated with graft infection.[124]

9 It is imperative that patients are followed-up long term given the uncertainty associated with the endovascular repair and the need for remedial procedures. A variety of protocols and imaging techniques have been described. The Society for Vascular Surgery recommends an abdominal/pelvic CT scan at 1 month. In the absence of endoleak or sac enlargement, contrasted CT scan or color duplex ultrasound can be repeated in 12 months.[61] If there is no sac enlargement or endoleak at that point, the patient can be followed with annual color duplex ultrasound, or CT scan if ultrasound expertise is not available. More frequent imaging is necessary if the aneurysm continues to grow or there is evidence of an endoleak. A multicenter trial demonstrated that the absence of an endoleak at 1 and 12 months predicted favorable long-term outcome.[125] Of note, color duplex ultrasound has been shown to be very effective in detecting endoleak and minimizing patient radiation and contrast exposure, but this technique is predicated on comfort level and training of the local vascular laboratory.[126,127] Surveillance CT scans should include noncontrast and biphasic contrast views with delayed images to help identify any late endoleaks.[128]

Complications and Outcome

The mortality rates in randomized trials and national series is less than 2%,[85,86] the perioperative complication rate is <25%,[43] the rupture risk is approximately 1%/yr,[81] and the incidence of remedial procedures approximately 10%/yr.[129] Many of the same complications that can occur

after open repair can occur after endovascular repair. However, the relative incidence of the various complications is significantly different, and several complications inherent to EVAR have been identified.

A variety of potential complications may arise during insertion of the delivery catheter or introducer sheath. Indeed, access problems secondary to iliac stenosis and/or tortuosity are the most common procedure-related complication. The outer diameters of the delivery sheaths are device dependent, but can range up to 24 Fr. Excessive force during insertion of these large sheaths or delivery catheters can result in serious injury and perforation/disruption of the vessels. Predictably, this can lead to significant hemorrhage and hemodynamic changes. The diagnosis can be confirmed by arteriography and the bleeding controlled intraluminally using the device sheath or a balloon catheter. A variety of endovascular salvage techniques are possible in this setting including deployment of either the main device or a covered stent across the disrupted artery. Most major arterial disruptions can be managed with endovascular techniques, but in the event they are unsuccessful, a retroperitoneal incision with direct control of the iliac arteries must be performed expeditiously.

Safe conduct of an EVAR is predicated by sufficient knowledge of the various salvage techniques, the necessary catheter and guidewire skills to execute these techniques, and a complement of ancillary equipment. However, the adage that “prevention is better than the cure” holds true and endovascular surgeons should maintain a low threshold for constructing a retroperitoneal iliac conduit prophylactically. Besides rupture, the access vessels can be dissected from misdirection or excessive force during sheath or device insertion. If non–flow limiting, no intervention is necessary; but, if a flow limitation is present, the dissected segment typically requires stenting. Prior to doing so, confirmation that the wire is within the true lumen is critical.

Graft deployment can be associated with mechanical problems related to the delivery system or inappropriate positioning. A host of mechanical problems have been described, and the list will likely expand with widespread application of the devices and the introduction of updated systems. Many of the mechanical problems are device specific and related to the actual sequence of events and manipulations required. Troubleshooting guidelines and specific recommendations are available from the

manufacturers. Deployment of the endovascular graft below the proximal target site along the infrarenal aorta may be corrected using an aortic extension cuff. Attempting to reposition the graft more cephalad after deployment is not recommended. Deployment of the endovascular graft across the orifices of the renal arteries can potentially be corrected by displacing the graft caudally. A guidewire can be passed over the flow divider and out the contralateral groin. The entire graft can then be retracted caudally by pulling on the wires. Alternatively, a large balloon can be inflated above the flow divider and retracted. Extreme care must be exercised during these maneuvers to prevent complete dislodgement of the proximal main body from the neck. Deployment of the graft across part of the renal orifice with subsequent renal malperfusion can be corrected by placing a "chimney" or "parallel" stent within the lumen of the renal artery. This typically requires brachial artery access in order to cannulate the target vessel. Deployment of the endograft across the lumen of one internal iliac artery is usually tolerated provided the contralateral vessel is patent and relatively free of occlusive disease. With coverage of a single hypogastric artery, severe complications are rare. Occlusion of both internal iliac arteries or occlusion of one vessel in the presence of contralateral disease may render the pelvis ischemic. In the event of unintentional hypogastric artery coverage, the iliac limb can be pushed cephalad using a sheath and its dilator. It should be emphasized that many of these remedial procedures are not manufacturer approved and should only be attempted by experienced endovascular surgeons. Due to the advanced age of many of these patients and their attendant comorbidities, open surgical conversion should be contemplated only as a last resort after the endovascular options have been exhausted, again emphasizing the need for advanced endovascular skills.

It is relatively common to see an endoleak on the completion arteriogram. Treatment is contingent upon the specific type of leak and its associated natural history although the majority of these early endoleaks ultimately resolve. Type 1a/b (a-proximal, b-distal attachment site) and type 3 (fabric tear or modular component separation/leak) endoleaks are particularly concerning and every reasonable attempt to correct these defects should be made. The aneurysm sac is often exposed to systemic pressure in the presence of a type 1 or type 3 endoleak, and, therefore, the rupture risk likely approaches that associated with the untreated aneurysm. Both the type 1 and

3 endoleaks can potentially be corrected by repeat balloon angioplasty at the proximal/distal attachment sites or at the modular interface. If these measures are not successful, additional extension devices can be deployed if there is adequate length before the target vessel. With the exception of large proximal type 1 endoleaks, it is reasonable to manage most perioperative endoleaks expectantly since most resolve spontaneously after reversal of the anticoagulation or within the first 6 months. Indeed, even type 1a endoleaks often thrombose before the first postoperative imaging study, although patient selection, aneurysm diameter, and risk of rupture should be carefully considered before leaving the operating room with a persistent endoleak of this nature. Thus, the surgeon should be mindful that the inability to obtain a satisfactory exclusion of the aneurysm at the time of endograft implantation does not mandate a surgical conversion at the same setting. In situations where there is concern for a persistent endoleak, an earlier postoperative CT than the usual 1-month study may be advisable.

In the event that a significant type 1a endoleak persists on postoperative imaging, the potential options include remediation with branched/fenestrated endograft, aortic cuff extension with renal chimneys, application of EndoAnchors, embolization, or open surgical repair with endograft explant. Numerous nonrandomized series have reported relatively feasible and durable results with the above options.[130] Type 2 endoleaks have a relatively benign natural history and do not merit aggressive intervention unless the aneurysm continues to increase in size over time. Type 4 endoleaks are self-limiting, and do not merit treatment at all. They are identified as a diffuse contrast "blush" at the time of the completion arteriography. They represent a diagnosis of exclusion and mandate that the more worrisome type 1 endoleak be excluded.

The spectrum of immediate postoperative complications after EVAR is comparable to that outlined for after open repair and will not be repeated. However, the incidence of major, systemic complications after EVAR is quite uncommon. It is noteworthy that the incidence of both paraplegia and bowel ischemia are comparable after endovascular and open repair although the mechanisms are different and likely due to atheroembolism.[131]

The long-term complications after EVAR include endoleak, structural failure, need for remedial procedures, need for open conversion, and rupture. These ongoing risks further emphasize the importance of conscientious

lifelong surveillance. Device migration has been reported to cause type 1 endoleaks and has been associated with neck length, site of deployment below the renal arteries, and surgeon/center experience.[132] The treatment of late-occurring type 1 and 3 leaks is identical to that for those occurring earlier as previously described.[130] Type 2 endoleaks merit intervention and treatment if the aneurysm continues to increase in diameter, although the clinical scenario is an important deciding factor in these cases. Identification of the type 2 endoleak can be challenging and may require selective catheterization of the superior mesenteric or internal iliac arteries. A variety of approaches have been described to treat the type 2 endoleaks including coil embolization, laparoscopic ligation of the feeder vessels, and direct translumbar or transcaval injection of the aneurysm sac with glue or other thrombotic agents.[133]

Aneurysms that continue to increase in size after EVAR merit further intervention and may require open conversion due to their ongoing rupture risk. It should be emphasized that the goal of aneurysm repair is to prevent rupture/death from rupture and that endoleak and sac enlargement are surrogate markers of potential late failure of the therapy. Even more concerning is recent evidence that failure of sac regression has been associated with higher long-term mortality.[134] The clinical significance of an enlarging sac in the absence of a visible endoleak is controversial as long as a secure proximal and distal fixation of the endograft has been demonstrated. To confound the issue further, rupture of aneurysms without an endoleak or a change in sac diameter has also been reported, leading some to describe the phenomenon teleologically as endotension. A presumed endoleak that is not detected on a properly performed contrast CT scan is typically not identified on a catheter-based arteriogram. The proper diagnostic investigation of an endoleak should include interrogation of all the fixation sites and modular interfaces and selective injections of mesenteric and hypogastric arteries with sufficient contrast dose and proper acquisition techniques. It should be emphasized that open conversion and explant of the endovascular graft can be technically more challenging than a de novo open repair and usually requires suprarenal or supraceliac aortic control. In the absence of infection, it is not always possible (or necessary) to remove the entire device, particularly when the device has suprarenal fixation. It is possible to transect the endovascular graft near the usual site of the infrarenal aortic anastomosis

and incorporate the fabric/stents of the graft into the anastomosis. Temporary distal vascular control can be achieved by clamping the limbs of the endovascular graft. The limbs of a bifurcated surgical graft may be anastomosed directly to the endograft limbs if they are securely attached to the iliac artery, typically incorporating the native terminal aorta or common iliac arteries. In properly chosen elective patients, open conversion can be performed with similar outcomes to primary open juxtarenal AAA repair.[135]

A variety of device-specific complications, including strut fracture, fabric tears, and buckling of the graft, have been identified. Importantly, these may present at any time throughout the postoperative period. An extensive discussion of all the potential device-related complications and their treatment is beyond the scope of this chapter.

REPAIR OF RUPTURED ABDOMINAL AORTIC ANEURYSMS

Open Repair

The approach to the patient with a ruptured AAA is similar to the elective scenario with the exception of several points that merit further comment. Prompt communication with all operating room personnel is critical for a good outcome. The blood bank should be notified as the case may require massive transfusion of blood products. The patient should be prepared and draped before induction of anesthesia with a broad operative field from the chin to the toes. This allows access to both groins if percutaneous insertion of an aortic occlusion balloon is necessary to obtain proximal control, and the chest in the event that resuscitative thoracotomy is required. The surgeon should be ready to make the incision at the time of induction, since patients with ruptured aneurysms frequently become hypotensive at this point.

A midline incision should be made and supraceliac aortic control obtained. The aorta/esophagus can be difficult to identify, especially in a hypotensive patient. The placement of a nasogastric tube can facilitate identification of the gastroesophageal junction, and thus guide proper placement of the supraceliac clamp. The esophagus should be manually moved to the patient's left and the gastrohepatic ligament, the crus of the

diaphragm, and the connective tissue enveloping the aorta can be divided using blunt finger dissection. The aorta can be temporarily controlled manually by either occluding the aorta between the fingers and thumb or compressing it against the vertebral bodies. Definitive control should be obtained with an aortic clamp. Care should be utilized during these maneuvers to prevent injury to the esophagus or the aorta itself.

Aortic control can also be achieved through a variety of other means: thoracotomy with occlusion of the descending thoracic aorta, intraluminal control of the infrarenal aorta with a compliant balloon placed through the common femoral artery, or supraceliac control via a retroperitoneal incision. The surgeon should be familiar with these various techniques because they can be helpful in certain clinical settings, but the midline approach with supraceliac control is recommended for most ruptured *infrarenal* aneurysms. After supraceliac aortic control has been obtained, the infrarenal aorta is dissected and vascular control is achieved below the level of the renal arteries to restore visceral perfusion. The hematoma from the ruptured aneurysm often facilitates the dissection by displacing the normal tissue planes. However, the normal tissues may be obscured, and care should be taken not to injure the venous structures, particularly the left renal vein. It is imperative that these various steps are coordinated with the anesthesia team, and it is recommended that the supraceliac clamp be left in position to facilitate reapplication if necessary. Distal vascular control can be achieved with either vascular clamps or intraluminal balloons, depending on the character of the iliac vessels.

The decision to anticoagulate the patient is contingent on a variety of factors, including the quantity of blood lost, presence of coagulopathic bleeding, body temperature, and hemodynamic status. Anticoagulation potentially reduces thrombotic complications, but it exacerbates coagulopathic bleeding. It is recommended that the inferior mesenteric artery be implanted (if patent) to reduce the risk of postoperative colonic ischemia. The heparin effect can be reversed with protamine. The administration of plasma, platelets, and/or additional clotting factors should be considered at this point if indicated.

The postoperative course after repair of a ruptured aneurysm is predictably more complicated and protracted than after elective repair. Both the intensive care unit and total hospital length of stay are significantly

increased. The mortality and complication rates are likewise significantly increased. The contemporary mortality rate for patients with ruptured AAAs who make it to the operating room is approximately 41%, which is improved compared to outcomes from several decades ago.[47] The spectrum of postoperative complications after repair of a ruptured aneurysm is essentially the same as after elective repair although the incidences are increased. The incidence of bowel ischemia may be as high as 40% and routine colonoscopy may be indicated.[114] Abdominal compartment syndrome has been reported in up to 34% and merits consideration in patients that are not doing well.[136] Notably, adrenal insufficiency was identified in almost 70% of patients with unexplained postoperative hypotension after ruptured aneurysm repair.[137]

ENDOVASCULAR REPAIR FOR RUPTURE

A recent meta-analysis comprising data of ~60,000 patients showed that endovascular repair of ruptured *infrarenal* AAA has significantly improved outcomes compared to traditional open repair.[138] Randomized controlled trials and observational series report 30-day mortality rates of 31% to 33% with EVAR.[139,140] However, these studies may be subject to selection and publication bias. A study querying the NSQIP database showed that endovascular approach had significantly lower 30-day mortality for both unstable and stable ruptured AAAs compared to open repair.[141] However, a more recent risk-adjusted meta-analysis of 30-day mortality showed no significant difference between the two approaches.[142] The Society for Vascular Surgery currently recommends EVAR over open repair, if anatomically feasible, for treatment of ruptured AAA, albeit the Society acknowledges the relatively poor quality of evidence to support this guideline.[61]

An endovascular approach requires a defined protocol/program consisting of an experienced endovascular surgeon, a committed team, an available operating room with the necessary imaging equipment, and an inventory of suitable devices. Studies estimate that approximately 40% to 50% of patients with ruptured aneurysms are anatomically suitable for endovascular repair using conventional devices.[143] This number would be about 10% higher if

taking into account those patients suitable for advanced proximal fixation techniques (e.g., use of renal chimneys, etc.).[144]

The endovascular approach for the treatment of ruptured AAAs can be briefly described.[145] Oversizing of the aortic neck ≥20% and encroachment on the orifices of the renal arteries with adjunctive stenting are both tolerated in an attempt to limit the necessary inventory and increase the proximal fixation zone, respectively. Access to the common femoral arteries can be obtained using a percutaneous approach with Perclose application or directly repaired at the completion of the procedure. In the absence of severe hypotension, the remaining conduct of the procedure is essentially the same as described in the elective setting. It is not usually necessary to occlude the aorta with an intraluminal balloon although one should be readily available in the event that the patients become hemodynamically unstable. The criteria for an acceptable result are somewhat less in the emergent setting and persistent attempts to achieve a perfect radiographic result should be avoided. Further interventions including conversion to open repair may be necessary at a later date, but these can usually be performed in an elective fashion.

Notably, patients treated with EVAR are at risk of developing abdominal compartment syndrome as a result of the intra/retroperitoneal hemorrhage and/or aggressive volume resuscitation. A meta-analysis estimated this rate to be 20% with half of these patients ultimately dying.[146] The surgeon should consider prophylactic laparotomy or retroperitoneal evacuation with placement of an open abdominal vacuum dressing at the conclusion of the procedure depending on the clinical status.

ADDITIONAL CONSIDERATIONS

Isolated Iliac Artery Aneurysms

Isolated iliac artery aneurysms are rare comprising less than 2% of all aneurysms.[147] The common iliac artery is involved in approximately 70% of the cases, and the internal iliac artery in the remainder. Aneurysmal involvement of the external iliac artery, either in combination with the common iliac artery or alone, is distinctly rare. These isolated iliac artery

aneurysms should be differentiated from the common iliac artery aneurysms that occur concomitantly with AAAs. Simultaneous aneurysmal involvement of the aorta and common iliac arteries occurs in about 10% to 20% of all AAAs[6] and should be considered as one disease process.

The natural history of isolated iliac artery aneurysms is poorly defined because of their low incidence. The clinical risk factors appear to be similar to those for AAAs with the highest incidence seen among elderly men. Unlike patients with AAAs, a significant proportion of patients with isolated iliac artery aneurysms present with symptoms. These symptoms may result from either rupture or compression of adjacent structures including the bowel, ureters, iliac veins, and nerves. The clinical presentation of patients with a ruptured iliac artery aneurysm is similar to that of ruptured AAAs, and the diagnosis should be included in the differential for patients with genitourinary symptoms and normal findings on urinalysis and testicular examination. CT arteriography is optimal for confirming the diagnosis of an isolated iliac artery aneurysm. The utility of ultrasonography is limited by the posterior course of the iliac vessels and the overlying bowel.

The principles of treatment for asymptomatic, isolated iliac artery aneurysms are similar to those for AAAs, and operative repair is justified when the risk for rupture offsets the risk of repair. Unfortunately, the natural history of isolated iliac artery aneurysms and the appropriate threshold for repair remain unresolved. Although rupture has been reported for aneurysms smaller than 2 cm, it is incredibly rare for aneurysms smaller than 3 cm to rupture. Consequently, operative repair is generally recommended for good-risk patients with isolated iliac artery aneurysms ≥3.5 cm.[147]

The treatment or repair of isolated iliac artery aneurysms depends on the specific vessel involved and the extent of the aneurysm. Theoretically, common iliac artery aneurysms can be repaired with an interposition graft or a covered stent provided that there is a sufficient proximal and/or distal neck to sew the anastomosis or seat the graft. However, this is rarely an option because the aneurysm involvement of the vessel usually extends over its whole length. Therefore, open repair necessitates replacing the whole common iliac artery with a bifurcated graft similar to the approach for patients with combined aortoiliac disease. Likewise, an endovascular approach should adhere to the same principles outlined for treatment of an

infrarenal AAA and may require the use of a iliac branch device to achieve distal seal and maintain internal iliac perfusion, as previously discussed.

The treatment of internal iliac artery aneurysms is typically exclusion. This can be performed using either an endovascular or open approach although the former is likely preferred due to its simplicity. Bypass of an internal iliac artery aneurysm is often not possible because there is rarely a proximal or distal neck. Indeed, the aneurysmal involvement usually extends to the common iliac bifurcation and the distal aspect usually arborizes into multiple smaller vessels. An alternative to open bypass is to ligate the origin of the internal iliac artery and oversew its distal branches from within the aneurysm although this is feasible only if the aneurysmal degeneration does not involve the origin of the vessel. Obtaining the necessary distal control for this approach can be challenging. It is certainly important to assess the status of the contralateral internal iliac artery and overall pelvic circulation before ligating this artery. The principles of an endovascular approach include obliterating both the inflow and outflow of the aneurysm along with complete sac thrombosis. The inflow of the vessel can be occluded by placing a covered stent across the origin of the internal iliac artery and the outflow can be occluded using selective embolization of the various branches using a variety of other agents including coils, plugs, glues, or gelfoam. Alternatively, an iliac branch device may be used to fully exclude the aneurysm sac and maintain internal iliac perfusion but this option depends on the size and quality of the posterior and anterior divisions of the internal iliac artery. The 1-year patency with this technique is 95%, but additional long-term data is necessary to determine its efficacy.[148]

INFLAMMATORY ABDOMINAL AORTIC ANEURYSMS

Approximately 5% of all AAAs are described or considered inflammatory.[149] These aneurysms are characterized by a dense inflammatory response encasing the anterior and lateral walls of the infrarenal aorta with sparing of the posterior aspect. The inflammatory response consists of a dense cellular infiltrate that has a white, glistening appearance on inspection.

The inflammation results in an increase in wall thickness with the difference between the inner and outer diameters of the aorta ranging from 1 to 5 cm. The cause of this inflammatory process remains unresolved, but it is likely an autoimmune phenomenon. Indeed, some type of autoimmune disorder has been identified in up to 20% of patients with inflammatory aneurysms.[150]

Patients with an inflammatory abdominal aneurysm are predominantly male and frequently present with symptoms of back or abdominal pain. The triad of a pulsatile abdominal aortic mass, abdominal pain, and an elevated erythrocyte sedimentation rate (ESR) has been described. CT findings are characteristic and include a thick, contrast-enhancing wall in the distribution described. An inexperienced observer may confuse the CT findings with those of a ruptured AAA. Hydronephrosis with *medial* displacement of the ureters is frequently seen in contradistinction to the lateral displacement seen with noninflammatory aneurysms. Indeed, this entity may share some pathophysiologic pathways with retroperitoneal fibrosis.

The treatment of inflammatory AAAs is essentially the same as that for the more common, noninflammatory variety. Nonoperative treatment with corticosteroids has been advocated in the past, although this approach is likely ineffective and has largely been abandoned. It has been suggested that the rupture risk of inflammatory aneurysms is less than that for noninflammatory variety because the wall thickness is increased. However, this is likely untrue, and patients should not be lulled into a false sense of security. It should be emphasized that most aneurysms rupture through their posterior or posterolateral aspect, which is not involved in the inflammatory process. The open repair of an inflammatory AAA is complicated by the fact that the adjacent structures, including the duodenum, colon, and ureters, may be involved in the process and densely adherent to the aortic wall. No attempt should be made to mobilize the adherent structures, specifically the duodenum, because of the potential for accidental injury. Proximal aortic control can be achieved either immediately above the renal arteries or above the visceral vessels. A retroperitoneal approach can reduce the technical difficulties associated with the open repair. The preoperative placement of ureteral catheters may facilitate their identification intraoperatively and can be helpful in patients with hydronephrosis. Perioperative complications, length of stay, and most notably graft infections were greater with open repair of inflammatory AAAs compared to the more conventional bland AAA.[151]

If anatomically feasible, EVAR has been shown to be the optimal treatment for inflammatory AAAs given its reduced morbidity and mortality compared to open repair.[149,152] In Stone's series of inflammatory aneurysms, there were no aneurysm-related deaths or major morbidity in those undergoing EVAR.[149] Kakkos showed a decreased operative time, transfusion requirement, and length of stay.[152] Puchner et al. performed a meta-analysis of patients undergoing endovascular repair for inflammatory aneurysms and reported that the inflammatory process resolved in approximately 50% of the cases.[153]

Juxtarenal and Suprarenal Abdominal Aortic Aneurysms

The management of aneurysms extending to the level of the renal arteries or more cephalad is more complicated, and, predictably, the morbidity rates associated with open repair are increased.[106] Interestingly, reports from centers of excellence have documented mortality rates comparable to those reported for infrarenal repairs although it is unlikely that these findings are applicable nationwide.[154] Repair of these complex aneurysms is complicated by the obligatory period of renal and visceral ischemia associated with aortic occlusion during the proximal anastomosis. Indeed, the renal complication rates range from 15% to 20% even from these select centers of excellence.[106,154] These increased morbidity and mortality rates should be factored into the decision algorithm and threshold for open operative repair. Elective open operative repair is usually recommended for patients with aneurysms 6 cm or larger in diameter in this setting although the 5.5-cm criterion may be appropriate for low good-risk patients and those with juxtarenal aneurysms who will require only a short period of suprarenal aortic occlusion.

The open operative approach for AAAs extending to the renal arteries or more cephalad may be repaired achieved through either a retroperitoneal or a transperitoneal exposure although the former is optimal, especially with more cephalad disease. The *retroperitoneal* approach, with anterior reflection of the left kidney, obviates the concerns about the left renal vein (except when a retroaortic renal vein is present) and simplifies exposure of the abdominal aorta. The distal descending thoracic aorta is easily exposed

by incising the diaphragm and its crus. Of note, the right renal artery and right common iliac artery are more difficult to expose via the retroperitoneal approach because of their trajectory, but this is not prohibitive in most cases. The proximal anastomosis may be fashioned as a beveled anastomosis incorporating the orifices of the renal and visceral arteries, or a Carrel patch can be fashioned from the aortic segment with reimplantation or bypass of the left renal artery in situations where the aneurysm involves the entire visceral segment.

For juxtarenal aneurysms repaired through the *transperitoneal* approach, the aorta can be clamped in the supraceliac or suprarenal position, depending on the extent of the disease and the patient's body habitus. Suprarenal clamp is preferred to avoid unnecessary visceral ischemia. Of course, if the aneurysmal tissue extends above the renal arteries, a supraceliac clamp may be required. The supraceliac exposure is similar to that described above for a ruptured infrarenal AAA, but performed in a more controlled fashion. After mobilization of the left lobe of the liver, the esophagus should be reflected left laterally. Placement of a nasogastric tube facilitates identification of the esophagus/gastroesophageal junction. The gastrohepatic ligament should be divided making note of aberrant hepatic arterial anatomy to avoid dividing a replaced hepatic vessel during this portion of the dissection. The crus of the diaphragm can be divided bluntly or sharply followed by division of the dense connective tissue surrounding the aorta for placement of the clamp. If a clamp is to be placed in the suprarenal position, this is facilitated by retracting the left renal vein superiorly or inferiorly after ligating its adrenal, gonadal, and lumbar branches. As noted previously, the left renal vein may be ligated near its confluence with the vena cava without adverse sequelae provided that its branches are preserved. The anterior surface of the aorta at the level of the visceral vessels is encased by dense neural tissue, which can be incised. Incising the crus of the diaphragm that envelops the lateral aspect of the aorta further facilitates clamp application. The configuration of the proximal anastomosis in the setting of the transperitoneal approach depends on the extent of the aneurysm and the vessels involved.

EVAR for juxtarenal AAAs has become widely available with the FDA approval of the Zenith Fenestrated Endovascular Graft (Cook Medical) in 2012.[72] The approach is based upon constructing a suitable landing zone for the more traditional endograft in patients with an inadequate or short

infrarenal neck (<4 mm). This is accomplished using a custom-designed fenestrated endograft that contains a combination of fenestrations and/or scallop that correspond to the renal and superior mesenteric arteries (SMAs). There are, however, several restrictions as to where the fenestrations/scallop can be placed on the endograft. The typical combination is two small fenestrations for the renal vessels and a scallop or large fenestration for the SMA. The fenestrations permit the introduction of individual covered stents into the side branch vessels once they are selected from within the endograft. For aneurysms that extend further cephalad on the aorta (i.e., outside of the IFU for the ZFEN device), fenestrations and/or branches are necessary for all visceral and renal vessels in order to obtain adequate proximal seal. Such a configuration requires more complex device designs that are accomplished through physician modifications of an endograft (PMEG) on the back table under sterile conditions, ordered through company-manufactured custom-made device (CMD) programs, off-the-shelf devices that are in an ongoing clinical trial, or with chimney/parallel grafts. It is important to note that access to CMDs is limited to a select number of centers in the United States. Additional details regarding these complex devices are beyond the scope of this chapter.

The worldwide experience with fenestrated EVAR (FEVAR) for juxtarenal aneurysms is vast, and the technique has been shown to be safe and effective. Oderich et al. reported a 100% technical success rate with a 1.5% 30-day mortality in the prospective Zenith Fenestrated trial.[155] A nationwide series using NSQIP data reported 30-mortality rate of 0.8% for FEVAR with 19% sustaining any complication.[156,157] In this series, these outcomes were significantly better than traditional open repair. Similarly, a recent meta-analysis comparing the two approaches for juxtarenal AAAs demonstrated significantly better 30-day mortality and complication (acute renal failure, spinal cord ischemia, bowel ischemia) rates for FEVAR compared to open repair.[158] Data regarding long-term survival and reintervention is somewhat lacking. In general, most studies have reported similar overall survival rates for FEVAR and open repair. For instance, Freyrie et al. reported 4-year overall survival of 81% and 87% for open repair and FEVAR, respectively.[159] The 4-year outcomes are lacking, however. As with more conventional EVAR, durability after FEVAR remains a concern. Maeda et al.

reported the 7-year secondary intervention rate after FEVAR to be as high as 40%, notably different than open repair.[160]

Combined endovascular and open (i.e., "hybrid") approaches have also been used to treat the juxtarenal and more complex proximal aneurysms. These techniques are based upon constructing a suitable aortic neck to land a traditional endograft by "debranching" the renal or visceral vessels. For example, a suitable landing zone below the SMA could be created for a juxtarenal aneurysm by performing bilateral iliorenal bypasses. These debranching procedures, however, are typically reserved for those who have a true thoracoabdominal aortic aneurysm as opposed to a juxtarenal aneurysm.

Infected Abdominal Aortic Aneurysms

Infected AAAs comprise a small subset of all AAAs, accounting for less than 1% of all repairs.[161] The term *mycotic aneurysm* coined by William Osler to describe aneurysms that developed after septic cardiac emboli caused an arterial infection has often been used to refer to all infectious etiologies for aneurysms. Unfortunately, "mycotic" is a misnomer that has led to a significant amount of confusion. A more specific classification system consists of four groups based on the underlying mechanism: (a) classic "mycotic aneurysm" caused by embolus from the heart infecting an artery; (b) microbial arteritis, in which bacteria infects an atherosclerotic but nonaneurysmal artery and leads to aneurysmal degeneration; (c) an existing aneurysm that becomes infected; (d) traumatic pseudoaneurysm with concomitant bacterial inoculation. Microbial arteritis resulting from hematogenous bacterial spread currently accounts for approximately 80% of all cases of infected aortic aneurysms.[162] *Salmonella* causes approximately 40% of all aneurysmal infections in contemporary series with the remainder caused by *Staphylococcus, Streptococcus, Bacteroides, Arizona hinshawii, Escherichia coli,* and *Pseudomonas aeruginosa.*[162]

The diagnosis of infected aortic aneurysm is often difficult and the clinical presentation insidious. Patients may present with fever, back/abdominal pain, or both. The physical examination is often remarkable for a palpable abdominal mass and the presence of peripheral emboli. Laboratory studies are notable for an elevated leukocyte count and positive blood cultures

although the latter are present only 50% of the time and negative blood cultures do not exclude the diagnosis. CT is the most useful diagnostic study, and the features suggestive of an infected aneurysm include a periaortic mass, an aneurysm in an atypical location, periaortic fluid or gas, retroperitoneal inflammation, and frank rupture. The angiographic finding of a saccular or eccentric/irregularly shaped aneurysm in an atypical location is also suggestive of an infected aneurysm.

The treatment of an infected aneurysm requires control of hemorrhage in the presence of rupture, aggressive debridement of all infected tissues, and restoration of perfusion to the viscera and lower torso. Indeed, these treatment concerns and the management options are identical to those for patients with infected aortic grafts. Patients should be started on broad-spectrum antibiotics when the diagnosis is suspected although antibiotic therapy alone is not sufficient and the operative intervention should not be delayed in an attempt to sterilize the retroperitoneum. Patients with suspected rupture should undergo emergent exploration through either a transperitoneal or retroperitoneal approach. After vascular control has been obtained, the retroperitoneum should be explored, and intraoperative cultures along with stat Gram stain should be obtained. Several options for arterial reconstruction are available, depending on the clinical scenario and the individual patient's anatomy. These options include in situ replacement with autogenous femoral vein or a prosthetic or cadaveric graft, ligation of the infrarenal aorta with extra-anatomic bypass (axillofemoral, femoral–femoral configuration), or in situ replacement with staged extra-anatomic bypass and subsequent removal of the in situ graft. The choice is contingent on the character of the aorta, degree of inflammation in the retroperitoneum, suspected organism, and hemodynamic status. In situ replacement of the infected aneurysm with a prosthetic or cadaveric graft is a reasonable option if retroperitoneal inflammation is minimal and the Gram stain is negative. The integrity of the aortic stump at the time of ligation and the potential for dehiscence or breakdown of the suture line are major concerns. The aorta should be debrided back to grossly uninvolved tissue and sutured in two layers with a running horizontal mattress and a simple continuous technique using nonabsorbable monofilament suture. A pedicle of omentum can be mobilized and approximated next to the aortic stump to help control the retroperitoneal inflammation and minimize the risk for stump dehiscence.

When the diagnosis is suspected preoperatively and no evidence of rupture is found, a staged approach with extra-anatomic bypass followed by graft removal may decrease the physiologic impact of any one procedure. The procedures are usually performed 2 to 3 days apart to allow the patients a period of recovery. Patients should be anticoagulated between procedures to prevent thrombosis of the extra-anatomic bypass resulting from competitive flow. Fortunately, the risk of graft thrombosis and graft infection during the intervening period is small.

Endovascular repair of infected aortic aneurysm can be considered an additional alternative. Although the long-term safety of EVAR in this clinical scenario remains unclear, it may serve as a temporizing approach that converts an urgent problem to an elective one. A meta-analysis by Kan et al.[163] reported that the endovascular approach was reasonable, but the incidence of subsequent endograft infection was significant in patients with ruptured aneurysms and those with fevers. They concluded that endovascular repair could be used as a bridge in this setting (i.e., ruptured aneurysm, febrile) prior to definitive open repair.

Infected aneurysms involving the suprarenal aorta pose a particularly challenging problem, but fortunately are uncommon. In situ replacement with a prosthetic or cadaveric graft is frequently the only available option. This can be accomplished in a number of ways, but the principle of aggressive removal of all infected tissue should be adhered to in order to prevent recurrent infection, typically a fatal event. If the thoracic aorta is of good quality, an antegrade debranching of the visceral segment can be performed to limit the ischemia time to the visceral/renal vessels. If there is a contained rupture of the aorta or the tissues are particularly inflamed, it may be best to obtain proximal and distal control above and below the disrupted/infected segment before attempting to dissect the visceral/renal vessels from the inflammatory mass. After obtaining sites for proximal and distal aortic control, a branched prosthetic graft soaked in Rifampin is sewn to the aorta in an end-to-side manner using a partial-occluding, side-biting clamp on the thoracic aorta to allow antegrade perfusion during the anastomosis. It is important to leave enough good aorta below this bypass to allow a cross-clamp and separate end-to-end anastomosis. The left renal, superior mesenteric, and celiac arteries can be bypassed individually in some cases and then a cross-clamp placed on the aorta distal to the end-to-side graft. The

aorta is then transected and aggressively debrided as dictated by the extent of the infection. A separate tube or bifurcated graft can then be sewn from the distal thoracic aorta to the bifurcation of the abdominal aorta, or to the iliac/femoral arteries, as indicated. This technique limits the ischemia time on the individual viscera/renal arteries, and allows full removal of all atherosclerotic material and infected aorta along with the infected periaortic tissues after complete revascularization of the visceral vessels.

Patients with infected aneurysms, regardless of the arterial reconstruction, require long-term antibiotics with tailoring of the medications based on culture results. If culture-directed therapy is not possible, broad-spectrum antibiotics for 6 weeks are indicated. The patient should then be placed on oral antibiotics although the duration of treatment remains unresolved and many surgeons will treat the patient with lifelong suppressive antibiotics. In addition, patients should undergo serial CT scans to assess the retroperitoneum and the status of the in situ graft as applicable. In the event that stable imaging is obtained over the first few CT scans, later imaging may not be warranted. Predictably, the morbidity and mortality rates associated with infected AAAs are significant with a 40% mortality rate.[164]

Aortoenteric Fistulae

An aortoenteric fistula is a communication between the aorta and the bowel. The duodenum is involved most commonly at the site where it crosses anterior to the aorta, but the communication can develop between almost any portion of the intestine. Primary aortic fistulae result when an aortic aneurysm erodes into the bowel and are distinctly rare with a reported incidence of 0.04% to 0.07% in autopsy series.[165] Secondary aortic fistulae result from the erosion of a prosthetic aortic graft into the bowel; are significantly more common, with a reported incidence of 0.1% to 2.0% after either open[166] or endovascular[167] aortic reconstruction. The management of both primary and secondary aortic fistulae is the same.

The diagnosis of an aortoenteric fistula is often difficult and mandates a high index of suspicion. Patients usually present with gastrointestinal bleeding manifested as either hematemesis or melena. The initial episode of gastrointestinal bleeding is often self-limited and has been described as a “herald” bleed. The diagnosis of aortoenteric fistula should be foremost

among the differential when a patient with a known aneurysm or prior aortic reconstruction presents with intestinal bleeding. Patients should undergo endoscopic evaluation of the upper and lower intestinal tract to determine the source of bleeding. It is imperative that the clinical suspicion of an aortoenteric fistula be communicated to the endoscopist to ensure that the third and fourth portions of the duodenum are adequately examined. The endoscopic findings of erosion, thrombus, active bleeding, or visible prosthetic graft in third or fourth portion of the duodenum are diagnostic of an aortoenteric fistula and mandate emergent treatment due to the risk of massive hemorrhage. Mild duodenitis and gastritis without frank erosion are frequently seen at the time of endoscopy and do not exclude the diagnosis of an aortoenteric fistula. Notably, the findings during upper endoscopy are normal in up to 30% of patients. A CT should be performed if the results of endoscopy are inconclusive. The findings on CT that suggest an aortoenteric fistula include inflammation within the retroperitoneum, an anastomotic pseudoaneurysm, close approximation of the bowel, and the prosthetic aortic graft or aneurysm, and loss of the normal tissue planes between the duodenum (or any other bowel segment) and the aorta or prosthetic graft. Occasionally, both endoscopy and CT are nondiagnostic despite the clinical suspicion of an aortoenteric fistula. Exploratory laparotomy is recommended in this setting for both diagnosis and treatment. Adherence of the bowel to the aorta at the time of the initial exploration suggests an aortoenteric fistula and mandates obtaining suitable proximal and distal control of the aorta, iliac vessels, or prosthetic graft before further dissection. The diagnosis cannot be excluded until the bowel is entirely separated from the retroperitoneum and graft.

The treatment of an aortoenteric fistula requires repair of the defect in the gastrointestinal tract in addition to repair of the aneurysm or treatment of the infected prosthetic graft. Treatment of the gastrointestinal defect is usually straightforward and is based on standard surgical principles. After the fistula is disassembled, the edges of the bowel can be debrided and a primary closure performed. A limited bowel resection or enteral diversion may be necessary. The intraoperative and longer-term management of the aortic aneurysm or prosthetic graft is the same as that outlined above for infected aortic aneurysms. In situ replacement of the prosthetic graft or infrarenal aorta using autogenous femoral vein or cryopreserved aortic allograft,

ligation of the infrarenal aorta with excision of the prosthetic graft and extra-anatomic bypass, or temporary in situ aortic replacement with staged extra-anatomic bypass and subsequent graft excision are all reasonable options. The decision algorithm is based upon the hemodynamic stability of the patient, their baseline physiologic state, and the anatomy and involvement of the aorta. In older/sicker patients, the most expeditious procedure is best. Replacement of the infected graft using autogenous femoral vein (neo-aorto-iliac system [NAIS]) is reasonably well tolerated in younger/healthier patients, and may be a better option that obviates the risk of aortic stump blow-out. If the visceral segment is involved, ligation of the aorta may not be possible without sacrifice of the renal arteries. In any case, these patients should be maintained on long-term antibiotics and undergo serial imaging studies, as outlined for infected aneurysm patients.

Venous Anomalies Relevant to Aortic Surgery

Anomalies of the vena cava and renal veins are occasionally encountered at the time of aortic reconstruction. The common anomalies are related to the embryologic development of the iliac veins and vena cava. The four most clinically relevant anomalies include duplication of the inferior vena cava (0.2% to 3.0%), left-sided vena cava (0.2% to 0.5%), circumaortic left renal vein (1.5% to 8.7%), and retroaortic renal vein (1.2% to 2.4%).[168] Patients with a duplicated inferior vena cava have large veins that run parallel to the infrarenal aorta and join together either anterior or posterior to the aorta at the level of the renal vein. In the case of a left-sided inferior vena cava, the cava runs parallel to the left side of the aorta, and the normally located right-sided vena cava is absent. The left-sided vena cava typically crosses the aorta at the level of the renal vein to become the suprarenal inferior vena cava, and the gonadal and adrenal veins on the right drain directly into the renal vein in a mirror image of the normal anatomy. The circumaortic left renal vein forms a collar of veins that surrounds the aorta at the normal level. In the case of a retroaortic left renal vein, a single vein runs posterior to the aorta at a slightly more caudal location. Notably, both duplication of the

inferior vena cava and left-sided vena cava can be associated with other venous anomalies, including a circumaortic or retroaortic renal vein.

The diagnosis of the various venous anomalies can usually be made preoperatively on CT. Identification of the vena cava and left renal vein should be part of the mental checklist used when the preoperative CT scans are reviewed. The various anomalies may not become evident immediately in the operating room if missed on the preoperative imaging studies. A very prominent left renal vein at the usual location or slightly inferior is suggestive of a left-sided vena cava, whereas the absence of a left renal vein despite dissection along the anterior aspect of the aorta at the level of the SMA is suggestive of a retroaortic renal vein.

Open repair of an infrarenal AAA in a patient with a venous anomaly is essentially the same as the standard approach although additional care should be exercised to prevent inadvertent injury of the aberrant vein. Exposure of the infrarenal neck is more difficult in the presence of a duplicated or left-sided vena cava. However, sufficient exposure can usually be obtained by gentle dissection and mobilization of the venous structures. The presence of a duplicated or left-sided vena cava is a relative contraindication to the left retroperitoneal approach. A circumaortic left renal collar or retroaortic left renal vein presents a potential hazard when the proximal aortic clamp is applied. A vertical aortic clamp is recommended and obviates the dissection on the posterior aspect of the aorta. Transecting the aorta may facilitate exposure of a retroaortic renal vein when significant bleeding is encountered.

Renal Anomalies

Congenital variations in the kidney anatomy may complicate the repair of an AAA. Specifically, aberrant kidney anatomy may complicate the dissection during open repair because they are frequently associated with multiple renal arteries, aberrant venous return, and abnormally positioned ureters. The various congenital anomalies of the upper urinary system have been classified in an attempt to standardize the approach for vascular surgeons.[169] The anomalies have been broken down into abnormalities of position, including simple ectopia, and abnormalities of both form and fusion, including horseshoe kidney, crossed renal ectopia without fusion, and crossed renal ectopia with fusion. An ectopic kidney may be positioned

anywhere from the pelvis to the thorax. Common forms of ectopic kidney include the pelvic kidney, located opposite the sacrum and below the aortic bifurcation; the lumbar kidney, located opposite the sacral promontory in the iliac fossa and anterior to the iliac vessels; the abdominal kidney, located above the iliac crest adjacent to the second lumbar vertebra; and the thoracic kidney, which can be located above the diaphragm in the posterior mediastinum. In a horseshoe kidney, two distinct renal masses are fused together by either a bridge of renal parenchyma or fibrous tissue; in the overwhelming majority, the lower poles are fused. In crossed renal ectopia, the kidney mass is located on the side opposite to its insertion in the bladder. Multiple configurations of crossed ectopia with and without fusion have been described.

The preoperative objective for the various renal anomalies is to image the renal mass adequately, delineate the course of the ureter, and establish the arterial and venous supply. The approach is simplified by the fact that most patients undergo abdominal/pelvic CT as part of the preoperative evaluation. The location and position of both the kidneys and ureters, like the position of the left renal vein, should be established as part of the review of every CT scan for patients with aneurysms. Formerly, it was recommended that patients with renal anomalies undergo preoperative arteriography to confirm the location and number of renal arteries. However, this information can now be obtained from the CT arteriogram, which is now part of the routine preoperative evaluation.

Patients with renal anomalies can safely undergo repair of an AAA using either an open or endovascular approach. The specific operative approach depends on the location of the renal mass, blood supply, course of the ureters, and presence of fusion. A left-sided retroperitoneal or transperitoneal approach with medial visceral rotation is the most helpful for open repair, particularly in patients with a horseshoe kidney. A standard transperitoneal approach with transection of the fused parenchyma can be used in patients with a horseshoe kidney although this may be associated with both significant bleeding and a urine leak and, therefore, is discouraged. The multiple renal arteries can be handled most expeditiously by using a Carrel patch technique, in which a cuff of aorta including the renal artery orifices is reimplanted into the aortic graft after completion of the proximal anastomosis. Endovascular repair is possible in many cases with the

feasibility dictated by the location of the renal arteries in addition to the other standard anatomic considerations.

Coexistent Renal or Visceral Artery Occlusive Disease

Coexistent renal or visceral artery occlusive disease is frequently found in patients undergoing AAA repair. The optimal management of patients with coexistent lesions remains unresolved. The options include repair of the aneurysm alone, simultaneous repair of the aneurysm and revascularization of the renal or visceral vessels, and staged repair, with either aneurysm repair or revascularization performed first. Furthermore, the specific treatment options include both open and endovascular alternatives for the aneurysm repair and visceral/renal revascularization (i.e., angioplasty/stent). The rapid expansion of the endovascular technologies has afforded effective, safe approaches that have replaced open surgical revascularization for both renal and visceral artery lesions to a great degree. Regardless, the optimal approach represents a balance between the indications for the procedure and the associated added risk.

Renal/visceral revascularization is mandatory at the time of open aneurysm repair if the affected vessels are involved in the aneurysm, as in a suprarenal aneurysm or a horseshoe kidney. More commonly, a lower pole or accessory renal artery may arise from the aneurysm. The decision to perform a concomitant revascularization with either reimplantation or a bypass graft in this setting depends on the size of the vessel and the quantity of kidney parenchyma perfused. Revascularization is recommended for larger vessels (>3 mm) that supply a significant portion of the renal mass. The presence of any accessory renal arteries should factor into the operative plan and the general feasibility for endovascular repair. Covering small, accessory renal arteries with an endograft has been reported to be safe with no significant decline in renal function.[170]

Combined aneurysm repair with renal or visceral artery revascularization may be justified if the indications for renal or visceral artery revascularization are satisfied. The traditional indications for renal revascularization included poorly controlled hypertension in a patient with a

significant renal artery stenosis and rapidly progressive renal insufficiency in a patient with adequate renal mass and bilateral renal artery stenosis. However, the antihypertensive agents have improved to the point that renal revascularization is currently reserved for patients with poor blood pressure control despite optimal medical therapy with at least three separate medications, including a diuretic.[171] Endovascular treatment of the renal artery stenosis (when indicated) can be performed prior to open aneurysm repair or simultaneous with the endovascular approach.

The traditional indications for mesenteric revascularization include symptoms of chronic mesenteric ischemia and critical stenosis of either the SMA alone or two of the three visceral vessels. Patients with chronic mesenteric ischemia and AAAs should have their visceral occlusive disease corrected prior to aneurysm repair when possible. Repairing the aneurysm first potentially increases the risk of developing acute mesenteric ischemia in the perioperative period, and performing concomitant mesenteric revascularization with AAA repair carries significant morbidity/mortality over and above that seen with open mesenteric revascularization alone.[172] Endovascular treatment with stent placement is probably the optimal treatment for the visceral lesions but long-term surveillance is necessary given reintervention rates.[173]

The optimal treatment for patients with aneurysms and *asymptomatic* renal or visceral artery lesions remains poorly defined. Analysis of patients with asymptomatic renal artery stenosis who underwent aortic reconstruction found that the natural history of the renal artery lesions is fairly benign when untreated and is associated only with an increase in the antihypertensive requirements.[174] Little is known about the natural history of asymptomatic mesenteric occlusive lesions with concomitant abdominal aneurysms. Ultimately, consideration should be given to mesenteric revascularization prior to aneurysm repair in patients with severe visceral artery occlusive disease due to the potential risk of mesenteric infarction at the time of aneurysm repair as noted above.

Additional Concurrent Intra-Abdominal Disease

The finding of an AAA and an additional intra-abdominal process that may require operative repair is a frequent event. A second surgical problem may be identified as part of the preoperative evaluation or discovered at the time of the exploratory laparotomy during open aneurysm repair. Alternatively, an AAA may be identified during the surgical treatment of another problem. No algorithms have been defined for the management of such concurrent problems, and the overall approach certainly requires sound clinical judgment. Options include simultaneous performance of the necessary operations, or a staged operation with repair of the AAA as either the first or second procedure. The approach depends on the risk for aneurysm rupture, natural history of the second surgical problem, and potential for infection of the prosthetic graft during simultaneous repair. Notably, both the laparoscopic and endovascular approaches have impacted the approach to patients with combined problems due to their reduced morbidity and mortality facilitates a more rapid, definitive treatment.

The generic recommendation for patients with an AAA and an additional intra-abdominal surgical problem is that the most life-threatening problem be addressed first. The natural history of untreated AAA has been defined reasonably well and has been outlined extensively earlier in this chapter. It has been suggested that the risk for aneurysm rupture is increased after major intra-abdominal surgery and that it is potentially related to an increase in collagenase activity.[175] However, this reported increased rupture risk is speculative and should not necessarily be factored into the decision algorithm. The management of concurrent colon cancer and AAA is a frequent treatment dilemma that provides an excellent illustration of the approach to these problems. Indeed, the reported incidence of colon cancer and an AAA occurring simultaneously ranges from 0.5% to 2.1%.[108] The treatment principles include the following: (a) aneurysm repair first in the presence of rupture; (b) colon resection first in the presence of hemorrhage, perforation, or obstruction; (c) aneurysm repair first in the presence of a large aneurysm and a small colon cancer; (d) colon resection first in the presence of a large colon cancer and a small aneurysm.[176]

Simultaneous AAA repair and cholecystectomy is probably safe for patients with cholelithiasis or evidence of chronic cholecystitis. The safety of these simultaneous procedures has been documented in several series, and the concerns about an increased incidence of aortic graft infection have not

been substantiated.[177] Regardless, the cholecystectomy and other simultaneous procedures should not be performed until after the aneurysm repair is completed and the retroperitoneum closed in an attempt to reduce the hypothetical risk for graft infection. Again, the exponential rise in EVAR has made some of the above concerns somewhat obsolete.

The safety and utility of other simultaneous procedures remain poorly defined although a wide range of procedures have been combined with open aneurysm repair. The repair of ventral hernias is often mandatory to achieve a tension-free abdominal closure and should be viewed more as an extension of the aneurysm repair than as a simultaneous procedure.

Lower Extremity Aneurysms

Katherine E. Hawkins and Amy B. Reed

Key Points

1 Femoral artery aneurysms are the most common peripheral aneurysm if both true and false aneurysms are considered together. Popliteal artery aneurysms are the most common true peripheral aneurysm.

2 Femoral and popliteal aneurysms are often incidental findings on imaging or routine physical examination.

3 Extremity aneurysms are potentially limb threatening and frequently associated with other aneurysmal disease, including life-threatening abdominal aortic aneurysms.

4 Screening imaging studies should be done to evaluate for concurrent abdominal aortic aneurysms or contralateral femoral or popliteal artery aneurysms.

5 Femoral artery aneurysms should be repaired at a size ≥3.5 cm, if intraluminal thrombus is present, or if symptomatic.

6 Popliteal artery aneurysms should be repaired at a size of 2 to 3 cm or if symptomatic, to prevent limb-threatening complications.

7 Anastomotic aneurysms result from a disrupted suture line between a graft and the host artery.

8 Pseudoaneurysms after percutaneous intervention result from failed hemostasis.

9 Thrombolytic therapy is a useful adjuvant in patients presenting with acute limb ischemia secondary to thrombosis of a popliteal artery aneurysm.

PERIPHERAL ANEURYSMS

1 The significance of peripheral aneurysms comes from their potential for limb-threatening complications, more so than rupture, and their association with abdominal aortic aneurysms. Popliteal artery aneurysms are the most frequently encountered peripheral true aneurysm. True femoral artery

aneurysms are rare, with iatrogenic and anastomotic pseudoaneurysms being more common.

Incidence

An aging population, increased arterial trauma, more common use of invasive therapies for vascular disease, and increased use of imaging modalities all contribute to the rise in number of peripheral aneurysms being diagnosed. In a screening study of men between the ages of 65 and 74 years, abdominal aortic aneurysms were identified in 4.9% of patients.[1] In patients with abdominal aortic aneurysms, 6.8% had femoral artery aneurysms and 9.6% had popliteal artery aneurysms.[2] Screening of men between the ages of 65 and 80 years identified popliteal artery aneurysms in 1%.[3]

An increasing number of false aneurysms—"pseudoaneurysms"—are occurring coincident with the increased use of catheter-based diagnostic and therapeutic interventions in addition to lower extremity bypass surgery. Pseudoaneurysms can be iatrogenic, infectious, or traumatic in nature and are identified by their lack of involvement of all three vessel wall layers, as compared to true aneurysms. Femoral pseudoaneurysms most commonly develop after cannulation with arterial sheaths used for coronary or arterial interventions and may vary based on patient anatomy and habitus.[4]

Degenerative (often called atherosclerotic) femoral and popliteal artery aneurysms are encountered far more frequently in men than women. The male to female ratio in patients with femoral and popliteal aneurysms is about 30:1.[5,6] This predilection for men is markedly different from aortic aneurysms, where male to female patient ratio is approximately 4:1.[2]

Pathogenesis

The cause of femoral and popliteal aneurysms has changed significantly since they were first recognized centuries ago. Once primarily infectious in origin, most true aneurysms in the 21st century have a degenerative cause, commonly called *atherosclerotic aneurysms*. Peripheral pseudoaneurysms usually follow surgery or trauma. Rarely, peripheral aneurysms develop secondary to connective tissue disorders, such as Marfan syndrome or Behçet syndrome. Notably, tibial and pedal artery aneurysms are rare.

The cause of degenerative aneurysms of the femoral and popliteal vessels is not clear. One factor believed to contribute to aneurysm formation is turbulent flow beyond a relative stenosis resulting in poststenotic dilatation beyond the inguinal ligament at the groin or beyond the tendinous hiatus of the adductor magnus or the arcuate popliteal ligament and the heads of the gastrocnemius muscle at the popliteal level. Arterial wall fatigue resulting from vibration and turbulence proximal to a major branching or caused by stress during hip and knee flexion may also contribute to aneurysm formation.

The frequent occurrence of multiple peripheral aneurysms in the same patient suggests a systemic abnormality in the arterial wall, which promotes aneurysmal degeneration at locations where hemodynamic or mechanical factors put unusual stress on the arterial wall. There are multiple factors that contribute to aneurysmal degeneration and are felt to contribute to degenerative femoral and popliteal aneurysms, as well as aortic aneurysms. The presence of an inflammatory infiltrate has been noted in the wall of femoral and popliteal aneurysms, similar to aortic aneurysms.[7] The exact role of this inflammatory process, with potential release of reactive oxygen species and matrix metalloproteinases, is unknown. Apoptosis of smooth muscle cells may also play a role in the formation of aneurysms by limiting the ability of the arterial wall to respond to the degenerative process.[8] These factors, however, do not explain the male predilection for femoral and popliteal aneurysm formation. X-linked genetic abnormalities for aneurysm formation in popliteal artery aneurysms have not been noted in humans.

Clinical Manifestations

Femoral and popliteal aneurysms are often asymptomatic. They may be detected on routine physical examination by a bounding, expansile pulse, or discovered incidentally on imaging. When symptomatic, femoral and popliteal artery aneurysms may be accompanied by sensations of local fullness, pain caused by pressure on the adjacent nerve, limb edema, and venous distention or thrombosis caused by compression of the adjacent vein. Secondary complications from thrombosis or distal embolization include lower extremity ischemia with intermittent claudication, rest pain, or gangrene. Because the natural history and complication rate in femoral and popliteal aneurysms differ, they are considered separately here.

FEMORAL ARTERY ANEURYSMS

2 Femoral artery aneurysms are the most common peripheral aneurysm if both true and false aneurysms are considered together, with the vast majority being pseudoaneurysms. Their clinical significance is related to limb-threatening complications from thrombosis, embolization, or rupture. True aneurysms are predominantly degenerative from atherosclerosis, whereas femoral pseudoaneurysms include anastomotic, traumatic, and mycotic lesions.

Degenerative (Atherosclerotic) Aneurysms

Incidence

The exact incidence of degenerative (atherosclerotic) common femoral artery aneurysms in the general population remains undefined; one study suggests 5 in 100,000 patients may be affected.[6] Femoral aneurysms are found in 6.8% of all patients with abdominal aortic aneurysms; conversely, 85% of patients with femoral artery aneurysms have abdominal aortic aneurysms.[2,5]

Pattern of Disease

As with all aneurysms, femoral artery aneurysms are defined as being greater than 1.5 times the diameter of the disease-free proximal adjacent arterial segment. The average size of the common femoral artery is approximately 8 to 10 mm, with variations based on age and sex; an average of 9.8 mm in males and 8.2 mm in females was demonstrated in healthy volunteers.[9] Femoral aneurysms most frequently affect the common femoral artery. They may be classified as *type I,* those limited to the common femoral artery, or *type II,* those involving the orifice of the profunda femoris artery.[10] Type I and type II aneurysms occur with nearly equal frequency. This classification becomes important in reference to vascular reconstructive procedures, with type II aneurysms requiring more complex reconstructions to ensure continued patency of both the superficial and profunda femoris arteries. Isolated lesions of the profunda femoris artery are rare (2% of femoral artery aneurysms), and are prone to rupture because they are difficult to diagnose at

the asymptomatic stage. Isolated superficial femoral artery aneurysms are also uncommon, but one-third of patients present with rupture and one-quarter with thrombosis.[11]

Multiple aneurysms are common in patients with femoral artery aneurysms. In a series of 100 patients with degenerative femoral artery aneurysms seen at a single institution, 72% of patients had bilateral femoral artery aneurysms.[5] In addition, aortoiliac aneurysms were detected in 85% of patients, thoracic aortic aneurysms in 6%, and popliteal aneurysms in 44%, of which 55% were bilateral.

Clinical Manifestations

The typical patient with a degenerative femoral artery aneurysm is a male in his 60s or 70s with the usual risk factors for atherosclerosis. Of these patients, 86% are cigarette smokers, 36% have hypertension, and 14% have diabetes mellitus.[5] Associated cardiovascular disease is common, with clinical manifestations of coronary artery disease and cerebrovascular disease present in 34% and 7%, respectively.

As with aneurysms in other locations, femoral artery aneurysms may be complicated by embolization, thrombosis, or rarely rupture. Peripheral embolization may be identified incidentally on angiography or produce signs as mild as spotty discoloration of the toes to as severe as peripheral gangrene. Although embolization is reported in about 10% of aneurysms, the femoral artery aneurysm is not necessarily the source of these emboli because many patients have a concomitant popliteal aneurysm.[5] In larger clinical series, approximately 30% of patients are symptomatic, with thrombotic or embolic events developing in 2.5% to 15% of patients and rupture in 4% to 14%.[6,12,13]

Compression symptoms are present in 34% of patients. Lower extremity venous disease is present in 8%, being attributable to venous obstruction by the femoral artery aneurysm in 4%. A palpable mass is found in 23% of patients, and localized pain in just under 10% of patients with femoral aneurysms.[6,12]

Natural History

The natural history of degenerative femoral artery aneurysms is poorly defined. One study of 236 isolated femoral artery aneurysms found that 66% were asymptomatic on presentation. 114 patients were initially managed nonoperatively, with 64% later undergoing repair, but only 10% of the initial cohort doing so for acute complications. The authors found that the femoral artery aneurysms rarely developed complications unless >3.5 cm in size or if intraluminal thrombus was present.[5,6]

Diagnosis

In most cases the diagnosis of femoral artery aneurysm is suspected by the finding of a pulsatile groin mass on routine physical examination or during evaluation for vascular disease. If the femoral artery aneurysm is small or thrombosed, detection on physical examination may be difficult. Although a radiograph of the region may occasionally demonstrate the calcified rim of the aneurysm, only ultrasonography, computed tomography (CT), or magnetic resonance imaging (MRI) can reliably establish the diagnosis of the femoral aneurysm. In addition, these modalities are useful in accurately defining the size of the lesion and evaluating associated aneurysmal disease in the distal aorta and popliteal regions. The diagnostic accuracy of arteriography is limited because it demonstrates only the residual lumen and an aneurysm filled with smooth mural thrombus may be missed, but the definition of the vascular anatomy of the lower extremity provided by angiography is helpful in planning the appropriate operative procedure (**Fig. 95.1**).

Treatment

Operative treatment of femoral aneurysms is indicated for asymptomatic aneurysms >3.5 cm in size, or for any size causing local symptoms or presenting with limb-threatening complications. In patients with small, asymptomatic aneurysms, observation may be appropriate. When nonoperative management is selected, the size of the aneurysm should be documented by ultrasonography. The patient should be followed at regular intervals with ultrasound scans and careful examination for complications; no consensus guidelines exist for follow-up intervals. Operative treatment should be undertaken without undue delay if the femoral aneurysm enlarges,

produces symptoms, or is complicated by embolization, thrombosis, or rupture.

Figure 95.1 Arteriogram demonstrating bilateral femoral artery aneurysms that extend into the superficial femoral arteries. Unlike many patients with femoral artery aneurysms, this patient did not have an associated aortic aneurysm or popliteal aneurysms.

Surgical Strategy

The operative approach is individualized based on associated aneurysmal disease. In patients with multiple asymptomatic aneurysms, treatment is staged. Generally, aortic aneurysm repair precedes extremity repairs, and popliteal aneurysms are repaired prior to femoral aneurysms. Aortic lesions are treated before femoropopliteal lesions, based on the rationale of life-versus-limb threat. If an aortofemoral bypass is necessary, the femoral aneurysm should be treated at the same time, to avoid later anastomotic

aneurysm formation. The graft limb can be anastomosed into an interposition graft that has replaced the femoral aneurysm. Similarly, if a stent graft is placed for treatment of an abdominal aortic aneurysm in a patient with femoral artery aneurysms, the aneurysm should be repaired with an interposition graft. In patients with severe lower extremity ischemia, the femoral aneurysm is treated with an interposition graft, from which the proximal anastomosis of the required femoropopliteal or femorotibial bypass is based.

Technique

The operative procedure for treatment of an isolated femoral artery aneurysm is determined by aneurysmal involvement of the superficial and deep femoral arteries as well as by the existence of lower extremity occlusive disease. The femoral artery aneurysm is usually approached through a longitudinal groin incision. As a special consideration when addressing an unusually large aneurysm or a ruptured aneurysm, however, initial proximal control of the external iliac artery through a retroperitoneal approach is advisable. After proximal and distal arterial control is obtained, the aneurysm sac is opened and the atheromatous debris is removed. Small aneurysms may be excised, but routine excision of large aneurysms is not recommended as these lesions can often be adherent to the adjacent vein and nerve.

For type I aneurysms, the preferred treatment is reconstruction with an interposition graft of Dacron or expanded polytetrafluoroethylene, with the proximal anastomosis at the distal external iliac artery or proximal common femoral artery and the distal anastomosis at the femoral bifurcation.

For type II aneurysms with patent superficial and profunda femoris arteries, an interposition graft to the profunda femoris artery with reimplantation of the superficial femoral artery is one standard configuration. If the superficial femoral artery is chronically occluded and the patient has minimal symptoms, an interposition graft to the profunda femoris artery alone is sufficient. If the patient has severe lower extremity ischemia, this is typically followed by a standard distal reconstruction. If recent emboli or in situ thrombosis has occluded the outflow tract, percutaneous mechanical thromboembolectomy or catheter-directed thrombolytic therapy is useful before open arterial reconstruction is undertaken.

Results

Results of surgical therapy depend upon the patency of the distal vasculature. More than 80% of asymptomatic patients have excellent long-term results, whereas 68% of those presenting with lower extremity ischemia achieve satisfactory long-term outcomes.[5]

Anastomotic Pseudoaneurysms

Incidence

3 Anastomotic pseudoaneurysms result from a disrupted suture line between a graft and the host artery. The incidence varies with the location of the anastomosis and the type of graft that is used. Involvement of the femoral artery accounts for nearly 80% of these lesions, and 3% of all femoral anastomoses.[14,15] After infrainguinal bypass procedures, the incidence is higher with prosthetic grafts than with autogenous vein grafts; 6% of femoral anastomoses develop aneurysms when Dacron is used, compared with 0.9% when a vein graft is placed.[14] Anastomotic pseudoaneurysms are a late complication of bypass procedures; the mean interval from primary procedure to recognition is more than 6 years.[16,17] A notable subset exists in aortofemoral bypass; 6% of femoral anastomoses after aortofemoral bypass develop this complication compared with 0.2% of the proximal aortic anastomoses.[14] Patient factors that are associated with increased likelihood of developing a femoral anastomotic aneurysm after aortofemoral bypass include chronic obstructive pulmonary disease, current smoking, and postoperative groin wound infection.[18]

Pathogenesis

Several factors contributing to anastomotic pseudoaneurysm formation have been identified: weakness of the arterial wall, the type of graft material and suture utilized, the presence of infection, the method of construction of the anastomosis, and the stress on the suture line from hypertension, leg motion, or excess tension on the graft limb.[14,16,17] Progressive degeneration of the recipient artery accounts for most anastomotic pseudoaneurysms, and an increased incidence has been noted following endarterectomy of the artery at

the anastomosis. False aneurysms occur less frequently with saphenous vein grafts than synthetic vascular grafts, a reflection of more complete healing of autogenous tissue. With the use of monofilament synthetic suture, anastomotic pseudoaneurysms rarely result from a loss of suture integrity, although occasionally a broken suture is a factor in pseudoaneurysm formation. Although most anastomotic aneurysms are not accompanied by overt graft infection, occult infections with coagulase-negative *Staphylococcus* species may be an important factor in development of anastomotic aneurysms.[17] A higher incidence is noted in patients with wound-healing complications, and the use of anticoagulants may increase such complications.

Clinical Manifestations

Femoral anastomotic pseudoaneurysms usually present as a pulsatile groin mass, which may or may not be accompanied by pain, redness, or symptoms of venous obstruction. Acute complications include hemorrhage, embolization, and occlusion with acute limb ischemia.

Diagnosis

The diagnosis of an anastomotic pseudoaneurysm is usually made on physical examination by the presence of a pulsatile groin mass in a patient who has undergone a femoral arterial reconstructive procedure. The differential diagnosis includes nonpulsatile groin masses, such as hernia, lymphocele, or abscess, through which pulsation is transmitted from an underlying normal femoral artery. Diagnosis of an anastomotic disruption in one region should raise suspicion of other anastomotic pseudoaneurysms as multiple lesions are found in at least 30% of patients.[16] The presence of multiple anastomotic pseudoaneurysms suggests infection. Evaluation of an anastomotic aneurysm includes ultrasonography, CT, or angiography to define all anastomoses of the graft (**Fig. 95.2**).

Treatment

Because of the progressive nature of anastomotic pseudoaneurysms, surgical treatment is generally undertaken for all lesions >2 cm except those in high-risk patients. Principles of surgical therapy are those of primary aneurysms: obtain proximal and distal control and replace the aneurysmal segment.

Securing proximal control often requires dividing the inguinal ligament to isolate the graft limb. Distal control is most easily obtained using intraluminal balloon catheters. If intrinsic arterial disease requires extension of the graft distally on the profunda femoris or superficial femoral artery, these arteries can be identified by dissection through unscarred tissue distal to the previous exposure. After débridement of the degenerated artery, an interposition graft is placed between the prosthetic graft limb and the healthy native artery. Cultures of the graft and vessel wall are essential to exclude infection as an etiologic factor in the development of the anastomotic aneurysm. If infection is obvious at the time of surgery, the approach is the same as that of any infected graft with removal of infected prosthetic material and reestablishment of blood flow, if necessary, with a bypass through an uninfected tissue route, such as an obturator, lateral femoral, or axillofemoral bypass.

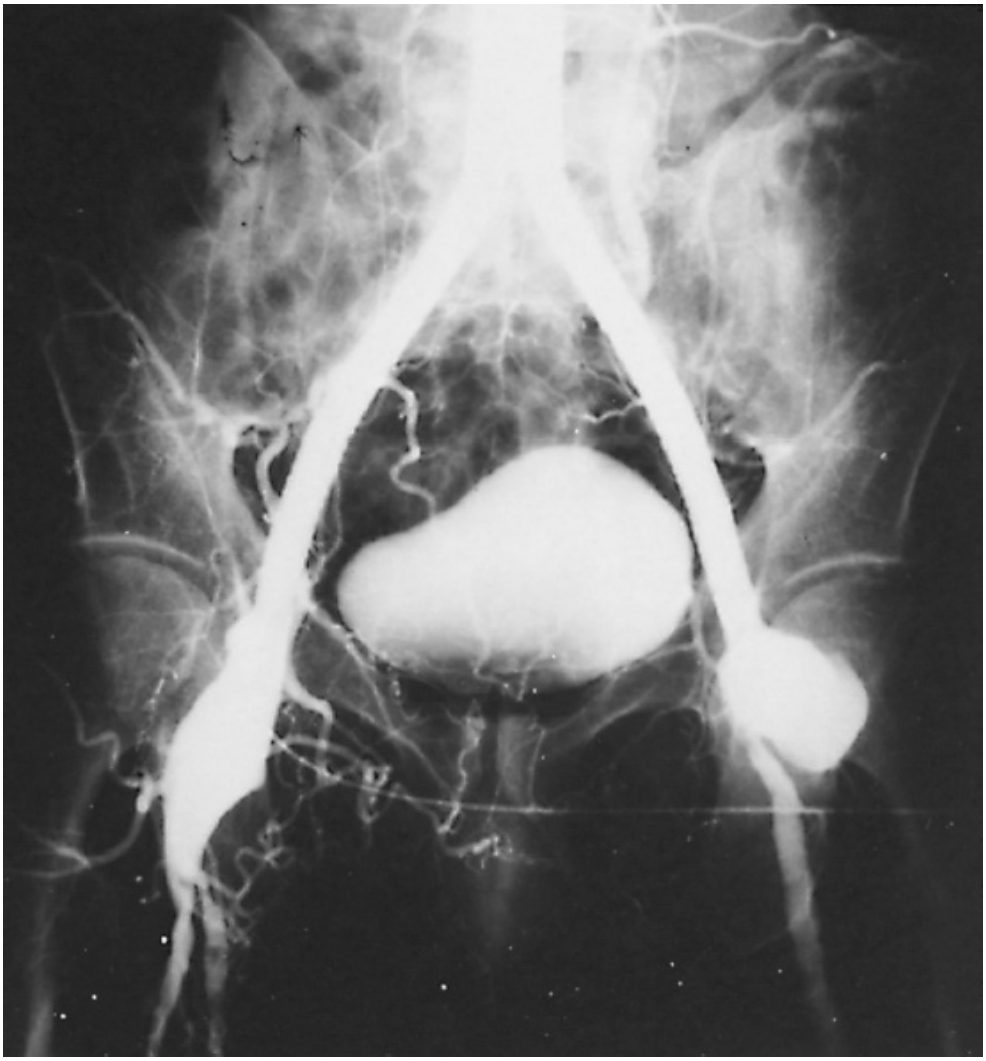

Figure 95.2 Arteriogram demonstrating bilateral femoral anastomotic aneurysms after an aortofemoral bypass and a left femoropopliteal bypass.

Results

Results of elective operations on femoral anastomotic pseudoaneurysms are excellent with 2% operative mortality, 97.5% graft patency at 2 years, and 2% amputation within 2 years of surgery.[16] Recurrence is reported in less than 16% of cases.[14,15] Patients presenting with aneurysms complicated by hemorrhage, occlusion, or embolization have significantly increased operative morbidity and mortality.

Femoral Pseudoaneurysms

Incidence

Femoral pseudoaneurysm incidence has increased as a result of diagnostic and therapeutic angiography. Therapeutic angiography often requires prolonged arterial cannulation, large-bore sheaths, and anticoagulation, which are associated with a higher rate of arterial complications than diagnostic studies. One study with routine ultrasound surveillance following 254 therapeutic interventions via femoral access in patients with known arterial disease showed a pseudoaneurysm development rate of 2.75%.[19] A meta-analysis of 7,889 femoral arterial access procedures demonstrated an increase in pseudoaneurysm formation with arterial closure devices (odds ratio 3.8) versus surgical cutdown, albeit with fewer other complications including seroma, surgical site infection, and wound dehiscence.[20] A registry analysis of 12,937 patients undergoing percutaneous interventions through the femoral artery showed pseudoaneurysm rates of 0.6% with manual compression versus 0.1% with arterial closure devices ($p < 0.5$).[21] The overall reported rate of pseudoaneurysm formation after percutaneous procedures is reported to be anywhere between 0.05% and 8%.[22]

Pathogenesis

Pseudoaneurysms from iatrogenic catheter trauma are defined as collections of blood in continuity with the arterial system, and not enclosed by all three layers of the arterial wall.[4] These lesions form because of failed hemostasis at the arterial wall defect created by sheath insertion. Normally hemostasis seals the defect promptly, aided by direct focal application of pressure or hemostatic devices, and the arterial wall repairs itself. When hemostasis is not successfully obtained, blood under arterial pressure leaks from the artery, dissects surrounding tissue planes, and forms what is perceived on physical examination to be a pulsatile mass. The gross findings at surgery are a blood-filled cavity surrounded by a capsule. As pseudoaneurysms, these lesions can cause symptoms by rupture or compression of surrounding structures.

Diagnosis

The diagnosis of femoral pseudoaneurysm is suspected when a pulsatile groin mass is noted after arterial catheterization. The differential diagnosis includes hematoma, lymphadenopathy, and abscess. Duplex ultrasound with

color flow or CT is typically used to establish the diagnosis, differentiate pseudoaneurysm from hematoma, and aid in defining the communication between the mass and the arterial lumen. Color-flow duplex scanning is the diagnostic test of choice, providing accurate diagnosis with a characteristic to-and-fro waveform and a "yin-yang" pattern of color swirling, along with localization and sizing of the false aneurysm (**Fig. 95.3**).[23]

Natural History

Color-flow duplex scanning has been used to define the incidence and natural history of pseudoaneurysms after percutaneous transluminal coronary angioplasty.[24] Many pseudoaneurysms smaller than 2.0 cm in diameter will thrombose spontaneously within 4 weeks; anticoagulation and size greater than 2.0 cm are predictors of failure of spontaneous thrombosis. About 30% of patients with pseudoaneurysms will require intervention.[25]

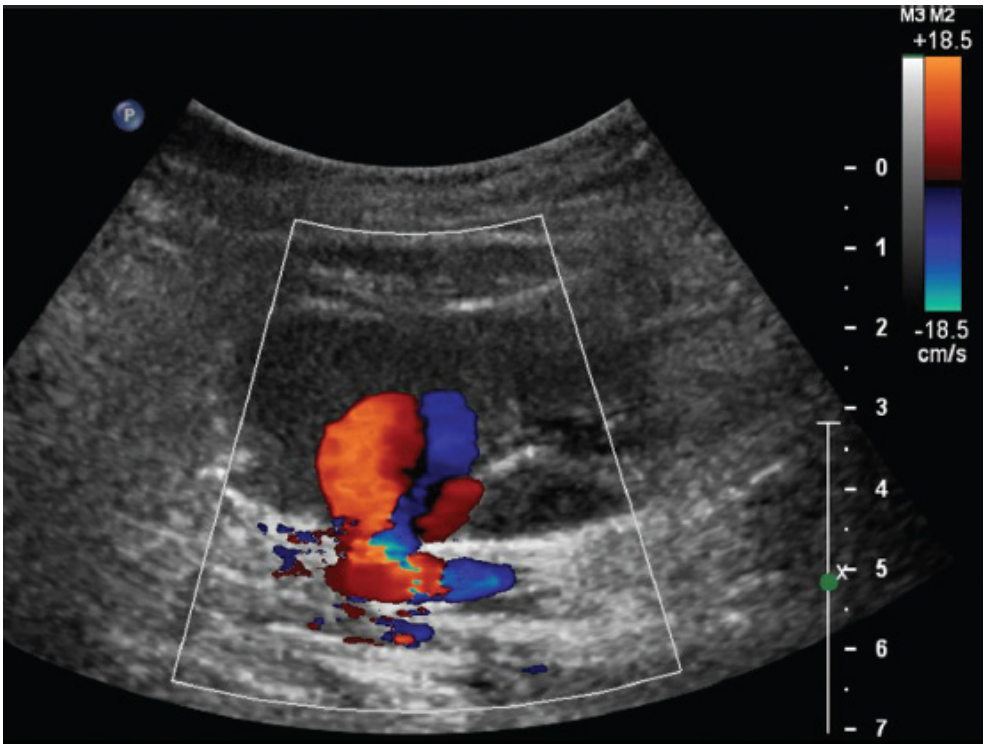

Figure 95.3 Ultrasound findings with a to-and-fro flow pattern in a femoral pseudoaneurysm.

Treatment

Therapy of femoral pseudoaneurysms is influenced by aneurysm size and symptoms, and whether the patient requires continuous anticoagulation (**Algorithm 95.1**). Surgical intervention is mandatory for all pseudoaneurysms that are acutely expanding, compressing adjacent nerves, or compromising the overlying skin. Proximal and distal arterial control is obtained, and the arterial defect is repaired directly, rarely requiring placement of more than one or two sutures.

Ultrasound-guided compression and ultrasound-guided thrombin injections are alternative treatment strategies when urgent evacuation of the hematoma and arterial repair are not required. Compression therapy entails identification with a color-flow ultrasound probe and directed intermittent compression of the pseudoaneurysm with the transducer, allowing the visualization and documentation of flow cessation when effective. This technique may be limited by body habitus, patient discomfort, and requires up to 30 minutes of compression by the ultrasonographer.

Another nonoperative treatment option of femoral pseudoaneurysms is percutaneous ultrasound-guided injection of 0.5 to 1.0 mL thrombin (1,000 U/mL) into the pseudoaneurysm sac, at a site away from the neck of the aneurysm.[26–28] Thrombin injection avoids the discomfort of prolonged compression and is effective in anticoagulated patients. Continuous ultrasonographic imaging is used to monitor thrombosis of the pseudoaneurysm.

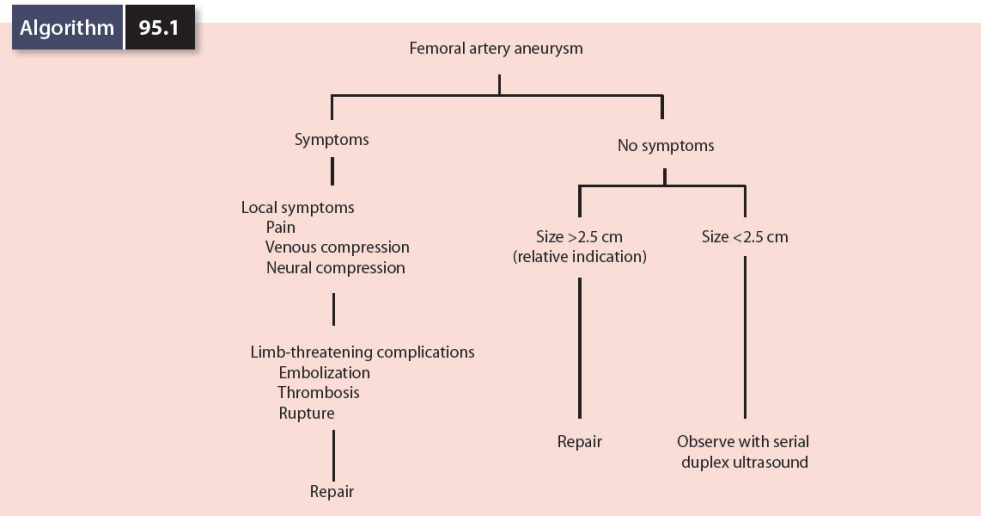
Results

A meta-analysis of studies involving 992 patients treated with ultrasound-guided compression versus ultrasound-guided thrombin injection showed pooled success rates of 69.3 versus 97.4%, respectively, without significant difference in the rate of complications.[22]

In one of the largest series of pseudoaneurysms treated with ultrasound-guided compression, thrombosis was achieved in 86% of anticoagulated patients, and in 98% of those not anticoagulated, with a 20% recurrence rate in less than 24 hours in anticoagulated patients.[29] Success using this therapeutic modality requires a knowledgeable ultrasonographer and meticulous postcompression follow-up, though patient discomfort from

prolonged compression often renders the technique unsuccessful in achieving hemostasis.

Thrombin injection to induce thrombosis of pseudoaneurysms is successful in 94% to 98% of patients, with thrombosis occurring in less than 1 minute.[26–28] This technique can be complicated by arterial thrombosis if an excessive volume of thrombin is used and may not be appropriate for pseudoaneurysms with large necks. Remote thromboembolic events are rare and probably are not a result of a systemic effect of the thrombin. Allergic reactions to bovine thrombin occasionally occur. Large pseudoaneurysms, greater than 8 cm in diameter, and an associated arteriovenous fistula (AVF) are predictors of failure with thrombin injection.[30]



Algorithm 95.1 Management of femoral pseudoaneurysm.

Mycotic Aneurysms

The term *mycotic aneurysm* is currently used to refer to any infected aneurysm. Mycotic aneurysms today are often a complication of parenteral drug abuse, but can follow arterial trauma of any form and have been associated with iatrogenic injury, osteomyelitis, endocarditis, or idiopathic etiologies. Historically, septic emboli from bacterial endocarditis were a major cause of mycotic aneurysmal degeneration, as were tuberculosis and late-stage syphilis. With the change in cause, the location of mycotic aneurysms has shifted from central to peripheral arteries, with the femoral

artery being the most common site.[31,32] The importance of mycotic aneurysms comes from their propensity to rupture.

Pathogenesis

The pathogenesis of mycotic aneurysms can be divided into four major categories, although other less common causes also exist.[31] First, septic emboli from bacterial endocarditis may lodge in normal arteries, causing infection that weakens the arterial wall, resulting in aneurysm formation. These lesions are often multiple. Second, during an episode of bacteremia, microorganisms may lodge in a pre-existing atherosclerotic plaque or aneurysm and begin to multiply with the same result. A third cause of mycotic aneurysms is the contiguous spread of bacteria from a local abscess. The inflammatory process destroys the arterial wall, leading to pseudoaneurysm formation. Finally, trauma to the artery with concomitant contamination may result in formation of an infected pseudoaneurysm. Bacteria may be introduced concomitantly with needle puncture or by migration during prolonged arterial catheterization. Mycotic aneurysms accompanying drug abuse may be secondary to direct contamination of the arterial wall, or they may result from destruction of the vessel wall by a local abscess.

A contemporary case series of 29 patients with mycotic peripheral aneurysms found *Staphylococcus aureus* in 38.5%, *Streptococcus* sp. in 11.5%, other *Staphylococcus* spp. in 7.7%, and gram-negative rods (*Serratia* and *Pseudomonas* spp.) in 7.7% of patients.[33] Staphylococcal species, *Salmonella* sp., *Escherichia coli*, and *Proteus* sp. have also been cultured.

Clinical Manifestations

The typical patient with a mycotic femoral aneurysm presents with a history of chills and fever, and a tender, enlarging, pulsatile groin mass. The patient may have a history of intravenous drug use, recent arterial catheterization, penetrating trauma, or bacterial endocarditis. Local signs of infection, including tenderness, erythema, and warmth are noted on physical examination. Lower extremity edema may occur secondary to venous or lymphatic obstruction. Petechial skin lesions, splinter hemorrhages, cutaneous abscesses, and septic arthritis may occur as a result of emboli

originating from a mycotic aneurysm. A “sentinel bleed” may occur and signals impending rupture and life-threatening hemorrhage. Urgent or emergent surgical intervention is indicated for these aneurysms.

Diagnosis

The diagnosis of a mycotic aneurysm is usually straightforward, but distinguishing an abscess adjacent to the femoral artery from a femoral mycotic aneurysm may be difficult. In the patient with a pulsatile groin mass, laboratory findings including a leukocytosis, elevated erythrocyte sedimentation rate, and positive blood cultures are suggestive, but not specific, for a mycotic aneurysm. Multiple blood cultures or downstream arterial blood cultures may be necessary to yield positive results. Ultrasonography and CT angiography are helpful in establishing the diagnosis of an aneurysm (**Fig. 95.4**), but lack precision in distinguishing infected from bland aneurysms. The diagnosis of a mycotic aneurysm is confirmed at operation by demonstration of organisms on Gram stain or by positive cultures of the aneurysm wall.

Figure 95.4 Computed tomography scan of an infected femoral anastomotic aneurysm that was diagnosed 5 years after aortofemoral graft placement.

Treatment

Mycotic aneurysms represent a serious life- and limb-threatening disease because their natural history is one of expansion and rupture, and should therefore be treated when discovered. The goal of treatment is eradication of the infection. Before operative intervention is performed, the patient is started on antibiotics that are subsequently modified based on sensitivity testing of intraoperative cultures. The complexity of the operative procedure varies with the location and extent of the mycotic aneurysm, with excision, tissue débridement, and staged revascularization through noninfected tissue planes the main goals of treatment.

Stent grafts have been used in selected cases of mycotic aneurysms when other approaches were not feasible; however, concern about latent infection of the stent graft oftentimes renders this more of a bridging technique than a long-term solution.

Although a direct approach to the femoral artery may be taken, a retroperitoneal exposure of the distal external iliac artery for proximal control is often safest for large or proximal femoral lesions to avoid excessive hemorrhage. In more than 50% of cases, the mycotic aneurysm involves the femoral artery bifurcation, and treatment requires resection of the femoral bifurcation to afford débridement to healthy arterial wall. Three options for repair exist: ligation, immediate revascularization, or selective revascularization. (1) The distal external iliac or proximal common femoral artery, as well as the superficial and deep femoral arteries, are oversewn with nonabsorbable monofilament suture. This results in significant ischemia in most patients, but with the patient heparinized, symptoms gradually improve as collateral circulation increases. The majority of patients will not need revascularization for limb salvage, but up to one-third of patients will have limb-threatening ischemia.[34,35] (2) In patients in whom sepsis can be adequately controlled at the initial procedure, aggressive débridement may be followed by immediate revascularization using autogenous vein graft as the conduit and covering the graft with a muscle flap.[35] This technique is most effectively utilized when the area of arterial infection is limited. If the field was significantly contaminated, immediate revascularization will frequently be met with blowout. (3) Another option is to observe patients for 24 hours after arterial ligation and selectively revascularize only those patients in whom limb-threatening ischemia persists. Use of prosthetic material through the original infected tissue planes is avoided because of the high incidence of early and late septic complications. If necessary, synthetic graft may be tunneled through uninfected tissue such as the obturator canal or via the lateral femoral route. Antibiotics are begun preoperatively and continued for at least 4 to 6 weeks postoperatively.

POPLITEAL ARTERY ANEURYSMS

5 Popliteal aneurysms are limb-threatening lesions, the vast majority of which are degenerative in etiology. Rarely, anastomotic, traumatic, or mycotic popliteal aneurysms are encountered in contemporary practice. The remainder of this section addresses only popliteal aneurysms that are degenerative in etiology. The average popliteal artery size is approximately

4 to 7 mm; one study identified a mean diameter of 5.2 mm in healthy male subjects.[36] Again, aneurysmal dilatation is defined as being greater than 1.5 times the diameter of the disease-free proximal adjacent arterial segment.

Incidence

Popliteal artery aneurysms are the most common degenerative true peripheral aneurysm. They occur slightly more frequently than femoral artery lesions; however, popliteal aneurysms are relatively unusual compared to abdominal aortic aneurysms. Aortic aneurysms are diagnosed with about 10 times the frequency of popliteal aneurysms.[37,38]

Pattern of Disease

Like patients with femoral artery aneurysms, multiple aneurysms occur frequently in patients with popliteal aneurysms. About 50% of patients have bilateral popliteal aneurysms, and 55% have extrapopliteal aneurysms.[39,40] Of patients with popliteal artery aneurysms, 40% have femoral artery aneurysms; 40% to 50% have abdominal aortic aneurysms; and bilateral popliteal artery aneurysms are associated with aortic aneurysms in 70% of cases. The association with other aneurysms has resulted in the recommendation that patients discovered to have femoral or popliteal aneurysms should have completion imaging to exclude contralateral limb aneurysms and abdominal aortic aneurysms.[41] Even when popliteal aneurysms are initially asymptomatic, patients will develop symptoms at a mean rate of 14% per year, and one-third will develop complications requiring emergent intervention within 5 years, resulting in poorer outcomes for both life and limb.[42,43]

Clinical Manifestations

The typical patient with a popliteal aneurysm is a male in his 60s or 70s with the usual risk factors for atherosclerosis. Of patients with popliteal aneurysms, 50% to 75% are smokers, 40% to 60% have hypertension, and about 15% have diabetes mellitus.[44–47] Other manifestations of cardiovascular disease are also common, with 10% of patients having

manifestations of cerebrovascular disease and more than 40% having evidence of significant cardiac disease.[46]

The clinical manifestations of popliteal artery aneurysms range from an asymptomatic pulsatile mass to severe lower extremity ischemia. About 40% of patients are asymptomatic at diagnosis.[5] More than 50% of patients present with symptoms of limb ischemia, usually claudication, but the ischemia may be more advanced and manifested as rest pain or gangrene. Local symptoms, including sensation of a mass, local pain, and leg swelling or phlebitis secondary to compression of the adjacent vein, account for the remainder of symptoms. A popliteal artery aneurysm may be complicated by thrombosis, embolization, or rarely rupture. Thrombosis is reported in approximately 40% of patients, and embolization occurs in about 25% of cases. This may result in isolated digital embolic occlusion, the "blue toe syndrome," or occlusion of multiple tibial outflow vessels. Rupture occurs in fewer than 5% of popliteal aneurysms; in these cases, the hemorrhage is usually confined to the popliteal space, thus permitting surgical intervention and arterial reconstruction in a timely fashion.[44,45]

Natural History

The natural history of popliteal aneurysms is not well defined because most series are composed primarily of aneurysms that have been treated surgically. Additionally, there is not a clear predictive relationship between aneurysm size and risk of thrombosis, embolization, and compression, all of which are more common complications than rupture in popliteal aneurysms.[41] In a review of 29 reports in the English literature published between 1980 and 1994, patients whose aneurysms were observed rather than intervened upon showed that a mean of 35% of patients with nonoperative follow-up developed ischemic complications, and 25% of these required amputation even with modern therapy.[5] Thus, a significant percentage of popliteal aneurysms will develop a complication if left untreated, and although this is not synonymous with limb loss, the amputation rate is high. Rupture of popliteal artery aneurysms is reported in only 2% to 4% of cases.[40]

Diagnosis

Palpation of the popliteal space with the knee flexed reveals a pulsatile mass in approximately two-thirds of patients. Small aneurysms may not be palpable, and if thrombosis has occurred, the mass may be nonpulsatile. Radiographs of the knee demonstrating a calcified arterial wall occasionally suggest the diagnosis of a popliteal artery aneurysm, but it must be confirmed by duplex ultrasonography, CT (**Fig. 95.5**), or MRI. These diagnostic modalities can establish diagnosis of popliteal artery aneurysms and exclude other etiologies of a popliteal fossa mass (such as tumors or Baker cyst). Angiography can be misleading in the diagnosis of aneurysms because intraluminal thrombus may obscure the true size of the vessel (**Fig. 95.6**); however, it is essential for visualization of the inflow and outflow vessels necessary for revascularization. CT angiography can be a noninvasive way to provide this information (**Fig. 95.7**).

Treatment

Indications

Surgical treatment is indicated for all symptomatic popliteal aneurysms. Controversy exists regarding management of asymptomatic aneurysms, with size of 2 to 3 cm generally regarded as an indication for treatment.[48] In some reports, the average diameter of symptomatic aneurysms is smaller than asymptomatic lesions, and the degree of tortuosity or distortion of the aneurysm and the amount of mural thrombus have also been correlated to risk of complications.[39,47,49] Proponents of early repair at smaller sizes cite greater 5-year patency and limb salvage rates with elective aneurysm repair.[39]

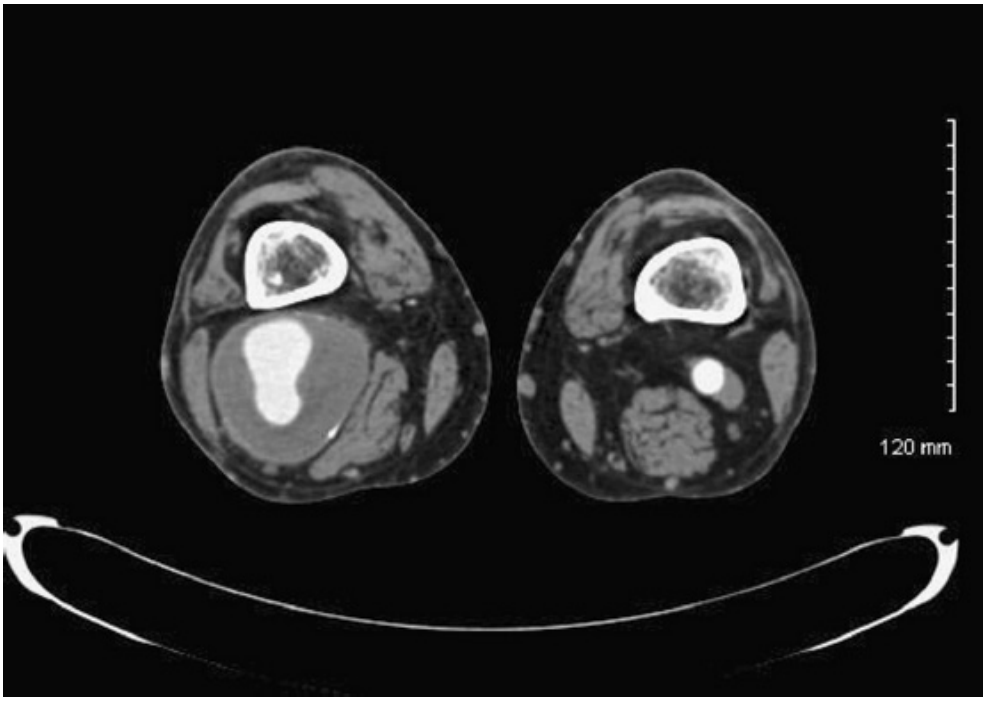


Figure 95.5 Computed tomography of a large right popliteal aneurysm with significant laminar thrombus present.

Figure 95.6 Arteriogram demonstrating a popliteal aneurysm associated with occlusion of the outflow tract presumably from repeated episodes of embolization. A bypass to the distal posterior tibial artery was successful.

Figure 95.7 Computed tomography arteriogram demonstrating right popliteal artery aneurysm and associated inflow and outflow.

The goals of surgical treatment are to eliminate the potential for complications and to preserve or restore adequate blood flow to the limb.

Surgical Technique

Most popliteal aneurysms are easily approached through standard medial thigh and calf incisions for exposure of the distal superficial femoral artery and the distal popliteal artery, respectively. The proximal anastomosis will need to originate from the common femoral artery if the entire superficial femoral artery is aneurysmal. Occasionally, the posterior approach is preferred for lesions confined to the popliteal fossa, especially when accompanied by symptoms due to compression of adjacent structures. Most aneurysms are left in situ, bypassed using a segment of saphenous vein, and ligated proximally and distally. The conduit of choice for bypass is autologous saphenous vein, which is harvested from the thigh, reversed, and tunneled along the course of popliteal artery. The proximal and distal anastomosis may be either end to end or end to side in configuration, with the aneurysm excluded from the circulation by proximal and distal ligatures. Ligation should be adjacent to the aneurysm to minimize the number of patent collaterals that are in continuity with the aneurysm.[49] Late expansion and rupture of a bypassed and ligated popliteal aneurysm can occur when patent geniculate arteries continue to perfuse and pressurize the aneurysm sac.

Tibial outflow is a concern in the management of popliteal artery aneurysms. When the distal popliteal and proximal tibial vessels are occluded with recent emboli, preliminary catheter-directed thrombolytic therapy is indicated prior to bypass.[41] Alternatively, balloon catheter embolectomy may be attempted. Frequently, bypass grafts must be carried to the distal tibial arteries. Extensive, combined femoral and popliteal aneurysms may require a femoral-popliteal or femoral-tibial bypass using in situ saphenous vein with a prosthetic graft segment replacing a common femoral artery aneurysm.

Popliteal aneurysms have been treated by an endovascular approach with stent-graft placement to exclude the aneurysm sac. Small series show a primary patency rate of about 50% at 14 to 18 months, and a cumulative patency of 74%, suggesting that this approach should be reserved for the more high-risk patient who requires intervention.[50–52]

The patient who presents with an acutely ischemic extremity secondary to popliteal aneurysm thrombosis is a management challenge. Popliteal aneurysms often thrombose because of repeated episodes of emboli to the

outflow vessels, which result in their occlusion. An expeditious arteriogram may identify a suitable outflow vessel for the bypass graft. If no target vessel is identified, intra-arterial thrombolytic therapy should be initiated with the goal of lysing thrombus in the tibial arteries to identify a suitable outflow vessel for vascular reconstruction. Although the embolic process may be chronic, results with thrombolytic therapy followed by bypass of the aneurysm have been much better than surgical therapy alone for the patient with an acutely occluded aneurysm and severe leg ischemia.

Results

Excellent results are obtained in asymptomatic aneurysms with intact distal vasculature. Patients with thrombosed aneurysms, or those in whom multiple episodes of embolization have occluded the tibial arteries, have less optimal results. Operative mortality is in the 0% to 2% range, with asymptomatic patients faring better than those presenting with acutely symptomatic lesions.[53,54] In patients undergoing revascularization before ischemic complications occur, 5- and 10-year graft patency rates are greater than 80% and limb salvage is 93% to 98%.[44,55] Graft patency rates in patients undergoing surgery after developing complications of their aneurysms are 60% and 48% at 5 and 10 years, respectively, and limb salvage rates are 60% to 80%.[40,44,55,56] Thrombolytic therapy, when successful, improves primary graft patency in patients presenting with acute limb ischemia.[57]

Venous Disease

Andrea T. Obi, Katherin E. Leckie, Michael C. Dalsing, and Thomas W. Wakefield

Key Points

1. New drug therapies are impacting the treatment of acute deep venous thrombosis (DVT) and pulmonary embolism (PE).
2. Characterization of the disease is being scrutinized to allow for a better understanding of how treatment truly impacts patient outcomes.
3. The diagnosis and treatment of acute and chronic venous disease have made significant advances in the last decade.
4. The care of venous disease is an active and maturing discipline within the realm of the surgical disciplines.
5. Chronic venous disease treatment has experienced a resurgence of interest in the United States with new endoluminal and surgical interventions being investigated and utilized clinically.

VENOUS THROMBOEMBOLISM

Incidence, Risk Factors, and Categories

Venous thromboembolism (VTE), including deep venous thrombosis (DVT) and pulmonary embolism (PE), is a national healthcare concern. DVT affects greater than 250,000 patients annually, whereas PE affects greater than 200,000 patients per year. The incidence has remained constant since 1980 and increases with age. The cost of treatment for both DVT and PE (termed VTE) is in the billions of dollars per year. Although Virchow triad of stasis, vessel wall injury, and hypercoagulability have defined the events that predispose to DVT formation for the past 150 years, today the understanding of events that occur at the level of the vein wall including the influence of the inflammatory response on thrombogenesis is increasingly being recognized.[1–3]

Acquired risk factors for VTE include increasing age, malignancy, immobilization, surgery and trauma, oral contraceptive use, hormone replacement therapy, pregnancy and the puerperium, neurologic disease, cardiac disease, obesity, and antiphospholipid antibodies. Genetic risk factors include deficiencies of antithrombin, protein C and protein S, factor V Leiden, prothrombin 20210A, blood group non-O, dysfibrinogenemia, dysplasminogenemia, hyperhomocystinemia, reduced heparin cofactor II activity, elevated levels of clotting factors (e.g., factors II, VII, VIII, IX, X, and XI), and elevations in plasminogen activator inhibitor-1 (PAI-1). When a patient presents with an idiopathic VTE, there is family history of VTE, there is recurrent thrombosis, or there is thrombosis in unusual locations, workup for a hypercoagulable state may be indicated. Hematologic diseases associated with VTE include heparin-induced thrombocytopenia (HIT) and thrombosis syndrome, disseminated intravascular coagulation, antiphospholipid antibody syndrome, thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, and myeloproliferative disorders. Risk assessment that takes all of these factors into consideration, such as the Caprini score, has been validated in many different clinical settings.[4]

Most DVTs affect the iliac, femoral, or popliteal lower limb veins. Presenting symptoms include unilateral leg pain and swelling, but some DVTs are silent, with the first manifestation of a PE. Some of the more common comorbidites include hypertension, surgery within 3 months, immobility within 30 days, cancer and obesity.

Venous Thromboembolism Diagnosis

Venous color duplex imaging is now standard, although D-dimer may be considered in low probability settings. The positive and negative predictive values for gray-scale imaging are inferior to color imaging. A meta-analysis of 13 studies comparing CT with ultrasound for proximal DVT found a sensitivity of 71% to 100% and specificity between 93% and 100%.[5] In symptomatic patients, sensitivity is approximately 93%, specificity 98%, accuracy 97%, with approximately 30% of studies indeterminate in the calf.[6] Data from the Prospective Investigation of Pulmonary Embolism Diagnosis II, a multicenter study of 711 patients, were used to compare the clinical value of CT venography (CTV) after multidetector CT angiography (CTA) with venous compression ultrasonography for the diagnosis of VTE. There was 95.5% concordance between CTV and ultrasonography for the diagnosis or exclusion of DVT ($\kappa = 0.809$). Attesting to the accuracy of ultrasound, the sensitivity and specificity of combined CTA and CTV were equivalent to combined CTA and ultrasonography.[7]

The biomarker D-dimer is a useful test to rule out, not rule in DVT. In a patient with a low pretest probability for DVT (such as with a negative Wells score), if a D-dimer biomarker test is negative, no further testing is necessary and ultrasound imaging may be omitted in this situation. D-Dimer requires that a high-sensitivity D-dimer assay (such as the advanced turbidimetric method or ELISA) is used. On the contrary, if the D-dimer is positive, then duplex must be performed even if the pretest probability is high, as a positive D-dimer and a positive risk assessment is associated with DVT in only approximately 70% of cases.[8] A highly soluble P-selectin, along with a positive Wells score, may allow for the diagnosis of DVT in greater than 90% of cases, although this biomarker is research based and is not clinically available.[9]

The high negative predictive value (NPV) of color duplex Doppler ultrasound both above and below the knee supports withholding anticoagulation on the basis of a good-quality negative study alone, and clinical data also support that strategy.[10] A single good-quality color duplex Doppler study is sufficient (NPV >99.5%) to exclude proximal DVT; repeat scanning is seldom indicated unless the initial study was technically

suboptimal. A truly negative study means that all the segments of the leg, including the external iliac, common femoral, femoral, popliteal, and calf veins, are negative by ultrasound imaging and clear by Doppler flow. While duplex ultrasound has a high accuracy for proximal DVT, it is less accurate for the diagnosis of distal DVT and it is highly operator dependent in this location. During pregnancy the aforementioned recommendations remain, but it is very important to attempt to assess for iliac vein thrombosis at the time of ultrasound evaluation. For the future, other biomarkers in addition to D-dimer for the diagnosis of DVT are under investigation, as a means to augment venous imaging.[11]

For the diagnosis of superficial vein thrombophlebitis (SVT), duplex ultrasound is also important.[12] In a prospective epidemiologic study, including 844 patients with symptomatic SVT, 210 (24.9%) had concomitant DVT at the time of diagnosis of SVT. Of the 600 patients without DVT, over the next 3 months, 58 (10.2%) developed thromboembolic complications, including 3 (0.5%) with PE, 15 (2.8%) with DVT, 18 (3.3%) with extension, and 10 (1.9%) with recurrence of SVT. These events occurred despite the use of anticoagulant treatment. Thus, it is important to perform good duplex imaging in patients diagnosed with SVT.

For pediatric DVT, as symptom development is often subtle, the diagnosis again is usually made with compression color duplex imaging.[13] Magnetic resonance venography (MRV) and computed tomography venography may also be useful in evaluating upper extremity DVT as well as iliocaval DVT, balancing the risk of anesthesia (when it is required in this age group), radiation, and contrast usage.

Other conditions may be confused with DVT and include lymphedema, muscle strains, and muscle contusion. Iliac vein obstruction may lead to unilateral leg edema (May–Thurner syndrome), while the presence of a cyst behind the knee may produce unilateral lower leg pain and edema. Other causes of leg swelling include systematic problems such as cardiac, renal, or hepatic abnormalities. These systemic problems usually lead to bilateral edema.

Pulmonary Embolism

Testing for PE begins with prior probability estimation for all patients. Two of the most widely known and validated diagnostic scoring systems are the Wells criteria (or modified/dichotomous Wells criteria) and Geneva score.[14–16] They use a combination of physical examination, history, and vital signs to predict the likelihood of PE. D-Dimer testing is used to exclude PE for patients with low prior probability for DVT. D-Dimer testing has no role in diagnosis if prior probability is not low. Use of D-dimer testing in PE diagnosis requires that a high-sensitivity D-dimer assay (such as the advanced turbidimetric method or ELISA) validated at the local institution be used. Patients with both low probability and negative D-dimer require no further investigation as the NPV is 99%.[17]

The diagnosis of PE has involved ventilation-perfusion (V/Q) scanning and pulmonary angiography. However, newer techniques include spiral computed tomographic scanning and magnetic resonance imaging. The sensitivity of V/Q scanning was defined in PIOPED I at 98%, but specificity was low at 10%.[18] By combining clinical factors with V/Q scan, levels of sensitivity and specificity greater than 95% were achieved. With a high-probability V/Q scan, two risk factors positive for PE, the sensitivity was 97%; with one risk factor, 84%; and with no risk factors, 82%. Similarly, with a normal V/Q scan, the chance of PE was essentially 0, irrespective of the risk factor status. Thus, a normal V/Q scan or a high-probability scan provided good diagnostic information that could be used to base treatment on. However, only a small portion of V/Q scans are in one of these two categories, leaving many patients needing further testing.

Multidetector helical CTA is the primary imaging modality, although V/Q scanning remains viable (particularly for patients with otherwise normal lungs in whom interpretability of the test is optimal), and a positive lower-extremity color duplex Doppler study in a high-probability patient can establish the diagnosis of VTE without lung imaging. However, the problem with using only lower extremity duplex imaging is that a baseline study in the chest is not obtained for later comparisons and as such, we do not favor using lower extremity duplex imaging as a substitute for the diagnosis of PE. Additionally, the accuracy for lower extremity imaging as a surrogate for PE is relatively low. Multidetector scanners have significantly improved the sensitivity and specificity, as well as the positive and negative predictive

value of CTA. Outcome studies have found the sensitivity and specificity of CTA to be greater than 95%, and a negative CTA carries a 3-month risk of VTE of 1% to 2%. CTA establishes the diagnosis of PE if it is positive in an intermediate- or high-probability patient, or in a low-probability patient with findings of a mainstem or lobar embolus. It excludes the diagnosis of PE in low-probability patients with negative scans. Discordance between prior probability and CTA findings requires further investigation, as well as technically inadequate studies.[7] Other diagnostic tests may include V/Q imaging or pulmonary angiography.

Outcome studies have found comparable results between pulmonary angiography and CTA; a negative result with either study confers approximately a 1% VTE rate within 6 months. However, because angiography is invasive, it carries a greater risk of complications and mortality. The mortality from angiography has been estimated at 0.5%, while 1% may experience major complications, including arrhythmias, hypotension, bleeding, and nephrotoxicity.[19] Without a higher standard to appeal to, one cannot discuss specificity and sensitivity of pulmonary angiography using commonly accepted definitions of these terms. Instead, the accuracy of pulmonary angiography is discussed in terms of interobserver variability in the reading of pulmonary angiograms obtained in the context of large multicenter trials. Studies demonstrate that the larger the embolus, the better the interobserver agreement. For segmental and larger emboli, agreement exceeds 95%. For subsegmental emboli, agreement is considerably less. We do not recommend pulmonary angiography, except in certain circumstances, such as with inadequacy of V/Q imaging or when catheter-directed thrombolysis (CDT) is recommended.

Recently, the efficacy of magnetic resonance angiography (MRA), MRV, or the combination of the two in the diagnosis of acute PE has been studied.[20] The gold standard used for comparison was a composite end-point of CTA, CTA-CTV, V/Q scan, lower extremity ultrasonography, D-dimer assay, and clinical assessment. Overall, MRA and MRA-MRV were found to be poor tests for the diagnosis of PE. Approximately 25% of the 371 patients enrolled in a large multicenter study had a technically inadequate MRA, and 48% had either an inadequate MRV or MRA. Considering all patients enrolled, MRA alone identified only 57% of PEs and had a sensitivity of

78% when only patients with adequate studies were considered. The combined MRA-MRV studies had a sensitivity of 92%, but only about half of the patients had technically adequate studies. These poor results are generally felt related to the technical difficulties of MRA in identifying abrupt vessel termination and capturing adequate images of the chest vessels secondary to motion artifact. At this time, MRA-MRV is not generally recommended and only considered in centers with a great deal of experience. Because of its low sensitivity and specificity, transthoracic or transesophageal echocardiography has limited diagnostic value for PE.[21]

For critically ill patients too unstable for transport, echocardiography can suggest the diagnosis of PE by showing dilatation of the RV or hypokinesis. Commonly, acute changes in the RV pressure, size, and function are seen, indicating increased RV strain and pulmonary arterial pressures. These changes suggest PE in the absence of alternative diagnoses. Although of limited value in the diagnosis of PE, echocardiography is of great prognostic use in stratifying risk for patients with acute PE. Right ventricular dysfunction or dilatation in acute PE is associated with worse outcomes, including increased mortality rate.

Biomarkers include B-type natriuretic peptide (BNP), released by ventricular myocardial cells in response to wall stretch and volume overload. BNP is a prognostic (not diagnostic) biomarker for PE. BNP levels generally indicate RV strain due to elevated pulmonary vascular resistance in the lungs. If measured early (within 4 hours of admission for PE), elevated BNP levels (>90 pg/mL) demonstrate a sensitivity of 85% and a specificity of 75% in predicting PE-related outcomes. Conversely, normal BNP values in the setting of acute PE carry a 97% to 100% NPV for in-hospital death. Another biomarker is troponin released from damaged myocardial cells. When elevated in acute PE, troponins represent myocyte ischemia and microinfarction due to acute cardiac strain of the right ventricle. Approximately 30% to 50% of patients with large PE will have elevations in troponins I and T that are mild and short lived. They correlate with worse RV function and a high incidence of complications. Normal troponin T levels have a 97% to 100% NPV for in-hospital death. These two biomarkers are not part of routine algorithms.[17]

Axillary/Subclavian Vein Thrombosis

Thrombosis of the axillary/subclavian vein accounts for less than 5% of all cases of acute DVT. However, it may be associated with PE in up to 10% to 15% of cases and additionally can also be the source of significant disability. Primary axillary/subclavian vein thrombosis results from obstruction of the axillary vein in the thoracic outlet, the so-called Paget–Schroetter syndrome, noted especially in healthy muscular athletic individuals. Such thrombosis may also occur in patients with hypercoagulable states. Secondary axillary/subclavian vein thrombosis results from mediastinal tumors, congestive heart failure, and nephrotic syndrome. Patients with axillary–subclavian venous thrombosis often present with arm pain, edema, and cyanosis. Superficial venous distention may be apparent over the arm, forearm, shoulder, and even the anterior chest wall.[22]

Upper extremity venous duplex ultrasound is used to diagnose suspected axillary–subclavian vein thrombosis. Thrombolysis and phlebography are often considered next. If phlebography is performed, it is important that the patient undergo positional phlebography with arm abduction to 120 degrees to confirm extrinsic subclavian vein compression at the thoracic outlet. Venous compromise is further evidenced by prominent collateral veins. Since a cervical rib may be the cause of such obstruction, chest x-ray film should be obtained to exclude its presence.[23]

Standard Therapy for VTE

Treatment

The traditional treatment of VTE is systemic anticoagulation, which reduces the risk of PE, extension of thrombosis, and thrombus recurrence. Immediate anticoagulation should be undertaken as the recurrence rate for VTE is higher if anticoagulation is not therapeutic in the first 24 hours. For DVT, since duplex imaging is rapidly obtained, usually testing precedes anticoagulation while for PE, anticoagulation is recommended either simultaneous with or before testing. Recurrent DVT can still occur in up to one-third of patients over an 8-year period, even with appropriate anticoagulant therapy.

As a result of the evidence demonstrating the effectiveness and safety of DOACs, they are now recommended as first-line treatment of acute VTE over VKAs in patients whom do not have an associated cancer (grade 2B).[24] Currently, the direct Xa inhibitors apixaban, rivaroxaban, and edoxaban have been FDA approved for the treatment of VTE, while dabigatran is the sole-approved direct thrombin inhibitor. The DOACs are all administered orally, have fixed doses that do not need to be weight based adjusted, and do not need monitoring. One of the appealing aspects of VKAs (and to a lesser extent LMWH), is the ability to be quickly reversed by protamine (for heparin and to a lesser degree LMWH), fresh frozen plasma (FFP), or prothrombin complex concentrate (PCC) if indicated. In addition, there are available laboratory tests to monitor reversal. Until recently, DOAC reversal was limited to supportive measures, PCC or selective dialysis. The FDA recently approved idarucizumab (Praxbind™), a monoclonal antibody, that binds to dabigatran and can reverse its anticoagulant effects within minutes[25] and andexanet alfa, a recombinant factor Xa decoy, for all factor Xa inhibitors, including DOACs, LMWHs, and fondaparinux.[26] Clinical trials have shown the andexanet alfa can effectively reverse DOACs anticoagulant effect without any known thrombotic events in healthy patients.[27] The final reversal agent progressing in development with FDA fast track designation for hemorrhage is Aripazine (PER-977, ciraparantag, Perosphere Inc.), a water-soluble, catatonic molecule available in intravenous formulation. This agent noncovalently binds to and reverses the anticoagulation of all anticoagulation agents (LMWH, UFH, FXa inhibitors, dabigatran) in animal models and healthy volunteers.[27]

There are several scenarios which would preclude the use of DOACs; for example, patients with mechanical heart valves, patients who cannot afford the cost of the medication, and patients with impaired renal function. Given that all of the comparison studies showed noninferiority, in many cases either a DOAC or VKA is acceptable. However, certain patients are at much higher risk of treatment failure with VKAs than others defined by a scoring system SAMe-TT_2R_2.[28]

Unfractionated heparin or low–molecular-weight heparin (LMWH) is given along with oral anticoagulation with vitamin K antagonists (usually warfarin [Coumadin]). It is recommended that the international normalized

ratio (INR) be therapeutic for 2 consecutive days before stopping heparin or LMWH.[29] LMWH has become the standard for treatment because it is administered subcutaneously, requires no monitoring (except in certain circumstances, such as renal insufficiency or morbid obesity), and is associated with a decrease in bleeding potential.[30]

Compared to standard unfractionated heparin, LMWH has significantly improved bioavailability, less endothelial cell binding and protein binding, and improved pharmacokinetics.[31] The half-life of LMWH is dose independent and it is administered in a weight-based fashion. LMWHs may decrease indices of chronic venous insufficiency (CVI) compared with standard therapy when used over an extended period. Warfarin should be started after heparinization is therapeutic to prevent warfarin-induced skin necrosis, as warfarin causes inhibition of protein C and S before factors II, IX, and X, leading to paradoxical hypercoagulability at the initiation of therapy. For standard unfractionated heparin, this requires a therapeutic activated partial thromboplastin time; for LMWH, warfarin is administered after an appropriate weight-based dose of LMWH is administered and allowed to circulate.

Complications

Bleeding is the most common complication of anticoagulation. All currently approved VTE treatment agents carry the risk of significant bleeding complications, as they all target various aspects of the coagulation cascade. When treating VTE, the incidence of major bleeding at 3 months using unfractionated heparin or enoxaparin is approximately 4.3% and 2.9%, respectively. The rate of major bleeding using warfarin for the treatment of VTE is also approximately 2% during the initial 3 months of anticoagulation. Apixaban and rivaroxaban have a major bleeding incidence of approximately 0.5% (at 3 months) and 0.8% (during treatment follow-up period), respectively.[32,33]

HIT occurs in 0.6% to 30% of patients. Although historically morbidity and mortality rates have been high, it has been found that early diagnosis and appropriate treatment have decreased these rates.[34] HIT usually begins 3 to 14 days after heparin is begun, although it can occur earlier if there has been exposure to heparin in the past. A heparin-dependent antibody binds to

platelets, activates them with the release of procoagulant microparticles leading to an increase in thrombocytopenia, resulting in thrombosis.[35] Both bovine and porcine unfractionated heparin and LMWH have been associated with HIT, although the incidence and severity of the thrombosis are less with LMWH. Even small exposures to heparin can cause the syndrome. The diagnosis should be suspected with a 50% or greater drop in platelet count, when the platelet count falls less than 100,000/mL or when thrombosis occurs during heparin or LMWH therapy.[36] A highly sensitive but poorly specific ELISA test detects the antiheparin antibody in the plasma. The serotonin release assay is another test that is more specific but less sensitive.[37]

When the diagnosis is made, heparin must be stopped and warfarin should not be given until an adequate alternative anticoagulant has been established and the platelet count has normalized. LMWHs cannot be used as substitutes as studies demonstrate high cross-reactivity with standard heparin antibodies. Agents that have been approved by the Food and Drug Administration (FDA) as alternatives include the direct thrombin inhibitor argatroban and bivalirudin (Table 96.1). Fondaparinux has also been found effective for treatment of HIT, but it is not FDA approved for this indication. The use of these alternative agents is given 2C and 1C evidence.[38]

Duration of Anticoagulation

The recommended duration of anticoagulation for the treatment of provoked proximal and symptomatic distal VTE is 3 months (Grade 1B). Extended therapy is considered under the following circumstances: Previous VTE event, thrombophilias associated with a high risk of recurrence, and unprovoked VTE. Virtually all agree that for a second unprovoked VTE, anticoagulation should be continued due to the high recurrence risk well past 3 months in those patients with low/moderate bleeding risks (grades 1B, 2B).[24] For patients with diagnosed hereditary thrombophilias, those that are associated with a higher risk of VTE recurrence (protein C/protein S deficiency [especially with a family history], antithrombin deficiency, homozygous factor V Leiden and homozygous prothrombin 20210 gene mutation, and multiple thrombophilias in the same patient), prolonged therapy is recommended. Although Factor V Leiden heterozygous mutation alone

does not confer an increased risk of recurrence, when combined with prothrombin 20210 gene mutation, recurrence is increased and prolonged anticoagulant therapy is recommended. Among acquired thrombophilias, antiphospholipid antibodies and active cancer mandate extended therapy.[39]

Unprovoked first-time VTE remains a difficult clinical scenario, as one must balance the competing risks and implications of recurrent VTE and major bleeding. D-dimer and repeat duplex testing have both been advocated to determine risk of recurrence with cessation of anticoagulation. D-dimer is measured approximately 1 month after stopping oral anticoagulation. Elevation of D-dimer suggests that active thrombosis is occurring and the rate of recurrence is higher (15%) compared to 6.2% with a normal D-dimer. This risk can be mitigated with resumption of anticoagulation which reduces the VTE rate down to 2.9%.[24,40] The use of repeat serial lower extremity ultrasound to determine the state of the thrombosed veins has been studied, with the assumption that if the veins are occluded with fibrotic scar tissue, flow will be sluggish and the risk of recurrent VTE elevated. The usefulness of this test is less certain, as it is difficult to reproduce in day to day clinical practice.

Table 96.1 Elements of a Complete Hypercoagulability Evaluation

Hypercoagulability Evaluation
Activated Protein C Resistance
Antithrombin III Activity
Antithrombin III Antigen
Cardiolipin Antibody
D-dimer
Dilute Russell's Viper Venom Test
Factor VIII Assay
Fibrinogen (Clottable)
Fibrinogen Antigen
Hexagonal Phospholipid Neutralization
Plasma Homocysteine Plasminogen Activity
Protein C Activity
Protein C Antigen
Protein S Antigen (Free)
Prothrombin 20210 Mutation Detection
PT (Prothrombin Time)
PTT (Partial Thromboplastin Time)

Not all tests for every evaluation are recommended.

Emerging Medical Treatments and Trends in VTE Managements

1 In patients with cancer who develop acute VTE, LMWH has been considered definitive first-line treatment. However, meta-analysis of cancer patients enrolled in phase 3 DOAC trials demonstrates the feasibility and safety in cancer patients, although this analysis was hampered by lack of comparison to LMWHs as the standard of care.[41] Recently, the DOACs rivaroxaban and edoxaban have been studied in patients with active malignancy. The Hokusai-VTE cancer trial enrolled 1,050 patients with cancer-associated VTE who were then randomized to edoxaban compared to LMWH. Results from this trial demonstrated that the primary event (recurrent DVT or major bleeding) occurred in 12.8% with edoxaban and 13.5% with LMWH, meeting the endpoint of noninferiority for DOAC compared to LMWH.[42] Overall, a reduction in recurrent VTE events in the edoxaban group was offset by an increase in bleeding complications, higher in patients with primary GI malignancy.[42] A smaller RCT, SELECT-D, evaluated rivaroxaban compared to LMWH in patients with cancer-associated VTE with similar findings: recurrent VTE was 4% with rivaroxaban and 11% with dalteparin, but with an increased rate of major bleeding in patients treated with rivaroxaban.[43] As a result of this new information, the International Society of Thrombosis and Haemostasis has recommended the use of DOACs in patients with cancer-associated VTE but without GI cancer and with low bleeding risk.[44]

One new advance is the validation of the HERDOO2 score, which was developed and prospectively validated. This score identifies women at low risk of recurrence following unprovoked VTE who may safely discontinue anticoagulation following short-term (standard) treatment. In this score, women receive a point for (a) hyperpigmentation, edema, or redness in either leg, (b) VIDAS D-dimer ≥250 μg/L, (c) Obesity (BMI ≥ 30), and (d) Older age (≥65 years). Patients with 0 or 1 point are at low risk for recurrent VTE and may discontinued long-term anticoagulation therapy. Women who were defined as both low risk and discontinued therapy have a 3.0% risk of recurrent VTE per patient year, compared to an 8.1% risk in high-risk women who discontinue anticoagulants.[45]

The advent of the DOACs has reinvigorated the use of low-dose anticoagulation to improve the risk–benefit profile of extended therapy via decreased bleeding risk. Historically, low-dose VKAs resulted in similar

bleeding profile to standard therapy.[46] More recently, both treatment and thromboprophylaxic doses of rivaroxaban and apixaban have been shown to be more effective in prevention of VTE recurrence with no increased risk of bleeding compared to placebo or ASA.[47,48] The WARFASA and ASPIRE trials have also demonstrated a reduced risk of VTE recurrence in patients treated with aspirin compared to placebo.[49,50] However, this decrease in VTE recurrence with ASA was much less than with low-dose DOAC. Indeed, network meta-analysis has shown that some DOACs have the most favorable profiles compared to warfarin, and aspirin.[51,52]

Calf Vein DVT

There is clinical equipoise to the treatment of calf vein DVT. Withholding anticoagulation in outpatients with suspected calf vein DVT, if serial compression ultrasound is negative for proximal DVT at baseline, and if again negative 1 week later results in 3-month pooled estimate thromboembolic risk of 0.6%.[53] Given these findings, the recently completed Compression Alone Versus Anticoagulation for Symptomatic Calf Vein Thrombosis Diagnosed by Ultrasonography (CACTUS) trial was performed with the goal of assessing the safety of withholding anticoagulant treatment in patients with isolated symptomatic calf vein DVT at low risk for proximal extension/VTE, as defined by no personal VTE history or active malignancy.[54] LMWH did not reduce proximal extension or VTE and resulted in increased bleeding complications. A limitation of this study is that it was underpowered for its endpoints, as only 259 patients were enrolled and the calculated power calculation for the study was 572 patients. Despite poor enrollment, the CACTUS trial signifies progress in one of VTE's most debated topics: it represents the first effort to rigorously study treatment algorithms for calf vein DVT and adds to accumulating data suggesting that avoiding anticoagulation may be safer and more cost effective for low-risk patients. Data from smaller studies evaluating low-risk patients with calf vein DVT suggests that shorter duration (1 month) and intensity (full-dose LMWH ×1 week and ½ dose for 3 weeks) had a low recurrence and VTE complication rate, raising the provocative question as to whether patients at high risk need to be treated in the same manner as proximal DVT.[55]

For pediatric DVT, the two mainstays of treatment are either anticoagulation with continued monitoring or thrombolysis. Recently LMWH has been FDA approved for the treatment of pediatric DVT. Current recommendations are to use LMWH for 3 to 6 months, with subsequent continuation of therapy based on the persistence or absence of clinically significant prothrombotic risk factors. Recurrence of DVT in children carries a lower risk than in adults, with cumulative incidences of 6% to 11% versus 12% to 22%, respectively. The risk of PTS appears as great in children as in adults, although severe PTS is uncommon. Compression stockings are indicated in children to treat PTS. For neonatal DVT, standard LMWH is indicated, with a shortened duration compared to older children.[13]

Nonpharmacologic Treatments

Postthrombotic syndrome (PTS) results from loss of competence of the venous valves as a result of DVT and vein wall fibrosis or persistent venous obstruction, or a combination of both. It can cause significant morbidity in the form of pain, swelling, skin breakdown, and ulcerations. A Cochrane meta-analysis found a strong effect (OR 0.31) for prevention of PTS using graduated compression stockings beginning within 2 weeks of onset of DVT, with important data highlighted from two open-labeled randomized single-center studies that utilized stockings of 30 to 40 mm Hg for 2 years after DVT.[56]

From these data, stockings of 30 to 40 mm Hg gradient should be recommended to most patients with DVT, for a minimum of 2 years post-DVT, and longer if they have symptoms of PTS. There is a new study (the SOX trial) that would suggest that stockings may not prevent PTS after a first proximal DVT.[57] In addition, ambulation with good compression does not increase the risk of PE, while significantly decreasing the incidence and severity of the PTS.[58,59] Based on the SOX trial results, the most recent ACCP guidelines suggest not using compression stockings to prevent PTS (grade 2B evidence). It must be remembered that the use of strong compression and early ambulation after DVT treatment can significantly reduce the symptoms of pain and swelling resulting from the DVT, even if the development of PTS is not prevented, and a new study suggests that immediate application of compression (rather than the more liberal criteria

in the SOX trial) after DVT diagnosis may result in a small decrease in PTS and residual vein obstruction.[60] Early ambulation has the potential to decrease PTS and improve patients' quality of life (QOL). Thus, patients should be encouraged to ambulate as part of their post-DVT care recommendations and use stockings, especially if they have pain and swelling from their DVT.[24]

IVC Filters

The traditional indications for the use of IVC filters include a complication of anticoagulation, a contraindication to anticoagulation, and failure of anticoagulation. Protection from PE has been greater than 95% using cone-shaped wire-based permanent IVC filters.[61] Cone-shaped filters have a lower incidence of IVC thrombosis compared with basket-shaped filters, and a recent study between the two filter types was stopped early because of the high rate of IVC thrombosis with the basket-shaped device.[62]

The success achieved with filters has expanded the indications, including free-floating thrombus longer than 5 cm, when bleeding risk with anticoagulation is excessive, when the risk of PE is felt to be very high, and to allow for the use of perioperative epidural anesthesia.[63–65] Filters can be permanent or optional (retrievable). If a retrievable filter is left in to become a permanent filter, the long-term fate of that filter has yet been defined.

Filters are usually placed in an infrarenal location. However, they may also be placed in the suprarenal location or in the superior vena cava. Indications for suprarenal placement include high-lying clot, pregnancy, women of childbearing potential, or a previous device that has failed or become filled with clot. Sepsis is not a contraindication to the use of wire-based filters since the trapped material can be sterilized with antibiotics. Although filters have been placed under x-ray guidance, percutaneous techniques for filter insertion using bedside external ultrasound or intravascular ultrasound are now being recommended. Transabdominal external ultrasound is difficult in the face of morbid obesity, overlying bowel gas, or open abdominal wounds. In these instances, intravascular ultrasound has been found to be more successful.[66]

Other than one randomized prospective study on the use of filters as treatment of DVT (which is not how filters are traditionally used), evidence

for the use of filters is given a 2C level of evidence.[24]

Thrombolytic and Surgical Procedures for Deep VTE

For DVT treatment, the goals are to prevent extension or recurrence of DVT, prevent PE, and minimize the late squeal of thrombosis, namely CVI. Standard anticoagulants accomplish the first two goals but not the third goal. The PTS (venous insufficiency related to venous thrombosis) occurs in up to 30% of patients after DVT and even greater with more proximal iliofemoral DVT. Experimentally, prolonged contact of the thrombus with the vein wall increases damage.[67] The thrombus initiates an inflammatory response in the vein wall that can lead to vein wall fibrosis and valvular dysfunction. Some patients with proximal DVT may also be candidates for thrombus removal, if they meet specific criteria, or if they have venous ischemia, as described below. Early thrombus removal may be performed for patients with all of the following: First episode of acute iliofemoral DVT, symptoms less than 14 days in duration, low risk of bleeding, ambulatory patient with good functional capacity and acceptable life expectancy, and moderate to severe symptoms (which can be determined by a Villalta score ≥10 after a trial of anticoagulation).[68–75]

While not currently endorsed by major society guidelines, CDT has been shown to decrease symptoms of pain and swelling at 30 days and may decrease development of PTS in highly selected patients. Following initial symptoms, CDT is ideally performed within 2 weeks but may be performed up to 4 weeks. CDT has been employed in many nonrandomized studies and, in small randomized trials, was more effective than standard therapy in patients with acute proximal lower extremity DVT, improving QOL. Results are optimized by combining CDT with mechanical devices.[69,71] These devices hasten thrombolysis, decrease the amount of thrombolytic agent needed, and decrease bleeding potential. The Attrack trial, while not showing a benefit in PTS overall, did results in improvements in patients with specific iliofemoral DVT.[76] Importantly, this multicenter NIH sponsored trial demonstrated that there is no benefit in performing aggressive thrombus removal in the femoropopliteal location alone.

Phlegmasia and venous gangrene is a rare clinical phenomenon that places the affected limb at risk of ischemia. Phlegmasia cerulea dolens (PCD) is an uncommon form of DVT characterized by severe pain, swelling, cyanosis, and edema. This is preceded by phlegmasia alba dolens, which is characterized by the same clinical signs except the limb is pale and white due to early ischemia, and not yet cyanotic. Venous gangrene is defined as skin necrosis, discoloration, and documented VTE. Treatment for PCD or venous gangrene is the same as for proximal DVT, with an emphasis on immediate anticoagulation. Early thrombus removal is the treatment of choice in patients with limb-threatening venous ischemia due to iliofemoral venous thrombosis, with or without associated femoropopliteal venous thrombosis.[68,77,78] These patients require CDT with pharmacomechanical assist. Surgical venous thrombectomy is reserved for patients who have contraindications to thrombolysis[79] or when thrombolysis is not indicated or effective, although the number of times surgical venous thrombectomy is actually necessary and used in quite small.

Thrombolytic therapy for PE remains controversial. Although agents lyse thrombus effectively, recurrence rates and patient mortality rate were not reduced. However, the original studies were not powered to address this outcome. Results are best if patients are young, the embolus is less than 48 hours old, and the embolus is large. Streptokinase, urokinase, and tissue plasminogen activator have all been used.[80]

All agents rapidly dissolve clot, but by 7 days, the advantages for all three agents decrease. The benefit of thrombolytic agents for PE thus appears to be greatest in patients who would die as a result of massive PE in the first hour after the PE occurs, which can occur in up to 10% of cases. However, more recent data suggest that thrombolysis may be useful in patients with right ventricular dysfunction without hemodynamic instability and it has been suggested that thrombolysis will improve outcomes if patients have evidence of right-sided heart changes.[81–86] In addition, thrombolysis therapy has been recommended in patients without hypertension who are judged to have a low risk of bleeding.[24] The development of multidisciplinary teams for the aggressive treatment of patients with significant PE is a national trend which appears to be having a positive effect on the morbidity and mortality of PE.

Contraindications to thrombolytic therapy include:

Allergies

- Alteplase (recombinant tissue plasminogen activator); Heparin; Iodinated contrast

Anatomic criteria

- DVT not involving the iliac system (i.e., distal DVT, isolated femoral-popliteal DVT; Symptoms lasting > 28 days)

Bleeding risk

- Active bleeding; Bleeding diathesis; Recent (<10 days) history of surgery, CPR, trauma, obstetrical delivery, cataract surgery, major invasive procedure; Recent (<3 months) internal eye surgery, hemorrhagic retinopathy, gastrointestinal bleed; Recent history of stroke or intracranial lesion; Severe liver dysfunction

Comorbidities:

- Active cancer (except nonmelanoma primary skin cancer); Pregnancy; Severe hypertension; Severe renal impairment

Functional status:

- Chronic nonambulatory status; Inability to provide consent; Inability to tolerate catheter-directed therapy (strict bedrest 24–72 hours); Life-expectancy <2 years[87]

Pulmonary Embolectomy

Surgical approaches for PE are indicated for patients with massive PE with hypotension who require large doses of vasopressors. These are often patients in whom thrombolytic agents have been unsuccessful. Open pulmonary embolectomy is associated with high rates of morbidity and mortality. Today, open pulmonary embolectomy is limited to those who require manual cardiac massage for hypotension or those in whom catheter pulmonary embolectomy fails. However, there may be a more expanded role for pulmonary embolectomy in the future.[88]

Superficial Thrombophlebitis

SVT is a well-recognized clinical entity, characterized by a painful erythematous and palpable cord-liked structure, usually compromising the lower extremities but capable of affecting any superficial vein in the body. Thrombophlebitis is believed to have a multifactorial etiology, in which Virchow triad of altered blood flow, changes in the vessel wall, and abnormal coagulation are recognized to play a significant role. SVT has been considered a benign disease requiring only conservative management with compression, nonsteroidal anti-inflammatory medications, and lower extremity elevation. Recently SVT, especially above-the-knee superficial thrombophlebitis, has been reported to coexist with DVT, to propagate to popliteal or femoral level and to even cause PE.[89] A medical approach using anticoagulant therapy appears as the treatment of choice when there is above-knee SVT with deep venous system involvement.

The incidence of SVT occurs in approximately 125,000 people in the United States per year. However, the actual incidence is likely far greater as these statistics may be outdated and many cases go unreported. Approximately 54% to 65% of the reported cases affect females with an average age of 58 years. The most frequent predisposing risk factor for SVT is varicose veins, occurring in 62% of patients. Other risk factors include immobilization, trauma, postoperative states, age >60 years, obesity, tobacco use, history of DVT or SVT, pregnancy, puerperium, autoimmune disease, use of oral contraceptives or hormonal replacement therapy, and hypercoagulable state. Hypercoagulable screening should be considered in patients with ascending or worsening thrombophlebitis despite initial treatment.[90,91] Malignancy has been reported as a risk factor for developing SVT, affecting 13% to 18% of patients.

The overall recurrence of SVT was described as 18% over 15 months, equally frequent in varicose and nonvaricose phlebitis. Deep venous reflux increases the recurrence rate to 33%, while hypercoagulable states increase the recurrence rate to 42% over the same period of time. The clinical symptoms and signs for SVT are overt. Duplex ultrasound imaging of the affected extremity should be performed to rule out extension of the process into the deep venous system or concomitant DVT.[90]

Duplex ultrasound shows the extent of the SVT, its relation to the veins connecting with the deep vein system, and the presence of concomitant DVT. In addition, duplex ultrasound allows checking the competence of the valves

in the superficial and deep veins. Complete thrombophilia workup is not routinely recommended. However, it may be indicated in selected patients with recurrent primary thrombophlebitis or aggressive thrombophlebitis. Screening for underlying diseases, including malignancy or vasculitis, is performed if signs or symptoms suggest the presence of such a problem.

Treatment

Several therapeutic approaches have been proposed for patients with SVT. These include ligation or vein stripping of the affected vein, elastic stockings, NSAIDs to reduce pain and inflammation, and variable doses of unfractionated heparin or LMWH followed by oral anticoagulant therapy. There is no consensus on the optimal treatment of SVT in clinical practice.

The course of treatment for SVT should be tailored accordingly to its location and concomitant DVT if there is any associated infectious process. Thrombus location in trunks of either the great saphenous vein (GSV) or small saphenous vein (SSV) may have the highest risk of extension into the deep vein system and thus require more aggressive treatment than other locations. The treatment for primary SVT localized in the distal GSV and tributaries veins consists of ambulation, warm soaks, compression, and NSAID agents. If the patient presents risk factors for DVT, pharmacologic prophylaxis should be considered seriously.

In a large prospective randomized study (CALISTO), fondaparinux was found effective in limiting a series of endpoints including death, PE, DVT, and extension or recurrence at days 47 and 77 after SVT diagnosis. This was in patients with axial vein SVT of at least 5-cm length with the thrombus at least 3 cm from the SFJ. Less extensive SVT requires only symptom control with oral or topical NSAIDs.[92] Both fondaparinux and LMWHs are administered subcutaneously, which can be inconvenient, painful and lead to decreased compliance. In recent years, the rapid adoption of direct oral anticoagulants (DOACs) for a variety of indications has led to the question as to whether DOACs may offer comparable results for patients with SVT. This hypothesis was tested recently in the SURPRISE trial, a randomized, open-label trial enrolling 472 patients. A departure from CALISTO which had excluded patients with history of malignancy treated within the last 6 months, the SURPRISE trial was designed to include patients at highest risk

for VTE, including those with cancer. In SURPRISE, patients were included only if they had a supragenual location and one of the following risk factors associated with a higher rate of thromboembolic complications: age >65 years, male sex, previous cancer, history of VTE, and absence of varicose veins.[93] When comparing 6 weeks of prophylactic fondaparinux to daily rivaroxaban (10 mg qday), rivaroxaban was noninferior to fondaparinux in the prevention of DVT, PE, and progression or recurrence of SVT. Rivaroxaban therapy was postulated to be a less expensive and a more patient-friendly treatment for SVT. In the "high-risk" SVT patients in this study thromboembolic events increased after the end of the active treatment in both treatment groups.[94]

Septic thrombophlebitis requires treatment with broad-spectrum IV antibiotics. If rapid resolution of the cellulitis occurs, no treatment beyond a short course of antibiotics and standard treatment for the superficial thrombophlebitis are required. However, if the patient becomes septic, excision of the infected vein is required. With positive blood cultures, an extended course of antibiotics specific for the identified organism is indicated additionally. The majority of episodes of uncomplicated superficial thrombophlebitis respond to conservative management. However, the recurrence rate for superficial thrombophlebitis has been estimated between 15% and 20%.[95–97]

CHRONIC VENOUS DISEASE

Normal Venous Anatomy

The lower extremity venous system is composed of deep, perforating, and superficial veins.[98] The common femoral, femoral, deep femoral veins in addition to the popliteal, sural and tibial/peroneal veins make up the deep system. The deep veins lie beneath the investing fascia of the muscles of the leg and thigh (the deep compartment) while the superficial veins lie above this muscular fascia. The GSV and SSV lie within the subcutaneous tissue and are surrounded by a separate saphenous compartment formed by the muscular fascia below and the saphenous fascia above. The saphenous nerve lies within the GSV compartment below the knee, which places the nerve at

risk of injury during surgery or percutaneous intervention. Similarly, the sural nerve lies in close proximity to the SSV and within its compartment.

In the past, various terminology and eponyms abounded but modern nomenclature prefers more descriptive terms designating location.[98] The names of other typical veins found in the lower extremity include the term of "accessory saphenous veins" for those superficial veins that lie outside the saphenous compartment, but parallel to the GSV or SSV, while "*communicating* veins" connect veins of the same system and "*perforating* veins" penetrate the muscular fascia to connect the superficial and deep systems.

The variability of the lower extremity venous system is well recognized with certain anatomic variations of clinical importance. The popliteal and femoral veins have variable anatomy and are often double much like the tibial veins. The deep femoral vein commonly connects directly or through tributaries to the popliteal vein. Complete duplication of the GSV in the thigh may occur in 8% of cases with some partial duplication in another 25%.[99] The saphenofemoral junction (SFJ) generally has at least four branches in addition to the GSV, but the configuration of the branches is quite variable.[100] The most cephalic branch is generally the superficial epigastric vein which acts as a landmark for percutaneous interventions and ideally remains patent following the procedure. The SSV is usually singular, dives under a thickened fascia in the upper calf (bringing it in proximity to the deep muscles), in less than two-thirds of cases actually ends in the popliteal creases and can travel well above the knee before diving to meet the deep system.[101] The varied location of perforating veins especially in the lower leg is important when deep to superficial reflux is a concern.

With the exception of foot veins, the valves promote blood flow from superficial to deep and from caudal to cephalad. The valves are made of a fine connective tissue skeleton covered by endothelium and are generally bicuspid, delicate, and extremely strong. Each tibial and peroneal vein contains about 7 to 19 valves. The popliteal vein contains one or two valves and the femoral vein generally three. Approximately 70% of common femoral veins have a valve located within 1 cm of the inguinal ligament while only 25% of external iliac and 10% of the internal iliac veins have a valve.[102] The common iliac vein generally has no valves. The GSV commonly has more than six valves (range, 4 to 25) with at least one valve

within a few centimeters of the SFJ and the SSV has an average of 7 to 10 valves (range, 4 to 13).[103] Perforating veins and even larger venules have venous valves.[102]

The veins of the abdomen and pelvis begin at the inguinal ligament as the external iliac vein that is joined medially by the internal iliac to form the common iliac vein. The internal iliac vein drains the pelvis via connections such as the obturator, gluteal, and internal pudendal veins and their interconnections. To the right of the fifth lumbar vertebrae and aorta, the common iliac veins join to form the IVC. Compression of the left iliac vein by the right common iliac artery can lead to a venous obstructive condition called May–Thurner syndrome. The IVC typically ascends to the right of the aorta and vertebral column terminating in the right atrium. Its direct tributaries are the lumbar veins, the right gonadal vein, the renal veins, the right suprarenal vein, the right inferior phrenic vein, and the hepatic veins. Other named veins generally join one of these tributaries to empty into the IVC. Because of the embryonic evolutions that lead to the "normal" IVC and its branches, variations are common. Duplication of the IVC occurs in 0.2% to 0.3% of cases, transposition or a left-sided IVC can occur in 0.2% to 0.5%, a retroaortic left renal in 1.2% to 2.4%, and circumaortic left renal vein in 1.5% to 8.7% of cases.[104] In the face of IVC occlusion, veins of the chest and abdominal wall, the azygos and hemiazygos systems, and vertebral plexuses may play a prominent role in venous drainage of the lower extremities, abdomen and retroperitoneum.

Normal Venous Physiology

Morphologically veins have a thin wall and lack external support. Small intramuscular veins are extremely compliant such that increasing the venous volume (VV) by over 1½ times results in a minimal increase in pressure (0 to 15 mm Hg).[105] This allows a significant volume of blood (at least 500 mL in the standing position) to become sequestered in the lower limb without a significant rise in intraluminal pressure. However, once the full capacitance of the venous system is reached, further increases in VV result in a proportional increase in intraluminal pressure and changes the vein from an elliptical to a circular configuration. In general, this forgiving design can compensate for much pathology but when overstressed sustained venous

hypertension results in decompensation at the cellular level with resulting edema in the lower leg tissues. The many factors that can affect peripheral venous pressure including arterial inflow are addressed in a recent experimental model.[106]

In contrast to intramuscular veins, the compliance of large axial veins (e.g., femoral, popliteal) mimics that of an artery in that pressure changes are more reflective of volume changes. They are conduit rather than compliance vessels.

The calf and possibly the thigh muscles act as a pump, the "peripheral heart," which can generate pressures of up to 300 mm Hg in the deep system and 100 to 150 mm Hg in superficial veins during exercise.[102] Normally, modest exercise of the muscles will expel the contained blood volume present in the veins and reset the capacitance of the venous system maintaining a homeostatic environment.

The venous valves (superficial, deep, and perforating) play a key role because they allow blood to move forward in response to an increased distal pressure gradient (muscle pumps) and by preventing reflux, protects the capacitance vessels from overload and, thereby, the superficial structures (i.e., skin, soft tissues) from the high pressures generated in the deep system.

Prevalence and Impact

Chronic venous disease (CVD) is a common, costly malady in Western countries. CVI is defined as venous pathology that results in advanced clinical symptoms (edema to venous ulceration). If one considers the entire spectrum of the disease based on modern methods of classification, approximately 21.7% have reticular veins/telangiectasia, 18% varicose veins, 15% edema, 7% hyperpigmentation, 1.4% healed ulcers, and 0.7% active ulcers.[107,108] A population-based study in San Diego that included Duplex imaging demonstrated that 5.8% of those studied presented with edema while 6.2% had skin changes and/or prior or active venous ulcers.[107] The estimated cost of venous ulcer care to the healthcare system is 1.5 to 3 billion annually and significantly more if actual patient cost is considered.[109,110] The negative impact on QOL for other less severe forms of venous pathology would greatly surpass this cost to the healthcare system.

Relevant risk factors for varicose veins are advanced age, a positive family history, female gender, multiparity, and obesity, while the risk factors for CVI are advanced age, positive family history, and obesity.[111]

Pathophysiology and Etiology

Three pathophysiologic states exist: obstruction, valvular insufficiency, and calf muscle pump malfunction. These conditions reflect a failure of one or more of the components of the normal venous system and are not mutually exclusive.

Venous obstruction causes an increased resistance to blood exiting the lower extremity. Once thought to be an uncommon etiology of treatable lower leg venous pathology, venous occlusive disease in combination with venous insufficiency was evident in over 50% of patients with CVI in one study, especially noted in those with the most severe symptoms. The result is elevated intravenous pressure noted clinically as pain especially after exercise as one added manifestation of the disease.[112]

Asymptomatic primary iliac venous compression is quite common, one study of 50 patients without symptoms of CVI demonstrated that 24% had greater than 50% narrowing (compression) of the left common iliac vein by the right common iliac artery.[113] It has been suggested that this type of nonthrombotic stenosis (compression with potential for intramural fibrosis) is a "permissive lesion" not clinically significant until other components of the lower extremity venous circulation fail or the occlusive disease progresses.[114] Less common causes of obstruction include intraluminal webs from repetitive trauma as well as extrinsic compression of the iliac and pelvic veins by tumor, fibrosis, infection, femoral hernias, or arterial aneurysms.

Postthrombotic obstruction is also a common cause of venous occlusive disease due to the rather high prevalence of DVT and can impact any part of the venous system. Acute thrombosis is associated with inflammation and remodeling during resolution and results in external vein wall scarring with stiffening and thickening, as well as intraluminal recannulation with webs and bands. The venous valves are generally incorporated into the scarring process leading to valve malfunction.

In one of the largest experiences treating iliofemoral venous occlusive disease involving nearly 1,000 patients, compression of the common iliac vein was observed in 36%, external iliac vein in 18%, and both sites in 46% of limbs. Of these patients, 53% of limbs had nonthrombotic compressive lesions (absent history of DVT, no venographic or ultrasound findings indicating previous DVT); 40% had postthrombotic obstruction; and 7% had a combined etiology. Furthermore, 20% of the patients were men and 25% of the symptomatic lower limbs were on the right side.[114]

Valvular insufficiency occurs throughout the lower extremity veins and is estimated to account for 80% of symptomatic CVD cases.[115,116] While superficial reflux is most common, deep venous insufficiency frequently coexists with superficial and perforator disease[107,117] and duplex imaging studies suggest that patients with minimal symptoms tend to have isolated superficial reflux while those with edema, skin changes, and past or present ulcers have an increasing presence of perforator and deep disease as well as a postthrombotic etiology.[115] The presence of both obstructive and reflux pathology denotes more risk for the development of skin changes[118] and the degree to which combined obstructive and insufficient venous pathology contribute to CVD is likely underestimated.[114,119] No matter the clinical stage, the superficial system is most commonly affected (90%) with GSV involvement in 70% to 80%, SSV in 15% to 20%, and nonsaphenous veins in approximately 10%. The deep veins are involved in about 30% and perforator veins in about 20% of cases in one series.[115]

Reflux allows the transmission of high venous pressures to the lower leg when standing and is not relieved by exercise. Primary valvular insufficiency is rare but can be a consequence of congenital valve absence.[120] There are predisposing genetic factors that can lead to primary venous reflux including Klippel–Trenaunay syndrome, FOXC2 gene mutation, desmulin dysregulation, the Ehlers–Danlos syndrome, and a CADASIL gene mutation, to name a few, but these do not reflect the typical patient.[121] The muscle cell–dilating effect of estrogens may explain the genesis of varicose veins noted in the first trimester of pregnancy. Prolonged exposure to high venous pressures can cause vein dilation as occurs from an arteriovenous fistula or occupations requiring prolonged periods of standing. For our standard patient, venous valve prolapse (elongated, floppy valves) and defects in the vein wall that cause the valve ring to dilate results in malfunctioning valve

cusps with retained valve architecture.[122] Whether the vein wall changes precede valve insufficiency or the valve insufficiency causes wall distention and wall changes is less clear.[123]

Roughly 50% of deep vein valvular dysfunction occurs secondary to DVT whereas the remainder appears to be of a primary etiology.[124–126] Inflammation and thrombosis associated with DVT tend to cause valve scarring, whether or not recanalization is complete, leaving a damaged valve in most cases. Sometimes, however, whether due to rapid resolution of thrombi or lack of actual involvement of the valve, the valve may escape damage remaining architecturally intact, and can be repaired surgically.[127]

CVD can result from failure of calf muscle pump function. The pump becomes unable to generate the force needed to eject blood from the leg while standing, resulted in sustained venous hypertension. Patients with muscle disuse (e.g., paraplegia, traumatic injury, elderly or bedridden patients) may not have sufficient muscle for effective exercise. Pathologic conditions that result in muscle fibrosis (e.g., muscular dystrophy, multiple sclerosis) can destroy the calf muscle pump. Thrombus and scarring in the gastrocnemius and soleal veins can prevent blood from entering the pump chamber resulting in a deficient volume for ejection with contraction. Calf pump function and ankle range of motion progressively diminish with increasing severity of CVI.[128,129] Physical conditioning can improve the metrics of pump function, however, evidence regarding improved clinical outcomes is lacking.[130–132]

Regardless of the etiology, the sequelae of venous hypertension/stasis are changes observed in the lower leg skin and subcutaneous tissues, the end organ. The current belief holds that the fundamental basis for CVD and ulceration is inflammation within the venous microcirculation when subjected to increased hydrostatic pressure. Research remains active in this component of venous pathophysiology and excellent reviews are available for further information on the current understanding of basis venous pathophysiology.[133,134]

Clinical Signs and Symptoms

Venous disease presents in many ways. A telangiectasia, spider vein, is a confluence of dilated intradermal venules less than 1 mm in caliber. A

reticular vein is a dilated bluish subdermal vein, 1 mm to less than 3 mm in diameter and usually tortuous. These venous abnormalities may be associated with a larger, more deeply located, pathologic vein but not always. Hereditary varicose veins usually appear during the second decade of life. If the varicosities are due to a secondary etiology (e.g., thrombosis, trauma), presentation can be several years after the inciting event. These veins appear alone or in clusters as dilated, often bluish, serpentine, and palpable protrusions of branches of the GSV, SSV, or collateral veins lying beneath the skin in the subcutaneous tissues. Varicose veins measure 3 or more millimeters in diameter when measured in the upright position.[135] One finding thought to be an early sign of advanced disease is corona phlebectatica, a fan-shaped pattern of small intradermal veins located around the ankle or dorsal foot (also called ankle flare or malleolar flare). If the varicose veins observed are the result of proximal disease, such as pelvic reflux or obstruction; the location of the varicosities may be scrotal, perineal, vulvar or posterior/lateral in the lower extremity.[103]

Symptoms may be those associated with any type of CVD and are noted as pain, edema, hyperpigmentation, stasis dermatitis/eczema, and/or venous ulcers. These changes often occur in the "gaiter" area just above the medial malleolus. Important perforating veins lay in this area. The observed hyperpigmentation is thought to result from extruded red blood cells that are degraded by macrophages leaving hemosiderin deposits. Less definable but described symptoms of CVD include tingling, burning, muscle cramping, a sensation of throbbing or heaviness, itching, restless or tiredness of the legs, and fatigue.[136] They are more specific for venous disease if made worse with standing and heat and if relieved by rest and leg elevation.

Venous claudication is a pain syndrome experienced when walking and is associated with cyanosis, a sensation of increased swelling, and increased prominence of the superficial veins, which is relieved with rest in combination with elevation of the extremity.[137]

2 Critical to patient management and treatment evaluation is an accurate classification of the disease at any given time. Each patient is stratified according to the *c*linical picture, the *e*tiology, the *a*natomic distribution, and the *p*athophysiology (CEAP) classification system (Table 96.2).[135] This classification system helps the physician define the venous disease and then formulate an appropriate management strategy. An extension of the clinical

classification, the Venous Clinical Severity Score, is available to quantify the extent of venous disease and, therefore, to evaluate the patient's clinical response to treatment (Table 96.3).[138,139] The anatomic and pathophysiologic improvement following a treatment of venous disease can be scored using the Venous Segmental Disease Score, while the Venous Disability Score provides some information of what a person can do when afflicted with venous disease.[139] QOL surveys developed specifically for patients with venous disease help to determine the impact of the disease on the patient's life and the effect therapy has on the patient's overall well-being.[140,141] Consistent application of these treatment outcome tools is imperative to improve our ability to precisely determine the effect and benefit of a given intervention.

Table 96.2 Clinical Classification of Chronic Venous Disease

Class	Description
0	No visible or palpable signs of venous disease
1	Telangiectasias and/or reticular veins
2	Varicose veins
3	Edema
4a	Skin changes (pigmentation and/or eczema)
4b	Skin changes (lipodermatosclerosis and/or atrophie blanche)
5	Healed venous ulcer
6	Active venous ulcer
S (in addition to the class)	Symptoms including ache, pain, tightness, skin irritation, heaviness, muscle cramps as well as other complaints attributable to venous dysfunction
A (in addition to the class)	Asymptomatic

Diagnostic Evaluation

The diagnosis of CVD begins with a thorough history and physical examination. Prior DVT, pregnancies, a family history of varicosities, obesity, or the presence of other factors associated with CDV will add support to the presence of venous disease. When performing the physical examination: the location, distribution and size of varicosities, skin changes,

and/or presence or indication of past ulcers should be noted. Swelling should be quantified, the location specified, and a determination made as to whether it is pitting or nonpitting in nature. Inspection, palpation, and auscultation (presence of a bruit) may be keys to the presence of a vascular malformation or arteriovenous fistula. Utilization of the CEAP clinical classification will provide a snapshot of the patient being examined, whereas the use of the more detailed Venous Clinical Severity Score and the other measurement tools mentioned above will allow for some impression of how any patient therapy is performing.

In addition to determining and classifying the signs and symptoms of venous disease, the history and physical examination should exclude other potential causes for the patient's complaints such as arterial occlusive disease, collagen vascular disorders, allergic reactions, infection, or malignancy. Appropriate confirmatory diagnostic studies may be required to confirm the clinical suspicion, such as a lower extremity arterial Doppler study, biopsy, or specific blood analyses when the diagnosis is unclear. Such studies become most pertinent during the evaluation of advanced venous disease, especially in patients with venous ulcers.[142] Only in selected patients, such as those with recurrent, early, or unusual sites of DVT or recurrent venous ulcers, is evaluation for thrombophilia recommended.[103,142]

Venous duplex ultrasonography provides a B-mode picture of the vein, as well as spectral analysis of the blood flow within. It is recommended as the first diagnostic test for all patients with suspected CVD.[143] To provide an accurate impression of the venous disease present, a standardized technique is mandatory.[143,144] Venous duplex imaging clearly visualizes deep, superficial, and perforator veins and often the valves that lie within the veins. The venous duplex study can help to clarify the etiology, better define the anatomic location, and aid in determining the pathophysiology of the venous problem (EAP of CEAP). While once considered unnecessary in the evaluation of patients with simple varicose veins, it has become common practice prior to treating superficial reflux due to the known anatomic variability present and the need for precise targeting of veins during endoluminal intervention.[144–146]

Valvular insufficiency is defined as prolonged reflux time through a valve following a provocative test when duplex imaging is the diagnostic modality. To aid in the standardization of the test, a rapidly deflating distal cuff

technique is used in some vascular laboratories, while others use manual compression of the distal leg after which valve reflux is determined by duplex imaging. An abnormal reverse venous flow (reflux) in the saphenous, tibial, and deep femoral veins is ≥ 0.5 seconds while the femoral and popliteal veins have a cutoff value of 1 second.[147] Since perforating vein reflux can also be associated with venous pathology, significant work has gone into determining how to define abnormal reflux. Current consensus and available data suggest that a "pathologic" perforating vein is defined as a vein with an outward flow of ≥0.5 seconds with a diameter of >3.5 mm, which is located beneath a healed or open venous ulcer.[103,142,143] The duplex examination for reflux is performed in the upright position but many other provocative maneuvers to generate venous reflux exist (Valsalva, standardized Valsalva, etc.) in addition to performing the test in different positions (e.g., 15% Trendelenburg, sitting) and are used in many laboratories for particular patients who have difficulty standing.[148] Each may be acceptable if standardized and validated for an individual laboratory.

Venous obstruction is seen as thickened, scarred, and constricted veins with poor flow and diminished augmentation following distal and/or proximal compression. Respiratory variation is lost as a result of local occlusive disease or proximal occlusion. Disease within the SSV should not be ignored because it can have a significant clinical impact as an isolated finding.[149] By imaging the entire lower leg venous system, the surgeon possesses a detailed roadmap of all veins with determination of obstruction or reflux within segments separated by valves. This is often the only diagnostic tool needed for the evaluation of superficial and even perforator disease requiring treatment.

A difficult area of investigation from a noninvasive perspective is the pelvic, abdominal, and chest veins. CT and MRI can provide details of anatomy and the effect of surrounding structures and can be particularly useful in evaluating for the pelvic congestion syndrome.[150–152]

Plethysmography assesses the overall hemodynamics of the lower extremity venous system. Air plethysmography (APG) can measure several venous hemodynamic parameters. A plastic cylinder filled with air is fitted over the calf and foot and changes in leg volume with positional change or exercise are detected by pressure changes in the cylinder. Calculated parameters include venous filling index (<2 mL/s is normal) which assesses

the competency of the venous system, ejection fraction (>60% is normal) and residual volume fraction (<35% is normal) which suggest that the calf pump is working well.[153] In current clinical practice, it is being used only in complex cases or for research purposes. Current consensus encourages the use of plethysmography in the patient with advanced CVD if duplex scanning cannot provide a definitive diagnosis regarding the underlying pathophysiology.[103]

As in acute venous disease, venography has no significant role in the initial evaluation of patients with CVD. Unfortunately, ascending venography can suggest venous occlusion when duplex imaging clearly demonstrates an open system.[154] The absence of significant collaterals on transfemoral venography may underestimate the degree of venous occlusion as documented by intravascular ultrasound.[155] The use of ascending venography is selectively used in specific cases to complement noninvasive studies when considering intervention in the deep venous system or in research protocols.

DIAGNOSIS

Table 96.3 Venous Clinical Severity Score

Attribute	Absent 0	Mild 1	Moderate 2	Severe 3
Pain	None	Occasional, not restricting activity or requiring analgesics	Daily, moderate activity limitation, occasional analgesics	Daily, severe limiting activities, regular use of analgesics
Varicose veins[a]	None	Few, scattered: branch VVs with competent GS/SS	Multiple: single-segment GS/SS reflux	Extensive: multisegment GS/SS reflux
Venous edema[b]	None	Evening ankle edema only	Afternoon edema, above ankle	Morning edema above ankle and requiring activity change, elevation
Skin pigmentation[c]	None or focal, low intensity (tan)	Diffuse, but limited in area and old (brown)	Diffuse over gaiter distribution (lower 1/3) or recent pigmentation (purple)	Wider distribution (above lower 1/3) and recent pigmentation
Inflammation	None	Mild cellulitis, limited to marginal area around ulcer	Moderate cellulitis, involves most of gaiter area	Severe cellulitis (lower 1/3 and above) or venous eczema
Induration	None	Focal, circummalleolar (<5 cm)	Medial or lateral, less than lower third	Entire lower third of leg or more
No. of active ulcers	0	1	2–4	>4
Active ulceration, duration	None	<3 mo	>3 mo and <1 y	Not healed >1 y
Active ulcer, size[d]	None	<2-cm diameter	2- to 4-cm diameter	>4-cm diameter
Compressive therapy[e]	Not used or not compliant	Intermittent use of stockings	Wears elastic stockings most days	Full compliance: stockings + elevation

[a]Varicose veins must be >4-mm diameter to qualify so that differentiation is ensured between C1 and C2 venous pathology. Occasional or mild edema and focal pigmentation over varicose veins does not qualify for C3 or C4.
[b]Presumes venous origin by characteristics (e.g., brawny [not pitting or spongy] edema), with significant effect of standing/limb elevation and/or other clinical evidence of venous etiology (i.e., varicose veins, history of DVT). Edema must be regular finding (e.g., daily occurrence). Occasional or mild edema does not qualify.
[c]Focal pigmentation over varicose veins does not qualify.
[d]Largest dimension/diameter of largest ulcer.
[e]Sliding scale to adjust for background differences in the use of compressive therapy.
GS, great saphenous; SS, small saphenous; VV, varicose vein.
From Rutherford RB, Padberg FT Jr, Comerota AJ, et al. Venous severity scoring: an adjunct to venous outcome assessment. *J Vasc Surg* 2000;31(6):1307–1312.

Descending venography is used to determine valve leaflet integrity and anatomic location and demonstrate the extent of reflux.[156] Assessment of the competence of the profunda femoris venous system in addition to the femoral system is imperative prior to valve transposition or isolated proximal femoral vein repair.[157–159] And while descending venography is not infallible in determining the presence or absence of a normal valve,[127] when combined with a careful venous duplex examination, it is currently the best method available to determine preoperatively if an in situ reconstruction will be possible.

Intravenous pressure measurements can aid in the diagnosis of venous disease but is invasive and generally used only when invasive surgery of the deep system is being considered. This study can help to determine the overall

magnitude of reflux and can be correlated with the incidence of venous ulceration.[160] Although IV pressure measurements and venography were once 3 the gold standard for evaluating venous disease, duplex scanning—with the addition of intravascular ultrasonographic techniques when required—is the anatomic and functional test of choice in current medical practice.

4 Treatment Options and Results

Medical Therapy

Compression has been the mainstay of the medical treatment for all stages of CVI for centuries. The goals are to manage clinical symptoms and to control venous hypertension. Roughly speaking, there are two types of compression: elastic (e.g., support stockings or long stretch bandages) and inelastic (e.g. Unna's paste boot, short stretch bandages, multilayer [four-layer] bandage, or Velcro band devices). In general, the more layers the less elastic and more stiff the compression. The degree to which any particular bandaging is one or the other will depend on the care provider who applies the compression along with other factors. The mechanical effect is dependent on the level and type of compression and the desired amount of compression is influenced by the underlying venous pathology being treated.

Consistent narrowing of superficial and calf veins occurs at a median of 30 to 40 mm Hg pressure on standing while complete occlusion occurs at a median pressure of 70 mm Hg.[161] Complete occlusion is not the goal. Therapeutic calf compression improves calf muscle pump function expressed as a reduction in residual volume fraction during walking[162] and even compression <20 mm Hg results in improved symptoms and QOL data when used to treat mild disease.[163,164]

It is interesting that an elastic stocking maintains a rather constant pressure during exercise and at rest. Alternatively, inelastic wraps demonstrate a more dramatic increase in pressure during exercise since they do not stretch but have decreasing pressure with recumbence as the edema exits the leg and the bandage maintains its shape.[165] Inelastic wraps are much better tolerated when left on for days and especially when recumbent at night when compression is not required to contra-act gravity. Constant compression at night can be perceived as discomfort/pain. Further, inelastic compression has

been found to result in a greater improvement in venous hemodynamics when applied at the same pressure as elastic compression[166–168] and maintains greater effect despite loss in pressure over time[169] (pressure loss likely related to the decreased volume of the leg). The significant decrease in swelling noted early in compression treatment explains why compression stocking often need to be changed more frequently during the early stages of care.

Although there has been concern that compression may impede microcirculatory flow and thereby jeopardize tissue viability, it is known that compression, when used to treat edema, has favorable effects on extracellular fluid balance, capillary density, and transcutaneous oxygen tension.[170] Compression therapy also decreased levels of endothelial growth factor and tumor necrosis factor which correlated with ulcer healing[171] and actually increases microcirculatory flow.[172]

Patients with concomitant arterial occlusive disease pose a unique challenge. In one center, 15% of those presenting with leg ulceration and venous reflux had an ankle to brachial artery index (ABI) <0.85.[173] There is some suggestion that standard compression can actually increase arterial blood flow in certain circumstances.[165,174] Overall, data suggest that improvement in tissue level perfusion is likely related to improvement in the microangiopathy of CVD, offloading of the outflow system, and through a decreased burden on the lymphatic system (often damaged in patients with CVI).[175]

In patients with concomitant arterial occlusive disease with ABI of ≥0.80, the use of standard compression is safe and effective.[176]

In those with more advanced arterial occlusive disease defined as an ABI ≥0.50 (but <0.80) or an ankle systolic pressure ≥ 60 mm Hg or toe pressure ≥30 mm Hg as a minimum; modified compression dressings with lower pressure ratings not to exceed the tissue perfusion pressure can improve tissue perfusion and aid in healing ulcers of mixed etiology.[176,177] These data support the current SVS/AVF practice guideline suggesting that in a patient with a venous leg ulcer and underlying arterial disease, compression bandages or stockings are not indicated if ABI is ≤0.5 or if the absolute ankle pressure is <60 mm Hg.[142]

Evidence-based medicine confirms our clinical impression and basic science findings regarding the potential benefits of compression garments for

the treatment of CVI. Substantial evidence exists to demonstrate that compression is statistically beneficial for most clinical stages of symptomatic venous disease ($C_{2–6}$). Whether compression stockings should be the primary treatment for symptomatic varicose veins is challenged by data from the United Kingdom. The randomized trial (REACTIV) demonstrated that in 246 patients with class C_2 disease, surgical intervention resulted in a statistically significant benefit in quality-adjusted life-years and in symptomatic and anatomic measurements compared to conservative management.[178] Likewise, cost-effective analysis demonstrated a benefit for the surgical intervention.[179] Therefore, in contradistinction to current third-payer policies, and based on available statistical data, the SVS/AVF Guidelines Committee recommends against compression therapy as the primary treatment of symptomatic varicose veins in those patients who are candidates for saphenous vein ablation (grade 1B recommendation).[103] Certainly in those who do not desire interventional options or are not candidates for superficial venous ablation, the Guidelines Committee suggests compression therapy (20 to 30 mm Hg) for symptomatic benefits (grade 2C).

Compression is the standard of care for patients with advanced CVD ($C_{3–6}$) and the majority of the evidence-based data investigate the benefits of treating venous ulcers since the rate and degree of healing are measurable. The evidence suggests that venous ulcers heal more quickly with compression therapy than without compression[180] and that noncompliance with therapy is associated with both nonhealing of the ulcer as well as increased risk of recurrence.[181] Compression also decreases the risk of recurrence following surgical intervention.[182] The modality of the compression therapy is also a factor and there is some evidence to support multicomponent compression over single component compression[180] and high compression over medium compression to treat venous ulcers.[183] However, these results are not consistently reproducible[184] and both the skill of those applying the dressing[185] as well as patient compliance likely remain significant confounding factors.[181] The SVS/AVF Guidelines Committee recommends that compression be used to heal venous ulcers (grade 1A), to decrease recurrence (grade 2B), and it is suggested that multicomponent compression bandages be used to treat venous ulcers (grade 2B).[103]

As a general approach, multilayer relatively inelastic wraps are preferred for the therapy phase of venous disease (ulcer healing). With ulcer healing, elastic wraps, such as compression stockings, are used to maintain a stable clinical condition (maintenance phase). In addition, elevating the legs when possible during the day, avoiding prolonged periods of standing or sitting, and elevating the foot of the bed 4 to 6 in above the heart while sleeping are adjuvant components of conservative therapy.[186,187]

Intermittent pneumatic compression (IPC) provides pulsatile emptying of the venous system via compressive bladder(s) that inflate and deflate. A Cochrane review suggests that there is advantage in using IPC compared to no compression, but little evidence to support that it adds to compression therapy alone.[188] Currently it is recommended that IPC be employed when compression has failed, is unavailable, or cannot be used.[142]

Other forms of conservative therapy for CVI include lifestyle changes such as exercise as well as pharmacologic agents, which are generally not available in the United States. Structured exercise can improve dynamic muscle strength and calf muscle pump function in patients with essentially all levels of CVI from varicose veins to venous ulceration.[130,132] A meta-analysis of five RCTs found that exercise was as associated with healing of venous ulcers at 12 weeks[189] and the use of supervised active exercise to improve muscle pump function and to reduce pain and edema in patients with leg ulcers is a guideline recommendation (grade 2B).[142]

In Europe and other countries, various oral agents (e.g., rutosides, hidrosmin/diosmine, dobesilate) are used to improve the feeling of heaviness, fatigue, and even edema associated with CVD but these agents are not available in the United States.[103,142] A Cochrane review of 53 studies of such agents concluded that there was possible benefit regarding edema control and other signs and symptoms of venous disease (cramps, restless legs, paresthesias), however, there was no improvement in ulcer healing and many phlebotonic agents were poorly tolerated.[190] A drug which is potentially useful in treating patients with venous ulcers and is available in the United States is pentoxifylline. A review of 12 trials indicated that pentoxifylline does provide an incremental benefit in ulcer healing when used as an adjunct to compression and may also have some effect in the absence of compression but the trade-off is more gastrointestinal adverse effects.[191] This is currently an off-label use of this medicine, originally

prescribed for patients with claudication. For long-term effects and as an adjunct to compressive therapy when treating large venous ulcers, pentoxifylline, in combination with compression therapy, is recommended (grade 1B).[142] Current practice is to prescribe 400 mg of pentoxifylline three times per day and, if tolerated, 800 mg three times per day may accelerate ulcer healing.[192] Prophylactic use of systemic antibiotics in the treatment of venous ulcers does not improve healing and may only select resistant organisms.[193] Certainly, an established infection (cellulitis or deeper) must be treated as it would be at any site and is recommended best care by the SVS/AVF Guidelines Committee. In addition, the recommendation is for oral agent use for 2 weeks unless evidence of clinical infection continues (grade 1C).[142] Limb cellulitis with or without a venous ulcer generally requires systemic gram-positive antibiotic coverage and is a grade 1B recommendation for patient care.[142,194]

5 Surgical Therapy

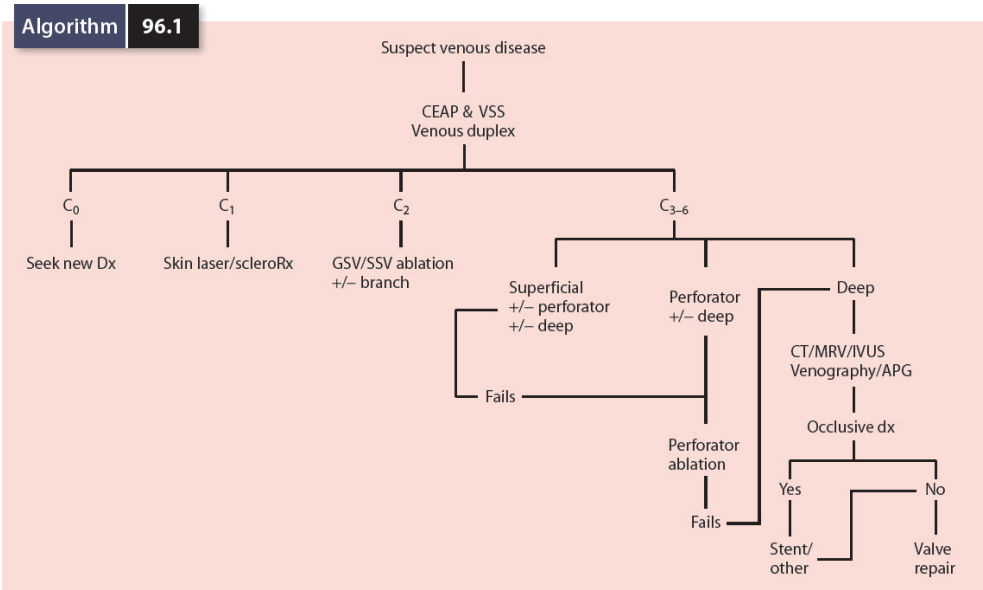
The use of surgical intervention in the realm of venous disease as in all areas of vascular surgery is driven by the documented presence of disease, the risk of the intervention, and the expected outcome (Algorithm 96.1).

Telangiectasia, Reticular Veins, and Branch Varicose Veins

Laser or intense pulsed light (IPL) ablates telangiectasias with reasonable success, inducing vessel destruction by targeting the absorption peaks of hemoglobin. Various devices exist with selection based on the wavelength and pulse duration most appropriate for the size and location of the lesion.[195] In general, shorter wavelengths work best for smaller diameter vessels. Dyspigmentation can occur and tanned skin is a contraindication to treatment because melanin is a strong competing chromophore that absorbs the light energy and causes a tattoo.[196]

Sclerotherapy (needle injection of detergents, hypertonic solutions, or chemical irritants directly into superficial veins with or without ultrasound guidance) is used to treat varicosities most often remaining after saphenous ablation, small isolated varicosities, telangiectasias, and reticular veins. Sclerotherapy alone appears an effective treatment for branch varicosities in patients without major saphenous reflux or when combined with techniques to treat major saphenous reflux when present.[197,198] The FDA-approved

sclerosing agents are sodium tetradecyl sulfate, sodium morrhuate, polidocanol, and glycerine. Hypertonic saline (23.4%), although not approved for sclerotherapy in the United States, is used and has been for many years. All act to damage the vein endothelium, inducing inflammation and scarring with ultimate lumen collapse.[199] Polidocanol has rapidly been adopted as the workhorse for venous sclerotherapy because of a very low allergic and anaphylactic reaction rates, a low risk of tissue necrosis, in addition to being essentially painless. Foam sclerotherapy is the addition of air, carbon dioxide or other gases to a sclerosants such as polidocanol to allow a more protracted contact of the sclerosing agent to the vein wall. The most popular technique uses two syringes and a three-way stopcock to allow the gas to be aspirated into one of the syringes, while the other syringe contains a detergent sclerosant, which results in a one part of drug to four parts of gas mixture. Aggressive agitation of the mixture between the syringes allows for a more stable, microbubble containing foam.[200] Now there are commercially available products. The exact concentration of sclerosant, liquid or foam, used for sclerotherapy is dependent on vein size and agent used.[199] These interventions are generally outpatient procedures with low complication rates. Transient local discomfort is common and rarely extravasation of the agent, especially if ultrasound guidance is not used, can cause fat or skin necrosis with ulceration.[201] Hyperpigmentation can occur and is reduced by microthrombectomy of clotted blood trapped in treated veins especially in veins 1 mm or less in diameter.[202] Other potential complications of sclerotherapy include allergic reactions and systemic toxicity if too much agent is used at one sitting.[199,201,203] Rarely neurologic events including visual disturbance, migraine, and stroke are reported and this possibility must be discussed with the patient prior to its use.[201,204] The presence of a patent foramen ovale is associated with a higher frequency of transient neurologic events[201,205] while the use of CO_2 as the mixing gas used for foam sclerotherapy appears to decrease the risk of such adverse events.[206] On the basis of the available data, the SVS/AVF Guidelines Committee recommends that liquid or foam sclerotherapy be used to treat telangiectasia, reticular veins, and varicose veins (grade 1B).[103]



Algorithm 96.1 Treatment of chronic venous insufficiency.

Phlebectomy (ambulatory phlebectomy, stab avulsion, stab phlebectomy, microphlebectomy, and microextraction are synonymous terms) is a technique in which varicose veins are removed through small skin stab incisions with hooks or small mosquito clamps used to pull the vein from its bed.[207] It can be performed in an ambulatory setting with local anesthesia or in conjunction with a more invasive procedure. There is evidence that phlebectomy has fewer recurrences than sclerotherapy but is still associated with risks (blisters, telangiectatic matting, scar formation, and bruising).[208] Tumescent anesthesia has allowed for extensive interventions with little pain and on an ambulatory basis.[209]

Saphenous Vein Stripping/Ablation

Saphenous preservation or conservative hemodynamic management of varicose veins (e.g., CHIVA) can lead to good results in the hands of skilled interventionalist willing to interpret detailed preoperative imaging (proper patient selection) and a meticulous technical approach. It involves removal of only selected branch varicosities resulting in improved saphenous function and preservation of saphenous drainage with a reported lower rate of recurrence when compared to saphenous stripping in selected series.[210] Because of limited data available and the technical nuances, treating saphenous veins reflux and associated varicose veins in this manner is only

suggested for those with experience (grade 2B/C) by the SVS/AVF Guidelines Committee.[103]

If axial and extensive saphenous insufficiency is present, some method of eliminating reflux is required for best results. Entirely removing the refluxing vein from the venous system is the current best and most studied solution. Lower leg deep venous occlusive disease is not an absolute contraindication to removal of the saphenous system and may actually be indicated in patients with mixed obstruction/reflux disease. It is often the first step in cases of combined deep and superficial insufficiency.[211,212]

There are several methods available to accomplish this task. Open surgical removal involves preoperative marking of the dilated veins while standing so that apparent varicose veins can be removed during operation. The operation includes ligation and disconnection of the GSV at the SFJ via open incision followed by complete removal of the vein to the knee by one or more distal incisions centered over the vein. If the below-knee GSV is incompetent based on preoperative diagnostic studies, it may be excised. The method of vein removal may involve the introduction of long metal or plastic stripping wires with removable heads of varying size or various other tools to facilitate pulling the vein from the distal leg incision.[213] Both the GSV and SSV can be treated by these methods with proper patient positioning and knowledge of existing anatomic variability especially of concern in the case of the SSV. In particular, protection of the sural nerve by limited deep dissection is critical. More technical details are found in a recent review and description of technique.[214]

In addition to classic ligation and stripping, either saphenous vein may be removed from the venous circulation via endovenous ablative techniques. These include thermal methods such as radiofrequency ablation (RFA) or laser ablation as well as sclerotherapy with the common premise of scarring the vein such that it does not act as the conduit for venous blood. In addition, there are nonthermal methods of endovenous ablation: mechanochemical and cyanoacrylate embolization. These techniques also cause intravenous scarring, fibrosis, and occlusion.

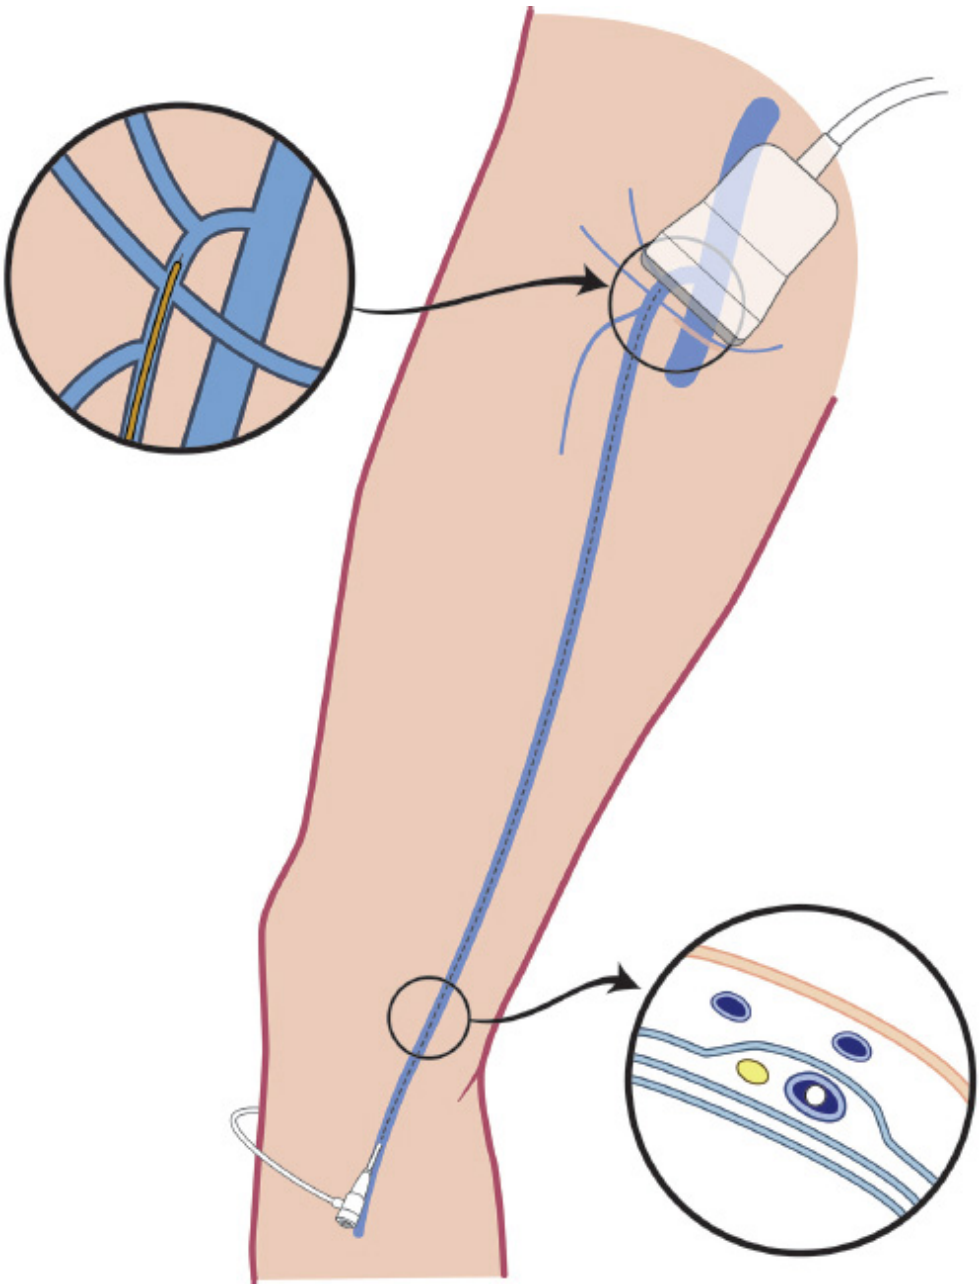


Figure 96.1 An artist depiction of percutaneous radiofrequency ablation of the great saphenous vein. Note percutaneous access of the vein around the knee and advancement of the device to about 2 cm below the CFV. The vein is serially treated with the RFA probe (or laser, glue, sclerosant in other methods) to result in ablation. Pulling the sheath and applying pressure is sufficient to prevent bleeding from the access site. Note the close location of the saphenous nerve near the GSV at the knee and below. (Lower magnification demonstrates saphenous nerve in saphenous tunnel [yellow structure] near the great saphenous vein and is protected somewhat by tumescent anesthesia. Outside the saphenous compartment can be one or more accessory saphenous veins.) Note that the superficial epigastric vein generally maintains flow after ablation. (Upper magnification demonstrates typical

side branches, RFA device ~2 cm below the common femoral vein and somewhat below the superficial epigastric vein.)

For laser or RFA interventions, access is gained either percutaneously or rarely by venous cut down and the respective device is advanced into the vein to about 2 cm below the SFJ using duplex imaging for proper positioning (Fig. 96.1). The saphenous vein is sequentially heated throughout its length as the heating probe (laser fiber or RFA device) is pulled back to the entrance site. Tumescent anesthesia is administered within the saphenous compartment providing anesthesia, a heat sink, and some venous compression during the procedure. The precise parameters for heating the RFA probe is standardized for each pullback length and treatment cycle (e.g., 7-cm sections and 20-second cycles) and usually two treatment cycles are used in the more proximal segment of the vein to ensure proximal ablation at the point of maximal reflux from the deep system.[215]

Laser energy of various wavelengths (810 to 1,470 nm) delivered via bare-tipped fiber will cause a localized thermal injury to the vein wall. The laser probe technique is more physician directed and involves a slow, continuous withdrawal as opposed to the stepwise removal of the RFA probe (generally 1 to 2 mm/s at 10 W with a desired 60 to 100 J/cm). The exact rate and energy delivered depends on the device used but like RFA typically more ablative effort is applied to the first 10 cm of the vein.[215] One of the best technical description of RFA, laser and hybrid (surgical excision of residual disease) to treat saphenous reflux is included in a recent atlas.[216]

The nonthermal methods generally do not require tumescent anesthesia (no need for a heat sink or anesthesia) and so are potentially better tolerated by patients. These are the newest of the ablation methods which do not rely on local heat so may have less issues with nerve/skin injury. The mechanical occlusion chemical-assisted (MOCA) ablation technique (ClariVein) requires distal percutaneous saphenous access and positioning of the rotating wire 2 cm below the SFJ or at the fascial curve of the SPJ. Only the wire is activated for the first centimeter (induces spasm), for the remainder of the 1.5 mm/s pull pack of the rotating wire sclerosant (8 to 12 mL of 1.5% sodium tetradecyl sulfate [STS] or polidocanol [PLD]) is injected from the tip. The cyanoacrylate closure (CAC) technique (VenaSeal) involves percutaneous distal access with 7-Fr sheath placed 5 cm distal to the SFJ then within the

sheath is placed a 5-Fr catheter through which is extruded cyanoacrylate by a specially designed delivery gun. 0.1 mL is delivered every 3 cm after 30 seconds of ultrasound-guided pressure and the catheter is pulled down 3 cm. In general, 1.3 to 1.5 mL of adhesive is required for completion. An excellent review of the techniques and results expected is available in a recent review.[217] There are other techniques continually being studied but currently these are mature representations of the options.

Sclerotherapy can be applied to large vein ablation (great or small saphenous). Percutaneous access above the knee if proximal and below the knee if distal saphenous involvement is present, allows placement of a 4- or 5-Fr sheath or 18-gauge angiocatheter into the vein. The foam is injected until it is seen nearing the SFJ at which time duplex-guided compression (usually by a second person) is applied for 3 to 5 minutes and the injection is stopped. A polidocanol propriety foam (Varithena) mixes nitrogen gas and 1% polidocanol liquid in a cannister to produce the consistent foam superior to physician-compounded foam.[217,218] Other agents previously noted (sodium morrhuate, sodium tetradecyl sulfate, etc.) are available for use.[215] Ultrasonography-guided foam sclerotherapy (UGFS) was found superior to liquid preparations and is effective in elimination saphenous vein reflux at least initially.[219]

Efforts to evaluate and compare the outcomes of these various techniques provide useful generalizations. Direct comparisons between surgical and endovenous modalities support that RFA and laser have comparable results to open surgery and to each other but that UGFS may have a lower technical success rate and a higher rate of recurrent reflux at 5 years.[220,221] Furthermore, a recent meta-analysis comparing nonthermal to thermal saphenous ablation found that nonthermal were as effective as thermal techniques initially and at 1 year with potentially less procedural pain but no difference in paresthesia, phlebitis, or skin pigmentation.[222]

Clinically recurrent varicose veins after GSV high ligation and stripping are observed in less than 25% of cases at 2 years,[223] around 55% at 5 years,[224,225] and in one study reached 62% at 11 years.[226] It should be noted, however, that recurrent varicosities do not indicate recurrent reflux at the SFJ; in a meta-analysis, following high ligation and stripping only 12% of 549 legs developed recurrent reflux at the SFJ at 5 years.[221] Rather other sites of reflux (perforators, neovascularization of parallel veins, etc.) result

in the recurrences noted.[224] Recurrences occur with all techniques used for saphenous ablation.

Complications of GSV interventions are rare but include wound infection, DVT, nerve damage, and hematoma formation.[214,215,217,227] Saphenous nerve injury can result in an area of numbness around the knee or foot (may be clinically unrecognized)[228] but does highlight that surrounding structures must be protected from thermal injury during RFA or laser ablation by appropriate use of tumescent. Complications from SSV interventions although rare include bleeding, hematoma formation, sural nerve damage, DVT, and wound infection.[229] Potential complications of sclerotherapy have been mentioned previously with embolization to local arteries or the systemic circulation as specific risks.[214,215,217]

The following guidelines are proposed regarding the treatment of C_2 (patients with varicose veins) to improve QOL and to prevent recurrence: high ligation and stripping of the GSV to the knee are suggested for incompetent GSVs (grade 2B) with a 1-week period of postoperative compression (grade 1B). For the incompetent SSV, the recommendation is high ligation of the vein at the knee crease about 3 to 5 cm distal to the saphenopopliteal junction with selective stripping of the incompetent portion (grade 1B). In addition, the consensus was that endovenous thermal ablation (RFA and laser) was recommended over surgery for saphenous incompetence treatment based on reduced convalescence, pain, and morbidity (grade 1B) and over foam sclerotherapy due to improved efficacy (grade 1B).[103]

The elimination of saphenous reflux is useful in treating more advance stages of CVD in the patient with a venous ulcer (C_6). A randomized controlled trial comparing compression alone versus compression plus saphenous surgery in patients with active or recently healed venous ulcers found a significant decrease in ulcer recurrence in the surgery group, 31% versus 56% at 4 years but there was no difference in ulcer-healing rates, 89% versus 93% at 3 years.[182] A meta-analysis conducted in 2014 also failed to find more than low-quality evidence favoring ablation over compression therapy alone to improve ulcer healing.[230] However, a recent RCT compared early endovenous ablation of superficial venous reflux with late intervention (after ulcer healing or greater 6 months after enrollment) in

450 patients with leg ulcers and found faster healing in the early intervention group with a median time to healing of 56 versus 82 days.[231] Extrapolating these results to the patients with a healed ulcer, ablation in addition to standard compression therapy is recommended to prevent recurrence (grade 1C). In patient with skin changes at risk of venous ulceration, the same treatment is suggested (grade 2C).[142]

Perforator Vein Ablation

Perforator vein reflux is amenable to open or percutaneous ablative methods. Open methods of perforator ablation, subfascial endoscopic perforator surgery (SEPS) or the "Linton's procedure," although successful[232] have been replaced by less invasive methods of treatment.

Methods of percutaneous perforator ablation include RFA, laser and UGFS. No matter the ablating energy delivered (radiofrequency, laser or chemical) during percutaneous perforator vein ablation, ultrasonographic access, operative monitoring, and confirmation of results are routine and the procedure is accomplished under local anesthesia. The ablating device is inserted into the pathologic perforator and is serially pulled back during activation to burn the perforator for its length or the sclerosant injected into it with a similar result. Prevention of energy delivery to the deep system prevents unwanted thrombosis, accomplished by positioning the ablation device (when used) away from the deep system or by properly compressing the vein at or just slightly below the fascia when using sclerotherapy.[233] All percutaneous methods have a high initial technical success rate.[234,235] One series studying sclerotherapy reports 75% obliteration of perforators through 20 months.[234] RFA results in an 80% occlusion rate at 1 year while laser ablation results in a >85% occlusion rate at 6 months.[235] A recent retrospective review of 296 ablations comparing all three modalities reported differing closure rates: 57% for UGFS, 73% for RFA, and 61% for laser at 2 weeks, and found that thermal ablation was statistically superior to UGFS. Thermal ablation was used with success after failed UGFS.[236] Data on ulcer healing following percutaneous methods are scarce. One study of sclerotherapy in 37 limbs demonstrated a 67% rate of ulcers healing but with a 32% recurrent rate,[234] consistent with the findings of a recent systematic review.[237] Complications are rare but there is risk of DVT, phlebitis, local necrosis, and other risks associated with thermal and chemical ablations.

The available data allowed the SVS/AVF Guidelines Committee to provide four basic recommendations.[142] In patients with active ulcers and both superficial and perforator incompetence to the pertinent ulcer bed, it is suggested that both are ablated to aid in ulcer healing and to prevent recurrence (grade 2C) and in patients without active ulcers the addition of perforation ablation can be simultaneous or staged on the basis of outcome (grade 2C). It is suggested that isolated "pathologic" perforators are ablated (grade 2C). It is recommended that "pathologic" perforation ablation be percutaneous rather than an open procedure to eliminate the need for incisions in areas of compromised skin (grade 1C). The pertinent available data have resulted in an SVS/AVF guideline which recommends that incompetent perforator veins in patients with varicose veins should not be treated (grade 1B).[103]

Iliac Stenting and Venous Bypass

Endovascular stenting of iliac vein stenosis/obstruction involves percutaneous access of a disease-free caudal vein (popliteal, femoral, common femoral vein) with guidewire/catheter advancement across the lesion under fluoroscopic guidance and generally intravascular ultrasonographic confirmation of stenosis >50%. If confirmed, dilation with a 12- to 18-mm diameter percutaneous balloon, depending on the vein involved from common femoral to common iliac, is undertaken with subsequent self-expanding stent deployment to maintain the dilation. This is accomplished from normal outflow (generally distal IVC without impinging the contralateral common iliac vein) to distal normal vein even to the area of lesser trochanter within the common femoral vein if needed to ensure good inflow.[238] The procedure may include recanalization of an obstructed inferior vena cava.[239,240] Eliminating significant outflow obstruction in symptomatic patients has decreased edema, pain symptoms, and improved QOL parameters.[112,117,239–243] It will often result in venous ulcers healing, many of which have associated untreated lower leg venous insufficiency.[112,117,241] In one study, 133 patients with active ulcers had an initial healing rate of 65% at 6 months and 54% at 5 years following venous stenting[117] and rates may be even higher when complete obstruction is relieved.[239,240] Parameters of venous reflux are not worsened following resolution of the iliac vein occlusive disease.[112,117,241] The primary and assisted primary stent patency

rates at 3 years are 75% and 92% and at 6 years 67% and 89%, respectively,[241] and patency is in general higher for nonthrombotic than thrombotic obstructions (Fig. 96.2).[241,244]

Potential complications include major bleeding, pulmonary embolism, early thrombosis, access site complications, retroperitoneal hematoma, and other catheter- and balloon-related problems. Overall, however, complications are rare with essentially no mortality associated with the procedure.[244]

When technically feasible, endovascular intervention has replaced more invasive approaches. As a result of accumulating data, the SVS/AVF Guidelines Committee has recommended venous angioplasty and stent recanalization in addition to standard compression therapy to aid in venous ulcer healing and prevention of ulcer recurrence in patients with proximal venous occlusion/severe stenosis and C_{4b}, C_5, and C_6 disease (grade 1C).

The open surgical procedures used to relieve proximal IVC or iliac vein occlusions utilize the native saphenous vein or polytetrafluoroethylene (PTFE) graft material as the conduit to bypass from a nondiseased distal vein to a disease-free proximal or collateral axial vein. Vena cava or bilateral iliac veins occlusion reconstructions often use PTFE grafts to allow a proper size match. If a single iliac vein is severely stenosed or occluded and percutaneous methods have failed, cross-femoral venous bypass or direct repair of the iliac vein provides therapeutic options.[245,246] Overall, patient survival is considered prior to aggressive intervention if iliac vein compression is due to cancerous encroachment. The cross-femoral venous bypass (Palma procedure) involves passing a vein graft or synthetic conduit via a suprapubic subcutaneous tunnel from the common femoral vein on the affected side to contralateral femoral vein and normal outflow system. The saphenous vein or prosthetic graft is connected to the unaffected femoral vein by an end-to-side technique after anastomosis on the affected side. The key to success of this surgery may be graft diameter. If the native vein is less than 4.5 mm in diameter, better success may be achieved with a 10-mm diameter PTFE graft, although in retrospective studies PTFE does have lower patency.[246]

In one series of 64 open surgical or hybrid reconstructions for iliofemoral venous or IVC obstructions, the overall 5-year secondary patency was 59%.

For the femoroiliac and ilio-infrahepatic IVC reconstructions, the 5-year secondary patency was 86% while it was 78% for the Palma procedure while longer bypasses, complex or hybrid procedures had lower patency rates.[245] The use of an adjunctive AVF to improve conduit flow and thereby patency remains controversial due to the observation that it has been associated with decreased patency[245] but this finding is likely confounded by its use as an adjunct when the risk of failure is thought to be excessively high.

Based on the limited current available data, the guidelines for treating bilateral proximal venous occlusion/stenosis in patients with recalcitrant venous ulceration and no endovascular option is an open intervention using externally supported PTFE graft in addition to standard compression therapy (grade 2C). In the same scenario, but with unilateral iliofemoral venous disease, the suggested therapy is an open surgical bypass using saphenous vein if available and sufficiently large with the alternative being a synthetic graft (grade 2C). When inflow is an issue during open operation, a distal adjunctive arteriovenous fistula (4 to 6 mm in diameter) is suggested (grade 2C).[103]

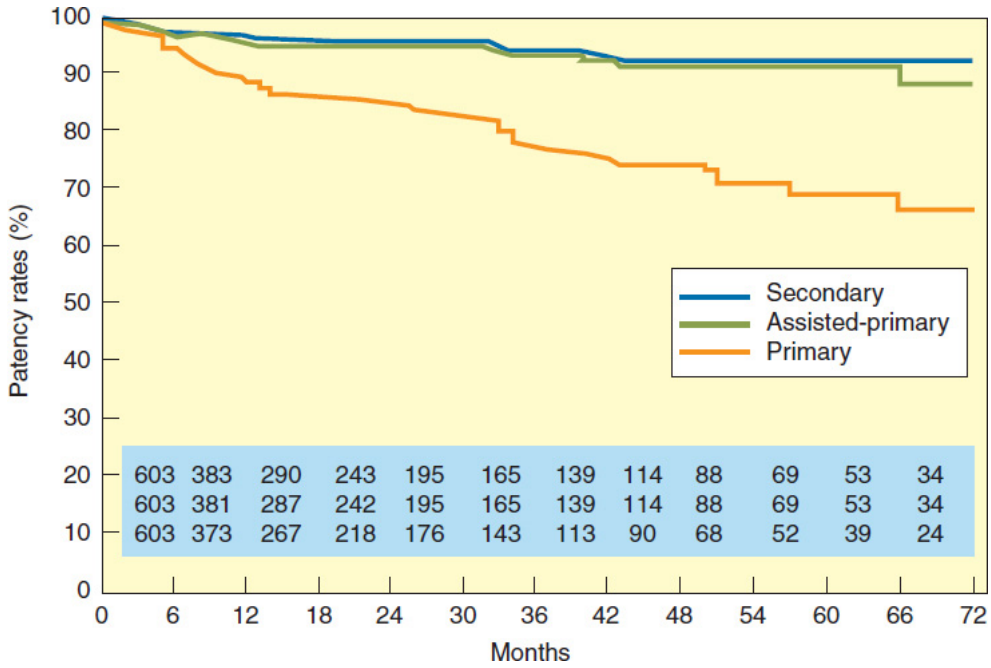

Figure 96.2 Life-table presentation demonstrates the patency rates of iliac venous stents placed for symptomatic occlusive venous disease. (After Neglen P, Hollis KC, Olivier J, et al. Stenting of the venous outflow in chronic venous disease: long-term stent-related outcome, clinical, and hemodynamic result. *J Vasc Surg* 2007;46(5):979–990.)

In the case of more distal venous obstruction, venous bypass, endophlebectomy and patch venoplasty or hybrid open and endovenous procedures have been used.

In patients with chronic symptomatic occlusion of the femoral or proximal popliteal vein, saphenopopliteal vein bypass may be considered if conservative therapy has failed. The patient's distal GSV is transected and anastomosed end to side to the deep system at a site distal to the obstruction allowing venous drainage to bypass the obstruction. This procedure is relatively rare, however, as it necessitates that the patient has a patent proximal common femoral and iliocaval systems as well as a competent GSV. In a series of 17 patients with a median follow-up of 103 months, secondary patency was 75%.[247]

For occlusion of the common femoral vein or distal iliac disease, a hybrid approach involving endophlebectomy and patch angioplasty in combination with angioplasty and stenting of the iliac vein has been explored. In one small series, endophlebectomy sites in 10 patients had a primary patency rate of 77% at 12 months and in the 6 patients who had hybrid procedures the primary and secondary patency rates of iliac vein stents at 15 months were 83% and 100%.[248] However in the experience of other investigators, the 2-year secondary patency in 12 patients was just 30% and this approach is currently not recommended except as a last resort.[245]

Venous Valve Repair or Replacement

The goal of venous valve repair or replacement is the prevention of deep venous reflux and, consequently, a decrease in sustained distal venous hypertension. These interventions are considered only after all other more easily treated venous pathology has been addressed. In planning and during these operations, several observations influence what the surgeon can offer a patient. Preoperative planning helps to determine if a valve is present locally or remotely, and if the recipient conduit is sufficiently disease free to allow a valve repair or replacement. If operative handling of the suspect valve results in vasoconstriction and secondary competence (often determined by a standard "strip test"), an external valvuloplasty or a prosthetic sleeve technique may be viable options. The later simply involves using an external synthetic sleeve wrapped circumferentially around the vein at the valve and tightened to diminish the size of the vein lumen until the valve is competent.

The sleeve is then anchored in place to the adventitia by sutures to avoid slippage.[249,250] In one series of 42 limbs, valvular competence was maintained in 90% of patients with a mean follow-up of 86 months and 80% of venous ulcers healed.[250]

Valves which are architecturally intact but incompetent due to redundancy of the valve leaflets may benefit from valvuloplasty and numerous techniques exist to restore valve competence. If an absence of valve attachment lines are noted during surgery this may signify the destruction of the valve as a consequence of the PTS, prevent valvuloplasty and prompting other than an in-situ repair.[125] The technical aspects and results of the various methods of repair have been recently reviewed.[251–254]

An internal valvuloplasty or an open direct valve repair has been the mainstay for the repair of primary venous valvular reflux for decades. This technique involves venotomy and suturing of the elongated valve leaflets under direct visualization with fine polypropylene suture (7 or 6 to 0) to tighten the valve cusps. The type of venotomy used to expose the valve leaflets varies between practitioners and those described include a single longitudinal,[255] single supravalvular transverse,[256] a T incision,[257] and a trapdoor incision (Fig. 96.3).[258]

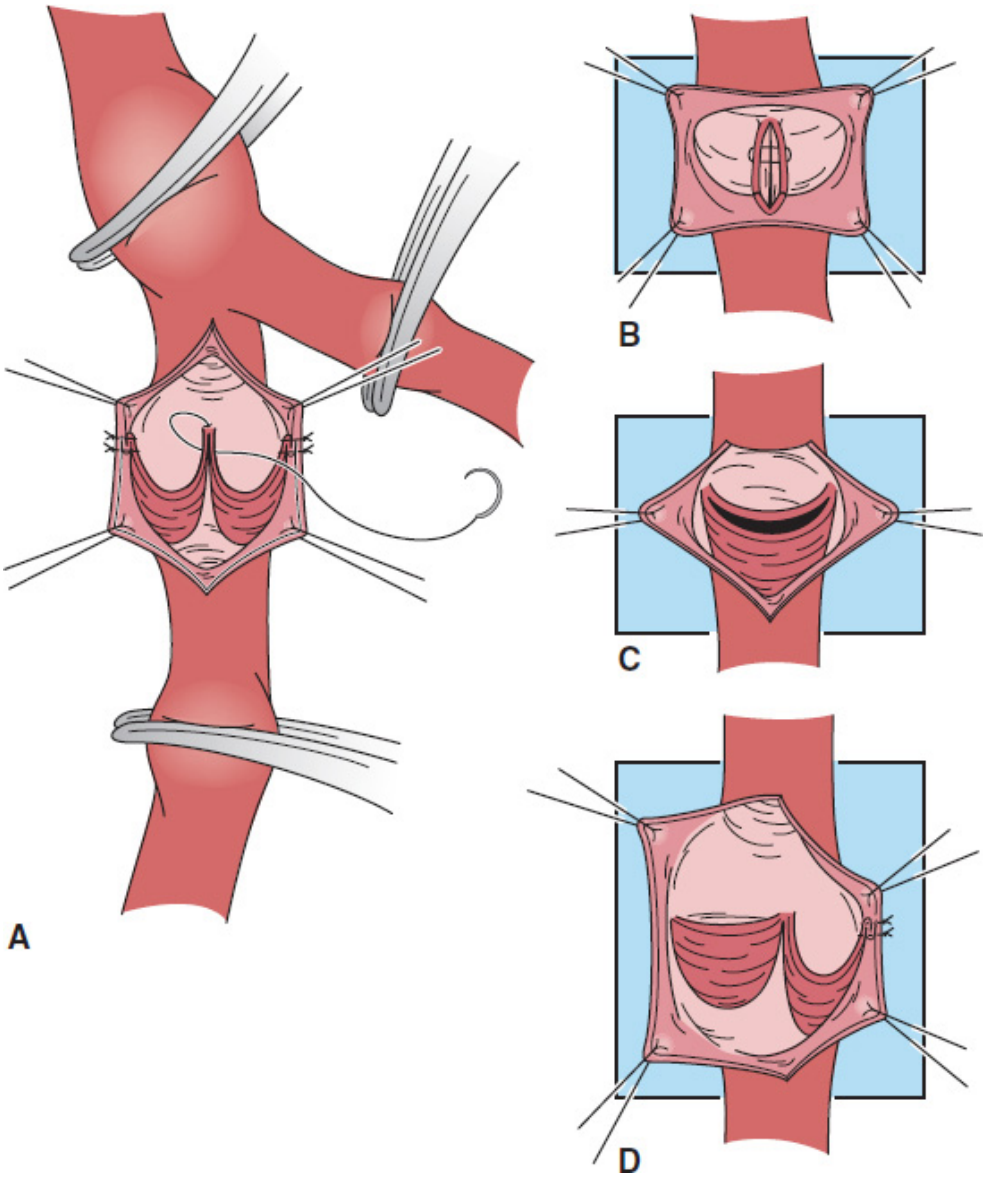

Figure 96.3 Open valvuloplasty to repair an insufficient valve can be accomplished by various venotomy incisions. **A:** Single longitudinal (Kistner). **B:** Single supravalvular transverse (Raju). **C:** T-shaped (Sottiurai). **D:** Trapdoor (Tripathi et al.).

Each approach has a different balance between adequacy of exposure, potential for iatrogenic valve injury and complexity of the closure. Regardless of initial venotomy, once the valve has been visualized the redundant cusps are reefed by suturing their lateral edges to the apices of the respective commissures[255–258] or by excising the excess and reimplanting the cusp.[259] In either case, plication of approximately 20% of the valve leaflet length tends to restore valve competency in the majority of cases.[260] Internal

valvuloplasty has a documented clinical success rate of ~70% at 5 years with ulcer recurrence or ulcer nonhealing occurring in <30% of patients.[251–253] In general, a patent and competent valve translates into clinical improvement and a healed ulcer, while the reverse is true with recurrent reflux. This is true for all types of single-station venous valvular reconstructions.

The technique of external valvuloplasty offers the advantage of valve repair without venotomy. It is performed by placing sutures transmurally through the valve attachment lines and, when tied, reduces the commissural angle and vein diameter, resulting in a competent valve. At 5 years, one can expect a 50% overall success of valve competence and clinical success. The valve leaflets are generally not captured or reefed by this method. In a "transcommissural" modification of the technique, the venous valve cusps are actually engaged with the suture and the cusps are tightened directly much like in the open method of repair.[251–253] The results can approach those noted for open valvuloplasty after significant experience. This approach is either performed blindly (limited anterior plication) which involves only anterior vein dissection and then reefing of the cusps using a running mattress suture[261] or under direct visualization by the use of an angioscope.[262]

Venous valve transplantation is an option when the valve is absent or destroyed. The incompetent femoral vein is clamped and opened below the takeoff of the profunda femoris vein, and the donor vein segment (with valve inside) is sutured into place following the removal of an appropriate length of the recipient vein. The donor vein containing valve segment is often harvested from the axillary vein. If the femoral location does not control all axial reflux into the leg, such as if the profunda femoral vein system is also incompetent, then the popliteal location may be the more appropriate recipient site. For the anastomoses, interrupted sutures are preferred to avoid suture line stenosis.[260] The proximal connection may be accomplished first to confirm the competence of the newly transplanted valve and to allow distention and lengthening of the vein/valve to facilitate the distal anastomosis.[251,252,254]

Reported outcomes of valve transplantation series are highly variable but about a 50% clinical improvement at 5 years was noted in several studies.[251,252,254] There is some evidence that transplantation to the popliteal location may have better outcomes.[263]

A less common option for venous insufficiency is valve transposition.[251,252,254] If a venous valve is competent in one of the major thigh venous systems, then a transposition procedure can be performed placing the incompetent venous system below a competent valve in an adjacent system, effectively shunting the incompetent system into a competent one. Most commonly, the femoral system is incompetent and can be transected and reimplanted distal to a competent valve in either the profunda femoris vein or the GSV. Analogously, if the profunda femoris venous system is incompetent, it may be placed distal to a competent valve in either the femoral vein or the GSV.

A technique has also been described for transposition of the ipsilateral valve competent GSV to the femoral vein with proximal ligation of the femoral vein just distal to the takeoff of the profunda femoris vein thereby escaping problems with diameter mismatch.[264]

Clinical series of vein transposition are few, with small patient accrual and with variable follow-up; outcomes are not as favorable as noted with primary valve repair. Overall, the 3- to 5-year favorable clinical results are about 40% to 50% of cases with similar valve competency.[251,252,254]

Whether valvuloplasty, transplant or transposition; aggressive venous valve surgery requires appropriate consideration of perioperative adjunctive care. This care includes prophylactic antibiotics, intraoperative heparinization especially if the vein is opened, the use of pneumatic compression devices postoperatively, and the use of LMWH or IV heparin in the postoperative period. Some use closed-suction drainage of wounds to avoid hematoma and seroma formation. Warfarin should have an initial target INR range of 2.0 to 2.5 for the first 6 weeks and some would advocate a subsequent decrease to 1.7 to 2.0 until 4 months when it is discontinued. Adjustments are made to accommodate those with an increased risk of thrombosis.

Valve repair procedures are well tolerated by most patients and have a low morbidity, as well as essentially zero mortality in most series. Hematoma and seroma formation are noted in less than 15% of cases, depending on the level of anticoagulation used. DVT occurs in less than 10% of cases in most series, while the pulmonary emboli risk is well less than 1%. Wound infections have been seen in 2% to 7% of cases.[251,252,254]

In general, patients with postthrombotic reflux tend to have more problems maintaining healed ulcers than those with a primary etiology of reflux, as noted from the results of internal valvuloplasty (generally a primary etiology) versus those requiring transplantation or a transposition operative approach.[126,265] Review of pertinent data has resulted in guidelines as to when and how to treat patients with C_{4b}, C_5, and C_6 disease.[142] It is suggested that in such patients with structurally preserved deep venous valves, individual valve repair can be offered (grade 2C). If no structurally intact exists, then valve transposition or transplantation is a suggested treatment (grade 2C).

Valve Substitutes

Autogenous tissues appear to be the only material that currently can act as a substitute valve with some hope of success in the clinical arena. Using a thin-walled donor vein such as the GSV, after trimming adventitia and part of the media, to fashion semilunar cusps within the deficient recipient vein, rapid ulcer healing was reported in five of seven patients and all were patent at 1 year.[125] A recent innovation has been to use an ophthalmic knife or other fine tool to dissect the intima/media wall of the thickened postthrombotic vein wall (or even normal wall) into one or two sheets and thereby fashion the valve cusp(s).[266,267] Adding two sutures on the cusp(s) to hold the valve in the semi-open position and prevent valve collapse, 21 operations resulted in a 95% ulcer-healing rate and late two recurrences (9.5%).[251,254,266,267] The SVS/AVF Guidelines Committee suggests consideration of autogenous valve substitutes in addition to standard compression therapy to aid in venous ulcer healing and recurrence prevention (grade 2C).[142]

Venous Ulcer Wound Care

The quest to heal venous ulcers has generated a myriad of potential topical agents to aid in ulcer healing. Topical antibiotics and dressings containing antimicrobials may retard wound healing and cause allergic reactions and are not recommended for the treatment of venous ulcers.[142,193,268] Growth factors and cytokines demonstrate inconsistent results or studies with insufficient data to determine with any certainty the efficacy of such adjuvants.[269] A number of topical dressings applied on the ulcer bed and beneath the compression dressing have been investigated. A recent meta-

analysis of 78 trials found low-quality evidence that silver may be superior to foam (397 patients in 4 trials) and hydrocolloid (58 patients in 1 trial) and that sucralfate may be superior to hydrogel (100 patients in 1 trial).[270] Insufficient data are available to make firm conclusions, but it is recommended that the nature and amount of the exudates present may provide a rationale for dressing selection as an absorbent dressing should be applied to wet wounds to decrease the risk of surrounding skin maceration and infection while dry wounds should be treated with dressing that will keep them moist to accelerate healing.[270] The SVS/AVF Guidelines Committee suggests that the wound dressing be selected, which absorbs wound exudates and protects the periulcer skin from damage (grade 2B).[142]

Surgical debridement to healthy tissue, when required, benefits the rate of ulcer healing and does not lead to a higher risk of systemic infection.[268,271] The use of local anesthetic (EMLA) during debridement of venous leg ulcers has been found statistically beneficial in lowering pain scores in a Cochrane analysis of six trials.[272] Surgical debridement is recommended to remove slough, nonviable tissue and eschar (grade 1B) using local anesthesia to minimize discomfort (grade 1B).[142]

Autolytic or enzymatic ulcer debridement has also been studied, but has failed to demonstrate increased healing on meta-analysis.[273] Current guidelines suggest each as a potential alternative to surgical debridement when a trained practitioner is not available to provide surgical debridement (grade 2B/C).[142]

For resistant venous ulcers, defined as those that fail to demonstrate improvement in a minimum of 4 to 6 weeks of standard wound therapy, adjuvant wound therapy options should be considered.[274] Skin grafting allows for coverage of raw surfaces to speed the healing process and there are reports on improved healing with skin grafting for chronic venous ulceration.[275,276] A number of skin substitutes have been used to aid in venous ulcer healing and two have shown promise. A bioengineered bilayered human skin equivalent with an allogenic epidermal and dermal layer statistically improved the time to complete healing[277] and an extracellular matrix graft derived from porcine small intestinal submucosa also significantly increased wound healing.[278] The use of these skin substitutes is suggested as guideline adjuvant therapy in recalcitrant venous ulcer care (grade 2 A/B).[142]

Miscellaneous Pelvic Disorders

The complex interconnections of the renal, ovarian, common and internal iliac and lower extremity veins can explain how distention in one or more of the proximal veins can result in distal distention and symptoms. The May–Thurner syndrome has already been discussed. Compression of the left renal vein between the superior mesenteric artery and aorta can result in the "nutcracker syndrome" so called because the renal vein is being crushed like a nut between the respective arteries.[279] The most common symptoms are left flank pain and microscopic or gross hematuria but as the disease progresses the pelvic veins are more affected resulting in symptoms related to the "pelvic congestion syndrome." Upper thigh and pelvic varicosities may be noted. Duplex imaging followed by CT or MRI confirms the clinical suspicion with often venography demonstrating renal vein compression and a pressure gradient. Open surgical vein repositioning or endovascular stenting can relieve the compression.[280] Reflux in the ovarian and internal iliac veins overload the distal veins resulting in pelvic pain as a rather constant complaint which can be disabling and may be associated with dyspareunia, dysuria, dysmenorrhea, and postcoital pain. Varicosities may be noted in the pelvis or upper thigh. Duplex, CT, or MRI can help confirm the diagnosis but venography provides venous detail and potential therapeutic options. Gonadal vein excision is described but has been supplanted by endovascular techniques using coils, sclerosants, or a combination thereof. Hypogastric vein reflux may be best managed by percutaneous embolization.[281] When the elimination of proximal reflux does not resolve superficial varicosities, the management involves techniques used for saphenous vein branch varicosities.

Fetal, Pediatric, and Neonatal Physiology

Chinwendu Onwubiko, Aaron R. Jensen, and Hanmin Lee

Key Points

1. A knowledge of embryology is essential as alterations in fetal development lead to congenital surgical disorders.
2. Persistence of fetal circulation may have clinical significance and affect postnatal hemodynamics.
3. Children compensate well for shock and hypotension is a late finding. Bradycardia is more ominous than tachycardia.
4. Septic shock in neonates and infants manifests as low cardiac output syndrome or "cold" shock, which is preferentially treated with inotropic agents such as dopamine, versus vasodilatory "warm" shock in older children and adults, which is treated primarily with vasoconstrictive agents such as norepinephrine.
5. Children have a higher metabolic rate and lower functional reserve capacity than adults and therefore develop hypoxemia and respiratory distress quicker.
6. Fluid and energy requirements are greatest for neonates and gradually decrease over time until they reach adult levels.
7. Neonatal sepsis may present with subtle signs and will progress to septic shock if not recognized and treated.

INTRODUCTION

Caring for pediatric patients requires an understanding and knowledge of the unique embryologic, anatomic, physiologic, and behavioral characteristics of neonates and children that differ from adults. Furthermore, providers that may need to care for pregnant patients also need a fundamental understanding of fetal development and physiology. The purpose of this chapter is to provide the reader with a fundamental understanding of the unique aspects of fetal, neonatal, and pediatric physiology that differ from those of adults. Physiologic attributes change with development, as such, we have organized this chapter into fetal and transitional, neonatal, and pediatric sections to further exemplify the unique physiologic characteristics of children.

This chapter is intentionally not an exhaustive overview of human physiology, as that content is covered in the foundational chapters found in the Scientific Principles section of this textbook. Many disease- and technology-specific aspects of pediatric care are presented in other sections of this text (see Chapters on Congenital Heart Disease, Pediatric Chest, Fetal Intervention, and Mechanical Circulatory Support).

Fetal and Transitional Physiology

Introduction

An understanding of fetal and neonatal development is an asset to surgeons providing perioperative care of the neonate and infant. Many of the surgical disease processes with which these patients present are a result of fetal development gone awry. The physiologic details discussed below may not seem directly related to surgical 1 pathology, but an understanding of these unique physiologic aspects of development enables a surgeon to appreciate aspects of neonatal care that impact treatment options.

Early Fetal Development and Organogenesis

During the first week after conception, the fertilized egg undergoes a series of divisions, forming a blastocyst, which becomes implanted in the uterine wall. This is followed by the establishment of uteroplacental circulation. The formation of the ectoderm, mesoderm, and endoderm occurs during week 3 and then further differentiation into derivative organs and tissues occurs during the embryonic period, which continues up through week 8.[1] Key events include the diaphragm separating the body into the thoracic and peritoneal cavities, the gut tube differentiation into the gastrointestinal (GI) tract, limb formation, and central nervous system development. During this period, the developing embryo is sensitive to various insults that may lead to congenital defects.[1] For example, from the 6th to the 10th week of gestation, the intestines undergo a process of rapid growth, so that they are no longer contained within the fetus but herniate through the umbilicus.[1] At that time, they also undergo rotation 270 degrees counterclockwise prior to returning to the abdomen. Failure of the complete rotation and fixation upon return to the

abdomen (or if the intestines do not return to the abdomen as is the case in abdominal wall defects and diaphragmatic hernia) results in intestinal malrotation and places infants at risk for volvulus. Failure of complete formation of the lateral pleuroperitoneal folds of the abdominal wall leads to an omphalocele. Gastroschisis occurs if the herniation does not occur through the umbilical ring, but through part of the abdominal wall immediately to the right of the umbilicus and then fails to return to the abdomen. Any of the above processes can compromise intestinal blood flow, resulting in an intestinal atresia. By week 9, the fetus enters a period of rapid growth and continued development and maturation of organs, which continues until 40 weeks' gestation, which is considered full term.[1]

The Placenta and Placental Function

The placenta is a specialized organ that develops between the maternal and fetal circulations that functions in gas and nutrient exchange, filtering of waste products, and trafficking of immunologic mediators. Early in the first trimester, nutrients are obtained directly from the uterine environment, with the role of the mature placenta in supporting the fetus becoming more pronounced at the transition from the first to the second trimester.[2] While not mature for several weeks, placental development begins soon after implantation. In the second week, villi from the chorionic plate (fetus) and maternal spiral arteries from the decidual plate (uterus) meet at the junctional zone where intervillous "lakes" filled with maternal blood form, creating the initial mechanism for blood, nutrient, and gas exchange between the mother and fetus. The chorionic vessels mature, propagate, and coalesce into the umbilical vessels. A majority of the population has two umbilical arteries and one umbilical vein, but 0.5% of the population is born with a "two-vessel cord" that contains only one umbilical artery.[1] Particular attention to this examination finding is essential on the newborn examination, as up to 20% of infants with this finding may have an associated cardiovascular anomaly and may have other noncardiac anomalies.[3]

The placenta is mature by 14 weeks' gestation and continues to grow with the fetus, increasing the surface area for filtration and exchange until 40 weeks. It is at 14 weeks' gestation that passive immunity to the fetus occurs by transmission of immunoglobulin G from the mother.[1] For reasons that are

not completely clear, a placenta may not adequately provide nutrients to the fetus (placental insufficiency)—potentially related to inadequate perfusion of the placenta and/or an increased demand by the fetus, such as in multiple pregnancies.[4] Placental insufficiency can lead to intrauterine growth restriction, maternal preeclampsia, and/or preterm birth. Infection of the placenta (i.e., chorioamnionitis) can also induce preterm birth, and can place the neonate at risk for perinatal sepsis and cardiorespiratory failure.[4]

Amniotic Fluid Production and Resorption

A key component of the neonatal history is the identification of any prior abnormality in the amount of amniotic fluid seen on prenatal ultrasound, as this can provide clues as to possible surgical lesions to be addressed postnatally. The fetus is normally surrounded in the amniotic cavity by amniotic fluid. The amount of fluid increases over time as the fetus grows, and can exceed 1 L of fluid at term.[1] Fluid initially originates from maternal blood and is diffused along an osmotic gradient into the fetal environment by cells of the amniotic sac.[5] During the second trimester, most of the production of amniotic fluid shifts to the fetus through swallowing and absorbing fluid through the enteral route and by excreting fluid through urine and respiratory secretions.[5] Alterations in the normal levels of fluid may be an indicator of underlying congenital abnormality. Oligohydramnios is a decreased amount of fluid and can originate from either placental insufficiency or from anomalies leading to decreased urine production, such as renal dysgenesis or urinary obstruction. Adequate amniotic fluid volume is essential in maintaining alveolar back pressure to promote lung development and in maintaining adequate space for fetal development; severe oligohydramnios due to renal abnormalities can be associated with pulmonary hypoplasia, limb development anomalies, and craniofacial anomalies (Potter sequence).[6] Polyhydramnios refers to more fluid present than expected and usually results from proximal GI obstruction (e.g., esophageal or duodenal atresia) that keep the fetus from swallowing and absorbing amniotic fluid. Additionally, cardiac high-output states can also result in polyhydramnios.

Fetal Circulation and Transitional Physiology

2 A knowledge of the fetal circulation is essential in understanding anatomic vascular remnants that one may encounter even while caring for adult patients. There are three fetal shunts that work to ensure maximum distribution of oxygenated blood to the fetus—one shunt to bypass the hepatic portal circulation and two shunts to bypass the pulmonary vascular bed. Oxygenated blood (typically at 80% saturation) enters the fetus from the placenta via the umbilical vein, passes through the liver, flows into the inferior vena cava, and then to the right atrium. The first shunt encountered is the ductus venosus (Fig. 97.1), which diverts blood away from the hepatic sinusoids and into the inferior vena cava, preventing the immediate consumption of oxygen and nutrients prior to blood reaching the brain and remainder of the systemic circulation. A majority of blood flow into the right atrium is then diverted through a second shunt—the foramen ovale. The foramen ovale is an intracardiac shunt through the atrial septum between the right and left atria that bypasses the right ventricle to allow flow of oxygenated blood directly to the left heart. The remainder of the blood (<10%) from the right atrium follows the normal pathway into the right ventricle, where it encounters the third shunt—the ductus arteriosus. This last shunt connects the pulmonary artery to the aorta just distal to the arch, feeding into the systemic circulation and allowing the remaining oxygenated blood to bypass the pulmonary vascular bed and to flow directly into the systemic circulation. The lungs do not play a role in gas exchange in the uterine environment and the vascular resistance in the pulmonary vascular bed is high, which maintains a right-to-left shunt through the patent ductus arteriosus (PDA) and minimizes unnecessary pulmonary blood flow. This shunting ensures the brain and heart receive more oxygenated blood and minimizes energy expenditure of the right heart pumping blood through a dormant pulmonary vascular tree.[1,7] Despite these shunts, systemic blood remains quite deoxygenated due to mixing at the level of the IVC (<60% saturation). Blood flow back to the placenta is derived from the systemic circulation, with blood flow returning to the placenta via the paired umbilical arteries arising from the iliac arteries bilaterally.

The fetus develops in an oxygen-poor environment, relying on a partial-pressure gradient of oxygen from the maternal circulation to provide adequate transplacental oxygen delivery to the fetus. To augment oxygen extraction from the placenta, fetal red blood cells contain primarily fetal

hemoglobin (α2γ2) chains, which have a higher affinity for binding oxygen than normal adult hemoglobin chains (α2β2) (Fig. 97.2), facilitating transfer of oxygen from maternal blood to the fetus. As the fetus transitions to postnatal life, oxygen demands increase, but the fetal hemoglobin chain preponderance impairs oxygen delivery to the neonatal tissues. During the 1- to 2-month transition period of fetal to adult hemoglobin, higher levels of 2,3 diphosphoglycerate (2,3 DPG) and the resulting mild acidosis decrease oxygen affinity and increase oxygen delivery.[8]

Immediately at birth a number of anatomic and physiologic triggers occur that lead to the transition from fetal circulation to postnatal circulation. Initiation of respiration causes a resultant decrease in hypoxic pulmonary vasoconstriction resulting in a drop in pulmonary vascular resistance (PVR) and an increase in pulmonary blood flow.[1,9] Around the time of birth, pulmonary pneumocytes cease producing fluid and start to absorb the fluid into the interstitial space and into the fetal circulation, thereby clearing fluid from the alveolar spaces.[1,9] A delay in this process can lead to transient tachypnea of the newborn (TTN), which should start to improve within 2 hours and usually resolves completely within 48 hours.[1,9] Due to the fact it is transient in nature, the diagnosis is usually made retrospectively and is often a diagnosis of exclusion. Treatment is supportive care.

Changes in blood flow through the pulmonary, systemic, and mesenteric vascular beds at the time of delivery promote closure of the three shunts of the fetal circulation. Upon clamping of the umbilical cord, the newborn's separation from the placental blood flow causes a drop in mesenteric blood return resulting in closure of the ductus venosus, and increases the systemic vascular resistance due to decreased runoff from the iliac arteries to the placenta. After initiation of respiration, the resultant decrease in PVR and increase in systemic vascular resistance leads to decreased right heart pressures and increased left heart pressures. These changes in pressures result in reversal of the directionality of flow through the foramen ovale, leading to closure of the valve of the foramen ovale (developed by the growth of the septum primum and secundum). Persistent patency of the foramen ovale is a result of incomplete septal fusion and occurs in 20% of the population.[1,8] Closure of the ductus arteriosus occurs secondary to vasoconstriction of the vessel in response to increasing oxygenation of the blood and decreasing levels of prostaglandins (PGE). The ensuing ischemic

changes to the inner muscular layer render it resistant to the vasodilatory effects of PGE and cause tissue remodeling that obliterates the lumen of the ductus in term infants. In premature neonates, however, blood oxygen levels within the ductus do not drop to the same level of hypoxemia needed to promote the remodeling process, resulting in an increased risk for PDA.[10]

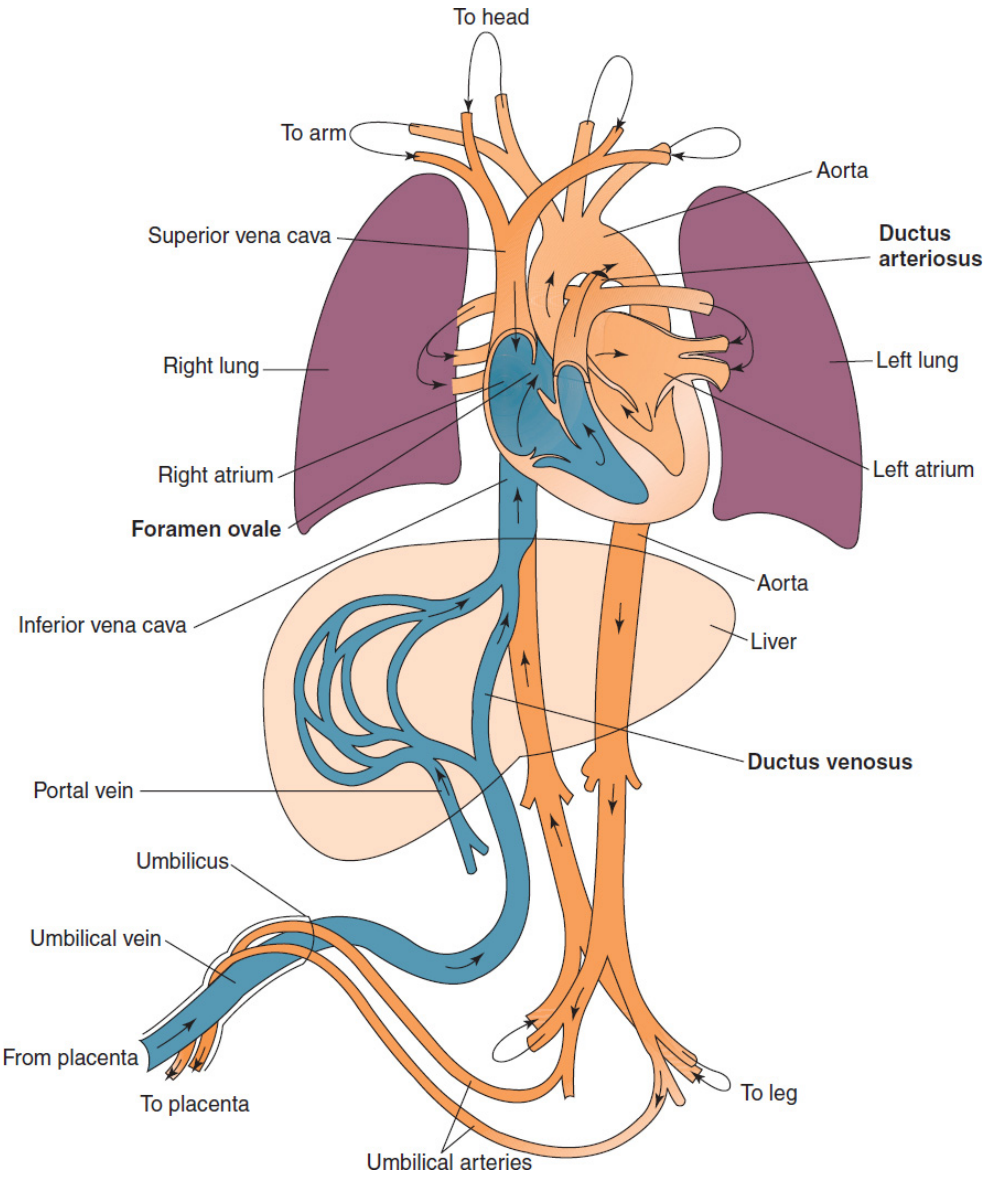

Figure 97.1 Fetal circulation. (From Rosdahl CB, Kowalski MT, eds. *Textbook of Basic Nursing*. Philadelphia, PA: Wolters Kluwer Health; 2012.)

Persistent elevations in PVR (persistent pulmonary hypertension of the newborn; PPHN) can lead to persistence of the PFO and PDA. In the presence of persistent elevation of PVR, shunts through the PDA and PFO

remain right to left, with deoxygenated blood from the right heart passing through the patent foramen ovale and from the main pulmonary artery through the ductus arteriosus, leading to lower oxygen saturation measured in the left arm and bilateral legs (postductal saturation) compared to that measured in the right arm or head (preductal saturation).[7]

In the absence of elevated PVR, the ductus arteriosus is expected to close within the first 48 hours in 96% of term neonates without other cardiac anomaly and who are otherwise healthy.[11] Failure of closure leads to a PDA, which has been reported in 56.7 per 100,000 live births, not including those incidentally found on echocardiogram.[12] In premature neonates, younger gestational age and lower birth weight are associated with lower rates of closure by 1 week of life.[13] Left-to-right shunting through persistent large PDAs results in pulmonary overcirculation, and can lead to heart failure and an increased risk of chronic lung disease.[14,15] When PDA closure is desired, medical treatment options include indomethacin, ibuprofen, or acetaminophen.[16] Operative PDA ligation was first reported by pediatric surgeon Robert Gross in 1939[17,18] and remains an option for treatment of PDAs that fail attempts at medical therapy. In the last decade, enthusiasm for surgical PDA ligation and pharmacologic treatment has waned with evidence emerging for "watchful waiting" being associated with no increase in adverse outcomes.[19–23]

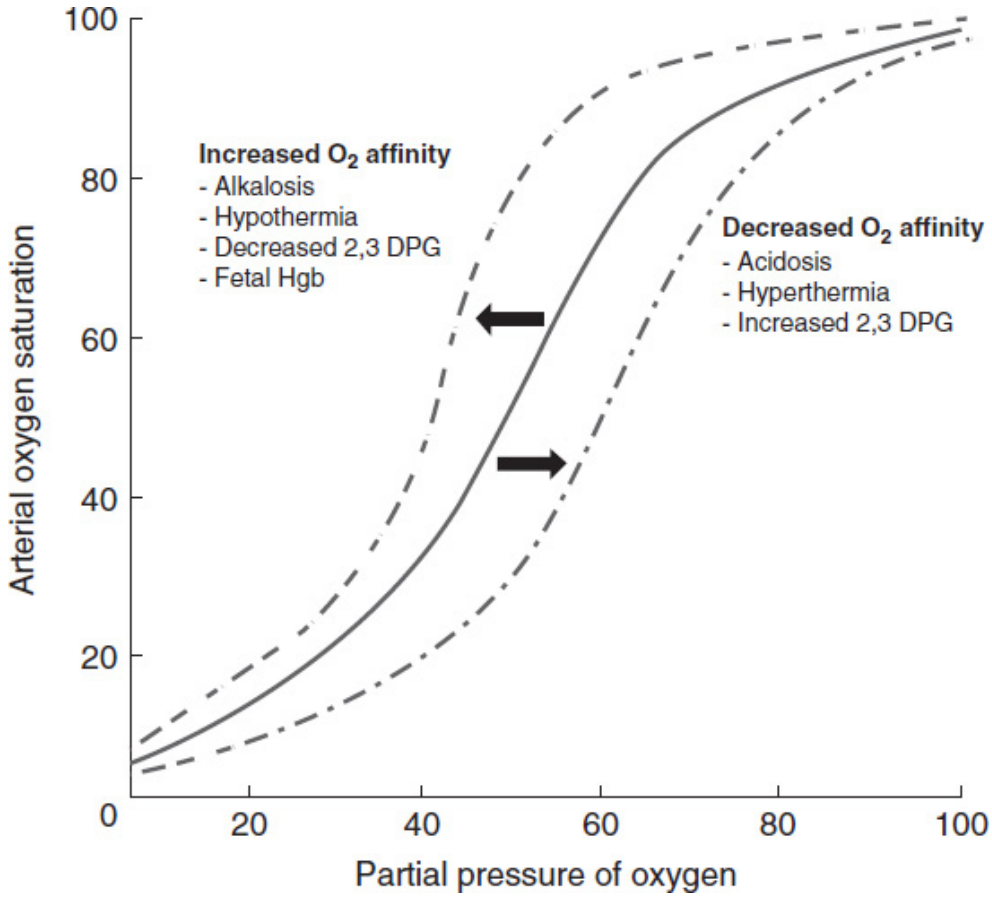

Figure 97.2 The oxygen dissociation curve shows the percent of oxygenated hemoglobin at various partial pressure of oxygen levels, and demonstrates factors that alter the affinity for oxygen.

Fetal Lung Development

The respiratory system has its beginnings in the fourth week of gestation when the respiratory diverticulum first appears as an outpouching of the foregut. The tracheoesophageal septum subsequently forms, dividing the respiratory tract from the GI tract. Failure of this septum to completely close results in variations of tracheoesophageal fistula (with or without esophageal atresia).[1] At week 5, the pseudoglandular phase of respiratory development begins, in which lung buds enlarge and begin to divide into main and secondary bronchi, ultimately forming terminal bronchioles by 16 weeks. In the following 10 weeks, the canalicular phase sees the further division of the terminal bronchioles into respiratory bronchioles and alveolar ducts. During the terminal sac phase (week 26 until birth), the early alveoli develop and come in close contact with the capillaries. In addition, type I pneumocytes

(gas exchange cells) and type II pneumocytes (cells that produce surfactant) are first identified in this phase. The final stage is the alveolar phase that starts in utero during the last few weeks of gestation but is not completed until early childhood. This time is allotted for further increase in alveoli number and final maturation of the relationship between the alveoli and the capillaries to allow for adequate gas exchange.[1] Fetal lung development has profound implications on the viability of extremely premature infants, as only in the late canalicular phase is the lung functional for gas exchange, with surfactant production (see below) beginning in the saccular phase. Though current American Academy of Pediatrics guidelines define the lower limits of viability at 22 weeks,[24] the generally accepted practice is to recommend resuscitation of premature infants delivered at 25 weeks or later, with resuscitation of premature infants between 22 and 24 weeks remaining controversial.[25]

Surfactant is an essential lipoprotein that is produced and secreted by type II pneumocytes starting during the saccular phase of development. The surfactant lines the alveolus and protects it from complete collapse during expiration by lowering the surface tension between the air and alveolar surface interface. Lack of an adequate amount of surfactant in premature neonates is the cause of respiratory distress syndrome (RDS), a major cause of morbidity and mortality in infants who fail to make it to term. The respiratory consequences of preterm birth can be potentially mitigated by the administration of corticosteroids (typically betamethasone) to any woman who is at risk for preterm labor. A complete course of steroids given to women who are less than 34 weeks' gestation (but greater than 24 weeks) prior to preterm delivery can stimulate fetal production of surfactant, as well as hasten fetal lung maturity, decreasing the risk of developing RDS.[26] Once the neonate is born, treatment includes supplemental oxygen and respiratory support (continuous positive airway pressure [CPAP] or mechanical ventilation) as needed. Postnatal administration of exogenous surfactant has also been successful in prevention and treatment of RDS, though in rare cases it can cause pulmonary hemorrhage.[26]

Neonatal Physiology

Prematurity and Physiologic Implications

Gestational age at birth plays a role in the prognosis of the child and the complications they may be susceptible to at birth or shortly thereafter. Neonates born at full term (37-0/7 weeks' up to 42 weeks' gestation) have typically completed intrauterine development, while infants born prior to completing 36 weeks of gestation are considered preterm. Infants born after 42 weeks are considered postterm and have an increased risk of delivery-related complications. The most recent data estimates 10.6% of all live births worldwide are preterm infants.[27] Further classification of preterm infants into "very preterm," "moderate preterm," and "late preterm" has been proposed due to differences in complication rates and outcomes by these strata, though there is no clear consensus on what gestational ages fall within each group. Prematurity disposes infants to a number of physiologic consequences of incomplete development, discussed briefly by systems in the following sections.

Neurologic Considerations

The central nervous system in an adult is a fragile system and prone to insult, but the developing nervous system in neonates—particularly premature neonates—is particularly prone to injury. The immature brain is most vulnerable at the germinal matrix. This area has a high concentration of thin-walled vessels that develop during fetal life between 24 and 34 weeks of gestation.[28,29] These vessels are poorly tolerant to changes in systemic blood pressure and are prone to rupture leading to intracranial hemorrhage. Preterm infants are unable to adequately regulate cerebral blood flow, and any hemodynamic instability increases the risk of vascular injury and intraventricular hemorrhage.[29] The risk of bleeding is particularly increased in conditions leading to prematurity with hemodynamic instability, such as placental abruption, chorioamnionitis leading to sepsis, birth trauma, temperature instability, or perinatal hypoxia.[28] Routine screening cranial ultrasounds are recommended in premature infants <33 weeks to evaluate for potential bleeding in the setting of any these risks.[30]

As an extension of the central nervous system, the neonatal retina is particularly susceptible in premature infants. Normal development of the retina involves angiogenesis that starts at the optic nerve and progresses

peripherally and is dependent on the hypoxic fetal environment triggering production of vascular endothelial growth factor (VEGF). The process begins at 16 weeks and is typically complete by 40 weeks, with migration completion on the medial side of the eye occurring prior to the lateral side (by 36 weeks). In retinopathy of prematurity (ROP), VEGF is inhibited by the introduction of oxygen that occurs upon the neonate's first breath. During this first stage of ROP pathogenesis, the systemic hyperoxia-induced VEGF inhibition halts the normal development of the retinal vasculature. However, since normal angiogenesis did not occur, the retina is avascular and therefore hypoxic during the second stage. This local retinal hypoxia abnormally reestablishes VEGF production and results in abnormal vascular proliferation in the retina that extends into the normally avascular vitreous. The ensuing destructive process can eventually lead to blindness secondary to retinal detachment.[31,32]

As indicated by its name, prematurity with associated low birth weight is the greatest risk factor for ROP,[33] with an incidence of 84% in neonates less than 28 weeks.[34] Other risk factors include oxygen exposure, need for ionotropic support, intraventricular hemorrhage, and need for mechanical ventilation.[31] The longest recognized and greatest modifiable risk factor is oxygen exposure that can cause hyperoxia. Efforts to limit supplemental oxygen exposure in premature neonates must be carefully balanced with the increased mortality risk for when lower oxygen saturation goals are used—as hypoxia can contribute to neurologic injury and increased rates of cerebral palsy. The ideal balance is not yet known.[33–35] Patients should undergo regular retinal examination screening by specialized ophthalmologists to identify ROP early and continue to monitor until retinal maturation or resolution in patients developing ROP.[36] Traditional treatment options include laser photocoagulation, cryotherapy, and in severe cases, retinal reattachment.[31] Newer medical management options include bevacizumab, propranolol, and caffeine.[32,37,38]

Cardiovascular Considerations

Evaluation and management of a neonate or infant with a surgical condition requires a fundamental understanding of normal and abnormal cardiovascular function in this age group with additional consideration of whether or not the

heart is structurally normal. This chapter will not cover congenital heart disease in detail—for this we will refer the reader to the chapter in the textbook (Congenital Heart Disease), but will point out that an increased index of suspicion of structural heart disease should be raised in patients presenting with cyanosis, presence of a heart murmur, or evidence of fluid overload. Additionally, several pediatric general surgical conditions (VACTERL association, duodenal atresia, congenital diaphragmatic hernia, omphalocele, and intestinal rotational anomalies) are known to be associated with structural heart disease, and these patients should be evaluated with echocardiogram prior to undergoing general anesthesia. Some cardiac lesions are not apparent until the ductus arteriosus begins closing, which results in the loss of persistent fetal circulation that allowed the child to compensate; in these cases, prostaglandins may be used to open or maintain patency of the ductus arteriosus.

In the absence of structural heart disease, there are still a number of unique physiologic characteristics in neonates and infants that warrant attention. Of paramount importance for the surgeon is an understanding of normal vital signs in infants and children—and the implications of abnormal vital signs (Table 97.1). An important distinction to note in neonates is that the cardiac output is highly dependent on heart rate; they compensate solely by increasing their heart rate as infants are not able to substantially increase stroke volume. Bradycardia is a sign of myocardial ischemia and 3 impending cardiac arrest if untreated. The myocardium is less compliant in neonates and therefore less tolerant to rapid changes in volume, so providers must be careful to avoid excessive fluid resuscitation in times of illness.[7] Fluid overload can lead to right heart failure and reopening of a ductus arteriosus. Premature neonates are often treated with smaller (10 mL/kg) fluid boluses and earlier initiation of inotropes to account for the decreased tolerance of volume overload. Infants in septic shock typically present with tachycardia and signs of increased systemic vascular resistance: weak pulses, delayed capillary 4 refill, and decreased urinary output (i.e., cold shock). Resuscitation should be with sequential fluid boluses of 10 mL/kg at a time (up to 40 to 60 mL/kg), while watching for evidence of fluid overload on examination (Fig. 97.3).[39] If pharmacologic support is needed, dopamine is usually initiated first (Fig. 97.3) for increased chronotropy and inotropy, as children in fluid-refractory septic shock generally have a hypodynamic shock

state with low cardiac output and high systemic vascular resistance.[40] Epinephrine is generally used as a second-line agent over norepinephrine due to its preferential inotropic profile. Milrinone is an inodilator that is often used as an adjunct due to its inotropic and vasodilatory effects to improve the dynamic state, as well as lusitropic effects that improve cardiac relaxation and diastolic function.[7,41]

Neonates and infants have a reactive pulmonary vascular bed. Pulmonary hypertension can result from sepsis, meconium aspiration, pulmonary hypoplasia associated with congenital diaphragmatic hernia, and a number of other disease processes. Clinical indicators include differential oxygen saturation at pre- and postductal measurements and hypoxemia that does not sufficiently improve with increasing supplemental oxygen support. Treatment involves mechanical ventilation, pulmonary vasodilation (supplemental oxygen, milrinone, inhaled nitric oxide), and avoidance of hypotension and acidosis. If these initial measures fail, extracorporeal membrane oxygenation can be utilized for cardiopulmonary support.[42]

Respiratory Considerations

There are a number of key physiologic characteristics of neonates and infants that impact management. Compliance is a major determinant of how well a patient ventilates and is based on both lung compliance and chest wall compliance. Neonates have a very compliant chest wall due to the fact that the rib cage is cartilaginous and the musculature is underdeveloped as compared to the bony and muscular adult chest wall. Though intrinsic lung compliance is similar in infants and adults,[43] the difference in the negative pressure due to chest wall compliance makes infant lungs more likely to collapse.[8] The ability to sustain functional reserve capacity (FRC) in the setting of increased tendency for lung collapse is enabled by the narrower glottic openings and shorter expiratory times.[44] “Grunting” with respiration (expiring against a closed larynx to increase FRC) in an infant is a compensatory mechanism and a telltale sign of impending respiratory failure.

Table 97.1 Normal Heart Rate and Blood Pressure Ranges for Infants and Children

Age	Awake Heart Rate (BPM)	Sleeping Heart Rate (BPM)	Systolic Blood Pressure (mm Hg)	Diastolic Blood Pressure (mm Hg)
Neonate	100–190	80–160	50–70	25–45
Infant	100–180	75–160	70–100	50–70
Toddler	80–140	60–90	80–110	50–80
Preschooler	70–120	60–90	80–115	50–80
School age	65–110	60–90	80–120	55–80
Adolescent	60–100	60–90	90–130	60–80

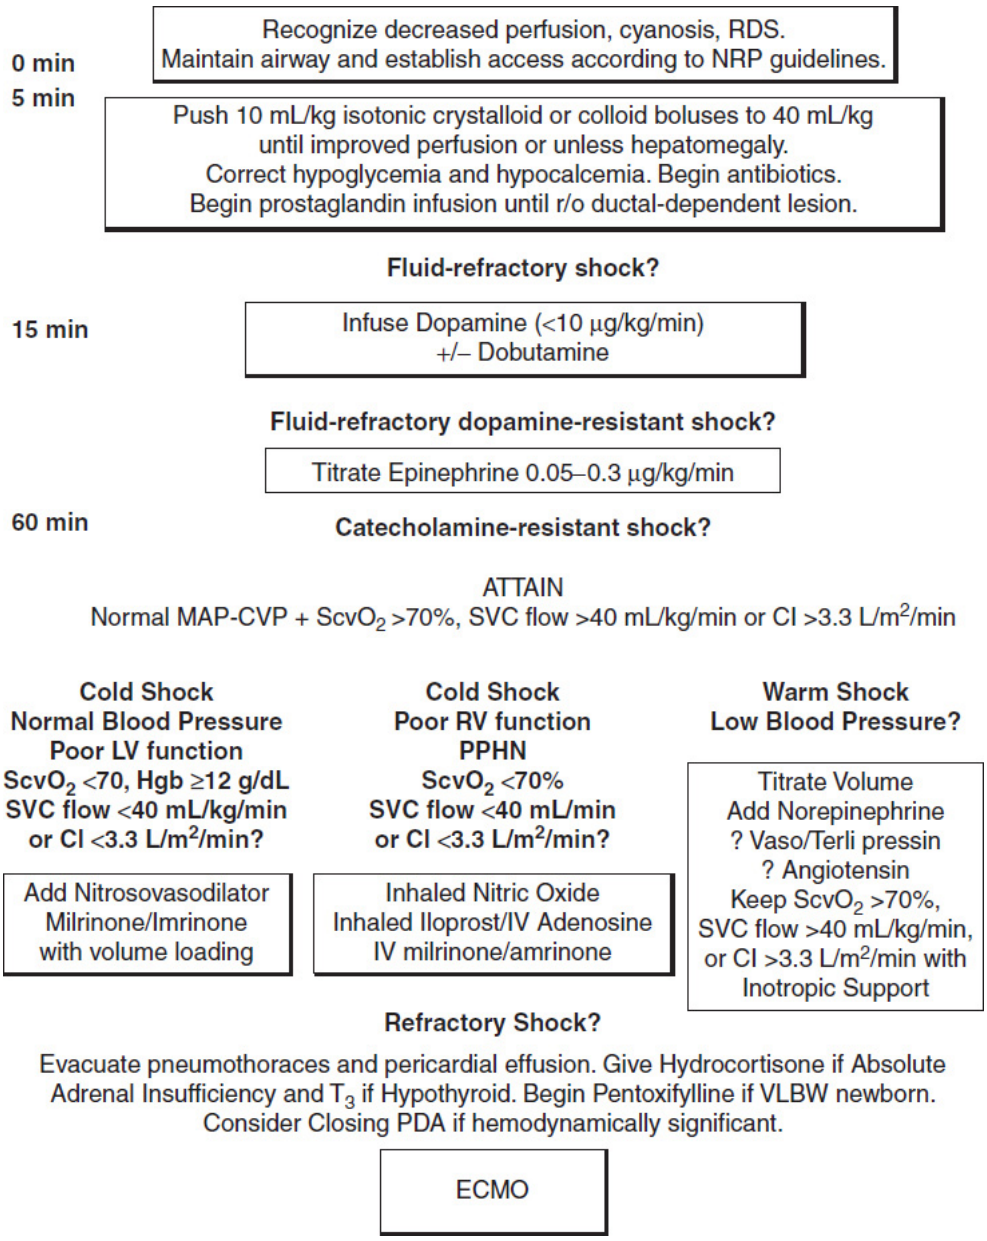

Figure 97.3 Neonatal algorithm—goal-directed therapy for sepsis algorithm. (From Davis AL, Carcillo JA, Aneja RK, et al. American College of Critical Care Medicine clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock. *Crit Care Med* 2017;45[6]:1061–1093. Wolters Kluwer Health, Inc.)

5 High metabolic demand predisposes infants to a high risk of respiratory decline, hypoxemia, and inadequate oxygen delivery. Neonatal indications for respiratory support include apnea, airway obstruction, pulmonary effects of congenital heart defects, poor respiratory drive in premature infants, and other disease-specific reasons, such as congenital diaphragmatic hernia.[45]

Noninvasive measures, including CPAP and noninvasive positive-pressure ventilation (NIPPV) are preferred if sufficient to sustain adequate oxygenation and ventilation due to a decreased risk of developing ventilator-induced damage to already fragile premature lungs.[46] If endotracheal intubation and mechanical ventilation are required, neonatal-specific ventilators have been designed to provide adequate tidal volumes and take into account factors related to neonatal respiratory mechanics.[46] High-frequency oscillatory ventilation (HFOV) and high-frequency jet ventilation (HFJV) are nonconventional modes often used in the neonatal period. These modes rapidly deliver small "subtidal" volumes on the order of hundreds of breaths per minute, thereby using relatively constant pressure and volume to maintain lung expansion. The use of high-frequency ventilation in neonates with bronchopulmonary dysplasia is often recommended though the benefits compared to conventional ventilation are less clear as previously thought.[45,47]

Apnea of prematurity is one of the most common respiratory disorders in premature neonates. Most preterm infants less than 28 weeks' gestational age have some level of apnea, with decreasing incidence at increasing gestational age.[48] Apnea may be obstructive or central nervous system mediated, but is often a result of both. Treatment includes initiation of methylxanthines, most commonly caffeine, and noninvasive positive airway pressure. Transfusion of anemic patients may also decrease apneic episodes.[48] Resolution of apnea spells usually occurs by the time the child has reached term.[48] Postoperative apnea may occur in 25% of preterm infants up to 44 weeks' gestational age,[49] with the risk decreasing to <1% only after postconceptual age of 56 weeks.[50] As a result, current accepted practice is to avoid elective operations in preterm infants until they reach 55 to 60 weeks' total gestational age, or to admit them for 24 hours of apnea and bradycardia monitoring after undergoing general anesthesia if it is necessary to proceed with surgery prior to 55 to 60 weeks.

Chronic lung disease of prematurity, previously referred to as bronchopulmonary dysplasia (BPD), is the need for supplemental oxygen in a premature (<32 weeks) infant for more than 28 days. The severity of chronic lung disease is determined by the level of oxygen support required at 36 weeks' postmenstrual age, with the most severe cases seen in patients still supported by mechanical ventilation or positive airway pressure and

supplemental oxygen levels at 30% or greater.[51] Development of chronic lung disease is multifactorial, but one mechanism is ventilator-induced inflammatory injury to premature lungs.[51] Dexamethasone administered within the first week of life decreased rates of chronic lung disease at 28 days and 36 weeks, but was also associated with hyperglycemia, hypertension, GI bleeding and/or perforation, and development of cerebral palsy.[52] Waiting until after the seventh day of life had a decreased risk of GI complications and was associated with lower mortality at 28 days, lower need for home oxygen and higher rates of earlier extubation, in addition to the overall decrease in chronic lung disease of prematurity rates.[52] Due to the concerning side effect profile, dexamethasone is only recommended in select neonates, but ongoing studies are evaluating more directed steroid administration. Prevention of chronic lung disease is targeted at neonatal lung protection. The mainstay of this preventative strategy is minimization or avoidance of mechanical ventilation if possible by using various methods including CPAP, noninvasive surfactant treatment, temporary intubation for administration of surfactant, or NIPPV, all of which have shown some benefit against mechanical ventilation in decreasing the odds of chronic lung disease or death in preterm infants.[53]

Gastrointestinal Considerations

Development of the upper and lower esophageal sphincters and coordinated peristalsis are mature by 31 weeks' gestation.[54] Gastroesophageal reflux (GER) itself is a common occurrence in neonates and infants, in which gastric contents pass retrograde into and through the esophagus after a feed that may result in the "spit up" but has no other serious consequences. Transient relaxation of the lower esophageal sphincter has been shown to be the primary cause of reflux in premature infants.[54] Increased gastric volume from feedings may trigger relaxation, making these events more common after a meal.[55] This phenomenon is separate from gastroesophageal reflux disease (GERD), which is defined as reflux episodes that result in "troublesome symptoms and/or complications."[56] Though these are somewhat difficult to define in infants, they may include aspiration events with subsequent pneumonia and poor weight gain.[57] No treatment is needed for pure uncomplicated reflux episodes in infants as they typically resolve with time;

88% of infants have resolution by 1 year,[58] and treatment options for GERD include diet modification such as thickening feeds and/or behavioral pacing of feeds by the caretaker, positional changes after feeds (head of bed elevation), medical treatment with prokinetics and acid suppression, nasojejunal feeding, and Nissen fundoplication for refractory cases.

The GI tract develops with contributions from the endoderm, mesoderm, and ectoderm and is separated into foregut, midgut, and hindgut. Although a full discussion of gut embryology will not be undertaken at this time, a few notable events of intestinal development will be mentioned. Intestinal villi with their columnar epithelium first develop at 10 weeks, followed by formation of Paneth (enzyme secretion) and goblet cells (mucin production).[59] Digestive enzymes begin to appear as early as 10 weeks, but some may not reach normal levels until up to 34 weeks' gestation, while mucin production does not reach postnatal levels until infant is term.[60,61] Lymphoid tissue congregates in the ileum to form Peyer patches by week 14, and both T and B lymphocytes are identified within these patches by week 18.[59,60] The lamina propria also develops at the time but lies mostly dormant due to the lack of antigen presentation and inability to produce immunoglobulin A, which normally acts to bind antigens, preventing their translocation across the gut wall.[59] Gastric motility is seen as early as 20 weeks, but intestinal motility can take up to 34 weeks for full development of factors associated with intestinal mobility (e.g., motilin, migrating myoelectric complexes).[60,62] The ability for coordinated suck and swallow is fully developed usually by 34 weeks.[62] Due to the incomplete development of these (and many other) anatomic and functional aspects, feeding of premature infants should be initiated slowly.

In addition to the lack of gut development, prematurity brings added consequences that may affect intestinal barrier function and increase the risks of necrotizing enterocolitis. Hypotension and associated vasopressor requirement can cause visceral ischemia and mucosal sloughing, while withholding or delaying feeding can lead to atrophy of intestinal villi and prevent normal colonization of gut bacteria. Gastric acid acts as a primary defense against bacteria, and acid-suppressive medications can therefore increase the risk of necrotizing enterocolitis and pneumonia.[63] Decreased mucin production and peristaltic action also make the intestinal mucosa vulnerable to invasion. Premature infants lack the ability to mount an

appropriate anti-inflammatory response as evidenced by increase in proinflammatory markers and cytokines in premature infants with necrotizing enterocolitis.[63]

Total energy requirements for neonates and infants range from 80 to 120 kcal/kg/d,[64] and up to one-third of this energy is used for growth. The expected daily growth rate for weight is based on age, while babies up to 3 months old are expected to grow in length at a rate of 0.15 cm/d, followed by up to 0.075 cm/d until a year of age.[65] 6 The basic metabolic rate is higher in premature infants and neonates than in older children, which is in turn higher than in adults. Fats provide most of the energy for the growing infant and are the most common way that energy is stored.

Though carbohydrates cease being the main mode of energy at birth, glucose metabolism is a key concern during the perinatal period. After being separated from the maternal circulation, infants only have enough glucose stores (glycogen) for at most 24 hours and with a high turnover rate (up to 5 mg/kg/min in neonates compared to 2 to 3 mg/kg/min in adults), stores can be quickly depleted. It is therefore imperative for infants who are not able to feed to be started on dextrose-containing fluids as soon as possible. Most infants require a glucose infusion rate (GIR) of 4 to 9 mg/kg/min at birth to keep up with glucose metabolism; the GIR is increased slowly over subsequent days to a maximum rate of up to 14 mg/kg/min.[65,66] The majority (90%) of glucose is used by the brain, so hypoglycemia (glucose <45 mg/dL) can affect early neurodevelopment if left untreated.[67]

If there is no contraindication, enteral feeding is the preferred method of providing nutrition to neonates and infants. Very premature infants may not developmentally be able to take feeds by mouth due to the lack of oral coordination that usually develops at 32 to 34 weeks of gestation, and usually require nasogastric access for feeding. Oral aversion is a concern for infants who have need to be nil per os for an extended period of time (e.g., prolonged intubation, long-gap esophageal atresia). Breastmilk (20 kcal/oz) is recommended due to immunologic benefits, but formula may be augmented/substituted if breastmilk is insufficient/unavailable or not tolerated (i.e., milk protein allergy). Fortification may be utilized for additional calories, but can increase the risk of necrotizing enterocolitis, especially in premature infants.

If unable to proceed with enteral nutrition, parenteral nutrition (PN) can be initiated. PN is recommended in very low-birth-weight/extreme preterm infants as their intestinal immaturity puts them at high risk for necrotizing enterocolitis with early initiation of full feeds. Since they are unable to immediately tolerate full enteral feeds, have high protein turnover rates, and require supplemental protein to maintain a positive nitrogen balance and prevent starvation, premature infants are started on PN as soon as possible after birth.[66] PN is also useful for infants with bowel obstruction or in the postoperative state. Some infants who have lost a large portion of small bowel secondary to midgut volvulus (anatomically) or gastroschisis (functionally) may be dependent on PN for a long period of time and are at risk of the development of PN-associated cholestatic liver disease.[65] Recent advances in alternative lipids have been show to decrease the risk of PN-related cholestasis with the use of fish oil–based lipid formulations (as opposed to the standard soy-based lipids) containing omega-3 fatty acids.[68,69] Infants receiving PN must have their electrolytes and glucose levels monitored closely to avoid metabolic derangements. While lifesaving and sustaining, prolonged PN use places infants at risk for complications, including catheter-related complications (central line–associated bloodstream infections, thrombosis) and cholestasis, and therefore transition to enteral nutrition whenever possible is preferred.

Hyperbilirubinemia is common in infants and an understanding of the natural progression of bilirubin levels is needed in the approach to the evaluation of the GI surgical neonate. Bilirubin levels in the blood are determined by the amount created from the breakdown of heme, primarily from red blood cells, and the amount reabsorbed from the enterohepatic circulation. The normal level of bilirubin in infants is higher because neonates produce two to three times the amount of bilirubin as adults, in part because of the increased turnover of red blood cells.[70] Unconjugated hyperbilirubinemia is a result of decreased ability to conjugate due to deficiency of the conjugating enzyme uridine diphosphogluconurate glucuronosyltransferase (UGT). Additionally, absorption of unconjugated bilirubin from the GI tract can occur if the conjugated bilirubin normally excreted in stool is instead unconjugated by β-glucuronidase. This GI resorption can be increased in diseases that result in prolonged retention of stool, such as Hirschsprung disease or distal atresias. Typically, during the

first 1 to 2 weeks, unconjugated bilirubin levels transiently rise to 6 to 12 mg/dL, depending on gestational age of child (full-term infants have lower levels) before returning to normal levels of <2 mg/dL.[70,71] Neurotoxic effects of hyperbilirubinemia can be avoided by clearing bilirubin with phototherapy (first-line therapy) or exchange transfusions. Established nomograms that incorporate postnatal age and rate of rise can be helpful in determining the proper threshold at which to initiate phototherapy.

Fluid, Electrolyte, and Genitourinary Considerations

As mentioned previously, fetal fluid balance is influenced by placental factors and fetal factors. Fetal kidneys regulate amniotic fluid levels, but after birth, they assume control of the electrolyte and fluid maintenance. Renal blood flow starts around 5% of cardiac output and rises over the first few weeks to adult levels of 25% as systemic (and renal) vascular pressure decreases. Glomerular filtration rate (GFR) likewise increases over time from 40 mL/min/1.73 m^2 at birth to goal rate of 125 mL/min/1.73 m^2 by age 2 in term neonates and later in childhood for preterm infants. Delay in the first urine output up to 24 hours is not uncommon in neonates, though premature infants seem to be more likely to urinate earlier (within the first 8 hours) than term or postterm infants.[72] The urine that is passed is quite dilute because their concentrating ability is poor, though it doubles over the first 30 days of life and continues to increase over the first year.[73] Once urination begins, minimal adequate urine output is 1 mL/kg/hr, but should ideally be 2 to 3 mL/kg/hr. The use of creatinine to measure renal function in the early neonatal period must be interpreted with care, as neonatal levels mirror maternal creatinine and reflect maternal renal function. This false alteration in creatinine usually clears by 2 weeks of life in term infants (by 4 weeks in premature infants) when levels are more reflective of the child's own renal function.[73]

Neonatal body composition is 80% water compared to 55% to 60% for adults. The excess body water is primarily intracellular, and migrates into the extracellular space and is subsequently excreted—leading to the typical weight loss seen during the first few days of life. Typical fluid requirements for a term neonate start at 60 to 80 mL/kg/d and gradually increase to 150 to 160 mL/kg/d but may be higher for very low–birth-weight and premature

neonates or neonates with conditions that lead to excessive fluid losses (e.g., gastroschisis).[67] Neonates do not excrete sodium in their urine for the first few days due to low GFR, so supplemental sodium during this time frame is not required. Normal sodium requirements thereafter are 2 to 4 mEq/kg/d. Similarly, potassium is not initially added to fluids as levels are elevated at birth due to shifts into the extracellular space. After the first void and subsequent excretion of potassium, supplemental potassium may be added for goal of 1 to 3 mEq/kg/d. Transient hypercalcemia and hypermagnesia can occur in neonates immediately after birth due to passage from the mother via the placenta.[67,73] Otherwise, electrolyte abnormalities and management of them are similar to the adult population as has been discussed in the foundational chapters in this textbook.

Hematologic Considerations

Coagulation factor measurement studies of fetal and newborn coagulation reveal longer clotting times before 30 weeks' gestation, followed by an increase in the amount of clotting factors between 30 and 38 weeks.[74] There were significantly lower coagulation factor levels in late preterm fetuses than levels of full-term neonates, possibly indicating some trigger for further rapid maturation at the time of birth.[74] Lower coagulation levels in preterm infants may be related to hepatic synthetic immaturity.[75] In the absence of an underlying coagulation disorder, these levels will improve over time to adult levels. If the child does have a bleeding disorder, it may manifest in a number of ways. Bleeding following circumcision is the most common presentation of hemophilia overall, followed by spontaneous hemorrhage (subgaleal hematoma, cephalohematoma, and intracranial hemorrhage).[76]

Vitamin K levels in the fetus and neonate are low, and decrease further over the first 48 to 72 hours. A lack of bacterial production from the mostly sterile GI tract and low levels of dietary vitamin K consumed leads to deficiency until about 7 to 10 days after birth.[77] Vitamin K is a cofactor for coagulation factors II, VII, IX, and X and for proteins C and S; carboxylation of these factors by vitamin K activates them in the coagulation cascade. Because of this transient vitamin K deficiency, neonates are at increased risk of hemorrhage, which may manifest as intra- or extracranial hemorrhage, GI bleed, or, in males, bleeding at the time of circumcision. Diagnosis can be

made in patients with prolonged PT and PTT and elevated PIVKA (proteins induced by vitamin K absence) levels.[77] Complications can be prevented by administration of exogenous intramuscular vitamin K at birth.[78] Surgeons must be aware of this entity in perioperative planning of neonates, especially as there have been increasing reports of parental refusal of vitamin K treatment.[79,80] In these instances, operations should be delayed if possible.

Infectious Disease Considerations

Neonates can become quite ill without many of the typical signs seen in older children and adults. 7 They may not have any specific symptoms, but may present with unexplained respiratory distress, apnea, or bradycardic episodes, even with nonrespiratory causes of illness. Temperature instability usually manifests itself as hypothermia instead of febrile illness. Because of their poor physiologic reserve, clinical deterioration can occur quickly if signs are not recognized and appropriate treatment initiated. Within the first 3 days of life, illness is thought to be a result of maternal–fetal transmission as a result of early and/or prolonged rupture of membranes or maternal infection (chorioamnionitis, colonization with group B streptococcus). Conversely, late-onset sepsis usually occurs after 1 week of life and is more likely a result of some environmental insult or exposure (ventilator-associated pneumonia, catheter-related bloodstream infection). Premature infants are at risk for either type of sepsis due to their weaker immune systems.[81]

Positive cultures of body fluid (blood, urine, sputum, cerebrospinal fluid) are preferred for diagnosis of sepsis in the appropriate clinical context. Ancillary studies may be used in conjunction with cultures (or in instances of culture-negative illness) for the workup of sepsis. Though leukocytosis on a standard complete blood cell count (CBC) is concerning for infection in older children and adults, leukopenia is of greater concern in neonates. The ratio of immature neutrophils to total neutrophils (I/T ratio) is a more sensitive indicator of sepsis (ratio ≥ 0.2) and is commonly used in neonates to help identify those with infection. C-reactive protein (CRP) increases in response to an inflammatory process and is one of the most common trended laboratory values in neonates. It has a high specificity and positive predictive value (both >90%) for neonatal infection.[81] A benefit of the CRP, I/T ratio, and the absolute neutrophil count (another commonly used lab test)

is that normal results have a high negative predictive value (>95%).[82] Thrombocytopenia is also associated with neonatal sepsis, though the mechanism is not entirely clear. Neonates with gram-negative sepsis are more likely to consume platelets compared to those with gram-positive sepsis (42% vs. 17%) and experience a greater drop in platelet levels.[83] Additionally, severe thrombocytopenia ($\leq 50 \times 10^9$/L) is associated with higher rates of mortality.[83]

Temperature instability can be an early sign of neonatal sepsis, presenting as low temperatures. Neonates lose heat more easily than adults for a variety of reasons, including increased relative body surface area and thin skin, through which evaporative losses may occur. They lack the ability to generate heat through shivering, instead creating heat by the breakdown of stores of brown fat. Premature infants have more pronounced issues with heat loss because of their skin immaturity, and they also have less brown fat, making them even more prone to hypothermia. Environmental measures (blankets, increasing room temperature, and radiant warmers) are vital in temperature maintenance; these measures are key to perioperative temperature management. Surgeons should be mindful and try to limit the time a neonate is uncovered on the operating table; use forced-air heating units and maintain higher operating room temperatures to keep the child normothermic.[84]

Pediatric Physiology

Normal physiology of children continues to change as children grow and mature, and mimics that of adults as children enter into adolescence. A fundamental understanding of normal age-adjusted vital signs is imperative in caring for children (Table 97.1) in order to recognize impending shock states and respiratory failure. This section will highlight important aspects of pediatric physiology that differ from adults and that impact the care of a child.

Cardiovascular Considerations

As with neonates, an awareness of any pre-existing congenital cardiac lesion (repaired or unrepaired) is imperative in treating general surgical conditions.

Survival of children with congenital heart defects is increasing and encounters with patients with a history of congenital cardiac lesions are becoming more common—even into adulthood.[85] We refer the reader to the chapter on congenital heart disease for a detailed discussion, but will point out here the specific implication of single-ventricle physiology on laparoscopy. Children having undergone Fontan palliation of single-ventricle congenital heart disease have passive perfusion of the pulmonary vasculature and are therefore sensitive to changes in preload and may not tolerate standard pressure pneumoperitoneum for laparoscopy, which compresses the IVC and may lead to decreased venous return to the pulmonary vascular bed and consequently to the heart. Laparoscopy, carefully performed, has been shown to be safe in children with single-ventricle physiology in the context of an experience multidisciplinary team.[86] Close attention to volume status is essential in these children, as children with single-ventricle physiology are also sensitive to changes in vascular tone and can become unstable with the induction of general anesthesia if induced in a hypovolemic state, while children with unrepaired septal defects may be sensitive to volume resuscitation and are prone to pulmonary edema if aggressively resuscitated. Arrhythmias are uncommon in children overall, but have an increased incidence in children with congenital heart disease, or may be secondary to acid–base disturbances, medications, central venous catheters, or electrolyte imbalances.[87,88]

Shock states in children are generally classified as "warm" or "cold" shock. Septic shock in young children tends to mimic the physiology of neonates ("cold shock") with predominantly low cardiac output and high systemic vascular resistance. Septic shock in older children and adolescents more commonly mimics the physiology of adults ("warm shock") with peripheral vasodilation and a high cardiac output state. Resuscitation of children with septic shock begins with fluid resuscitation and should then follow the algorithm in Figure 97.4 to guide initiation of inotropic and vasoconstrictor support, with a key branch point in determining vasodilatory ("warm") shock or a low cardiac output ("cold") shock state based on physical examination findings.[89] Central venous pressure monitoring in children can be utilized, but physical examination of the abdomen to assess for hepatomegaly (congestive hepatopathy) is a useful adjunct in assessing volume status. Cardiogenic, neurogenic, obstructive, and hypovolemic shock

states in children mimic the physiology of adults and should be managed in a similar fashion with attention paid to weight-based dosing of fluids, blood products, and vasoactive agents.

Respiratory Considerations

Young children, like neonates, have a diminished respiratory reserve due to high metabolic rate and low FRC and can decompensate rapidly. It is important to recognize compensatory physical examination findings associated with respiratory distress such as tachypnea, nasal flaring, subcostal and supraclavicular retractions, expiratory grunting (to maintain recruitment and higher FRC), and head bobbing. Young children have large heads in relation to the torso, leading to flexion at the neck and relative airway obstruction when lying supine. A blanket or roll can be placed behind the shoulders to extend the neck to neutral and improve airway positioning.

An important consideration when caring for a pediatric patient in respiratory distress is the contribution of small airway size to limitation in laminar airflow. As detailed in the respiratory physiology chapter, airway flow is primarily limited by airway resistance, which in turn is proportional to the radius of the airway to the fourth power. Therefore, very small changes in airway diameter can lead to substantial increases in airway resistance in young children. Airway mucosal edema, mucus plugging, and foreign bodies can all lead to significant respiratory compromise.

Respiratory failure in children can be managed with noninvasive ventilation or may be escalated to endotracheal intubation and mechanical ventilation. Pediatric airway sizes are age dependent; therefore, a working knowledge of tube sizes or an easily available resource such as a length-based color-coded tape is needed. Appropriate endotracheal tube size can be estimated using the formula (age in years + 4)/4 (for an uncuffed tube) or by referring to a length-based color-coded tape. Mechanical ventilation is generally initiated targeting tidal volumes of 6 to 8 mL/kg of predicted body weight (based on length, age, and sex).[90] Tidal volumes in mechanically ventilated young children can be challenging to measure at the level of the ventilator as the dead-space volume of the ventilator tubing far exceeds the tidal volume of the patient. For this reason, inline flow sensors at the level of the endotracheal tube are used to more precisely measure actual tidal

volumes.[91] Compliance is highly variable across ages and disease processes; therefore, initial ventilator pressures are generally estimated using bag ventilation with a handheld manometer and visual inspection of chest rise to determine the pressure needed to deliver adequate volume. Pediatric minute ventilation is higher than in adults, and younger children generally require higher respiratory rates (15 to 30 breaths/min) that need to be titrated to maintain adequate CO_2 clearance. Tracheostomy timing in children remains a controversial issue. The incidence of subglottic stenosis with prolonged intubation in children is much higher (11%, mean length of mechanical ventilation 9 days, range 3 to 33 days) than previously thought, and increases with duration of intubation (50% increased risk for every 5 days of endotracheal intubation).[92] The incidence of tracheostomy-related complications, however, is much higher than in adults with a 2-year tracheostomy-related complication rate of 39% and in-hospital mortality rate of 9%, which decreases the enthusiasm for tracheostomy in young children unless deemed absolutely necessary.[93] Within the specific population of pediatric traumatic brain injury, tracheostomy at 14 days is associated with faster time to discharge and lower complication rates without significantly increasing the number of unnecessary tracheostomies performed.[94]

American College of Critical Care Medicine clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock. *Crit Care Med* 2017;45[6]:1061–1093. Wolters Kluwer Health, Inc.)

Gastrointestinal and Nutritional Considerations

Outside of the neonatal period, GI physiology mimics that of adults. Growing children do have higher metabolic needs, and daily baseline caloric requirements are higher in younger children (Table 97.2).[64] PN is commonly used in pediatric patients with prolonged inability to tolerate adequate

enteral nutrition, with the recommended timing of initiation generally similar to adult patients at 7 days in the absence of pre-existing malnutrition.[95]

Genitourinary, Fluid, and Electrolyte Considerations

Renal function is not mature at birth and does not mature until 2 years of age. Normal urine output is higher in infants and younger children (1 to 2 mL/kg/hr) and approaches adult levels (0.5 to 1 mL/kg/hr) by adolescence. Children have a higher body surface-to-mass ratio and higher minute ventilation, leading to greater insensible losses. Daily maintenance fluid requirements in children per unit body weight are higher than in adults and the hourly fluid requirements can be calculated using the 4-2-1 rule initially described by Holiday and Seger in 1957 or daily fluid requirements similarly referenced in Table 97.3.[64,96] Outside of infancy, daily electrolyte requirements mimic those of adults.

Table 97.2 Parenteral Nutrition Baseline Caloric and Protein Needs by Age

Age Group	Daily Caloric Needs (kcal/kg/d)	Daily Protein Needs (g/kg/d)
Premature Neonate	90–120	3–4
<6 mo	85–105	2–3
6–12 mo	80–100	2–3
1–7 yrs	75–90	1–2
7–12 yrs	50–75	1–2
>12 yrs	30–50	0.8–1.5

Hematologic Considerations

Pediatric blood volumes are relatively higher in infants (90 mL/kg) and young children (80 mL/kg) and approach adult levels (65 to 70 mL/kg) by adolescence.[97,98] In general, transfusion of 5 mL/kg of red blood cells should result in an expected 1 g/dL increase in hemoglobin.[99] Massive transfusion in children is generally defined as more than 40 mL/kg/24 hrs of combined blood product (red blood cells, plasma, platelets, and cryoprecipitate), with improved outcomes demonstrated with high ratio RBC:plasma transfusion—similar to adults.[100,101] Venous thromboembolic disease (VTE) is less common in children, but does occur—often in critically ill or injured patients and in association with indwelling central venous catheters, oncology diagnoses, oral contraceptive use, postpubescence, and obesity.[102] While the efficacy of pharmacologic VTE prophylaxis likely mimics that of adults in adolescents, it is unclear if pharmacologic chemoprophylaxis is effective in decreasing VTE rates in younger children.[103]

Infectious Disease Considerations

Evaluation of febrile infants—particularly under 3 months of age—involves complex algorithmic decision making and is beyond the scope of this chapter. It is important to understand that young infants are susceptible to central nervous system seeding from bacterial bloodstream infections due to the immature meninges. Risk factors such as young age (<60 days), appearance on physical examination, presence of alternative etiology of fever (otitis media or positive urinalysis), hematologic abnormalities (sickle cell or asplenia), and degree of laboratory abnormality (white blood cell count and CRP) have all been used to risk stratify patients and guide decision making around the necessity for lumbar puncture and admission for empiric intravenous antibiotics.[104]

Table 97.3 Pediatric Fluid Requirements by Weight

Body Weight (kg)	Daily Fluid Requirement
<1.5	130–150 cc/kg/d
1.5–2	110–130 cc/kg/d
2–10	100 cc/kg/d
11–20	1,000 cc/d (for first 10 kg) + 50 cc/kg/d for every kg over 10 kg
>20	1,500 cc/d (for first 20 kg) + 20 cc/kg/d for every kg over 20 kg

Fetal Intervention

Diana L. Farmer and Tippi MacKenzie

Key Points

1. There are seven fetal conditions currently treated with fetal intervention: twin-to-twin syndrome (TTTS), myelomeningocele (MMC)/spina bifida, congenital diaphragmatic hernia (CDH), congenital heart defects (CHDs), congenital lung lesions (CLLs), lower urinary tract obstructions (LUTO), and sacrococcygeal teratomas (SCTs), all of which are dependent on the severity in utero.
2. Fetal surgery will only occur if (a) there is significant chance of the procedure being lifesaving or preventing serious or irreversible disability in the fetus, (b) the procedure involved low mortality and morbidity risk to the fetus, and (c) the operation has low mortality and morbidity risk to the pregnant woman, including impact on future pregnancies.
3. Fetal surgery originally was only recommended when the fetus would not survive without it, and thus the risk–benefit ratio was favorable.
4. The first fetal surgery for a nonlethal defect was for MMC.
5. *Ex utero*intrapartum treatment (EXIT) procedure is most often used for fetuses with predicted compromised airway access at birth.
6. Fetal molecular therapies allow potential treatment of fetuses with numerous stem cells, proteins, or viral vectors.
7. In utero gene therapies show promise in treating genetic abnormalities.

INTRODUCTION

The Development of a New Surgical Subspecialty

Fetal surgery is a multidisciplinary subspecialty that emerged at the crossroads of pediatric surgery and maternal–fetal medicine.[1] During initial stages of development, the idea of surgically operating on a human fetus within the womb was considered impossible, radical and questionably unethical. Nevertheless, pioneers took on the task of confronting and overcoming numerous obstacles in pursuit of an innovative concept that would eventually become the accepted standard of care for many congenital conditions.

Modern fetal surgery was envisioned and established in the late 1970s as a multidisciplinary translational program by Doctors Alfred de Lorimier and Michael Harrison at the University of California, San Francisco.[1] In 1981, Dr. Harrison performed the first open surgical intervention on a fetus with obstructive uropathy.[1] Prior to this landmark case, intrauterine interventions were limited to diagnostic procedures such as amniocentesis and chorionic villus sampling, or limited procedures such as intrauterine transfusion for Rh incompatibility. Harrison's success proved that surgeons could accomplish an operation on a pregnant uterus, return the fetus to the womb, and maintain the pregnancy.

CORE PRINCIPLES

In 1982, pediatric surgeons, neonatologists, perinatologists, radiologists, and anesthesiologists from 13 centers and five different countries attended a collaborative conference in Santa Ynez, CA, to review and discuss the potential benefits and liabilities of various interventions in fetal treatment.[2] The group, now recognized as the International Fetal Medicine and Surgical Society (IFMSS), reached a medical consensus by the end of the conference and established the following principles which have been updated and remain in place today (Table 98.1).

In the last 40 years, the field of fetal surgical intervention has advanced tremendously and will continue to do so with evolving techniques and clinical improvements in safety for both women and the unborn patient.

FETAL SURGERY—KEY ELEMENTS LEADING TO SUCCESS OF FETAL SURGERY

Fetal Imaging

Technologic advancement in fetal imaging not only furthered medical insight but also led to the evolution of surgical techniques and conceptual innovation. With the development of 3D and 4D ultrasound, diagnoses of facial, neural tube, and skeletal abnormalities can be made with increasing accuracy. Real-time spatiotemporal resolution is used in surgical intervention to guide instrument placement.[3] Moreover, magnetic resonance imaging (MRI) provides improved soft tissue contrast for imaging of central nervous system, lungs, kidneys, and placenta to overcome some limitations of ultrasound.[3] Fetal MRI provides significant benefits of gaining additional anatomical information, demonstrating complex structural relationships and studying these relationships from alternative angles, and allowing preparation of a more detailed surgical plan.[3]

Prenatal Genetic Diagnosis

The advances made in prenatal diagnosis with analysis of fetal DNA circulating in maternal blood has improved and eased the ability to diagnose genetic abnormalities in the fetus.

Table 98.1 Criteria for the Advancement of Fetal Therapy

Topic	Principles
Most fetal abnormalities are now detectable	
Best treatment for most abnormalities	Remains after birth. Prenatal diagnosis allows patient, family, and physician to discuss and develop a delivery and treatment plan for optimal outcome.
Nature of the disorder in the fetus (i.e., fatal or disabling); fetal natural history	The natural history of the fetal condition must be understood; appropriate animal models should be employed to test potential efficacy of intended therapies.
Reporting requirements	Voluntary reporting is a moral obligation in the field. Self-imposed registry efforts are in progress, mandatory reporting is not established as reporting largely lacks funding and resources.
Appropriate use of therapies' criteria	Effective therapies for multiple pregnancies with or without an "innocent bystander" (e.g., TTTS, selective reduction of an anomalous twin) may be considered if therapy will prolong and/or improve outcome of that pregnancy
Candidate diseases	Improvements in prenatal diagnosis have enhanced diagnosis of fetal conditions and understanding of fetal physiology and pathophysiology. Predictive measures of morbidity and mortality help providers weigh risks and benefits for mother and fetus. Candidate diseases will continue to change and evolve.
Center infrastructure	Levels of care for newborn and for pregnant woman have been refined and

	redefined.
Checks and balances	Multidisciplinary teams should be tailored to the defect(s) being treated and include a variety of disciplines. Procedures for informed consent and formal reporting must be in place. Any experimental or innovative procedure must have ethical oversight, participation in registries, and transparent counseling and reporting. Parents must be counseled regarding any alternative therapies, and the options of pregnancy termination and neonatal palliative care where appropriate.
Goals of treatment	There is increasing focus on short- and long-term effects of fetal therapy on maternal reproductive health. Issues are becoming increasingly complex as the goals of fetal treatment move from primarily achieving survival, to decreasing morbidity and improving the functional and neurodevelopmental outcome of the child.
Maternal safety and autonomy	Maternal expectations have evolved. Fetal abnormalities are expected to be prenatally diagnosed, and for some abnormalities the option for fetal treatment (where available and evidence based) will be available. As fetal therapy becomes more available, uptake has become greater. In addition, some are willing to incur greater personal risk to improve the prognosis for their fetus. Care must be taken to avoid the pitfalls in perception—just because a procedure

is offered within or outside a research protocol does not imply proven efficacy.

MATERNAL–FETAL RISKS

Unlike standard operations, fetal surgery involves two patients simultaneously. This reality presents challenging moral and ethical conflicts that must be considered and balanced in each circumstance. Chervenak and McCullough[4] and others have helped to provide an ethical framework within which fetal surgery should exist. The keys to this framework are that (a) the fetal operation has significant chance of being lifesaving or of preventing serious or irreversible disease in the fetus; (b) the procedure involves low mortality and morbidity risk to the fetus; and (c) the operation has very low mortality and morbidity risk to the pregnant woman, including risks to future pregnancies. In light of these considerations, several contraindications to fetal intervention exist, including chromosomal abnormalities, the presence of other major anomalies, and significant maternal comorbidities.

The significant maternal and fetal risks associated with fetal surgery must be weighed for each patient. For the fetus, there is risk of preterm delivery, fetal death, or survival with poor outcome. Most indications for fetal surgery, however, are ones in which the fetus would not survive without it, and therefore the risk-benefit ratio is very favorable. For interventions aimed at improving the outcome of fetuses with nonlethal conditions, the risk–benefit ratio is more difficult to assess.

The risks and benefits to the mother depend on the invasiveness of the fetal surgical operation. In any intervention, benefits to the mother include the psychological reward from doing everything possible to improve the condition of the unborn baby. In selected cases, there is physiologic benefit in preventing the possibility of "mirror syndrome," a preeclampsia like condition in which the mother's condition "mirrors" that of a sick or dying fetus.[5] In the presence of this syndrome, fetal surgery is contraindicated and urgent fetal delivery is important to ensure maternal health. For all women having open fetal surgery, there are theoretical risks to subsequent pregnancies and future fertility. When maternal fertility following fetal surgery was studied, it was found that 32 of 35 mothers were able to achieve

successful subsequent pregnancies and 31 live births resulted.[6] However, after open fetal surgery, all subsequent deliveries must be performed by cesarean section, and labor in the index pregnancy and ALL future pregnancies must be avoided to prevent uterine rupture.[7] As with all obstetric surgery, blood loss may be significant and mothers undergoing fetal surgery occasionally require blood transfusion.[8] Chorioamniotic membrane separation and preterm labor remain the Achilles heel of fetal interventions.[9,10] Surgical approaches that involve a smaller hysterotomy and more minimally invasive techniques appear to lower these risks.[10] Specifically, fetoscopic and percutaneous approaches appear to lessen the maternal and fetal risks.[11] These techniques allow vaginal delivery after fetal surgery and appear to decrease the incidence of preterm delivery.[12] Overall the maternal risk profile has been quite favorable with NO maternal deaths from open fetal surgery occurring at major fetal surgery centers in the United States or Europe in the past 30 years.

CURRENT FETAL CONDITIONS AMENABLE TO FETAL INTERVENTION

Originally, fetal interventions were carried out only for conditions that were deemed lethal, as only saving the life of the fetus was thought to be of enough benefit to warrant the surgical risks to the mother. Once techniques of fetal access were standardized, open, fetoscopic, or needle-based procedures were developed based on the anatomy and subsequent physiology of each anomaly.

Twin-to-Twin Transfusion Syndrome

Twin-to-twin transfusion syndrome (TTTS) is a complication occurring in twin pregnancies as a result of aberrant vascular connections formed between twins sharing one placenta. Although all monochorionic (one placenta) pregnancies are considered high risk, TTTS is only present in 9% to 15% of pregnancies.[13] Diagnosis occurs during early-to-mid second trimester when unequal vascular utilization results in a “donor” twin

providing vascular flow to a “recipient” twin. This causes oligohydramnios in the donor twin and polyhydramnios in the recipient twin. The risk of discordant growth, cardiac failure, and hydrops often leads to fetal demise in both twins.

Rationale for Prenatal Treatment

Fetal intervention for TTTS is a minimally invasive procedure in which a fetoscope is introduced through the mother’s uterus (Fig. 98.1). A laser is used to ablate the offending communicating vessel across the shared placenta. Fetal laser ablation can be performed from 16 to 26 weeks of gestation. Randomized controlled trials of laser ablation in advanced TTTS have demonstrated a significantly higher likelihood of survival of at least one twin and decreased neurologic complications, although the risk of premature rupture of membranes and preterm delivery has increased.[14] This treatment converted a disease that previously had a near 80% mortality into one that has a greater than 80% survival and is now the standard of care for this condition today.

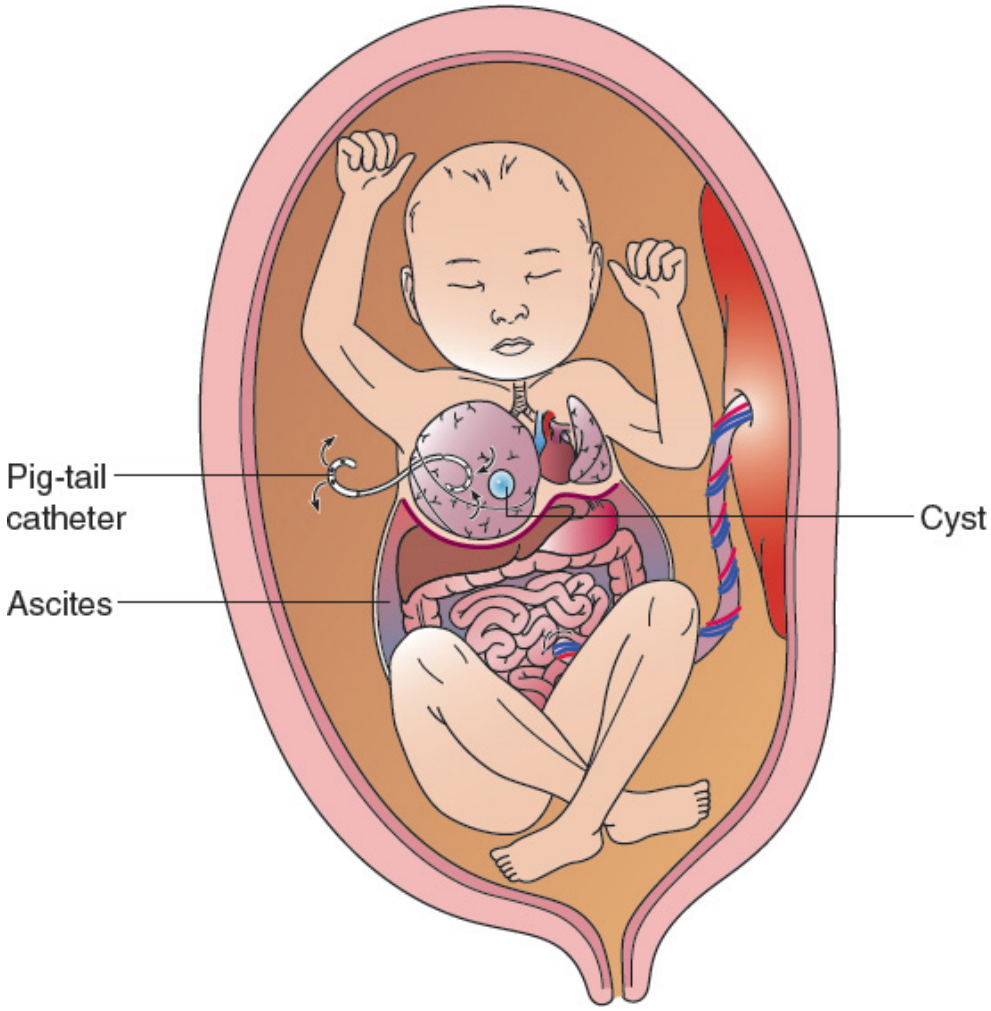

Figure 98.1 Treatment of twin-to-twin transfusion syndrome using fetoscopic laser ablation.

Myelomeningocele aka Spina Bifida

In the United States, roughly four children are born daily with MMC, making it one of the most common congenital defects resulting in paralysis.[6] Myelomeningocele (MMC) or spina bifida is a neurologic defect characterized by incomplete closure of the neural tube during early embryonic development, resulting in exposed neural tissue and leakage of cerebrospinal fluid (CSF). Depending on the vertebral level of the spinal defect, patients with MMC display a wide range of lifelong clinical consequences, which include paralysis, bowel and bladder incontinence, musculoskeletal deformities, hindbrain herniation, hydrocephalus, and cognitive disabilities.[15]

Until the late 1950s, surgical treatment was only offered to MMC patients who survived at least 2 years after birth. Survival rates were 10% to 12% until the groundbreaking development of ventriculoperitoneal shunts.[6] Shunt procedures managed CSF build-up and associated hydrocephalus.[5,6] Survival rates in the mid-1960s improved as treatment provided within 12 to 48 hours post delivery became standardized.[15] Still, shunts required constant revision; urinary tract infections and subsequent renal failure were still unresolved; and paralysis was not improved.[16]

Rationale for Prenatal Surgery

Neurologic deficits of MMC are explained by the "two-hit hypothesis," in which the neural tube fails to close, enabling CSF leakage and neural placode exposure (first hit), thereby allowing direct trauma by uterine wall contact and chemical trauma from amniotic fluid toxicity (second hit).[4,5] Fetal MMC intervention was hypothesized to potentially avert acquired injury of the second hit.

The hypothesis was tested in fetal lamb models with study results showing (1) reversal of hindbrain herniation in fetal lambs that received MMC surgical repair,[7] and (2) that distal neurologic function could be improved by prenatal coverage of the exposed placode.[17]

These promising animal studies led surgeons to begin fetal surgery for the first nonlethal fetal defect, MMC. Eventually a three-center, randomized controlled clinical trial that examined the efficacy of surgical repair in fetal patients with MMC compared to standard postnatal repair, known as the Management of Myelomeningocele (MOMS) trial, was performed. Study outcomes showed a 50% decrease in need for ventriculoperitoneal shunting and decreased occurrence of Chiari neurologic malformations.[8] Moreover, follow-up observed 42% of infants walking at 30 months as compared to 21% of infants in the control group, with complications primarily related to maternal outcomes.[8,9] For the first time, a fetal intervention definitively provided superior outcomes to postnatal repair. The MOMS trial results are one of the most important milestones in the clinical success of fetal surgery. Current work in the fetal treatment of MMC includes expansion of the inclusion criteria, modifications of surgical technology including fetoscopic approaches to hopefully lessen maternal morbidity, and scientific

investigation into further ways to improve the distal neurologic functioning for patients.

In 2020, the first in-human clinical trial for fetal intervention of MMC with placental derived stem cells was FDA approved. The cellular therapy for in utero repair of myelomeningocele (CuRE) study will examine the safety and preliminary efficacy of placental mesenchymal stem cells (PMSCs) seeded on a commercially available dural graft extracellular matrix (ECM) used for dural closure during standard fetal MMC repair. Other technologies are under preclinical investigation to help ameliorate the consequences of this devastating disease (Fig. 98.2).

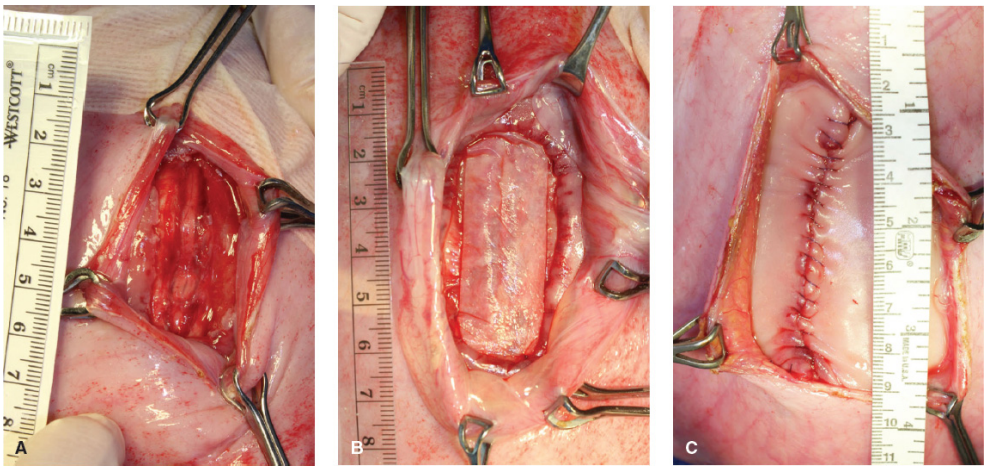

Figure 98.2 PMSC-ECM application for MMC in utero—representative images. **A**: The MMC defect in the fetal sheep model. **B**: The PMSC-ECM patch applied during repair surgery. **C:** The closure of the overall repair. *MMC*, myelomeningocele; *PMSC*-ECM, placenta mesenchymal stem cell–extracellular matrix.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernias (CDHs) are congenital defects in the diaphragm that allow abdominal contents to herniate into the fetal chest and may cause fetal or neonatal death due to pulmonary hypoplasia and pulmonary hypertension.[10] CDH is observed in one to four cases for every 10,000 births and survival rates in this country range from 69% to 93%. Unlike conditions of MMC and sacrococcygeal teratomas (SCTs) where defects are typically isolated, high CDH mortality rates may be attributed to

a wide variety of associated anomalies such as congenital heart disease or chromosomal abnormalities.[10]

Treatment Methods

Establishing fundamental criteria for CDH fetal intervention remains controversial in the absence of confidence in the condition's natural history. Poor outcomes in initial attempts to treat CDH with open fetal surgery led to an increased use of tracheal occlusion as primary treatment to address the underlying lung growth failure. Tracheal occlusion reversibly blocks the trachea of the fetus, causing fluid build-up that stretches fetal lung and enables a pathway for airway and pulmonary vessel growth.[11] Tracheal occlusion studies of pulmonary hyperplasia in fetal lamb models with CDH showed accelerated lung growth and improvement in pulmonary function. Persistent efforts in Europe to develop fetoscopic tracheal occlusion (FETO), and the results of a randomized control trial, have revived investigative research in the United States (Fig. 98.3).[12]

Congenital Cardiac Lesions/Congenital Heart Defects

Congenital heart defects (CHDs) are structural abnormalities of the heart or intrathoracic vessels with functional significance. Occurring in approximately 5 to 10 cases for every 1,000 live births, an estimated 25% of infants with CHDs will require surgery within 1 year after birth.[18] CHD malformations are detected using fetal echocardiography and remain relatively unvaried throughout gestation except for the following three lesions:

1. Severe aortic stenosis with evolving hypoplastic left heart syndrome (AS/eHLS)
2. Pulmonary atresia with intact ventricular septum with evolving hypoplastic right heart syndrome (PA/IVS)
3. Hypoplastic left heart syndrome with intact or severely restrictive atrial septum (HLS/IAS)

Rationale for Prenatal Intervention—Treatment Methods

Fetal cardiac intervention (FCI) intends to alter in utero anatomy and physiology for the three lesions listed above. AS/eHLS and PA/IVS FCI can result in biventricular circulation which avoids single-ventricular palliation and associated complications.[19] HLHS/IAS FCI can improve in utero left atrial hypertension and decrease the need for emergent postnatal intervention; although overall survival benefit is less apparent. FCI limitations that lead to the inability to demonstrate long-term survival benefit include restricted patient eligibility, late patient referrals for specialized fetal cardiac centers, and lack of providers with technical expertise.[19] The lack of good animal models for robust preclinical investigations also limits progress with fetal cardiac diseases. Open fetal interventions for cardiac lesions have been limited to fetal cardiac tumors (teratomas) resulting in fetal hydrops.

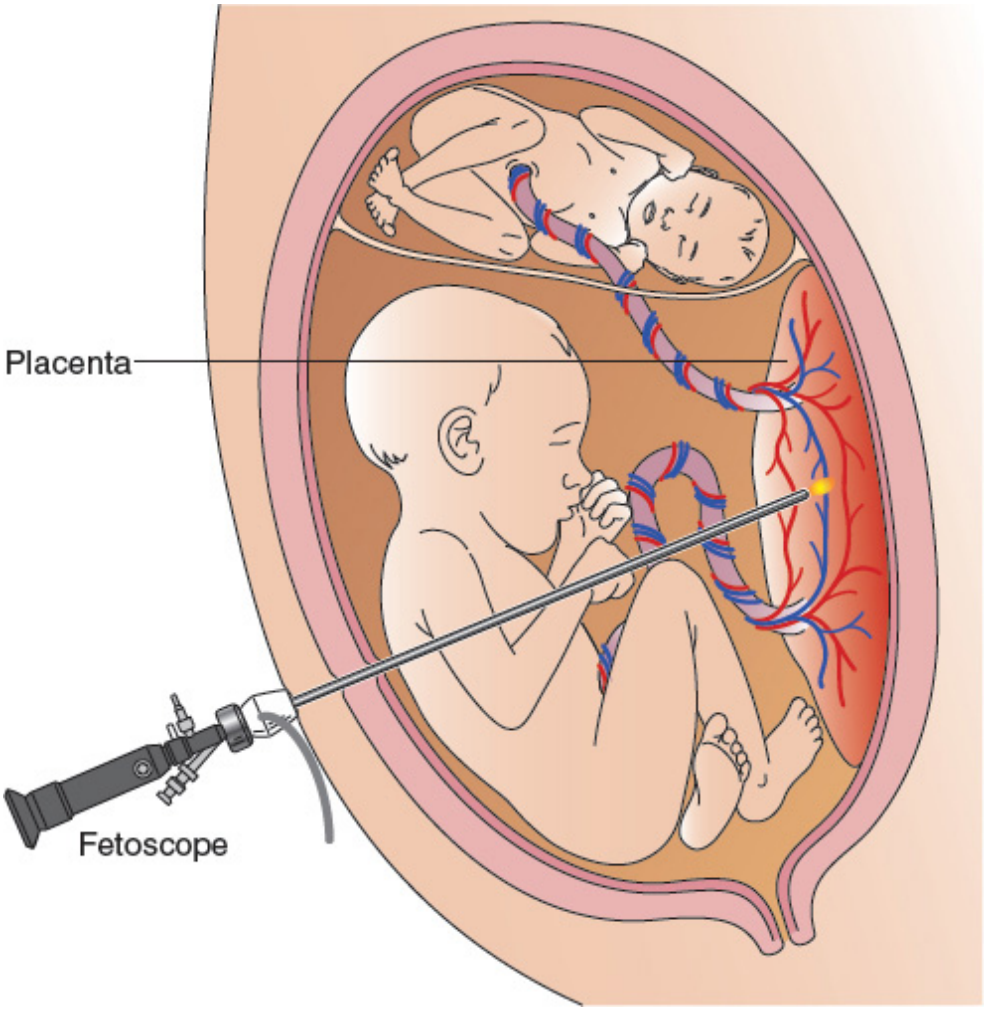

Figure 98.3 Fetal endoscopic tracheal occlusion.

Congenital Lung Lesions

Congenital lung lesions (CLLs) comprise a group of prenatal pathologies occurring at a rare incidence of 1 in 10,000 to 35,000 pregnancies.[20] Ultrasound imaging between 18 and 20 weeks of gestation is used to detect and diagnose CLLs ranging from relatively small asymptomatic lung cysts to large congenital pulmonary airway malformations (CPAMs) that can lead to fetal demise.[21] Early diagnosis is critical in CLLs because lesions exhibit fetal growth variability ranging from third trimester regression to rapid expansion with hydrops development and fetal demise.

Serial ultrasonography is a useful tool in defining the natural history of CLLs, identifying pathophysiologic features, and formulating course of

treatment based on prognostic information. A fetal echocardiogram detects abnormalities of increased/decreased cardiac output, ventricular hypertrophy, atrial or ventricular chamber dictation, cardiomegaly, significant valvular regurgitation, and diastolic dysfunction.[22,23] Through fetal imaging, including fetal MRI, prognoses are predicted based on the size of the lung mass and associated pathophysiologic effects.

Treatment Methods

Various options for fetal management are available for CLLs. Administration of maternal steroids can reverse early hydrops and is primarily used in cases of microcystic CPAM.[14] Cyst aspiration is an option allowing decompression in large macrocystic lesions.[14] Thoracoamniotic shunting is a method used to reverse hydrops when a CLL is composed of a dominant cyst and no large solid components.[24] Complications associated with this approach include shunt dislodgement, fetal distress, and consequential repeat procedure to correct shunt maladjustment (Fig. 98.4).[18]

Finally, open fetal surgery with surgical fetal lobectomy is required only rarely for select CPAMs with impending fetal demise. Alternative methods, such as laser ablation in solid CPAMs, have been limited by high mortality. A third procedure reserved for fetal patients of at least 30 weeks in gestational age is an EXIT-resection surgery. This procedure attempts to provide a more stable transition for fetuses when CLLs associated with hydrops are diagnoses late in gestation.

Sacrococcygeal Teratoma

Fetal SCTs, although rare, is the most common prenatally diagnosed congenital tumor occurring at approximately 1:35,000 to 1:40,000 births.[25] Most SCTs are diagnosed before birth through routine fetal screening and do not typically require treatment until after birth.[26] Conversely, diagnosis of large fetal SCTs requires active clinical attention due to associated obstetric complications and high rates of fetal mortality.[27] Detrimental effects of large SCTs can include rapid growth rate, hydrops development caused by high-output fetal heart failure, preterm delivery, erratic hemorrhaging and tumor rupture, and maternal mirror syndrome.[26]

The causes of death in fetal SCT are multifactorial, but primarily involve tumor rupture and bleeding at the time of delivery, or high-output cardiac failure and hydrops from high blood flow within the mass.[28] The development of high-output cardiac failure and hydrops in a fetus with SCT is the sole indication for fetal surgical intervention.

Rationale for Prenatal Surgery—Treatment Methods

Fetal surgical intervention for SCT treatment is only considered when a fetus shows rapid decline in cardiovascular function prior to 26 weeks of gestation, when the alternative outcome is prenatal fatality.[29] Fetal echocardiographic markers include increased aortic velocity, cardiac output, a dilated inferior vena cava, or reversed end-diastolic umbilical blood flow. These markers appear to be sensitive early predictors of impending hydrops and fetal demise.[13] For fetuses greater than 27 weeks of gestation, these findings are an indication for emergency cesarean delivery and postnatal resection. For fetuses less than 27 weeks, open fetal surgery and resection is the treatment of choice. Minimally invasive approaches to interrupt the tumor's blood supply with radiofrequency ablation have had limited success, but may warrant further investigation as an alternative for a fetus that is a poor candidate for open fetal resection.

Gastroschisis

Gastroschisis is a congenital defect of abdominal wall that involves herniation of the intestine and other intra-abdominal organs. Despite decreasing mortality in recent decades, gastroschisis occurs worldwide in 1 of 4,000 live births and the considerable impact of morbidity remains at the forefront of clinical concern.[18] Following gastroschisis repair, poor intestinal peristalsis and absorption impairs the speed of recovery in gut function leading to prolonged requirement of total parenteral nutrition (TPN). Early detection and diagnosis during the first trimester are key factors for indicating risk and predicting prognostic severity.[30] Unfortunately,

inconsistencies in current predictors of prognosis impose clinical limitations for counseling patients on outcome severity.

At present, because survival outcomes of gastroschisis with postnatal treatment is quite good in developed countries, fetal surgical considerations remain in the preclinical/experimental domain. Investigational studies of fetal lamb models are still in early stages.[31] High mortality in low- and middle-income countries has driven renewed interest in potential fetal interventions.

Lower Urinary Tract Obstruction

Lower urinary tract obstruction (LUTO) is a congenital defect obstructing fetal bladder outflow resulting in upstream urinary congestion. This often results in renal failure and pulmonary hypoplasia since amniotic fluid is formed by fetal urine and is necessary for normal lung development. LUTO occurs in approximately 2.2 to 3.3 cases per 10,000 with devastating impacts of fetal morbidity and mortality.[32] LUTO is caused by a variety of pathophysiologic processes resulting in distal urinary tract obstruction, decreased urinary flow, and regionalized urinary congestion.

Fetal ultrasound remains the primary tool for diagnosing LUTO by detecting megacystis or bladder enlargement with bilateral hydronephrosis. Although the use of ultrasound imaging is problematic when differentiating underlying etiology, it remains important in determining treatment options because it can detect renal parenchymal abnormalities.[32] Recent studies also indicate fetal MRI may provide additional diagnostic information.

Rationale for Fetal Treatment

While it seems logical that relieving the blockage of fetal urine would be ideal, not all fetuses with LUTO have favorable urinary biochemistry to benefit from fetal intervention. Different treatments are determined by severity of the disease in addition to diagnostic criteria. When indicated, fetal intervention is recommended as treatment in order to restore amniotic fluid (fetal urine) and enable normal lung development and preserve renal functioning. This can be accomplished by several means, but placement of a fetal vesicle (bladder) amniotic shunt is currently most common.

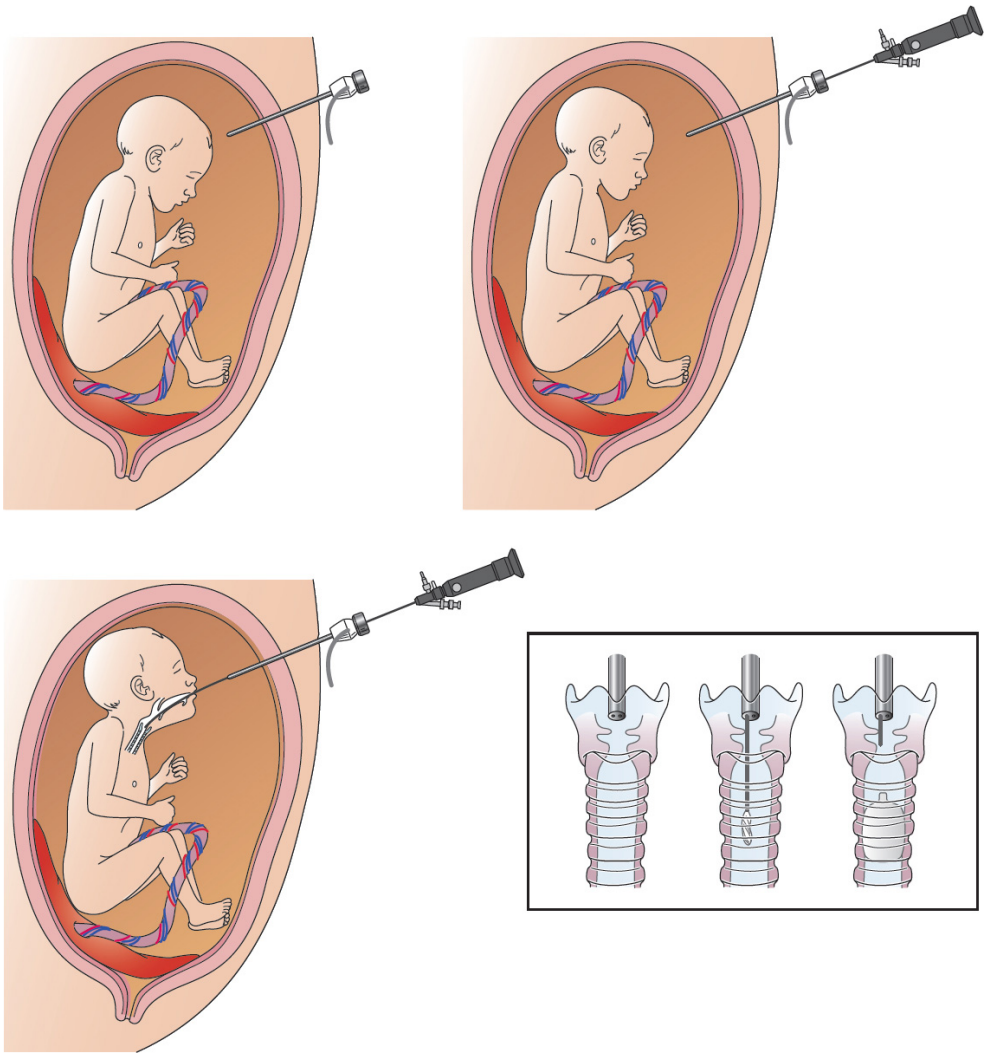

Figure 98.4 Thoracoamniotic shunting for a congenital lung lesion.

Cervical Teratoma, Airways Masses, and EXIT Procedures

Ex-utero intrapartum treatment (EXIT) is a surgical procedure similar to fetal surgery that allows time to stabilize the obstructed airway in a fetus, prior to delivery. EXIT-to-airway operations partially deliver the head and neck of a fetus to attempt direct endotracheal intubation through laryngoscopy, bronchoscopy, or tracheostomy.[33] Complete resection may be necessary in large teratomas, placing the mother under deep anesthesia to maintain maternal–fetal uteroplacental circulation as is required in open fetal surgery

to maintain the pregnancy. Following resection, the umbilical cord is cut, and the baby can be completely delivered.[34]

FUTURE DIRECTIONS

Although the past for fetal surgery has been marked by extraordinary progress for an entirely new field of medicine, it is the future that shines most brightly. From discoveries on the fetal origins of adult diseases, to ever increasing applications for fetal gene and stem cell therapies, or the induction of tolerance for future transplants, the promise of fetal medicine and surgery is extraordinary and holds a lifetime of investigative promise for young scientists. As fetal surgery is evolving, promising animal work is underway, exploring the technical feasibility and pathophysiologic rationale for in utero interventions.

Fetal Molecular Therapies

Fetal molecular therapies represent the newest frontier of prenatal therapy for genetic diseases. The ability to access the fetal umbilical vein, a procedure performed frequently for in utero transfusions, allows potential treatment of fetuses with numerous stem cells, proteins, or viral vectors. For example, in utero hematopoietic stem cell (HSC) transplantation can be performed to treat fetuses with blood disorders such as thalassemia. This concept has been demonstrated well in animal models and in patients with immunodeficiencies. There is now an ongoing phase 1 clinical trial of in utero transplantation in patients with alpha thalassemia major.

Other potential therapies include in utero enzyme replacement therapy for fetuses with lysosomal storage disorders. Fetuses with MPS7 (Sly syndrome) often have hydrops, a sign of impending demise. Infusion of the missing recombinant enzyme has improved outcomes in mouse models of MPS7 and has potential implementation in clinical trials.

In Utero Gene Therapy

In utero gene therapy takes an inward approach to fetal intervention by using stem cells to regenerate normal function in genetic abnormalities. Anticipated benefits associated with gene therapy are optimistic as immature development in fetal immune systems increase the likelihood of successful stem-cell receptivity. The procedure is relatively less invasive than alternative methods of fetal intervention and capitalizes on accessible stem cells located in amniotic fluid or pathologic states.[35]

In utero gene therapy could improve outcomes in multiple disorders for which postnatal gene therapy has been tested, such as spinal muscular atrophy or hemophilia. The specific benefits of these strategies include (a) inducing tolerance to the missing protein, as the fetal immune system is more prone to tolerance; (b) ability to cross the blood–brain barrier before it is formed, potentially addressing the neurologic aspects of diseases; and (c) low costs of enzymes or viral vectors due to the small size of the fetus.

Gene editing tools play a vital role in the feasibility of gene therapy by enabling manipulation of genes into a variety of target cells and organisms. Among available gene editing tools, clustered regularly interspaced short palindromic repeats (CRISPRs)/CRISPR-associated protein-9 nuclease (Cas9) (CRISPRs/Cas9) is the most widely used. CRISPR/Cas9 binds synthetic gRNAs to chromosomal DNA sites specified by Cas9 enzyme.[35]

As with other fetal interventions, maternal safety is the paramount concern when embarking on fetal molecular therapies. While preclinical studies do not indicate significant risk to the mother from in utero administration of stem cells enzyme replacement or gene therapy, clinical implementation requires careful attention for any unanticipated adverse events.

The extent of research for in utero gene therapy remains in the preliminary stages of animal studies, and human clinical trials are just beginning. Several issues in fetal gene therapy require attention and are mostly related to moral and ethical disagreements.

In Utero Stem Cell Transplantation

In utero stem cell transplantation emerged as a highly anticipated treatment when fetal imaging technology enabled access to the fetus and further understanding of fetal development. During early gestation, fetuses exhibit immunologic immaturity and plasticity meaning that differentiation in cell

function occurs gradually. As a result, expectations for successful fetal stem cell receptivity are greater than those of adults with fully matured immune systems.[32] Stem cells used for fetal transplantation are sourced from bone marrow, placenta, and two forms of amniotic fluid. Overall, HSCs are the most widely investigated due to effective transplant abilities with potential blood cell differentiation, suggesting clinical benefits of HSC transplantation as possible cures for prenatal hemoglobinopathies requiring bone marrow transplants.[28]

Other directions of in utero stem cell transplantation focus on mesenchymal stem cells (MSCs). MSCs exhibit migratory responses to sites of injury where they engraft to target tissues, suggesting possible involvement in site repair. Reported cases of bone injury strongly indicate MSCs engraft as reparative course of action to repopulate regional damage with healthy cells.[36] Compared to adult derived MSCs, fetal MSCs hold higher prevalence during fetal life and are more frequently in tissues of fetal liver, umbilical cord, blood, amnion, placenta, and amniotic fluid as early as 15 weeks of gestation. The FDA has recently approved a phase I clinical trial of placental derived MMC's in the treatment of spina bifida in utero.

Osteogenesis imperfecta (OI) is a common disorder of abnormal skeletal, osteopenia, numerous painful fractures, and short stature. Postnatal treatments thus far decrease the severity of associated morbidity but do not offer a cure. Pre-clinical mouse studies comprise the majority of research in OI, however, two cases of MSC stem cell intervention performed in Singapore, demonstrated remarkable benefit for each patient.

Tissue Engineering

Tissue engineering approaches often combine the use of a matrix with stem cells aimed at regenerating missing or malformed structural organs.

In alignment with normal fetal biology, stem cells enable transplanted cells to piggyback on natural processes of migration, engraftment, differentiation, and expansion. Early tissue engineering studies demonstrate sustained release of basic fibroblast growth factor (bFGF) using gelatin-based hydrogel on fetal rats with MMC. Other investigators are exploring amniotic fluid derived MSCs to provide a skin-like covering to the MMC lesion,

while others are using placental derived engineered MSCs to augment existing fetal surgery repairs.

Just as the early pioneers in open fetal surgery had to persevere despite grave doubts as to the feasibility, ethics, and efficacy, so do the current fetal gene and cell therapy pioneers. It is only with persistence that science advances and diseases are vanquished.

Pediatric Head and Neck

Nikolaus E. Wolter and Reza Rahbar

Key Points

1. The site of the neck mass is important (midline vs. lateral) for narrowing the differential diagnoses.
2. Benign cervical lymphadenopathy is the most common neck mass in the pediatric population.
3. Although rare, always consider malignancy to avoid delay in diagnosis.
4. Infants are obligate nasal breathers for the first 3 to 6 months of life; therefore, any nasal obstruction can cause respiratory distress.
5. History is important in the workup and treatment of an airway foreign body.

INTRODUCTION

The differential diagnosis of pediatric head and neck lesions includes a broad range of congenital and acquired etiologies. In contrast to the adult population, the majority of pediatric neck masses are benign with only 11% of neck masses demonstrating a malignancy on biopsy.[1] In pediatrics, neck

masses can be congenital, infectious, inflammatory, traumatic, lymphovascular, or neoplastic. Neck masses can range in presentation from an asymptomatic lesion to acute respiratory distress, depending on their size and location. Inflammatory cervical lymphadenitis is the most common cause of pediatric neck masses found in children. Congenital masses, such branchial cleft cysts and thyroglossal duct cysts (TGDC), often become clinically apparent when infected. Malignant processes are rare in children, and the most common malignancy seen in the pediatric neck is lymphoma. This chapter will focus on the most common head and neck pathologies found in the pediatric population along with their clinical presentation and treatment.

Imaging

Imaging is not always required for the diagnosis of a pediatric neck mass, but can be helpful in clarifying extent and size, location, and radiologic characteristics of a lesion. Ultrasound (US), computed tomography (CT), or magnetic resonance imaging (MRI) can be helpful in narrowing the differential, but often a biopsy or excision is still required for diagnosis.

Ultrasound

US is a good first choice for imaging in children. US has the advantages of being portable, fast, does not require sedation, and does not expose the pediatric patient to ionizing radiation. Disadvantages of US include variability of the technician's skill/experience as well as lower resolution images. The pediatric neck often has less subcutaneous adipose tissue, which lends to better imaging with US.[2] Moreover, US offers the ability to differentiate solid from cystic lesions, and color Doppler can determine the presence and characteristics of vascular flow within a mass.[3] US can be very helpful in determining the stage of an abscess, helping to differentiate early lymphadenopathy (LAD) that can be treated with antibiotic therapy from a mature abscess that requires surgical drainage.

Computed Tomography

CT scans and MRI provide a more detailed study of the anatomy of the neck. CT scans are readily available in emergent situations with scans completed quickly for patients who are critically ill. This speed can also help to eliminate the need for sedation and help to minimize artifact from movement. CT scans offer more osseous detail such as remodeling or erosion, as well as calcifications. The main disadvantage of CT scans is the exposure to ionizing radiation, which could potentially have carcinogenic effects in the long term.[4–6] Newer techniques offer reduced exposure with CT scans, but MRI and US should be utilized when appropriate.

Magnetic Resonance Imaging

MRI is the scan of choice for neck masses due to excellent soft tissue detail and avoidance of ionizing radiation. Details of the margins and possible neural spread or intracranial extension of a mass can be noted with the use of a contrast-enhanced MRI. The longer length of time required to obtain an MRI often requires sedation due to concerns of movement artifact in the pediatric population, which is the main disadvantage of the MRI.

Congenital

Congenital lesions of the head and neck are diverse and often the location of the lesion can greatly assist in narrowing the diagnosis (Table 99.1).

Branchial Anomalies

The branchial apparatus in the fetus eventually develops into head and neck structures. Any deviation in the development of these structures can result in an anomaly that can present as a mass in the neck. Sinus tracts and fistulas tend to present at a younger age due to their physical appearance, whereas cysts usually present when they get infected and enlarge. A sinus tract has an external opening to the neck, whereas a fistula has an external and internal opening. The location of the lesion is predicted by the portion of the branchial apparatus that is involved. Broadly speaking, remnants of the branchial clefts run deep to the structures derived from the corresponding arch but superficial to the structures derived from the next arch.

These lesions often present with infection. It is best to settle inflammation and infection with antibiotics prior to excision, making the dissection and identification of important structures easier. Abscesses can be treated with minimal intervention, such as needle aspiration or if needed, incision and drainage. During the procedure, it is important to communicate with anaesthetist to avoid paralysis for proper nerve monitoring. Radiologic imaging with CT or MRI can be helpful (Fig. 99.1). Rate of recurrence for branchial cleft cysts is quoted around 3%, but this increases to 20% in cases that have undergone a prior attempt at excision.[7]

Table 99.1 Benign Congenital Pediatric Neck Masses Based on Location

Location		Diagnosis		
		Developmental	Inflammatory/Reactive	Neoplastic
Lateral	Anterior to sternocleidomastoid (anterior triangle)	Branchial cleft cyst, vascular malformation, thymic cyst	Reactive LAD, lymphadenitis, sternocleidomastoid tumor of infancy	Lymphoma, rhabdomyosarcoma, metastatic lesion
	Posterior to sternocleidomastoid (posterior triangle)	Vascular malformation, thymic cyst	Reactive LAD, lymphadenitis	Lymphoma, metastatic lesion
	Preauricular	Hemangioma, vascular malformation, type I branchial cleft cyst, preauricular cyst	Reactive LAD, lymphadenitis, parotitis, atypical mycobacterium	Pilomatrixoma, salivary gland tumor
	Submandibular	Branchial cleft cyst, vascular malformation	Reactive LAD, lymphadenitis, atypical mycobacterium	Salivary gland tumor
	Supraclavicular	Vascular malformation, bronchogenic cysts	Reactive LAD, lymphadenitis	Lymphoma, metastatic lesion
Midline	Anterior neck	Thyroglossal duct cyst, dermoid cyst, teratoma, ectopic thymus, external laryngocele	Reactive LAD, lymphadenitis	Thyroid tumor, metastatic lesion (e.g., delphian node)
	Submental	Thyroglossal duct cyst, dermoid cyst, plunging ranula	Reactive LAD, lymphadenitis, Ludwig angina	—
	Occipital	Vascular malformation	Reactive LAD, lymphadenitis	Metastatic lesion

Anatomy and Embryology

The branchial arches form during the fourth to eighth week of gestation as four pairs of well-developed ridges with associated clefts. Each has a cartilaginous center (mesoderm), a cleft (ectoderm), an internal pouch (endoderm), and an associated artery and nerve (Table 99.2). These structures mature into the major structures of the head and neck (Fig. 99.2).

First branchial cleft anomalies, which comprise 8% of branchial cleft anomalies, are divided into type 1 and type 2.[8] Type 1 branchial cysts often present as a fistula around the conchal cartilage. The tract can follow the course of the external auditory canal and is lined by squamous epithelium.[9] Type 2 branchial lesions are found near the angle of the mandible and are composed of both epithelium and mesoderm (as opposed to only epithelial elements in type 1). Both type 1 and type 2 first branchial cleft anomalies can be closely associated with the facial nerve, although type 2 lesions are more likely to be intimately involved with the nerve. Type 2 branchial lesions can loop under the facial nerve, pushing it laterally and inferiorly.[10] The tract for a first branchial cleft usually extends from the opening near the mandible, near the posterior aspect of the parotid, and toward the external auditory canal. One should monitor the facial nerve at all times, with visualization of the face during the entire excision and avoidance of paralysis with anesthesia.

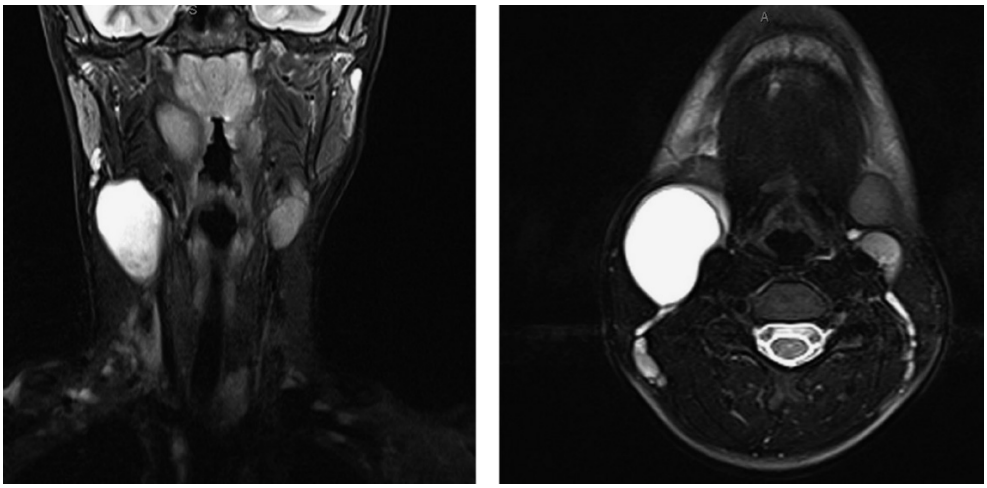

Figure 99.1 Coronal and axial view of MRI for second branchial cleft cysts.

Table 99.2 Pharyngeal Arch Structures

Arch	Nerve	Artery	Muscular Contributions	Skeletal Contributions
1st	Trigeminal nerve (V2 and V3)	Maxillary artery	Muscles of mastication, anterior belly of the digastric, mylohyoid, tensor tympani, tensor veli palatini	Premaxilla, maxilla, zygomatic bone, part of the temporal bone, mandible (only as a model for mandible not actual formation of mandible), incus, malleus. Meckel cartilage and the sphenomandibular ligament
	Pouch	Pharyngotympanic tube, middle ear cleft, part of mastoid air cells		
	Cleft	External auditory canal		
2nd	Facial nerve	Stapedial artery	Muscles of facial expression, buccinator, platysma, stapedius, stylohyoid, posterior belly of the digastric, auricular muscles	Stapes, temporal styloid process, hyoid (lesser horn and upper part of body), stylohyoid ligament, Reichert cartilage
	Pouch	Tonsillar fossa		
	Cleft	Obliterates		
3rd	Glossopharyngeal nerve	Common carotid, proximal internal carotid	Stylopharyngeus	Hyoid (greater horn and lower part of body)
	Pouch	Ventral: thymus; Dorsal: inferior parathyroid glands		
	Cleft	Obliterates		
4th	Vagus nerve (X), superior laryngeal nerve	Right: proximal subclavian artery Left: aortic arch	Cricothyroid muscle, all intrinsic muscles of soft palate (including levator veli palatini) *except* tensor veli palatini	Thyroid cartilage, superior parathyroids, epiglottic cartilage
	Pouch	Ventral: ultimobranchial body; Dorsal: superior parathyroid glands		
	Cleft	Obliterates		
6th	Vagus nerve (X), recurrent laryngeal nerve	Right: pulmonary artery Left: pulmonary artery and ductus arteriosus	All intrinsic muscles of larynx except the cricothyroid muscle	Cricoid cartilage, arytenoid cartilages, corniculate cartilage, cuneiform cartilages

The most common branchial anomaly is derived from the second branchial cleft, representing 90% of branchial cleft anomalies.[11] It can occur as an isolated cyst or as a sinus tract/fistula that extends from the cervical skin to the tonsillar fossa. The cysts will often present at the time of an upper respiratory tract infection as an enlarging, tender mass. If a fistula is present, it will course between the internal and external carotid arteries, over the hypoglossal and glossopharyngeal nerves to end in the tonsillar fossa. A cyst can occur anywhere along this tract, but most commonly occurs in the anterior triangle of the neck below the hyoid.

Third and fourth branchial cleft lesions are rare. Third branchial cleft cysts present low and anterior in the neck. Fistulas can course from the

piriform fossa and drain to the anterior cervical skin. This tract pierces the thyrohyoid membrane and tracks under the glossopharyngeal nerve and internal carotid artery, but stays above the vagus nerve. These lesions can be intimately involved with the thyroid, and sometimes a hemithyroidectomy is required for repeated recurrences. An infected TGDC or third branchial cleft cyst may be the cause of suppurative thyroiditis in children.[12] The external location for a fourth branchial cleft is the same as the second and third, but the internal opening is near the apex of the piriform sinus. Fourth arch masses are extremely rare but reports do exist. Third and fourth branchial sinus/tract dissections are similar to a second branchial cleft. Endoscopy at the beginning of the case can greatly assist in locating and resecting the tract. One promising surgical option for third or fourth sinus tracts is cauterization or sclerotherapy.[13]

The standard treatment for all types of branchial anomalies is complete surgical excision. The surgery is performed under general anesthesia and the patient is positioned with the neck slightly extended with a shoulder roll. If there is a sinus tract or fistula present, a small ellipse is made around this opening after it has been cannulated with a small lacrimal probe. The tract is then dissected cephalad until the end of the sinus tract or until the internal opening of the fistula is reached. The dissection for the most common branchial cleft anomaly, the second branchial cleft, penetrates the platysma, rises along the carotid sheath and turns medially near the branches of the internal carotid artery and courses between the posterior belly of the digastric muscle and stylohyoid muscle, and over the hypoglossal nerve before ending near or in the tonsillar fossa. The tract is then ligated with absorbable suture. Often a direct laryngoscopy or simply a finger placed in the oropharynx can help to visualize the course of the tract and assist with dissection. Some patients might require a “stepladder” incision to trace the tract superiorly.

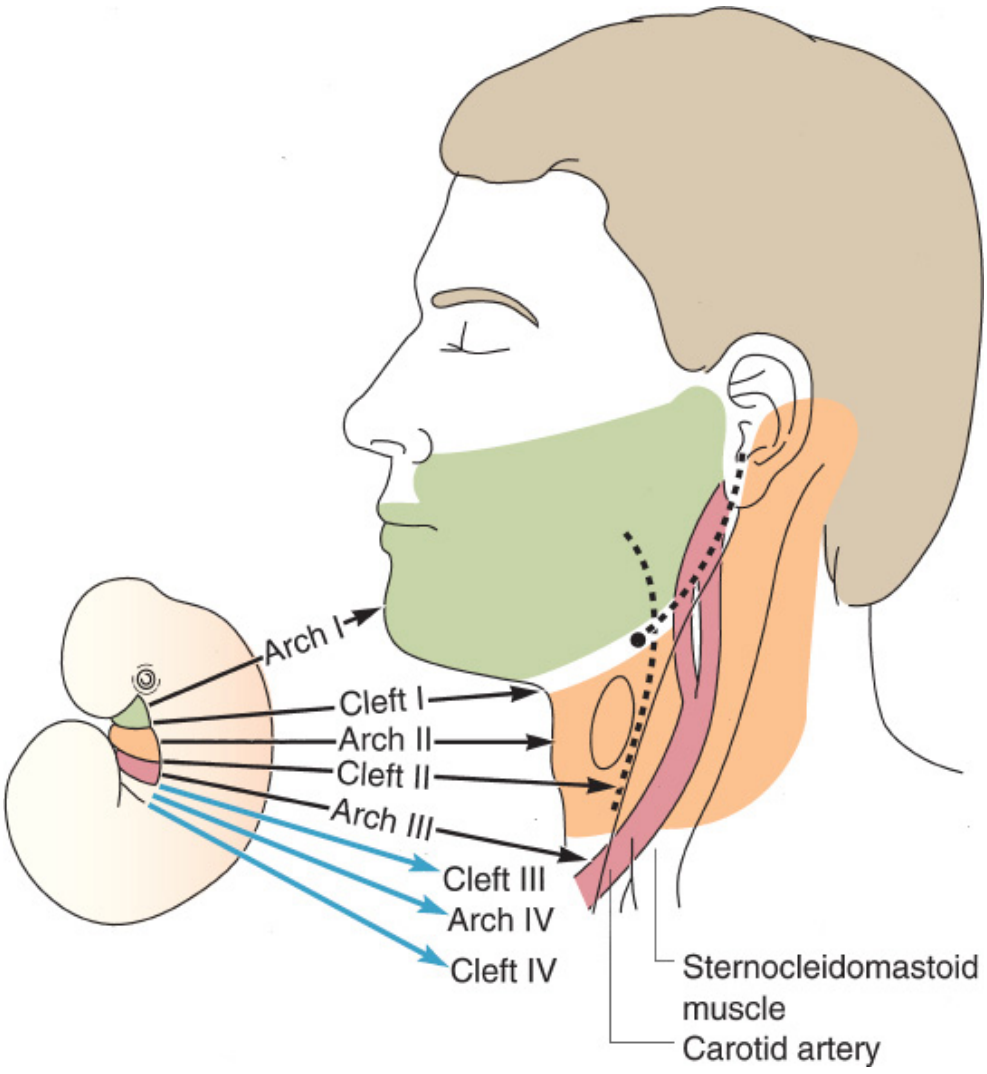

Figure 99.2 Derivation of various areas of the head and neck from the branchial arches and clefts of the embryo.

Preauricular cysts, pits, and sinuses are common in children and are thought to develop from the ectodermal hillocks of His which are found along the first two branchial arches. They are more common and more often bilateral in comparison to first branchial cleft cysts. The tracts extend from the skin down to the helical cartilage of the auricle and are lined with squamous epithelium. Treatment is surgical excision and the recurrence rate ranges from 19% to 40%.[14]

Thyroglossal Duct Cysts

TGDCs are congenital lesions that develop from the thyroglossal duct tract that occurs during the descent of the thyroid from the foramen cecum at the sixth week of gestation. The duct descends along the anterior neck in close association with the developing hyoid bone. This tract usually involutes, but if it persists the tract can present as a TGDC at any point from the foramen cecum to the thyroid (Fig. 99.3). TGDCs are the most common neck mass besides benign LAD in the pediatric population.[15] Physical presentation reveals a midline neck mass that may move with protrusion of the tongue (Fig. 99.4). US is useful to look at the characteristics of the cyst, but is most important to determine if there is a normal thyroid gland present (Table 99.3). In rare cases, the TGDC could be the sole functioning thyroid tissue in the patient.

Treatment is surgical excision and removing the entire tract with a core of tissue and the central portion of the hyoid bone can minimize recurrence. Rarely, papillary thyroid carcinoma can be found in the specimen.[18] The procedure is performed under general anesthesia with the neck extended and placement of a shoulder roll. A horizontal skin incision is made over the cyst, with no need to excise skin unless a fistulous tract or infection has involved the dermis. Careful dissection around the cyst then allows continued dissection superiorly toward the hyoid bone. Muscular attachments to the central hyoid bone are removed with cautery and the hyoid is removed en bloc with the cyst and tract. A core of tissue is then removed above the hyoid bone toward the base of tongue. The tract is then ligated with absorbable suture. Placing a gloved finger at the base of tongue can sometimes facilitate this maneuver. The wound should then be irrigated copiously and closed in a layered fashion but the hyoid should not be sutured back together. A drain is often used. Complete excision is considered curative and TGDCs have a recurrence rate of less than 10% when using this method.[17]

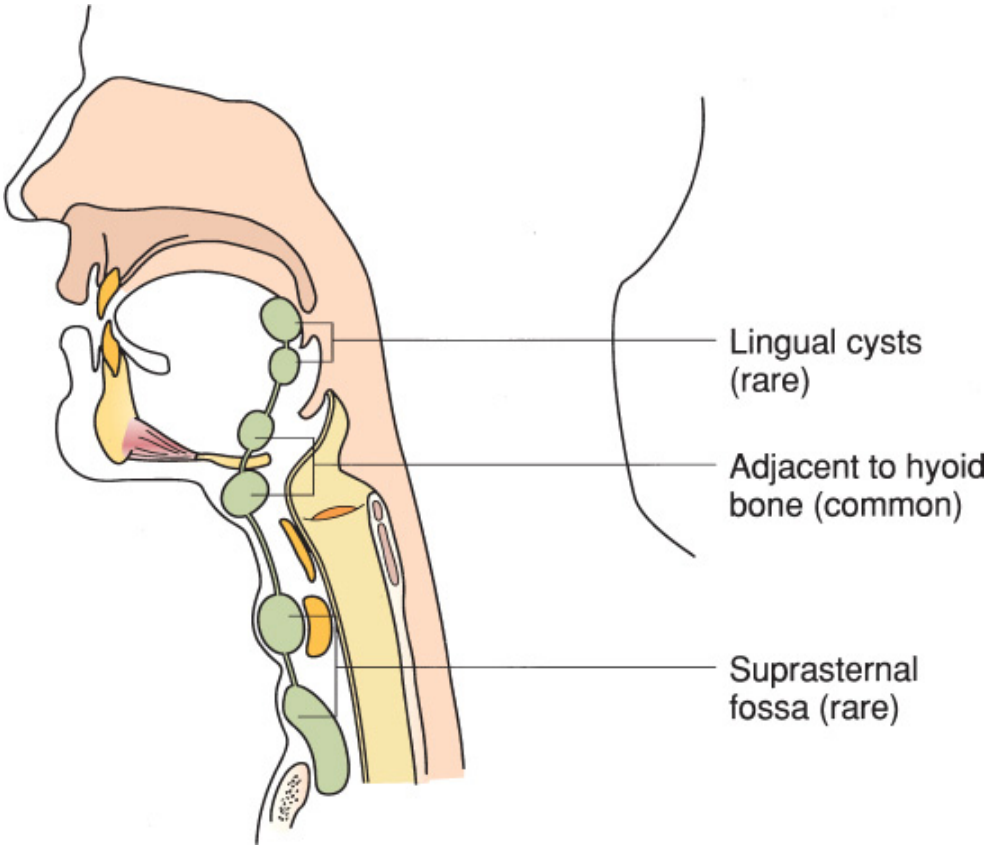

Figure 99.3 Locations of thyroglossal duct cysts.

Figure 99.4 Thyroglossal duct cyst.

Table 99.3 Ultrasonographic Features of Thyroglossal Duct Cysts[16,17]

Feature	Description
Internal septae	An internal septum is a hyperechoic linear structure in two places coursing between the walls of a cystic structure. They are usually thin
Irregular wall	The inner contour of the cyst is not well defined
Solid	Iso- or hypoechoic nodular lesions that have internal flow and no evidence of posterior acoustic shadowing
Tract	Presence of an abnormal connection between the cyst and tongue along the embryologic path of descent

Dermoid Cysts

Dermoid cysts should be considered in the differential of any midline lesion, although they can be off midline as well. On examination, dermoid cysts present as firm masses that are soft, mobile, nontender, and grow slowly. While epidermoids only include epidermal tissue, dermoid cysts contain hair follicles, sweat glands, and sebaceous glands within the wall of the cyst. Endoderm is never found within a dermoid. Treatment is total surgical excision.

Thymic Cysts

Lesions of the thymus usually occur in the lower neck, but can present anywhere from the piriform sinus to the chest along the path of the thymopharyngeal duct.[19] They can be solid, cystic, or mixed. Histologically they are identical to their thoracic counterparts and are characterized by the presence of Hassall's corpuscles. Biopsy is the gold standard for diagnosis but typical US and MRI features are useful for diagnosis as well.[20] The differential includes thymic cysts, thymic hyperplasia, or thymoma.

Infectious

2 The most common cause of a neck mass in the pediatric population is benign cervical LAD. Cervical lymph nodes are palpable in 40% of infants and 55% of pediatric patients.[21,22] Lymph nodes that are <1 cm in size and asymptomatic are considered normal in children under 12 years old.[12] Infectious LAD is most commonly seen in the submandibular region and cervical nodes, and the source of infection can be viral, bacterial, fungal, or neoplastic. Bacterial and viral infections causing upper respiratory infections are the most common cause of cervical LAD. Other possible sources of infectious LAD include, cat scratch disease, mononucleosis, atypical mycobacterium, and tuberculosis. Malignancy must always be included on the differential diagnosis in a child with cervical LAD. Biopsy should be considered if: (1) suspicion of malignancy, (2) no resolution of LAD over 4 to 6 weeks, (3) LAD steadily increases in size over 2 to 3 weeks, (4) LAD greater than 2 cm, or (5) concerning features on imaging.[23,24] Although rare, one should also consider Kawasaki disease, sarcoidosis, Rosai–Dorfman syndrome, and histiocytosis X.

Suppurative Lymphadenitis

Acute suppurative lymphadenitis is most common in the 6-month to 3-year range, with lymph node enlargement associated with an upper respiratory tract infection. The most common etiologies include *Staphylococcus aureus* and group A beta-hemolytic streptococci. There are commonly cellulitic changes in the overlying skin, leukocytosis, and fever. The lymph node enlarges and eventually outgrows the blood supply, resulting in central necrosis. Management can sometimes include needle aspiration of purulence, but often requires an incision and drainage with placement of a drain or packing under anesthesia. An incision is made in the area of fluctuance and blunt dissection should break up all loculations. It is important to place the incision in a place that minimizes risk to vital structures, such as the facial nerve, and allows for the best cosmesis. Antibiotics are geared toward *Staphylococcus* and *Streptococcus*, but cultures should be taken with a change in antibiotic therapy if necessary. The induration from the abscess can take several weeks to resolve, but recurrence is rare. If the abscess recurs, it

should prompt investigation of a possible underlying anomaly. Viral infections rarely cause suppurative adenitis.

Atypical Mycobacterial Infections

Atypical mycobacterial infections, usually caused by the *Mycobacterium avium-intracellulare-scrofulaceum* (MAIS) complex, can be very challenging to manage. The pathogens are usually acquired through the mucous membranes during the eruption of teeth, not through person-to-person transmission. The organisms can also be found in soil and nonpasteurized milk products. These lesions often cause discoloration of the skin and can fistulize over time (Fig. 99.5). Antibiotic therapy is not always curative. It most commonly occurs in children 1 to 5 years of age with a mean age of 3 years and often has associated asymptomatic LAD but no fever or leukocytosis.[25,26] The response to antibiotic therapy is variable and sometimes surgery excision of curettage is required. Long-term adjuvant treatment with clarithromycin or Rifabutin is often indicated, as is a consultation with the infectious disease team. In contrast, children with *Mycobacterium tuberculo*sis usually have fever and respiratory symptoms along with positive findings on chest x-ray and the purified protein derivative skin test.

Cat Scratch Disease

Cat scratch disease, caused by *Bartonella henselae,* can cause tender cervical lymph node enlargement in 25% of cases. Usually there is a history of contact with a cat within 2 weeks of the development of tender LAD. The site of inoculation is usually an extremity. The diagnosis can be made using *B. henselae*–based serologic indirect fluorescent antibody test or enzyme immunoassays. The disease is usually self-limited with resolution in 2 to 8 weeks and no antibiotic therapy is necessary; however, rarely patients can suffer disseminated disease.[27]

Figure 99.5 Atypical mycobacterium infection.

Vascular Malformations

Infantile Hemangioma

Infantile hemangiomas (IHs) are the most common tumor of infancy. IHs are endothelial tumors characterized by an increased proliferation and turnover of endothelial cells, which differentiate this from other vascular malformations. IH is not present at birth and then grows rapidly during the first 9 months (proliferative phase) and then slowly regresses (involuting phase). Regression is usually complete by 4 to 5 years of age.[28] They can occur anywhere in the body, with frequent involvement of the tongue and parotid gland. Usually hemangiomas occur as a solitary lesion, but 20% of

patients can have multiple affected sites. On examination, hemangiomas are a well-demarcated, raised, red mass that blanches with pressure (Fig. 99.6). Known risk factors include female sex, Caucasian race, preterm birth, and low birth weight. Most hemangiomas are not visible at birth but become apparent in the first few months of life and 90% are noticeable by 6 months of age.[29] Hemangiomas can occur in the subglottic region and present with biphasic stridor, presenting between 1 and 3 months of age. Similarly, parotid hemangiomas present as an enlarging mass within the parotid gland at age 1 to 3 months. Evaluation by Doppler US showing fast flow is diagnostic.

Treatment for most IH is conservative, as 90% are small, localized, and not problematic. IH can ulcerate, bleed, and cause deformities and in these cases local wound care can help.[30] Injection with steroids can stabilize the growth of IH in 95% of patients and decrease the size in 75% of patients.[31] Systemic corticosteroids were the mainstay of treatment for large or complicated lesions that become symptomatic. Topical and systemic beta-blocker therapy has also been used in the treatment of IH with varying results. Patients must be monitored closely while on propranolol therapy due to possible serious side effects.[32]

Figure 99.6 Hemangioma.

Figure 99.7 Picture of a patient with lymphatic malformation.

Lymphatic Malformation

Lymphatic malformations (LMs) are slow-flow vascular anomalies and 75% of LMs present in the head and neck. The incidence ranges from 1 in 2,000 to 4,000 births. The lymphatic system develops around week 5 of gestation and although the mechanism for the development of an LM is not completely

understood, it is generally thought to occur due to parts of the lymphatic system that fail to establish connections with the main lymphatic system or venous channels (Fig. 99.7). Histopathology of LMs shows progressive dilation of abnormal vessels, and LMs are composed of vascular spaces filled with eosinophilic and protein-rich fluid. LMs are present at birth, but sometimes are not apparent until enlargement due to infection or trauma with hemorrhage. Some patients are diagnosed with LM when found on prenatal US, and can potentially obstruct the airway and may require an ex utero intrapartum treatment procedure (EXIT procedure).

LMs are divided in microcystic, macrocystic, and mixed lesions. Microcystic lesions are usually above the mylohyoid and can involve the floor of mouth, tongue, parotid, and lip. These lesions have poorly defined borders and infiltrate nearby muscle and fatty planes. Macrocystic lesions are usually below the mylohyoid and have multiple large, loculated cysts in varying size and shape. LMs can enlarge with infection or trauma, which can lead to airway obstruction, functional issues (swallowing, speech), or deformity. Imaging can be helpful to determine the extent of the lesion as well as involvement of surrounding structures.

Treatment for these lesions is challenging and the main options include observation, sclerotherapy, or surgery. LMs are benign lesions and this must be kept in mind when planning treatment. Macrocystic lesions are more amenable to both sclerotherapy and surgical excision, whereas complete removal of microcystic lesions would often result in unacceptable morbidity due to their infiltrative nature. Subtotal resection leads to a high recurrence rate and surgery can be difficult due to previous inflammation and scarring from sclerotherapy. Radiofrequency ablation can be useful in relief of ulceration tongue lesions or oral mucosa.[33] The CO_2 laser can help with symptomatic lesions of the airway or oral cavity, which can reduce bleeding and ulceration. Recently, rapamycin has been investigated as a possible oral medication for LMs with variable results.[34]

Airway

Airway obstruction can occur from congenital or acquired lesions at any level from the nose to distal airway. Children can present with tachypnea,

dyspnea, and chest-wall retractions and it is imperative to establish an airway while investigating the potential causes with history and physical, chest radiograph, and arterial blood gas if appropriate. Laryngoscopy and bronchoscopy are often warranted.

Nasal Airway Obstruction

4 Infants are obligate nasal breathers and nasal obstruction, especially bilateral obstruction, can cause acute respiratory distress at birth.[35] Choanal atresia or stenosis, piriform aperture stenosis, or nasal septal deviation can cause significant obstruction. Piriform aperture stenosis is a narrowing of the anterior nasal passageway that can also cause similar symptoms to choanal atresia. Nasal obstruction can also result from lesions such as a nasolacrimal duct cyst, encephalocele, or nasal glioma. Nasal examination and sometimes a CT scan can help to determine the diagnosis.

Oral Airway Obstruction

Macroglossia or retrognathia/micrognathia may also cause obstruction of the oral cavity in the infant. In the oropharynx, a TGDC, a vallecular cyst, or lingual thyroid can cause airway obstruction.

Supraglottic Airway Obstruction

In the supraglottic region, laryngomalacia can affect the larynx in newborns. Laryngomalacia results from immature cartilage in the larynx and discoordination of the arytenoids and epiglottis. The diagnosis is made using a flexible laryngoscope and viewing the larynx while the patient is awake. High-pitched inspiratory stridor that is worsened with exertion, crying, or excitement is the classic description. In the absence of respiratory distress or failure to thrive, most children do not require any intervention. Supraglottoplasty can be performed when laryngomalacia causes breathing or feeding difficulties and is tailored to each airway to address the redundant or malacic tissue.

Glottic Airway Obstruction

At the level of the glottis, obstruction can occur for several reasons, including vocal cord paralysis and glottis webs. Bilateral vocal cord

paralysis can present with a normal cry but biphasic stridor, whereas unilateral vocal cord paralysis usually presents with a weakened cry and no respiratory distress. Iatrogenic injury is the most common etiology followed by idiopathic causes. In the absence of an obvious etiology, the entire path of the recurrent laryngeal nerve must be assessed from the brain to the mediastinum.[36] In bilateral vocal cord paralysis, a neurologic assessment for possible Arnold–Chiari malformation or hydrocephalus is required. A tracheotomy may be necessary for patients with bilateral vocal cord paralysis if they are in respiratory distress.

Glottic webs usually affect the anterior portion of the vocal cords and can range from a thin membrane to a thick web that can extend inferiorly to the subglottis. Patients present with dysphonia and sometimes respiratory distress. Treatment is dependent on the extent of the glottis web, which can be divided endoscopically in the majority of cases.[37]

Subglottic Airway Obstruction

The subglottis is the narrowest part of the airway in an infant due to the cricoid cartilage. Stenosis can occur congenitally or can be acquired after long-term intubation. Subglottic hemangiomas are another source of airway obstruction that enlarge after birth and are associated with segmental cutaneous hemangiomas typically in the "beard" distribution. They can be found as part of the PHACES syndrome (posterior fossa malformation, arteriovenous malformations, cardiac/aortic defects, eye anomalies, and sternal defect). Treatment can be beta blockers, systemic or intralesional corticosteroids, laser therapy via endoscopic approach, or open excision.

In patients with a prior intubation, one or multiple subglottic cysts may form and cause airway obstruction. Treatment entails endoscopic evaluation with marsupialization or removal with a laser or laryngeal microdebrider.

Tracheal Airway Obstruction

Tracheomalacia can occur in a primary or secondary form. Primary tracheomalacia is a rare congenital disease in which the tracheal cartilages collapse on expiration. Most cases of primary tracheomalacia are mild and no intervention is required, although if severe, a tracheostomy may be required. Secondary tracheomalacia occurs when an extrinsic compression

causes collapse of the trachea on expiration. Treatment is then tailored to the source of compression, whether a vascular anomaly or mass.

Tracheal stenosis can occur due to congenital complete tracheal rings and can involve a segment or the entire trachea. Depending on the extent of the stenosis, a tracheal resection or a slide tracheoplasty may be performed.

Acquired obstruction of the airway includes infectious sources, such as epiglottitis, and foreign-body aspiration. Although rare, epiglottitis is a life-threatening disease caused by *Haemophilus influenzae* type B (90% of cases) that occurs most commonly in children ages 2 to 4 years. The *H. influenzae* vaccination has reduced the number of cases, but pneumococci and beta-hemolytic streptococci can also cause epiglottitis. The disease presents rapidly, with stridor, airway obstruction, drooling, odynophagia, fever, tachypnea, and tachycardia. As the disease progresses, the child will often assume the "tripod" position by leaning forward, drooling, and suffering from air hunger. It is important not to agitate the patient and obtain an airway in the operating room with a tracheostomy set available. Depending on the stability of the patient, a lateral neck film can confirm the diagnosis with the "thumbprint" sign demonstrating an edematous epiglottis. The patient should be started on antibiotic therapy and laryngoscopies performed until the patient's epiglottis/airway edema allows for a safe extubation.

Airway foreign bodies can be life threatening and the history is of utmost importance. Combining the convincing history of a coughing/choking episode with an abnormal chest radiograph warrants a bronchoscopy. Sometimes a bronchoscopy is warranted on the history alone, as less than half of the patients with an airway foreign body have an abnormal chest radiograph.[38] If it was a witnessed aspiration, obtaining a detailed description of the object and practicing with the bronchoscopy foreign-body forceps on a similar object can be helpful if the patient is stable.

SUMMARY

Pediatric disorders of the head and neck range broadly from masses arising within the neck to anomalies of the aerodigestive tract from the nose to lungs and the lips to the stomach. The differential diagnosis of pediatric head and neck lesions includes congenital and acquired etiologies. History, physical examination, and appropriate imaging in addition to a low level of suspicion are of the utmost importance. Knowledge of the embryology and physiology of the head and neck as well as commonly encountered entities are critical to anticipating issues that children may develop.

Pediatric Chest

Robert E. Cilley and Mary Catherine Santos

Key Points

1 Pectus excavatum is repaired in late childhood or adolescence. Repair is most frequently performed with a rigid transversely oriented pectus excavatum bar that pushes the deformity back into place. Improved pain management has shortened hospital stay.

2 Pectus carinatum is less common than pectus excavatum and does not cause physiologic impairment; external compression bracing has become the method of choice for treatment.

3 Pulmonary sequestrations (PSs) are abnormal lung tissue with anomalous systemic blood supply that can be either intralobar or extralobar based on their relationship with the investing visceral pleura and adjacent lung tissue. They do not communicate normally with the trachea or a bronchus.

4 Congenital cystic adenomatoid malformations (CCAMs) have a normal vascular supply and communicate with the normal tracheobronchial tree. They result from excessive proliferation of bronchial structures without the development of the corresponding alveoli. Management of asymptomatic CCAMs remains controversial. Thoracoscopic lobectomy is commonly performed.

5 Benign cysts of the mediastinum are relatively common and include thymic cysts, enterogenous cysts, dermoid cysts, lymphatic malformations (cystic hygromas), and pericardial cysts. Resection is usually recommended because of the possibility of progressive enlargement with compression, hemorrhage, or infection.

6 Primary lung tumors in children are rare and include bronchial adenoma, pleuropulmonary blastoma, inflammatory pseudotumor, hamartoma, and rarely bronchoalveolar carcinoma. Resection is usually required.

7 Metastasectomy for many solid embryonal neoplasms can improve survival if the primary disease is controlled by resection.

8 Tracheoesophageal fistula (TEF) can occur as esophageal atresia with proximal pouch and distal TEF (most common, 85% to 95%), esophageal atresia without fistula (“pure esophageal atresia,” 5% to

7%), TEF without esophageal atresia ("H-type fistula," 2% to 6%), and rarer forms of this anomaly including esophageal atresia with proximal TEF and esophageal atresia with both proximal and distal TEF.

9 Approximately 75 children die from foreign-body aspiration or ingestion each year. Bronchoscopic evaluation and foreign-body removal are performed in the operating room under general anesthesia, where the rigid bronchoscope with optical forceps can be used to remove most aspirated foreign bodies safely. "Button battery" ingestion has emerged as a cause of serious injury and death. Emergent endoscopic removal from the esophagus is required.

10 Congenital diaphragmatic hernia (CDH) is a physiologic emergency and not a surgical emergency. The newborn with CDH should be stabilized by nonsurgical means and delayed, well-planned surgical repair undertaken subsequently. Pulmonary hypertension and lung hypoplasia determine outcome.

CHEST WALL DEFORMITIES

Deformities of the chest wall may be obvious at birth but often become more noticeable at the time of preadolescent and adolescent growth. The physical appearance may vary from barely detectable to severely deforming. Although there may be some physiologic benefit from surgical correction of these deformities, restoration of a more normal appearance is equally important in the decision to treat. The impact of these deformities on normal psychosocial development, as well as evidence of cardiorespiratory impairment, justifies correction.

Embryology, Development, and Etiology of Chest Wall Deformities

Ribs are derived from individual somites as mesoderm differentiates into cartilage and advances ventrally toward the developing sternum. Rib cartilage eventually approaches the sternum. The sternum is derived independently from two parallel bands of mesoderm that develop away from the midline. The two sternal bands fuse cranial to caudal and become progressively chondrified. Transverse divisions of the cartilaginous sternum differentiate into segments opposite each end of the rib pairs. At birth, small ossification centers are present in the sternum; the ribs have largely ossified. Final ossification is usually complete by mid adolescence. The timing of sternal ossification is sufficiently predictable to be a reliable method of determining bone age. There is a sharp demarcation in each rib between the ossified portion and the cartilaginous portion, with the latter becoming ossified only much later in life. The etiology of chest wall deformities is uncertain.[1] Abnormal intrauterine pressure applied to the chest, abnormalities of diaphragmatic development, connective tissue abnormalities, and genetic predisposition may contribute. Abnormal, excessive, or asymmetric growth of the costal cartilages associated with the 3rd to 10th ribs is most implicated.[2] Sternal clefts result from a failure of fusion of portions of the sternal bands.

Pectus Excavatum

Pectus excavatum from the Latin “hollowed chest” is the most common deformity of the anterior chest wall occurring in 1 in 400 to 1 in 1,000 children, accounting for the majority of chest wall deformities. A family history is present in half.[2,3] There is male predominance. Pectus excavatum results from abnormal regulation of the growth of the costal cartilages. There is a corresponding posterior curve in the body of the sternum beginning at the manubrium and extending to the xiphoid. The deformity is rarely precisely symmetric, with one side (usually the right) slightly more curved in than the other. Asymmetry may be pronounced with the sternum rotated nearly to the sagittal plane. The deformity may be apparent at birth but often becomes more apparent during adolescence. Scoliosis is increased in this population although rarely needs surgical correction. Patients often have an asthenic build and stoop-shouldered posture. Connective tissue disorders are

associated with pectus excavatum. The diagnosis of Marfan syndrome should be considered.

Concerns about cardiopulmonary implications are often paramount in the mind of the referring physician as well as the family. Many patients will have complaints of chest pain and/or shortness of breath. Most patients are disturbed by the appearance of the deformity, and some may be profoundly depressed and dysfunctional. The physiologic consequences of the deformity are less certain. Invasive and echocardiographic assessment of cardiovascular performance has demonstrated improvement in cardiac function and resolution of mitral valve prolapse in some patients following surgical correction of pectus excavatum. Studies have also demonstrated improved body image and subjective physical ability.[2–9] The cardiorespiratory benefits of the repair remain controversial with more recent studies demonstrating improvement after bar removal especially with dynamic testing.[9] Multiple studies confirm patient and parent satisfaction.[2–12] Clinical assessment of the severity of the deformity has included chest radiographs, computerized tomography (CT), caliper measurements, contrast volume measurements of the cavity, and more recently 3-dimensional image scanning. Indices, including the "Haller Index," the Compression Index, and the Depression Index help quantitate the deformity.[7] An echocardiogram is usually indicated. Pulmonary function testing may be helpful.

Surgical Correction of the Pectus Excavatum

1 Although pectus excavatum may be present in infants and young children, repair should be deferred to adolescence to avoid recurrence and acquired thoracic dystrophy.

"Open" Operations

Traditional "open" surgical correction was performed through an inframammary incision (Fig. 100.1). The operation requires the exposure of costal cartilage by elevation of the pectoral muscles from the chest wall. The involved cartilages usually from 3 to 7 and parts of 8, 9 and 10 are removed by subperichondrial excision, with careful preservation of the perichondrial sheaths. The xiphoid is detached from the sternum and the rectus muscles are

detached inferiorly. The undersurface of the sternum is dissected free of the pericardium and pleura. A transverse wedge osteotomy is created in the sternum at the point where the sternum deflects posteriorly and the posterior surface is gently fractured. A strut is usually placed beneath the sternum to maintain the position of the sternum. The strut, typically a stainless steel bar, is removed in 6 months to 1 year.[2] The pectoral and rectus muscles are reapproximated. Closed suction drains are usually left in place in the submuscular layer. Pain is controlled using multimodal techniques. Complications may include pneumothorax, wound seromas, pleural effusions, and recurrence. Migration of implanted struts and bars has caused the most serious problems, including cardiac injury.

Minimally Invasive Repair/Nuss Procedure

Since its description in 1998 by Nuss, the minimally invasive repair has gained widespread popularity. Conspicuous incisions, resection and osteotomies are avoided. Using small lateral incisions, one or two rigid U-shaped bar is inserted transversely across the chest and then "flipped." The sternum is pushed back into a normal position (Fig. 100.2).[13] Modifications of the technique including the use of stabilizers, and routine use of thoracoscopy to guide bar insertion[2,11,14] reported complications include pneumothorax, cardiac injury, bar displacement, chronic pain, pericarditis, allergic metal reactions and extraosseous bone formation.[14] Multimodal postoperative pain management and intercostal nerve cryoablation shorten hospital stay.[15,16] The bar is left in for up to 3 years during a period of development when most children are active and may engage in contact sports. Graded activity restrictions allow return to normal activity while the bar is in place. Recent studies have demonstrated that the early-to-late teenage years are the appropriate time for repair.[10,17] Older teenagers and young adults can also be repaired.[18]

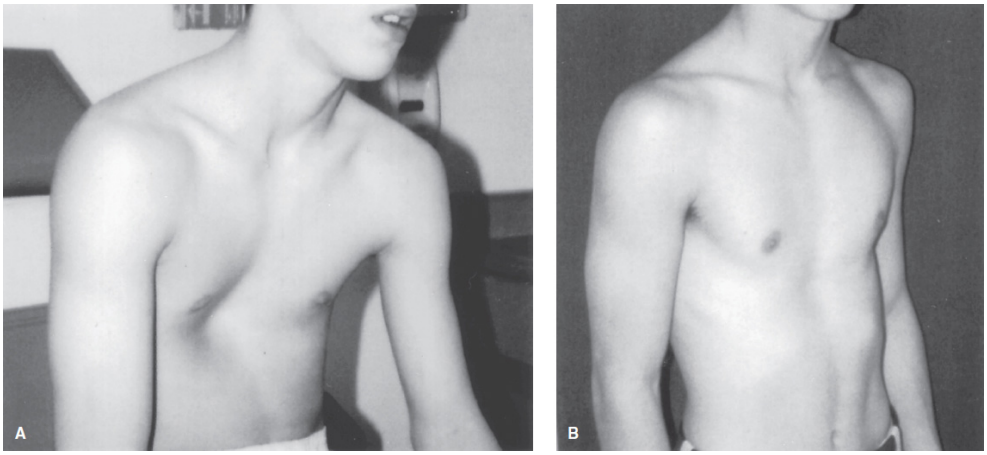

Figure 100.1 Pectus excavatum. **A:** Appearance of an adolescent male with a typical depression deformity. Note "stoop-shouldered" posture. **B:** Postoperative appearance at 6 months. Erect posture and subpectoral incision give a good cosmetic result.

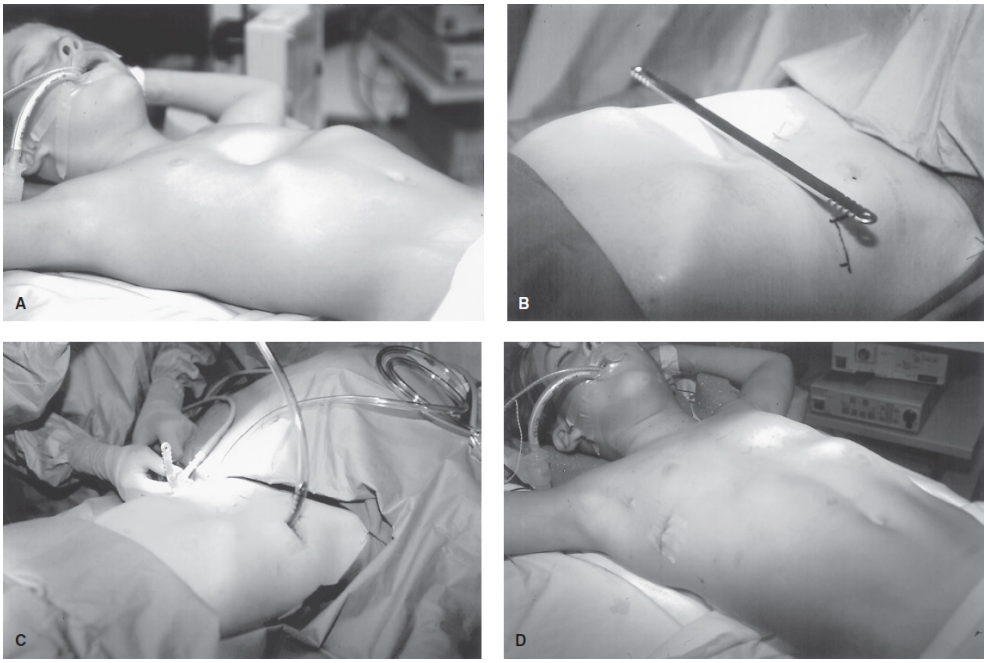

Figure 100.2 Thoracoscopically assisted Lorenz Bar insertion (Nuss procedure). **A:** Preoperative appearance with symmetrical depression deformity. **B:** Lorenz bar. **C:** Pectus excavatum bar inserted with thoracoscopic guidance. **D:** Immediate postoperative appearance. (Digital images provided by William Hardin, MD, University of Alabama, used with permission.)

Other Techniques

Implantation of submuscular silastic molds to alter the chest contour may result in a very acceptable appearance.[19] This technique does not address any of the potential physiologic problems associated with pectus excavatum and has not been used widely.

Externally applied suction may also be used to treat depression deformities of the chest wall and implanted devices that use magnetic forces to pull the sternum forward show promise in correcting the pectus excavatum defects.[20,21]

Pectus Carinatum

2 Pectus carinatum, from the Latin word for "keel," is a chest wall defect where there is a protrusion of the sternum and ribs. This type of defect occurs less commonly than pectus excavatum and is present in 1 in 1,000 to 1,500 teenagers. Physiologic impairment is absent; however, the concern for appearance may be even greater than with depression deformities of the chest wall. Protrusion deformities may be very difficult to hide even when fully clothed. Rapid growth of the costal cartilages occurring during puberty makes the deformity more pronounced at that time. Compression bracing is the first choice for correction of most pectus carinatum deformities, with surgery reserved for failures of therapy.[22,23] Bracing is most successful when performed for more than 16 hours per day. Surgical correction involves costal cartilage resection and sternal osteotomies. Minimally invasive techniques use a bar passed anterior to the sternum.[24]

Poland Syndrome

Named after the English surgeon Sir Alfred Poland, this rare congenital syndrome occurs in 1 in 30,000 births and includes a hypoplasia or aplasia of the thoracic wall components. These features may include absence of the sternal portions of the pectoralis major muscle; absence of the pectoralis minor muscle; absence of portions of the serratus anterior and external oblique muscles; forearm and hand deformities; ipsilateral hypoplasia of the nipple, breast, and chest wall subcutaneous tissues; absence or deformity of the second to fifth costal cartilages; and absence of axillary hair on the affected side. Surgical treatment includes correction of any deformed ribs,

formation of the anterior axillary fold using the latissimus dorsi muscle, and creation of the ipsilateral breast in females.[25,26] Minor forms of this developmental abnormality are more common.

Sternal Clefts

Congenital sternal clefts result from failure of midline fusion of the paired sternal bands. The cleft is usually in the superior portion of the sternum and may extend to but not include the xiphoid. The defects are rare and are usually repaired in the neonatal period when the chest is more pliable.[27] The purpose of the correction is to protect the underlying mediastinal structures. After subcutaneous and substernal mobilization, the fibrocartilaginous sternal bars are approximated in the midline. If the cardiac structures are at risk, more elaborate repairs are required. Typically, the cleft is incomplete and a V-shaped excision of the sternum at the most inferior aspect of the cleft may be required to avoid buckling of the sternum.[27] Pentalogy of Cantrell refers to a distal sternal cleft, omphalocele, diaphragmatic defect, pericardial defect, and intracardiac defect. Thoracic ectopia cordis (exstrophy of the heart) may occur as a part of this abnormality and this spectrum continues to have a high mortality.[27]

Jeune Asphyxiating Thoracic Dystrophy

Jeune asphyxiating thoracic dystrophy is a rare developmental abnormality that results in the failure of chest wall growth. Traditional surgical procedures have involved sternotomies with placement of graft material to expand the chest. More recently, a vertically expandable prosthetic titanium rib (VEPTR) device has been used. The posterior aspect of the ribs (typically 3–9) is divided along with the costochondral junction. The rib plate is then elevated to the curved VEPTR strut by wires, thus expanding the chest. This is done for both chests, and the device is serially expanded to promote chest enlargement.[28,29]

The “Slipping Rib” Syndrome

Slipping rib syndrome is an unusual cause for recurrent lower chest and upper abdominal pain. The cause is likely an inadequacy or rupture of interchondral fibrous attachments of the 9th or 10th rib. The symptoms tend to be a popping or clicking sensation with truncal movement associated with pain. Pain is usually reproducible with manipulation of the rib cartilage anteriorly. Surgical therapy involves excision of the affected rib and cartilage relieving pressure on the involved intercostal nerve.[30,31]

"Flaring" of the Costal Margin

Patients are sometimes referred for surgical opinions regarding unusual prominence of the costal margin. The "flaring" is most pronounced when the patient is supine. This finding represents a variation of the normal development of the chest wall. Surgical correction is usually unnecessary.

Costochondral "Tumor"

Prominence of a single costal cartilage may raise a concern of a tumor of cartilage or bone. This abnormality is usually found in preadolescents and adolescents. Patients may have undergone a diagnostic workup that includes chest radiographs, ultrasound, CT, or magnetic resonance imaging (MRI) prior to surgical consultation. This abnormality most likely represents a minor variation of a chest wall deformity, such as a pectus carinatum. The area of enlargement is rarely tender so that costochondritis is an unlikely explanation. Excision of the involved cartilage is rarely helpful. Plain radiographs or thoracic imaging are usually sufficient to exclude a tumor.[32]

CONGENITAL LUNG LESIONS

Congenital lung lesions have been characterized as lesions of defective budding, differentiation and separation of the foregut, as well as airway maldevelopment with resultant obstruction.[33,34] These lesions include pulmonary sequestration (PS), congenital pulmonary airway malformation (CPAM; formerly CCAM), bronchogenic cyst (BC), and congenital lobar overinflation (CLO). The first three are in the family of bronchopulmonary

foregut malformations. PS is characterized by aberrant blood supply, CPAM by hamartomatous lung parenchyma, and BC by an isolated cyst. There is overlap among the types; many lesions are found to be hybrid.[33,34] CLO is likely a secondary response to abnormal compression or obstruction of a bronchus during lung development.

Pulmonary Sequestration

3 PSs consist of nonfunctioning pulmonary tissue without a normal bronchial communication with the tracheobronchial tree. The blood supply is from an aberrant systemic vessel often originating from the descending aorta. The lesions are most commonly found in the lower lobes, more commonly on the left. They are characterized as intralobar or extralobar based on pleural lining.

Intralobar sequestrations are incorporated into the surrounding lung and are invested by its visceral pleura. They are most common in the left medial or posterior basal segment of the lower lobe. The arterial supply is from the descending aorta and the venous return is usually into a pulmonary vein. Usually asymptomatic at birth, but aberrant air space connections can result in recurrent pneumonia.

Extralobar sequestrations occur outside of the pleura of the normal lung. They are most common in the lower left side of the chest but have been reported in a variety of locations including the retroperitoneum.[33–35] In the retroperitoneum, they may be difficult to distinguish from neuroblastoma. These have occasionally been associated with congenital diaphragmatic hernia (CDH). In 20% of cases, the blood supply originates from the infradiaphragmatic aorta. Arteriovenous shunting in rare cases can lead to high output heart failure.

Radiographic evaluation of PS involves chest radiographs, ultrasound, and CT scans with contrast enhancement to identify the vascular supply. Intralobar sequestrations are treated with lobectomy. Extralobar sequestrations may be removed by excision of the sequestration. The lesions may be removed with thoracotomy or thoracoscopy with attention to safe ligation of the vascular supply (Fig. 100.3).[33–39]

Congenital Pulmonary Airway Malformations

4 CPAMs result from overgrowth of bronchial structures at the expense of the associated alveoli associated with an abnormal supplying airway affecting a single lobe in 95% of cases. This group of anomalies represents 30% to 40% of the developmental lung bud anomalies. On gross appearance, they can be solid, cystic, or both. The malformations have a normal blood supply and communicate with the normal tracheobronchial tree. The common classification separates these lesions into three main types. Type I CPAMs consist of cysts with large, irregular widely dispersed spaces larger than 2 cm or a single large cyst with multiple small surrounding cysts and represent 50% to 65% of postnatal cases. Type II CPAM is described as numerous smaller cysts (0.5 to 2 cm) and account for 10% to 40% of cases. Type III CPAMs are made of small cystic lesions (generally 0.2 cm) or solid lesions appearing similar to immature lung devoid of cartilage and make up of 5% to 10% of cases. CPAMs generally affect one lobe but multilobar and bilateral involvement occurs. Most commonly, the lesions are left sided and affect the lower lobes. Prenatal diagnosis is common and has led to an increase in diagnosis of lung lesions.[44] CPAMs may compromise fetal cardiac function leading to hydrops that can be life-threatening. Fetal surgery has included open resection and thoracoamniotic shunting with survival of some of the affected fetuses.[33,42] The natural history of prenatally diagnosed CPAMs is variable and even large lesions may regress. Growth tends to plateau at 26 to 28 weeks of gestation.[35,40]

The incidence is reported to be between 1:25,000 and 1:35,000 live births which likely underrepresent the incidence. Although 80% are asymptomatic at birth, many will have respiratory symptoms within the first month of life.[35] Less commonly, patients may present with pneumonia later in life (Fig. 100.4).

Symptomatic lesions require resection of the involved lobe. Those with severe respiratory compromise may require resection on extracorporeal membrane oxygenation (ECMO) with excellent results. Other infants may benefit from an ex utero intrapartum treatment (EXIT) to ECMO approach when gas exchange is predicted to be compromised at delivery[40,41] Best treatment for asymptomatic lesions is less certain as the natural history of the lesion is unknown. There is concern for future infection and the possibility of

malignancy.[33,34,40–42] Those who recommend resection favor timing between 2 and 10 months of age. With antenatal diagnosis, a CT is used to assess resolution and to aid preoperative planning. Thoracoscopic resection has become the standard. With multilobar and bilateral disease, CT scans assist in planning lung-preserving resections. Bilateral and multilobar lesions are associated with the development of pleuropulmonary blastoma.[33]

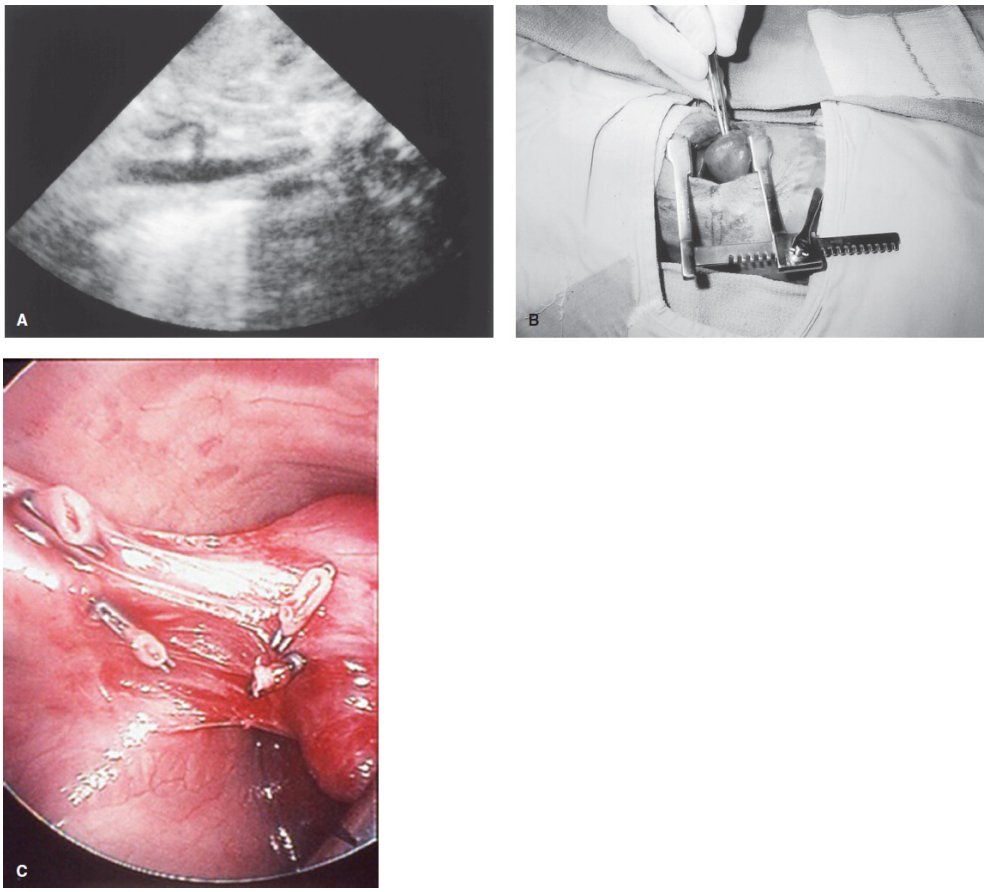

Figure 100.3 Pulmonary sequestration (PS). **A:** Sagittal ultrasound view of the aortic branch supplying an extralobar PS. **B:** Left-sided extralobar PS excised via a muscle-sparing thoracotomy. **C:** Intraoperative view of extralobar sequestration removed thoracoscopically. Note the main blood supply with clips.

Bronchogenic Cysts

BCs are uncommon anomalies arising from defective foregut development. They can be mediastinal or intrapulmonary and cause symptoms of cough as well as recurrent and chronic infection. These cysts appear as discrete masses and develop associated with the esophagus or large airways. They

are usually extrapulmonary and do not communicate with the normal tracheobronchial tree. Resection via thoracotomy or thoracoscopy is recommended due to the risk of bleeding, infection, or enlargement with compression of adjacent structures (Fig. 100.5).[33,43,44]

Congenital Lobar Overinflation

CLO (previously called congenital lobar emphysema) is caused by abnormal development or compression of a lobar bronchus resulting in retention of fluid during fetal lung development and subsequent air trapping and overinflation after birth. The cause ranges from a deficiency of bronchial cartilage to compression from an extrinsic mass. They usually involve the upper lobe of either lung and are rarely multilobar. A definitive cause is rarely identified. Lobar overinflation may present as worsening respiratory distress caused by enlargement of the overinflated segment with compression of the normal surrounding lung (Fig. 100.6). Symptomatic infants should undergo complete resection of the lobe. Care must be taken at resection as positive-pressure ventilation may worsen symptoms and require immediate thoracotomy. With relatively asymptomatic patients, symptoms may improve and surgery avoided.[33,34,45]

Diagnosis

Due to the routine use of prenatal ultrasound, many cystic lesions of the lung are now detected and followed prior to birth.[33–35,46–48] Patients with these lesions may be asymptomatic in the perinatal period. Standard chest radiographs remain the standard for diagnosis and follow-up. Rapid thoracic CT scanning with contrast provides definitive mapping of the lesions including demonstration of aberrant vessels. Contrast esophagograms are indicated for children with dysphagia and suspicion of connection with the GI tract. In lesions with suspected aberrant blood supply, MRI angiography can be helpful if the CT is not definitive.

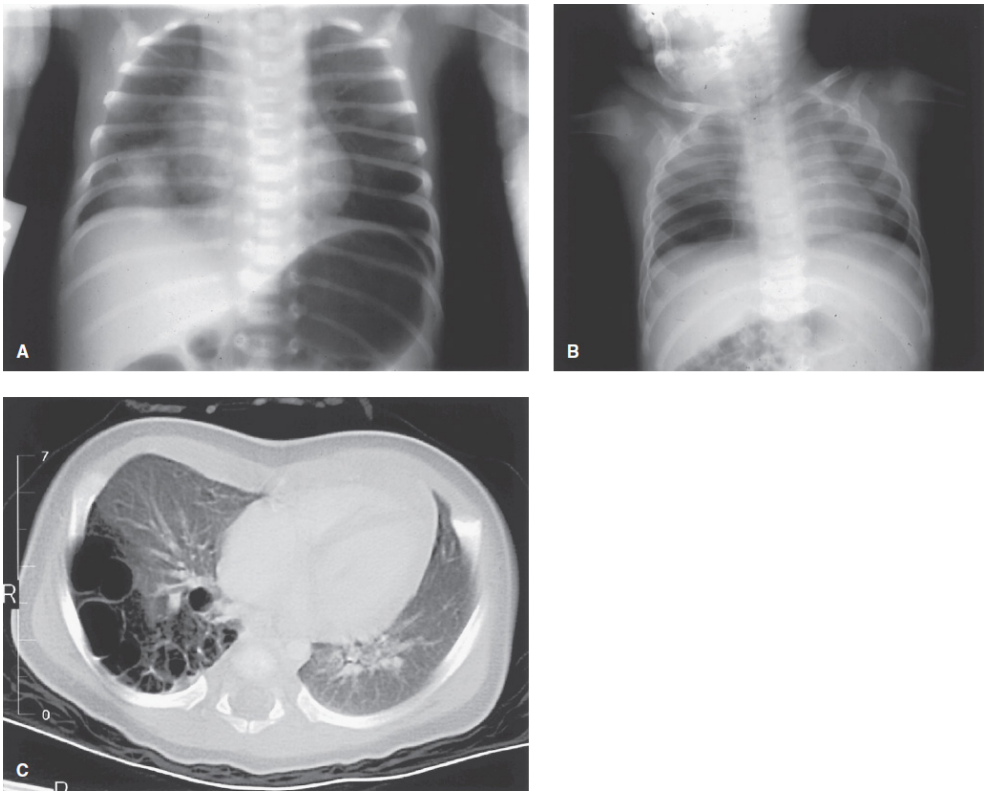

Figure 100.4 Congenital cystic adenomatoid malformation (CCAM). **A:** Newborn chest x-ray of a patient with prenatal diagnosis of CCAM. Note that immediately after birth, the mass is fluid filled and appears as a density in the right hemithorax. **B:** Chest x-ray of the same child at 5 months of age prior to surgical excision. Note the air-filled cystic appearance of CCAM. **C:** Transverse thoracic computerized tomographic view of CCAM.

Cysts of the Mediastinum

5 Benign cysts of the mediastinum are relatively common in the pediatric population. Most of these are relatively asymptomatic but surgery is usually recommended due to the possibility of enlargement with symptoms related to compression, hemorrhage, or infection. The symptoms which occur include cough, chest pain, stridor, hemoptysis, or dysphagia. The common lesions include thymic cysts, enterogenous cysts, lymphatic malformations (cystic hygromas), and pericardial cysts.

Thymic Cysts

Thymic cysts present in the neck and mediastinum and are usually unilocular but may be multilocular. They are most commonly seen in the anterosuperior mediastinum. They are benign lesions with presence of cholesterol granulomas. Symptoms may arise from rapid expansion due to infection. Resection is recommended.[47,48]

Enteric Duplication Cysts/Enterogenous Cysts

Enteric duplication cysts are usually located in the posterior mediastinum with microscopic evidence of double-layer smooth muscle and esophageal or gastric mucosa. They are from the same spectrum as bronchopulmonary cysts. These may communicate with the stomach or esophagus and may transverse the diaphragm. The cysts may also extend into the spinal canal.[47,48] The lesions may have gastric mucosa leading to bleeding. Other symptoms may include airway compression or dysphagia (Fig. 100.7). Resection is indicated for all symptomatic lesions and is favored for asymptomatic lesions.

Lymphatic Malformations

Lymphatic malformations (cystic hygromas) are unilocular or multilocular cysts which are thin walled and derived from failure of adequate drainage of embryonic lymph sacs. These may occur in the head, neck, and mediastinum. The lesions insinuate around great vessels and nerves in the superior mediastinum. The incidence is 1 in 6,000 live births. Symptoms if present are related to enlargement (frequently due to hemorrhage) or infection. Treatment options include resection and intralesional sclerotherapy. Immunomodulating drugs such as sirolimus may have a role in some cases.[49] The most frequent complications are recurrence and accumulation of lymph in the resection bed.[46–48]

Pericardial Cysts

Pericardial cysts are asymptomatic usually found incidentally on chest radiograph. The cysts are found in the cardiophrenic sulcus as a discrete mass. They are thin walled with a flat mesothelial lining and contain clear fluid. Resection can be performed with thoracotomy or thoracoscopy.[46,48]

THORACIC TUMORS IN CHILDREN

6 Thoracic tumors are rare in children and diagnostic evaluation must include evaluation for both primary and metastatic conditions. Tumors may occur in the lung or the mediastinum.[50] Primary lung neoplasms in children are extremely rare.[50,51] Metastatic lung lesions are more common in the

pediatric population.[50,51] Mediastinal tumors reflect the nature of the section of the mediastinum in which they arise. Diagnostic evaluation begins with routine radiographs with CT scans and MRIs for further evaluation.[50–52]

Metastatic Lung Tumors

7 Resection of metastases in the pediatric population has been proven to be beneficial for pediatric cancers. Eradication of the primary tumor and absence of other metastases are necessary for improvement in survival.[58] Resection is considered most frequently for osteogenic sarcoma, soft tissue sarcoma, and Wilms tumor.[53,54]

Osteogenic Sarcoma

There is good evidence that resection of metastases in osteogenic sarcoma improves survival if a complete resection can be performed. The factors which improve survival are ipsilateral involvement, smaller tumor size, and longer disease-free survival between diagnosis and occurrence of metastasis.[55,56] Metastases which are more peripheral have a better outcome compared with centrally located metastases.[55,56] In addition to metastectomy, chemotherapy is required for elimination of micrometastatic disease. Metastases become calcified and therefore are palpable aiding with resection. There are some data that the outcomes are comparable between initial resection of metastases and resection of a second recurrence.[55,56] Improved survival is seen with tumor necrosis greater than 98% and disease-free interval of greater than 1 year. Thoracoscopy is inferior to thoracotomy since CT scans underestimate the number of lesions which can be directly palpated at thoracotomy.[55,56] Bilateral lesions can be identified even when CT scans demonstrate only unilateral lesions leading some authors to recommend prophylactic contralateral thoracotomy.[57]

Soft Tissue Sarcomas

Nonrhabdomyosarcomas such as synovial sarcoma respond poorly to chemotherapy and radiation therapy. In these tumors, complete resection of pulmonary metastases, but not debulking, improves survival.[58–61] Lung

metastasis in rhabdomyosarcoma responded to chemotherapeutic regimens but local treatment of the metastases did not improve survival.[60] Ewing sarcoma has a high rate of pulmonary metastases which have traditionally been treated with radiation therapy. More recent data suggest that metastectomy after irradiation leads to improved survival.[61] Delayed surgery after neoadjuvant therapy with resection of the chest wall lesion leads to decreased extent of excision and a higher rate of negative margins in tumors less than 8 cm.[61]

Wilms Tumor

Pulmonary metastectomy in Wilms tumor is only indicated for persistent lesions after chemotherapy and radiation therapy.[62] Thoracoscopy with resection of lesions is indicated for diagnostic purposes.[63]

Primary Lung Tumors

Pediatric primary tumors are rare (Table 100.1). The majority of primary neoplasms are malignant but benign lesions also have significant morbidity due to location of the lesions. Operative exploration with total resection of all involved tissues is recommended.[64]

Bronchial Adenomas

Bronchial adenomas are the most common of the malignant lung lesions (40%) in the pediatric population and include several different histologies including carcinoid tumor (85%), mucoepidermoid carcinoma (10%), and adenoid cystic carcinoma (5%). Cough, pneumonitis, fever, respiratory distress, and hemoptysis are the most common presenting symptoms. Delay in diagnosis is common due to the nonspecific symptomatology. The disease is diagnosed with chest radiograph followed by CT scan. Bronchoscopy is required for diagnosis and biopsy can be performed but there is a high risk of hemorrhage. Treatment is by surgical resection which can include lobectomy, bilobectomy, pneumonectomy, or sleeve resection with regional lymphadenectomy. Intraoperative frozen section is useful to assure complete resection and to limit lung resection. Endobronchial cryoablation may reduce

tumor size, permitting less extensive resection. Carcinoid syndrome is rare and a sign of extrapulmonary disease.[65]

Table 100.1 Primary Pulmonary Neoplasms

Type of Tumor	CT Findings
Benign	
Inflammatory myofibroblastic tumor	Well-defined solitary masses, peripheral and lower lobe, amorphous or dystrophic calcification
Pulmonary hamartoma	Well-circumcised, peripheral, intralesion fat and calcifications
Primary sclerosing hemangioma	Well-defined smooth round or oval enhancing mass adjacent to pleura
Subglottic hemangioma	Mass in subglottic trachea with early intense contrast enhancement
Recurrent respiratory papillomatosis	Numerous nodular lesions within the airway
Malignant	
Pleuropulmonary blastoma	Varied appearance, peripherally located, often multiple lobes, usually right
Adenocarcinoma	Solitary nodule to complete opacification of lung, ground glass to solid
Kaposi sarcoma	Bilateral perihilar opacities and large pleural effusions
Carcinoid and other neurendocrine	Well-defined lobulated endobronchial mass with marked enhancement, calcification 30%
Mucoepidermoid carcinoma	Central mass or endobronchial nodule, calcification 50%

Bronchogenic Carcinoma

Bronchogenic carcinoma is the second most common malignant lung tumor in children. Bronchogenic carcinoma consists of adenocarcinoma and undifferentiated carcinomas in the pediatric population. These tumors have been associated with CPAMs but have been reported in normal lung as well.[56,70] Human papilloma virus has been associated with the squamous cell variant. Resection with ipsilateral lymphadenectomy is the treatment of choice. Prognosis for bronchogenic carcinoma is poor as the presentation tends to be with advanced stages. Symptoms are related to metastases with bone pain or tumor burden with weight loss.[52,64]

Pleuropulmonary Blastoma

Pleuropulmonary blastoma is the third most frequent lung tumor in children and is most common in children under 4 years of age.[52,66,67] The lesion consists of mesenchymal elements and embryonal stroma without epithelial neoplasia. The tumor is known to be part of the spectrum of tumors related to the mutation of the DICER1 gene.[68] The tumor usually presents peripherally. These tumors are associated with CPAMs. There are three types: type I consisting of multilocular cysts, type II consisting of a combination of cystic and solid components, and type III having proliferating mesenchyme without cysts.[66,67] Treatment is with resection and adjuvant chemotherapy. Survival in type I has been reported at 91% while type II/III have survivals of 43%.[66,67] A Pleuropulmonary blastoma registry has expanded understanding of this tumor.[67]

Other Malignant Tumors

Sarcomas, including fibrosarcoma, rhabdomyosarcoma, and leiomyosarcoma, are the next most common primary malignant lung neoplasm in children. These have been reported to arise in documented cystic disease.[50,52,69] Inflammatory pseudotumor is considered to be the most common “benign” tumor in children. The tumor is a myofibroblastic spindle cell soft tissue tumor with infiltrative plasma cells, lymphocytes, and eosinophils. Recently these have been classified as intermediary lesions with

a molecular rearrangement involving the tyrosine kinase receptor anaplastic lymphoma kinase. Symptoms are nonspecific such as fever, chest pain, cough, and recurrent pneumonias.[50,52,69] They may present as an endobronchial lesion but are more often peripherally located. The lesion may invade local structures and be aggressive locally and may recur locally but spontaneous regression has been reported. Complete resection is recommended as no adjuvant regimen has gained widespread acceptance. Nonsteroidal anti-inflammatory agents have been utilized with some success (Fig. 100.8).

Hamartoma

Hamartomas are lung nodules composed of cartilage and gland-like formations in an irregular and haphazard orientation. They grow slowly and are the most common benign lesion in adults but the second most common in children.[50,53,69] Radiographically, they have a "popcorn" calcification in 10% to 25% of cases. The majority are located in the periphery of the lung. Conservative surgical resection is recommended. These may be associated with gastric smooth muscle tumors and extra-adrenal paragangliomas (Carney triad) in adolescent females; and in this age group, a workup should be performed to exclude these diagnoses.

Mediastinal Tumors

Mediastinal tumors in the pediatric population can be benign (63%) or malignant (37%).[51,71,72] Neurogenic tumors are the most common, arising in the posterior mediastinum from the sympathetic ganglia, intercostal nerves, and paraganglia cells.[51,70–72] They may grow very large before detection and may manifest with Horner syndrome or opsoclonus–myoclonus syndrome. Malignant neurogenic tumors include neuroblastoma and ganglioneuroblastoma. Benign tumors include ganglioneuroma, schwannoma, or neurofibroma.[51,70] Neuroblastoma originating in the mediastinum has a better prognosis than other sites. These tumors have more favorable biology and lower rates of N-myc amplification as well as improved rates of event-free and overall survival.[71] Diagnosis is by CT and MRI with MRI allowing improved assessment of extension into the spinal foramina.[51,70,71] Tumors

may be resected by a thoracoscopic approach or via thoracotomy (Fig. 100.9).[73,74]

Neurofibromas and schwannomas arise from intercostal nerves or sympathetic nerves. The schwannomas are encapsulated without nerve fibers within the tissue. Neurofibromas are unencapsulated, have nerve fibers running through the mass, and are common in patients with neurofibromatosis.[73] Isolated tumors may be removed but tumors associated with neurofibromatosis tend to extend over nerve sheaths precluding complete removal. These are associated with malignant degeneration.

Lymphomas arise in the anterior and middle mediastinum and are the most common anterior mediastinal mass in children.[51,70,72] They are usually inhomogeneous and resection is not required. Both Hodgkin and non–Hodgkin lymphoma arise in the mediastinum. Diagnostic workup involves biopsy for tissue diagnosis as the diagnosis often requires tissue subtyping.[75] Due to risk of airway compromise, the most accessible tissue, such as supraclavicular lymph nodes, should be biopsied and special care is required for biopsy of the mediastinum including partial upright positioning, spontaneous ventilation, availability of rigid bronchoscope, and avoidance of muscle relaxants. Risk of airway compromise is increased in patients with greater than 50% reduction in tracheal cross-sectional area, or those with dyspnea and orthopnea. Treatment is chemotherapy.

Teratomas are the most common mediastinal germ cell tumor and are composed of all three germinal cell layers.[51,70,72] They are typically benign, usually cystic and encapsulated. They frequently contain calcification on radiography (Fig. 100.10). Most are asymptomatic but symptoms can include stridor, tachypnea, and respiratory distress especially when lying supine.[70,72] The cysts frequently contain mature ectodermal elements such as hair, skin, and neuroglial elements and may contain bone, teeth, and fat. The tumors may be large and tend to displace rather than invade surrounding tissue.[51,72] Workup includes preoperative measurement of α-fetoprotein and β-HCG. Resection is the treatment of choice and confirms the diagnosis. Treatment of mature teratomas is resection. Immature teratomas which contain malignant elements are treated with chemotherapy and radiation in addition to surgery.

Other mediastinal tumors are very rare but often require surgical biopsy or extirpation. These include neurolemmoma, pheochromocytoma germ cell tumors, rhabdomyosarcomas, and thymic tumors.

Chest Wall Tumors

Ewing sarcoma, chondrosarcoma, and liposarcoma are malignant tumors which may arise from the chest wall. Local resection may require extensive chest wall excision and prosthetic reconstruction.[76] Primitive neurectodermal tumors are malignant small cell tumors carrying a poor prognosis. Improvement in survival is accomplished with multimodal therapy which includes chemotherapy, radiation, and surgery with aggressive management of pulmonary metastases.[76]

Respiratory Papillomatosis

Recurrent respiratory papillomatosis is caused by neoplastic proliferation associated with acquisition of papillomavirus during delivery. It is usually confined to the larynx and upper tracheal airway with spread in less than 1% of cases. Treatment is with laser ablation and may require multiple treatments. Prognosis is poor due to the recurrence of the disease.[50,65,69]

ESOPHAGEAL ATRESIA/TRACHEOESOPHAGEAL FISTULA

The first description of esophageal atresia was by Durston in 1670 who found a blind esophageal pouch in one pair of thoracopagus conjoined twins.[77] The first description of the classic proximal esophageal atresia with distal fistula was by Thomas Gibson in 1697. Initial attempts at repair or palliation were unsuccessful. Leven and Ladd reported survivors but only after staged reconstruction. The first successful primary repair was reported by Cameron Haight in 1941.[78,79] Outcomes have improved related to refinements in surgical technique and postoperative care.[77,80–84] In the modern era, survival is related to the degree of prematurity and the presence of cardiac disease.

Embryology

The development of the human respiratory system begins as a folding of the flat endodermal layer into the primitive gut tube. The respiratory system is derived from the foregut endoderm with the appearance of the laryngotracheal groove in the ventral floor just caudal to the level of the pharynx. The precise morphogenic events that follow are not well understood. The respiratory system may develop as a rapid outgrowth from

the original foregut tube. The fusion of the lateral foregut walls separating the trachea from the esophagus may also contribute.[85,86] TEF is caused by failure of tracheal growth and failure of the active separation of the trachea and esophagus. Sonic hedgehog patterning gene has been implicated in the development of esophageal atresia/TEF based on adriamycin-induced malformations in rats.

Classification

8 Descriptive terminology is used to indicate the anatomic configuration of a patient with esophageal atresia. The most common type of lesion is a proximal atresia with a distal TEF which accounts for 76% to 85% of all cases in recent series.[80–84] Esophageal atresia without fistula occurs in 3% to 17% (referred to as "pure esophageal atresia") and TEF without esophageal atresia in 4% to 6% ("H-type fistula"). Proximal fistula and both proximal and distal fistula occur in approximately 1% of cases each. Initially alphabetic classification schemes were devised and the most common variety of esophageal atresia/TEF is still commonly referred to as "Gross type C" (Fig. 100.11).

Incidence and Epidemiology

Esophageal atresia is relatively common occurring in 1:2,500 to 1:4,500 live births. There is a slight preponderance of males.[77,84,87] Chromosomal anomalies, congenital heart disease, and other anomalies are more common than expected.

Clinical Findings, Diagnosis, and Pathophysiology

Diagnosis of esophageal atresia is suspected with a history of choking with feeding and is confirmed by the inability to pass an NG tube into the stomach. Excessive drooling may be noted. Maternal polyhydramnios should raise suspicion for the diagnosis. If not diagnosed early, respiratory distress and aspiration may occur. Confirmation of the diagnosis is with radiograph

identifying a tube in a proximal pouch in most cases. Occasionally injection of air to outline the pouch will be necessary for confirmation. Presence of a scaphoid abdomen with no intragastric air on radiograph taken several hours after birth confirms the diagnosis of pure esophageal atresia.[88,89] Reflux of gastric contents through the fistula can enter the lungs which becomes more problematic in the face of respiratory compromise and is less of an issue with spontaneous ventilation.

Associated Anomalies

Associated anomalies are present in approximately one-half of the neonates with esophageal atresia. The most common associated anomalies are cardiovascular defects which occur in 17% to 50% of infants. Genitourinary, other gastrointestinal, skeletal neurologic, and craniofacial defects are also found. The occurrence of *v*ertebral anomalies, *a*norectal malformations, *c*ardiac, *t*racheo*e*sophageal *r*enal, and *l*imb (usually radial) anomalies is known as the VACTERL association. Two or more of the defects must occur to be denoted as VACTERL, occurring in 10% to 21% of cases.

Preoperative Management

Attempts at feeding are discontinued and sump tube is placed in the upper esophageal pouch. Precautions such as head-up position are advocated to decrease reflux via the fistula into the lung. Intubation is avoided as it increases the risk of reflux into the lungs via the fistula. Ventilatory support is more likely to be needed for low birth weight or prematurity. Preoperative antibiotics are given in the majority of patients.[82] Emergent bedside gastric decompression may be necessary before definitive surgery. If gastrostomy decompression does not improve ventilation, emergency operative ligation or placing an occluding distal esophageal balloon may allow for ventilation.[82–84,90]

In addition to chest radiograph, echocardiography is performed to determine the side of the aortic arch as well as to evaluate for major cardiac anomalies. In patients with a right-sided arch, the operative approach may be modified.[90] Radiographs of the spine are also commonly performed. The genitourinary system is evaluated by ultrasound.

In an attempt to stratify infants into groups to determine outcomes, Waterston developed criteria based on birth weight, pneumonia, and associated anomalies. With improvements in neonatal critical care, the criteria have been revised to with the current Spitz classification which uses a 1,500 g weight as the cutoff, with or without major cardiac disease. Currently survival for greater than 1,500 g infants without cardiac disease is approximately 97%, survival for either cardiac disease or less than 1,500 g approaches 82% and for both birth weight less than 1,500 g and cardiac anomaly survival is approximately 50%.[81–84]

Surgical Technique

In most patients, gastrostomy is unnecessary. A right extrapleural posterolateral or auscultatory triangle thoracotomy is used (Fig. 100.12). There is no need to divide the serratus or the latissimus muscles. The extrapleural plane is established at the fourth intercostal space and developed sufficiently to allow control of the fistula and mobilization of the proximal pouch. The fistula is divided and closed. Anastomosis is performed in a single layer with an absorbable suture. If needed there are various techniques for elongation and the esophagus may be mobilized both proximally and distally. Myotomies on the upper pouch, either circular or spiral and flap tubularization have been described. In situ stretching of both the proximal and distal esophagus facilitates repair of longer gaps. A transesophageal tube may increase stricture. A postoperative esophagram is performed 5 to 10 days after repair.[82,83,90–95]

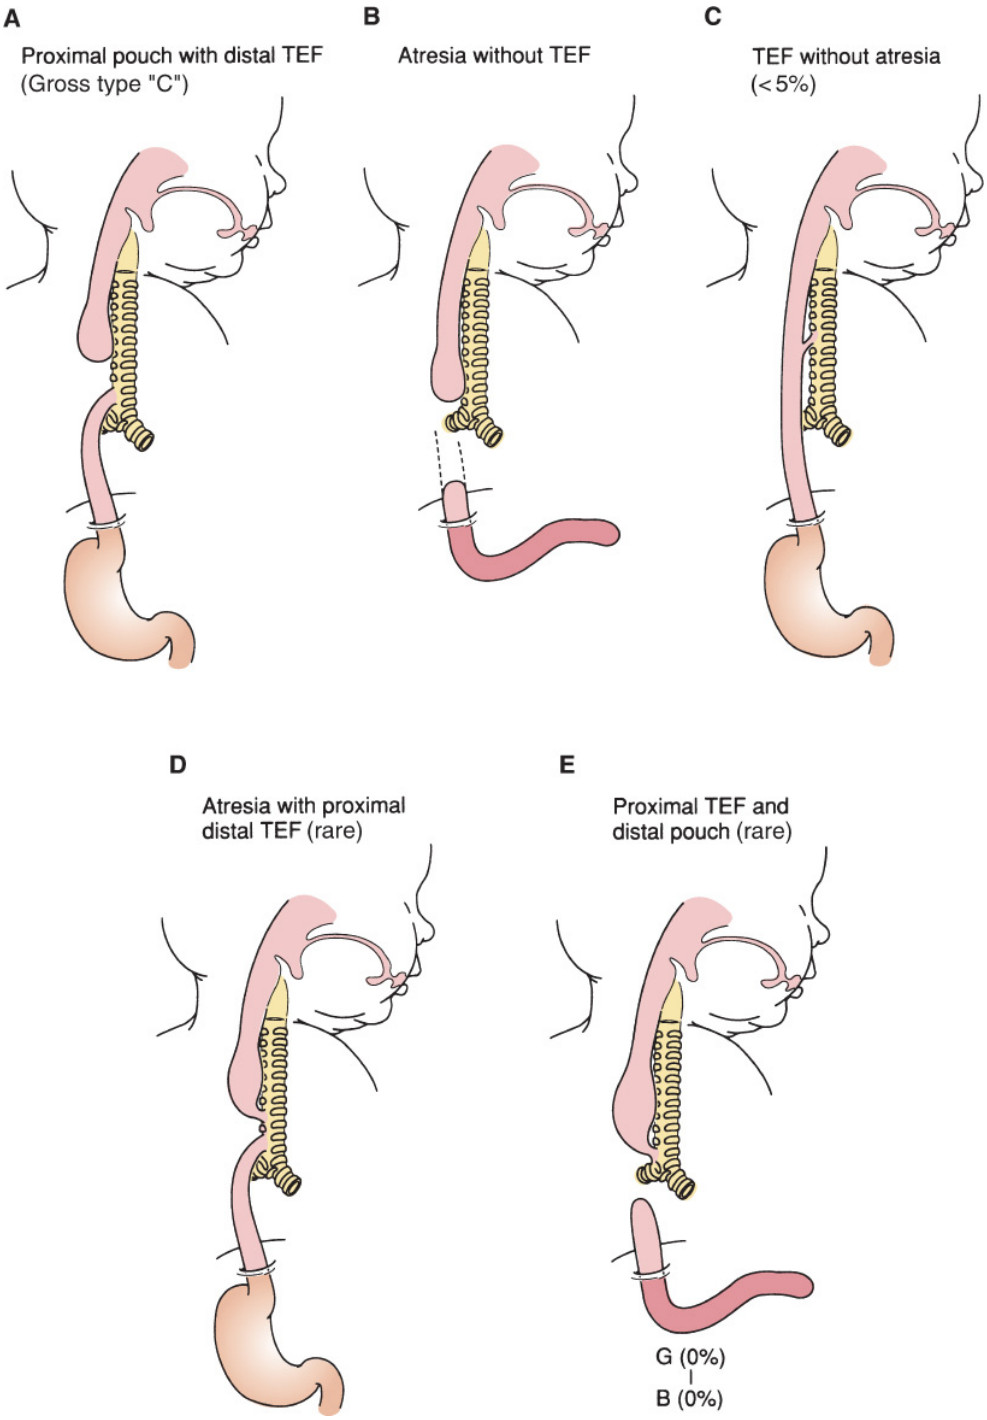

Figure 100.11 The anatomy of the variants of esophageal atresia and tracheoesophageal fistula (TEF). **A:** Proximal pouch with distal TEF (most common type occurring in 85% of patients; gross type "C"). **B:** Esophageal atresia without TEF (5%). **C:** TEF without esophageal atresia (<5%). **D:** Esophageal atresia with proximal and distal TEF (rare). **E:** Proximal TEF and distal pouch (rare).

High-risk infants who cannot safely undergo surgical correction of their esophageal abnormality may be treated with delayed repair. A decompressive gastrostomy, proximal pouch suctioning, and parenteral nutrition are used until the infant is ready for operation. Severe respiratory failure (usually from prematurity) and structural heart disease are the most common reasons to delay esophageal surgery. A staged repair that employs gastrostomy, surgical division of the TEF, followed by esophageal anastomosis as a second thoracic operation is rarely used except as a lifesaving approach.

In the case of pure esophageal atresia without fistula, a prolonged period before definitive repair may be used to improve the likelihood of completing a primary repair. A feeding gastrostomy is the initial operative management and may be technically challenging due to microgastria. Using bouginage the ends of the esophagus are elongated and once the ends are close, a thoracotomy is performed to repair the esophagus (Fig. 100.13). Other methods of elongation have been described with staged repair using traction sutures in the upper and lower esophagus (Fig. 100.14). Daily tensioning results in lengthening of the esophagus over a few weeks.[94] Alternatively, extrathoracic elongation may be utilized.[92]

Esophageal replacement is reserved for the worst cases of long-gap atresia, pure atresia, or failed initial operations. The esophagus may be replaced later using stomach, gastric tube, or colon. These cases may be temporized with a cervical esophagostomy ("spit fistula") and sham feeds. Esophageal replacement for esophageal atresia is rarely if ever required.

TEF without esophageal atresia is referred to as H-type or N-type fistula. The orientation is such that the opening into the trachea is always proximal to the esophageal entry site. Repair is performed via a cervical approach after bronchoscopically stenting the fistula with a small catheter. The catheter aids in dissection and care must be taken to stay in the plane of the esophagus to avoid recurrent laryngeal nerve injury.

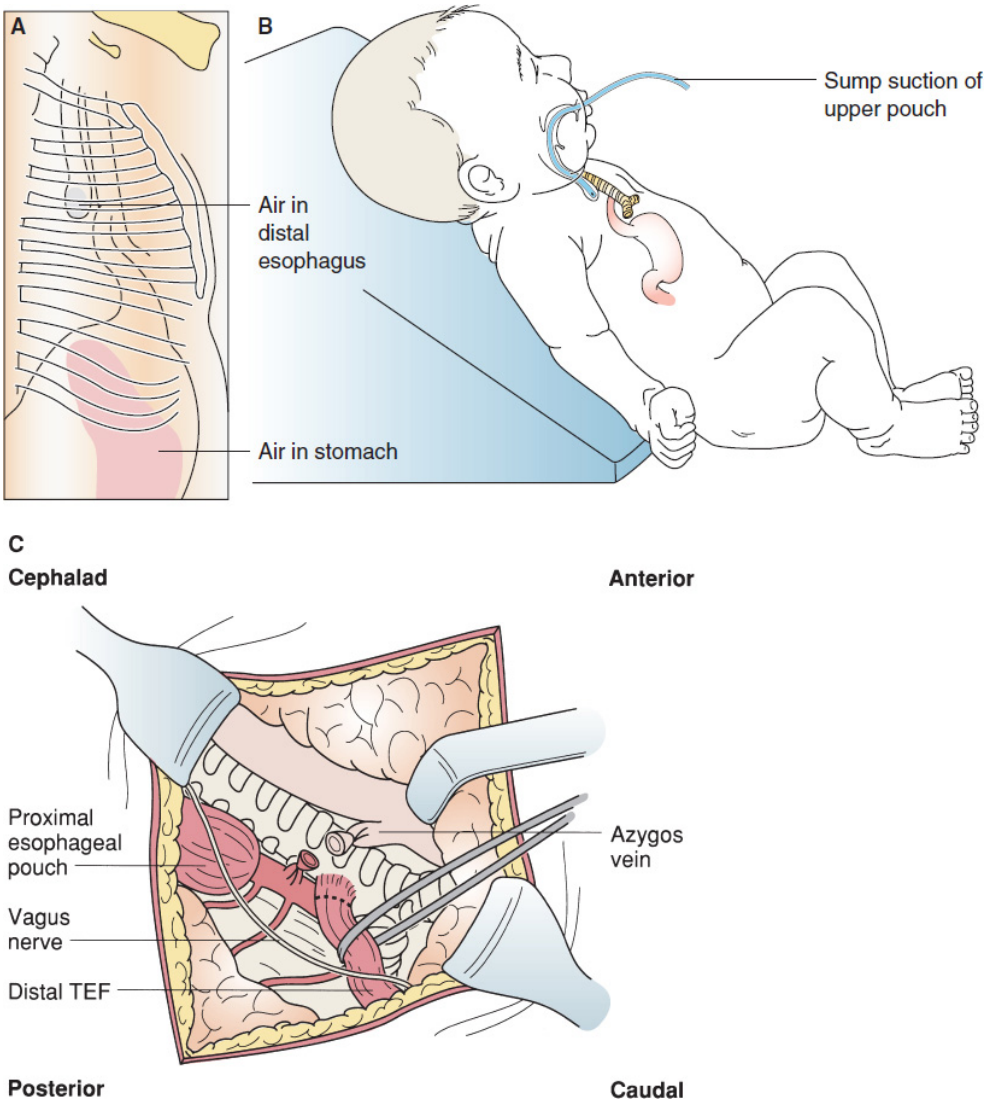

Figure 100.12 **A:** Schematic illustration of esophageal atresia with distal tracheoesophageal fistula. **B:** The initial management of this anomaly includes upright or prone posture, sump suction of the blind esophageal pouch. **C:** The right extrapleural operative approach. After division and closure of the fistula, primary esophagoesophagostomy is performed.

Thoracoscopic approaches to the repair of esophageal atresia have been described with results demonstrating equivalent outcomes to open repair.[93,94] Thoracoscopic techniques for esophageal lengthening in long-gap atresia have also been described.[95]

Results, Complications, and Outcomes

Technical mishaps may occur during the procedure when anatomy is misidentified or dissection is carried out improperly. Injury to the vagus nerves, recurrent laryngeal nerves, posterior trachea, and adjacent vessels must be avoided.

Anastomotic leak occurs in approximately 10% to 20% of cases and most may be treated nonoperatively. The presence of a leak prolongs hospitalization.[82–84,89] When detected, the retropleural tube is left in place, the infant is not fed, and antibiotics are administered. Repeat contrast radiographs are employed to document healing prior to initiation of oral feeds.

Esophageal stricture is seen in up to 40% of infants after repair. These usually respond to a few sessions of dilation performed in the operating room with endoscopic and fluoroscopic assistance as necessary to assure the safe traverse of dilators or placement of balloon dilators.[96] More recalcitrant strictures require more frequent dilation sessions, medical and/or surgical control of gastroesophageal reflux, and occasionally reoperation with stricture resection and reanastomosis.

Recurrent TEF is reported in up to 10% of patients. These may respond to endoscopic ablation, a construct placed into the fistula or may require operative division placing tissue between the esophagus and trachea to separate the suture lines.[96,97]

Gastroesophageal reflux is present in nearly all patients with esophageal atresia but is asymptomatic in many. When symptomatic, it may lead to respiratory symptoms and stricture formation. Medical management with thickened feeds, acid reduction, and prokinetics is the first line of therapy. Refractory reflux may require surgical control of reflux. Routine use of acid reduction medication is not recommended.[83]

Esophageal dysmotility is present in the majority or patients and may be responsible for dysphagia and recurrent respiratory problems.

Tracheomalacia occurs in approximately 10% of patients and may be diagnosed after the repair of esophageal atresia. On bronchoscopy, the trachea appears oval in shape rather than round and the anterior and posterior walls coapt during the respiratory cycle. Patients may develop tracheomalacia “fits” when agitated and the condition may deteriorate with complete inspiratory block and unconsciousness. Intubation and resuscitation may be required. The symptoms are completely relieved by intubation.

Patients with less severe symptoms may improve over time as the trachea grows. Severe symptoms require either tracheostomy or a tracheal suspension with an aortopexy under bronchoscopic guidance. It may be difficult to determine whether the symptoms are from gastroesophageal reflux or tracheomalacia and sometimes both an antireflux procedure and a tracheomalacia procedure may be required.[98,99]

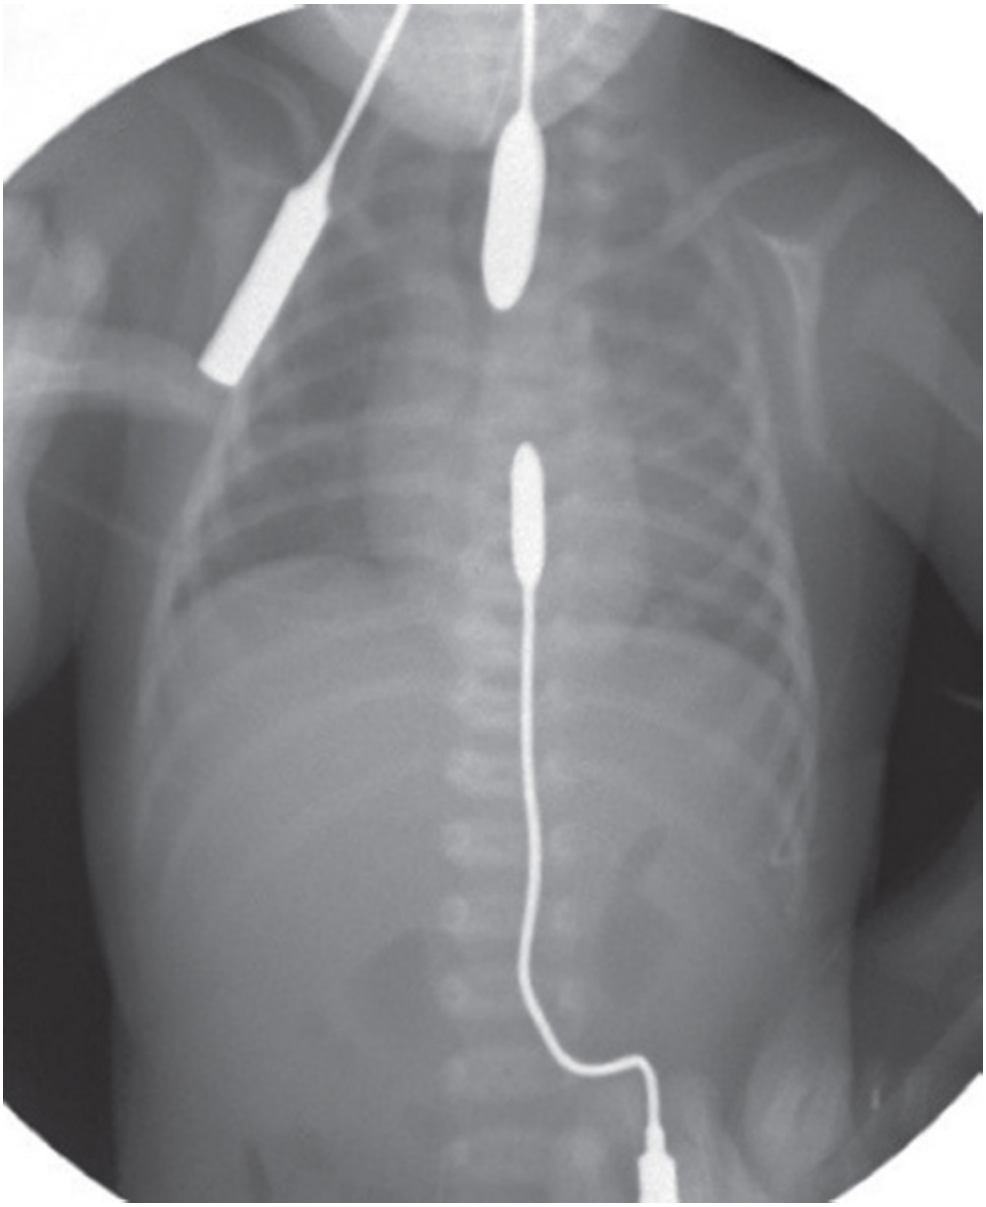

Figure 100.13 Patient with pure esophageal atresia treated initially with feeding gastrostomy, and proximal pouch stretching. This "gap-o-gram" demonstrates close approximation of a dilator in the proximal pouch and a probe placed in the distal esophagus via the gastrostomy. The child subsequently underwent primary repair of the esophagus.

Long-term results have improved and most children can look forward to normal existence. Although growth may be slow in the first 5 years of life, by 20 years of age less than one-third of the children have heights or weights below the 25th percentile.[99,100] Mortality remains high for infants with severe congenital heart defects and chromosomal anomalies. Late deaths may occur

related to respiratory disease (tracheomalacia, reactive airway disease, gastroesophageal reflux, and aspiration). Adult survivors of esophageal atresia repair have a normal quality of life with the exception of morbidity from esophageal, functional, and respiratory disorders.[100] The very long-term effects are unknown but Barrett esophagus and esophagitis have been reported.[101] The incidence is low and further studies are required to determine the need for long-term surveillance.

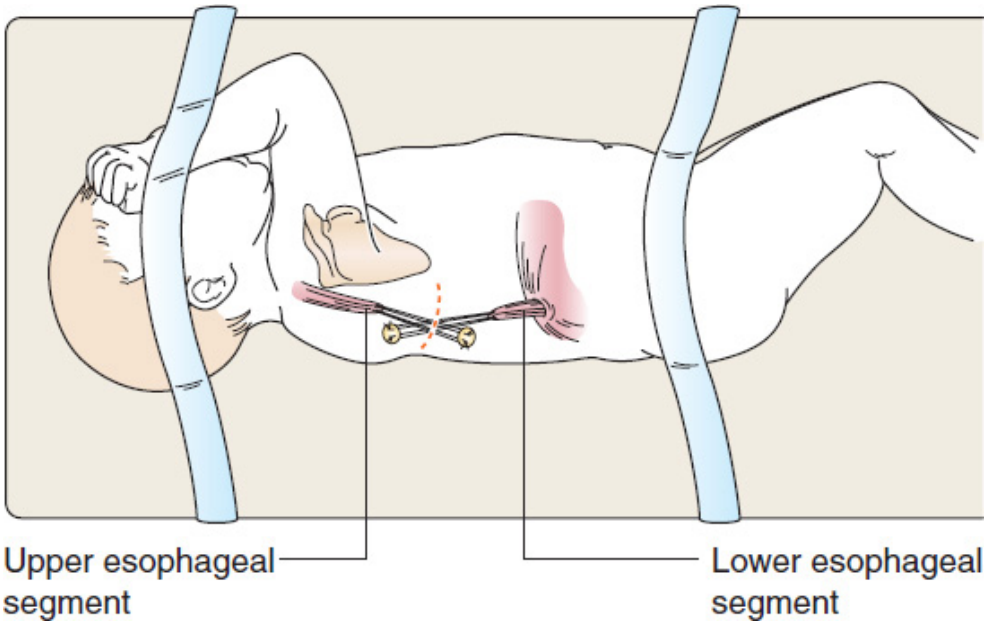

Figure 100.14 In patients with ultra-long-gap esophageal atresia, traction sutures are placed on the upper pouch and lower segment. Tension is increased daily until the segments lengthen, allowing primary repair.

OTHER CONGENITAL ANOMALIES OF THE TRACHEA AND ESOPHAGUS

Laryngotracheoesophageal Cleft and Tracheal Agenesis

Laryngotracheoesophageal clefts are rare anomalies resulting from the failure of normal separation of the esophagus and trachea. These are the most severe anomalies and the presence of the common aerodigestive channel plus the association of gastroesophageal reflux leads to aspiration with respiratory

damage and a high mortality rate. The lesions are classified by the length of the common channel. Type I clefts involve the supraglottic larynx. Type II defects extend beyond the carina to the cervical trachea. Type III clefts involve the entire trachea and type IV defects extend onto one or both bronchi. Type III and IV clefts are frequently associated with other anomalies such as esophageal atresia, microgastria, and congenital heart disease.

Type I clefts may be repaired via an endoscopic or translaryngeal approach and do not require tracheostomy. Type II clefts require cervical exposure either laterally or via the anterior wall of the larynx and trachea. The anterior approach provides good exposure and decreases the risk of damage to neurovascular structures. The approach to type III and IV defects is via a right thoracotomy and a right neck incision. However reports of midline exposure have been described. The common channel is divided and repaired with interrupted sutures with tracheostomy.[102] Oromotor function and chronic aspiration are problems and most children require gastrostomy and many require operative control of gastroesophageal reflux.

Tracheal agenesis (TA) is a rare and fatal congenital malformation that occurs in less than 1 in 50,000 live births. Approximately 150 cases have been reported with near universal lethality. At birth cyanosis, respiratory distress, and aphonia are noted. Survival requires the presence of an adequate TEF to permit lifesaving esophageal intubation. TA is classified into three anatomical variations, originally defined by Floyd.[103]

The etiology of this rare anomaly remains unknown. No genetic pattern has been implicated. However, associated congenital malformations are present in 90% of cases. All long-term survivors (older than 1 year of age) have undergone airway reconstruction with external scaffolding and use of the esophagus to create an airway. ("trachealization" of the esophagus). Survival is rare.[104] We have recently **successfully created a "neotrachea" in a patient with Type I TA using a 3D-printed scaffold and the esophagus. Colonic esophageal replacement has been performed with 3-year survival.**[105]

Congenital Esophageal Stenosis

Congenital esophageal stenosis is a rare condition. The stenosis is frequently within 2 cm of the gastroesophageal junction. The true incidence is unknown

but is reported to be 1:25,000 to 1:50,000 live births. The narrowing of the lumen is present at birth but may not present with clinical symptoms immediately. There are three histologic subtypes: ectopic tracheobronchial remnants, segmental fibromuscular hypertrophy, and a membranous diaphragm or stenosis. Esophageal stenosis has been associated with esophageal atresia. Symptoms may only occur when solids are started. Diagnosis is by esophagograms. CT scans may confirm the diagnosis. Esophagoscopy confirms the diagnosis. Initial management is esophageal dilation. If the stenosis is due to respiratory tract remnants, need for surgery is more common. Surgery consists of resection of the stenotic segment with end-to-end anastomosis.[106]

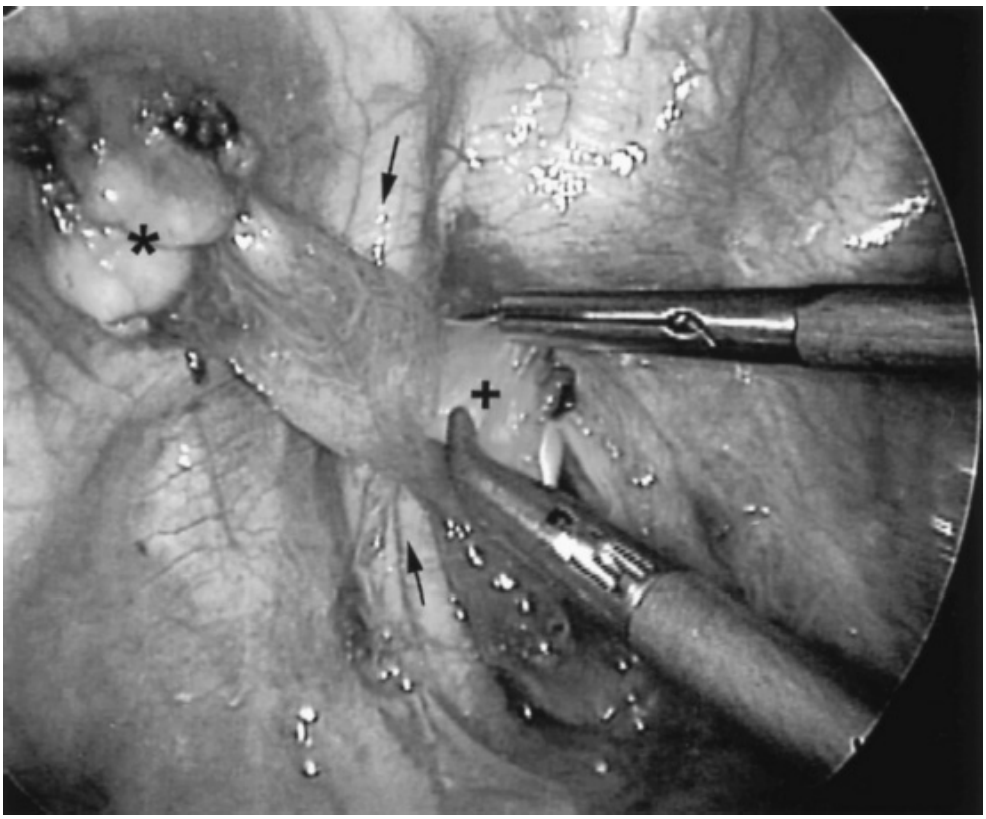

Figure 100.15 Thoracoscopic excision of an esophageal duplication cyst in a patient presenting with dysphagia. Video endoscopic view of the left superior hemithorax. (+) indicates site of original esophageal duplication cyst. Light from the intraesophageal endoscope can be seen. *Arrows* demonstrate the subclavian artery. The mass (*) is nearly excised.

Esophageal Duplication

Esophageal duplications are found in the posterior mediastinum and are covered by a muscular wall. Most are attached to the wall of the esophagus. Approximately 10% communicate with the lumen of the esophagus. Although many are asymptomatic, they may present with airway or esophageal compression. In older children and adults, the presentation may be dysphagia, retrosternal pain, and epigastric discomfort. There are reports of bleeding from acid dyspepsia. Excision is recommended and is usually accomplished by thoracoscopy (Fig. 100.15).[46,47] Neurenteric cysts are anatomically similar but communicate with the spinal canal.

Vascular Rings

Vascular rings are a set of congenital defects in which the trachea or esophagus are encircled and compressed by vascular structures associated with the development of the aorta and great vessels. These account for approximately 1% of all congenital cardiovascular anomalies. Vascular rings may lead to tracheal narrowing with associated tracheomalacia. Symptoms may include stridor, respiratory distress, or dysphagia. Barium swallow may be suggestive of the lesion. CT scan and MRI are utilized to demonstrate the anomaly. Echocardiography is performed to rule out structural cardiac anomalies. Bronchoscopy may also be useful to determine the degree of tracheal narrowing. The most common type of abnormality is the double aortic arch resulting from persistence of both the right and left embryologic aortic arches. The ascending aorta bifurcates, surrounding the trachea and esophagus. Other causes of complete or incomplete rings include pulmonary artery sling and aberrant right subclavian artery. When the vascular ring is symptomatic, the patient should be treated by the appropriate division of the ring and lysis of the fibrous bands surrounding the trachea and esophagus.[107]

Congenital Tracheal Stenosis

Congenital tracheal stenosis represents a spectrum of obstructive lesions most commonly treated with operative repair. The etiologies include complete tracheal rings, compression from anomalous cardiovascular anatomy, and tracheomalacia. Short stenosis may respond to resection and anastomosis. Longer lengths of stenosis can be managed by patch

tracheoplasty and slide tracheoplasty. Use of cardiopulmonary bypass during repair may improve outcomes.[108,109]

FOREIGN BODIES OF THE TRACHEOBRONCHIAL TREE

9 Foreign-body aspiration occurs commonly in infants and young children and is a potentially life-threatening event. A report in 2001 found that nonfood choking was a cause of death for 449 persons under the age of 14 with 65% of the deaths in children under 3 over a 20-year period. Choking on food causes death of approximately 75 children per year.[110–112]

Pathophysiology

Complete airway obstruction can occur at the level of the pharynx, hypopharynx, or trachea. Back blows, abdominal thrust, or the Heimlich maneuver may dislodge the obstruction and save a life. An inhaled foreign body which reaches the bronchial level may cause a ball-valve phenomenon allowing bi-directional but unequal flow of air. Air trapping and hyperinflation of the affected lobe lead to mediastinal shift. Complete blockage results in loss of volume due to atelectasis.

Foods are the most common aspirated items and include peanuts, carrots, popcorn, hotdogs, and grapes. Toy parts are the most common nonfood items aspirated.

Clinical Presentation

Most affected children are less than 3 years of age. History of choking crisis is present in the majority of children. Other symptoms include cough, wheezing, dyspnea, and fever. The most common signs are unilateral decreased breath sounds, unilateral wheezing, and rhonchi.

Management

Chest radiographs, including bilateral lateral decubitus films, are performed unless the patient is in respiratory distress. Radiographs demonstrate hyperinflation on the affected side. In case of questionable foreign-body aspiration, CT imaging may be performed. Alternatively, radiographs may show pneumonia or atelectasis with a completely occluding foreign body.

Bronchoscopic evaluation and foreign-body removal is performed in the operating room under general anesthesia. The rigid bronchoscope and Hopkins rod-lens system with optical forceps can be used to retrieve most aspirated foreign bodies (Fig. 100.16). Flexible graspers, Fogarty balloon catheters, and baskets can be useful especially if the foreign body has migrated distally or has a smooth or round surface. Fluoroscopic assistance can be useful with radiopaque objects which have migrated into the peripheral airways.

Over time, pneumonia or atelectasis may develop and a foreign body presenting with chronic lung infection may require surgical resection of the associated potion of the lung.

CONGENITAL ABNORMALITIES OF THE DIAPHRAGM

Advances in management of neonatal respiratory failure, fetal surgery, and lung developmental biology have arisen from the clinical and laboratory evaluation of CDH (CDH, Bochdalek, or posterolateral hernia). CDH, which is relatively rare, occurring in 1 in 3,000 neonates has led to a significant amount of clinical and basic science research.

In 1754, McCauley described the clinical course and postmortem anatomy of an infant with CDH.[113] Although Bochdalek's[114] understanding of the embryology of CDH was incorrect, this congenital defect continues to carry his name. Prior to 1940, the successful repair of this defect was rare.[115] In 1946, Gross[116] reported the postoperative survival of an infant less than 24 hours of age. From that time until the 1980s the standard of care was emergent operative repair. At that time, CDH was considered to be an anatomic derangement treated by an anatomic correction (the thought was that

by getting the bowel out of the chest, lung compression would improve and outcomes would improve).

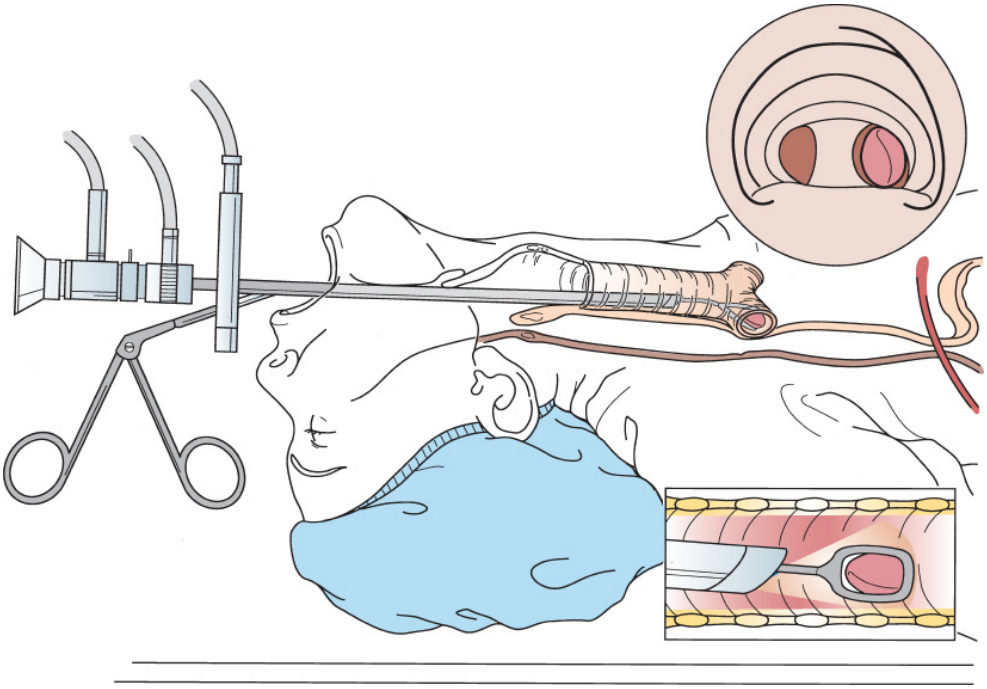

Figure 100.16 Schematic illustration of a peanut foreign body being extracted from the right main stem bronchus under direct vision.

Until the 1980s, emergency surgery was considered the primary therapeutic goal based on mechanical concept of providing space for growth of lungs. The overall published survival rates in the 1980s were 50% with ranges from 20% to 70% based on case selection. In the late 1980s, there was a change in management from emergency surgery to initial stabilization.[117] Management in the postnatal period is directed at decreasing pulmonary hypertension while maintaining adequate oxygen saturations.[117,118] Surgical repair is deferred until after physiologic stabilization. This has led to improved survival of infants with CDH.

Embryology of the Diaphragm

Mammalian lung development occurs in vivo as a coordinated developmental process that includes (a) airway and acinar development, (b) cellular differentiation, (c) biochemical maturation, (d) interstitial development including vasculature and extracellular matrix, and (e) physical

growth or enlargement. These parallel developmental processes occur in such a fashion that at any one time during development, there are characteristic relationships among each component that define the so-called, "stages of lung development."[119–121] Hormones such as the glucocorticoids, thyroid hormone, and retinoic acid have been shown to regulate several of the crucial cellular interactions required for proper pulmonary organogenesis and differentiation. In the human embryo, respiratory tract development begins in the fourth week of gestation as a ventral out pouching of the foregut that soon has bifurcated and begun branching into the surrounding mesenchyme. The primitive, pluripotent epithelial cells differentiate into both bronchial and alveolar cell lines, under the control of the surrounding mesenchyme. By a process of asymmetric branching, the divisions are complete by the 16th week of gestation. Lung at this phase has columnar epithelium with thick mesenchyme giving rise to the descriptive term *pseudoglandular phase* of development because of its histologic appearance. The *canalicular phase* that follows and continues up to about the 24th gestational week is characterized by flattening of the epithelium of the distal airways, thinning of the mesenchyme, and the growth of the capillary network that surrounds the terminal airways. Gas exchange becomes functionally possible at the end of this phase. The *terminal sac period* that follows refers to the appearance of a thin respiratory epithelium in apposition to a capillary network capable of supporting gas exchange. The *alveolar phase* of development in humans begins shortly before or around the time of birth. Alveolar maturation and multiplication takes place after birth and may continue up to 8 years of age.

The precursors of the mesoderm-derived diaphragm begin to form during the fourth week of gestation with the appearance of the peritoneal folds from lateral mesenchymal tissue. At the same time, the septum transversum forms from the inferior portion of the pericardial cavity and serves to delineate the thoracic from the abdominal cavities. Eventually, the septum transversum leads to the formation of the central tendinous area of the fully developed diaphragm. The pleuroperitoneal folds extend from the lateral body wall and grow medially and ventrally until they fuse with the septum transversum and dorsal mesentery of the esophagus during the sixth gestational week. Complete closure of the canal takes place during the eighth week of gestation, with the right side closing before the left.[122] Muscularization of the

diaphragm appears to develop from the innermost layer of thoracic mesoderm, although other mechanisms have been proposed (Fig. 100.17).[123]

Congenital Diaphragmatic Hernia Pathology and Pathophysiology

CDH occurs in 1:3,000 to 2:4,000 live births. Approximately one-third of antenatally diagnosed infants with CDH are stillborn, with most of the deaths ascribed to other fatal anomalies. Defects are more common on the left side.[124] CDH represents a sporadic developmental anomaly with some familial cases reported. One-third of patients have associated major defects. CDH associated with an abnormal karyotype or cardiac defect is associated with a poor outcome.[125]

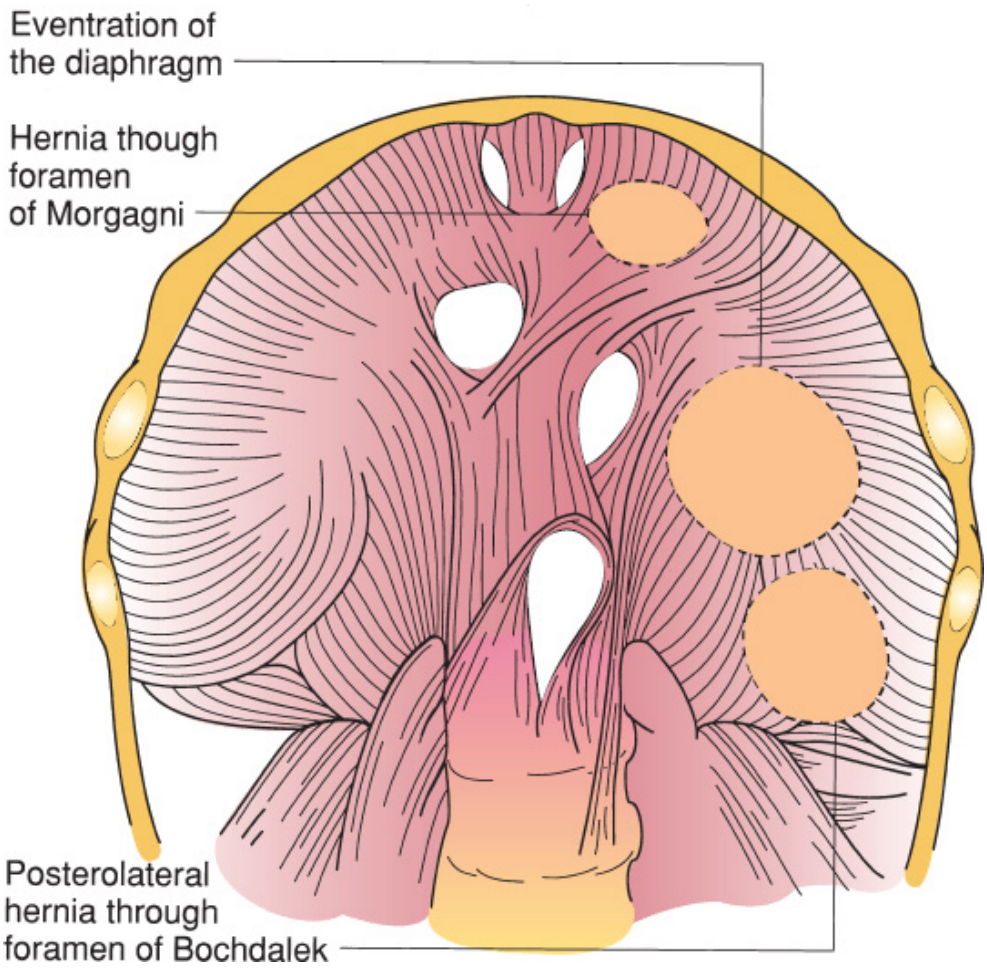

Figure 100.17 Anatomy of the diaphragm showing the location of congenital diaphragmatic defects.

The cause of CDH is unknown but is presumed that some combination of intrinsic predisposition (genetic factors) and environmental factors (teratogen or deficiency) results in abnormal diaphragm and lung development.[122] A nitrofen-induced model of CDH also inhibits retinal dehydrogenase leading to decreased retinoic acid, which has also been found in human infants with CDH.

During the early development of the diaphragm, the midgut is largely extracoelomic. If closure of the pleuroperitoneal canal has not occurred by the time the midgut returns to the abdomen during the 9th and 10th weeks of gestation, the abdominal viscera herniate through the lumbocostal trigone into the ipsilateral thoracic cavity. The resulting abnormal position of the bowel prevents its normal counterclockwise rotation and fixation. No hernia sac is present if the event occurs before complete closure of the pleuroperitoneal

canal, however a nonmuscularized membrane forms a hernia sac in 10% to 15% of CDH patients. In addition to the small bowel, other intra-abdominal organs such as the spleen, stomach, colon, and liver may also herniate through the diaphragmatic defect.

Left-sided CDH is characterized by a 2- to 4-cm posterolateral defect in the diaphragm through which the abdominal viscera have translocated into the ipsilateral thoracic cavity. On a right-sided defect, the large right lobe of the liver can occupy most of the hemithorax. The hepatic veins may drain ectopically into the right atrium, and the liver and lung may be fused.[123]

The pathophysiology of CDH has been attributed to pulmonary parenchymal compression by the herniated organs and its effect on growth and maturation of the lung. An emerging school of thought attributes the pulmonary hypoplasia to an early mesenchymal developmental insult to the lung and diaphragm. Unilateral diaphragmatic hernia is associated with both ipsilateral and contralateral abnormal pulmonary development, although hypoplasia is more severe on the ipsilateral side. The lung on the side of the hernia is much smaller than its contralateral counterpart, and both are smaller than normal lungs (Fig. 100.18). The pulmonary vascular disease associated with CDH is characterized by abnormal pulmonary vascular development, abnormal vasoreactivity, and a disorganization of vascular remodeling. There are fewer capillaries which are unevenly distributed. Both the media and the adventitia have structural abnormalities consistent with increased muscularization in utero. Sonic hedgehog signaling which is involved in the development of respiratory bronchioles is delayed in CDH. Levels of several regulatory proteins are changed compared to controls but no causative relationship has been demonstrated.[120,123]

Figure 100.18 Autopsy specimen of an infant with severe pulmonary hypoplasia secondary to congenital diaphragmatic hernia. Pulmonary hypoplasia is bilateral, but the left lung is most severely affected.

Pulmonary blood flow accounts for only 7% of cardiac output during normal fetal development. Pulmonary vascular resistance is high. The fetus preferentially shunts oxygenated blood from the placenta through the foramen ovale and ductus arteriosus in a right-to-left direction into the systemic circulation. With the institution of breathing at birth, oxygen levels rise

causing pulmonary vascular resistance to fall, which in turn allows an increase in pulmonary blood flow. Increased arterial oxygen tension induces spontaneous closure of the ductus arteriosus. Persistent fetal circulation may develop if this process is interrupted. Elevated pulmonary vascular resistance results in right-to-left shunting of blood at either the atrial or ductal levels with the delivery of unsaturated blood into the systemic circulation. As shunting increases, the oxygen saturation in the systemic circulation falls. The resulting hypoxia further increases pulmonary vascular resistance and compromises pulmonary blood flow while increasing the right-to-left shunt flow. Factors that contribute to the persistence of high pulmonary vascular resistance in CDH lungs are thought to be the structural changes of decreased total arteriolar cross-sectional area in the involved lungs and the increased muscularization of the arterial structures that are present. Additional exacerbations of pulmonary vascular resistance may be induced by the known stimulators of pulmonary hypertension, which include hypoxia, acidosis, hypothermia, and stress. Alternations in the levels of prostaglandins, leukotrienes, catecholamines, and the renin angiotensin system had been implicated as mediators of this complex process. The combination of hypoplastic lungs and lungs prone toward increased vascular resistance often proves deadly; a vicious cycle may ensue in which hypoplastic lungs and associated hypoxia leads to pulmonary hypertension in a lung vasculature already prone toward reactive vasospasm. The increase in pulmonary pressures results in a greater shunt, which in turn further reduces oxygen levels.

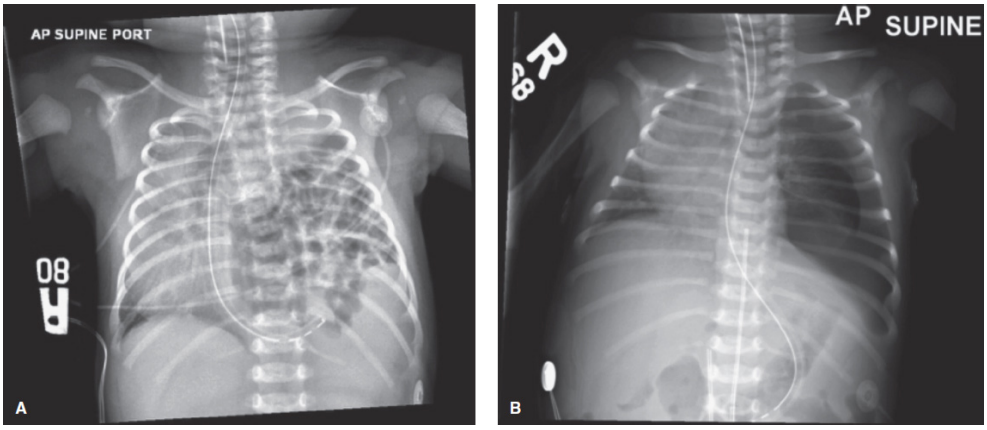

Figure 100.19 **A:** Chest radiograph of a newborn with a left congenital diaphragmatic hernia. Mediastinal structures are shifted to the right. Abdominal viscera occupy the left hemithorax. The nasogastric tube locates the stomach. The child underwent repair of the congenital diaphragmatic hernia after treatment and resolution of pulmonary hypertension. **B:** Immediate postoperative photograph demonstrates hypoplastic lung, flattening of diaphragm, and return of abdominal viscera to normal position.

Diagnosis

Diagnosis of CDH is typically made on prenatal ultrasound examination.[124,125] Polyhydramnios is common. Prenatal MRI is utilized for more accurate delineation of the defect.[124–126] Postnatal presentation includes cyanosis and respiratory distress shortly after birth in severely affected neonates. On physical examination, the patients have a scaphoid abdomen. A plain chest radiograph with loops of intestine in the chest confirms the diagnosis of CDH with an NG tube in place to confirm the position of the stomach (Fig. 100.19). After confirmation of diagnosis, echocardiography should be performed to evaluate pulmonary hypertension and to determine presence of cardiac defects. Differential diagnosis includes eventration of the diaphragm, anterior diaphragmatic hernia (Morgagni), congenital pulmonary malformations, unilateral pulmonary effusion, and primary agenesis of the lung.[127]

Prognostic Factors

Poor prognosis is associated with low lung-to-head ratio (LHR) is determined by sonographic measurements of the size of the contralateral lung

in an anteroposterior and lateromedial direction, and the head circumference. Ratios less than 1 have been associated with poor outcome. Because the LHR increases with age, the percent of predicted value for gestational age has been used with no survivors below 15% of predicted.[124,128,129] Liver above the diaphragm ("liver up") is also associated with decreased survival. The combination of a low LHR with "liver up" has a very poor prognosis. The size of the defect, presence of a major cardiac anomaly, and 1-minute Apgar sores of ≤4 are also associated with increased mortality.[124,128,129] Physiologic parameters have also been used to predict survival based on birth weight, 5-minute Apgar, SNAP-II scores, gestational age, and blood gas values in first 24 hours.[130] The Congenital Diaphragmatic Hernia Study Group and the Canadian Neonatal Network have published predictors of survival.[131,132]

Treatment

At the time of antenatal diagnosis, the mother and fetus should be referred to an appropriate tertiary care perinatal center with the availability of the full array of respiratory care strategies.

Resuscitation should begin with standard neonatal resuscitation guidelines and then proceed with endotracheal intubation and nasogastric tube insertion. Bag–valve mask should be avoided. Careful management of temperature regulation, glucose homeostasis, and volume status should be performed. Fluid resuscitation should be performed with crystalloid, blood products, and colloid. Inotropes such as dopamine or dobutamine are utilized if needed. Most infants can be managed with simple pressure-cycled ventilation with a goal of maintaining a preductal PaO_2 greater than 60 correlating with saturation between 85% and 95%. Keeping peak pressures below 25 and accepting CO_2 between 45 and 65 decreases barotrauma. For failure of "gentle ventilation strategies," the jet ventilator or oscillator ventilator may be uses.[124,127]

In addition to ventilatory methods, a variety of agents are utilized to modify pulmonary vascular resistance, including inhaled nitric oxide, phosphodiesterase-5 inhibition with sildenafil, Milrinone (a phosphodiesterase-3 inhibitor), prostacyclin and prostaglandin E1. Other

medications such as tyrosine kinase inhibitors and endothelin receptor antagonists may show promise.[133,134] Surfactant has been demonstrated to be reduced in CDH infants. However, surfactant has not been demonstrated to improve survival.[124,127,133]

Failure to improve with ventilatory and pulmonary hypertension management strategies should prompt consideration of ECMO. ECMO can be used for an extended period of time when ventilator therapy has failed. Indication for the use of ECMO is the failure to improve in the setting of severe pulmonary hypertension. In recent years the use of ECMO has decreased but still ranges from 15% to 40% of diaphragmatic hernias; with survival following ECMO of 51%.[127] There is no consensus on repair on ECMO or after ECMO.[135]

Surgery

10 Delayed surgery has been demonstrated to improve survival in some studies. The diaphragm defect is usually approached through a subcostal incision, although the repair can be performed through a thoracotomy incision (Fig. 100.20). Both thoracoscopic and laparoscopic approaches have been described. The abdominal organs are returned to the abdomen. The defect in the diaphragm is repaired. Primary repair with nonabsorbable suture is preferred. If the defect cannot be repaired primarily due to size, a prosthetic patch such as Gore-Tex may be utilized. The major drawback of the use of a patch, either inert or bioactive is recurrent herniation which may occur in up to 50% of infants.[136] There may have been loss of intra-abdominal domain and difficulty with closing the abdomen. In these cases, a silo may be used.[137] Tube thoracostomy is used at the surgeon preference. A recent meta-analysis of minimally invasive versus open repairs demonstrated that recurrence rate is higher after MIS and operative time is longer.[138] Postoperative ventilator time and postoperative mortality were higher after open surgery but none of the studies were randomized and this may have represented selection bias.[138]

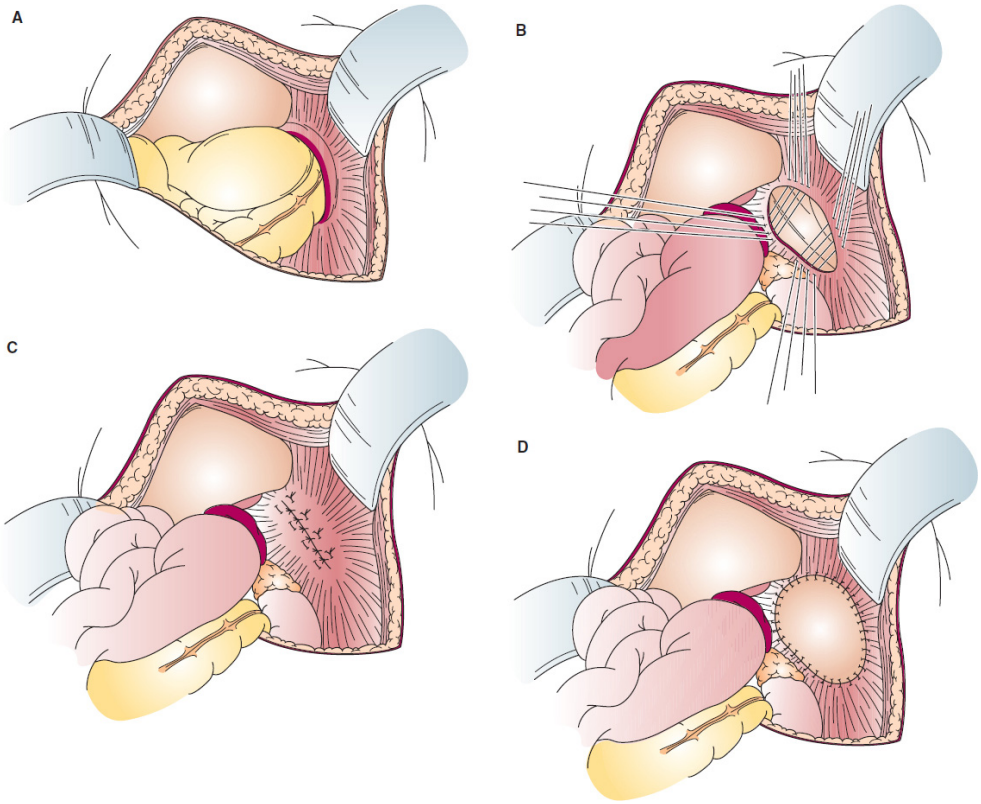

Figure 100.20 Repair of a congenital diaphragmatic hernia (CDH). **A:** Operative appearance of CDH. **B:** Placement of sutures for repair of a typical left posterolateral diaphragmatic defect. **C:** Completed repair. **D:** Prosthetic material may be used for large defects to avoid tension.

Postoperative management should continue the goals set before surgery. Continued attention to fluid status is important in the postoperative period. Weaning from the ventilator should be slow and deliberate. Refractory postoperative pulmonary hypertension is relatively common in those who required ECMO and is often treated with iNO and prostacyclin in conjunction with frequent echocardiography.

Outcome

Survival rates have been reported at 60% to 80% improved from 50% in the past. As survival has improved, other morbidities have been demonstrated including long-term use of bronchodilators, need for gastrostomy for nutritional support, and increased rate of gastroesophageal reflux disease (GERD) requiring surgery. Musculoskeletal deformities also occur with scoliosis, pectus excavatum, pectus carinatum, and chest wall asymmetry

described.[139] Adult survivors of CDH have demonstrated higher incidence of GERD, recurrent intestinal obstruction, and recurrent abdominal pain. Scores in the Gastrointestinal Quality of Life Index and the Health-related Quality of Life Survey are good or satisfactory.[140]

Evolving Therapies

Open fetal repair of diaphragmatic hernia has been performed but there was no survival benefit and there was an increase in preterm delivery so this is not currently offered. Tracheal occlusion in utero has been developed as a strategy to promote lung development based on observations that the lungs of neonates with congenital high airway obstruction developed hyperplastic lungs. Fetal tracheal occlusion improved lung volume but there was still impairment in the lung. Fetal endoscopic tracheal occlusion has been trialed with fewer premature deliveries. In the U.S. trial there was no improvement in survival in a randomized trial. The European trials added a second fetal surgery to remove the balloon to allow for improvement in the development and function of type II pneumocytes and to increase surfactant production. With the European trial, vaginal delivery is possible but with the U.S. trial, the infants were delivered by EXIT procedure, using the placenta to maintain oxygenation until an airway is secured.[124,126]

Foramen of Morgagni Hernia

The anterior CDH is rare and accounts for 3% to 5% of all CDHs. It is typically diagnosed during childhood from chest or abdominal radiographs being performed for presumed pneumonia or gastrointestinal symptoms (Fig. 100.21).[141] This is an anteromedial hernia at the junction of the septum transversum and the thoracic wall with contents being seen in a retrosternal position. There is a hernia sac present and the sac may contain colon, small intestine, or liver. The hernias are repaired due to the risk of segmental intestinal volvulus or obstruction. Laparoscopy has been demonstrated to be an effective method for repair of this type of hernia. The sac is excised and the diaphragm is sutured to the undersurface of the posterior rectus sheath at the costal margin.[141–143]

A

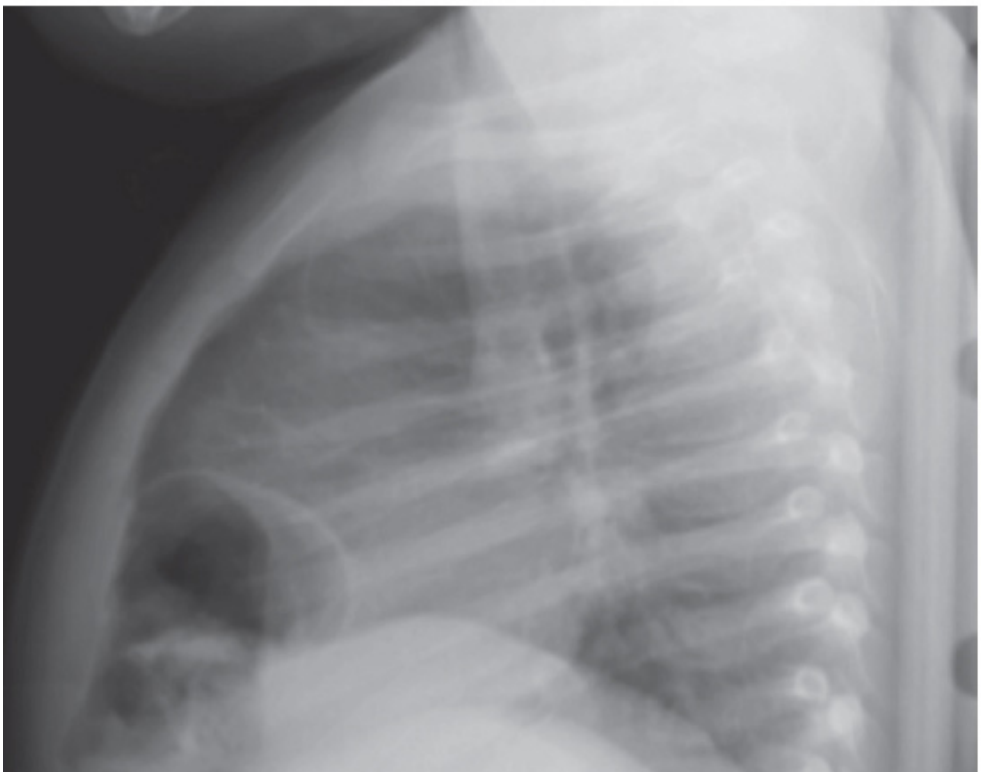

Figure 100.21 Morgagni hernia. (**A**), Anteroposterior and (**B**), lateral radiographs of patient with Morgagni hernia.

Eventration of the Diaphragm

Eventration of the diaphragm is diagnosed by the abnormal elevation of one or both hemidiaphragms and can be congenital or acquired. The congenital form may appear very similar to a diaphragmatic hernia with a sac. The cause of the congenital form is unknown although infectious causes have been implicated. The acquired form is a consequence of injury to the phrenic nerve. Asymptomatic patients may be observed. Surgical management in symptomatic patients involves plication of the diaphragm. The repair may be performed through the abdomen or the chest and both thoracoscopic and laparoscopic techniques are applicable.[143,144]

Diaphragmatic Pacing

Ventilator-dependent children with spinal cord injury or central hypoventilation syndromes may benefit from diaphragm pacing.[145] The application of repetitive stimulus patterns to the phrenic nerves causes rhythmic contractions of the diaphragm. Phrenic nerve pacing wires are implanted at the cervical or intrathoracic level. Receivers are implanted in subcutaneous pockets, while an external microprocessor-controlled transmitter/antenna assembly activates the receiver. Patients with injured phrenic nerves (high spinal cord injury) may benefit from diaphragm pacing after intercostal-to-phrenic nerve transfer.[146]

PLEURAL DISEASES

Empyema

Empyema is the accumulation of purulent material in the pleural space. In children, empyema is most often the sequelae of bacterial pneumonia. Empyema develops when a parapneumonic effusion becomes infected or when a necrotizing pneumonia erodes into the pleural space. Empyema may also be caused by penetrating thoracic trauma, intrathoracic, or cervical esophageal perforation or as a complication from surgery on the chest. The American Thoracic Society divides the empyema process into 3 stages:

1. Exudative: Thin free-flowing fluid with a low cell count.
2. Fibrinopurulent: Frank pus is present and fibrin formation begins to cover the pleura with development of loculations.
3. Organizing: Thick peel with fibroblasts.[147]

The most common organism responsible for empyema is *Streptococcus pneumoniae*. Other common organisms are *Staphylococcus aureus* and *Haemophilus influenzae*.[147] The signs and symptoms include worsening pneumonia with fever, tachypnea, dyspnea, and sometimes cyanosis. Abdominal pain may be present. Chest radiograph demonstrates the presence of fluid and loculation. CT imaging is the best method of determining the extent of loculated fluid versus underlying pulmonary pathology (Fig. 100.22).

With a small amount of fluid, the empyema may resolve with antibiotics alone. When the collection becomes larger, the treatment is drainage of the collection. Several trials have compared fibrinolytics to video-assisted thoracoscopy (VATS). Both VATS and chest tube with fibrinolytics have been shown to be effective with a systematic review demonstrating no superiority of VATS. Other studies have demonstrated improvement after VATS.[147,148]

Pneumothorax

Spontaneous pneumothorax is relatively uncommon. The etiology seems to be lung connective tissue changes predisposing to leaks into the pleural space. Apical lung blebs are associated with the disease. The presentation is usually with chest pain and shortness of breath but may also be associated with cough. The pain may be pleuritic in nature. Diagnosis is best confirmed

with chest radiograph.[149] Chest CT has been utilized for identification of blebs but a negative examination does not predict freedom from recurrence.[150]

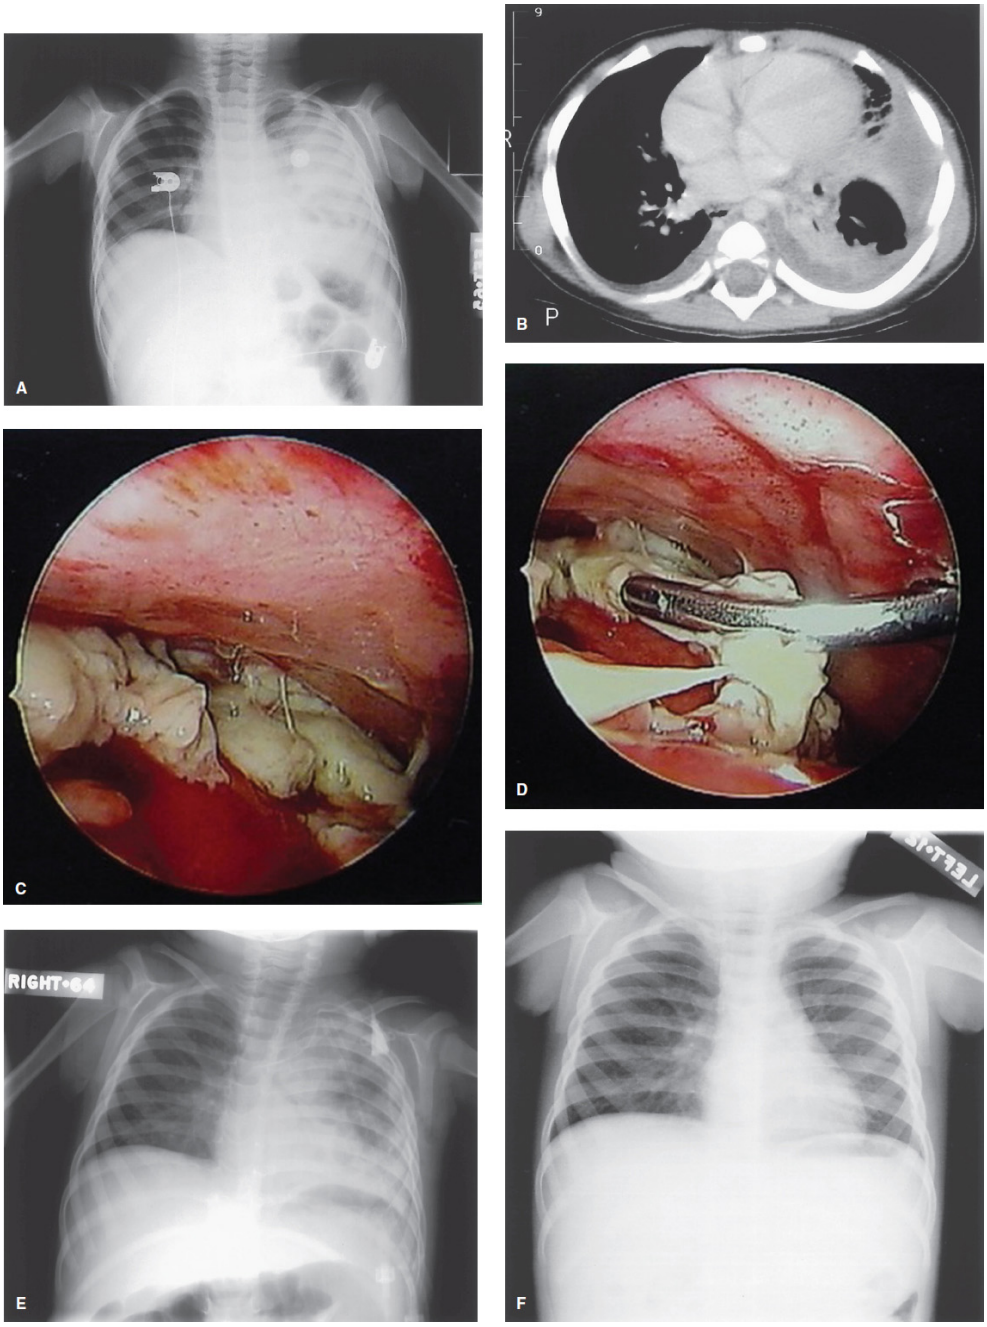

Figure 100.22 Video-assisted thoracoscopic treatment of complicated empyema in children. **A:** Chest radiograph of a 2-year-old child presenting with pneumonia and pleural effusion. **B:** Computerized tomography demonstrates complicated pneumonia with loculated empyema. **C:** Video endoscopic view of organized empyema debris. **D:** "Decortication" procedure includes removal of all loculated, organized debris from the hemithorax. All surfaces of the visceral and parietal pleura are accessible using video endoscopic techniques. **E:** Immediate postoperative chest x-ray shows the expected residual parenchymal lung disease. **F:** One month later, the chest radiograph findings have resolved.

Treatment of pneumothorax depends on the patient. Observation with or without high-flow oxygen is appropriate for the relatively asymptomatic patient. Chest tube placement is the next stage of treatment. VATS with bleb resection and pleurodesis has also been described with good results.[149] For recurrent pneumothoraces, intrapleural sclerosing agents can be used.

Chylothorax

Chylothorax, the accumulation of chyle in the pleural space, is a rare cause of effusion in children but is the most common cause in the neonate.[151] Chylothorax is associated with pulmonary lymphangiomas and lymphangiectasia. Chylothorax may also be a manifestation of Down, Turner, and Noonan syndromes. Chylothorax may occur due to trauma to the thoracic duct either iatrogenic or due to blunt trauma. Malignancy and granulomatous diseases may cause obstruction of the thoracic duct leading to chylothorax.

The initial symptoms are related to accumulation of fluid in the pleural space with dyspnea, cough, and chest discomfort. Pleuritic pain and fever are rare. Diagnosis is by chest radiograph combined with findings on thoracentesis. The fluid is usually milky in appearance with triglycerides greater than 1.1 mmol/L, total cell count greater than 1,000 cells per mL, and lymphocyte predominance greater than 80%.[151]

Management consists of expansion of the lung with thoracentesis or tube thoracostomy. Minimization of lymph flow is managed by either parenteral nutrition or diet manipulation using medium-chain fatty acids. Long-term loss of lymphatic fluid can lead to life-threatening immunologic problems. Surgical management includes thoracic duct ligation, performed either via thoracotomy or thoracoscopy. Administration of cream via a nasogastric tube in the hours before surgery may facilitate identification of the leak. Pleurectomy and pleurodesis or pleuroperitoneal shunting may also be used.

Pediatric Abdomen

Andrea Hayes-Jordan and Michael Phillips

Key Points

1 Gastroschisis occurs with an incidence rate of 1 in 2,000 live births and is characterized by exposed intestine herniating through a defect to the right of the umbilicus. In contrast, omphalocele is a midline abdominal wall defect characterized by herniated visceral contents contained within the umbilical cord covering and has a high incidence rate of associated congenital anomalies.

2 A congenital, indirect inguinal hernia is an abnormal, patent continuation of the peritoneum through the internal inguinal ring; inguinal hernia repair is the most common elective procedure in pediatric surgery.

3 Neonatal bilious emesis should be considered the result of an acute mechanical intestinal obstruction until proven otherwise; emergent surgical evaluation is warranted to determine whether intestinal malrotation with midgut volvulus is present.

4 Necrotizing enterocolitis (NEC) is a progressive, inflammatory intestinal condition of the surviving premature neonate. Perforated NEC is the most common neonatal surgical emergency.

5 Hirschsprung disease is caused by aganglionosis of the myenteric nervous system in the rectum. Most commonly, the rectosigmoid colon is involved, but the length of contiguous aganglionosis varies in length proximally. Both propulsion and reflexive relaxation may be disordered or absent in the rectum, leading to functional bowel obstruction in the neonate and chronic constipation in the older child or adolescent. Enterocolitis associated with Hirschsprung disease is a potentially life-threatening condition.

6 Intussusception is the invagination or telescoping of a proximal segment of intestine into an adjacent distal segment and is the most common cause of intestinal obstruction in infants and children 3 months to 3 years of age.

7 The incidence of biliary atresia is 1 in 8,000 to 12,000 live births and is the most common cause of chronic cholestasis in infants and children as well as the most frequent indication for pediatric liver

transplantation. Early diagnosis and management is necessary for optimal outcome.

ABDOMINAL WALL DEFECTS

Gastroschisis

1 Gastroschisis occurs with an incidence of about 1 in 2,000 to 4,000 live births. Infants with gastroschisis tend to be born to mothers who are younger (teenage), white, and consumed alcohol or tobacco during pregnancy.[1–3] Familial cases of gastroschisis are distinctly rare.[4] Associated congenital anomalies are uncommon. However, in about 10% of cases, intestinal atresia or stenosis can be seen and is thought to be a result of mechanical or vascular compromise to the herniated bowel. Rarely, infants with gastroschisis have complete loss of small bowel secondary to volvulus in utero.

The pathophysiology of gastroschisis remains unknown. In normal fetal development, two umbilical veins are initially present. As the intestine returns to the abdominal cavity through the umbilicus, the right umbilical vein undergoes resorption, leaving the left umbilical vein intact. Weakness of the umbilical membrane at the site of umbilical vein resorption may allow the evisceration of the intestine through the defect. This explanation is consistent with the clinical observation that the gastroschisis defect is almost always located to the right of the umbilicus. Routine antenatal ultrasonography has documented the sequential development of gastroschisis as a consequence of a ruptured hernia of the umbilical cord in utero.[5] Therefore, gastroschisis should be considered an isolated mechanical defect of the developing umbilical cord rather than a global defect in embryogenesis.

The amount of bowel eviscerated in gastroschisis can be extensive because the bowel has not undergone complete mesenteric rotation and fixation at this particular time in embryogenesis. The bowel may be thickened and the mesentery may be foreshortened secondary to the inflammatory response induced by direct exposure to amniotic fluid. In gastroschisis, herniation of the liver is distinctly unusual (Fig. 101.1).

Figure 101.1 Gastroschisis. The defect is to the right of the normal umbilicus, and the bowel is thickened and inflamed.

Figure 101.2 Omphalocele. The herniated intestines and liver are visible inside the sac. The umbilical cord attaches to the sac.

Omphalocele

Anatomy, Embryology, and Pathophysiology

The incidence rate of omphalocele is approximately 1 in 6,000 to 10,000 live births and has been stable over the past several decades. *Omphalocele* is a midline abdominal wall defect of varying size characterized by the presence of herniated visceral contents into the translucent sac of the umbilicus. The sac is composed of amniotic membrane, mesenchymal tissue known as *Wharton jelly,* and peritoneum. The umbilical cord attaches to the sac and may be eccentric in origin (Fig. 101.2). The sac may be inadvertently ruptured before or during delivery but it is always present. Similar to gastroschisis, intestinal malrotation is usually present. Unlike gastroschisis, the bowel is typically normal in appearance because it has not been directly exposed to the amniotic fluid. Small omphaloceles are defined as 2 to 3 cm in diameter and have only a small amount of herniated bowel within the sac. Closure of small omphaloceles is typically performed without significant physiologic complications. In contrast, giant omphaloceles defined as greater than 4 cm in diameter can lead to extensive herniation of the stomach, bowel, liver, and spleen with subsequent underdevelopment of the abdominal cavity (Fig. 101.3).

Omphalocele results from incomplete closure of the anterior abdominal wall at the umbilicus during embryogenesis. During week 4 of gestation, the midgut undergoes progressive elongation in the yolk sac outside the embryonic coelomic cavity. The midgut returns to the abdominal cavity during week 10, where it undergoes normal rotation and fixation of the mesentery to the posterior abdominal wall. Normal closure of the anterior abdominal wall requires return of the midgut to the abdominal cavity, along with growth and fusion of the anterior body folds (cephalic, caudal, and two lateral) at the base of the umbilicus. Failure of growth, migration, or fusion of the lateral body folds leads to omphalocele. Failure of growth and fusion of the cephalic folds may lead to either a supraumbilical omphalocele associated with a midline sternal defect (Fig. 101.4) and a herniated heart, termed *ectopia cordis,* or a constellation of defects known as the *pentalogy of Cantrell.*[6] This sequence includes a sternal cleft, an absence of the septum transversum of the diaphragm, a pericardial defect, a cardiac defect, and an epigastric

omphalocele. Infants born with either ectopia cordis or pentalogy of Cantrell have significant morbidity and often, these conditions are lethal.

Figure 101.3 Ruptured omphalocele. Although the bowel is relatively normal in appearance, the abdominal cavity is extremely underdeveloped.

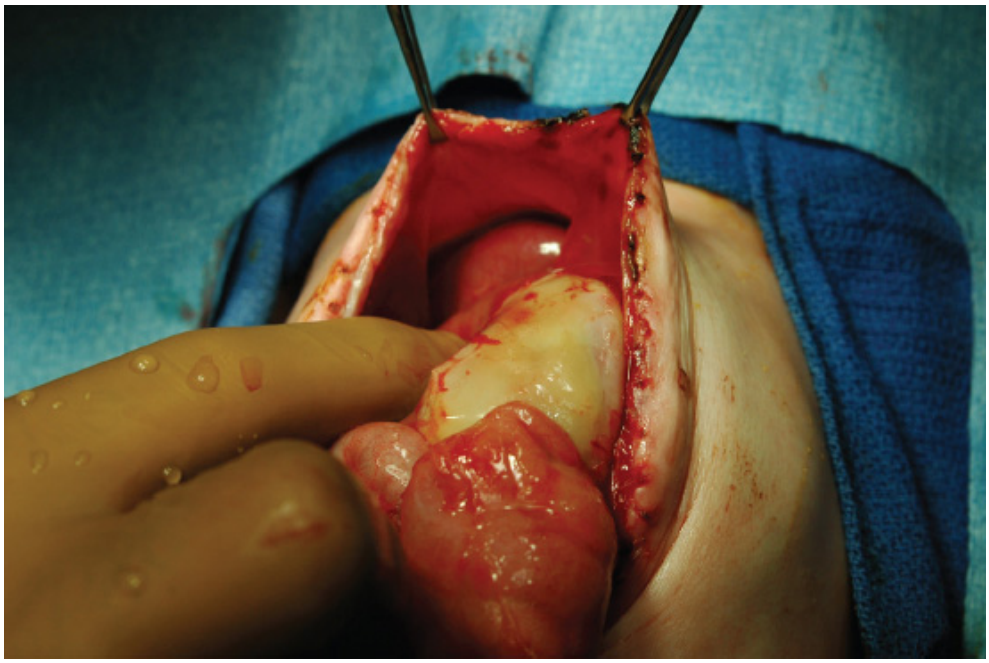

Figure 101.4 Operative exploration of giant omphalocele with abdominal wall defect, absence of the septum transversum of the diaphragm, pericardial defect, and cardiac defect.

Associated anomalies are more common in infants with omphalocele than with gastroschisis, reflecting the more global abnormality of embryogenesis in omphalocele. About 50% to 60% of infants with omphalocele have at least one associated congenital anomaly involving the skeleton, gastrointestinal tract, nervous system, genitourinary system, and cardiopulmonary system.[7,8] In addition, infants with omphalocele have a higher incidence of chromosomal abnormalities and other conditions such as Beckwith–Wiedemann syndrome. A comparison of gastroschisis and omphalocele is summarized in Table 101.1.

Perioperative Management for Gastroschisis and Omphalocele

In contemporary practice, infants with gastroschisis can be safely delivered vaginally.[8,9] Studies comparing vaginal delivery with elective cesarean section for infants with gastroschisis demonstrated no significant differences in outcome.[10,11] Early delivery to minimize intestinal damage in gastroschisis patients has not been proved to be efficacious.[12,13] Fetal well-being has been advocated to be the primary determinant for gastroschisis. To prevent birth-related hepatic injury, cesarean section is preferable for prenatally diagnosed infants with giant omphaloceles.

After delivery, infants with either gastroschisis or omphalocele have similar initial management priorities. If necessary, an adequate airway with effective ventilation and oxygenation is established. The infant should be maintained under either an external warmer or a humidified incubator. An orogastric sump tube should be inserted early and placed on suction to prevent intestinal distention. In gastroschisis, the herniated viscera should be examined to make certain that the mesentery is not twisted. In addition, the tightness of the opening of the abdominal wall should be assessed to ensure that there is sufficient perfusion of the bowel. The infant's entire lower torso can be placed inside a plastic bowel bag, or the viscera can be covered with moisten gauze, to prevent further contamination, hypothermia, and volume depletion. The initial therapeutic goal is to provide rapid, effective temporary coverage of the viscera. Adequate support of the herniated viscera must be provided to prevent intestinal ischemia. This can be done by placing the baby on his or her side, and placing support under the intestines. With large

omphaloceles, the position of the infant's liver and viscera may impair venous return from the inferior vena cava when the infant is supine, and these infants may preferentially require a left-side-down position to maintain normal hemodynamics. Intravenous dextrose and broad-spectrum antibiotics are administered. Infants with gastroschisis will have higher intravenous fluid requirements to maintain euvolemia. If the infant is not delivered at a center where definitive surgical care can be provided, urgent transport should be arranged.

DIAGNOSIS

Table 101.1 Comparison of Gastroschisis and Omphalocele

Characteristic	Gastroschisis	Omphalocele
Defect size (diameter)	2–3 cm	2–15 cm
Sac	Never	Always, may be ruptured
Gestational age	Prematurity	Term
Umbilical cord	Adjacent (left side) of defect	Attached to sac
Herniated viscera	Small bowel, stomach, colon	Small bowel, stomach, colon, liver
Malrotation	Yes	Yes
Bowel character	Inflammatory, edematous	Normal
Enteral nutrition	Delayed	Normal
Associated anomalies	Uncommon (10% atresia)	Common (50%)

Gastroschisis

Once the infant with gastroschisis has been stabilized, measures are taken to secure the viscera and, if possible, correct the abdominal wall defect. One option is to take the infant to the operating room, where reduction of the herniated viscera with primary fascial closure of the abdominal wall is an achievable goal in approximately 60% to 70% of infants with either gastroschisis. Gentle but definitive stretching of the abdominal wall is performed, and proximal decompression of the bowel is maintained with orogastric decompression. The defect may need to be enlarged to evaluate the intestinal tract fully and/or reduce the viscera into the abdominal cavity. The limiting factor in primary closure of a congenital abdominal wall defect is the increased intra-abdominal pressure generated by the reduction of the herniated viscera. Increased intra-abdominal pressure can lead to abdominal compartment syndrome. Features of neonatal abdominal compartment syndrome include impaired venous return caused by compression of the inferior vena cava, reduction of splanchnic blood flow leading to mesenteric ischemia, and respiratory compromise secondary to impaired diaphragmatic excursion. Intraoperative measurement of intragastric or intravesical pressure, end-tidal CO_2, central venous pressure, or regional oximetry may be helpful in determining the safety of primary abdominal wall closure. If the herniated viscera cannot be reduced primarily, the viscera is placed in a constructed Silastic pouch or preformed spring-loaded silo. Daily partial reduction of the viscera within the silo is performed. This technique allows gradual reduction of the herniated viscera into the abdominal cavity, and complete reduction is usually obtained within 3 to 7 days. The infant is returned to the operating room for removal of the temporary silo with delayed primary closure of the abdominal wall defect (Fig. 101.5). Alternatively, a large abdominal wall defect may be effectively covered with abdominal skin flaps, or biologic mesh, with delayed repair of the ventral hernia months to years later (gross closure).

Figure 101.5 Silastic chimney or silo for temporary coverage and staged reduction of giant omphalocele.

In some centers, all babies with gastroschisis are managed by placing a preformed silo at the bedside after the baby is born. Thereafter, the viscera is slowly reduced into the abdomen and eventual fascial closure is attained.[14] Some studies caution that this practice may lead to longer ventilator and fluid requirements.[14,15] Another method that has been described in gastroschisis patients with noninflamed pliable intestines is to reduce the viscera with some sedation at the bedside, fold the umbilical cord stump over the skin closure, and place a pressure dressing over the defect.[16] The use of the umbilical stump has been described even for patients requiring staged or silo closure.[17] In some retrospective studies, this method of closure has been shown to effect fewer days of mechanical ventilation, decreased antibiotic and opioid utilization, but with a higher rate of umbilical hernia at follow-up.[17–21] A wound vacuum closure can be used to augment this technique.

Omphaloceles

Given the high incidence of associated anomalies, infants with omphalocele should undergo diagnostic investigation, guided by the clinical presentation and physical examination. These studies include chest radiography, echocardiogram, and renal ultrasound, in addition to baseline blood work. Chromosomal analysis may be necessary. Until the decision is made with

respect to the timing and method of repair, the omphalocele should remain covered and protected with a gauze dressing. If the omphalocele is ruptured or torn, immediate closure or coverage is necessary.

Closure of omphaloceles is dictated by the size of the defect, the amount of viscera extruded into the sac, and the abdominal domain. There is no standard definition of what constitutes a regular versus a giant omphalocele. Practically, a giant omphalocele has an abdominal wall defect larger than 4 cm, containing a portion of liver, and is difficult to close primarily in the first days of life without physiologic compromise.

Omphaloceles with a small abdominal wall defect typically would have operative fascial closure with sac excision in the newborn period. Many techniques have been described to close giant omphaloceles including sac excision and temporary coverage with grafts, use of intraperitoneal tissue expanders,[22,23] and allowing the omphalocele sac to scar and then epithelialize in the latter technique.

The sac can be physically supported and left undisturbed, allowing epithelialization of the sac over several weeks to months. Antibiotic solutions or ointments are usually applied to control desiccation.[23–26] Delayed repair of the ventral hernia is required. This delay is particularly useful in the infant with a giant omphalocele and a small, underdeveloped abdominal cavity that prohibits primary closure.

Infants with repaired omphalocele usually have relatively prompt return of bowel function after definitive repair, while infants with gastroschisis may require up to 4 weeks after repair to have bowel function normalize. The time to achieve full enteral feeding is not affected by the use of erythromycin as a prokinetic agent.[27] Approximately 15% of infants with gastroschisis develop necrotizing enterocolitis (NEC), a diffuse, often life-threatening inflammatory complication of the neonatal intestinal tract.[28] In addition, infants with gastroschisis are at risk for nutrient malabsorption and intestinal dysmotility with inability to tolerate full enteral feeding. In particular, infants with gastroschisis and associated intestinal atresia may have pronounced intestinal dysmotility and may require long-term, sometimes lifelong, dependence on TPN for caloric intake.[29]

Long-term outcome of infants operated on for gastroschisis or omphalocele is usually dependent on the morbidity and mortality of associated conditions rather than the abdominal wall defect itself. Surgical conditions such as

undescended testicles, Meckel diverticulum, and adhesive small bowel obstruction are encountered with moderate frequency. Adhesive small bowel obstruction most commonly occurs in the first year of life and requires operative management in the majority.[30] Most children with repaired abdominal wall defects enjoy satisfactory health and quality of life, although they have been reported to have a lower degree of physical fitness measured by exercise time and maximal oxygen consumption.[31]

Umbilical Hernia

Anatomy and Embryology

Congenital umbilical hernia is the most common abdominal wall defect in infants and children. The umbilical ring begins to contract circumferentially after birth and normally is reinforced by the paired lateral umbilical ligaments (the obliterated umbilical arteries), the singular round ligament (the obliterated umbilical vein), the urachal remnant, and the transversalis fascia. Incomplete growth or impaired development of any one of these structures can lead to weakness at the umbilical ring and cause a congenital umbilical hernia.

Clinical Issues and Management

Congenital umbilical hernias generally do not pose significant problems during childhood, with incarceration of intra-abdominal contents within the sac occurring about 1:1,500 cases.[32] Infants and children may also present with infection or drainage at the umbilicus from associated urachal or vitelline duct remnants. The incidence rate of congenital umbilical hernia has been reported to be 25% to 50% in black infants and 4% to 9% in white infants in the first few months of life.[33] There is an increased incidence of umbilical hernia in premature infants, and there is a tendency for familial inheritance.

Diagnosis of umbilical hernia is usually made after separation of the umbilical cord remnant from the umbilicus and is often initially noted by parents or pediatrician. The size of the defect may vary from a few millimeters to several centimeters and is typically reducible and asymptomatic. Age and size of the defect are the most important factors

determining spontaneous closure rates.[34] Many umbilical hernias spontaneously close within the first 2 to 3 years of life. Given the high rate of spontaneous closure and the relatively asymptomatic nature of most umbilical hernias, operative repair is generally not performed during the first 2 years of life. Skin ulceration or an episode of incarceration should prompt earlier repair. Large defects with significant protrusion may necessitate surgery, and parents may desire repair if an older child appears to be self-conscious about the hernia.

Nearly all umbilical hernia repairs can be performed as outpatient surgical procedures. An incision is made along the umbilicus and the hernia sac is dissected free circumferentially. The sac is completely excised and primary fascial closure is performed. The umbilical skin is typically preserved and sutured to the fascial closure, and an acceptable cosmetic result is almost always achievable. Large umbilical hernias with redundant skin may require umbilicoplasty. The incidence of complications such as wound infection and recurrence is low.

Inguinal Hernia and Hydrocele

Anatomy, Embryology, and Pathophysiology

2 Inguinal hernia repair is the most common elective general surgical procedure performed by pediatric surgeons. Three distinct anatomic types of inguinal hernias are observed in children: congenital indirect (99% of infants and children), direct (0.5%), and femoral (<0.5%). An *indirect inguinal hernia* is an abnormal, patent continuation of the peritoneum through the internal inguinal ring. The hernia sac originates lateral to the deep inferior epigastric vessels and descends along the spermatic cord within the cremasteric fascia. The sac can reside completely within the inguinal canal or descend through the external inguinal ring into the scrotum. A *direct inguinal hernia* originates medial to the deep inferior epigastric vessels and is external to the cremasteric fascia. The hernia sac protrudes directly through the posterior wall of the inguinal canal and can descend through the external inguinal ring and into the scrotum. A *femoral hernia* originates medial to the femoral vein and descends inferior to the inguinal ligament along the femoral canal. A femoral hernia never enters the scrotum or the labia.

The developing testicle is initially adjacent to the mesonephros and subsequently descends to the scrotum during the third trimester of gestation. The peritoneal extension that descends alongside the chorda gubernaculum of the testicle is called the processus vaginalis. A slightly higher incidence rate of right-sided indirect inguinal hernia is thought to reflect delay of right-sided testicular descent from the developing inferior vena cava and right external iliac vein. As the testicle descends into the scrotum, the processus vaginalis forms a serous covering around the testicle known as the tunica vaginalis. Normally, the patent processus vaginalis undergoes obliteration, closing the communication between the peritoneal cavity and the inguinal canal. A patent processus vaginalis can lead to a variety of anatomic conditions of the inguinal region (Fig. 101.6).

The incidence of patent processus vaginalis has been reported to be as high as 80% to 94% in newborn infants undergoing autopsy,[35] whereas in adulthood, the incidence is 20% to 30%. Infants with unilateral inguinal hernias have been found to have a patent contralateral processus vaginalis in 60% during the first few months of life. By the age of 2 years, 20% of these hernias were obliterated, and half of the remaining 40% became clinical hernias.[36] At least 30% of infants requiring placement of a ventriculoperitoneal shunt for hydrocephalus have been observed to have a patent processus vaginalis in the first few months of life, with a rapid decline in patency in older children.[37] These studies, along with contemporary use of laparoscopic exploration of the contralateral internal ring, demonstrate that although a patent processus vaginalis is common in infancy, there is some degree of obliteration that occurs with increasing age, and a patent processus vaginalis by itself does not constitute a clinical inguinal hernia.

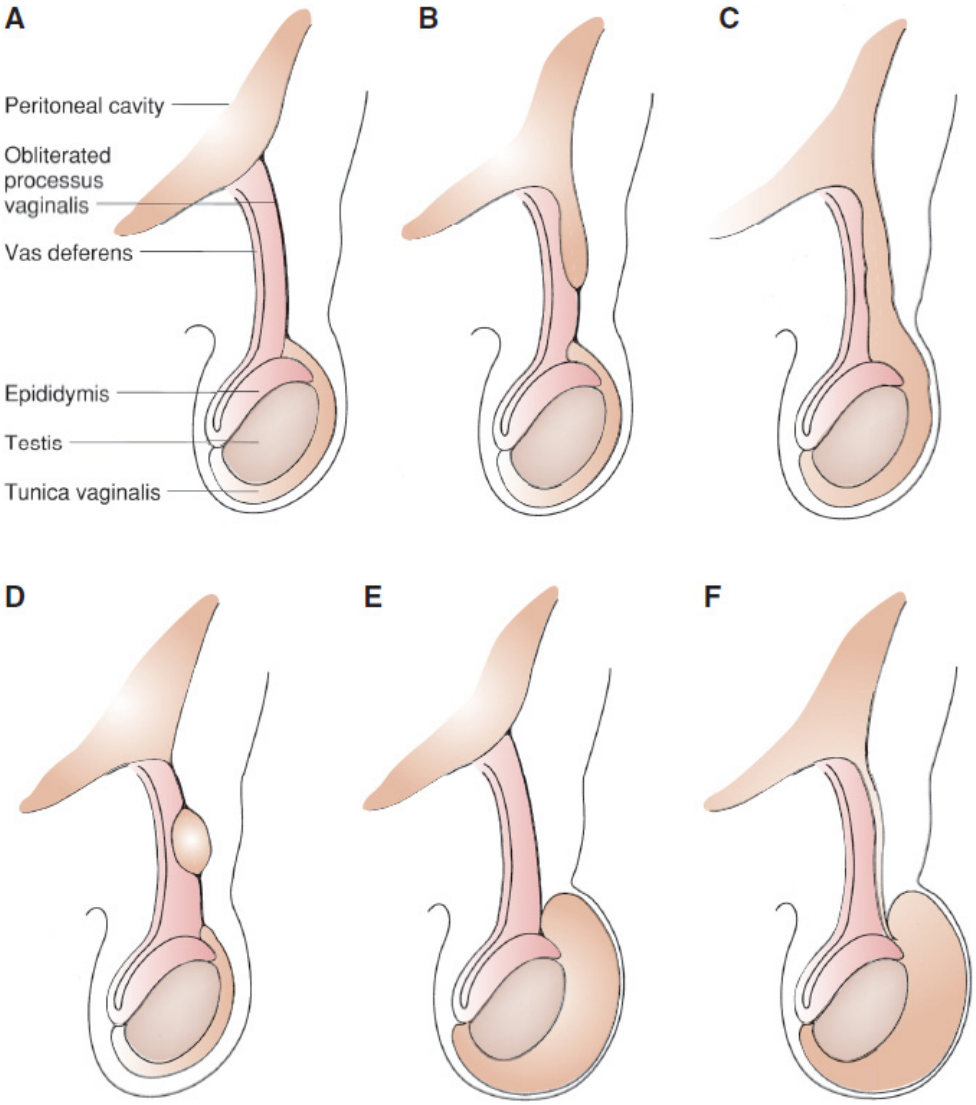

Figure 101.6 Anatomic variations that occur with different degrees of obliteration of the processus vaginalis. **A:** Normal; obliterated processus vaginalis. **B:** Proximal hernia sac; distal obliterated processus. **C:** Hernia sac extending into scrotum; no obliteration. **D:** Proximal and distal obliteration with hydrocele of the cord. **E:** Hydrocele of the scrotum, obliterated processus. **F:** Patent processus with communicating hydrocele.

Clinical Issues

Inguinal hernias occur in 1% to 3% of all children and in 3% to 5% of premature infants. There is no known inheritance pattern, but there is an increased incidence of inguinal hernia in children with connective tissue disorders such as Ehlers–Danlos syndrome and Marfan syndrome. There is a 6:1 predominance of males to females. At least 30% of children are younger

than 6 months at the time of operative repair. Inguinal hernia more commonly presents as right-sided (56.2%) compared with left-sided (27.5%) or bilateral (16.2%).[38]

Most infants and children with an inguinal hernia have a history of an intermittent inguinal mass or bulge that may descend into the scrotum or labia. The hernia may become more pronounced during times of increased intra-abdominal pressure, such as crying or defecating. Most inguinal hernias in children reduce spontaneously or are reducible with gentle, manual pressure along the inguinal canal. Female infants may have an ovary and fallopian tube in the hernia sac, identified clinically as a firm, slightly mobile, nontender mass in the labia or the inguinal canal. Most parents or pediatricians give a characteristic history that is sufficient to warrant inguinal exploration, even in children in whom the hernia cannot be clinically demonstrated at the time of examination. Depending on institution and surgeon preference, infants and children with a strong history consistent with inguinal hernia and an equivocal clinical examination may be offered ultrasound or diagnostic laparoscopy to effectively confirm the diagnosis before groin exploration.[39]

Incarceration is a common consequence of untreated inguinal hernia and presents as a nonreducible mass in the inguinal canal, scrotum, or labia.[40] Clinical symptoms and signs are related to the duration of incarceration. If the incarceration has been present for several hours, the infant may be inconsolable and have feeding intolerance, pain, abdominal distention, vomiting, and lack of flatus or stool, signaling complete intestinal obstruction. The affected groin may become quite edematous, and a reactive scrotal hydrocele may evolve. Elevation of the infant's lower extremities with a pillow may help encourage spontaneous reduction. Attempts at manually reducing an incarcerated inguinal hernia should be performed by an experienced surgeon. If necessary, sedation to calm the infant before attempting manual reduction may be cautiously used. Ice packs should be avoided in infants and children. Following successful reduction of an incarcerated hernia, expedient elective repair of the hernia should be performed after the edema has subsided. This may be up to 48 hours later. If reduction of an incarcerated hernia requires several attempts and is difficult, overnight inpatient observation is warranted to rule out reduction of strangulated bowel; fortunately, this is an uncommon occurrence in the pediatric population. Inability to reduce an incarcerated hernia is a clear

indication for urgent operative exploration and repair. Incarcerated inguinal hernia must be differentiated from an acute, noncommunicating hydrocele, or inguinal lymphadenitis. With acute hydrocele, it is usually possible to transilluminate the hydrocele and palpate normal cord structures above the scrotal mass. In addition, symptoms of bowel obstruction are absent with acute hydrocele. Acute lymphadenitis typically is associated with fever, erythema, and tenderness, and there may be a history of lower extremity infection on the ipsilateral side. If the inguinal mass is not reducible and an incarcerated hernia cannot be excluded, urgent groin exploration is required.

Operative Considerations and Outcome

The diagnosis of inguinal hernia in an infant or a child is an indication for operative repair. The rationale for elective repair is to prevent the complications associated with incarceration. At least 71% of infants who require operative reduction of incarcerated inguinal hernia are younger than 11 months.[41] Therefore, an approach emphasizing timely elective repair of inguinal hernia is warranted, particularly during infancy. Delay of elective repair may be necessary in premature, extremely low–birth-weight (<1,500 g) infants and in children with other conditions such as congenital heart disease, pulmonary disease, infection, or metabolic disease.

Elective inguinal hernia repair in the pediatric age group is usually performed as an outpatient surgical procedure using general anesthesia, although spinal anesthesia is an effective alternative in selected high-risk infants.[42] A regional caudal block or local inguinal nerve block using local anesthetic is useful to diminish perioperative pain and increase patient comfort. These techniques, along with the use of rapid-acting general anesthetics, allow the vast majority of children to be discharged home within hours of operation. Overnight observation and monitoring are required for high-risk infants and children with disorders that increase anesthetic risk for postoperative apnea.

Repair of pediatric inguinal hernia relies on high ligation of the hernia sac at the internal inguinal ring. Sensory nerves deep to the external oblique aponeurosis should be identified and preserved. Careful identification and dissection of the hernia sac from the vas deferens and the testicular blood supply must be performed. The vas deferens must be carefully dissected free

from the sac, and direct handling or pinching of the vas with forceps is avoided. The absence of a vas deferens or a blind-ending vas may be observed in children with cystic fibrosis (CF). In female infants, opening the hernia sac to visualize the ovary and fallopian tube may help avoid inadvertent injury to these structures during suture ligation of the sac. The distal component of the hernia sac is opened widely, and any fluid in the sac is evacuated. If the internal inguinal ring is attenuated or enlarged, it can be repaired with a few sutures. Experience with laparoscopic inguinal hernia repair using purse-string suture closure of the patent internal ring without direct inguinal exploration has been described.[43] The testicle is returned to its scrotal position by gentle traction on the gubernaculum, and the spermatic cord is carefully aligned along the inguinal canal. Postoperative pain is managed with oral acetaminophen for 24 to 48 hours; older children may require postoperative narcotics. In addition, abnormalities of the vas deferens may be associated with genitourinary anomalies. A renal ultrasound should be performed to rule out kidney malformations.

Operative exploration of the asymptomatic contralateral groin remains controversial but is often performed in infants younger than 2 years because of the reported 60% to 70% incidence of a patent processus vaginalis on the opposite side.[44] In a survey of the surgical section of the American Academy of Pediatrics, 65% of the respondents perform contralateral exploration in male patients younger than 2 years, and 84% perform exploration for female infants up to 4 years of age.[45] Direct visualization of the contralateral groin can be performed using a laparoscope inserted either through the umbilicus or through a side-viewing laparoscope inserted through the hernia sac. Experience with diagnostic laparoscopy demonstrates that approximately one-third to one-half of children have a patent processus vaginalis on the contralateral, asymptomatic groin, with higher rates in infants younger than 1 year.[46,47] This approach avoids unnecessary contralateral groin exploration in about half of all children who undergo surgery for unilateral inguinal hernia. However, the presence of a patent processus alone does not necessarily translate into a clinically significant hernia, and via systematic review, the reported risk of developing a metachronous contralateral inguinal hernia following open unilateral hernia repair in children is 7.2%.[48]

The major risk of inguinal hernia repair in infants and children is related to general anesthesia. Complications in pediatric inguinal hernia repair include

wound infection, injury to the vas deferens or testicular vessels, injury or displacement of the testicle, and recurrence. Fortunately, all these complications are infrequent. The overall complication rate is higher for children requiring emergent operation for incarcerated or strangulated hernia. Recurrent inguinal hernia following elective repair is unusual and may be an indication of an underlying connective tissue disorder such as Ehlers–Danlos syndrome.

Hydrocele

A *hydrocele* is a fluid collection that resides in the tunica vaginalis in the scrotum or the processus vaginalis in the inguinal canal. A hydrocele may be present at birth, or it may occur acutely as a result of an incarcerated hernia or torsion of the appendix testis. On examination, a hydrocele transilluminates with a bright handheld light. A hydrocele is described as either *communicating* or *noncommunicating* depending on whether there is direct patency between the hydrocele and the peritoneal cavity. A history of intermittent fluctuation in the size of the hydrocele is generally diagnostic for communicating hydrocele. A communicating hydrocele is synonymous with a patent processus vaginalis, and, therefore, a communicating hydrocele is treated operatively in the same fashion. In male patients, a hydrocele of the cord is a collection of fluid in the processus vaginalis separate from the tunica vaginalis. In female patients, fluid trapped in the processus vaginalis is considered a hydrocele of the canal of Nuck. In noncommunicating hydrocele, the isolated fluid collection is typically asymptomatic and tends to spontaneously resolve before age 12 months. Operative management of noncommunicating hydrocele is usually reserved for lesions that persist after this age, acute enlargement of the hydrocele, or if there is any question of communication.

GASTROINTESTINAL DISORDERS

Neonatal Intestinal Obstruction

3 A variety of congenital anatomic defects, inherited metabolic diseases, and acquired physiologic disorders may present as intestinal obstruction in a newborn. Neonatal intestinal obstruction is characterized clinically by bilious emesis and is often associated with abdominal distention. Bilious emesis in a neonate must be considered to be acute mechanical intestinal obstruction until proven otherwise. Emergent surgical evaluation is warranted for any newborn with bilious emesis. Table 101.2 provides differential diagnoses for neonatal intestinal obstruction along with salient features of the history, physical examination, and diagnostic studies.

The clinical presentation of neonatal intestinal obstruction depends, in part, on the site of obstruction and the age of the infant. Clinical examination of the infant typically provides the surgeon with a preliminary diagnosis and helps guide further diagnostic studies. Abdominal distention is a characteristic physical finding with distal bowel obstruction, whereas the abdomen may be flat in proximal obstruction. The presence of bile in the gastric contents or stool provides clinical evidence of the location of an obstruction relative to the ampulla of Vater. Bilious emesis in an infant or child should be considered an anatomic obstruction requiring emergent surgical evaluation. An infant with bilious emesis who has already passed meconium and has tolerated feeding is unlikely to have intestinal atresia and more likely to have intestinal malrotation with midgut volvulus. If volvulus is suspected, emergent evaluation must be performed to diagnose and prevent catastrophic bowel injury or death.

Definitive diagnosis of neonatal intestinal obstruction may often be made by physical examination and readily available radiologic studies. Incarcerated inguinal hernia is an important cause of neonatal bowel obstruction, and examination leads to a straightforward diagnosis. Some congenital conditions have clearly recognizable features and may be associated with anatomic intestinal obstruction. For example, infants with trisomy 21 have a higher probability of having duodenal atresia or Hirschsprung disease than the general population. An approach to imaging the neonate suspected of having an intestinal obstruction is to obtain a plain abdominal radiograph, followed by either a contrast enema or an upper gastrointestinal series. Plain films of the newborn abdomen can be extremely useful because swallowed gas acts as a contrast agent. For example, duodenal atresia gives rise to a dilated, gas-filled stomach and duodenum

proximal to the obstruction; the remainder of the bowel remains gasless, giving rise to the “double-bubble” appearance on plain films. Other causes of proximal intestinal obstruction may lead to a microcolon on contrast enema, which is a small, unused but otherwise normal colon. If a retrograde contrast enema does not pass into the dilated segment of bowel, an upper gastrointestinal series may be useful to identify a more proximal obstruction. Upper gastrointestinal series is also the most useful diagnostic test for intestinal malrotation.

Table 101.2 Neonatal Intestinal Obstruction

Diagnosis	History	Physical Examination	Diagnostic Studies
Intestinal atresia or stenosis	Bilious emesis Failure to pass meconium	Abdominal distention	Plain abdominal film Contrast enema
Duodenal atresia or stenosis	Bilious or nonbilious emesis Feeding intolerance	Gastric distention Trisomy 21	Plain abdominal film Upper GI contrast study
Imperforate anus	Failure to pass meconium Bilious emesis (late)	Absent anus or visible fistula Abdominal distention VACTERL association	Plain chest, abdominal film Ultrasound kidneys, sacrum, rectum Echocardiogram
Necrotizing enterocolitis	High-risk, premature infant Bilious emesis	Abdominal distention Abdominal wall erythema Hematochezia, guaiac positive stool	Plain abdominal film
Meconium ileus	Cystic fibrosis (10%) Bilious emesis	Acholic meconium Abdominal distention	Plain abdominal film Contrast enema
Malrotation	Bilious	No abdominal	Plain abdominal

	emesis Term, healthy infant	distention	film Upper GI contrast study
Hirschsprung disease	Delayed passage of meconium Bilious emesis	Abdominal distention Trisomy 21	Plain abdominal film Contrast enema
Uncommon causes of obstruction (intussusception, Meckel diverticulum, duplication)		Abdominal mass, incarcerated hernia	Variable
Medical conditions associated with ileus	Bilious emesis	Sepsis, hypothyroidism, etc.	Plain abdominal film

GI, gastrointestinal; VACTERL, vertebral, anal, cardiac, tracheal, esophageal, renal, and limb anomalies.

Several medical conditions of the newborn appear clinically similar to mechanical intestinal obstruction (see Table 101.2). In particular, bilious emesis from ileus secondary to neonatal sepsis is not uncommon. Congenital hypothyroidism is an infrequent and medically treatable condition that can produce delayed intestinal motility that mimics mechanical intestinal obstruction.

Intestinal Atresia or Stenosis

Embryology and Anatomy

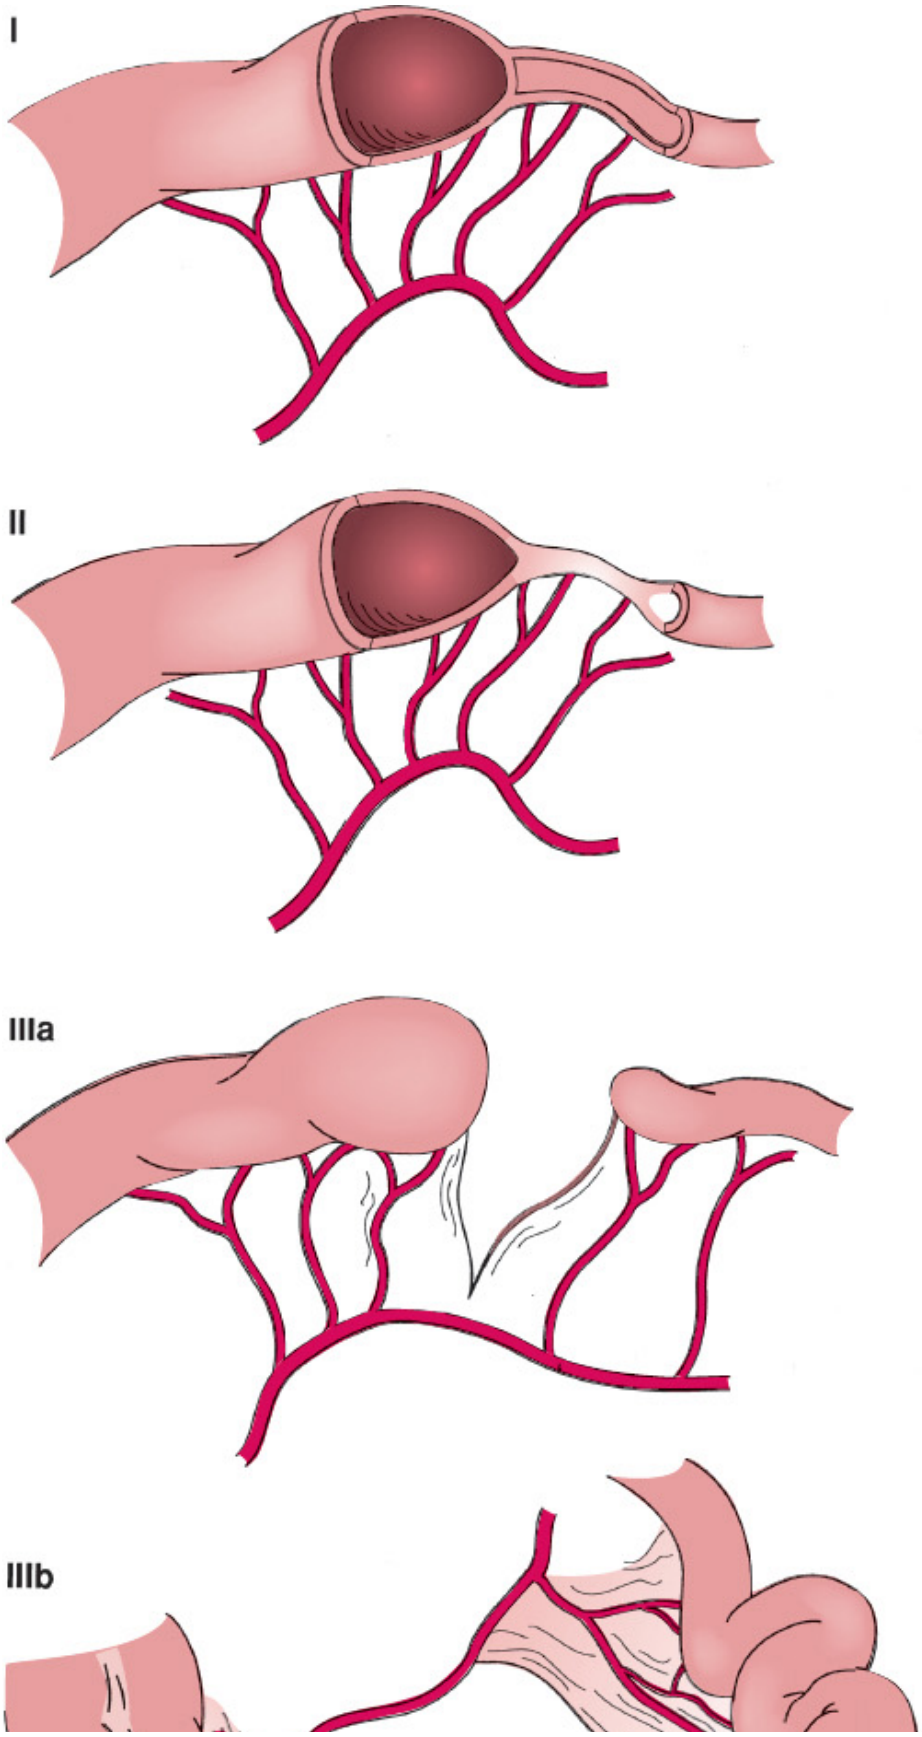
The embryonic intestine undergoes segmental development during the third week of gestation. The septum transversum demarcates the developing foregut from the midgut. The midgut can be considered a tubular structure that

progressively undergoes several predictable, developmental stages: (a) elongation; (b) herniation from and reduction into the coelomic cavity; (c) rotation; and (d) fixation of the mesentery to the posterior body wall.

Several different types of intestinal atresia are clinically observed (Fig. 101.7). *Type I* atresia is an intraluminal web or diaphragm that can either be complete or fenestrated with intact seromuscular layers of bowel. *Type II* and *IIIa* atresia are believed to be a result of in utero mesenteric vascular accidents. Experimental interruption of the fetal mesenteric blood supply in utero leads to this type of atresia.[49,50] *Type IIIb* atresia, also known as the *apple-peel* or *Christmas tree deformity,* has complete mesenteric discontinuity, with the distal bowel concentrically surrounding a singular mesenteric blood supply. *Type IV* atresia has multiple segmental areas of discontinuous bowel. Type IIIb and IV atresia are thought to be consequences of major and multiple fetal mesenteric vascular interruption.

At least 90% of infants with congenital intestinal obstruction of the small bowel have complete atresia, whereas the remaining children have either stenoses or fenestrated intraluminal webs. The most common location is the distal ileum, and multiple areas of atresia are discovered in 3.6% to 20% of these infants.[39] Infants with a fenestrated intraluminal web may have a small, often eccentric, opening that is only millimeters in diameter. These infants may not have obstructive symptoms until the introduction of solid food at 6 to 12 months of age and present with feeding intolerance, failure to thrive, or abdominal pain.

Congenital colonic atresia is a distinctly unusual condition. In a contemporary series of 277 infants treated with intestinal atresia, only 21 children had colonic atresia.[51] Similar to small bowel atresia, colonic atresia is believed to reflect fetal mesenteric vascular injury. Given the distal nature of colonic atresia, initial feeding may be well tolerated and definitive diagnosis may be delayed for several days. The diagnostic evaluation and surgical treatment of colonic atresia is identical to the approach used for small bowel atresia. Colonic atresia may be associated with abdominal wall defects, skeletal or cardiac defects, congenital aganglionosis (Hirschsprung disease), or coexisting intestinal atresia.



I
II
IIIa
IIIb

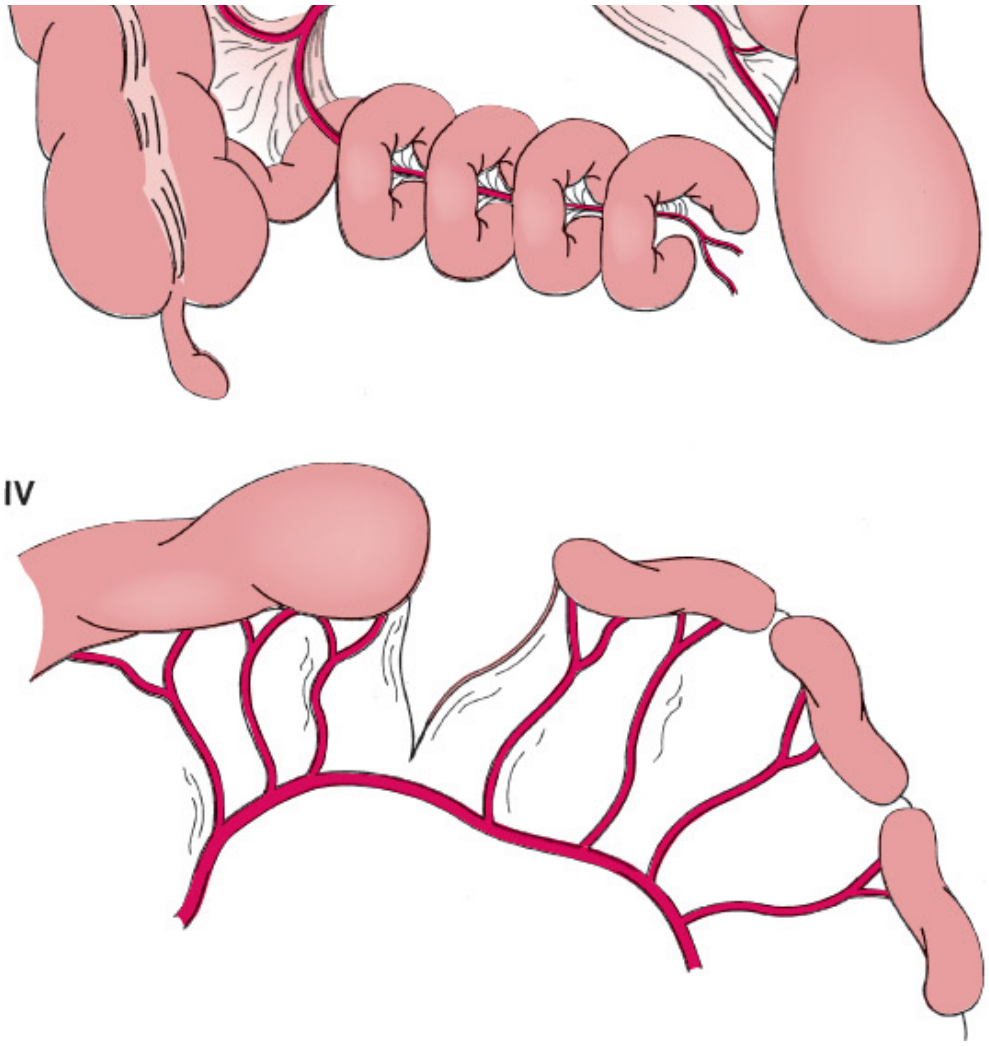


Figure 101.7 Classification of intestinal atresia. Type I, muscular continuity with a complete web. Type II, mesentery intact, fibrous cord. Type IIIa, muscular and mesenteric discontinuous. Type IIIb, apple-peel deformity. Type IV, multiple atresias.[57]

Clinical Presentation

Estimated incidence of intestinal atresia in the United States are 3.5 to 3.75 cases per 10,000 total births.[52] Infants with jejunal or ileal atresia have a low incidence rate of significant associated anomalies. Approximately 10% of infants with gastroschisis have intestinal atresia or stenosis secondary to mechanical interruption of the mesenteric vascular supply.

Detection of maternal polyhydramnios on routine prenatal ultrasound screening can be an indication of proximal bowel obstruction caused by the interruption of normal amniotic fluid absorption in the fetal gut.[53] Following

delivery, the classic clinical presentation of intestinal atresia is bilious emesis, abdominal distention, and failure to pass meconium. The degree of abdominal distention depends on the site of obstruction, the infant's age, and the efficacy of proximal decompression. Abdominal distention may be absent with proximal intestinal atresia. Distal intestinal atresia may lead to abdominal distention with visible or palpable intestinal loops on examination. Rectal examination and evaluation of stool character remains important when intestinal obstruction is suspected.

Diagnosis

Following history and physical examination, plain radiographic abdominal films should be obtained. Plain films in jejunal or ileal atresia demonstrate marked gaseous distention of the proximal intestine with gasless distal small bowel and colon. Haustral markings are normally not apparent in the neonatal colon, and, therefore, discrimination between small bowel and colon in the newborn is difficult without intraluminal contrast. A contrast enema is can be obtained to confirm the diagnosis of jejunoileal atresia and to rule out distal obstructions. A diminutive, unused but otherwise normal microcolon is typical, and the inability to reflux contrast into the proximal, dilated small bowel segment is diagnostic for congenital intestinal obstruction. This radiographic finding, in conjunction with the clinical setting, warrants operative exploration. An upper gastrointestinal series is unnecessary and may increase the risk of further emesis and aspiration in the newborn with obstruction. Incomplete obstruction from a fenestrated intraluminal web may require more sophisticated imaging techniques such as catheter-directed enteroclysis.

Treatment

Anatomic lesions causing neonatal intestinal obstruction require operative treatment. Whereas malrotation with midgut volvulus requires emergent diagnostic workup and operative intervention, obstruction resulting from intestinal atresia is generally not associated with life-threatening physiologic disturbances. Therefore, initial treatment is aimed at treating any other associated problems, confirming diagnosis, and preparing the infant for an operation. During this period, the infant should always have an orogastric or

nasogastric tube in place to provide proximal decompression of the obstructed bowel.

The operative strategy in treating intestinal atresia is to restore gastrointestinal tract continuity while preserving as much intestinal length as possible. The operation is straightforward and an end-to-end or end-to-oblique (end-to-back) anastomosis is typically performed (Fig. 101.8). Short-segmental bowel resection and excision of an intraluminal web or diaphragm are done when necessary. Visual inspection and instillation of intraluminal saline or air to exclude distal atresia or web prior to anastomosis is important to evaluate patency of the downstream bowel. The size discrepancy between the proximal and distal bowel is usually considerable, and delayed postoperative bowel motility is common. Some surgeons advocate the use of technical procedures to improve emptying of the proximal bowel by reducing overall bowel diameter. These procedures include resection of 4 to 5 cm of proximal jejunum or ileum, plication, and tapering enteroplasty. Complex atresia associated with apple-peel deformity or multiple segmental atresias may require multiple serial anastomoses to preserve as much bowel length as possible. The ileocecal valve is preserved whenever possible, allowing improved tolerance of enteral nutrition in infants with limited small bowel length. It is estimated that approximately 40 cm of small bowel without an ileocecal valve, compared with 15 to 20 cm with an ileocecal valve, is sufficient for long-term enteral feeding tolerance in the neonate.[54] Contemporary management of colonic atresia includes primary anastomosis when technically possible.

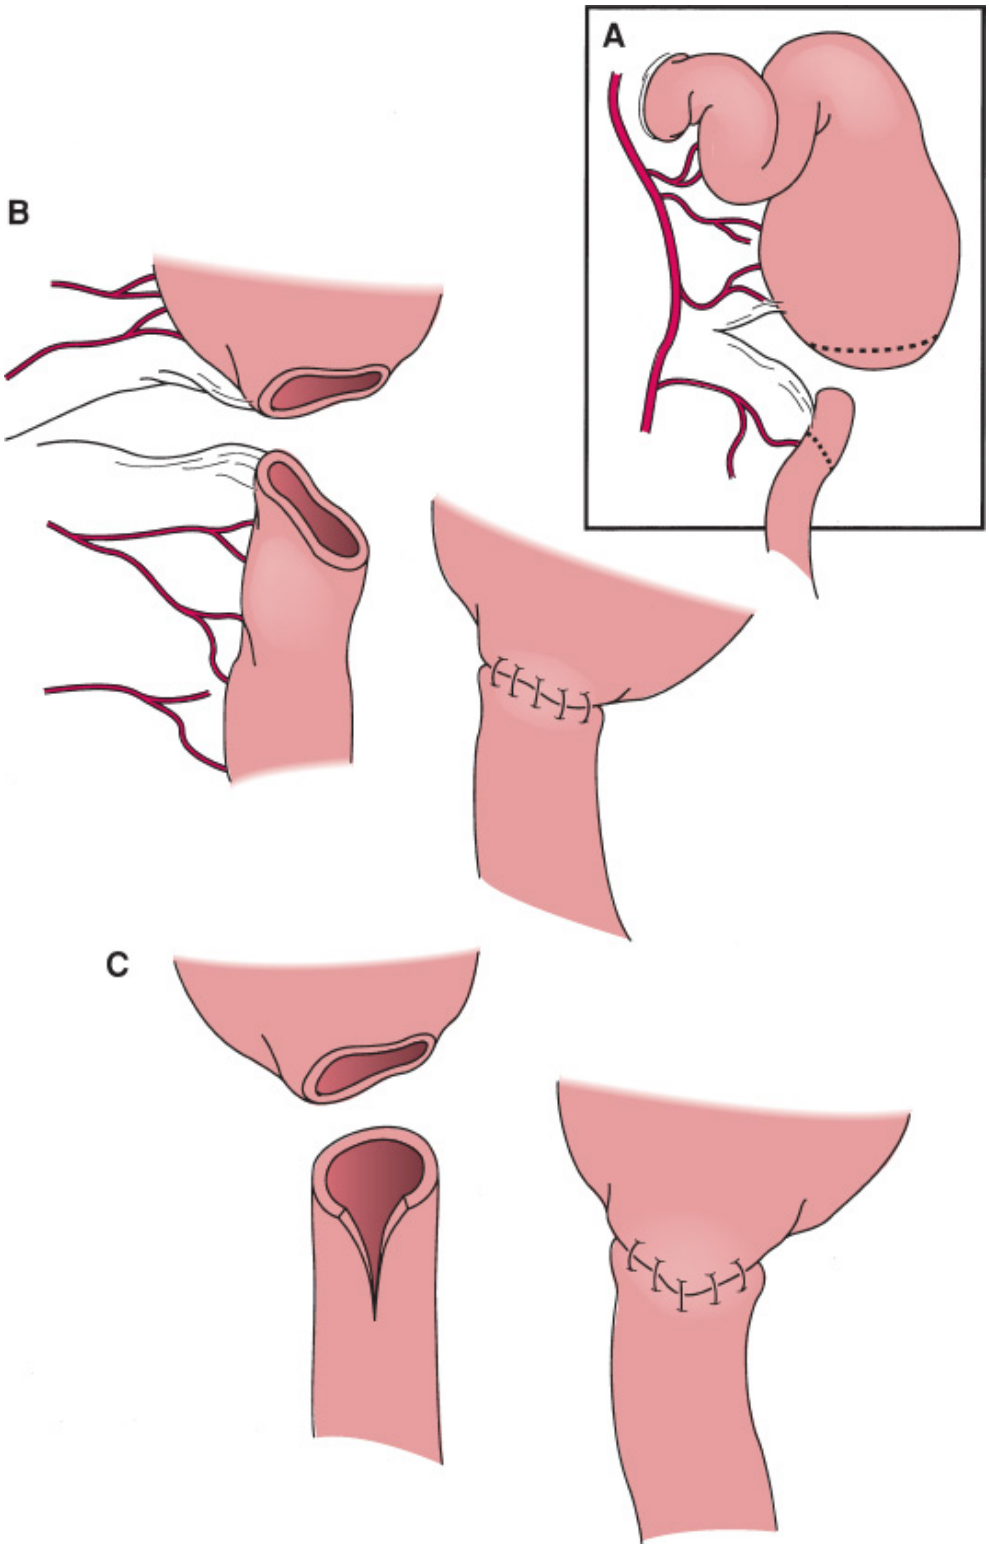

Figure 101.8 **A, B:** The end-to-oblique anastomosis for small bowel atresia. **C:** An extension of the distal enterostomy along the antimesenteric border may be used to create proximal and distal lumens of equal size for anastomosis.

Results and Outcome

Currently, the overall survival rate for infants treated for intestinal atresia or stenosis (including duodenal atresia) exceeds 93% in most large series.[51,55] Mortality in these infants is generally related to cardiac anomalies, birth weight less than 2 kg, and associated congenital anomalies.[56] Infants with a limited amount of intestinal length for nutritional absorption (short bowel syndrome with less than 40 cm) usually require long-term TPN and are at moderate to high risk for sepsis and liver injury. Infants with normal gastrointestinal length may still have prolonged intestinal dysfunction and dysmotility for several weeks.

Congenital Duodenal Obstruction

Causes of duodenal obstruction in the newborn include duodenal atresia or stenosis, duodenal intraluminal web, and annular pancreas. Because of the common embryologic basis, clinical presentation, and treatment, these entities are considered jointly.

Embryology and Anatomy

The duodenum is derived from both the caudal segment of the foregut and the cranial segment of the midgut. Duodenal development is intimately related to the developing pancreaticobiliary system. The fetal pancreas arises from paired dorsal and ventral foregut diverticula during week 6 of gestation. The dorsal anlage gives rise to the body and tail of the pancreas as well as the main pancreatic duct. The ventral anlage migrates 180 degrees to fuse with the dorsal gland, forming the uncinate process and the distal portion of the duct of Wirsung (Fig. 101.9). An annular pancreas is characterized by glandular persistence surrounding the duodenum at the site of the embryonic ventral anlage. It is invariably associated with intrinsic duodenal obstruction, and a patent accessory pancreatic duct is common (Fig. 101.10).[58]

It is believed that congenital duodenal obstruction results from abnormalities of pancreatic development, failure of duodenal recanalization, or vascular compromise to the duodenum. Duodenal atresia may occur with or without seromuscular continuity, and an intraluminal duodenal web may occur with or without fenestration. The most frequent location for duodenal

atresia is in the descending duodenum distal to the ampulla of Vater. Most series report a 5% to 10% incidence of duodenal atresia proximal to the ampulla, giving rise to nonbilious gastric contents and emesis. Another important variant is a periampullary web projecting distally into the duodenal or jejunal lumen, forming a "wind-sock" deformity (Fig. 101.11). In this instance, the ampulla must be clearly identified before excision and repair because of the proximity of the ampulla to the web.

Clinical Presentation

The incidence rate of congenital duodenal obstruction is estimated to be about 1 in 6,000 to 10,000 births.[59] About 30% of these infants have trisomy 21.[60] Infants born with duodenal atresia should be examined with a high degree of suspicion for trisomy 21 and undergo routine karyotype analysis. Other associated anomalies such as congenital heart disease, genitourinary tract malformations, and musculoskeletal disorders are common in these infants, and appropriate preoperative workup is necessary.

Congenital duodenal obstruction most commonly presents in the first 24 to 48 hours of life with feeding intolerance and bilious emesis; duodenal obstruction proximal to the ampulla of Vater results in nonbilious emesis. On physical examination, infants with untreated duodenal obstruction may have a palpable epigastric mass, and gastric peristaltic waves may be visible. The collapsed and unused distal small intestine typically does not produce diffuse abdominal distention. Partial duodenal obstruction from a fenestrated web may not produce symptoms in the newborn period, and delayed diagnosis is common.

Diagnosis

Prenatal diagnosis of duodenal atresia is possible given contemporary fetal ultrasound techniques. Following birth, infants with suspected duodenal atresia should obtain plain abdominal radiographs. The classic radiographic finding of duodenal atresia is a double bubble from the air-filled stomach and duodenum (Fig. 101.12). In complete duodenal obstruction, no gas is seen distal to the duodenum; in this setting, the plain film is sufficiently diagnostic that no further imaging of the gastrointestinal tract is necessary. If there is incomplete obstruction, gas may be seen distally in the small or large

intestine. Infants with suspected incomplete obstruction at the duodenal level may have either a fenestrated web or volvulus secondary to malrotation. Given the need for emergent operative intervention in malrotation with acute volvulus, an urgent upper gastrointestinal series with contrast should be strongly considered to exclude a neonatal surgical emergency. Importantly, all anatomic lesions causing neonatal duodenal obstruction require operative repair using a similar approach.

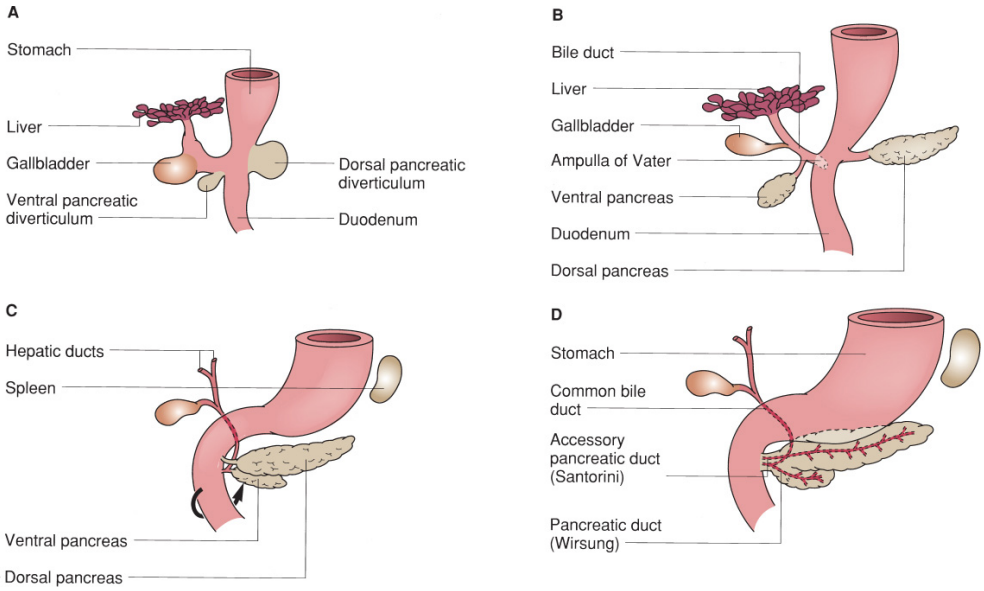

Figure 101.9 Normal embryologic development of the duodenum, pancreas, and bile ducts. **A:** Fifth gestational week. **B:** Sixth week. **C:** Seventh week. **D:** Eighth week.

Treatment

Following expedient treatment of any associated life-threatening medical conditions and preoperative evaluation, the operative goals are to restore gastrointestinal continuity without sacrificing intestinal length or absorptive surface area. Because most lesions causing congenital duodenal obstruction are near the ampulla of Vater, great care must be exercised in treatment to avoid inadvertent injury to the ampulla or the pancreas.

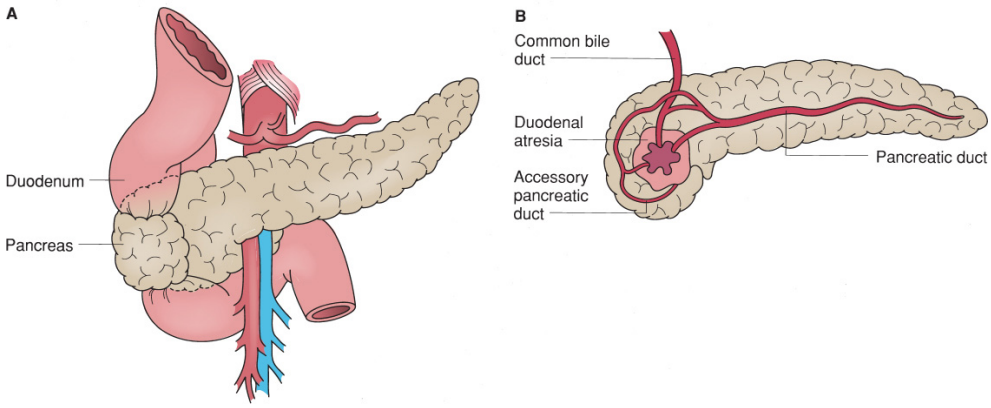

Figure 101.10 Annular pancreas. **A:** The associated duodenal atresia is shown. **B:** The relationships of the annular pancreas to the common bile duct and main and accessory pancreatic ducts are shown in cross section.

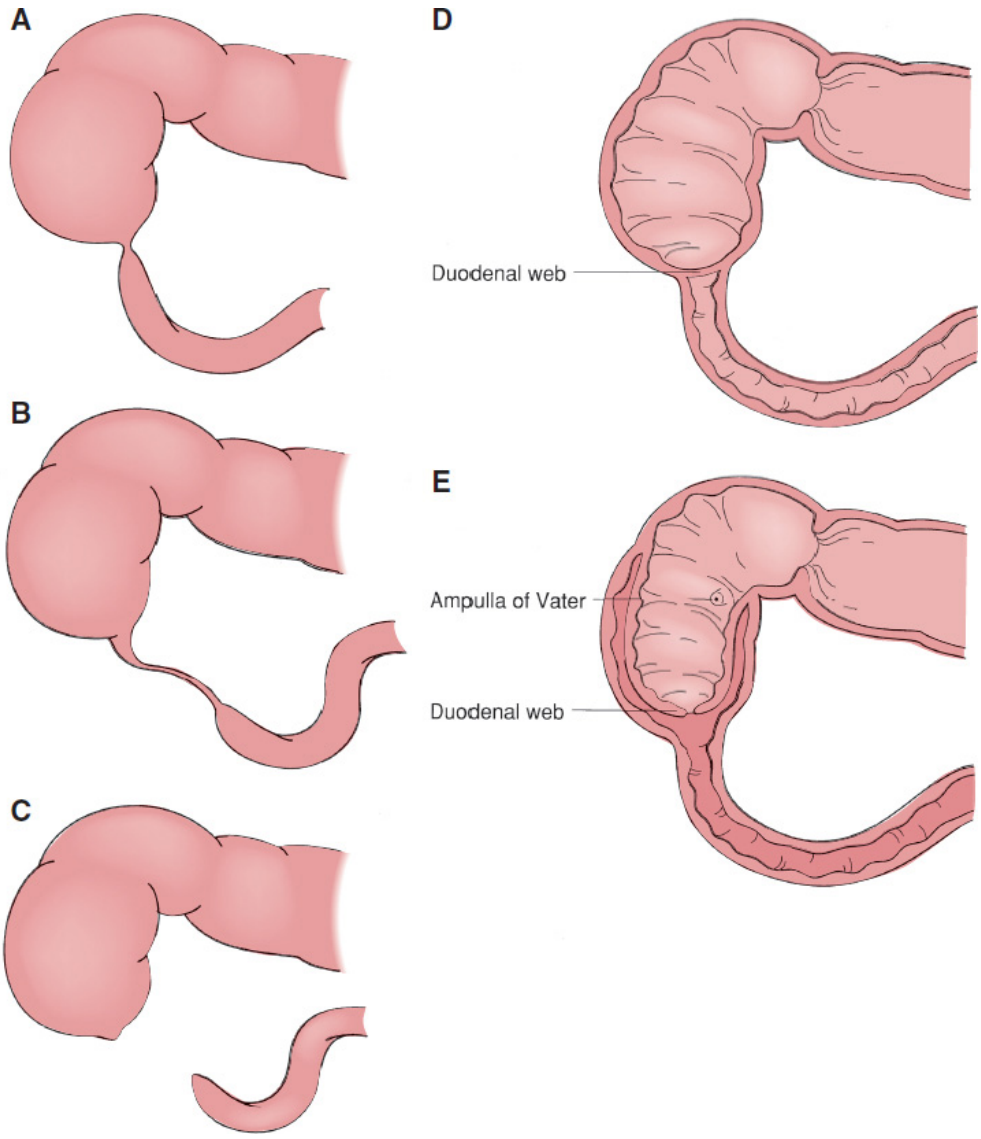

Figure 101.11 Anatomic forms of duodenal atresia (**A–C**) and webs (**D, E**). In particular, (**E**) demonstrates the unique wind-sock deformity. This lesion is important and potentially confusing because the point of obstruction is not at the apparent point of change in luminal diameter.

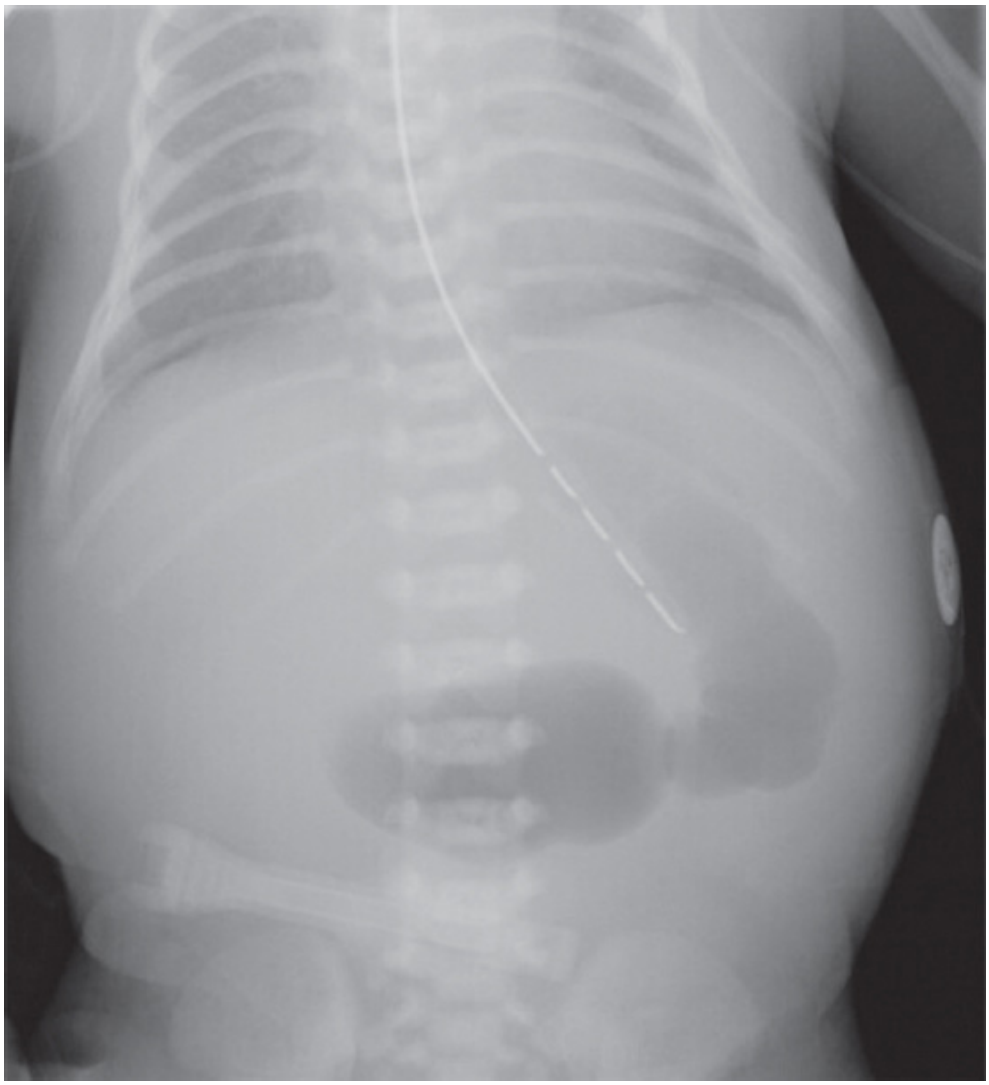

Figure 101.12 Classic radiographic appearance of duodenal atresia. There is a double bubble of gas in the stomach and the proximal duodenum, with no gas in the distal intestinal tract.

Congenital duodenal atresia is treated by duodenoduodenostomy. Duodenal obstruction secondary to annular pancreas is also treated by duodenoduodenostomy. Direct division of annular pancreas is not performed because this does not address the underlying intraluminal duodenal obstruction, and there is significant risk of injury to the accessory pancreatic duct (see Fig. 101.10).

Duodenoduodenostomy is performed by making a transverse incision in the dilated, proximal duodenum and a longitudinal incision in the unused, downstream duodenum. The lumens are sutured together to form a diamond-shaped anastomosis (Fig. 101.13).[61] Downstream duodenal patency should be

demonstrated by passing a catheter or infusing saline or air distally to avoid overlooking synchronous distal intestinal atresia. Successful and efficacious laparoscopic duodenal atresia repair has also been reported.[62]

Duodenal webs are excised through a longitudinal duodenotomy. The wind-sock duodenal web must be clearly identified because the visible transition from the distended, proximal duodenum to the small, downstream duodenum may be several centimeters distal to the base of the web. The ampulla of Vater must be unequivocally identified before duodenal web excision to avoid injury. Closure of the longitudinal duodenotomy is performed transversely to avoid narrowing of the duodenum.

There is usually great size discrepancy between the dilated, proximal pouch and the distal duodenal lumen, leading some surgeons to advocate procedures designed to reduce the diameter of the proximal duodenum in an effort to facilitate improved postoperative bowel motility. The efficacy of these procedures, which include tapering duodenoplasty and duodenal plication, has been described in anecdotal fashion without randomized comparison.

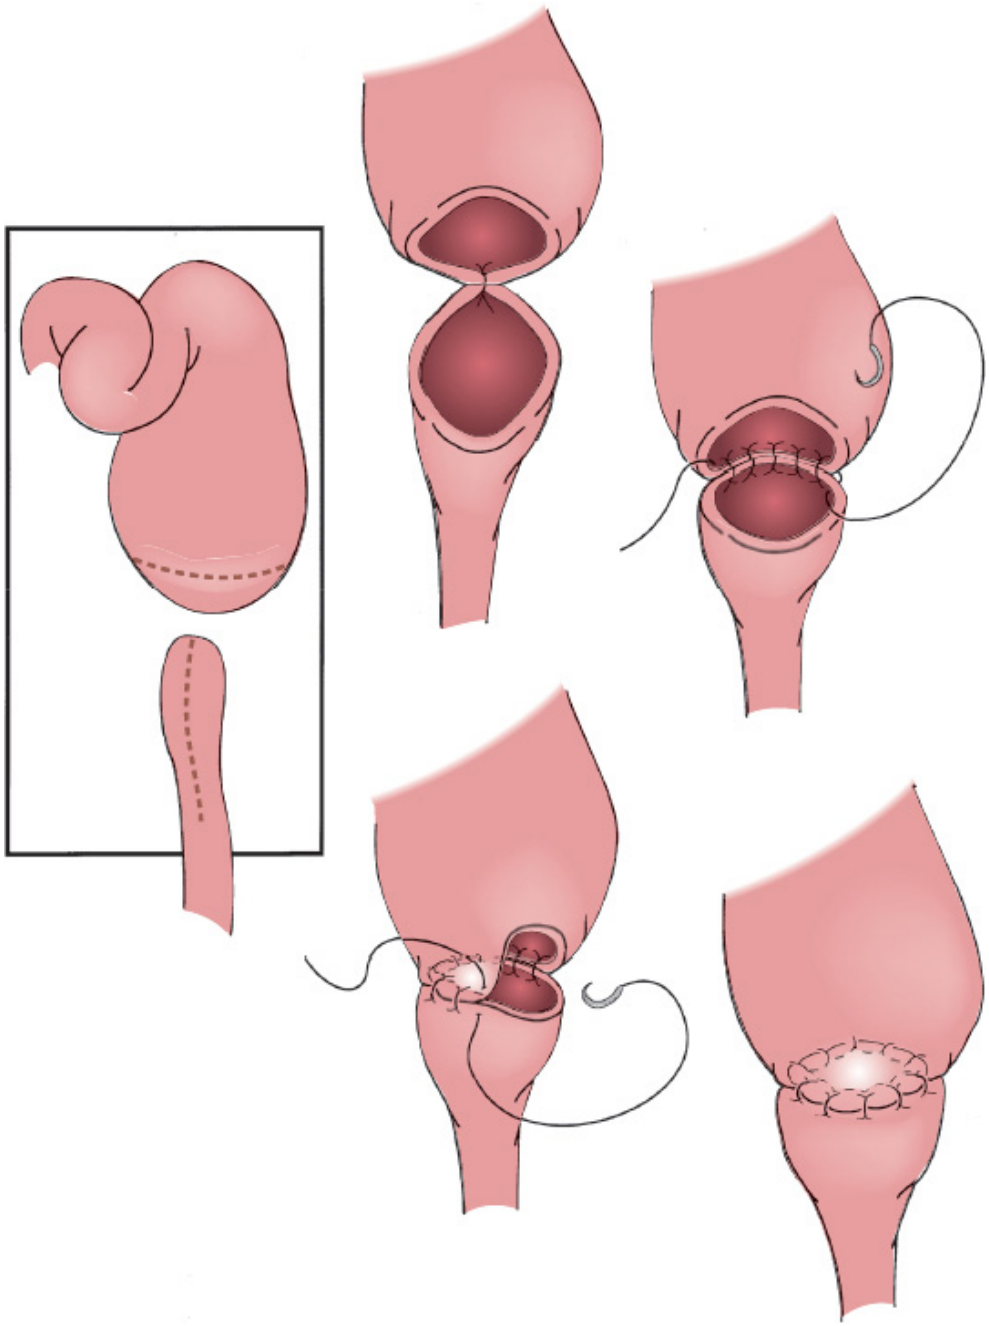

Figure 101.13 Diamond-shaped duodenoduodenostomy for repair of duodenal atresia.

Results and Outcome

After successful operative repair of duodenal atresia or stenosis, delayed gastric emptying is common and typically manifests as enteral feeding intolerance. Patience and persistence are essential during the postoperative period as recovery of bowel function may take up to 10 days post op.

Surgical outcomes after repair of congenital duodenal obstruction are excellent,[60–63] with perioperative survival exceeding 95%. Perioperative mortality is generally related to other congenital anomalies and, in particular, congenital heart disease in infants with trisomy 21. Other late problems may be encountered that reflect gastroduodenal motility issues such as poor gastric emptying, gastroesophageal reflux, and duodenal dilatation. These symptoms may appear several months to years following repair and, therefore, long-term surgical follow-up remains important.

Anorectal Malformations (Imperforate Anus)

Embryology

By week 5 of gestation, the fetal cloaca is identifiable with the adjacent hindgut, allantois, and vestigial tailgut (Fig. 101.14). The mesoderm of the urorectal septum extends caudally to fuse with the cloacal closing plate. Fusion of the lateral cloacal ridges completes division of the cloaca into the rectum and the urogenital sinus. The caudal aspect of the urorectal septum forms the perineal body. The anal membrane normally ruptures during week 8 of gestation, completing the patency of the distal rectum to the skin. Further development of the urogenital sinus leads to the formation of the urethra and the bladder. In female infants, the uterus and the proximal vagina develop from the müllerian ducts. The diverse anatomic variation observed with anorectal malformations is thought to reflect anomalous or interrupted development of these structures during normal embryogenesis.

Anatomy and Classification

The normal anatomy of the anus and the rectum is reviewed in previous chapters. Normally, the rectum descends to the perineum and ultimately to the anal orifice through a striated muscle complex in the pelvis resembling a funnel. The striated muscle complex is under voluntary control and is responsible for providing fecal continence (Fig. 101.15). Contiguous portions of the *levator ani,* the *external sphincter,* and the *puborectalis* muscles compose the *striated muscle complex.* These anatomically indistinct components of the muscle complex act together to provide control of defecation. The concept of the striated muscle complex and anatomic

relationships leading to normal fecal continence with respect to anorectal malformations has evolved from both clinical and anatomic data as described by Peña.[64]

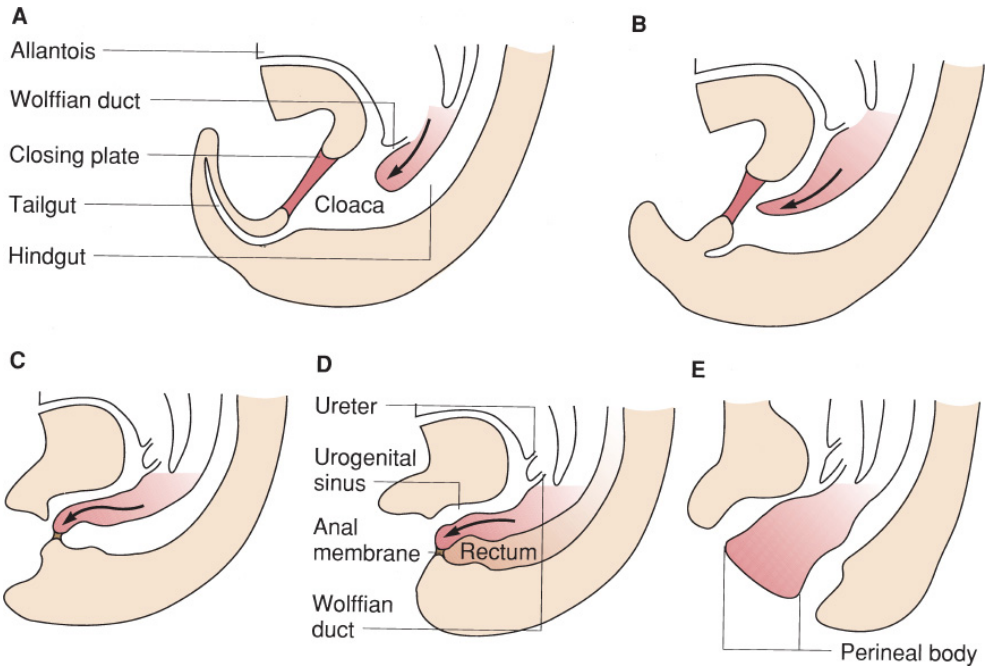

Figure 101.14 Normal embryologic division of the cloaca by the urorectal septum into the ventral urinary tract and the dorsal rectum. This process is normally completed by the ninth or tenth week of gestation.

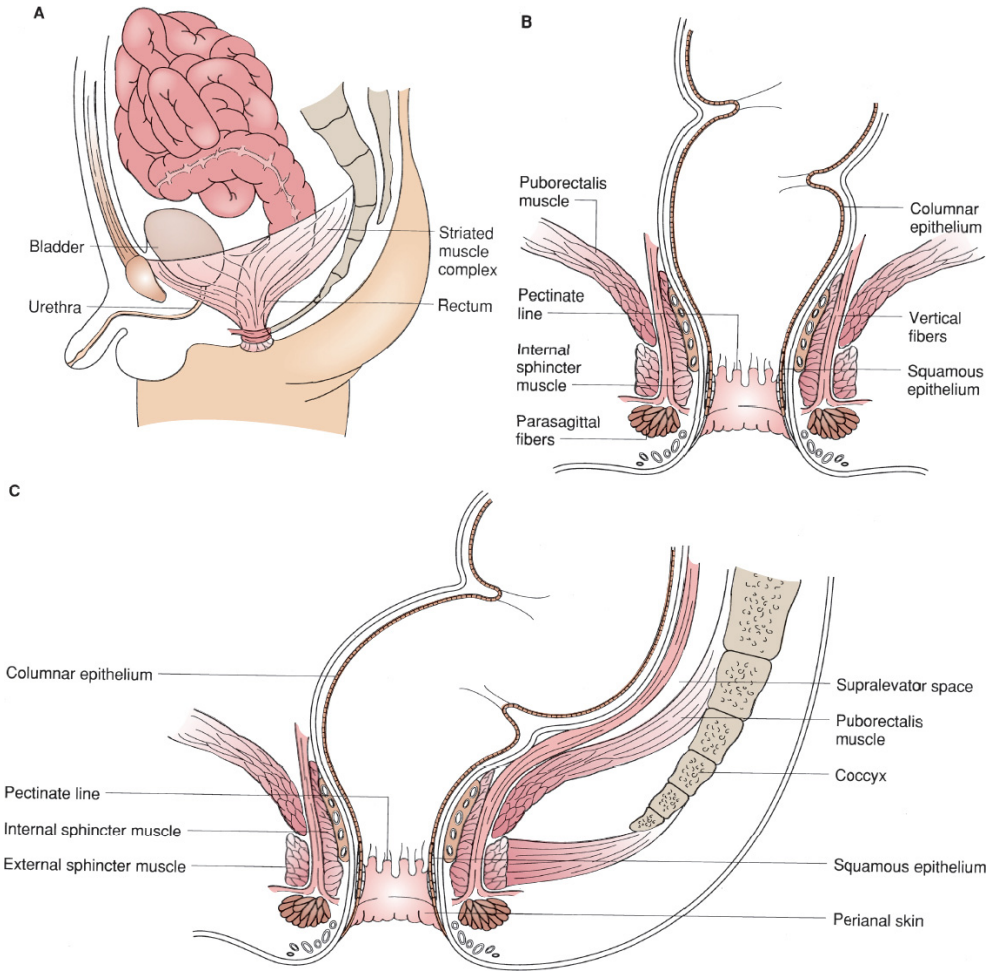

Figure 101.15 The normal relations of the pelvic striated muscle complex and the rectum. **A:** Normal male anatomy. **B:** Coronal view showing individual components of the striated muscle complex. **C:** Sagittal view of normal anatomy.

Because of the variety of anorectal malformations observed, different classification systems have been proposed in an attempt to characterize the defects. A summary of the Wingspread Classification is provided in Table 101.3. This anatomically descriptive classification scheme is useful in planning the operative management of anorectal malformations.

In male subjects, the two most common anorectal malformations observed are low imperforate anus with a perineal fistula (Fig. 101.16) and high anorectal agenesis with a rectoprostatic urethral fistula (Fig. 101.17). Male patients without a visible perineal fistula are assumed to have high imperforate anus with a rectourethral fistula until proven otherwise. In female subjects, the most common malformation encountered is low imperforate anus with a fistula from the rectum to either the perineal body or the vaginal

vestibule (Fig. 101.18). As these malformations result from developmental arrest at various times during migration of the urogenital septum, considerable anatomic variability exists in both male and female subjects.

A common anatomic feature of imperforate anus is incomplete rectal descent to the perineum. Consequently, the rectum is not completely within the striated muscle complex. The caudal portion of the striated muscle complex remains a solid mass of striated muscle, whereas the cephalad portion may be normally positioned circumferentially around the rectal pouch. In low imperforate anus, the rectum nearly reaches the perineum, and the configuration of the striated muscle complex surrounding the rectum more closely approximates normal. With high imperforate anus, less striated muscle surrounds the rectal pouch. All anorectal malformations are considered to have some component of striated muscle complex hypoplasia and dysfunction, although the physiologic effects are variable. Low anorectal lesions have a more favorable prognosis for fecal continence than intermediate or high lesions.

CLASSIFICATION

Table 101.3 Anatomic Classification of Anorectal Malformations

Female	Male
High	
Anorectal agenesis with rectovaginal fistula without fistula	Anorectal agenesis with rectoprostatic urethral or rectocystic fistula or without fistula
Rectal atresia	Rectal atresia
Intermediate	
Rectovestibular fistula	Rectobulbar urethral fistula
Rectovaginal fistula	Anal agenesis without fistula
Anal agenesis without fistula	
Low	
Anovestibular fistula[a]	Anocutaneous fistula[a]
Anocutaneous fistula[a,b]	Anal stenosis[a,c]
Anal stenosis[c]	Rare malformations
Cloacal malformations[d]	
Rare malformations	

[a]Relatively common lesion.

[b]Includes fistulas occurring at the posterior junction of the labia minora, often called *fourchette fistulas* or *vulvar fistulas.*

[c]Previously called *covered anus.*

[d]Previously called *rectocloacal fistulas.* Entry of the rectal fistula into the cloaca may be high or intermediate, depending on the length of the cloacal canal.

Classic delineation between low and high anorectal malformations is made anatomically at the pubococcygeal line. The vast majority of low lesions have

associated perineal or vestibular fistulas. High imperforate anus has a blind-ending rectal pouch above the pubococcygeal line and, therefore, above the striated muscle complex (or levator ani).

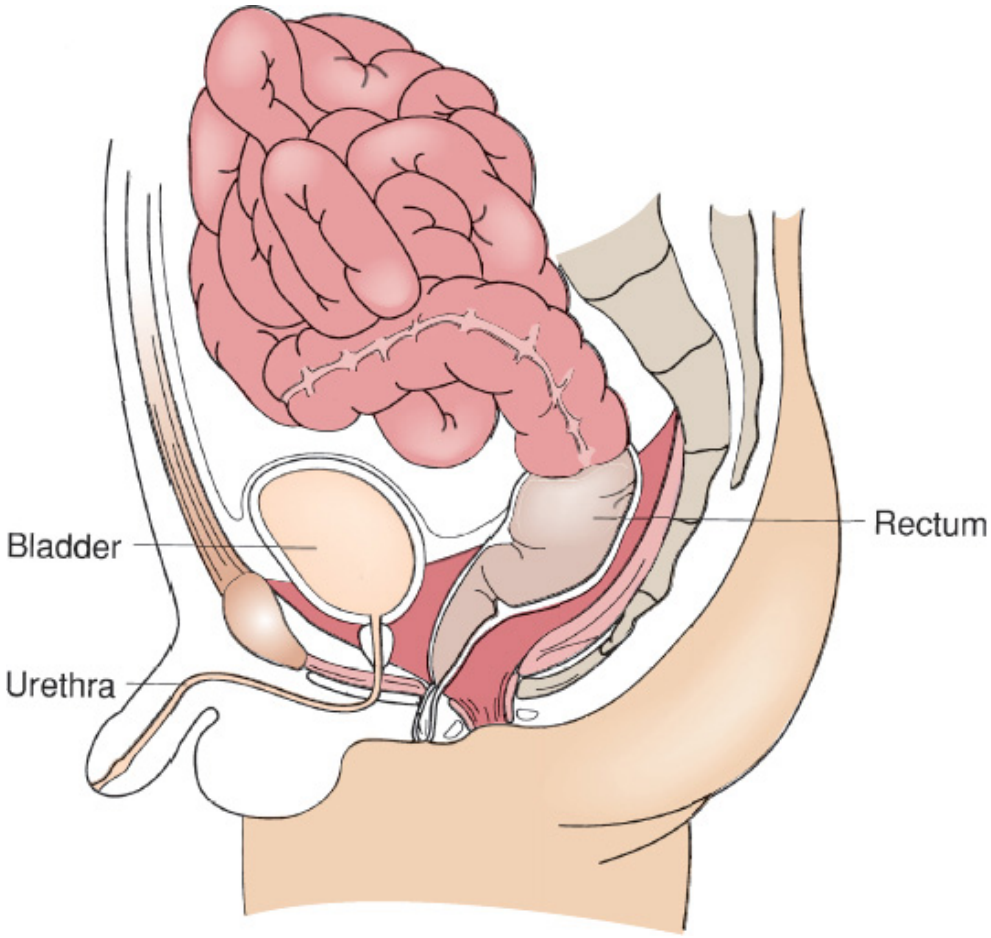

Figure 101.16 Male infant with low imperforate anus and perineal fistula. Note that the fistula is anterior to the striated muscle complex.

Associated Anomalies

Associated anomalies in infants with anorectal malformations are common and may be found in more than 70% of patients. The VACTERL (vertebral, anal, cardiac, tracheal, esophageal, renal, and limb) association is important and requires consideration in any infant with imperforate anus. *Vertebral anomalies* are common and include sacral dysplasia and agenesis. Infants with sacral anomalies commonly have high imperforate anus and sacral nerve dysfunction that can lead to poor long-term fecal continence and neurogenic bladder. A variety of spinal cord malformations can also be observed in these

infants, including tethered spinal cord syndromes and some myelodysplastic syndromes. During the neonatal period, these spinal lesions may be detected by using ultrasound or magnetic resonance imaging (MRI), and surgical treatment may be necessary within the first 8 to 18 months of life. *Tracheoesophageal* fistula with or without esophageal atresia is estimated to occur in about 10% of infants with anorectal malformations. *Renal anomalies* are the most common associated abnormalities with anorectal malformations and include both upper and lower tract conditions. Genitourinary screening in the form of a renal ultrasound and voiding cystourethrogram is routinely performed. *Cardiac* anomalies are common and screening echocardiography is clinically indicated. *Limb abnormalities,* in particular, involvement of the radius, complete the associated anomalies defined by the acronym.

Clinical Presentation

The incidence rate of anorectal malformations is estimated at 1 in 2,524 to 5,000 live births,[65] with a slightly higher rate in males. Careful examination of the neonatal perineum reveals the diagnosis. If unrecognized and left untreated, high imperforate anus eventually leads to signs and symptoms of complete bowel obstruction characterized by abdominal distention, feeding intolerance, and bilious emesis. Because of the nearly uniform rectourethral or rectovesicular fistula in males with high lesions, some of these infants will pass meconium or gas through the urethra during urination. In contrast, infants with low malformations typically pass meconium through a perineal or vestibular fistula within the first 24 hours of life. Occasionally, infants with large perineal fistulas are not diagnosed with an anorectal malformation until progressive constipation is noted weeks to months after birth.

In male infants, more than 95% of low malformations are associated with either a thin anal membrane or a fistula to the perineum or the scrotal raphe. The presence of a “bucket-handle” skin deformity at the presumptive anal dimple is also diagnostic of a low lesion. Infants with high malformations typically lack anal skin dimpling, have a flat gluteal contour, and may have little or absent contraction of the external sphincter with cutaneous stimulation. In female infants, 90% to 95% of low malformations have a perineal or vestibular fistula. In both male and female infants, a perineal

fistula may not become apparent in the first 12 to 24 hours of life until meconium progresses distally through the rectum into the fistula.

Diagnosis

Because surgical treatment of a high or intermediate anorectal malformation is different from that of low lesion, a primary diagnostic goal is to determine whether an infant with imperforate anus has a high or low malformation. A secondary diagnostic goal is to determine the specific anorectal malformation as it relates to the rectourethral or rectovesicular fistula.

Clinical examination of an infant with low imperforate anus almost always reveals an external fistula to the perineum or the vestibule. The classic radiographic study of newborns with imperforate anus is the Wangensteen–Rice invertogram, with a lateral view of the pelvis obtained 12 to 24 hours after birth with the infant in a head-down position. This technique has been largely replaced by ultrasound-directed imaging.[66] Real-time ultrasound is currently well accepted as an accurate method of determining the distal extent of the rectal pouch. Computed tomography (CT) imaging and MRI can be useful in evaluating the pelvic striated muscle complex in difficult cases and, in particular, cloacal malformations. MRI is also useful in evaluation of the distal spinal cord in these infants.

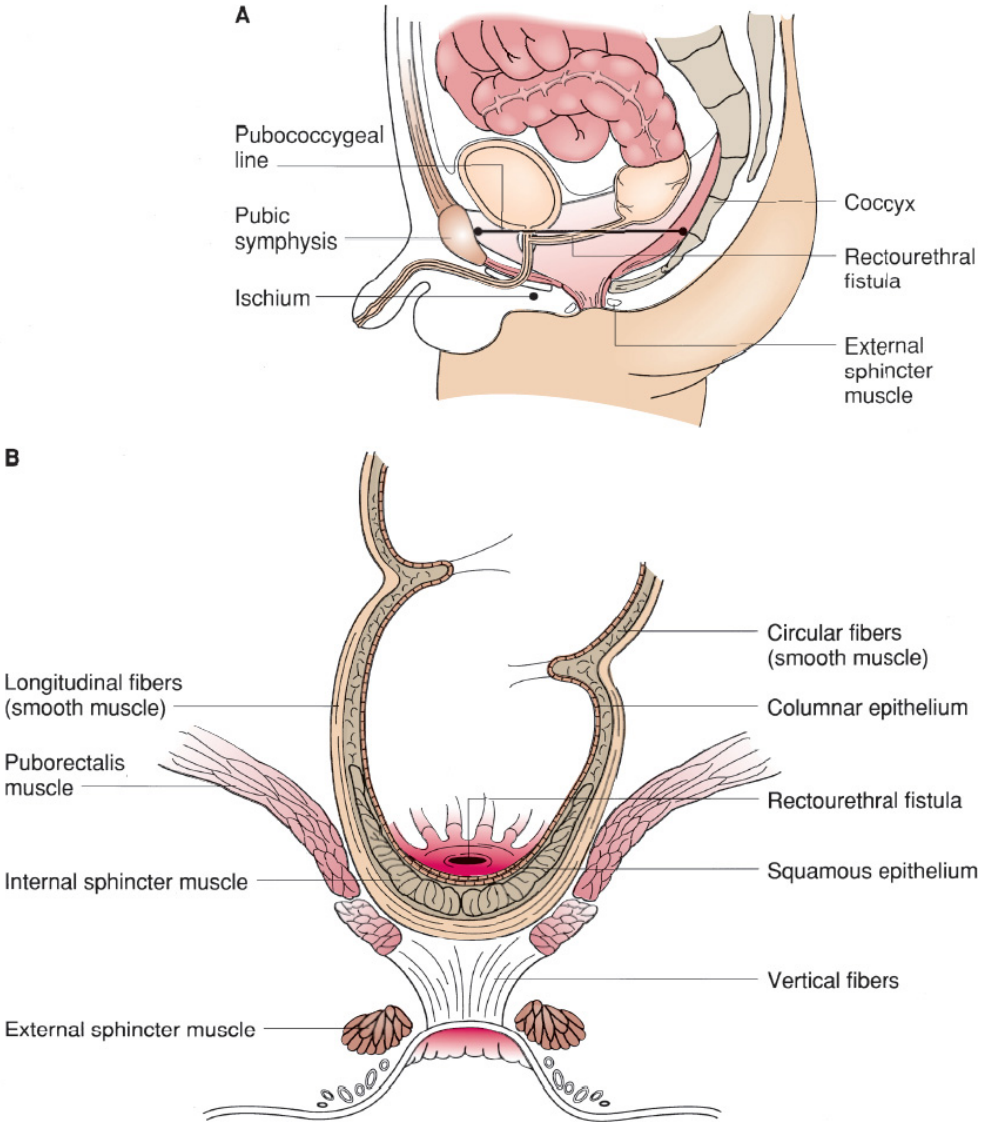

Figure 101.17 Male infant with high imperforate anus, showing the pubococcygeal line, ischium, and striated muscle complex. **A:** The rectal pouch ends cephalad to the pubococcygeal line. This location of the rectourethral fistula is typical. **B:** Coronal view showing incomplete development of the rectal pouch within the striated muscle complex. The rectourethral fistula is shown.

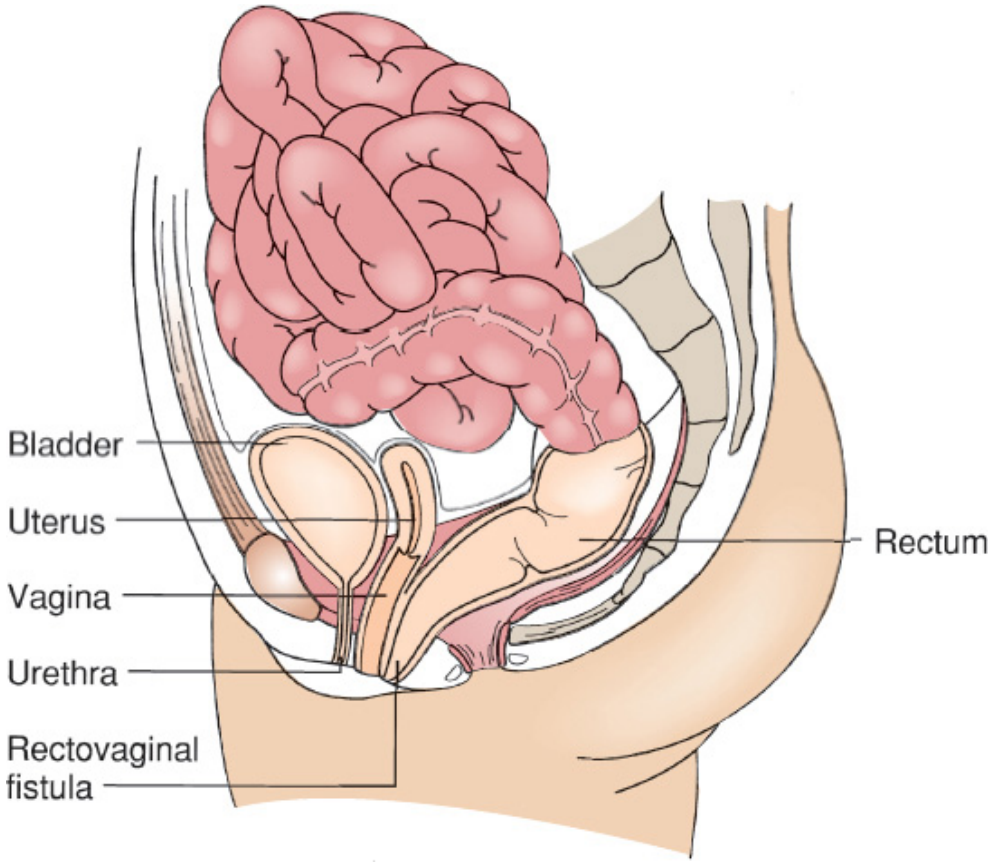

Figure 101.18 Female infant with low imperforate anus and vestibular fistula.

If there is a suspected perineal fistula or covered anus, diagnostic needle aspiration under anesthesia may be useful. Aspiration of meconium not only localizes the rectum or fistula but can also provide an estimation of the distance between the perineum and the rectum or the fistula. In general, low lesions are within 1 cm of the perineum. An infant not clearly found to have a low lesion by physical examination, radiographic studies, or examination under anesthesia should be considered to have a high anorectal malformation and treated accordingly.

Treatment

Imperforate anus by itself is not a life-threatening condition, and, in many instances, observation for 12 to 24 hours may help delineate the presence or absence of a fistula. The surgical management of anorectal malformations has been well described elsewhere[64] and a brief summary follows below.

Low Malformations

Definitive repair of most low anorectal malformations can be performed in the newborn period with perineal procedures that do not require diverting colostomy. Simple dilatation of the fistula or unroofing of a covered anus may relieve the anatomic obstruction. For more complex anal stenoses or anterior perineal fistulas, a formal perineal anoplasty may be required. A common perineal procedure performed is cutback anoplasty, in which the anterior fistula or anal orifice is opened posteriorly by dividing the perineum to the external sphincter. More complex alternative approaches may be preferred in female infants with low vaginal or anterior perineal fistulas. These lesions generally require circumferential mobilization of the anterior fistula with transposition to the center of the external sphincter. Anterior reconstruction of the perineal body is then performed. Transposition anoplasty is designed to position the neoanus within the center of the external sphincter and separate the neoanus from the vaginal introitus.

Intermediate and High Malformations

Infants determined to have an intermediate, high, or indeterminate anorectal malformation generally require diverting divided colostomy as initial surgical management. Care must be taken to ensure that the proximal diverting colostomy provides adequate length and mobility of the distal colon in anticipation of eventual anorectoplasty. A divided colostomy is preferred over a loop colostomy by many surgeons to provide maximal fecal diversion from the downstream rectourinary fistula. Following diverting colostomy, a distal contrast study into the rectal pouch can also define the fistula and delineate the position of the rectum relative to the perineum.

Anorectoplasty is generally performed when the infant is approximately 8 to 12 months of age. Many different approaches have been described, and considerable personal and institutional variation is common. No single approach has superior results, and all have technical merits and difficulties. The common surgical objectives in the treatment of anorectal malformations include (a) relief of the rectal obstruction; (b) creation of a new anus; (c) position the rectum as normally as possible within the striated muscle complex; and (d) divide the rectourinary fistula. In addition, preservation of the surrounding structures (prostate, urethra, seminal vesicles, vaginal wall) is essential.

For repair of high and intermediate anorectal malformations, the most widely used procedure in the United States is the posterior sagittal anorectoplasty described in detail by Peña.[64] The infant is placed prone and a posterior sagittal incision following the gluteal crease is used. The external sphincter and the striated muscle complex are divided posteriorly along the midline to expose the rectal pouch. A muscle stimulator is used to define and map the striated muscle complex and to confirm symmetric dissection along the midline. Typically, the rectal pouch can be adequately dissected by this approach to allow enough length to reach the perineum. Infrequently, a combined abdominoperineal approach is required. The mobilized rectal pouch is opened and the rectourinary fistula identified and closed directly. The rectal pouch is placed centrally within the striated muscle complex, which is reconstructed circumferentially around the rectum. The neoanus is centered within the external sphincter and the mucosa is sutured to the perineum.

Other accepted and practiced surgical approaches to imperforate anus include a sacroperineal approach as proposed by Stephens,[67] and an approach that uses components of endorectal dissection as attributed to Rehbein.[68] Both these surgical procedures are characterized by blind pull-through of the distal rectum to the perineum without direct visualization of the striated muscle complex. Experience with laparoscopic dissection and division of the rectourinary fistula with perineal pull-through reconstruction has been reported, but is only needed in approximately 10% of cases.[69,70] It appears that personal preference, experience, and familiarity rather than differences in outcome dictate the selection of procedure. In general, diverting colostomy in all of these procedures is maintained until the anorectoplasty has completely healed, after which the colostomy is closed electively.

Results, Complications, and Outcome

Mortality following anorectoplasty is related to the presence of associated congenital anomalies other than imperforate anus. A careful review of 284 infants undergoing repair of anorectal malformations observed an 18.7% mortality,[71] suggesting that this group is at moderate to high risk for complications and death secondary to coexisting congenital anomalies.

Complications are similar to other gastrointestinal surgical procedures and include infection, leak, recurrent fistula, or anastomotic stricture. Leak or stricture formation is observed in 5% to 10% of infants undergoing tapering rectoplasty during posterior sagittal anorectoplasty. Anorectal strictures are treated by gradual postoperative anal dilatation for weeks to months. Recurrent rectourethral fistula or urethral stricture is uncommon.

Long-term functional outcome in infants with low malformations is generally good given the relatively normal descent of the distal rectum within the striated muscle complex. Infants with higher lesions have a less predictable prognosis and are much more likely to have difficulty with fecal continence. Currently, the outcomes appear to be independent of the type of surgical reconstruction performed and more related to anatomic patient factors, including degree of rectal descent, integrity of the striated muscle complex, and sacral innervation. However, there are no established accurate predictors of long-term fecal continence, and as such these children should be followed until at least 4 years of age.[72] Few or perhaps none of these children have completely normal bowel habits after operation. About half of the infants have acceptable to good results with episodic fecal soilage that can be improved with bowel management programs enemas and cathartics.[73–75] A comprehensive bowel management program is essential in preventing fecal impaction and subsequent motility dysfunction in the rectum. The remaining children require major adjustments in lifestyle secondary to fecal incontinence, chronic constipation, or fecal smearing and odor. In some instances, socially acceptable continence can be assisted by the use of daily antegrade enemas via a cecostomy or appendicostomy. In other situations, a permanent diverting colostomy may be desirable.

Necrotizing Enterocolitis

Pathophysiology

4 NEC is a neonatal disease characterized by an initial intestinal mucosal injury that may ultimately progress to transmural bowel necrosis. NEC is the most frequently encountered neonatal surgical emergency and a major cause of morbidity and mortality in the premature infant. Despite its frequency and extensive study, the pathogenesis remains obscure, and surgical treatment is

directed largely at controlling the complications of intestinal necrosis. The development of NEC occurs in association with a variety of associated conditions, including perinatal stress, sepsis, respiratory failure, hypoxemia, hypotension, and congenital cardiac defects. In general, NEC is observed in the premature infant with multiple risk factors and potential etiologic events and conditions. To create a murine model of NEC, the necessary factors are hypoxemia and to formula (not breast milk) feed the animals.[76–78] Current clinical and experimental data support the concept that the pathophysiology of NEC remains enigmatic and multifactorial.

The intestinal mucosal injury observed in NEC is likely to be the end result of an ischemic insult in a susceptible host. Normally, the neonatal pulmonary and systemic vascular smooth muscle undergoes rapid structural and physiologic changes shortly after birth. The premature infant appears to be particularly vulnerable to vasoconstriction. With regard to NEC, it is hypothesized that hypoperfusion and ischemia of the premature neonatal intestinal tract may be the result of uncontrolled splanchnic vasoconstriction. This situation may be worsened in critically ill premature infants with low cardiac output states impairing oxygen delivery to the intestines.

A common characteristic of NEC is the host inflammatory response to the initiating mucosal injury. Experimental data are consistent with an important role for inflammatory mediators in the propagation of intestinal injury in NEC.[79] More than 90% of cases of NEC occur after the initiation of enteral feeding, and several studies document that the osmolarity or rate of initial feeding may be important. Although controversy exists, most neonatal centers now avoid rapid advancement of hyperosmolar enteral feedings and attempt to prevent excessive fluid volume in premature infants.[80,81] A multicenter, randomized controlled clinical trial using *Bifidobacterium* and *Lactobacillus* as a probiotic given with initial feeding demonstrated significant reduction in death from NEC in very low–birth-weight premature infants.[82]

The most common site of involvement of NEC is the terminal ileum and right colon. NEC may be localized, segmental, or it may involve the entire gastrointestinal tract. Histopathologic examination of intestinal tissue from infants with NEC demonstrates submucosal edema, hemorrhage, and microvascular thrombosis leading to transmural necrosis. The histopathology of NEC resembles that of experimental intestinal ischemia, with areas of reversible mucosal injury adjacent to areas of transmural necrosis. Dissection

of intraluminal gas through the injured mucosa leads to gas within the bowel wall, known as *Pneumatosis intestinalis*. The finding of pneumatosis intestinalis is a classic radiographic and pathologic feature of NEC. Initially, the gas may be localized in the submucosa or lymphatic vessels, but it may dissect into the muscularis, the portal venous tract, or into the subserosa. Intestinal perforation, inflammatory phlegmon, and diffuse peritonitis are common with advanced NEC.

Clinical Presentation

NEC is estimated to occur in 1 to 3 of 1,000 live births and 30 per 1,000 low–birth-weight births.[83] NEC may also occur in term infants, and in this group, it has a tendency to involve the colon and may present without classic signs.[84] The actual incidence of NEC remains difficult to determine because the diagnosis is subjective; classic signs on physical examination and diagnostic imaging are not always uniformly present. The classic clinical signs of NEC include abdominal distention, feeding intolerance, bilious emesis, and either occult or gross blood in the stool. Gastrointestinal mucosal bleeding is present in the vast majority of cases (80% to 90%) but is rarely significant from a hemodynamic standpoint. On physical examination, abdominal tenderness with distention is common, and individual loops of thickened or fixed bowel may be palpable. Edema, erythema, crepitus, or discoloration of the abdominal wall suggests intestinal necrosis, perforation, or intra-abdominal abscess (Fig. 101.19). Hematochezia or guaiac-positive stool is typical. Systemic signs of inflammation and sepsis such as temperature instability, apnea, bradycardia, hypoxemia, acidosis, and thrombocytopenia are also common. The primary diagnostic goal during initial clinical evaluation is to determine whether irreversible, transmural intestinal necrosis is present. There is no single physical finding or laboratory test that makes this distinction.

Diagnosis

The diagnosis of NEC relies on clinical evaluation and judgment based on symptoms and signs in the appropriate setting. Table 101.4 summarizes diagnostic criteria and a staging system for NEC most commonly used in the United States.[85] Radiographic confirmation of NEC requires only plain

abdominal films. During the acute inflammatory phase, contrast studies may be hazardous and are contraindicated. The classic radiographic finding of pneumatosis intestinalis (Fig. 101.20) confirms the diagnosis in the appropriate clinical setting but is variably present. Other radiographic findings consistent with NEC include thickened bowel loops, ascites, and portal venous gas. Serial abdominal films, including a left lateral decubitus or upright film, should be obtained every 6 to 8 hours during the early course of the disease. These sequential studies help document the progression or resolution of the inflammatory process and, importantly, evaluate for the presence of intestinal perforation presenting as free intraperitoneal gas or pneumoperitoneum. The presence of pneumoperitoneum mandates operative intervention; however, up to half of infants with perforated NEC do not have discernible pneumoperitoneum on plain films.

Figure 101.19 Clinical presentation of diffuse staining of abdominal wall in an extremely low–birth-weight infant with perforated necrotizing enterocolitis.

Table 101.4 Necrotizing Enterocolitis

Stage I NEC (Suspected)

Any one or more historical factors producing perinatal stress

Systemic manifestations

- Temperature instability
- Lethargy
- Apnea
- Bradycardia

Gastrointestinal manifestations

- Poor feeding
- Increasing pregavage residuals
- Emesis
- Mild abdominal distention
- Occult blood in stool

Abdominal radiographs showing distention with mild ileus

Stage II NEC (Definite)

Any one or more historical factors

Above signs and symptoms, plus

- Persistent occult or gross gastrointestinal bleeding
- Marked abdominal distention

Abdominal radiographs showing significant intestinal distention with

- Ileus
- Small bowel edema
- Pneumatosis intestinalis
- Portal venous gas

Stage III NEC (Advanced)

Any one or more historical factors

Above signs and symptoms, plus: Deterioration of vital signs

- Evidence of septic shock
- Marked gastrointestinal hemorrhage
- Abdominal radiographs showing pneumoperitoneum in addition to findings listed for stage II

From Bell MJ, Kosloske AM, Benton C, et al. Neonatal necrotizing enterocolitis: prevention of perforation. *J Pediatr Surg* 1973;8:601–605, with permission.

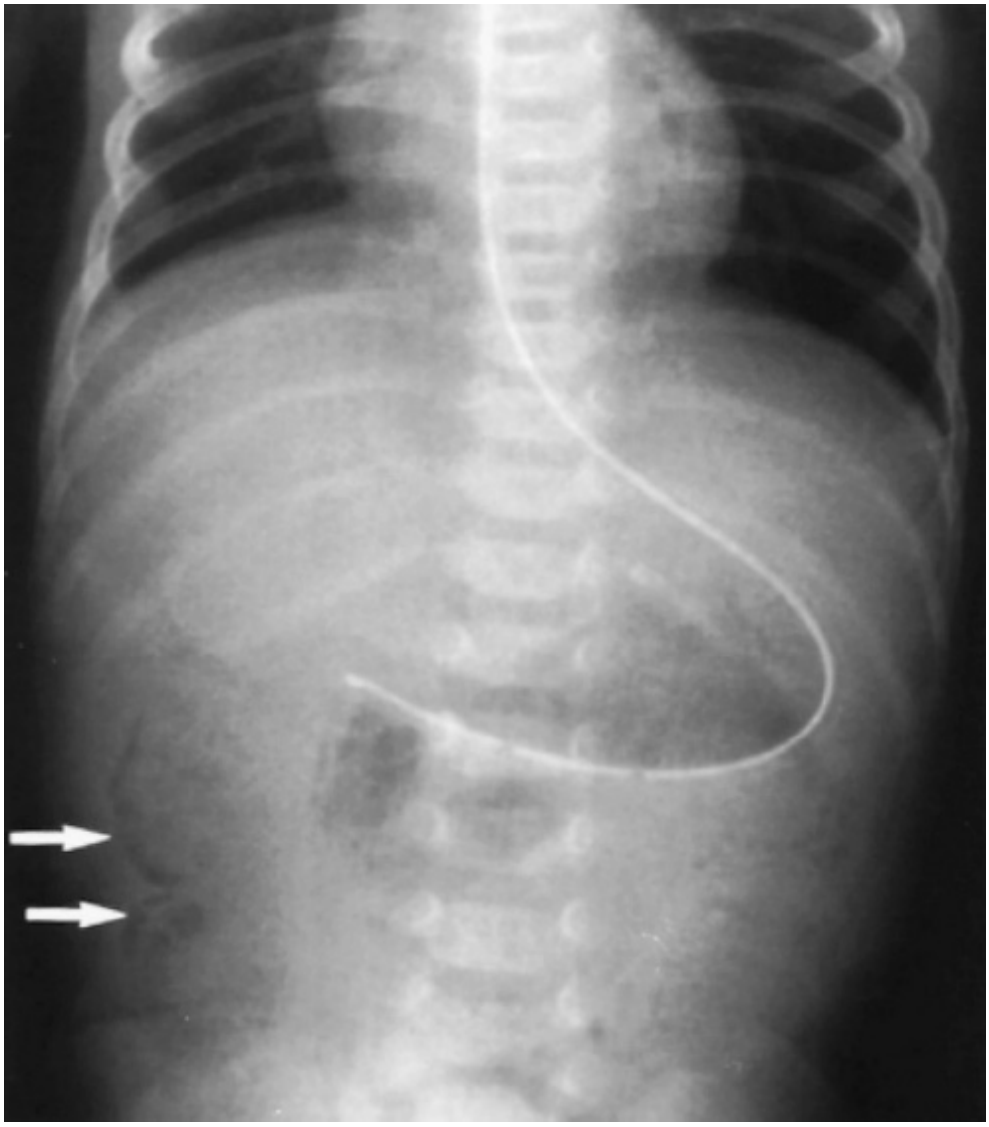

Figure 101.20 Plain abdominal film demonstrating *pneumatosis intestinalis* (*arrows*) in an infant with necrotizing enterocolitis.

Treatment

Nonoperative

The vast majority of infants with NEC can be managed medically. Initial management of NEC includes proximal decompression with a nasogastric or orogastric tube, bowel rest, and broad-spectrum intravenous antibiotics. Prompt correction of hypotension, hypoxemia, and inadequate ventilation must be undertaken. Intravenous fluid management, with particular attention to electrolytes and acid–base status, is essential. Central venous access is secured and TPN is initiated. Oxygen delivery and cardiac performance must

be maintained, which in a premature neonate may require operative closure of a patent ductus arteriosus; this approach is preferable over the use of indomethacin in the setting of NEC.[86] Serial physical examinations and blood work are useful in monitoring disease progress.

Most infants with NEC improve with medical management. Typically, reversal of the systemic inflammatory response occurs rapidly, and the abdominal distention and ileus resolve over a period of days. Nasogastric tube decompression and intravenous antibiotics are usually continued for 7 to 14 days. Enteral feeding usually is resumed once antibiotics have been discontinued and there has been return of gastrointestinal function. The usual course of medically treated NEC is rapid clinical response and stabilization in the first 24 to 36 hours. Infants with significant intestinal necrosis typically have signs of either pneumoperitoneum or clinical deterioration during the initial 24 to 72 hours of treatment.

Indications to abandon medical management and escalate surgical therapy include evidence of intestinal perforation or clinical deterioration with persistent or progressive systemic illness despite maximal medical therapy. Evidence of persistent or progressive systemic sepsis includes temperature instability, refractory hypotension, acidosis, hypoglycemia, neutropenia, and thrombocytopenia. Local findings such as portal venous gas, abdominal wall cellulitis, or crepitus also may signal intestinal necrosis and the need for operative intervention. A palpable, fixed abdominal mass consistent with intestinal perforation with an inflammatory phlegmon or abscess also may be a relative indication for operation. Because there is not complete agreement on what constitutes clinical deterioration, some controversy exists regarding operative indications for NEC in the absence of pneumoperitoneum. Because the interpretation of clinical deterioration criteria remains subjective, the decision to operate remains a multifactorial clinical judgment. In equivocal situations, abdominal paracentesis of ascitic fluid may be helpful in diagnosing intestinal necrosis with perforation in the absence of pneumoperitoneum if the aspirate contains bacteria or stool.[87]

Operative

Operative indications in NEC include the presence of intestinal necrosis with or without frank intestinal perforation. Conventional operative intervention is aimed at treating the complications of NEC (i.e., intestinal necrosis). In

general, resection of intestine involved with NEC does not prevent further extension of disease in other involved areas of the bowel. For isolated segmental disease, the traditional surgical treatment of NEC is resection of necrotic bowel with proximal enterostomy and distal mucous fistula placement. In infants with diffuse NEC, multiple resections with several enterostomies may be required. The primary operative goal is an expedient operation with preservation of as much intestinal length as possible, including the ileocecal valve. Because the risk of developing short-gut syndrome is substantial in infants with diffuse disease, preservation of marginal areas of involved intestine with a planned second-look operation to reevaluate intestinal viability may be useful. Accurate measurement of the remaining bowel length is important from a diagnostic and prognostic standpoint, with the length of bowel resected determined by the extent of transmural intestinal necrosis. Resection with primary anastomosis in selected infants with NEC has been reported,[88] with a recent study observing recurrent NEC in 22% and strictures in 17% of 18 treated infants following primary anastomosis.[89] Complete intestinal necrosis of the small intestine and the colon is uncommon and is not compatible with long-term survival without the sequelae of short-gut syndrome and the potential need for chronic TPN dependence and ultimately intestinal transplantation (Fig. 101.21).

Infants with NEC are typically fragile and premature, and complications in this population are not well tolerated. Survival in this situation may be more dependent upon disease severity and coexisting medical problems than the operative approach. For the high-risk, low–birth-weight infant, initial management with primary bedside peritoneal drainage rather than laparotomy and bowel resection may be useful as either a temporizing measure or, in some instances, a definitive procedure.[90] A multicenter, randomized controlled surgical trial comparing laparotomy with primary peritoneal drainage in premature infants with perforated NEC found that overall survival, dependence upon TPN, and length of stay were independent of the type of operation performed.[91] However, 18-month follow-up of neurodevelopmental outcomes demonstrates worse neurodevelopmental scores in prospective cohort studies.[92]

Complications, Results, and Outcome

Most infants with NEC are treated successfully without operative intervention. Morbidity and mortality for this group are related primarily to problems associated with prematurity. Given the delay of bowel function and the need for TPN, cholestatic jaundice commonly occurs but is generally reversible. Infants placed on broad-spectrum antibiotics for an extended period are at risk for developing fungal sepsis. For infants with intestinal necrosis from NEC, infectious complications including wound sepsis, central venous catheter infections, and pneumonia with respiratory failure may occur.

Figure 101.21 Fulminant necrotizing enterocolitis involving the entire gastrointestinal tract in a premature infant. Note the presence of pneumatosis intestinalis.

The overall surgical complication rate in infants with NEC is at least 20% to 40%. Immediate technical complications in treating NEC include intestinal leak, fistula formation, stoma necrosis, bleeding, and liver injury during exploration (Table 101.5). These complications are obviously magnified in the extremely low–birth-weight infant with preexisting intestinal injury. Fluid and electrolyte losses from proximal diverting enterostomies can be significant and even life-threatening in extremely low–birth-weight infants whose circulating blood volume is less than 50 to 100 mL. A review of 68

infants treated surgically for NEC observed a 26% mortality rate and a 68% complication rate related to the stoma or its closure in the perioperative survivors.[93] Complications included intestinal stricture, incisional or parastomal hernia, stoma prolapse, intussusception, wound dehiscence or infection, small bowel obstruction, and anastomotic failure. The complications associated with diverting enterostomy in this unique population provide a compelling rationale for early enterostomy closure once the inflammation from peritonitis has resolved. A prospective, randomized trial comparing resection and enterostomy with resection and primary anastomosis in the treatment of NEC has not been reported; however meta-analysis of retrospective outcomes has shown decreased odds of mortality in primary anastomosis. There is some concern that these retrospective studies are biased toward ostomy placement in the most critically ill patients.

COMPLICATIONS

Table 101.5 Operations for Necrotizing Enterocolitis

Infection (wound, intra-abdominal, central venous catheter, pneumonia)
Bleeding
Stoma-related complications (stenosis, retraction, prolapse)
Electrolyte or nutritional disturbances from enterostomy output
Enterocutaneous fistula
Anastomotic leak, stenosis, failure
Adhesive small bowel obstruction
TPN-associated cholestasis
Short-bowel syndrome, malabsorption
Sepsis, cardiopulmonary failure
Intraventricular hemorrhage

Intestinal stricture formation following NEC, whether managed operatively or nonoperatively, is not uncommon. This consequence usually results from a normal host inflammatory response to transmural intestinal injury. The degree of fibrosis and subsequent stricture formation are clearly related to the severity and extent of disease. Less frequently, mesenteric vascular compromise secondary to an intra-abdominal adhesion may lead to stricture formation. Although stricture can develop anywhere in the gastrointestinal tract involved with NEC, a higher rate of demonstrable stricture is observed in the left colon, occurring in as many as 36% of medically treated infants.[94] Routine contrast enema 4 to 6 weeks after clinical resolution of NEC treated operatively or nonoperatively has been advocated in some institutions. Symptomatic strictures generally require segmental resection with anastomosis, although fluoroscopically guided balloon catheter dilatation has been reported.

Overall survival rates for infants with NEC have improved significantly over the past three decades and are currently about 60% to 80% for both operative and nonoperative groups.[95] The observed improvement in survival is thought to reflect improved neonatal intensive care, the use of TPN, and early, aggressive treatment of suspected NEC. Most neonatal intensive care units initiate aggressive medical treatment in any infant with suspected NEC. Whether surgical interventions such as resection with primary anastomosis or limited primary peritoneal drainage can improve morbidity and mortality in these critically ill infants remains to be fully determined. Long-term outcome for NEC survivors generally reflects associated problems of prematurity. In particular, many of these infants have persisting neurodevelopmental, ophthalmologic, and pulmonary diseases, but morbidity from the gastrointestinal system generally is limited to infants with short-gut syndrome following extensive bowel resection. These infants present complex ethical and management issues beyond the scope of this review. Most NEC survivors (75%) enjoy a good to excellent quality of life, suggesting that the treatment cost relative to the potential benefit for these infants is worthwhile.[96]

Meconium Ileus

Meconium ileus is a descriptive term for small bowel obstruction in a newborn infant with CF. About 10% to 20% of infants with CF initially

present with meconium ileus. A review of CF is useful to understand the pathophysiology and treatment of meconium ileus.

CF is the most common fatal hereditary disease in Europe and North America. It is an autosomal recessive disorder found with a heterozygous carrier incidence rate of 1 in 20 to 25 in white populations. The estimated incidence rate of homozygous gene expression and phenotypic manifestation of CF is about 1 in 2,000 to 2,500 in this population.[97] Screening of at-risk couples with a family history of CF is recommended, however, and in this setting, carrier discovery approaches 100% so that appropriate genetic counseling can be provided. Molecular genetic screening should also be offered to parents and infants with clinically suspected CF as well as asymptomatic infants born to at-risk couples. This approach allows rapid identification and confirmation of virtually all infants homozygous for CF.

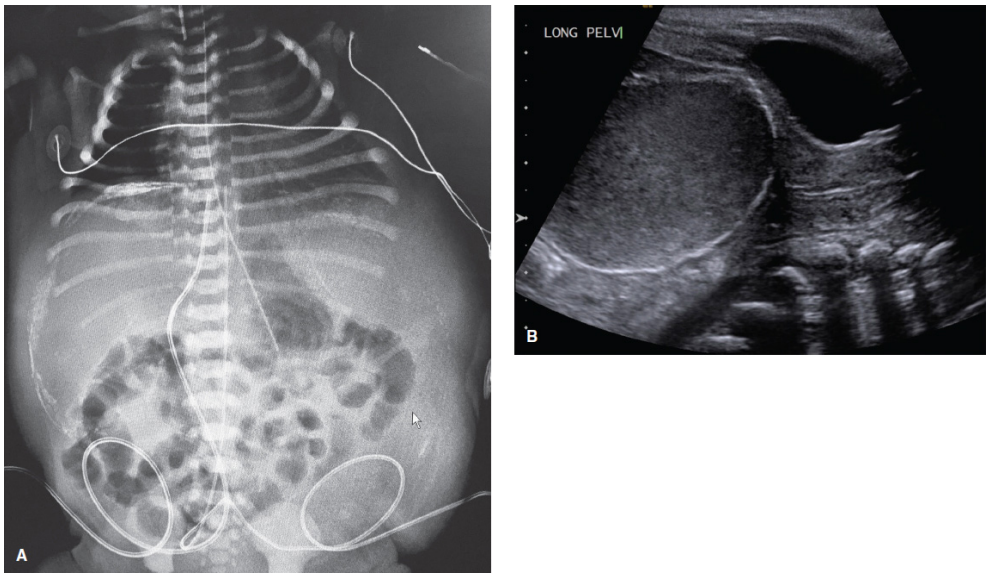

Figure 101.22 **A:** Plain film radiograph of calcified pseudocyst in complicated meconium ileus. **B:** In utero ultrasound demonstrating calcified pseudocyst.

Pathophysiology

Table with CF manifestations

Cystic Fibrosis Clinical Manifestations	
Organ System	**Clinical Manifestation**
Apocrine sweat glands	Increased loss of sodium chloride in sweat
Tracheobronchial tree	Diminished volume and increased viscosity of airway secretions leading to decreased clearance
Pancreas	Deficiency of pancreatic proteinases, impaired chloride resorption, and abnormally thick meconium
Gastrointestinal tract	Abnormal thick inspissated stool, can lead to appendicitis, rectal prolapse, and intussusception
Liver	Chronic hepatic inflammation, fibrosis, and cirrhosis

In utero events such as proximal volvulus of the dilated segment of ileum, perforation from distention, or atresia occur in approximately one-third to one-half of fetuses with meconium ileus. These clinical entities are characterized together as *complicated meconium ileus*. A classic clinical presentation of complicated meconium ileus is in utero intestinal perforation with sterile meconium peritonitis and formation of a calcified pseudocyst (Fig. 101.22). Gastrointestinal conditions presenting later in life occur in 10% of children with CF and include acute appendicitis, recurrent rectal prolapse, and intussusception. These conditions reflect abnormal transit of thick, inspissated stool causing proximal distention or obstruction of the bowel lumen. Small bowel obstruction in CF outside the neonatal period was historically called *meconium ileus equivalent,* and is now termed *distal intestinal obstruction syndrome* (DIOS). Treatment of DIOS is similar to initial nonoperative management of uncomplicated meconium ileus in the newborn discussed later. Prevention of DIOS relies on conscientious pancreatic enzyme replacement. Finally, children with CF are at risk to cholestasis secondary to obstruction of small intrahepatic bile ducts. Chronic hepatic inflammation can occur with subsequent fibrosis and cirrhosis,

causing hepatic failure and portal hypertension in approximately 5% of CF patients.

Diagnostic Evaluation

In nearly all newborns with CF, the diagnosis is clinically apparent by the presence of meconium ileus, a family history of CF in a sibling, or a positive newborn screening test. Laboratory confirmation of *CFTR* gene dysfunction is performed in several ways. The historical standard for the detection of CF has been analysis of the sodium chloride content of the sweat. The most commonly used and reliable technique uses pilocarpine iontophoresis, with positive sweat test results showing sodium and chloride concentrations exceeding 60 mEq/L.[99] This test is less useful during the first 4 to 6 weeks of age because normal neonates do not reliably conserve sodium chloride in sweat. Generally, abnormal *CFTR* gene is documented by two elevated sweat chloride tests obtained on separate days. With the emergence of genetic technology capable of providing accurate assessment of *CFTR* gene mutations, the sweat test is now largely used to provide clinical confirmation of *CFTR* gene dysfunction along with molecular diagnosis of CF.

Clinical Presentation

With routine prenatal ultrasound practices along with selected fetal DNA screening, the prenatal diagnosis of CF or meconium ileus is feasible, potentially allowing for improved management of anticipated clinical problems following delivery.[100] Initial signs of meconium ileus include neonatal bowel obstruction with abdominal distention, bilious emesis, and failure to pass meconium. On examination, the neonate may have palpable loops of meconium-filled intestine with a texture on palpation described as "doughy." Similar to other causes of proximal neonatal intestinal obstruction, rectal examination and evaluation of the meconium typically reveals clear white mucus or thick gray meconium. In utero intestinal perforation with pseudocyst formation in complicated meconium ileus may cause a palpable abdominal mass that is not particularly tender. On plain films or ultrasound, calcification is visible in the pseudocyst wall. In contrast, volvulus or intestinal perforation secondary to meconium ileus following birth generally

results in diffuse peritonitis and sepsis. Intestinal atresia may also be seen as a consequence of complicated meconium ileus.

Diagnosis

Abdominal plain films may be diagnostic in meconium ileus, demonstrating multiple, distended loops of bowel. Fluid- or meconium-filled loops of bowel mixed with gas give a characteristic "soap bubble" or "ground glass" appearance. Classic air–fluid levels seen in other causes of intestinal obstruction are not expected because of the tenacious, sticky intraluminal meconium. The presence of intraperitoneal calcifications or a calcified cyst is consistent with prenatal intestinal perforation of sterile meconium.

A water-soluble contrast enema is useful in the evaluation and treatment of simple meconium ileus. This study usually demonstrates an unused but functionally normal microcolon. Reflux of contrast into the terminal ileum may confirm the presence of inspissated meconium pellets. In conjunction with a family history and plain films, this finding is sufficient evidence to confirm the diagnosis of neonatal meconium ileus. Upper gastrointestinal contrast studies are generally unnecessary and may complicate further therapeutic efforts.

Treatment

Nonoperative

Nonoperative management of simple meconium ileus is achieved in about 60% to 70% of newborns. Once the diagnosis of meconium ileus is confirmed, the initial treatment of choice is to perform retrograde irrigation of the terminal ileum with one of several solutions designed to dissipate the obstructing meconium. In the United States, several different enema techniques and a variety of contrast media have been described, including normal saline, hyperosmolar contrast agents, and dilute *N*-acetylcysteine. Initially, it was believed that using hyperosmolar contrast material was necessary to create an osmolar gradient. The resultant influx of fluid into the intestinal lumen was thought to solubilize the inspissated meconium. Recent data suggest that successful meconium clearance is not necessarily related to the osmolality of the contrast agent; however, a significantly higher overall success rate is reported with the use of Gastrografin (sodium and meglumine

amidotrizoate) and the use of other solubilizing agents such as Tween-80 and *N*-acetylcysteine.[101] As long as clinical progress is being made, sequential enemas may be required to disimpact the inspissated meconium from the terminal ileum. In similar fashion, children and older patients presenting with DIOS are treated with retrograde enemas until the obstruction resolves. The distinct advantage of this treatment approach is the avoidance of general anesthesia and exploratory laparotomy. Reported complications with this approach include rare intestinal perforation, intestinal mucosal injury, and persistent obstruction resulting from meconium concretions.

Operative

The major indications for operative intervention are either failure to clear the obstruction by retrograde enema or complicated meconium ileus with cyst formation, volvulus, atresia, or perforation. For simple meconium ileus with persistent obstruction despite contrast enemas, the operative goals are meconium disimpaction from the ileum and evacuation of the remaining stool from the small intestine. These steps can be accomplished by either milking the meconium downstream into the colon or solubilizing the meconium by transmural needle instillation of irrigant. However, enterotomy or enterostomy and direct irrigation of the bowel lumen are usually required to completely clear the inspissated meconium. Simple closure of the enterotomy is preferred, but segmental resection may be required if marginal or compromised intestine is found. End-to-end anastomosis is the appropriate reconstruction technique following segmental bowel resection. A temporary enterostomy may be required, and several historical techniques have been described. Another surgical option is the placement of a T-tube into the ileum for continued irrigation with dilute *N*-acetylcysteine. Following clearance of meconium from the intestine and the return of bowel function, the T-tube can be safely and simply removed.[102]

Complicated meconium ileus occurs in about one-third of patients. The surgical management of this entity is individualized. Intestinal atresia is not uncommon in meconium ileus, and the entire length of the intestine must be inspected for patency. When possible, resection of nonviable, stenotic, or perforated intestine is performed with immediate reconstruction via primary anastomosis. Patency of the downstream bowel must be confirmed to prevent anastomotic leak resulting from distal obstruction. If the infant is critically ill

or has diffuse peritonitis, a safe primary anastomosis may not be possible and a diverting enterostomy is required. Stoma closure may be performed promptly after resolution of peritonitis and inflammation.

Postoperative Care and Results

If the meconium has been successfully cleared without opening the intestine, dilute *N*-acetylcysteine may be given through the nasogastric tube or by enema. Alternatively, if a T-tube has been placed, dilute *N*-acetylcysteine or other irrigant can be used directly into the ileum. These efforts are aimed at keeping the meconium soluble and preventing recurrent ileal obstruction. Following return of bowel function, enteral feeding using breast milk or an elemental formula is started along with oral pancreatic enzyme replacement. Vigilant pulmonary therapy is routine and includes mucolytics and antibiotics when indicated. Nutritional assessment and support are essential in long-term management.

Successful nonoperative management of simple meconium ileus historically was associated with a more favorable outcome; however, the operative mortality rates of infants with meconium ileus have improved dramatically over the past several decades, and current short-term operative survival rates of 70% to 100% are reported.[103,104] Long-term survival following meconium ileus is generally determined by the course of the underlying pulmonary disease. Contemporary management of CF has produced a mean survival age that approaches 30 years in most centers. With the exception of the development of portal hypertension in about 5% of patients, intestinal manifestations of the CF are treatable. Future medical and surgical efforts to improve the long-term outcome in these patients include direct replacement of the diseased pulmonary system by lung transplantation, manipulation of the epithelial chloride transport defect with pharmacologic agents, and gene therapy directed at *CFTR* gene transfer into respiratory epithelial cells.

Meconium Plug Syndrome

Meconium plug syndrome is characterized by functional obstruction of the colon or the rectum by a meconium plug. It affects both normal and premature infants with immature gastrointestinal motility and must be differentiated from

other causes of neonatal intestinal obstruction. Unlike meconium ileus, in meconium plug syndrome the colon is of normal caliber and the meconium is not inspissated. The infant's symptoms within the first few days of life are abdominal distention and bilious emesis. Spontaneous passage of meconium is often absent. On examination, the infant is normal with a patent anus and a distended abdomen. Digital rectal examination may deliver the meconium plug. Plain films of the abdomen demonstrate dilated loops of bowel consistent with distal bowel obstruction. The diagnosis is confirmed by contrast enema, which is also therapeutic in helping the meconium plug pass. The meconium plug is followed by bile-stained meconium of normal consistency. Importantly, although the vast majority of these infants are normal, a few have Hirschsprung disease or CF. Therefore, infants presenting with meconium plug syndrome may require rectal suction biopsy and have CF screening tests performed.

Malrotation

Embryology

Normal midgut fixation requires sequential growth, elongation, and rotation of the intestine beginning as early as week 5 of gestation as illustrated in Figure 101.23. Three distinct events occur during normal midgut fixation. The first stage involves herniation of the primary midgut loop into the base of the umbilical cord, where it remains until week 10 of gestation. The axis of the midgut loop is the superior mesenteric artery (SMA), with the omphalomesenteric duct at the apex of the midgut loop. The midgut loop rotates 180 degrees counterclockwise so that the proximal half passes posterior to the SMA. The proximal portion gives rise to the proximal duodenum, which lies to the right of midline. A portion of this segment becomes the third and fourth portions of the duodenum. The distal duodenum is normally fixed to the left of the aorta at the ligament of Treitz, having rotated 270 degrees counterclockwise from its original position. The jejunoileal segment undergoes dramatic elongation, forming about six primary intestinal loops. The distal midgut loop gives rise to the cecum and the right colon, which also undergoes growth and elongation with concomitant rotation 270 degrees counterclockwise. Therefore, the cecum is initially positioned to

the left, then anterior, and finally to the right of the SMA before reaching its final location.[105]

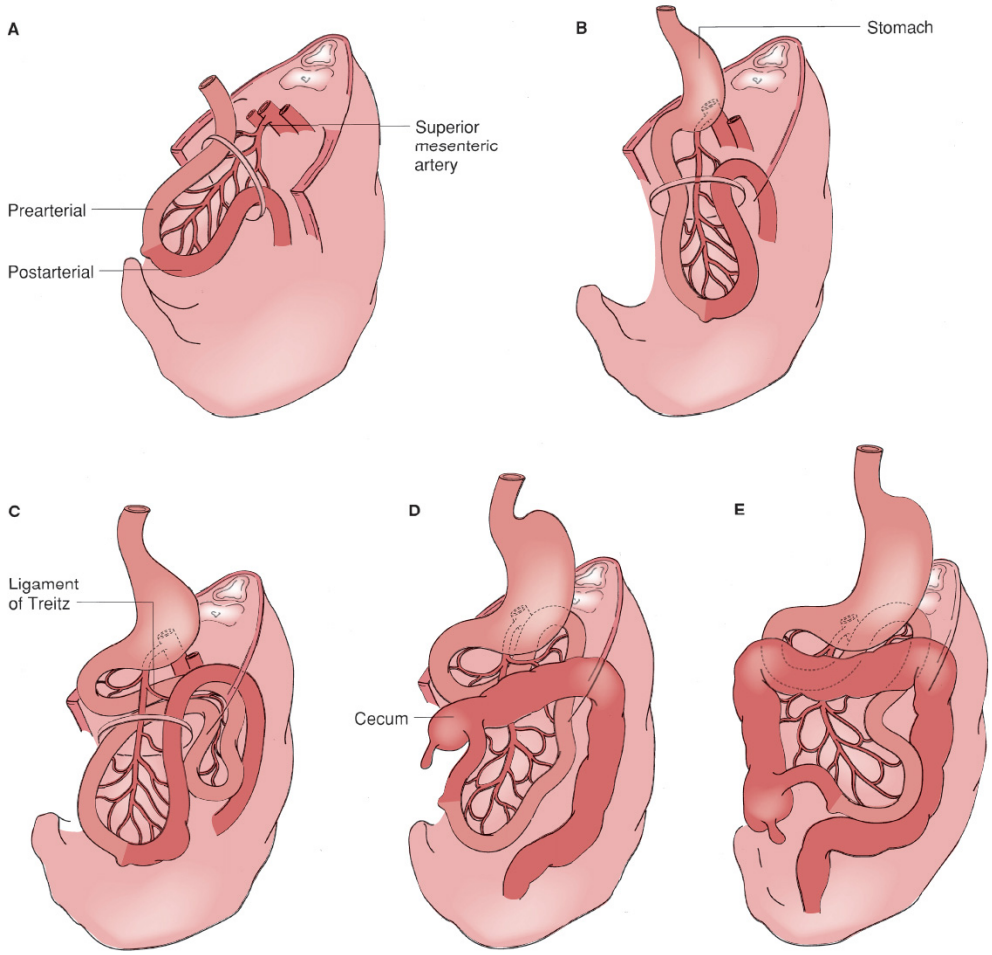

Figure 101.23 Normal midgut rotation is shown with appropriate positioning of the stomach, duodenum, small intestine, and cecum from the fifth gestational week (**A**) through completion by the 12th week (**E**).

Reduction of the extracoelomic gut is the second stage of midgut development and fixation, occurring between weeks 10 and 12 of gestation. By this time, the duodenojejunal junction has passed posterior to the SMA and the midgut has rotated 180 degrees counterclockwise; however, the small intestine initially remains to the right side of midline, and the cecum and ascending colon are anterior to the SMA after return of the gut into the abdomen. Many common abnormalities of intestinal fixation occur as a result of arrested development during this 2-week period.

The final stage of midgut development is fixation of the intestine to the posterior body wall, occurring after week 12 of gestation. Cecal descent occurs at this time. Normal points of fixation include the cecum in the right iliac fossa and the duodenojejunal junction at the ligament of Treitz just to the left of the aorta and anterior to the left renal vein (Fig. 101.24). Therefore, the normal intestinal mesentery is fixed with a broad base extending from the ligament of Treitz to the cecum. This broad-based mesenteric attachment prevents volvulus from occurring. In contrast, in disorders of intestinal rotation, the base of the mesentery is neither fixed nor broad, placing the entire midgut at risk for volvulus.

Anatomy

The normal sequence required for intestinal positioning and fixation can be interrupted at any developmental stage, producing a diverse spectrum of rotational abnormalities. Some neonatal surgical conditions are nearly always associated with abnormal intestinal rotation or fixation resulting from displacement of the midgut from the abdominal cavity during embryologic development. These anomalies include omphalocele, gastroschisis, and congenital diaphragmatic hernia. The term *malrotation* has been applied generically to describe disorders of intestinal rotation and fixation, although specific definitions of the more commonly encountered lesions are provided in the following sections.

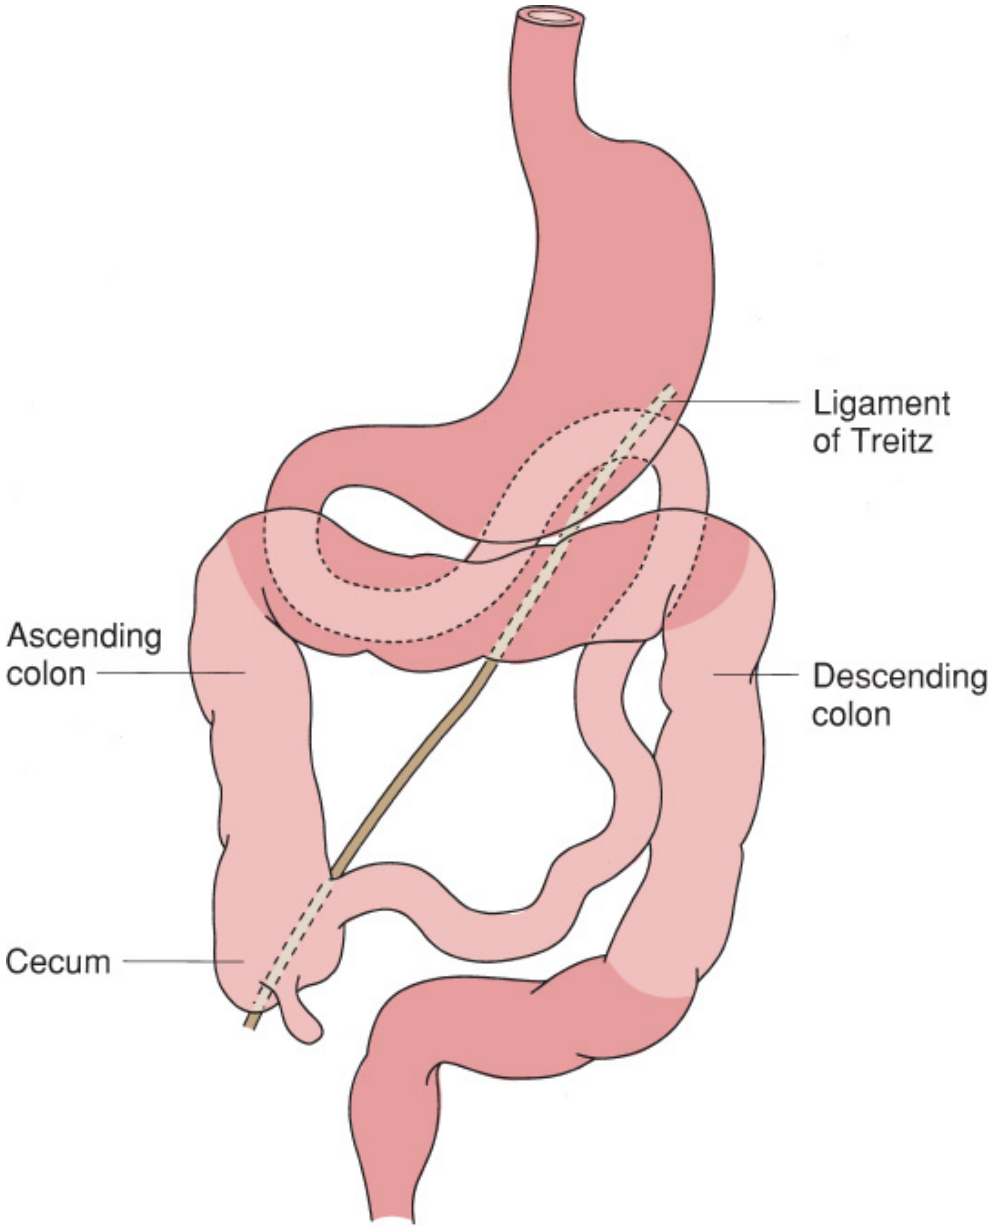

Figure 101.24 Normal oblique fixation of the midgut mesentery at the ligament of Treitz and in the right lower quadrant. The blue portions of the colon are extraperitoneal.

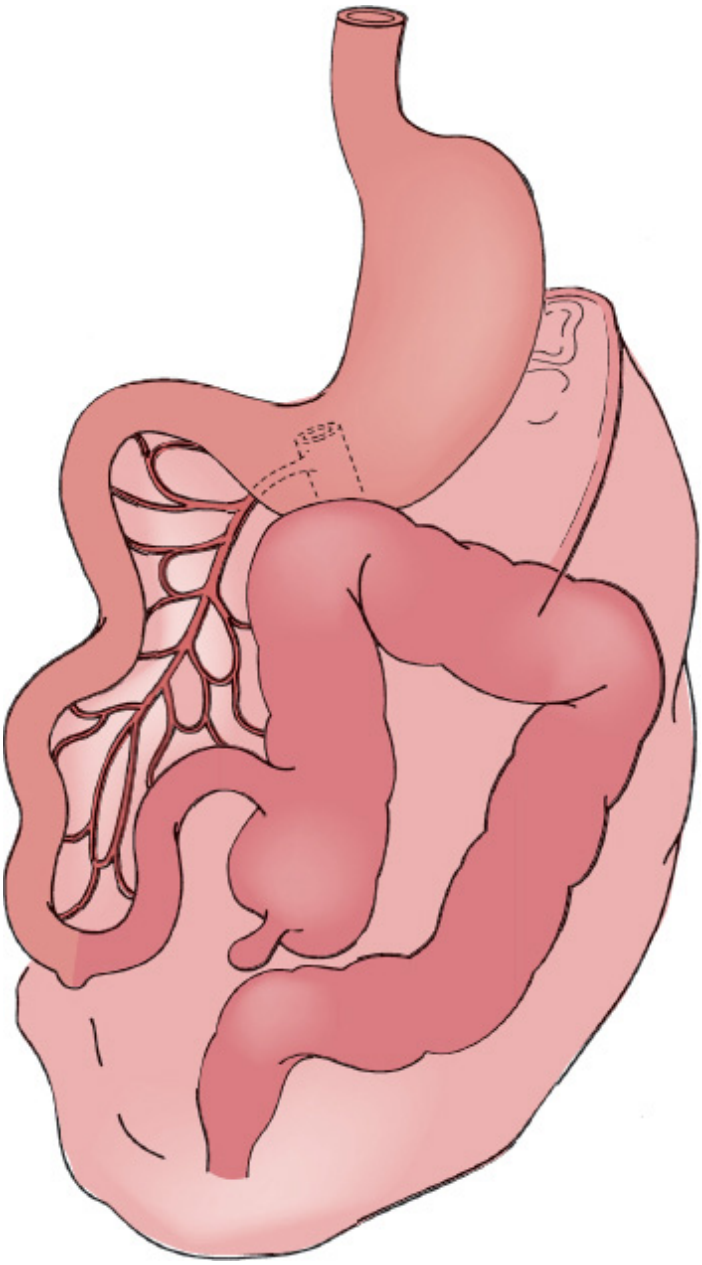

Figure 101.25 Nonrotation. The proximal segment of the small intestine resides on the right side of the abdomen, and the distal segment (*colon*) is on the left. Neither has rotated normally.

Nonrotation

This common anomaly is characterized by inadequate counterclockwise rotation of the midgut around the SMA. Instead of the normal 270-degree arc, rotation is either absent or arrested before exceeding 90 degrees (Fig. 101.25). The small intestine resides on the right side of midline, the colon resides on the left, and the cecum is anterior and near the midline. The

duodenojejunal junction is to the right of midline and more caudal and anterior in position. Nonrotation carries a significant clinical risk of midgut volvulus because the mesenteric vascular pedicle is narrow. Duodenal obstruction also may occur as a result of peritoneal attachments known as *Ladd bands*. These peritoneal bands fix the cecum to the posterior body wall by passing anterior and lateral to the distal duodenum.

Mixed or Incomplete Rotation

This rotational abnormality is characterized by arrest of the normal rotation at or near 180 degrees rather than the normal 270 degrees (Fig. 101.26). Instead of rotating posterior and to the left of the SMA, incomplete or arrested rotation of the prearterial segment leaves the duodenojejunal junction to the right of midline. The cecum also does not complete its counterclockwise passage anterior to the SMA; it usually resides in the upper abdomen just to the left of the SMA. Similar to nonrotation, fixation of the cecum to the posterior body wall by Ladd bands places the duodenum at risk for compression or obstruction. In addition, the SMA pedicle is narrow and places the midgut at risk for volvulus.

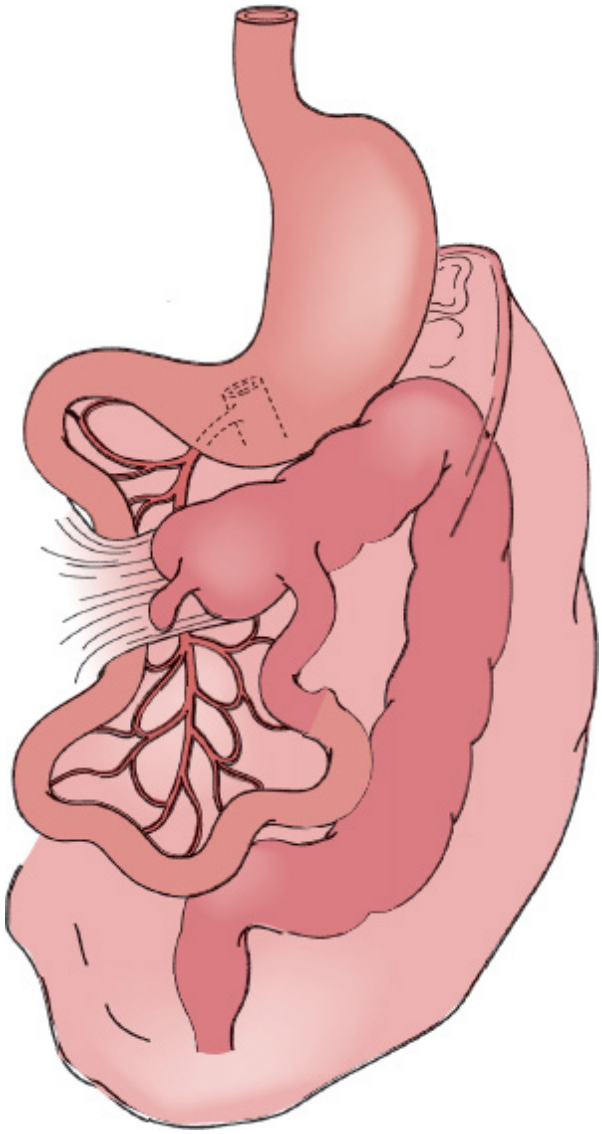

Figure 101.26 Incomplete rotation. The proximal segment has failed to rotate and is on the right. The distal segment has rotated to reside anterior to the duodenum so that cecal bands to the posterior abdominal wall may compress and obstruct the duodenum.

Mesocolic Hernias

Mesocolic hernias are rare but important anomalies characterized by failure of fixation of either the right or left mesocolon to the posterior body wall. Small bowel can become entrapped in the resulting potential cavities on either side of the abdomen. A right-sided mesocolic defect (paraduodenal hernia) is associated with nonrotation of the proximal midgut segment. Small bowel entrapment posterior to the right colon and cecum may occur. Similar entrapment of small bowel may occur from an incompletely fixed left

mesocolon but is associated with normal colonic and cecal position. Entrapped small bowel in a left mesocolic hernia usually is contained within a hernia sac with the neck composed of the inferior mesenteric vein and peritoneal bands extending to the posterior body wall. Both left and right mesocolic hernias carry the potential risks of obstruction, incarceration, and strangulation of bowel.

Clinical Presentation

Abnormalities of intestinal rotation are estimated to be present in about 1% of the population. Most persons with intestinal rotational anomalies are clinically asymptomatic; therefore, some children are found to have malrotation incidentally by upper gastrointestinal contrast studies conducted for other reasons. Symptomatic malrotation is usually encountered clinically in the setting of duodenal obstruction or midgut volvulus. Duodenal obstruction may occur as a result of Ladd bands fixing the abnormally positioned cecum to the posterior body wall. These peritoneal bands cause duodenal obstruction by extrinsic compression. Children with symptomatic duodenal obstruction typically present with bilious emesis and distention of the stomach and the proximal duodenum. Similar to proximal neonatal intestinal obstruction, newborn infants may present with bilious emesis without abdominal distention secondary to partial duodenal obstruction. A paucity of small bowel gas may be seen on plain abdominal films.

A potential consequence of intestinal malrotation is midgut volvulus. Midgut volvulus should be considered in any infant or child presenting with bilious emesis. The clinical outcome of midgut volvulus is time dependent, which is the fundamental reason that signs and symptoms of acute intestinal obstruction in an infant or a child must be pursued aggressively until a clear diagnosis is made. The devastating, life-threatening consequence of midgut volvulus is vascular insufficiency, gut ischemia, and, if untreated, infarction of the entire bowel supplied by the SMA. The initial symptoms may be subtle and limited to feeding intolerance, abdominal pain, and irritability, followed by bilious emesis. Guaiac-positive stool from mucosal injury is a common early finding. Late findings include progressive abdominal distention, hematemesis, and hypotension. Metabolic acidosis, coagulopathy, and shock

may become prominent clinical features. If unrecognized or left untreated, transmural necrosis of the entire midgut will occur.

At least 50% to 75% of intestinal rotational abnormalities are discovered within the first week to month of life, and about 90% occur in children younger than 1 year.[106,107] Symptomatic infants and children require emergent surgical exploration and correction. Older children and adults initially may present with acute volvulus but also may have a history of vague symptoms of episodic intestinal obstruction and chronic abdominal pain. It is essential to recognize that, regardless of age or chronicity of symptoms, midgut volvulus from malrotation occurs in a completely unpredictable manner.[108] Therefore, it is generally recommended that patients with incidentally discovered, asymptomatic malrotation undergo operative management to reduce the risk of volvulus.

Diagnosis

As with other forms of neonatal intestinal obstruction, the diagnostic evaluation begins with a plain abdominal radiograph. Classic findings with malrotation include gastric and proximal duodenal distention with a paucity or absence of distal small bowel gas (Fig. 101.27**A**). The plain film alone may not differentiate malrotation from duodenal atresia or stenosis. In most cases of suspected duodenal obstruction with concern of malrotation, an upper gastrointestinal series is a conclusive imaging study (Fig. 101.27**B**). Malrotation with volvulus typically produces incomplete duodenal obstruction with a corkscrew or coiled appearance in the distal duodenum. Extrinsic compression of the duodenum by Ladd bands may be visible on contrast study. Duodenal atresia and stenosis may occur anywhere within the duodenum but tends to be more proximal. Complete absence of small bowel gas is typical of duodenal atresia, whereas diminished but discernible distal gas is characteristic of duodenal stenosis or malrotation with volvulus.

Other radiographic findings in malrotation include incorrect position of the duodenojejunal junction, particularly to the right of midline. Failure to achieve normal cephalad and posterior fixation is typical in malrotation and may be best appreciated on lateral views. The small bowel resides in the right side of the abdomen, the colon, and cecum on the left (Fig. 101.27**C**). In a symptomatic infant or child, radiographic evidence of malrotation alone is

enough to warrant emergent exploration. A contrast enema is helpful in the evaluation of neonatal intestinal obstruction, although it may not be the initial study of choice if malrotation is suspected. The classic finding on contrast enema for malrotation is cecal malposition, usually in the left abdomen or near the midline. Finally, the relative position of the SMA to the superior mesenteric vein may be assessed by ultrasound. Normally, the superior mesenteric vein is to the right of the SMA on transverse sonograms. Abnormal position of the superior mesenteric vein either ventral or to the left of the SMA is associated with malrotation.[109]

Treatment

The management of bowel obstruction from malrotation or an internal hernia is operative. Initial assessment, resuscitation, and preoperative preparation in a symptomatic newborn should be conducted simultaneously so that confirmation of malrotation can be followed immediately by laparotomy. Urgent laparotomy is required to reduce the ischemic injury to the intestine. Shock, if present, must be treated aggressively by insuring adequate gas exchange and establishing restoration of intravascular volume prior to the induction of general anesthesia. Volvulus with complete infarction of the midgut, if not immediately lethal, is survivable only with enterectomy, followed by permanent or long-term TPN support. In older, asymptomatic children with incidentally discovered malrotation, operative repair remains controversial. Given the devastating consequences of midgut volvulus, however, elective surgical correction appears warranted in most asymptomatic individuals as well.

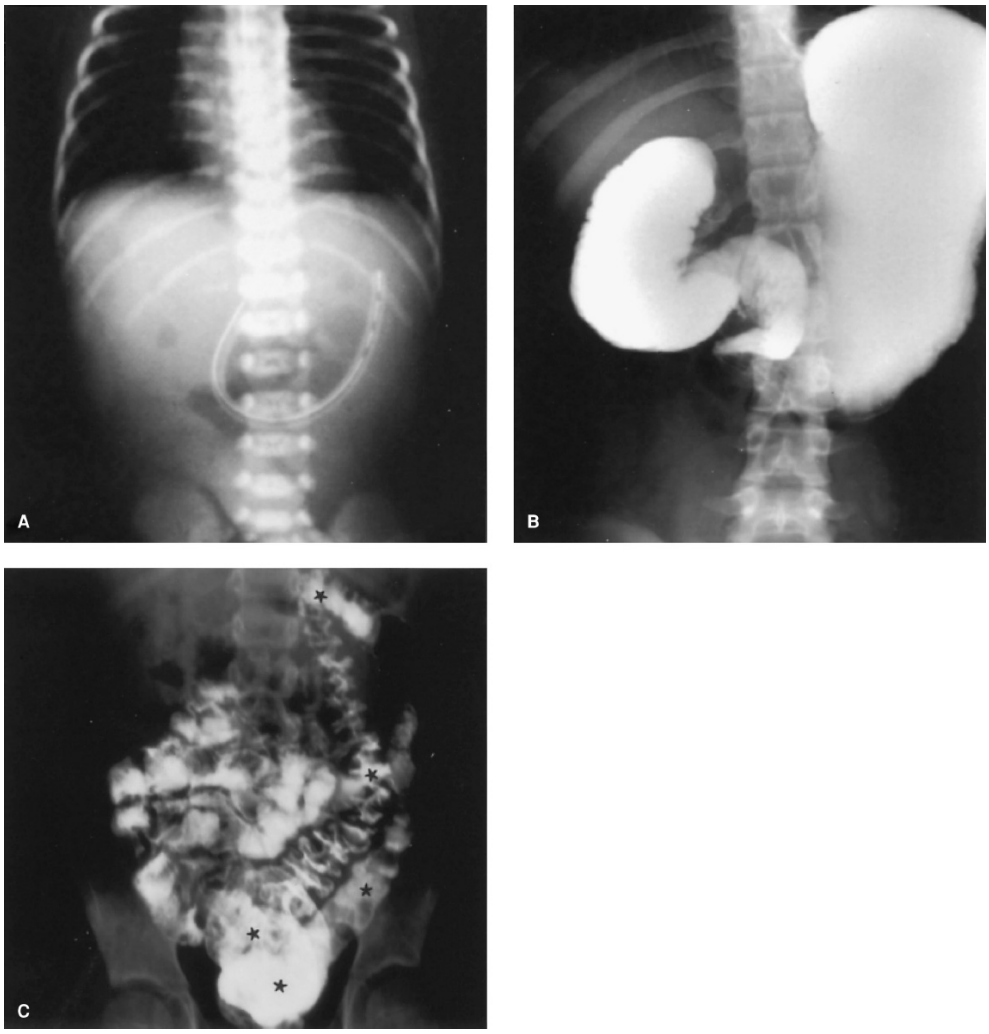

Figure 101.27 **A:** Plain radiograph of an infant with malrotation. There is a paucity of small bowel gas. **B:** Upper gastrointestinal contrast study demonstrating malrotation with midgut volvulus and duodenal obstruction. The position of the duodenojejunal junction is abnormal. **C:** Plain film showing a contrast-filled colon and cecum on the patient's left (*asterisks*). The entire small bowel is to the right of midline. These are typical radiographic findings of malrotation.

Operative repair of malrotation is performed by Ladd procedure.[110] The first objective is to relieve the midgut volvulus, if present. This is accomplished by delivery and detorsion of the affected midgut, usually in a counterclockwise direction. Recurrent volvulus is prevented by broadening the base of the mesenteric vascular pedicle by dividing the peritoneal bands that tether the cecum, small bowel mesentery, mesocolon, and duodenum around the base of the SMA (Fig. 101.28). Once completed, the mesentery

and the mesocolon open widely and the mesenteric pedicle is at low risk for recurrent volvulus.

The second objective of Ladd procedure is to divide the abnormal peritoneal attachments between the cecum and the abdominal wall. A modified Kocher maneuver involving meticulous and complete mobilization of the entire duodenum with division of all anterior, lateral, and posterior attachments is performed. Duodenal and distal small bowel patency should be demonstrated using intraluminal air or saline because synchronous intestinal webs and atresia have been reported. An appendectomy is performed to eliminate potential confusion from acute appendicitis developing in an abnormally positioned appendix. Performance of laparoscopic Ladd procedure has been demonstrated to be feasible and may help reduce time to enteral feeding and hospital length of stay; however, the long-term efficacy of this approach has been debated.[111] Fixation of the mesentery by cecal or duodenal plication to the body wall has been abandoned for lack of data supporting efficacy. Postoperative small bowel obstruction secondary to adhesions is reported in about 10% of patients.

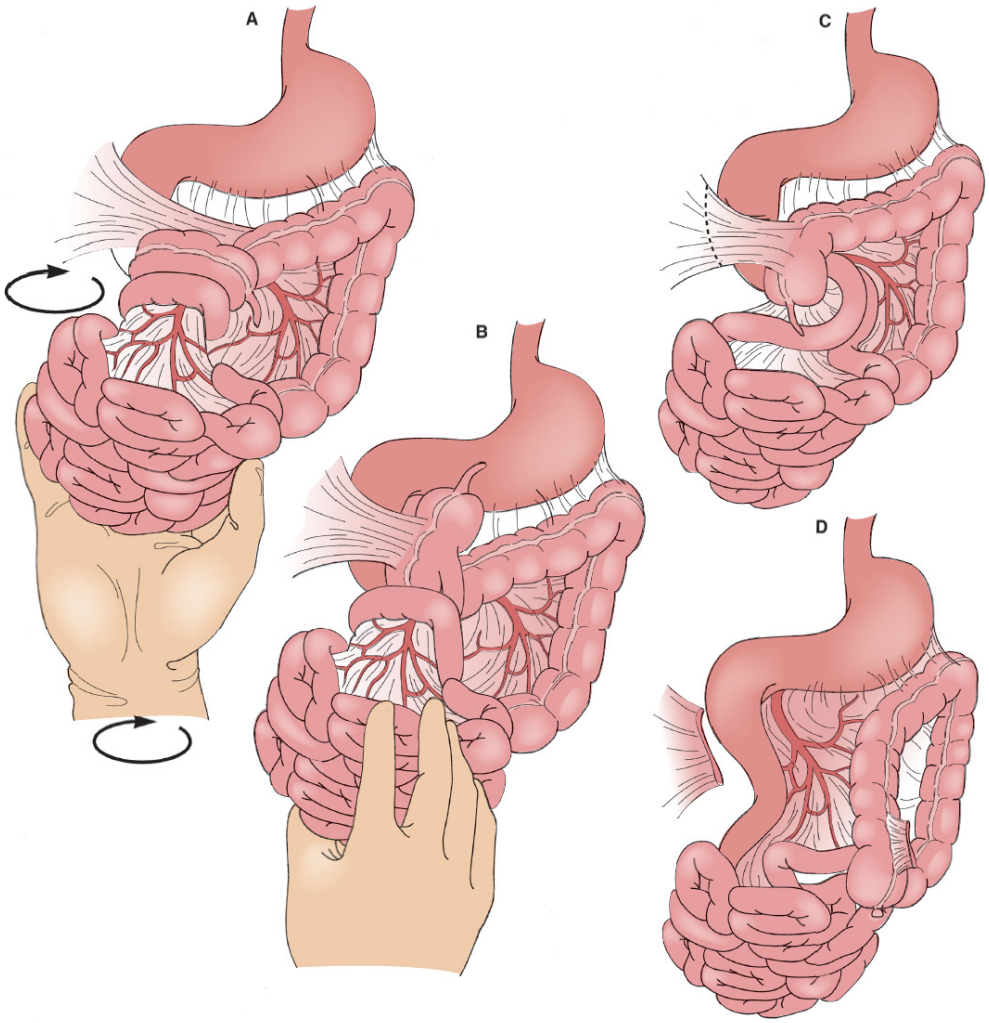

Figure 101.28 Correction of malrotation. **A, B:** Detorsion of midgut. **C, D:** Division of peritoneal attachments (Ladd bands) of cecum to abdominal cavity.

Volvulus with intestinal necrosis is treated by preserving as much bowel length as possible. If bowel viability is unclear during initial exploration, a second-look procedure may be helpful to delineate reversible from irreversible injury. The management of nonviable bowel from volvulus is not different from other situations in which intestinal necrosis is encountered, and clinical decisions regarding resection and anastomosis are individualized. In situations in which the entire small intestine is lost and long-term survival is doubtful, treatment decisions must be made with the family.

Surgical management of right mesocolic hernia is directed at dividing the lateral peritoneal attachments of the cecum and right colon to eliminate the hernia. In addition, given the associated nonrotation of the proximal bowel, the vascular pedicle should be broadened as much as possible. Left

mesocolic hernia is treated by mobilization of the inferior mesenteric vein, reduction of the small bowel from the hernia sac, and closure of the neck of the hernia sac to eliminate the potential space.

Results and Complications

Results following surgical correction of intestinal rotational abnormalities should be excellent, and life expectancy should be normal in the absence of intestinal necrosis. Recurrent volvulus and recurrent duodenal obstruction are distinctly unusual if the initial procedure is technically complete. Adhesive small bowel obstruction following Ladd procedure is reported in 1% to 10% of patients. Long-term outcome is obviously less favorable in patients with intestinal necrosis at the time of exploration.

Congenital Aganglionosis (Hirschsprung Disease)

Embryology

5 Congenital aganglionosis of the intestine (Hirschsprung disease) is characterized by the absence of intestinal ganglion cells. The pathogenesis of aganglionosis remains unknown. In normal development, neuroblasts derived from neural crest precursors become evident by week 5 of gestation. The neuroblasts begin maturation and caudal migration along with vagal nerve fibers. The initial caudal migration in an intermuscular plane is followed by intramural dispersal into both superficial and deep submucosal nerve plexuses. Ultimately, the neuroblasts give rise to the ganglion cells of the myenteric nervous system, with functional maturation continuing well into infancy. The orderly migration pathway of myenteric innervation has been documented in human embryos; normally, ganglion cells can be identified in the esophagus at week 6 of gestation, in the transverse colon at week 8 of gestation, and in the rectum by week 12 of gestation.[112]

Anatomy

Hirschsprung disease is characterized by a lack of ganglion cells in the distal intestine. The length of aganglionosis is variable but most commonly involves

the distal rectosigmoid colon in 75% to 80% of affected infants. In about 5% of cases, the transition zone between the normal, proximal bowel and the distal, aganglionic segment occurs in the small intestine.[113] Discontinuous aganglionosis has been reported but should be considered distinctly unusual. Therefore, in virtually all cases, the aganglionic intestinal segment is continuous with the distal rectum to the anal verge and also includes the internal sphincter. Because of this distribution, the pathogenesis of congenital aganglionosis is often attributed to failure of neuroblast migration. The characteristic lesion in the distal bowel is the aganglionosis in the intermuscular and submucosal plexuses. Large, hypertrophied, nonmyelinated nerve fibers are present within the muscularis mucosa, lamina propria, submucosa, and Auerbach intermuscular plexus. Both adrenergic and cholinergic fibers are prominent in the aganglionic segment, and acetylcholinesterase staining is useful diagnostically. Abnormalities in the peptidergic nervous system, including vasoactive intestinal peptide, substance P, and neurotensin immunoreactive fibers, are also described in the aganglionic bowel segment.[114] Deficient neuronal nitric oxide synthase mRNA and subsequent decreased local nitric oxide synthase activity in the aganglionic bowel have also been described.[115] These experimental data are consistent with the concept that a defect in nitric oxide–mediated smooth-muscle relaxation may account for some of the characteristic clinical features of Hirschsprung disease.

The transition zone between the normal, proximal bowel and the aganglionic distal bowel is distinguished grossly by distention of the proximal bowel with histologic evidence of muscular hypertrophy. The transition zone often becomes evident to direct inspection or on contrast enema during the first few weeks of life as functional obstruction leads to progressive proximal dilatation. On gross inspection, the transition zone may appear as a short funnel or cone-shaped colonic segment. The discrepancy in bowel lumen diameter is somewhat age dependent and may be subtle in a newborn or in a child with total colonic aganglionosis. Therefore, it may be difficult for the surgeon or the radiologist to define the exact transition zone site based on gross inspection or contrast enema. Gross examination alone is not sufficient for surgical decision making, and histologic confirmation of the level of ganglion cell transition is required. Given the continuous nature of

aganglionosis, a rectal biopsy performed 1.5 to 2 cm above the dentate line demonstrating ganglion cells effectively excludes Hirschsprung disease.

Neuronal intestinal dysplasia is a clinically described entity similar to or associated with Hirschsprung disease.[116,117] Despite the presence of ganglion cells, dysplastic changes in the myenteric nervous system affect bowel motility in similar fashion to aganglionosis. Clinical presentation and treatment are similar to those of classic Hirschsprung disease. There is considerable controversy regarding neuronal intestinal dysplasia, but it is reasonable to suggest that this represents an entity within the spectrum of abnormalities found in the intestinal myenteric nervous system.

Pathophysiology

Normal intestinal motility depends on coordinated propagation of segmental contraction waves immediately preceded by relaxation of the enteric smooth muscle. Patients with Hirschsprung disease lack a functional myenteric nervous system in the aganglionic segment; therefore, both propulsion and reflexive relaxation are disordered or absent in the distal bowel. Loss of neuronal nitric oxide synthase activity appears to play an important role. The internal sphincter is aganglionic and lacks the normal reflexive relaxation following rectal distention. In fact, patients with Hirschsprung disease may exhibit a paradoxical increase in sphincter tone in response to rectal distention. The functional result is tonic contraction of the aganglionic segment of bowel with ineffective peristalsis. Clinically, this presents as incomplete, distal intestinal obstruction in the newborn or as chronic constipation in the older child or adult.

Hirschsprung disease has been associated with mutations in at least three specific genes: the *RET* protooncogene, the endothelin B receptor (*EDNRB*) gene,[118] and the endothelin 3 (*EDN3*) gene. In addition, several other candidate genes are under investigation. In mice, natural and in vitro induced mutations affecting the *RET, EDNRB,* and *EDN3* genes generate intestinal aganglionosis identical to Hirschsprung disease.[119,120] Although widely accepted, it is still unknown whether the primary event in aganglionosis is failure of neuroblast migration to the distal bowel. Alternatively, ineffective microenvironmental support of neuroblasts that have already migrated may fail to promote normal neuroblast development and survival.[121]

Clinical Features

Incidence and Associations

The incidence rate of Hirschsprung disease is estimated at 1 per 5,000 live births with a marked male-to-female (4:1) preponderance. Most cases are sporadic, but long-segment, total colonic aganglionosis and female gender are strongly associated with familial inheritance. Genetic chromosomal analysis suggests that multiple loci may be involved, including chromosomes 13q22, 21q22, and 10q, among others.[122] Familial Hirschsprung disease has been clearly associated with *RET* protooncogene mutations. From a clinical standpoint, mutations of the *RET* protooncogene are associated with disorders of neural crest development, namely, multiple endocrine neoplasia (MEN) types IIA and IIB as well as familial medullary thyroid carcinoma, and patients with familial Hirschsprung disease associated with RET mutation are at risk for the development of medullary thyroid carcinoma.[123] Congenital cardiac defects are present in 2% to 5% of patients with Hirschsprung disease. Other rare congenital anomalies have been reported, but a consistent and important association is a 5% to 15% incidence of trisomy 21.[111] Infants presenting with meconium plug syndrome should undergo rectal suction biopsy to exclude aganglionosis.

Presentation

Most infants with Hirschsprung disease fail to pass meconium within the first 24 to 48 hours of life. Nonspecific signs of neonatal intestinal obstruction (feeding intolerance, abdominal distention, and bilious emesis) may develop. About half of the patients with Hirschsprung disease are diagnosed as neonates. Infrequently, older children or adults are diagnosed with aganglionosis during evaluation for chronic constipation. In this setting, symptoms may be minimal to disabling, and parents or patients often develop elaborate strategies to deal with chronic constipation. Abdominal distention is characteristic, and sometimes failure to thrive and malnutrition may occur. Digital rectal examination may demonstrate spasm, and, in the presence of enterocolitis, forceful expulsion of foul-smelling, liquid stool may occur.

Enterocolitis occurs in about 10% to 30% of infants and children with Hirschsprung disease and may be the presenting clinical manifestation. Enterocolitis associated with Hirschsprung disease has an unknown

pathophysiology, but obstructive stasis and bacterial overgrowth are thought to be important factors. *Clostridium difficile* and rotavirus have been implicated as important pathogenic organisms; diagnostic and treatment plans should consider these possibilities. The early presenting symptoms and signs of enterocolitis include fever, abdominal distention, and diarrhea, which may be explosive, foul smelling, and bloody. Systemic sepsis, transmural intestinal necrosis, and perforation are all possible later findings. The clinical progression can be rapid, with death occurring in as few as 12 to 24 hours if treatment is not initiated. Infants are particularly vulnerable to this complication and enterocolitis accounts for virtually all mortality directly related to Hirschsprung disease in modern pediatric surgical practice. Infants with known Hirschsprung disease and suspected enterocolitis should be treated aggressively. Initial treatment includes resuscitation, broad-spectrum antibiotics, cessation of feeding, and rectal irrigation. If the enterocolitis does not respond promptly, emergent intestinal decompression with an enterostomy proximal to the transition zone is indicated.

Diagnosis

A high index of suspicion for Hirschsprung disease should be maintained for any newborn infant with abdominal distention failing to pass meconium in 24 to 48 hours. The signs of neonatal intestinal obstruction should lead to a stereotypical workup. In the presence of characteristic findings on history, examination, or radiographic studies, any infant suspected of having Hirschsprung disease should undergo rectal biopsy.

Plain Abdominal Radiographs

Plain film radiographs of the neonate with Hirschsprung disease are nonspecific and typically demonstrate distended, air-filled loops of bowel throughout the abdomen. It is often difficult to discriminate between small intestine and large intestine on plain films at this age, but the pattern is consistent with distal intestinal obstruction. Older children or adults may have a stool-filled megacolon on plain radiographs. In the presence of enterocolitis, thickened, dilated intestinal loops and pneumatosis intestinalis may be present.

Contrast Enema

When distal neonatal intestinal obstruction is suspected on plain abdominal films, a contrast enema should be performed. With an experienced pediatric radiologist, findings consistent with Hirschsprung disease can be accurately detected in most instances. The classic radiographic finding in Hirschsprung disease is a transition zone (Fig. 101.29A). A definitive transition zone may not be apparent in a neonate because proximal dilatation takes some time to develop. In addition, infants with short-segment disease or total colonic aganglionosis may not have obvious transition zones on contrast enema. In these instances, a lateral view of the rectum may show abnormal spasm (Fig. 101.29B). Contrast remaining in the rectum more than 24 hours following a study is suggestive of Hirschsprung disease.

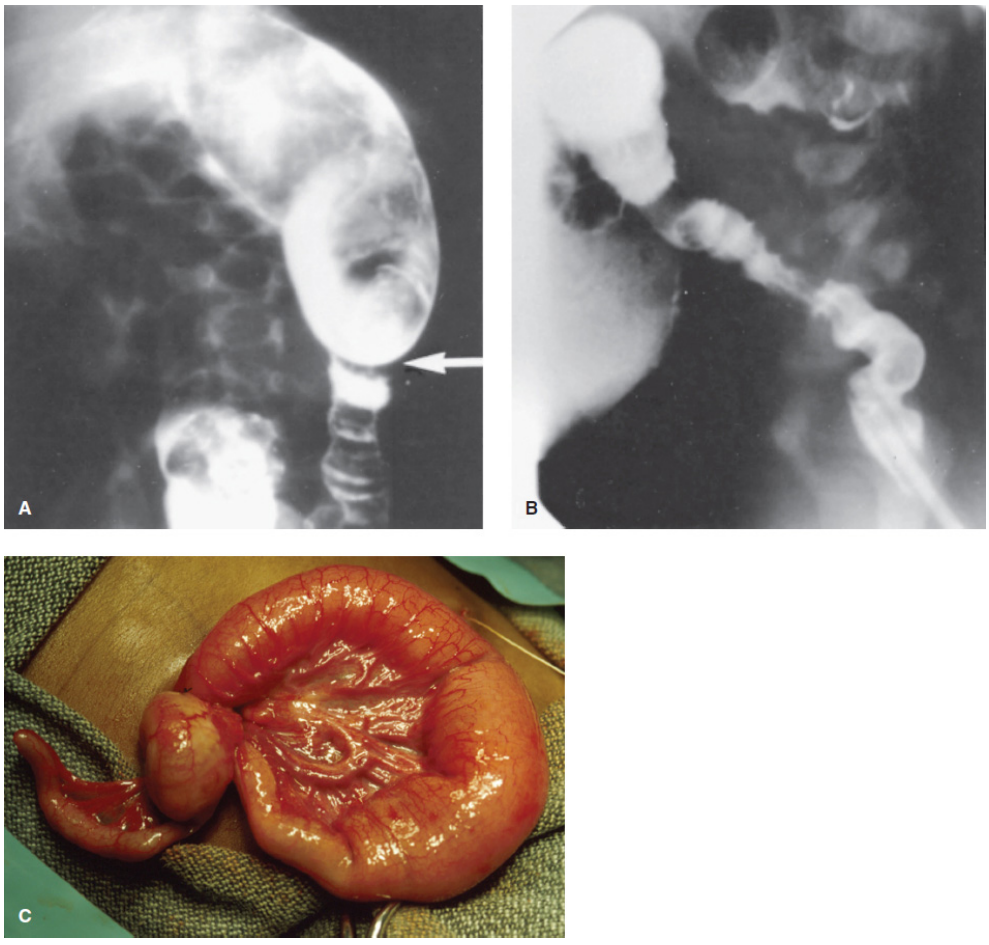

Figure 101.29 **A:** Contrast enema demonstrating a classic rectosigmoid transition zone (*arrow*) in Hirschsprung disease. **B:** Lateral view of rectum illustrates typical distal spasm of rectum. **C:** Operative photograph of rectosigmoid transition zone.

Rectal Biopsy

The diagnostic standard for aganglionosis is the rectal biopsy. Several commercially available instruments capable of performing rectal suction biopsies are in widespread use. The rectal suction biopsy can be performed at bedside or in clinic without anesthesia in all newborns and most children up to several months of age. The desire for early diagnosis and the technical simplicity of the procedure allow liberal use of this technique. When applied liberally, the vast majority (85% to 90%) of infants undergoing this procedure have normal ganglion cells on biopsy, effectively excluding Hirschsprung disease. Using the rectal suction biopsy technique, a biopsy of the mucosa and the submucosa is obtained. This is sufficient to establish the diagnosis because ganglion cells are absent from all intramural plexuses in Hirschsprung disease. The biopsy must be taken 1 to 1.5 cm proximal to the dentate line. Complications of infection, perforation, and bleeding with rectal suction biopsy are infrequent. Full-thickness rectal biopsy under general anesthesia is reserved for older children and in infants in whom suction biopsy is inadequate. An experienced pediatric pathologist must read the biopsies for maximal diagnostic accuracy. Evaluation for ganglion cells and the axons of the myenteric neurons is performed (Fig. 101.30), which may be accomplished using conventional hematoxylin-eosin staining or histochemical staining for acetylcholinesterase and calretinin. Similar histochemical staining for nitric oxide synthase can be performed. These adjunctive techniques are used routinely in some centers and can help provide additional evidence of Hirschsprung disease rather than simply demonstrating aganglionosis in the biopsy specimen. Diagnostic accuracy for Hirschsprung disease is excellent with a correctly obtained rectal suction biopsy and an experienced pediatric pathologist.[124,125]

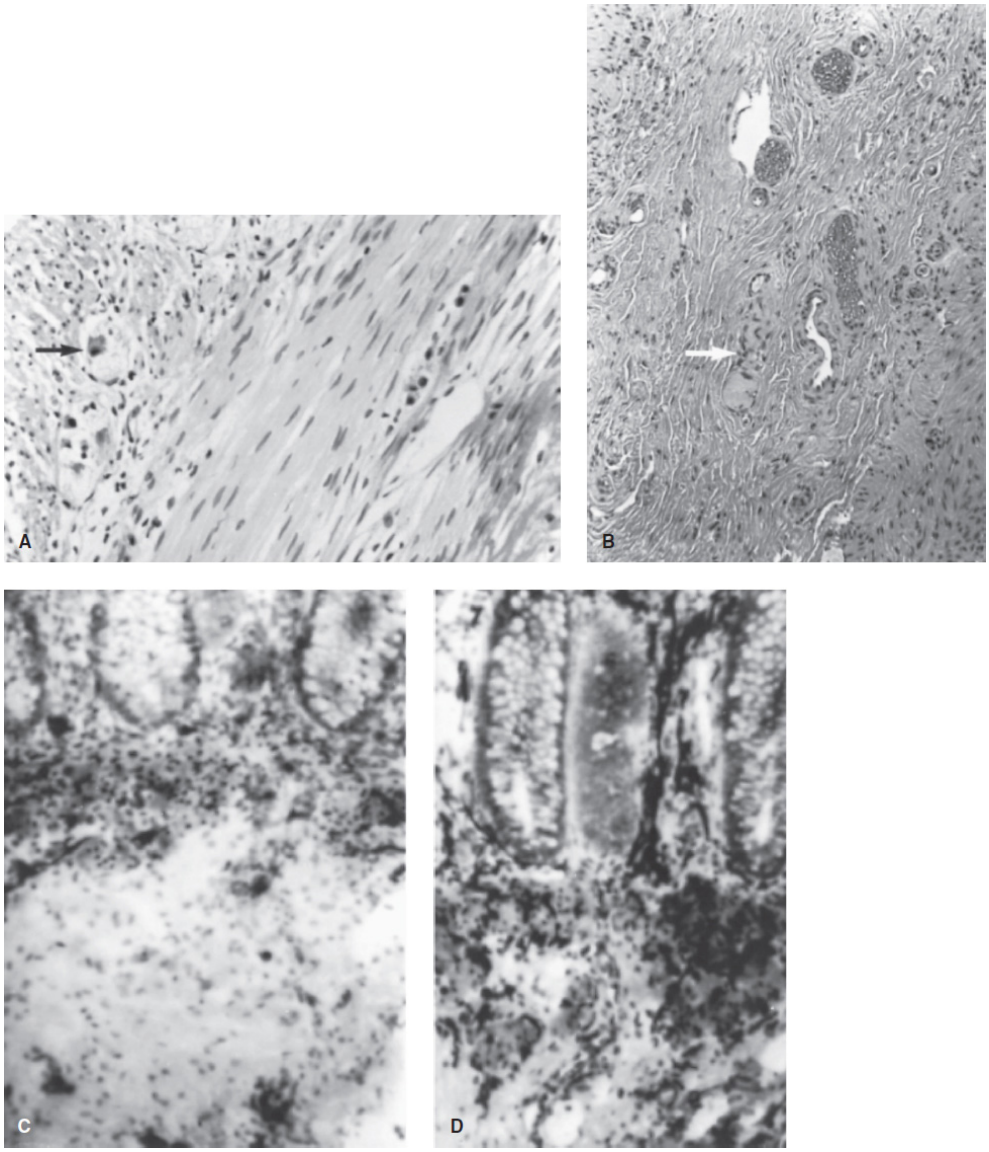

Figure 101.30 **A:** Normal rectal biopsy with ganglion cells indicated by *arrow* (hematoxylin-eosin). **B:** Rectal biopsy specimen with aganglionosis (hematoxylin-eosin). Note the characteristic thickened nerve fiber (*arrow*). **C:** Normal rectal biopsy using acetylcholinesterase histochemical staining. **D:** Similarly stained specimen from a patient with Hirschsprung disease. Many thickened submucosal nerve fibers stain densely black.

Anorectal Manometry

The absence of sphincter relaxation in response to rectal dilatation is consistent with Hirschsprung disease. Because of the relative ease and accuracy of rectal suction biopsy, anorectal manometry is not widely used in the United States for the primary diagnosis of Hirschsprung disease in infancy; however, this is used in some centers around the world and, when

applied carefully with an appropriate transduction probe, accurate manometric diagnosis is achievable in 85% to 90% of cases.

Treatment

Diverting colostomy should be considered for a newborn infant with Hirschsprung disease who has enterocolitis or multiple associated medical problems or anomalies. In the presence of enterocolitis, rectal irrigation and decompression can be an effective temporizing measure while resuscitation and broad-spectrum antibiotics are being instituted. Prompt proximal diversion will be required once the patient has stabilized. In the neonate, one approach following diagnosis is to perform proximal diversion by means of a colostomy (or enterostomy) placed in normal, ganglionated intestine. The diverting colostomy must be proximal to the histologic transition zone, and a series of biopsies examined by frozen section may be necessary to find the correct level for diversion. For classic rectosigmoid disease, a leveling colostomy is placed just proximal to the transition zone. This approach is generally done in two stages, with takedown of the stoma and definitive pull-through operation performed together weeks to months later, typically when the infant reaches 9 to 12 months of age. In older children, definitive pull-through is deferred until the colon has decompressed to relatively normal caliber.

For many infants and children without enterocolitis, a single-stage approach that eliminates the diverting colostomy has been advocated.[126,127] Despite a number of different operative techniques in performing a single-stage pull-through, results and outcomes appear nearly equivalent. Definitive repair of Hirschsprung disease with a single operation is desirable from technical and economical standpoint and essentially eliminates the complications associated with neonatal stomas. As with most aspects of pediatric surgery, an increasing experience with laparoscopically assisted, single-stage pull-through operations has been reported.[128] The contemporary, laparoscopic single-stage approach in the management of Hirschsprung disease has gained wide acceptance in the pediatric surgical community and is considered by many surgeons as the current standard of care for most infants and children.

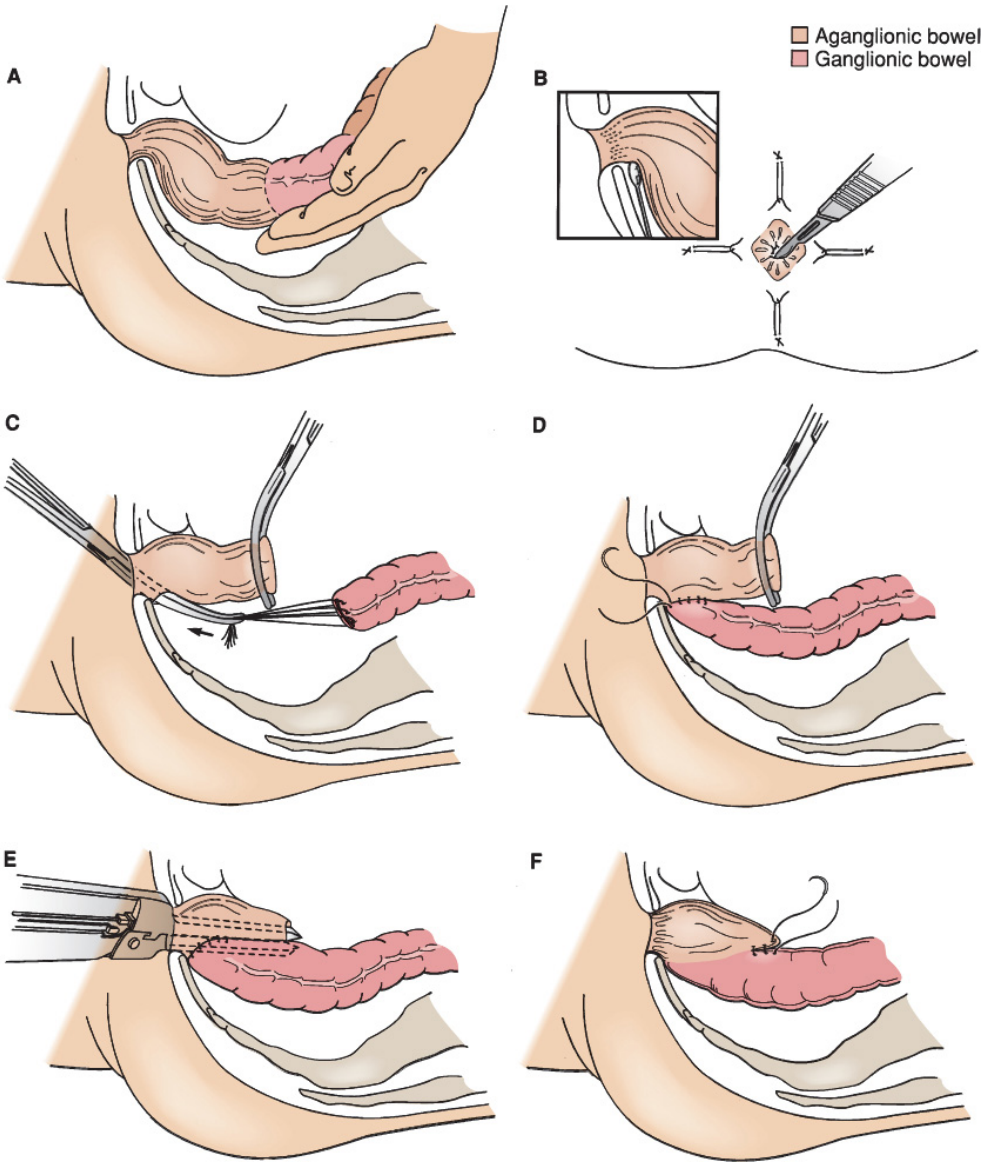

Figure 101.31 Duhamel procedure (Martin modification). **A:** Blunt retrorectal dissection. **B:** Incision in the posterior wall of the aganglionic rectum. **C:** Retrorectal pull-through after resection of the proximal aganglionic segment. **D:** End-to-side colorectal anastomosis preserving aganglionic rectum (as originally described). **E:** Stapled conversion of anastomosis into an extended side-to-side colorectal anastomosis (Martin modification). **F:** Completed procedure.

Definitive Operations for Hirschsprung Disease

The major goal of operative therapy in the treatment of Hirschsprung disease is to provide resection or bypass of the distal aganglionic rectum with the performance of a low rectal anastomosis with normally innervated proximal intestine. Numerous definitive procedures were designed to treat

Hirschsprung disease, and a brief description of the principal procedures in use follows. In general, the selection of a procedure depends on a surgeon's individual training and preference rather than compelling differences in outcome.[129,130]

Duhamel Procedure (Martin Modification)

The key elements of the Duhamel procedure are illustrated in Figure 101.31. After minimal pelvic dissection, resection of the aganglionic colon is performed. The aganglionic rectum is left in situ. Normal proximal colon is brought caudad into the retrorectal space, and a colorectal anastomosis is performed 1 cm above the dentate line. The original operation left the defunctionalized rectal pouch as shown, which proved problematic. The procedure has been modified by Martin to include a longer side-to-side colorectal anastomosis. Advantages of this procedure include its relative technical ease and limited pelvic dissection. Adoption of the stapled anastomosis has simplified this procedure significantly.

Soave Procedure

The Soave procedure is illustrated in Figure 101.32. Following resection of aganglionic colon, an endorectal dissection in the submucosal plane is performed from proximal rectum to anus. The endorectal dissection is started in the extraperitoneal rectum. This dissection is typically much easier than similar dissection for ulcerative colitis given the lack of mucosal inflammation. The dissected rectal mucosal tube is everted through the anus, excised, and normal proximal bowel is pulled through the rectal muscular cuff. The original operation did not suture the pull-through segment of proximal bowel to the rectum. A formal sutured colorectal anastomosis is now universally performed. Care must be taken to ensure that the pull-through segment is not obstructed by the muscular cuff.

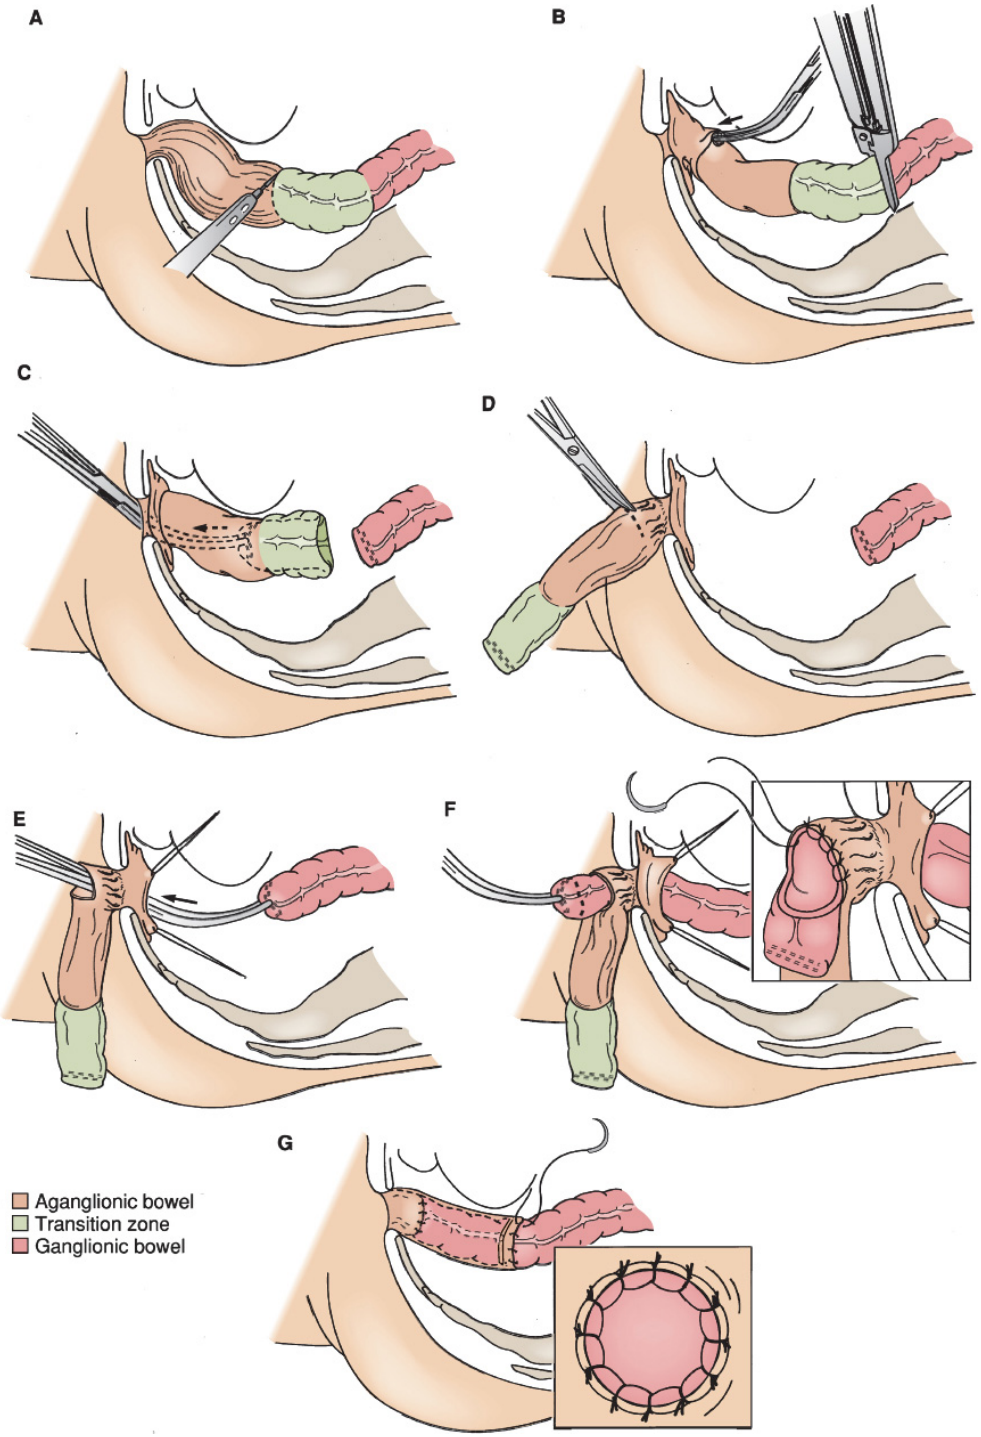

Figure 101.32 Soave endorectal procedure. **A:** Endorectal dissection initiated. **B:** Endorectal dissection complete. **C:** Eversion of the aganglionic segment and rectal mucosal tube. **D:** Incision of everted rectal tube. **E:** Endorectal pull-through. **F:** Colorectal anastomosis. **G:** Completed procedure.

Swenson Procedure

The Swenson procedure is the original definitive procedure for the treatment of Hirschsprung disease. Long-term outcome in children who undergo a properly performed Swenson procedure is equivalent to other procedures. The basic strategy is outlined in Figure 101.33. The aganglionic segment of colon is resected and a careful, nearly complete extramural dissection of the distal rectum is performed. Care must be taken to avoid inadvertent injury to the seminal vesicles, vas deferens, ureters, and pelvic splanchnic nerves. The dissected rectum is everted through the anus onto the perineum and excised.

Normal proximal bowel is pulled through and a colorectal anastomosis is performed.

Laparoscopically Assisted Endorectal Pull-through

A multi-institutional clinical experience with a laparoscopically assisted endorectal pull-through technique for the treatment of Hirschsprung disease has been reported.[128] Potential advantages of this approach include excellent visibility of the distal rectum during dissection, early return of postoperative bowel function, and decreased length of hospital stay. The early results report outcomes similar to the other established procedures. The procedure is reviewed in Figure 101.34. Complete transanal excision of the distal aganglionic segment with primary coloanal anastomosis has also been performed for short-segment or typical rectosigmoid aganglionosis as well.

Rectal Myectomy

Resection of a longitudinal strip of the posterior rectal muscular wall has been used for definitive management of ultrashort-segment Hirschsprung disease. This procedure can be performed via transanal approach combined with submucosal dissection or by a posterior sagittal approach. Although controversial, the use of rectal myectomy as a definitive operation for Hirschsprung disease may be considered most useful in the selected older child identified with ultrashort-segment disease.[131]

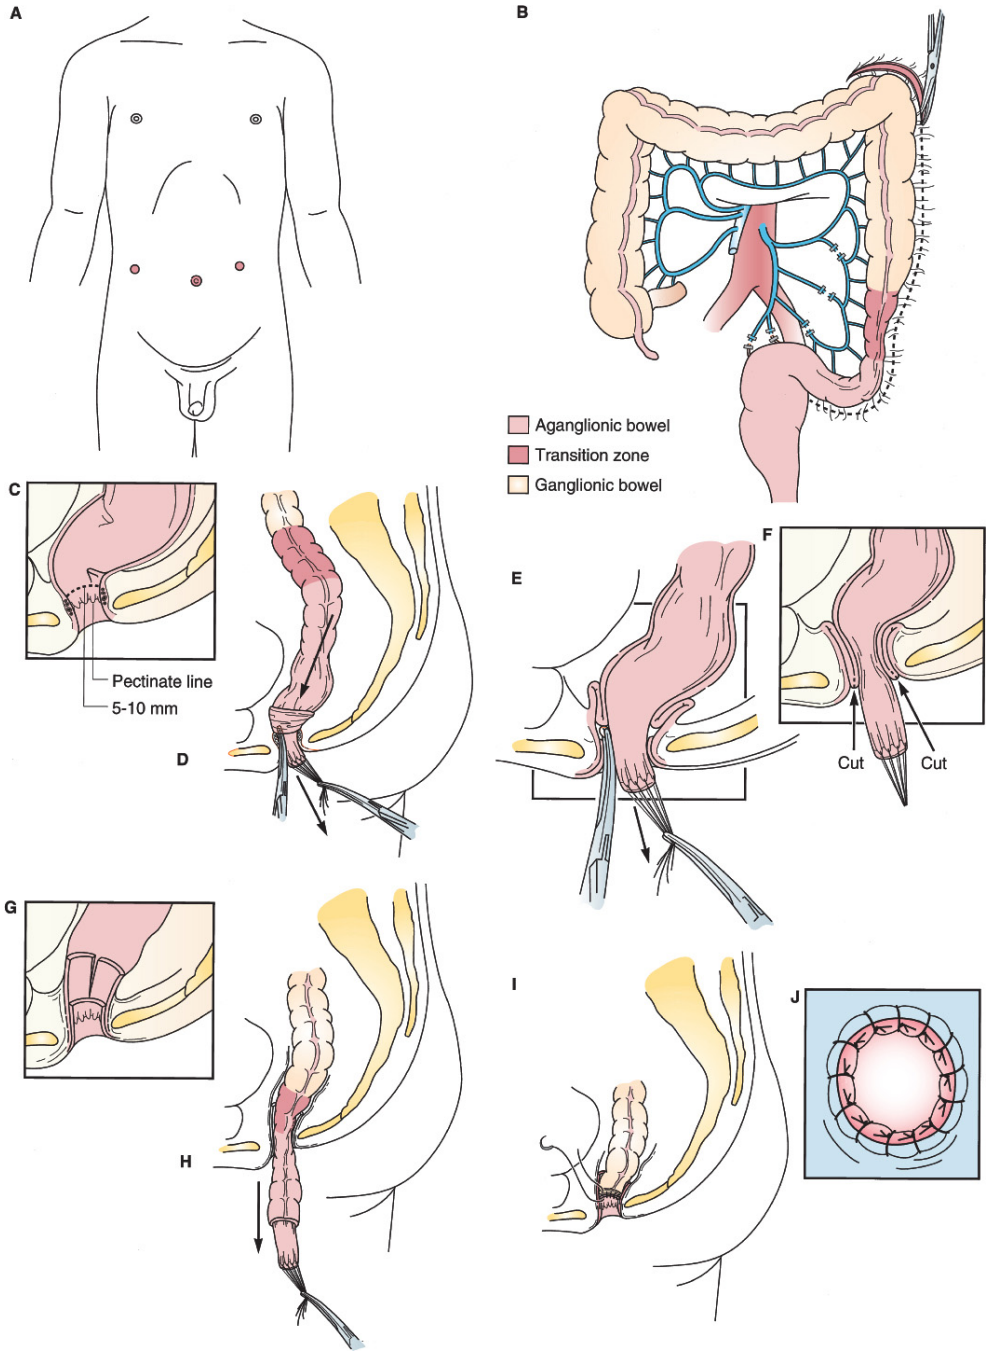

Figure 101.34 Laparoscopically assisted pull-through for Hirschsprung disease. **A:** Sites for operative trocar placement. **B:** Division of colon and rectal mesentery with mobilization of proximal colon. **C:** Circumferential incision in rectal mucosa 5- to 10-mm cephalad to the pectinate line. **D:** Mucosal traction sutures to facilitate further dissection from rectal muscular cuff. **E:** Transanal submucosal dissection is continued cephalad to meet the caudal extent of the transperitoneal rectal dissection. **F:** Circumferential incision of rectal muscular cuff. **G:** Rectal muscular cuff is split posteriorly to accommodate the pull-through segment (the pull-through segment is not shown here to clarify this maneuver). **H:** Rectum and sigmoid colon are pulled

through the rectal muscular cuff to the anastomotic site. **I:** Colon is transected at appropriate site with confirmation of ganglion cells by frozen section. **J:** Transanal, end-to-end single-layer colorectal anastomosis.

Total Colonic Aganglionosis

Total colonic aganglionosis is complex and, fortunately, relatively rare. Several different operative procedures have been described and treatment must be individualized. The endorectal pull-through with ileoanal anastomosis has been used with good success when most or all of the small bowel is normal. For extensive small bowel aganglionosis, an extended side-to-side anastomosis of normally innervated proximal small bowel to the aganglionic colon has been successfully performed. For complete intestinal aganglionosis, extended intestinal myectomy has been described.

Complications and Outcome

Complications resulting from definitive procedures for Hirschsprung disease include anastomotic leak, stricture, pelvic or rectal muscular cuff abscess, intestinal obstruction, and wound infection. These occur with a frequency of 1% to 10% with most experienced pediatric surgeons. Mortality from Hirschsprung disease is distinctly unusual unless enterocolitis is the presenting feature or associated medical problems or anomalies are present.

A unique complication following definitive repair of Hirschsprung disease is postoperative enterocolitis. The clinical presentation and pathogenesis have been discussed, and it remains an important and significant cause of morbidity. The incidence of postoperative enterocolitis ranges from 10% to 30% in most large series. Although rare, Hirschsprung enterocolitis can occur even in the presence of a diverting colostomy. Long-term outcomes appear quite good for all the procedures used, with 80% to 90% of patients maintaining good to excellent bowel function.

OTHER CHILDHOOD GASTROINTESTINAL DISORDERS

This review is limited to relatively common surgical conditions that are either congenital or unique in children. For other surgical conditions that can

affect both children and adults, the reader is referred to other chapters in this text.

Infantile Hypertrophic Pyloric Stenosis

Anatomy and Pathophysiology

The pathogenesis of infantile hypertrophic pyloric stenosis is unknown, but data suggest that local deficiency of neuronal nitric oxide synthase in the pylorus may be responsible for the clinical manifestations of the disease.[132,133] The deficiency of neuronal nitric oxide synthase leads to a lack of nitric oxide–mediated relaxation of smooth muscle and subsequent pyloric obstruction. Luminal narrowing occurs as a result of concentric hypertrophy of the pyloric smooth muscle. Clinically, this presents as progressive gastric outlet obstruction that becomes symptomatic by 2 to 4 weeks of age. The maximal narrowing and clinical symptoms of hypertrophic pyloric stenosis occurs between 4 and 8 weeks of age. The hypertrophic pyloric muscle ultimately undergoes gradual involution over a period of weeks to months.

Clinical Presentation

The reported incidence rate of hypertrophic pyloric stenosis is approximately 0.1% to 0.4% among white infants and is slightly lower in the black population. There is a distinct familial predisposition with an approximate 7% incidence rate in children of parents with a history of pyloric stenosis. The incidence rate is about four times higher in males than in females and is higher in first-born infants.[134] There is an apparent increased risk of hypertrophic pyloric stenosis in infants receiving oral erythromycin for pertussis prophylaxis.[135] Association of pyloric stenosis in infants treated for esophageal atresia and in infants with Smith–Lemli–Opitz syndrome has been reported.[136]

Infants with hypertrophic pyloric stenosis have a history of nonbilious, postprandial emesis that becomes progressively projectile. The infant otherwise appears well and will feed vigorously until late in the clinical course. The typical age at diagnosis is between ages 2 and 12 weeks of age. A history of identified feeding intolerance and formula change is common.

The definitive clinical finding on examination is a palpable, hypertrophied pylorus in the right upper quadrant to midepigastric region, often described as a firm, mobile "olive" on examination. This is a pathognomonic finding, and in the correct clinical setting, no further diagnostic imaging studies are required. An experienced clinician should be able to palpate a hypertrophied pylorus in nearly all cases. A successful physical examination requires an empty stomach, a quiet infant, and patience; repeated examinations may be necessary. Inability to palpate the pyloric mass in a quiet or anesthetized infant should place the diagnosis of hypertrophic pyloric stenosis in question. Other physical findings include visible or palpable gastric peristaltic waves, which can also be seen with any cause of gastric or duodenal obstruction.

Late findings with advanced symptoms include dehydration and a hypochloremic, hypokalemic metabolic alkalosis from gastric fluid losses. Profound metabolic alkalosis is less common in current practice but occasionally can be encountered in an extremely dehydrated infant with a long-standing history of emesis. The intravascular volume depletion and chloride-responsive alkalosis must be corrected prior to operative repair. The serum chloride should be restored to at least 90 to 95 mEq/L, and the measured CO_2 should be less than 30 mEq/L prior to induction of general anesthesia.

Diagnosis

If the examination is equivocal, either an upper gastrointestinal contrast series or a pyloric ultrasound examination can be performed. Both examinations are highly accurate and have sensitivity and specificity exceeding 95% in experienced hands. A typical contrast study demonstrating a narrowed, elongated pyloric channel is shown in Figure 101.35. Contrast studies have the advantage of evaluating other causes of symptomatic emesis, including gastroesophageal reflux disease, malrotation, and antroduodenal webs. The disadvantage of this approach is the presence of contrast in a poorly emptying stomach. Ultrasound examination of the pylorus is a preferred diagnostic test in most pediatric institutions. Ultrasound criteria for hypertrophic pyloric stenosis include a pyloric muscle thickness of 4 mm or greater and a pyloric channel length of 15 mm or greater. In general, the diagnosis of hypertrophic

pyloric stenosis is being made at an earlier age compared with several decades ago.

Figure 101.35 Ultrasound image of pyloric stenosis in coronal plane with pylorus marked by measurement bars.

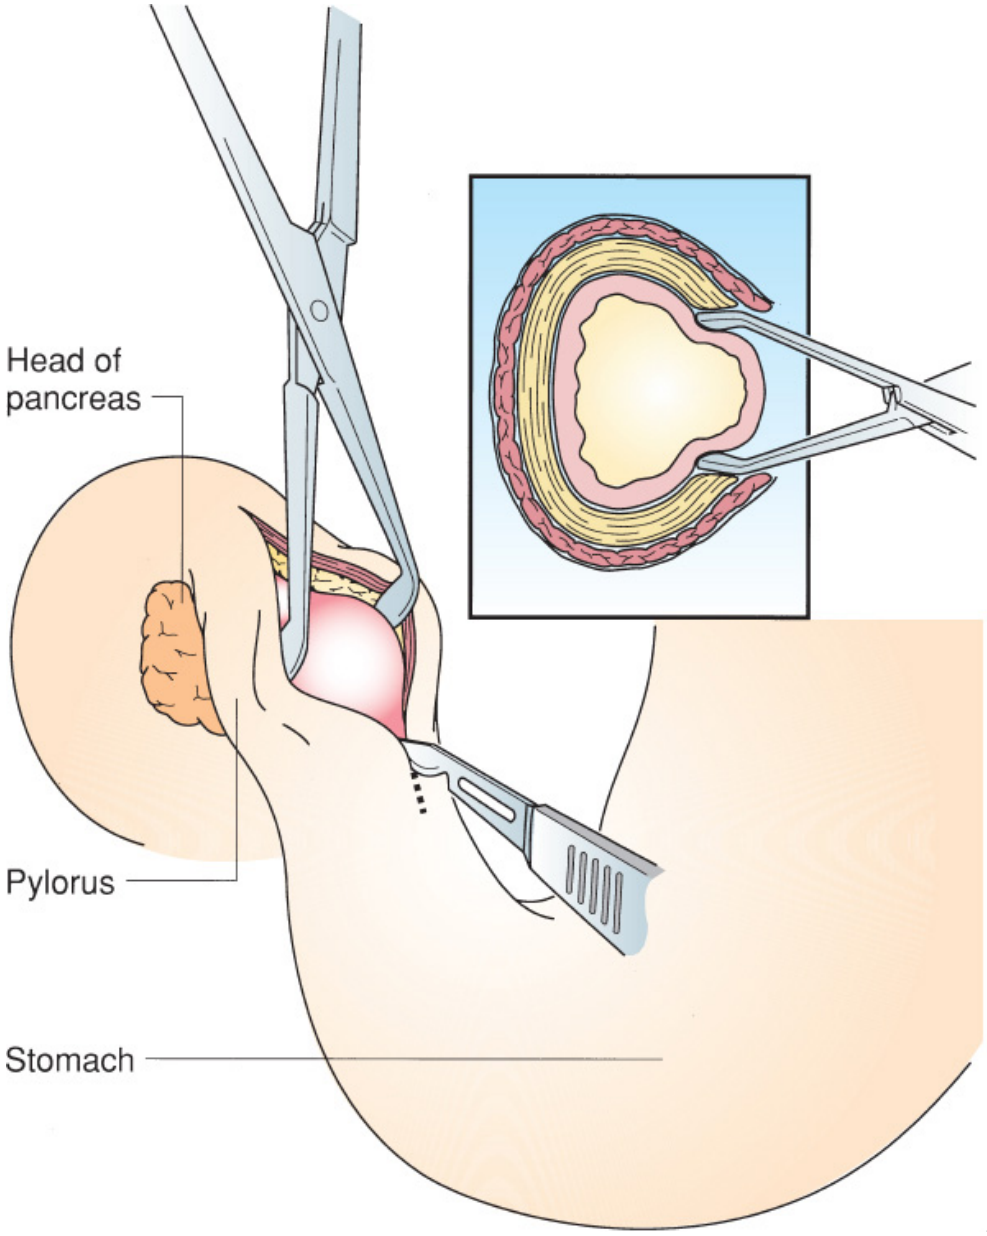

Figure 101.36 Ramstedt pyloromyotomy for infantile hypertrophic pyloric stenosis. The cross-sectional view shows herniation of the submucosa into the myotomy site, indicative of an adequate myotomy.

Treatment

Surgical pyloromyotomy has achieved universal acceptance because it offers definitive, rapid cure in virtually all infants, and morbidity rates have been negligible (Fig. 101.36). The operation is performed once the infant is rehydrated and the serum electrolytes are corrected. A single longitudinal incision is made in the hypertrophied pyloric muscle. The hypertrophied

circular pyloric muscle must be meticulously divided from the stomach to the junction of the proximal duodenum. An adequate pyloromyotomy is achieved when the submucosa bulges into the myotomy site and both edges of the divided pyloric muscle are freely mobile and can be accomplished via laparotomy or laparoscopy. Laparoscopic pyloromyotomy has been demonstrated to be efficacious and safe with similar operative times and outcome to the open repair; laparoscopic pyloromyotomy has become a standard approach at most children's hospitals.[137,138]

Postoperative feeding typically is started within 6 to 8 hours after recovery from anesthesia. Most infants are tolerant of enteral feeding and can be discharged home safely within 24 hours of operation. The surgical treatment of pyloric stenosis is straightforward, and the recovery is typically uncomplicated. A population-based study reviewing 1,777 infants with pyloric stenosis demonstrated a shorter length of stay and a lower overall complication rate in infants operated on by specialty-trained pediatric surgeons compared to general surgeons.[139] Mortality following pyloromyotomy is distinctly unusual in the absence of concomitant medical problems. Complications are rare and usually represent wound infection, technical failures related to an inadequate pyloromyotomy, or inadvertent entry into the duodenum or the stomach. Rarely, infants with inadequate pyloromyotomy may require reexploration and a second myotomy on the posterior pyloric wall. Inadvertent duodenotomy or gastrotomy must be recognized and repaired.

Intussusception

Anatomy and Physiology

6 *Intussusception* is defined as the invagination or telescoping of a proximal segment of intestine into an adjacent distal segment and is the most common cause of intestinal obstruction in infants and children aged 3 months to 3 years (Fig. 101.37). The invaginated proximal bowel is referred to as the *intussusceptum* and the recipient distal bowel is called the *intussuscipiens*. This process most commonly originates in the small intestine either at or near the ileocecal valve, with the terminal ileum passing into the cecum and colon (ileocolic intussusception). In the pediatric population, the vast majority

(95%) of cases are considered idiopathic because of a lack of an identifiable anatomic lesion causing the intussusception. Older children are more likely to have a pathologic lead point causing the intussusception. In similar fashion, infants and children with repeated episodes of intussusception have a greater probability of a pathologic lead point. Table 101.6 describes several factors that have been associated with the development of intussusception.

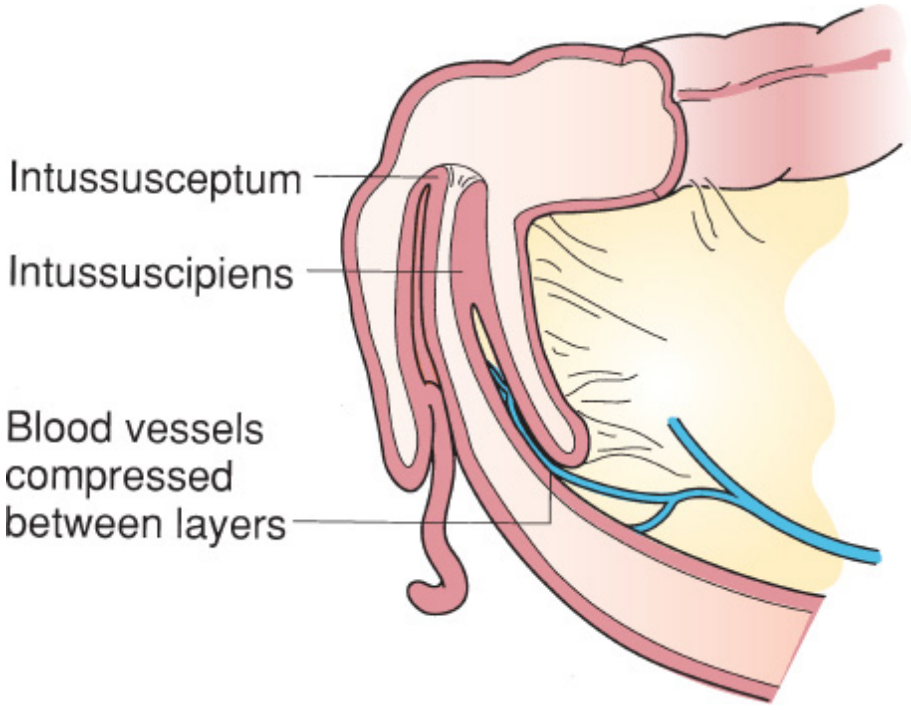

Figure 101.37 Ileocolic intussusception with the intussusceptum and intussuscipiens indicated.

Table 101.6 Predisposing Factors Leading to Intussusception
Anatomic Lead Points
Meckel diverticulum
Polyp
Lymphatic hypertrophy (Peyer patch)
Appendix
Duplication or enteric cyst
Lymphoma
Other neoplasm
Heterotopic pancreatic tissue
Associated Infections
Adenovirus
Rotavirus
Parasitic infestation
Other
Bleeding Disorders[a]
Henoch–Schönlein purpura
Hemophilia
Leukemia
Trauma
Blunt abdominal trauma
Major retroperitoneal dissections
Others
Cystic fibrosis

[a]These factors are more likely to be associated with small bowel-to-small bowel intussusception than with ileocolic intussusception.

Many cases of idiopathic intussusception in infants are probably caused by the normally prominent intramural lymph nodes (Peyer patches) in the terminal ileum acting as functional lead points. The anatomic consequence of intussusception is obstruction of the distal bowel. As bowel edema and inflammation progress, mesenteric vascular insufficiency from compression and congestion may occur. Incarceration, strangulation, and intestinal

perforation ultimately may result if this condition remains unrecognized or untreated.

Clinical Presentation

Intussusception is estimated to occur with an incidence rate of one to four cases per 1,000 children. There is a slight (3:2) male predominance; in a large retrospective series of children with intussusception, 79% were younger than 12 months, and seasonal variation in incidence was not observed.[140] An association between the development of intussusception and the administration of a previously available, tetravalent rhesus-based rotavirus vaccine (RotaShield, Wyeth Laboratories, Inc., Marietta, PA) was reported.[141] The currently available rotavirus vaccine does not appear to be associated with intussusception.[142]

Otherwise healthy infants who develop intussusception may have a characteristic clinical triad of abdominal pain, vomiting, and bloody stool. The typical infant develops the acute onset of severe, colicky abdominal pain. Intermittent episodes of irritability and crying may be associated with drawing the legs up to the abdomen. Between bouts of colic, the infant is often lethargic or sleepy. During periods of relative exhaustion, the abdominal examination may not be impressive; however, on careful physical examination, a palpable mass in the right abdomen may be appreciated in 80% to 90% of cases. Emesis is common and is often the presenting complaint. As intestinal obstruction progresses, intractable vomiting with abdominal distention and intravascular volume depletion may occur. Guaiac-positive stool is present in 90% to 95% of infants as a result of the ischemic mucosal injury to the intussusceptum. The passage of bloody stool mixed with mucus, classically described as *currant-jelly stool,* may be observed.

Diagnosis

Plain radiographs of the abdomen are generally nonspecific and may show a paucity of gas in the right lower quadrant with a mass effect in the ascending colon. Late findings demonstrate mechanical small bowel obstruction with proximal distention, air–fluid levels, and a decrease or absence of gas distally. Ultrasound examination typically reveals a mass resembling a bull's eye or target sign, corresponding to the intussusceptum within the

intussuscipiens. The target sign of intussusception also may be demonstrated by CT. Both these latter modalities do not allow for potential therapeutic reduction and may be more useful in diagnosing suspected cases of proximal jejunoileal or enteroenteral intussusception. Diagnostic enema techniques using either air or contrast approach 100% accuracy with typical ileocolic intussusception (Fig. 101.38). An approach using hydrostatic or pneumatic enema allows therapeutic reduction of intussusception as well.

Figure 101.38 Contrast enema demonstrating classic ileocolic intussusception with the intussusceptum visible in the ascending colon (*arrows*).

Treatment

Any infant with suspected intussusception in the absence of peritonitis should undergo diagnostic hydrostatic or pneumatic enema. A high index of clinical suspicion and liberal application of this approach should be maintained. The incidence of normal contrast enema examinations in this setting may exceed

75% in most pediatric centers, and this is justified by the considerable risk inherent in a missed diagnosis. An experienced pediatric radiologist and surgical evaluation are essential. Intravenous access and resuscitation should occur before attempts are made at diagnostic or therapeutic enemas.

Successful hydrostatic or pneumatic reduction of ileocolic intussusception is achieved in 60% to 90% of infants in most pediatric centers in the United States. The ability to reduce intussusception using these techniques is time dependent and diminishes substantially after the duration of symptoms exceeds 24 hours. In this setting, a contrast enema is still diagnostic and potentially therapeutic if carefully performed.[143] With most experienced pediatric radiologists, the risk of perforation or reduction of a strangulated intussusceptum is low.

The technique of retrograde reduction of intussusception is straightforward. Contrast or air is introduced into the rectum by a balloon catheter, with the height of the hydrostatic column 1 m or less. Most centers use three attempts at reduction, with each attempt no longer than 3 minutes in duration. As long as progress is being made, however, attempts can be repeated until reduction is achieved. Successful reduction of ileocolic intussusception is demonstrated by observing retrograde flow of contrast or air into the terminal ileum. Inability to demonstrate retrograde flow into the ileum suggests incomplete reduction requiring surgical exploration.

Operative Management

Infants presenting with peritonitis and small bowel obstruction with a clinical diagnosis of intussusception should undergo immediate resuscitation and exploration without attempts at retrograde enema. Surgical exploration is also required after incomplete retrograde enema reduction of intussusception or in the relatively infrequent situation of bowel perforation during diagnostic or therapeutic enema. The operative strategy is dictated by the findings. Spontaneous reduction of the intussusception is reported to occur in up to 20% to 30% of infants following induction of general anesthesia. In this situation, exploration confirming the reduction and examining the bowel for a pathologic lead point is sufficient. With persistent intussusception and viable bowel, the bowel is manually reduced, generally pushing the intussusceptum out of the distal bowel. If manual reduction cannot be performed or the intussusceptum is strangulated, then segmental resection with primary

anastomosis is performed. Attempts at reducing intussusception with clearly necrotic bowel should be avoided. Diverting enterostomy as a result of peritoneal contamination usually is not required. Appendectomy is routinely performed in all infants undergoing operative exploration for intussusception. A successful laparoscopic approach to the diagnosis and management of intussusception has been reported in approximately two-thirds of selected patients.[144–146]

Complications and Outcome

Following successful enema reduction, the infant is given intravenous fluids and observed for tolerance of oral feeding is rapid. Recovery from operative reduction or bowel resection is generally no different than from other similar gastrointestinal procedures. Most infants enjoy a complete recovery with minimal or no morbidity. Recurrent intussusception after either nonoperative or operative reduction occurs in about 5% of infants and usually can be treated with repeat enema. Mortality from intussusception is rare and is almost always the result of systemic sepsis and shock from unrecognized, strangulated intestine.

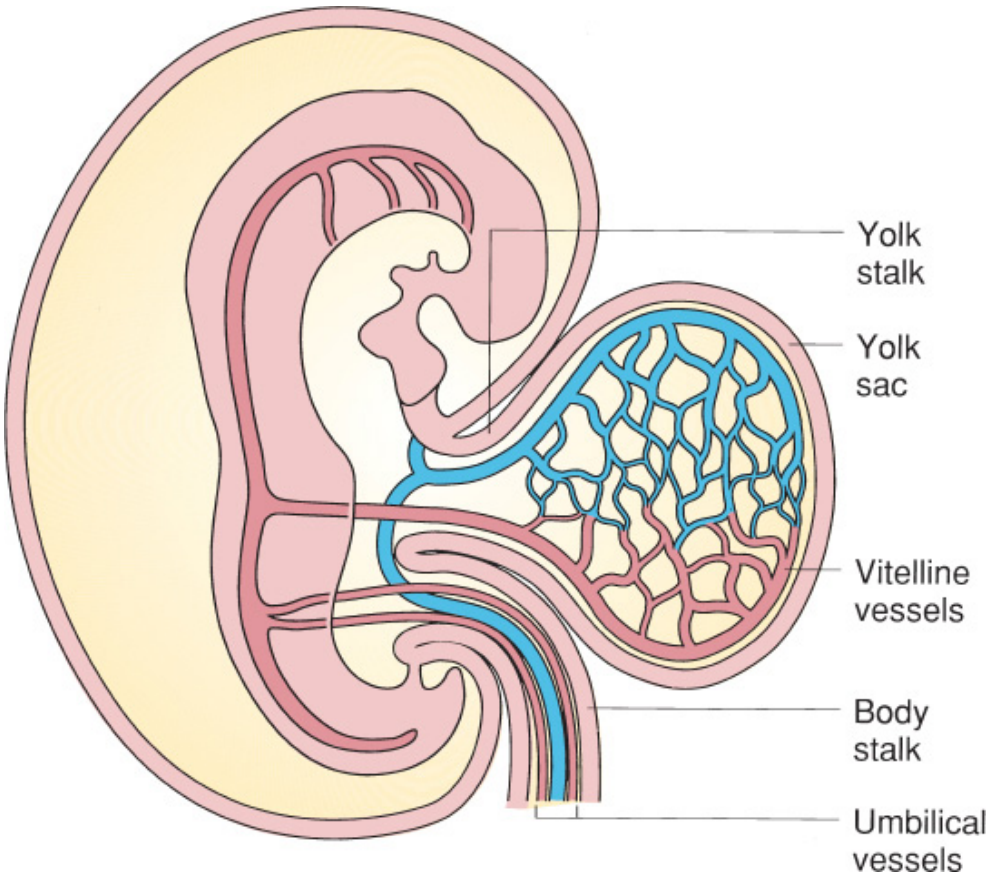

Figure 101.39 Normal embryonic relations of the yolk sac, yolk stalk, and developing gut.

Meckel Diverticulum and Related Disorders

Embryology and Anatomy

The most frequently encountered congenital anomaly of the gastrointestinal tract is Meckel diverticulum, representing one of several malformations resulting from persistence of the yolk stalk (synonymous with *vitelline duct* and *omphalomesenteric duct*) and its components. The embryonic yolk stalk connects the yolk sac and the developing midgut (Fig. 101.39). Between weeks 5 and 7 of gestation, the yolk sac involutes and the stalk fuses with the umbilical cord. Developmental failure or arrest of yolk sac involution creates a spectrum of clinical malformations as outlined in Figure 101.40, with Meckel diverticula constituting greater than 95% of these anomalies. Meckel diverticulum is a true diverticulum of variable size derived from the intestinal remnant of the yolk stalk. Typically, it is found on the antimesenteric border

of the terminal ileum approximately 40 to 50 cm from the ileocecal valve in adults. The blood supply is derived from persistent vitelline vessels supplied from the SMA. About 25% of the diverticula have a fibrous or vascular attachment to the anterior abdominal wall at the umbilicus (Fig. 101.40C). Heterotopic gastric mucosa or pancreatic tissue is found in about half of the diverticula examined at autopsy. In about 75% of patients with symptomatic diverticula, gastric mucosa is present. When symptoms occur, bleeding or perforation is generally the result of peptic ulceration of the adjacent ileal mucosa and not from the diverticulum itself.

Clinical Presentation

Symptomatic yolk stalk anomalies are usually diagnosed by history and clinical examination. Umbilical drainage from a persistent fistula or sinus tract may be noted in a newborn following separation of the umbilical cord. Intestinal prolapse or passage of stool from the umbilicus signifies a patent omphalomesenteric duct. Small bowel obstruction in an otherwise healthy infant without a history of laparotomy may be a result of volvulus around an omphalomesenteric band or intussusception from a Meckel diverticulum acting as a lead point.

The incidence rate of Meckel diverticula in the general population is about 2%, with a 2:1 male-to-female predominance. The risk of developing symptoms from the diverticulum decreases with age, and the vast majority of subjects remain asymptomatic. About half of the persons who do become symptomatic are younger than 2 years. Table 101.7 outlines several of the more common clinical presentations of symptomatic Meckel diverticulum.

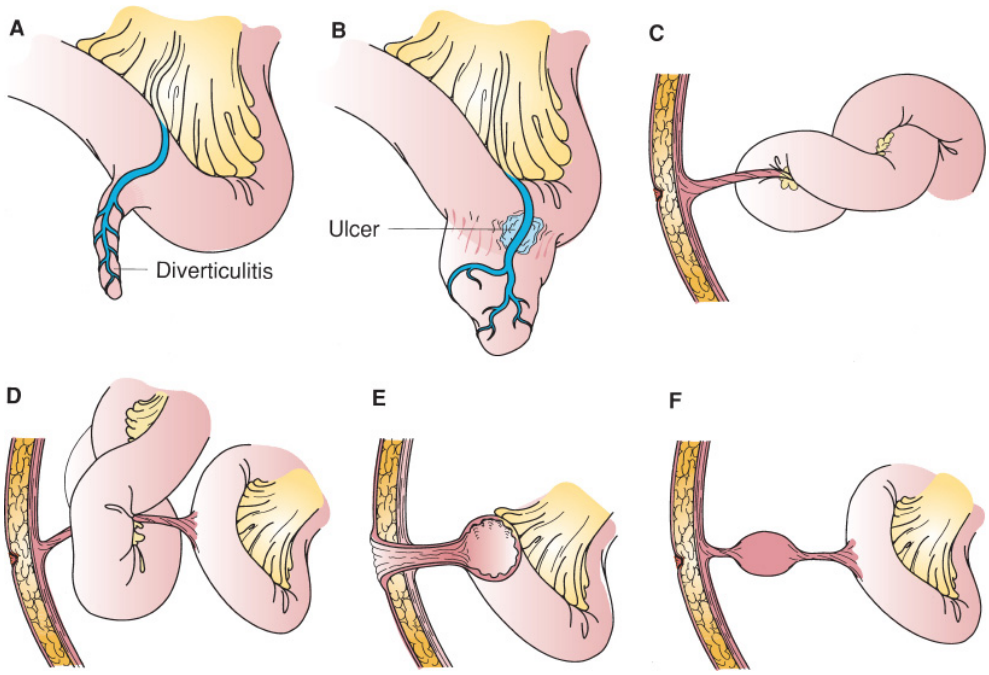

Figure 101.40 Common variants of yolk stalk malformations. **A, B:** Meckel diverticulum can manifest with inflammation (diverticulitis) or hemorrhage from acid-induced ulceration. **C, D:** Meckel diverticulum in association with abnormal band attached to the abdominal wall predisposing to volvulus and intestinal obstruction. **E:** Patent omphalomesenteric duct. **F:** Omphalomesenteric sinus and cyst formation.

Hemorrhage

Gastrointestinal bleeding related to Meckel diverticulum generally results from peptic ulceration of the adjacent ileal mucosa. Clinically, it manifests as painless, episodic hemorrhage that is typically bright red to maroon in color; melena is not characteristically seen. Bleeding from Meckel diverticulum is generally not hemodynamically significant or exsanguinating, but it can be persistent enough to require transfusion. The diagnostic test of choice is the ^{99m}Tc-pertechnetate radioisotope scan (Meckel scan) because of the high affinity of the isotope for gastric mucosa and the high probability of gastric mucosa within a symptomatic Meckel diverticulum. Diagnostic accuracy is reported to be as high as 90% for Meckel-related bleeding. Contrast studies and endoscopy have a limited role when the problem is hemorrhage from a Meckel diverticulum.

Obstruction

Intestinal obstruction associated with omphalomesenteric duct anomalies usually results from either intussusception or volvulus around an abnormal attachment between the bowel and the abdominal wall. In about 5% to 10% of persons with symptomatic Meckel diverticula, intussusception is the initial symptom. In patients with Meckel diverticula whose initial symptom is small bowel obstruction, about half have intussusception, and the remainder have volvulus, internal hernias, or other mechanical causes. Intussusception secondary to a Meckel diverticula has a decreased likelihood for successful enema reduction. Small bowel obstruction from volvulus around an omphalomesenteric band requires operative exploration and treatment.

DIAGNOSIS

Table 101.7 Signs and Symptoms of Meckel Diverticulum

Clinical Presentation	Approximate Frequency (%)
Hemorrhage	30–35
Small bowel obstruction	30–35
Diverticulitis	20–25
Umbilical fistula	10
Other	Uncommon

Diverticulitis

About one-third of patients with symptomatic Meckel diverticulum have acute diverticulitis. Similar to appendicitis, intraluminal obstruction at the base of a Meckel diverticulum can lead to distal inflammation, gangrene, and subsequent perforation. Peptic ulceration also can lead to local inflammation and perforation with the development of peritonitis. The signs and symptoms of Meckel diverticulitis are virtually indistinguishable from appendicitis, and exploration is both diagnostic and therapeutic.

Umbilical Anomalies

About 10% of patients with yolk stalk or persistent omphalomesenteric duct anomalies have umbilical problems. The usual clinical presentation is persistent drainage or intestinal mucosa found at the umbilicus. The diagnosis can be confirmed by contrast sonogram of the umbilical orifice or tract. Occasionally, ultrasound examination may be useful to demonstrate omphalomesenteric cysts. Ultimately, surgical exploration may be required for both diagnosis and treatment.

Meckel Diverticulum as an Incidental Finding

The management of an incidentally discovered Meckel diverticulum during abdominal exploration for other reasons is controversial. The risk of resecting an asymptomatic diverticulum must be weighed against the reasons for the operative exploration, patient age, and the potential for future symptoms from the diverticulum. Infants younger than 2 years are at greater probability of becoming symptomatic from Meckel diverticula. Resection is clearly indicated with demonstration of heterotopic gastric mucosa in the diverticulum to prevent peptic ulceration. This finding may occasionally be determined by direct palpation because the gastric mucosa is thicker than ileal mucosa. Abnormal omphalomesenteric bands to the abdominal wall should also be excised. If clinical judgment suggests that the diverticulum is at risk for luminal obstruction, resection is warranted.

Treatment

Infants and children with symptomatic umbilical abnormalities from yolk stalk remnants are usually well, and umbilical exploration with possible laparotomy can be undertaken electively. The yolk stalk remnant is excised, and, if present, the communication with the ileum is closed primarily with minimal morbidity and mortality. Operative exploration is required for patients with symptomatic Meckel diverticula. Typically, exploration can be accomplished through a variety of incisions. The treatment of choice is resection through either antimesenteric wedge excision or segmental bowel resection with primary closure or anastomosis. Laparoscopic diagnosis and management of Meckel diverticulum has also been described.[147] In the absence of associated medical problems, excellent functional outcome is expected with minimal morbidity and essentially no mortality unless intestinal necrosis has occurred.

Foreign Bodies

Ingestion of foreign bodies by infants and children is common. Toddlers in the age range of 9 months to 2 years are at particular risk given newly acquired mobility and the tendency for oral exploration. The type of foreign body and the location in the gastrointestinal tract on discovery dictate overall management.

Esophagus

In normal children, ingested coins and small toys can become impacted at predictably narrow portions of the esophagus, including the cricopharyngeus, the esophagus at the level of the left mainstem bronchus, and the gastroesophageal junction. Previous areas of esophageal repair or injury predispose to points of obstruction. In particular, infants and children with repaired esophageal atresia, gastroesophageal reflux, or caustic esophageal injury are at risk for impaction at these sites.

Esophageal foreign bodies produce clinical symptoms of drooling, feeding intolerance (particularly to solids), dysphagia, and pain. Unrecognized foreign bodies with unusual configuration or sharp points and edges may cause esophageal perforation and mediastinitis. The diagnosis is straightforward on plain radiographs if the object is metallic or radiopaque. If a radiolucent object is suspected, an upper gastrointestinal contrast study is usually required to confirm the diagnosis. Lateral plain films of the neck or chest may be useful to differentiate between small foreign bodies in the esophagus or the trachea.

Foreign bodies impacted in the esophagus cause partial esophageal obstruction and can cause complications including aspiration, erosion, perforation, and late stricture formation. Therefore, all esophageal foreign bodies should be removed. Extraction of foreign objects can be accomplished by using balloon catheter retrieval under fluoroscopic guidance or direct visualization using endoscopy. Performed within 24 hours of ingestion, balloon catheter retrieval of esophageal foreign bodies is relatively straightforward. This technique is limited to smooth radiopaque objects such as coins to minimize the risk of esophageal perforation. The most significant risk with balloon catheter retrieval is potential aspiration from an unprotected airway, and this must be anticipated as the foreign body traverses the pharynx.

Alternatively, for esophageal coin impaction of less than 24 hours' duration in children without a history of esophageal surgery or injury, esophageal bougienage with clearance of the coin into the stomach has been successful.[148]

Retrieval of esophageal foreign bodies under direct endoscopic vision requires general anesthesia. Either flexible or rigid endoscopy systems are widely available and used with individual and institutional preferences. Esophageal perforation, the major risk, occurs in fewer than 5% of cases in most reported series. Long-standing esophageal foreign bodies may erode into the aorta and cause life-threatening hemorrhage from aortoesophageal fistula.[149]

Distal Gastrointestinal Tract

More than 95% of foreign bodies that pass beyond the gastroesophageal junction proceed uneventfully through the gastrointestinal tract. The transit time for an asymptomatic foreign body is highly variable and can take hours to weeks. Progress of an asymptomatic radiopaque foreign body can be followed by abdominal plain films, but this is rarely useful from a clinical standpoint unless it is a battery. The stool may also be screened to confirm passage of a known foreign body.

Operative exploration or endoscopic retrieval of distal gastrointestinal foreign bodies is generally reserved for clinical symptoms related to either obstruction or intestinal injury heralded by abdominal pain, vomiting, fever, or peritonitis. In addition, persistence of an asymptomatic foreign body in the stomach for several weeks is a relative indication for upper endoscopic retrieval, particularly with foreign bodies with irregular shape, configuration, or sharpness. This is a clinical judgment that is best reserved for an experienced pediatric surgeon because remarkably complex and improbable objects may pass uneventfully through the gastrointestinal tract. For asymptomatic foreign bodies lodged distal to the stomach, a relative indication for operative removal is a fixed, persistent location in the intestine longer than 1 week in duration.

Ingested batteries, in particular alkaline disc batteries, are a potentially serious hazard to children and require a more aggressive approach. Disruption of the battery casing and spillage of the contents have been

reported to cause intestinal injury and perforation, presumably because of leakage of potassium or sodium hydroxide. Esophageal impaction of a battery warrants prompt removal when recognized because the risk of acquired esophageal injury, perforation, and development of traumatic tracheoesophageal fistula is present.[150] In the distal bowel, cathartics may be helpful to expedite passage of the battery. Operative removal may be necessary if the battery fails to progress distally over a few days or if symptoms related to the battery occur. Notably, the vast majority of batteries pass through the gastrointestinal tract uneventfully. Ingestion of multiple magnets can cause problems with small bowel obstruction or enteroenteric fistula formation.

Gastrointestinal Hemorrhage

The subject of gastrointestinal hemorrhage and general principles of management are discussed elsewhere in this book. The following section reviews some of the important and age-dependent clinical causes and unique issues of gastrointestinal bleeding in pediatric population. These causes are age dependent and are summarized in **Tables 101.8** and **101.9**.

Diagnostic workup of an infant or a child with gastrointestinal hemorrhage requires coordinated participation among pediatricians, surgeons, gastroenterologists, and radiologists. Several general principles governing the diagnostic approach to gastrointestinal bleeding in infants and children follow:

1. A clear diagnosis can be made in most situations; given the current technology available to assist with diagnosis, an aggressive approach is warranted. Diagnostic procedures such as flexible fiberoptic endoscopy, radioisotope imaging, and angiography are widely available, safe, and applicable to any age group, including the newborn. Despite these measures, in approximately 16% of cases, the cause of guaiac-positive stools in a neonate or infant remains unknown,[151] and the bleeding is self-limited.
2. The primary diagnostic investigation of choice for upper gastrointestinal bleeding is esophagogastroduodenoscopy. This procedure is optimally performed within the first 24 hours after cessation of active hemorrhage and usually requires general

anesthesia. Imaging studies for active upper gastrointestinal hemorrhage are limited in their ability to aid with diagnosis.

c. Infants and children presenting with minor lower gastrointestinal bleeding are best evaluated by a careful perineal and digital rectal examination, followed by anoscopy.

d. Massive lower gastrointestinal hemorrhage in an infant or a child outside the newborn period is most likely the result of a bleeding Meckel diverticulum.

e. If a definitive source for lower gastrointestinal hemorrhage is not found on colonoscopy, evaluation for an upper gastrointestinal source, including upper endoscopy and diagnostic laparoscopy, is warranted.

f. Pain is an uncommon symptom with pediatric gastrointestinal hemorrhage and implies a more complex problem such as volvulus, ischemic bowel, or inflammatory bowel disease. Painful gastrointestinal hemorrhage in pediatric patient requires urgent evaluation and prompt diagnostic workup.

g. In contrast to that in adults, gastrointestinal bleeding in children is rarely a symptom or sign of gastrointestinal neoplasm.

Table 101.8 Etiology and Causes of Upper Gastrointestinal Hemorrhage[a]

Patient Age Group	Common Causes	Less Common Causes
Neonatal (0–30 days)	Gastritis Esophagitis Ingested maternal blood Peptic ulcer	Iatrogenic trauma Primary coagulopathy Vascular malformation (hemangioma, telangiectasia, arteriovenous malformation) Nasal or pharyngeal bleeding Miscellaneous (leiomyoma, gastric polyp, duplication)
Infant (30 days to 1 year)	Gastritis Esophagitis Peptic ulcer	Same as less common neontal causes, plus: Drugs (steroids, nonsteroidal anti-inflammatory drugs) Foreign body, caustic ingestion Esophageal varices
Child (1–12 years)	Esophageal varices Esophagitis Peptic ulcer	Same as less common infantile causes, plus: Acquired thrombocytopenia (chemotherapy)
Older child (12 years to adult)	Esophageal varices Esophagitis Peptic ulcer	Same as less common childhood causes

Neonates (0 to 30 Days of Age)

The most common cause of gastrointestinal hemorrhage in a neonate is gastritis. Endoscopic evaluation of newborns with symptomatic upper gastrointestinal hemorrhage demonstrates gastritis or esophagitis in 50% to 75% of cases. About 10% to 15% have swallowed maternal blood during birth, and 10% of newborns are found to have an underlying coagulopathy. Anatomic lesions requiring operative control are distinctly unusual in this age group. Significant and sometimes massive upper gastrointestinal hemorrhage may occur in a neonate without a definable anatomic lesion despite endoscopic evaluation. This finding is usually the result of gastritis, and treatment is directed at blood and volume replacement and correction of any underlying coagulopathy.

Significant conditions responsible for lower gastrointestinal bleeding in the newborn include NEC, malrotation with volvulus, enterocolitis, or bowel obstruction secondary to an incarcerated inguinal hernia. These clinical entities present with characteristic histories, findings on clinical examination, and surgical treatment guidelines previously discussed. Anorectal fissure is also common and easy to diagnose in neonates, and bleeding is typically self-limited.

Infants (30 Days to 1 Year)

Infants with upper gastrointestinal bleeding deserve comprehensive evaluation, including endoscopy, to identify potential lesions requiring operative intervention. The most common causes of lower gastrointestinal hemorrhage in this age group include infectious diarrhea, intussusception, food allergy, and bleeding Meckel diverticulum. Most of these lesions have distinct symptoms, signs, and diagnostic findings to facilitate diagnosis. Infectious diarrhea is usually accompanied by fever, feeding intolerance, possibly emesis, and abdominal pain. Fecal leukocytes may be present on stool examination, and enteric pathogens or their toxins can be identified by stool culture.

Children (1 to 12 Years)

An important surgical cause of upper gastrointestinal bleeding in this age group includes esophageal variceal bleeding from portal hypertension. Children with biliary atresia or extrahepatic portal venous obstruction account for most cases of variceal bleeding in this age group. In the acute setting, endoscopic sclerotherapy or banding is used as a temporizing measure for hemorrhage control; some investigators advocate maintenance sclerotherapy. Ultimately, for these children, orthotopic liver transplantation may offer definitive surgical treatment. The use of operative portosystemic shunts for acute variceal hemorrhage is not widely used in pediatric surgical practice in the United States.

Conditions causing lower gastrointestinal bleeding in this age group include juvenile polyps. These are benign, hamartomatous polyps and represent the single most common cause of lower gastrointestinal bleeding in children. About 20% to 30% of the polyps are palpable on digital rectal examination. A history of painless, bright red blood per rectum during a bowel movement is typical. The bleeding results from mucosal irritation, involution, and sloughing of a pedunculated polyp and is usually not associated with hemodynamically significant hemorrhage. Tissue may be passed or the pedunculated polyp may prolapse out the anus. A hypochromic, microcytic anemia may be present. Diagnostic workup generally involves a contrast enema to identify the polyp and evaluate the colon for synchronous lesions. Colonoscopy may require general anesthesia in this age group, and endoscopic snare polypectomy is the treatment of choice for appropriate-

sized polyps. Infrequently, transanal excision or open resection of larger polyps is required. In the case of multiple juvenile polyps not amenable to endoscopic polypectomy, management may be expectant based on the benign natural history characterized by involution during adolescence. Histologic confirmation is necessary to differentiate these lesions from adenomatous polyps seen in familial polyposis syndromes or Gardner syndrome.

Older Children and Adolescents (Older than 12 Years)

Causes of both upper and lower gastrointestinal hemorrhage in this age group include most etiologic conditions found in adults. Importantly, inflammatory bowel disease is significant in this age group.

Intestinal Duplication

The embryologic origin of enteric duplication formation remains controversial, but duplication likely represents abnormal development of either a diverticulum or adjacent portion of the developing gut. In some cases, duplication cysts of the upper gastrointestinal tract may be associated with thoracic spinal cord or vertebral defects; this association appears to reflect abnormal sequestration and integration of developing primitive notochord elements in addition to duplication. The resulting lesions are described as either *cystic* or *tubular* based on their gross appearance (Fig. 101.41). All types of gastrointestinal-derived epithelia are found, but the clinically relevant finding is ectopic gastric mucosa. Duplications are commonly found along the mesenteric border of the native bowel. The muscular wall is typically well developed and intimately attached to the functional bowel. In addition, the blood supply is also shared with the functional intestine, an important surgical consideration.

Common blood supply
Cystic duplication of terminal ileum
B

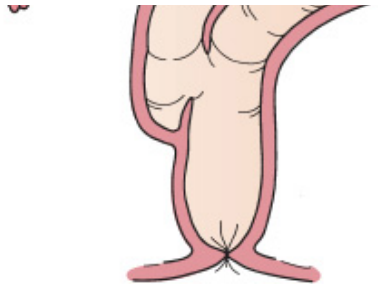

Figure 101.41 Enteric duplication. **A:** Cystic duplication of the terminal ileum. **B:** Tubular duplication of the terminal ileum and the colon.

Cystic Duplications

Cystic duplications may be found throughout the gastrointestinal tract. They are frequently located in the esophagus and the hindgut, particularly the rectum. Direct communication between a duplication cyst and the functional gut lumen is unusual. Typically, asymptomatic duplications are discovered as incidental mass lesions during diagnostic imaging studies, particularly when the location is the thoracic cavity or the rectum. Duplications also may present as symptomatic lesions from ectopic gastric mucosa leading to ulceration and bleeding. Other potential presenting symptoms of enteric duplication include obstruction, intussusception, perforation or traumatic rupture, torsion, infection, and occasional malignant degeneration. Useful examinations to define the extent of the lesion include ultrasound, CT scanning, MRI studies, and contrast studies. The identification of enteric duplication on routine prenatal ultrasound examination has been reported.

The treatment of all cystic duplications is operative. Even in asymptomatic infants and children, uncertainty regarding the nature of the mass and the potential for subsequent problems dictates surgical exploration. Esophageal and rectal duplication cysts are generally amenable to simple excision. In contrast, duplication cysts of the small intestine usually require segmental resection and primary anastomosis, given the intimate attachment and shared blood supply with the native bowel. For large cystic duplications involving longer segments of native bowel, individualized treatment strategies are required. One option is cyst marsupialization with resection of the duplication cyst wall with preservation of the common blood supply and wall between the cyst and the native bowel. This technique is combined with submucosal dissection and stripping of the remaining epithelium from the cyst wall. Another approach is internal drainage of the cyst into the adjacent

native intestine, for example, creation of a cystoduodenostomy for duodenal duplication not amenable to local resection and anastomosis; this would be distinctly unusual.

Tubular Duplications

Tubular duplications may be found anywhere along the length of the gastrointestinal tract. They are less frequent than cystic duplications and have a tendency to involve the ileum and the colon. It is believed that tubular duplication generally reflects abnormal, disordered recanalization of the gastrointestinal tract. Similar to cystic duplications, tubular lesions share a common wall and blood supply with the native bowel. Communication between the tubular duplication and native bowel lumen is common. Tubular duplications may be extensive and can involve the entire length of terminal ileum and colon. Malformations of the entire colon and rectum are associated with genitourinary anomalies, particularly duplications of the external genitalia or bladder.

Tubular duplications manifest clinically in similar fashion to cystic lesions. Symptomatic lesions most commonly present with gastrointestinal bleeding or obstruction. Treatment is operative, and an individualized strategy is required that is based on the location and nature of the duplication. Resection with primary anastomosis may require removal of an unacceptable length of normal bowel. Marsupialization with submucosal stripping of the duplication epithelium may be particularly helpful if ectopic gastric mucosa is suspected or found. Obstruction from a long, blind-ending parallel duplication that communicates with the functional gut lumen can be treated effectively with a reentry procedure such as a distal enteroenterostomy. This approach avoids a potentially complex resection of a significant length of bowel.

The outcomes of surgical management of enteric duplications are generally excellent in the absence of other associated anomalies or medical problems. Mortality attributable to the duplication itself is unusual. Postoperative morbidity is generally dependent on the nature and location of the duplication.

Mesenteric and Omental Cysts

Mesenteric and omental cysts are rare lesions thought to result from the sequestration of lymphatic tissue during development. Mesenteric cysts are

twice as common as omental cysts. Both are characterized by thin, often incomplete walls lined with endothelial cells absent of surrounding smooth muscle. They may be filled with either serous lymphatic fluid or chyle and may be unilocular or multilocular. These cysts may become extraordinarily large before producing symptoms.

Most infants and children with mesenteric or omental cysts are diagnosed prior to adolescence. Asymptomatic children are usually diagnosed incidentally during studies for other reasons. Symptomatic children present with abdominal pain, and, on examination, a soft, mobile abdominal mass is characteristic. Bleeding, rupture, obstruction, torsion, or cyst infection may be observed. Most of these lesions can be diagnosed by ultrasound or CT scan imaging. Ascites, duplication cysts, pancreatic pseudocysts, and large ovarian cysts may have a similar appearance on diagnostic imaging. Peripheral calcification and evidence of recent hemorrhage may be seen in mesenteric or omental cysts (Fig. 101.42).

The treatment for these lesions is simple excision. Total excision of mesenteric or omental cysts is generally preferable over partial excision with marsupialization. Limited resection with primary anastomosis may be required for a mesenteric cyst located adjacent to the intestinal wall, particularly if there is concern that the cyst actually may be an enteric duplication. Morbidity and mortality are generally limited to concurrent problems associated with the intestine. In particular, volvulus of a mesenteric cyst may cause vascular compromise and infarction of the adjacent intestine.

Primary Peritonitis

Bacterial peritonitis without a specific, identifiable cause is referred to as *primary peritonitis.* Spontaneous bacterial peritonitis in children with ascites or nephrosis is generally included in this group. Hematogenous seeding of ascitic fluid is probably responsible for the development of spontaneous bacterial peritonitis. The infecting bacterial organisms were classically gram-positive with a variety of staphylococcal, streptococcal, and other species accounting for most cases. In a series of infants and children with primary peritonitis, more than two-thirds of the cases were caused by gram-negative organisms such as *Escherichia coli.*[152] This trend may reflect the use of antibiotic prophylaxis directed against gram-positive organisms.

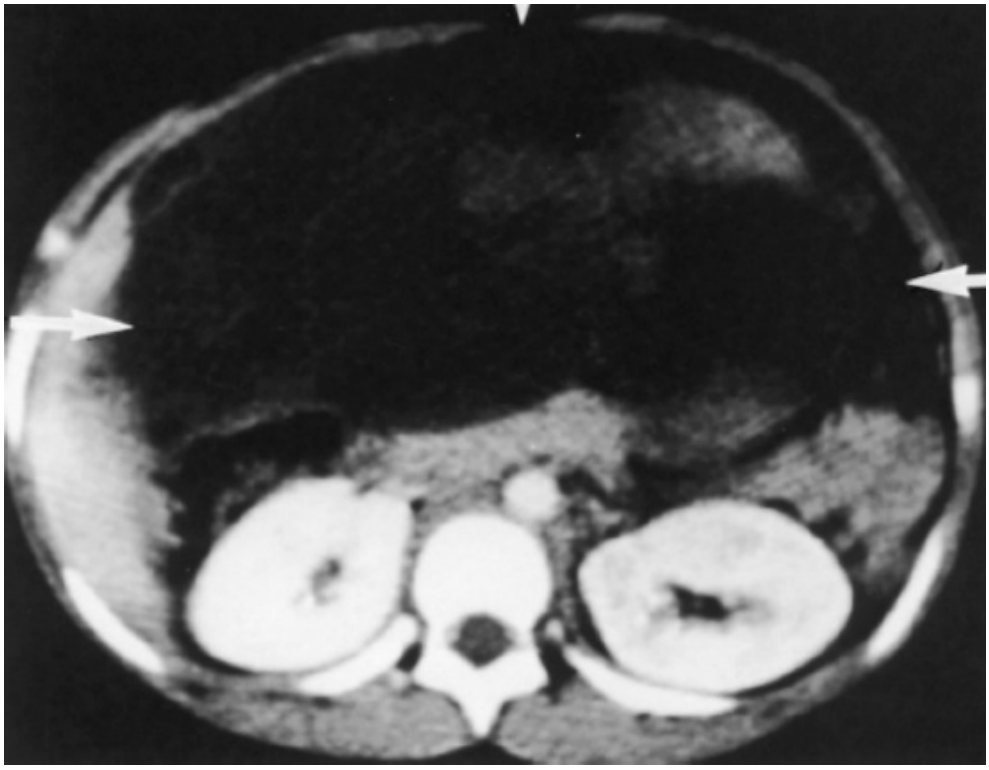

Figure 101.42 Computed tomographic scan of a child after abdominal trauma. Hemorrhage into large omental cyst is apparent (*arrows*).

The other etiologic mechanism for the development of primary peritonitis is believed to involve retrograde inoculation of the peritoneal cavity via the genitourinary tract. This etiology is characteristic of prepubertal girls 5 to 10 years of age, accounting for as many as half of the cases of primary peritonitis. The initial signs and symptoms in these children are virtually identical to those in children with perforated appendicitis: fever, emesis, abdominal pain, and tenderness on examination. Leukocytosis is characteristic, and an ileus is observed on plain abdominal films. On exploration, these children have inflammatory peritonitis without an identifiable enteric cause. Gram-negative enteric organisms are commonly cultured from the peritoneal fluid.

Infants and children with peritonitis in association with an indwelling peritoneal dialysis catheter or ventriculoperitoneal shunt may be treated successfully with intravenous broad-spectrum antibiotics. The catheter or shunt should be removed or exteriorized promptly if peritonitis does not resolve within 24 to 48 hours.[153] In association with ascites or nephrosis, diagnostic paracentesis should be performed and the peritoneal fluid

examined by Gram stain and culture. If there is any diagnostic uncertainty, laparoscopic or open operative exploration may be required to exclude intestinal perforation as a cause of peritonitis. If the appendix is normal, peritoneal cultures should be obtained and a thorough, complete abdominal exploration for other causes should be performed. Appendectomy is generally performed when the diagnosis of primary peritonitis is established by a right lower-quadrant incision. Other than perforated appendicitis, distinct causes of intestinal perforation or peritonitis in this age group include perforated Meckel diverticulum, duodenal ulcer, and acute pancreatitis. About half of the peritoneal fluid cultures are positive for a single organism. Treatment with specific antibiotics is continued until the patient is afebrile with a normal white blood cell count and normal clinical examination. Following operative exploration in primary peritonitis, the morbidity is no different than that for appendectomy, and the recovery is generally uneventful.

ETIOLOGY

Table 101.10 Common Causes of Neonatal Ascites

Maternal–fetal Rh incompatibility (rare) Structural malformations Urinary obstruction Congenital heart disease Malrotation, duplications, cyst (associated with intestinal volvulus) Biliary perforation Ovarian ascites Pulmonary abnormalities

Cysts (torsion, rupture)
Tumors

Malignant Ascites Intra-abdominal neoplasm
Idiopathic

Ascites

The common causes of neonatal and childhood ascites are listed in **Tables 101.10** and **101.11**. The clinical presentation is that of abdominal distention with bulging flanks and demonstrable fluid on palpation and percussion. Ultrasound or CT scan imaging may be useful to confirm the clinical diagnosis. Paracentesis and routine examination of the fluid for Gram stain, cell count, cytology, protein, chemistries, and culture should be performed. Chylous ascites is characterized by a white milky appearance, high lymphocyte count, and high triglyceride content. Bile-stained fluid in the absence of demonstrable bowel perforation is characteristic of biliary ascites. High-fluid amylase content is seen in pancreatic ascites, and a low protein count (<3 g/dL) is consistent with serous ascites. Elevated urea nitrogen or creatinine in the fluid may suggest urinary ascites, particularly in a male patient. Cytology should be performed to exclude peritoneal ascites secondary to malignancy, particularly in pubertal and adolescent females.

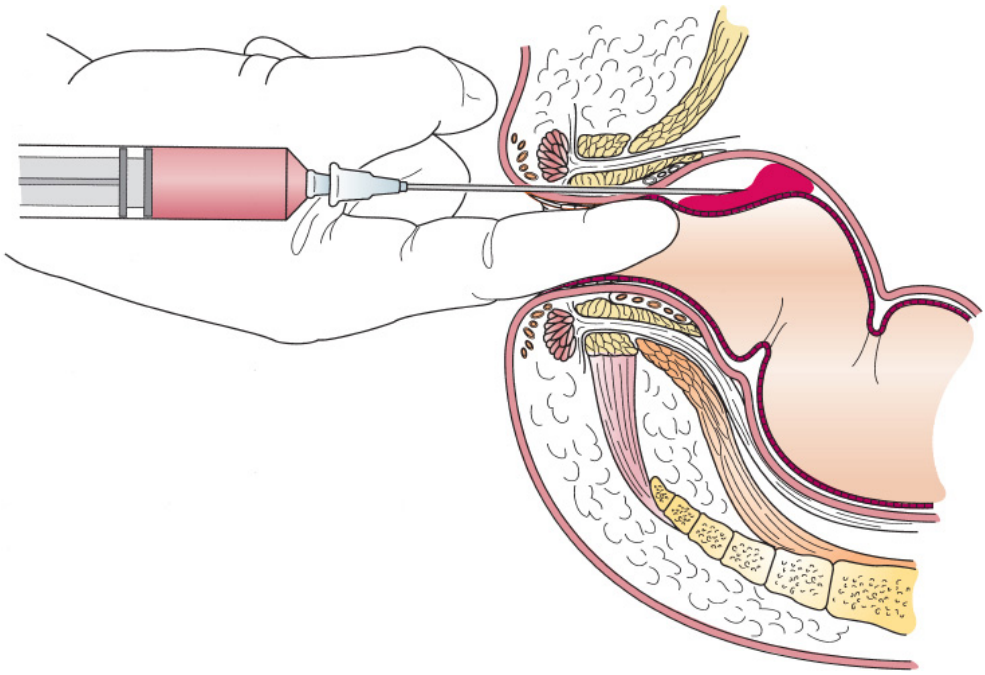

Figure 101.43 Four-quadrant injection of sclerosant into the rectal submucosa for the treatment of childhood rectal prolapse.

If the initial fluid does not provide a diagnosis in an otherwise normal-appearing child, a comprehensive diagnostic imaging evaluation is warranted. An echocardiogram should be obtained and either ultrasound or CT scan imaging performed to evaluate the genitourinary system, the hepatobiliary system, and the pancreas. A voiding cystourethrogram may also be indicated.

Treatment of neonatal or childhood ascites depends on the establishment of a specific diagnosis. In the absence of anatomic lesion or injury, spontaneous resolution of chylous ascites occurs in 50% to 75% of cases with the temporary cessation of enteral feeding and administration of parenteral nutrition. Persistence of chylous ascites for longer than 4 to 6 weeks is an indication for operative attempts to ligate the cisterna chyli. Neonatal biliary ascites may result from spontaneous bile duct perforation, in which case a diagnosis of CF must be considered. Transient bile duct obstruction typically leads to perforation at the junction of the cystic duct with the common duct. Simple external drainage is the treatment of choice, and complex hepatobiliary tract reconstruction in this setting is unnecessary and potentially hazardous. Urinary ascites in a male patient requires a workup that includes a voiding cystourethrogram to exclude posterior urethral valves. Urinary

ascites resolves with the treatment of obstructive uropathy. Pancreatic ascites is typically self-limited, and treatment by drainage procedures is generally not required or limited for relief of persistent symptoms.

Massive neonatal ascites may cause hypoventilation secondary to impairment of diaphragmatic excursion, and therapeutic paracentesis may be required. Childhood ascites generally responds to adequate treatment of the underlying problem and occasionally requires medical therapy. Placement of a peritoneovenous shunt in children for intractable ascites is rare.

Rectal Prolapse

Spontaneous rectal prolapse is relatively common in toddlers and children up to 5 years of age. A peak incidence occurs at or near the time of toilet training. There is an association between straining during bowel movement and rectal prolapse; it may be more commonly observed in children with CF, myelodysplasias with sacral neuropathy, congenital anorectal malformations, Hirschsprung disease, and colorectal polyps. However, most children presenting with rectal prolapse are normal.

A history of protrusion of mucosa or full-thickness rectum with or without bleeding is usually described. Other lesions of childhood that have a similar appearance are prolapse of an intussusceptum or passage of a polyp through the anus. The rectal examination is diagnostic. If the protruding intestine is an intussusceptum, a finger can be placed adjacent to it within the rectum; this maneuver is not possible with rectal prolapse.

Nonoperative management using manual reduction is successful in most infants and children. Sedation may be required in some instances. Therapeutic interventions include stool softeners and parental instruction on manual reduction. Spontaneous resolution over a few weeks is typical. For persistent rectal prolapse in children, operative intervention is generally governed by doing the least invasive procedure possible. Unlike adults, complex operations involving bowel resection and pelvic suspension are generally unnecessary in children with rectal prolapse. The most useful and commonly used procedure is rectal submucosal injection using a sclerosant (Fig. 101.43). With the patient under general anesthesia, injection with 5% sodium morrhuate or cow's milk[154] has been performed successfully on an outpatient basis. About 90% of children can be treated successfully with a single four-

quadrant sclerosant technique, but on occasion further sclerosis is necessary. Submucosal dissection or cauterization is also successful but may have a higher incidence of postoperative bleeding or stricture formation and usually requires a short period of hospitalization. The major objective in treating childhood rectal prolapse is to create a local extraperitoneal inflammatory process in the perirectal space. Morbidity is low and the long-term outcome is excellent.

PEDIATRIC LIVER

Tumors of the Liver

Primary hepatic tumors are rare in children and at least 60% to 70% are malignant.[155,156] Table 101.12 reviews the incidence rates and types of hepatic tumors presenting during infancy and childhood. Pediatric hepatic tumors often manifest as asymptomatic abdominal masses discovered by parents or pediatrician. Symptoms related to the tumor, such as pain, hemorrhage, hypertension, and precocious puberty, are less frequent. Initial diagnostic imaging studies include plain abdominal radiographs and ultrasound to assist in early determination as to whether the mass is cystic or solid and whether calcifications are present. CT scan imaging and MRI remain definitive in the ability to discern anatomic characteristics of the mass and its relationship to adjacent structures. Most children require operative exploration for either definitive excision or incisional biopsy in lesions deemed unresectable.

Table 101.12 Incidence of Liver Tumors in Childhood

Tumor Type	Incidence Rate (%)
Benign	
Vascular tumors	13
Hemangioma	9
Hemangioendothelioma	4
Mesenchymal hamartoma	6
Focal nodular hyperplasia	2
Adenoma	2
Teratoma	2
Other	3
Malignant	
Hepatoblastoma	43
Hepatocellular carcinoma	23
Malignant mesenchymal tumor	4
Sarcoma	2
Embryonal cell carcinoma	2
Angiosarcoma	1

Benign Tumors

Of all primary liver tumors of childhood, 30% are benign. The most common benign tumors are hemangiomas, hemangioendotheliomas, mesenchymal hamartomas, cysts, focal nodular hyperplasia, and hepatic adenoma. In most large series, hemangiomas constitute about 50% of the benign hepatic tumors observed.[157]

Vascular Tumors

Infantile hepatic hemangiomas represent a clinically diverse spectrum of vascular endothelial anomalies. They are characterized by a phase of proliferative growth over the first year of life, with subsequent involution over several years. The International Society for the Study of Vascular Anomalies classifies vascular tumors into two categories based upon the presence or absence of GLUT-1, an erythrocyte-type glucose transporter protein expressed in the endothelium of the placenta and hemangiomas.[158] Therefore, hemangiomas are GLUT-1 positive, and other, more heterogeneous vascular anomalies such as vascular malformations are GLUT-1 negative. Most asymptomatic infantile hepatic hemangiomas are detected as incidental findings on diagnostic imaging studies performed for unrelated reasons. A smaller proportion will create symptoms of enlarging abdominal mass, progressive hepatic failure, high output cardiac failure due to shunting, thrombocytopenia, or hypothyroidism from excess production of type III iodothyronine deiodinase.[159]

Most benign vascular lesions of the pediatric liver do not require operative management. Operative intervention is generally reserved for bleeding secondary to traumatic rupture symptoms not controllable with medical management. Treatment strategies remain highly individualized based upon the whether the lesions are focal, multifocal, or diffuse.[160,212] In the face of multifocal or diffuse disease associated with congestive heart failure and thrombocytopenia secondary to sequestration, medical treatment with corticosteroid therapy may be useful. More invasive procedures such as irradiation, selective hepatic arterial ligation, angiographic embolization, or hepatic transplantation remain useful in selected patients with uncontrollable symptoms. Chemotherapeutic agents, including recombinant alpha-interferon, low-dose vincristine, and cyclophosphamide, have been used for life-threatening vascular lesions. Hepatic resection is generally reserved for mass lesions of unknown diagnosis, ruptured vascular lesions with signs of active hemorrhage, or for symptomatic, locally resectable lesions.

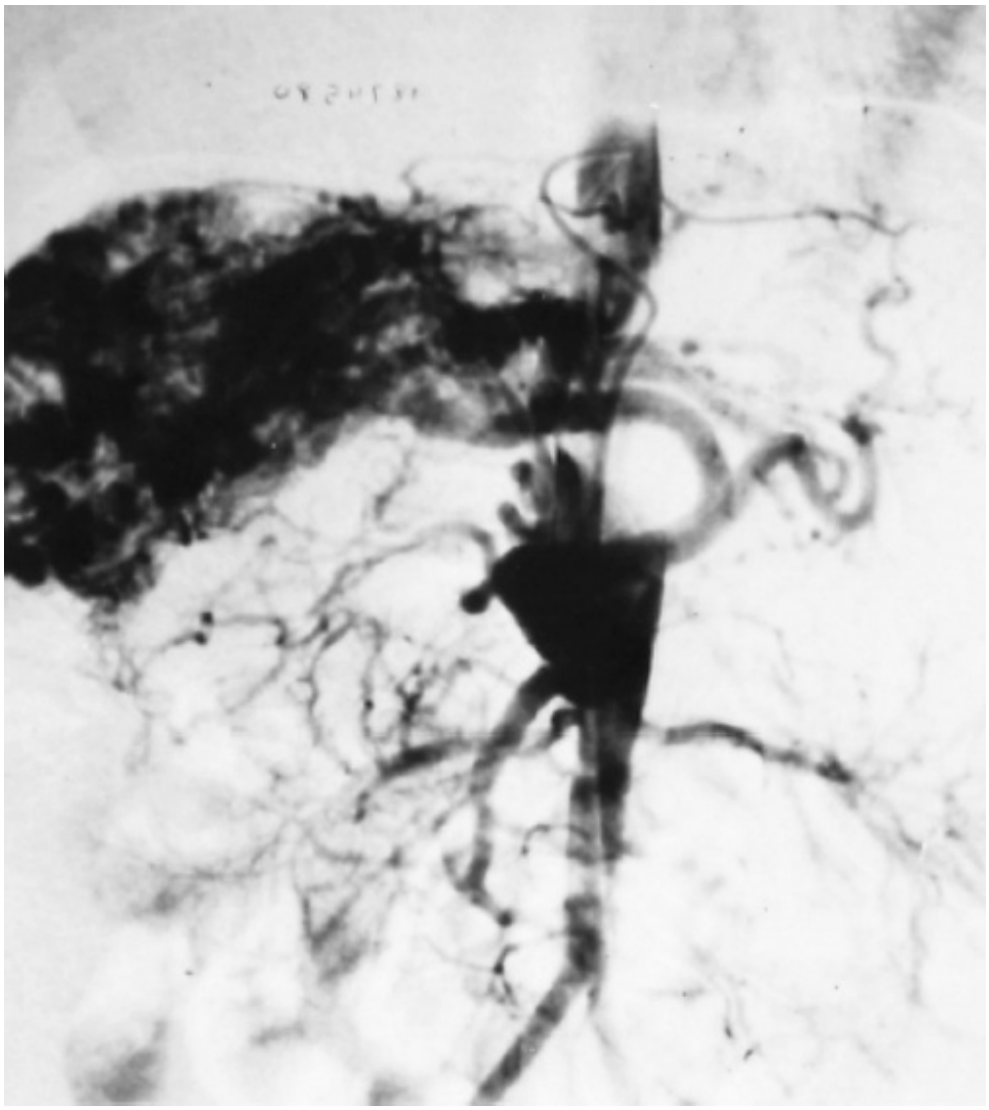

Figure 101.44 Selective visceral angiogram demonstrating large hepatic vascular malformation in a neonate with congestive heart failure. This finding is consistent with a bilobar hemangioendothelioma.

Hemangioendotheliomas are important vascular anomalies encountered in infants. The lesions vary in size from 1 cm to several centimeters in diameter and may be multiple (Fig. 101.44). Symptomatic neonates may present with an abdominal mass, hepatomegaly, and congestive heart failure. These infants may also experience spontaneous rupture and hemoperitoneum, with tachycardia, tachypnea, and hypovolemic shock. On examination, the infant may have other cutaneous hemangiomas visible on the skin. Affected infants may develop thrombocytopenia secondary to platelet sequestration in the vascular malformation (*Kasabach–Merritt syndrome*). CT scan imaging or

MRI is diagnostic. Treatment is directed at controlling symptoms using medical management principles as discussed previously; however, hemangioendotheliomas tend to be more problematic than hemangiomas because of the tendency to occur during infancy and the more extensive, symptomatic nature of the lesions.

Mesenchymal Hamartomas

Approximately one-third of benign hepatic tumors in children are mesenchymal hamartomas. A mesenchymal hamartoma is often quite large and typically presents within the first year of life as an asymptomatic, solitary abdominal mass. CT scan imaging or MRI studies are usually diagnostic and show a solid mass that may have cystic components within the liver parenchyma. Definitive diagnosis may require open tissue biopsy, and the therapy of choice is complete excision, although spontaneous involution has been described. Simple enucleation may be adequate because these tumors tend to be well circumscribed. On occasion, formal hepatic resection may be required.[161] Recurrence is low after adequate resection.

Focal Nodular Hyperplasia

This tumor occurs primarily in female children and in adults and may be associated with the use of oral contraceptives or focal hepatic injury. Focal nodular hyperplasia is usually a well-defined, solitary mass that has characteristic findings on CT scan imaging. Open or percutaneous biopsy may be required to differentiate the lesion from hepatic adenoma. This lesion results from a focal inflammatory response of normal hepatic parenchyma surrounded by areas of micronodular fibrosis and cirrhosis. Operative management is generally unnecessary unless there is a question of diagnosis or active hemorrhage from the lesion.

Hepatic Adenoma

Adenomas are rare in infants and children and constitute less than 5% of all benign hepatic lesions in the pediatric age group. There is an association between the use of oral contraceptives, exogenous anabolic steroid use, and glycogen storage disease type I (von Gierke disease). These tend to be large, solitary lesions located in the right hepatic lobe. The typical presentation is an asymptomatic abdominal mass, although symptoms are seen more commonly than with focal nodular hyperplasia. About 20% to 25% of patients

with hepatic adenoma present with hemoperitoneum from tumor rupture. On histologic examination, these lesions are composed of normal hepatocytes without evidence of dysplasia. Operative therapy is usually directed at either making definitive diagnosis or treating hemorrhage. Enucleation or local resection is adequate and recurrence rates are low.

Hepatic Cysts

Congenital cysts of the liver may be either solitary or multiple. These cysts are thought to result from failure of the intralobular or interlobular biliary ducts to fuse during development. They may be lined with cuboidal, columnar, or squamous epithelium.[162] The presence of multiple hepatic cysts is associated with polycystic kidney disease, and development of progressive hepatic and renal failure is a potential problem with this disease. The majority of children with hepatic cysts are asymptomatic. Adjunctive diagnostic imaging, including ultrasound and CT scan imaging, may be useful.

Asymptomatic congenital hepatic cysts do not require surgical therapy. Operative therapy is reserved for symptomatic cysts. Resection or drainage by marsupialization or hepaticocystenterostomy may be required. If patency to the biliary tract is present on contrast injection study of the cyst, internal drainage is necessary.

The differential diagnosis includes hydatid disease of the liver, which is suggested by calcification and loculation of the cyst wall. Hydatid disease can be diagnosed using specific serologic tests, which is an important surgical consideration prior to exploration. Patients with echinococcal cysts should be treated with mebendazole and undergo cyst injection with hypertonic saline or other scolicidal agents into the parent cyst before surgical excision. Careful control of the cyst contents is required during echinococcal cyst excision or marsupialization.

Teratomas

Teratomas of the liver are exceedingly rare and have potential for harboring immature elements capable of transforming into malignancy. Surgical resection on discovery is recommended.

Malignant Tumors

Two-thirds of childhood hepatic tumors are malignant, with hepatoblastoma constituting half of the malignancies, followed by hepatocellular carcinoma, malignant mesenchymal tumors, and sarcoma.[155] Malignant hepatic tumors are fortunately rare, and effective treatment requires a multidisciplinary approach that is best achieved in an experienced pediatric center.

Hepatoblastoma

Most hepatoblastomas are discovered in children younger than 2 years. There is a 2:1 male-to-female predominance. Hepatoblastomas usually are found as either an asymptomatic abdominal mass or symptoms of gastrointestinal obstruction from extrinsic compression by the mass. There is an association of hepatoblastoma in patients with Beckwith–Wiedemann syndrome and hemihypertrophy. On examination, a firm, palpable upper abdominal mass is notable. Obstructive jaundice is unusual. More than 90% of children with hepatoblastoma have elevated levels of alpha-fetoprotein, which is useful serum tumor marker for postoperative surveillance. In few instances, children have initial symptoms and signs of excess androgen secretion, including virilization and precocious puberty. Diagnostic imaging with CT scan imaging or MRI is essential to evaluate the extent of the tumor and evaluate for metastatic disease (Fig. 101.45).

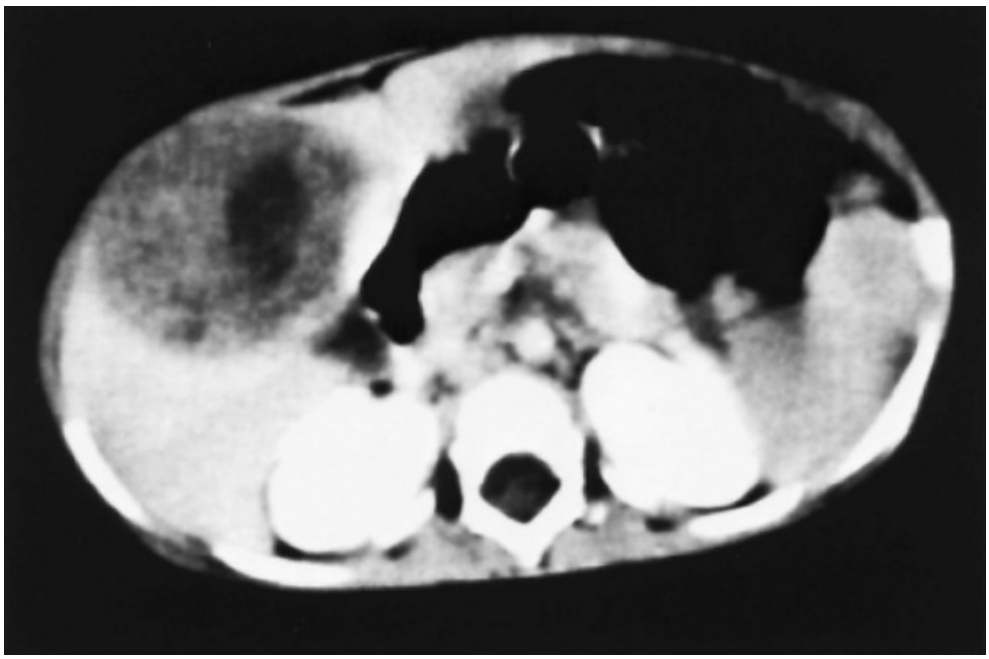

Figure 101.45 Computed tomographic scan of the abdomen demonstrating an infant with hepatoblastoma of the right hepatic lobe.

Children with hepatoblastoma require multidisciplinary management at centers familiar with their management protocols. Resectability is based on the pre-treatment extent of tumor (PRETEXT), and POSTTEXT and their approach should be standardized.[163] Most children presenting with hepatoblastoma initially have unresectable disease. However, PRETEXT 1 tumors should be amenable to primary resection whereas PRETEXT 4 tumors should be considered for liver transplant. In the absence of metastatic disease, however, an aggressive surgical approach is used. Cure and long-term survival with hepatoblastoma requires complete surgical excision of the primary lesion. Therefore, localized, resectable tumors usually are excised by formal hepatic lobectomy or extended trisegmentectomy. Children with hepatoblastomas considered initially unresectable or with metastatic disease should undergo percutaneous or incisional biopsy to confirm the histologic diagnosis, followed by multiagent chemotherapy to reduce the size of the primary tumor and control metastases.[164,165] Delayed resection is appropriate if enough functional, normal hepatic parenchyma remain after resection. More than half of the patients who initially have unresectable hepatoblastoma can be rendered disease free with the combination of chemotherapy and subsequent surgery. Cure rates for hepatoblastoma range from 60% to 80% if histologically clear margins and no metastatic disease are present. All patients with hepatoblastoma, which are not stage 1 pure fetal histology, receive chemotherapy after resection. As treatment of this disease is complex and dependent on several clinical and anatomic factors, current treatment recommendations should be referenced.[163]

Hepatocellular Carcinoma

Hepatocellular carcinoma is significantly more common in adults but is occasionally seen in older children and adolescents. There is a male predilection (2:1) and, except for the age at diagnosis, the clinical presentation is similar to that for hepatoblastoma. Children with hepatocellular carcinoma are more likely to have jaundice and abnormal liver enzymes. The high association of cirrhosis in adults (80%) is not seen in children with hepatocellular carcinoma; only 5% of children develop hepatocellular carcinoma in the background of cirrhosis. An increased risk of hepatocellular carcinoma is seen in children with Beckwith–Wiedemann syndrome, hemihypertrophy, von Gierke disease, hepatitis B, and Fanconi

syndrome. Exposure to oral contraceptives, anabolic steroids, and some chemotherapeutic agents also has been associated with hepatocellular carcinoma. This malignancy carries a poor prognosis with an overall survival rate of 10% to 20% despite aggressive surgical resection and multiagent chemotherapy. A histologic variant, fibrolamellar hepatocellular carcinoma, carries a more favorable prognosis. As with hepatoblastoma, complete surgical resection with clear histologic margins is necessary for long-term survival and cure. In the absence of metastatic disease, unresectable hepatoblastoma or hepatocellular carcinoma in children has been successfully treated by orthotopic liver transplantation. Review of data from the United Network for Organ Sharing database demonstrates good long-term survival for both hepatoblastoma (66% 10-year survival) and hepatocellular carcinoma (58% 10-year survival) treated with liver transplantation.[166]

Malignant Mesenchymal Tumors

These rare hepatic malignancies occur in children 5 to 10 years of age; initial signs are fever, pain, and an abdominal mass, which is usually quite large on diagnosis and may have both solid and cystic components. Multidisciplinary treatment, including complete surgical resection, multiagent chemotherapy, and radiation therapy, is required for cure. In general, the prognosis of primary malignant mesenchymal tumors of the liver remains poor.

Sarcomas

Children may rarely have a primary sarcoma of the liver. Embryonal rhabdomyosarcoma of the biliary tract is distinctly unusual. It may manifest with obstructive jaundice attributable to both extrinsic and intrinsic biliary tract obstruction. Undifferentiated, embryonal sarcoma of the liver has also been described. Angiosarcoma developing in the liver may be associated with exposure to toxins such as arsenic. Aggressive surgical resection may be required, but long-term survival is uncommon. Despite radical surgery, chemotherapy, and radiation therapy, the prognosis and long-term survival of children with these malignancies remain poor, and data regarding effective drug regimens are limited.[167,168]

Liver Resection

Operative principles and techniques for hepatic resection are discussed elsewhere in this book. Several unique issues in the safe performance of hepatic resection in children should be emphasized.[169] The circulating blood volume of an infant or a child is less compared to an adult, and children are sensitive to compression of the inferior vena cava causing decreased venous return to the right heart. Blood must be available for transfusion and adequate intravenous access is essential. Resection can be performed through either a subcostal incision or a right thoracoabdominal incision; in general, the ability to perform the operation safely should not be limited by the size of the incision. In children, the right and left hepatic veins are difficult to control near the inferior vena cava because of their short lengths, and intraparenchymal control from an anterior approach may be safer (Fig. 101.46).

Hepatic Infections

Hepatic infections are generally rare in the pediatric population, and their management is similar to that used in adults. An important issue is the development of hepatic abscess in an immunocompromised child and, in particular, the association of chronic granulomatous disease with pyogenic hepatic abscess formation.

Pyogenic Abscess

The most common causative factor in the development of pyogenic hepatic abscess in children with chronic granulomatous disease and other causes of immunosuppression.[170] Chronic granulomatous disease is an inherited disorder characterized by a defect in oxidative burst-mediated bacterial killing by neutrophils. These children develop skin, soft-tissue, and solid organ abscesses. A significant number of children with pyogenic liver abscesses have chronic granulomatous disease or other inherited/acquired immunodeficiency states. Liver abscesses are infrequently seen as a complication of umbilical vein catheterization, omphalitis, biliary tract disease, and hepatobiliary operations.

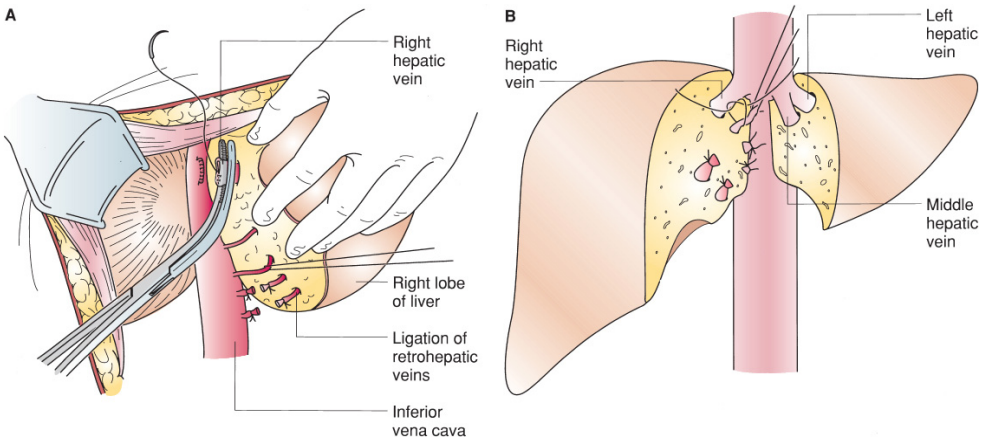

Figure 101.46 **A:** The hepatic veins in infants and children may be extremely short, making extrahepatic control impossible or dangerous. **B:** Intrahepatic control of the hepatic veins via an anterior approach may be safer in infants and children.

Patients with pyogenic liver abscess present with fever, jaundice, and leukocytosis. Hepatosplenomegaly and a tender liver may be found on physical examination. Common responsible organisms include staphylococcal species, streptococcal species, and *E. coli.* Gram-negative organisms and anaerobic bacteria are becoming increasingly prevalent. Treatment involves the use of broad-spectrum antibiotics. Large abscess cavities may require image-guided percutaneous drainage to expedite resolution of sepsis. Rarely, hepatic abscesses require open operative drainage. The outcome is dependent upon the underlying disease process. Recovery from the abscess is predictably good following adequate antibiotic therapy and drainage when necessary.

Amebic Abscess

Amebic abscess of the liver is uncommon in the United States, but it is endemic to areas of Central and South America. It is caused by infection with the parasite *Entamoeba histolytica.* Children with amebic dysentery develop hepatic infection as the parasite travels through the portal circulation. Patients have a history of chronic illness, fever, and abdominal pain. Examination typically demonstrates a tender right upper quadrant. Infection can be confirmed by a serum antibody test, and amebic abscess can be demonstrated by ultrasound or CT scan. Spontaneous rupture of amebic abscess is reported in as many as 10% of patients in some series.[171] The treatment of choice is

the antibiotic metronidazole. Surgical resection or drainage of amebic liver abscess is typically not required for resolution.

PEDIATRIC BILIARY TRACT

Embryology

The fetal liver and biliary tract develop between weeks 4 and 10 of gestation, representing the fusion of an endodermal foregut diverticulum with a mesodermal component from the septum transversum. The hepatocytes are derived from cords of endodermal cells in the hepatic diverticulum and ultimately give rise to the hepatic sinusoidal endothelium. The proximal hepatic diverticulum gives rise to the extrahepatic biliary tract, including the gallbladder, cystic duct, and common bile duct. As the intrahepatic and extrahepatic ductal systems develop, they unite to form a connected, arborizing system of cords composed of primitive ductular epithelial cells. These epithelial cells assume tubular configuration with ductal patency established between weeks 6 and 12 of gestation. Bile flow from the hepatocytes and into the biliary duct system is apparent by the beginning of the second fetal trimester.

This embryologic sequence appears to take place normally in infants who develop biliary atresia. In fact, the term *biliary atresia* does not reflect embryologic atresia resulting from failure of recanalization of the biliary tree. Rather, biliary atresia is caused by an uncontrollable inflammatory process that produces progressive obliteration of the normally developed extrahepatic biliary tract.

Biliary Atresia

Anatomy

7 The overall incidence rate of biliary atresia is about 1 in 8,000 to 12,000 live births and is the most common cause of chronic cholestasis in infants and children as well as the most frequent indication for pediatric liver transplantation.[172] Extrahepatic biliary atresia must be differentiated from biliary hypoplasia. Biliary hypoplasia describes a diminutive but patent biliary system and can result from many underlying situations such as

neonatal hepatitis and alpha$_1$-antitrypsin deficiency. Biliary hypoplasia involves both intrahepatic and extrahepatic ductal systems.

Microscopic Anatomy

Biliary atresia is characterized by replacement of the extrahepatic biliary tract with dense, fibrous inflammatory tissue. In most cases, complete obliteration of the extrahepatic biliary tract, including the gallbladder, occurs. There appears to be gradual progression of the inflammatory process with advancing age. The common hepatic duct and common bile duct are almost uniformly obliterated by the inflammatory process. Few or absent patent ductal remnants and an absence of portal inflammation may be associated with a less favorable prognosis.[173] Intraoperative evaluation for duct patency by frozen section analysis has historically been used help guide the extent of proximal resection at the porta hepatis; however, this is no longer in widespread use. The presence of bile ducts at the porta hepatis with diameter greater than 150 μm has been reported to be associated with postoperative bile flow in up to 90% to 95% of cases.[174]

Histologic features of biliary atresia reflect hepatic parenchymal injury. Neocholangiogenesis, or biliary duct proliferation of disorganized and nonpatent ducts within the liver, is considered highly suggestive but not specific for biliary atresia. Other findings include bile pigment deposition throughout the liver. Characteristic early findings in biliary atresia include evidence for acute inflammation with neutrophil predominance in the periportal regions. Older infants and children typically have chronic inflammatory changes with considerable fibrosis. Periportal bridging fibrosis is commonly seen in intermediate stages of the disease. Ultimately, progressive biliary atresia leads to intractable cirrhosis. Nearly all patients with biliary atresia have histologic evidence of liver injury. The severity and extent of liver damage may be the most important predictor of long-term outcome and survival in biliary atresia.

Pathophysiology

The mechanism causing biliary atresia remains unknown. The current concept is that the normally developed biliary tract undergoes inflammatory sclerosis and subsequent obliteration. This process appears to occur during the first few weeks to months of life. Early establishment of biliary drainage via

portoenterostomy within the first 2 to 4 months of age may be associated with reversal of liver injury and subsequent long-term survival. Conversely, infants operated on after 120 days of life typically have obliterated bile ducts. Neonatal biliary atresia shares some clinical and morphologic features of sclerosing cholangitis in adults. Data supporting an infectious etiologic agent and, in particular, reoviruses, rotaviruses, and hepatitis C, have been reported and may play a role in some cases. In addition, other noninfectious stimuli may trigger an inflammatory response directed at the neonatal extrahepatic bile duct.[175] The actual mechanism may reflect a stereotypical inflammatory response initiated by a variety of different stimuli that is ultimately directed preferentially against the neonatal bile duct.

Clinical Presentation and Diagnosis

The cardinal sign of biliary atresia is progressive neonatal jaundice during the first few weeks of life. Dark urine and acholic stools are expected findings. Progressive hyperbilirubinemia produces clinical jaundice around 2 to 4 weeks of age. The physical examination is generally unremarkable except for jaundice and possibly mild hepatomegaly. Alagille syndrome, which presents with neonatal jaundice, can usually be distinguished from biliary atresia on physical examination. Children with Alagille syndrome have biliary hypoplasia and distinctly abnormal facies, growth retardation, vertebral defects, and pulmonic stenosis.

A characteristic laboratory finding is conjugated hyperbilirubinemia consistent with obstructive jaundice. A direct fraction of bilirubin greater than 50%, or greater than 2 mg/dL, in an infant requires prompt investigation. Mild elevation of hepatic transaminases is commonly seen. The alkaline phosphatase is significantly elevated, often in the range of 500 to 1,000 IU/L. There are no specific biochemical markers for biliary atresia, as these serum profiles can be seen in other causes of neonatal cholestasis. Late findings in biliary atresia include failure to thrive, feeding intolerance, stigmata of portal hypertension, and fat-soluble vitamin deficiency.

ETIOLOGY

Table 101.13 Causes and Associations of Neonatal Cholestasis

Congenital Infectious Causes
Cytomegalovirus[a]
Rubella virus[a]
Herpes virus
Hepatitis virus B[a]
Echovirus 14, 19
Coxsackievirus B
Toxoplasmosis
Syphilis
Genetic Associations
Galactosemia
Tyrosinemia
Congenital fructose intolerance
$Alpha_1$-antitrypsin deficiency
Cystic fibrosis
Niemann–Pick disease
Trisomies 17, 18, 21
Turner syndrome
Menkes syndrome
Zellweger syndrome
Polysplenia syndrome[b]
Miscellaneous Associations
Hemolytic disease
Bacterial sepsis
Pyelonephritis
Total parenteral nutrition (prolonged)
Congestive heart failure
Hypoplastic left heart syndrome
Necrotizing enterocolitis, gastroschisis, omphalocele
Neonatal hypopituitarism
Inspissated bile syndrome (without hemolysis) neonatal shock, respiratory distress syndrome, acidosis

[a]Rarely associated with biliary atresia.

[b]Frequently associated with biliary atresia.

Table 101.13 is a partial list of the causes of neonatal cholestatic syndromes. Neonatal physiologic jaundice is commonly encountered. Because of the numerous causes of neonatal jaundice and the relative infrequency of biliary atresia, a delay in diagnosis is common. Given the age-sensitive nature of biliary atresia and the improved outcome in younger infants, the diagnostic workup should be expedient.

Radioisotope Scanning

Pertechnetate 99 m–iminodiacetic acid (^{99m}Tc-IDA) analogs are widely used for hepatobiliary imaging and provide the basis for a sensitive and specific test for biliary atresia. The sensitivity of this diagnostic examination for biliary atresia can be 100%, with a specificity of 94%.[176] To improve sensitivity, infants are administered oral phenobarbital (5 mg/kg daily) to induce hepatic microsomal enzymes and increase hepatocyte processing of ^{99m}Tc-IDA. Both hepatic uptake of radionuclide and excretion into the gastrointestinal tract are evaluated over a timed interval. Infants with primary hepatocellular disorders characteristically have impaired hepatocyte uptake of radionuclide, whereas normal infants and infants with biliary atresia have prompt uptake. Normal infants excrete the isotope rapidly into the gut through the biliary tract. In biliary atresia, there is no excretion into the gut because of the obliteration of the extrahepatic bile ducts (Fig. 101.47). The hepatobiliary scanning is a rapid test that can be performed simultaneously with other diagnostic examinations, for example, ultrasound. This test reliably identifies infants with choledochal cyst as well.

Ultrasound. A standard examination of the jaundiced infant is a comprehensive abdominal ultrasound, with particular attention given to the liver and the biliary tract. The most common ultrasonographic finding in biliary atresia is a diminutive or absent gallbladder without associated intrahepatic duct dilatation. Biliary tract obstruction from a choledochal cyst also can be reliably identified by ultrasound. Other rare causes of extrahepatic biliary duct obstruction are associated with proximal duct dilatation.

Liver Biopsy. Because the histologic findings in biliary atresia are not specific, about 20% to 25% of infants who undergo percutaneous liver

biopsy remain undiagnosed. Liver biopsy is often performed in conjunction with the workup of conjugated hyperbilirubinemia following hepatobiliary scanning and ultrasonography, but in the setting of biliary atresia, it has limited utility. The histologic examination of a percutaneous liver biopsy is probably most helpful in diagnosing nonoperative causes of neonatal jaundice, thus avoiding anesthesia and operative exploration.

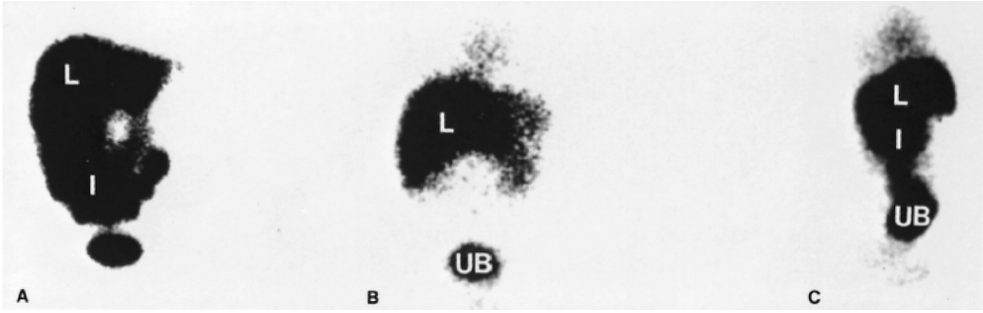

Figure 101.47 **A:** Normal scan using p-isopropyl acetanilidoiminodiacetic acid (PIPIDA) as the hepatobiliary scanning agent. At 45 minutes, isotope is clearly visible in the liver (*L*) and the intestine (*I*). **B:** Scan after phenobarbital administration in infant with biliary atresia. Even after 8 hours, isotope is apparent only in the liver and the urinary bladder (*UB*). **C:** Patient with cholestatic jaundice. At 65 minutes, isotope is visible in the liver (*L*) and the intestine (*I*). Hepatocyte uptake is variable but usually decreased or normal, whereas excretion into the gut is predictably present with cholestatic jaundice or hepatocellular disease.

Alpha$_1$-Antitrypsin Deficiency. Alpha$_1$-antitrypsin deficiency is perhaps the single most important medical condition that may be difficult or impossible to differentiate from biliary atresia. All jaundiced infants should have plasma alpha$_1$-antitrypsin levels determined before operative exploration for suspected biliary atresia. Infants with alpha$_1$-antitrypsin deficiency do not benefit from operative exploration or portoenterostomy.

Treatment

Infants with biliary atresia require surgical therapy as the initial management intervention. Medical therapy is directed to the postoperative management of the chronic liver disease. The use of sequential surgical treatment, using portoenterostomy in infancy and orthotopic liver transplantation for children with progressive hepatic failure, provides improvement in overall survival.[177,178] Limited organ availability and a higher rate of perioperative

complications limit primary liver transplantation for most infants with biliary atresia younger than 1 year. In the rare instance of unrecognized biliary atresia in an older child with established hepatic dysfunction, primary orthotopic liver transplantation may be a reasonable option.

Portoenterostomy

The recommended initial procedure for the treatment of biliary atresia is portoenterostomy. Before the development of portoenterostomy in Japan by Morio Kasai during the late 1950s, all infants with biliary atresia died of chronic liver disease and cirrhosis. Current management dictates that operative exploration and portoenterostomy be performed promptly. Early intervention by portoenterostomy to provide biliary drainage has been proposed to arrest or reverse the parenchymal liver injury, but the point at which the liver injury becomes irreversible remains unknown. From a clinical standpoint, most long-term success with portoenterostomy alone appears to be achieved in infants younger than 2 to 3 months, whereas infants older than 3 to 4 months appear to have a less favorable prognosis. Portoenterostomy for this "late" group has been reported successfully in approximately one-third of infants, however, and should be considered a potential alternative in the absence of available liver transplant donors.[179]

The initial approach to the infant with suspected biliary atresia is to perform an operative cholangiogram. If the diagnosis is confirmed, a portoenterostomy is constructed (Fig. 101.48). An open liver biopsy is routinely performed to document the state of parenchymal injury. The cholangiogram is generally attempted through the gallbladder. In the 10% to 15% instance of a patent distal biliary tree, treatment still requires portoenterostomy. A nonpatent, fibrous cord rather than a normal common bile duct is found in the hepatoduodenal ligament. This cord is dissected free proximally to the level of the porta hepatis between the portal vein bifurcation. The fibrous remnant is sharply transected at this level to preserve any patent bile ducts. A short, 15- to 25-cm retrocolic, jejunal Roux-Y limb is constructed. There has been no clear advantage with longer or modified conduits with intussusception-type antireflux valves in the prevention of cholangitis.[180,181]

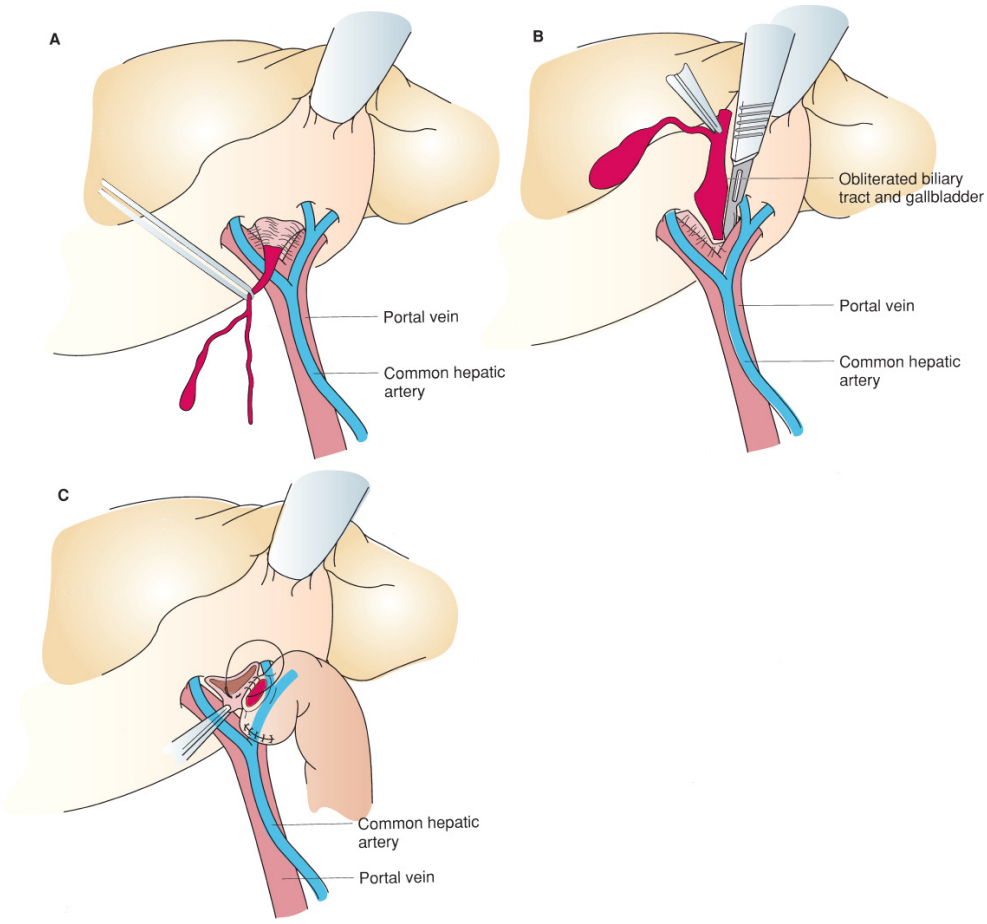

Figure 101.48 The essential features of the portoenterostomy for biliary atresia include appropriate mobilization (**A**) and transection (**B**) of the fibrous biliary tract remnant. **C:** Creation of a Roux-Y jejunal conduit with biliary enteric anastomosis completes the procedure.

Historically, some surgeons preferred to exteriorize the biliary conduit, but this practice has been abandoned due to complications and high likelihood of future liver transplantation.

Results and Complications. Following portoenterostomy, bile flow occurs in about 66% to 75% of all infants when operated on at less than 60 days of age; however, establishment of bile flow may take weeks to months. The probability of bile flow appears related to age at the time of operation.

Cholangitis is a constant concern and an important postoperative problem after portoenterostomy. The clinical signs include fever, leukocytosis, and decreased bile flow in the absence of other systemic illness. All patients are

at risk for the development of postoperative cholangitis, but reported postoperative rates of cholangitis are 40% to 50%. Cholangitis following portoenterostomy is characterized by a systemic inflammatory response and may be associated with progressive liver injury. Treatment is generally intravenous fluid resuscitation and broad-spectrum antibiotics. Occasionally, steroids or other anti-inflammatory agents may be helpful, whereas reoperation or endoscopic revision of the portoenterostomy usually is not.[182] In an effort to determine the optimal treatment of infants with biliary atresia, a group of investigators have formed the Biliary Atresia Research Consortium (BARC).[183] The primary objectives of the consortium are to establish a clinical database and tissue repository. A retrospective BARC study of 104 children with biliary atresia treated in the United States demonstrated that at 2 years of age, 58 patients were alive with their native liver and 42 had undergone liver transplantation.[184] Data from the United Kingdom demonstrated improved measurable outcomes in children with biliary atresia treated with Kasai portoenterostomy by regionalization of care to three centers in the U.K. health care system.[185]

Nearly all patients with biliary atresia have residual liver injury. Hepatic synthetic failure, portal hypertension with esophageal variceal bleeding, hypersplenism, and fat-soluble vitamin deficiencies can be problematic. Most institutions report 5-year survival rates between 30% and 50% for portoenterostomy alone. About 25% to 35% of patients undergoing a portoenterostomy survive more than 10 years without liver transplantation. The remaining two-thirds of children with biliary atresia ultimately require liver transplantation for survival. Although the failure rate for portoenterostomy is high, the possibility of long-term success is notable. In addition, the limited availability of infant donor organs and the technical limitations of liver transplantation in infants younger than 1 year make portoenterostomy an accepted initial treatment of biliary atresia in most centers.

Hepatic Transplantation

Hepatic transplantation is discussed in detail elsewhere in this text. For biliary atresia, transplantation offers a means of long-term survival in children with failed portoenterostomies. The current 5-year survival of children with biliary atresia who undergo liver transplantation ranges from

75% to 94.4%.[186,187] In addition, with the use of reduced-size cadaveric donor livers as well as living-related donor livers, the mortality rate for infants on transplant waiting lists may be decreasing. Indications for liver transplantation in biliary atresia include progressive hepatic failure despite portoenterostomy, growth retardation, and complications of portal hypertension. It is important to consider the consequences of life-long immunosuppression in these children, including the risks of infection and treatment-related malignancy.

Congenital Choledochal Cystic Disease of the Biliary Tract

Anatomy

The anatomic description and classification scheme for choledochal cystic disease initially proposed by Alonso-Lej et al. in 1959 and modified by Todani et al. are illustrated in Figure 101.49.[188,189] The most frequently encountered are type I cysts, accounting for approximately 85% to 90% of the lesions in most series. Type I cysts are characterized by fusiform dilatation of the entire common bile duct with only mild dilatation of the common hepatic duct; the intrahepatic ducts are normal. Variations are common and biliary atresia is occasionally seen in association with choledochal cystic disease.

Type I cysts are generally quite large and often cause displacement of neighboring viscera. The fusiform dilatation usually begins at the origin of the common bile duct, generally sparing the common hepatic ducts. The distal common bile duct is diminutive and typically is distorted mechanically by the large cyst, leading to the common clinical presentation of obstructive jaundice. The junction of the distal common bile duct and the pancreatic duct is not within the normal intramural duodenum but rather is extrinsic and proximal to the duodenal wall and the sphincter of Oddi (Fig. 101.50). It remains unknown whether the configuration of a long, extramural common channel allows greater pancreatic secretion reflux into the common bile duct.

Microscopic examination of the choledochal cyst wall reveals that the normal biliary epithelium is absent or replaced by abnormal and

occasionally dysplastic columnar epithelium. The cyst wall has normal smooth muscle with variable degrees of inflammation and fibrosis. The exception to this common histologic characteristic is the type III cyst, which is generally lined by normal duodenal mucosa. Choledochal cysts tend to have less inflammation in infancy and early childhood. In contrast, there is well-established inflammation involving the cyst and surrounding structures in the hepatoduodenal ligament in adolescents and adults.

Pathophysiology

The mechanism for the development of cystic lesions of the biliary tract is unclear. Choledochal cysts have been identified accurately by prenatal ultrasound, and it appears likely that these lesions represent abnormalities in the developing biliary tract. Several hypotheses for the development of choledochal cyst have been proposed. Whether the cystic dilatations result from abnormal recanalization of the primitive bile duct cords or from inflammation caused by reflux of pancreatic secretions into the common bile duct remains unknown. The pathophysiology of choledochal cyst is that of obstructive jaundice. The obstruction may be primarily the result of mechanical outflow obstruction of a diminutive distal common bile duct with a dilated choledochal cyst. Alternatively, a large inflammatory cyst can cause obstruction of the biliary tract and of neighboring viscera by extrinsic compression. When discovered during infancy, obstructive jaundice is usually the initial clinical finding. The liver injury is typically reversible, and progression to biliary cirrhosis is rare. The exception to this situation is type V disease, which is associated with a high incidence of hepatic fibrosis.

Other initial clinical situations include cholelithiasis and acute bacterial cholangitis secondary to diminished bile drainage. Children with type III cysts may have acute pancreatitis. Infrequently, extrinsic compression of the portal vein by a large choledochal cyst may produce symptoms and signs of portal hypertension. Abdominal pain and tenderness following minor injury may lead to an incidental diagnosis of choledochal cyst on imaging studies.

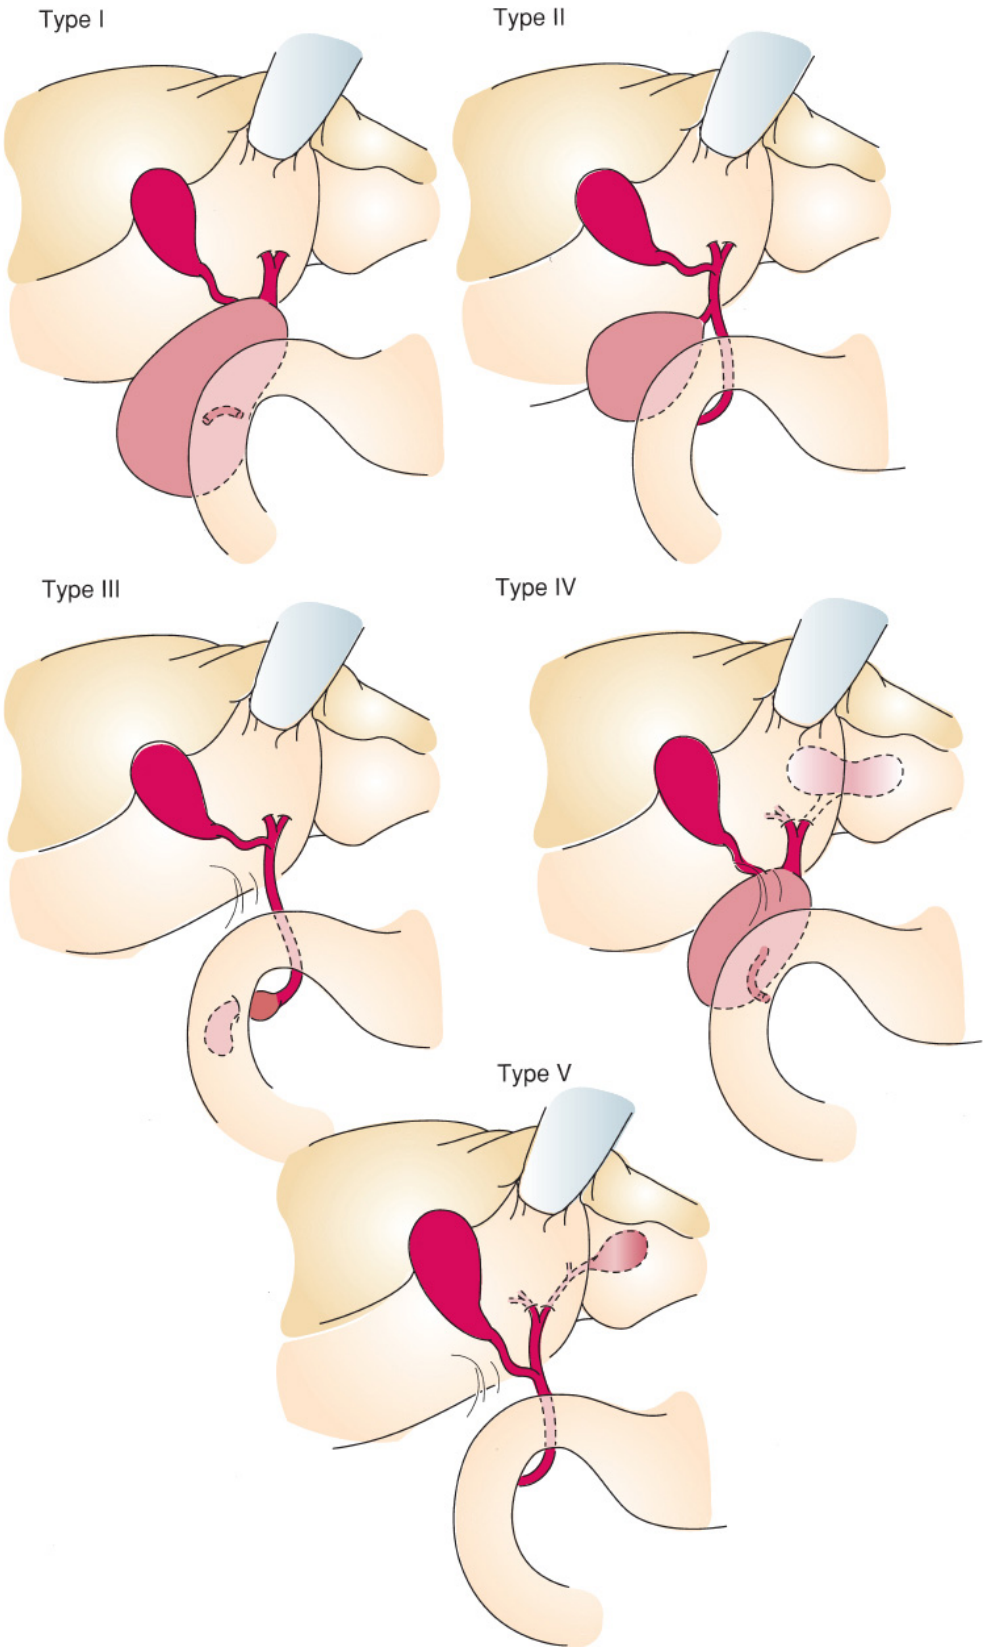

Figure 101.49 Classification of choledochal cyst.

Carcinoma of the biliary tract occurs in about 3% to 5% of patients with choledochal cyst. The number of reported cases remains small in the literature, but the incidence for biliary tract neoplasm is about 1,000 times that of the normal population.[190] Patients with choledochal cyst are at increased risk for the development of biliary tract carcinoma in adolescence or early adulthood. The dysplastic cyst epithelium may be susceptible to malignant change from chronic inflammation. Interestingly, there appears to be an increased risk of malignancy to develop anywhere in the biliary tract, gallbladder, or pancreas, and not just the choledochal cyst itself.[191] Therefore, current treatment emphasizes complete cyst excision or the cyst epithelium while providing adequate biliary drainage to prevent stasis and chronic inflammation. Infants and children treated for choledochal cyst should have long-term follow-up for complications and potential malignancy.

Clinical Presentation and Diagnosis

Choledochal cysts present most commonly in infancy and early childhood with symptoms of obstructive jaundice. In older children and adults, the classic clinical triad of episodic abdominal pain, a palpable right upper-quadrant mass, and jaundice occurs in fewer than 50% of patients. Adults occasionally present with hepatomegaly or evidence of portal hypertension. The diagnosis in infants and most children can be confirmed by ultrasound examination and ^{99m}Tc-IDA imaging studies (**Figs. 101.51** and **101.52**). In older children, both MRI cholangiography and endoscopic retrograde cholangiopancreatography (ERCP) are highly sensitive and specific in confirming diagnosis. These lesions also are diagnosed incidentally during radiologic imaging studies for other reasons. Partial duodenal obstruction may lead to an upper gastrointestinal series that shows extrinsic compression from a large type I cyst or an intraluminal filling defect from a type III cyst. CT imaging of the abdomen following blunt trauma may lead to the diagnosis of biliary tract dilatation. Liver biopsy is not specific in choledochal cyst and has little diagnostic role other than to document the extent of liver injury.

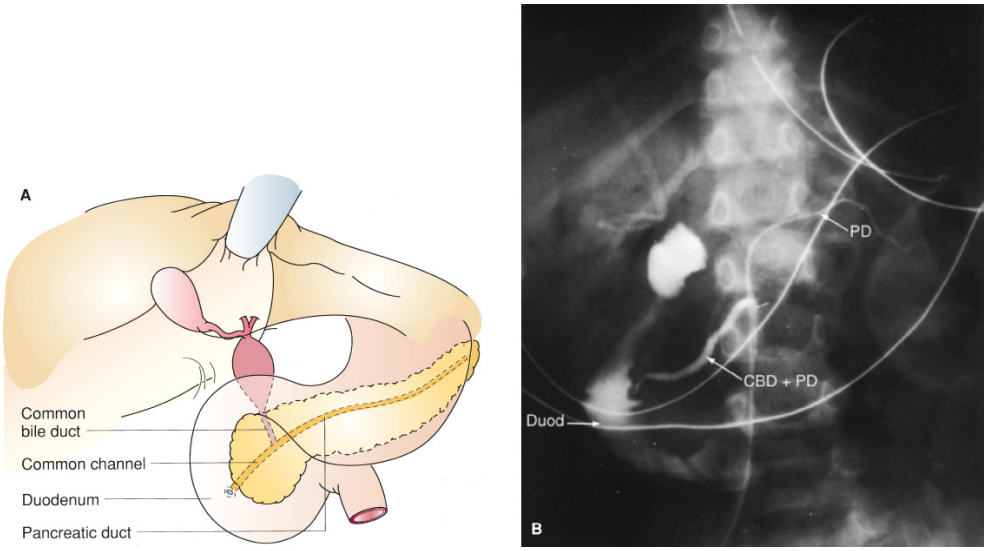

Figure 101.50 An anomalous, extramural junction between the distal common bile duct and the pancreatic duct is characteristic of type I choledochal cyst. **A:** Schematic depiction of this anatomy. **B:** Operative cholangiogram from a patient with a long extramural common channel. It has been suggested that the long common channel may allow reflux of pancreatic secretions into the common bile duct resulting in inflammation and proteinase-mediated injury to the common duct, possibly contributing to the development of the cyst itself. CBD + PD, common bile duct and pancreatic duct; Duod, duodenum; PD, pancreatic duct.

Treatment

Type I Cysts

Initial operative strategy for a type I choledochal cyst is exploration and cholangiography, usually through the gallbladder, but occasionally contrast injection must be made directly into the common bile duct. Cholecystectomy is routinely performed. Internal drainage procedures without cyst excision have been abandoned. Current consensus for the surgical management of type I choledochal cyst is performance of primary cyst excision with Roux-Y hepaticojejunostomy reconstruction (Fig. 101.53). Primary cyst excision is accomplished routinely in infants and children.[192] For adults with severe inflammation and fibrosis, dissection may present problems resulting from inflammation and adhesion of the cyst wall to the hepatoduodenal ligament. A safer approach in this situation may be intramural cyst dissection and removal of the cyst wall epithelium, leaving the posteromedial outer cyst wall adjacent to the portal vein and hepatic artery intact.

Other Types of Cysts

Type II cysts are excised completely and the choledochotomy closed primarily. Type III choledochoceles require a transduodenal approach with either marsupialization or excision of the cyst. Care must be taken to identify the ampulla, and a formal sphincteroplasty may be required to ensure adequate drainage from the biliary tract and the pancreas. Type IV and V intrahepatic cystic diseases must be approached on an individualized basis. In general, unilobar or focal cystic disease can be either resected or drained with Roux-Y jejunostomy reconstruction. Bilobar intraparenchymal disease, particularly in the setting of hepatic fibrosis, may be difficult, if not impossible, to obtain complete, adequate drainage.

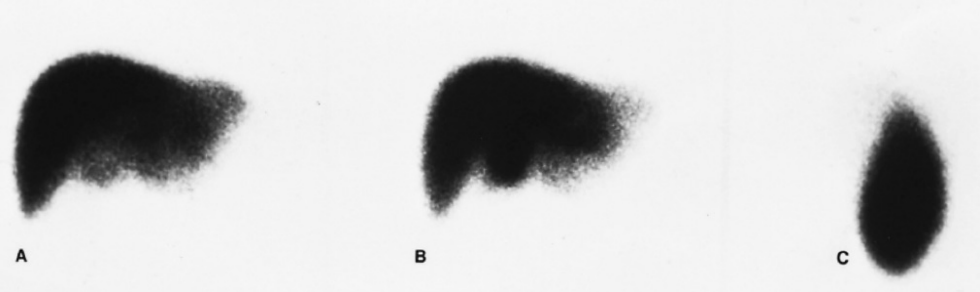

Figure 101.51 Typical ^{99m}Tc-N-substituted-2,6-dimethylphenyl carbamoylmethyl iminodiacetic acid (HIDA) scan from a child with a type I choledochal cyst. Images were made in 5 minutes (**A**), 30 minutes (**B**), and 3 hours (**C**), after isotope injection. The isotope is retained within the choledochal cyst more than 24 hours, and the pattern of hepatocyte uptake is normal.

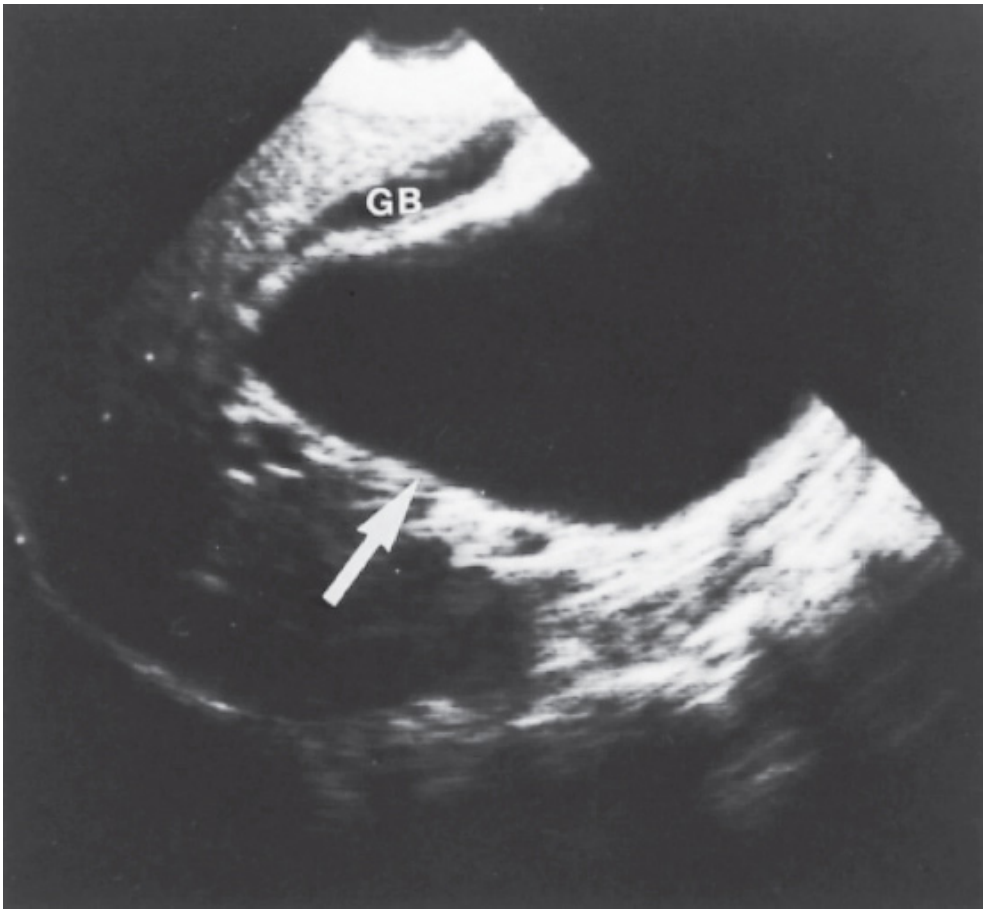

Figure 101.52 Ultrasound image of a type I choledochal cyst (*arrow;* longitudinal image). The gallbladder (GB) is also shown.

Complications and Outcome

The major complications associated with operative repair of choledochal cyst include cholangitis, stricture formation, choledocholithiasis, and development of biliary tract malignancy. A summary of the incidence of complications, mortality, and reoperation for the different procedures in 955 cases reported in the literature demonstrated a clear advantage for primary cyst excision in terms of morbidity and need for reoperation, and no significant increase in mortality occurred using this approach.[193] Currently, several series have reported excellent results with little or no mortality using total transmural excision of choledochal cysts.[194] Primary transmural excision with biliary tract reconstruction continues to be a safe and desirable operative approach for cystic lesions of the biliary tract.

PEDIATRIC PANCREAS

The embryology of the pancreas is discussed elsewhere in this chapter.

Primitive duct cells of the pancreas give rise to both the acinar cells and the islet cells of the normal pancreas. Primary islet cells become apparent at week 8 of gestation within the interlobular tissue, with acini becoming visible shortly thereafter. The primary islet cells regress after the fifth month of gestation and are usually nonexistent by term. Secondary islet cells arise from centroacinar proliferation during the third month of gestation. These intralobular cells migrate out of the acini in which they were formed and develop into islets that remain connected to the duct by a thin cellular stalk (the tubule of Bensley).

Exocrine pancreatic anomalies generally arise from defective development during embryogenesis. The most common of these conditions is annular pancreas. The circumferential distribution of pancreatic tissue around the duodenum is thought to result from interrupted migration of the ventral pancreatic anlage. Less common defects include pancreatic ductal abnormalities, pancreatic duplications, heterotopic pancreatic tissue, and congenital agenesis of portions of the pancreas.

Acute Pancreatitis

Acute pancreatitis is the most common disorder of the pancreas in both infants and children. Adult pancreatitis is often caused by either alcohol ingestion or gallstones. In contrast, 50% to 80% of cases in children, particularly adolescents, are posttraumatic or idiopathic in origin. An important clinical condition seen with moderate frequency is acute pancreatitis in the setting of immunosuppression, in particular, high-dose corticosteroids. Steroid-induced acute pancreatitis typically accounts for the third most common cause of pancreatitis in most children's hospitals. Other causes of acute pancreatitis include gallstones, CF, hyperlipidemia, juvenile diabetes mellitus, mumps, coxsackievirus infection, infectious mononucleosis, collagen vascular diseases, and anatomic lesions such as choledochal cyst. Medications significantly associated with acute pancreatitis include oral contraceptives, chlorothiazide, tetracyclines, azathioprine, and L-asparaginase. Valproic acid, an anticonvulsant useful in

some children with seizure disorders, is associated with a particularly virulent form of acute necrotizing pancreatitis that may be life-threatening.

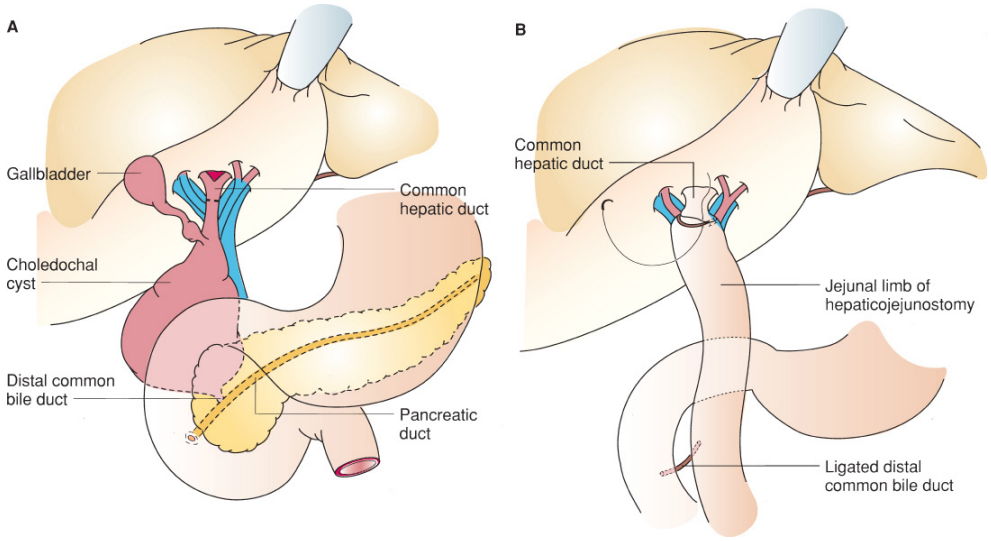

Figure 101.53 The preferred operative treatment of type I choledochal cyst consists of primary total transmural cyst excision with Roux-Y hepaticojejunostomy.

A child with acute pancreatitis presents with a history of midepigastric abdominal pain, anorexia, and emesis. On examination, the child usually has a tender abdomen with distention. Fever and leukocytosis are common. Serum amylase and lipase levels are elevated, although significant pancreatitis can occur despite a normal amylase level. Conversely, the lipase may be mildly elevated in the absence of clinical symptoms or signs of acute pancreatitis. Ultrasonography and CT imaging of the abdomen are probably the most commonly used adjunctive diagnostic tests. CT imaging is particularly useful in demonstrating edema of the gland as well as evaluating for peripancreatic fluid collections. While usually deferred during the acute phase of pancreatitis, ERCP or MRI cholangiography may be useful to evaluate the hepatobiliary tract anatomy once the inflammatory process has resolved.

Treatment principles for childhood acute pancreatitis are not different from strategies used in adults. The vast majority of children have simple edematous pancreatitis. Hemorrhagic pancreatitis and necrotizing pancreatitis are distinctly unusual in this age group but can be seen in immunosuppressed patients. Therefore, initial therapy is designed to be supportive and nonoperative in approach. Endotracheal intubation and

mechanical ventilation may be required. Intravenous fluid resuscitation, pancreatic rest by nasogastric tube decompression, analgesia, and TPN are provided. No clinical efficacy data are available to support the widespread use of anticholinergics or somatostatin analogs for acute pancreatitis in children. Operative intervention is reserved for complications of pancreatitis such as hemorrhage, infected pancreatic necrosis, or pancreatic pseudocyst.

Recurrent pancreatitis in a child usually is associated with an anatomic abnormality or specific physiologic problem. Following recovery from the acute inflammatory event, an aggressive diagnostic workup, including consideration of ERCP or MRCP to define ductal anatomy, should be performed. In particular, the presence of pancreas divisum with stenosis of the accessory papilla should be considered. Children with pancreatitis in the setting of cholelithiasis should undergo laparoscopic cholecystectomy after resolution of the pancreatitis.

Pancreas Divisum

Pancreas divisum occurs with failure of normal fusion between the dorsal and ventral pancreatic ducts. About 10% to 15% of normal persons have two separate pancreatic ducts, and up to 10% of asymptomatic persons undergoing ERCP have two complete ductal systems. The anatomic variant of pancreas divisum is not necessarily pathologic, but if the orifice of the accessory papilla is stenotic or obstructed, pancreatitis can occur.[195] Approximately 25% of affected individuals are thought to be at risk for developing pancreatitis. Because pancreas divisum is characterized by a dominant dorsal duct system dependent on secretion through the accessory papilla, stenosis of the accessory (lesser) papilla is probably necessary to produce pancreatic symptoms. Most of the experience with surgical treatment of pancreas divisum is reported in adults. Successful surgical management of children presenting with recurrent pancreatitis secondary to accessory papilla stenosis with pancreas divisum also has been reported.[196]

To diagnose pancreas divisum, ERCP is required. Endoscopic visualization of the major and accessory papillae is essential. Radiographic findings with pancreas divisum demonstrate a short or absent duct of Wirsung that does not communicate with the duct of Santorini (see Fig. 101.54).

Definitive diagnosis of pancreas divisum is made by demonstrating two separate, parallel ductal systems.

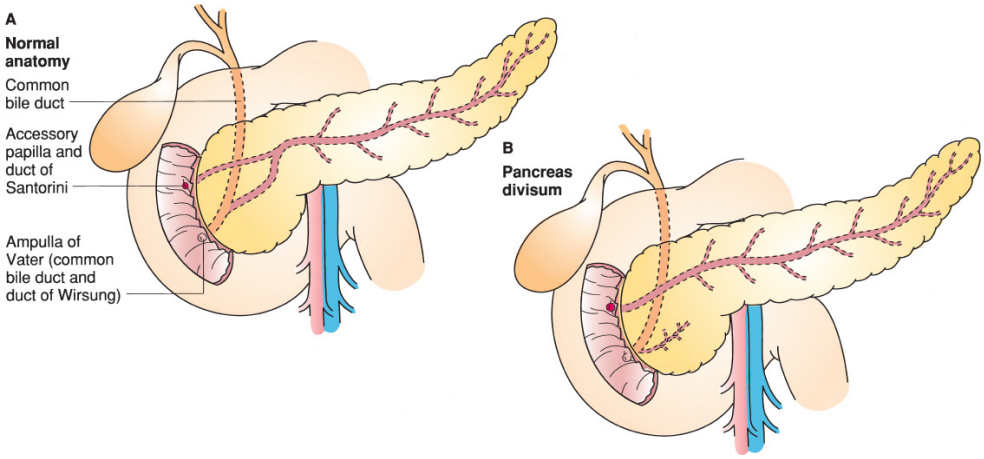

Figure 101.54 **A:** Normal pancreatic ductal anatomy. **B:** Pancreas divisum. There is no communication between the duct of Wirsung and the duct of Santorini. The duct of Wirsung is short or absent. Most of the pancreas is drained by the duct of Santorini through the accessory papilla. This anatomy is found in about 10% to 15% of normal individuals.

Few pediatric patients with pancreatitis and pancreas divisum requiring operation have been reported. Most of these children were female patients who had a history of recurrent pancreatitis. The primary operative goal is to provide adequate drainage of the duct of Santorini by performing a sphincterotomy of the accessory duct. An open dorsal duct sphincterotomy appears to be more durable than endoscopic sphincterotomy. Some surgeons advocate sphincterotomy of the main papilla as well, but dorsal duct sphincterotomy alone appears effective in preventing acute pancreatitis associated with pancreas divisum. The reported surgical outcome in the limited number of children treated for pancreatitis associated with pancreas divisum is favorable.

Pancreatic Cysts

Pancreatic pseudocysts are uncommon in the pediatric age group and are usually the result of blunt traumatic abdominal injury or acute pancreatitis. Children typically present with abdominal pain, nausea, emesis, and weight loss. There may be a palpable midepigastric mass on examination. Diagnosis

usually is made with ultrasound or CT imaging of the abdomen. The serum amylase and lipase are usually elevated.

In children, many small asymptomatic pseudocysts regress spontaneously with resolution of the pancreatic inflammation. Larger or symptomatic pseudocysts may require drainage. Symptoms and potential complications of untreated pseudocysts include hemorrhage, infection, perforation, gastrointestinal or biliary tract obstruction, or, rarely, development of pancreaticoenteric fistula. The decision to use either external or internal drainage procedures for a pseudocyst depends on the status of the pancreatic duct. In many centers, definitive external drainage of a large or symptomatic pseudocyst is performed with acceptable morbidity and mortality rates by an ultrasound- or CT-guided percutaneous approach.[197] Pseudocyst recurrence or persistent external drainage without resolution suggests significant pancreatic duct injury or complete ductal transection. Determination of whether a major pancreatic ductal injury is associated with a pseudocyst may be made by either percutaneous contrast injection of the pseudocyst or ERCP.[198] Pseudocysts associated with pancreatic duct injury may not resolve with percutaneous external drainage or endoscopic pancreatic duct stenting, so internal drainage procedures such as cystgastrostomy or cystojejunostomy with or without distal pancreatectomy may be required.[199]

Epithelial cysts of the pancreas are rare in children. Congenital cysts are lined by epithelium and acinar tissue and are seen most commonly in the body and tail of the pancreas. They may be associated with other syndromes such as von Hippel–Lindau disease, which is characterized by hereditary cerebellar cysts, retinal hemangioma, and pancreatic cysts. Congenital pancreatic cysts are typically asymptomatic unless they are large enough to cause compression or obstruction of the stomach or colon. In the absence of trauma, spontaneous rupture of a pancreatic epithelial cyst is rare. Treatment is cyst excision or internal drainage into the stomach or the jejunum.

Other rare cystic lesions of the pancreas in children include retention cysts. These cysts result from chronic ductal obstruction. They are characteristically lined by epithelium unless inflammatory obliteration has occurred. Enteric duplication cysts of the stomach or the duodenum can also be associated intimately with the pancreas and communicate with the pancreatic duct. Treatment of both retention cysts and enteric duplication cysts either within or associated with the pancreas includes excision,

occasionally internal drainage, and, if necessary, distal pancreatectomy. Not all pancreatic cysts in children can be uniformly considered benign. Suspicious lesions should be investigated thoroughly and biopsy performed. Cystadenoma, cystadenocarcinoma, and rhabdomyosarcoma associated with a pancreatic cyst have been reported. These neoplasms are treated by anatomic pancreatic resection following histologic confirmation on biopsy.

Pancreatic Neoplasms

Childhood malignant neoplasms of the pancreas are uncommon. Typically, pancreatic malignancy in childhood is found on discovery of an asymptomatic abdominal mass. Infrequently, the lesion may be found incidentally or during a diagnostic imaging workup for abdominal trauma. Jaundice may occur with a lesion in the pancreatic head causing common bile duct obstruction. The most frequently encountered lesions include islet cell carcinoma and adenocarcinoma. The treatment of choice for localized malignant neoplasms of the pancreas is surgical resection.[200] Pancreaticoduodenectomy in children can successfully control some malignancies of the pancreatic head. To promote adequate nutrient absorption and growth, children undergoing pancreaticoduodenectomy should be considered for oral pancreatic enzyme replacement and fat-soluble vitamin supplementation.[201]

Two pancreatic neoplasms seen in childhood and adolescence deserve further discussion. The *papillary cystic neoplasm* of the pancreas occurs predominantly in younger female children, is typically slow growing with low malignant potential, and is highly curable with surgical resection.[202] This tumor is thought to be a neoplasm of the ductuloacinar primordial cells of the pancreas. The other lesion is the *pancreatoblastoma,* also referred to as *juvenile adenocarcinoma of the pancreas.* Pancreatoblastoma is somewhat more common in boys than in girls and typically has slow growth with low malignant potential as well. Histologic examination demonstrates undifferentiated ductular and acinar areas with nodules of squamous epithelium, suggesting that these tumors arise from primordial pancreatic cells. Both papillary cystic neoplasm and pancreatoblastoma have more favorable prognoses than adenocarcinoma following surgical resection.

Endocrine Lesions of the Pancreas

Zollinger–Ellison Syndrome

Zollinger–Ellison syndrome is characterized by gastric hypersecretion and is discussed in detail elsewhere in this book. However, its presentation in childhood should prompt work-up for MEN syndrome. About 25% of gastrinomas occur in the setting of MEN syndrome, reviewed elsewhere in this book. At least 90% of patients with MEN type I have hyperparathyroidism secondary to hyperplasia. In addition, 30% to 80% of patients have pancreatic islet cell tumors and 15% to 50% have pituitary tumors.[203]

Hypoglycemia

There are diverse metabolic causes for hypoglycemia in infancy and childhood. These include endocrinopathies such as panhypopituitarism, hypothyroidism, adrenal insufficiency, and congenital adrenal hyperplasia (adrenogenital syndrome). Several inborn errors of metabolism interrupt normal glucose regulatory mechanisms. Systemic disease states, perinatal stress, and sepsis can predispose an otherwise normal infant to low blood glucose levels. Infants who remain unresponsive to glucose infusion typically have inappropriately high circulating insulin levels for a given blood glucose level. Hyperinsulinemia should be suspected in any infant or child younger than 1 year with persistent hypoglycemia. There are heterogeneous causes for hyperinsulinemic hypoglycemia, but the most common historical cause in infancy is nesidioblastosis, which is characterized by uncontrolled development of the pancreatic endocrine tissue that functions abnormally during infancy.[204,205] Clinically, these cells secrete inappropriately high amounts of insulin, causing clinical hypoglycemia in infants. Two distinct histologic lesions appear to be responsible for congenital hyperinsulinism. Mutations in the beta-cell K_{ATP} channel genes may lead to either focal, adenomatous hyperinsulinism or diffuse hyperinsulinism; both genotypes lead to phenotypic hypoglycemia if left untreated.

Infants with congenital hyperinsulinism usually become symptomatic from hypoglycemia within the first few hours or days of life. These infants

commonly present with neurologic symptoms such as lethargy or generalized seizures and have corresponding fasting blood glucose levels below 40 mg/dL. The diagnosis of hyperinsulinemia is supported by the clinical features of Whipple triad that includes (a) neurologic changes with fasting or activity, (b) fasting blood glucose levels below 40 to 50 mg/dL, and (c) neurologic symptoms reversed by the administration of glucose. The diagnosis is made by demonstrating inappropriately high levels of circulating insulin for a given level of blood glucose. An insulin (IU/mL) to glucose (mg/dL) ratio that is greater than 0.5 in a fasting patient is consistent with hyperinsulinemic hypoglycemia. In infants and children, an absolute insulin level greater than 5 IU/mL in the presence of a blood glucose less than 40 mg/dL is diagnostic. Ketone body production is impaired in infants with congenital hyperinsulinism.

The initial management of a hypoglycemic infant with congenital hyperinsulinism is to provide adequate glucose concentrations to prevent permanent neurologic injury. Dextrose-containing intravenous solutions are titrated to maintain blood glucose levels greater than 40 mg/dL and may require a central venous catheter. The short-term administration of somatostatin analogs to increase blood glucose levels in hyperinsulinemic states has been demonstrated to be useful.[206] Other pharmacologic agents used to reduce insulin levels and raise blood glucose concentration include diazoxide (15 mg/kg daily). The use of streptozocin to control hyperinsulinemia most often is reserved for adults with metastatic islet cell carcinoma and is not widely used in infants because of the potential side effects.

Following initial control of blood glucose and clinical confirmation of hyperinsulinemia, operative intervention should be considered a means of providing definitive control of hypoglycemia. Diagnostic imaging using CT scan imaging, MRI, or more recently, 18F-FDOPA PET scanning may be useful either to identify or to exclude a focal lesion.[207] Localization of focal lesions is important in that this approach may lead to effective glucose control with selective partial pancreatectomy and allow for preservation of normal pancreatic tissue and function.[208,209]

Operatively, the abdomen is explored thoroughly, and the entire pancreas must be visualized. Preoperative localization data guided by intraoperative ultrasound and frozen section analysis may identify focal lesions amenable to

partial resection. In the absence of a focal lesion, the infant is presumed to have diffuse islet cell hyperplasia. In this setting, the general operative strategy is total or near-total pancreatectomy.[210] Lesser procedures such as subtotal (80%) pancreatectomy do not effectively treat diffuse congenital hyperinsulinism and recurrent hypoglycemia places the infant at risk for hypoglycemic encephalopathy. Near-total pancreatectomy involves resection of the distal 95% of the gland with preservation of the spleen. The entire distal pancreas, including the uncinate process, is resected, leaving a small rim of pancreatic tissue adjacent to the duodenum (Fig. 101.55). Total pancreatectomy is usually reserved for persistent or recurrent hypoglycemia following lesser procedures. Near-total pancreatectomy controls hypoglycemia in 90% of infants with diffuse congenital hyperinsulinism. The remaining infants with persistent hypoglycemia may require further pancreatic resection. With extensive pancreatic resection, the typical postoperative course is a transient period of hyperglycemia with subsequent stabilization of blood glucose levels. Pancreatic exocrine function is ablated and oral replacement therapy is required. Despite clinical remission following resection, however, diabetes mellitus may occur as a long-term consequence in children treated either medically or surgically for diffuse congenital hyperinsulinism.[211] Therefore, these infants need long-term metabolic follow-up for both pancreatic endocrine and exocrine function.

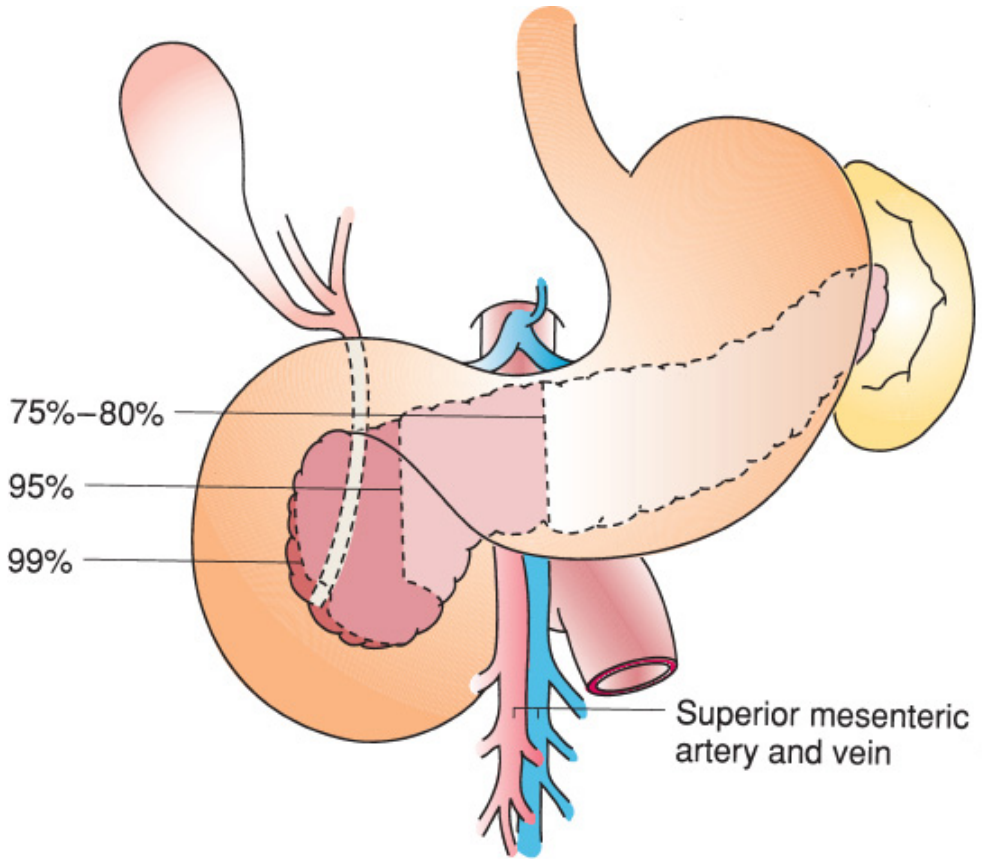

Figure 101.55 Illustration of the various degrees of pancreatic resection.

Pediatric Genitourinary System

Natalia V. Leva and Hillary Copp

Key Points

1 Embryonic kidneys develop from the intermediate mesoderm, with the definitive kidney forming as result of inductive interaction between ureteric bud and metanephric mesenchyme. Paramesonephric (müllerian) and mesonephric (wolffian) ducts contribute reproductive structures.

2 Multicystic dysplastic kidney (MCDK) is the most common form of congenital cystic disease. It rarely causes any clinical problems and involutes over time.

3 Prenatal hydronephrosis is one of the most common anomalies detected on prenatal ultrasound, however the majority are low grade and over 80% resolve spontaneously over time. The severity of hydronephrosis correlates with the likelihood of necessary intervention.

4 Ureteral duplication is a common anomaly. Upper pole ureter can be associated with either obstructing ureterocele or ectopic ureter, whereas lower pole ureter is more likely to be associated with vesicoureteral reflux (VUR).

5 VUR is an important problem to identify and manage in children who present with urinary tract infection (UTI). VUR can lead to recurrent renal parenchymal infections, resulting in renal scarring and other lifelong problems such as hypertension and kidney disease.

6 Posterior urethral valve (PUV) is the most common congenital obstructive uropathy that leads to end-stage renal failure and renal replacement therapy. These patients are at risk for developing bladder dysfunction overtime and need lifelong follow-up with urology.

7 Hypospadias is common, occurring in 1 of 200 live births. Most cases are mild, presenting with urethral opening near the distal shaft and glans. When associated with cryptorchidism, the differential diagnostic possibilities must include disorders of sex development.

8 Undescended testes occur in 3% to 4% of full-term newborn males, and are diagnosed by physical examination. Ultrasound is not a part

of the standard workup for undescended testicle. Ninety percent of testes descend by 6 months of age, and the remainder typically descend by 9 months. The AAP recommends orchiopexy around 1 year of age.

9 Mature teratoma, which is classically benign, is the most common benign tumor in prepubertal children. Yolk sac tumors are the most common malignant testicular tumors in prepubertal boys; these are associated with elevated alpha-fetoprotein (AFP). Testicular-sparing enucleation is appropriate treatment for mature teratoma.

10 Patients with neurogenic bladder disorders (most commonly secondary to spinal dysraphisms such as spina bifida) must be evaluated with urodynamic pressure—volume study to characterize its urine storage and emptying function. Managing bladder pressure and emptying with clean intermittent catheterization (CIC) is paramount to preserve renal health and improve quality of life.

1 FETAL DEVELOPMENT OF GENITOURINARY SYSTEM

Kidneys develop as paired intermediate mesodermal structures stretching craniocaudally along the length of the abdomen. The embryonic kidneys, in order of their appearance, are pronephros, mesonephros, and metanephros. *Pronephros* is nonfunctional and transitory in mammals. By the fifth week, it is replaced by the *mesonephros*. The *mesonephros* is thought to provide a transient excretory function and also provides substrate for subsequent reproductive structures. The final step in renal development is the *metanephros,* which becomes the true functional kidney. It develops in the sacral region as a result of inductive interaction between the ureteric buds (sprouting from the distal portion of mesonephric ducts) and the condensing blastema of metanephric mesenchyme. The nephron, which consists of the glomerulus, proximal tubule, loop of Henle, and distal tubule, derives from the metanephric mesenchyme, while the collecting system, made up of collecting ducts, calyces, pelvis, and ureter, is formed from the ureteric bud.

The kidneys ascend from their initial pelvic position to their final position in the upper retroperitoneum.

At fifth week, the terminal portion of the endoderm-lined yolk sac dilates to become the cloaca. It is partitioned by the developing urorectal septum to form urogenital (UG) sinus anteriorly (future vesicourethral canal and vaginal vestibule) and anorectal canal posteriorly. During the fifth week of development, primordial germ cells migrate from the yolk sac to the posterior body wall near the mesonephros to form the genital ridges. In males, under the influence of SRY (the sex-determining region of the Y chromosome), primordial germ cells begin to differentiate into Sertoli cells, which then drive the formation of testis cords and Leydig cells (responsible for producing androgen). In females, the *paramesonephric ducts* (lying medially adjacent to the mesonephros; also known as the müllerian ducts) develop into reproductive structures, namely the uterus, and fallopian tubes. In males, mesonephric ducts (known as the wolffian ducts) develop into vas deferens and epididymis under the influence of androgen. The presence of müllerian-inhibiting substance (MIS) produced by Sertoli cells in a developing testicle causes müllerian ducts to regress in males. In females, in the absence of Sertoli and Leydig cells, mesonephric (wolffian) ducts regress and müllerian ducts continue to develop into female reproductive structures. Starting in the sixth week, under the influence of dihydrotestosterone (converted intracellularly from testosterone by the enzyme 5-alpha reductase), the genital tubercle elongates and the genital and urethral folds fuse in the midline to form the scrotum, penis, and penile urethra. Under the influence of androgens, the tubular urethra forms by canalization of the urethral plate to form a wide diamond-shaped urethral groove whose edges fuse in the midline, known as the zipper theory.[1] Both developing testicles and ovaries move to the pelvic location by the third month. In males, with androgen-influenced regression of cranial suspensory ligament and swelling/contraction of gubernaculum, the testicles undergo inguino–scrotal descent during the third trimester.

ANOMALIES OF THE KIDNEY

Renal anomalies can be categorized into several recognized variants in position, number, and shape.[2] When the kidney does not move to the normal expected position, it is termed an *ectopic kidney.* A kidney that fails to ascend and remains near the bladder becomes a *pelvic kidney,* thought to occur in 1 of 3,000. It can travel too far and rise above the ipsilateral diaphragm to become an *intrathoracic kidney.* It can cross over to the other side and end up in a contralateral position as a *crossed ectopic kidney.* Crossed renal ectopia occurs with renal parenchymal fusion in 90%. Unlike the more commonly encountered ureteral duplication, crossed ectopic kidney's ureter crosses over the midline and drains into the bladder on the contralateral side and thus the trigone appears normal on cystoscopy. In 30% to 50%, ectopic kidneys can have varying degrees of hydronephrosis and vesicoureteral reflux (VUR). Most ectopic kidneys are asymptomatic and clinically insignificant, except in cases of associated ectopic ureter. The adrenal glands develop independently from the kidney, and should be in normal position beneath the diaphragm, even if the ipsilateral kidney is ectopic. The possibility of an ectopic kidney must be entertained if a kidney is missing in the usual location during an exploratory laparotomy.

The embryonic metanephros can become fused at their caudal ends. The most common form of this anomaly is the *horseshoe kidney,* so named because the lower poles of the kidneys are linked either by a fibrous band or a section of functional tissue. It has an incidence of 0.2%. Horseshoe kidneys are notable for their low position in the body due to isthmus trapping by the inferior mesenteric artery. VUR and ureteropelvic junction obstruction (UPJO) have been found in up to 50% of patients with a horseshoe kidney.

In addition to anomalies of position and fusion, there can be an extra or *supernumerary kidney.* This very rare finding is usually discovered incidentally and occurs because there is separation of the metanephric blastema allowing a distinct kidney to develop. This should not be confused with a duplicated system where there are two collecting system draining a single kidney.

Failure of the ureteric bud to form or join the metanephric mesenchyme will result in *renal agenesis.* Bilateral renal agenesis is very rare and infants with this condition are either stillborn or perish soon after birth due to respiratory failure. The characteristic Potter face and the presence of severe oligohydramnios are pathognomonic. When unilateral renal agenesis occurs,

it is associated with a variety of other genitourinary findings; about 50% will still have a vestigial ureter, and about 30% will have VUR. Anorectal anomalies are also common. Müllerian duct anomalies—such as uterine duplication or vaginal septum—occur in 25% to 50% of females with unilateral renal agenesis, and likewise, up to one-third of females with müllerian duct anomalies will have unilateral renal agenesis. It is important to note that true agenesis is relatively rare and should not be confused with a regressed dysplastic kidney, which is often the fate of a *multicystic dysplastic kidney (MCDK)*.

2 Cystic Conditions of the Kidney

Renal cystic conditions are among the most common causes of pediatric abdominal masses, especially in infants.[3] It is important to accurately diagnose them due to their different prognoses and other associated conditions (**Table 102.1**).

MCDK is the most common form of nonheritable renal cystic condition.[4] Prior to prenatal sonographic screening, it used to be the most common cause of an infantile palpable abdominal mass and was often confused with the UPJO. MCDK is a developmental anomaly resulting in multiple noncommunicating cysts of varying sizes and is without identifiable renal parenchyma. There is typically an associated atresia of the ureter. The classic ultrasound findings are: absence of a large central lucency (i.e., no dilated, central renal pelvis); variably sized, noncommunicating cysts; and absence of renal parenchyma. MCDK is nonfunctional, and nuclear scintigraphy shows no activity. Majority of MCDK will involute and become undetectable on conventional ultrasound. For patients with a very large MCDK, they may not complete involution and a small residual clump of cysts may persist into adulthood. In these patients, there is a high incidence (15% to 25%) of contralateral VUR. Several long-term registries have shown that patients with MCDK do well, and previous concerns of hypertension, infection, malignancy, and pain are thought to be very rare. Surgery is rarely necessary unless there is confusion about the diagnosis with a cystic Wilms tumor or failure to regress with worrisome changes on serial imaging. Rarely, it will cause any symptoms.

Table 102.1 Classification of Congenital Renal Cystic Diseases
Inheritable
Autosomal recessive (infantile) polycystic kidney disease (ARPCKD)
Autosomal dominant (adult) polycystic kidney disease (ADPCKD)
Juvenile nephronophthisis Medullary cystic disease Congenital nephrosis (familial nephrotic syndrome) Familial hypoplastic glomerulocystic disease Renal cystic syndromes (tuberous sclerosis, von Hippel–Lindau disease)
Noninheritable
Multicystic dysplastic kidney (MCDK)
Benign multilocular cyst (cystic nephroma)
Simple cysts
Medullary sponge kidney Acquired renal cystic disease Calyceal diverticulum

Autosomal recessive polycystic kidney disease (ARPCKD) results from mutations in the PKHD1 gene of the chromosomal locus 6p12.2. The classic presentation is a child born with bilateral large palpable kidneys that appear very echogenic on ultrasound. The hyperechogenic appearance is due to the multiple cystic surfaces reflecting the sonographic waves. Kidney function is uniformly poor, and oligohydramnios with pulmonary hypoplasia occurs in up to 50%. Among those who survive infancy, 30% progress to end-stage renal failure. Long-term survivors can also develop portal hypertension, esophageal varices, and hypersplenism due to concomitant periportal fibrosis. There is no specific therapy other than kidney transplantation.

Autosomal dominant polycystic kidney disease (ADPCKD) affects 1 in every 400 to 1,000 people. It primarily affects the kidneys but also can have significant effects on the pancreas, liver, brain, and blood vessels. The most

common period for onset is postpubertal with most patients progressing to renal failure by the fourth to sixth decade of life, depending on the severity of penetrance. However, it can present at any age, including the newborn period. Usually, the earlier the onset, the more severe the disease.[5] Two gene mutations are associated: PKD1 (85%) and PKD2 (15%) on chromosome 16. These genes encode membrane proteins that affect cilium and calcium signaling. Cysts are present in the pancreas and liver, as well as cerebral berry aneurysms in the circle of Willis.

Acquired renal cystic disease of renal failure (ARCD) is a term that refers to the development of renal cysts in patients with end-stage renal failure. Regardless of the type of therapy (peritoneal or hemodialysis), cysts can develop in the kidneys. The longer the period of time of dialysis the more prevalent the cysts become. By 10 years of dialysis, 90% will have cysts. Transplantation and the restoration of normal renal function lead to cessation and regression of the cysts. The cysts are notable because they can bleed and develop infections. More worrisome is the development of renal cell carcinoma in about 0.2% of patients with ARCD. The condition occurs in equal frequency in adults and children.

There are other conditions that are associated with renal cysts. *Tuberous sclerosis* is an autosomal dominant condition characterized by developmental delay, epilepsy, sebaceous acne, and renal mass. The renal tumors are benign hamartomas (usually angiomyolipomas), but cysts are also common. *Von Hippel–Lindau syndrome* is an autosomal dominant condition with cerebellar hemangioblastoma, retinal angiomata, pheochromocytoma, renal cell carcinoma (30% to 40% of all VHL patients), and cysts of the pancreas and kidney.

Solitary Kidney

Patients with a solitary functional kidney in most cases can be expected to live a nearly normal life with few limitations.[6] Solitary kidney can be due to surgical removal for disease, congenital malformation, trauma, regression of an MCDK, renal donation, or in rare cases, true agenesis. In general there are no limitations on sports or other activities. Participation in contact sports (such as football, rugby, and ice hockey) is allowed with the understanding that the participant use all of the needed protective gear and that the risk of

injury leading to organ loss is very small but not zero.[7] The official position of the American Academy of Pediatrics is to allow participation in general. It is advisable that patients know their history and be able to identify the side of their functional kidney. It is also important to be aware that not every protective gear is subject to standardized testing and evaluation. Helmets used in American football, soccer shin guards, and eye protections are regulated, but most abdominal paddings are not. Therefore, although it would seem that protection should be helpful, use of such gear should not give a false sense of security.

Figure 102.1 Ultrasound demonstrating dilated renal pelvis and calyces caused by ureteropelvic junction obstruction.

3,4 ANOMALIES OF THE URETER

Ureteropelvic Junction Obstruction

UPJO is the most common form of congenital ureteral obstruction.[8] Multiple factors lead to poor transit of fluid across the obstructed UPJ. There can be an intrinsic adynamic portion of the ureter wherein the muscles lining the UPJ are aberrant. The muscle fibers are deficient and replaced with collagen. The

net effect is to alter the normal propagation of the peristaltic waves. In addition to these intrinsic issues, there can be extrinsic factors such as fibrous bands or aberrant lower pole crossing vessels trapping the ureter at the UPJ.

The classic symptoms of UPJO are flank/abdominal pain, hematuria, and infection. Inexplicable vomiting may be mistakenly termed idiopathic. Today many UPJO cases are diagnosed antenatally due to abnormal prenatal ultrasound (**Figs. 102.1** and **102.2**). Ultrasound findings of dilated renal pelvis and calyces without ureteral dilation are indicative of UPJO, but it cannot definitely establish the presence of a true surgical obstruction. Functional study, such as diuretic nuclear renography, is commonly required to assess both relative renal function and severity of obstruction. Magnetic resonance urography is a newer modality, which is increasingly utilized because it avoids ionizing radiation and yields excellent functional and anatomic details. The drawback is that it requires the patient to remain still for the duration of the study, thus general anesthesia is typically necessary. The majority of antenatally diagnosed hydronephrosis can be safely observed with spontaneous resolution in some, especially those with a preserved relative renal function.[9]

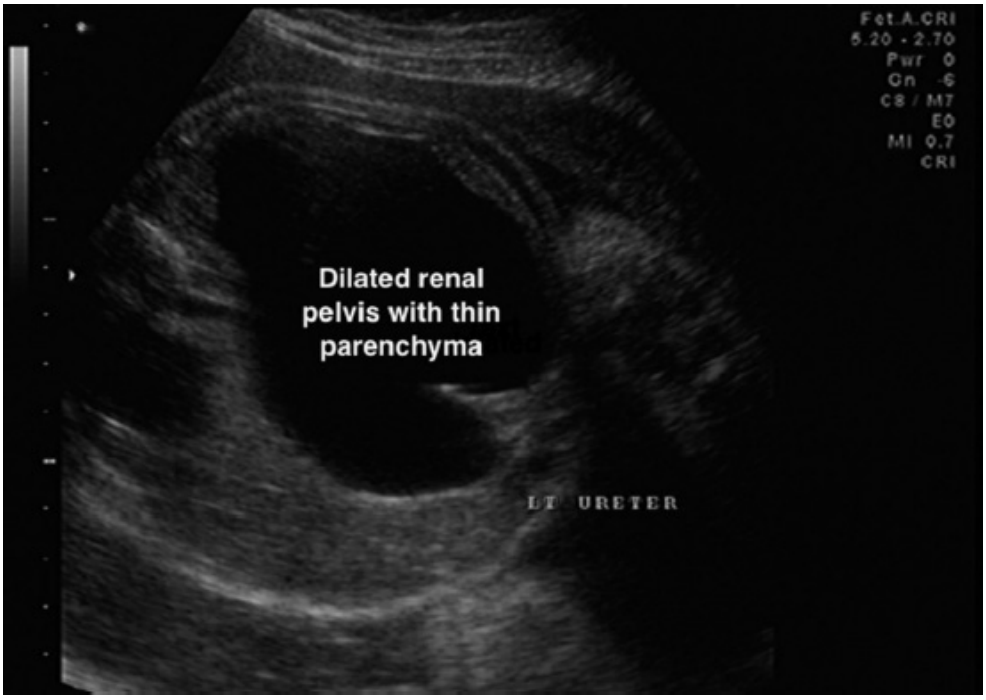

Figure 102.2 Prenatal sonography showing dilated left renal pelvis with thin parenchyma caused by ureteropelvic junction obstruction.

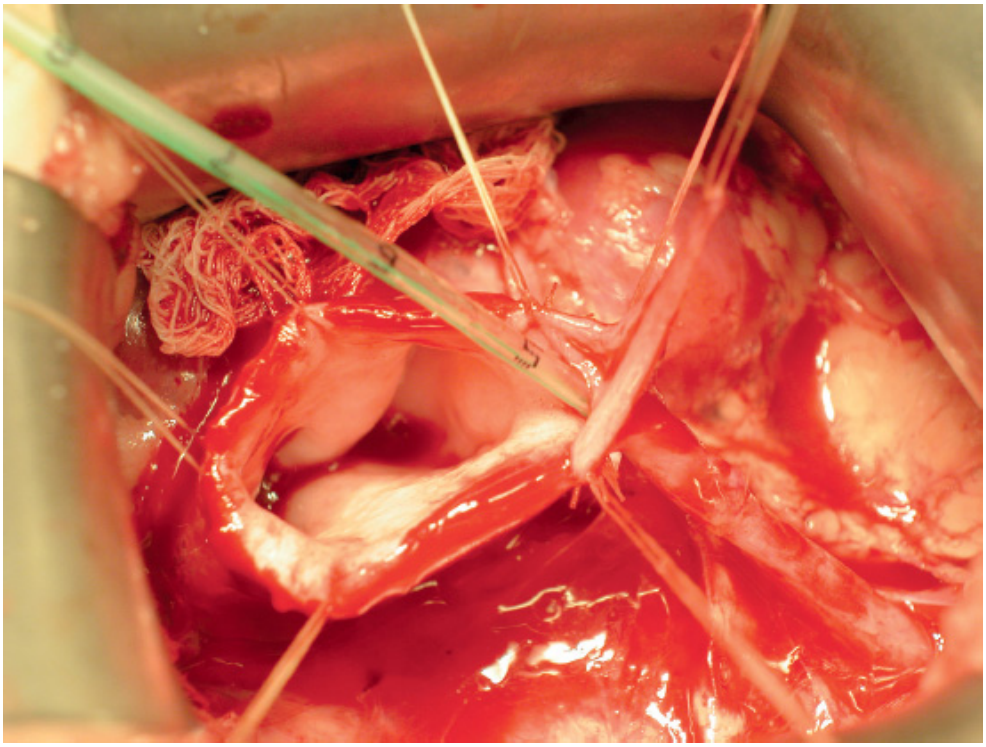

Figure 102.3 Dismembered pyeloplasty where the obstructive segment has been excised and the anastomosis is performed between the pelvic opening and spatulated ureter, creating a dependent drainage.

UPJO repair can be performed effectively using an open or laparoscopic approach, with possible aid of a surgical robot. The principle is to excise the narrowed, dysplastic portion and reconnect the ureter and renal pelvis to create a dependent drainage system (**Fig. 102.3**). This dismembered pyeloplasty can be done with a better than 95% success rate. Other approaches using renal pelvis flap are applied selectively based on the anatomy.

Ureteral Duplication

Ureteral duplication is a common anomaly of the urinary tract. The partial duplication has two ureters exiting the kidney, but they join prior to entering the bladder, so there is only one ureteral orifice in the bladder. A complete duplication has two ureters that enter the bladder separately, resulting in two orifices. These occur in about 1 in every 150 to 500 individuals. In a complete duplication, the upper pole ureter has a more inferior and medial orifice closer to the bladder neck while the lower pole ureter has a superior and lateral orifice (Weigert–Meyer rule). The more lateral position of the lower pole ureter can result in potentially shorter submucosal tunnel, making it more prone to VUR. The more medial upper pole ureter, on the other hand, can enter ectopically into the bladder neck and proximal urethra, resulting in obstruction. In females, the ectopic upper pole ureter can drain to the vestigial Gartner duct (wolffian duct remnant) and thereby open up onto the anterior lateral vaginal wall, resulting in continuous urinary incontinence. In males, the ectopic upper pole ureter can insert into reproductive structures such as vas deferens and seminal vesicle, resulting in obstruction or recurrent epididymitis. Most patients with partial or complete duplication are otherwise healthy.

Ectopic Ureter

Ectopic ureter usually drains more caudal and inferior to the normal trigone. It is commonly associated with a complete duplication as described previously. In males, they can exit into the prostatic urethra, bladder neck, and epididymis (rare). In females, they can drain into the bladder neck, urethra, and vagina. In females, an ectopic ureter that drains outside of the

bladder is the classic cause of persistent day and night wetting despite otherwise excellent toilet habits. This can be a vexing condition for many patients and families, but once properly diagnosed, it offers one of the most successful surgical solutions for incontinence (**Fig. 102.4**). Treatment is usually upper pole partial nephrectomy, upper to lower pole ureteroureterostomy, or reimplant of the upper pole ectopic ureter into the bladder.

Figure 102.4 Ectopic ureter opening outside the bladder and urethra causing continuous incontinence. Catheter is inserted into the left upper pole ectopic ureter.

Ureterocele

Ureterocele is a saccular dilation of the terminal ureter. It is classified based on location (intra versus extravesical) and number of collecting systems (single versus duplex). In duplex collecting systems, it is associated with the upper pole. The dilation varies in severity. It can be mild, contained wholly

within the bladder (**Fig. 102.5**). Or it can be massive and create a cavernous space under the trigone, extending beyond the bladder neck and into the urethra (**Fig. 102.6**). Ureteroceles are typically associated with the upper pole ureter of a complete duplication as described previously. Single-system ureteroceles do occur but are rare. Similar to UPJO, they are often found during an antenatal hydronephrosis evaluation. Other common presentations include symptomatic urinary tract infection (UTI) or prolapse. Infected ureterocele can cause severe sepsis and requires an emergent decompression of the ureterocele using an endoscopic transurethral puncture. Endoscopic puncture may ultimately be the only treatment required, however if patients have recurrent UTI or poor renal function of the obstructed kidney, other treatment approaches are available. Surgical approach depends on the function of the upper pole moiety. If the upper pole is functional, it is usually preserved, and the surgery is aimed at eliminating the distal ureteral obstruction at the level of the ureterocele. The dilated ureter is tapered and reimplanted into the bladder after excising the ureterocele, either separately or en bloc with the normal lower pole ureter in a common sheath. Alternatively, the upper pole ureter can be connected to the lower pole pelvis (ureteropyelostomy) near the kidney. If the upper pole is nonfunctional, a partial nephrectomy is preferred. Advances in minimally invasive surgery make laparoscopic and robotic techniques practical in even small children.

Figure 102.5 Intravenous urogram demonstrating ureterocele that has an appearance of "Pearl onion."

Megaureter

A persistently dilated ureter from the kidney all the way to the ureterovesical junction (UVJ) is referred to as a megaureter.[10] They are classified by description and causation; they can be refluxing, obstructing,

refluxing/obstructing, and nonobstructing/nonrefluxing. When it is due to an intrinsic abnormality of the distal ureter (such as aperistalsis or fibrosis of the UVJ), it is a called primary megaureter. When it is caused by another condition of the bladder (such as a neurogenic bladder or bladder outlet obstruction), it is called a secondary megaureter. Primary megaureters, like UPJO and ureterocele, are often diagnosed prenatally. The majority of moderate megaureters—especially those detected in utero—improve with observation. If they require treatment because of pain, UTI, or poor renal function, there are various temporizing management options including cutaneous ureterostomy. Definitive management is achieved with ureteral reimplantation with or without tapering of the wide ureter.

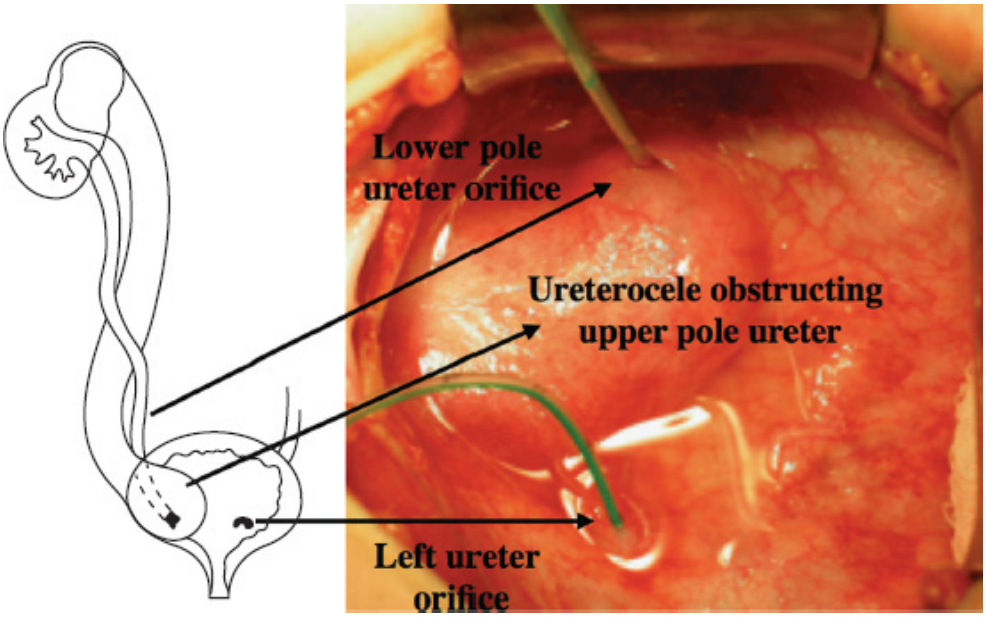

Figure 102.6 Bulging right ureterocele belonging to the upper pole. Bladder has been opened. Catheters are inserted into the right lower pole ureter and left ureter.

5 Vesicoureteral Reflux

The ureter transports urine from the renal pelvis to the bladder with active antegrade peristalsis. Once in the bladder, the urine is stored until it is emptied without sending the urine back toward the kidney. This whole process is independent of gravity. When the bladder urine moves in a retrograde manner toward the kidney, it is termed VUR (**Fig. 102.7**).[11] It is an abnormality that can occur primarily due to a congenital deficiency in the

UVJ submucosal tunnel or secondarily to high bladder pressures such as in patients with neurogenic bladder or posterior urethral valves (PUVs). The incidence of VUR in general population is estimated to be around 1%. The incidence is much higher in children who present with UTI and hydronephrosis. Among children of age 4 years or less who present with a first-time UTI, the VUR incidence can be as high as 40%. VUR is found in 25% to 30% of children with antenatal hydronephrosis. The primary form of VUR occurs because the length of the intramural tunnel is insufficient to seal the ureter during bladder filling and emptying. The secondary form usually occurs because of high storage pressure that overwhelms an otherwise normal intramuscular tunnel. Reflux is of clinical significance because it interferes with effective emptying of urine and allows bacteria to ascend to the kidneys more easily, thereby transforming cystitis into potentially damaging renal parenchymal infection (pyelonephritis). Pyelonephritis may, in turn, increase the risk of long-term kidney damage by causing parenchymal scar. Infants and children may be more prone to scarring than adults. Renal scarring and damage early in life may increase the risk of hypertension and pregnancy-related complications in females.[12,13]

Figure 102.7 Vesicoureteral reflux to the left lower pole ureter.

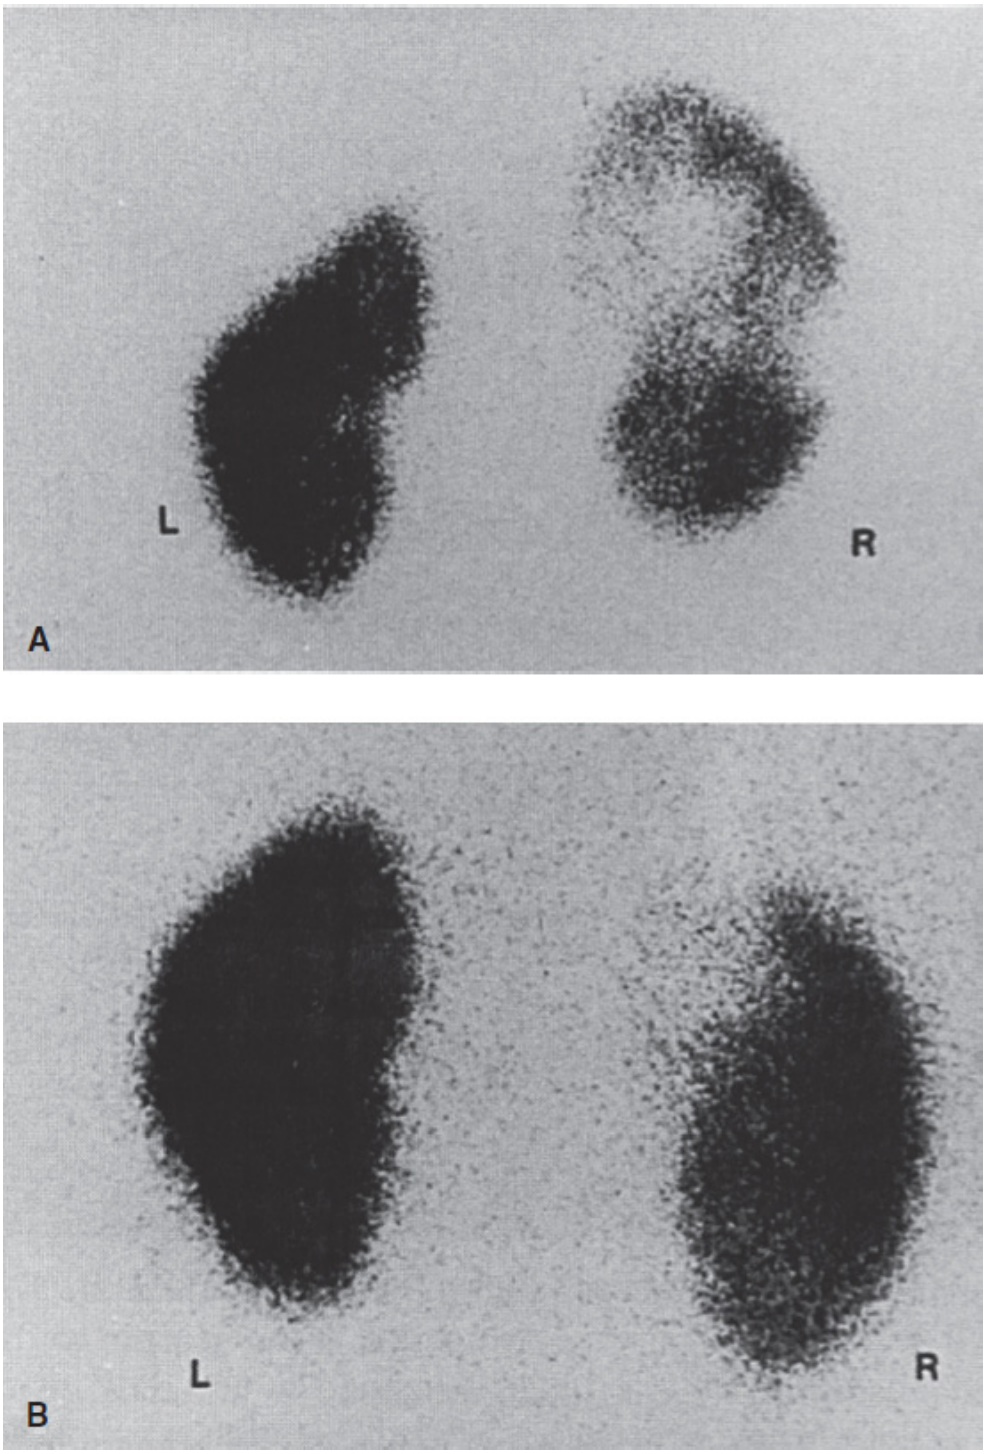

Figure 102.8 DMSA renal scintigraphy demonstrating renal parenchymal defect associated with pyelonephritis. **A:** Cortical defects seen in the right kidney during the acute phase of pyelonephritis. **B:** The same kidney 6 months later showing a persistent cortical scar involving the upper pole.

VUR severity is described using the International Reflux Study scale. Grading is important for several reasons. Most VUR patients (80%) have grades I or II with an excellent chance of spontaneous resolution (75% to 90%) over time. The higher grades (III to V) are less likely to improve with time. The diagnosis of VUR depends on the demonstration of reflux on an imaging study. Voiding cystourethrogram (VCUG) is most commonly used to diagnose reflux. It offers excellent anatomical detail of the entire lower urinary tract (bladder and urethra) and reproducible grading. In males, it provides important details regarding urethra such as possible PUVs. The presence of other anomalies such as periureteral diverticulum can affect the clinical decision making. Alternative options include nuclear cystogram (NUC) or contrast-enhanced voiding urosonography (ce-VUS) which do not require radiation. Standard ultrasound of the kidneys and bladder, while helpful in assessing renal size and appearance, cannot diagnose reflux. The detection of kidney scarring is usually confirmed with nuclear renal scintigraphy using DMSA (**Fig. 102.8**).

The management of children with VUR depends on their presentation and other clinical factors (**Fig. 102.9**). Antibiotic prophylaxis is recommended for children less than 1 year of age with febrile UTI or high-grade VUR diagnosed on prenatal ultrasound. If low-grade VUR is detected prenatally, antibiotic prophylaxis may be offered. Management of children who are older than 1 year of age takes into account bowel and bladder dysfunction in addition to grade of reflux evidence of renal scarring and parental preference.[14] The vast majority of patients have low-grade VUR and are expected to resolve spontaneously with time. The most recent multi-institution randomized clinical trial suggested that antibiotic prophylaxis is beneficial in children with dilating, high-grade reflux (grade III or higher). If they cannot remain infection free and sustain breakthrough infections, surgery may be necessary to prevent recurrent renal parenchymal infection.[15] For most patients, spontaneous resolution occurs after 4 to 5 years. However those with persistent high-grade reflux who fail conservative management may need surgery. There are two major surgical options: endoscopic antireflux surgery and ureteral reimplant. Endoscopic management consists of injection of a bulking material into the floor of the ureteral orifice. This creates a submucosal mound that turns the usual round oval ureteral orifice into an upside-down crescent. Currently, FDA-approved

dextranomer/hyaluronic acid copolymer (Deflux) is available for this approach. The efficacy of Deflux injection ranges from 70% to 80%, though current literature consists of small studies and demonstrates that rates of febrile UTI after endoscopic intervention are comparable to prophylactic antibiotics alone.[16,17] Ureteral reimplantation (ureteroneocystostomy), where the ureter is revised or repositioned to create a more effective ureterovesical flap-valve mechanism by restoring the submucosal tunnel, is the gold standard treatment for VUR. The affected ureter is detached and mobilized. A new submucosal tunnel of sufficient length (approximately three to five times the width of the ureter) is created, and the ureter is placed into it. It is critical that the muscle underneath the tunnel is firm and secure to allow the collapse of the reimplanted ureter with bladder filling and emptying. The ureter may require tapering (in megaureter or obstructed upper pole of duplication anomaly), so it can meet the needed width-to-length ratio of the tunnel. An extravesical approach is called detrusorraphy, where the muscle flaps are freed from the underlying bladder mucosa and wrapped behind the ureter at the UVJ to create a more effective flap-valve mechanism. The success rate of open surgery for VUR is very high (96% or more for grades III or less).

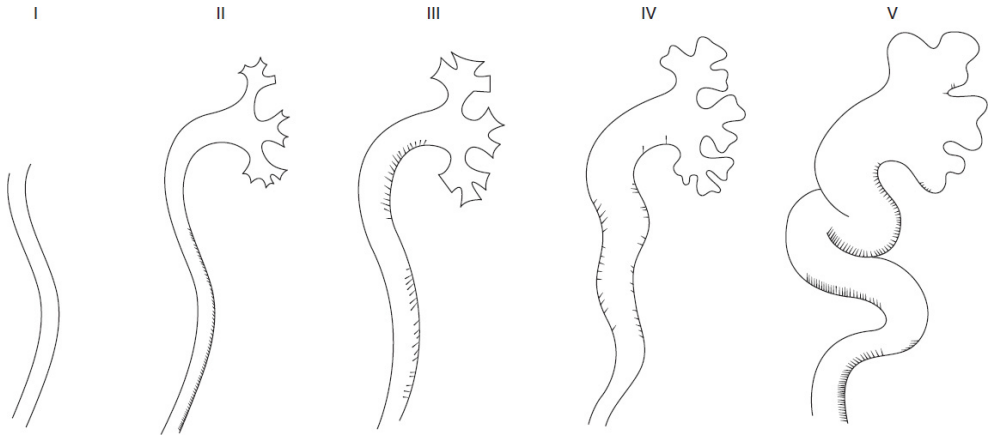

Figure 102.9 International reflux grading system. Majority of reflux are grades I or II, with high likelihood of spontaneous resolution, whereas higher grades (III to V) with dilating ureters are at a greater risk of UTI, renal injury, and nonresolution, often requiring surgery.

Traditionally, all children who present with a culture-proven UTI were recommended to undergo evaluation for VUR using ultrasound and VCUG. However, the morbidity of VUR seems to be mostly due to infections and

related complications rather than the reflux itself. It is important to stratify patients according to their risk of infection, taking into consideration grade of reflux and presence of bladder and bowel dysfunction, as not all reflux needs to be treated.[18] The goal of managing children with VUR is to prevent UTIs, renal injury and minimize the morbidity of treatment. Because most incidences of VUR are low grade and most cases of low-grade VUR resolve spontaneously, it may be reasonable to defer VCUG for only those patients who have recurrent UTIs or abnormal ultrasound. This has led to a major shift in the recommendations from the American Academy of Pediatrics (AAP) in 2011. DMSA renal imaging should be obtained to assess renal scarring and function if the renal ultrasound is abnormal. Recently a double-blind controlled randomized clinical trial looked into the benefits of antibiotic prophylaxis. The Randomized Intervention for Children with Vesicoureteral Reflux (RIVUR) study that completed in 2014 studied 600 children with proven VUR.[19] Half received antibiotic prophylaxis and half received a placebo. Prophylaxis reduced the risk of recurrent UTI by 50%, especially in those with dilating, high-grade reflux (III to V). The occurrence of new renal scarring however did not differ significantly between the two groups.

Women with a history of VUR may be at increased risk later in life for UTI during pregnancy regardless of whether the VUR was corrected or not. Renal scarring rather than the presence of active VUR itself appeared to be a key risk factor for pregnancy-related morbidity. Furthermore, there is an increased rate of VUR in offspring of parents with VUR. In general, for girls with VUR, the families should be aware that when they become adults of child-bearing age, it is important to know their medical histories, so that appropriate perinatal care and monitoring is instituted.

BLADDER ANOMALIES

Urachal Abnormality

During fetal development, urachus is the cephalad attachment of the cloaca to the allantois. As the bladder and urethral sphincter develop, it becomes atretic. It remains only as a fibrous cord from the dome of the bladder to the

umbilicus. Occasionally the urachus remains patent either completely or partially. When completely open (patent urachus), urine can be found exiting the umbilicus. In other cases, there can be a deep sinus or entrapped cyst. These can be asymptomatic and incidentally diagnosed on imaging, or they can become infected due to poor drainage and present with fever, nausea, and umbilical drainage. Detection is usually made by clinical suspicion, along with abdominal ultrasound or other imaging. Because the epithelial lining of the urachus is that of the bladder and not of the skin, rarely tumors can occur. Mucinous adenocarcinoma can arise from the urachal remnant in middle-aged or elderly patients, though the incidence is very rare. For this reason, the literature supports conservative management of asymptomatic urachal remnants.[20]

Figure 102.10 Male bladder exstrophy with associated epispadias.

Exstrophy–Epispadias Complex

During embryologic development if the cloacal membrane fails to breakdown at the appropriate time, medial migration of the mesenchyme to form the anterior abdominal wall is affected. The bladder can end up as an

exposed urothelial plate (*bladder exstrophy*) (**Fig. 102.10**).[21] The urethra may be incompletely formed dorsally (*epispadias*). The whole lower abdomen can be exposed with the hindgut or colon being unformed with the bladder split into two halves (*cloacal exstrophy*). The pelvis is also abnormally developed, and there is a diastasis of pubic symphysis.

The least severe manifestation is epispadias. In males, it is a defect with a dorsally placed urethral meatus and urethra, along with dorsal penile curvature. Visually it looks like a reverse, dorsal form of hypospadias. When the meatus is very proximal, the bladder neck and continence can be affected. In females, epispadias typically present with bifid clitoris (**Fig. 102.11**). It is more commonly associated with bladder exstrophy, but can occur as an isolated defect. Recognition and protection of the bladder plate against contact irritation is important. If possible, primary closure of the exposed bladder plate, pelvic placement, and abdominal closure should be done during infancy. Most studies have suggested that a concomitant pelvic osteotomy is beneficial for successful initial closure, especially if primary closure is delayed beyond 72 hours,[22] as well as the subsequent bladder function. Repair can be staged with closure of the bladder first, followed by subsequent bladder neck reconstruction and epispadias repair. Alternatively a complete primary repair can be accomplished with simultaneous closure of the bladder plate and reconstruction of the epispadias and genitalia. Bladder exstrophy is associated with other anomalies including inguinal hernia and VUR.

Figure 102.11 Female epispadias with its classic bifid clitoris.

The most severe form of exstrophy disease is the cloacal exstrophy. The hindgut (colon, rectum, and anus) is absent or rudimentary. The bladder plate is split into two parts on either side of the exposed cecum and hindgut remnant along with omphalocele. Initial management involves repairing the omphalocele, creating a colostomy, dissecting the bladder plates free and reconstruction to form a reservoir. In cloacal exstrophy, children are born with varying degrees of spinal dysraphism.

6 ANOMALIES OF THE URETHRA

Posterior Urethral Valves

One of the most important obstructive uropathies in males is PUVs.[23] This condition occurs when a thin membrane of tissue forms below the verumontanum and above the external sphincter, causing a blockage of antegrade flow of urine from the bladder. This results in high voiding pressures proximally leading to prostatic urethral dilation, bladder wall hypertrophy (similar to cardiac hypertrophy due to hypertension or aortic

stenosis), and VUR. Most patients today are diagnosed antenatally when they are found to have hydronephrosis. Classic prenatal sonographic findings are bilateral hydroureteronephrosis, dilated bladder, and enlarged prostatic urethra (so-called "keyhole" urethra). The poor bladder emptying throughout fetal development can result in dysplastic, poorly functioning kidneys and low urine production. Oligohydramnios (as result of low urine output) can lead to poor pulmonary development and concomitant respiratory issues. Initial postnatal treatment is to achieve immediate urethral drainage (usually with a small diameter feeding tube) and obtain VCUG when stable to establish diagnosis (**Fig. 102.12**). Most patients undergo endoscopic resection of the valves. If the patient is too small to accommodate an infant resectoscope (8.5 Fr), a temporary diverting vesicostomy may be appropriate. Supravesical diversion such as ureterostomy is rarely needed.

There are several long-term urologic concerns for boys with PUVs. PUV remains the leading urologic cause resulting in renal insufficiency and transplantation, therefore the importance of long term urologic follow-up cannot be overstated. The initial nadir creatinine with complete bladder drainage is prognostic. Patients with nadir serum creatinine values at or above 0.7 mg/dL are associated with an increased need for renal replacement therapy.[24] The early fibrosis and hypertrophy of the bladder makes valve boys more prone to develop poorly compliant bladders. These bladders have higher than normal storage pressures and over time can lead to the development of stones, incontinence, urinary retention, and worsening renal function. When recognized early, appropriate therapy using clean intermittent catheterization (CIC) along with antimuscarinic agents (such as oxybutynin) to relax the bladder muscle can help manage these so-called "valve bladders."

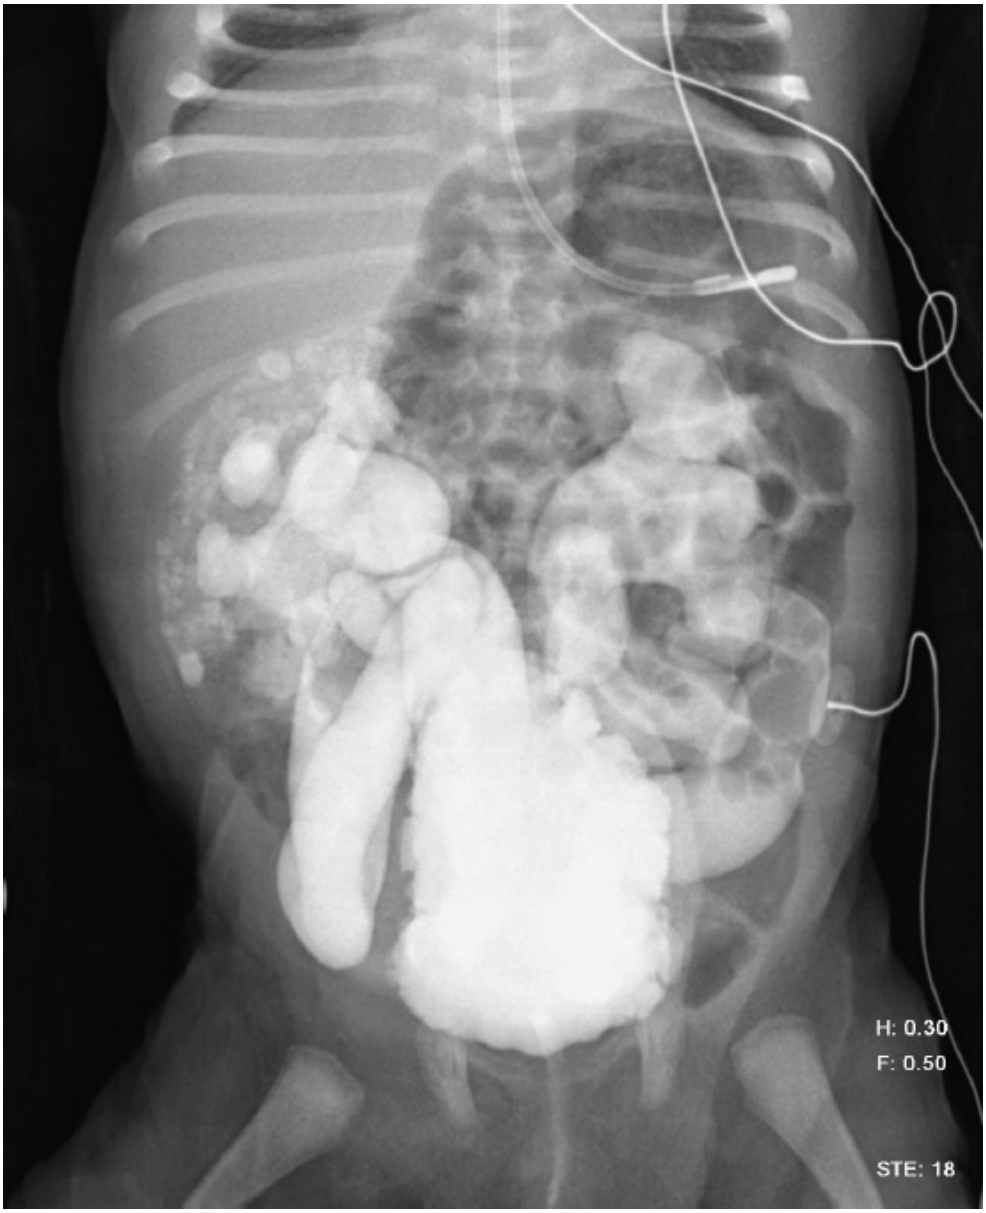

Figure 102.12 Voiding cystourethrogram of a newborn with posterior urethral valve. Bladder wall is thickened from chronic in utero obstruction. Bilateral severe vesicoureteral reflux is also shown.

7 Hypospadias

Hypospadias occurs when the ventral genital folds do not fuse completely.[25] The majority of cases do not have a known cause. There are a few important associations. When hypospadias is found concomitantly with one or more undescended or missing testicles, the probability of a disorder of sex development (DSD) is high enough to warrant a formal workup. Recently

there has been a growing interest in the role of endocrine disruptors. These are a class of agents that are not steroids but may act on steroid receptors. They include agents such as bisphenol A, polychlorinated biphenyls, phytoestrogens, and other common commercial and industrial compounds. They can fully or partially mimic natural hormones by binding with androgen receptor, thus altering the effect of endogenous sex hormones.

There are three anatomic elements in hypospadias: the urethral opening is proximal, the ventral shaft is less well developed and classically curves toward the scrotum (called ventral curvature or chordee), and the foreskin is deficient creating a dorsal hooded foreskin (**Fig. 102.13**). Most cases (80%) are distal with the meatus between the tip of the penis and the corona. Not all cases require surgery. Milder forms which do not interfere with normal voiding and whose erections are sufficient for future sexual intercourse may not need correcting, other than for cosmetic concerns. Circumcision should be delayed if a newborn is suspected to have hypospadias.

Surgical repair aims to create a functional penis that allows stand-up voiding and straight erections with good cosmesis.[26] The urethral meatus is advanced to the orthotopic position on the glans with a slit-like opening and any significant ventral curvature is corrected as well. There are a variety of techniques that can be used depending on the severity of the hypospadias. These are performed as a single stage or in multiple stages for the severe type (**Fig. 102.14**). The prepuce is an important source for free and vascular flaps. In some cases, particularly those who have undergone failed prior attempts at repair, there may not be sufficient local tissue. Grafts taken from the buccal mucosa of the inner lip or cheek can be used effectively to form a urethra. Complications of hypospadias repair include urethrocutaneous fistula, stricture, meatal stenosis, recurrent ventral curvature, and surface skin irregularities. Long-term follow-up is important for these patients because complications can occur years after the total repair.

Figure 102.13 Mild hypospadias with urethral meatus located near the neck (corona), along with dorsal hood foreskin.

Differences in Sex Development

When the genitalia do not develop in a manner that is clearly male or female in appearance, the term disorders in sexual development (DSD) is applied.[27] It replaces older terms such as hermaphroditism. This is an evolving field

and covers a spectrum of conditions, some of which can pose a significant physiologic and mental health risk. There are important concerns regarding gender assignment and genital reconstruction. For these reasons, children with DSD should receive care at a center with a multidisciplinary DSD clinic comprised of experts from urology, general surgery, gynecology, genetics, endocrinology, social work, psychology, and ethics. This multidisciplinary approach provides comprehensive and systematic evaluation and management of children with DSD.

Figure 102.14 Severe hypospadias with perineal urethral opening along with severe ventral shaft curvature (chordee).

All patients with suspected DSD require a thorough physical examination, especially of the genitalia and perineum, along with a detailed pregnancy, family, and social history. Evaluations, including electrolytes, steroid levels and precursors, gonadotropins, and karyotype, are typically assessed with further specialized tests ordered as necessary. Imaging includes renal/pelvic ultrasound and genitogram. Magnetic resonance imaging, cystoscopy, laparoscopy, and gonadal biopsies may also be necessary.

Management of DSD is complex and shared decision making with the child (when possible), family, and medical team is critical. Management options may include observation, pharmacotherapy, and/or surgery. Ultimately it is the right of the affected children's parents to make well-informed decisions on behalf of their child. However, controversy and concern exist regarding the requirement for early surgery without consent by the patient when surgery is not medically necessary. Much of what is known of the long-term outcome remains anecdotal and incomplete, lacking robust clinical outcomes data to guide management during infancy. Continued research on DSD management and outcomes is necessary to better understand how to optimally address the medical, psychological, developmental, and genetic issues for each unique individual with DSD. The primary goal of the care team is to provide parents with as much information about the condition as possible, including the wide range of management options with regard to assigning sex of rearing and the impact it may have on future gender declaration, child development, and medical and surgical management.

Anomalies of the Penis and Prepuce

Physiologic phimosis, when the foreskin cannot be retracted to expose the glans, presents in all uncircumcised infant males and resolves spontaneously as the child matures. It is inappropriate and unnecessary to retract the foreskin in most boys until they are between ages of 5 and 7 years. No special care of the uncircumcised phallus is needed. Spontaneous separation due to the accumulation of sloughing skin cells and secreted oil (forming smegma) and normal erections that occur even in small children naturally lift the prepuce away from the glans. No forceful retraction should ever be done during early childhood, since it can be very painful, traumatic, and can result in foreskin tear that will heal as a solid scar.

The indications for neonatal circumcision, arguably the single most common procedure performed worldwide, remains controversial.[28] The clear-cut medical indications are not in dispute—phimosis, paraphimosis, and balanitis. Pathologic phimosis is the inability to retract the foreskin when the child is of an age when it should have occurred naturally. Treatment with topical steroid ointment of the phimotic ring has been found to have success rates between 50% and 74%. In cases where medical therapy is not

effective, circumcision is curative. For families and patients who do not want to be circumcised a dorsal slit or partial circumcision can be performed. In paraphimosis, the foreskin is pulled back but cannot be repositioned, causing a vascular constriction in the corona. Emergent reduction is required because over time the prolonged retraction will cut off lymphatic and blood flow causing glandular necrosis. Finally for patients who have recurrent bouts of infection due to entrapment of bacteria under the foreskin (balanoposthitis), circumcision may be medically advisable. Uncircumcised males under 1 year of age are at increased for UTI and therefore circumcision may be recommended for boys with underlying genitourinary anomalies that placed them at increased risk for UTI such as PUV or VUR.

Parents may elect to circumcise their infants neonatally as part of a religious rite, social or family custom, or concerns about future hygiene. Similarly, parents may elect not to circumcise their infants as part of religion, or social or family custom. Following circumcision the glans skin changes from columnar moist epithelium to a dry tougher squamous epithelium. This change and the exposure of the glans were long theorized to help increase resistance to infection to sexually transmitted diseases (STDs) and UTI. The data from the three large-scale randomized African studies on young men who underwent circumcision to assess its effect on STD transmission (notably HIV) demonstrated a statistically significant difference. However, clinically this effect has limited utility because circumcision does not prevent or cure any infection—these studies suggest that the tougher epithelium and a dry environment may lower infection-carrier risk. Penile cancer most commonly occurs in the prepuce, thus elective early removal is theorized to help prevent later cases. However, the small benefit of reducing a relatively rare condition while subjecting many children to the risk of circumcision limits this argument. Meatal stenosis is the most common long-term complication after circumcision and occurs in 5% to 7% of circumcised boys. It classically presents with upward deflection of urinary stream but also narrow stream, straining to void. Treatment is by splitting the web of skin that has developed over the urethral meatus (meatotomy).

8 ANOMALIES OF THE TESTICLE AND SCROTUM

Undescended Testicle or Cryptorchidism

Embryologically, testicles develop just beneath the kidneys.[29] During the 12th to 18th weeks of gestation, the testicles migrate down to a pelvic position just inside the internal inguinal ring. During the third trimester, the testicle travels through the inguinal canal, exits the external inguinal ring, and enters the scrotum, driven by the swelling and contraction of the gubernaculum under the influence of androgens. Patients with undescended testicles have two times the risk of developing a germ cell malignancy, and orchiopexy more significantly reduces this risk when performed prior to puberty.[30] A scrotal position is advantageous for several reasons. Descended testicles are exposed to a lower temperature environment, which is necessary for achieving full sperm development and fertility. A scrotal position makes self-examination after puberty easier, thus facilitating an early detection. Finally, undescended testicles that are positioned near the pubic bone can be more vulnerable to injury.

Physical examination plays a key part in the diagnosis of an undescended testicle. When boys are anxious or nervous, their inguinal cremasteric muscles tense up and can draw the testicle upward into the groin. This condition is termed retractile testicles. In most cases, the retractile testicle settles in the scrotal position around the time the child goes through puberty. In some, retractile testicles can ascend to the inguinal region as the boys grow older, requiring a surgical intervention. This is referred as an ascended testicle, and may occur up to 5% to 10% of boys who are followed for retractile testicles.

About 3% to 4% of normal full-term boys may have an undescended testicle at birth. The incidence is higher in premature infants. By age 1 year corrected for prematurity, this number drops down to around 1%. This figure remains stable through puberty. For this reason, undescended testicles diagnosed within the first 6 months of life are often observed in case they descend spontaneously, but at around 1 year of life surgical orchiopexy should be performed. Furthermore, leaving a testicle in an ectopic position

beyond age 2 to 3 is thought to adversely affect future sperm cell (Ad spermatogonia) development. The location of an undescended testicle may be intra-abdominal, along the inguinal canal (canalicular), or through the external ring but not in the scrotum (superficial pouch). An undescended testicle can also be ectopic, such as perineal or femoral. Finally, it can be aberrant, dysmorphic, atrophic, or nonexistent. These are usually testicles, which suffered some form of perinatal vascular compromise that was not recognized prior to birth. The testicle seems to "vanish" over the first year of life (thus called vanishing testicle syndrome).

For palpable undescended testicles, the operative approach is usually through an inguinal incision. The testicle is mobilized by detaching the gubernaculum, cremasteric muscle, and internal spermatic sheath around the cord structures, and a tunnel is created from the inguinal incision to the scrotum. There is usually an associated patent processus (up to 80% in infants), and this is separated from the cord and ligated at the internal ring. For nonpalpable testicles, the most effective initial approach is laparoscopy. The key is to find the spermatic vessels. If spermatic vessels pass into the internal ring then the laparoscope is removed and a groin exploration is done. This may lead to a small inguinal testicle, which may have been difficult to palpate in the inguinal fat. In other cases, there is an atrophic nubbin (typically within the scrotal sac) due to a probable perinatal torsion and vascular compromise. If the testicle is seen within the abdominal cavity and well away from the internal ring, the only viable surgical option may be a Fowler–Stephens orchiopexy (done as either single or two stage), where the gonadal vessel is divided and the testicle is brought down with a vassal collateral circulation (**Figs. 102.15** and **102.16**). In a staged orchiopexy, the dominant gonadal vessel is gently clipped laparoscopically, allowing the testicle to develop a dependence on the collateral circulation. At a second procedure 6 months or later, the gonadal vessel is divided, and the testicle is carefully brought down (either open or laparoscopically) with the vasal vessels. Laparoscopy has been shown to be the most effective in determining the absence of viable testicle (vanishing testicle syndrome). The pathognomonic finding is blind ending gonadal vessels. If a blind-ending vas is seen but not the vessels, one must continue to explore for hidden testicular tissue since there is an unusual phenomenon of testicular–epididymal dysjunction, where the testicle is disconnected from the wolffian structures

(epididymis and vas). One may have to look very far to locate the vessels, even going up behind the colon and near the lower pole of the kidney. Leaving testicular tissue trapped within the abdominal cavity will increase the risk of germ cell malignancy. There are currently no reliable imaging studies that obviate the need for surgical exploration, and diagnostic laparoscopy remains the gold standard. Ultrasound is not recommended because although it is noninvasive, it has sensitivity of 45% and specificity of 78%.[31] More importantly, the surgical decision and planning are not altered by ultrasound findings. For bilateral nonpalpable testicles, biochemical markers—such as HCG stimulation test or serum MIS level—may be useful to determine the presence or absence of functional testicular tissue.

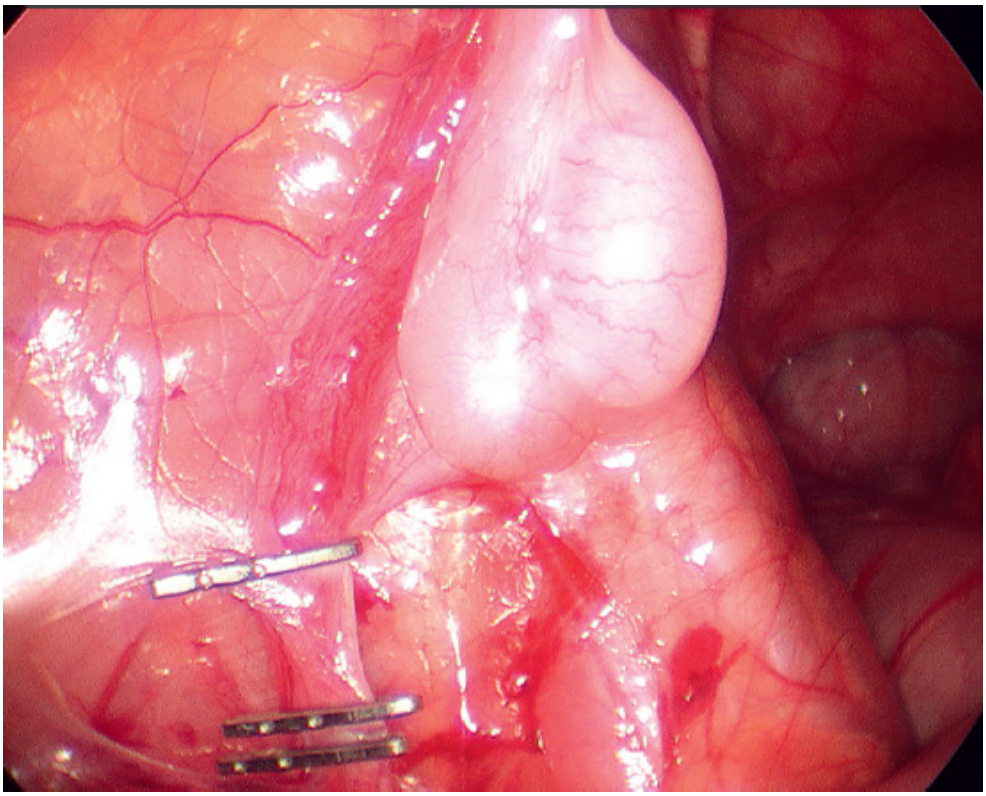

Figure 102.15 Intra-abdominal testicle is gently clipped to force its dependence on the vassal collateral circulation (first-stage Fowler–Stephens orchiopexy).

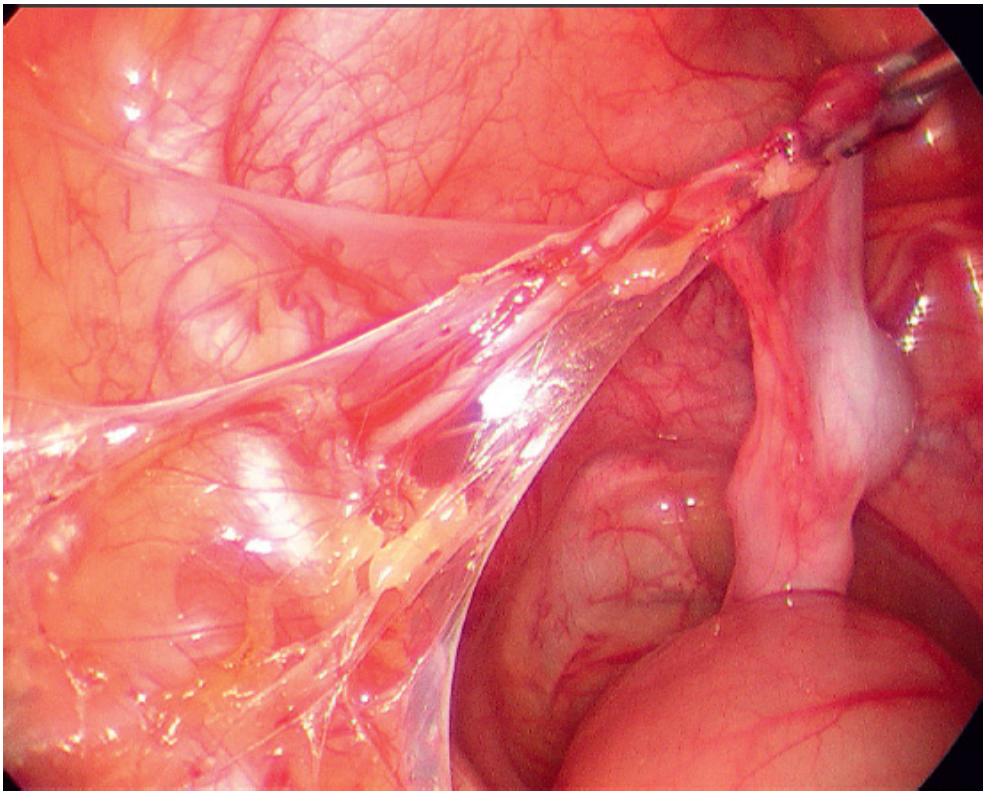

Figure 102.16 During the second-stage orchiopexy, the testicle is dissected while being attached to the vassal collateral circulation.

Torsion of Testicle and Appendages

Torsion of the testicle is the leading nontraumatic cause of loss of the testicle in boys (**Fig. 102.17**).[32] It is an emergent condition that occurs as result of the spermatic cord twisting. This results in occlusion of the lymphatic vessels, veins, and arteries leading to ischemia, necrosis, and atrophy. If there is complete occlusion of blood flow, the testicle may be salvageable up to 6 hours after onset. After 6 hours the odds of salvage diminish exponentially.[33] Most torsion occurs in older boys and adolescents—although it can occur at any age—with the torsion occurring inside the tunica vaginalis (intravaginal torsion). A horizontal lie (known as the bell-clapper deformity) caused by poor posterior fixation is believed to predispose toward torsion. Torsion can also occur among neonates, but this occurs due to poor gubernacular fixation and twisting of the cord outside the tunica vaginalis (extravaginal torsion). Neonatal torsion classically is associated with a prolonged labor. The testicle is very firm, nontender, and there can be a dark ecchymotic look

about the scrotum. Successful salvage is very rare in perinatal torsion, and exploration is controversial due to anesthesia concerns. Because of the very low salvage rate, some do not advocate an emergent exploration, while others suggest that if it is anesthetically safe, exploration is important because it establishes definitively not only the state of the suspected torsed testicle but allows fixation of the contralateral testicle. Metachronous torsion can occur and is difficult to monitor clinically. Exploration and preemptive fixation can prevent loss of the contralateral testicle.

The presentation is a sudden onset acute unilateral scrotal pain. The pain can be intense and lead to nausea and vomiting. With time, there will be increasing swelling and discoloration. The signs and symptoms will evolve over time. Initially there can be little swelling or redness. Later when the nerve endings have died, the testicle and scrotum may still be swollen and ecchymotic but less painful. Various clinical clues may help guide physical examination. These include a noticeably shortened spermatic cord, absence of a cremasteric reflex, and lack of relief of discomfort with elevation, but these are often of limited practical use when faced with an anxious patient with a tender scrotum. If one has a strong clinical suspicion based on presentation, and there are no other medical or anesthetic reasons not to go to surgery, emergent exploration—without any further imaging is appropriate. Doppler ultrasound—now readily available in most modern emergency departments—can be useful but should not delay exploration. Ultrasound can help identify other cases of acute scrotum such as torsed appendix testis, epididymitis, hernia/hydrocele, and idiopathic scrotal edema. Exploration is done through a transverse scrotal incision in each hemiscrotum or a vertical incision along the median raphe. If the testicle is necrotic, it should be removed to alleviate pain, and the contralateral testicle explored and sutured inside the scrotum in three to four quadrants to prevent future torsion. If a safe surgery is not an option, one may attempt a manual detorsion with a cord block. Untwisting as if one were opening a book (inside out) is the most commonly recommend technique, but it is by no means certain. Immediate exploration is recommended even if there is relief with manual detorsion.

Figure 102.17 Left intravaginal testicular torsion. The nontorsed contralateral testicle is also explored and secured to prevent future torsion.

When the Müllerian ducts atrophy in males, they can leave a remnant as a testicular appendage on the head of the testis. These can twist and mimic a full torsion. In pale-skinned patients, the torsed appendage during early presentation can resemble a painful small blue dot that is seen through the stretched skin. Because the appendage is vestigial and functionally useless, its torsion is managed with pain relief, anti-inflammatories, and exertion restrictions.

9 Prepubertal Testicular Tumors

There is a separate chapter that discusses common childhood tumors.[34] For this chapter, we will limit our discussion to prepubertal testicular tumors. Most testicular tumors are nonseminomatous germ cell tumors. They usually present as a distinct palpable painless mass in the scrotum. They can have a reactive hydrocele, and it is important to palpate the entire testicle before

assuming that the hydrocele is harmless. The primary imaging study is a scrotal ultrasound and biomarkers. The two most useful biomarkers are the alpha-fetoprotein (AFP) and beta-HCG. The most common types of prepubertal tumors are teratoma and yolk sac. Teratoma is benign in prepubertal age group. Histologically they contain all three germ layers (ectoderm, mesoderm, and endoderm). Due to the benign nature, testis-sparing approach is warranted. An enucleation of the mass through a tunica albuginea incision is performed if the frozen section confirms the diagnosis (**Figs. 102.18** and **102.19**). Yolk sac tumors are the most common malignant prepubertal tumor. Most present early as stage 1 (limited to the testicle and completely resected), and the AFP level will be elevated in the vast majority of cases. After radical inguinal orchiectomy, most are observed with serial imaging and tumor markers, provided that other staging workup is negative, with retroperitoneal lymph node dissection and systemic adjuvant chemotherapy being reserved for those with advanced disease (persistent retroperitoneal lymph adenopathy or increased serum markers). Seminomas and mixed germ cell tumors are extremely rare in prepubertal children, and their management should be as in adults. There are gonadal stromal tumors that can mimic a germ cell tumor. The most common are Sertoli cell tumors. They occur as painless masse and usually have no major endocrine effect. Simple orchiectomy is all that is needed. Leydig cell tumors are the second most common stromal tumor. They can be associated with precocious puberty, gynecomastia, and elevated levels of 17-hydroxy ketosteroids. They can be similar to hyperplastic adrenal nodules that are found in boys with poorly controlled congenital adrenal hyperplasia.

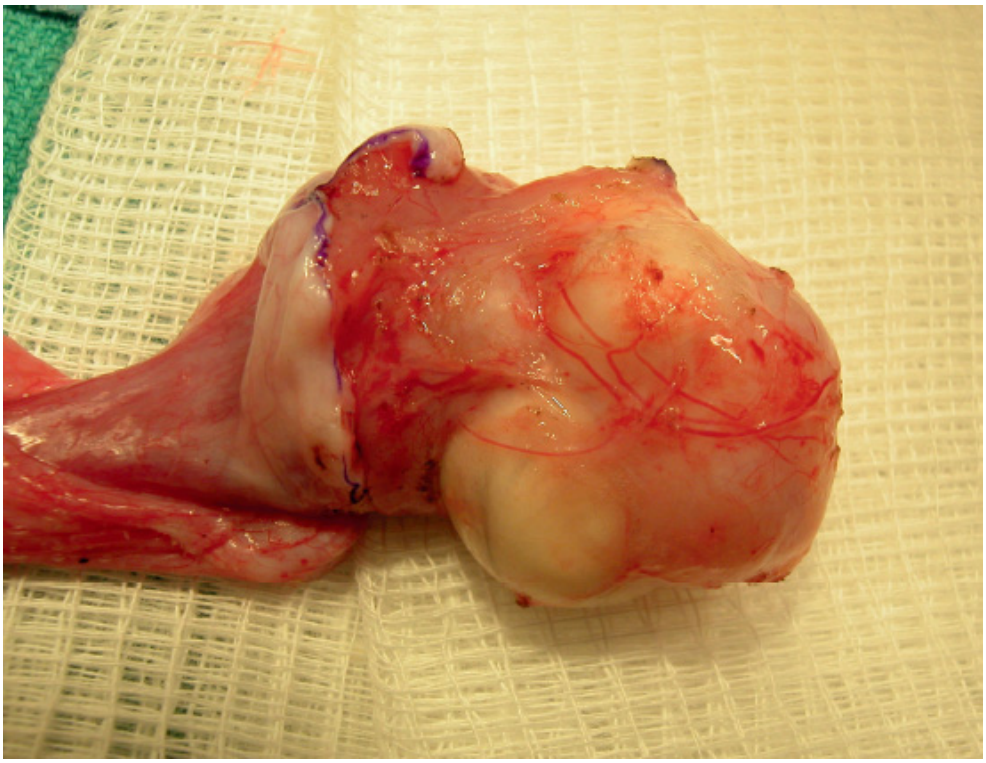

Figure 102.18 Testis-sparing enucleation of prepubertal testis tumor with cystic mass seen on the ultrasound and negative markers, likely indicating a teratoma.

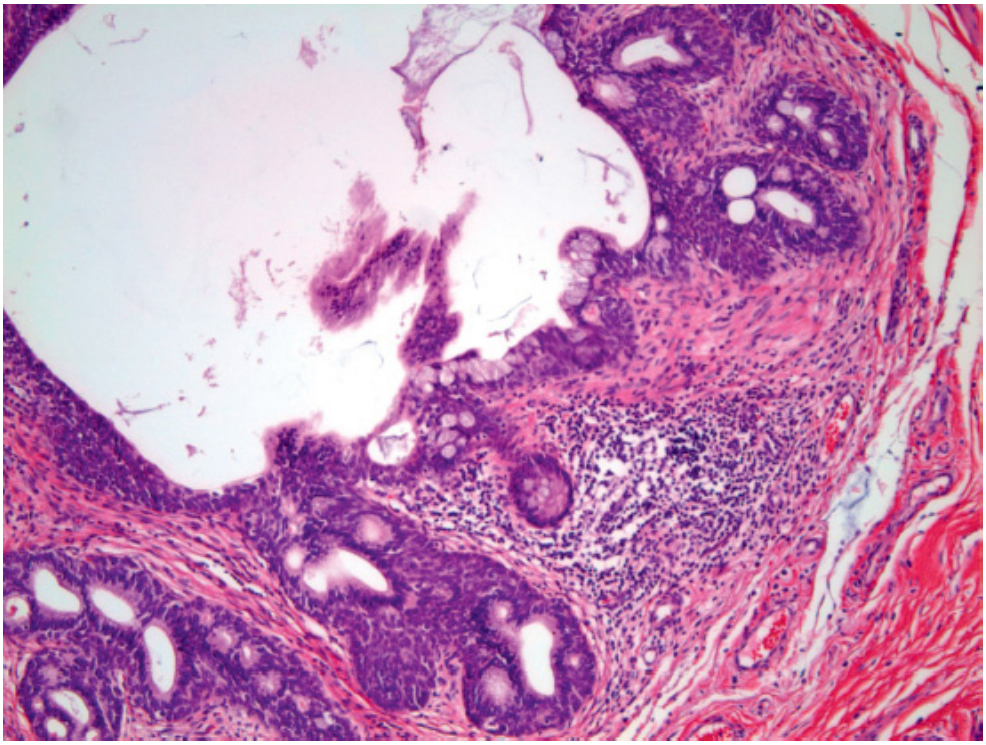

Figure 102.19 Histology of prepubertal testis tumor demonstrating mature teratomatous differentiation into ectodermal elements.

Varicocele

Varicocele is a collection of engorged varicose veins in the spermatic cord and usually is most prominent in the scrotum in the region of the pampiniform plexus. Varicoceles are graded according to their size and prominence. Grade I are varicoceles only palpable with exertion or a Valsalva maneuver. Grade II are varicoceles that can be palpated without exertion or a Valsalva maneuver and collapse when supine. Grade III varicoceles are visibly bulging and do not collapse when supine. There is also a subclinical (or grade 0) varicocele that is only detected on imaging and not on physical examination. Varicoceles are most common on the left side comprising >90% of all varicoceles. The left-sided predominance relates to the different nature of the left and right spermatic vein drainage. The right spermatic vein is shorter and inserts directly into the inferior vena cava. About 10% are bilateral. The solitary right varicocele is worrisome as it can be associated with a retroperitoneal tumor and when found warrants further evaluation with abdominal ultrasound. Varicoceles come to attention because of two major concerns. First, they can be quite sizable and uncomfortable. Second, varicoceles are associated in some cases with infertility. This is believed to be the result of two effects. The pooling of venous blood allows toxic waste products to accumulate. The pooled blood in addition may also raise the temperature of the whole scrotum. Normally, the scrotum is several degrees cooler than the deep core body temperature. At random, up to 10% to 20% of all adult males can be found to have some form of varicocele. Among men who attend infertility clinics, varicocele-associated subfertility can be as high as 40%. These observations suggest that there are many men in whom a varicocele is a trivial finding, but there are some in whom it can be an important reproductive issue. For males undergoing puberty and sexual maturation, semen analysis findings are variable and unreliable in addition to ethical concerns. For this reason, the clinical indication for intervention in boys is comparative testicular volume on ultrasound. In some, the involved testicle will have a smaller volume or lag in growth. If there is a substantial volume discrepancy (20% or greater) between the testicles, surgery is warranted. If the volumes are stable and there is no major discrepancy, observation with annual ultrasounds is recommended until the age when a semen analysis can be obtained reliably. There are several methods of

treating varicoceles; including laparoscopic, subinguinal, or inguinal incision. The vas deferens and spermatic artery are identified and may or may not be spared. The varicocele veins are then ligated and the segment between the ligatures is removed. The use of an operating microscope allows sparing of the lymphatics thereby reducing the risk of postsurgical hydrocele to well under 1%.

VAGINAL ANOMALIES

Labial Adhesions

Labial adhesions are commonly incidentally detected on well child check examinations. They occur when edges of the labia minora attach in the midline and form a thin web of skin (**Fig. 102.20**). This can obstruct the normal path of the urinary stream leading to postmicturition spotting when the girl stands up. Other symptoms include dysuria or UTI. If they are asymptomatic then there is no need for treatment and they often resolve spontaneously. Treatment in very mild cases can be successfully achieved with estrogen cream applied to the surface of the webbing over several weeks. For more severe or refractory cases, surgical incision and separation under anesthesia are needed. Minor adhesion may be left alone without clinical concerns.

Figure 102.20 Labial adhesions.

Imperforate Hymen

Occasionally the hymen will be imperforate at birth. This will present with a bulging hydrocolpos and can be confused with a prolapsing ureterocele or bladder tumor (such as sarcoma) (**Fig. 102.21**). Ultrasound or MRI can usually identify the prominent fluid-filled vagina. Puncture and drainage are

usually all that is required. In some older patients the condition may not be diagnosed until after the onset of menses. At this time, there may be cyclic discomfort due to the inability to allow the menstrual flow to pass creating a hydrometrocolpos. After a complete workup surgical drainage in the operating room is advisable to avoid introducing bacteria into the sterile collection; an infection can lead to pyocolpos or pyometrium leading to scarring and affecting future fertility.

Urogenital Sinus Anomalies

Between the fifth and seventh week of fetal development the urogenital sinus forms.[35] The caudal portion forms the lower-third of the vagina. The Müllerian ducts form the uterus as well as fallopian tubes. Anomalies can occur as part of DSD conditions resulting in either vaginal agenesis or urogenital sinus (such as that seen in masculinized females with congenital adrenal hyperplasia). Surgical reconstruction is usually required to create distinct urethral and vaginal channels. Traditional surgical approach aimed at separating the vagina from the UG sinus tract and bringing it down to the perineum, has often led to vaginal vascular compromise and stenosis. Modern techniques employ urogenital sinus mobilization en bloc, keeping the urethrovaginal confluence intact. Total mobilization has been discouraged due to concern for future urinary incontinence and pelvic prolapse. A combination of partial mobilization—leaving the anterior urethral suspensory ligaments intact—and various perineal flaps can result in an excellent outcome. The Mayer–Rokitansky–Kuster–Hauser syndrome occurs in normal genotypic females with vaginal and/or uterine dysgenesis. About one-third of these patients will have associated urologic issues—the most common being unilateral renal agenesis. The diagnosis is usually made incidentally or around the age of puberty due to amenorrhea. Treatment is vaginal dilation with estrogen cream or surgical vaginoplasty if dilation fails. There are also a variety of duplication anomalies and vaginal and/or uterine septa and consultation with gynecology is advisable on the necessity and timing of intervention. Typically the goals are to relieve any obstruction to restore normal menses and to preserve reproductive potential.

Figure 102.21 Imperforate hymen.

Prune-Belly Syndrome

The prune-belly syndrome (PBS) is a constellation of malformations also known as the triad syndrome or the Eagle–Barrett syndrome.[36] The syndrome has three key components: severe deficiency or absence of the abdominal wall musculature, bilateral hydroureteronephrosis, and bilateral undescended

intra-abdominal testicles (**Fig. 102.22**). There are also other associated genitourinary conditions including renal dysplasia, fusiform urethra, large bladder, patent urachus, hypoplastic prostate, and dilated proximal urethra. The newborn will present with a lax and wrinkled abdominal wall, along with empty scrotum. Renal dysplasia is frequent and when severe, it can lead to pulmonary hypoplasia. Stillbirths and early neonatal demise often occur because of the combination of poor renal and pulmonary function. Hydroureteronephrosis can be massive but is typically nonobstructive, and no procedure should be done simply to improve appearance. Nearly all of the patients are infertile with an anecdotal report of successful fertility using the assisted reproductive technology. For infants who survive into childhood, bilateral orchiopexy and abdominal wall reconstruction may be necessary. Evaluation for bladder function is also required since many will have a poor bladder muscle tone and high postvoid residual.

Figure 102.22 Prune-belly syndrome. Notice the wrinkled appearance of the abdominal wall due to deficiency of musculature. Scrotum is empty due to bilateral intra-abdominal testicles.

10 Neurogenic Bladder

The nervous system plays an important role in modulating the normal behavior of the lower urinary tract. There are nerve roots (emanating from the spinal cord) and peripheral pelvic nerves that carry sensory and motor signals to the bladder and urethral sphincter. Injuries or anomalies to these nerves can denervate the bladder, leading to poor emptying. The spinal cord up to the brain stem is critical to regulation of lower urinary tract function, especially the thoracolumbar sympathetic and sacral parasympathetic segments. The brain stem acts as the coordinating center. With filling, the bladder musculature—under the influence of the sympathetic input—remains relaxed thereby keeping bladder storage pressures low until emptying occurs (driven by parasympathetic input). The higher centers in the cerebral cortex allow conscious control and inhibition of reflex activity. Without this influence the bladder fills, and at a certain volume it spontaneously empties with coordination. This occurs normally in infants prior to toilet training. When the higher centers are affected (such as due to a cerebrovascular accident, tumor, traumatic brain injury, or multiple sclerosis), this control is lost or diminished and many patients will report sudden urgency and loss of urinary control. When the spinal cord is affected, the bladder will lose its inhibitory control by the brain stem and cerebral cortex and will act autonomously. The bladder will contract earlier than full capacity, and it is termed hyperreflexia. The loss of coordination between bladder muscle and sphincter, leading to poor emptying is known as detrusor–sphincter–dyssynergia.

Patients with spinal cord injury, traumatic brain injury, and acquired conditions that affect the nervous system (e.g., diabetes mellitus, multiple sclerosis, varicella zoster, brain tumors, and encephalitis) should trigger awareness about possible urinary effects.[37] Mere urine egress from the bladder is not necessarily a sign of normal voiding. It can be due to overflow incontinence or some form of dysfunctional voiding (Valsalva voiding). Likewise continence is not necessarily a sign of neurologically coordinated normal bladder function. The storage pressures can be higher than normal. When the bladder urine storage pressures are too high, it can overcome the peristaltic pressure driving urine from the kidneys down the renal pelvis and ureter. Ideally the storage pressure should be below 40 cm H_2O.[38] Above this pressure, loss of renal function will occur. A urology evaluation with

urodynamic pressure–volume assessment of the lower urinary tract should be considered if there is any condition with significant effects on the central nervous system.

Spinal dysraphism is the most common congenital cause of a neurogenic bladder in children. During development the spinal column does not form properly resulting in an exposed spinal cord, and patients are born with a neurogenic bladder and other neurologic defects. Surgical closure in utero is now being done with some evidence that volitional voiding improves.[39] The goals of effective neurogenic bladder management in the pediatric population include protecting the kidneys, achieving urinary continence and independence, and avoiding or delaying reconstructive surgery. Early evaluation of bladder storage pressures is crucial. Regular, proactive bladder pressure monitoring with urodynamics, along with ultrasound assessment of the upper tracts, has shown to reduce urologic morbidity in these patients. Children who do not empty with a safe bladder pressure require CIC. Patients with poor bladder compliance and high storage pressures may need antimuscarinic bladder muscle relaxants (such as oxybutynin). For older children, achieving social continence becomes important and a variety of surgical options may be considered in addition to CIC and antimuscarinics. Surgical bladder augmentation using intestinal segments (enterocystoplasty) is the most effective way to improve the bladder storage function (**Fig. 102.23**), but there are many well-known long-term complications, such as metabolic acidosis, mucus production, UTI, bladder stones, spontaneous perforations, and malignancy. In some patients who have difficulty with urethral CIC (such as those with severe scoliosis or girls in wheelchair), surgical creation of alternate continent catheterizable channel is an option. The Mitrofanoff procedure (the classic appendicovesicostomy where the appendix is implanted into the bladder within the submucosal tunnel for continence) can improve the quality of life significantly. If the bladder outlet is inadequate, surgical options include artificial urinary sphincter, bladder neck reconstruction with sling, and bladder neck closure. Similarly, many patients will also choose the surgical option of Malone antegrade continence enema where a catheterizable channel is created into the colon using the appendix for easy, self-administration of enema for achieving fecal continence.

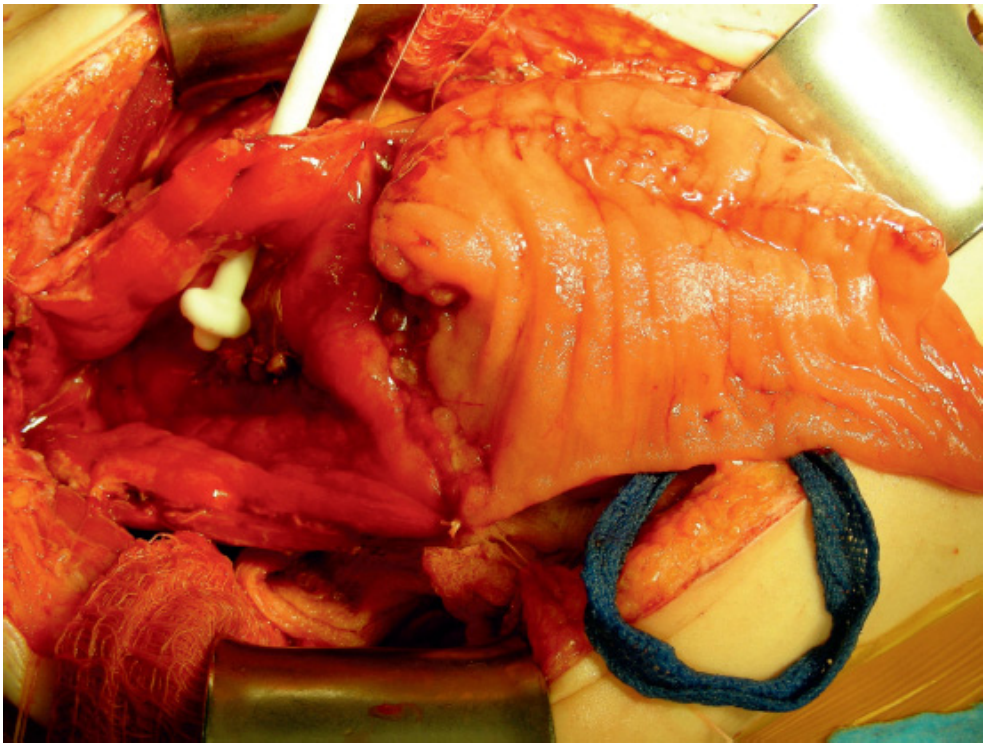

Figure 102.23 Bladder augmentation using a patch of detubularized ileum.

As children with spina bifida are living well into adulthood, consideration of long-term management of neurogenic bladder and patients with complex genitourinary reconstruction is critical. The field of transitional urology is a developing subspecialty that aims to address the needs of adolescents as the move from child-centered to adult-oriented health care.

ACKNOWLEDGMENT

This chapter is an update of a chapter previously written by John M. Park and Julian Wan. We thank them for their work in creating such an excellent chapter in the previous edition.

Childhood Tumors

Erika A. Newman

Key Points

1 Neuroblastoma occurs in the youngest of children and is the most common solid tumor in infants.

2 The landmark feature of neuroblastoma is broad clinical heterogeneity from spontaneous regression in neonates to deadly refractory metastatic disease in school-age children. This is thought to result from diverse genetic and biologic features that predict prognosis.

3 The genomic alterations that have consistently been shown to predict neuroblastoma prognosis are DNA ploidy, MYCN amplification, loss of heterozygosity (LOH) of chromosome 1p, 17q gain, loss of 14q, and loss of 11q.

4 The International Neuroblastoma Risk Group (INRG) classification system defines pretreatment cohorts based on expected survival at diagnosis. INRG classification includes INRG stage, age, histologic category, grade of tumor differentiation, MYCN status, 11q alterations, and DNA ploidy. These criteria are used to define 16 pretreatment groups that include very low-, low-, intermediate-, and high-risk categories.

5 Anaplasia is the single most important prognostic indicator in children with Wilms tumors, the second most common extracranial tumor in children.

6 In the United States, the standard of care for children with Wilms tumor starts with radical nephrectomy at the time of diagnosis for resectable primary tumors followed by chemotherapy. Radiation is administered to sites of residual and metastatic disease. Tumors with extensive intracaval and hepatic vein extension receive biopsy and neoadjuvant chemotherapy, and may require cardiopulmonary bypass for resection.

7 Treatment of rhabdomyosarcoma requires a multimodal approach that begins with complete surgical excision of resectable lesions and incisional biopsy for tumors that encroach upon contiguous

structures, blood vessels, and nerves. Modern therapies are based on prognostic factors and risk of subsequent relapse.

8 Standard surgical care for children with hepatoblastoma is complete primary resection at diagnosis for pretreatment extent of disease (PRETEXT) I and II tumors that do not involve major central venous structures. PRETEXT III and IV tumors undergo biopsy and neoadjuvant chemotherapy with early referral to a liver transplantation center for multifocal or large, central lesions.

INTRODUCTION

It is a great privilege to provide surgical oncology care for children. The surgeon is a key figure in the management of children with malignant tumors. From diagnosis through posttherapy surveillance, the surgical team has a pivotal role in ensuring the highest outcomes in the care of children with solid cancers. Surgical decisions guide clinical pathways from the mode of biopsy, central venous access for chemotherapy administration, and definitive tumor resection. Because pediatric cancers are rare with diverse presentations and histology that differ from adult cancers, the overall care of children with cancer has been improved by multidisciplinary approaches and pediatric cooperative groups set the standard in current oncologic care. The Children's Oncology Group (COG) and the International Society of Paediatric Oncology (SIOP) have made significant progress in clinical and basic science studies of pediatric malignancies and current pediatric tumor care is based upon treatment standards established through phase 1 to 3 clinical translational trials. It is a universal goal that every child diagnosed with cancer be enrolled in a cooperative group clinical trial. These trials are aimed at further understanding pediatric tumor biology and for evolving innovative treatments that have recently led to drastic rises in survival rates for various malignancies.

Compared to adults, the classification of childhood cancer is based on tumor morphology rather than emphasis on primary site in adults. The current classification scheme is the International Classification of Childhood Cancer,

Third Edition (ICCC-3) based on the third edition of ICD-0-3.[1] The ICCC-3 classifies tumors into 12 main groups that are further characterized into 47 subgroups and is used for population-based epidemiologic studies and cancer registries such as the Surveillance, Epidemiology, and End Results (SEER) program, administered by the National Cancer Institute (NCI). Utilization of a standard classification system is useful for comparing incidence and survival across regions and time periods.

INCIDENCE OF CHILDHOOD SOLID TUMORS

Each year in the United States, approximately 12,400 children and adolescents younger than 20 years of age are diagnosed with cancer. Cancer is the most common cause of disease-related mortality in children, with approximately 2,500 children dying each year. Leukemia is the most common cancer diagnosis for children 1 to 5 years of age, 5 to 9 years of age, and 10 to 14 years of age, while neuroblastoma is the most common cancer in infants. For 15 to 19 year olds, lymphomas are the most common diagnosis. Pediatric solid tumors are a spectrum of different malignancies and behind neuroblastoma, Wilms tumor is the second most common extracranial solid tumor followed by rhabdomyosarcoma. In general, there have been no large increases or decreases in pediatric cancer incidence in the last several decades when improvements in diagnostic modalities such as magnetic resonance imaging (MRI) and ultrasound are taken into consideration.

In the United States, the cancer survival rate in children has improved over time. This is largely due to multidisciplinary approaches to pediatric oncology care. There have been steady improvements in survival for childhood renal tumors, retinoblastoma, and lymphomas since the beginning of the SEER program. Although mortality rates have declined steadily for nearly all major childhood cancer categories, survival rates for high-risk tumors like neuroblastoma and rhabdomyosarcoma have not had the same survival successes.[2] Targeted immunotherapies and tumor genomic sequencing are new innovative treatment strategies that have recently provided hope for improving outcomes in resistant and refractory cases.

NEUROBLASTOMA

Epidemiology and Genetic Risk

1 In the United States, approximately 700 children are diagnosed with tumors of the sympathetic nervous system each year and of these, 650 are neuroblastoma. Neuroblastoma is the most common cancer in infancy and the most common extracranial tumor in all children. The disease accounts for 7.2% of cancers in children younger than 15 years of age. The incidence of neuroblastoma is slightly higher among males than females and is highest among Caucasians from North America, Europe, Australia, and Israel.[3] The most recent SEER data reported minimal changes in neuroblastoma incidence in the last five decades. The overall survival rate for neuroblastoma is 65% based upon SEER data from 1985 to 2000 and the disease continues to represent approximately 15% of all pediatric cancer deaths.[4,5] There is variability in 5-year survival rates based on age and stage. Survival is highest among infants and children with localized and regional disease. Black and Native American patients with neuroblastoma were found to have a higher prevalence of high-risk neuroblastoma compared with white patients, and have worse event-free survival.[6] The underlying genetic and biologic basis of this disparity is not known and warrants further study.

No causal factors for neuroblastoma have been identified. Studies examining maternal risks have been conflicting for prior miscarriage, induced abortion, repeat Cesarean birth, and vaginal infection.[7] There have been international case series reporting the use of maternal hormones for bleeding and ovulation induction. The largest study to date did not find significant association with infertility hormonal use, although results suggested an elevated risk of neuroblastoma in male offspring after maternal Clomid use.[8] These results warrant further evaluation but may serve as the focus of larger clinical studies. Parental occupation and environmental exposures have been studied.[9] They suggest that the risk of several industrial occupations, particularly power plant operators, painters, and electronic-related fields should also serve as lead points for further study. A case-control study investigating parental tobacco smoking and alcohol consumption did not find any evidence for lifestyle exposures and increased risk of neuroblastoma.[10] Associations between premature delivery (<33

weeks), very low birth weight (<1,500 g), and neuroblastoma have been observed but results are inconsistent.[7] Further investigations of parental and perinatal risk factors are required in order to draw definitive conclusions.[11]

Most cases of neuroblastoma are sporadic and data for inheritance patterns are conflicting. There are studies that link neuroblastoma occurrence with other neural crest cell anomalies such as Hirschsprung disease, neurofibromatosis, and central hypoventilation syndrome.[12] These syndromes are components of the neurocristopathies and are considered alterations in neural crest cell development that may occur with inherited loss of function mutations of PHOX2B, a regulator of autonomic nervous system development.[13,14] Despite these findings, there is not a strong pattern of inheritance of neuroblastoma and only 1% to 2% of cases are familial in an autosomal dominant manner.[15,16] Recently genome-wide sequencing studies have located heritable mutations in the anaplastic lymphoma kinase (ALK) gene as the cause of most hereditary neuroblastoma cases, the first example of a pediatric cancer arising due to a mutation in a critical oncogene.[17] Given this, genetic testing for ALK and PHOX2B should be considered in children with a family history of neuroblastoma. It is recommended that children in families found to have heritable mutations in ALK or PHOX2B undergo screening surveillance with ultrasound and urinary catecholamine metabolites.

ALK copy number mutations are also somatically acquired and highly associated with an aggressive clinical phenotype in 5% to 15% of neuroblastoma tumors.[18,19] Genome-wide association studies in sporadic cases of neuroblastoma have also recently discovered susceptibility genes that include FLJ22536, NBPF23, and BARD1 that may increase the relative risk of malignant transformation of developing neuroblastic tissue.[20–23] In general, there is a relative paucity of recurrent somatic mutations in neuroblastoma and the majority of tumors are likely driven by rare germline variants, copy number alterations, and epigenetic modifications.[23]

Pathology and Biologic Features

Neuroblastoma originates from embryonic cells of the neural crest that appear along the distribution of sympathetic nervous tissue from the neck to pelvis, most commonly in the adrenal medulla. The precise molecular

mechanisms that give rise to embryonic neural crest cells that in turn give rise to neuroblastoma are unknown. The current thinking is that defects in genes that control neural crest differentiation and proliferation underlie tumorigenesis. Peripheral neuroblastic tumors are categorized on a spectrum from malignant neuroblastoma to ganglioneuroblastoma and benign ganglioneuroma. 2 Neuroblastoma tumors have diverse clinical heterogeneity from complete spontaneous regression in neonates to resistant metastatic disease in school-age children. The origins of this disparity are unknown but may be explained by a spectrum of genetic and biologic features that are used to stratify patients for treatment.

Neuroblastoma generally occurs in the youngest of children with a median age of presentation of 19 months.[24] The age at which a child is diagnosed with neuroblastoma is an indicator of biologic features and clinical course. Neonates and infants younger than 18 months of age are more likely to have disease that either spontaneously regresses or is cured without cytotoxic therapy. In contrast, older children are more likely to have refractory metastatic disease and are at high risk for death despite multimodal cytotoxic therapies. Age contributes to prognosis in a continuous manner with the optimal age cutoff between 15 and 19 months.[24] Much of this discrepancy in outcome of neuroblastoma is thought to be associated with underlying tumor biology because there is an association between age and other biologic factors such as MYCN amplification and histopathology. Given this, accurate and complete molecular analysis of neuroblastoma tumor specimen is an important factor in treatment planning and risk stratification.

Cellular heterogeneity is a hallmark of neuroblastoma. Neuroblastic small, round blue cells with hyperchromatic nuclei characterize neuroblastoma cells with varying degrees of differentiation from immature to mature. Homer Wright pseudorosettes that palisade around blood vessels and neuritic processes are characteristic (**Fig. 103.1**). Neuroblastoma cells stain for neuron-specific enolase (NSE), synaptophysin, NB84, and tyrosine hydroxylase, a neural protein-staining pattern that differentiates neuroblastoma from other childhood tumors with similar small round blue cells.

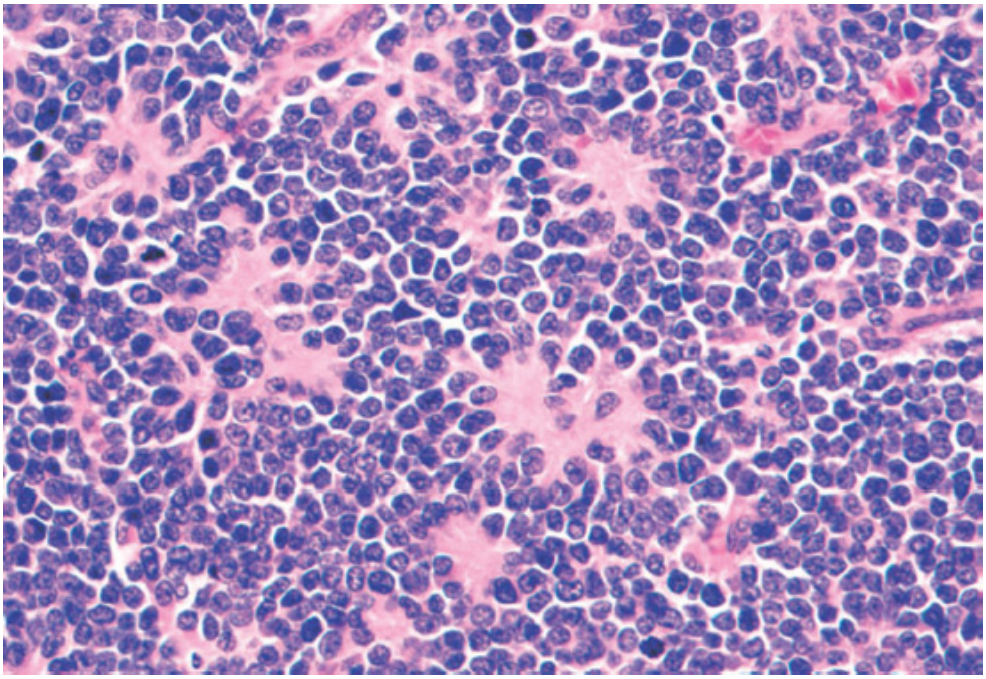

Figure 103.1 Typical neuroblastoma with small round blue cell features and Homer Wright pseudorosettes that palisade around blood vessels.

Treatment strategies for children with neuroblastoma are largely based on risk as determined by histopathologic and biologic characteristics of the tumor. The Shimada histopathologic classification system is the most widely accepted standard for microscopic evaluation of neuroblastoma tumors and distinguishes favorable and unfavorable clinical groups. The International Neuroblastoma Pathology Classification System was developed based on the original Shimada system.[25] Morphologic features of neuroblastic differentiation, schwannian stromal development, mitosis–karyorrhexis index (MKI), and patient age at diagnosis determines the important distinction between favorable and unfavorable histology (**Table 103.1**).

In addition to histopathology, combinations of prognostic features are utilized for risk assignment and treatment stratification. The DNA content (DNA index or ploidy) is the amount of DNA within the nucleus of tumor cells compared to normal cells and is an important indicator of treatment success. DNA index is determined by flow cytometry or by cytogenetic analysis. Hyperploidy or near-triploid tumors (DNA index >1) are whole chromosome gains and losses without structural genetic alterations and are associated with a better response to chemotherapy.[26] In contrast, diploid

tumors are characterized by segmental chromosomal alterations and predict poor response to therapy.

Table 103.1 Shimada Histopathologic Classification of Neuroblastoma

Favorable
Stroma rich, all ages, no nodular pattern
Stroma poor, age 1.5–5 yrs, differentiated, MKI <100
Stroma poor, age <1.5 yrs, MKI <200
Unfavorable
Stroma rich, all ages, nodular pattern
Stroma poor, age >5 yrs
Stroma poor, age 1.5–5 yrs, undifferentiated
Stroma poor, age 1.5–5 yrs, differentiated, MKI >100
Stroma poor, age >1 yr, MKI >200
MKI, mitosis–karyorrhexis index (number of mitoses and karyorrhexis per 5,000 cells)

The MYCN oncogene is a transcription factor located on chromosome 2p and also predicts survival and risk in neuroblastoma. The amplification of MYCN is the best characterized genetic abnormality, occurring in approximately one-third of neuroblastoma patients.[27,28] Significant amplification of MYCN within tumor cells (more than 10 copies detected by fluorescent in situ hybridization) reliably predicts poor survival and advanced-stage disease. Though the molecular mechanism of MYCN amplification is unknown, targeted expression in transgenic mice leads to the development of neuroblastoma tumors.[29] Enhanced expression of MYCN increases proliferation and confers growth potential both in vitro and in vivo, adding to the notion that MYCN has a critical role in neuroblastoma tumorigenesis.[30] Approximately 30% of neuroblastoma tumors have MYCN amplification, and of these, 90% are high-stage or refractory to multimodal cytotoxic therapies.[31]

Nerve growth factor (NGF) and its receptor tyrosine kinase (TRK) also correlate with disease outcome in neuroblastoma tumors. The TRK receptors are thought to have a role in regulating growth and differentiation of normal nerve cells and have been implicated in neuroblastoma pathogenesis. The expression of TRK-A, a transmembrane tyrosine kinase that is required for high-affinity binding of NGF, is strongly predictive of a favorable outcome in neuroblastoma tumors.[32,33] TRK-B, the receptor for brain-derived neurotrophic factor (BDNF) is preferentially expressed in neuroblastoma tumors with MYCN amplification while TRK-C, the primary receptor for neurotrophin-3 (NT-3) mirrors TRK-A and is expressed primarily in lower-stage tumors with favorable outcomes.[33] The absence or lack of TRK-A correlates inversely with MYCN amplification and reliably predicts poor overall survival. Differential expression of TRK-A and TRK-B indicate that NGF receptors may function in growth arrest and differentiation in neuroblastoma tumors, critical factors that may have a role in clinical course.[34]

3 Several nonrandom genomic imbalances have been identified in neuroblastoma and the presence of segmental chromosome alterations is the strongest predictor of neuroblastoma relapse.[35] The loss of heterozygocity (LOH) of chromosome 1p is a reliable prognostic factor in neuroblastoma tumors that is independent of age and stage. The loss of 1p identifies patients who are at high risk of poor survival outcomes despite otherwise favorable biologic predictors (stage 1, 2, and 4S disease).[36] LOH at 1p is most clinically valuable in predicting patients at high risk of death in the subgroup of patients without MYCN amplification, specifically those with low-stage disease.[36] Gain at 17q most commonly occurs with loss of 1p in an unbalanced translocation. Unbalanced gain of chromosome arm 17q is the most frequent segmental genetic alteration in neuroblastoma cells and is also associated with adverse outcomes.[37] The gain of 17q is strongly associated with other negative risk factors including age of more than 1 year, presence of high-stage disease, MYCN amplification, and diploidy. The most likely candidate genes involved at 17q are NM23 and BIRC5 (surviving gene).[38] Chromosome 11q loss is found in approximately 40% of neuroblastoma patients and is associated with high-risk disease features and decreased survival.[39] Similar to loss of chromosome 1p, loss of 11q is independently associated with decreased survival in the subgroup of patients with low-

stage disease and in patients without MYCN amplification. In all, the genomic alterations that have consistently been shown to predict prognosis are DNA ploidy, MYCN amplification, loss of chromosome 1p, 17q gain, loss of 14q, and loss of 11q. A systematic review of prognostic tumor markers and meta-analysis showed that of these, MYCN amplification and DNA ploidy have the strongest prognostic impact.[40]

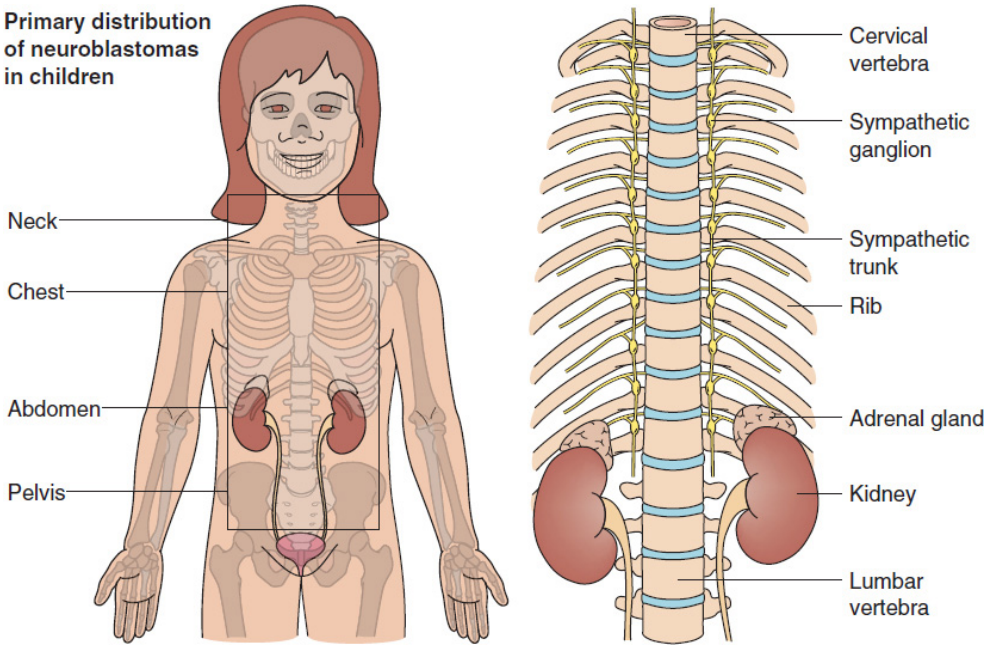

Figure 103.2 Primary distribution of neuroblastoma tumors in children.

Presentation, Diagnosis, and Staging

The majority of children with neuroblastoma are diagnosed at less than 4 years of age, with median age between 19 and 22 months. Forty percent of tumors occur in the adrenal medulla with the remaining occurring in the neck, chest, abdomen, and pelvis along the sympathetic chain. The organ of Zuckerkandl is the second most common site of neuroblastoma of abdominal origin. Compared to older children, infants are more likely to present with thoracic and cervical primary sites. Tumors at the sympathetic chain along the spinal column may expand into the intraforaminal spaces and can cause spinal cord compression (5% to 15% of patients) (**Fig. 103.2**). More than half of patients may present with regional or distant spread through lymphatic and hematogenous routes. Metastatic disease most commonly involves

regional lymph nodes, bone marrow, and cortical bone. The most common cortical bone sites are metaphyseal, skull, and the orbit. Patients with orbital bone metastases commonly present with perioribtal ecchymosis and swelling (raccoon eyes) and cortical bone metastases may result in generalized bone pain and limping. Liver metastases occur most commonly in patients with stage 4S tumors. Neonates with stage 4S neuroblastoma may present with massive hepatomegaly, respiratory compromise, and abdominal compartment syndrome requiring urgent surgical intervention. Incidental findings on prenatal ultrasound may identify fetal neuroblastoma and there may be associated maternal signs of catecholamine excess with excessive sweating, headaches, flushing, or anxiety.[41]

Most often patients with localized disease are asymptomatic with tumors diagnosed on routine physical examinations or testing for other medical conditions. In contrast, children may have a mass or abdominal distention as presenting symptoms. There are several well-documented clinical syndromes that can be present at diagnosis of neuroblastoma. Opsoclonus/myoclonus syndrome and or ataxia can occur in children with neuroblastoma and present as irregular jerking movements of the muscles. The underlying mechanism of opsoclonus is unknown but an immunologic mechanism–related antineuronal antibody is likely and patients may have late neurologic sequelae despite tumor removal.[42] The condition may be treated with adrenocorticotrophic hormone (ACTH), with plasmapheresis and intravenous gamma globulin reserved for refractory cases.[43] Most patients with opsoclonus/myoclonus syndrome tend to have localized disease and excellent survival. Up to 50% of patients with opsoclonus/myoclonus syndrome are found to have neuroblastoma tumors while only a small percentage of neuroblastoma patients present with opsoclonus. Neuroblastoma tumors that occur in the neck or upper chest may present with Horner syndrome (ptosis, miosis, anhidrosis), symptoms that may not go away with surgical excision.

Perinatal Neuroblastoma

The improvement of ultrasound and maternal imaging techniques has increased the diagnosis of neuroblastoma within the fetal and neonatal periods. Most perinatal tumors are located within the adrenal gland and are localized tumors. Upon detection, tumor growth is monitored with serial

ultrasound prior to birth and maternal care proceeds to assure optimal health of the mother. As long as there are no complications, pregnancy is carried to term. Nearly all perinatal cases have favorable biology without adverse prognostic indicators, including non-MYCN amplification. Several lines of evidence suggest that small, localized adrenal tumors detected during the perinatal period may be managed with expectant observation without surgical resection.[44–46] Given the considerable evidence of spontaneous regression in this subset of neuroblastoma tumors and the risk of adrenal surgery in infants, the COG conducted a prospective trial (ANBL00P2) of expectant observation of infants diagnosed within the first 6 months of life.[47] This study found that observation of small adrenal masses in infants younger than 6 months, without biopsy and without surgical resection was safe with excellent event-free and overall survivals. Adrenal tumors less than 3 cm (16 mL) if solid or 5 cm (65 mL) if ≥25% cystic are safely monitored with ultrasound volume measurements, computerized tomography (CT) scan, and urine catecholamine metabolite levels. If there are signs of tumor growth or dedifferentiation, the patient is referred for surgical resection without risk of upstaging of disease.

Diagnosis

The diagnosis of neuroblastoma requires an adequate biopsy specimen and a pathologist experienced with pediatric tumors. The diagnosis is established with histologic confirmation from either tissue biopsy or the presence of tumor cells within a bone marrow biopsy and increased urinary catecholamine metabolite levels. The majority of patients with neuroblastoma have elevated urinary vanillylmandelic acid (VMA) and homovanillic acid (HVA) levels and these should be evaluated during the diagnostic workup. Complete blood count and serum chemistries are evaluated as components of initial diagnostics. Levels of lactate dehydrogenase (LDH), ferritin, and neuron-specific enolase (NSE) are biologic markers that may indicate poor prognosis in patients with neuroblastoma.[48,49] Elevated ferritin (>150) and LDH (>1,000) may indicate increased risk of adverse outcomes. More than half of patients present with metastatic disease at presentation therefore initial evaluation should include cross-sectional imaging by either CT scan or MRI to define the primary

tumor size and to determine regional or distant spread (**Fig. 103.3**). Calcifications are commonly detected on imaging in patients with neuroblastoma and the mass tends to displace structures inferiorly and toward the midline. Unless the patient has neurologic symptoms, or an abnormal neurologic examination, lumbar puncture or brain imaging is not indicated. Sympathetic nervous tissue concentrates metaiodobenzylguanidine (MIBG), an analog of norepinephrine. Radioactive iodine–labeled MIBG scan is utilized in neuroblastoma staging and is used to determine treatment response.[50] MIBG scan is accurate in detecting metastatic spread, particularly cortical bone disease that may have otherwise been missed by traditional imaging techniques. Posterior iliac crest aspirates and core biopsies are required as a component of initial diagnostic testing to exclude bone marrow involvement. PET scanning or bone scans may be utilized in patients with non-MIBG avid disease.

Figure 103.3 Computerized tomography (CT) scan of a child with stage 3 neuroblastoma, crossing the midline displacing the aorta, vena cava, kidney, pancreas, and spleen.

Staging

Standard staging criteria allows physicians to tailor treatment plans based on patient risk. Until recently, the International Neuroblastoma Staging System (INSS) was the most widely accepted surgical/pathologic staging system and was established in efforts to standardize risk-group stratification by cooperative groups[51] (**Table 103.2**). INSS was largely based on the surgeon's definition of resectability and surgical approach to the primary tumor and lymph nodes. There is international variation in surgical decision making and approach to locoregional disease that may alter the prognostic value of INSS staging. This has made the performance and comparison of international clinical trials difficult. Moreover, biologic prognostic factors have become increasingly important in treatment planning and risk stratification. To address this, the European International Society of Pediatric Oncology Neuroblastoma Group proposed radiographic characteristics of the primary tumor as useful predictors of resectabil-ity and risk for developing postoperative complications (International Neuroblastoma Risk Group Staging System [INRGSS]).[52] INRGSS determines the extent of locoregional disease by the presence or absence of image-defined risk factors (IDRFs) (**Table 103.3**).[53] Stage L1 tumors are localized tumors that are confined within one body compartment and do not involve vital structures or major blood vessels, without any IDRF. L2 tumors are locoregional tumors with one or more IDRF that may involve ipsilateral continuous body compartments and have lower event-free survivals compared to L1 tumors. Stage M is distant metastatic disease and MS is limited to children less than 18 months with skin, liver, and/or bone marrow metastases (**Table 103.4**). The benefit of INRGSS is that treatment stratification is based on preoperative diagnostic imaging, rather than variable operative approaches. INRGSS now functions as one of the seven prognostic factors in the new 4 INRG pretreatment classification system.[54] The INRG classification system defines pretreatment patient cohorts based on expected 5-year event-free survival at the time of diagnosis. INRG classification includes INRG stage, age, histologic category, grade of tumor differentiation, MYCN status, 11q alterations status, and DNA ploidy. These criteria are used to define 16 clinically different pretreatment groups that include very low–, low-, intermediate-, and high-risk categories (A-R) in terms of 5-year event-free survivals of >85%, >75% to ≤85%, ≥50% to ≤75%, and <50%, respectively. These clinical categories may further assist physicians and

cooperative groups in risk-group stratification based on reliable expected event-free survival cutoffs. Importantly, INRG classification will allow comparison of international risk-based clinical trials with potential to enhance international collaborative efforts (**Table 103.5**).

Table 103.2 International Staging Criteria for Neuroblastoma

Stage	Criteria	Overall Survival (3 yrs) (%)	Event-free Survival (3 yrs) (%)
1	Localized tumor, complete gross resection with or without microscopic margin, all identified ipsilateral and contralateral lymph nodes negative	97	88
2A	Unilateral tumor, incomplete resection, negative lymph nodes	87	72
2B	Unilateral tumor, incomplete or complete resection, positive ipsilateral but negative contralateral lymph nodes	86	63
3	Infiltration of tumor across the midline with or without ipsilateral lymph node involvement; unilateral tumor with contralateral lymph node involvement, midline tumor with bilateral lymph nodes positive	62	58
4	Distant metastases to lymph nodes, bone marrow, cortical bone, liver, other organs	<40	<40
4S	Localized primary tumor with distant metastatic disease to liver, skin, bone marrow only (<10% involvement), typically neonatal presentation	75	75

Table 103.3 Image-Defined Risk Factors (IDRFs)

Ipsilateral tumor extension within two body compartments (neck/chest, chest/abdomen, abdomen/pelvis)
Neck Tumor encasing carotid, vertebrals, internal jugular vein Tumor extending to base of skull Tumor compressing trachea
Cervicothoracic junction Tumor encasing brachial plexus roots Tumor encasing subclavian vessels, carotid or vertebral artery Tumor compressing trachea
Thorax Tumor encasing the aorta or major branches Tumor compressing trachea or main bronchi Lower mediastinal tumor, infiltrating costovertebral junction between T9–T12
Thoracoabdominal Tumor encasing the aorta and/or vena cava
Abdomen/pelvis Tumor infiltrating the porta hepatis or hepatoduodenal ligament Tumor encasing branches of the SMA at the root Tumor invading one or both renal pedicles Tumor encasing the aorta and/or vena cava Tumor encasing the iliac vessels Pelvic tumor crossing the sciatic notch
Intraspinal tumor extension More than one-third of the spinal canal in the axial plane is invaded and/or the perimedullary leptomeningeal spaces are not visible, and/or the spinal cord signal is abnormal
Infiltration of adjacent organs/structures Pericardium, diaphragm, kidney, liver, duodenopancreatic block, mesentery
Conditions to be recorded but not considered IDRFs

	Multifocal primary tumors, pleural effusion with/without malignant cells, ascites with/without malignant cells

Table 103.4 International Neuroblastoma Risk Group Staging System

Stage	Description
L1	Localized tumor, not involving vital structures as defined by the list of image-defined risk factors (IDRFs) and confined to one body compartment
L2	Locoregional tumor with presence of one or more IDRFs
M	Distant metastatic disease (except MS)
MS	Metastatic disease in children <18 mo with limited metastases at skin, liver, and/or bone marrow

Treatment

The treatment of neuroblastoma requires a multidisciplinary approach in order to assure the most optimal outcomes. Treatment is often multimodal with surgery, chemotherapy, radiation, bone marrow/stem cell transplantation, and immunotherapy. Risk-group assignment is essential for surgical and medical treatment decisions, as therapies are specifically tailored to risk. Patients are categorized based on INRG classification as non–high risk (very low, low, intermediate) or high risk. In general, the overall goal is to minimize surgical risks and to limit exposure to chemotherapy in patients with localized disease and favorable biologic features.

In the United States, the current treatment for children with neuroblastoma is guided by protocols established by the COG and it is recommended that

every child be enrolled on a clinical trial. ANBL00B1 is the most recently opened COG study that will determine risk stratification and treatment plans based on histology, MYCN amplification, ploidy, and serum analysis (https://clinicaltrials.gov/ct2/show/NCT00904241). This study will also further investigate other tumor biologic properties including the prevalence of segmental chromosomal alterations 1p, 11q, 14q, and 17q and analyze for independent clinical significance compared to standard prognostic indicators such as MYCN, INSS, and age.

Very Low Risk and Low Risk

For tumors that are classified as very low-risk and low-risk with favorable biologic characteristics (L1, L2, non-MYCN, no 11q alteration), survival rates are >95% with surgery alone without the need for postoperative chemotherapy.[55] Children with low-risk neuroblastoma are treated based on results of the COG Study P9641 that demonstrated excellent survival rates in asymptomatic low-risk patients with stages 1, 2a, and 2b neuroblastoma after surgery alone.[56] The study demonstrated 3-year overall survival of ≥95% with surgery alone in patients with low-risk, favorable histology disease. The goal of surgery in low-risk patients is complete surgical resection without compromising surrounding organs or blood vessels.

Surgical standards for low-risk neuroblastoma are to establish diagnosis and to resect as much tumor as safely possible without damage to contiguous structures or major blood vessels. Sampling of nonadherent regional lymph nodes and obtaining adequate tissue for biologic studies is critical. Chemotherapy in this group is reserved for patients who relapse or have treatment failure. Chemotherapy is also for patients with less than partial primary tumor resection (<50%), disease that compromises organ function or is life-threatening, and patients at risk of developing spinal cord compression. If utilized, low-dose chemotherapy is platin-based (carboplatin), cyclophosphamide, doxorubicin, and etoposide. Chemotherapy is 6 to 24 weeks depending upon patient age, weight, and extent of disease. Radiation is seldom given in this group and is reserved for patients with life-threatening symptoms.

Stage MS neuroblastoma tumors without MYCN amplification are very low–risk classification and most often spontaneously regress. Children with

MS disease require biopsy of either primary or metastatic tumor for biology studies. This subset may be spared both surgery and chemotherapy. Exceptions are patients with massive hepatomegaly causing abdominal compartment syndrome when low-dose chemotherapy and radiotherapy is given to reduce organ dysfunction. Patients with MS tumors may require decompressive laparotomy and ventilator support. In this case, attempts should be made to biopsy extra-abdominal sites and diagnosis may also be made by bone marrow biopsy. In rare and extreme life-threatening cases, treatment may be initiated based on diagnostic imaging alone.

Table 103.5 International Neuroblastoma Risk Group Classification System

INRG Stage	Age (Months)	Histologic Category	Differentiation	MYCN Aberration	11q	Ploidy	Pretreatment Risk Group
L1/L2		GN maturing, GNB intermixed					A Very low
L1		Any, except GN maturing or GNB intermixed		NA Amp			B Very low K High
L2	<18	Any, except GN maturing or GNB intermixed		NA	No Yes		D Low G Intermediate
	>18	GNB nodular; neuroblastoma	Differentiating	NA	No Yes		E Low H Intermediate
			Poorly differentiating or undifferentiated	NA Amp			H Intermediate N High
M	<18 <12 12–<18 <18 >18			NA NA NA Amp		Hyperdiploid Diploid Diploid	F Low I Intermediate J Intermediate O High P High
MS	<18			NA Amp	No Yes		C Very Low Q High R High

Cohn SL, Pearson ADJ, London WB, et al. The International Neuroblastoma Risk Group (INRG) Classification System: An INRG Task Force Report. *J Clin Oncol* 2009;27(2):289–297.

Intermediate Risk

The intermediate-risk group encompasses a broad spectrum of neuroblastoma tumors. The survival rate for patients in this group is between 75% and 90%. All patients in this subgroup receive surgery and chemotherapy. The goals of surgical resection are similar to low-risk cases, to establish the diagnosis with enough tissue for histologic and genetic testing with the most complete tumor resection, preserving organ function. If the primary tumor is resectable

without damage to surrounding organs and major blood vessels, then full resection is performed with lymph node sampling for staging upfront. Many patients in the intermediate-risk group will have locoregional disease that encroaches upon surrounding organs and major blood vessels (aorta, vena cava, mesenteric vessels, kidney, spleen). The surgeon should defer to the INRG image-defined risk factors (**Table 103.3**) during assessment for resectability. For L2 tumors with INRG image-defined risk factors and those judged to be unresectable at diagnosis, biopsy is performed with plan for neoadjuvant chemotherapy. Delayed surgical resection after 4 to 6 cycles of induction chemotherapy minimizes surgical complications and may improve resection of the primary tumor and overall survival.[57] Moderate-dose chemotherapy for intermediate-risk tumors consists of 12 to 24 weeks of cisplatin, cyclophosphamide, doxorubicin, and etoposide. The prognosis in this subgroup depends upon patient age, tumor histology, and biologic properties. Treatment protocols for children with intermediate-risk neuroblastoma are currently based on results of the COG trial A3961. This study demonstrated a high rate of survival with biologically based treatment assignment utilizing substantially reduced duration and doses of chemotherapy agents compared with previously used intensive regimens.[58] The promising results have reduced cytotoxic therapy for patients with regional disease and favorable biologic characteristics and provided framework for ANBL0531, a COG trial that further examined reduction in cytotoxic therapy as more refined risk factors emerged.[38,59]

High Risk

High-risk neuroblastoma remains one of the most challenging problems in pediatric oncology. Survival in this group remains poor despite multimodal therapy that includes aggressive surgery, intensive cytotoxic chemotherapy, and radiation. The long-term survival is between 10% and 40%. High-risk tumors are characterized by undifferentiated neuroblasts with unfavorable histology and poor prognostic indicators (MYCN amplification, 11q alterations, and diploidy). The initial surgical management of high-risk tumors begins with an adequate operative biopsy and vascular access placement. Initial biopsy can be approached by open or minimally invasive techniques including thoracoscopy, laparoscopy, and percutaneous core

biopsy. Obtaining an adequate sample size to allow for histologic and cytogenetic studies is of utmost importance and is the primary focus when determining biopsy technique. An initial biopsy should obtain tissue greater than 1 cubic centimeter of viable tumor tissue with avoidance of placement of the specimen in formalin in order to optimize cytogenetic studies. The adequacy of the biopsy specimen should be confirmed with the pediatric pathologist before leaving the operating room. Standard treatment then begins with induction chemotherapy followed by surgical local control, myeloablative consolidation therapy, and biologic agents.

Induction chemotherapy is administered to improve tumor resectability and to decrease tumor growth. Most neuroblastoma primary tumors and bone marrow are initially sensitive to chemotherapy and will have high response rates. Standard induction therapy consists of combinations of cisplatin, cyclophosphamide, vincristine, doxorubicin, and etoposide. The response rate of induction chemotherapy correlates with survival.[60] Postinduction persistent bone lesions and bone marrow involvement predict poor overall survival.[61]

Local control is achieved with the combination of aggressive surgical resection and external beam radiotherapy to the primary tumor site. Delayed resection with postinduction chemotherapy excision of as much of tumor as safely possible offers the highest treatment success. After induction chemotherapy consisting of four to five cycles, surgical exploration with the goal of gaining local control of the primary tumor is undertaken. Although the role of primary tumor resection in high-risk neuroblastoma patients has been controversial, recent studies have shown that aggressive removal of all primary tumors in high-risk neuroblastoma patients improves survival to 50% and decreases local recurrence to 10%.[62] Gross total resection of the primary tumor is defined as the removal of all visible and palpable neuroblastoma from the primary tumor site and regional lymph node tissue. The microscopic margin is nearly always positive therefore the goal is safe gross total resection with external beam radiation therapy to the surgical bed (2,000 to 2,100 cGy).

Safe tumor dissection typically requires exposure of the great vessels and spine (**Fig. 103.4**). The incision type depends on the location of the primary tumor with thoracoabdominal or transverse abdominal for large adrenal masses and midline incision for pelvic neuroblastoma. Thoracic

neuroblastoma typically has favorable biology and better survival outcomes than abdominal tumors and surgical resection is often curative. Primary thoracoscopic gross total resection is safe in neuroblastoma tumors less than 6 cm and may yield surgical and survival outcomes similar to open thoracotomy.[63,64] Cervical chain tumors may be approached by radical neck incisions and if located at the lower cervical region or apex of hemithorax, a trap-door incision often utilized in the setting of vascular trauma may be applied.[65] Every effort should be made to preserve the vagus and phrenic nerves. In general, for all neuroblastoma resections, organs and structures should be preserved, particularly the kidney. The operative complications to avoid are excessive blood loss, kidney and renal vessel injury, damage to surrounding major blood vessels or nerves, and postoperative infection and abscess. The tumor is removed by meticulous dissection in the peritumoral capsular plane. Early control of the aorta and vena cava are essential as the major blood vessels are traced. The major blood vessels often include the celiac axis, superior mesenteric artery, renal vessels, and inferior mesenteric artery. Tightly adherent tumor to blood vessels or major nerves should be left rather than risk injury though neuroblastoma typically does not invade beyond the adventitia. At times, it is beneficial to divide the tumor over major blood vessels for safe exposure when en bloc resection is not possible at encased blood vessels. Pelvic neuroblastoma typically arises from the organ of Zuckerkandl or elsewhere along the sympathetic chain and is associated with excellent long-term survival, despite residual or microscopic disease. Injuries to the lumbosacral plexus or damage to innervation to the bowel or bladder should be avoided. Selective MRI for pelvic lesions may help define neural involvement and enhance surgical planning. Nerve stimulation may be useful when approaching the pelvic sidewall. The presence of residual tumor correlates with risk of recurrence. Patients with incomplete resection may benefit from higher-dose radiation.[66]

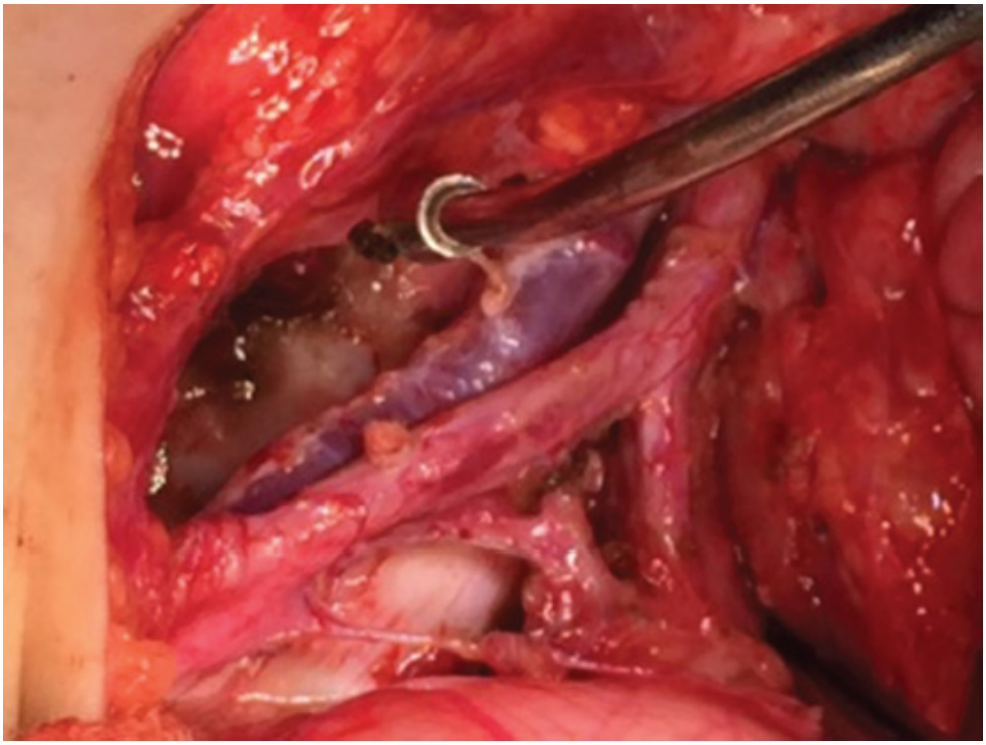

Figure 103.4 Intraoperative depiction of critical exposure during neuroblastoma resection exposing the aorta and vena cava from bifurcation distal to proximal.

Myeloablative consolidation therapy was investigated in the CCG-3891 study that demonstrated myeloablative therapy with purged bone marrow transplant improved outcome for patients with high-risk neuroblastoma.[60] The data from this trial has been confirmed with several international studies.[67] High-dose myeloablative therapy (cisplatin, etoposide, cyclophosphamide) with autologous stem cell transplantation improves outcome and progression-free survival compared to maintenance chemotherapy or observation. Over the last several decades, intensification of consolidation therapy with myeloablative doses of chemotherapy followed by autologous stem cell rescue has allowed for steady reduction in relapse rates in first remission and has now become standard of care for patients with high-risk disease.[68] The ability to harvest peripheral blood stem cells along with advances in transplant methodology has enhanced the safety of bone marrow transplantation in children.

Maintenance and biologic therapies have also improved high-risk neuroblastoma treatment. COG (ANBL0532) found that the addition of monoclonal antibody (MAB CH14.18) targeting disialoganglioside (GD2)

improved survival rates in patients with high-risk disease.[69,70] GD2 is a sialic acid–containing glycosphingolipid expressed uniformly on the surface of neuroblastoma cells. The Food and Drug Administration (FDA) approved Unituxin (dinutuximab, formerly MAB CH14.18) specifically for treatment of pediatric patients with high-risk neuroblastoma who achieve at least a partial response to first-line multimodality treatment (**Table 103.6**).

Future Directions

Despite advances in cytotoxic and biologic multimodality therapies, up to 60% of patients with high-risk neuroblastoma relapse and there are currently no curative salvage treatment regimens. Advances in understanding neuroblastoma tumor biology are essential for the development of novel therapies for high-risk tumors. The use of high-throughput genomic sequencing technologies will aid in patient-specific prognostic data and allow for a personalized approach to treatment. The success of anti-GD2 monoclonal antibody has launched great interest and research into improving antibody-based approaches and synergistic immunotherapies. A recent study showed promise in humanized anti-GD2 engineered to target the delivery of interleukin-2 to tumor microenvironment in patients with small tumor burden.[71] The addition of MAB CH14.18 with granulocyte/macrophage colony-stimulating factor (GMCSF), interleukin-2, and retinoic acid may prevent late relapse. Radiolabeled MIBG is also being investigated as a therapeutic agent in neuroblastoma and has a high response rate in patients with relapse and refractory disease.[50,72,73] Targeted radionucleotide has little nonhematologic toxicity though most patients experience some level of myelosuppression requiring autologous hematopoietic cell transfusion.

Table 103.6 Standard Treatment for Children with Neuroblastoma

Risk	Standard Treatment Plan
Low-risk tumors *Landmark Trials:* COG CCG P9641 trial ANBL00P2 trial	Observation Surgery alone (maximally safe resection)
Intermediate-risk tumors *Landmark Trials:* CCG A3961 ANBL0531	Chemotherapy (risk stratification, less intense, dose reduction) Surgery
High-risk tumors *Landmark Trials:* CCG 3891 ANBL0532 ANBL0032	Chemotherapy Surgery Dose intense, myeloablative chemotherapy Autologous stem cell transplant External beam radiation therapy Immunotherapy with differentiating agent

Challenges also remain in the ability to identify patients with low-risk and intermediate-risk tumors who would benefit from reduction in therapy versus those that are at risk for relapse and refractory disease. There are several large collaborative research efforts focusing on the discovery of new therapeutic targets with respect to understanding the relationship between risk and the molecular basis of neuroblastoma. One such effort is the Therapeutically Applicable Research to Generate Effective Treatments (TARGET) program.[4] TARGET in conjunction with the Cancer Genome Atlas project conducts genomic profiling and tumor sequencing for neuroblastoma along with other pediatric solid tumors with the goal of discovering novel mechanisms that drive tumorigenesis and identifying new molecular targets for drug development.

WILMS TUMOR

Epidemiology and Genetic Risk

Various tumors arise in the kidneys in children that range from benign to malignant. Wilms tumor (nephroblastoma) is the most common renal tumor in children and is the second most common solid tumor outside of the brain in infants behind neuroblastoma. Wilms tumors occur almost exclusively in the kidney. Extremely rare extrarenal sites include the retroperitoneum, pelvis, and inguinal canal.[74] The overall incidence of Wilms tumor is 8 per million children less than 15 years of age with approximately 500 new cases per year in the United States.[4] Children most commonly present within the first 2 years of life, with nearly all diagnosed before the age of 5 years. The incidence of Wilms tumor varies by ethnicity with highest incidence in Africa and African-American children and lowest in East Asian populations.[75] The National Wilms Tumor Study (NWTS) reported the median age for Wilms tumor in boys is 36 months and 43 months for girls with unilateral tumors.[76] Bilateral Wilms tumors occur in slightly younger children with median ages of 23 months for boys and 30 months for girls. The survival of children with Wilms tumor has improved significantly over the past several decades from 30% to over 90% 5-year survival currently.[77]

Most Wilms tumors are sporadic with only 1% to 2% of cases being familial. Several genetic syndromes are uniquely associated with Wilms tumor. Sporadic aniridia, hemihypertrophy, genitourinary tract abnormalities, and Beckwith–Wiedemann syndrome are known to be associated with an increased risk of Wilms tumor in children.[78] The study of patients with sporadic aniridia and Beckwith–Wiedemann syndrome led to the discovery of WT1, a tumor suppressor gene located on chromosome 11p necessary for normal renal development.[79,80] **Table 103.7** lists known genetic syndromes associated with increased susceptibility to Wilms tumor.

Pathology and Biologic Features

Wilms tumors arise from pluripotent developmental renal precursor cells. In most cases, only one kidney is affected but may present as bilateral disease in up to 6% of children. Multicentric disease is found in 7% of patients.

Wilms tumors arise within the renal medulla and cortex and may invade renal calyces, renal vein, and inferior vena cava. The tumor is most commonly a well-circumscribed mass with a fibrous capsule. The most common sites of metastatic spread are lungs, lymph nodes, and liver. Wilms tumors are composed of a classic triphasic combination of blastemal, stromal, and epithelial cells. Characterization of histologic subtype is critical for risk stratification and for treatment planning. Blastemal predominance may indicate a high-risk category of patients with increased risk of recurrence.[81] Importantly, anaplastic cells characterize 7% of Wilms tumors and are defined by the presence of enlarged nuclei and hyperchromasia with multipolar polypoid mitotic figures (**Fig. 103.5**).[82] Compared to tumors without anaplasia, anaplastic Wilms tumors are generally found in older children and are more likely to have lymph node metastases. Differences in race are also observed with African or Latin-American children having the highest proportion of tumors with anaplasia. Tumors with diffuse anaplasia (present in more than one area of the tumor or extrarenal sites) are defined "unfavorable histology" and have higher resistance to chemotherapy compared to tumors without anaplasia.[83] 5 The single most important prognostic indicator in Wilms tumors is the presence of anaplasia.

Clear cell sarcoma and rhabdoid tumor of the kidney are also unfavorable histologic subtypes and are considered distinct entities from Wilms tumors.[77,84] Nephrogenic rests represent the persistence of developmental renal tissue in the kidney after the 36th week of gestation and 1% undergo malignant transformation to Wilms tumor. Two major categories of nephrogenic rests have been characterized, perilobar (PL) and intralobar (ILNR), distinguished by their position within the renal lobe.[80] Nephrogenic rests are considered precursor lesions of Wilms tumor and are found in nearly half of cases.[85] ILNR characterizes early developmental disturbances and occurs in aniridia and Denys–Drash syndrome, while PL develops later in nephrogenesis and occurs in patients with Beckwith–Wiedemann syndrome and hemihypertrophy. Nephroblastomatosis is the term used to describe the presence of diffuse nephrogenic rests and typically involves both kidneys. The presence of nephrogenic rests demonstrates the vast degree of heterogeneity in Wilms tumor biology as they either involute or progress to hyperplastic overgrowth or neoplastic induction.[77] Patients with nephrogenic rests are at risk for bilateral kidney involvement that decreases with age.

Several biologic factors have been identified in Wilms tumors that associate with risk. Tumor-specific LOH at chromosomes 1p and 16q are independent prognostic indicators and are associated with greater risk of relapse and mortality. The fifth National Wilms Tumor Study Group trial (NWTS-5) found that tumors with LOH at 16q had an adverse effect on prognosis with relapse rates three times higher and mortality rate 12 times higher than those without LOH at chromosome 16q.[86] Patients with LOH for chromosome 1p also had relapse and mortality rates higher than those without LOH at 1p.[87] LOH for both chromosomes 1p and 16q are found in up to 5% of Wilms tumors.

Table 103.7 Syndromes Associated with Increased Susceptibility to Wilms Tumor

Syndrome	Gene	Phenotype
WAGR (Wilms tumor, aniridia, genitourinary abnormalities, mental retardation)	11p13/WT1: deletions, PAX6	Absence of iris, genitourinary defects, mental retardation, 30% develop Wilms tumors
Denys–Drash	11p13/WT1: point mutations	Genitourinary defects, renal mesangial sclerosis and intersex disorder; 90% develop Wilms tumors
Frasier	11p13/WT1: point mutations	Genitourinary defects, focal glomerular sclerosis, and intersex disorder; rarely develop Wilms tumors
Beckwith–Wiedemann	11p15: several genes (IGF2, H19, p57, and LIT1)	Organomegaly including tongue, hemihypertrophy, hypoglycemia, umbilical hernia, increased risk of tumors (Wilms tumor, hepatoblastoma, adrenal carcinoma), 5% develop Wilms tumors
Simpson–Golabi–Behmel	Xq26/GPC3: point mutations, microdeletions	Organomegaly, renal dysplasia, excess digits, diaphragmatic and heart defects, 7.5% develop Wilms tumors
Sotos	5q35/NSD1: point mutations, microdeletions	Overgrowth, craniofacial dysmorphism, mental retardation, and increased risk of tumors (Wilms tumor, neuroblastoma, acute lymphocytic leukemia), 5%

		of patients develop Wilms tumor
Perlman	Unknown	Macrosomia, visceromegaly, cryptorchidism, excess amniotic fluid, characteristic facial features, 30% of patients develop Wilms tumors
Familial Wilms tumor 1	17q12–21	20% of patients develop Wilms tumors
Familial Wilms tumor 2	19q13,4	70% of patients develop Wilms tumors

GPC3, glypican 3; IGF2, insulin-like growth factor 2; NSD1, nuclear-receptor–binding SET-domain protein 1; PAX6, paired box gene 6; WT1, Wilms tumor protein 1.

Presentation, Diagnosis, and Staging

Children may present with a palpable asymptomatic abdominal mass identified by parents or pediatrician during well-visit examination. If present, symptoms may include intermittent abdominal pain, gross or microscopic hematuria (25% of patients), and hypertension (25% of patients). Hypertension occasionally results from either an increase in renin secretion by the tumor or by compression of the renal artery by tumor mass effect. Intraparenchymal bleeding and preoperative rupture may occur causing systemic symptoms of fever and anemia. The mass is typically nontender and nonmobile on physical examination. The child should be examined for aniridia, macroglossia, hemihypertrophy, and genitourinary abnormalities. Signs of intravascular spread may present as ascites, hepatosplenomegaly, and cardiac murmur. Standard complete blood count and serum chemistries should be assessed though renal function is usually unaffected. Red blood cells may be present on urinalysis.

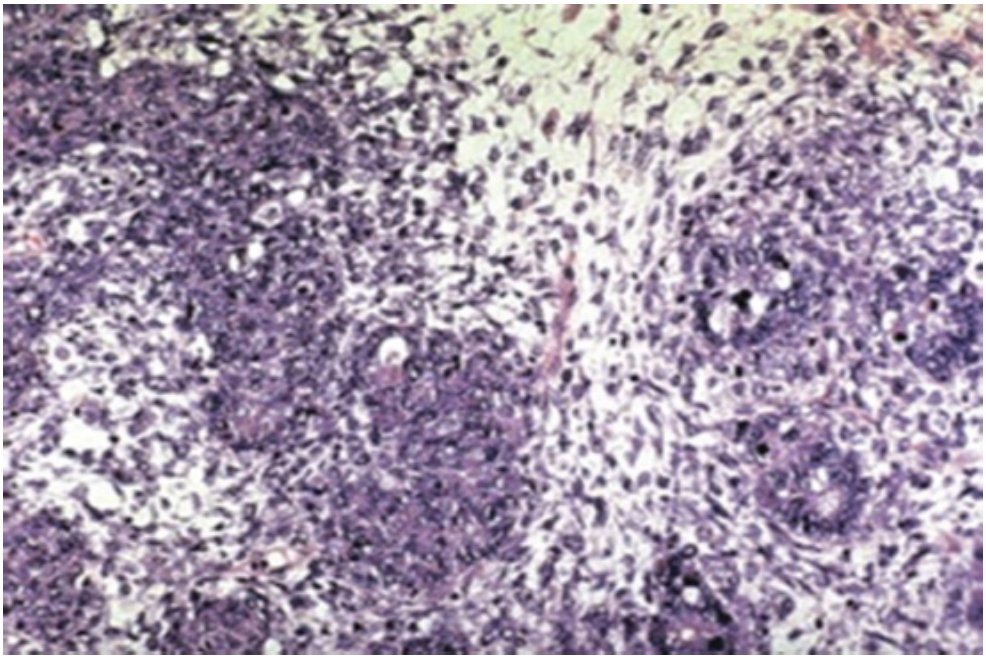

Figure 103.5 Microscopic examination of Wilms tumor showing highly cellular areas composed of undifferentiated blastemal with loose surrounding stroma with undifferentiated mesenchymal cells and immature tubules. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999, permission granted with previous edition.)

The diagnostic imaging workup is initiated with abdominal ultrasound and CT scan with oral and intravenous contrast. CT scan is the standard imaging modality that will provide information about mass location, size, extent of tumor invasion, and involvement of the contralateral kidney (**Fig. 103.6**). Critical examination of renal vasculature and intracaval extension is evaluated by Doppler ultrasonography. A good posteroanterior and lateral chest radiograph is obtained to determine the presence of lung metastases. It is critical to determine if a patient with Wilms tumor has lung metastases because these patients are assigned to higher disease stage and receive radiation to the lungs and more intensive chemotherapy. There is considerable controversy regarding the utilization of chest CT scan versus plain chest radiograph to detect lung metastases in patients with Wilms tumor because of interobserver variability in interpretation.[88] If utilized for staging workup, chest CT should be performed with standardized techniques and interpretation through a central review process. Pulmonary metastases identified on chest CT but not by plain chest radiograph may identify a subgroup of patients at increased risk of pulmonary relapse.[89] It may be

beneficial to obtain histopathologic confirmation of pulmonary metastases by surgical biopsy given the potential for upstaging and radiotherapy.[90]

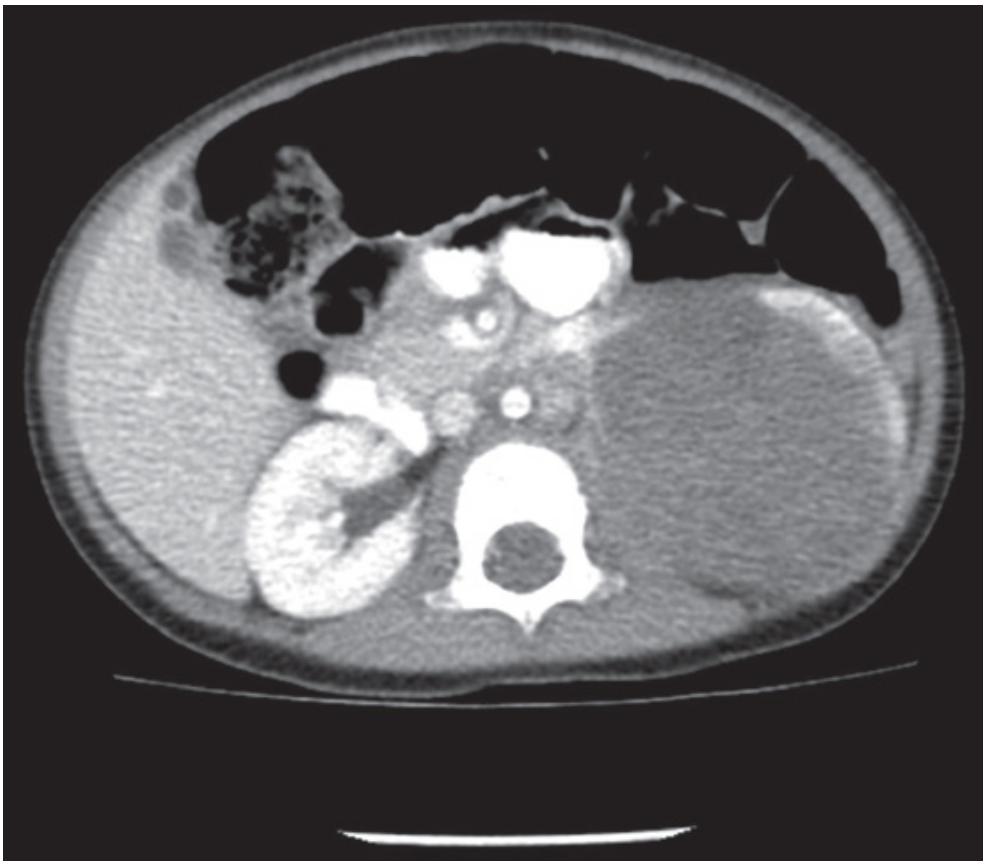

Figure 103.6 Abdominal CT scan with left Wilms tumor displacing midline organs and vessels, rim of kidney enhancing at lateral border.

In the United States, nephrectomy follows the initial diagnostic workup allowing the combination of surgical and histologic parameters to be included in staging at diagnosis. During the procedure, the surgeon must determine tumor extent, tumor rupture, and the status of regional, para-aortic and paracaval lymph nodes. Distant metastatic disease should also be determined by inspecting the peritoneal surfaces, diaphragm, and liver. The COG no longer recommends direct visualization and manual palpation of the contralateral kidney as long as the contralateral kidney is clear of tumor on cross-sectional imaging.

The staging of Wilms tumor is based on the anatomy of the tumor and lymph nodes as detailed by the National Wilms Tumor Study Group (NWTSG) staging system. The staging system incorporates clinical, surgical,

and pathologic information and allows stage-based approach to treatment to minimize exposure to cytotoxic agents (**Table 103.8**). Advanced tumor stage at diagnosis predicts an increased risk of relapse. Additionally, tumor rupture at surgery predisposes to relapse.[91] Older age is also an adverse prognostic factor and predicts disease recurrence.[92] Tumor stage and histology are the most significant prognostic factors for children with Wilms tumor.

Treatment

Most children diagnosed with Wilms tumor are cured by multimodal therapy. Much of the success in therapy is the result of collaboration and research trials conducted by three cooperative groups, the NWTSG, now a part of the COG, the United Kingdom Children's Cancer Study Group (UKCCSG), and the SIOP. In the United States and Canada, nearly all children are treated according to protocols established by the NWTSG. The primary goals of therapy are to treat based on well-defined risk groups and to achieve the highest cure rates with minimal toxicity.

Surgery is a critical component of local primary tumor control and treatment outcomes.[6] In the United States, the standard of care starts with radical nephrectomy at the time of diagnosis of resectable primary tumors followed by chemotherapy and radiation to sites of residual and metastatic disease. Preoperative chemotherapy is given to patients with inoperable tumors, bilateral disease, solitary kidney, and for tumors with intravascular extension above the hepatic veins. A significant number of patients are downstaged after preoperative chemotherapy without altering recognizable anaplasia.[93] In contrast to this treatment approach, SIOP therapy begins with chemotherapy administration for several weeks prior to nephrectomy in all patients presenting with Wilms tumors.[94] The standard chemotherapeutic drugs with activity against Wilms tumors are vincristine and actinomycin D. Doxorubicin is added to patients with stage 3 tumors and to those with unfavorable histology or adverse biologic prognostic markers such as LOH at chromosome 1p or 16q. Combinations of cyclophosphamide, ifosfamide, carboplatin, and etoposide are utilized for select stage 3 and 4 cases with unfavorable biology and for resistant or relapsed cases. In the United States, the optimal combination, duration, and mode of administration of

chemotherapy are optimized through clinical trials and studies of the NWTSG and COG.

Table 103.8 Wilms Tumor Staging Criteria

Stage	Criteria	4-Year Survival Rate (%)
1	Tumor is limited to kidney, completely excised; no evidence of rupture, intact surface	97
2	Tumor extends beyond kidney but completely excised, infiltration through renal capsule, extension into vessels outside kidney, local or open biopsy or spillage confined to flank, no residual tumor	95
3	Residual nonhematogenous tumor	91
4	Hematogenous metastases to lung, liver, cortical bone, brain, other organs	78
5	Bilateral renal involvement at diagnosis'	Same as highest unilateral stage

Survival based on outcome form patients with favorable biology in the National Wilms Tumor Study-3. Courtesy of the National Wilms Tumor Study.

The first two NWTSs, NWTS-I and NWTS-II, found that routine postoperative radiation was unnecessary in patients with tumors confined to the kidney and completely resected. Combination therapy of vincristine and actinomycin D was more effective than single-agent therapy and the addition of doxorubicin improved survival in higher-stage patients. Additionally, the duration of combination chemotherapy was successfully reduced in low-

stage patients from 15 months to 6 months without compromising survival outcomes.[95,96] These studies established criteria that identify unfavorable (anaplasia) and favorable histologic features that stratify patients into high-risk and low-risk treatment groups. High-risk patients are at a higher risk of recurrence and also include those with unresectable tumors, lymph node metastases, and diffuse tumor spill. This patient group benefits from intensified chemotherapy and abdominal radiation. These findings paved the way for NWTS-III that demonstrated successful treatment of stage 1 favorable histology Wilms tumors with lower dosing and further reduced duration of vincristine and actinomycin D. The 4-year relapse-free and survival rates with this regimen were 89% and 95%.[97] This study found that stage 2 patients with favorable histology were treated successfully with vincristine and actinomycin D without postoperative radiotherapy or doxorubicin and stage 3 patients had no differences in abdominal recurrence with reduction of abdominal radiotherapy compared to patients with high-dose radiotherapy when doxorubicin was administered (10.8 Gy compared to 20 Gy). The NWTS-III also found that patients with stage 4 favorable histology tumors were successfully treated with vincristine, actinomycin D, doxorubicin, and local radiotherapy based on local tumor stage. The addition of cyclophosphamide was without benefit. This group received lung radiation to both lungs (12 Gy) with 4-year relapse-free and overall survivals of 79% and 80.9%. The NWTS-IV trial was largely based on improving treatment results through modifying drug administration utilizing shorter and "pulse-intensive" chemotherapy regimens compared to standard divided dose regimens.[98] The results of this study revealed that shorter pulse-intensive regimens were equivalent to standard treatment regimens in terms of overall survival with total chemotherapy duration of 6 months. Since the NWTS-IV trial, survival rates for children with Wilms tumor have steadily improved with shorter chemotherapy schedules and lower treatment costs.[99] Based on results of NWTS-IV, the current overall survival rate for children with favorable histology Wilms tumor approaches 90%. Current 10-year relapse-free and overall survival for stage 1 favorable histology Wilms tumors are 91% and 96%, and for stage 2 tumors, 85% and 93%, respectively.[100] NWTS-V completed enrollment in 2003 and was designed as a nonrandomized single-arm therapeutic trial to treat patients with stage- and histology-specific treatment plans. In this study, patients were not

randomized to therapy, rather biologic properties of tumors were assessed. The aims included determining if tumor LOH for chromosomes 1p and 16q were associated with poorer prognosis in patients with favorable histology Wilms tumors and to determine if increased DNA content in tumor cells was associated with adverse outcomes.[101] LOH for 1p and 16q identified a subgroup of favorable histology patients who have a significantly increased risk of relapse and death.[87] LOH for these chromosomes is now used as an independent prognostic factor as patients with LOH for chromosome 1p and 16q have 75% relapse-free survival.

The NWTS-V also attempted to verify that surgery alone may have acceptable overall survival rates in a subgroup of children younger than 2 years of age at diagnosis with very low–risk favorable histology Wilms tumors that weigh less than 550 g.[102] The incidence of relapse was higher in this subgroup of patients receiving surgery only, but the salvage rate was surprisingly high with long-term survival being the same as patients receiving conventional postoperative chemotherapy. Given this, cooperative group trials will further study optimal management of surgery alone in this subgroup to determine if very low–risk patients may be spared adjuvant therapy.

Since 2006, the COG has opened four clinical trials for the treatment of children with Wilms tumors. For these therapeutic studies, patients are stratified into very low-, low-, standard-, and high-risk groups based on tumor histology, stage, biologic assessment, tumor weight, and age. To facilitate accurate risk assessment, it is currently recommended that all patients diagnosed with Wilms tumor be enrolled and follow protocol recommendations of AREN03B2, a biology classification-based trial. The current treatment recommendations are summarized in **Table 103.9** and are based on the most recent COG trials developed to build upon and refine results of previous NWTS.[103] The protocol guidelines recommend that stage 1 and 2 favorable histology patients undergo initial nephrectomy and lymph node sampling followed by vincristine and actinomycin D chemotherapy (Regimen EE-4A). Doxorubicin (Regimen DD-4A) is added to the treatment plan in patients with stage 1 and 2 tumors with favorable histology and LOH at chromosome 1p and 16q, as this subgroup has been shown to have an increased risk of relapse and death. Stage 1 tumors with unfavorable histology (focal or diffuse anaplasia) have lower 10-year relapse-free and

overall survivals of 69% and 82% and are treated with vincristine, actinomycin D, doxorubicin (Regimen DD-4A), and abdominal radiotherapy. Stage 3 patients with favorable histology are treated with nephrectomy, lymph node sampling, vincristine, actinomycin D, and doxorubicin (Regimen DD-4A) and abdominal radiotherapy, with 10-year relapse-free and overall survivals of 84% and 89%. Cyclophosphamide and etoposide (Regimen M) are added to the treatment regimen for stage 3 tumors with favorable histology and LOH at chromosomes 1p and 16q. The presence of diffuse anaplasia also intensifies therapy in stage 2 and 3 tumors with the addition of cyclophosphamide, carboplatin, and etoposide for 30 weeks (Regimen UH-1) and abdominal radiotherapy, with 10-year relapse-free and overall survivals of 43% and 49%. Stage 4 patients with favorable histology and pulmonary metastases are treated with nephrectomy, lymph node sampling, vincristine, actinomycin D, and doxorubicin for 24 weeks. In patients with stage 4 disease, the primary tumor is staged separately to determine the requirement for abdominal radiation. Lung radiotherapy is currently utilized if metastases remain detectable after 6 weeks of chemotherapy. For these reasons, it remains advantageous to resect the primary tumor prior to the initiation of chemotherapy even in patients with stage 4 disease. Based on results of NWTS-4, the 10-year relapse-free and overall survivals for patients with stage 4 favorable histology Wilms tumor is 75% and 81%. Stage 4 favorable histology tumors with LOH at chromosomes 1p and 16q are treated with the addition of cyclophosphamide and etoposide (Regimen M) and abdominal radiation. Stage 4 tumors with focal or diffuse anaplasia (without measurable disease) are treated with the addition of cyclophosphamide, carboplatin, and etoposide for 30 weeks (Regimen UH-1) and radiotherapy. This subgroup of patients has the worst 10-year relapse-free and overall survivals of 18%. Stage 5 Wilms tumors (bilateral tumors) with favorable histology have 10-year relapse-free and overall survivals of 65% and 78%. Patients with bilateral Wilms tumors are treated with preoperative chemotherapy (vincristine, actinomycin D, doxorubicin) and renal-sparing surgery.

Table 103.9 Recommended Therapy According to COG Protocols

Stage/Histology	Radiotherapy	Chemotherapy
Stage 1 FHWT, <2 yo, <550 g	None	None
Stage 1 FHWT, >2 yo, >550 g	None	Regimen EE-4A
Stage 2 FHWT	None	Regimen EE-4A
Stage 1, II FHWT	None	Regimen DD-4A
LOH 1p,16q		
Stage 3 FHWT	Yes	Regimen DD-4A
No LOH 1p, 17q		
Stage 1–3 focal AHWT	Yes	Regimen DD-4A
Stage 1 diffuse AHWT	Yes	Regimen DD-4A
Stage 3, 4 FHWT	Yes	Regimen M
LOH 1p,16q		
Stage 4 FHWT		
Pulmonary mets		
lesions resected at diagnosis	Yes	Regimen DD-4A
lesions resolve after 6 wks chemo	None	Regimen DD-4A
lesions persist after 6 wks chemo	Yes	Regimen M
Stage 4 FHWT nonpulmonary mets	Yes	Regimen M
Stage 2–3 diffuse AHWT	Yes	Regimen UH-1
Stage 4 diffuse AHWT	Yes	Regimen UH-1

Regimen EE-4A: Pulse-intensive AMD plus VCR (18 weeks). Regimen DD-4A: Pulse-intensive AMD, VCR, and DOX (24 weeks). Regimen M: VCR, AMD, DOX, alternating with CYCLO and ETOP (24 weeks). Regimen UH-1: CYCLO, carboplatin, ETOP alternating with VCR, DOX, CYCLO (30 weeks). Regimen I: VCR, DOX, CYCLO alternating with CYCLO, ETOP (24 weeks). Regimen UH-2: VCR, DOX, CYCLO alternating with CYCLO, carboplatin, ETOP and VCR, Irinotecan (30 weeks).

FHWT, favorable histology Wilms tumor; AHWT, anaplastic histology Wilms tumor; CCSK, clear-cell sarcoma of the kidney; MRT, malignant rhabdoid tumor of the kidney; AMD, dactinomycin; VCR, vincristine; DOX, doxorubicin; CYCLO, cyclophosphamide; ETOP, etoposide.

Ko EY, Ritchey ML. Current management of Wilms' tumor in children. *J Pediatr Urol* 2009;5(1):56–65.

Surgical Considerations

Preoperative biopsies are contraindicated unless a tumor is surgically unresectable. Unilateral radical ureteronephrectomy with abdominal exploration is accomplished through a wide transverse abdominal incision that will allow safe resection and regional lymph node sampling without rupture. A thoracoabdominal incision may be utilized as necessary for tumors reaching beyond the diaphragm. Complete abdominal and pelvic exploration is performed. The contralateral kidney does not require exploration if preoperative imaging does not suggest involvement. The lateral peritoneal reflection is incised, and the colon is reflected medially. Though a formal retroperitoneal lymph node dissection is not recommended, lack of adequate lymph node sampling along with the primary tumor resection automatically upstages treatment to stage 3 disease because of the risk of local relapse.[103] Gentle handling of the tumor is critical to avoid tumor rupture and spillage as there is a sixfold increase in local relapse and also automatic tumor upstaging to stage 3.[104] Both local and diffuse tumor rupture will increase relapse risk. It is often unsafe to attempt to ligate the renal vein prior to tumor manipulation given the size of most Wilms tumors as traditionally recommended by most authors. Later ligation of the renal vein after tumor mobilization has not been shown to adversely affect survival outcomes and early ligation should not be attempted if technically difficult. The dissection is carried out along the tumor capsule and outside of Gerota fascia identifying the renal hilum and isolating the renal artery, vein, and the ureter (**Fig. 103.7**). The renal vein and inferior vena cava are palpated for intravascular tumor extension. The ureter is divided as distal as possible to

the renal hilum though it is not necessary to remove the entire ureter. The tumor and kidney is then removed en bloc. The adrenal gland may be left in place if it is not adherent to the tumor or if the tumor arises from the lower pole of the kidney.[105] Titanium clips should be utilized to identify any gross residual tumor. The tumor and nephrectomy specimen should not be placed into fixative but delivered fresh and sterile to the pathologist to optimize histologic and cytogenetic analysis based on pediatric tumor protocols.

There have been reports of laparoscopic resection of Wilms tumor.[106] These are more likely feasible after preoperative chemotherapy with lower risk of tumor rupture, though safety has not been confirmed. Success of laparoscopy for Wilms tumor is hindered by tumor spill and by inaccurate staging.

Patient selection for preoperative chemotherapy is a critical step in surgical and treatment planning. The overall incidence of surgical complications in patients undergoing nephrectomy for Wilms tumor is 12.7%.[107] The most common surgical complications are small bowel obstruction (5.1%) and excessive hemorrhage (1.9%), followed by wound infection (1.9%) and vascular injury (1.5%) as reported by the NWTS-IV trial. Higher-stage tumors, intravascular extension, and resection of contiguous organs are risk factors associated with surgical complications. The risk of renal insufficiency after unilateral nephrectomy for Wilms tumor is low (.25%) and patients with Denys–Drash syndrome are most at risk for progressive tumor in the remaining kidney.[108] For these reasons, nephron-sparing procedures are currently reserved for children with bilateral Wilms tumor and for those at risk for developing renal failure, and not indicated for patients with standard unilateral tumors with a normal contralateral kidney.

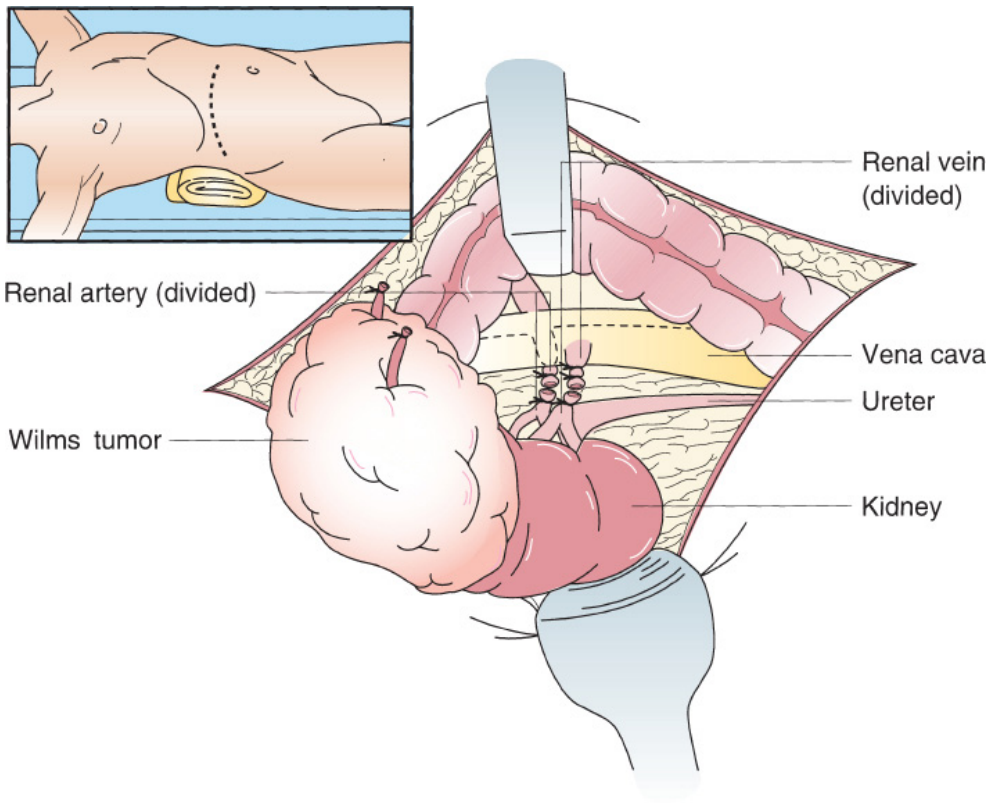

Figure 103.7 Anatomy and operative approach to resection of a Wilms tumor.

Renal Vein/Inferior Vena Cava

Four percent to 10% of patients with Wilms tumor have intravascular extension into the renal vein, inferior vena cava, and rare cases extending into the atrium. Patients may have symptoms of vascular involvement depending on the degree of venous obstruction that may include hypertension, hepatosplenomegaly, ascites, and heart failure. The preoperative ultrasonography and CT scan are accurate in detecting intravascular tumor extension, but the vessels should still be palpated prior to ligation of the renal vein during tumor excision. Studies of Wilms tumors with intravascular extension have found that preoperative chemotherapy facilitates resection by decreasing the extent of tumor thrombus. Overall frequency of complications and the 3-year relapse-free survival rates were similar between the preoperative therapy group and the upfront resection group.[109] Control of the renal vessel and vena cava below and above the tumor thrombus is essential to obtain vascular control and to minimize bleeding after venotomy. Effort should be made to avoid transecting tumor thrombus. If the patient has

intracardiac tumor extension after preoperative chemotherapy, a combined thoracoabdominal incision with cardiopulmonary bypass is the safest surgical approach for tumor thrombus excision. The overall survival of children with intravascular extension is the same as children with disease limited to the kidney of similar stage and histology.[110]

Bilateral Wilms Tumor

Five percent to 8% of patients with Wilms tumors present with bilateral disease. Bilateral Wilms tumor is found more frequently in patients with hemihypertrophy and genitourinary anomalies. Primary tumor excision at diagnosis is discouraged and patients may be enrolled on NWTS trials without an initial biopsy. If obtained because of uncertainty in diagnosis, core needle biopsies through a posterior approach are preferable to minimize contamination of the abdominal cavity and three-drug chemotherapy is initiated. All children with bilateral Wilms tumors should receive preoperative chemotherapy with the goal of renal preservation. The current COG protocol recommends reevaluation by abdominal CT scan after 6 weeks of chemotherapy to determine the feasibility of a renal-sparing procedure. If the tumor response is less than 50% shrinkage, the COG recommends bilateral open renal biopsies to assess tumor histology prior to additional chemotherapy. After 12 weeks of therapy, all patients should undergo surgical resection as continuing therapy beyond 12 weeks has not been shown to improve outcomes. The primary surgical goal is to spare as much renal parenchyma as possible while obtaining complete tumor resection. Children with synchronous bilateral Wilms tumor or tumor with contralateral nephrogenic rests that have complete radiographic response may not require surgical excision and have low risk for local relapse.[111] These children are monitored for recurrence by serial imaging. If partial nephrectomy is not safe after 12 weeks of chemotherapy then nephrectomy is recommended. In NWTS-IV, children with bilateral Wilms tumor who had partial resection with complete resection of all gross disease had local relapse rate of 8% and 4-year overall survival of 81.7%.[112]

Partial Nephrectomy

Nephron-sparing surgery is utilized in patients with bilateral Wilms tumor and in select patients at high risk for bilateral disease or renal failure. Partial nephrectomy is not indicated in patients with standard unilateral Wilms tumor given the low risk of renal failure with unilateral nephrectomy. Children with Wilms tumor predisposing syndromes such as WAGR, Beckwith–Wiedemann, and Denys–Drash syndrome are predisposed to the development of tumors in the contralateral kidney and are therefore managed with a nephron-sparing partial nephrectomy approach for unilateral tumors. Screening imaging studies in such patients at risk of developing Wilms tumors may detect lesions that are appropriate for nephron-sparing procedures. These patients may still benefit from preoperative chemotherapy to minimize the extent of renal resection. A radionucleotide renal scan (dimercaptosuccinic acid/DMSA scan) is useful to assess preoperative and postoperative renal function.

Partial nephrectomy is typically feasible only if tumor involves one pole and less than one-third of the kidney and if the collecting system and renal vein are uninvolved. For bilateral tumors, the kidney with the lowest tumor burden is addressed first to determine if partial nephrectomy is feasible. A transverse abdominal incision is utilized for abdominal exploration and partial nephrectomy utilizing the same principles of radical nephrectomy with respect to tumor spillage. Manual compression of the kidney may control blood loss and avoid vascular ischemia. Tumor resection is accomplished by opening Gerota fascia and mass excision via wedge resection with 0.5- to 1.0-cm margin of normal renal parenchyma. Enucleation may be considered for large centrally located lesions. The specimen should be examined closely for rhabdomyomatous changes and anaplasia, and nephrectomy considered in patients with positive margins or high-risk histology.[113] Renal functional outcomes after nephron-sparing surgery are assessed by serum creatinine level, glomerular filtration rate (GFR), hypertension, and proteinuria.[105] Improved surgical techniques and intraoperative ultrasound have vastly improved the safety and feasibility of nephron-sparing surgery in children at risk of postoperative renal failure.

Future Directions

Future studies will continue to focus on personalized treatment plans based on tumor biology and patient risk stratification. New COG protocols are currently in place with efforts to further improve curative outcomes while minimizing toxicity with refined stratification based on tumor-specific biologic properties. Next-generation exome sequencing has enhanced the capacity to identify disrupted molecular pathways in Wilms tumors and there is extensive research on identifying their role in Wilms tumor development and pathogenesis.[114] There are very few known genetic alterations in Wilms tumors that have been shown to drive tumorigenesis or progression. Examples of this are the discovery of new mutations in Wilms tumor genes involved in miRNA processing including SIX1 and SIX2.[115] Mutations in this pathway may underlie high-risk Wilms tumors and serve as biomarkers and new therapeutic targets. Several researchers have found significant epigenetic alterations such as changes in DNA methylation or chromatin structure in Wilms tumors. Epigenetic changes at the imprinted region at chr11p15.5 show an allele-specific pattern of methylation resulting in abnormal expression of IGF2. Targeting IGF2 is an active area of investigation in preclinical drug development.[116] Circulating epigenetically modified DNA and miRNAs have been detected in the blood of patients allowing researchers to investigate the utilization of tracking genetic mutations in the circulation as a mechanism of diagnosis, risk stratification, and tracking tumor burden in Wilms tumor.[114,117] Other areas of intense research continue in the role of myeloablative chemotherapy and the role of autologous bone marrow transplantation in patients with relapsed Wilms tumors.

NON-WILMS RENAL TUMORS

Congenital Mesoblastic Nephroma

Congenital mesoblastic nephroma (fetal renal hemartoma) is the most common renal neoplasm in neonates and infants younger than 3 months of age and is considered a separate clinical entity from Wilms tumor. In contrast to Wilms tumor, classic congenital mesoblastic nephroma is considered a benign solid tumor of infancy, occurring in a younger age group with an

excellent overall prognosis. Almost all cases are diagnosed within the first 6 months of life, representing 5% of renal neoplasms in children.[118] There may be a slightly higher incidence in boys.[119] Congenital mesoblastic nephroma has distinctive spindle cell histopathologic and clinical features that are generally considered benign and rarely metastasizes to other organs. Congenital mesoblastic nephroma is a mesenchymal tumor with three pathologic variants: classic congenital mesoblastic nephroma, a cellular subtype, and a mixed variant. Cellular congenital mesoblastic nephroma subtype is a more aggressive tumor and though rare, is capable of recurrence and metastases.[120] The cellular subtype is similar in histology to infantile fibrosarcoma and may represent a visceral form of the disease while classic histology is similar to infantile fibromatosis.[121] The cellular variant of congenital mesoblastic nephroma has been found to have a translocation (t12;15) (p13;q25) that results in ETV6-NTRK3 fusion protein, a genetic alteration also found in congenital infantile fibrosarcoma.[122] Similar to congenital infantile fibrosarcoma, trisomy 11 is also found in the cellular subtype of congenital mesoblastic nephroma.[123] These chromosomal aberrations distinguish the cellular variant of congenital mesoblastic nephroma from the classic variant.

Neonates and infants with congenital mesoblastic nephroma present with a palpable abdominal mass that is indistinguishable from other solid abdominal masses on physical examination. Hematuria is often present along with vomiting and jaundice in rare cases.[124] Hypertension or hypercalcemia is rarely present. The most common diagnostic imaging studies utilized are ultrasound and CT scan detailing the presence of a unilateral solid mass with or without cystic components, necrosis, or calcifications. The mass can be detected on prenatal ultrasound and polyhydraminos may be found in up to 70% of patients.[125] The diagnostic workup precedes in much the same manner as Wilms tumor and the lesions are often not discernible on physical examination or preoperative imaging. The standard treatment for congenital mesonephric nephroma is complete surgical resection with nephrectomy. Wide margins are recommended because these tumors can infiltrate surrounding renal parenchyma and perinephric tissues. Local recurrence, though rare, has been reported and is associated with the cellular variant.[124] Systemic chemotherapy is reserved for tumors that recur and in rare cases of metastases or unusually cellular histology.

Clear Cell Sarcoma

Clear cell sarcoma of the kidney is a rare renal neoplasm of childhood, distinct from Wilms tumor. There are approximately 20 new cases in the United States each year. The median age of diagnosis of clear cell sarcoma of the kidney is 36 months and the tumor is one of the "unfavorable histology" tumors studied by the NWTSG and the COG. There is a male predominance with male to female ratio of 2:1.[126] Clear cell sarcoma of the kidney has morphologic diversity and is composed of sarcomatous, nonepithelial cells.[127] The classic microscopic pattern of clear cell sarcoma of the kidney is cords of round or spindle-shaped cells with clear cytoplasm and frequent empty-appearing "Orphan Annie" nuclei. The cord cells are surrounded by variants of regularly spaced arborizing fibrovascular septa resulting in cord widths of between 4 and 10 cells.[127] The cellular septa are characteristic of clear cell sarcoma and aid in diagnosis. The cord cells range from ovoid to spindle-shaped and the septa range from thin "chicken-wire" capillaries to sheaths of fibroblast-like cells in a collagenous matrix.[126] Most tumors have the classic histologic pattern though almost all demonstrate a secondary variant pattern. There are eight variant patterns recognized: myxoid (50%), sclerosing (35%), cellular (26%), epithelioid (13%), palisading (11%), spindle cell (7%), storiform (4%), and anaplastic pattern (2.6%).[126] Necrosis is associated with poor prognosis and tumors without necrosis are more often stage 1 tumors with superior outcomes.

Patients with clear cell sarcoma of the kidney present with a large unilateral abdominal mass that is best visualized by abdominal ultrasound and CT scan. The tumors are typically well circumscribed and consist of a solid mass with cystic foci components. Necrosis and hemorrhage are common. There is gross extension into the renal vein in 5% of cases. The most common site of metastatic disease is ipsilateral renal hilar lymph nodes (29%) and bone metastasis is the most common mode of relapse.[126] Radiographic skeletal survey and radionucleotide bone scan is critical to determine if there are bone metastases at diagnosis. Patients may also have lung, brain, or liver metastases and therefore should have chest and central nervous system (CNS) imaging prior to initiation of chemotherapy for accurate staging. The staging system is similar to Wilms tumor. There is a high rate of metastases and relapse in early-stage tumors and intensive

chemotherapy is utilized for all cases. The current COG treatment recommendations for patients with clear cell sarcoma of the kidney include radical resection of the primary tumor and involved regional lymph nodes, followed by adjuvant chemotherapy consisting of vincristine, actinomycin D, doxorubicin, and abdominal radiotherapy (10 Gy) for all stages. Since the addition of doxorubicin to the treatment protocols of clear cell sarcoma of the kidney, patients with stage 1 disease have 6-year overall survival of 97%, stage 2 and 3 patients have 6-year survivals of 75% and 77%, respectively (compared to 30% for both stages prior to doxorubicin), stage 4 patients have 6-year survival of 50%.[126] There is active study within the COG on the benefit of the addition of cyclophosphamide and etoposide to treatment plans of patients with clear cell sarcoma of the kidney.[128] There is propensity for late relapse and patients are monitored with abdominal imaging, chest radiograph, brain MRI, and bone scans.

Rhabdoid Tumor of the Kidney

Rhabdoid tumor of the kidney is a rare and aggressive cancer in infancy, constituting 1.8% of renal neoplasms in children. The cell of origin is unknown, and the tumor was originally classified as a rhabdomyosarcomatoid subtype of Wilms but is now recognized as a distinct histologic tumor type. Histologically, rhabdoid tumors are well demarcated from the surrounding kidney and composed of solid and monotonous appearance of sheets of large cells with abundant cytoplasm, cytoplasmic inclusions, and prominent nucleoli.[129] Intense vimentin immunoreactivity is characteristic, and these tumors may also stain for cytokeratin, desmin, and neurofilament. Rhabdoid tumors may have areas of necrosis and foci of sclerosis.[129] Rhabdoid tumors may occur as separate CNS primary tumors and up to 15% of patients with rhabdoid tumor of the kidney develop CNS lesions.[130] The overall prognosis of patients with rhabdoid tumor of the kidney remains poor and age is an important prognostic factor.[131] Patients diagnosed with rhabdoid tumors at less than 1 year of age have extremely poor prognoses and are at high risk for CNS tumors, while patients older than 1 year at diagnosis have better outcomes. Low stage and female gender have also been reported as features that predict improved survival.[130] Because of the small number of patients with this disease and overall poor

outcomes, few other prognostic indicators have been identified. Rhabdoid tumors are characterized by loss-of-function mutations of the tumor suppressor gene hSNF5/INI1 located at chromosome 22q11 which encodes a chromatin-remodeling protein complex (SWI/SNF).[132] This chromosomal alteration is thought to be a characteristic genetic defect for rhabdoid tumors of all sites.[133] Both acquired and germline mutations have been observed.[134] Though the functional consequences are not yet known, mutations in INI1 have been found to result in altered transcription of genes involved in growth and differentiation.

Patients with malignant rhabdoid tumor of the kidney present with a palpable abdominal mass and often have hematuria. The diagnostic workup proceeds with an abdominal CT scan showing a large heterogeneous solid mass with areas of necrosis, hemorrhage, or calcifications. The tumor typically involves the renal hilum. A chest radiograph or chest CT scan should be obtained to evaluate for lung metastases. Lung metastasis is present in 56% of patients with rhabdoid tumor of the kidney at diagnosis and is the most common site of metastatic spread.[130] Evaluation for CNS disease should also occur at diagnosis because of the frequency of CNS primaries and metastases in patients with rhabdoid tumors. Therapy begins with radical nephrectomy and complete surgical resection including involved regional lymph nodes with paracaval and para-aortic lymph node sampling. Meticulous sampling of any potentially involved lymph nodes is critical for accurate staging. Patients are staged according to NWTS staging system and all patients receive intensified adjuvant chemotherapy and abdominal radiotherapy. Based on current COG protocols, children with stage 1 to 3 malignant rhabdoid tumor of the kidney are treated with cyclophosphamide, carboplatin, and etoposide alternating with vincristine, doxorubicin, and cyclophosphamide for 30 weeks (Regimen UH-1). Stage 4 patients receive vincristine, doxorubicin, and cyclophosphamide that are alternated with cyclophosphamide, carboplatin, etoposide, vincristine, and irinotecan for 30 weeks (Regimen UH-2). All patients receive abdominal radiotherapy. The survival rate for children with rhabdoid tumor of the kidney is dismal with overall survival rates below 25%, and very few survivors of stage 4 disease. Despite aggressive multimodal therapy, children less than 1 year of age with rhabdoid tumor of the kidney have a 4-year survival of 8.8% and children over 2 years of age have 4-year survival of 41.1%. Because previous

protocols have had minimal successes with improving relapse and survival in children with malignant rhabdoid tumors, current COG clinical trials are examining intensive chemotherapy regimens and experimental agents in this high-risk renal tumor.[131]

Renal Cell Carcinoma

Renal cell carcinoma is rare in pediatric patients and comprises approximately 5% of all renal tumors in children and adolescents.[4] The tumor is highly aggressive with frequent distant metastases. The median age of diagnosis of renal cell carcinoma in children is 9 to 10 years and children who have previously received cytotoxic chemotherapy may have predisposition to developing this cancer.[135] Pediatric renal cell carcinoma differs from adult renal cell cancer with distinct clinical and biologic differences. The microscopic pattern does not typically fit well within the standard adult subtypes. In general, histology is consistent with papillary adenocarcinoma, renal cell carcinoma not otherwise specified (NOS), and clear cell adenocarcinoma subtypes.[136] High nuclear grade and increased vimentin expression are found in higher-stage cases.[137] Patients with von Hippel–Lindau syndrome may present with bilateral renal cell carcinoma. Tuberous sclerosis, Birt–Hogg–Dube syndrome, and hereditary leiomyomatosis are other hereditary syndromes associated with renal cell carcinoma.[5] It is routine to test for translocations of the Xp11.2 and 6p21 loci, nonrandom genetic alterations that are characteristic of renal cell carcinoma.[138] Tumors with Xp11.2 translocations have papillary and clear cell features and are a separate entity in the World Health Organization classification of renal tumors.[139] This translocation may be present in up to 70% of pediatric renal cell carcinoma and involves the fusion of the TFE3 gene, a transcription factor belonging to the microphthalmia (MiTF) family.[140] The translocation involving 6p21 is the second most common translocation in pediatric renal cell carcinoma and results in the fusion of TFEB, also a member of the MiTF transcription factor family.[140]

Patients may present with a large palpable abdominal mass. Abdominal pain, hematuria, weight loss, joint pain, and anorexia may also be present. Cross-sectional abdominal and pelvic imaging (CT scan or MRI) along with chest radiograph and/or chest CT scan is critical to define the locoregional

extent of the mass and to determine metastatic spread. Distant metastatic disease is present in up to 30% of pediatric patients at diagnosis, most commonly to lung (64%), liver (57%), and bone (42%).[140] Local lymph node involvement does not necessarily predict poor outcome in renal cell carcinoma in children.[141] Imaging may show a large nonenhancing renal mass with necrosis or hemorrhage. Calcifications are more common in children with renal cell carcinoma compared to Wilms tumor.[142] Compared to adults, children with renal cell carcinoma present with higher-stage and higher-grade disease.[140] Children with renal cell carcinoma are staged based on the International Union Against Cancer (UICC)/American Joint Committee on Cancer (AJCC; tumor, node, and metastases [TNM]) system although some studies utilize the modified Robson staging classification system.[138,143] The overall survival at 20 years for pediatric renal cell carcinoma is 54.9%.[144]

If the mass is resectable at diagnosis, standard treatment is radical nephrectomy with lymph node sampling followed by combination adjuvant chemotherapy, immunotherapy, and radiotherapy based on surgical pathology. The role of lymph node dissection for renal cell carcinoma has not been determined. Partial nephrectomy is reserved for patients at high risk of postoperative renal failure and multiple renal tumors, particularly patients with genetic syndrome–related disease. There are reports of successful partial nephrectomy for small, unilateral, low-stage tumors. The role of chemotherapy is unproven, as the administration of chemotherapy has not significantly improved survival outcomes. There is some evidence that immunotherapy (IL-2) may be beneficial in select cases of renal cell carcinoma.[145] The COG completed a clinical trial (2006–2014) examining outcomes of high-risk renal tumors with complete surgical resection, intensive chemotherapy regimens, and radiotherapy. The most common agents utilized are combinations of vincristine, actinomycin D, doxorubicin, cyclophosphamide, irinotecan, etoposide, and carboplatin (https://clinicaltrials.gov/show/NCT00335556). This prospective study should yield critical results on the optimal management of adjuvant therapy for this tumor.

RHABDOMYOSARCOMA

Epidemiology and Genetic Risk

Rhabdomyosarcoma is the most common soft tissue sarcoma in children with an overall incidence of approximately 350 cases per year in the United States.[146] The median age of presentation is 7 years of age and the majority of patients are diagnosed prior to 10 years of age. There is a slight male predominance and a slightly higher incidence in African-American children.[4] Rhabdomyosarcoma tumors are classified as either embryonal, alveolar, or pleomorphic histologic subtypes. Embryonal rhabdomyosarcoma (68%) is the most frequent histologic type and occurs in children younger than 4 years of age.[146] Alveolar rhabdomyosarcoma (31%) and pleomorphic subtypes (1%) occur more commonly in older children. The overall incidence of rhabdomyosarcoma has not changed much in the last 30 years although there has been an increase in incidence of the alveolar subtype and in cases presenting with distant metastases.[146] The overall survival for rhabdomyosarcoma has increased from 25% to over 80% in the last four decades. This is largely due to improvements in multimodal therapies including radical surgery, intensive combination chemotherapy and radiotherapy. Patients with embryonal subtype have the best overall survival. Patients with smaller size tumors and favorable anatomic sites also have significant survival advantage. Age relates independently to survival outcomes with infants (<1 year of age) and adolescents (>10 years of age) more likely to have poor outcome and unfavorable histologic features.[147]

Rhabdomyosarcoma is often associated with congenital malformations, most commonly the CNS and genitourinary systems, with nearly an eightfold increase in CNS anomalies in children with rhabdomyosarcoma.[148] At least 32% of children with rhabdomyosarcoma have at least one congenital anomaly and nearly half are considered major defects. The rate of genitourinary defects in rhabdomyosarcoma is similar to that seen in children with Wilms tumors. There are also several familial syndromes associated with rhabdomyosarcoma. Children in families with Li–Fraumeni syndrome are at risk of developing rhabdomyosarcoma along with cancers of the breast, bone, brain, lung, and adrenal gland.[149] Rhabdomyosarcoma has been reported at an increased incidence in patients with neurofibromatosis type 1 and in patients with Beckwith–Wiedemann syndrome.[150–152] Environmental factors have also been found to have a role in the development of

rhabdomyosarcoma. Parental use of recreational drugs has been associated with an increased risk. Several studies have suggested that cocaine and marijuana use in parents may increase the risk of rhabdomyosarcoma in offspring.[153]

Pathology and Biologic Features

Rhabdomyosarcoma is a heterogeneous group of tumors. The origin is thought to be embryonal mesenchyme that gives rise to striated skeletal muscle. Rhabdomyosarcoma can occur in any skeletal muscle group, but most commonly affected sites are head and neck, trunk, and genitourinary. The Intergroup Rhabdomyosarcoma Study Group (IRSG), now the Soft Tissue Sarcoma Committee of the COG, classifies patients with rhabdomyosarcoma into the International Classification of Rhabdomyosarcoma (ICR) that is predictive of outcome among patients with different histologic subtypes.[154] Embryonal rhabdomyosarcoma is a heterogeneous subtype with histologic features that range from primitive mesenchymal cells to highly differentiated muscle cells. The small round blue cells consist of nuclei that are generally small with a light chromatin pattern. The microscopic pattern is moderately cellular with loose myxoid stroma.[154] Embryonal rhabdomyosarcoma comprises up to 75% of rhabdomyosarcoma tumors and is considered an intermediate prognosis tumor in terms of outcomes. Alveolar rhabdomyosarcoma is associated with poor prognosis. The tumors consist of small round cells with coarse chromatin and anastomosing fibrovascular connective tissue septa forming an alveolar pattern that is similar to lung in appearance (**Fig. 103.8**).[154] Botryoid tumors have excellent prognosis and have similar histologic characteristics of embryonal tumors but grow into hollow spaces like bladder or vagina, assuming a characteristic grapelike appearance. Spindle cell rhabdomyosarcoma is another subtype of embryonal rhabdomyosarcoma that occurs most commonly at paratesticular sites and generally have excellent prognosis. Pleomorphic rhabdomyosarcomas are extremely rare in children and more common in adults. Rhabdomyosarcoma is detected on immunohistochemistry by desmin, myoglobin/Myo-D, or muscle-specific actin staining.[155] Myogenic phenotype may also be determined by electron microscopy.[156]

Recurrent chromosomal alterations have been identified in rhabdomyosarcoma, particularly in alveolar subtypes.[157] Consistent translocations between chromosome 2 and 13, t(2:13)(q35;q14) have been identified and occur in up to 55% of alveolar rhabdomyosarcoma tumors. The translocation results in fusion of the PAX3 and FKHR genes, both transcription factors that function in muscular development. The resulting gain of function fusion gene is thought to alter cellular apoptosis, growth, and oncogenesis.[158] Another PAX gene translocation, t(1;13)(p36;q14), results in fusion gene PAX7-FKHR and also occurs in alveolar tumors.[159] These recurrent chromosomal alterations rarely occur in embryonal rhabdomyosarcoma. Nearly 80% of alveolar tumors have PAX3-FKHR or PAX7-FKHR fusions detectable by polymerase chain reaction (PCR) and may aid in diagnosis.

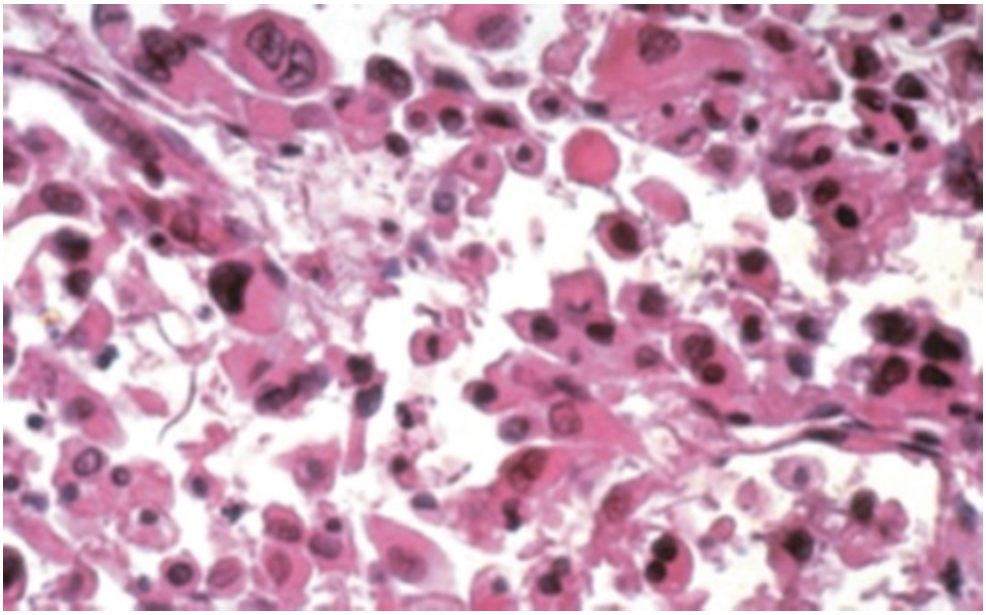

Figure 103.8 Microscopic image of typical lung-like appearance of an alveolar rhabdomyosarcoma. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1997 with permission.)

Embryonic rhabdomyosarcoma is associated with allelic loss at chromosome 11p15.5, a possible tumor suppression region.[160] The mechanism of loss appears to preferentially maintain the paternal allele and lose the maternal allele, suggesting genomic imprinting.[161] Other genetic abnormalities have been identified through comparative genomic

hybridization (CGH) detecting whole chromosome gains and losses in embryonal rhabdomyosarcoma.[162] Genomic amplifications have been detected in alveolar subtypes and in embryonal rhabdomyosarcoma with anaplasia.[162]

Presentation and Diagnosis

Rhabdomyosarcoma can arise at any mesenchyme-containing site in the body. The presenting signs and symptoms depend on the site affected. Approximately 35% of all rhabdomyosarcoma tumors arise in the head and neck region and include parameningeal and nonparameningeal sites. Tumors in these areas may cause headache, facial and cervical swelling, nasal obstruction or discharge, recurrent otitis media, and cranial nerve palsies.[163] Tumors of the genitourinary track account for 25% of rhabdomyosarcoma and are most commonly located in the bladder and prostate gland. Perineal and perianal lesions may also occur. Patients may present with a palpable abdominal or pelvis mass, hematuria, dysuria, or urinary retention. Botryoid tumors are common in the vagina and cervix and may present with vaginal bleeding and inflammation. The friable grapelike mass may protrude from the vaginal orifice. Paratesticular rhabdomyosarcoma presents with a painless mass in the scrotum that is typically distinguishable from the testicle. Extremity rhabdomyosarcoma tumors may present as swelling and pain after a traumatic injury to the extremity involved. Chest wall, paraspinal, and abdominal wall rhabdomyosarcoma are considered trunk sites and often present with palpable masses or chest wall pain. Additional primary sites include retroperitoneum, abdomen, and pelvis. These lesions may present as a palpable abdominal mass or with abdominal pain. There is seldom mass effect such as rectal or bladder obstruction. Biliary rhabdomyosarcoma may cause jaundice, fever, and right upper quadrant abdominal pain.

The diagnostic workup for rhabdomyosarcoma includes a thorough history and physical examination followed by cross-sectional imaging of the involved site by CT scan or MRI. Local, regional, and distal metastatic extent of disease should be determined with assessment for abnormal-appearing lymph nodes. PET scan may aid in detection of disease for adequate staging.[164] Complete blood count, serum chemistries and liver function tests are routinely evaluated. Patients with suspected

rhabdomyosarcoma should have bone marrow biopsies and aspirates performed to determine metastatic spread to bone marrow. CT chest or chest radiograph is required to identify lung metastases. Bone scintigraphy should be obtained to search for cortical bone metastases. For most cases, brain CT scan and cerebral spinal fluid testing is reserved for patients with known CNS lesions or symptoms. An adequate biopsy is required to histologically confirm diagnosis. If the lesion is small or judged resectable on presentation, excisional biopsy with clear microscopic margins should be performed. If the tumor involves contiguous organs, major blood vessels, or nerves, then incisional biopsy is performed. It is critical that the specimen is sent fresh to the pathologist without formalin and that enough tissue is obtained for microscopic evaluation and cytogenetic analysis.

Table 103.10 TNM Pretreatment Staging System for Childhood Rhabdomyosarcoma

Stage	Site	T	Size	N	M
1	Orbit, head, and neck (excluding parameningeal), genitourinary (nonbladder/prostate)	T1 or T2	a or b	N0, N1, or N2	M0
2	Bladder/prostate, extremity, head and neck (parameningeal), other (trunk, retroperitoneum)	T1 or T2	a	N0 or Nx	M0
3	Bladder/prostate, extremity, head and neck (parameningeal), other (trunk, retroperitoneum)	T1 or T2	a b	N1 N0, N1, or Nx	M0
4	All	T1 or T2	a or b	N0 or N1	M1

Children's Cancer Study Group. Pediatric Oncology Group. *Cancer* 1997;80(6):1165–1170. Permission granted from previous edition.

Staging

The most widely utilized staging system for rhabdomyosarcoma is based on the (TNM) staging system. TNM staging system is applied prior to treatment and assesses disease site of origin, tumor size, nodal status, and metastases as factors in prognosis (**Table 103.10**). This system was prospectively tested in IRSG clinical trials IRS-III and IV and reflects the biology of the tumor.[165] Most tumors are greater than 5 cm in size and 20% present with distant metastases at diagnosis (stage 4). Stage 1 tumors involve the head and neck, genitourinary (nonbladder/prostate), and biliary tract sites. Regional nodes may or may not be involved with stage 1 tumors. Stage 2 tumors involve the bladder/prostate gland, extremity, cranial, parameningeal, retroperitoneal,

and trunk sites and are less than 5 cm without lymph node involvement. Stage 3 tumors are the same anatomic sites as stage 2 and are greater than 5 cm with or without lymph node involvement. Any rhabdomyosarcoma tumor with distant metastases is considered stage 4 disease.

Clinical Group Assessment and Risk Status

Both stage and group assessment is used to assign risk categories and to determine treatment plan. The IRSG developed a surgical–pathologic clinical grouping system to standardize risk assessment in the IRS I and II therapeutic clinical trials. Patients are grouped into four risk groups based on postoperative assessment of disease before initiating chemotherapy or radiation (**Table 103.11**).[166] Clinical group accurately predicts outcomes in patients with rhabdomyosarcoma.[166] Group I patients have excellent prognosis with localized tumors that are completely excised while group II patients have tumors that have microscopic residual disease or regionally invasive disease involving lymph nodes. Group III patients have gross residual disease or incisional biopsy, and Group IV patients have distant metastases at presentation. Stage, clinical group, histology, age, and anatomic site are utilized to identify low-, intermediate-, and high-risk categories, and therapy is allocated based on patient risk status. Favorable sites are orbit, head and neck (except parameningeal), genitourinary (except bladder and prostate), and biliary tract sites. Unfavorable sites are bladder/prostate, extremity, parameningeal, trunk, retroperitoneal, pelvis, and all other sites. Combinations of chemotherapy and radiotherapy are administered based on risk-group assignment. Alveolar and embryonal histology subgroups contrast in prognostic factors and in survival outcomes.

In patients with nonmetastatic rhabdomyosarcoma, tumors considered low risk are embryonic rhabdomyosarcoma tumors (stage 1 or 2) located at favorable histology sites.[167] Embryonal tumors at unfavorable sites may also be assigned as low-risk group if the tumor is grossly completely resected (group I or II). There are two subsets of low-risk patient groups. Subset A (stage 1, group I or IIa, stage 2, group1, group III orbit) is associated with worse failure-free survival (82%) in patients >10 years old, though overall survival is the same as younger patients (92%). This suggests excellent salvage therapy in this subgroup of patients. Low-risk subset B patients

(stage 1, group IIb or IIc, stage 1, group III nonorbit; stage 2, group II, stage 1, group I or II) with tumors larger than 5 cm also have worse failure-free survival (77%) but similar overall survival as patients with smaller tumors (93%).[167] Intermediate-risk embryonal rhabdomyosarcoma are patients with unfavorable anatomic sites with tumor remaining after surgical excision. This risk group has worse survival outcomes than patients with low-risk tumors. In this group, patients with unresectable extremity rhabdomyosarcoma have extremely poor failure-free (43%) and overall (46%) survival.

Table 103.11 Surgical–Histopathologic Clinical Grouping System for the Intergroup Rhabdomyosarcoma Studies I and II

Group I Localized tumor, completely resected A. Confined to organ or muscle of origin B. Infiltration outside organ or muscle of origin, regional nodes not involved
Group II Compromised or regional resection including A. Grossly resected tumors with "microscopic" residual B. Regional disease, completely resected, in which nodes may be involved and/or tumor extends into an adjacent organ C. Regional disease with involved nodes, grossly resected, evidence of microscopic residual
Group III Incomplete resection or biopsy, gross residual disease
Group IV Distant metastatic disease, present at presentation

Reprinted from Crist WM, Garnsey L, Beltangady MS, et al. Prognosis in children with rhabdomyosarcoma: A report of the Intergroup Rhabdomyosarcoma Studies I and II. Intergroup Rhabdomyosarcoma Committee. *J Clin Oncol* 1990;8(3):433–452, with permission. © American Society of Clinical Oncology.

In general, children with alveolar rhabdomyosarcoma have worse survival outcomes compared to those with embryonal histology. Patients with stage 1 or 2 disease that is grossly resected (group I or II) have 5-year failure-free survival of 80% and overall survival of 85%. Stage 1 or 2 (group III) patients have overall favorable outcomes as well. Children less than 1 year of age with alveolar histology have considerably worse survival outcomes

(43%). Patients with stage 3 tumors with nodal involvement also have poor survival outcomes (34%). Survival correlates with stage and patients with high-risk tumors with distant metastases as diagnosis continue to have the worse expected survival of 25% despite intensified cytotoxic therapy and radiotherapy.

Treatment

Much of the treatment success of rhabdomyosarcoma is credited to successful clinical trials conducted by the IRSG and the Soft Tissue Sarcoma Committee of the COG. Multimodal therapy aims to minimize the risk of relapse and optimize curative outcomes, while also minimizing treatment toxicities. The INRG has completed five major clinical trials (IRS-I, II, III, IV, V/D) that provide the foundation upon which the current treatment schema is based for all children diagnosed with rhabdomyosarcoma. IRS-V or the "D" studies further refined treatment protocols based on prognostic factors and risk stratification.[166–169]

7 The mainstay of therapy begins with surgery, either complete excision with adequate margins or incisional biopsy. The goal for surgical margins is at least 0.5 cm of normal tissue surrounding tumor. Margins should be marked and oriented to assure that pathologists can accurately identify each microscopic margin. Contiguous structures, organs, major blood vessels or nerves that would result in major disability should not be resected in the initial operation, rather an adequate biopsy should be obtained and chemotherapy given upfront. In contrast, lesions that are small and not invading surrounding structures may be completely resected prior to chemotherapy. Resection of rhabdomyosarcoma tumors with wide and completely clear microscopic margins is the most ideal initial procedure for all stages to obtain local tumor control. Pretreatment reexcision is recommended after the initial operation if there is gross residual tumor or microscopically involved margins prior to the administration of chemotherapy. This is critical for accurate staging and for optimal clinical group assignment. Debilitating or highly morbid operations are performed only after chemotherapy and radiation have been given in attempt to decrease tumor burden and minimize extent of resection.

Lymph node sampling is indicated for patients with lesions that involve the extremity (even if clinically negative) or for clinically positive lymph nodes for all other sites. Biopsy by open, core, or sentinel lymph node biopsy techniques are all acceptable based on current COG guidelines. Staging ipsilateral retroperitoneal lymph node dissection is recommended for paratesticular rhabdomyosarcoma for all males older than 10 years of age and for those less than 10 years of age with enlarged appearing lymph nodes on CT scan. In this group, staging ipsilateral retroperitoneal lymph node dissection is required for adequate staging and risk-group assessment. A nerve-sparing ipsilateral retroperitoneal lymph node dissection is recommended. The boundaries of the dissection begin at the level of the renal veins surrounding the aorta and the vena cava, extending to the deep inguinal ring. The procedure may be performed laparoscopically or through an open abdominal incision. Patients with intermediate-risk tumors may benefit from radical debulking of clinically positive lymph nodes if feasible.

The addition of chemotherapy and radiotherapy to treatment protocols for rhabdomyosarcoma has dramatically improved survival rates. Currently all children diagnosed with rhabdomyosarcoma receive adjuvant chemotherapy with or without radiotherapy. Current treatment protocols for patients with low-risk rhabdomyosarcoma (subgroups A and B) consist of vincristine, actinomycin D, cyclophosphamide, and local radiotherapy to sites of residual disease (group II and III). A recent clinical trial from the Soft Tissue Sarcoma Committee of COG (D9602) focused on eliminating cyclophosphamide, and reducing radiotherapy doses in patients with lowest-risk rhabdomyosarcoma.[170] This study found that the 5-year failure-free and overall survival were lower than similar ISR-IV patients receiving cyclophosphamide. Given these results, the COG is currently studying a more modest dose reduction of cyclophosphamide (ARST0331, closed 2012) for both low-risk subgroups with aims of maintaining the excellent outcomes of IRS-IV and further reducing toxicity.[169]

Intermediate-risk tumors are nonmetastatic and include alveolar rhabdomyosarcoma at any site (stage 1 to 3). Embryonal rhabdomyosarcoma in an unfavorable site that is incompletely excised (stage 2, 3, group III) are also considered intermediate risk. The standard chemotherapy for this group is vincristine, actinomycin D, and cyclophosphamide with radiotherapy. Improvements in survival have not progressed as much in this group

compared to low-risk tumors. IRS-IV did not show improvement in outcomes for intermediate-risk group patients by the addition of ifosfamide and ifosfamide/etoposide substituting for actinomycin D and cyclophosphamide.[171] The COG recent intermediate-risk study (D9803) compared standard vincristine, actinomycin D, cyclophosphamide to a regimen that alternated standard therapy with vincristine, topotecan, and cyclophosphamide.[172] This regimen did not significantly improve outcomes compared to standard therapy. The COG's most recent trial (ARST0531, closed 2013) randomized patients to receive standard therapy versus standard therapy alternating with vincristine and irinotecan, and earlier-onset radiotherapy.[169] The actions of vincristine and irinotecan are thought to be synergistic with enhanced cytotoxic activity based on preclinical and pilot studies. Unfortunately, this study found that despite interventions to improve local control, local failure was higher on ARST0531 than D9803 for unclear reasons that may be related to the reduced cyclophosphamide.[173]

High-risk patients have metastatic disease on presentation with dismal outcomes despite intensive cytotoxic therapy. Current therapy for high-risk tumors is based on results of the COG high-risk rhabdomyosarcoma phase II window studies (D9802) and previous IRS-I-IV trials.[174] These studies were the backbone for ARST0431 (closed 2010) which treated patients with multiple combinations of intensive chemotherapy that included vincristine, actinomycin D, doxorubicin, irinotecan, cyclophosphamide, and ifosfamide/etoposide.[175] The feasibility of concurrent early administration of radiotherapy and irinotecan is also being evaluated. Long-term follow-up on the most optimal combinations of intensified chemotherapy in high-risk rhabdomyosarcoma patients is needed. Recently, the COG study (ARST08P1) examined novel biologic agents. Cixutumumab, a monoclonal antibody against insulin-like growth factor-I receptor (IGF-IR) and temozolamide were added to intensive chemotherapy backbone regimens. Early results were promising for improved failure-free survival with cixutumumab but overall survival remains poor.[176]

Radiotherapy in the form of external beam radiation is utilized in group II to IV patients and in group I alveolar cases to enhance local control.[177] Radiotherapy is utilized as the primary means of local control in rare cases where surgical excision carries excessive risk or concern for disfigurement (orbital and vaginal). Parameningeal tumors are treated with radiotherapy

because of the high likelihood of residual disease with surgical excision. The most commonly utilized doses range from 36 Gy to 50 Gy and higher doses are administered to patients with group III or IV disease (50 Gy given in 28 fractions).[177] The IRSG studied a trial of hyperfractionated radiotherapy versus conventionally fractionated radiotherapy in patients with group III rhabdomyosarcoma and found no differences in failure rates or survival outcomes.[178]

Future Directions

Future clinical trials are focused on further tailoring therapies to reduce treatment toxicities and late adverse effects while improving curative outcomes. The current focus is incorporation of novel biologic agents to known active backbone chemotherapy regimens, particularly for patients with intermediate-risk and high-risk rhabdomyosarcoma. Human patient tumor–derived xenograft models are guiding future development of novel targeted therapies for this cancer. The NCI supports the Pediatric Preclinical Testing Consortium; a program to evaluate novel molecules for genetically characterized solid tumors, including rhabdomyosarcoma (https://ctep.cancer.gov/MajorInitiatives/Pediatric_Preclinical_Testing_Consortium.htm).

NONRHABDOMYOSARCOMA SOFT TISSUE SARCOMA

Epidemiology

Soft tissue sarcomas in children and adolescents occur in approximately 8% of all childhood solid tumors. Nonrhabdomyosarcoma soft tissue sarcoma (NRSTS) represents approximately half of these cases, occurring in 250 to 300 children per year in the United States.[179] Infants and adolescents are more commonly affected, and there is a slightly higher incidence in males and in African Americans. NRSTS comprises 27% of sarcomas in infants (<12 months), of which, 24% are fibrosarcomas, 1.7% are malignant fibrous histiocytoma (MFH), and 1.3% are peripheral nerve sheath tumors.[180] The

incidence of NRSTS has not changed in the last several decades. The overall 10-year survival has also remained steady at 73%. The tumors are distinct from rhabdomyosarcoma in terms of clinical characteristics, tumor biology, and prognosis. Most cases are sporadic although patients with Li–Fraumeni syndrome, neurofibromatosis type I (peripheral nerve sheath tumors), Gorlin syndrome (fibrosarcoma and leiomyosarcoma), and hereditary retinoblastoma have a higher risk of developing soft tissue sarcomas.[181–183] Children that are survivors of childhood cancer are at an increased risk for NRSTS, particularly those with a history of receiving radiation, high-dose anthracyclines, and alkylating agents.[184]

Pathology and Biologic Features

NRSTSs originate from developmental mesenchymal cells with heterogeneous histologic subtypes and diverse sites of origin. These tumors are classified based on histology-specific cytogenetics of the tumor. NRSTS may have segmental chromosomal alterations (balanced translocations) or widespread genomic instability (**Table 103.12**). Most of the translocations found in NRSTS generate fusion proteins from two different transcription factors that disrupt normal embryonic development and drive sarcomagenesis.[185] ETV6-NTRK3 found in infantile fibrosarcoma and ALK found in inflammatory myofibroblastic tumors are tumor cell-specific activated kinases that may have important roles in pathogenesis.[186] Dermatofibrosarcoma protuberans contain the COLIA1-PDGFB fusion gene.[187] Genetic analysis is a powerful tool for diagnosis of NRSTS and is an important component of the histopathologic assessment. Detection of tumor-specific chromosomal alterations by RT-PCR, FISH, or high-throughput sequencing analyses often aid in confirming the diagnosis and in treatment planning.

Table 103.12 Nonrhabdomyosaroma Tumor Characteristics

Tumor	Incidence[a]	Normal Counterpart[a]	Cytogenetic Abnormality[a]	Genes[a]	Common Primary Sites
Fibrosarcoma	0.6	Fibroblasts	t(12;15)	TEL (ETV6), NTRK3(TRKC)	Lower extremity, upper extremity
Desmoplastic round cell tumor[b]	Approximately 200 case reports	Lineage epithelial, neural, myogenic cells	t(11;22)	EWS, WT1	Abdomen, paratesticular, thoracic cavity
Leiomyosarcoma	0.3	Smooth muscle	Variable	Multiple gene alterations	Gastrointestinal or genitourinary, superficial dermis, retroperitoneal, lungs, uterus, vascular
Alveolar soft parts tumor	0.1	Unknown	t(x;17)	ASPL, TFE3	Thigh, buttocks, abdominal and chest wall
Neurofibrosarcoma	0.6	Schwann cell	Variable, abnormalities of chromosome 17	Multiple genetic alterations, NF1	Extremity, retroperitoneum, trunk
Liposarcoma	0.1	Adipocyte	t(12;16)	FUS, CHOP	Lower and upper extremity, retroperitoneum
Tendosynovial sarcoma	0.7	Synovial cells	t(x;18)	SYT, SSX-1, or SSX-2	Lower extremity (thigh, foot, posterior knee), upper extremity (shoulders, forearm)
Dermatofibrosarcoma protuberans	1.0	Fibroblasts	t(12;22)	COL1A,PDGF	Trunk, proximal extremities

Presentation, Diagnosis, and Staging

NRSTS typically present as a painless slow-growing solid mass that may invade surrounding structures. Approximately 15% of patients present with metastatic disease at presentation, most commonly lungs.[188] Survival for patients presenting with metastatic disease remains poor (35%) and disease-free progression is only 15% despite aggressive multimodality therapy. In general, diagnostic workup for NRSTS consists of cross-sectional imaging (MRI) of the primary site along with imaging (CT scan) of chest, abdomen, and pelvis for surgical planning and adequate staging. Bone scintigraphy is used only for patients with bone pain or symptoms. Bone marrow biopsy is typically not indicated. Brain imaging is reserved for patients with CNS symptoms.

An adequate tissue specimen is required to determine the histologic subtype and grade of NRSTS. Complete surgical resection of all gross disease is recommended at presentation unless a wide resection is not feasible or accompanied by high surgical morbidity. Multiple core needle biopsies may be sufficient though the quality and quantity of specimen must be adequate for histologic and cytogenetic studies. Fine-needle biopsy is not acceptable for diagnosis. The fresh specimen should be evaluated for routine histopathology, immunohistochemistry, and molecular studies including DNA and RNA cytogenetic studies, flow cytometry, and electron microscopy.[184] Array technologies are being increasingly utilized in analysis of NRSTS, allowing measurements of tumor RNA expression and gene copy number.[189] A pathologic tumor grade is assigned to NRSTS based on extent of malignancy and is an indicator of prognosis. The grading system utilized in pediatric NRSTS was developed by the Pediatric Oncology Group using concepts of adult grading systems integrating characteristics of pediatric sarcomas.[190] The Pediatric Oncology Group grading system for NRSTS assesses mitotic rate, extent of necrosis, differentiation, and histologic type and can be used as a predictor of outcome.

The size of the mass is important in initial surgical planning and determines surgical approach.[191] Tumor sizes of 5 cm is utilized by the American Joint Cancer Commission staging system of sarcoma as standard "cutoff" for resectability, though this has been difficult to translate to children with small body surface areas. This was addressed by development of an equivalency factor that is utilized to calculate prognosis of soft tissue sarcoma based on size of the mass and body surface area.[192] Although tumor size is a key prognostic factor in adult soft tissue sarcomas, the risk is not the same in patients of different body sizes and 5-cm cutoff may not pertain to infants and children.

Extent of disease, grade, size, age, and extent of resection all influence prognosis and survival outcomes in NRSTS.[193] Patients are grouped into low-, intermediate-, and high-risk (metastatic disease) categories. High-risk patients have overall survival of approximately 15% and most patients succumb to widespread metastatic disease. Intermediate-risk patients have unresectable tumors at presentation with residual disease or large (>5 cm), high-grade tumors. The survival in this risk group is approximately 50%. Low-risk tumors are completely resectable (<5 cm or equivalent) and are

low grade.[184] Low-risk patients have the best prognosis with overall survival of 90%. In general, patients with negative microscopic margins have the best outcomes and the addition of radiotherapy minimizes the risk of recurrence. A pediatric NRSTS staging system has not been validated. The IRSG surgicopathologic staging system for rhabdomyosarcoma is often utilized as well as the TNM sarcoma staging systems for adults. The COG is addressing the issue of staging for pediatric NRSTS in ongoing clinical studies.

Treatment

Complete surgical resection is critical in the management of NRSTS because of resistance to chemotherapy and radiotherapy. Primary tumors that appear grossly resectable should be excised upfront. If the surgeon anticipates that gross residual disease is likely following surgery or if complete excision is debilitating or disfiguring, tumor biopsy should be performed. This is typically seen with large (>5 cm), high-grade regionally invasive or metastatic tumors that will benefit from neoadjuvant chemotherapy and delayed tumor resection. Tumor debulking is generally not recommended. Large, potentially morbid resections like amputation and pelvic exoneration are performed only after neoadjuvant therapies. In general, incisions on the extremities should be placed longitudinally and incisions on the trunk are oriented in the axial plane. If the surgeon determines that the mass is not amendable to full excision upfront, a generous incisional biopsy is required. Primary reexcision of the primary tumor is recommended if there is gross residual resectable tumor after the initial resection with at least a 0.5-cm margin. Reexcision is also recommended if the margin status is unknown. Previous scars or needle tracts should be included en bloc with the specimen. Lymph node sampling is required for abnormal-appearing lymph nodes on clinical examination or imaging. Several histologic subtypes of NRSTS also require lymph node evaluation for risk assessment and staging purposes, even in patients without enlarged lymph nodes. These include synovial cell sarcoma, epithelioid sarcoma, and clear cell sarcoma with up to 30% risk of lymph node metastases.[191] In these groups, patients without radiologic evidence of nodal metastases may benefit from sentinel lymph

node mapping with technetium 99m and biopsy rather than traditional lymph node sampling, though results have been mixed.

The most active chemotherapeutic agents for NRSTS are doxorubicin and ifosfamide, though most NRSTSs are relatively chemoresistant. Current treatment strategies are based on protocols from the COG clinical trial ARST0332 that assigned NRSTS patients to treatment groups based on risk. Low-risk patients (grossly resected, low grade, any size) receive surgical excision alone with or without radiotherapy, depending on margin status. Intermediate-risk and high-risk (metastatic disease) patients are treated with ifosfamide and dose-intensive doxorubicin and radiotherapy either before or after surgical excision. The risk-based treatment strategy set a new standard that produced outcomes similar to or better than historical controls with radiotherapy less frequently and at lower doses.[193] Because of the limited efficacy of chemotherapy in NRSTS, novel targeted therapeutic approaches are warranted, especially for children with high-grade or relapsed tumors.[184,193]

HEPATIC TUMORS

Hepatoblastoma

Epidemiology and Genetic Risk

Hepatoblastoma is the most common malignant liver tumor in children, occurring in 0.7 to 1 per million children <15 years of age, yielding approximately 100 cases per year in the United States.[4] The incidence of hepatoblastoma has increased roughly 4% in the last three decades in the United States.[194] Hepatoblastoma occurs most commonly in infants and children between the ages of 6 months and 3 years. A slight male predominance is reported and there does not appear to be significant differences in incidence among race. The median age at diagnosis is 18 months of age. Hepatoblastoma is the third most frequent abdominal tumor after neuroblastoma and Wilms tumor. Environmental risk factors have not been confirmed. Hepatoblastoma has been found in association with prematurity and low birth weight.[195] There is a strong association with very

low–birth-weight neonates (<1,500 g) though the underlying mechanism is not yet unknown.[194]

Several inherited syndromes are associated with hepatoblastoma. Patients with Beckwith–Wiedemann syndrome are at risk for developing hepatoblastoma and require routine screening.[196] Most cases are due to defective imprinting on chromosome 11p15.[197] Hepatoblastoma may also occur in children with hemihypertrophy and trisomy 18.[198] There is an increased risk of hepatoblastoma in children of families with familial adenomatous polyposis (FAP) syndrome though no specific genetic alteration in chromosome 5 has been identified.[199] There is a nonrandom association between hepatoblastoma and children with trisomy 18.[200]

Sporadic hepatoblastoma has not been characterized by any single chromosomal abnormality and cytogenetic analyses have not revealed consistent patterns. The most common genetic abnormalities are trisomies 2, 8, and 20.[201] These genetic alterations are thought to have a role in hepatoblastoma pathogenesis, but the precise molecular mechanism is not understood. LOH of 11p15 has been detected in up to 33% of children with hepatoblastoma and it is hypothesized that a tumor suppressor gene may be located in this region.[202] Insulin-like growth factor 2 (IGF-2), a fetal mitogen is an imprinted gene on 11p15 affected by β-catenin mutations.[203] LOH at 11p is most often of maternal origin and commonly found in patients with Beckwith–Wiedemann syndrome. LOH has also been found at chromosome 1p and 1q and may have a role in tumorigenesis.[204] Translocations involving the NOTCH2 gene at chromosome 1 have been detected in hepatoblastoma tumors.[205]

Pathology and Biologic Features

Hepatoblastoma displays a combination of histologic patterns that range from epithelial and mesenchymal elements. This tumor is thought to originate from undifferentiated embryonal hepatic cells that maintain pluripotency and have potential to develop into both hepatocytes and biliary epithelial cells.[206,207] Hepatoblastoma may be classified by five different histologic subtypes that carry prognostic value: well-differentiated fetal (pure fetal), embryonal, macrotrabecular (epithelial fetal or embryonal), small cell undifferentiated, and cholangioblastic (bile ducts predominate) (**Table 103.13**).[208,209] Of

these, the most favorable outcomes are seen with well-differentiated fetal subtypes. Small cell undifferentiated tumors (anaplastic subtype) carry the worse prognosis.[210] Small cell undifferentiated tumors are often associated with low or normal serum α-fetoprotein (AFP) levels (<100) and predict adverse outcomes with poor response to chemotherapy.[211] The majority of hepatoblastoma tumors are epithelial with mixed embryonal and fetal patterns (67%), and 21% of these have mesenchymal components.[209,212] Hepatoblastoma tumors secrete interleukin 1β which induces IL-6 production, enhancing hepatocyte growth factor.[213] There is evidence that hepatocyte growth factor is secreted postoperatively and functions as a growth factor for hepatoblastoma tumor cells.[214]

Table 103.13 Relative Risk of Death for Histologic Subtypes of Hepatoblastoma

Histopathologic Subtype	Relative Risk of Death[a]
Fetal	1.07
Embryonal	1.74
Mixed	0.53
Macrotrabecular pattern	1.20
Small cell undifferentiated	3.71

[a]Adjusted for age, sex, and stage compared with other histologic subtypes.

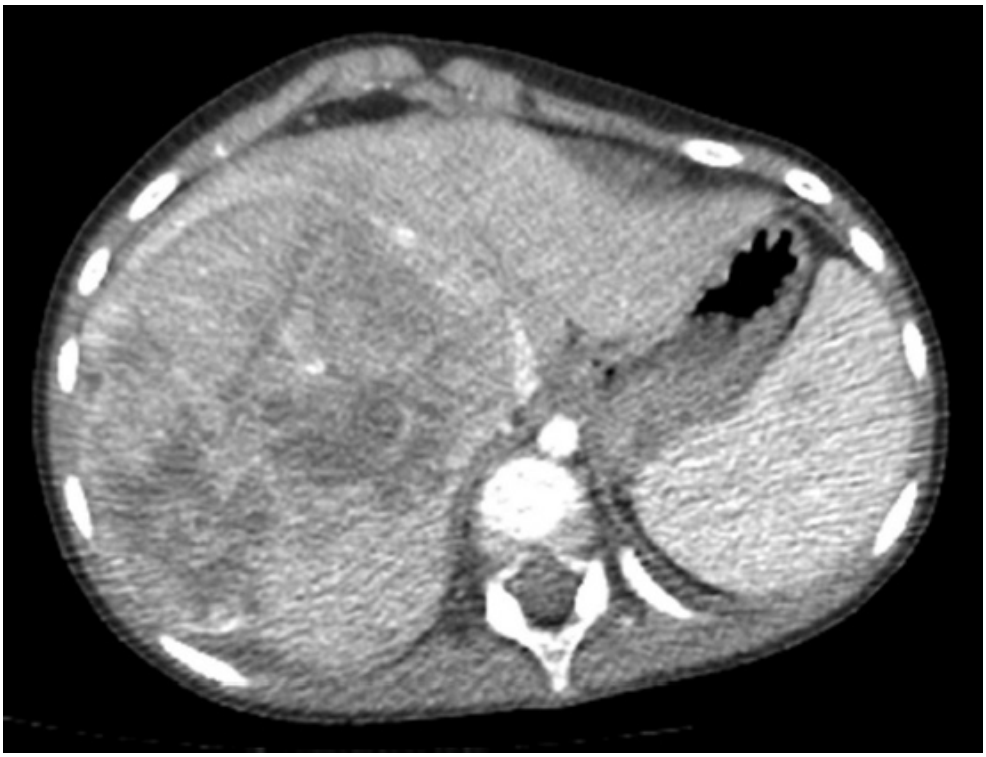

Figure 103.9 Abdominal CT scan with right hepatic lobe hepatoblastoma displacing normal hepatic vasculature and parenchyma.

Presentation, Diagnosis, and Staging

Children with hepatoblastoma present with an asymptomatic abdominal mass or abdominal swelling. Systemic symptoms like weight loss, failure to thrive, or anorexia may indicate advanced disease. Jaundice and biliary obstruction does not typically occur in patients with hepatoblastoma. Distant metastases are present in approximately 20% of patients at diagnosis and the most common site is lungs.[215] Ultrasound and cross-sectional imaging (three-phase CT scan or MRI with EOVIST) will define segmental extension of the tumor within the liver and assess for distant metastases (**Fig. 103.9**). The majority of hepatoblastoma tumors are located in the right lobe of the liver (up to 70%). The tumor appears as a solid mass with low attenuation. On MRI the lesion appears as low intensity on T1-weighted images and high intensity on T2-weighted images. There is no evidence that MRI is superior to CT scan for diagnosis or surveillance of hepatoblastoma. It is important to distinguish central venous structures and to evaluate the liver for multifocal disease. Chest CT scan is obtained to evaluate for lung metastases. Anemia and thrombocytosis are common in children with hepatoblastoma and is likely

related to cytokine secretion by tumor cells. AFP is elevated in approximately 90% of patients with hepatoblastoma and is a useful clinical marker for monitoring tumor responsiveness and recurrence. Interpretation of AFP may be difficult because the protein is expressed in the fetus and commonly remains elevated in normal neonates and infants up to 6 months of age. AFP may also be elevated in patients with hepatitis, hepatocellular carcinoma (HCC), and germ cell tumors. A high serum cholesterol level is also detected in 50% to 60% of children with hepatoblastoma.

Staging is based on the COG hepatoblastoma staging system (**Table 103.14**). This system is a postsurgical staging system that is based on outcome of the primary operation before the administration of chemotherapy.[216] Stage 1 (22%) is complete resection with clear margins. Stage 2 (0.5%) is complete gross resection with microscopic residual disease at the margins. Stage 3 (53%) is grossly positive margins, biopsy only at diagnosis, nodal involvement or tumor spill. Stage 4 disease (23%) is metastatic tumor at diagnosis.[217]

Table 103.14 Children's Oncology Group Staging for Hepatoblastoma

Stage 1	Complete resection
Favorable histology	Purely fetal histology with low mitotic index
Other histology	All other stage 1 tumors
Stage 2	Gross total resection with microscopic margins or total resection with preoperative or intraoperative rupture
Stage 3	Unresectable tumors as determined by the attending surgeon, partially resected tumors with microscopic margins, or any tumor with lymph node involvement
Stage 4	Measurable metastatic disease to lungs or other organs

Pretreatment extent of disease (PRETEXT) grouping is used internationally in combination with COG stage to stratify patients based the tumor's radiographic characteristics prior to treatment.[218] PRETEXT describes the anatomic involvement and Couinaud hepatic segments affected by the tumor and can be applied to patients who have not yet had operations[219] (**Fig. 103.10**). PRETEXT divides the liver into four parts termed sectors. The left lobe is divided into a lateral sector (segments 2 and 3) and a medial sector (segment 4). The right lobe is divided into an anterior sector (segments 5 and 8) and posterior sector (segments 6 and 7). PRETEXT is further annotated by V (venous involvement), P (portal vascular involvement), E (extrahepatic involvement), M (distant metastatic disease), C (caudate lobe), F (multifocal), and R (rupture prior to diagnosis) categories. Imaging is obtained after every two cycles of chemotherapy, where POSTTEXT (posttreatment of disease) is then used to reassess anatomy.

The COG utilizes stage, PRETEXT, histology, and AFP at diagnosis to determine risk for therapy assignment and for clinical trial standards. In general, excellent prognosis is expected for stage 1 tumors completely resected at diagnosis with pure fetal histology. Poor prognosis is associated with PRETEXT IV, metastatic tumors, AFP less than 100, and tumors with small cell undifferentiated histology.[212]

Treatment

Complete surgical resection is the mainstay of curative therapy for hepatoblastoma. Completely resected tumors have significantly improved survival outcomes compared with all other hepatoblastoma patients. The tumor may present as large bulky disease with mass effect on surrounding abdominal structures. The umbilical fissure is typically not involved. If the tumor appears resectable, conventional resection is performed. If the mass is judged unresectable at diagnosis, incisional biopsy is performed, and the patient is treated with chemotherapy prior to conventional resection. A complete preoperative evaluation is necessary to assess full extent of disease, PRETEXT, and to determine a safe surgical plan that will achieve the highest survival outcomes. In the United States, tumor resection at diagnosis whenever possible is the preferred standard. This is based on the

notion that a subset of patients may be spared toxicity of unnecessary neoadjuvant chemotherapy and that tumors have capacity to become resistant to prolonged chemotherapy.[216,220] The COG currently determines surgical resectability based on PRETEXT grouping.[8] Primary resection is recommended for localized PRETEXT 1 or PRETEXT 2 tumors with >1 cm radiographic margin on the middle hepatic vein, without vena cava or contralateral portal venous invasion.[216] Neoadjuvant chemotherapy is recommended for PRETEXT III or IV tumors and for multicentric tumors with central venous invasion. Patients with pulmonary metastases also receive chemotherapy upfront. Tumor volume and AFP measurements may be utilized to monitor tumor responsiveness after each cycle. Minimal benefit may be seen by prolonging induction therapy after cycle 2, therefore tailoring exposure to response may help reduce toxic effects.[221]

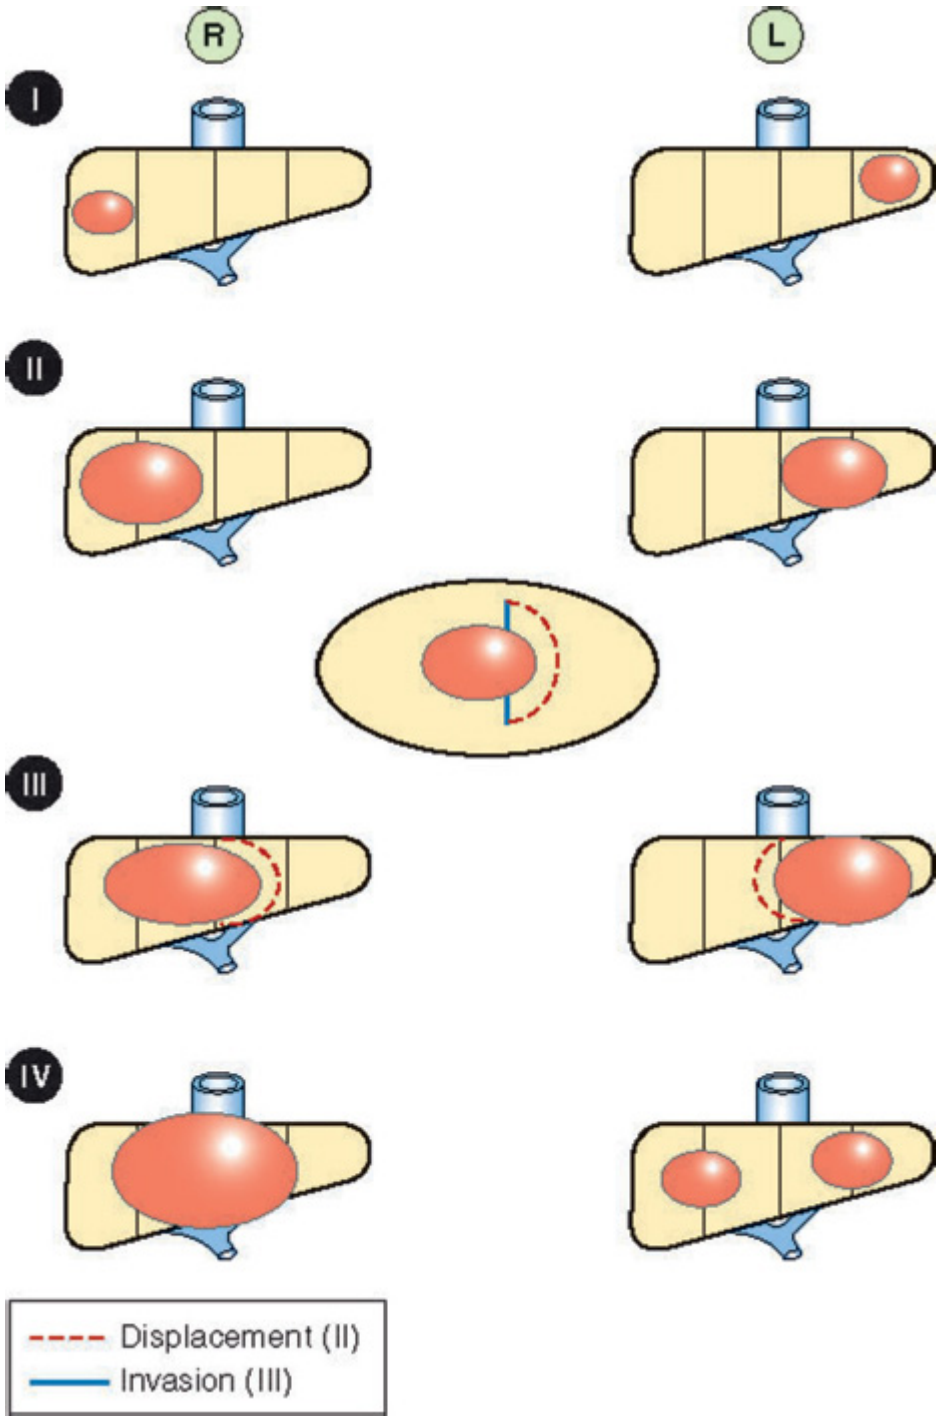

Figure 103.10 The Liver Tumor Study Group of the International Society of Pediatric Oncology (SIOP) SIOPEL-1 pretreatment extent of disease (PRETEXT) grouping system, PRETEXT Groups I–IV. R, right; L, left. (From Schnater JM, Aronson DC, Plaschkes J, et al. Surgical view of the treatment of patients with hepatoblastoma: results from the first prospective trial of the International Society of Pediatric Oncology Liver Tumor Study Group (SIOPEL-1). *Cancer* 2002;94(4):1111–1120, with permission.)

Conventional liver resection is safe and effective in children with hepatoblastoma and surgical techniques have been optimized in the last three decades.[222,223] An anatomic resection is recommended and is most often required. As much as 85% of hepatic parenchyma may be safely removed in children with full regeneration expected despite postoperative chemotherapy.[224] Mortality from liver resection in children should be low (0% to 3%) with technical advances such as the Cavitron Ultrasonic Surgical Aspirator (CUSA; Cooper Lasersonics, Santa Clara, CA) and metallic clip applicators for hemostasis while dividing liver parenchyma. The surgical principles include a generous incision with wide exposure using subcostal incisions. Dissection of the hilum with identification and isolation of the ductal and vascular structures of the segment of resection is critical. Hepatic arterial and portal venous inflow is obstructed or ligated, allowing demarcation of the resection plane. This allows the operation to proceed with minimal blood loss. Intraoperative Doppler ultrasound is often utilized to aid in locating major venous structures traversing the tumor and for assuring adequate resection margins of at least 1 cm.

Chemotherapy improves resectability of hepatoblastoma and improves prognosis in nearly all cases. Currently most patients diagnosed with hepatoblastoma receive chemotherapy either before or after resection of the primary tumor. Based on results from the Pediatric Oncology Group/Children's Cancer Study Group studies INT-0098 and P9645, patients with completely resected well-differentiated fetal histology (WDF or pure fetal histology) tumors and low mitotic activity may be treated exclusively with surgery alone.[225] Children with WDF histology tumors comprise 7% of hepatoblastoma cases and have 100% event-free survival. Most hepatoblastoma tumors are sensitive to cisplatin-based chemotherapy and overall survival increased from 30% to 70% with the addition of cisplatin.[226] The COG currently recommends cisplatin, 5-fluoruracil, and vincristine for all low-risk tumors (non–well-differentiated fetal histologic subtypes). Low-risk patients are patients with completely grossly resected tumors (stage 1 and 2, PRETEXT I or II) without any small cell undifferentiated histology elements and who do not have a low diagnostic AFP (<100). This group can expect 5-year event-free and overall survivals of 84% and 96%, respectively.[212] Intermediate-risk patients (PRETEXT II, III, or IV) are patients with gross residual disease or grossly resected

disease with small cell undifferentiated histology (without metastases) and without low diagnostic AFP (<100). High-risk tumors are any patients with metastatic disease and low diagnostic AFP level <100. Patients with intermediate-risk and high-risk tumors are currently treated with cisplatin, 5-fluorouracil, vincristine, and doxorubicin. The COG is currently determining the efficacy of the addition of doxorubicin to intermediate and high-risk patients and for patients with minimal radiographic response to standard therapy. Depending on risk group protocol, patients will receive two to six cycles of cisplatin, 5-fluorouracil, vincristine with or without doxorubicin prior to primary resection or transplantation. Outcomes for patients with hepatoblastoma after surgical resection and chemotherapy was documented in INT-0098 with 5-year event-free survivals for stage 1, 2, 3, and 4 of 91%, 100%, 64%, and 25%, respectively.[226] Overall survivals were similar. The subsets of patients with stage 3 or 4 disease that were able to have complete tumor resection and were tumor-free after induction chemotherapy had 5-year event-free survival of 83%. The role of radiotherapy in hepatoblastoma has not been defined because of the risk of hepatic toxicity and low hepatic tolerance to radiation in children. There may be a role for focal radiotherapy up to 45 Gy in patients with incomplete resection or microscopic residual disease.[227]

Liver transplantation has become a promising treatment option for children with unresectable hepatoblastoma without metastatic disease after neoadjuvant chemotherapy.[228] Liver transplantation has improved overall survival in children with large, or multifocal unresectable hepatoblastoma.[229,230] Tumors with extensive major vessel involvement or multifocal disease should be referred to centers that have pediatric liver transplant expertise.[216] Primary transplantation is also recommended for multifocal PRETEXT IV tumors despite apparent clearance after chemotherapy because of the risk of persistent microscopic disease.[231] If after four cycles of chemotherapy, the tumor remains unresectable by conventional liver resection, liver transplantation is recommended. These are typically POSTTEXT IV or POSTTEXT III with major vascular involvement that would jeopardize blood supply to the contralateral lobe.[232] A review of the United Network for Organ Sharing (UNOS) database revealed overall 1-, 5-, and 10-year graft survivals were 71%, 61%, and 58%, respectively, for patients receiving liver transplant for hepatoblastoma.

Overall 1-, 5-, and 10-year patient survivals were 79%, 69%, and 66%, respectively.[233] Other series have reported similar success.[230] The primary cause of death was metastatic and relapsed disease. For transplantation eligibility, patients with hepatoblastoma must not have any active extrahepatic or metastatic sites that have not cleared with surgery or chemotherapy. Patients with lung metastases are not excluded from transplantation if the lung disease is clear after neoadjuvant chemotherapy. It is critical to correctly identify patients who will benefit from primary liver transplant prior to attempts at conventional resection because liver transplant after incomplete tumor resection or hepatic relapse has had disappointing results, with reported survival for "rescue" transplant of only 40%.[234]

The COG and other large international cooperative groups are investigating novel therapeutic strategies. COG AHEP-0731 is a COG study that is randomizing patients with metastatic disease to receive a novel upfront window design of vincristine, irinotecan, and vincristine, irinotecan, temsirolimus prior to standard cisplatin, 5-fluorouracil, vincristine, and doxorubicin therapy.[235] Chemotherapeutic intensification by dosing and duration has had promising preliminary results and may be beneficial in patients with high-risk hepatoblastoma. The expanding role of antibodies and T lymphocytes as anticancer therapy for pediatric solid tumors may also hold promise as novel treatment agents for hepatoblastoma.[236]

Hepatocellular Carcinoma

HCC occurs more commonly in older children and is similar in histopathology to the disease in adults. HCC accounts for less than 0.5% of pediatric tumors and is the second most common malignant liver mass in children after hepatoblastoma. Risk factors and pre-existing liver diseases for HCC include cirrhosis, type 1 glycogen storage disease, autoimmune hepatitis and primary sclerosing cholangitis.[216] Areas endemic for hepatitis B have higher incidences of HCC in children. HCC is rare in infancy and there is a slight male predominance. HCC tumors are classified as either epithelial variant (75%), fibrolamellar (15%), and rarely poorly differentiated or clear cell.[237] Differences in outcome or treatment response among children with different histologic subtypes of HCC have not been confirmed. The fibrolamellar subtype is seen more often in younger children

and rarely occurs with cirrhosis. The most common presenting symptom is hepatomegaly and abdominal pain although HCC is often indistinguishable from hepatoblastoma on physical examination, imaging, and laboratory values. The diagnostic workup mirrors hepatoblastoma and diagnosis is confirmed by histopathologic examination of tumor biopsy or resection. HCC is more likely to have multifocal nodules with intrahepatic venous and lymphatic spread. More than one-third of patients have lung metastases at diagnosis. The PRETEXT grouping system is utilized for risk assessment and to determine resectability. PRETEXT III and PRETEXT IV are the most common categories at presentation in patients with HCC.

As reported by the Intergroup Pediatric Oncology Group Study 8945/CCG 8881, 17% of patients diagnosed with HCC had stage 1 disease, none had stage 2 disease, 54% had stage 3, and 28% had stage 4 disease.[217] It is not clear whether AFP levels can be used to predict outcome in HCC similarly to hepatoblastoma as study results have not been consistent.[217] The overall event-free survival for children with HCC at 5 years was 19%. Stage 1 disease had the best outcome compared to stage 3 and 4. The 5-year event-free survivals for stage 1, 3, and 4 were 88%, 8%, and 0%, respectively.[217] Overall survival was similar to event-free survival for each disease stage. Complete surgical resection or transplantation has the highest potential for cure in children with HCC. Unfortunately, fewer than 20% of patients with HCC have tumors that are resectable at diagnosis and multifocal tumors are common. In contrast to hepatoblastoma, HCC tumors are generally unresponsive to chemotherapy and outcomes for patients with stage 3 disease and higher are dismal. Transplantation is reserved for patients with localized tumor without any evidence of metastatic disease at presentation because of high risk of pulmonary metastatic relapse.[216] The guidelines for liver transplantation in HCC are largely derived from the adult experience using the Milan criteria (not more than three tumors, less than 3 cm in size, or single tumor less than 5 cm in size).[238] The COG studies on liver tumors and hepatoblastoma include children with HCC and treatment regimens have generally been the same. Treatment protocols for HCC currently consist of cisplatin, vincristine, doxorubicin, and 5-fluorouracil in multiple combinations. Compared to hepatoblastoma, these agents are not as effective in HCC and patients generally remain with poor prognosis.[226] The majority

of patients do not undergo postinduction surgery or liver transplantation because of the presence of either unresectable or metastatic disease.

Alternative approaches for local control have demonstrated some benefit in children with HCC. Hepatic arterial chemoembolization (HACE) in patients with refractory and unresectable disease requires cooperative group study, but has been shown to be well tolerated and may be effective in inducing surgical resectability in select cases of HCC.[239]

The Pregnant Patient

Eugene S. Kim and Michael J. Zobel

Key Points

1. Maternal administration of antenatal corticosteroids is one of the most significant advances in the reduction of morbidity of prematurity.
2. Understanding the relative increase in the size of the gravid uterus and the displacement of intra-abdominal and pelvic structures is a critical step in surgical planning, specifically with regards to incision location, laparoscopic port placement, and patient positioning in the operating room.
3. There is no evidence that tocolytic therapy has a direct benefit on improving neonatal outcome, except for short-term prolongation of pregnancy to allow for the administration of antenatal steroids.
4. Fetal heart rate monitoring, the most commonly performed procedure during pregnancy, is associated with a substantial decrease in early neonatal morbidity, particularly in preterm fetuses.
5. Ultrasonography is considered the first-line diagnostic imaging modality of the pregnant surgical patient. Computed tomography is safest and most useful in the second and third trimester; dose-reduction protocols result in reduction in the probability of biologic effects to the fetus without sacrificing the necessary diagnostic image quality.
6. Acute appendicitis is the most common nonobstetric cause of acute surgical abdomen during pregnancy, and delays in diagnosis can have serious consequences for both mother and fetus.
7. Biliary tract disease is the most common cause of maternal hospitalization in the first year after delivery; when possible, cholecystectomy should be deferred to the second trimester to reduce the risk of pregnancy-related complications.
8. Pregnant patients with breast cancer should be managed by similar treatment strategies as nonpregnant patients, without delay of treatment, but with a few adjustments to account for potentially teratogenic interventions. Pregnancy termination does not result in improved outcomes for pregnant patients with breast cancer.

9 The most important principle of managing the pregnant patient after major trauma, the leading cause of nonobstetric maternal and fetal mortality, is that any diagnostic test or treatment should be performed if that intervention is required to save the mother's life, even if that intervention is potentially dangerous for the fetus.

10 A multidisciplinary approach is essential for safely managing these complex patients.

Nearly every general surgeon will encounter a pregnant patient with a surgical diagnosis. While many basic principles of care remain consistent, there are some critical differences that must be noted. To provide appropriate pre-, intra-, and postoperative care, the general surgeon must possess a complete understanding of the unique physiology of the pregnant patient. Moreover, any surgeon managing a gravid patient must be aware of the effects that diagnostic and therapeutic interventions might have on the fetus. To ensure the safety of the mother and the fetus, a multidisciplinary approach is essential for managing these complex patients. This chapter will review the most common surgical diseases that present during gestation and current management recommendations.

DEVELOPMENT OF THE FETUS

Human development begins immediately following fertilization of the oocyte by the sperm. Prior to 20 weeks of gestation, ultrasonography provides a better estimate of gestational age of the fetus than the estimated last menstrual period. The optimum timing of the ultrasound examination occurs during the first trimester when crown-rump length is within 5 days of the date of conception.[1–3] The earliest stages of development is referred to as the embryonic period, which extends to the end of the 8th week. By the completion of the embryonic period, organogenesis has begun with critical development of the brain and central nervous system (CNS), heart, lungs, diaphragm, intestines, and abdominal wall. Exposure to toxins, medications, or ionizing radiation during this period can have catastrophic effects on the

developing fetus. During the ensuing fetal period, which lasts from the 9th week to birth, growth and development of tissues and organs occur in preparation for birth. By the beginning of the third trimester, the fetus may survive if born prematurely, though the functional status of the respiratory system is crucial in determining viability.[4] Surfactant production, which begins by the 20th week of gestation, is necessary for both reduction of surface tension at the alveolar–air interface and proper oxygen exchange. In general, surfactant is present in only small amounts before 24 weeks, but this can be augmented by maternal administration of 1 antenatal corticosteroids, one of the most significant advances in the reduction of morbidity of prematurity.[4] Corticosteroids not only increase surfactant secretion in the fetal lung but also induce morphologic development of pulmonary epithelial cells and increase lung compliance. Corticosteroids also stimulate development of other organ systems, decreasing the incidence of necrotizing enterocolitis, intraventricular hemorrhage, periventricular leukomalacia, and death. The maximum developmental effects can be seen as early as 24 hours after maternal administration of dexamethasone or betamethasone, and administration at the first sign of premature onset of labor can improve survival, particularly before birth between 22 and 25 weeks.[5–7]

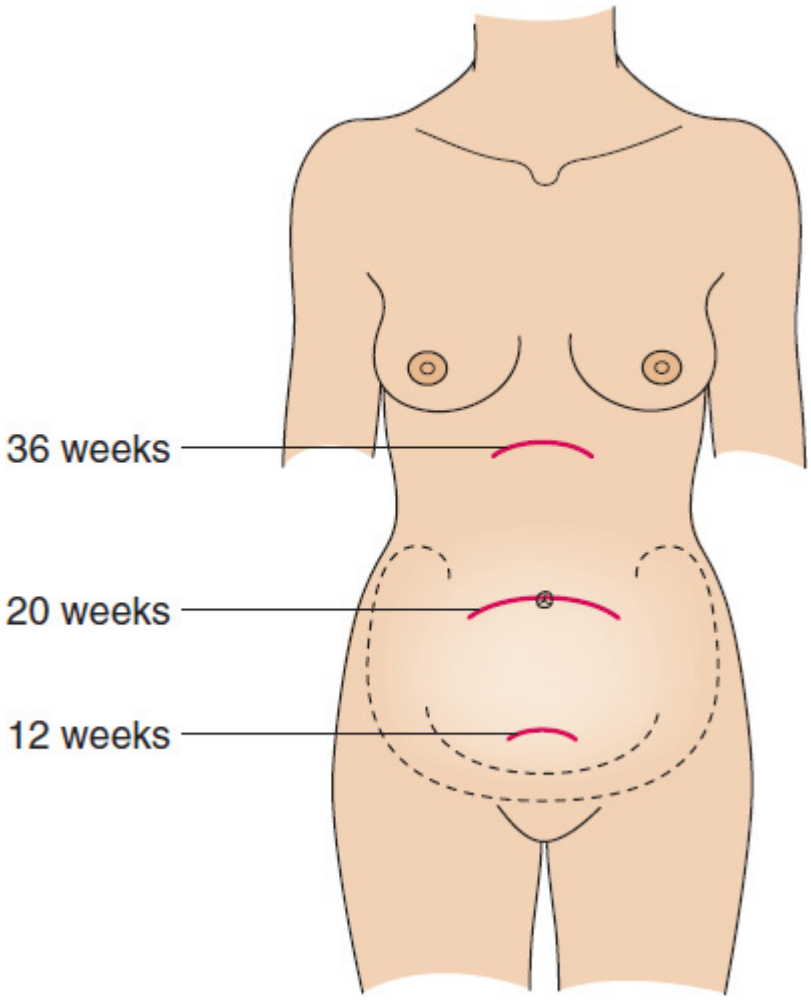

Figure 104.1 Enlarging uterus during gestation. At 12 weeks, the uterus rises out of the pelvis into the abdomen. At 20 weeks, the fundus is at the height of the umbilicus, and at 36 weeks, the uterus reaches to the upper abdomen.

ANATOMY OF THE CHANGING UTERUS

In a nonpregnant woman, the uterus resides within the pelvis, weighs approximately 70 g, and has a cavity volume of 10 mL. By the end of the first trimester, the uterus expands out of the pelvis and reaches the level of the umbilicus by 20 weeks. With progressive increase in size, the uterus contacts the anterior abdominal wall, displacing the bowel laterally and superiorly, and nearly reaching the liver by 36 weeks (**Fig. 104.1**).[8] Coupled with its ascent from the pelvis, the uterus usually rotates to the right due to the presence of the sigmoid colon on the left side of the pelvis. By the

completion of the first trimester, the size of the uterus frequently precludes entry into the abdomen below the level of the umbilicus, and thus altering port placement for laparoscopic surgery and incision location for open abdominal exploration. Furthermore, when the pregnant woman lies supine, the gravid uterus can compress the inferior vena cava, decrease cardiac preload and potentially cause hypotension. As such, patient positioning, particularly in the operating room is even more important during pregnancy to avoid aortocaval compression syndrome.

PREMATURE ONSET OF LABOR

Preterm birth is defined as birth prior to 37 weeks of gestation. Although only 12% of all live births in the United States fit this criterion, prematurity is responsible for approximately 70% of neonatal deaths, 36% of infant deaths, 25% to 50% of cases of long-term neurologic impairment in children, and a high cost to the health care system.[9–12] The etiology of preterm labor is often multifactorial, but the onset of labor from fetal and uterine stress during surgical manipulation or intra-abdominal inflammatory processes is of most concern to the surgeon. Bacterial infection of the amniotic tissues or peritoneum can also contribute to early initiation of labor, secondary to a local increase in eicosanoids, while endotoxin acts on inflammatory cells to increase production of IL-1 and IL-6, which can also amplify local prostaglandin production.[13] Uterine trauma due to surgical manipulation can affect these same mechanisms, leading to premature uterine contractions. The interrelations at various levels between the inflammatory response, uterine and maternal trauma, and the initiation of labor can represent the body's attempt to expel the fetus from a hostile uterine environment.

Tocolysis

To date, there is no evidence that tocolytic therapy has a direct benefit 3 on improving neonatal outcome, except for short-term prolongation of pregnancy to allow for the administration of antenatal steroids, transport of the patient to a tertiary care facility, and fetal neuroprotection.[14–16] In general, tocolysis is indicated between the potential period of fetal viability, beginning at 24

weeks of gestation, and 34 weeks of gestation in women with preterm contractions with cervical change. However, it is acceptable to administer tocolytics before 24 weeks of gestation following events known to cause preterm labor, such as intra-abdominal surgery and in utero fetal surgery, although evidence of efficacy for such intervention is lacking.[17,18] Prostaglandin synthesis inhibitors, magnesium sulfate, beta$_2$-adrenergic agonists, and calcium channel blockers represent the four most common pharmacologic tocolytic agents used. Studies report a 95% tocolytic success rate at 48 hours and a potential delay in delivery of 1 week in 80% of patients.[19] However, maternal and fetal side effects can be serious with tocolytic agents. Premature constriction of the fetal ductus arteriosus and necrotizing enterocolitis with the use of indomethacin has been reported and can result in neonatal pulmonary hypertension and even death.[20,21] Maternal cardiovascular side effects, including pulmonary edema, can occur in 5% of beta$_2$-agonist users and 10% of those treated with magnesium. Although this complication is rare, it can result in maternal death. The decision to use tocolytics must be made only after the diagnosis of premature onset of labor is confirmed, and the benefits of prolonging gestation outweigh the risks of tocolysis. Initiation of tocolytic therapy for potential but unconfirmed preterm labor is discouraged.[22] Maintenance therapy with any of the aforementioned tocolytic agents has not been demonstrated to prolong pregnancy or improve neonatal outcomes after an initial treated episode of threatened preterm birth and, therefore, should not be used for this purpose.[23–25]

MONITORING OF THE FETUS

Perioperative fetal monitoring, as well as the monitoring of premature uterine contractions, is based on technology developed for intrapartum fetal monitoring from the late 1950s and early 1960s. Observational studies performed at that time and in the mid-1970s convincingly established a relationship between the degree of fetal acidemia and the presence and depth of decelerations and decreased or absent fetal heart rate variability.[26,27] Established heart rate patterns and variable cardiac responses to fetal and maternal stimuli reflect an intact, well oxygenated CNS. Identification of

deviation from those patterns indicative of metabolic acidosis was hoped to decrease the incidence of hypoxic-ischemic encephalopathy and death. Research studies using the U.S. 2004-linked birth and infant death data found that the use of electronic fetal monitoring was associated with a substantial decrease in early neonatal morbidity particularly in preterm fetuses.[28] Recent data 4 indicates that of the approximately 4 million live births a year in the United States, 85% are assessed with fetal heart rate monitoring, making it the most common procedure in pregnancy.[29]

Fetal heart rate monitoring may be performed externally or internally. Most external monitor devices use the Doppler principle with computerized logic to count and interpret the Doppler signals originating from the fetal heart and maternal uterus. Internal fetal heart rate monitoring is accomplished with a spiral device attached to the fetal scalp or other presenting part. A transcervical intrauterine pressure catheter is sometimes used to monitor more accurately the strength and frequency of uterine contractions (**Fig. 104.2**). Both tracings are printed on a continuous strip of paper, with the fetal heart rate plotted at the top of the graph and uterine activity at the bottom.

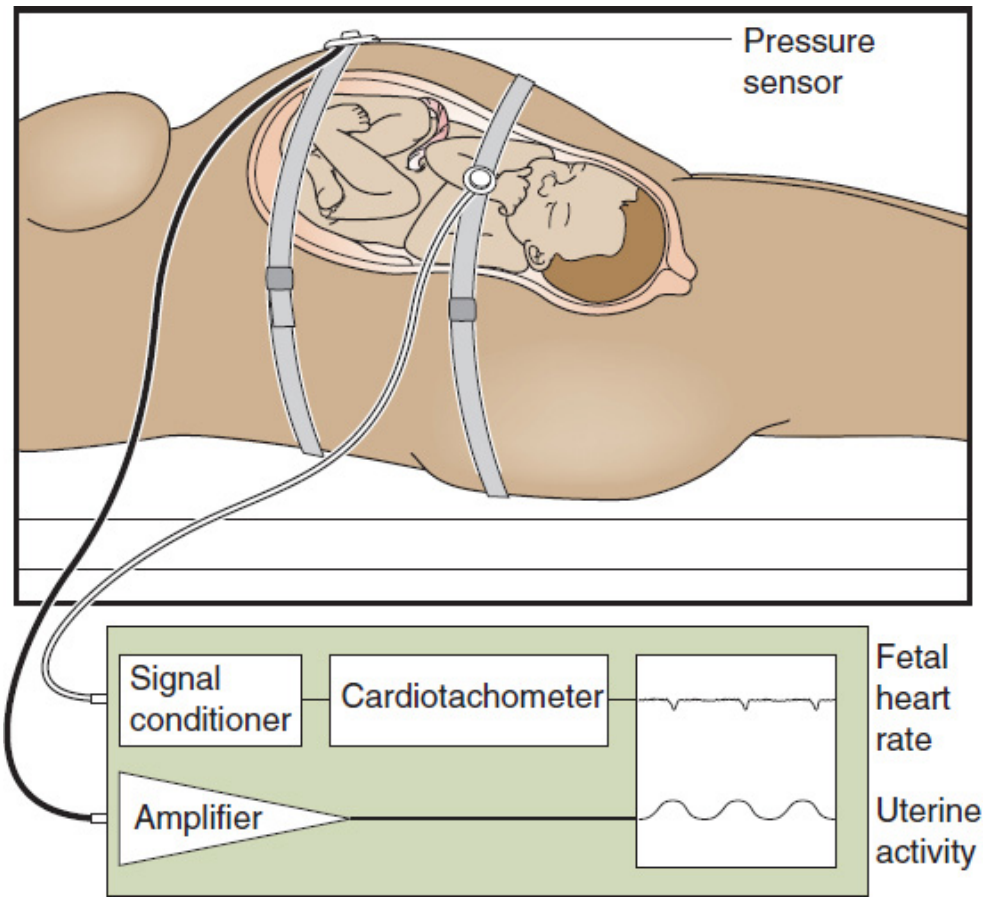

Figure 104.2 Intraoperative and postoperative fetal monitoring using noninvasive surface Doppler and pressure sensor to monitor uterine contractions. (Reproduced from Miller DA, Paul R. Antepartum–intrapartum monitoring. In: Scott JR, DiSaia PJ, Hammond CB, et al., eds. *Danforth's Obstetrics and Gynecology*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:243–255.)

Fetal Heart Rate

Normal fetal heart rate during pregnancy ranges between 110 and 160 beats/min. A prolonged baseline above 160 beats/min is considered tachycardia, whereas that below 110 beats/min is bradycardia. These terms refer to long-term patterns, and minute-to-minute variations in the heart rate away from baseline are known as accelerations or decelerations. Normal fetal heart rate tracings express continuous adjustment in the vagal tone through variability in the heart rate. The fetal heart rate response governed by a nonacidotic, well-functioning vagal conduction system manifests both long-term and short-term variability, with fluctuations of peaks and troughs ranging from 6 to 25 beats/min (**Fig. 104.3**). Decreased heart rate variability,

either long or short term, can signal diminished CNS activity. Although this can be a physiologic response of the fetal sleep–wake cycle or maternal medication and sedatives, persistently decreased reactivity can signal CNS acidosis. Fetal heart rate accelerations are normal findings in the second half of pregnancy and occur as a result of increased sympathetic stimulation and decreased parasympathetic stimulation with fetal movements. Fetal heart rate decelerations are usually encountered during uterine contractions of the intrapartum period. Evaluation of decelerations during labor and as part of intraoperative fetal monitoring can give clues to the status of the placental blood supply. Early decelerations are characterized by a symmetrical and gradual decrease and return of the fetal heart rate that mirror uterine contractions and reflect increased vagal tone from a transient increase in intracranial pressure. This pattern is considered a benign physiologic manifestation of a functioning autonomic nervous system and has no adverse outcome. Variable decelerations are distinctively recognized by their abrupt decrease in fetal heart rate of 15 beats/min or greater from the onset of the deceleration to the beginning of the fetal heart rate nadir of 30 seconds, lasting 15 seconds or greater, and less than 2 minutes in duration. When variable decelerations are associated with uterine contractions, their onset, depth, and duration vary with successive uterine contractions. Isolated variable decelerations have little clinical significance, but if persistent with inadequate recovery between contractions, fetal hypoxemia and acidosis can occur. Late decelerations present usually as a symmetric and gradual decrease and return of the fetal heart rate associated with a uterine contraction. But, late decelerations can have an ominous connotation as they can represent significant uteroplacental compromise, caused by maternal hypotension due to inferior vena cava compression, hypoxia or anemia.[30] Intraoperative fetal compromise as indicated by an ominous heart rate tracing must be treated by correcting maternal hypotension or increasing oxygen delivery with increased FiO_2, positional changes, aggressive fluid resuscitation, or blood transfusion. The inability to improve the intrauterine milieu can necessitate an emergent cesarean section to prevent fetal demise.[31]

The decision to use continuous fetal heart rate monitoring during nonobstetric surgery in pregnancy is controversial and should be based on

gestational age, type, site, duration, and extent of the procedure. For previable pregnancies (<23 weeks), documentation of fetal heart activity by Doppler before and after the procedure suffices.[32] For viable gestations, there is mixed support for fetal heart rate monitoring, but at a minimum, simultaneous electronic fetal heart rate and contraction monitoring should be performed before and after the procedure to assess fetal well-being and the absence of contractions. If the decision is to perform intraoperative electronic fetal heart monitoring, then all the necessary provisions should be made to provide optimal safety for the mother and the fetus. These include availability of obstetric care providers, anesthesiologists, neonatologists, and nurses working as a team and ready to intervene during the surgical procedure for fetal indications. Informed operative consent should thus be obtained in anticipation for a possible emergency delivery.[33]

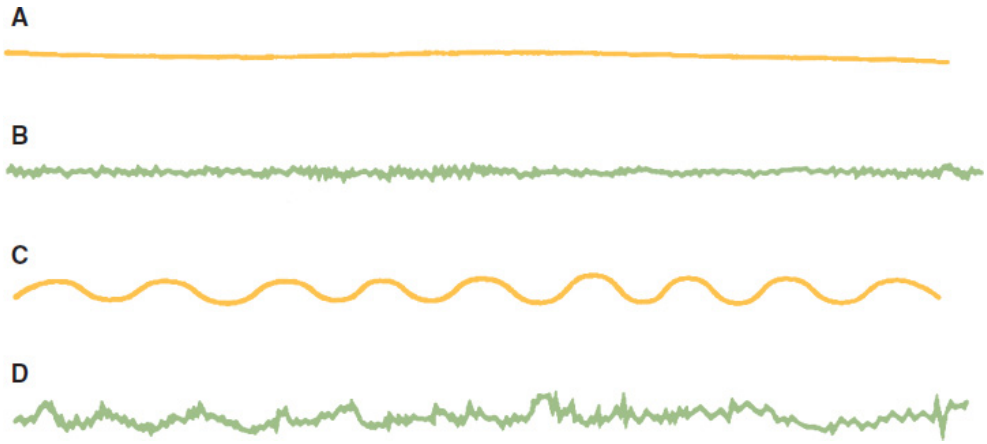

Figure 104.3 Fetal heart variability. **A:** Short-term and long-term variability both absent: abnormal. **B:** Short-term variability present, long-term variability absent: abnormal. **C:** Long-term variability present, short-term variability absent: abnormal. **D:** Both short- and long-term variability present: normal. (Reproduced from Miller DA, Paul R. Antepartum–intrapartum monitoring. In: Scott JR, DiSaia PJ, Hammond CB, et al., eds. *Danforth's Obstetrics and Gynecology*. 8th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:243–255.)

IMAGING THE PREGNANT PATIENT

The most commonly used imaging modalities during pregnancy include plain radiography, ultrasonography, magnetic resonance imaging (MRI), and computed tomography (CT). The first and the latter are forms of ionizing

radiation. The risks of ionizing radiation can be an important source of anxiety for health care providers and patients and can alter the decision to perform the appropriate diagnostic study of choice for fear of injuring the fetus. This misconception could place both the mother and the fetus in greater danger from misdiagnosis. Although experimental data regarding the effects of ionizing radiation on the developing human fetus are impossible to obtain, animal exposure and follow-up of those inadvertently exposed to diagnostic and therapeutic radiation have provided some information. Retrospective studies of atomic bomb survivors in Hiroshima, Nagasaki, and victims of the atomic power plant disaster in Chernobyl have also allowed for evaluation of the effects of massive radiation exposure in utero.[34,35]

Ionizing Radiation

Fetal effects of ionizing radiation depend on the dose absorbed by the fetal tissue and the stage of fetal development during exposure. Exposure is defined as the amount of ionic charge created by the radiation on passing through a defined mass of air. It is a misconception to assume that the radiation dose that a pregnant woman is exposed to or absorbs is the same as that absorbed by the fetus as the latter is partially protected from radiation injury by a pregnant woman's surrounding soft tissues and uterus, both of which generally stop alpha and beta particles from penetration if they are not ingested, injected, or inhaled.[36,37] Radiographic evaluation of the abdomen and pelvis is most likely to expose the fetus to direct ionizing radiation, whereas examination of the extremities and chest leads to exposure from scatter radiation only (**Table 104.1**).[37] The potential deleterious consequences of radiation-induced ionization of vital cellular structures can be divided into four categories: (1) lethal effects, (2) teratogenic effect, (3) growth retardation, and (4) oncogenic potential. The occurrence of each effect depends upon the gestational age at the time of radiation exposure, the dose of radiation absorbed by the fetus, and fetal cellular repair mechanisms. The first three categories of adverse pregnancy outcomes have a deterministic effect whereby a threshold or No-Adverse-Effect Level exists. After exceeding the No-Adverse-Effect Level, a deterministic effect generally shows a gradient relationship with the absorbed dose—the larger the absorbed dose, the more severe the effect. On the contrary, cancer

appears to have a stochastic effect in which, the probability, but not the severity of the effect, increases with the radiation dose. Stochastic effects are monoclonal, resulting in changes to the cell genome and altered differentiation and function of the affected cells.

Table 104.1 Radiation Dosing to the Conceptus and Uterus from Selected Radiographic Examinations

Endoscopic retrograde cholangiopancreatography with no permanent films and shielding of abdomen	4 mrad
Routine chest radiograph	8–50 mrad
Routine mammography	<50 mrad
Abdomen (flat plate)	250–300 mrad
Computed tomography, chest	25–1,000 mrad (uterus shielded and not exposed)
Computed tomography, upper abdomen	670–3,000 mrad (uterus shielded and not exposed)
Computed tomography, abdomen	2,000–3,000 mrad

Diagnostic modalities in the pregnant patient. *Emerg Med Clin North Am* 1994;12(1):9–43; and Baillie J, Cairns SR, Cotton PB. Endoscopic management of choledocholithiasis during pregnancy. *Surgery Gynecol Obstet* 1990;171(1):1–4.

Lethal Effects of Ionizing Radiation

The developing human is most sensitive to the lethal effects of ionizing radiation during the first 14 days after conception (3 to 4 weeks of gestational age). During this period, the "all or none" principle applies to the radiation-exposed embryo; it either survives undamaged or succumbs. At that gestational age, a dose of 100 to 200 mGy (10 to 20 rad) can be lethal for an embryo. Shortly thereafter, the threshold for fetal death increases to 250 to

500 mGy (25 to 50 rad). The estimated radiation dose to kill all embryos or fetuses less than 18 weeks of gestational age is 5,000 mGy (500 rad). At term, the fetal risk equals the pregnant woman's risk at 20,000 mGy (2,000 rad).[38,39]

Teratogenic Effects of Ionizing Radiation

Teratogenic effects of radiation can be seen during early organogenesis in animal studies. Exposure of rats to 100 rads at various points of development reveals a narrow window for teratogenesis. This window corresponds to weeks 2 to 4 in human development, coinciding with early organ formation. Despite these experimental data, it is difficult to link any specific human malformation with radiation exposure other than those of the CNS. Microcephaly, pigmentary changes in the retina, hydrocephalus, and optic nerve atrophy have all been reported at a significantly higher rate after exposure to radiation in pregnancy.[40] These patients were exposed to a minimum estimated dose of 100 rads, and no visceral, limb, or other malformations were found unless the child also exhibited CNS abnormalities. One explanation for this discrepancy is that the developmental period of the CNS is much longer, continuing throughout gestation and into the neonatal period, whereas other organs have a very narrow period during which morphologic alterations can be produced. Exposure to high doses of radiation during this narrow window is rare, and even if an isolated congenital abnormality were to occur, it would be difficult to separate this event from the background malformation rate. The extended period for CNS sensitivity to teratogenesis increases the prevalence of CNS malformation. CNS malformation also occurs at threshold doses; however, low levels of exposure to 10 to 20 rads of radiation do not increase the incidence of microcephaly in experimental animals over baseline.[41]

Growth Retardation from Ionizing Radiation

Growth retardation results from radiation-induced cellular depletion. Although catch-up growth can occur if exposure happens early in gestation, permanent cell depletion and growth retardation occur with exposure during later fetal stages.[42] Wood and colleagues studied growth retardation of children exposed in utero to the Japanese atomic blasts.[43] The children

within 1,500 m, when followed through age of 17 years, were 2 to 3 cm shorter and 3 kg lighter and had a head circumference 1 cm smaller than normal. Those beyond 1,500 m from the blast received less than 25 rads and had a normal head circumference, height, and weight.[44–46] Further, animal and human data support the contention that exposures of less than 5 rads should not cause either anatomic malformation or growth retardation.[41]

Oncogenic Potential of Ionizing Radiation

The correlation between childhood cancer and in utero exposure to radiation has been demonstrated. Although conclusions regarding the cause-and-effect relationship of this correlation cannot be definitively established, further studies using twins and extensive data analysis have strengthened the argument that in utero radiation can increase the rate of childhood cancer even at doses of 1 rad.[47,48] The current increase in childhood cancer is estimated at one to two cases per 3,000 children exposed to 1 rad in utero.[49] Although these risks are very small, the parent must be counseled regarding this potential danger. By reviewing the current data, it is obvious that exposure to diagnostic levels of radiation carries little chance for spontaneous abortion, teratogenesis, or growth retardation. The increased risk of future cancer, however, does exist and must be weighed against the utility of the information provided by the study.

Ultrasound

Ultrasonography uses high-frequency, acoustic radiation to create images. A surface transducer containing piezoelectric crystals converts electrical energy into sound waves. Sound waves pass through tissue layers and are reflected back to the transducer when they encounter an interface between tissues of different densities. Digital images generated at 50 to more than 100 frames per second undergo postprocessing that produces the appearance of real-time imaging. Ultrasonography is considered the first-line diagnostic imaging modality of the pregnant surgical patient because it is nonionizing, widely available, portable, and of adequate diagnostic performance. This imaging technique has been used in obstetrics for more than 50 years without reported fetal damage or harmful effects.[50,51] Ultrasonography 5 is,

however, a form of energy with effects on tissues through which the waveform penetrates. The two major mechanisms with potential effects are either direct, resulting from the alternation of positive and negative pressures (mechanical or cavitation effects) or indirect, caused by heating of tissues secondary to transformation of the acoustic energy (thermal effects). Because of these theoretical concerns, several organizations have recommended that this diagnostic procedure be performed only when there is a valid medical indication and using the lowest possible ultrasonic exposure setting.[52–54]

Computed Tomography

In the past 10 years, the use of radiologic examinations in pregnant women has increased by 107%, with the greatest increase occurring in the use of CT.[55] Computed tomography is most valuable in the second and third trimesters, when ultrasonography is of limited value, in a patient with a large body habitus, and when MRI is inconclusive or not available.[44] Because of its sensitivity for the detection of abdominal and pelvic injury as well as retroperitoneal injury in which the clinical urgency requires prompt diagnosis, CT is the test of choice for injured pregnant patients.[56–58] When CT is performed during pregnancy, using dose-reduction protocols (e.g., abdominal and internal barium shielding) results in reduction in the probability of biologic effects to the fetus without sacrificing the necessary diagnostic image quality.[59]

Magnetic Resonance Imaging

Like ultrasonography, MRI does not use ionizing radiation, instead relying on the magnetic properties of tissues to create images. Four magnetic fields interact during an MRI examination to create the image. The intrinsic magnetic field of an atomic nucleus, usually that of a hydrogen proton, is combined with a strong, uniformly applied external magnetic field and a weaker magnetic field gradient. In addition, a magnetic field is intermittently generated by pulsed radio frequency waves.[38] When the radio frequency ceases, the nuclei return to their previous orientation and emit the radio frequency they absorbed. These signals are detected, stored, and processed by a computer to create an image. Theoretical concerns include the effects of

fluctuating electromagnetic fields and high sound intensity levels with potential damage to the fetal ear. Other known dangers of MRI exposure include trauma from projection of small metal fragments into the eyes, interference with the operation of implantable electronic devices, position of metallic implants, and burns from heating of conductive materials in implants. Despite these concerns, present data have not conclusively documented any deleterious effects of MRI exposure on the developing conceptus or the pregnant woman.[45]

APPENDICITIS IN THE PREGNANT PATIENT

Acute appendicitis is the most common nonobstetric cause of acute surgical abdomen during pregnancy.[46] Disease is 6 confirmed in 65% to 75% of suspected cases for an incidence of approximately 1:1,500 births.[60] Although previous series suggested that the condition had similar incidences for nonpregnant adults, equal distribution throughout pregnancy, and a more common occurrence later in gestation, a large case-control study showed a lower incidence of appendicitis than among nonpregnant individuals, particularly in the third trimester.[61–64] The incidence decreases in the third trimester to 15% to 30% compared to rates ranging from 20% to 60% in the first and second trimesters.[65,66] A well-known fact is that the anatomic and physiologic changes of the gravid state make the diagnosis difficult. Attributing abdominal pain to other etiologies (e.g., pyelonephritis, false labor, gastroenteritis), failure to pursue further investigation, and the physicians' fear of surgically induced premature labor all contribute to delayed diagnosis and timely appendectomy in pregnancy. Appendiceal perforation rates are higher when compared with those from nonpregnant populations (55% vs. 4% to 19%).[67] This is probably explained by confounding variables leading to the delay of diagnosis and therapy. Several studies have documented a correlation between a delay in diagnosis and gestational age. In the first trimester, most diagnoses were made promptly, while a significant delay in operation with a rate of perforation of 49% was reported for patients presenting in the second trimester and a rate as high as 70% for those presenting in the third trimester.[61,68] Perforated appendicitis presents a greater infectious risk in the pregnant patient than in the population

as a whole. The large uterus interferes with proper omental migration throughout the abdominal cavity and prevents the walling off of the inflammatory process. Braxton Hicks contractions disrupt adhesion formation, and the general increase in vascularity of the abdomen with greater lymphatic drainage allows rapid dissemination of infection. The high circulatory levels of adrenocorticoids in pregnancy have also been hypothesized to diminish the tissue inflammatory response and hinder containment of infection.[69–71] All of the classic signs and symptoms of appendicitis can be masked by pregnancy (**Table 104.2**). Anorexia, nausea, and vomiting occur in 58% to 77% of pregnant patients with appendicitis.[61,68] Although anorexia, nausea, and vomiting in the first trimester are common, their occurrence during the second and third trimesters, especially if associated with abdominal pain, require a thorough investigation. In a classic 1932 study, Baer and colleagues[72] evaluated the migration of the appendix through the duration of pregnancy with barium enemas. Beginning in the first trimester, the appendix and the cecum are gradually displaced by the uterus and start a caudal migration out of the pelvis into the upper abdomen. By the third trimester, the appendiceal tip can abut the gallbladder (**Fig. 104.4**). The vague, referred epigastric pain due to early appendiceal obstruction is not changed by this anatomic consideration, but the location of the somatic pain is. In a large study of pregnant women with appendicitis, abdominal pain was present in all patients. Location of pain in the right lower quadrant, however, was common only early in gestation, and a portion of patients reported pain in the right upper quadrant. This change in symptomatology is easily understood if the anatomic changes of the appendix are taken into consideration. Both guarding and rigidity are valuable findings on physical examination but are common only in the first trimester. Elevation of the abdominal wall from the more laterally placed, upward-directed appendix and the laxity of the abdominal wall musculature caused by this distention decrease the reliability of these findings. Only 42.9% of patients in the third trimester are reported to have abdominal spasm and guarding, compared with 80% during the first trimester.[73] Psoas and obturator signs are similarly obscured as the appendix is moved from its normal location and have not been shown to have clinical significance. The results of laboratory examinations commonly used to assist in the diagnosis of appendicitis are also obscured by pregnancy. The physiologic

leukocytosis of pregnancy, ranging from 5,000 to 12,000 white blood cells (WBCs)/mL, overlaps that of appendicitis. In one collected series, the WBC count of pregnant patients with proven appendicitis was not significantly elevated over these values, and only 25% of patients had a WBC count over 15,000. Most patients (50%) had WBC counts ranging between 10,000 and 15,000, and 25% had less than 10,000 WBCs/mL.[61] Urinalysis is a useful adjunct in the workup of appendicitis but again presents a dilemma in pregnancy. Urinary tract infection is common in pregnancy as the enlarging uterus compresses the right ureter. Dilatation and stagnant flow in the right collecting system can contribute to bacterial overgrowth and infection. Pyuria without bacteria can also indicate involvement of the right ureter in the appendiceal inflammatory process. The presence of pyuria and bacteriuria does not rule out appendiceal inflammation because the two conditions may coexist in 40% of pregnant patients.[68]

Table 104.2 Variation in Signs and Symptoms of Appendicitis during Pregnancy

Signs and Symptoms	First Trimester (%)	Second Trimester (%)	Third Trimester (%)
Right lower quadrant pain	100	50	14
Right upper quadrant pain	0	17	57
Guarding (muscle spasm)	80	50	43
Nausea and vomiting	53	60	23
Tenderness on rectal examination	60	17	0
Perforation rate	20	49	70

Data from Weingold AB. Appendicitis in pregnancy. *Clin Obstet Gynecol* 1983;26(4):801–809; Tamir IL, Bongard FS, Klein SR. Acute appendicitis in the pregnant patient. *Am J Surg* 1990;160(6):571–575; and Cunningham FG, McCubbin JH. Appendicitis complicating pregnancy. *Obstet Gynecol* 1975;45:415–420.

The risk of adverse pregnancy outcomes following appendectomy has been reported by two large population-based studies. From the California Inpatient File of 3,133 pregnant women undergoing surgery for suspected appendicitis, the fetal loss rate was 23%, and it was doubled—6% versus 11%—with simple versus complicated disease.[74] In the other study, the fetal loss rate within 1 week of the procedure was 22%, particularly when the surgery was performed after 23 weeks.[60] Fortunately, these same researchers noted no additional increase in the preterm birth rate among the pregnancies that continued beyond the first postoperative week. Perforated appendicitis in pregnancy rapidly leads to diffuse peritonitis, premature labor, and fetal loss.[63,75]

Imaging Modalities

Ultrasonography is the initial nonionizing imaging modality of choice in patients with appendicitis. Findings suggesting appendicitis include visualization of a tubular structure with a diameter of more than 6.0 mm, a wall thickness of more than 3.0 mm, and lack of peristalsis (**Fig. 104.5**).[76,77] One study reviewed the value of ultrasonography in diagnosing appendicitis in pregnancy, reporting a range of sensitivity of 67% to 100% and a range of specificity of 83% to 96%, compared to diagnostic performance in the general population of 86% and 96%, respectively.[78] Ultrasonography, however, does have limitations due to body habitus, intraluminal air, and operator level of experience. The examination can also be difficult because of abdominal guarding and pain during examination. Distortion of anatomic landmarks and the displacement of the appendix by the gravid uterus complicate the diagnosis. Other structures such as an inflamed salpinx can also mimic appendicitis on ultrasonogram and a dilated uterine vein during pregnancy has been mistaken for an acutely inflamed appendix.[79,80] Chest radiography should be considered in the evaluation of patients with suspected appendicitis because right lower lobe pneumonia may manifest with lower abdominal pain. Abdominal plain films are usually avoided unless there is suspicion for visceral perforation or bowel obstruction.

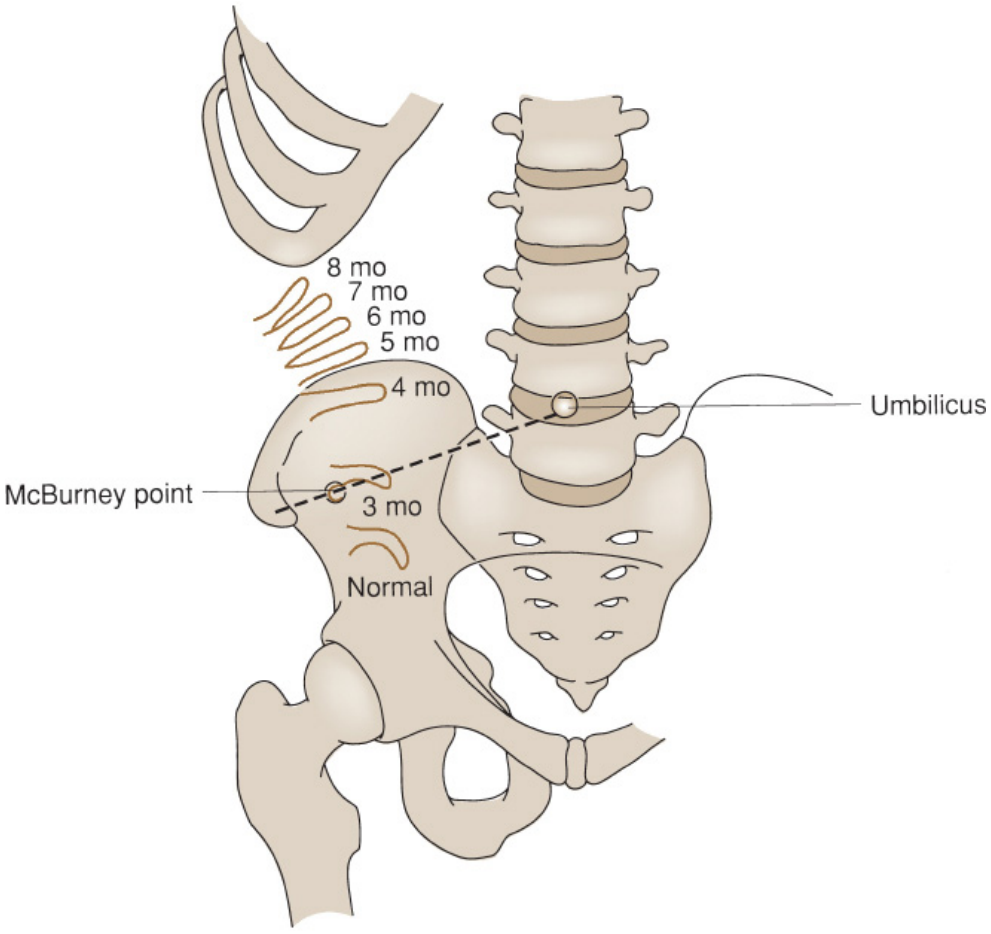

Figure 104.4 Changing location of the appendix throughout gestation.

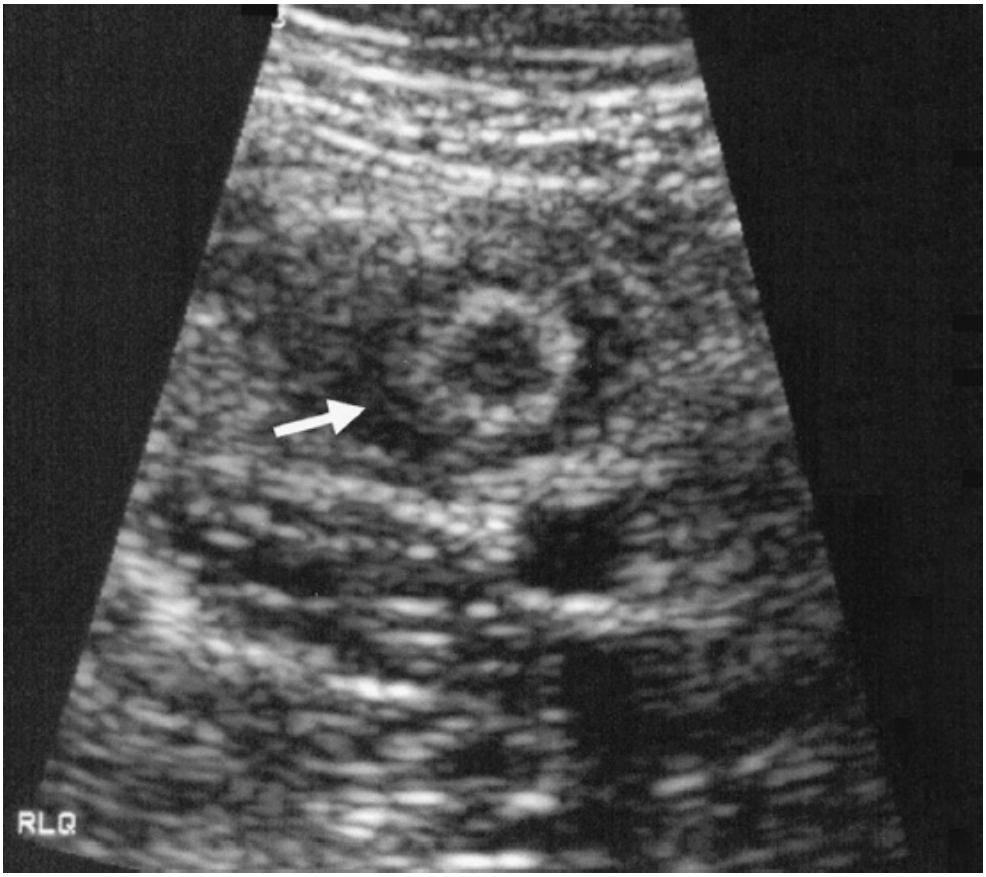

Figure 104.5 Ultrasonographic appearance of appendicitis. The appendix appears as a thick, noncompressible tubular structure with central hypoechogenicity. The walls are 5-mm thick, over the 3-mm limit for a normal appendix. (Courtesy of Dr. Beverly Coleman, Department of Radiology, Hospital of the University of Pennsylvania, Philadelphia, PA.)

Computed tomography (CT) has emerged as a highly reliable modality in the diagnosis of appendicitis. Appendiceal CT with rectally administered contrast can be performed within 10 to 20 minutes and does not require a waiting period for oral contrast to progress down through the cecum; it also exposes the patient to only one-third the radiation of a regular CT scan.[81] Computed tomography in the nonpregnant population is more sensitive and specific than sonography (approximately 98% each) to confirm suspected appendicitis.[82] A computed tomographic scan is considered abnormal if there is an enlarged appendix (>6 mm in maximum diameter) or if there are periappendiceal inflammatory changes such as fat stranding, phlegmon, fluid collection, and extraluminal gas. Routine use of this modality has been shown to reduce costs, expedite the diagnosis, and reduce perforation rates from

22% to 14% while decreasing the incidence of negative laparotomy from 20% to 7%.[83–85] Radiation exposure is 300 mrad with a limited helical CT scan, which is one-third of the amount of the average abdominopelvic CT scan.[86] Because even low levels of radiation in utero can increase the incidence of childhood cancer, widespread use of this modality in the pregnant patient with abdominal pain may be detrimental. Reserving the CT scan for those cases in which the clinical history, physical examination, and ultrasonography are indeterminate should still decrease the rate of perforation and negative exploration, just as it has in the nonpregnant population (**Fig. 104.6**).

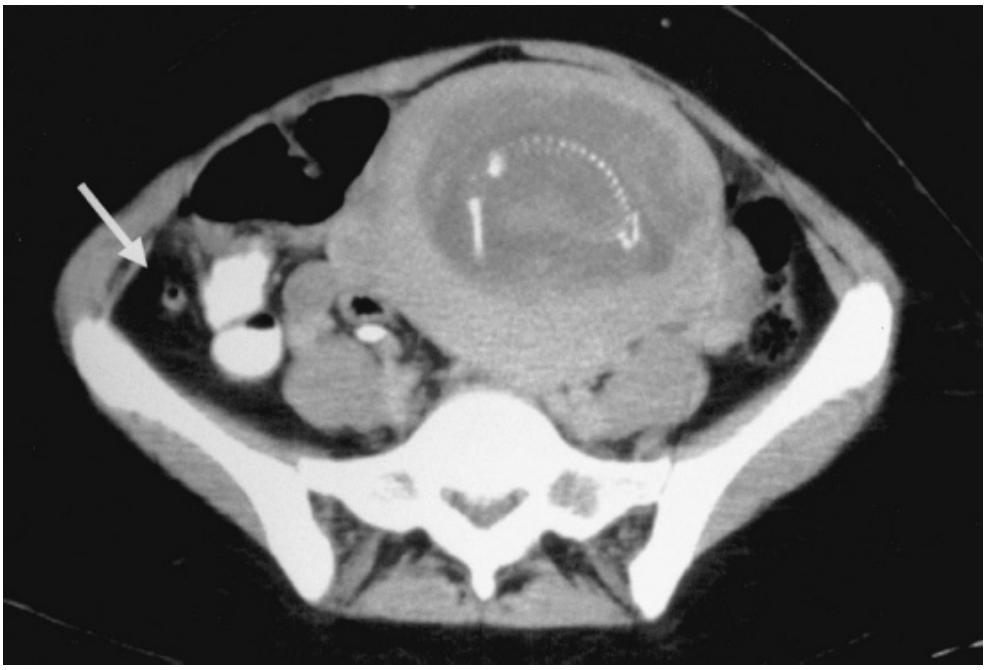

Figure 104.6 Computed tomographic (CT) scan of a woman in the 18th week of gestation presenting with a 12-hour history of right-sided abdominal pain. Abdominal examination on presentation revealed significant tenderness, and after a nondiagnostic ultrasonography, a laparotomy is considered for presumed appendicitis. A CT scan is obtained instead, revealing a normal, air-filled appendix with no sign of periappendiceal inflammation (*arrow*). The laparotomy was postponed, and 12 hours later the patient aborted a septic fetus. An unnecessary laparotomy for an atypical presentation of chorioamnionitis was avoided by the judicious use of the CT scan. (Courtesy of Dr. David Weiss, Chestnut Hill Hospital, University of Pennsylvania Health System, Philadelphia, PA.)

MRI utilizes nonionizing radiation, which has no known adverse fetal effects, and like CT, has the potential to image the whole abdomen. On MRI,

an appendix is considered abnormal when it is fluid-filled, greater than 6 or 7 mm in diameter, or demonstrates the presence of periappendiceal inflammatory changes. A study suggested that a normal appendix on MRI had a high specificity (98% to 100%) and a high negative predictive value (94% to 100%) in excluding acute appendicitis.[87] The American College of Radiology Guidance Document on MR Safe Practices in 2013 reaffirmed the use of MRI in pregnancy if considered necessary irrespective of gestational age. Intravenous gadolinium contrast has no known adverse effects in humans but its use should be based on whether the potential benefits to the patient exceed the theoretical risks to the fetus.[88]

Diagnostic Laparoscopy

Laparoscopy to evaluate the appendix is a feasible diagnostic modality during pregnancy but may be difficult during later gestation. Anatomic changes alter placement of trocars above the gravid uterus and require the use of the open Hasson technique of trocar placement under direct visualization rather than blind insufflation with a Veress needle.[89] Maneuvers to enhance operative safety of laparoscopy in pregnancy have been outlined by the Society of American Gastrointestinal Endoscopic Surgeons (**Table 104.3**).[90]

Appendectomy

Once the diagnosis of appendicitis is made, treatment is a combination of antibiotics and surgical removal, just as with nonpregnant patients. Antibiotics should be broad-spectrum, but should include Gram-negative and anaerobic coverage with care taken to avoid any teratogenic medications. A second- or third-generation cephalosporin, expanded-spectrum penicillin, or even triple agent therapy may be selected.[91] Laparoscopy is almost always used to treat suspected appendectomy during the first two trimesters, however this may vary based on surgeon preference. Recent studies have failed to demonstrate superiority of laparoscopic or open techniques, although each approach is associated with particular advantages. One recent meta-analysis of 20 studies, containing over 6,220 pregnant patients, concluded that laparoscopic appendectomy in the pregnant patient was

associated with lower overall complication rates and shorter hospital stays, while open appendectomy was associated with a reduced risk of fetal loss and later overall gestational age at the time of delivery.[92] If an open approach is selected, a muscle splitting incision is made over the *point of maximum tenderness* because the appendix customarily lies beneath that point.[46,61,68] This is opposed to the classic right lower quadrant paramedian incision, which usually necessitates medial retraction of the uterus for exposure and thus increases the risk of precipitating premature labor. In addition, by tilting the patient 30 degrees to the left, the uterus is shifted away from the operative field and off the inferior vena cava. Because of the migration of the appendix, the classic incision over McBurney point in the late second and third trimesters is not optimal. If diffuse peritonitis is present, a midline incision is usually performed. Perforated appendicitis or pus in the abdominal cavity demands thorough peritoneal cleansing along with the appendectomy. A periappendiceal abscess, just as with nonpregnant patients, can be treated with percutaneous drainage, followed by an interval appendectomy 2 to 3 months later.[93]

Table 104.3 Guidelines for Laparoscopic Surgery during Pregnancy

1. Diagnostic laparoscopy is safe and effective when used selectively in the workup and treatment of acute abdominal processes in pregnancy.
2. Laparoscopic treatment of acute abdominal disease has the same indications in pregnant and nonpregnant patients.
3. Laparoscopy can be safely performed during any trimester of pregnancy.
4. Gravid patients should be placed in the left lateral decubitus position to minimize compression of the vena cava.
5. Initial abdominal access can be safely accomplished with an open (Hasson) technique, Veress needle, or optical trocar, if the location is adjusted according to fundal height and previous incisions.
6. CO_2 insufflation of 10–15 mm Hg can be safely used for laparoscopy in the pregnant patient.
7. Intraoperative CO_2 monitoring by capnography should be done during laparoscopy in the pregnant patient.
8. Intraoperative and postoperative pneumatic compression devices in early postoperative ambulation are recommended prophylaxes for deep venous thrombosis in the gravid patient.
9. Laparoscopic cholecystectomy is the treatment of choice in the pregnant patient with gallbladder disease, regardless of trimester.
10. Cholelithiasis during pregnancy may be managed with preoperative endoscopic retrograde cholangiopancreatography (ERCP) with sphincterotomy, followed by laparoscopic cholecystectomy, laparoscopic common bile duct exploration, or postoperative ERCP.
11. Laparoscopic appendectomy may be performed safely in pregnant patients with appendicitis.
12. Obstetric consultation can be obtained pre-and/or postoperatively on the basis of the severity of the patient's disease, gestational age, and availability of the consultant.
13. Tocolysis should not be used prophylactically in pregnant women undergoing surgery but should be considered perioperatively when signs of preterm labor are present.

Adapted from SAGES Committee on Standards Practice. Guidelines for laparoscopic surgery during pregnancy. *Surg Endosc* 2011;25:2479–3492.

Cesarean section at the time of appendectomy is rarely indicated. Unless there is gangrene, perforation, or a periappendiceal phlegmon, antimicrobial therapy can usually be discontinued after surgery. Although uterine contractions are common, tocolytic therapy is generally not recommended. If exploration reveals a normal appendix, an appendectomy still should be performed; removal of the normal appendix adds little to morbidity while eliminating potential confusion if symptoms should recur.[61] Laparoscopic appendectomy has been shown to demonstrate a good safety record in all trimesters with a complication rate similar to that for nonpregnant laparoscopy.[89,92,94–97] Certainly, the presence of the enlarged uterus does increase the risk of inadvertent injury with a trocar or Veress needle, which can be mitigated by the use of an open Hasson technique and direct visualization of trocar insertion after careful consideration of fundal height.[98] In addition, limiting intra-abdominal pressures to less than 12 mm Hg and reducing operative time can reduce concerns about maternal hypercarbia and subsequent fetal acidosis.

BILIARY TRACT DISEASE IN PREGNANCY

Acute cholecystitis is the second most common nonobstetrical indication 7 for surgery in pregnant women and the most common cause of maternal hospitalization in the first year after delivery.[99] Pregnancy and the postpartum period appear to predispose women to gallstone formation. This is attributed to increase in sex steroid hormone levels in pregnancy, causing biliary stasis, prolonged intestinal transit, and increased cholesterol saturation of bile. Multiparity and prepregnancy obesity are two major independent risk factors for cholelithiasis in pregnancy. One study found that gallstones occurred in 7% of nulliparous women, with the rate rising to 19% of women with two or more pregnancies. This risk of gallstones appears to increase during gestation, with sludge or stones found in 5.1% of 3,254 prospectively studied women in the first trimester, 7.9% in the second trimester, and 10.4% by 4 to 6 weeks after delivery.[100] However, among women with sludge or stone,

only 1.2% developed any symptoms attributable to the gallbladder during pregnancy.[101] Despite the predilection for stone formation in pregnancy, acute cholecystitis does not occur more frequently during pregnancy. Data suggest that cholecystitis affects only 0.1% of pregnant women.[102] Most patients with symptomatic gallstones present with complaints of typical biliary colic likely resulting from gallbladder contractions and increased pressure and luminal expansion characteristically exacerbated by a fatty meal. Less frequently, the symptoms are those of one of the complications of gallstones, acute cholecystitis, cholangitis, or pancreatitis. Signs and symptoms may include right upper quadrant pain, fever, tachycardia, leukocytosis, anorexia, and vomiting. Sepsis and jaundice may also be seen. Abdominal examination usually demonstrates voluntary and involuntary guarding and frequently a positive Murphy sign.

Laboratory studies should be normal in patients with uncomplicated cholelithiasis. However, mild elevations in serum aminotransferases and amylase may occur as a result of the passage of small stones or sludge. It is important to note that serum alkaline phosphatase levels normally increase during pregnancy because of production of an alkaline phosphatase isozyme by the placenta. Significant elevations in aminotransferases, hyperamylasemia, or increased direct bilirubin may be signs of complicated gallbladder disease. The differential diagnosis includes appendicitis, pancreatitis, peptic ulcer disease, pyelonephritis, right-sided pneumonia, acute fatty liver of pregnancy, and preeclampsia.

Abdominal ultrasound is a reliable diagnostic tool for identifying gallstones, sludge, and acute or chronic cholecystitis with a high sensitivity and specificity.[103] A diagnosis of acute cholecystitis is suspected by findings of gallbladder distention, gallbladder wall thickening, and pericholecystic fluid on ultrasonography.[104] Transabdominal ultrasonography is relatively insensitive for the detection of common bile duct stones, whereas endoscopic ultrasound is highly accurate for that purpose. Magnetic resonance cholangiopancreatography (MRCP) may be used when extrahepatic ductal stones are suspected or in complicated cases when ultrasound is nondiagnostic. Endoscopy of the biliary system by endoscopic retrograde cholangiopancreatography (ERCP), with its associated radiation exposure, can be performed safely in pregnant patients but should be limited to cases in which treatment of ductal stones is required.

The appropriate management for symptomatic cholelithiasis and acute cholecystitis during pregnancy is controversial. Suggested management for a pregnant patient with symptomatic cholelithiasis during the first trimester consists of conservative measures until elective cholecystectomy can be performed safely during the second trimester. Nonoperative management of symptomatic cholelithiasis is associated with significant recurrence bouts of symptoms, prolonged total parenteral nutrition, higher rates of preterm delivery, cesarean section, and more technically difficult cholecystectomies compared with laparoscopic cholecystectomy.[105–107] Cholecystectomy can be performed safely and effectively during pregnancy in all trimesters, though the second trimester is the optimal time to perform an elective cholecystectomy. Organogenesis is complete and the gravid uterus is not yet large enough to impinge on the operating field.[108] Removing the diseased gallbladder eliminates the potential for recurrence, and the minimal uterine retraction needed with laparoscopic access to the right upper quadrant should decrease the risk for preterm labor. Either an open or laparoscopic approach may be chosen, however laparoscopic cholecystectomy is the preferred technique for removal of the gallbladder in pregnant women.[109] Just as with nonpregnant patients, laparoscopy is associated with shorter postoperative stay and earlier diet initiation with less pain and rate of postoperative hernia.[94,110,111] After an open cholecystectomy, the reported rate of premature labor ranges from 0% to 40%, based on trimester, and a spontaneous abortion or premature birth rate of up to 22% has been reported.[112,113] The incidence of premature uterine contractions with laparoscopic cholecystectomy has been reported at 0% to 21%, but contractions are usually well-controlled by tocolytics. Most series report rates of premature birth or spontaneous abortion ranging from 0% to 7% with the laparoscopic approach.[89,114,115] Those patients presenting later in gestation can most commonly be managed symptomatically until the postpartum period, with cholecystectomy generally performed 6 weeks following delivery to allow the mother to recover and to bond with her infant.

Choledocholithiasis

Indications for evaluation of the common bile duct are no different in the pregnant patient than in the population as a whole—namely, a bilirubin elevated over 1.5 mg/dL, a dilated common bile duct, or gallstone pancreatitis.[89] ERCP can be performed in pregnancy. With proper lead shielding, judicious use of fluoroscopy time, and avoidance of permanent roentgenographic films, ERCP has been performed with no direct exposure of the fetus to radiation. Calculated scatter radiation on the order of 4 mrads during the whole examination presents the only risk from ionizing radiation.[116] Evaluation of the biliary tree, stone retrieval, and sphincterotomy can be performed under these conditions without maternal or fetal complications.[117] Other methods avoid radiation altogether and include imaging of choledocholithiasis with endoscopic ultrasonography, endoscopic papillotomy under ultrasonographic control, and MRCP for choledocholithiasis.[118–120] Success with all these modalities has been reported but may be limited by operator experience and availability.

BREAST CANCER IN THE PREGNANT PATIENT

Breast cancer diagnosed during gestation poses a complex clinical 8 situation given the need to consider the welfare of both mother and developing fetus. In general, pregnant patients should be managed by similar treatment strategies as nonpregnant patients with few adjustments to account for potentially teratogenic interventions. The most critical component of managing breast cancer in the pregnant patient is timing, as treatment should not be delayed simply due to pregnancy. That being said, pregnancy termination has also not been shown to improve outcomes for patients, so this should not be universally recommended as a means to accelerate treatment.[121] The decision to terminate a pregnancy should be made individually by each patient in conjunction with her clinician. Factors to consider include potential risks of treatment to the fetus and her anticipated ability to care for a child postpartum.

Surgical Management

The definitive treatment for localized breast cancer is surgical resection. Both mastectomy and breast-conserving surgery (BCS) are available treatment options for women with carcinoma and carcinoma in situ. Mastectomy may be chosen by women who wish to avoid radiation therapy. BCS is a safe, feasible option for the pregnant patient with no reported adverse effects with regards to locoregional recurrence or survival. Those women who elect BCS should defer radiation therapy (RT) until after delivery whenever feasible given that RT is contraindicated during pregnancy. As such, women diagnosed with breast cancer early in pregnancy might consider mastectomy given the significant delay before receiving RT. For women preferring BCS during pregnancy who do not want to defer RT, a discussion is necessary to review risks and benefits. The degree of radiation exposure to the fetus will vary based on the dose administered, as well as the gestational age and fundal height.

Axillary staging is another critical component of managing a patient with breast cancer. Most recently, the American Society of Clinical Oncology concluded there was insufficient evidence to recommend sentinel lymph node (SLN) biopsy during pregnancy.[122] The safety of SLN biopsy during pregnancy has not been fully explored but generally requires minimal radiation exposure to the abdomen.[123,124] Furthermore, Han and colleagues report that efficacy of SLN biopsy in pregnant patients is equivalent to that in nonpregnant patients, allowing for the identification of those patients who would benefit from axillary node dissection.[125] Following SLN, those patients with indication for axillary lymph node dissection should proceed just as for nonpregnant patients. Reconstruction, when indicated, should be deferred until after delivery though placement of tissue expanders at the time of mastectomy or oncoplastic closure during BCS are appropriate with little appreciable risk to the fetus with the exception of prolonged time of general anesthesia.[126]

Systemic Therapy

Chemotherapy is generally contraindicated during the first trimester due to the severe potential teratogenic effects of these therapies. During the first trimester, when organogenesis is occurring, chemotherapy has been shown to contribute to complications including congenital and chromosomal

abnormalities, as well as increased risk of spontaneous abortion or stillbirth.[127–129] After the first trimester, chemotherapy may be safely administered to pregnant patients with little if any appreciable effect on prenatal fetal development. Specifically, chemotherapy given during the second and third trimester has not been shown to increase peripartum complications or to affect cardiac, cognitive, or general development of fetuses or children in early childhood.[130,131] Importantly, chemotherapy should be stopped prior to delivery such that the mother is not experiencing chemotherapy-related toxicity at the time of delivery. Selection of chemotherapeutic agents should be made on a case-by-case basis under the guidance of an oncologist with experience treating pregnant patients. One caveat is the use of selective estrogen receptor modulators (SERMs) such as tamoxifen, which are generally avoided during pregnancy, given their association with vaginal bleeding, spontaneous abortion, and fetal death.[132] Furthermore, tamoxifen can suppress postpartum lactation, so it should be avoided in nursing mothers.

MANAGEMENT OF THE PREGNANT PATIENT WITH TRAUMA

Most cases of major maternal trauma are due to motor vehicle collisions, falls, or domestic partner violence. Approximately 7% of pregnancies are affected by trauma and as such it is the leading cause of nonobstetric maternal and fetal mortality.[133] While blunt trauma is significantly more common in pregnant patients, mortality is much higher for both mother and fetus in cases of penetrating trauma.[134] Evaluation and management of trauma in these patients are made more complex by the need to assess and care for both the mother as well as the fetus. As such, a multidisciplinary approach is preferred whenever feasible, including a trauma surgeon, an obstetrician, and a neonatologist, when appropriate. The most important principle of managing the pregnant patient after major trauma is that 9 any diagnostic test or treatment should be performed if that intervention is required to save the mother's life, even if that intervention is potentially dangerous for the fetus. The second most important element is to establish an accurate gestational age

for the fetus given that fetal intervention, including premature delivery by emergency Cesarean section, would only be indicated if the fetus has reached viability.

Primary and Secondary Survey

Evaluation of the pregnant patient should be performed systemically, in a fashion which mirrors the typical algorithm of assessing the nonpregnant patient, though with important additional considerations. Sequential assessment of the airway, breathing, circulation, and disability ("ABCD") should be completed efficiently. The pregnant patient may be more likely to experience airway edema, thus increasing the risk of a difficult airway.[135] As such, earlier intubation may be indicated. Although the cephalad growth of the uterus impinges upon the diaphragm, the thorax of the pregnant patient does increase anterior-posterior and lateral dimensions to allow for improved compensation.[136] Circulatory changes during pregnancy are frequently the most dramatic when compared to the nonpregnant patient. First, the circulating blood volume and cardiac output of the pregnant patient increases to account for the systemic vasodilation that occurs, possibly due to progesterone and estrogen. Vital signs of the pregnant patient at baseline may also more closely reflect signs of hypovolemic shock, so care should be taken in interpreting the initial heart rate and blood pressure. Second, the gravid uterus and placenta may both serve as unique sources of significant bleeding. Third, the uterus may cause compression of the inferior vena cava, particularly when the patient is in the supine position, increasing the risk of hypotension. As such, a rolled towel placed beneath the right hip or spinal board, can achieve a left lateral tilt which reduces this effect. Taken together these elements complicate assessment of the patients initial circulatory status. Neurologic assessment, including Glasgow Coma Scale, should be unaffected by pregnancy. In addition to a head-to-toe assessment of the patient for other signs of trauma, a thorough obstetric assessment of the patient should be obtained during the secondary survey. Particularly relevant areas of focus include the abdominal and vaginal exam.

Radiographic Assessment

As with assessment of potential surgical pathologies in the pregnant patient, appropriate imaging studies should not be avoided simply due to the risk of adverse effects on the fetus. The Focused Assessment with Sonography for Trauma (FAST) is an essential part of the evaluation of pregnant patients which does not confer increased risk to the fetus. FAST allows for the detection of intraperitoneal blood after blunt trauma with a reported sensitivity of 80% and specificity of nearly 100% for major abdominal injury.[137] While a small amount of physiologic free fluid is expected within the pelvis of pregnant patients, this volume is too small to be detected by FAST, so any free fluid should be assumed to be pathologic until proven otherwise.[138] FAST also allows for immediate assessment of the pregnancy, specifically rapid identification of the number of fetuses and their respective positions, estimation of gestational age, detection of cardiac activity, and placental location.[139] If CT scan is indicated for assessment of the mother in order to detect a potentially life-threatening or critical injury, this should be performed without delay. Plain films of the chest or extremities may be performed with an abdominal lead shield in place to limit fetal exposure, though this is likely not feasible for pelvic films.

Fetal Monitoring and Emergency Delivery

Continuous fetal monitoring is indicated for pregnant patients who have undergone more than minor abdominal trauma with a fetus that has reached viability. Monitoring generally consists of both an external fetal heart monitor and a tocodynamometer. The duration of monitoring is debated though most sources agree that a minimum of 4 hours is recommended in the absence of warning signs which include an abnormal abdominal or vaginal examination, abnormal fetal heart tracings, regular contractions, or the presence of coagulopathy.[140,141] All RhD-negative pregnant patients should undergo a Kleihauer–Betke test to detect fetomaternal transfusion, although any RhD-negative woman who has not been previously immunized should receive anti-D immune globulin after abdominal trauma.

Emergency cesarean section should be reserved for specific life-threatening circumstances. Generally, it is avoided in any infant who has not reached viability, as delivery would thus almost uniformly be fatal. If an infant is viable, cesarean section may be performed for an abnormal fetal

heart tracing or if maternal death is imminent. It may also be performed as a means to improve the chances of maternal survival, namely if cardiopulmonary resuscitation is ineffective or if emptying of the uterus will assist with surgical exposure for the mother.

SUMMARY

Management of the pregnant patient poses unique challenges for the general surgeon. A thorough understanding of the unique anatomic and physiologic characteristics of mother and fetus is necessary. While the first priority of surgical management of the pregnant patient is ensuring the health and safety of the mother, a surgeon must constantly be aware of the effects that interventions may have on the fetus. We have reviewed the diagnostic and therapeutic management strategies for the most common surgical pathologies encountered during pregnancy. A multidisciplinary approach to the 10 pregnant patient is ideal for ensuring the safety of the mother and the fetus.

Cutaneous Malignancies

Lesly A. Dossett, Amod A. Sarnaik, Allison B. Durham, and Vernon K. Sondak

Key Points

1 Cutaneous malignancies are the most commonly diagnosed cancers in the United States, with basal cell and squamous cell carcinomas, melanomas, and Merkel cell carcinomas (MCCs), in that order, the most frequently diagnosed.

2 Melanoma prognosis is inversely correlated with tumor thickness, ulceration, mitotic rate, and nodal tumor burden.

3 Excision margins for primary melanoma are based on Breslow thickness. Sentinel lymph node biopsy (SLNB) should be considered for clinically node-negative patients with melanoma between 0.8 and 1.0 mm and is recommended for lesions >1 mm Breslow thickness.

4 Treatment decisions for patients with regional or metastatic melanoma should be made in a multidisciplinary setting, reflecting the increasing role for systemic therapy (immunotherapy and molecularly targeted therapy) even for potentially resectable disease.

5 Advanced basal and squamous cell carcinomas are generally treated surgically, but radiation, immunotherapy, and molecularly targeted therapy are all useful in advanced and the rare metastatic cases.

6 MCC is an aggressive cutaneous neuroendocrine carcinoma, treated with surgery, radiation, and increasingly, immunotherapy.

7 Dermatofibrosarcoma protuberans (DFSP) is a rare soft tissue sarcoma with a propensity for local recurrence rather than systemic metastasis. It is generally treated surgically, but it is responsive to molecularly targeted therapy, which is used for advanced and the rare metastatic cases.

INTRODUCTION

1 Cutaneous malignancies are the most commonly diagnosed cancers in the United States, with several million new cases annually. One in five

Americans born today will be diagnosed with skin cancer in their lifetime. More than half of all cancers diagnosed in the United States are skin cancers.[1] The most common skin cancer types are basal cell carcinoma (BCC) and cutaneous squamous cell carcinoma (SCC). Cutaneous melanoma accounts for <2% of skin cancer diagnoses but the majority of skin cancer deaths, with an estimated 6,850 deaths due to melanoma in 2020.[1] Approximately 100,350 new cases of invasive melanoma (60,190 in men and 40,160 in women) were diagnosed in the United States in 2020, along with 95,710 cases of melanoma in situ. Invasive melanoma is the fifth most common cancer in men and the sixth most common cancer in women.[1] By 2030, it has been predicted that melanoma will be the fourth most common cancer in men and women.[2] Note that BCC and SCC are not included in these annual and future estimates of cancer frequency.[1] Merkel cell carcinoma (MCC) and dermatofibrosarcoma protuberans (DFSP) are two less common but clinically important forms of cutaneous malignancy of relevance to the surgeon.

MELANOMA

Etiology and Risk Factors

Numerous environmental and genetic risk factors have been implicated in the development of cutaneous melanoma (**Table 105.1**).[3,4] Risk factors include acute and chronic exposure to ultraviolet (UV) radiation, such as a history of blistering or peeling sunburns, outdoor recreational activities or occupations, and the use of tanning beds, and factors related to increased sensitivity to UV, such as fair complexion (blue or green eyes, blonde, or red hair). Other factors that denote an increased risk for melanoma are a personal or family history of melanoma, nonmelanoma skin cancer, atypical nevi, or multiple typical nevi (“moles”).

Table 105.1 Risk Factors for Primary Melanoma

Risk Factor	Description of High-Risk Features
Gender	Male
Age	>60 yrs
Skin phenotype	Fair skin, red hair, blue eyes, multiple typical and atypical nevi
Ultraviolet exposure history	Prior sunburns, chronic sun-induced skin damage, previous UV tanning bed use, geographic residence in areas with high UV environmental exposure
Family history	Multiple prior first-degree relatives with melanoma, pancreatic cancer, astrocytoma, uveal melanoma, mesothelioma
Other factors	Prior skin cancers or precancerous lesions, immunosuppression, rare genetic disorders (xeroderma pigmentosum, mutations in *CDKN2a, CDK4, MC1R, BRCA2, BAP1*)

Adults with more than 100 clinically normal-appearing (typical) nevi, children with more than 50 clinically normal-appearing nevi, and any patient with atypical or dysplastic nevi are at increased risk for melanoma development. An atypical nevus is not only a potential precursor lesion of melanoma but also a marker for increased risk of development of melanoma. In fact, more than 50% to 75% of melanomas develop on clinically normal skin de novo, not in pre-existing nevi. A prior history of melanoma is a marker for increased risk of developing second-primary melanomas, with 5% to 10% of individuals developing a second melanoma.

Congenital nevi are present at birth or appear within the first 6 months of infancy.[5] An estimated 1% to 6% of children are born with congenital nevi. Most congenital nevi are small, measuring less than 1.5 cm in diameter. Medium congenital nevi measure between 1.5 and 19.9 cm in diameter. Large (also termed giant) congenital nevi, measure 20 cm or greater (**Fig. 105.1A**).

The risk of melanoma development in small- and medium-sized congenital nevi is minimally increased compared to normal skin, if at all. Hence, routine removal of small and medium congenital nevi is rarely indicated in the absence of visible changes. Conversely, giant congenital nevi carry a notably increased risk for melanoma, with melanoma developing in 5% or more of these very large lesions. Of melanomas occurring within giant congenital nevi, 70% are diagnosed prior to the age of 10 years. Prophylactic removal of giant congenital nevi, often done in stages, can reduce the risk of subsequent melanoma development.[5]

Ten percent to 15% of patients with melanoma report a positive family history, but relatively few of these patients are ever found to have a specific genetic predisposition to the disease, as opposed to shared susceptibility factors like living in a geographic region with high UV exposure and engaging in similar outdoor activities as other family members. The most common inherited mutation associated with melanoma involves *CDKN2A*, also known as *p16*. This germline mutation, however, only accounts for about 0.2% of all melanoma cases. The *MC1R* gene regulates skin and hair color; inherited mutations in this gene are clearly a risk factor for cutaneous melanoma. The combination of *MC1R* mutation and red hair is associated with a very high risk of melanoma development.

Xeroderma pigmentosa is a rare autosomal recessive disorder associated with a reduced or absent ability to repair DNA damaged by UV light. Consequently, this disorder results in the development of multiple primary cutaneous malignancies, including melanoma as well as BCC and SCC. Individuals are usually diagnosed with their first cancer before the age of 10 years. Unfortunately, the development of skin cancers is relentless, with innumerable skin cancers developing unless strict sun avoidance is practiced from a very young age.

Figure 105.1 Examples of cutaneous melanocytic lesions. **A:** Giant congenital nevus involving a large portion of the back. **B:** Superficial spreading melanoma. **C:** Nodular melanoma. **D:** Lentigo maligna (a form of melanoma in situ, also called Hutchinson melanotic freckle) on the side of the face. **E:** Lentigo maligna melanoma (melanoma arising in a lentigo maligna) on the cheek. **F:** Acral lentiginous melanoma on the instep of the foot. **G:** Subungual melanoma of the thumb. **H:** Amelanotic desmoplastic melanoma (note overlying telangiectasias and dark-colored punch biopsy site) on the heavily sun-exposed scalp.

Clinical Diagnosis and Classification

Melanoma typically has a characteristic appearance, but this is not always the case. The ABCDE rule was developed to help clinicians distinguish skin lesions concerning for melanoma from benign moles (**Table 105.2**). However, many benign skin lesions exhibit some or even most of the features associated with the ABCDE rule and, conversely, some primary melanomas present with few or none of these features. An alternative and complementary diagnostic aid is the "ugly duckling sign," where any skin lesion that is substantially different from all the others should be approached with a relatively high index of suspicion. The risk factors for melanoma should also be accounted when determining the clinical suspicion for melanoma.

Cutaneous melanomas have been classified into four major histologic subtypes (**Table 105.3**): superficial spreading (**Fig. 105.1B**), nodular (**Fig. 105.1C**), lentigo maligna melanoma (**Fig. 105.1D,E**), and acral lentiginous melanoma (**Fig. 105.1F**), which includes subungual melanoma (**Fig. 105.1G**). In general, the prognoses associated with all these subtypes are based on the same factors, such as the Breslow thickness, the presence or absence of ulceration, and regional/distant disease. Thus, the subtype classification of a melanoma generally does not constitute an independent prognostic factor.

Table 105.2 The ABCDE Diagnostic Aid for Primary Melanoma[a]

Asymmetry	A portion of the pigmented lesion does not match the remainder
Border Irregularity	Edges are blurred, jagged, or notched
Color Variation	Lesion has variable areas of color with shades of brown, black, white, red, and/or blue
Diameter	Greater than 6 mm
Evolution/Elevation	Change over time or lesion raised above skin level

[a]Adapted from American Academy of Dermatology Ad Hoc Task Force for the ABCDEs of Melanoma, Tsao H, Olazagasti JM, et al. Early detection of melanoma: reviewing the ABCDEs. J Am Acad Dermatol 2015;72(4):717–723.

Table 105.3 Common Subtypes of Cutaneous Melanomas

Name	Approximate Frequency (%)	Features
Superficial spreading melanoma	60	Common in melanomas arising from a pre-existing nevus Typically exhibits the classic clinical features of melanoma (see **Table 105.2**)
Nodular melanoma	20	Frequently lacks classic ABCDE features of melanoma Often diagnosed late
Lentigo maligna melanoma	18	Typically occurs on sun-exposed areas of head and neck or hands, often in older individuals Lesions are flat, broad, and asymmetric Extensive subclinical extension relatively more
Acral lentiginous melanoma	2	Occurs on hands and feet ("acral skin") Represents up to 60% of all melanomas occurring in people of color Often diagnosed late due unusual location and appearance Subungual melanoma commonly mistaken for hematoma

Other rare but notable melanoma subtypes include mucosal, ocular, desmoplastic (**Fig. 105.1H**), nevoid, amelanotic, and pediatric melanomas.[7] Mucosal melanomas occur in the nasal, oral, esophageal, anal, and vulvovaginal regions. Ocular melanomas can be either uveal or conjunctival.

Uveal melanomas occur in the iris, ciliary body, or choroid of the eye and have a predilection to metastasize to the liver. Mucosal and uveal melanomas are associated with relatively poor prognoses, related in part to advanced disease at presentation due to delayed detection. When patients present with metastatic melanoma of unknown primary origin, these subtypes should be considered as possibly overlooked sites of primary origin. Desmoplastic melanomas are named for their characteristic microscopic appearance, and can be pure or mixed (the latter with more than 10% of the lesion having nondesmoplastic features). Desmoplastic melanomas tend to be amelanotic and thicker at presentation (**Fig. 105.1H**), and are associated with a higher rate of neurotropism, a lower rate of lymph node metastasis, and a higher risk of local recurrence than other forms of cutaneous melanoma. Desmoplastic melanomas tend to have a higher mutational burden compared to nondesmoplastic melanomas, which can have implications for treatment and response to immunotherapy.[8] Nevoid melanomas and amelanotic melanomas often lack classic clinical features of melanoma, and histologically may share features with benign nevi. As such, they are often misdiagnosed or diagnosed late. Pediatric melanomas are those arising in children before age 18. Some represent typical adult melanomas detected earlier in life and hence share all the epidemiologic factors and presenting features associated with melanoma in adulthood. Most melanomas occurring in the first few years of life arise from giant congenital nevi, while many melanomas in children and adolescents have histologic features similar to benign Spitz nevi—and are called Spitzoid melanomas—and have a distinct epidemiology, presentation, and likely outcome compared to typical adult melanoma.[7]

Staging and Prognostic Factors

2 A great deal of information is available regarding various factors that correlate with the clinical outcome for patients with melanoma.

Microstaging

Microscopic characteristics of the primary tumor provide prognostic features of cutaneous melanoma—the so-called "microstaging." The microstaging method that is used routinely was originally described by Breslow. This

method classifies the primary tumor according to its thickness in millimeters, as measured with a micrometer inside the microscope eyepiece, from the top of the granular layer of the skin to the base of the tumor. Many investigators have documented an inverse correlation between tumor thickness and survival.[9,10] The series of >46,000 patients reported by Gershenwald et al. is summarized in Table 105.4.[11] The ulceration status and mitotic count are also independent prognostic factors, but currently only ulceration is used to determine microstaging of the primary lesion. Prior to the use of the Breslow method, melanomas were microstaged according to the level of invasion into the histologic layer of skin. This is known as the Clark level of invasion. Several studies have confirmed that Breslow thickness conveys more accurate prognostic information than Clark level. Furthermore, patients frequently misinterpret the Clark level as representing the overall tumor stage —leading to confusion and undue concern. For these reasons, use of Clark level has diminished.

Table 105.4 Melanoma TNM and Staging Categories with Survival Rates

Pathologic Stage	TNM[a]	5-Yr Survival (%)	10-Yr Survival (%)
IA	T1aN0M0 T1bN0M0	99	98
IB	T2aN0M0	97	94

[a]AJCC 8th Edition Staging System, see **Table 105.5** and Gershenwald JE, Scolyer RA, Hess KR, et al. Melanoma staging: evidence-based changes in the American Joint Committee on Cancer Eighth Edition cancer staging manual. CA Cancer J Clin 2017;67(6):472–492.

[b]Stage IV 5-year survival outcome data from Siegel RL, Miller KD, Jemal A. Cancer statistics, 2020. CA Cancer J Clin 2020;70(1):7–30.

The presence of regional lymph node metastases is associated with a worsened prognosis. The tumor burden (clinically occult vs. clinically detected) of involved lymph nodes has a significant correlation with long-term survival.[9–11] In contemporary data, the 10-year survival rate for patients with involved lymph nodes ranges from as high as 88% (Stage IIIA) to as low as 24% (Stage IIID), based primarily on tumor burden (size and number of nodal metastases) and thickness and ulceration status of the primary lesion.[11] The use of sentinel lymph node biopsy (SLNB) has identified a subgroup of patients with clinically occult nodal disease who have a favorable prognosis compared with patients with clinically detected nodal involvement.

Clinical and Pathologic Staging

The American Joint Committee on Cancer (AJCC) developed a staging system that classifies melanomas according to tumor thickness (T), nodal status (N), and absence or presence of metastatic disease (M). The current AJCC 8th edition system took effect in 2018 and is summarized in **Tables 105.4 and 105.5**: stage 0 (in situ melanoma), stage I (localized disease, thin primary), stage II (localized disease, thicker primary), stage III (regional nodal, in transit, or satellite metastases), and stage IV (distant metastases).[11]

Other Prognostic Factors

The major prognostic factors that predict survival in melanoma patients have been accounted for in the AJCC staging system—namely, tumor microstaging, nodal status, and absence or presence of distant metastases. The presence of ulceration in a melanoma is associated with a poorer prognosis. Men have a higher proportion of ulcerated lesions than women (27% vs. 19%, respectively).[10] Although ulceration appears to correlate with thickness of the melanoma, the presence of ulceration is an independent prognostic factor and has been included in the staging system.[9,11] In addition, a mitotic count of 1 per mm^2 or greater is an independent prognostic factor.[12] The presence of grossly visible or microscopic satellites, by definition located within 2 cm of the primary melanoma, or in-transit metastases (located more than 2 cm from the primary and between the primary and the regional nodal basin) are also

poor prognostic signs and are considered evidence of intralymphatic metastasis in the AJCC staging system.[11,13]

Treatment of Primary Melanoma

Biopsy

For localized melanoma, the tumor thickness is the single most impactful variable that determines therapy and prognosis. The ulceration status and mitotic count also represent independent prognostic variables. The ideal biopsy allows the pathologist to characterize the entire lesion. If the melanoma is transected with a partial-thickness biopsy, the ability to obtain an accurate measurement of tumor thickness may be lost. Therefore, a superficial shave biopsy is never recommended for a pigmented lesion suspected of representing melanoma. Saucerization, also called a deep shave biopsy, down to the subcutaneous fat is a better approach.

Excisional biopsy with 1 to 2 mm margins is the preferred method for biopsy of suspicious pigmented skin lesions, as it provides the pathologist with the total specimen for histologic interpretation and accurate microstaging. Formalin-fixed, paraffin-embedded permanent sections should be used for biopsy diagnosis of primary cutaneous melanoma to accurately determine tumor thickness and other histopathologic prognostic variables. Frozen sections have essentially no role in the diagnosis or microstaging of primary melanoma. If the lesion proves to be a melanoma, the biopsy represents the first stage of a two-stage procedure. The second stage is radical wide excision, with margins ranging from 0.5 to 2.0 cm depending on the tumor thickness, with or without SLNB. Performing a wide excision with 1 or 2 cm margins as the first diagnostic step is not recommended, as several benign and malignant lesions can mimic melanoma and doing so may compromise the ability to accurately perform SLNB if the diagnosis of melanoma is confirmed. For a suspected melanoma on the extremities, the excisional biopsy should optimally be oriented along the long axis of the extremity, parallel to the lymphatics. Performing a biopsy oriented transversely on the extremity may compromise the accuracy of lymphatic mapping and could also obligate the patient to a skin graft to close the subsequent wide excision defect.

For suspicious lesions that are too large for excisional biopsy, an incisional biopsy may be performed, typically using a punch biopsy. Incisional biopsies for melanoma do not increase the risk of local recurrence and distant metastasis or affect patient survival. They should generally be performed on the most raised area of the lesion to maximize the obtainable diagnostic and prognostic information. The most raised area usually corresponds to the maximal thickness of the lesion, but not always. Several incisional biopsies can be obtained from different areas for large lesions to provide the best possible information for making treatment decisions.

Staging Workup

Current consensus guidelines have attempted to standardize staging workup for melanoma.[14,15] The staging workup starts with a history (concentrating on constitutional, respiratory, neurologic, hepatic, musculoskeletal, gastrointestinal, skin, and lymphatic systems) and physical examination (including a total body skin examination and palpation of lymph nodes). Routine imaging (chest x-ray, computed tomography [CT] scans, positron emission tomography [PET] scans), and blood studies (complete blood cell count, comprehensive metabolic profile, liver function tests, serum lactate dehydrogenase [LDH] levels) in asymptomatic, clinically node-negative patients are low in both sensitivity and specificity and are not routinely performed. False-positive and indeterminate staging tests are common and lead to more evaluation and patient distress. For appropriate patients, SLNB represents the best baseline staging test, with both relatively high sensitivity and specificity in patients at significant risk for metastasis. The likelihood of detecting stage IV disease with imaging studies is very small if the SLNB is negative. Both ultrasound and PET scanning have been examined as methods of identifying nodal metastases prior to surgery. While they detect disease in a minority of patients, most metastases to the regional nodes are smaller than the threshold ultrasound and PET can detect, so their routine use is not a cost-effective strategy.[16,17] If a thorough history and physical and detailed review of systems reveal no signs or symptoms suspicious for regional or distant disease, then no further staging is necessary prior to surgery. However, a high index of suspicion should be maintained, and a thorough

symptom-directed workup should be initiated for any worrisome finding on the history and physical.

Table 105.5 American Joint Commission on Cancer Melanoma Staging System, TNM Definitions

Primary Tumor	
TX	Primary tumor thickness cannot be assessed
T0	No evidence of primary tumor (unknown primary or completely regressed primary)
Tis	Melanoma in situ
T1	≤1.0 mm Breslow thickness[a] a. <0.8 mm without ulceration b. With ulceration or ≥0.8 mm
T2	1.1–2.0 mm a. Without ulceration b. With ulceration
T3	2.1–4.0 mm a. Without ulceration b. With ulceration
T4	>4.0 mm a. Without ulceration b. With ulceration
Regional Lymphatic Metastasis	
NX	Nodal status cannot be assessed and no in-transit or satellite metastasis
N0	No regional lymphatic metastasis
N1	Metastasis in one regional node or only in-transit or satellite metastases without nodal metastases a. One clinically occult nodal metastasis (diagnosed by SLNB) b. One clinically detected nodal metastasis (palpable or found on imaging studies) c. In-transit or satellite metastasis without documented nodal metastasis
N2	Metastasis in two to three regional nodes or one regional

	node plus in-transit or satellite metastases a. Two to three clinically occult nodal metastases (all diagnosed by SLNB) b. Two to three clinically detected nodal metastasis (at least one palpable or found on imaging studies) c. One clinically occult or clinically detected nodal metastasis plus in-transit or satellite metastases
N3	Metastasis in ≥four regional nodes, matted nodes, or in-transit or satellite metastasis with metastasis in at least two regional nodes a. ≥4 clinically occult nodal metastases (all diagnosed by SLNB) b. ≥4 clinically detected nodal metastasis (at least one palpable or found on imaging studies) or any matted nodes c. ≥2 clinically occult or clinically detected nodal metastases, or any matted nodes, plus in-transit or satellite metastases
Distant Metastasis	
M0	No evidence of distant metastasis
M1a	Distant skin, subcutaneous, muscle, or nonregional lymph node metastasis (0). With normal serum LDH level (1). With elevated serum LDH level
M1b	Lung metastasis without or with M1a sites of disease (0). With normal serum LDH level (1). With elevated serum LDH level normal LDH
M1c	Non-CNS visceral metastases without or with M1a and/or M1b sites of disease (0). With normal serum LDH level (1). With elevated serum LDH level
M1d	CNS metastases without or with M1a, M1b, and/or M1c

sites of disease
(0). With normal serum LDH level
(1). With elevated serum LDH level

[a]Breslow thickness should be reported rounded to the nearest 0.1 mm.

CNS, central nervous system; LDH, lactate dehydrogenase; SLNB, sentinel lymph node biopsy.

[a]There was no difference in any outcomes in the first four trials. UK 2004 showed increased locoregional recurrence but no difference in local or in-transit recurrence.
E, extremity; H&N, head and neck; T, trunk; UK, United Kingdom; WHO, World Health Organization.

Approximately 5% to 10% of newly diagnosed melanoma patients present with clinically involved lymph nodes. Any clinically suspicious node should be confirmed to represent melanoma, preferably by fine-needle aspiration (FNA) biopsy, as enlarged lymph nodes may be reactive (particularly after a skin biopsy). Ultrasound-guided FNA biopsy can be useful in cases where the suspicious node is difficult to localize and/or immobilize. To facilitate subsequent management, excision of the enlarged node(s) as a diagnostic maneuver should be limited to cases where a needle biopsy was unable to establish a diagnosis. Patients documented to have macroscopic regional disease should undergo formal staging prior to definitive treatment, as a significant percentage may have more advanced regional or distant disease that may alter the therapeutic approach. Staging for clinical stage III melanoma should include a serum LDH level; brain MRI and either CT scan of the chest, abdomen, and pelvis (as well as neck for primary sites draining

to the cervical nodes such as head, neck and upper chest/back primary sites) or whole-body PET/CT scan.

Excision of Primary Melanoma

3 The goal of surgical excision of primary melanomas is to reduce the risk of local recurrence. For melanoma in situ, excision margins of 0.5 to 1.0 cm are accepted as the standard of care; however, this practice is not based on a prospective clinical trial. For invasive melanomas, the accepted standard of care is radical wide excision with margins ranging from 1 to 2 cm—to a depth down to, but not necessarily including, the underlying investing muscular fascia. The recommended excision margin is dependent upon the Breslow thickness as based upon results of several randomized controlled trials listed in **Table 105.6**.[18] Current consensus guidelines recommend margins of 1 cm for melanomas 1.0 mm or less in thickness, 2 cm for melanomas greater than 2.0 mm thick, and 1 to 2 cm for melanomas 1.1 to 2.0 mm thick (**Table 105.7**). For this last group, the width of the margins should be based on the anatomic location of the melanoma and the morbidity of excising 2 cm versus 1 cm, including the need for an advancement flap or skin graft. For several locations, such as melanomas on the head/neck or mucosal surfaces, the maximum attainable margins are dictated by anatomic constraints. Most subungual invasive melanomas (**Fig. 105.1G**) are best managed by partial amputation of the digit, although conservative excisions with skin grafting can be considered for thin and noninvasive subungual melanomas.

For melanomas with ill-defined borders—especially lentigo maligna melanoma on the head and neck—subclinical extension well beyond the clinically evident tumor is commonplace and staged contoured marginal excision may be useful. The first stage involves removal of narrow (~2 mm wide) peripheral strips of normal-appearing skin at the locations of the anticipated margin edge (i.e., the strips are taken circumferentially using a 1 to 2 cm margin from the tumor periphery/biopsy edge as appropriate for the thickness). If any of the peripheral strips are positive, additional strip(s) constituting the new, anticipated margin are excised (**Fig. 105.2**). The second stage of central tumor excision (inside of the previous peripheral strips) with definitive reconstruction may proceed once the peripheral strips are

confirmed negative on final pathologic analysis.[19] For lesions thick enough to require SLNB, this can be performed in conjunction with the initial marginal excision.

Sentinel Lymph Node Biopsy

For clinically node-negative patients with melanoma ≥1.0 mm thick, SLNB is recommended for tumor staging. SLNB should not be routinely performed for all patients with thin melanoma, but should be considered for patients with a melanoma Breslow thickness of 0.8 to 1.0 mm, particularly if they have other risk factors for regional metastases, including a mitotic count of 1 mitosis/mm^2 or greater, ulceration, angiolymphatic invasion, younger age, or a broadly transected deep margin on shave biopsy.[15,20] Reasons to avoid SLNB include significant medical comorbidities and if the patient does not desire SLNB after an informed discussion.

Two tracers are typically used for identifying sentinel nodes: a radiolabeled colloid and a blue dye—either 1% isosulfan blue (Lymphazurin) or methylene blue. Isosulfan blue carries a risk of allergic reaction in a very small number of patients, which can be life-threatening.[21] Methylene blue dye has an extremely low risk of allergic reaction, but if not diluted or completely resected can cause skin necrosis. One to 4 hours before surgery, or in some cases the afternoon before surgery, the radiolabeled colloid solution is injected intradermally around the primary tumor or excisional biopsy site. Lymphoscintigraphy imaging is then performed to identify SLN both in and outside the expected nodal basin. Most commonly, planar lymphoscintigraphy images are obtained, but SPECT-CT provides enhanced anatomical localization and is particularly useful for head and neck melanomas and for lymph nodes in unusual sites (**Fig. 105.3**). The blue dye is injected intradermally in the operating room immediately prior to the procedure. Using a combination of a hand-held gamma probe and visualization of blue-stained lymphatics or nodes can help identify nodes. The combination of the blue dye and radiolabeled colloid enables the detection of sentinel nodes in >97% of cases.[22] Sentinel nodes are serially sectioned by the pathologist for hematoxylin and eosin staining and immunohistochemical staining for melanoma markers such as S-100, Melan-A, and HMB-45. This is done to examine for micrometastases that can be

missed by the traditional process of bisecting nodes.[23] If metastases are found in the sentinel node, BRAF immunohistochemistry can be performed to assess for the presence of a BRAF V600E mutation (**Fig. 105.4**).

Table 105.7 Recommended Surgical Margins for Melanoma Excision

Melanoma Thickness (mm)	Recommended Excision Margin (cm)
In situ	0.5–1.0
≤1.0	1.0
1.1–2.0	1.0–2.0
>2.0	2.0

Margins may need to be modified on the basis of anatomic considerations but still should obtain histologically confirmed tumor-free margins.

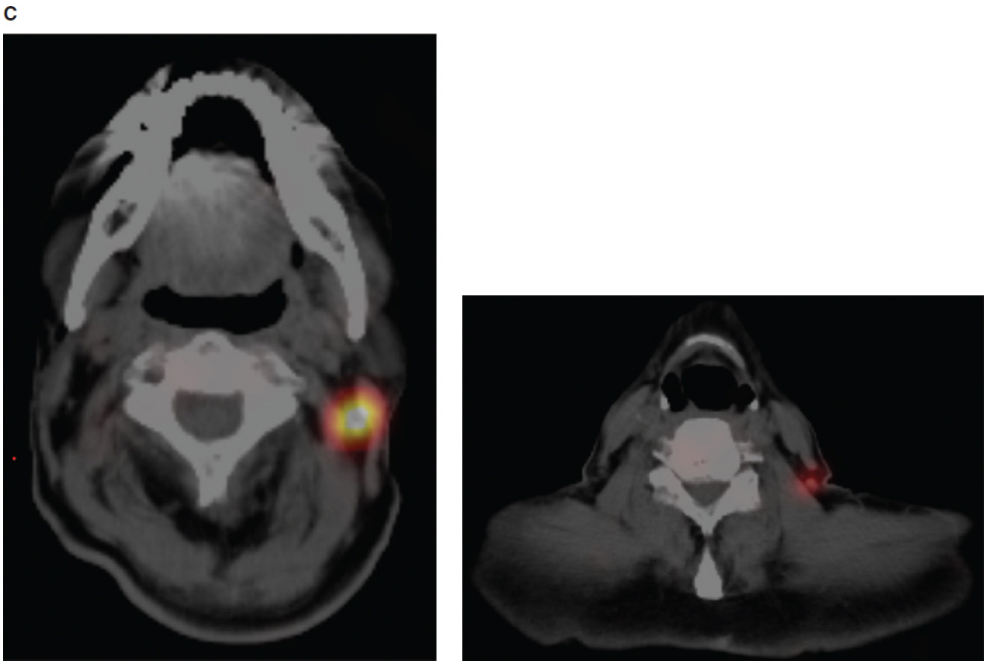

Figure 105.3 **A:** Planar lymphoscintigraphy for sentinel lymph node localization in patient with an intermediate-thickness melanoma of the left frontal scalp. One cervical node is identified (**lower left panel**). In the **lower right panel**, the nuclear medicine technologist has used a radioactive marker to outline the left ear, sternocleidomastoid muscle, and clavicle. **B:** Coronal SPECT-CT lymphoscintigraphy in the same patient shows the primary site on the scalp, and upper cervical (**left panel**) as well as lower cervical (**right panel**) sentinel nodes. **C:** Axial views show the upper cervical lymph nodes to be directly subjacent to the center of the left sternocleidomastoid muscle (**left panel**), while the lower cervical nodes are just posterior to the posterior edge of the muscle (**right panel**).

The Multicenter Selective Lymphadenectomy Trial I (MSLT-I) randomized patients to radical wide excision alone or in combination with SLNB.[24] Those with isolated nodal progression on the nodal observation arm underwent a therapeutic lymph node dissection while those with a positive SLNB underwent completion lymph node dissection (CLND). The final results indicated a superior disease-free survival rate in the SLNB group, for patients with both intermediate-thickness melanoma (71.3 ± 1.8% vs. 64.7 ± 2.3%; hazard ratio [HR] 0.76, $P = 0.01$) and thick melanoma (50.7 ± 4.0% vs. 40.5 ± 4.7%; HR 0.70, $P = 0.03$). Although MSLT-I showed no overall survival benefit with SLNB, subset analysis showed that SLNB-positive patients had a 10-year melanoma-specific survival of 62.1 ± 4.8% compared with 41.5 ± 5.6% for patients who recurred during observation. Even after

accounting for false-negative SLNB, the results remained significant (HR 0.67, 95% confidence interval [CI] 0.46 to 0.97, $P = 0.04$).

Treatment of Regional Metastatic Melanoma

4 Until recently, all patients with sentinel node micrometastases were recommended to undergo CLND of the positive lymph node basin(s). However, the clinical utility of this practice has been questioned, as approximately 80% of CLND specimens do not have residual nodal disease and the morbidity of CLND can be substantial—including chronic lymphedema in about 20% to 25% of patients.[25] Attempts to retrospectively identify clinicopathologic factors that predict disease within the non-SLNs did not identify reliable ways to identify those who could potentially benefit from CLND. In addition, retrospective studies questioned the clinical utility of CLND for SLN-positive patients.[26]

The practice of performing CLND following a positive SLNB has largely been abandoned after MSLT-II demonstrated CLND does not improve overall survival. This trial randomized 1,934 patients with a positive sentinel lymph node to CLND or nodal basin surveillance with serial ultrasonography. MSLT-II demonstrated no overall survival benefit for patients undergoing CLND (86 ± 1.3% vs. 86 ± 1.2%, $P = 0.42$) at a median follow-up of 43 months. Non-SLN metastases, identified in 11.5% of the patients in the CLND group, were a strong, independent prognostic factor for recurrence (HR 1.78, $P = 0.005$). Lymphedema was observed in 24.1% of the patients in the CLND group and in 6.3% of those in the nodal observation group.[27] These results were confirmed in another randomized trial, the German DeCOG-SLT study.[28] Given these results, most patients with a positive SLNB are preferably managed by active nodal surveillance, with therapeutic node dissection performed in the event of subsequent isolated nodal metastasis. Active nodal surveillance typically involves evaluation of the nodal basin by clinical examination and ultrasound every 3 to 4 months for the first 2 years, every 6 months for years 3 to 5, and annually until year 10.

Therapeutic Lymphadenectomy

For melanoma patient presenting with clinically detected tumor-involved nodes (AJCC 8th edition stage IIIB–D), including those who recur in the nodal basin after a positive or false-negative SLNB, therapeutic lymphadenectomy (radical node dissection) remains the standard of care, typically in combination with postoperative (adjuvant) or even preoperative (neoadjuvant) systemic therapy. A small percentage of stage III melanoma patients (about 10% of all clinical stage III cases) present with clinically evident nodal disease in the absence of a known primary cutaneous melanoma.[29] Almost all of these cases represent nodal metastases from primary cutaneous melanomas that either regressed spontaneously or were removed in the past but not recognized as malignant.[7] When patients present with isolated nodal disease from an unknown primary site, the outcomes of lymphadenectomy are generally as good or better than those for patients with known primary tumors.[29]

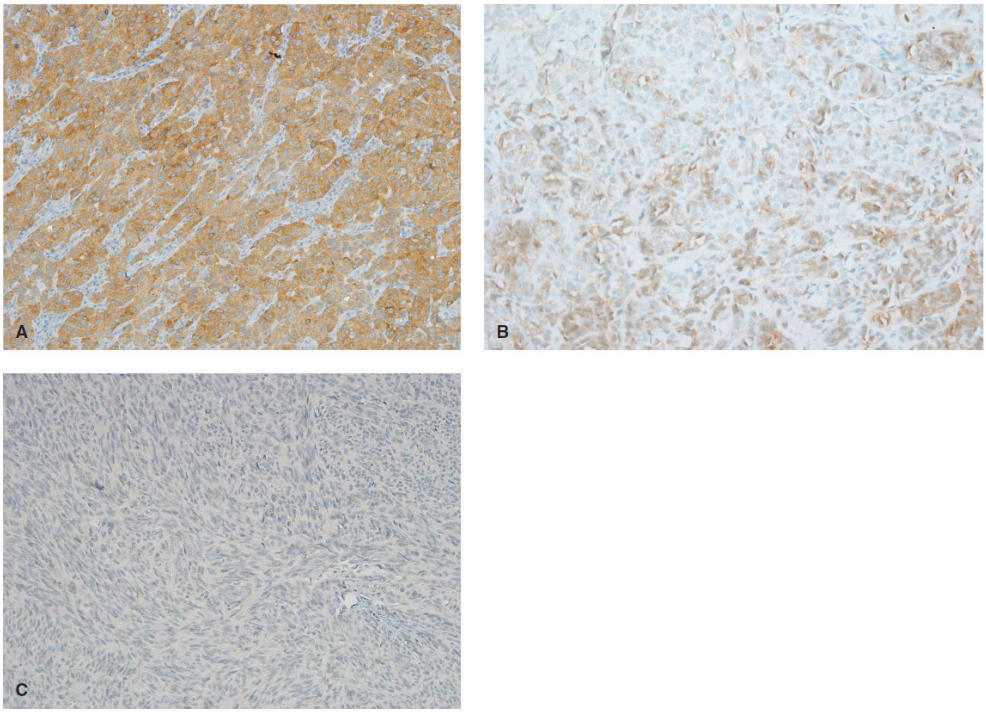

Figure 105.4 Sentinel lymph node micrometastases from melanoma stained with a BRAF V600E antibody: **A:** The result is strongly positive, with nearly 100% of tumor cells showing strong staining. **B:** The result meets minimum criteria for a positive result, with over 50% of tumor cells showing staining above background. **C:** A negative result, with virtually no staining of tumor cells, in a patient whose tumor proved to have a BRAF V600D mutation on molecular pyrosequencing. Adjuvant Therapy

Although the prognosis for patients with early-stage cutaneous melanoma is quite good, a lesser percentage of patients with thick primaries (>4 mm) or regional node involvement are cured by surgery alone. The development of effective adjuvant therapy capable of increasing survival in high-risk groups of patients has been a long-standing goal. Until recently, numerous randomized trials evaluating systemic chemotherapeutic agents (most notably dacarbazine), nonspecific immunotherapy (such as Bacille Calmette–Guérin [BCG]), tumor-specific vaccines, biochemotherapy, and interferons in the adjuvant setting either failed to demonstrate any impact on survival or were associated with prohibitive toxicity that limited their clinical value.[30,31] The success of new immunotherapy and molecularly targeted agents in the treatment of unresectable metastatic melanoma, however, spawned a series of randomized clinical trials that revolutionized the adjuvant therapy of high-risk resected melanoma.

Immune checkpoint inhibitors are intravenously-administered antibodies which block key regulatory molecules on the surface of T cells, enhancing an antitumor immune response. Ipilimumab, an anti-CTLA4 antibody which blocks the negative regulatory CTLA4 molecule, was the first immunotherapy proven to increase survival for metastatic melanoma and was the first new adjuvant therapy agent to be approved for stage III melanoma.[30,31] Compared to a placebo, adjuvant therapy with ipilimumab significantly improved relapse-free and overall survival in patients with stage III melanoma after lymphadenectomy. The 5-year overall survival was 65.4% in the ipilimumab arm compared with 54.4% in the placebo arm (HR 0.72, $P = 0.001$). Severe or life-threatening immune-related adverse events occurred in 41.6% of the ipilimumab arm patients, and 1.1% of patients died due to the toxicity of treatment.[32]

Anti-PD1 antibodies have improved antitumor efficacy with less toxicity than anti-CTLA4 antibodies in metastatic melanoma,[31] and randomized trials have compared adjuvant immunotherapy with an anti-PD1 antibody to either placebo or ipilimumab. Adjuvant therapy with the anti-PD1 antibody pembrolizumab significantly prolonged relapse-free survival compared to a placebo, with a lower incidence of severe or life-threatening adverse events (14.7%, with one treatment-related death) than was seen in the ipilimumab

trial.[31] Another randomized adjuvant therapy trial directly compared ipilimumab to the anti-PD1 antibody nivolumab. This trial confirmed that adjuvant anti-PD1 therapy was less toxic than adjuvant ipilimumab, with severe or life-threatening adverse events seen in 14.4% of the patients (and no treatment-related deaths) in the nivolumab arm versus 45.9% of those in the ipilimumab arm (and two treatment-related deaths). Importantly, adjuvant nivolumab resulted in significantly longer relapse-free survival than adjuvant ipilimumab.[34] Although adjuvant anti-PD1 immunotherapy is clearly less toxic than adjuvant ipilimumab, a small percentage of patients experience long-term, life-altering immune-related endocrine and cardiac toxicities. Somewhat surprisingly, overall survival was not significantly different between those treated with nivolumab and ipilimumab adjuvant therapy (4-year overall survival 77.9% versus 76.6% [HR 0.87, $P = 0.31$], respectively).[35] It remains possible that further analyses will demonstrate at least some survival advantage for anti-PD1 adjuvant therapy compared to ipilimumab or interferon, as some adjuvant therapy trials still await analysis. It is also possible that the immune-related adverse events seen with adjuvant immunotherapy represent a robust immune response that is associated with better outcomes,[36] although this remains to be definitively established.

Patients with metastatic melanoma whose tumor harbors a BRAF V600 mutation (about 45% of all cases) have another treatment option besides immunotherapy: BRAF/MEK molecularly targeted therapy has been shown to improve survival in these unresectable stage IV patients. The combination of dabrafenib (an oral BRAF inhibitor) and trametinib (an oral MEK inhibitor), administered for 1 year after lymphadenectomy for stage III melanoma, was compared to placebo in a randomized trial. Although there was concern that the inhibitory impact of the drugs would fade shortly after the year of therapy ended, long-term results of the trial suggest that is not the case. At a median follow-up of 59 months, 5-year relapse-free rates were 52% in the dabrafenib plus trametinib arm versus 36% in the placebo arm (HR 0.51). Distant metastasis-free survival also favored dabrafenib plus trametinib (HR 0.55).[37] Notably, an interim analysis of the overall survival impact of adjuvant dabrafenib plus trametinib, conducted using very strict statistical criteria, indicated that the combination was showing a survival advantage that was trending toward but has not yet reached statistical significance.[38] Although about a quarter of treated patients had to discontinue their adjuvant

therapy due to side effects, these adverse effects almost always resolved quickly after the drugs were stopped. As yet, adjuvant dabrafenib plus trametinib has not been compared head-to-head with adjuvant anti-PD1 immunotherapy in BRAF-mutant stage III melanoma.

In addition to defining the optimum adjuvant therapy for BRAF-mutant stage III melanoma, other questions remain about adjuvant therapy for melanoma. The possible added value of combining ipilimumab with nivolumab is being evaluated in adjuvant clinical trials, with one smaller randomized trial suggesting this more toxic combination might be superior for patients with resected stage IV melanoma.[39] All of the adjuvant clinical trials reported in stage III melanoma to date required CLND for patients with a positive SLNB, and most required a minimum tumor burden in the sentinel node of 1 mm for the size of the largest nodal metastasis. Therefore, significant questions remain about adjuvant therapy for SLNB-positive patients who are managed with active nodal surveillance, including how to manage resectable recurrence during adjuvant therapy, and for patients with lesser nodal tumor burdens.

Neoadjuvant Therapy

Neoadjuvant therapy is defined as systemic therapy delivered for a prespecified time to patients with resectable disease prior to proceeding with definitive surgery. For stage III melanoma, neoadjuvant therapy can involve single-agent or combination immunotherapy, or for patients whose tumors harbor a BRAF V600 mutation, combination BRAF plus MEK inhibition. In contrast, "upfront systemic therapy" can be defined as administration of systemic therapy prior to surgery with no specific plan to carry out resection at a defined point in time if at all. Sometimes upfront systemic therapy is carried out with the hope of converting unresectable stage III disease to a resectable state, but it can also be used in patients with resectable disease. Preoperative systemic therapy has several key advantages over giving the same drugs in the postoperative adjuvant setting,[31] the most important of which may be the ability to assess the response of the tumor to treatment clinically (by physical examination and/or cross-sectional imaging), metabolically (by ^{18}F-FDG PET scanning), and pathologically. Patients who obtain a complete or near-complete pathologic

response to preoperative treatment appear to have a particularly good outcome and may ultimately need less radical surgery and no postoperative systemic therapy (**Fig. 105.5**). Many clinical trials of neoadjuvant therapy are now underway, including some trials comparing preoperative treatment to the same drugs given entirely postoperatively.

Adjuvant Radiation Therapy

Although cutaneous melanoma is often thought of as radioresistant, there are clearly situations when adjuvant postoperative radiation can be useful. Desmoplastic melanoma is a rare subtype of cutaneous melanoma that appears to be particularly likely to recur locally, especially when there is evidence of perineural extension of the disease, yet particularly sensitive to radiation. Available evidence suggests that postoperative radiation can substantially decrease the risk of local recurrence of desmoplastic melanoma, especially when the primary tumor is thick, situated on the head or neck, or in the presence of perineural extension.[40] Postoperative radiation to the tumor-involved nodal basin after therapeutic lymphadenectomy has been studied in a randomized trial. Adjuvant postoperative radiation can decrease the in-basin regional recurrence risk, at the expense of an increase in the risk for lymphedema and other toxicities, but it does not impact overall survival.[41] Adjuvant nodal radiation should be considered in patients with multiple involved nodes, especially in the presence of extranodal extension.

Treatment of In-Transit Disease

In-transit metastatic melanoma is defined as any recurrence between the primary melanoma site and the regional lymph nodes and is thought to be due to intralymphatic metastasis. In-transit metastatic melanoma without distant metastasis is classified as stage III disease and can be challenging to treat. Treatment involves either excision, regional chemotherapy, intralesional therapy, or systemic therapy. Prior to proceeding with treatment, a complete staging workup for metastatic disease is recommended. Surgical excision should be considered when the number of lesions is relatively small, and particularly when the time from previous treatment to the development of the recurrence is relatively long.

When the in-transit disease is unresectable but limited to an extremity, regional administration of high-dose hyperthermic chemotherapy can be effective. Isolated limb perfusion (ILP) uses an extracorporeal membrane oxygenator (as used in cardiac surgery) to deliver chemotherapy doses 15 to 25 times higher than can be obtained with systemic delivery. The surgeon isolates the vessels and uses a tourniquet at the proximal aspect of the extremity to prevent systemic uptake of the chemotherapy. Using the bypass machine, the limb is oxygenated and perfused with hyperthermic (38° to 40°C) chemotherapy, most commonly melphalan alone or combined with other drugs. After 60 to 90 minutes of treatment, the drug is flushed from the circulation and systemic circulation is restored. Response rates between 80% and 90% are reported, with complete response rates between 40% and 65% that can be durable.[42,43] Toxicities can range from mild erythema and edema to epidermolysis, functional impairment, compartment syndrome, and extremely rarely, a need for amputation.

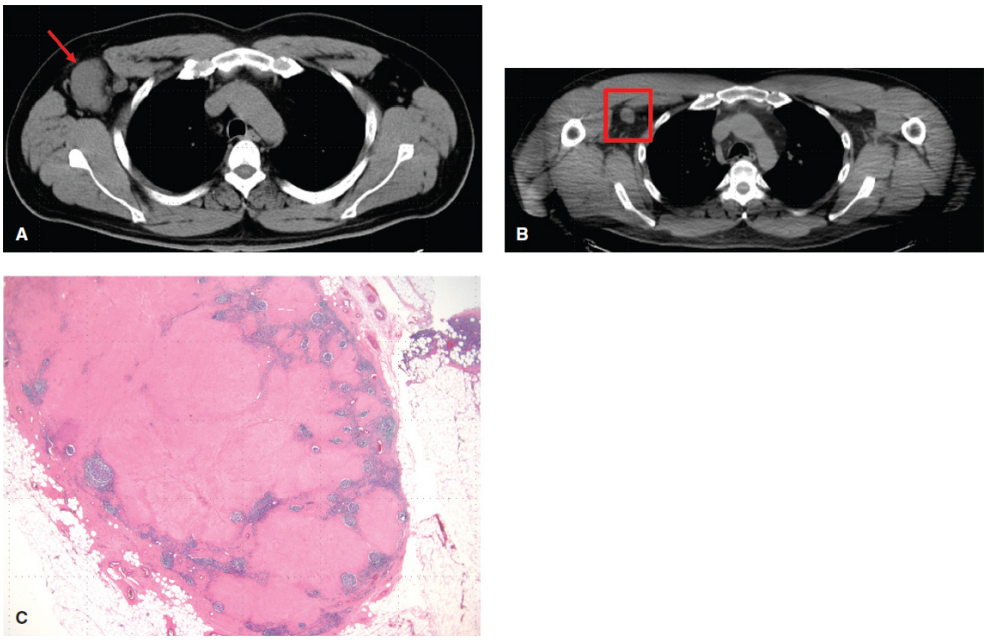

Figure 105.5 Neoadjuvant therapy for stage III melanoma. **A:** Pretreatment CT scan showing a large right axillary lymph node (*arrow*) that developed 2 years after radical wide excision of a thin (T1a) melanoma of the ipsilateral arm. **B:** Scans after 6 months of BRAF/MEK inhibition, showing a partial response to therapy (*box*). **C:** Histologic specimen from the lymphadenectomy, showing posttreatment changes but no viable tumor (pathologic complete response). The patient received no further therapy and remains disease-free more than 4 years later. (Images courtesy of Jane L. Messina, MD, Moffitt Cancer Center.)

Isolated limb infusion (ILI) is a minimally invasive alternative to ILP. Rather than surgical isolation of the vessels, percutaneous catheters are placed with fluoroscopic guidance into the artery and vein and connected to an extracorporeal circuit incorporating a heating coil but not using a cardiac bypass oxygenator. A tourniquet is placed on the proximal extremity, and slightly lower doses of chemotherapeutic agents are used. Some studies have reported response rates equivalent to ILP, although others report slightly lower response rates.[44,45] However, the greater convenience and lower toxicity of ILI, lack of evidence of a survival difference compared to ILP, and the ability to repeat the procedure if necessary has made ILI the regional chemotherapy approach of choice in most melanoma centers worldwide.

When resection or ILP/ILI is not feasible, a number of intralesional therapies have been utilized in the past, particularly BCG, interleukin (IL)-2, and granulocyte-macrophage colony–stimulating factor (GM-CSF). A relatively new intralesional therapy agent, talimogene laherparepvec (TVEC), is an oncolytic immunotherapy derived from the herpes simplex virus type-1. In a randomized phase III trial, TVEC demonstrated an improved response rate lasting at least 6 months compared to a control arm of subcutaneous GM-CSF (19.0% vs. 1.4%; $P < 0.0001$) and a trend toward improved overall survival.[46] A subsequent retrospective, nonrandomized study reported a 57% response rate with TVEC for patients with generally less advanced disease compared to the randomized trial (**Fig. 105.6**), highlighting the importance of patient selection.[47] Other intralesional or topical agents under investigation currently include PV10 (Rose Bengal), plasmid IL12 electroporation, and topical diphencyprone. A recent retrospective review of patients with in-transit metastatic melanoma treated with systemic immunotherapy (PD1 antibody blockade, CTLA4 blockade, or combination therapy) reported a 54% response rate.[48] The combination of intralesional therapy and systemic immunotherapy is an area of active clinical investigation.[49]

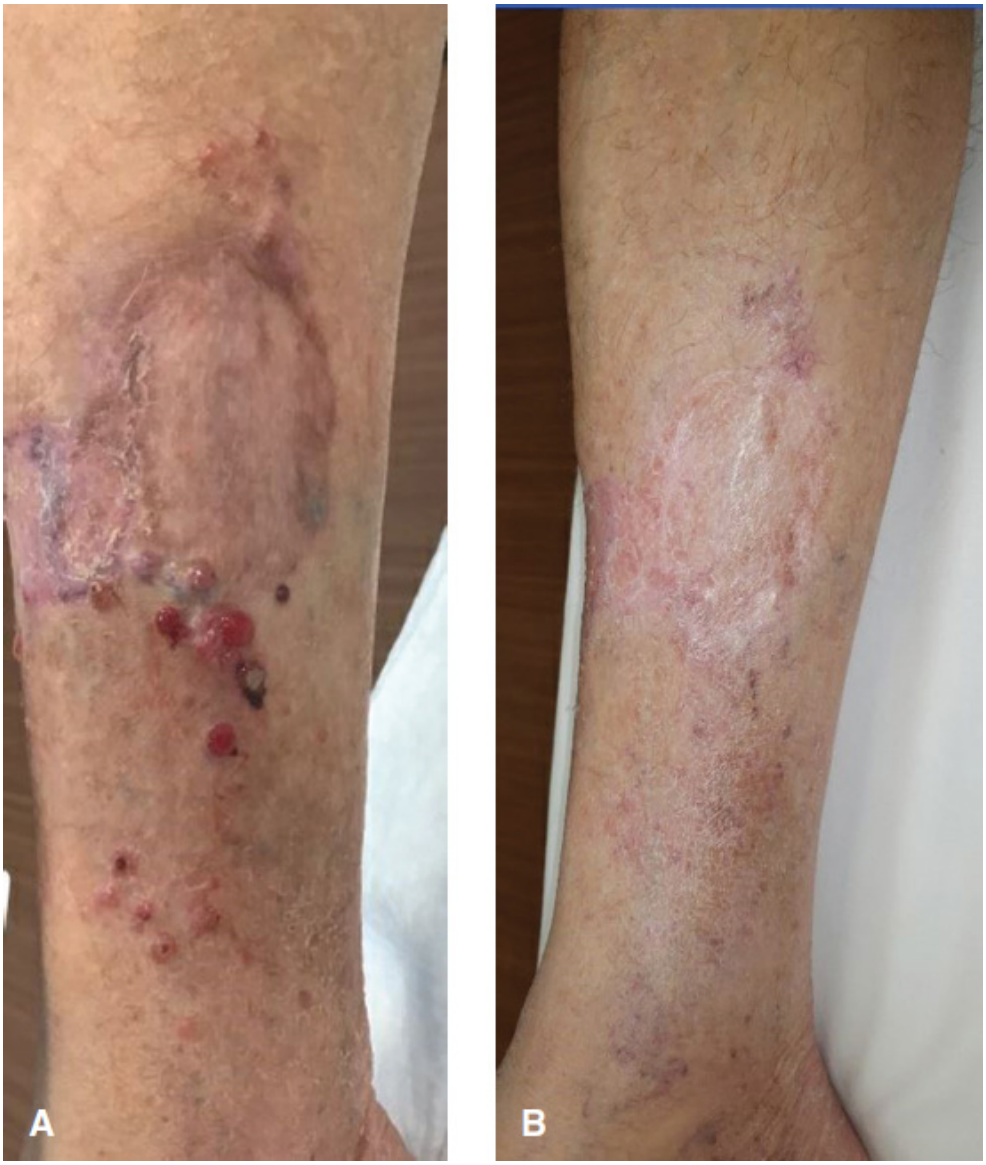

Figure 105.6 Example of response to intralesional talimogene laherparepvec (TVEC). **A:** Multifocal satellite (within 2 cm of the primary site) and in transit (>2 cm from the primary site but proximal to the draining nodal basin) metastases from a thick, ulcerated (T4b) primary melanoma of the leg previously treated with radical wide excision and split-thickness skin graft reconstruction. **B:** After eight injections of TVEC, there is no palpable or visible tumor remaining.

Treatment of Disseminated Melanoma

Evaluation for Metastatic Disease and Clinical Course

The follow-up evaluation for patients with AJCC stage I, II, or III melanoma who are rendered disease-free by surgery should include regular histories and physical examinations. The use of extensive and frequent radiographic studies and blood work in asymptomatic, clinically disease-free patients is rarely productive.[50] For AJCC stage IA to IIA, the consensus guidelines recommend that clinically disease-free patients should undergo a history and physical examination with emphasis on skin and nodal examinations every 6 to 12 months as clinically indicated. For AJCC stage IIB to IV, clinically disease-free patients should undergo a history and physical examination every 3 to 6 months for 2 years, then every 3 to 12 months for 3 years, and then annually as clinically indicated. Imaging studies (CXR, CT, or PET/CT) can be considered every 3 to 12 months for the first 3 to 5 years.[15]

Melanoma can disseminate to any organ. The most common sites of recurrence are skin, subcutaneous tissues, and distant lymph nodes, followed by visceral sites. Common visceral sites of metastasis are the lungs, liver, brain, bone, gastrointestinal tract, and adrenal glands. Most patients who die with disseminated disease have multiple organ involvement. Over the past 10 years, there have been tremendous advances in the systemic therapy of melanoma. There are now multiple molecularly targeted therapies and immune checkpoint inhibitors that have been approved for the treatment of advanced melanoma, with several new therapies and combinations in clinical trial.[31] How to proceed in the management of advanced melanoma should be based on several factors, including the patient's medical condition and comorbidities, the potential for cure or palliation, and the impact of treatment on quality of life.

Surgery

For most cancers, surgery is rarely considered as a curative option in stage IV disease. Historically, melanoma has been an exception to this, with documented long-term survival among patients who undergo resection of one or a few metastatic lesions. Several retrospective studies, as well as prospective studies, have suggested that metastasectomy may result in prolonged disease-free survival in select patients.[51,52] The rationale for surgical extirpation of metastatic disease was in part driven by the lack of effective systemic therapies in melanoma. The role of surgery for stage IV

disease is rapidly evolving as new, highly effective therapies have emerged. Despite the excitement surrounding these new agents, there may be potential advantages to metastasectomy. Careful patient selection is key, as is a true multidisciplinary approach. Patients being considered for metastasectomy should undergo a thorough search for additional sites of disease, including a detailed history and physical, serum LDH, CT or PET scan, and MRI of the brain. Factors to consider when formulating a treatment plan include the age and health of the patient, the number and locations of the metastases as well as the ability to achieve negative margins, the morbidity of the operation, the disease-free interval between the original diagnosis and the development of distant disease, the need for palliation of active symptoms or the prevention of impending problems (e.g., bowel obstruction from a small intestinal metastasis), and the available systemic options. For select patients, surgery may be considered as a first-line therapy, potentially delaying the need for systemic therapies, or be used in conjunction with systemic therapies, either after neoadjuvant therapy or for resection of lesions that fail to respond. The successful incorporation of surgery in the management of stage IV disease is dependent upon true multidisciplinary collaboration between surgical, medical, and radiation oncologists.

Chemotherapy

Melanoma is responsive to few chemotherapeutic drugs. The most widely used single chemotherapeutic agents have been dacarbazine and its oral analog temozolomide, with objective response rates of 5% to 12%.[53] Most responses are transient; only 1% to 2% of patients achieve a durable long-term response. Attempts to improve upon these results using combination chemotherapy, or biochemotherapy (where chemotherapy is combined with interferon and IL-2), failed to dramatically improve upon single-agent therapy alone, although biochemotherapy and combination chemotherapy with carboplatin and paclitaxel have slightly higher response rates than single-agent dacarbazine or temozolomide.[54]

High-Dose Interleukin-2

IL-2 is a cytokine secreted by antigen-activated helper T cells, initially discovered to be a T cell growth factor but subsequently found to have many other immunologic effects, including an important role in the enhancement of immune responses. High-dose IL-2 (600,000 IU/kg every 8 hours for up to 14 doses) is associated with an objective response rate of 15% to 20%, with a small percentage of patients (around 5%) experiencing long-term, durable complete responses.[31] However, IL-2 treatment requires inpatient care, as toxicity is often severe and can include hypotension, pulmonary edema, decreased renal function, respiratory insufficiency, and neurotoxicity. Currently, the main role for IL-2 treatment is in conjunction with adoptive cellular therapy using tumor-infiltrating lymphocytes (TILs), an area of active clinical investigation in patients with metastatic melanoma refractory to currently available treatments.[55] This treatment capitalizes on the phenomenon that melanoma-specific T cells naturally infiltrate tumors, but it is rare for the endogenous immune response to eradicate metastatic melanoma by itself. However, if a small piece of tumor can be safely surgically harvested and delivered under sterile conditions to a licensed Good Manufacturing Practices facility, the resident TIL can be selectively expanded to large numbers and then used as a cellular treatment product. TIL treatment as currently administered requires a preparative, nonmyeloablative chemotherapy regimen that is followed by adoptive transfer of TIL and IL-2. TIL treatment in patients with metastatic melanoma has been associated with responses of up to 56%.[56] A multicenter clinical trial has reported a 36% response rate in patients whose disease is refractory to anti-PD1 antibody therapy (**Fig. 105.7**).[57] The surgeon plays an important role in this treatment modality, as selection of nonnecrotic, sterile tumor for harvest via a procedure with an acceptable projected duration for recovery is of critical importance for the treatment to be successful.[58]

Immune Checkpoint Inhibitors

For many years, immunotherapy research centered on the generation of an antitumor immune response through the use of nonspecific immunostimulants, vaccines, and assorted adjuvants. However, immune checkpoint inhibition, which essentially takes the brakes off the patient's inherent antitumor immune

response, has rapidly emerged as an effective form of immunotherapy in melanoma.[31]

Ipilimumab is a monoclonal antibody that binds to the cytotoxic T lymphocyte–associated antigen-4 receptor. This receptor is found on regulatory T cells and cytotoxic T cells after they have been activated, with its primary function to inhibit T cell responses. Blocking the binding between CTLA-4 and its ligand B7 suppresses this inhibitory function (essentially removing the brakes) and promotes continued T cell activation. In an analysis of pooled data from several clinical trials, the 3-year overall survival rate for patients with unresectable metastatic was 22%, with many of them being durable as the rate of additional deaths between 3 and 10 years was relatively low.[59] Ipilimumab is associated with immune-related toxicities, specifically enterocolitis, hepatitis, endocrinopathies, and dermatitis. While these can be severe, most are reversible if recognized and treated early, although endocrine toxicities in particular can be long-lasting.

Figure 105.7 Example of response to adoptive cellular therapy with tumor-infiltrating lymphocytes (TILs). **A:** Extensive recurrent melanoma of the distal foot and toes after prior margin-positive excision, progressive after multiple lines of systemic immunotherapy and chemotherapy. The tumor was BRAF wild type, and the patient also had widespread metastatic disease. The patient was enrolled onto a clinical trial testing adoptive cellular therapy with TILs. After harvest of tumor from a metastasis in the groin, TIL were grown ex vivo and reinfused into the patient after preparative lymphodepleting chemotherapy. High-dose interleukin-2 was administered for several days, and the patient tolerated therapy well and received no further treatment. **B:** Three months after therapy, there is clear evidence of tumor shrinkage at the primary site (shown) and all metastases. **C:** Six months after therapy, the tumor has almost completely regressed. The patient received no further therapy and remains well 2 years later.

Activated CD4 and CD8 T cells also express the programmed death 1 (PD1) receptor which, once bound to its ligand PD-L1, triggers a decrease in T cell proliferation, IL-2 release, and T cell survival. Malignant cells often express PD-L1 that binds to the receptors and blocks T cell killing. Pembrolizumab and nivolumab are monoclonal antibodies against PD1 that prevent binding to PD-L1. Both have shown response rates in as many as 45% of treated patients, with frequent responses even in those patients who have already progressed on or after treatment with ipilimumab. They were both approved by the FDA. As with anti-CTLA4, anti-PD1 can be associated with immune-mediated toxicities, including colitis, endocrinopathies, and pneumonitis. In phase III randomized trials comparing either nivolumab or pembrolizumab with ipilimumab, in previously untreated patients, the anti-PD1 antibodies were associated with improved response rates, progression-free survival, and overall survival with lower toxicity,[31] leading to a shift

toward anti-PD1 therapy as the first-line therapy in advanced melanoma. In addition, studies of combination therapy with anti-PD1 and anti-CTLA4 antibodies have demonstrated improved response rates and progression-free survival with increased but manageable toxicity, but it remains to be seen if the survival is better for the combination than for anti-PD1 alone.[60]

BRAF and MEK Inhibitors

The mitogen-activated protein kinase (MAPK) pathway is a key pathway in melanoma pathogenesis, with nearly half of melanomas having constitutive activation due to mutations in the *BRAF* gene.[61] Activation of the pathway leads to unregulated cell proliferation. Vemurafenib, dabrafenib, and encorafenib are orally administered targeted therapies that block the constitutively active mutant BRAF. Common adverse effects include arthralgia, rash, fatigue, alopecia, and the development of cutaneous keratoacanthomas and SCCs, and even second-primary BRAF wild-type melanomas. Patients treated with BRAF inhibition have dramatic responses, but unfortunately the survival benefit is limited because of the eventual development of resistance in most patients. Combining a BRAF inhibitor with an inhibitor of MEK1/2, a downstream regulator of BRAF, was associated with an improvement in response rates, progression-free survival, and overall survival compared with the BRAF inhibitor alone.[62–64] In addition, combination BRAF/MEK inhibitor therapy is also associated with fewer secondary cutaneous malignancies than with a BRAF inhibitor alone. The FDA has now approved three BRAF/MEK inhibitor combinations, vemurafenib plus cobimetinib, dabrafenib plus trametinib, and encorafenib plus binimetinib, for the treatment of patients with advanced melanoma with BRAF V600 E/K mutations.

The Impact of Treatment on Unresectable Metastatic Melanoma

Metastatic melanoma was once one of the most treatment-refractory types of cancer, but the availability of the new drugs described above has changed that picture dramatically. Five-year survival rates for patients with

unresectable metastatic melanoma now reach levels previously thought impossible. In a large randomized trial comparing ipilimumab to nivolumab or the combination of nivolumab plus ipilimumab, 5-year survival was 52% in the nivolumab plus ipilimumab arm and 44% in the nivolumab alone arm, compared with 26% in the ipilimumab arm. Among the subset of patients whose melanoma had a BRAF mutation, their 5-year survivals were an astonishing 60% in the nivolumab plus ipilimumab arm and 46% in the nivolumab alone arm, reflecting the potential for salvage treatment with BRAF/MEK inhibitors.[60] The use of these powerful therapies earlier in the course of the disease, as adjuvant and/or neoadjuvant therapy, can potentially improve outcomes even more. This emphasizes the critical importance of multidisciplinary, multimodality treatment for patients with melanoma—even if it is readily resectable—in order to direct the right treatment to the right patient and maximize the benefits of both surgical and nonsurgical treatments.

NONMELANOMA SKIN CANCERS

5 BCC and cutaneous SCC account for over 95% of all skin cancers and are also referred to as keratinocyte carcinomas due to their cell of origin.[65] Based on 2012 data, 5.4 million keratinocyte carcinomas were diagnosed in the United States annually, and that figure has doubtless increased since. The public health burden on the U.S. population from these lesions is highly significant.[66] Patients with clinically localized keratinocyte cancers have an excellent prognosis, with the vast majority curable with appropriate local treatment and fewer than 1% resulting in death. Mortality is primarily associated with SCC rather than BCC, with immunosuppressed patients being at dramatically higher risk of metastatic disease and death.

Etiology

Both BCC and SCC are most commonly induced by significant exposure to UV light from the sun and/or tanning beds. These cancers are predominantly located on the head, neck, trunk, lower legs, and hands, where sun exposure is common. Skin cancer is a significant occupational hazard for people who work outdoors. The phenotype at increased risk is one with fair skin who

sunburns and freckles easily, has blue or green eyes, and has red or blonde hair. Melanin pigment in the skin appears to be a protective factor, and the incidence of keratinocyte cancers is substantially lower in dark-skinned individuals. Immunosuppression is a major risk factor for keratinocyte cancers.[65]

A number of genetic syndromes are associated with an increased risk of developing keratinocyte cancers, including Gorlin syndrome, xeroderma pigmentosa, and albinism. Gorlin syndrome is an autosomal dominant disorder associated with multiple BCCs, palmoplantar pits, jaw cysts, frontal bossing, and hypertelorism. The mutated gene in Gorlin syndrome is *PTCH1*, a gene in the Hedgehog pathway, which is the pathway that is overactivated in virtually all BCCs. Xeroderma pigmentosa is associated with markedly defective repair of DNA damage due to UV light. Albinism is a disorder characterized by a partial or complete deficiency in melanin production and, thus, loss of protective pigment.

Another factor associated with keratinocyte cancers, primarily SCC, is chronic exposure of the skin to chemicals such as arsenic and hydrocarbons (found in coal tars, soot, and asphalt). Cigarette smoking has been associated with SCC of the lip and mouth. Human papillomavirus has been associated with cutaneous SCC in the genital and acral/periungual areas and also in SCC arising in immunosuppressed patients. Radiation has been associated with increased risk of both SCC and BCC.[65]

Basal Cell Carcinoma

BCC is the most common form of skin cancer. BCCs rarely metastasize but are characterized by slow growth that can be relentless and highly destructive without treatment. The most common subtype of BCC is the well-circumscribed nodular variety. These tumors often present as pearly papules or nodules with telangiectasias. They may be pruritic and bleed occasionally. With time, the center ulcerates to create rolled borders; such ulcerating BCCs may be referred to as "rodent ulcers" (**Fig. 105.8A**). Occasionally, the lesions are pigmented and can be confused with melanoma. This variant has been called pigmented BCC (see **Fig. 105.1I**). In some cases, BCC has histologic features of squamous or eccrine differentiation. Superficial BCCs are another common entity and are frequently multifocal. Clinically, these are

flat, scaly pink to red lesions (**Fig. 105.8B**) but if neglected they can ulcerate (**Fig. 105.8C**). They can be confused with psoriasis or other eczematous, scaly dermatoses.

The most locally aggressive type of BCC is characterized by a histopathologic infiltrating, aggressive growth pattern, referred to as morpheaform, sclerosing, or fibrosing BCC (**Fig. 105.8D**). Clinically, these tumors may appear to be scar-like, and they frequently have microscopic finger-like fronds of tumor cells that invade the surrounding structures well beyond the clinical margins of the lesion. These small, finger-like islands may be missed with standard histologic margin analysis and are associated with an increased risk of local recurrence. Although most BCC tumors are relatively localized, extensive subclinical involvement is common even without a morpheaform histology. Numerous risk factors are associated with possible extensive subclinical invasion and increased rates of local recurrence for BCC after standard treatment (**Table 105.8**).

Figure 105.8 Examples of basal cell carcinoma. **A:** Nodular basal cell carcinoma on the nasal ala, illustrating the classic "rodent ulcer" central depression. **B:** Superficial basal cell carcinoma on the thigh. **C:** Ulcerated basal cell carcinoma on the ankle. **D:** Morpheaform basal cell carcinoma on the cheek (*arrow*).

Cutaneous Squamous Cell Carcinoma

SCC is the second most common form of skin cancer. SCC most often arises in chronically sun damaged skin or within an actinic keratosis but may also develop in burn scars or chronic inflammatory wounds, known eponymously as a Marjolin ulcer. SCC has a greater propensity for regional and distant metastasis than BCC, but metastatic disease is less frequent when compared to melanoma or MCC. Nonetheless, the high incidence rate of SCC means that metastatic SCC occurs frequently enough to be seen in any busy practice devoted to cutaneous surgical or medical oncology. Metastasis to regional lymph nodes accounts for approximately 80% to 90% of these cases of metastatic SCC. Involvement of distant sites, such as the lung, liver, brain, bone, and skin, account for the other 10% to 20%. In immunosuppressed

individuals, SCC occurs much more frequently and with a more clinically aggressive behavior than in the general population.[65]

Table 105.8 Basal Cell and Squamous Cell Carcinoma: Higher-Risk Factors for Subclinical Invasion and Recurrence

▪ Recurrent tumor
▪ Anatomic location *High risk:* Central face, eyelid, eyebrow, periorbital, nose, lip, chin, mandible, temple, ear, in front or behind the ear, genitalia, hand, and foot *Medium risk:* Cheeks, forehead, pretibia, scalp, and neck *Low risk:* Trunk, extremity (excluding hand/foot and pretibia)
▪ Size Lesions ≥6 mm on high risk area Lesions ≥10 mm on medium risk area Lesions ≥20 mm on low risk area
▪ Histology *Basal cell:* Aggressive growth pattern (morpheaform, fibrosing, sclerosing, infiltrating, micronodular) *Squamous cell:* Poorly differentiated, acantholytic, desmoplastic, adenosquamous, or carcinosarcomatous subtypes
▪ Depth of invasion Clark level IV (lesion that involves the reticular dermis), V (lesion that invades into subcutaneous fat), or ≥4 mm
▪ Perineural invasion
▪ Rapid growth and/or ill-defined borders
▪ Etiology Scar, chronic ulcer or inflammatory process, sinus tract, sites of prior radiation therapy
▪ Immunosuppression

Figure 105.9 Examples of squamous cell carcinoma. **A:** Squamous cell carcinoma presenting as a non-healing sore with ill-defined pink borders. **B:** Ulcerated squamous cell carcinoma. **C:** Keratoacanthoma type squamous cell carcinoma.

SCC often presents as a nonhealing sore with ulceration and inflammatory pink borders, or as an erythematous nodule with overlying keratotic crust or ulceration (**Fig. 105.9A,B**). One noteworthy variant, keratoacanthoma type SCC, is characterized by a typical cratered appearance (**Fig. 105.9C**) and rapid local growth but little or no propensity to metastasize. The lesions may develop in patients taking BRAF inhibitors, especially when used as single agents without a concurrent MEK inhibitor.[67] Several risk assessment tools

are available to stratify the risk of recurrence and metastasis in SCC.[68,69] Factors that may determine a higher risk for local recurrence, extensive subclinical invasion, and metastasis are noted in Table 105.8.

Surgical Treatment of the Common Nonmelanoma Skin Cancers

Most keratinocyte cancers are small, low-risk lesions with 90% to 95% cure rates after standard treatment techniques, including electrodesiccation and curettage (ED&C), cryosurgery, radiation therapy, or surgical excision. Most BCCs and SCCs can be removed with conservative excisions using narrower peripheral and deep margins of excision than are used for melanoma or MCC. Excision margins for most localized BCC and SCC lesions should be in the range of 0.4 to 0.5 cm, but larger resectable tumors should be treated surgically in a manner similar to melanoma using 1 cm margins of excision taken down to fascia. Mohs surgery should be considered for BCCs and SCCs that exhibit the higher-risk factors in **Table 105.8**, particularly if they are situated in an anatomical area (e.g., face or ears) where skin conservation is of critical importance. While SLNB may be considered for carefully selected SCC at high risk of regional metastasis, criteria that reliably identify cases with at least a 5% to 10% risk of nodal metastasis have not been prospectively validated.[70,71]

Mohs Surgery

Mohs micrographic surgery is useful for the treatment of selected high-risk keratinocyte cancers (**Table 105.8**) as a tissue-sparing technique that achieves high cure rates. Mohs surgery is usually performed with local anesthesia in an outpatient surgical unit. After removal of all gross tumor, the surgeon excises a further thin 2 to 3 mm layer of tissue that includes all peripheral and deep margins of the excision. This layer of tissue is mapped, color coded for orientation, and sent to the Mohs technician for frozen section processing. In this way, both the deep and peripheral margins are examined in one horizontal plane by frozen section analysis, theoretically allowing total margin analysis. After histologic interpretation of the frozen

section specimens by the Mohs surgeon, the precise anatomic location of any residual tumor can be identified and that area reexcised and reanalyzed by frozen section until all margins are tumor free (**Fig. 105.10**). If appropriate, rapid immunohistochemical staining can be used to augment the evaluation of the margins. Closure or relatively straightforward soft tissue reconstruction can be performed on the same day (**Fig. 105.11**) or subsequently for more complex defects. A multidisciplinary approach involving Mohs, plastic, head and neck, and oculoplastic surgeons and radiation oncologists may be needed for extensive tumors.

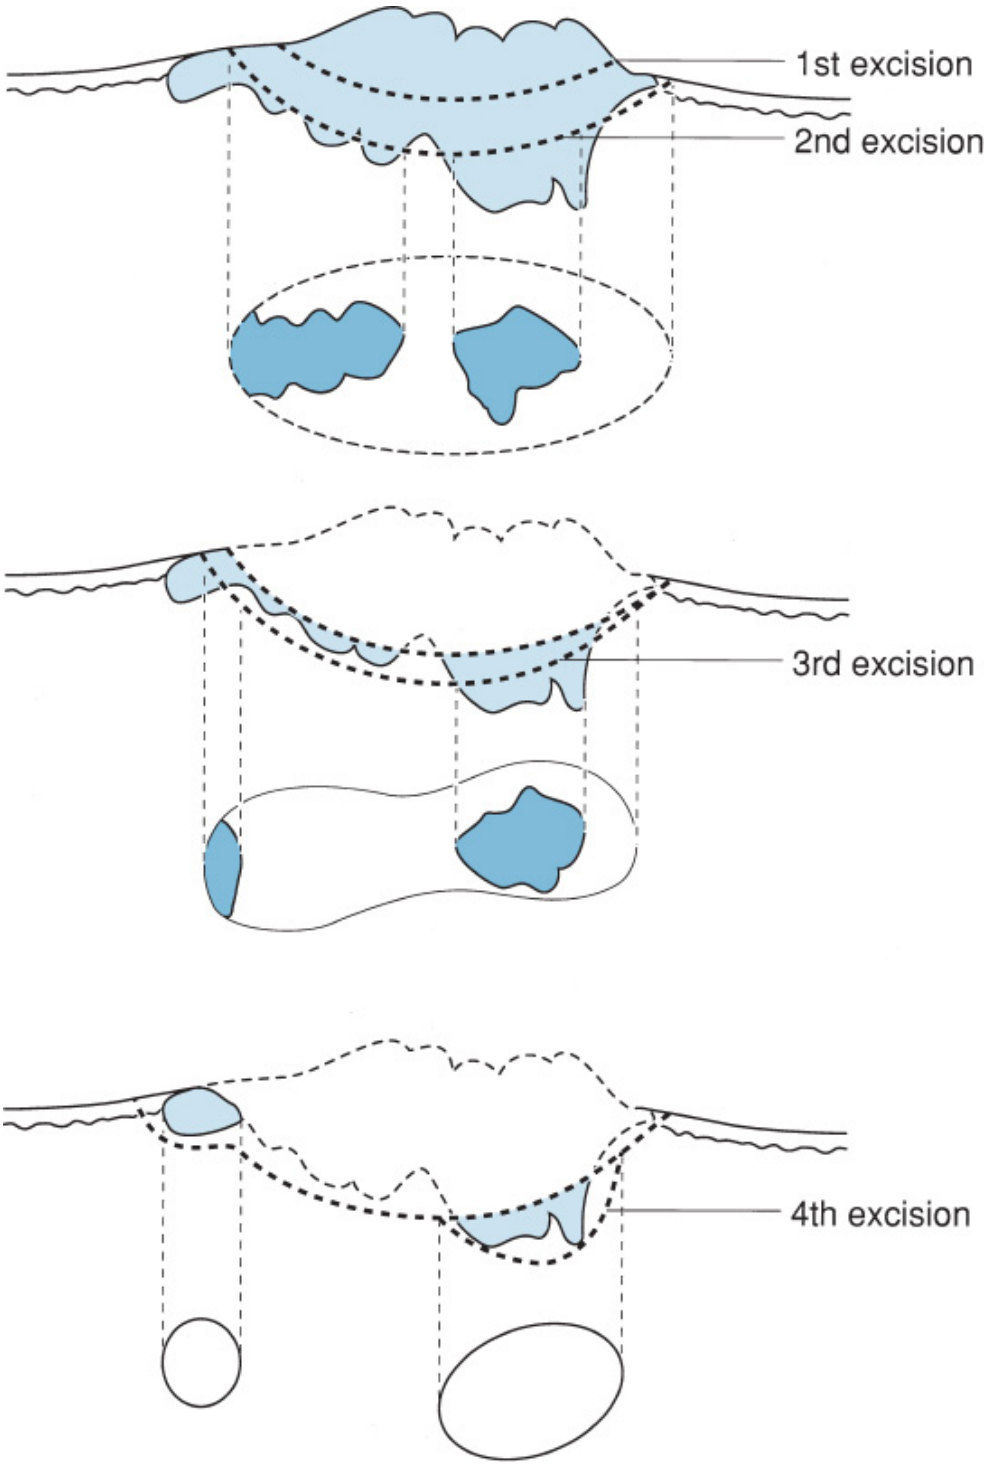

Figure 105.10 Mohs micrographic surgical technique. In this case, after the first excision to debulk the visible tumor, the second layer demonstrated relatively diffuse multifocal involvement of the margin by tumor. Accordingly, a third layer across most of the prior margin was obtained, which still showed two isolated foci of tumor at the excision margin. A fourth and final stage taking additional tissue only at those two sites resulted in complete, margin-negative excision of the tumor.

A randomized trial compared Mohs surgery to standard surgical excision for high-risk primary and recurrent basal cell cancer of the face.[72] A total of 408 patients with primary BCC were randomized; the 10-year recurrence rate was superior after Mohs (4.4% vs. 12.2%) but this did not reach statistical significance (P = 0.10). For 204 patients with recurrent BCC, however, the 10-year recurrence rate was significantly lower for Mohs than standard excision (3.9% vs. 13.5%, respectively; P = 0.02). Many recurrences occurred more than 5 years after surgery: 56% of the recurrences for primary and 14% of the recurrences for recurrent BCC.[72] In general, Mohs surgery should be considered for keratinocyte carcinomas that are associated with a relatively high risk of recurrence after standard treatment, especially recurrent tumors, and for primary sites where conservation of normal tissue is important.[73]

Adjuvant and Primary Radiation Therapy

Radiation therapy can be considered in the primary treatment of low-risk and even selected high-risk keratinocyte carcinomas and provides an alternative to surgery in cosmetically sensitive areas. For cutaneous SCC at high risk of local recurrence, such as those with perineural spread,[74] adjuvant radiation therapy to the primary site may decrease the risks of local recurrence after margin-negative resection as noted in consensus guidelines. Adjuvant radiation therapy may also be considered for selected aggressive, deeply invasive BCCs, particularly for recurrent tumors or those with extensive perineural spread or persistently positive margins after surgery as noted in consensus guidelines.

Locally Advanced and Metastatic BCC

The definition of locally advanced skin cancer is not universally accepted. Large, deeply invasive but resectable tumors can reasonably considered locally advanced, but some definitions restrict the term to encompass nonmetastatic keratinocyte cancers not amenable to either surgery or radiotherapy with reasonable expectation for cure due to multiple recurrences, infiltration through the fascia into underlying muscle or along major nerves, bony invasion, as well as tumors in which curative resection

would result in unacceptable complications, morbidity, or deformity.[76] BCC grows slowly, so locally advanced tumors usually represent long-neglected lesions. Uncontrolled Hedgehog pathway signaling is central to the pathogenesis of both hereditary and sporadic BCC and represents an opportunity for molecularly targeted therapy. Inactivating mutations of the tumor-suppressor *PTCH1* (patched) gene or less frequently activating mutations in the proto-oncogene smoothened (*SMO*) result in the unregulated activation of the Hedgehog pathway; aberrations in one gene or the other are found in virtually all BCCs, so routine mutational analysis is not required prior to initiating targeted therapy. Vismodegib and sonidegib are Hedgehog pathway inhibitors approved by the FDA for the treatment of locally advanced and (for vismodegib) metastatic BCC. Objective response rates approach 30% for metastatic BCC and exceed 40% for locally advanced BCC. Unfortunately, tumors frequently develop resistance to therapy. Adverse events occur in more than 30% of patients, and include muscle spasms, taste disturbances, alopecia, weight loss, and fatigue. In locally advanced BCC, preoperative use of one of these Hedgehog inhibitors can result in sufficient shrinkage to permit definitive treatment with surgery and/or radiation.[75] New treatment options are clearly needed for locally advanced and metastatic BCC that is refractory to Hedgehog inhibitors. Anti-PD1 immunotherapy has been shown to induce objective responses in some of these patients.[77]

Locally Advanced and Metastatic SCC

Locally advanced SCC represents another challenging clinical scenario. Feasibility of resection for locally advanced SCC should take both anticipated functional and cosmetic outcomes into account. Imaging to assess resectability and to rule out distant disease is typically warranted. Surgical excision of locally advanced SCC followed by adjuvant radiation therapy is the appropriate treatment for cases that are amenable to resection with acceptable cosmetic and functional outcomes. For unresectable cases, options include definitive radiation therapy up to 70 Gray with or without systemic chemotherapy (typically cisplatin or carboplatin)[69,70] and systemic immunotherapy with an anti-PD1 antibody such as cemiplimab or pembrolizumab.[77,78] These approaches can also be used to shrink locally

advanced tumors sufficiently to permit resection. Anti-PD1 immunotherapy has been associated with response rates for locally advanced and metastatic SCC that exceed the historical response rates and duration of response associated with chemotherapy or epidermal growth factor receptor (EGFR) inhibitor therapy.[79,80]

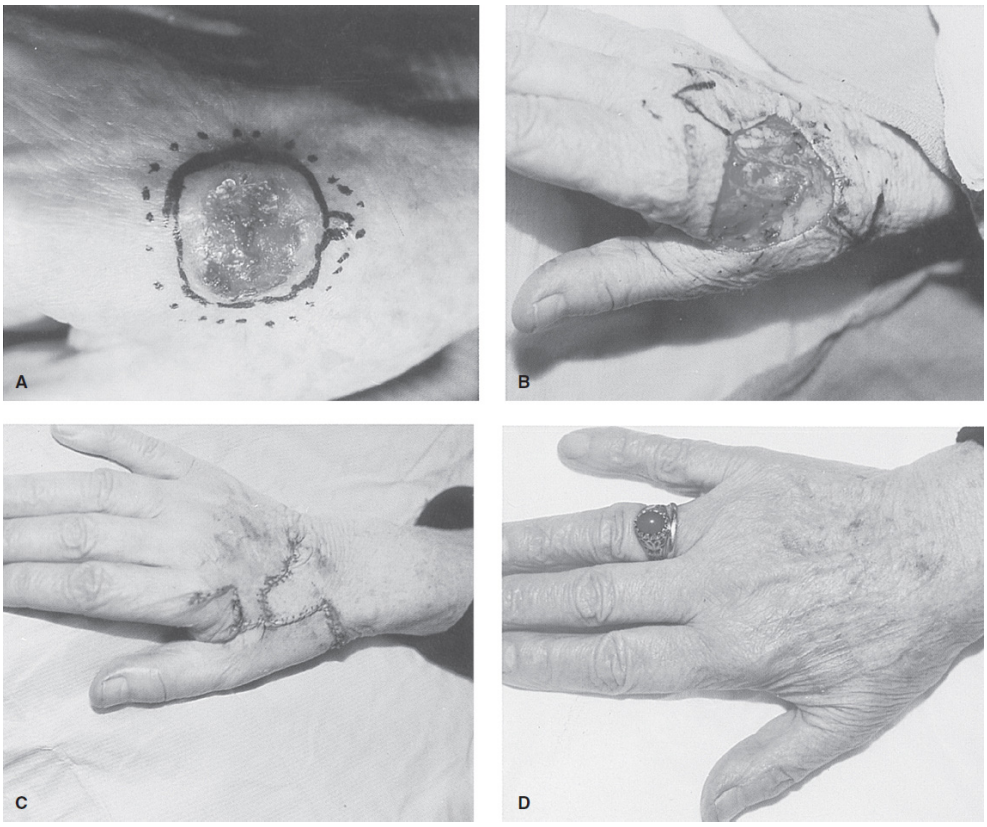

Figure 105.11 **A:** Patient with a 3 × 3 cm basal cell carcinoma on the right dorsal hand with mixed nodular and aggressive growth histologic pattern. **B:** Complete excision of the tumor required two Mohs stages involving 10 frozen sections. The final Mohs surgery defect measured 4.0 × 4.8 cm with preservation of underlying tendons. **C:** The defect was reconstructed immediately following the final Mohs stage under local anesthesia in the Mohs surgery unit using birhombic flap soft tissue reconstruction. **D:** Result 3 months after surgery.

Metastatic SCC may manifest as either regional nodal disease, in-transit disease, or distant disease. For resectable nodal metastatic SCC, radical lymphadenectomy followed by adjuvant radiation therapy is appropriate;[69] clinical trials of postoperative adjuvant anti-PD1 immunotherapy are underway. Distant metastatic disease is typically treated with systemic immunotherapy but this approach must be used with great caution in patients

with immunosuppression due to organ transplantation.[81] While systemic treatment options for distant metastatic SCC have traditionally included chemotherapy or EGFR inhibitors such as cetuximab,[69,70] anti-PD1 immunotherapy is now considered the first-line treatment of choice in patients who do not have a contraindication to this therapy.

Other Cutaneous Malignancies of Interest

Other cutaneous malignancies that may be encountered by the surgeon for further management include MCC, sweat gland carcinomas, and DFSP. Many other types of cutaneous malignancies exist, and their description is beyond the scope of this chapter.

6 MCC, also termed cutaneous neuroendocrine carcinoma, is an aggressive skin cancer with a higher per case mortality than melanoma.[82] The incidence of MCC is low compared to other cutaneous malignancies (approximately 1,500 annually in the United States), but the number of cases has at least tripled over the last two decades. MCC most commonly occurs in older individuals, with less than 5% of cases diagnosed before age 50. The majority of tumors (90%) are located on sun-exposed skin, equally distributed between the head and neck and extremities. The remaining 10% are located on the trunk and buttocks. Chronic UV exposure is an important pathogenetic factor in many cases, but the observation that MCC incidence is markedly increased in immunosuppressed patients ultimately led to the discovery of a virus (Merkel cell polyomavirus) as a contributing factor in the pathogenesis of MCC even in the absence of extensive UV exposure.[83,84] Primary MCC typically presents as a new-onset, growing, red or purple, dome-shaped or subcutaneous nodule, frequently mistaken for a sebaceous cyst (**Fig. 105.12A**). The most common location of metastasis is the draining lymph node basin. Histologically, MCC is a small blue round-cell tumor with positive immunohistochemical staining for cytokeratin-20 (CK-20) in a characteristic paranuclear dot-like pattern (**Fig. 105.12B**). Small cell lung cancer, another neuroendocrine carcinoma histologically indistinguishable from MCC and occasionally CK-20 positive, expresses thyroid transcription factor-1 (TTF-1), which is consistently absent in MCC.[85] AJCC staging for MCC distinguishes stage I (primary tumor <2 cm without nodal disease), stage II (primary tumor ≥2 cm without nodal disease), stage III (microscopic

or clinically apparent regional lymph node metastases), and stage IV disease (distant metastasis).[86] Presentation of MCC in the regional lymph nodes without an identified cutaneous primary is not uncommon.[87] Five-year survival rates for stages I, II, and III in the AJCC database were 81%, 67%, and 52%, respectively, while stage IV disease carried a dismal 11% 2-year survival rate. More recent results, however, suggest that these survival figures may be overly pessimistic.[88] The majority (70%) of patients with MCC present with clinically localized disease (stage I or II), 25% have palpable lymphadenopathy (stage IIIB), and 5% present with distant metastases (stage IV). Multidisciplinary management of MCC is clearly appropriate. Surgical treatment consists of radical wide excision with 1 to 2 cm margins, as performed for melanoma. MCC is much more sensitive to radiation than melanoma, however, so wide margins of excision are discouraged.[89] Postoperative radiation therapy to the primary tumor bed should be considered but whether all primary MCC cases should receive it and the impact of postoperative radiation on overall survival remains unclear.[90,91] SLNB with immunohistochemical staining using CK-20 is routinely recommended for primary MCC to stage the nodal basin and guide regional nodal therapy. Sentinel node–detected regional lymph node metastases can be treated by regional therapeutic lymphadenectomy and/or radiation therapy.[92] Adjuvant radiation therapy to the regional nodal basin should be considered for clinically detected nodal metastases. For nonsurgical candidates, primary treatment of MCC with radiation therapy may also be considered.

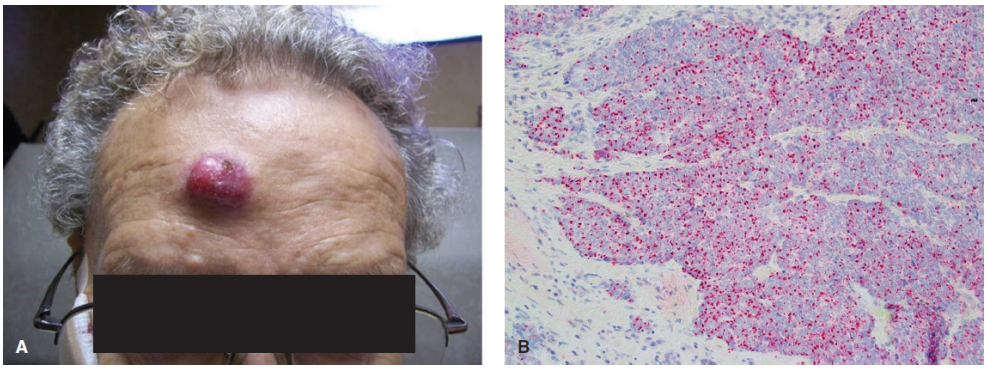

Figure 105.12 **A:** Primary Merkel cell carcinoma on the forehead. **B:** Characteristic immunohistochemical pattern showing dot-like positivity of cytokeratin 20 (CK20) staining in Merkel cell carcinoma. (Photomicrograph courtesy of Jane L. Messina, MD, Moffitt Cancer Center.)

The management of locally advanced and metastatic MCC dramatically changed with the recognition that MCC is very sensitive to immunotherapy with anti-PD1 or anti-PDL1 immunotherapy.[93,94] Interestingly, whether the MCC is associated with UV exposure or viral etiology does not markedly impact the response rates to immunotherapy. Adjuvant immunotherapy for MCC is currently under active investigation, and a trial of neoadjuvant anti-PD1 immunotherapy suggested that this is a very promising approach.[95,96] Chemotherapy has failed to demonstrate a survival benefit in an adjuvant setting in the treatment of localized or regional MCC and should be reserved for refractory unresectable or metastatic disease or patients with contraindications to immunotherapy.

Sweat gland carcinomas represent a broad scope of cutaneous adnexal malignancies with variable risk for local, regional, or distant metastasis, most commonly of eccrine or apocrine origin. These are rare tumors (0.005% of skin malignancies) that have a diverse and confusing nomenclature.[97] The aggressive types of sweat gland carcinomas have a propensity for both local recurrence and regional or systemic metastasis. Clinically, these tumors appear as indurated plaques, papules, or nodules commonly on the head and neck or extremities and are red, blue, pink, or skin colored (**Fig. 105.13**). Histologic subtypes that are particularly associated with a risk of regional lymph node or systemic metastasis include hidradenocarcinoma and porocarcinoma.[97] Recommended treatments have included wide excision of the primary tumor with consideration of SLNB for high-risk lesions based on larger tumor size, high histologic grade of atypia, or increased mitotic rate. Postoperative radiation therapy may also be considered as adjuvant treatment in selected cases.

Figure 105.13 Sebaceous carcinoma on the nose.

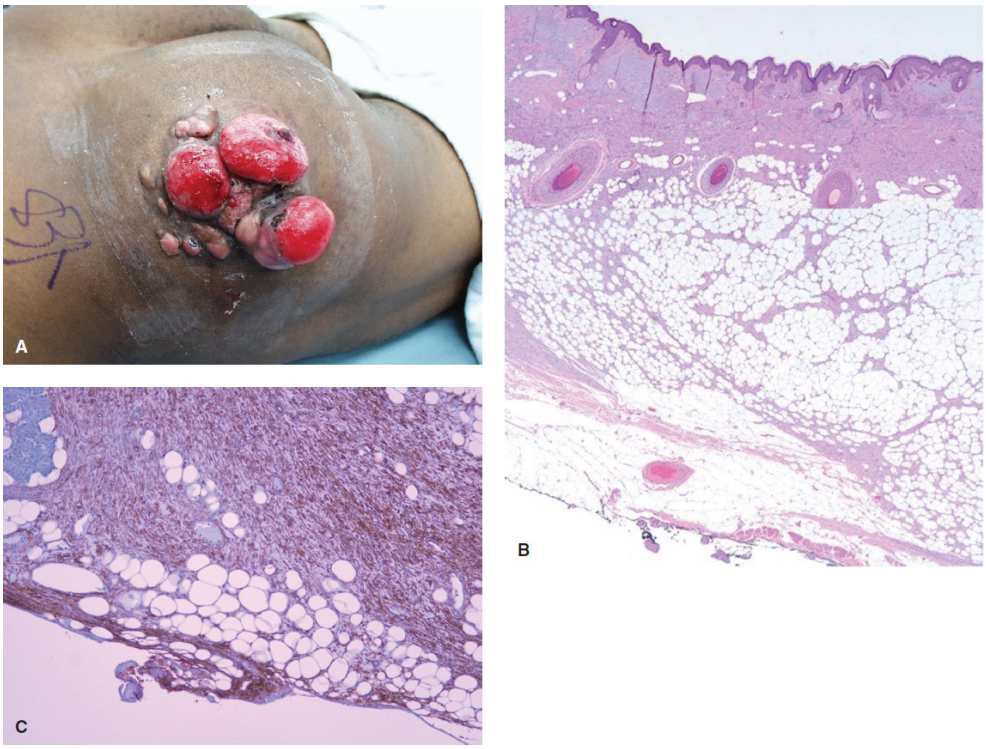

Figure 105.14 **A:** Dermatofibrosarcoma protuberans (DFSP) in an African-American patient. **B:** Low-power (20×) hematoxylin and eosin-stained microscopic appearance of DFSP showing a spindle cell neoplasm with infiltration through full thickness of dermis into subcutaneous fat, approaching the inked deep margin. **C:** High-power (200×) view with CD34 immunohistochemistry staining cells of DFSP extending through subcutaneous fat and present at the deep tissue margin. (Images courtesy of Jane L. Messina, MD, Moffitt Cancer Center.)

7 DFSP is a rare low-grade soft tissue sarcoma (accounting for approximately 1% of all soft tissue sarcomas) with a propensity for local recurrence rather than systemic metastasis.[98] It is a spindle cell tumor that typically demonstrates immunoreactivity to CD34 and has a characteristic gene translocation leading to activation of the platelet-derived growth factor receptor (PDGFR). These tumors appear as slow-growing, firm, flesh-colored to dull red plaques (**Fig. 105.14A**) that may be mistaken for keloids or hypertrophic scars. Although DFSPs may appear well circumscribed, they characteristically demonstrate extensive subclinical involvement, manifest histologically as finger-like projections of tumor cells (**Fig. 105.14B**). DFSP can undergo transformation into a high-grade soft tissue sarcoma, usually fibrosarcoma. For nontransformed DFSP, complete excision with negative margins is almost always curative, but a thorough assessment of the

peripheral and deep margins is critical to ensure that the entire tumor has been resected. Treatment commonly consists of radical wide excision with 1 to 2 cm margins and comprehensive pathologic margin assessment[99] or Mohs surgery,[100] particularly for lesions on cosmetically sensitive areas like the face. Reconstruction involving extensive undermining, skin grafts, or flaps should be delayed until negative histologic margins are confirmed.[98] Radiation therapy is indicated in those rare cases when negative margins cannot be obtained or for transformed lesions. Imatinib, a PDGFR inhibitor, has shown significant antitumor activity in the treatment of unresectable or metastatic DFSP, and can be used for neoadjuvant therapy of locally advanced lesions.[101]

Sarcomas of Soft Tissue and Bone

Chandrajit P. Raut and Sandra L. Wong

Key Points

1. Sarcomas are a rare and heterogeneous group of cancers that most commonly arise from mesoderm-derived elements such as muscle, fat, cartilage, blood vessels, bone, and other connective tissue but also from ectoderm-derived tissue such as nerve/nerve sheath. They are histologically distinct from cancers of epithelial origin.
2. Clinical behavior and prognosis are largely defined by anatomic location, histologic subtype, tumor grade, size, and ability to achieve complete resection.
3. For extremity sarcomas, radiotherapy is indicated for high-risk tumors to decrease disease relapse. Limb-sparing, function-preserving procedures are favored in order to maximize functional outcomes.
4. Increasing use of multimodality therapies, variably combining surgery, chemotherapy, and radiotherapy, have dramatically improved outcomes for sarcomas such as osteosarcoma and Ewing sarcoma.
5. Surgery is the cornerstone of treatment for intra-abdominal and retroperitoneal sarcomas. Complete resection for primary retroperitoneal sarcomas may require en bloc resection of adjacent or involved organs, most commonly the kidney and colon. The benefit of radiation therapy is less certain for retroperitoneal sarcomas, as it does not consistently reduce locoregional recurrence rates.
6. The use of imatinib mesylate, a selective tyrosine kinase inhibitor, in the management of gastrointestinal stromal tumors (GISTs), is a paradigm for the successful use of targeted molecular therapies.

INTRODUCTION

1 Sarcomas are a heterogeneous group of cancers that arise from mesenchymal cells, or mesoderm-derived elements, including muscle, fat,

cartilage, blood vessels, bone, and other connective tissue and ectoderm-derived tissue, such as nerve/nerve sheath. Though mesoderm-derived elements comprise nearly two-thirds of the body's mass, sarcomas are relatively rare. In 2020, just over an estimated 13,000 new cases of soft tissue and bone sarcoma were expected to be diagnosed in the United States,[1] which accounts for less than 1% of all new cancers. Sarcomas also represent an extremely heterogeneous group of cancers, but taken together, 5-year overall survival is about 50%[2] to 60%.[2,3] Anatomic location, tumor size, grade, and histopathology are important determinants of clinical presentation, treatment, and prognosis.

Sarcoma originates from the Greek word "sarkoma," meaning "fleshy excrescence." As early as AD 130–200, these fleshy tumors were regarded as cancerous by Galen.[4] With the evolution of light microscopy and cellular pathology, there was increasing recognition of soft tissue sarcomas as distinct pathologic entities. Sarcomas, then called "soft cancers," were differentiated from carcinomas by neuroanatomist Charles Bell as early as 1816. Rudolf Virchow refined the definition of sarcoma as "new formations of connective tissue," and developed classifications according to microscopic features which separated sarcomas from carcinomas of epithelial origin. Modern foundations for the classification and histogenic descriptions of sarcoma are attributed to the work of James Ewing, who over the course of his career as a pathologist refined the classification of sarcomas, including the importance of grade in disease outcome.[5]

Multimodality therapies, including surgery, radiation, and systemic/targeted therapy, have been combined to improve local and systemic tumor control. Over the past few decades, evolution of the multidisciplinary approach has enabled successful treatment options to evolve from radical amputation to limb-sparing procedures for extremity sarcoma. As refinements in pathologic classification continue, so does progress in the use of treatment modalities. Modern molecular diagnostics are increasingly being translated to clinical practice, and tailored treatment options are being developed as the histologic diversity of soft tissue sarcomas is continually elucidated and better understood. As with many rare tumors, referral to high-volume centers with multidisciplinary clinical expertise is indicated when feasible.

EPIDEMIOLOGY

Soft tissue sarcoma can occur in all age groups and are equally distributed between genders. While the median age at diagnosis varies by histopathologic subtype, sarcomas are relatively rare in the adult population. However, sarcomas are among the most common cancers seen in children and young adults, representing approximately 15% of pediatric malignancies and often occurring in children under 5 years of age.[6] There are over 75 distinct histopathologic subtypes. Further, sarcomas can occur at any anatomic site, and accordingly, anatomic site influences treatment and outcomes.

While the vast majority of sarcomas arise spontaneously, there are some predisposing conditions to consider. Sarcomas are not thought to be the result of malignant degeneration of a long-standing benign lesion such as a lipoma. An injury or other traumatic incident may lead to the initial recognition of a mass, but there are no data to support the notion that antecedent trauma leads to the development of either soft tissue or bony sarcomas. Clinical evaluation and subsequent workup, including biopsy, should be able to distinguish malignant growths from a variety of benign posttraumatic lesions, such as myositis ossificans, which must be differentiated from, for example, an extraosseous osteogenic sarcoma.

Toxic exposures have been related to the development of sarcoma. Largely of historic interest, the industrial use of thorium dioxide (Thorotrast), arsenic, and vinyl chloride led to accumulation of toxins in the liver and were associated with the development of hepatic angiosarcomas. Several other predisposing conditions are known to be associated with the development of sarcoma. The classic Stewart–Treves syndrome was originally described in patients with lymphedema following radical mastectomy and radiation for breast cancer who then developed lymphangiosarcoma of the affected arm. Since then, long-standing extremity edema from other causes has also been linked to the development of lymphangiosarcomas. Kaposi sarcoma was previously an uncommon cutaneous vascular tumor thought limited to elderly men of Mediterranean origin. In the early 1980s it became one of the first described opportunistic diseases associated with HIV infection. Though the incidence of HIV-associated Kaposi sarcoma has markedly declined with effective

antiretroviral therapy, it remains an important cause of morbidity among HIV-infected patients and other immunosuppressed patients such as renal allograft recipients.[7–9]

Various types of radiation have been implicated in the delayed development of sarcomas. For example, incidental ingestion of luminous paint containing ^{226}radium by factory workers led to the development of osteosarcomas. With the increasing use of external-beam radiation in cancer treatment, there has been a noted increase in the modern incidence of secondary sarcoma in patients previously treated with radiation for a variety of malignancies. Following median latent periods of approximately 8 years (range 6 to 20 years), radiation-associated sarcomas are being increasingly diagnosed in previously radiated areas. Common radiation-associated sarcoma subtypes are angiosarcomas, undifferentiated pleomorphic sarcoma, fibrosarcoma, osteosarcoma, and leiomyosarcoma, and they are commonly, but not uniformly, high grade.[10,11] Notably, with the advent of breast conservation therapy for breast cancer (consisting of partial mastectomy/lumpectomy and adjuvant radiation therapy), there should be an appropriate index of suspicion for breast angiosarcomas with findings of skin changes on the breast (**Fig. 106.1**).

Figure 106.1 Radiation-associated angiosarcoma. This 79-year-old woman developed skin changes on her breast 7 years after breast conservation therapy (lumpectomy and radiation therapy) for a 2-cm invasive ductal adenocarcinoma. Radical surgery including removal of all of the irradiated anatomic breast skin in addition to a mastectomy was performed.

GENETIC CANCER SYNDROMES

While the vast majority of sarcomas are sporadic, numerous genetic alterations are associated with both bone and soft tissue sarcomas.[12,12a] There are well-described genetic predispositions to sarcoma. Patients with neurofibromatosis type 1 (NF-1, or von Recklinghausen disease) have mutations in the neurofibromin 1 or 2 gene (*NF1* or *NF2*, respectively) which are associated with the development of malignant peripheral nerve sheath tumors (MPNST) in an estimated 5% of patients over a lifetime.[13] A genetic predisposition to desmoid tumors or desmoid fibromatosis is associated with familial adenomatous polyposis (FAP), or Gardner syndrome which is the result of germline mutations in the adenomatous polyposis coli (*APC*) gene.[14,15] Intra-abdominal and extremity desmoids are a common extracolonic manifestation of FAP and can be a source of increased

morbidity in these patients following proctocolectomy for the prevention or treatment of colon cancer.[16]

While somatic activation of c-KIT and overexpression of KIT protein are well described in the pathogenesis of gastrointestinal stromal tumors (GISTs), there are described germline mutations as well. Familial GISTs have been ascribed to germline mutation in *c-KIT* as well as in the *SDHB, SDHC*, and *SDHD* succinate dehydrogenase (SDH) subunits, in association with Carney triad (GIST, pulmonary chondromas, extra-adrenal paragangliomas) or Carney–Stratakis syndrome (GIST, paraganglioma).

One well-documented mechanism of sarcoma development is the inactivation of tumor suppressor genes. Retinoblastoma was known to be associated with a mutation in the retinoblastoma gene (*RB1*), a 13q chromosomal deletion. Investigation of the link between familial retinoblastoma and osteosarcoma led to the discovery that a genetic defect in *RB1* also plays a role in the pathogenesis of sarcomas.[17,18]

Another inherited defect of a tumor suppressor gene associated with soft tissue sarcomas is the Li–Fraumeni syndrome, caused by an inherited mutation in the *p53* gene, a key growth-regulatory gene.[19] Germline mutations in affected patients are associated with high incidences of childhood rhabdomyosarcomas, breast cancer, brain tumors, lung cancer, and leukemias.[20] *p53* abnormalities may be seen in as many as 60% of osteosarcomas and malignant fibrous histiocytomas, as well as approximately 33% of other sarcomas.[21] Several oncogenes that can induce malignant transformation and drive proliferation have also been associated with sarcoma development, including amplifications of *N-myc*, *c-erbB2* and members of the *ras* family.[22]

Cytogenetic aberrations have been recognized in a number of soft tissue sarcomas.[12] Several histologic subtypes of sarcomas have each been found to have specific genetic alterations—usually simple karyotypes including fusion genes due to reciprocal translocations or specific point mutations (**Table 106.1**). These chromosomal translocations serve as powerful diagnostic markers and may be important in determining tumor biology and subsequent tumor behavior. For example, identification of the translocation of t(X;18)(p11;q11) can confirm the diagnosis of synovial sarcoma if there is any doubt of its histopathology. There are data to suggest that the SYT-SSX1 fusion

transcript carries a worse prognosis than the SYT-SSX2 fusion transcript, with median survivals of 6.1 years and 13.7 years, respectively.[23,24]

A better understanding of the molecular biology of sarcomas has revolutionized diagnosis of specific histopathologic subtypes and has elucidated potential pathways for targeted molecular therapy.

SOFT TISSUE SARCOMAS

Clinical Presentation

The most common presentation of a soft tissue sarcoma is that of an asymptomatic mass. Most sarcomas tend to grow in a centrifugal fashion, usually pushing surrounding structures away rather than directly invading them and generally remaining within their compartment/fascial plane of origin. Encasement of structures can occur, but again, this largely occurs in the absence of direct invasion. Compression generally does not produce pain, swelling, or obstructive symptoms until the tumors become quite large or directly impinge on a nerve. Because of surrounding anatomic structures, some tumors of the extremities tend to be detected at a relatively smaller size, whereas tumors of the retroperitoneum are rarely smaller than 10 cm at the time of diagnosis.[5] Even very large abdominal or retroperitoneal sarcomas present with nonspecific abdominal symptoms such as fullness, early satiety, or minor abdominal discomfort (**Fig. 106.2**). While most sarcoma histologic subtypes displace surrounding structures, some do invade across fascial planes, including myxofibrosarcoma and fibromyxosarcoma. The differential diagnosis for a soft tissue sarcoma includes benign lesions (e.g., lipomas, leiomyomas, neuromas) and other malignant lesions (e.g., primary carcinoma, lymphoma, metastatic disease from melanoma or testes cancer).

Table 106.1 Cytogenetic Abnormalities in Soft Tissue Sarcoma Subtypes

Histologic Subtype	Cytogenetic Alteration	Molecular Alteration
Alveolar rhabdomyosarcoma	t(2;13)(q35;q14)	*PAX3-FOXO1* fusion
	t(1;13)(p36;q14) double minutes	*PAX7-FOXO1* fusion
	t(2;2)(q35;p23)	*PAX3-NCOA1* fusion
	t(X;2)(q35;q13)	*PAX3-AFX* fusion
Alveolar soft part sarcoma	t(X;17)(p11.2;q25)	*TFE3-ASPSCR1* fusion
BCOR-rearranged sarcoma	Inv(X)(p11p11)	*BCOR-CCNB3* fusion
	t(X;4)(p11;q31)	*BCOR-MAML3* fusion
	t(X;22)(p11;q13)	*ZC3H7B-BCOR*- fusion
CIC-rearranged sarcoma	t(4;19)(q35;q13) or t(10;19)(q26:q13)	*CIC-DUX4* fusion
	t(X;19)(q13;q13.3)	*CIC-FOXO4* fusion
Clear cell sarcoma	t(12;22)(q13;q12)	*EWS-ATF1* fusion
	t(2;22)(q32.3;q12)	*CREB1-ESWR1* fusion
Dedifferentiated liposarcoma	Ring and giant marker chromosomes	Amplification of 12q13-15: *MDM2, CDK4, HMGA2*
Desmoplastic small round cell tumor	t(11;22)(p13;q12)	*EWS-WT1* fusion
Dermatofibrosarcoma protuberans	t(17;22)(q21;q13); ring forms of chromosomes 17 and 22	*COL1A1-PDGFB* fusion
Endometrial stromal	t(7;17)(p15;q21)	*JAZF1-SUZ12* fusion

sarcoma, low grade		
	t(6;7)(p21;p15)	*PHF1-JAXF1* fusion
	t(6;10)(p21;p11)	*EPC1-PHF1* fusion
	t(1;6)(p34;p21)	*MEAF6-PHF1* fusion
	t(X;17)(p11;q21)	*MBTD1-CXorf67* fusion
Endometrial stromal sarcoma, high grade	t(10;17)(q22;p13)	*YWHAE-NUTM2* fusion
	t(X;22)(p11;q13)	*ZC3H7B-BCOR* fusion
Epithelioid hemangioendothelioma	t(1;2)(p36;q25)	*WWTR1-CAMTA1* fusion
	t(X;11)(p11;q22)	*YAP1-TFE3* fusion
Epithelioid sarcoma	Deletion 22q	*SMARCB1* inactivation
	t(8;22)(q22;q11)	
	t(10;22)	
Ewing sarcoma	t(11;22)(q24;q12)	*EWS-FLI1* fusion
	t(21;22)(q12;q12)	*EWS-ERG* fusion
Extraskeletal myxoid chondrosarcoma	t(9;22)(q22;q11)	*EWSR1-NR4A3* fusion
	t(9;17)(q22;q11)	*TAF2N-NR4A3* fusion
	t(9;15)(q22;q21)	*TCF12-NR4A3* fusion
	t(3;9)(q11;q22)	*TGF-NR4A3* fusion
	t(9;17)(q22;q11)	*RBP56-NR4A3* fusion
Fibrosarcoma	t(12;15)(p13;q26)	*ETV6-NTRK3* fusion
Gastrointestinal stromal tumor	Deletion 14q, 22q, 1p, 15q	*KIT* or *PDGFRA* mutation (85% of cases); *NF1, SDHX, BRAF* mutation, *SDHC*

		hypermethylation, other
Inflammatory myofibroblastic tumor	t(1;2)(q22;p23)	*TPM3-ALK* fusion
	t(2;19)(p23;p13)	*TPM4-ALK* fusion
	t(2;17)(p23;q23)	*CLTC-ALK* fusion
	t(2;2)(p23;q13)	*RANBP2-ALK* fusion
	t(2;2)(p23;q35)	*ATIC-ALK* fusion
	t(2;11)(p23;p15)	*CARS-ALK* fusion
	t(2;4)(p23;q21)	*SEC31L1-ALK* fusion
	t(2;12)(p23;p12)	*PPFIBP1-ALK* fusion
	t(2;20)(p23;p12)	*RRBP1-ALK* fusion
	t(3;6)(q12;q22)	*TFG-ROS1* fusion
	t(6;17)(q22;p13)	*YWHAE-ROS1* fusion
Fibromyxoid sarcoma, low grade	t(7;16)(q33;p11)	*FUS-CREB3L2* fusion
	t(11;16)(p11;p11)	*FUS-CREB3L1* fusion
Mesenchymal chondrosarcoma	t(8;8)(q13;q21)	*HEY1-NCOA2* fusion
Malignant peripheral nerve sheath tumor	Various	*SUZ12* or *EED* mutation (80% of cases), *NF1* inactivation
Myxoid/round cell liposarcoma	t(12;16)(q13;p11)	*FUS-DDIT3* fusion
	t(12;22)(q13;q12)	*EWSR1-DDIT3* fusion
Pseudomyogenic hemangioendothelioma	t(7;19)(q22;q13)	*SERPINE1-FOSB* fusion
Sclerosing epitheliod fibrosarcoma	t(11;22)(p11;q12)	*EWSR1-CREB3L1* fusion

	t(7;16)(q33;p11)	*FUS- CREB3L2* fusion
Solitary fibrous tumor	Inv(12)(q13q13)	*NAB2-STAT6* fusion
Synovial sarcoma	t(X;18)(p11;q11)	SS18-SSX1 orSS18-SSX2 fusion

Adapted from Schaefer IM, Cote GM, Hornick JL. Contemporary sarcoma diagnosis, genetics, and genomics. *J Clin Oncol* 2018;36(2):101–110.

In general, the vast majority of soft tissue masses tend to be benign, but concerning features which should prompt a higher index of suspicion for malignancy include large size (>5 cm), deep location (subfascial, intramuscular, intra-abdominal), variations in texture on examination, immobile nature or noted fixation to underlying structures, or changes to an existing lesion (increasing size or worsening compressive symptoms). There are no reliable tumor markers for sarcomas, so serum bloodwork is generally not useful in the evaluation of soft tissue masses. However, advances in the understanding and detection of circulating tumor DNA could lead to future serum tests for diagnosis of primary and recurrent sarcoma and measurement of response to therapy.

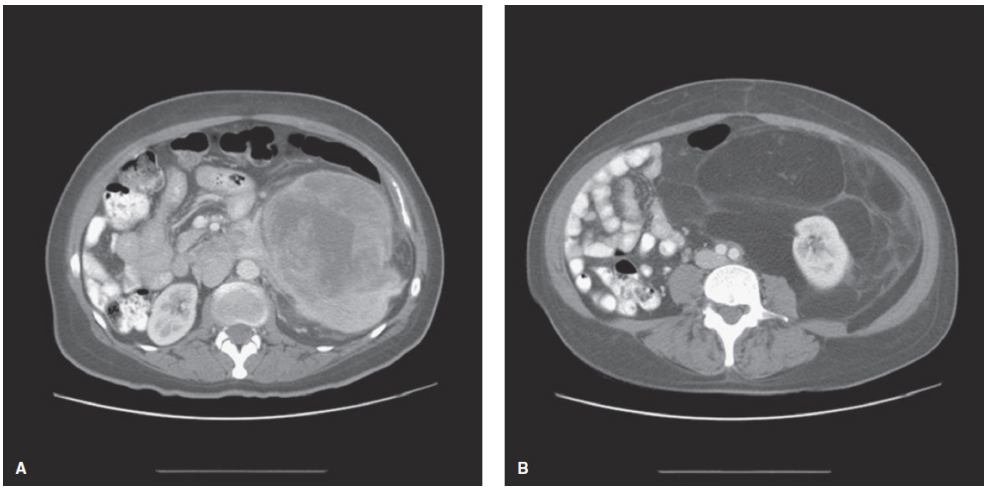

Figure 106.2 Dedifferentiated liposarcoma of the retroperitoneum. This 51-year-old woman presented with only vague symptoms of abdominal fullness from a very large retroperitoneal mass. The CT scan demonstrates a heterogeneous soft tissue mass in the upper abdomen (**A**) which blends into a more fatty component (**B**) which encases the left kidney and displaces abdominal contents. She underwent radical resection en bloc left nephrectomy, distal pancreatectomy, splenectomy, left colectomy, and segmental resection of inferior vena cava.

Diagnosis

Diagnostic Imaging

Accurate radiologic imaging is critical in the diagnostic workup of sarcoma to provide information about the precise location and extent of the primary tumor. Computed tomography (CT) scans and magnetic resonance imaging (MRI) are the most important imaging modalities for evaluating the resectability of soft tissue sarcomas, providing definition of the primary tumor in relation to bone, muscle, neurovascular structures, and adjacent organs. Plain radiographs of bones and radionuclide bone scans rarely provide useful information regarding invasion of bone by the tumor, though the former can be quite useful for primary bone tumors. Both CT and MRI can provide critical information for treatment planning. While MRI may be preferred for extremity sarcomas, CT is the modality of choice for abdominal, pelvic, and retroperitoneal tumors. However, there appears to be no difference between high-quality CT and MRI in terms of ability to determine involvement of nearby structures, bone, or neurovascular structures.[25–27]

Imaging is also important as part of the extent of disease workup. Because extremity sarcomas are known to predominantly metastasize to the lungs, directed chest imaging should be performed at the time of diagnosis. While chest radiography (CXR) may be used, CT scans are increasingly utilized as the primary screening examination of choice for higher-risk patients, such as those with high-grade lesions or tumors larger than 5 cm.[28] Any abnormal CXR must be followed by a chest CT scan per protocol, usually involving thinner sections without IV contrast, for more detailed evaluation of potential pulmonary metastases (**Fig. 106.3**). CT of the chest, abdomen, and pelvis should be considered in any patient with a myxoid liposarcoma of an extremity because this subtype often metastasizes to the abdomen or other "fat pads" such as the axilla. Paraspinal imaging with MRI may be indicated for myxoid liposarcoma as well, as bone and soft tissue metastases in this region may develop.

Figure 106.3 Pulmonary metastasis. A noncontrasted CT scan of the thorax demonstrates a 1.1-cm noncalcified nodule consistent with pulmonary metastasis in the upper lobe of the right lung.

MRI is the most commonly used imaging modality for the primary site of extremity sarcomas.[25,29] Sequencing routinely involves axial T2-weighted and precontrast/postcontrast T1-weighted images. Contrast enhancement with gadolinium is crucial for detecting and characterizing lesions with coronal, sagittal, and other reconstructions. This imaging modality can accurately delineate between muscle groups and distinguish tumor and neurovascular structures (**Fig. 106.4**). Magnetic resonance angiography (MRA) may be useful if more accurate delineation of vascular structures is required for surgical planning.

Positron emission tomography (PET) scanning using fluoro-13-deoxyglucose also offers the potential for noninvasive analysis of tumor

metabolism and has been shown to correlate with both tumor grade and response to treatment for many types of cancers.[30–33] PET may be helpful in distinguishing between benign and malignant lesions concerning for sarcoma and in assessing response to treatment.[34] However, its accuracy and potential for false-negative results are still incompletely defined, so its use is not routine, either for staging or for surveillance. Even with a PET scan, formal imaging with contrasted CT or MRI is necessary so costs and extent of imaging should be considered.

Diagnostic Biopsy

Properly performed biopsies are critical in directing a multimodality treatment approach. Image-guided techniques are commonly applied so that open biopsy is rarely required. Fine needle aspiration (FNA) is frequently used for the evaluation of enlarged lymph nodes, thyroid nodules, or breast masses. However, FNA often does not provide sufficient material for definitive histopathologic diagnosis (including subtype classification), especially for an index presentation of sarcoma. In select cases, FNA may be useful to demonstrate recurrent disease. Core-needle biopsy (CNB) is considered the initial procedure of choice for diagnosis of soft tissue sarcomas.[35] CNB, usually with multiple passes, retrieves sufficient material for immunohistochemical staining, and when necessary, for cytogenetic analysis or flow cytometry. Image-guided CNB, either using CT or ultrasound, allows for the biopsy of deep masses that may not be easily palpable and can help target suspicious areas in a heterogeneous field for better diagnostic value. An adequate sample from a viable area of sarcoma is required for definitive diagnosis and accurate grading. CNB is associated with low complication rates (<1%), including bleeding. Concerns about recurrence along the tract are obviated with judicious planning of the biopsy tract, the use of a sheathed needle device, and/or excision of the biopsy tract at the time of definitive resection when possible.

Open surgical biopsy, or incisional biopsy, is rarely needed given the success of CNB. However, open biopsy should be considered when core-needle specimens yield nondiagnostic findings *and* if preoperative diagnosis is definitely required for treatment planning. Several important technical factors must be considered when performing an incisional biopsy. Incisions

must be oriented along the long axis of extremities to facilitate subsequent complete resection with definitive surgical management. A transverse incision in the extremity often commits the patient to more more extensive procedures than would be otherwise necessary, potentially compromising the ability to obtain clear margins with definitive limb-sparing procedures. Attempts to enucleate the sarcoma within its "pseudocapsule" and without a proper margin is strongly discouraged, though excisional biopsy can be considered as the primary approach for small, superficial lesions by experienced surgical oncologists.[5] Extensive dissection during a biopsy, including undermining surrounding subcutaneous layers, should be consciously avoided in order to contain the extent of disease and best manage subsequent procedures. Attention to meticulous hemostasis also prevents extensive "seeding" of the area.

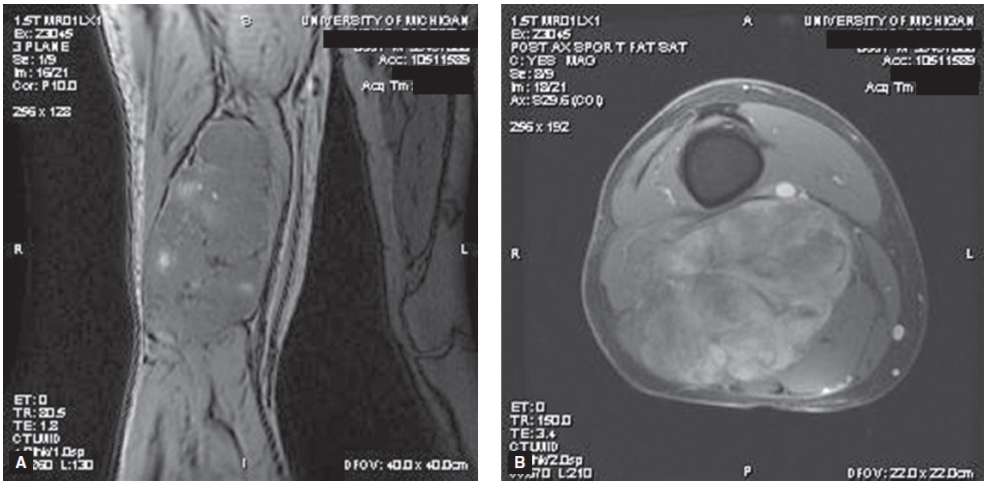

Figure 106.4 Extremity sarcoma. MRI demonstrates a 20-cm low-grade myxoid liposarcoma. **A:** Coronal reconstruction demonstrates location in the distal right thigh. **B:** Axial images show displacement of the popliteal vessels and vastus medialis anteriorly; the common tibioperoneal nerve and biceps femoris laterally; and, the semimembranosis and semitendinosus muscles medially.

PATHOLOGIC CLASSIFICATION

Histopathologic designation of soft tissue sarcomas reflect an extremely heterogeneous group of tumors. Sarcomas are generally classified according to the tissues they mimic rather than the type of tissue from which the tumor arises. Some sarcomas have no recognizable normal tissue counterpart and

are characterized by other distinguishing histologic features.[5,36,36a] The various types of benign and malignant soft tissue tumors are noted in Table 106.2. Bone tumors are listed in Table 106.3 for completeness, but discussion about their management is beyond the scope of this chapter. The development of specialized markers for identifying individual types of sarcoma has led to greater precision in their classification. In a small proportion of tumors (approximately 10% in most series), the tumor cells are so poorly differentiated that no specific histogenesis can be determined, and these may be designated as spindle cell sarcomas or undifferentiated pleomorphic sarcomas.

One of the most critical pieces of pathologic information for clinicians treating sarcoma patients is histologic grade. Histologic grade according to the Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) grading system is assessed based on the expert assessment of degree of tumor differentiation, the frequency of mitotic figures, and the presence or absence of spontaneous tumor necrosis (**Table 106.4**).[36b] While grading criteria have undergone numerous revisions over the years, in general, low-grade tumors have relatively little cellular atypia, few mitoses, and no tumor necrosis. High-grade tumors show a significant degree of necrosis in addition to atypia and frequent mitotic figures. Tumor differentiation scores, a component of the FNCLCC grading system, is assigned consistently for specific histologic subtypes, as detailed in Table 106.5 and representatively depicted in Figure 106.5. A consistently applied grading system discriminates between tumors with good prognosis (low grade) and those with relatively poorer prognosis (high grade). In the past, various grading systems have been used including a two-tiered systems (low and high), a three-tiered system (low, intermediate, and high), and a five-tiered system. The current American Joint Committee on Cancer (AJCC) staging system recognizes a classification system ranging from Grade 1 (G1) to Grade 3 (G3) tumors, taking into account histology, tumor differentiation, mitotic count, and tumor necrosis.[37–39] There can be disagreement about grading schemas and expert pathology opinion can vary from center to center.[40,41] As such, it is important to take note of tumor classification when interpreting results from clinical trials or retrospective reports.[42] The metastatic potential for low-grade lesions is approximately 5% to 10% compared to up to 50% to 60% for high-grade tumors.[2] For

sarcomas with intratumoral variability, the highest grade encountered is used to categorize the tumor.

Staging

Because of the prognostic importance of staging, stage classification of the primary tumor is based on both clinical and histologic information. The usual TNM classification used by the AJCC[39] for other solid tumors is modified to a TNMG system for most soft tissue sarcomas, including trunk and extremity sarcomas (**Tables 106.6A** and **106.6B**).

The most recent version of the AJCC staging system for sarcomas includes a number of changes. There is increased emphasis on individual histologies. There are new staging systems for retroperitoneal sarcoma (nodal disease is IIIB rather than IV), head and neck sarcoma (revised T stage size cut-offs, Table 106.6**C**), and visceral sarcoma (revised T stage, Table 106.6**D**), separate from the one for trunk and extremity sarcomas.[43–46] The principal difference between retroperitoneal and trunk/extremity sarcoma staging is that nodal disease is considered stage IIIB for the former and IV for the latter (**Tables 106.7A** and **106.7B**).[45,46] Uterine sarcomas and GIST[47] (**Tables 106.8A** to **106.8C**) continue to have separate staging systems, as do bone sarcomas. There is a new size category reflecting the increased risk of metastasis as tumor size increases. The previous distinction between superficial and deep has proven to be less useful, and has been eliminated.

Table 106.2 WHO Histologic Classification of Soft Tissue Tumors

Classification	Benign	Intermediate (locally aggressive)	Intermediate (rarely metastasizes)	Malignant
Adipocyte tumors	Lipoma Lipomatosis Lipomatosis of nerve Lipoblastoma/ lipoblastomatosis Angiolipoma Myolipoma Chondroid lipoma Extrarenal angiomyolipoma Extra-adrenal myelolipoma Spindle cell/ pleomorphic lipoma Hibernoma	Atypical lipomatous tumor/well-differentiated liposarcoma		Dedifferentiated liposarcoma Myxoid liposarcoma Pleomorphic liposarcoma Liposarcoma, not otherwise specified
Fibroblastic/ Myofibroblastic tumors	Nodular fasciitis Proliferative fasciitis Proliferative myositis Myositis ossificans Fibro-osseous pseudotumor of digits Ischemic fasciitis Elastrofibroma Fibrous hamartoma of infancy Fibromatosis coli Juvenile hyaline fibromatosis Inclusion body fibromatosis Fibroma of tendon sheath Desmoplastic fibroblastoma Mammary-type myofibroblastoma Calcifying aponeurotic fibroma Angiomyofibroblastoma Cellular angiofibroma Nuchal-type fibroma Gardner fibroma Calcifying fibrous tumor	Palmar/plantar fibromatosis Desmoid-type fibromatosis Lipofibromatosis Giant cell fibroblastoma	Dermatofibrosarcoma protuberans (DFSP) (fibrosarcomatous DFSP, pigmented DFSP) Solitary fibrous tumor Inflammatory myofibroblastic tumor Low-grade myofibroblastic sarcoma Myxoinflammatory fibroblastic sarcoma/atypical myxoinflammatory fibroblastic tumor Infantile fibrosarcoma	Adult fibrosarcoma myxofibrosarcoma Low-grade fibromyxoid sarcoma Sclerosing epithelioid fibrosarcoma Malignant solitary fibrous tumor
So-called fibrohistiocytic tumors	Tenosynovial giant cell tumor (localized type, diffuse type, malignant) Deep benign fibrous histiocytoma		Plexiform fibrohistiocytic tumor Giant cell tumor of soft tissue	
Smooth muscle tumors	Deep leiomyoma			Leiomyosarcoma (excluding skin)
Pericytic (perivascular) tumors	Glomus tumor (glomangiomatosis) Myopericytoma (myofibroma, myofibromatosis) Angioleiomyoma			Malignant glomus tumor

Skeletal muscle tumors	Rhabdomyoma (adult, fetal, and genital types)			Embryonal rhabdomyosarcoma (botryoid, anaplastic) Alveolar rhabdomyosarcoma (solid, anaplastic) Pleomorphic rhabdomyosarcoma Spindle cell/sclerosing rhabdomyosarcoma
Vascular tumors of soft tissue	Hemangioma (synovial, venous, arteriovenous hemangioma/ malformation, intramuscular) Epithelioid hemangioma Angiomatosis Lymphangioma	Kaposiform hemangio-endothelioma	Retiform hemangioendothelioma Papillary intralymphatic angioendothelioma Composite hemangioendothelioma Pseudomyogenic hemangioendothelioma Kaposi sarcoma	Angiosarcoma Epithelioid hemangio-endothelioma
Chondro-osseous tumors	Soft tissue chondroma			Extraskeletal chondrosarcoma Extraskeletal osteosarcoma
Gastrointestinal stromal tumors (GIST)	GIST, benign			GIST, malignant
Nerve sheath tumors	Schwannoma Melanotic schwannoma Neurofibroma (plexi-forma neurofibroma) Perineurioma Granular cell tumor Dermal nerve sheath myxoma Solitary circumscribed neuroma Ectopic meningioma Nasal glial heterotopia Benign Triton tumor Hybrid nerve sheath tumors			Malignant peripheral nerve sheath tumor (MPNST) Epithelioid MPNST Malignant Triton tumor Malignant granular cell tumor Ectomesenchymoma Malignant perineurioma
Tumors of uncertain differentiation	Acral fibromyxoma Intramuscular myxoma Juxta-articular myxoma Deep ("aggressive") angiomyxoma Pleomorphic hyalinizing angiectatic tumor Ectopic hamartomatous thymoma	Hemosiderotic fibrolipomatous tumor	Atypical fibroxanthoma Angiomatoid fibrous histiocytoma Ossifying fibromyxoid tumor Mixed tumor, not otherwise specified Myoepithelioma Myoepithelial carcinoma Phosphaturic mesenchymal tumor	Synovial sarcoma (including biphasic) Epithelioid sarcoma Alveolar soft-part sarcoma Clear cell sarcoma of soft tissue Extraskeletal myxoid chondrosarcoma Extraskeletal Ewing sarcoma Desmoplastic small round cell tumor Perivascular epithelioid cell tumor (PEComa) Intimal sarcoma
Undifferentiated/ Unclassified sarcomas				Undifferentiated spindle cell sarcoma Undifferentiated pleomorphic sarcoma Undifferentiated round cell sarcoma Undifferentiated epithelioid sarcoma Undifferentiated sarcoma NOS

Table 106.4 Histologic Parameters in the Federation Nationale des Centres de Lutte Contre le Cancer (FNCLCC) Grading System

Histologic Parameter	Score	Definition
Tumor differentiation	1	Closely resembling normal adult mesenchymal tissue, potentially difficult to distinguish from benign counterparts (e.g., well differentiated liposarcoma)
	2	Histologic typing is certain (e.g., myxofibrosarcoma)
	3	Undifferentiated or embryonal sarcomas, synovial sarcoma
Mitotic count	1	0–9 mitoses per 10 HPF
	2	10–19 mitoses per 10 HPF
	3	>19 mitoses per 10 HPF
Tumor necrosis	0	No necrosis
	1	<50% tumor necrosis
	2	≥50% tumor necrosis
Histologic grade	Grade 1	Total score 2–3
	Grade 2	Total score 4–5
	Grade 3	Total Score 6–8

Table 106.6A American Joint Committee on Cancer (AJCC): TNM Classification of Soft Tissue Sarcomas of the Trunk and Extremity

Classification	Description
Tumor Grade	
GX	Grade cannot be assessed
G1	Grade 1
G2	Grade 2
G3	Grade 3
Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of a primary tumor
T1	Tumor ≤5 cm in greatest diameter
T2	Tumor >5 cm and ≤10 cm in greatest diameter
T3	Tumor >10 cm and ≤15 cm in greatest diameter
T4	Tumor >15 cm
Lymph Node Involvement	
N0	No regional metastases to lymph nodes or unknown lymph node status
N1	Regional lymph node metastases
Distant Metastasis	
M0	No known distant metastasis
M1	Known distant metastasis

Not including Gastrointestinal stromal tumors.

One of the challenges with AJCC staging of sarcomas is that a critical factor, histologic subtype, is not included. Prognostic nomograms based on histologic subtype or site of origin have been developed.[48–52] These include prognostic factors as continuous rather than categorical variables. Some are now available for download on a smart phone app (www.sarculator.com).[48,49,51,52]

Additionally, some sarcomas are difficult to classify in the staging system, and descriptive clinical features are described for them instead. Sarcomas that fall into that category include alveolar soft-part sarcoma, angiosarcoma, desmoplastic small round cell tumor, epithelioid hemangioendothelioma, extraskeletal myxoid chondrosarcoma, inflammatory myofibroblastic tumor, Kaposi sarcoma, osteosarcoma of soft tissue, phyllodes tumor, rhabdomyosarcoma, and solitary fibrous tumor.[53] Finally some tumors are locally aggressive but have little to no risk of metastatic disease and are thus excluded from the AJCC staging system, including desmoid tumor.[53]

By far the most common site of metastasis is the lungs though metastases to other sites do occur. Metastases to the liver should be considered for GIST and pelvic or abdominal visceral sarcomas.

TREATMENT

Principles of Surgery

3 Complete resection remains the cornerstone of treatment for soft tissue sarcomas. Performing a wide excision of the tumor with negative margins is the goal of resection with curative intent. Simple enucleation, if even possible, usually results in an inadequate resection and should be avoided. Technical aspects of resection which must be taken into consideration include anatomic location and extent of disease. Often, soft tissue sarcomas are surrounded by a zone of compressed reactive tissue that forms a pseudocapsule. Care should be taken to avoid entry into the tumor and pseudocapsule during course of dissection. Enucleation commonly results in microscopically positive margins and re-resection should be considered though anatomic location may preclude effective clearance of margins even with a second operation.

Table 106.6D American Joint Committee on Cancer (AJCC): T Classification of Soft Tissue Sarcomas of the Abdominal and Thoracic Viscera

Classification	Description
Primary Tumor	
TX	Primary tumor cannot be assessed
T1	Organ confined
T2	Tumor extension into tissue beyond organ
T2a	Invades serosa or visceral peritoneum
T2b	Extension beyond serosa (mesentery)
T3	Invades another organ
T4	Multifocal involvement
T4a	Multifocal (2 sites)
T4b	Multifocal (3–5 sites)
T4c	Multifocal (>5 sites)

Metallic clips placed in the tumor bed following resection can help define the limits of resection and aid in surveillance as well as planning of future treatment. Closed suction drainage catheters may be used to obviate postoperative seroma formation following resection of extremity or truncal sarcomas. However, in the era of Enhanced Recovery After Surgery pathways, the true need and benefit for such drains should be re-evaluated. Drains should be placed reasonably close to the incision so that the site can be included in a postoperative radiation field and, for extremity sites, should be brought out distally rather than through a site proximal to the incision to minimize the extent of proximal involvement if amputation ever becomes necessary. A unique characteristic of sarcoma is the general lack of metastasis to regional lymph nodes. If regional lymphadenopathy is discovered in conjunction with a diagnosis of sarcoma, therapeutic lymphadenectomy can be considered since clearance of disease may be

associated with improved outcomes.[54,55] For selected histopathologic subtypes (e.g., epithelioid sarcoma, clear cell sarcoma), in patients with clinically negative node examination, there may be a role for sentinel lymph node biopsy to identify occult micrometastatic disease.[56]

Taken together, sarcomas of the upper and lower extremities and trunk make up the majority of soft tissue sarcomas. Large truncal tumors may require reconstruction with a myocutaneous flap or prosthetic materials if resultant defects cannot be closed primarily (**Fig. 106.6**). Largely of historical interest now, radical amputations were once the mainstay of treatment for extremity sarcoma, but modern surgical approaches involve limb-sparing procedures (**Fig. 106.7**), which maximize functional outcomes. As recently as the 1970s, more than 50% of all soft tissue sarcomas of the extremity were treated with radical amputations. The accepted standard of care changed after the group at the National Cancer Institute, led by Rosenberg,[57] published the results of a randomized trial of limb-sparing resection plus adjuvant radiation therapy compared to amputation, finding no differences in disease-free survival rates (71% vs. 78%, respectively) and the overall survival rates (83% vs. 88%, respectively) at 5 years. This trial demonstrated that amputation was not mandatory and in 1985, a National

Institute of Health consensus statement recommended limb-sparing procedures for most patients with high-grade extremity sarcomas.[58] Radical amputations, such as hemipelvectomy, hip disarticulation or forequarter amputation, are now reserved for patients who are not suitable candidates for limb-sparing approaches, usually because of extent of disease, bony or joint invasion, or for otherwise unsalvagable recurrence after previous limb-sparing surgery (**Fig. 106.8**).[59] There is no improvement in survival with this approach under these circumstances and serious morbidity must be taken into account.[60]

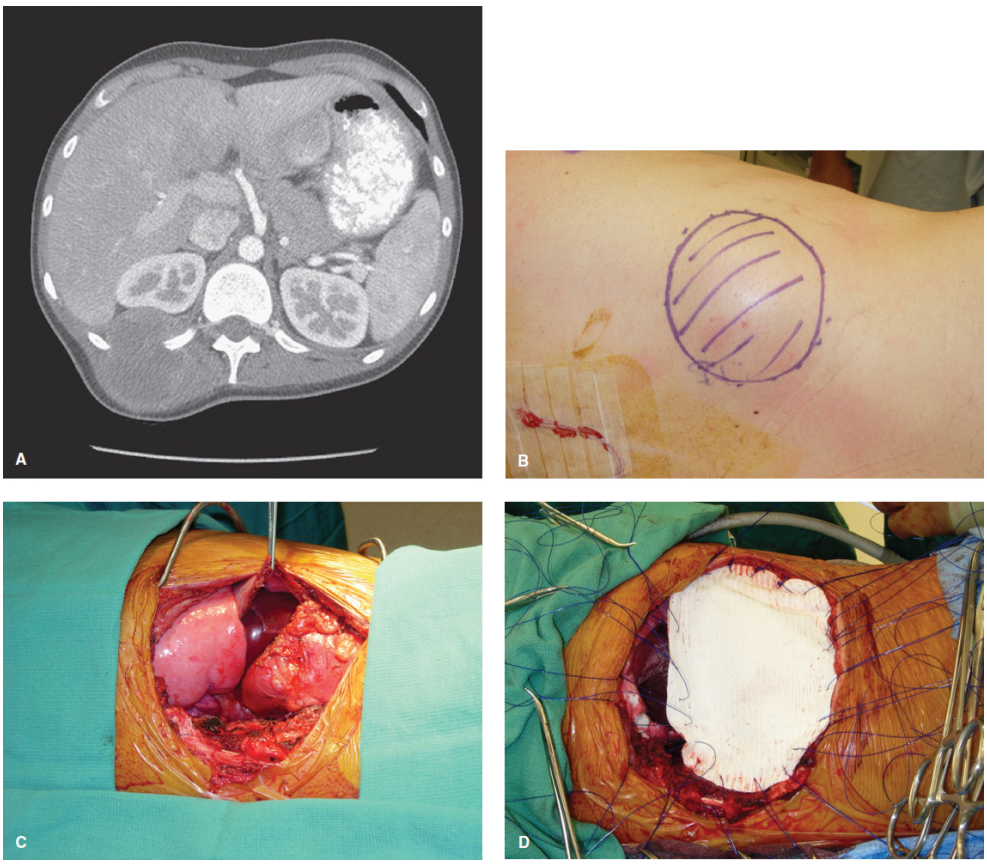

Figure 106.6 Chest wall sarcoma. A 20-year-old man with a 7.5-cm right posterior chest wall epithelioid sarcoma involves the 11th and 12th ribs as seen on CT scan (**A**) and on physical examination (**B**). Chest wall resection was performed, including a portion of diaphragm. Resulting chest wall defect (**C**) was repaired using prosthetic mesh (**D**).

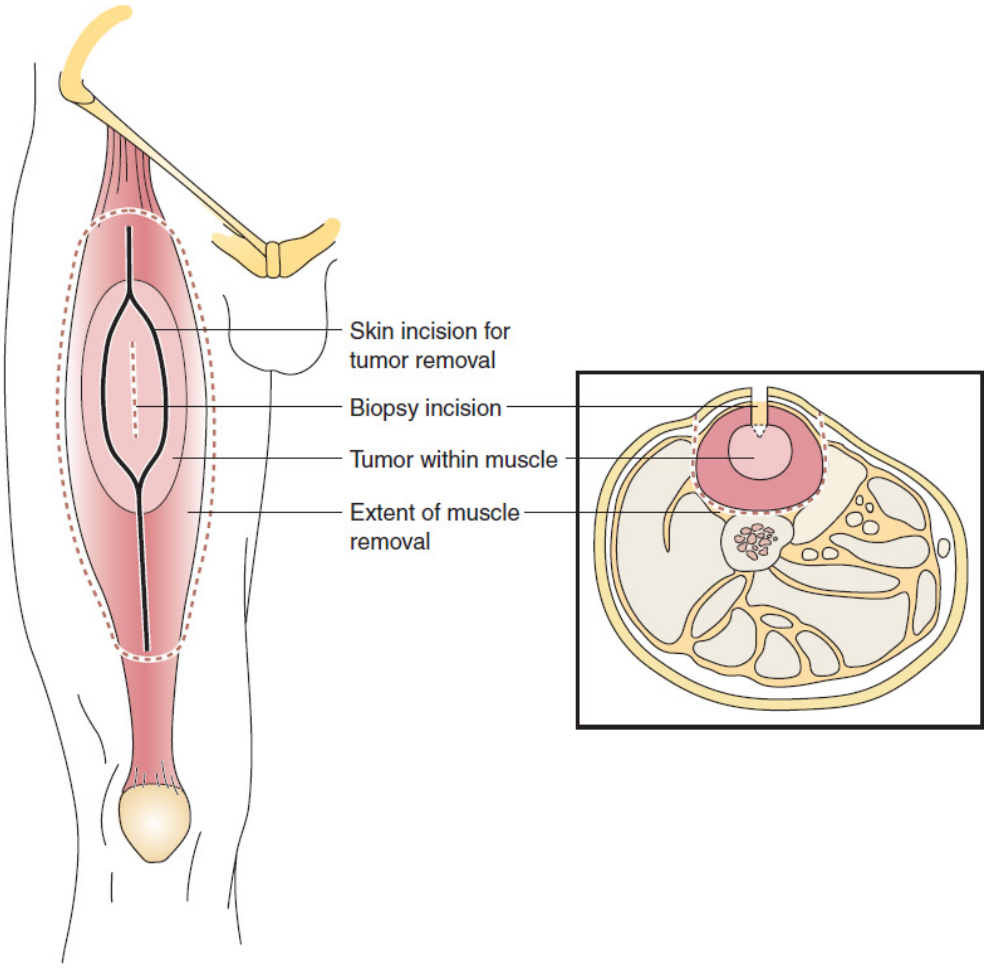

Figure 106.7 Wide excision involves removal of the tumor with a margin of normal tissue. If necessary, major vascular structures or nerves may be resected.

Acceptance of multimodality therapy has led to the ability to perform wide excisions while preserving function when treating extremity or truncal soft tissue sarcomas.[5,61,62] Radiation can be employed in the neoadjuvant or adjuvant setting, and evidence from randomized trials as well as retrospective studies support similar local control and progression-free survival rates with both strategies. A Phase III trial in which patients were randomized to preoperative or postoperative radiation showed similar primary outcomes, but found that preoperative radiation was associated with much higher wound complications (35% vs. 17%, respectively), and this was especially true for lower extremity tumors. The interesting tradeoff was a higher rate of late treatment effects in the postoperative radiation group, attributed to relatively higher treatment doses and volumes. Based on the data from this trial, either neoadjuvant or adjuvant radiation therapy may be

offered around resection of trunk or extremity sarcomas. Patients should be made aware of the tradeoffs—higher risk of wound healing complications with neoadjuvant radiation therapy versus higher risk of long-term joint stiffness and fibrosis with adjuvant radiation therapy.

Judicious use of radiation has allowed for the sparing of major neurovascular structures, though if necessary, arteries and/or veins can be resected en bloc with the tumor and subsequent reconstruction can be done with autologous or prosthetic graft materials. In cases of neurologic compromise, customized adjuncts from experienced physical medicine departments can help restore reasonable function. For instance, resultant foot drop from peroneal neuropathy can be managed with an ankle–foot orthotic and gait training. In appropriate cases, resection should be planned in conjunction with a plastic surgeon to provide complex soft tissue reconstruction with microvascular free flaps particularly if the size of defect following resection prohibits primary closure or if there is concern about a high risk of wound complications based on preoperative radiation.

Adjuvant and Neoadjuvant Therapy

4 The role of external-beam radiotherapy (EBRT) is best defined by a trial comparing limb-sparing surgery alone with limb-sparing surgery and adjuvant radiation, showing improved 10-year local recurrence rates with radiation. In high-grade sarcomas, the recurrence rate was 0% versus 22%, respectively though no significant effect on overall survival was appreciated.[63] Certainly, in the setting of involved surgical margins which could not otherwise be resected, adjuvant radiation therapy is associated with improved local control.[3,64]

Typically, the entire surgical bed and drain sites are included in the field, along with wide margins around the sarcoma, when postoperative radiation is given. Hemaclips marking the site of resection can be placed at the time of resection to help with radiation planning. It is important that an individualized approach be taken with each patient since radiation can result in severe complications when used inappropriately. For example, the entire circumference of the extremity should not be irradiated as this may cause massive lymphedema and could cause long-term neurovascular compromise. Severe fibrosis, necrosis, fractures, and contractures can also occur with

focused treatment and result in impaired function. Wound healing may be compromised in patients undergoing adjuvant radiation and in selected cases, use of rotational flaps for coverage can prevent or minimize chronic wound healing problems.[65] Similarly, radiation must be used judiciously in sensitive areas such as the abdomen and retroperitoneum since nearby visceral structures are exquisitely sensitive to higher doses of radiation. Dose-limiting toxicity must be considered when recommending such therapies.

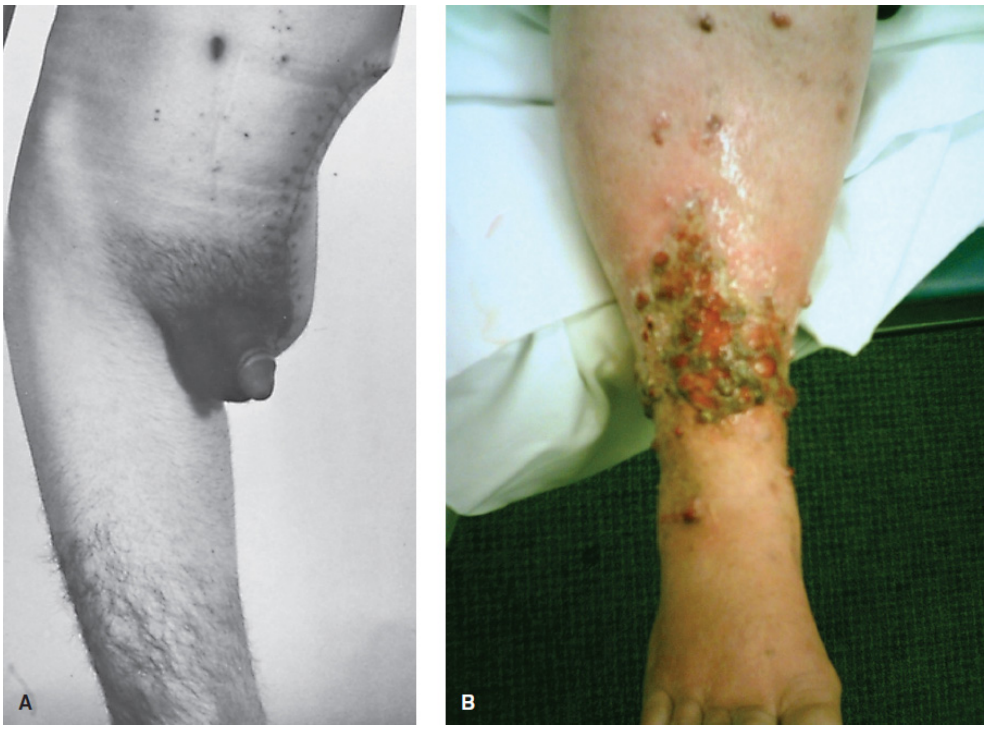

Figure 106.8 **A:** Radical amputations for extremity sarcomas include one joint above the most proximal extent of tumor. Now largely of historic interest, tumors of the proximal thigh or buttock were previously routinely treated with hemipelvectomy. **B:** While limb-sparing procedures are now done whenever possible, amputation may be necessary for certain cases. This 60-year-old woman had high-grade angiosarcoma of the right leg with extensive satellite metastases extending above her knee. She required above-knee amputation.

An alternate approach to adjuvant radiation is brachytherapy, which involves the placement of multiple catheters or seeds in the tumor resection bed to administer iridium-192. Unlike the several week course needed to complete external-beam radiation, a course of brachytherapy can be completed in a few days time. In theory, brachytherapy produces less radiation scatter in critical areas, decreasing toxicity while obtaining

equivalent functional outcome.[66] However, brachytherapy requires special equipment and can involve technically complex treatment planning by an experienced radiation oncologist. From a therapeutic standpoint, brachytherapy and external-beam radiation appear to be equivalent when properly administered. In recent years, stereotactic body radiation therapy (SBRT) has begun to replace some of the indications for brachytherapy. Nonetheless, brachytherapy can be particularly useful if the patient is no longer a candidate for EBRT due to prior radiation to that site. Some centers offer intraoperative radiation therapy (IORT), though its effectiveness is unproven. If IORT is employed, it is currently done in conjunction with a planned external-beam boost dose.[67]

Patients with high-risk (large [>10 cm], high-grade) extremity sarcomas may be considered for preoperative treatment with chemotherapy or with chemoradiation since overall local control rates are disappointing with postoperative radiation alone.[61] Local control rates were considerably higher when large tumors were treated before surgery and in some cases, tumors initially considered unresectable without amputation shrank sufficiently to permit limb-sparing resection. There are several benefits of preoperative radiation. With the tumor in situ, there tends to be a smaller overall treatment volume and the theoretical advantages of more effective radiation because it is being delivered to an undisturbed tumor bed. There is also the potential benefit of decreased seeding during the course of resection and improved margin status because the radiation may shrink the tumor's pseudocapsule and render it relatively acellular. However, there is one major disadvantage to preoperative radiation and that is its detrimental effect on wound healing. Some groups have used an intraoperative or postoperative boost dose of radiation to the resection bed if there are concerns that margins are involved.

Increasing data support the use of resection alone for selected patients; those who have small (<5 cm), low-grade tumors seem to have acceptable local control and excellent long-term survival without radiation if wide margins are obtained at the time of resection.[68,69] Most patients undergoing resection may be candidates for additional radiation therapy because of high risk for recurrence, though its role in lower- or intermediate-risk patients is somewhat undefined, and the so-called therapeutic ratio of risk and benefits to radiation treatment must be carefully considered. Validated prognostic

tools may be helpful for individual patients weighing the benefits of available treatment options. Kattan et al. developed a nomogram to help better predict individual risk for 12-year disease-specific mortality in sarcoma patients using multiple prognostic factors simultaneously.[50] More recently, Callegaro and colleagues developed a multi-institutional, externally validated nomogram which is now available as part of the smart phone app (www.sarculator.com).[48]

For extremity sarcomas, the importance of pathologically negative margins must be emphasized. While differing widths of margins have been called "optimal," it is generally agreed that 1 to 2 cm are adequate, but that microscopically clear margins may be sufficient. Involved margins, along with age, recurrent presentation, and fibrosarcoma or MPNST subtypes, significantly increases the risk of local recurrence.[3,70] Patients presenting with involved margins following the index operation should be offered re-resection in order to obtain surgical clearance of margins. Several studies have shown no compromise in survival if complete resection is achieved with a second operation.[71] Interestingly, it is unclear if local recurrence predisposes to subsequent distant metastasis or if margin status is merely a proxy for aggressive disease.[70,72] Some histologies, such as myxofibrosarcoma, tend to track microscopically along neurovascular structures and fascial planes well beyond the visible extent of disease, and wider surgical margins should be considered.

Since the main cause of death in patients with soft tissue sarcoma is distant metastatic disease, continued efforts have been made to develop effective systemic therapies.[5,73] Postoperative adjuvant chemotherapy has been controversial because risk of adverse toxic effects may not be outweighed by the relatively low response rates and lack of durable results. The histologic subtypes of sarcoma vary in their responsiveness to chemotherapy. For example, osteogenic sarcoma, rhabdomyosarcoma, and Ewing sarcoma (the "pediatric" sarcomas) have had high rates of success with multimodality treatments including adjuvant chemotherapy.[61] Unfortunately, most randomized trials are underpowered to detect modest differences in survival and promising response rates reported in smaller nonrandomized clinical trials are not duplicated in subsequent larger randomized trials. In general, adjuvant chemotherapy is never indicated for patients with low-grade sarcomas and patients with small sarcomas of higher grades. Initial interest

in adjuvant chemotherapy for extremity soft tissue sarcoma was piqued by a randomized trial reported by Rosenberg et al. which demonstrated an improvement in disease-free and overall survival with adjuvant doxorubicin, cyclophosphamide, and high-dose methotrexate.[74] After a longer follow-up period (median follow-up 7.1 years), however, both disease-free and overall survival were not statistically significant.[75]

Over the years, single agents as well as combination chemotherapy regimens have been used in the adjuvant treatment of soft tissue sarcomas. Two of the more active agents include doxorubicin and ifosfamide. However, multiple randomized trials of postoperative chemotherapy have not demonstrated an improvement in disease-free or overall survival with intermediate- or long-term follow-up though there was a trend toward improved outcomes with chemotherapy in many studies.[61,76–78] The Sarcoma Meta-Analysis Collaboration evaluated the effect of adjuvant doxorubicin-based chemotherapy in 1,568 patients from 14 trials.[79] Although the time to local and distant recurrences, as well as recurrence-free survival, were significantly better in the treatment group, an overall survival advantage was not seen (HR 0.89, $p = 0.12$). Because of the rarity of disease and heterogeneity of tumor characteristics, most studies are too small to provide adequate power for testing responses in specific histologic subtypes. In general, many regimens have combined two of the most active agents, doxorubicin (or other anthracycline) and ifosfamide, and results from a randomized trial did show improved disease-free survival and overall survival; distant relapse rates were not different however.[80] A phase III trial randomizing patients with high-risk extremity soft tissue sarcomas (ESTS) to 5 cycles of epirubicine/ifosfamide or no chemotherapy following surgery (with or without radiation) failed to show a significant difference in disease-specific survival with long-term follow-up.[80,81] Outside of clinical trials, adriamycin and ifosfamide combination therapy is commonly used for high risk, primary extremity, and truncal sarcomas in the adjuvant setting. Newer regimens with promising results include the combination of gemcitabine and docetaxel which was initially discovered to be active in heavily pretreated uterine leiomyosarcomas and is currently being considered for use in that subtype as well as in high-grade undifferentiated pleomorphic sarcomas and other high-risk subtypes.[82–84] A phase II study comparing adriamycin and ifosfamide to the combination of gemcitabine and docetaxel found that the

latter regimen had a slightly lower hospitalization rate and trends toward longer disease-free survival rates.

Even with advances in systemic chemotherapy and targeted agents, data supporting greatly improved overall survival rates are sparse, especially in the adjuvant setting. For advanced tumors, treatments with single agents or combination regimens such as dacarbazine, doxorubicin, epirubicin, ifosfamide, gemcitabine, docetaxel, temozolomide, trabectedin, and eribulin have been trialed extensively. Newer targeted therapies have shown some promise in certain histologic subtypes. For example, tyrosine kinase inhibitor (TKI) agents such as pazopanib, imatinib, sorafenib, and sunitinib have shown efficacy in multiple subtypes after initial success with GISTs. The class of mTOR inhibitors (sirolimus, temsirolimus, everolimus) have demonstrated promise for perivascular epithelioid cell tumors (PEComas), lymphangioleiomyomatosis, and angiomyolipomas.

One potential advantage of upfront systemic chemotherapy is the ability to assess tumor response in situ. By seeing whether the tumor responds to the chemotherapy, both radiologically and pathologically, it may be possible to spare patients prolonged therapy if they have not shown a response, or to continue therapy postoperatively if there is response. Interdigitated neoadjuvant chemotherapy (doxorubicin, ifosfamide, and dacarabazine) and radiation therapy improved survival in a single-institution series, but when generalized to a multi-institutional study, the toxicities were prohibitively high.[85–87] However, data from a trial of preoperative doxorubicin- and ifosfamide-based chemotherapy conducted by the European Organisation for Research and Treatment of Cancer (EORTC) and the National Cancer Institute of Canada did not demonstrate any survival benefit compared to surgery alone.[88]

A series of recent European trials have also explored the utility of neoadjuvant chemotherapy for extremity soft tissue sarcomas. These studies established that three cycles of neoadjuvant therapy are not inferior to five cycles.[89] One particularly innovative trial randomized patients with high-risk extremity sarcoma to three cycles of neoadjuvant epirubicin/ifosfamide or three cycles of a histotype-tailored regimen (trabectedin for myxoid liposarcoma, gemcitabine/dacarbazine for leiomyosarcoma, gemcitabine/docetaxel for unclassified pleomorphic sarcoma, high-dose ifosfamide for synovial sarcoma, and ifosfamide/etoposide for malignant

peripheral nerve sheath tumor).[90] The hypothesis was that a tailored, histotype-specific regimen would be superior, but that proved not to be the case.

Some agents such as gemcitabine may have chemosensitizing properties,[91] making preoperative chemoradiation strategies attractive. Based on current evidence, neoadjuvant chemoradiation, either concurrent or sequential, should only be offered to selected high-risk patients on clinical protocol.[92] It is important to follow patients on neoadjuvant therapy closely since tumor progression is expected to be seen in approximately 30% of patients.[93,94]

Commonly used measures of radiologic response to treatment may not be good surrogate endpoints for treatment response.[34] The pathologic correlations of treatment-induced necrosis or histologic response to therapy with clinical outcomes have also not been well defined in soft tissue sarcoma.[95] Some patients who have a clinical or pathologic response to chemotherapy may have improved local control and decreased distant disease-free survival, but no overall survival advantage.[96] In other cases, lack of measurable response did not seem to predict significant differences in event-free endpoints.[93] These issues must be carefully considered in the design of future trials.

Alternative approaches to standard systemic therapy have been attempted with limited success. For example, preoperative radiation therapy in combination with intra-arterial doxorubicin chemotherapy initially showed good local control, but results could not be duplicated in subsequent randomized trials and treatments were associated with high morbidity.[97,98] Regional chemotherapy administered via hyperthermic isolated limb perfusion has been attempted for advanced extremity sarcomas. Extracorporeal circulation allows the delivery of drug concentrations 10 to 20 times higher than with systemic delivery and a European study showed a limb-salvage rate of 71% for unresectable extremity sarcomas using melphalan and tumor necrosis factor-α.[99,100] However, this technique is uncommonly used in the United States and usually reserved for highly selected patient populations.

Retroperitoneal and Intra-Abdominal Sarcomas

5 Management of intra-abdominal (visceral) and retroperitoneal sarcomas deserves special consideration since specific anatomic location may dictate work-up and subsequent management. The grouping of visceral sarcomas generally includes tumors of the gastrointestinal tract and gynecologic organs, and less commonly, genitourinary organs. Location often precludes early diagnosis, unless the mass is found incidentally. Though some patients have noted increased abdominal girth, an abdominal mass can be appreciated with focused physical examination, but it is uncommonly the presenting complaint. Typically, vague symptoms of mass effect intra-abdominally triggers medical evaluation. Neurovascular symptoms related to compression or invasion can occur and manifest as paresthesia, dysesthesia, weakness, and swelling or varicosities in the lower extremities.

Complete history and physical examination should exclude signs and symptoms of lymphoma (e.g., B-symptoms such as fevers and night sweats) and presence of scrotal masses concerning for testes cancer. Serum laboratory testing can be helpful if lymphoma (e.g., elevated lactate dehydrogenase [LDH]), germ-cell tumors (e.g., elevated beta-human chorionic gonadotropin [β-HCG] or alpha-fetoprotein [AFP]), or adrenal tumors (e.g., cortisol levels or adrenocorticotropic hormone [ACTH]) are in the differential diagnosis. High-quality cross-sectional imaging with CT or MRI is critical for diagnosis and treatment planning. Use of oral and intravenous contrast defines extent of primary disease and the relationship of the tumor to nearby structures. Chest imaging should be obtained to assess for presence of pulmonary metastases. Hepatic involvement is the second most common site of distant spread in intra-abdominal and retroperitoneal sarcomas, so a CT scan that includes the proper contrast phasing for examination of the liver should be done.

For large tumors, preoperative image-guided CNB can almost always be performed by experienced interventional radiologists with minimal risk of needle track seeding (**Fig. 106.9**).[101–103] Complete resection is the treatment of choice for intra-abdominal (visceral) and retroperitoneal sarcomas whenever possible. Only complete resection is associated with long-term survival benefit, with retroperitoneal liposarcomas being a possible exception.[104,105] For retroperitoneal sarcomas, median survival for those with an incomplete resection is similar to those who were observed (unresectable)[106] (**Fig. 106.10**). In general, incomplete resection should only

be considered for palliation of intractable symptoms. While successful palliation may be achieved in carefully selected patients, aggressive tumor biology limits the ability to maintain sustained relief of symptoms.[107]

In order to completely remove the sarcoma, en bloc resection of nearby structures should be considered when necessary. Resectability is more a function of location than of size, grade, or histologic subtype. Common reasons for unresectability include distant metastasis, peritoneal metastasis, extensive multifocality, and prohibitive vascular involvement. Though sarcomas do not uniformly invade other structures, involvement of vascular structures or mesentery (mesocolon) may lead to resection of solid organs or bowel that may not be directly involved. Furthermore, detailed pathologic analysis does show that adjacent structures, such as ureters, can be invaded even when no invasion is suspected.[108–110] When nephrectomy may be necessary, it is important to assess bilateral renal function with preoperative contrast scanning. Concomitant nephrectomy, when necessary, is associated with comparable outcomes for retroperitoneal sarcomas overall.[111] Commonly resected organs include the following: kidney, colon, adrenal gland, pancreas, and spleen.[112] For tumors located in the pelvis, it may be necessary to perform en bloc resection of the colon/rectum, bladder, and uterus. When vascular structures limit complete resection of tumor, resection with ligation or reconstruction of vessels must be considered if technically feasible (**Fig. 106.11**).

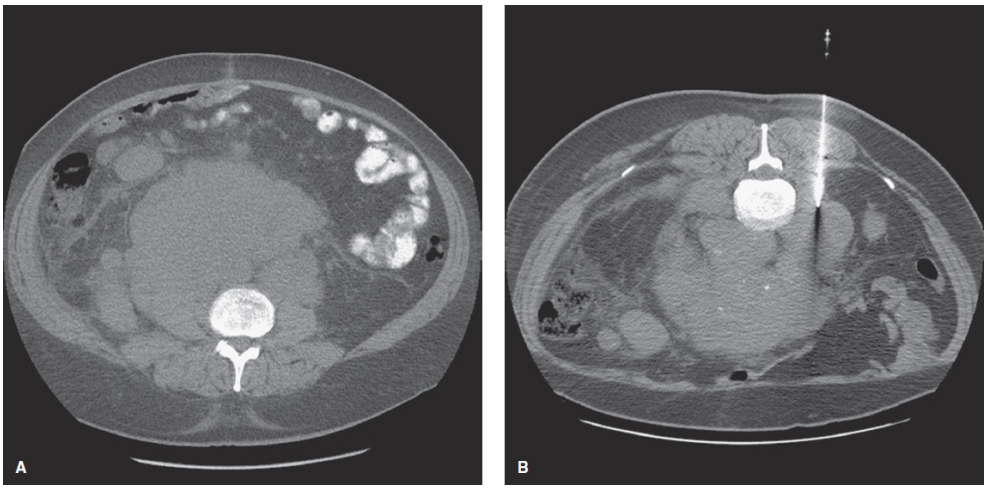

Figure 106.9 Biopsy can be helpful in the workup of retroperitoneal masses. **A:** CT scan shows a retroperitoneal mass encasing the IVC and aorta. **B:** Image-guided biopsy is demonstrated here. Pathology confirmed a diagnosis of large B-cell lymphoma.

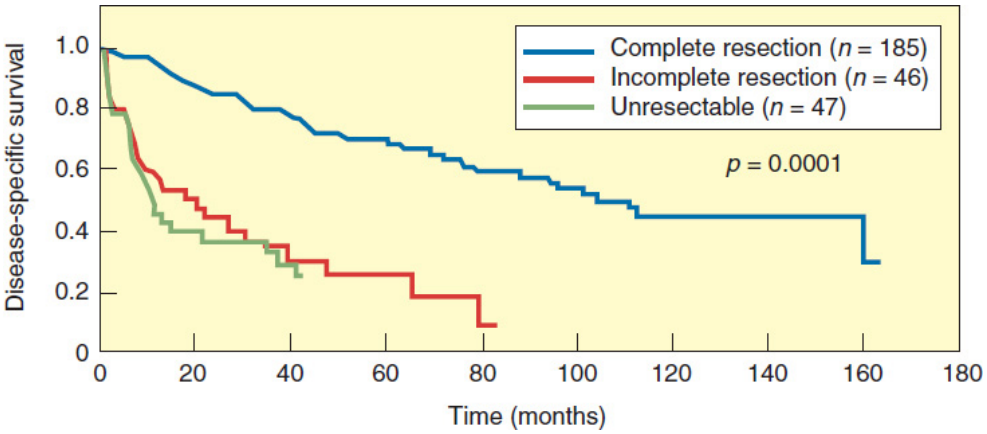

Figure 106.10 Kaplan–Meier plot of disease-specific survival for patients with retroperitoneal sarcomas treated at Memorial Sloan Kettering Cancer Center. Disease-specific survival is 103 months in patients who underwent complete resection of retroperitoneal sarcomas, compared to 18 months in those who had an incomplete resection or just observation. (From Lewis JJ, Leung D, Woodruff JM, et al. Retroperitoneal soft-tissue sarcoma: analysis of 500 patients treated and followed at a single institution. *Ann Surg* 1998;228(3):355–365.)

Even when resection is possible and complete gross resection is achieved, margin status is often compromised by constraints of visceral anatomy. A transperitoneal approach allows for excellent exposure and facilitates en bloc resection of with early control of the vascular supply to the tumor. Analyses of relatively aggressive approaches to resection include complete compartmental resections and liberal use of en bloc visceral resection show

better local control, but high-grade tumors tend to recur systemically.[113–115] Proper patient selection for the so-called "aggressive resection" needs to be weighed against the natural history of sarcoma. It is generally agreed that the best chance for curative intent resection is at the time of first operation. Complex multivisceral operations should be referred to higher-volume centers with experienced sarcoma surgeons when possible. Unfortunately, large national database studies suggest that only approximately 10% of patients undergoing surgery for primary retroperitoneal sarcoma are treated at high-volume centers.[116]

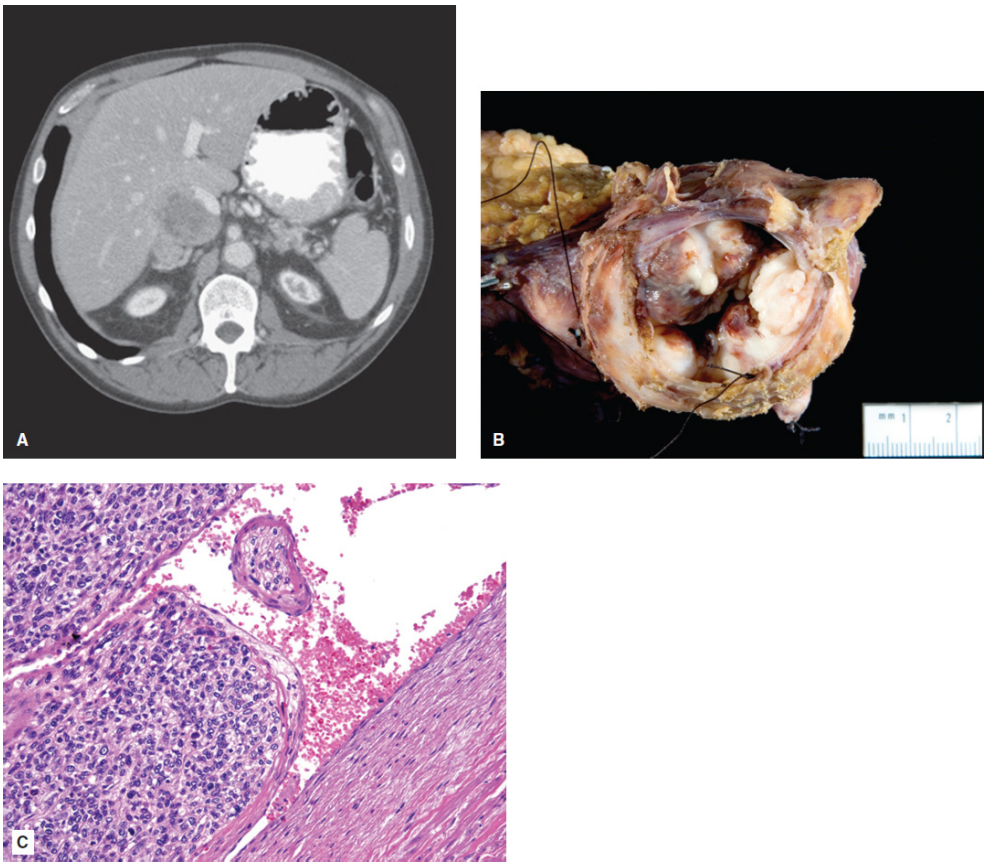

Figure 106.11 Inferior vena cava (IVC) leiomyosarcoma. **A:** CT scan demonstrates a 9.2 × 6.4 × 4.4 cm mass within the lumen of the retrohepatic IVC. **B:** Photograph of the gross specimen. Cross-sectional view from the superior aspect of the specimen demonstrates the extensive filling of the lumen with multilobulated tumor. **C:** Photomicrograph demonstrating intraluminal high-grade leiomyosarcoma with nuclear atypia and pleomorphism. Uninvolved smooth muscle of the IVC is shown (right lower quadrant). (Courtesy of Jason Carvalho, MD and David R. Lucas, MD, University of Michigan, Ann Arbor, MI.)

Even with aggressive surgical management, local recurrence rates range from 40% to 70% for high-grade tumors.[12,113,117] Unlike extremity sarcomas, local progression is associated with decreased survival. Difficulty obtaining negative margins and high recurrence rates support a role for carefully selected multimodality treatments. The major advantage of preoperative radiation is the displacement of small bowel and other structures by the in situ tumor. However, the benefits of radiation for extremity sarcomas have not been similarly appreciated for retroperitoneal sarcomas and no improvement in disease-free intervals has been noted.[118,119] In fact, the only randomized trial to examine the benefit of radiation plus surgery versus surgery alone found no improvement in the rate of abdominal recurrence-free survival, though there may be a potential use in selected patients with well-differentiated liposarcoma.[119] Large field sizes and the dose-limiting toxicity of abdominal viscera limit the utility of postoperative radiation. The role of chemotherapy, either in the pre- or postoperative setting, is unproven for intra-abdominal and retroperitoneal sarcomas.[120,121] Several trials of postoperative adjuvant chemotherapy do not show any benefit for patients with retroperitoneal sarcoma, and in one series, treated patients fared worse than those not receiving chemotherapy.[122] In one trial of an aggressive multimodality approach, there was an improvement in locoregional control but no overall survival advantage and significant toxicity from the chemotherapy and radiation therapy.[123] Though some histologic subtypes, such as leiomyosarcoma, pleomorphic sarcoma, or myxoid/round cell liposarcoma, may be relatively more responsive to systemic treatments, a paucity of data exist to guide appropriate use of therapy. Randomized controlled trials have been notoriously difficult to accrue patients to. Of note, different histologic subtypes arising in the retroperitoneum have different patterns of recurrence.[113] In particular, high-grade dedifferentiated liposarcoma and leiomyosarcoma can spread commonly to the lungs, and a phase 3 trial testing histotype-specific neoadjuvant chemotherapy is anticipated to start accrual in 2020.[113]

Special consideration is also given to complete resection with functional preservation in head and neck sarcomas and genitourinary sarcomas. As is true of sarcomas in other anatomic locations, histologic grade and size adversely affect prognosis for head and neck sarcomas.[124] Resections with negative margins may not require adjuvant radiotherapy treatments.

Similarly, grade, size, location, and histologic subtype similarly predict disease-specific survival for genitourinary sarcomas.[125] Regional relapse is influenced by margin status so radical resections are necessary. Unfortunately, recurrences are not uncommon and may be difficult to control due to anatomic location.

Recurrent or Metastatic Disease

About two-thirds of soft tissue sarcoma recurrences occur in the first 2 years after diagnosis and treatment, though recurrences may be seen at any time.[126] Recurrences may be classified as locoregional or distant. Though no standardized follow-up regimens exist, routine history and physical examination (clinical follow-up) and interval chest imaging are recommended for the first 2 to 3 years. Site-specific imaging guidelines are less clear. Directed cross-sectional imaging studies are helpful if location of tumor precludes early detection of recurrence on clinical evaluation alone. Of course, the choice of imaging study depends on availability, cost, and anatomic site being examined. MRI of the extremity or trunk can help detect locoregional recurrences when they are relatively small. CT scans may be useful for demonstration of intra-abdominal or retroperitoneal recurrences which would otherwise be clinically undetectable. However, there is no evidence that earlier detection improves survival for retroperitoneal sarcomas,[106] so a less aggressive imaging schedule may be appropriate. A randomized trial in India failed to find any survival benefit in using CT scans of the chest over CXR for surveillance for extremity sarcomas.[127] There are some retrospective data suggesting that lower-risk extremity sarcomas may simply need distant site surveillance, since risk of local recurrence is low and when it occurs, is often detectable on clinical examination alone.[128]

If chest radiography is used, abnormal findings should be followed with a CT scan of the chest. Low-grade lesions infrequently metastasize in the absence of local recurrence, though can recur locally up to 20 years after original resection. For high-grade lesions, surveillance should be directed toward detecting local recurrence and metastatic disease. Patients with locally recurrent or even metastatic sarcomas can be considered for subsequent resection if tumor biology supports potential cure or effective palliation with removal of known disease. A nomogram to predict the

outcomes after resection of recurrent retroperitoneal sarcoma has been reported, though these are subject to selection bias.[52] Recurrent disease, especially within the abdomen or retroperitoneum, becomes more difficult to treat with each recurrence.[117]

If a recurrence is suspected, a biopsy should be performed to confirm diagnosis and review histologic subtype as well as tumor grade, with comparison to the original tumor if possible. In the absence of distant disease, an aggressive surgical approach is warranted with the goal being the same as with a primary sarcoma: control of the tumor and preservation of as much function as possible. For patients who were initially treated with surgery alone and who recur locally, multimodality treatment with repeat resection, radiation, and sometimes chemotherapy is associated with survival rates close to those of previously untreated patients.[129–131] Independent predictors of survival in patients with locally recurrent extremity soft tissue sarcomas include histologic grade, size of recurrent disease, and recurrence-free interval.[132]

The most common site of distant metastatic disease is the lung, and its presence is not detectable by symptoms. Again, CT is the preferred imaging modality, though its very high sensitivity for detecting pulmonary nodules as small as 2 mm decreases its specificity.[133,134] Occasional patients have liver, bone, or central nervous system metastases, though these sites of disease are relatively uncommon. Once diagnosed, metastatic disease is best approached with systemic chemotherapy, either as a single agent or with combination treatments. Pulmonary metastases are the most common form of distant disease, and metastasectomy in carefully selected patients seems to improve outcomes. Taking patient selection into account, resection of pulmonary metastases in combination with radiation and/or chemotherapy, may improve outcomes compared to resection alone[135,136] (**Fig. 106.12**). However, there are no randomized trial data to determine if there is truly any benefit to resecting lung metastases. Patients considered for resection generally have better outcomes if they have a limited number of metastases, longer disease-free intervals, and leiomyosarcoma or osteosarcoma histologies.

Gastrointestinal Stromal Tumors

6 Another subtype of sarcoma which deserves separate consideration is GIST. Prior to modern molecular diagnostic techniques, these tumors were likely to have been considered leiomyosarcomas based on histologic features.[12] It is now known that GISTs are differentiated from GI leiomyosarcoma based on lack of well-differentiated smooth muscle cells. GISTs are composed of more primitive mesenchmyal cells and originate from the interstitial cell of Cajal, which functions within the GI autonomic nervous system. Immunohistologic diagnosis is primarily made via expression of KIT (CD 117) cellular markers (**Fig. 106.13**). KIT overexpression is usually related to mutations in the *KIT* gene, although *PDGFR*-α mutations can also result in KIT overexpression in approximately 3% to 5% of GIST. KIT-negative GISTs have been reported, though tumor genotyping should be done to either *KIT* or *PDGFR*-α mutations even with negative immunohistochemistry for KIT.[137] Mutations in *NF1* and *BRAF* have been reported in GIST, and deficiency in *SDH* can cause GIST as well.

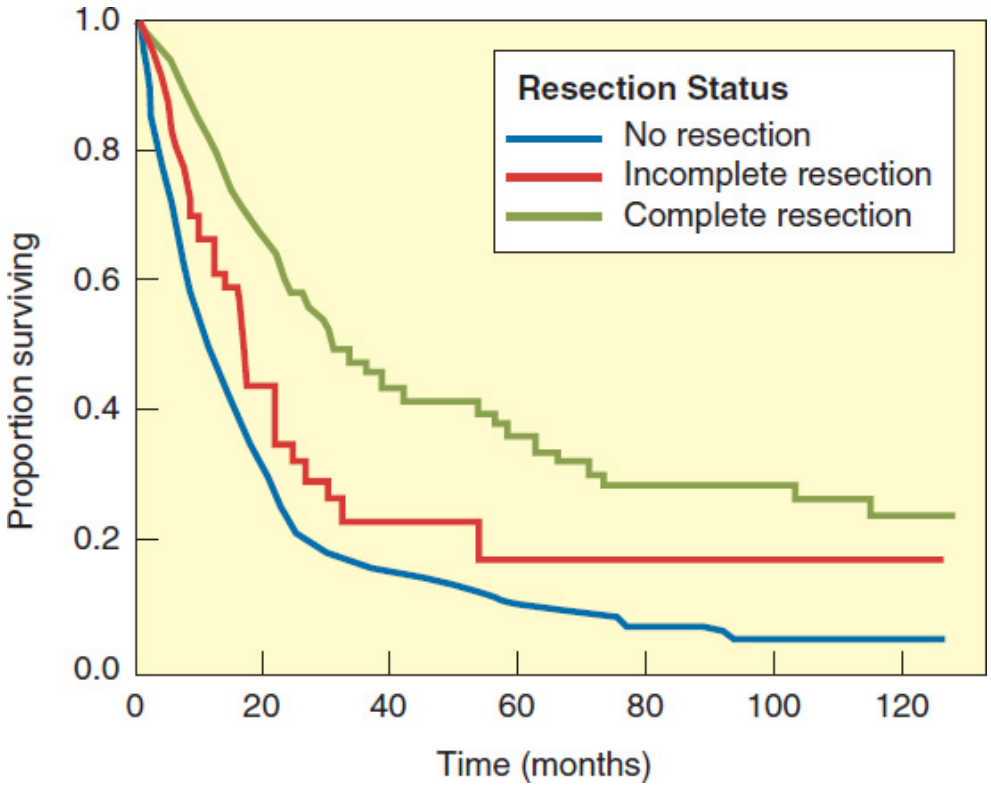

Figure 106.12 Kaplan–Meier plot of disease-specific survival for patients with pulmonary metastases treated at Memorial Sloan Kettering Cancer Center. Patients treated with complete resection had a median survival of 33 months. Patients who underwent incomplete resection or who did not undergo resection had median survival of 16 months and 11 months, respectively. (From Billingsley KG, Burt ME, Jara E, et al. Pulmonary metastases from soft tissue sarcoma: analysis of patterns of diseases and postmetastasis survival. *Ann Surg* 1999;229(5):602–610.)

The *KIT* proto-oncogene encodes for KIT protein, a transmembrane glycoprotein receptor with an intracellular tyrosine kinase domain. Binding of the KIT ligand induces dimerization and autophosphorylation of KIT, activating a cascade of intracellular signaling which results in cell proliferation and tumorigenesis. A gain of function mutation in KIT occurs in up to 90% of GIST[138] and results in ligand-independent (constitutive) activation of tyrosine kinase function.[139] KIT mutation is found in 90% of GISTs and the most frequent sites of mutation are found in exon 11 (70%) or exon 9 (10%), whereas rare mutations are found in exon 13 or exon 17.[140] Mutation status may affect prognosis, and testing has become more routine in the evaluation of GIST.

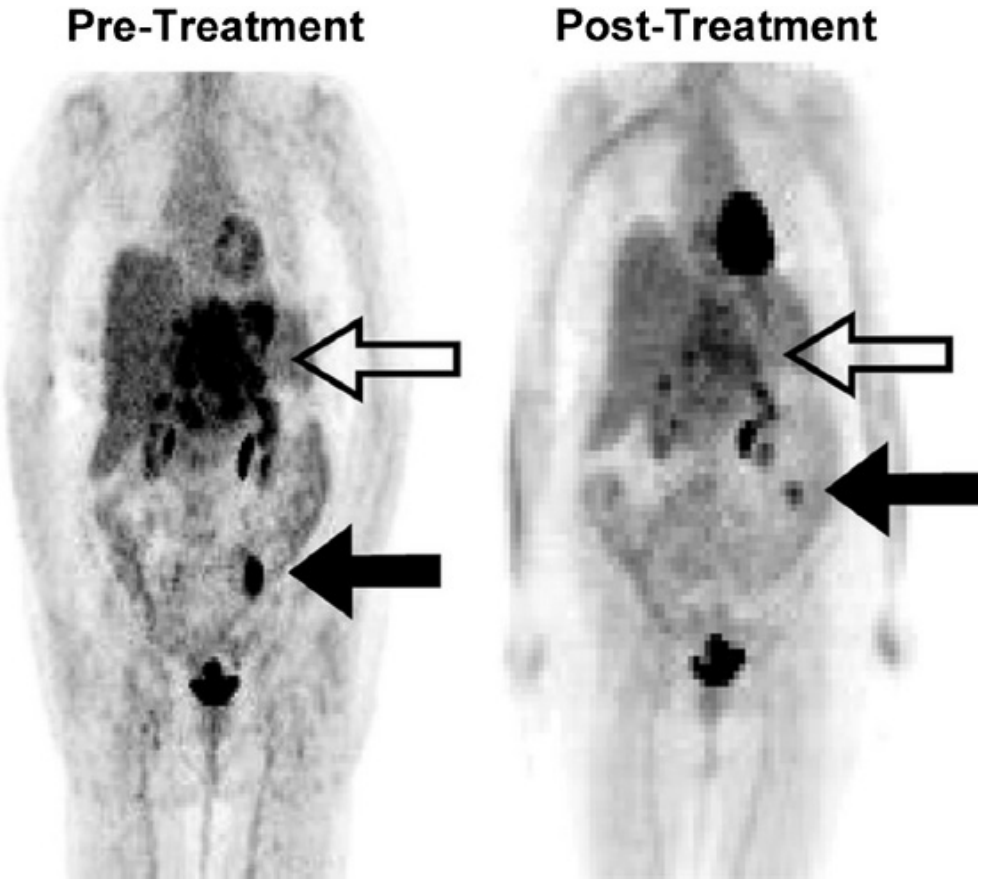

Figure 106.13 18FDG-PET scan showing response of metastatic GIST to imatinib mesylate. This patient presented with primary disease in the small bowel and synchronous metastatic disease in the liver. The scan at presentation (**left**) compared to the one obtained after 3 weeks of therapy (**right**) shows decrease in size of tumors and decrease 18FDG uptake in both the small bowel and liver tumors consistent with a good response to imatinib. The patient eventually went on to complete surgical resection. (From Gold JS, DeMatteo RP. Combined surgical and molecular therapy: the gastrointestinal stromal tumor model. *Ann Surg* 2006;244(2):176–184.)

Swedish epidemiologic data estimate 14.5 cases per million, which translate to an annual U.S. incidence of 4,000 to 5,000 new cases of GISTs per year.[141] GISTs are largely sporadic, but they have been seen in association with hereditary syndromes such as Von Recklinghausen disease and Carney triad, and familial germline mutations have been identified. Clinical presentation can be indolent: most patients have nonspecific symptoms such as nausea, emesis, or abdominal discomfort. Infrequently, GISTs can rupture or bleed, leading to a more emergent presentation. GISTs are most commonly found in the stomach (50% to 60%), with 30% to 40% of

tumors in the small bowel, 5% in the colon or rectum, and 5% in the esophagus. Rarely, GISTs develop within the mesentery, omentum, or retroperitoneum. Most GISTs are found in adults over the age of 40, with a median age of 60 years. Tumors found in children or young adults are considered a separate entity since pediatric GISTs have a more epitheliod histology and wild-type KIT or PDGFR-α genotype, often harboring mutations in one of the subunits of SDH.[142]

Complete resection is the treatment of choice for primary GIST, but recurrences are common and 5-year survival following resection of a localized tumor is approximately 50%.[143] Recurrences are common and thought to occur at 18 to 24 months from the time of the index operation. Lymph node dissection is not warranted because GISTs very rarely metastasize to regional nodes. Treatment of GIST was revolutionized with the development of imatinib mesylate (Gleevec), a selective tyrosine kinase inhibitor, representative of the emerging paradigm of molecularly targeted therapies. The proof of concept for this treatment paradigm was demonstrated in 2000 when a patient with diffuse metastatic disease achieved a near complete metabolic response[144] on PET and with 75% reduction in tumor size at 8 months and histologic evidence of myxoid degeneration and lack of mitotic activity. Contemporary use of imatinib in patients with metastatic GIST is considered an appropriate first-line treatment of metastatic disease (**Fig. 106.13**).

For patients who present with localized tumors, resection remains the mainstay of treatment. Interestingly, emerging evidence suggests that incidentally discovered, very small GISTs (<2 cm) may be successfully managed expectantly.

The use of imatinib in the adjuvant setting has been informed by a number of clinical trials. Mutation status is predictive of treatment success: *KIT* exon 11 mutations are associated with better response rates and survival endpoints than exon 9 mutations and wild-type GISTs. Because of high rates (>50%) of recurrence or metastasis following resection, at least 3 years of imatinib is recommended for high-risk tumors, including tumors which are greater than 5 to 10 cm in size or contain more than 5 mitoses per 50 HPFs, based on phase III trials.[145,146] Safety and efficacy for up to 5 years of adjuvant imatinib have been confirmed in a single-arm phase II study, and a randomized trial comparing 3 to 5 years of adjuvant imatinib is underway.[147] Risk

stratification must be approached with care; other factors which need to be considered include location of tumor and mutation status. It is reasonable to consider the use of imatinib for large or borderline resectable lesions prior to surgical resection. Most of these cases require continued treatment after resection given high risk of recurrence or metastasis. Second and third (and beyond) line therapies are available for drug-resistant disease, but as expected, responses following failure of first-line therapy are highly variable.

Desmoid Tumors/Desmoid Fibromatosis

Desmoid tumors warrant separate notation in the discussion of soft tissue sarcomas because of their distinct biologic behavior.[14,148] Desmoid tumors, or aggressive deep-seated fibromatosis, are part of a rare group of fibrous tissue proliferations which have no propensity for metastasis but tend to be locally aggressive. The natural history of desmoid tumors is not well defined and poorly understood. Clinical behavior and therefore, recommended treatments, are often dictated by anatomic site. Location of tumors can limit therapeutic options and result in significant morbidity with or without surgical resection.

Desmoid tumors are uncommon with an estimated incidence rate of two to four cases per million per year. The median age of diagnosis is 35, range 16 to 79 years. Desmoids are slightly more common in women than men. Desmoid tumors are classically described as an abdominal wall tumor, seen in young women during the postpartum period.[149] However, desmoids can occur at any site in the body and three main anatomic groupings are described: (1) trunk or extremity, (2) abdominal wall, and (3) intra-abdominal (bowel and mesentery). Fibromatosis is usually seen sporadically, but can be associated with FAP.

Desmoids are characterized by a monoclonal fibroblastic proliferation arising from muscular or aponeurotic structures. On gross examination, the tumors appear firm and smooth, with a surrounding pseudocapsule. However, microscopically, the tumor characteristically extends beyond this pseudocapsule, with fibrous septae of tumor extending radially. Desmoid tumors had previously been classified as an unchecked reactive process rather than a neoplastic process, but uniform patterns of X-chromosome

inactivation seems to confirm tumors of clonal composition.[150] There appears to be an increased estrogen receptor-β, but not estrogen receptor-α, expression in 80% of desmoid specimens.[151] These findings lend some support for the treatment of tumors with adjuvant agents such as tamoxifen.

Tumors tend to be located in deep in the muscles or along fascial planes, such as at a point of muscular insertion. Patients will usually present with a greater than 5 cm, localized, firm mass with an indolent pattern of growth, which can minimally painful. Intra-abdominal presentations can be associated with mass effect, intestinal obstruction, or mucosal ischemia. Desmoid tumors are notoriously infiltrative, and microscopically involved margins are seen in a significant number of patients following resection.

Surgery is no longer considered the standard of care or first-line treatment.[152,153] Many patients can undergo watchful waiting as a front-line approach, as many will never need resection. If tumors do grow under observation, systemic therapy or targeted therapy should be considered. Resection is only rarely needed and should not be offered without considering alternative options first. However, women with desmoids considering a pregnancy may be considered for resection as desmoids may grow during pregnancy.[154]

CONCLUSIONS

As understanding of sarcomas continues to evolve, it has become increasingly clear that therapy must be individualized to each unique presentation, taking into account histologic subtype, primary tumor site, tumor grade, patient comorbidities, and the full spectrum of multidisciplinary treatment options. Patient referral to a specialized sarcoma center is recommended.

Plastic and Reconstructive Surgery

Anthony P. Tufaro, Christian El Amm, E. Gene Deune, Michele A. Manahan, and Sachin M. Shridharani

Key Points

1. The process to obtain a closed wound will take a number of steps, the first of which will be excision of necrotic and grossly infected tissue. Antibiotics alone will not heal a problem wound.
2. The incidence of problem wounds is growing exponentially. Surgeons are seeing more patients with chronic medical problems that lead to nonhealing wounds. The management of these wounds requires a comprehensive evaluation of the patient factors that are adding to the problematic nature of the wounds.
3. The use of negative pressure devices has changed the approach to chronic wound management.
4. The ability to move vascularized soft and hard tissue from either local, regional, or distant sites allows surgeons to reconstruct congenital, traumatic, and oncologic defects and move patients forward and return them to a functional condition.
5. Pediatric congenital anomalies should be addressed with a comprehensive team of experienced specialists. Cleft lip and palate can be complete or incomplete, unilateral or bilateral. The problem affects speech, eating, swallowing, breathing, facial growth, hearing, and dental development.
6. Successful outcome for patients with complex hand problems requires meticulous surgical technique and careful attention to postop hand therapy.
7. Reconstructive and aesthetic procedures of the breast have become very common in our society. Oncologic reconstruction can be achieved with implant-based techniques or autologous tissue. Both offer women a safe and reliable return to appearance optimization and self-confidence.
8. The use of autologous tissue, for the most part, utilizes excess soft tissue of the lower abdominal wall. The tissue can be mobilized on and perfused by the rectus abdominis muscle or transferred as a microvascular free tissue transfer. The choice of techniques is based on patient factors and surgeon experience.

9 The request for aesthetic surgery procedures in our society is growing exponentially.

10 Aesthetic surgery is at its core elective surgery, performed on patients who are trying to achieve a change in something about their appearance. Whether that desired change is obvious to others is less important. Thus, there is very little room for error in evaluation, both physical and psychological. The surgery itself must be carried out by experienced surgeons who understand anatomic basis of the surgery.

11 The advent of nonsurgical aesthetic techniques, most of which utilize injectable medications, has opened up the field of aesthetic surgery to a much wider patient population.

The specialty of plastic surgery was initially approved as a subsidiary of the American Board of Surgery in 1938 and given the status of a major specialty board in 1941. The field of plastic surgery saw major growth during the two world wars. The urgent need for surgeons to treat burns, craniomaxillofacial trauma, hand and upper extremity injuries, and the associated ongoing reconstruction that many of these patients required, spurred a rapid development of new techniques and surgeons interested in limiting their practice to this field. The field of microsurgery, craniomaxillofacial surgery, reconstruction of peripheral nerves, oncologic reconstruction, and gender-affirming surgery are all fields that have been developed or expanded by plastic surgery. It is often forgotten that the first successful human renal transplant was performed by a plastic surgeon.[1] The scope of plastic surgery may be the broadest of any surgical specialty (**Table 107.1**). For this chapter we will limit our discussions to those areas that will be of the greatest interest and benefit to the reader.

MANAGEMENT OF THE PROBLEM WOUND

Plastic surgeons are often called upon by surgical and medical colleagues to assist in the management of recalcitrant wounds. When attempting to design a

treatment plan it is important to first do a thorough patient and wound analysis. The specific patient factors that are affecting the wound-healing process need to be identified. Maximizing the patient's nutritional status, controlling serum glucose, and physical therapy to improve patient conditioning to increase mobility will all help in management. A pressure wound can be improved by instituting algorithms such as pressure-reducing mattresses and other devices, eliminating soiling and moisture control and scheduled repositioning. Thus, we see that elimination of controllable factors can influence our success in closing a problem wound. The local wound [1] conditions can be improved with debridement of necrotic tissue and moisture control in an effort to maximize our eventual efforts at closure. While there are many different causes of nonhealing, problem wounds, the factors mentioned above will aid in in the management of all of them. Due to the varied types and locations of wounds there is no one reconstructive option to close a given defect. The use of an algorithmic approach needs to be followed and a number of options need to be considered for the given problem. You always need to have a fallback option.

Wound Evaluation

Problem wounds are often associated with a multiplicity of causes. These can be both local and systemic. It is critical to evaluate all of these factors if you want to achieve success. The causative etiology of the wound is the first factor to consider. A venous stasis ulcer is very different that an open tibial fracture. While both are lower extremity wounds the management of them is markedly different. The duration of the wound, previous surgical and nonsurgical treatment attempts and history of wound infections are important factors in decision making. Associated complicating factors such as previous malignancy, [2] irradiation, or chronic trauma are all associated with nonhealing wounds. Patient systemic factors that are associated with impaired wound healing such as immune deficiency, immune suppression, chemotherapy, and chronic medical conditions such as diabetes, problems requiring chronic steroid use, nicotine addiction, dietary deficiency, and the natural immune compromised state associated with old age must all be taken into consideration when addressing a nonhealing wound (**Fig. 107.1**, lower extremity wound in elderly diabetic female).

Table 107.1 The Spectrum of Plastic Surgery
Aesthetic surgery
Burns: acute and reconstructive surgery
Craniofacial surgery
Cutaneous and soft tissue oncology
Hand and upper extremity surgery
Head and neck oncology
Microvascular surgery
Maxillofacial and orthognathic surgery
Peripheral nerve surgery
"General" reconstructive surgery Face (ear, lip, nose, and eyelid) Breast Trunk Lower extremity

The careful examination of the wound requires recording the size and depth of the wound. All progress will be compared to these early measurements. The presence of compromised or exposed structures such as bone or vascular structures must be recognized early on and a plan to address them must be formulated. Traumatic wounds may contain foreign bodies. These wounds can be evaluated with plain films to evaluate for the presence any foreign material. The recognition and elimination of necrotic tissue is a necessity prior to any reconstructive effort. Chronic wounds may actually represent a malignant process either local or emanating from deeper tissues. All debrided tissue must go to pathology for evaluation. All chronic open wounds must be understood to be colonized. However, this is quite different than an "infected" wound. The classic signs and symptoms of infection that all surgeons recognize; pain, erythema, fetid drainage, swelling, fluctuance, and decreased function are all easily identified. The presence of a positive

bacterial culture from a surface swab does not indicate a clinically significant infection.[2] The soft tissue surrounding the wound must be evaluated. Will it tolerate the mobilization, and undermining needed to create a flap or other techniques used to move tissue in an effort to close a wound? Tissue that has been irradiated or has had previous surgical attempts at elevation and closure may not tolerate further surgical insult and actually lead to a larger wound. (See **Table 107.2** for factors associated with impaired wound healing.)

Figure 107.1 Problem lower extremity wound in elderly diabetic woman on chronic steroid therapy. The wound is secondary to minor shear injury.

Table 107.2 Local and Systemic Factors that Affect Wound Management

Local Factors	Systemic Factors
Infection	Immune deficiencies
Local malignancy	Distant malignancy
Foreign bodies	Diabetes mellitus
Local toxins	Cigarette smoking
Radiation	Chemotherapeutic agents
Ischemia	Hereditary healing disorders
Venous insufficiency	Nutritional deficiency
Lymphatic insufficiency	Old age
Repetitive trauma	Uremia
Reduced sensation	Glucocorticoid therapy, immunosuppressive agents

Obesity and diabetes are ubiquitous in our society and are recognized risk factors for compromised wound healing. These two factors may also make local flaps and tissue rearrangement fraught with problems.

Directed laboratory studies such as serum glucose, HA1c, prealbumin, hemoglobin and hematocrit, and renal and liver function tests may be useful adjuncts to treatment planning. Tissue biopsy rather than surface swabs may be useful in evaluating the need for antibiotic therapy.[3] Bacterial counts greater than 10^5 per gram of tissue represent a bacterial load that may not support wound closure with skin graft or tissue rearrangement. The use of wound biopsy information has been used in the management of burn wounds.[4] The presence of bacteria in the deep dermis closely correlates with burn wound sepsis. It is also very important to determine if osteomyelitis is a contributing factor in recalcitrant wounds. Open wounds that extend to bone can be evaluated with standard radiographs, CT, or MRI, however the only way to definitively prove or disprove osteomyelitis is with a well-directed bone biopsy. MRI can be used to delineate the extent of boney involvement. The imaging studies can reveal fractures, osteolytic areas and loss of cortical integrity, and suspicion of bone involvement with infection but not conclusively diagnose osteomyelitis. If osteomyelitis is diagnosed it will

require extensive resection/debridement and delay the reconstruction until you can be sure the infection is cleared. Antibiotics alone will not cure osteomyelitis. The necrotic bone is devascularized and antibiotics will not penetrate to the involved bone. The combination of bone debridement and antibiotics directed by the identification of the pathogens as cultured from the bone biopsy will allow for definitive elimination of bone infection and predictable wound closure.

The Treatment Paradigm for Wound Management

Following thorough evaluation of wound and patient factors you should address those factors discussed above that can be modified to optimize the outcome of wound closure. The goals are to have a closed wound and restore the patient's level of function. In our evaluation we recognize that some problems in wound healing should be anticipated and prevented prior to definitive surgery. The worst-case scenario is that the patient has a surgical procedure for wound closure and then goes on to develop another wound or the surgical site breaks down. As mentioned earlier, glucose control, control of fluids, and drainage and pressure off loading must be planned prior to surgery. The bedridden or paralyzed patient must have close nursing care for repositioning and the family must be educated as to the necessary preventive measures. Aggressive physical therapy will ensure maintenance of joint motion, decrease extremity edema, and optimize the patients conditioning for the postop period. These plans should be made and discussed with the care team, patient, and family prior to definitive surgery.

There will be, by necessity, some period of time prior to definite surgery when the wound will need to be optimized. We discussed the need for debridement of necrotic tissue, control of infection, and moisture/drainage control. Dressings and nonsurgical adjuncts can be very useful in preparing the site for surgery. Moist to dry dressings are the most commonly used dressing to debride a dirty wound. The operative word is moist not wet. If the dressings are too wet they will not dry out between dressing changes and will macerate the tissue causing more problems. These types of dressing have been used for over 100 years and are still recognized as being quite

effective for debriding wounds. Saline, calcium hypochlorite 3% to 4% or weak acetic acid solution can all be used as the moistening agent. The dressing actually debrides the wound by drying out and having the necrotic material stick to the dressing. The dressing is removed and the debris is removed with it. The dressing must be changed two to three times per day. Wounds with significant drainage will need to have the more frequent dressing changes.

Moist wound environments heal faster than dry wounds.[4,5] The best option for moist wound healing is keeping the native scab in place. Since there should not be a need for debridement with a clean wound, a nonadhering occlusive dressing can be applied. Hydrogels which are very effective in maintaining a moist wound healing environment are a good option for relatively clean wounds. A well-prepared wound cleared of necrotic debris can go on to heal by secondary intention with local wound care and dressing changes.

For the most part, the application of topical antibiotics is not indicated in the management of noninfected wounds. As discussed, all open wounds will be colonized and there is no real benefit to attempt to sterilize them. However, the judicious use of topical antibiotics can be helpful in certain situations. Significant burn wounds are often dressed with silver sulfadiazine. Silver sulfadiazine is bactericidal for many gram-negative and gram-positive bacteria as well as yeast. Mafenide acetate, also a sulfa-based drug, is also used for burns and other deep partial-thickness and full-thickness wounds. It is rapidly absorbed through open wounds and can be used on ear wounds due to its ability to penetrate cartilage. Mafenide is a potent carbonic anhydrase inhibitor and can cause hyperchloremic metabolic acidosis with chronic use. This drug can cause considerable pain on application, limiting its use. This drug also has antibacterial activity against most gram-positive and many gram-negative species commonly found in wounds. These topical drugs are not effective against methicillin-resistant *Staphylococcus aureus* (MRSA)–colonized wounds. Mupirocin topical ointment can be used in this situation with good effect. There has been an explosion in the use of nanocrystalline silver in dressings, both barrier and alginates. The silver dressings have low toxicity and excellent antibiotic properties. They can add significant cost to the dressing regimen.

Over the last number of years there have been a number of advances in the nonsurgical management of wounds, particularly problematic chronic wounds. These advances include the use of biologic and nonbiologic agents such as the application of growth factors to wounds, cellular therapies, and other physical modalities.[6] Recombinant platelet derived growth factors (PDGFs) may be useful in the management of chronic pressure wounds and diabetic foot ulcers[7,8]; there is no clear evidence that topical growth factors have a significant role in the management of acute wounds. Wound repair is a complex process and is influenced by numerous secreted factors, including cytokines, chemokines, and growth factors. In theory, application of stem cells to wounds is advantageous over administration of a single agent because stem cells have a unique feature of interacting with wound environment and modulate their activity to release multiple factors, which may facilitate wound healing process. However, the use of stem cell therapy to treat difficult wounds must be considered to be unproven and at this time investigational.[9]

The use of "off the shelf" skin substitutes such as bilaminate bovine collagen/silicone sheet have shown to have application in complex burn, oncologic, and trauma wounds.[10] It acts as a dermal substitute and renders a more stable construct and skin graft bed. Human and xenograft acellular dermal substitutes have been widely used in the management of all types of wounds. The thicker versions of these materials can be used to add structural support to complex abdominal wall and breast reconstruction.

Perhaps the most impactful innovation on the management 3 of chronic and problem wounds has been the development and application of negative pressure wound therapy. There are many options now available but all have the same basic elements of a sponge which is placed in the wound. It is then covered with an impervious plastic adhesive sheet and a suction device is place on a hole cut into the plastic sheet. There have been a number of innovations to the basic setup. The sponge can come with various pore sizes and can be impregnated with silver for infected wounds. Sponge and plastic sheeting systems have been modified for the management of complicated abdominal wounds with exposed viscera. These systems have changed the approach to complex open abdominal wounds. The use of the negative pressure device has been shown to control wound fluid, decrease wound edema, promote tissue perfusion, and stimulate granulation tissue in the

wound bed. There have been numerous clinical and experimental papers that attest to the efficacy of the negative pressure wound devices.[11] The systems are relatively easy to use, decrease the need for frequent dressing changes, help to control wound fluid, and decrease edema. The negative pressure wound devices should not be used in infected wounds. As pointed out throughout this discussion a positive culture from a surface swab indicates a colonized wound not an infected wound. The cost of the system needs to be balanced against all of the other positive factors including a shorter time to wound closure.

Surgery for Problem Wounds

Surgery for problem and chronic wounds falls into two categories; wound bed preparation and then wound closure. The use of aggressive surgical debridement can turn a chronic wound with hyperkeratotic margins, necrotic slough, and arrested progression to wound contraction into a wound that is ready for closure (**Fig. 107.2**, sacral pressure wound in elderly diabetic patient). Most chronic wounds will require at least one surgical debridement to put it in the optimum condition for reconstruction. Those wounds that involve bone will not respond to long-term antibiotics alone. This will just prolong the treatment course or lead to failed reconstruction Osteomyelitis will need to be totally excised to have any chance of successful closure.

Figure 107.2 Chronic sacral pressure wound in elderly diabetic man. Note the rolled hyperkeratotic margins and slough at base.

The Reconstructive Ladder

Plastic surgeons make a mental treatment plan when they see a chronic or problem wound. Of course, imaging and other adjuvant studies can cause a change in the plan but the basic process follows the very well-established "reconstructive ladder." The "ladder" (**Table 107.3** reconstructive ladder) helps to develop a treatment paradigm beginning on the first rung of the ladder, which presents the simplest approach to wound closure, [4] which would be allowing the wound to heal by secondary intention. The highest rung on the ladder would require a distant flap that may require a microvascular technique. It is not necessary to stop on every rung of the ladder and an experienced surgeon may understand that the return to normal function needs to take first priority. A single operation is the preferred method when possible, it is always preferred to use autologous tissue, and the long-term durability of the reconstruction must be considered. The use of autologous tissue will in most cases create a secondary wound. The harvest of split-thickness skin graft may effectively double the total wound burden. The harvest of a distant muscle or fasciocutaneous flap may have a

deleterious effect on the patient's function and again, create another wound. So clearly there is no "free lunch." The job of the reconstructive surgeon is to weigh the possible risk–benefit ratio and produce a reasonable outcome. Independent of the option chosen for wound closure, there are a few principles that are shared by all. First and foremost, careful surgical technique is required if we want to avoid complete or partial failure. The surgeon should incorporate these points into all they do. Make sure the bed is prepared for a graft or flap. Flaps, local or distant, do not do well when placed under tension. Pulling or forcing the tissue into the defect will cause microvascular compromise leading to macrovascular compromise and eventual partial or complete failure. Be sure there is good perfusion and venous drainage. If the flap appears to be ischemic or venous outflow appears to be compromised remove some of the insetting sutures and allow the flap to recover. In some cases, you may not be able to inset the flap at this juncture but rather will need to allow it to adjust to this new relative hypovascular situation. This is called the delay phenomenon. It is also referred to as vascular delay or ischemic preconditioning (**Fig. 107.3**, example of surgical delay). It describes the observation that a tissue rendered partially ischemic will undergo neovascularization and enhance its vascularity. The field of reconstructive surgery uses this phenomenon to facilitate the survival of flaps. Careful attention to hemostasis is a must in reconstructive efforts. Skin grafts, **whether of split-thickness or full-thickness type**, depend on being in intimate contact with the prepared recipient bed. The presence of even a minimal amount of blood or fluid will result in loss of some or all of the graft due to loss of that intimate contact. The distinction to be made here is the difference between a graft and a flap. A graft, which could be skin, tendon, nerve, fat, cartilage, or bone, is transferred without a blood supply and requires vascular ingrowth from the surrounding bed. Each tissue, and in fact, the volume of the transferred tissue has a particular physiologic requirement for vascularization and survival. So a split-thickness skin graft may survive where a full-thickness graft will not. A flap, on the other hand, is transferred with its vascularity intact. Thus, the flap is much less dependent on the local vascular milieu. The flap can be transferred with its vascular "leash" which may give it a limited arc of rotation. The option is to transfer the flap as a free tissue transfer. In this case the tissue is transferred with the vascular pedicle identified and dissected out

and divided just prior to transfer. The pedicle is then immediately anastomosed to an identified artery and vein at the recipient site. Obviously this technique will allow the movement of large amounts of tissue from distant sites to a defect and obtain a closed wound with one operation. This technique requires a great deal of expertise and sophisticated equipment but has changed the entire field of reconstructive surgery.

Table 107.3 The Reconstructive Ladder
Vascularized free tissue transfer
Local pedicled flap (fasciocutaneous or muscle)
Local cutaneous or fasciocutaneous advancement or rotation flaps
Skin grafts
Delayed primary closure
Primary closure
Healing by secondary intention

Healing by Secondary Intention

Allowing the wound to heal by secondary intention is a very acceptable course of action for smaller wounds. Some of the closure is due to wound contraction and then eventually epithelial migration to cover the surface. The process has a few problems that need to be recognized. The wound contraction can lead to a wound *contracture* which can distort adjacent soft tissue landmarks such as the labial commissure or the eyelid. Secondary healing across a joint may lead to limited range of motion of the affected joint. The time to closure may take months and may require debridement on a few occasions as the margins become hyperkeratotic and progress stagnates. After a period of no progression the decision may need to be made to move up the reconstructive ladder.

Primary Wound Closure

The next step on the ladder is closure of the wound with primary intention. This is the common approach for a laceration or acute soft tissue defect

following an excision of a small benign or malignant lesion. The principles outlined above apply here as well. Careful tissue handling, meticulous hemostasis, and closure without tension are required for a durable repair. A layered repair typically refers to the use of absorbable sutures to bring together the dermis and underlying subcutaneous tissue, which both closes dead space and relieves tension on the epidermis. Closing the deep and superficial fascia and the dermis in layers will almost effectively render a closed wound without any epithelial sutures. The skin sutures should be done with a monofilament nonabsorbable material, nylon or polypropylene would be preferred. When closed without tension and with the edges slightly everted there is less likelihood to develop obvious scar and wound dehiscence. The placement of a closed suction drain of appropriate size will help to decrease the chance of fluid buildup and keep the tissue in contact with the bed. Inability to close the wound without tension would dictate the use of another technique, moving to another rung on the ladder.

Figure 107.3 Example of surgical delay. Because of associated medical problems, the patient was not a candidate for microvascular tissue transfer. **A:** Lower-third tibial defect secondary to an open ankle fracture. Note exposed bone, which precludes use of a skin graft. **B:** In the first stage, a bipedicle flap was created anterior to the defect. The deep perforators to the skin of the flap were divided by full undermining. The flap is perfused only from the proximal and distal ends. **C:** The incisions were repaired, and the wound was dressed. **D:** After 5 days, the bipedicle flap was again elevated and part of the distal pedicle was divided (*arrow*). The incisions were again closed, and the wound was dressed. This procedure was repeated 10 days after the initial operation to leave only a small skin bridge at the distal end of the flap. **E:** Fourteen days after the initial procedure, the remaining distal skin bridge was divided and the flap transferred. The donor site was skin grafted. This photograph depicts full survival of the flap and complete take of the skin graft.

Skin Grafts

Skin grafts have changed the approach to the closure of open wounds. Their use was initially proposed in the 1880s but the technique fell out of favor due to failure to recognize the need for recipient bed preparation and careful

harvest techniques. The real understanding of skin grafting techniques did not develop until World War II. There was a tremendous need for improved management of burn injuries. Basic science and clinical research finally made the use of skin grafting a predictable and relatively easy way to close burn wounds and saved many lives.

Skin grafts are of two basic types: full thickness and split thickness. The difference is based on the amount of dermis harvested with the epidermis. The entire dermis is harvested with the full-thickness graft and the split-thickness graft can have a variable amount of dermis depending on the requirements of the wound. The full-thickness graft will contract less and heal with less of a noticeable depression because of the thickness of the graft. The full-thickness graft is often used for defects of the head and neck because it can be harvested locally from the face or neck and will maintain a good color match (**Fig. 107.4**, full-thickness skin graft to orbit). The full-thickness graft may have lower survival because of the thickness of the dermis representing an impediment to diffusion of serum into the graft. The take, or survival of the graft is dependent on the bed preparation and the ability to successfully revascularize the graft within 48 to 72 hours. The graft needs to be stabilized with some combination of sutures and dressings to keep the graft in intimate contact with the bed to encourage the revascularization of the graft. The presence of shear force on the graft will doom all or part of the graft. The early survival of the graft is dependent on plasmatic imbibition whereby serum from the bed needs to diffuse into the grafted tissue. Inosculation is the process by which blood vessels in skin graft grow to meet the vessels (inosculate = kiss) of the recipient bed. Within hours microvasculature from the wound bed grow into the graft and form connections with microvasculature of the graft. Thus, it is very clear that wound preparation is paramount for successful grafting. The graft will not take on bone that does not have adequate periosteum or tendon without paratenon. Skin grafts will not take on cartilage. If the bed cannot be prepared to support the process of imbibition and inosculation then the decision has to be made to move up the reconstructive ladder. The donor site for the full-thickness graft must be closed primarily. The use of the full-thickness graft is limited by the size of the defect and the ability to close the donor site primarily. With split-thickness skin grafts, the donor site wound heals by reepithelialization. Epithelial cells migrate from remnants of skin

adnexal organs, hair follicles, and sweat glands, in the underlying dermis and eventually grow across the wound bed. The donor site can be dressed with an occlusive dressing to maintain a moist environment or a petrolatum impregnated sheet of gauze which is allowed to dry onto the wound to create a pseudo scab. It will take 10 days to 2 weeks to heal the donor site.

Random Flaps

The use of local tissue rearrangement that is adjacent to the wound is a very common method for closing wounds. It can be simple undermining to separate the tissue from deeper fascia or complex designed flaps based on the principles of "Z" or "W" plasties with back cuts and elevation of tissue. The advantage of these reconstructive techniques is the fact that we are using adjacent tissue. The color match and tissue thickness and properties will mimic the tissue that was present in the wound. This is especially useful in closure of wounds on the head and neck. It must be remembered that these are random pattern flaps perfused by the dermal plexus of vessels. Care must be taken when designing the flap so that there are not scars crossing the flap indicating a disruption of the dermal plexus. Longitudinal scars running in the long axis are also associated with disrupted dermal vessels. The basic movements of these flaps are rotation, advancement, and transposition depending on how the tissue needs to be moved into the defect. The defect size and location, the nature of adjacent tissue, presence of scars, and previous surgery may dictate if these local flaps can be used to close the defect. While the length width ratio must be taken into consideration there are certain procedures that can improve the vascularity of the flap.[12,13] The use

of the delay phenomenon has been shown to improve random flap survival. Delay is defined as the partial interruption of blood flow to the designed flap. This preconditions the flap to relative ischemia prior to division of the tissue. The technique of random flaps can be augmented by expanding the flap using subcutaneous tissue expanders. The expander is placed in a subcutaneous pocket and is gradually filled with fluid in an effort to create new skin. The expansion of the tissue is actually functioning as a delay technique and preconditioning the expanded tissue to relative ischemia.

Axial Pattern Flaps

The identification of larger caliber vessels longitudinally traveling along a defined skin region has changed the way plastic surgeons can reconstruct wounds. This has moved the entire field forward. Random pattern flaps are limited by the dermal plexus supplying the tissue. The arc of rotation will be a limited and the flap will need to be in close proximity to the wound. With axial blood supply any piece of tissue can be transferred on its vascular pedicle; in essence the tissue is transferred with its own blood supply. Using the principles of Taylor and Palmer[14] and the angiosome concept they developed, we are able to design flaps based on our knowledge of vascular anatomy. An angiosome is defined as a region of tissue supplied by an artery and its venae comitantes. The choke vessels crossing the boundaries of a given angiosome are able to enlarge thus allowing us to incorporate an adjacent angiosome into the flap. This facilitates the use of larger flaps to fill the given defect.

Fasciocutaneous flaps are a category of axial pattern flaps. The application of these very widely used flaps developed out of the understanding that the inflow to the dermal plexus is derived from vertically oriented vessels arising at the level of the deep fascia. This fasciocutaneous system consists of vessels which reach the skin by passing along the fascial septa between adjacent muscle bellies and then fan out at the level of the deep fascia to form a plexus from which blood reaches the skin. Fasciocutaneous flaps depend on less immediately obvious anatomy and the concept is one of potential underlying skin vascular territories rather than the well-circumscribed anatomical territories of the axial-pattern cutaneous flaps. The vessels form a subfascial plexus based on a horizontal orientation at the deep fascial level. This horizontal orientation is relative to the skin

surface. Several workhorse fasciocutaneous flaps have been developed on the subfascial plexus of vessels. The radial forearm flap is a thin pliable fasciocutaneous flap that is very adaptable for head and neck reconstruction where the inherent bulk of other flaps would be an impediment. The radial forearm flap is also well suited for hand and foot reconstruction where again a thin pliable flap would be needed. The anterolateral thigh flap (ALT) is very well suited to larger defects. These flaps are based on septal and or muscular perforators based on the descending branch of the lateral femoral circumflex artery. A cuff of muscle can be taken with the fasciocutaneous portion to fill deep complex wounds. Perhaps the most elegant use of a fasciocutaneous flap is the fibula free flap. This flap is actually an osteoseptocutaneous flap which has the advantage of providing vascularized bone for structural integrity and thin pliable tissue for a soft tissue defect. This flap is most commonly used in composite reconstruction of the head and neck particularly defects of the mandible and adjacent soft tissue.

Muscle and Musculocutaneous Flaps (Table 107.4 Workhorse Muscle, Myocutaneous and Perforator Flaps)

These flaps based on the classification system described by Mathes and Nahai[15] came into wide use in the early 1980s. The understanding that tissue can be transferred on an axial blood supply had been widely accepted. Adapted from this principle is the fact that whole muscles and if needed, the overlying skin and subcutaneous tissue can be transferred on its dominant pedicle or the pedicle can be divided and the tissue transferred as a free tissue transfer with a microvascular anastomosis. Multiple expendable muscles have been transferred with excellent results (**Fig. 107.5**, Rectus femoris flap). The rectus abdominis, latissimus dorsi, and gracilis are used successfully for wounds of all sizes. Functional muscle transfers are possible if the motor nerve to the muscle is preserved or the motor nerve is coapted to another motor nerve at the transfer site. In our discussion of fasciocutaneous flaps we described perforators emanating vertically from the muscle surface or intermuscular septum to supply the skin. The use of this construct has revolutionized autologous breast reconstruction. The transverse rectus abdominis myocutaneous (TRAM) flap is a hardy myocutaneous flap with a large skin and subcutaneous paddle based on periumbilical perforators. The muscle carries the blood supply to the soft tissue to create the breast mound.

The TRAM flap has evolved into the perforator flap. The careful dissection of the perforators to the skin allows the muscle to be preserved and avoid the morbidity of the loss of a large motor muscle. The use of perforator flaps are now often preferred over muscular flaps. These flaps are most often transferred as free flaps requiring a microvascular anastomosis.

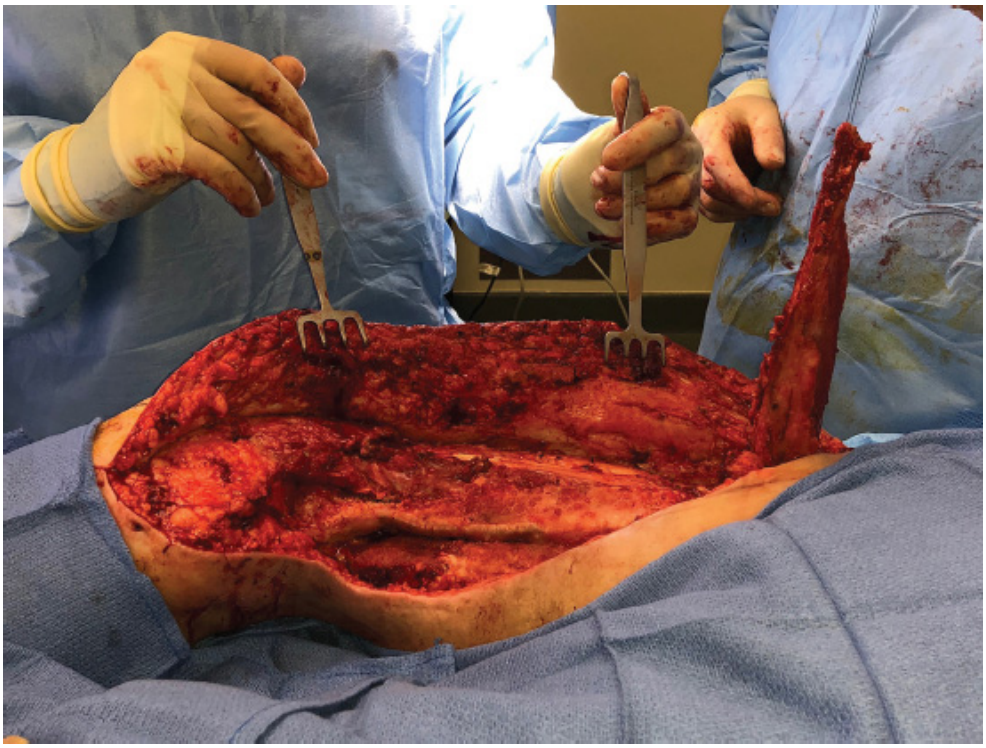

Figure 107.5 Pedicled rectus femoris flap to cover exposed vascular structure.

Table 107.4 Workhorse Muscle, Myocutaneous, and Perforator Flaps

Flap	Myocutaneous	Perforator	Common Uses
Temporalis	No	No	Orbital and intraoral reconstruction, facial reanimation (pedicled flap)
Pectoralis major	Yes	No	Intraoral and neck reconstruction; reconstruction of sternal defects (muscle only)
Latissimus dorsi	Yes	Yes	Breast reconstruction, neck reconstruction, free flap for very large defects
Rectus abdominis	Yes, including TRAM	Yes, including DIEP	Breast reconstruction, sternal reconstruction, reconstruction of groin defects, free flap for medium-sized defects
Gluteus maximus	Yes	Yes, including SGAP	Ischial pressure sores, sacral pressure sores, SGAP used for breast reconstruction
Biceps femoris	Yes	No	Ischial pressure sores
Tensor fascia lata	Yes	No	Trochanteric pressure sores, abdominal wall reconstruction
Gracilis	Yes	Yes	Perineal reconstruction,

			vaginal reconstruction, facial reanimation (muscle free flap), free flap for small defects
Rectus femoris	Yes	No	Infected hip wounds, abdominal wall reconstruction
Medial gastrocnemius	Rarely	No	Knee defects, proximal third tibial defects
Soleus	No	No	Middle third tibial defects

DIEP, deep inferior epigastric perforator; SGAP, superior gluteal artery perforator; TRAM, transverse rectus abdominis myocutaneous.

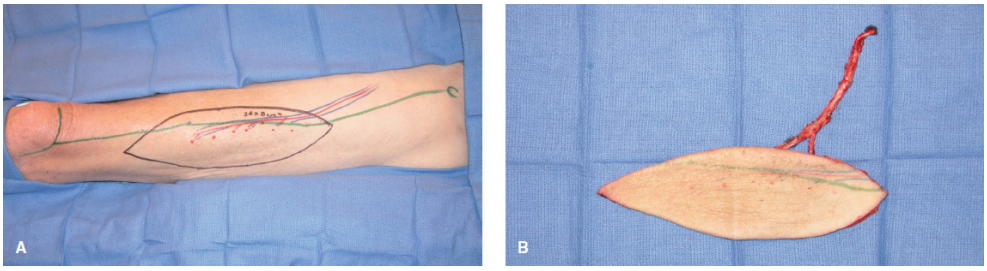

Figure 107.6 **A:** Anterolateral thigh flap designed on the leg and (**B**) free flap dissected out and ready for transfer.

Microvascular Free Tissue Transfers

Perhaps the most important innovation in reconstructive surgery is the development of microvascular surgery. The use of pedicled flaps limits the distance to which the flap can be moved. Historically there were a number of procedures developed to facilitate the movement of tissue to a site distant from the donor site. All of them require multiple operations and are not very efficient. An example of this is the so-called "walking flap" where a soft tissue flap is elevated and sutured into the form of a tube. It is left in situ for a few weeks to allow local vessel conditioning to ischemia. It is then

divided at one base and then "walked" to the next site where it is again sutured to a new site to allow vascular ingrowth. This process is repeated until the flap arrives at the site of the initial wound defect. With the wide use of microsurgery all of these adjunctive procedures are now of historical significance only. It is now felt that any tissue with an axial blood supply and a pedicle vessel of 1 mm or greater can be used for a reconstructive procedure. Now there is a trend to supermicrosurgery, a technique of dissection and anastomosis of small vessels ranging from 0.3 to 0.8 mm. This technique that has been developed over the last 20 years has revolutionized the fields of lymphedema treatment and soft tissue reconstruction.

The basic principle of microsurgery is that circulation can be established in the harvested tissue using microvascular anastomoses between the axial vessels, artery and venae comitantes in the flap and local vessels at the site of the wound. The vascular anastomosis, performed with 8-0 or 9-0 suture, is often done under the microscope or some surgeons prefer loupe magnification. Loupe magnification may move things along faster since there is less time expended in the setup of the operating scope. Obviously these procedures require a very high level of expertise and specialized equipment. However, the survival rate for free tissue transfers is greater than 95%. The ability to move large pieces of tissue, including composite tissues of skin, subcutaneous tissue, muscle, bone, and even sensory and motor nerves is really only possible using microvascular techniques. The movement of these tissues from distant sites means that the surgeon does not need to rely on local tissues for reconstruction and can move out of the zone of injury. Radiation, scar from previous surgery or damage from high-energy trauma are no longer a problem because the transfer of tissue is from a site outside of these problems (**Fig. 107.6**, ALT free flap). It cannot be stressed too strongly that microvascular surgery has changed reconstruction of head and neck oncologic defects with the ability to transfer composite grafts and bowel. Lower extremity limb salvage is much more predictable using microvascular free flaps. As stated earlier fasciocutaneous perforator free flaps have largely replaced musculocutaneous and muscle flaps. The most commonly used flaps are the anterolateral thigh flap (ALT), deep inferior epigastric artery perforator (DIEP), and the smaller radial forearm free flap.

The ALT is now a common first choice for head and neck reconstruction that does not require bone. The DIEP has totally changed the approach to

breast reconstruction often supplanting the TRAM flap.

The ubiquitous application of microsurgery has led to the evolution of new techniques that could not be imagined before. The ability to create prelaminated composite tissue flaps, whereby bone and other tissues can be embedded in a tissue flap and allowed to mature and become vascularized at the distant site and then be transferred with its own vascular supply represents a new approach to complex wound reconstruction. The incorporation of biologic and nonbiologic materials, even 3D printed constructs, to act as a scaffold for the application of stem cells and the eventual development of new tissues, is the exciting future of reconstructive surgery. The principles of microvascular reconstruction and immunomodulation for solid organ transplantation have opened up the field of vascularized composite allotransplantation (VCA). The use of these techniques for upper extremity and face transplantation are two areas of application. The inherent problems associated with the antirejection medications and the problem of chronic rejection are still limiting factors in the wide application of these new and exciting options on the frontier of reconstructive surgery.

PEDIATRIC PLASTIC SURGERY

Concern about interference with normal growth makes correction of pediatric deformities a four-dimensional challenge. Microsurgical precision as well as familiarity with brain development, developmental milestones, and acquisition of language are necessary to manage the spectrum of congenital, neoplastic, or traumatic deformities encountered in the 5 pediatric population. Additionally, familiarity with dysmorphology, genetics, dental organogenesis, otolaryngology, and the distinct growth trajectories of commonly affected structures define the scientific boundaries of this subspecialty. Surrounding oneself with a multidisciplinary team of specialists in those fields is common practice and the concentration of skills in the plastic surgeon places them in a central role.[16,17]

Congenital Anomalies

Cleft Lip and Palate

With an incidence of 1 in 650 live births approximately (7,000 new cases per year),[18] clefts of the lip and/or palate are the most common congenital anomaly in the United States. The clefting anomaly is along the midline of the posterior soft and hard palate, and branches laterally anterior to the incisor foramen, involving one or both anterior palate, alveolus, lateral incisor, lip vermilion and phitral column, nostril floor, and lateral pyriform aperture. Viewed from below, they map to a Y-shape (**Fig. 107.7**), with various involvements of each limb. They are thought to result from failure of fusion along the maxillary prominences and the lateral and medial nasal prominences within the first branchial arch and frontonasal process between the 6th and 12th week of gestation.[19,20] Correction of this anomaly is often staged, with ongoing debate about timing and techniques (**Table 107.5**). Tightness across a repair, extent of denuded bone surfaces, and early surgery adversely affect future growth. Conversely, early repair of the soft palate musculature may improve speech outcomes. Surgical tenets of avoiding straight line repair over the lip and soft palate, avoiding or minimizing lateral "relaxing" incisions over the hard palate, and meticulous technique under optical magnification are widely adopted (**Fig. 107.8**).

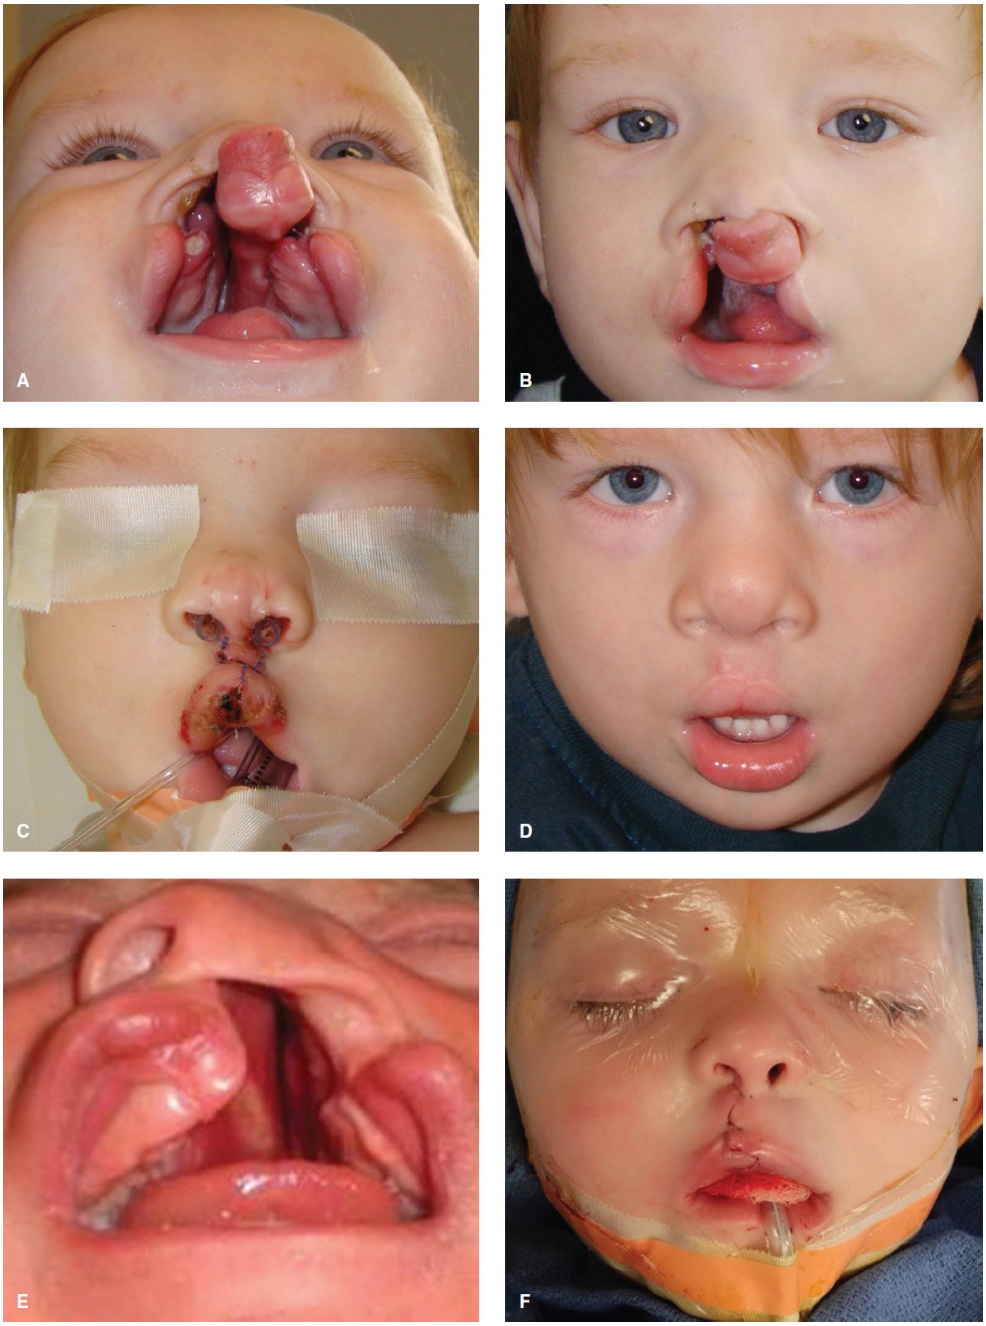

Figure 107.7 **A, B:** Bilateral cleft lip and palate, the complete expression of the anomaly. The maxillary palatal shelves are separate from each other and from the vomer in the midline. The oral and nasal cavities are communicating. The orbicularis oris muscle is discontinuous and inserts abnormally over the lateral pyriform. The nose is severely deformed and the anterior part of the maxillary arch is outside of the oral cavity (premaxillary escape). **C:** Intraoperative view of the completed repair, overcorrecting certain structures and undercorrecting others to account for differential future growth "Repair in the fourth dimension."[21,22] **D:** Results at 4 years post operatively. **E:** Unilateral cleft lip and palate, a misnomer since the unaffected side is secondarily deformed. **F:** The abnormally inserted

orbicularis oris musculature is reoriented and interdigitated, the lip skin, mucosa, and nose are reconstructed using anthropometric landmarks as a guide, placing scars along anatomical lines (philtral column) and avoiding linear scars.

Table 107.5 Stages of Repair for Complete Cleft Lip and Palate

0–3 mo	Presurgical orthodontics[a]
3–6 mo	Cleft lip repair
9–12 mo	Cleft palate repair
3–6 yrs	Pharyngoplasty or palatal lengthening[a]
7–9 yrs	Alveolar bone graft
10–12 yrs	Rhinoplasty and lip revision[a]
16–18 yrs	Orthognathic surgery[a]

[a]Optional or as indicated.

While the major surgeries are mostly completed in the first year of life, the child is followed by a multidisciplinary team until skeletal maturity in late teens (**Table 107.6**). The clefting anomaly affects major components of human communication systems, including hearing mechanism, speech musculature, and nonverbal communication using the facial musculature. Secondary revision surgery and esthetic procedures in this population challenge the surgical armamentarium of the Plastic Surgeon. In craniofacial surgery, “nothing short of perfection is acceptable.”

Craniosynostosis

The incidence of craniosynostosis is estimated around 1 in 2,500 live births. The condition arises due to premature fusion of the calvarial intramembranous sutures and/or the base of skull enchondrosis. The former condition is usually isolated, while the latter often syndromic. When multiple sutures are involved, elevated intracranial pressure is a concern, while base of skull suture involvement results in proptosis with risk of corneal exposure, nasopharyngeal airway restriction, and severe facial deformity (**Fig. 107.9**).[24]

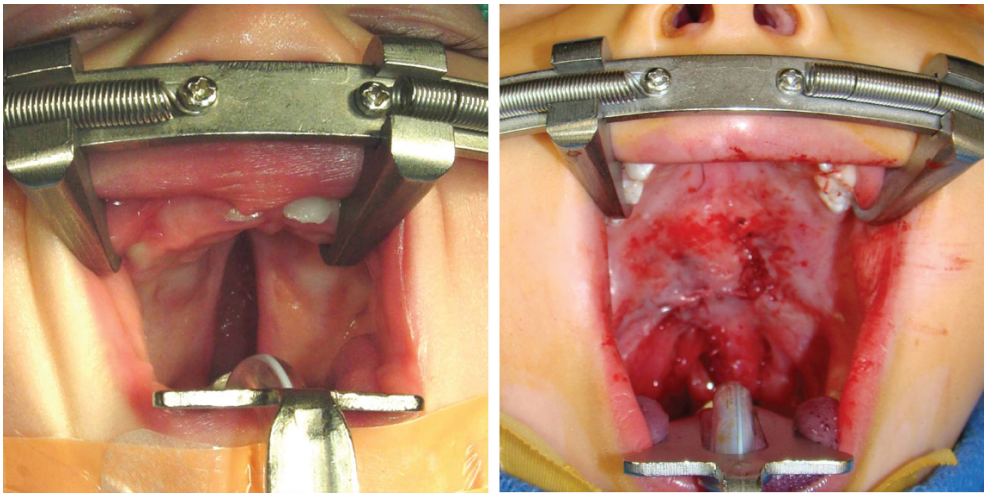

Figure 107.8 Cleft palate repair using a double-opposing Z-plasty technique.[23] The levator levi palatini muscle is abnormally inserted over the posterior palate shelf, and needs to be disinserted and rearranged into a sphincter configuration. The mucosal surfaces are lengthened using Z-plasty principles to prevent or minimize linear contracture. "Relaxing incisions" along the gingival edge of the palate facilitate repair but lead to severe secondary growth deformities and can be avoided in most cases. Cleft palate repair is a unique technical challenge due to anatomical space constraints and microsurgical precision needed. The vast majority of patients can expect a normal deglutition and speech mechanism using current techniques. **Left:** before, **right:** after palatoplasty.

Figure 107.9 Syndromic craniosynostosis: Crouzon syndrome. Calvarial sutures and base of skull enchondrosis fuse prematurely, resulting in restricted growth of intracranial volume and oropharyngeal spaces. Elevated intracranial pressure, proptosis with poor globe protection, and obstructive apnea can be corrected surgically by combined frontal, facial, and mandibular (FFM) advancement using distraction osteogenesis. **Above**, before, and **below**, after combined FFM with cranial vault expansion.

Restriction perpendicular to a suture results in overgrowth parallel to its axis generating seven distinct patterns of deformity (**Fig. 107.10**) distinguishable from the more common pattern of deformational plagiocephaly.

Intracranial volume doubles in the first year of life, and adds another volume between 12 and 42 months, reaching about 85% adult size, at which time growth rate slows down markedly. Afterward, growth of the intracranial compartment by resorption of the inner cortex and apposition of new bone on the external cortex is thought to be sufficient to compensate for absence of growth across suture lines. Based on these observations, surgical correction of synostosis is often performed between 6 and 12 months. Earlier surgery is

technically easier but may result in insufficient overcompensation, thus increasing the risk of secondary surgery. Surgical correction can be done by remodeling of large portions of the calvarial vault (**Fig. 107.11**). Alternatively, a more limited release of the affected suture can be done, followed by remodeling using external molding orthosis ("helmeting") or implanted expansion springs.

Microtia

Microtia is defined as partial or near-total absence of the external ear, often accompanied by atresia of the external auditory canal. The middle ear is variably affected, but the inner ear is often intact. The most important functional aspect of reconstruction is early restitution of hearing using band-held bone conduction hearing aids. This can be switched to a bone-anchored device after reconstruction of the external ear to avoid interference with local flap options. Drilling and relining of the external auditory canal is sometimes complicated by the position of the facial nerve in the middle ear, and has yet to produce consistent audiologic results.

Reconstruction of the absent pinna has significant psychosocial benefits to the affected child. Children seem to have poor compliance with bone-anchored external ear prostheses, while acceptance is much higher in adults. Options to replace the missing ear fibrocartilage framework include prosthetics (porous polyethylene, silicone) or autogenous rib hyaline cartilage. Coverage options include the temporoparietal fascial flap covered by skin grafts, or a retroauricular pocket of glabrous skin. A commonly practiced technique involves a custom-carved autogenous rib cartilage framework buried in a retroauricular pocket of glabrous skin and elevated secondarily to create a retroauricular sulcus. This technique has been used since the 1950s and is in constant refinement.[21] Although the pinna is 85% adult size by age 4 to 5 years, reconstruction often is deferred until 7 to 10 years of age to allow for development of rib cartilages. A template of the unaffected ear is made, reversed, and transposed to the affected side to an anthropometrically correct position. The anterior, cartilaginous portion of ribs 5 to 8 is harvested preserving as much perichondrium as possible. These are carved into a two- or three-layer cartilage framework emulating the external ear anatomy, with some modifications to accentuate contour, notably

in the scapha. The earlobe is often present and is transposed into correct position, while the cartilage framework is implanted into a subcutaneous pocket in the existing glabrous skin. Suction drainage and external pressure dressings are critical to emergence of the desired anatomy (**Fig. 107.12**). The retroauricular sulcus is secondarily created by elevation of the framework, placement of a retroauricular wedge of cartilage, and coverage with a fascial flap and skin grafting.

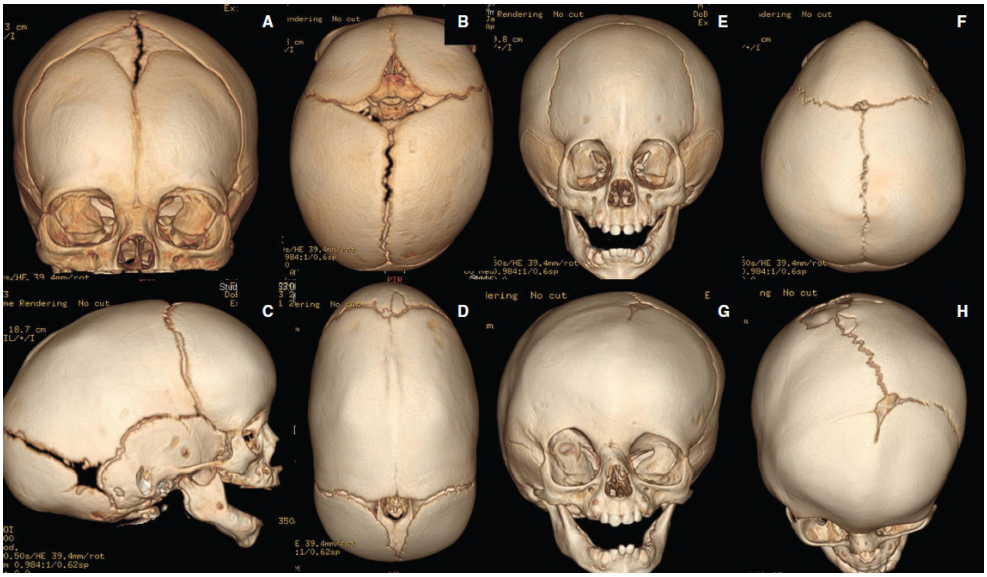

Figure 107.10 Isolated craniosynostoses: (**A**) frontal and (**B**) vertex view of normal suture configuration in an infant. The occipital skull flattening is due to positional deformation (deformational plagiocephaly). **C**: Lateral and (**D**) vertex view of the most common isolated premature synostosis of the sagittal suture, resulting in an elongated skull (dolichocephaly). **E**: Frontal and (**F**) vertex view of premature fusion, likely intrauterine, of the metopic midforehead suture resulting in a triangular head shape (trigonocephaly). **G**: Frontal and (**H**) vertex view of unilateral fusion of the right coronal suture resulting in asymmetry of the forehead and right orbit, and secondary bulging of the left parietal and right midface (right unicoronal synostosis).

Figure 107.11 Multiple suture synostosis in an infant, before and after total cranial vault remodeling. The risk of elevated intracranial pressure increases exponentially with the number of sutures involved. **Left,** before and **right:** after cranial vault remodeling.

Figure 107.12 Lobular-type microtia with near total absence of the pinna and external auditory canal. The lobule is often present, but maloriented. A vestigial cartilaginous remnant is present and needs to be carefully excised preserving overlying skin. Facial nerve, facial soft tissues, temporomandibular joint, ocular tumors, squamosal synostosis, and vertebral and other anomalies are sometimes present. Reconstruction involves harvesting an often large amount of autogenous rib cartilage that is carved into an ear framework based on a template of the contralateral ear. The framework is implanted under existing skin, and elevated secondarily.

Childhood Tumors

While pediatric malignancies are often encountered and may require extensive craniofacial approaches (**Fig. 107.13**), common tumors are usually benign and include hemangiomas, dermoid cysts, pilomatricomas, and melanocytic nevi.

Hemangiomas typically involute spontaneously but should be distinguished from the similar-looking vascular malformations. Hemangiomas respond to propranolol in spectacular fashion and this has changed their management markedly in recent years. Symptomatic hemangiomas that fail to respond to propranolol, or if they involve an orifice, block vision or breathing, or distort a cartilaginous structure such as nasal cartilages or tarsal plates

require surgical treatment (**Fig. 107.14**). Vascular malformations are treated according to their nature by surgical debulking, sclerotherapy, or pulse dye laser. Complete extirpation is usually not feasible due to extent of the anomaly (**Fig. 107.15**).

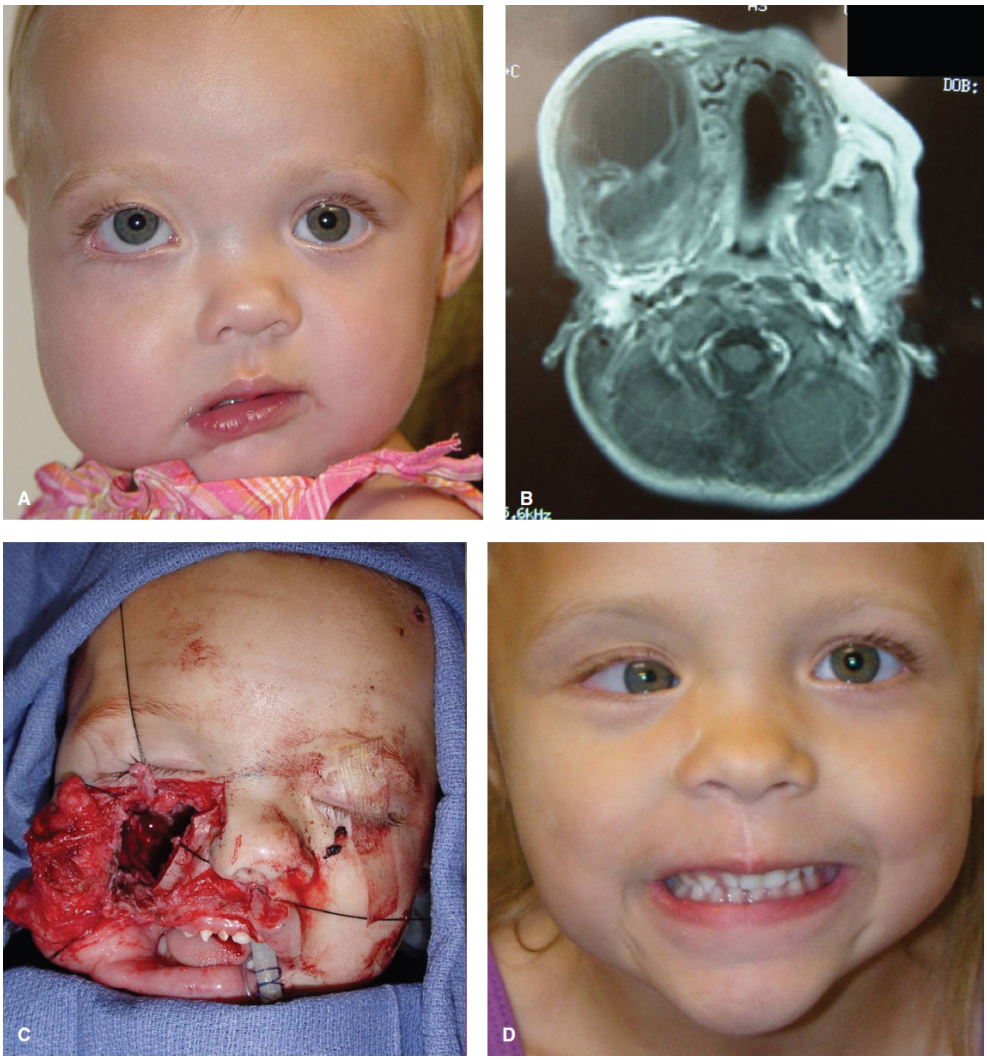

Figure 107.13 Childhood tumors sometimes require complex craniofacial approaches. This child with a large ganglioglioma of the pterygomaxillary space and medial orbit (**A**, **B**) was approached with a (**C**) Weber–Ferguson approach. Secondary deformities are carefully minimized with choice of approach and use of autogenous tissue for reconstruction (**D**). Multimodality treatments result in their own secondary growth restrictions.

Congenital melanocytic nevi are often a psychosocial concern but only large ones are thought to carry a risk of malignant degeneration. Management options include direct excisional biopsy, serial excision, or tissue expansion

(**Fig. 107.16**).[25] Excision and skin grafting often results in significant deformity, but may be needed for its expediency in cases of associated malignancy or severe atypia. Depigmenting lasers or chemical peels can improve cosmesis in cases where excision is prohibitive but may impede detection of an underlying malignancy.

Traumatic Deformities

Simple lacerations are appropriately managed in the emergency setting; however, compound injuries often require specialized care.

While most simple childhood fractures are treated by closed reduction, complex and compound fractures are a particular challenge. They require meticulous anatomical reduction of the involved segments, accounting for the hidden greenstick deformity, and the competing impetus of limiting soft tissue and growth center disruption while providing anatomical reduction and sufficient fixation. Long-term growth sequelae are a concern (**Fig. 107.17**).[26]

Figure 107.14 **A:** Bleeding nasal hemangioma resulting in 1.2 total blood volume transfusion prior to arrival. **B:** Hemostasis obtained using multiple large tacking sutures. A forehead flap is marked on the forehead. **C:** At the completion of excision, the nasal cartilages are splayed and will require repositioning. **D:** After transfer of the forehead flap.

Dog bites and lawnmower injuries produce devastating soft tissue defects that require the full spectrum of plastic surgery techniques. Facial soft tissue loss is particularly hard to replace in a child due to the lack of regional redundancy.

HAND AND UPPER EXTREMITY SURGERY

Hand surgery is a discipline shared by General Surgery, Plastic Surgery, and Orthopedic Surgery. Regardless of background, the trained hand surgeon should have a thorough understanding of 6 bony and soft tissue physiology and be able to diagnose and treat traumatic and nontraumatic conditions of the hand utilizing the advancements in imaging, microsurgery, and wound management. Successful outcome of complex hand reconstruction also depends on frequent postoperative vigilance and on competent postoperative hand therapy. The following section will show examples of common hand conditions due to trauma, congenital, or acquired causes. It is by no means a comprehensive review.

Nomenclature

Nonambiguous nomenclature is important for clarity. Avoid numerical identifiers. Some refer to the thumb as the first finger and the index finger as the second finger, while others refer to it as the first finger and the small finger as the fourth finger. Use instead: thumb, index, middle (long), ring, and small (little). For the phalanges, identify them by name: proximal, middle, or distal phalanges and NOT by numbers: P1, P2, or P3. The numbering of phalanges is confusing, as it is not obvious which bone P1 or P3 refers to: Is P1 the distal or the proximal phalanx? It is more confusing for the thumb, as there is no middle phalanx. So is it unclear which bone P2 refers to. For the metacarpals, the numerical system can be used, though the author recommends name descriptors to avoid confusion: thumb, index, ring, or small metacarpal bone. For laterality, use “radial” to identify the side of the hand or finger closer to the radius, rather than lateral. Use “ulnar” for the side closer to the ulna, rather than medial. This avoids confusion, particularly if the hand is rotated during the examination and not in anatomic position. Using “palmar” is more easily understood than “volar.” “Dorsal” is used for the back of the hand.

Figure 107.15 **A:** Lymphatic malformation of the right cheek, nasolabial fold, and upper lip. Overgrowth of the affected area is a common finding. **B:** After debulking using multiple subcutaneous and transmucosal approaches. Often, long-term improvement in form and function can be achieved with such methods. **C:** Large lymphaticovenous malformation of the left lower extremity, in the setting of Klippel–Trenaunay syndrome. **D:** Post debulking, improved contour is noted. This was done prior to orthopedic correction of overgrowth of the upper tibial metaphysis for improved postoperative fit of external splints and orthoses.

Anatomy and Examination

The hand at rest has a natural flexion cascade with each adjacent ulnar-sided finger slightly more flexed (**Fig. 107.18**). Any alteration to this can suggest a flexor or the extensor tendon rupture or laceration. At the wrist, the flexor carpi radialis and the palmaris longus tendon should also be visible. The thenar and hypothenar eminences should be full, and if either is flat, this can suggest nerve or musculoskeletal pathology. The fingers should be sensate, warm, and well vascularized. Evaluate the hand for disturbances in posture, skin, color, contour, and function.

Figure 107.16 **A:** Giant congenital melanocytic nevus of a large portion of the occipital scalp (40% total scalp area). **B:** During active tissue expansion of the unaffected scalp. **C:** After first-stage excision and flap advancement. Secondary expansion will be needed for complete excision.

Infection

Common hand infections include cellulitis, paronychia, deep space abscesses, and suppurative flexor tenosynovitis.

Cellulitis

It is an infection involving the dermis usually due to an abrasion, puncture, or a systemic infection (**Fig. 107.19**). Symptoms include increased warmth, erythema, and lymphadenopathy. For early and mild cases, it can be treated with warm compresses, elevation, removal of foreign body if present, and antibiotics. *S. aureus* and group A beta-hemolytic Streptococcus are the common organisms found. Cellulitis associated with an abscess requires incision and drainage, antibiotics, and wound care until resolution.

Paronychia

It is an infection of the lateral fingernail fold (paronychium). An eponychia is an infection of the dorsal nail fold (eponychium). If both the lateral and dorsal nail folds are involved, it is called a runabout infection. Paronychia occurs due to a break in the nail fold from trauma, hangnail, manicure, or nail biting. The most common organisms are *S. aureus* or oral anaerobes. Symptoms include swelling, erythema, and pain. With progression, there is fluctuance and purulence, and drainage from the nail fold. If severe, a paronychia can progress to a cellulitis ascending into the finger, hand, or forearm. Initial treatment for early paronychia consists of warm soaks, oral antibiotics, and splinting. Surgery is necessary if pain increases or worsening of fluctuance and purulence. Under digital block and a digital tourniquet, incise through the nail fold at the fluctuance. Send the fluid for culture and irrigate the wound with saline. Place a wick into the incision and dress with dry gauze and splint × 1 day. The patient should remove the dressing the following day and begin washing the finger and the wound twice a day with soap and warm water followed by a light gauze until the infection has resolved. We recommend oral anti-staphylococcal antibiotics for about 5 days.

Figure 107.17 **A:** Orbital dystopia secondary to untreated fracture of the left zygomaticomalar complex and orbital roof 2 years prior to presentation. Although most pediatric fractures can be treated with closed reduction, orbital roof fractures sometimes result in secondary deformities due to the pressure of the growing brain. Note the reflex head tipping to maintain binocular vision and harmonize visual and vestibular somatosensory orientation signals. **B:** Post–orbital wall reconstruction and translocation of the malar complex. Secondary strabismus surgery is typically deferred for a few months.

Figure 107.18 In its resting repose position, notice that the middle finger is more flexed than the index, and the ring more flexed than the middle, and the small finger more flexed than the ring. This is referred to as the "natural cascade."

Figure 107.19 Cellulitis of right hand. Note the erythema and swelling on the dorsal right hand, the index, and middle fingers. The *blue line* on the dorsal mid forearm represents the extent of the erythema upon presentation 1 day earlier, prior to intravenous antibiotics.

Figure 107.20 Deep space infection of the Thenar space.

Deep Space Infections

They occur in approximately 5% to 15% of all hand infections. There are six potential deep spaces defined by fascial separations: four in the palmar hand (thenar space, midpalmar, hypothenar space, and interdigital web space), one in the dorsal hand (the dorsal subaponeurotic space), and one in the volar forearm (Parona space). The most common organisms are *S. aureus* and Streptococcus species. Penetrating trauma is the most common cause. Other possibilities include contiguous spread from an adjacent deep space infection, subcutaneous abscess, or pyogenic flexor tenosynovitis. The hand is swollen and tender (**Fig. 107.20**). Active and passive finger motion results in severe pain. The swelling and purulence may be more noticeable dorsally because the dorsal skin has higher compliance. Should a deep space infection be suspected, CT scan is helpful to confirm and delineate the location and extent of the infection. Surgical drainage should be done by a hand surgeon in the operating room.

Suppurative Flexor Tenosynovitis

It is an infection within the potential space of the flexor tendon synovial sheath between the proximal borders of the A1 annular pulley at the distal metacarpal neck to the insertion of the flexor digitorum profunda (FDP) distal to the A5 pulley. The small finger sheath is continuous with the ulnar bursa, and the thumb flexor sheath is continuous with the radial bursa. Penetrating trauma is the most common cause followed by hematogenous dissemination from an adjacent infection (**Fig. 107.21**). The most common organisms are *S. aureus* and Group A Streptococcus. Mixed organisms and gram-negative bacteria are possible pathogens in intravenous drug users, diabetics, or in immunocompromised patients. The infection within the synovial sheath destroys the almost frictionless gliding surfaces causing scarring and tendon adhesions, thus early diagnosis and aggressive treatment is important. Kanavel first described the symptoms in 1925.[27,28]

Today his descriptions are known as the cardinal signs of Kanavel used to diagnose the infection. They are: (1) exquisite tenderness over the path of the flexor sheath; (2) marked symmetrical swelling of the finger described as "sausage shape"; (3) flexed posturing of the affected fingers; (4) pain on passive extension of the involved finger(s).

Treatment of early infection (24 to 48 hours) remains nonoperative with immobilization, elevation, and high-dose empiric intravenous antibiotics for *S. aureus* and Group A Streptococcus. Failure to improve, infection greater than 48 hours' duration, and gross purulence are indications for surgical intervention. Surgery is aimed at removing the purulence within the synovial sheath by open incision and irrigation. This should be done under general anesthesia and by a hand surgeon in the operating room.

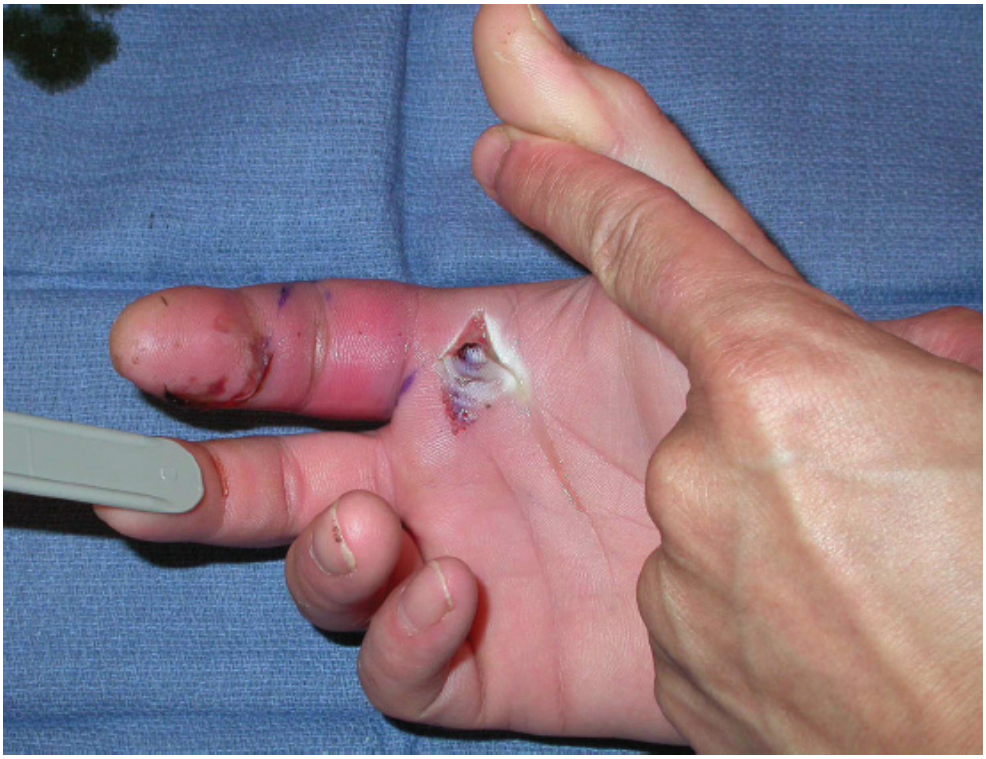

Figure 107.21 Note the fusiform swelling in the index finger with a flexed posture.

Other Infections

They include septic arthritis and human and animal bites (**Fig. 107.22**). Septic arthritis should be the diagnosis of exclusion, as many medical conditions such as gout and pseudogout may mimic an infection with joint pain, warmth, and erythema. Joint aspiration with Gram stain, white count, and culture of the fluid is done for definitive diagnosis. Human and animal bites are treated similarly with aggressive irrigation and debridement and directed antibiotics.[29]

Trauma

Trauma is the most common reason why patients come to the Emergency Department to be evaluated for hand concerns. Be sure to get three-view radiographs of the hand (PA, oblique, lateral). If the radiographs are equivocal and clinical suspicion is high for a fracture or abscess, get a CT scan.

Soft Tissue Injuries

Fingertip Injuries

These are common injuries resulting from recreational or 'industrial activities. If no bone or tendon is exposed, the wound can be treated with secondary intention, skin grafts, or be repaired with avulsed skin, if available, as a composite graft. If bone is exposed, the bone can be shortened slightly or it can be repaired with a local flap such as a V-Y flap (**Fig. 107.23**).

Figure 107.22 Marked erythema on the dorsal wrist due to a cat bite.

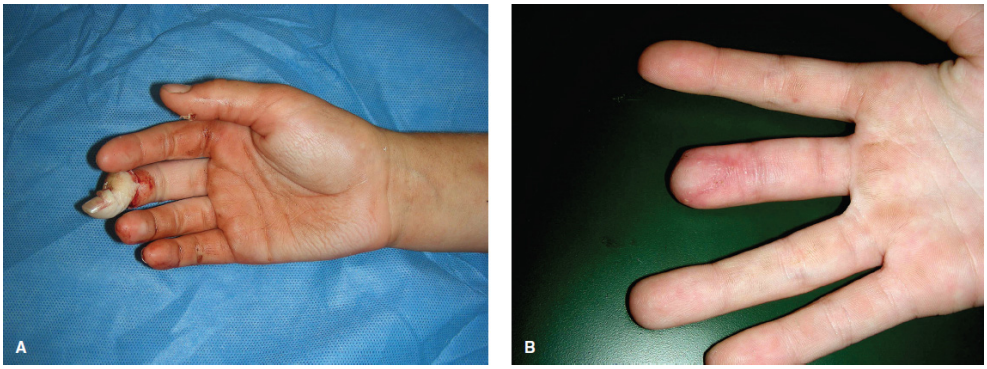

Figure 107.23 The distal right middle finger (**A**) was avulsed and was not suitable for replantation. The exposed DIP joint was closed with a V-Y flap (**B**) shown at 1 month postoperatively.

Nail Bed Injuries

The hallmark of a nail bed injury is a subungual hematoma that can be associated with an underlying distal phalangeal fracture. The pressure within the confined space caused by bleeding results in severe pain. The hematoma evacuation is done for pain relief. Previous teaching was that if the hematoma was 25% of the nail bed surface or larger, that the nail should be removed and the nail bed repaired. Recent studies showed no noticeable difference in the outcome between hematoma evacuation versus nail removal and nail bed repair, though there was an increase in cost by four times in the nail bed repair group.[30]

Nail bed repair could be done using medical adhesives (cyanoacrylates) instead of fine sutures. It has been shown that there is no difference in outcome between suture repair and medical adhesive for nail bed injuries.[31]

For hematoma evacuation, most recommendations have been to use an ophthalmic cautery for trephination. The author's preferred method is to decompress the hematoma using a freer elevator to detach the nail plate from the underlying nail bed at the area of hematoma using gentle sweeping motion starting at the edge of the nail and advancing forward until the hematoma drains. The nail is trimmed shorter. This method allows for improved passive drainage with gravity, rather than expecting the hematoma to drain dorsally against gravity through the trephinated nail. This method also avoids the possibility of iatrogenic nail bed injury, which can occur with the cautery or the biopsy punch.

Tendon Laceration

Causes of tendon ruptures are usually due to penetrating trauma by knife or ballistic injury. High-energy blunt trauma can cause closed tendon ruptures.

Flexor Tendons Lacerations

Generally, when the laceration is deep on the palmar surface, both the tendon(s) and the neurovascular structures are damaged in the fingers. On examination, there would be a visible laceration with loss of the natural cascade with decreased sensation to the finger distal to the laceration (**Fig. 107.24**). If one artery is lacerated, the other digital artery maintains perfusion. If both are lacerated, there is generally sufficient dorsal collateral circulation to keep the finger viable, unless there is vascular compromise from vascular injury, gross wound contamination or an associated open fracture. Tendon repairs can be done electively within 1 week of the injury.

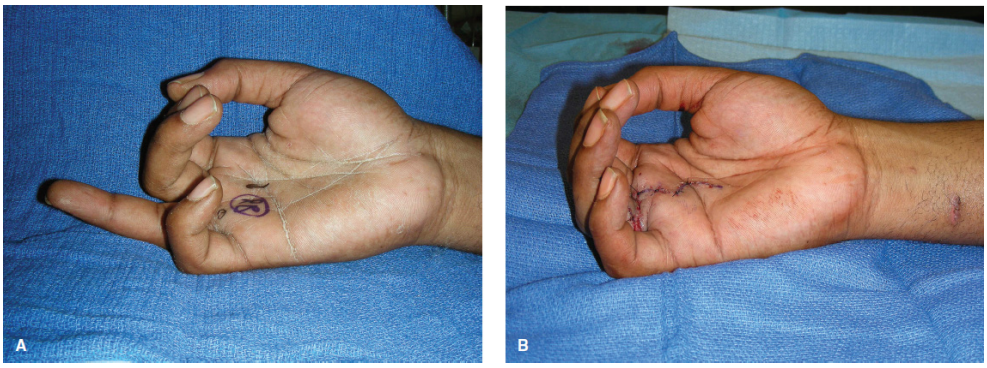

Figure 107.24 **A:** Zone II FDP and flexor digitorum superficialis (FDS) and digital nerve lacerations. Note the loss of the natural cascade at rest with the ring finger completely extended. **B:** Normal cascade reestablished after flexor tendon repair.

Figure 107.25 Mallet fracture with the extensor tendon still attached to the dorsal proximal distal phalanx. If there is more than 25% of the articular surface involved, most would recommend operative treatment.

If the penetrating trauma occurs in the forearm, the injury can appear deceptively benign and these require operative exploration as multiple tendons, ulnar or radial nerves, and arteries can be damaged. Postoperatively, protect the hand and the forearm with a dorsal splint with ongoing hand therapy starting 1 week postoperatively.

Extensor Tendon Laceration

Unlike flexor tendon lacerations, the lacerated ends of extensor tendons generally do not retract away from each other due to their attachments to adjacent structures. Most injuries are due to penetrating trauma, though closed injuries can result in: (1) mallet finger which the extensor tendon ruptures from the distal phalanx without a fracture or with a fracture consisting of a small dorsal piece of the distal phalanx (**Fig. 107.25**). The inciting cause is an axial load to the distal finger with forced flexion at the distal interphalangeal joint (DIP) or (2) a boutonniere deformity due to rupture of the central slip from the dorsal proximal phalanx. Most of the time, both the mallet and the boutonniere are treated with splints for 4 to 6 weeks. Open injures with extensor tendon lacerations are repaired in the operating

room. Postoperative splinting and hand therapy are critical in successful outcomes.

Fractures

There are 27 bones in the hand and 2 bones in the distal forearm that are subject to fractures. Most of the hand and finger fractures, including some Salter–Harris fractures, can be treated nonoperatively if nondisplaced. Surgery with reduction and internal fixation (with plate/screws or K-wires) (**Fig. 107.26**) is required for fractures that are unstable, displaced, or in bones known to have poor outcomes without surgery (e.g., Seymour fracture in the pediatric population and scaphoid proximal pole fracture). Fractures associated with a communicating wound require operative irrigation and stabilization. The benefit of hardware stabilization is the ability for early mobilization to decrease joint stiffness that can result in poor hand function.

Replantation

The first successful finger replantation was reported in 1968 by Komatsu and Tamai.[32]

Since then, guidelines have been established with the indications for replantation being: (a) thumb amputation, (b) multiple finger amputations, (c) pediatric population amputations, and (d) mid hand, wrist, or distal forearm amputations. Contraindications for replantation are (a) associated life-threatening injuries, (b) multiple-level injuries in the amputated part, causing injuries along the vessels and preventing blood flow into the replanted part, and (c) severe contamination of the part, which carries a high probably of systemic infection if replanted. Replantation of a single digit due to the tight fibro-osseous tunnel in flexor zone 2 is generally not recommended due to tendon adhesions that results in poor postoperative function. Single finger amputation in zone 1 is not contraindicated as stiffness in the DIP joint is well tolerated and nerve regeneration to the replanted part is rapid due to the short distance from the injury to the distal nerve receptors, and the appearance of the replanted finger is superior to that of an amputation.

Figure 107.26 Intraoperative fluoroscopy of intramedullary K-wire fixation of displaced index and middle metacarpal shaft fractures.

Complex Hand and Forearm Reconstruction

There are times when multiple tissue components (bone, skin, nerve, tendons, artery) are injured and require reconstruction. A systemic approach is required for the reconstruction to restore form and function. If secondary to trauma, initial treatment should address critical life or limb-threatening issues such as limb ischemia or compartment syndrome, followed by debridement if needed of any nonvascularized or infected tissue; then once

the soft tissue is free of contaminant, formal reconstruction of bone, tendon, nerves, and soft tissue deficits should begin (**Fig. 107.27**). For soft tissue reconstruction of wounds after tumor resection functional reconstruction, which includes tendon and nerve reconstruction, may be needed as well as soft tissue coverage.

Congenital Anomalies

Limb development can be interrupted by environmental or genetic factors during critical first trimester of embryo development.

Syndactyly

The term syndactyly is derived from the Greek prefix *syn-* ("with, together") and the Greek noun *daktylos* ("finger, digit"). Syndactyly has an incidence of 1 in 2,000 to 3,000 live births and is the most common of the congenital hand anomalies.[18,33] It is a failure of differentiation in which the fingers fail to separate into individual appendages, which usually occurs between the sixth and eighth weeks of in utero development.

Figure 107.27 Self-inflicted right distal forearm wound with lacerated FCR, radial artery, median nerve, and complete transaction of the FDS and FDP. He arrived to the hospital several days after his injury and was taken to surgery. His wounds became infected (**A**) requiring several operative debridements (**B**) and with allograft placement (**C**), eventual pedicled right groin flap and divided 3 weeks after placement.

Syndactyly can be an isolated occurrence or it can be associated with other abnormalities, for example, polydactyly, cleft hands, ring constrictions, and craniofacial syndromes such as Apert syndrome (**Fig. 107.28**). It is a shared feature of more than 28 syndromes, including Poland, Apert, and Holt–Oram syndromes.[34] Syndactyly is classified as simple when only the skin is involved and complete if it extends to the finger tips (**Fig. 107.29**) and incomplete if it is short of the tips. If there is bone and nail plate involvement it is classified as a complex syndactyly.

Figure 107.28 Complex syndactyly associated with Apert syndrome.

Untreated, syndactyly can impair finger and hand function, particularly if it is complete or involves the border digits (e.g., small and ring or thumb and index) as there is differential finger growth rates, which can result in finger deviation or joint contractures.

If it is complex or border digits are involved, surgical release can be done as early as 6 months of age and at about 1 year of age or later if only the central rays (middle or ring fingers) are involved in a simple complete or incomplete syndactyly. Bilateral operations can be done with reasonable patient tolerance up to about 12 to 18 months of age as both upper extremities need to be immobilized for about 2 weeks. Only one side of each digit is released should both sides of a finger be involved in the syndactyly, with the other side released at a later time—generally 6 months later. This is to avoid devascularizing the digit. Well-vascularized skin flaps are designed in a zigzag fashion on the dorsal and palmar surfaces with a trapezoidal-shaped dorsal skin flap to resurface the sides of the fingers and the web space. Full-thickness skin grafts from the groin are used to resurface the areas not covered by the flaps.[18]

Polydactyly

Polydactyly or extra fingers can occur on the ulnar side of the hand (postaxial), the radial side (preaxial), or the central rays (central).

Postaxial polydactyly has variable presentation. It can be mild and presents as a nubbin on the ulnar side of the little finger usually at the level of the proximal phalanx or as a rudimentary finger attached by a small neurovascular pedicle**.** Sometimes the accessory finger is partially or fully developed. The incidence is 1 in 143 live births in Africans and African Americans and has a strong hereditary component (often autosomal dominant) without other associated syndrome. In the Caucasians at about 1 in 1,339 live births and the patient should be evaluated for other syndromes.[35] Treatment may be as simple as observation if it is a nubbin or may require either bedside ligation with surgical clips or formal surgery for reconstruction for the more fully formed digit.

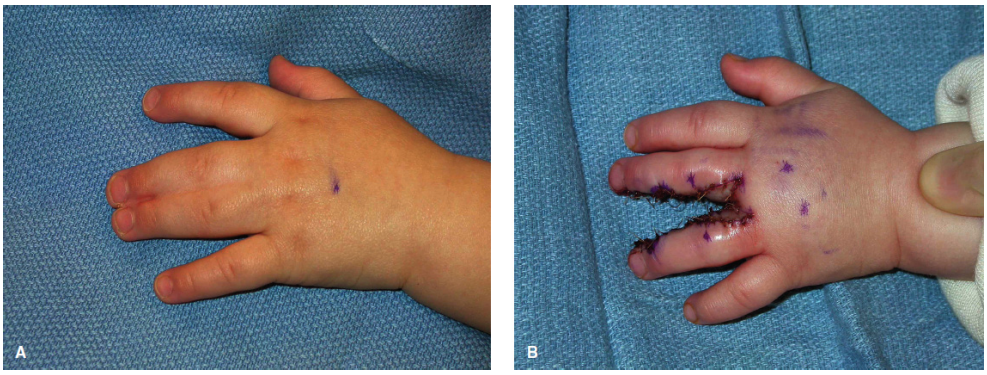

Figure 107.29 A 12-month-old child with a complete simple syndactyly between the middle and ring finger in the left hand (**A**) before and (**B**) after syndactyly release.

Preaxial polydactyly involves the radial side of the hand and usually the thumb. It occurs in 1 of every 3,000 live births and may be associated with several syndromes (Holt–Oram syndrome, Fanconi anemia).[36]

Central Polydactyly

It is rare and can present as incomplete to fully formed index, middle, or ring fingers. Central polydactyly can be associated with syndactyly, cleft hand, and other syndromes.[37,38]

Surgery is geared to removing the duplication and reconstructing the hand to make it appear and function as normal as possible.

Thumb Hypoplasia and Agenesis

Thumb hypoplasia occurs 1 in 100,000 live births with 50% being bilateral and in unilateral presentation the right is more commonly involved. It has a spectrum of presentation from mild diminution to complete absence. In 60%, it is associated with longitudinal deficiencies of the radius. In the embryo, the thumb develops between the fifth and eighth weeks at the same time as the cardiovascular system. Insults at this time can alter thumb development and 86% of hypoplastic thumb have associated abnormalities of the cardiovascular, neurologic, and hematopoietic systems. Thumb hypoplasia is associated with at least 30 syndromes (Holt–Oram syndrome, VACTERL association, and thrombocytopenia absent radius [TAR] syndrome).[39,40]

Thumb hypoplasia categorization has five types. Originally described by Muller in 1937, it has been improved by Blauth, Buck-Gramcko in 1967 and Manske in 1995.[41]

- Type I: Normal components are present but small with underdevelopment the abductor pollicis brevis and opponens pollicis. Type 1 does not require surgical intervention.[42,43]
- Type II: There is a contracted web space between the thumb and index finger with more severe hypoplastic thenar muscles. There is laxity of the metacarpophalangeal joint (MP) ulnar collateral ligament with joint instability. Surgery is aimed at restoring thumb stability and intrinsic function with opponensplasty and deepening of the web space usually with a four-flap Z-plasty.
- Type IIIA and type IIIB: The metacarpal bone is less developed and the thenar musculature is nearly absent. The thumb has poor function. Type IIIA has a stable carpometacarpal (CMC) joint, type IIIB does not. Treatment for type III is based on the presence of a stable CMC joint. Type IIIB requires reconstruction and type IIIB requires amputation and index finger pollicization.
- Type IV: The thumb is floating and also called pouce flottant. Similar to the appearance of a postaxial polydactyly, the thumb is incompletely formed and is attached to the adjacent finger by a neurovascular bridge.

There are no thenar muscles and no extrinsic tendons. Type IV in the Western countries is usually reconstructed with index finger pollicization.

- Type V: There is no thumb and requires pollicization.

Acquired Conditions

Osteoarthritis

There is gradual loss of cartilage in the joint with age. The DIP joints and the thumb CMC joints are more prone to be affected. Treatment is geared toward pain relief while maintaining function. This can be achieved by oral anti-inflammatory medication, gentle range of motion while avoiding strenuous activities, and splinting as needed. Should this not work, intra-articular steroid injection can provide temporary relief. Surgical treatment is reserved as the last option. For the DIP joint as there are no effective joint replacement, arthrodesis remains the only surgical option. For the proximal interphalangeal (PIP), MP, and the CMC joints, both arthroplasty and arthrodesis can be done. In general, for the thumb, arthroplasty with autologous tissue (generally the flexor carpi radialis) remains the preferred method for reconstruction (**Fig. 107.30**).

Tendinitis

Inflammation of tendons, from increased physical activities, can cause inflammatory synovitis around the tendon, decreases tendon glide and increases resistance, causing pain and decreased range of motion. When this occurs in the hand involving the flexor tendons at the A1 pulley, this results in trigger finger. Recommendations are for decreasing aggressive activities, rest/splinting, oral anti-inflammatory medications, steroid injections, and A1 pulley release if nonsurgical intervention is unsuccessful. Injections typically offers 30% efficacy.[44]

Figure 107.30 A 59-year-old with left thumb pain. Preoperative radiographs show advanced left thumb CMC joint arthritis.

When the tendinitis occurs in the first dorsal extensor compartment, this is known as De Quervain tenosynovitis. Treatment is similar to trigger finger.

Peripheral Nerve Compression

In the upper extremity, all three major nerves (radial, ulnar, and median) can be compressed at anatomic narrowings along their paths. The median nerve can be compressed at the carpal tunnel, resulting in numbness in the palmar thumb, index, middle, and radial side of the ring finger. With progression and severity there is weakness in thumb opposition and thenar atrophy. Less often the median nerve can be compressed by the pronator teres. The ulnar nerve is usually compressed at the cubital tunnel at the elbow more than at Guyon canal at the ulnar wrist. The radial nerve can be compressed in the dorsal proximal forearm, known as radial tunnel syndrome if the compression is more proximal and involves the extensor carpi radialis longus (ECRL) tendon nerve branch and the dorsal radial sensory nerve or posterior interosseous nerve (PIN) syndrome, if it involves only the PIN. Like tendinitis, treatment is nonsurgical. Evaluation with electrical studies (EMG/NCV) is recommended to confirm and to establish degree of compression and if there is progressive decline in sensory or motor function, surgery is then recommended. Less-invasive release with endoscopic assistance is alternative to the traditional open techniques.[45]

Dupuytren

Dupuytren contracture is a condition where the localized nodules develop in the palmar fascia. These nodules can progress to longitudinal pretendinous cords spanning the base of the palm to usually the PIP joint restricting finger extension and can later cause fixed contractures at the PIP and MP joints. Though found in all racial groups, it is found more frequently in the Northern European population. There is usually a familial history and slight male to female predominance (ratio: 1.7:1).[46] Surgical excision of the cord used to be the mainstay for treatment until 2010 when the FDA-approved collagenase injections to alter the mechanical properties of the cord.[47]

Rheumatoid Arthritis

Rheumatoid arthritis (RA) is an autoimmune condition mediated by inflammatory cells that attack the synovial tissues in the body. Persistent synovitis in the joints results in articular damage and degradation of the soft tissue support at the joint and rupture of the overlying tendon.

Prior to the advent of effective biologic agent (immunosuppressant or cytokine modulators, e.g., Humira and Enbrel [these are trade names]), surgery was a main stay in the treatment of RA. The goals of surgery were for pain control and improved and restoration of function. It did that in three different ways: preventative, corrective, and salvage.[48] Preventative surgery included synovectomy may be used to avoid the sequel of synovitis such as pain, joint destruction, and tendon rupture. Corrective surgery included tendon transfer for tendon ruptures.

With progressive attenuation of the supporting joint structures at the wrist, there is radial deviation of the metacarpal and with destruction of the metacarpophalangeal MP joints; there is subluxation and ulnar deviation of the fingers at the MP joints. This results in pain and difficulty with finger flexion and extension MP joints and irreversible joint damage. Salvage procedure entails joint arthroplasty at the MP joints with silicone joints and wrist fusion (**Fig. 107.31**).

PLASTIC SURGERY OF THE BREAST

The breast is an anatomic feature that signifies empowerment, 7 helps define self-image, and contributes to sexuality as well as serving a functional role for lactation during pregnancy in females.[49] As such, patients frequently request both aesthetic and reconstructive procedures of the breast. These will be subdivided in the following sections: reduction mammoplasty, mastopexy, augmentation mammoplasty, gynecomastia reduction of the male breast, breast reconstruction, and transgender surgery. Breast dimensions and anatomical characteristics are important considerations for all surgical procedures and will be addressed first. Special consideration should be given to the current scientific climate related to breast implants and this will be addressed separately as it pertains to both aesthetic and reconstructive patients.

Breast Characteristics

Results of plastic surgery of the breast are impacted by several anatomical considerations. Breast size, shape, composition, vector, footprint, and

nipple-areola complex (NAC) orientation are important factors. Breast shape can be impacted by whether the meridians of the breasts are more parallel or divergent. Poor-quality skin (e.g., with striae) and a breast with relatively more adiposity than gland can lead to a softer, less full, "saggier" appearance. The superior border of the breast is variable in different patients leading to significant differences in breast appearance. Size can be relative to overall body habitus. Some breasts have more lateral fullness than others. The intermammary space differs between patients.[50,51] NAC orientation greatly impacts breast appearance. Ptosis (**Fig. 107.32**) is defined in **Table 107.7**.[52]

Reduction Mammoplasty

The main goal of a breast reduction is to decrease the volume, and therefore weight, of the breast to decrease associated aggravating symptoms while maintaining or improving breast appearance. Preoperative considerations relate to patient expectations for appearance and financial coverage of the procedure. Surgical considerations include incision, and subsequent final scar, position, pedicle orientation to supply blood to the NAC and preserve parenchyma, and management of the NAC. Postoperative considerations include wound care and imaging changes.

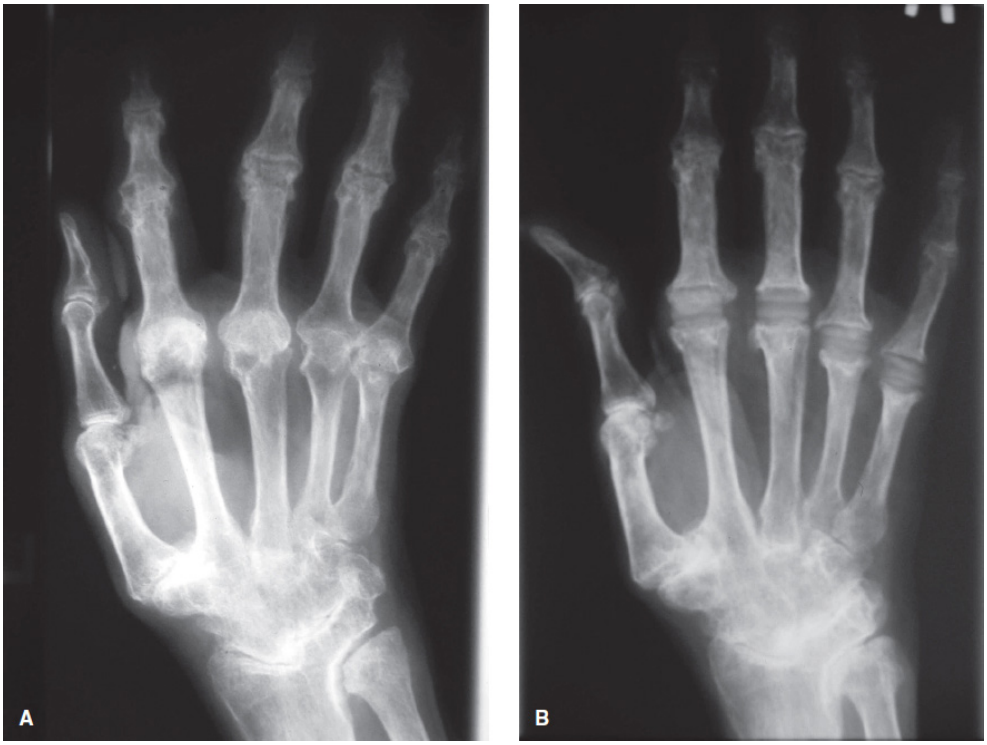

Figure 107.31 Preoperative (**A**) and postoperative (**B**) view of the right hand. Note the restoration of normal finger alignment.

Preoperative Evaluation

Patients seeking reduction mammoplasty often complain of neck and back pain, difficulty with the fit of clothes, management of breast mobility during exercise, grooving of the shoulders from brassiere (bra) straps, and recalcitrant rashes in the intertriginous folds. Most patients seek not just a smaller breast mound, but also a mound that is lifted with a footprint higher on the chest wall (rather than upper abdominal wall) and a NAC with less ptosis and reduced size (to match the overall smaller size of the breast mound).[53,54] A careful conversation must ensue regarding postoperative size preferences and inability to guarantee an exact size. Often the conversation will relate to bra cup size and should include counseling regarding the inexact nature of this methodology since bra cups are not standardized between companies and change with chest width (bra band size number). Many patients seek this procedure as a covered benefit through health insurance, and the surgeon should be familiar with various insurance criteria. A commonly used insurance coverage criterion relates to body surface area

calculated from height and weight, converted to a suggested weight of tissue to be resected through the Schnur table, though it is commonly believed that this table does not accurately convey a relationship between resected weight and symptom reduction.[55] A specific consideration in the preoperative workup is baseline imaging, and recommendations for baseline mammography relate to patient age and breast cancer risk factors.[56]

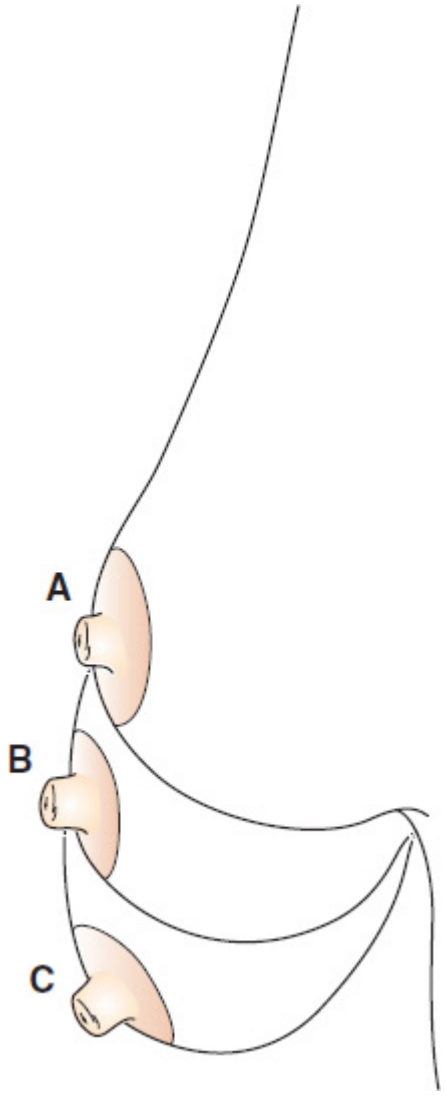

Figure 107.32 Breast ptosis. **A:** Mild. **B:** Moderate. **C:** Severe.

Surgical Approaches

Reduction mammoplasties can be done via a number of different approaches but the most commonly used are dermal parenchymal pedicles either

centrally or inferiorly based. The pedicle is designed to maintain blood supply and sensory function to the NAC. The widely used inferior pedicle technique (**Fig. 107.33**) produces an inverted "T"-shaped scar with the transverse portion in the inframammary fold. Many patients did not like this large scar. This led to the development of the vertical scar mammoplasty (**Fig. 107.34**). **Table 107.8** elucidates the typical components of breast reduction surgery.[53,54] Postoperative drain placement remains controversial. Several studies demonstrate no evidence of improvement in outcomes with drains, but common practice demonstrates high prevalence of ongoing drain usage in practice.[57] Most often this procedure is performed in an outpatient setting.

Table 107.7 Breast Ptosis Definitions[52]

Grade 1	Nipple at the level of the inframammary fold (IMF)
Grade 2	Nipple between the level of the inframammary fold and the lowest border of the breast
Grade 3	Nipple at the lowest border of the breast
Pseudoptosis	Breast gland hanging well below the IMF

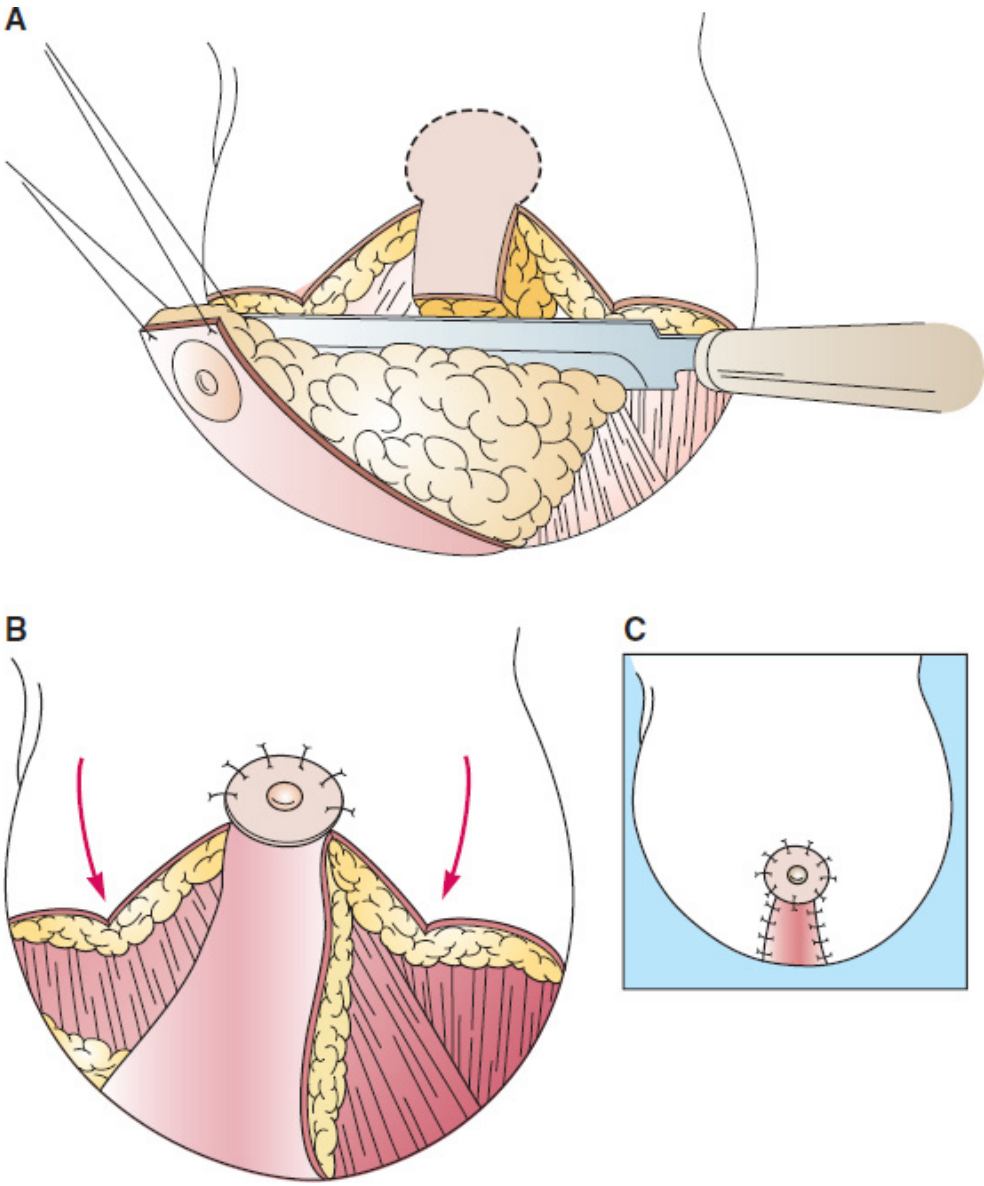

Figure 107.33 Inferior pedicle technique for reduction mammoplasty.

Postoperative Follow-Up

Patients overall demonstrate high rates of satisfaction and relief of symptoms following breast reduction surgery. However, complication rates, particularly wound-healing complications are relatively high and may require frequent clinic visits.[51,54] Imaging changes in mammography can include planar parenchymal scar, fibrosis, and fat necrosis, among other things (**Fig. 107.35**).[58]

Mastopexy

Mastopexy, or breast lift, is often considered by patients who have noted either ptosis of the NAC or pseudoptosis of the breast gland as defined earlier in this chapter. Preoperative discussions should clearly address the limitations of this technique, as the patient's baseline breast dimensions are not likely to change significantly. Namely, the patient is unlikely to achieve breasts that are separated more narrowly or widely. Neither is the patient likely to achieve significant upper pole fullness (often considered cleavage), since the upper border of the breast will be minimally changed and will likely still demonstrate a more natural "ski-slope" contour. Surgery *will* decrease ptosis and pseudoptosis and can remove some striae (stretch marks) resulting from weight or volume changes related to conditions like pregnancy, breastfeeding, or change in body habitus. However, skin quality that has predisposed to striae may predispose to further stretching of the breast skin envelope over time and decrease the longevity of the postsurgical results. Surgical approaches are similar to those discussed above for breast reduction, and the more minimal scar approaches are chosen more frequently for this surgery. NAC transposition is routinely expected, though risk of NAC loss or dysfunction is still present and should be discussed preoperatively.[59] Insurance coverage for this procedure is quite variable. Imaging considerations are similar to those for breast reduction, both pre- and postoperatively (**Fig. 107.36**).[56,58]

Augmentation Mammoplasty

Breast augmentation is designed to increase breast size and potentially influence breast shape and nipple position. Preoperative counseling is essential as decision for this surgery is most often driven by patient desire rather than strictly abnormal symptomatology or danger to health. Preoperative considerations relate to patient expectations and should include financial planning for likely future medical intervention related to the initial surgery. Intraoperative choices relate to material used for augmentation, incision (and, therefore, scar location), and manipulation of the pectoralis major muscle. Postoperative considerations relate to activities, garments, and future treatment.

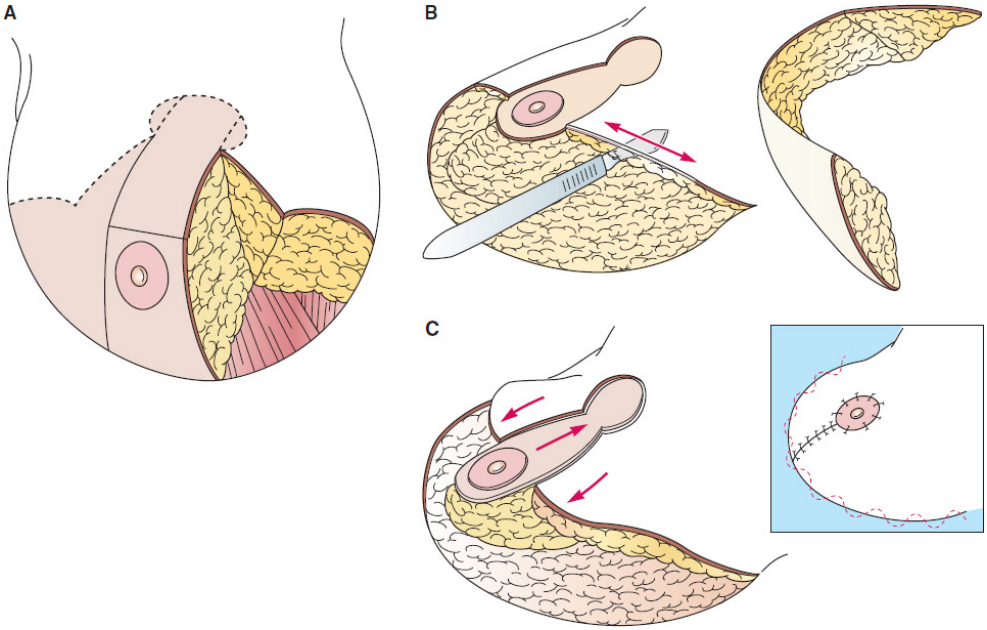

Figure 107.34 Central pedicle technique for reduction mammoplasty.

Table 107.8 Surgical Approaches for Reduction Mammoplasty[53,54]

Surgical Approach	Options	Considerations
Incision/scar	Periareolar (Scar only around the areola)	Scar only at junction of different types of skin so may be less visible, often used for smaller reductions because it allows for skin reduction in fewer dimensions, may distort areola or periareolar scar over time due to differential forces, areola may widen over time without permanent "blocking" suture
	Vertical ("Lollipop" scar: circle around the areola and vertical "stick")	Has risk of excess tissue or standing cone deformity at inferior most aspect of incision
	Inverted T ("Wise-pattern" or anchor-shaped scar adding scar along inframammary fold to vertical scar)	Used most commonly for largest reductions, healing concerns at "triple point" where vertical and inframammary scars meet
Pedicle	Inferior	Common choice, concern over pseudoptosis (bottoming out) of breast mound over time
	Superior	Often used with vertical skin incisions
	Superomedial	Often used in gigantomastia, considered to decrease risk of need for free nipple grafting
	Other	Lateral, superolateral, etc. could be

		used when technique is performed with lumpectomy for breast cancer in oncoplastic setting if common pedicles not feasible
Nipple-areolar complex (NAC)	Transposition	Most likely to maintain sensation, reactivity, functionality, and "normal" appearance of NAC
	Skin graft	More common in larger reductions with greater proposed nipple transposition distance, can be patchy in coloration, flat, nonreactive, and poor (if any) sensation
	3D tattoo	Considered a salvage technique if a NAC fails to survive

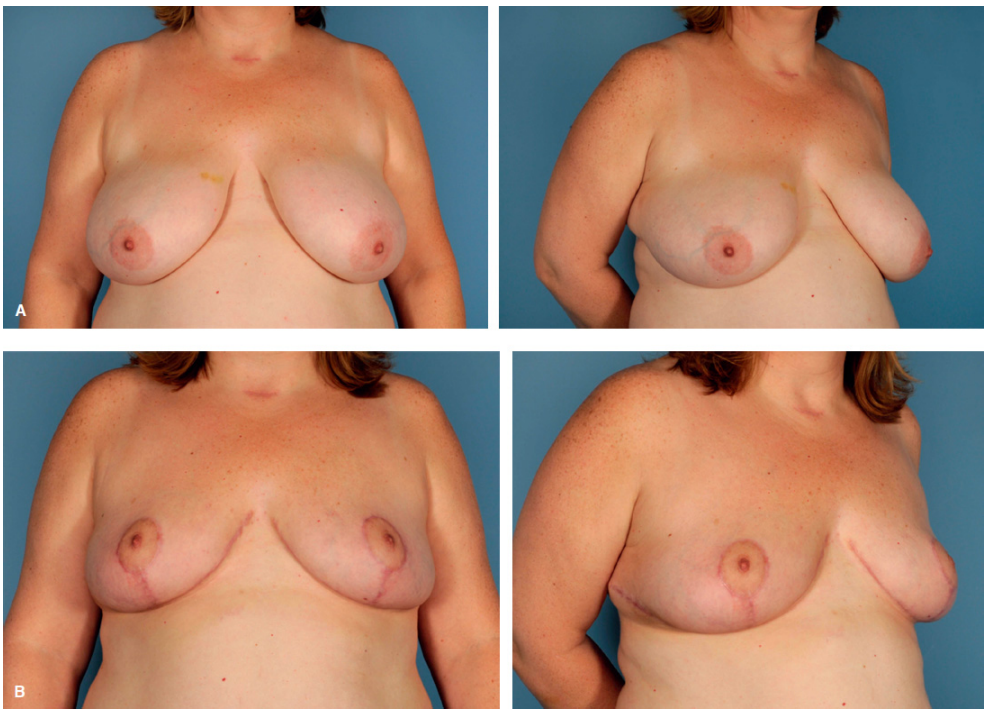

Figure 107.35 Wise-pattern bilateral breast reduction. **A:** Preoperative. **B:** Postoperative.

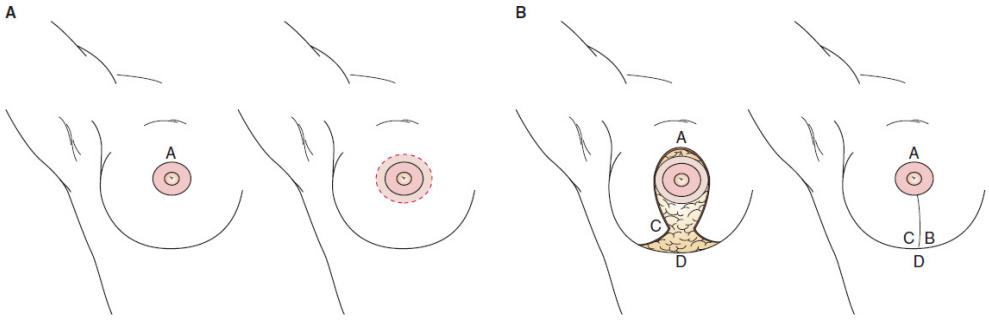

Figure 107.36 Mastopexy incisions. **A:** Circumareolar. **B:** Vertical.

Preoperative Evaluation

Patients should be assessed for the etiology of their interest in augmentation mammoplasty and their expectations for the impact surgery will have on their life situations. Goals related to overall size, lateral breast profile (e.g., the "hour glass" look), upper pole appearance (also known as "cleavage"), and noticeability of the result should be discussed. If prosthetic implants are planned, counseling should include the components discussed in a subsequent section on breast implants. Existing soft tissue quality assessed through a pinch test is important for surgical approach planning.[60] A specific consideration in the preoperative workup is baseline imaging, and recommendations for baseline mammography relate to patient age and breast cancer risk factors.[56] Patients planning to fund the augmentation without insurance intervention will need to understand that treatment of complications or subsequent likely maintenance surgery may not be covered by insurance policies either.

Surgical Approaches

Table 107.9 addresses the main choices related to surgical approaches for breast augmentation.[60,61]

Postoperative Follow-Up

As patients undergoing this surgery are concerned with appearance, surgeons must convey careful consideration of return to exercise and use of postoperative garments. Massage techniques and timing and scar therapies

may be important components of the postoperative period. Follow-up will likely be needed for prosthetic implants as they are not expected to last forever.[60] Important imaging considerations related specifically to breast implants are addressed in a subsequent section, and there may be changes to baseline breast imaging following breast implant placement (**Fig. 107.37**).[62]

Gynecomastia Reduction

Gynecomastia, or male breast enlargement, may have a variety of etiologies, including pubertal changes, hormonal abnormalities, medications, and more sinister causes such as testicular cancer. Assessing if and when to perform surgery is a critical component in the preoperative period. Surgical approaches differ significantly from those used for reduction of the female breast. Postoperative care remains important.

Table 107.9 Surgical Approaches for Augmentation Mammoplasty[60,61]

Surgical Approach	Options	Considerations
Incision/scar	Periareolar	Scar at junction of different types of skin considered minimally visible unless abnormal scarring occurs, requires dissection through breast gland
	Inframammary	Scar in fairly hidden location in most patient positions but through normally unmarked skin, IMF position may change with procedure
	Axillary	Somewhat remote, may make manipulation of surgical field more difficult
	Transumbilical	Remote from site, may make manipulation of surgical field more difficult
Implant placement	Subglandular	May help address a small amount of preoperative ptosis, may impact capsular contracture, increased visibility/palpability of implant if very thin soft tissue
	Partially submuscular	Multiple definitions, including "dual plane," considered to preserve surveillance imaging of gland more than subglandular approach
Augmentation material	Silicone implant	See "Breast Implants" section
	Saline implant	See "Breast Implants" section
	Autologous fat grafting	Use of liposuction to harvest slurry of tumescent solution, fat, oils, and other debris, followed by various

	fat separation techniques and injection of fat in small droplets throughout parenchyma of breast, imaging considerations as postoperative appearance is different than alternate augmentations

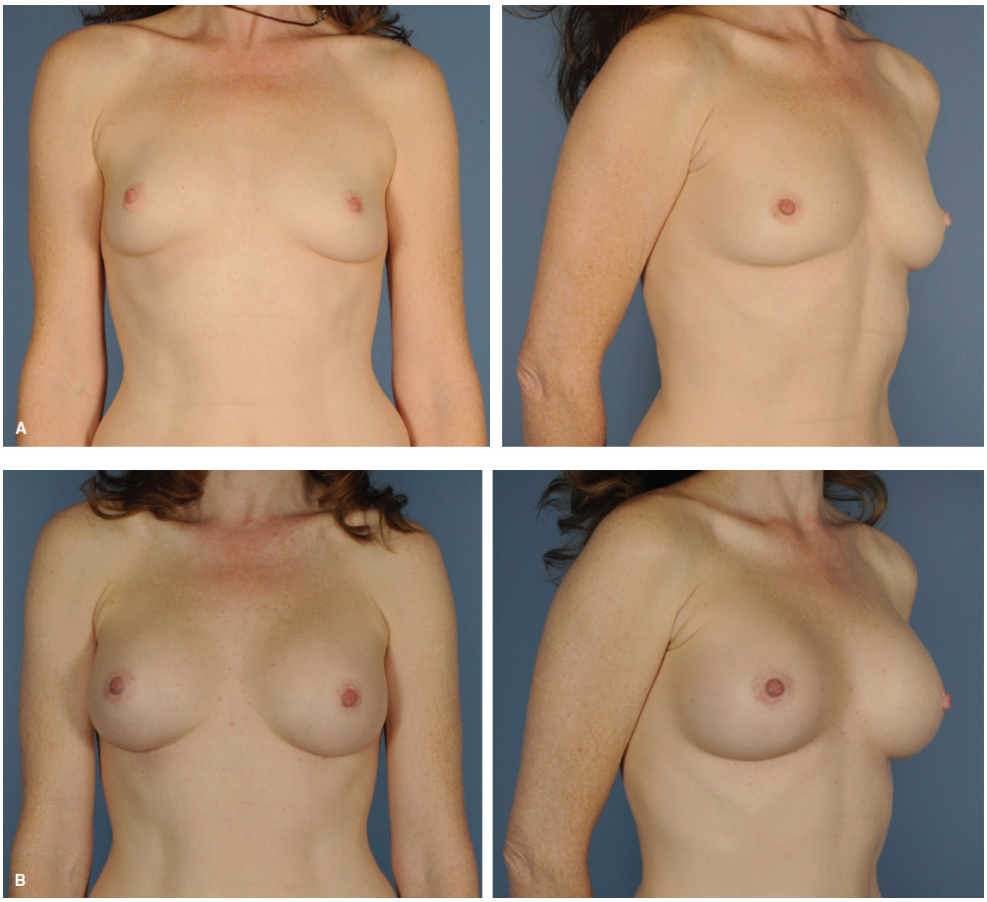

Figure 107.37 Breast augmentation via inferior mammary fold (IMF) incisions. **A:** Preoperative. **B:** Postoperative.

Preoperative Evaluation

Patients presenting for gynecomastia reduction are quite diverse. Some may be very young men, suffering from excess breast volume induced by pubertal changes in the recent past. Other patients have waited years to see spontaneous resolution of the peripubertal onset of disease without

improvement. Others may be of varying ages, complaining of breast tissue excess related to obesity, medications, or other medical conditions, including sinister causes such as testicular cancer. Given the complex etiologies, spontaneous resolution in some cases, and potential for nonsurgical interventions at times, careful coordination with other medical providers may be considered essential. Full medical history and physical examination and formal endocrinology workup should be considered preoperatively. Imaging may be necessary specifically related to the breast, particularly if asymmetry, irregularity, or mass increases the suspicion of male breast cancer.[63]

Surgical Approaches

Surgical approaches account for the increased visibility of the male chest (making scars less acceptable than in female breast reduction), the dense, fibrous, gritty nature of male glandular enlargement, and the expected male NAC position and size (drastically different than on the female breast). Many of the approaches have significant limitations. The more common approaches and their considerations are listed in **Table 107.10**.[64]

Postoperative Follow-Up

Routine postoperative care to follow healing is recommended. The diversity of surgical approaches necessitates a diversity of postoperative regimens. Scar therapy may be important given the visibility of the surgical site.

Breast Reconstruction

Breast reconstruction most commonly follows oncologic resection, but similar techniques may be applied after trauma or developmental irregularities. Preoperative considerations are many, and most importantly, must recognize the necessity of multi-disciplinary approaches for optimal outcomes. Surgical approaches are also multitudinous, regarding both technique and timing. Postoperative care largely focuses on complication minimization, recognizing the frequent need for adjuvant oncologic treatments.

Table 107.10 Surgical Approaches for Male Gynecomastia Reduction[64,65]

Approach	Consideration
Liposuction alone	Minimal scars, best used for gynecomastia with large adipose component and minimal skin excess
Marginal liposuction and direct periareolar excision of gland	Usually through partial periareolar scar, direct excision of gritty firm tissue under and around NAC with liposuction for feathering at margins, best if minimal skin excess
Amputation and nipple-areolar complex (NAC) skin grafting	Best for large amount of skin excess and NAC ptosis, scar for skin resection (transverse orientation) planned for subpectoralis muscle location often better tolerated than inframammary fold (IMF) since defined IMF in males is abnormal, direct excision of large amount of tissue in mastectomy-type approach, NAC position and size planned to match more "normal" male appearance, best if enough preoperative ptosis that NAC excision site is removed in resection of excess skin
Pedicled nipple transposition approaches	Variety of approaches, often uniquely designed for each patient to address moderate amounts of skin excess, tissue excess, and NAC ptosis, must take care not to apply female reduction techniques designed to "cone" the breast into a female shape

Preoperative Evaluation

Patients approach breast reconstruction with many different goals, including appearance optimization with and without clothes, sensation normalization,

scar minimization, and restoration of the feel of the breast to palpation.[66] Neoadjuvant and adjuvant cancer treatments including radiation therapy, chemotherapy, and previous surgery may alter surgical reconstruction options available. The surgical approaches span a diverse spectrum of complexity and technique, making medical comorbidities important considerations. Patients must understand that reconstruction most often requires staging with revisions to optimize the outcomes. Planning for repeated periods of decreased activities of daily living may be necessary. Various surgical techniques impact length of postoperative follow-up and potential for future necessary surgical interventions.[67–69] The delivery of this information occurs during a time in which the patient has other medical decisions to make which can impact survival and quality of life. Surgical planning must recognize the difficulty experienced by patients when confronted by the large amount of information and multiple decisions to be made and include future alternatives should complications arise or patients' preferences change.

Surgical Approaches

Table 107.11 addresses basic approaches to postmastectomy reconstruction technique.[67–72]

Table 107.11 Postmastectomy Breast Reconstruction Techniques[67–73]

Surgical Approach	Options	Considerations
Autologous tissue	Pedicled flaps (i.e., latissimus dorsi, thoracodorsal artery perforator [TDAP], rectus abdominus)	Requires donor site, often requires muscle sacrifice
	Free tissue transfer (i.e., rectus abdominus, deep inferior epigastric perforator [DIEP], superficial inferior epigastric perforator [SIEP], superior/inferior gluteal artery perforator [SGAP/IGAP], transverse/diagonal upper gracilis [TUG/DUG])	Requires donor site, perforator flaps designed to preserve muscle and minimize morbidity, longer surgeries with more inpatient requirements, more similar to natural breast tissue, maintenance surgeries not usually required after reconstruction complete
	Fat grafting	Minimal scarring at donor site, often requires multiple stages to achieve volume other methods accomplish in one surgery, often used as a revision technique
Implants	Tissue expander	Used as staging, temporary changeable volume implant with port for repeated transcutaneous access, can be prepectoral or subpectoral, recently the

		prepectoral location has been rapidly gaining popularity
	Implant (i.e., silicone vs. saline, round vs. anatomic, textured vs. smooth)	Likely requires maintenance surgery, requires adequate skin envelope, foreign body, shorter surgeries with fewer inpatient admissions, also can be prepectoral or subpectoral (see above), see "Breast Implant" section for further details
Biologics	Acellular dermal matrices	Used as an adjunct for tissue reinforcement, often used to reinforce the breast pocket, particularly with implant-based reconstruction or to reinforce the fascia at an autologous donor site (usually abdomen)

Timing is also an essential consideration in breast reconstruction. Ideally, all patients would have access to breast reconstruction counseling at the time of breast cancer diagnosis and initial treatment, but many patients present in delayed fashion after lumpectomy and radiation or mastectomy. Patients who have already undergone mastectomy who then desire reconstruction may consider tissue expansion followed by implant or autologous reconstruction or autologous reconstruction without expansion. Patients who present prior to mastectomy may consider immediate autologous reconstruction, immediate implant-based reconstruction, staging with a tissue expander, or planning for a delayed reconstruction.[67–69]

The application of free tissue transfer techniques has changed the approach to autologous breast reconstruction. The 8 use of pedicled rectus abdominis-based reconstruction, the TRAM flap, has given way to the widespread use of perforator flaps. The most widely used are based on the deep inferior epigastric perforators (DIEP). These flaps for the most part, spare the rectus abdominis muscle and create a breast mound from excess lower abdominal wall adipose tissue. The free flaps have proven to be quite hardy and tolerate radiation and chemotherapy well or can be staged as mentioned above.

Other cancer treatments may impact reconstruction choices. Radiation therapy increases wound healing complications, infections, and overall failures in implant-based reconstruction. Autologous reconstruction is most commonly planned, when possible, for after radiation, to deliver healthy soft tissue into a damaged area. Chemotherapy may alter the body's resistance to infections and may alter timing of reconstructive surgeries. Nipple-sparing procedures preserve the skin envelope and more of the natural breast architecture, but they allow for little manipulation of the skin envelope when irradiated and abnormal.[67,68]

Reconstruction after lumpectomy and radiation therapy is another consideration. If planned prior to lumpectomy, oncoplastic breast rearrangement techniques can be considered. These include reductions, lifts, and complex tissue rearrangements through various scar patterns. The contralateral breast may also be addressed for symmetry. Operating to reduce deformity after lumpectomy and radiotherapy has increased risks of complications related to issues such as wound healing and infections but may include techniques such as autologous fat grafting, implant placement, autologous flap reconstruction, or mastectomy and YYYreconstruction.[67,74]

Postoperative Follow-Up

Postoperative follow-up is usually frequent and occurs over time given the frequently staged nature of reconstruction. Postsurgical drains are often used. Complications like compromised skin, wound healing problems, infections, and seromas are encountered and can impact overall reconstructive success (**Figs. 107.38** and **107.39**).[67,69]

Transgender Surgery

Transgender surgery is increasing in frequency over time and will be more completely addressed elsewhere. A multidisciplinary approach to breast surgery in the setting of more global considerations of transgender health is considered important. Hormonal interventions are also important to include in the complete approach. Future cancer risk must also be addressed. Insurance coverage has greatly increased over time, expanding the reach of these techniques. Surgical approaches converting a female-appearing chest to a male-appearing chest are similar to those considered for gynecomastia surgery, particularly regarding scar location and NAC position and size. Converting a male-appearing chest to a female-appearing chest includes consideration of augmentation with special emphases on differences in baseline anatomy, breast gland amount and composition, pectoralis muscle differences, and potential staging due to stretch of tissue over time. Postoperative care remains important as discussed above.[75,76]

Breast Implants

Patient should be made aware of several factors including: predicted lifespan of implants, likelihood of leakage of contents over time, expectation of imaging and further surgery, and somewhat decreased ability to image as much of the breast tissue with mammography following implant placement. Anaplastic large cell lymphoma has been linked to breast implants and is under current active study. Breast implant–associated systemic symptoms (malaise, arthralgias, and many others) are also being reinvestigated, and at the current time seem to impact only small numbers of patients receiving implants. Patients will require counseling regarding smooth versus textured implants, silicone versus saline implants, and anatomic versus round implants. Current imaging recommendations for silicone implants should be discussed.[77–79]

AESTHETIC SURGERY

Plastic surgery at its core is a function of restoring structure and function. A principle such as "replace like with like" seems basic at face value; however, it is challenging on many levels as one can note from other sections of this chapter. A myriad of unique clinical issues must be addressed from scalp to toe and requires a full understanding of anatomy. In addition to the restoration of function in reconstructive plastic surgery, the discipline of plastic surgery encompasses aesthetic plastic surgery, colloquially termed "cosmetic surgery." The 9 quest to surpass normalcy and achieve "perfection" requires an artistic approach to medicine and is paramount in guiding patients who are seeking to enhance their own self-esteem and body image. In the process of undergoing these procedures, a functional benefit also may often result. After undergoing an abdominoplasty, repair of the rectus abdominis muscle diastasis has been noted to help patients improve posture, increase core strength, and decrease stress urinary incontinence—all sequelae of term pregnancy. A rhinoplasty improves the overall outward appearance of a patient's face, but also may improve nasal airway breathing.

No surgical discipline requires greater attention to the 10 patient's underlying psychological conditions/stability than aesthetic surgery. Carefully selected patients with realistic goals who have an appropriately executed procedure are likely to be satisfied in all facets. However, a patient poorly selected with unrealistic goals or elements of psychological instability may undergo a perfectly successful operation with an aesthetically pleasing outcome to an outsider but could be viewed as a colossal failure in the eyes of the patient leading to devastating consequences. Aesthetic surgery requires the surgeon to: pay meticulous attention to detail, carefully select patients, rigorously plan procedures, and precisely execute technically challenging procedures. Identifying the motivations of patients for undergoing the procedures is also important and through applying of sound surgical principles and technical expertise, the aesthetic plastic surgeon will experience lifelong career and personal satisfaction.

Cosmetic Procedures for the Head and Neck

Brow Lift

A natural sequela of facial aging is often brow ptosis. The dynamic nature of the frontalis muscle results in patients often contracting the muscle to elevate the brow to decrease the appearance of patient's ptosis. When left untreated, brow ptosis results in patients appearing fatigued, angry and/or aged. In severe cases, brow ptosis may cause visual field obstruction on upward gaze; correction of this deformity can produce dramatic aesthetic and functional improvements. Patients are often not aware of their brow ptosis and may present to the plastic surgeon's office complaining of "heavy eyelids." In many cases, the etiology of their complaint is brow ptosis rather than upper eyelid ptosis or dermatochalasis. These patients will require a brow life alone, or in conjunction with a blepharoplasty, to correct their aesthetic and functional concerns.

Figure 107.38 Staged bilateral implant-based breast reconstruction. **A, B:** Preoperative appearance. **C, D:** After tissue expansion. **E, F:** Final postoperative results after expander exchange for implant and nipple-areola complex tattooing.

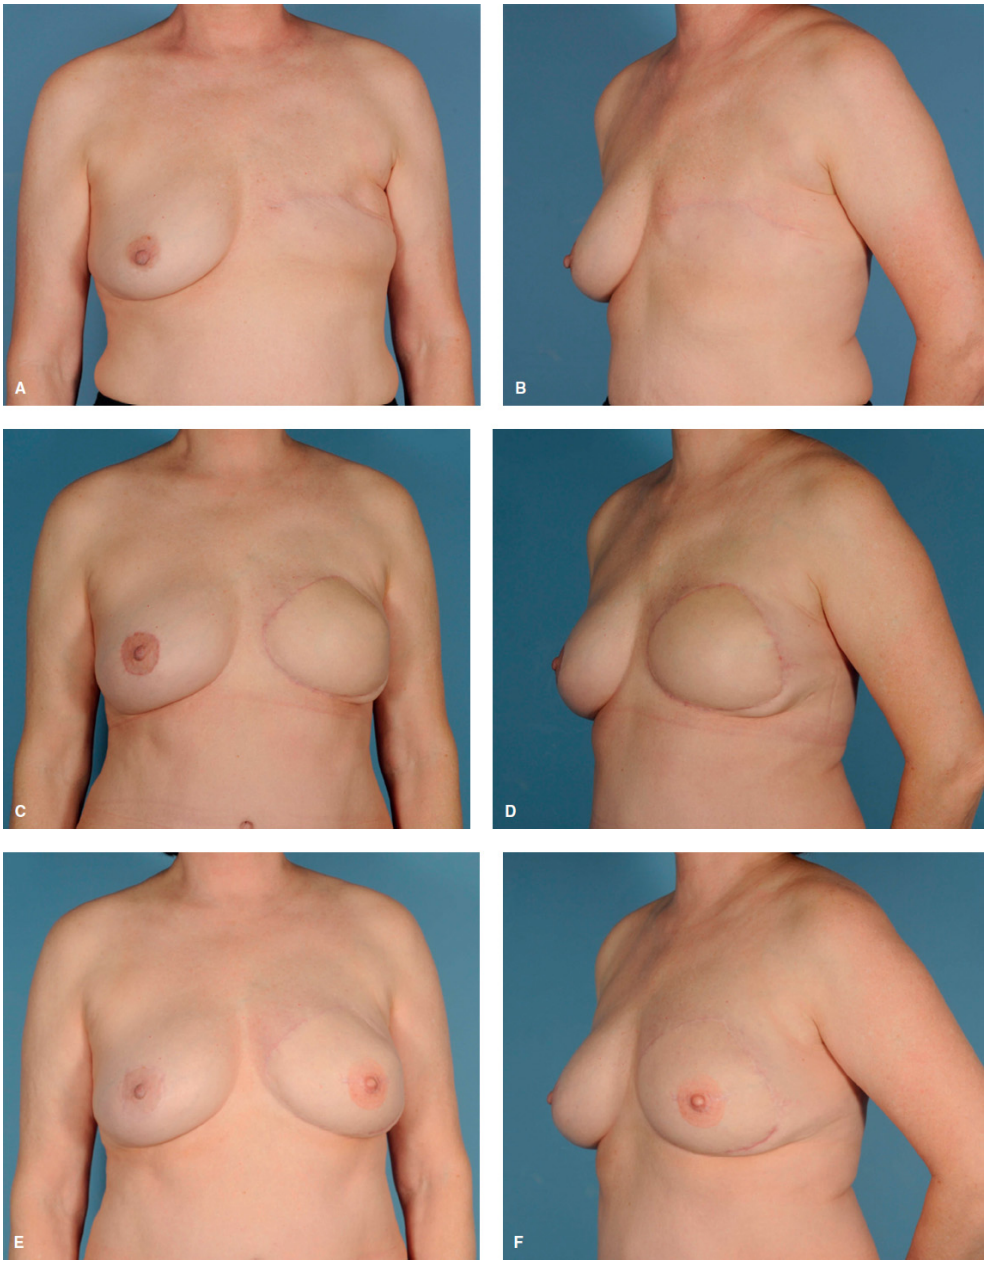

Figure 107.39 Delayed DIEP breast reconstruction. **A, B:** Appearance after mastectomy. **C, D:** Appearance after left DIEP flap reconstruction. **E, F:** Final result after tattooing of nipple-areola complex.[5]

Correction of brow ptosis can be achieved with either an open or endoscopic approach. The traditional open approach requires a bicoronal incision with resection of excess scalp or forehead. Unfortunately, this approach results in a lengthy scar, possible scar alopecia, and paraesthesia of the scalp and forehead due to transection of branches of the supraorbital and supratrochlear nerves. In addition, an open coronal brow lift in male

patients with a receding hairline or female patient with an elongated forehead requires resection of hair-bearing scalp moving non–hair-bearing forehead skin further posteriorly accentuated baldness. This tradeoff is not worth the aesthetic deformity of increasing the appearance of hairline recession. Techniques have evolved to decrease scar burden by performing temporal incision-only brow lifts. The limitations of this approach include minimal correction of central brow ptosis and medial eyebrow depression. To counteract the accentuation of a receding hairline from the bicoronal approach, an anterior hairline brow lift incision evolved which involves placing the incision at the junction of the hairline and forehead skin. Most male patients are not a candidate for this procedure as many men will experience elements of hairline thinning anteriorly. Female patients with elongated foreheads do well with this approach, however, are reluctant to wear their hair in a ponytail as they will likely expose a visible scar. Male patients can opt for a direct brow lift approach, which involves the surgeon selecting a deep horizontal forehead rhytid and resecting skin above or below landing the scar in the original rhytid. After 6 to 12 months of wound healing, the incision is often camouflaged within the natural crease. Finally, to reduce many of the complications associated with open approaches, the endoscopic brow lift was developed and has become the primary approach for repair of brow ptosis.[80] The endoscopic brow lift requires only three to five 1-cm incisions behind the hairline to gain access to the forehead and glabellar rhytids, producing less of an aesthetic deformity and limiting the amount of scarring. There is also evidence to suggest that the endoscopic approach produces a more lasting result than the traditional approach.[81] Finally, it has been reported that anesthesia of the forehead and scalp is significantly reduced when an endoscopic approach is utilized for correction of brow ptosis, as compared to an open coronal approach.

Endoscopic and open brow lifts may be performed under local or general anesthesia. Patients are marked preoperatively in the upright position. The desired brow position is at the level of the orbital rim in male patients and 1 cm above the orbital rim in female patients. The position of the brow in relation to the supraorbital rim changes from medial to lateral; the lateral brow should be more elevated than the medial brow. During an open brow lift, a coronal incision is made and the entire forehead it mobilized in a subgaleal or subperiosteal plane down to the orbital rim. The supraorbital

and supratrochlear nerves are dissected free of surrounding tissues and observed. The supraorbital muscle is resected if prominent glabellar rhytids are present. Excessive resection of the corrugator muscles will result in widening of the eyebrows in the midline. The periosteum is released at the level of supraorbital rim when a subperiosteal plane is utilized for mobilization of the forehead; the dissection is carried down to the level of the supraorbital rim when a subgaleal plane is used for forehead mobilization. The forehead is then elevated and redraped posteriorly, the redundant scalp is resected, and the wound is closed. In an endoscopic brow lift, incisions are made within the hair-bearing scalp at the midpupillary line and over the temporal fossa. The entire forehead flap is elevated under endoscopic guidance, the procerus and corrugator muscles are resected as necessary, and the forehead is retracted posteriorly. The forehead is then secured into its new position. Various methods of forehead fixation have been described including absorbable and nonabsorbable plates, screws, multipronged anchors, or cortical tunnels.[82]

Postoperatively, patients are instructed to avoid vigorous physical exercise for at least 6 weeks. Bruising and swelling are anticipated for the first 2 to 3 weeks following the procedure. The final result is not expected for at least 6 to 8 weeks following the procedure. Patients are instructed that the final scar appearance will mature between 9 and 12 months post surgery.

Rhytidectomy

Few areas of the body betray the age of an individual as greatly as the face. The negative impacts of aging process, gravity presence, solar exposure, and smoking are particularly manifested on the face. The loss of skin elasticity which lead to fine facial wrinkling and skin laxity can be attributed to ultraviolet radiation and tobacco. Aging and gravity result in gradual relaxation of the facial retaining ligaments producing midfacial ptosis, deepened and nasolabial folds, “jowling” along the mandibular border, and redundancy of cervical skin.[83] Many patients become aware of these aging features while reminiscing on old family photographs, as their youthful appearance consisting of high cheekbones, a sharp mandibular border, and smooth skin is more apparent. As the aging process continues and a patient reflects on his/her former features, he/she may lose self-confidence while

interacting in professional and social settings. This drop in self-esteem often leads one to consult with the plastic surgeon who will execute a facial rejuvenation plan in order to restore his/her youthful facial features. After this process is carefully completed, both the patient and surgeon will see gratifying results.

During the original consultation, the patient first outlines their surgical expectations and motivations, which are then evaluated by the surgeon. It is important that the concerns of the patient are reasonable and not out of proportion to their physical deformity. If this does occur, even a perfectly executed operation may still have an undesirable outcome in the eyes of the patient.

Many surgeons will refuse to perform a cervicofacial rhytidectomy in any patient who is actively smoking or utilizing any products containing nicotine. This is due to these patients having a significantly increased risk for developing postoperative complications, including skin flap necrosis, infection, or wound dehiscence. Patients are consequently instructed to quit prior to undergoing elective aesthetic surgery, and whether a patient has been utilizing nicotine in any form can be determined through urine cotinine levels. Additionally, patients with coexisting medical illnesses require preoperative medical clearance and are referred to a general practitioner for medical optimization. If the patient is deemed a moderate or high risk for general anesthesia because of medical comorbidities, then the operation may be postponed until those medical conditions are optimized. The surgery will ultimately be cancelled if the risk of anesthesia is too high for a patient.

Patients between the ages of 40 and 50 years with good skin quality, mild midfacial ptosis, and early “jowling” may benefit from a minimally invasive facelift. This operation is typically combined with an endoscopic brow lift to provide upper and lower facial rejuvenation with minimal scarring and is performed under local or general anesthesia. First, bilateral temporal and superior buccal sulcus incisions are made. The temporal force dissection is then carried down to the level of the superficial layer of the deep temporal fascia. Under endoscopic guidance, the superficial layer of the deep temporal fascia is then incised to expose the temporal fat pad. The dissection then proceeds caudally until the zygomatic arch is identified. A subperiosteal plane of the dissection provides access to the midface while preserving the integrity of the frontal branch of the facial nerve. The subperiosteal plane of

dissection is continued into the midface with care taken to avoid the infraorbital nerves. The masseter is mobilized from its lateral attachments. The superior buccal sulcus incisions are made, and a midface subperiosteal dissection is performed under both direct visualization and endoscopic guidance. Once the dissection is completed, the entire midface is suspended in the desired position with sutures or specialized anchors spanning from the superficial layer of the deep temporal fascia to the midface periosteum. Symmetry of the suspension is then confirmed, and the wounds are closed by layers. Mild midface ptosis, mild jowling, and early nasolabial fold prominence can all be corrected through this procedure, however deformities from significant skin laxity will not be corrected under this technique. In order to fix the latter, a traditional cervicofacial rhytidectomy will be required.[82,84]

A traditional rhytidectomy can be performed under local or general anesthesia in patients who require resection of excess skin. The skin incision is made over the temporal fossa 4 to 5 cm cephalad to the root of the helix and extended caudally toward the apex of the ear. The incision is then extended anterior to the ear, behind the tragus, around the base of the earlobe into the retroauricular sulcus, across the mastoid, and caudally along the anterior hairline of the neck. The skin flap is then elevated just superficial to the superficial musculoaponeurotic system (SMAS) and platysma. This plane of dissection maintains a thin layer of subcutaneous fat on the skin flap to preserve viability, while avoiding injury to the facial nerve branches, greater auricular nerve, parotid gland, and jugular vein. The flaps are elevated medially to the nasolabial fold in the face and to the midline in the neck. In some operations, a platysmal diastasis may exist which creates platysmal banding, an obtuse cervicomental angle, and a prominent neck. If this occurs, a platysmal plication may be performed through a 2- to 3-cm submental incision to correct the diastasis and improve the appearance of the neck. At this point, the remainder of the cervicofacial rhytidectomy can be performed in various ways, all with the goal of repositioning the tissues that have migrated into dependent positions, leading to facial aging changes. The surgeon may simply choose to not perform any additional dissection at this point and simply reposition the skin, resect the excess skin, and close the incisions. The surgeon may also choose to do one of the following: SMAS plication, standard SMAS dissection, extended SMAS dissection, or deep-

plane dissection. All of these operations are designed to improve control of facial and cervical tightening, while reducing the tension on the skin closure. Once the dissection of the facial tissues is completed and all planes are mobilized optimally, the SMAS and platysma are placed under tension and secured to create the desired facial appearance. The skin flaps are then redraped posteriorly, the patient is examined for symmetry, and a skin resection is performed. Hemostasis is obtained through judicious use of bipolar electrocautery. The wounds are closed in layers and a pressure dressing is applied. Drains are typically used in both the face and neck.[7,85–88]

Figure 107.40 A 63-year-old female presented to the office concerned with facial aging. The patient was displeased with the overall appearance of fatigue and looking sad, despite feeling well and energetic (**A**, **B**). She requested facial rejuvenation of the eyes, cheeks, neck, and overall skin texture. The patient underwent a facelift, neck lift, periorbital rejuvenation, and facial laser resurfacing. She is pictured here 1 week prior to surgery (**A**, **B**) and 1 year after her procedure (**C**, **D**).

Postoperatively, the patient is immediately evaluated for any evidence of a hematoma or facial nerve injury. Identifying a hematoma early is crucial in order to avoid overlying skin necrosis, and facial nerve injuries only occur in 2% to 3% of cases. On the first postoperative day, the pressure dressings and drains are removed, and the patient is further examined for evidence of a late hematoma, unrecognized facial nerve injury, or compromised skin flap. Patients should expect to have significant swelling and bruising for at least 2 weeks following the procedure. The final postoperative desired outcome is not realized until approximately 6 months following the procedure (**Fig. 107.40**).

Blepharoplasty

Eyelid surgery is one of the most frequently performed cosmetic surgery procedures. Blepharoplasty is often employed to correct both functional and/or aesthetic deformities. Visual field obstruction, or an angry, aged, or tired look in the patient may occur due to excessive skin and fat of the eyelids. In older patients, excess skin and wrinkling may occur, whereas in younger patients, persistent bags under their eyes or fine wrinkling ("crow's feet") at the lateral canthus is most common. Each clinical entity requires a unique approach based on the diagnosis and presentation, and meticulous attention to details is critical for the successful outcome of a blepharoplasty.[89] Preoperatively, all patients considering blepharoplasty should undergo a complete ophthalmologic examination to evaluate visual acuity, upper lid ptosis, exophthalmos, lower eyelid laxity, and symptoms of "dry" eye. Should lower lid laxity be present, and a standard blepharoplasty is performed, the patient may develop a lower lid malposition with ectropion postoperatively. Blepharoplasty may also significantly exacerbate symptoms of dry eye. Because of this, it is critically important to perform a comprehensive evaluation of the health of the eye prior to performing any eyelid surgery.

Once the optimal health of the eye is confirmed, an operative plan can be formulated and executed to correct the concerns of the patient. The operation can be performed under local or general anesthesia. The blepharoplasty incisions are first designed preoperatively with the patient in the upright position. Older patients frequently require skin excisions or removal or repositioning of orbital fat prior to the operation. To begin, local anesthesia with epinephrine is infiltrated for pain control and hemostasis.

The upper eyelid blepharoplasty begins with an elliptical excision of upper eyelid skin and orbicularis oculi muscle. This skin excision is designed based on the amount and location of the dermatochalasis. Very rarely will a patient require removal of fat from the upper eyelids, as these excessive fat resections will produce a "hollowed-out" appearance. Under some circumstances however, there may be a substantial amount of excess orbital fat in the upper eyelids and conservative fat resection may be helpful to achieve the desired postoperative outcome. If a fat resection occurs, small openings are made in the orbital septum to gain access to the two compartments of periorbital fat. A conservative fat resection is then performed to avoid a potential postoperative hollowed-out appearance. The

skin is then redraped and the wounds are closed in a single layer. If an upper lid blepharoplasty and brow lift are being performed within the same operation, the brow lift should be performed first, so that the amount of excess upper eyelid skin can be determined after the brow has been elevated.

The traditional lower eyelid blepharoplasty begins with a subciliary incision. A 4- to 5-mm rim of orbicularis oculi is then preserved along the lower eyelid margin. The dissection is then carried deep to the orbicularis oculi muscle until identification of the orbital septum. The orbital septum is then divided to gain access to the three compartments of periorbital fat in the lower lid. Fat may be resected in cases of prominent herniation, but it is necessary to avoid over resection. A trend in blepharoplasty surgery has emphasized repositioning the herniated periorbital fat over the inferior orbital rim rather than resecting fat in order to dramatically improve the appearance of the lower eyelids. This approach of repositioning the orbital septum medially has proven to be very helpful in eliminating tear trough deformities. Once the periorbital fat has been resected or repositioned, the skin/muscle flap is redraped superiorly and the redundant tissue is excised. The lower eyelid wounds are closed with interrupted sutures of 6-0 silk. Ancillary procedures, including a medical canthoplasty, a lateral canthoplasty, lateral canthopexy, or horizontal lid shortening may also be necessary to improve the position of the lower eyelid. If a lower lid blepharoplasty is being performed in conjunction with a rhytidectomy, the rhytidectomy should be performed first, so that the amount of excess lower eyelid skin can be determined after the facial soft tissues have been elevated.

The tired appearance of the lower eyelids is commonly a result of excessive or herniated periorbital fat in younger patients. A lower lid blepharoplasty through a transconjunctival approach allows for the removal or repositioning of the periorbital fat without creating an external scar. First, the conjunctiva is divided transversely 1 mm above the sulcus to gain access to the orbital septum. The septum is then divided, and the periorbital fat is removed or repositioned from all three compartments. Preserving the periorbital fat and simply repositioning the orbital septum into a more optimal location, obviates the need for fat resections. The transconjunctival incision is allowed to heal by secondary intention, allowing rejuvenation of the lower lids without an external incision. Recently, a multiplanar approach for the rejuvenation of the lower eyelids has been employed to reduce the

incidence of lower eyelid ectropion postoperatively. These approaches combine both subciliary incisions for removal of excess skin and transconjunctival incision for repositioning or resection of the periorbital fat. Experienced plastic surgeons have demonstrated outstanding outcomes with this approach as apparent through clinical case review. In conjunction with the non–external incision lower blepharoplasty, the surgeon can treat the lower eyelid skin with a resurfacing laser. The use of ablation and coagulation during full field ablative lasers induces a calculated "burn" of the skin leading to contraction and skin quality improvement. This technique often precludes the need for actual skin resection leading to no visible scar.

Postoperatively, patients are immediately evaluated for corneal abrasions, changes in visual acuity, or hematomas, which may require emergent intervention. Artificial tears are used to maintain appropriate lubrication and sutures are removed 5 to 7 days following the operation. Patients are instructed to not partake in any vigorous physical exercise during the early postoperative period. It is expected that patients will be bruised and swollen for approximately 2 weeks following the blepharoplasty and that it will be approximately 6 to 8 weeks before the desired outcome is noticed.

Rhinoplasty

No aesthetic surgical procedure may be a "game of millimeters" more than rhinoplasty. Cosmetic surgery of the nose requires meticulous planning and execution often involving alteration of both the external appearance and internal anatomy of the nose. The nose may be aesthetically unappealing or functionally impaired as a result of trauma, surgery, or a congenital deformity. Different familial and ethnic traits give rise to a plethora of nasal appearances. Because of this, it is necessary that any expectations the patient has regarding the procedure are realistic and achievable and align with the goals of both the patient and the surgeon. The patient must be prepared physical and mentally for the operation.

Preoperatively, a complete nasal history is obtained with particular attention paid to nasal airway obstruction, allergies, trauma, and previous surgery. A photographic analysis is performed to evaluate facial and nasal dimensions. The surgeon examines the photographs, discusses the plan with the patient, and the potential structural and functional outcomes are reviewed.

Rhinoplasty may be performed under local or general anesthesia. The patient is prepared for surgery by intranasal injections of vasoconstrictors containing lidocaine and epinephrine. Topical vasoconstrictors are applied to the nasal lining and septum. The operation can be performed in an "open" or "closed" fashion. The open technique requires a transcolumellar incision extended intranasally to allow exposure of the cartilage and bones of the nose. Direct visualization of the nose structure allows for greater precision in cartilaginous sculpting, grafting, and nasal bone repositioning. The paired lower lateral cartilages create the shape and provide the support for the nasal tip. Any deformity involving the nasal tip requires manipulations of this cartilage, including resections for a bulbous or over projecting tip, suturing to reposition an asymmetric nasal tip, or cartilage grafting to increase tip projection. The paired upper lateral cartilages and nasal bones define the shape of the nasal dorsum and control nasal airflow. A prominent dorsal hump may require resections of both the upper lateral cartilages and nasal bones. Osteotomies of the nasal bones may be required to narrow nasal width by disconnecting the base of the nasal bones from the maxilla. In contrast, "saddle nose" deformities may require cartilage or bone grafting to provide dorsal augmentation. Alloplastic materials have been described for use as dorsal graft, tip grafts, or columellar struts to increase nasal projection. Many surgeons discourage use of such alloplastic grafts due to problems with infection, extrusion, and migration producing a suboptimal result acutely or chronically. Autogenous cartilage grafts from the nasal septum, ear, or rib may also be used to improve nasal appearance or airflow. These grafts can be harvested and sculpted to create the desired cosmetic appearance of the nasal dorsum and tip. "Spreader grafts" can also be placed between the nasal septum and the upper lateral cartilage to increase the size of the internal nasal valve area, improving nasal airflow. The "closed" rhinoplasty technique allows access to the nasal cartilage and bones through intranasal incisions. This is the preferred method of experienced rhinoplasty surgeons because it is less invasive, however it is difficult to perform many of the complicated cartilage grafting and suturing techniques with limited exposure.

Following the rhinoplasty, an external splint is used to maintain the position of the nasal bones and cartilage for 10 to 14 days. Patients are instructed to keep their head elevated and apply ice packs, and should expect

nasal swelling, pain, and bruising for 2 to 3 weeks. If osteotomies are performed, the patient may also experience periorbital ecchymosis. A full year is required for complete resolution of nasal tip swelling, especially if an open-tip rhinoplasty has been performed. Approximately 10% of primary rhinoplasty patients will require an operative revision due to dissatisfaction with the cosmetic or functional outcome. This revision should not occur for at least 1 year following the original surgery in order to ensure all postoperative swelling and tissue remodeling has stabilized.

Genioplasty

Often performed in conjunction with rhinoplasty, facial harmony is achieved by simultaneously performing a genioplasty. This frequently executed plastic surgical operation improves facial appearance by manipulating the position of the central mandible aka "chin." The vertical height and anterior projection of the chin is able to be adjusted due to the design of the mandibular symphysis osteotomy.[90] An advancement genioplasty may be performed in patients with a "weak" chin to enhance chin projection and improve the cervicomental angle. Chin augmentation may also be accomplished with an alloplastic implant, eliminating the need for an osteotomy. A reduction genioplasty may be performed in patients with a very prominent chin, where the vertical height and anterior projection can be reduced. The lip position and neck appearance may be altered from these procedures; however, the dental occlusion is not affected.

After the initial consultation, a complete physical examination, photographic analysis, and radiographic evaluation are performed to evaluate facial harmony and determine the extent of the advancement or reduction. Dental occlusion is also carefully examined to ensure that orthognathic surgery is not required to correct chin position.

These operations are typically performed under general anesthesia but can also be performed under local anesthesia if desired. Local anesthesia containing epinephrine is first injected intraorally for hemostasis and postoperative pain control. An inferior buccal sulcus incision allows access to the mandibular symphysis. The osteotomy is then measured and marked based on the preoperative photographs and lateral radiographs, while avoiding the mental foramen. The bony segment is mobilized and secured in

its new position with plates and screws. If an alloplastic chin augmentation is to be performed, incisions can be performed in the submental region or intraorally to allow placement of the implant. Postoperatively, the swelling and pain is expected for approximately 4 to 6 weeks. During this time, the patient is instructed to perform meticulous oral hygiene and avoid foods that may traumatize the inferior buccal sulcus incision.

Cosmetic Procedures of the Trunk and Extremities (Body Sculpting)

Abdominoplasty

In recent years, there has been tremendous emphasis on body contouring. The explosion of technology-based nonsurgical modalities has led to increased interest in improving the appearance of the trunk. Abdominoplasty surgery addresses abdominal deformities such as excess abdominal skin, fatty tissue, and abdominal wall laxity through various surgical procedures. Abnormalities in any of these tissue planes may create a very aesthetically unappealing abdomen and create the need for the patient to seek surgical treatment. These procedures, which include dermatolipectomy, liposuction, and abdominal wall plication are able to correct the underlying pathology and are often combined and tailored to fit the surgical needs and desires of the patient. It is critical to define the physical anomaly responsible for the abdominal deformity so that the appropriate operative procedure or combination of procedures can be planned and executed.[91,92]

A standard abdominoplasty combines a dermatolipectomy, liposuction, and abdominal wall plication to correct deformity in each of the three previously mentioned abdominal wall layers. The operation is performed under general anesthesia and starts with a bikini-line incision extending from the cephalad margin of the pubic escutcheon to the iliac crests bilaterally. Once the skin incisions are made the abdominal flap is elevated off the underlying abdominal wall fascia. A circumferential incision is made around the umbilicus to allow complete elevation of the abdominal flap up to the costal margin. The patient is then placed in a flexed position, the abdominal flap is redraped caudally, and the redundant skin is resected. If any

abdominal wall laxity is identified along with the skin redundancy, then a vertical, midline abdominal wall plication is also performed. Occasionally, suction-assisted lipectomy (SAL) is performed at the time of abdominoplasty to help recontour the abdomen and flanks. Aggressive SAL of the abdomen flap, however, may critically compromise flap vascularity and contribute to flap necrosis. It is helpful to perform SAL along the lateral and posterior iliac crests bilaterally to reduce the prominence which may have developed following the anterior dermatolipectomy and caudal repositioning of the skin flap. A small incision is then made in the midline of the abdomen at the level of the iliac crests for delivery of the umbilicus into its new position. Closed-suction drains are placed prior to wound closure, but not necessary. In this instance, employing a series of progressive tension sutures is paramount to close the dead space. Typically, a series of 15 to 20 sutures are used to approximate the Scarpa fascia to the anterior rectus sheath.

A "mini-abdominoplasty" can be performed to treat mild abdominal skin redundancy and abdominal wall laxity. The previously described approach regarding a standard abdominoplasty is executed, except the skin incision is limited to the central portion of the abdomen. A limited skin resection can be performed through this approach along with an abdominal wall plication. If necessary, SAL can be used in combination with this procedure.

Endoscopic abdominoplasty can be used to treat abdominal wall laxity (i.e., postpartum rectus diastasis) and localized collections of fatty tissue. Patients who undergo this procedure must have good skin quality and only mild to moderate lipodystrophy. The endoscopic abdominoplasty is performed through two incisions, a 3- to 5-cm transverse incision within the pubic hair and a circumferential incision around the umbilicus. These incisions function as the two access ports through which the endoscopic instruments are passed. The entire abdominal wall is then elevated off of the abdominal wall fascia under endoscopic visualization with electrocautery, the midline of the abdominal wall is plicated from pubis to xiphoid, and the abdominal wall is then recontoured with SAL, which is also performed through the two incisions (**Fig. 107.41**).

Liposuction

Liposuction is world's most frequently performed cosmetic surgery procedure. Sculpting the body through this well-described technique is designed to eradicate deposits of fat from isolated anatomic regions by utilizing various diameter cannulas with a myriad of port sizes and configuration. It is not considered a form of weight loss and is therefore not performed in obese patients. Rather, patients who are within 20% to 30% of their ideal body weight and have localized collections of fat that are refractory to diet and exercise will see the greatest benefits. A complete evaluation of skin elasticity is necessary in patients who are considering liposuction because once fat is surgically removed, the skin must be able to contract down to the contour of the remaining subcutaneous tissue. If the skin quality is poor, then wrinkling, dimpling, or skin ptosis may severely compromise the desired aesthetic outcome.[91]

Over the past several years, various energy sources have been used in conjunction with SAL to liquefy fat and induce skin tightening by reaching a critical thermal threshold. Ultrasonic-assisted liposuction (UAL), laser-assisted liposuction (LAL), power-assisted liposuction (PAL), and helium plasma–assisted liposuction are the major types of energy and/or mechanical adjuvants to liposuction currently used. SAL can be used in all areas of the body, however its efficacy may be augmented by employing energy and/or mechanical power in more fibrous anatomic regions such as the flank, upper abdomen, or male breast.[91,93] A number of technologic advances have led to new techniques for performance of liposuction or liposculpting. None of these new techniques have yet to prove clinically superior in rigorous clinical trials, and standard SAL continues to be the most effective.

Figure 107.41 A 32-year-old female presented to the plastic surgery clinic with concerns related to the appearance of her abdomen. The patient was displeased with the "stomach" region after having three children. She had no further plans of having any children. Her primary complaints were extra skin and stretch marks above and below her umbilicus, fullness in the pubic region, and extra fat in her waist/love handles. The patient underwent a drain-less abdominoplasty with liposuction in the waist/love handles. She is pictured here 1 week prior to surgery (**A**–**C**) and 9 months after (**D**–**F**) her procedure.

As with all aesthetic procedures, it is necessary that patients undergo a complete evaluation preoperatively to ensure that their goals can be achieved through liposuction. Preoperative photographic documentation is performed on all patients. Markings are then made with the patient in the upright position. Access ports (6 to 8 mm), through which liposuction is performed, are marked in concealable areas. Patients can undergo these procedures under local or general anesthesia. Tumescent fluid (1,000 mL of LR, 50 mL

of 1% lidocaine, and 1 mg of epinephrine) is then infiltrated for pain control and hemostasis.

SAL is performed with metal cannulas connected to an aspirating device that generates a negative pressure of 1 atmosphere. Various cannula configurations are used to perform the resection. Fatty tissue is aspirated into the holes of the cannula and then resected by movement of the cannula tip. The operation is performed through multiple access ports, starting with large (6- to 8-mm diameter) cannulas and progressing to smaller (3- to 4-mm diameter) cannulas with fewer holes to allow more precise body contouring. Overlapping patterns of resection are used to avoid contour irregularities.

UAL and LAL are surgical techniques that allow body contouring through the liquefaction and aspiration of fatty tissue. Whether used alone or in combination with traditional SAL, UAL and LAL are effective for treating lipodystrophy in fibrous anatomic regions such as the flank, upper abdomen, and male breast. The UAL probe tip produces sound waves at an ultrasonic frequency of 20 to 30 kHz. The sound waves cause cavitation which disrupts lipocytes. LAL probe tip uses various nanometers of laser to heat and liquefy fat. Lower power suction is then employed to remove the resultant fluid. If UAL or LAL is used incorrectly, patients may experience severe complications, including full-thickness skin loss from incision and increased risk of seroma formation.

Postoperatively, all patients are placed in a compressive garment for 2 weeks, 24 hours per day. This early postoperative compression significantly reduces the chances of hematomas forming. Prolonged compression reduces swelling and the potential for skin wrinkling. All patients experience some degree of ecchymosis, swelling, and decreased sensibility. The final aesthetic result will not be realized for approximately 9 to 12 months following the procedure (**Fig. 107.42**).

Figure 107.42 A 47-year-old male presented to the plastic surgery clinic with concerns of abdominal contour. Despite aggressive diet and exercise, he was not able to achieve the definition he wanted (**A**, **B**). The patient underwent power-assisted liposuction with further abdominal etching to the abdomen and bilateral love handles. He is pictured here before and 12 months after the procedure (**C**, **D**), respectively.

NONSURGICAL AESTHETIC PROCEDURES

Minimally Invasive Procedures

11 Though not surgical in nature, the authors would be remiss to not mention the advent of minimally invasive procedures, primarily injectables, in the aesthetic plastic surgeon's armamentarium. Entire textbooks are devoted to these treatments, however, for the sake of completeness and cursory

overview, they are mentioned here. The 2002 FDA approval of Botox for moderate to severe frown lines resulted in a consequential sky rocket of the aesthetics industry.[94] In 2018 alone, 15.9 million minimally invasive cosmetic procedures were performed, a 228% increase since the year 2000.[94] Among the most popular of these treatments are three classes of injectables: neuromodulators, dermal fillers, and adipocytolytic agents.

Neuromodulators alter the interaction of a neuron with a neurotransmitter, and botulinum toxin type A specifically blocks the release of acetylcholine, the principal neurotransmitter at the neuromuscular junction.[95] When injected into the face, this causes temporary paralysis of the muscle, resulting in loss of function. Aesthetically, this is used to decrease the appearance of fine lines and creases. Botulinum Toxin Type A was first approved by the FDA in 1989 and is now the world's most frequently performed aesthetic procedure. In 2018, over 7.4 million injections were performed with botulinum toxin. The brand names include Botox, Dysport, Xeomin, and Jeuveau, and are most commonly injected to the forehead, glabellar, and crow's feet regions of the face. This muscle paralysis can last anywhere between 3 and 4 months, dependent on the metabolism of the patient.

Figure 107.43 A 66-year-old female presented to the clinic interested in improving the excess fat and loose skin in her neck, but without any surgical intervention. Patient is pictured before (**A**) and 8 weeks after (**B**) her FIRST treatment with deoxycholic acid (Kybella). She also underwent dermal fillers along the jawline to improve the contour.

Dermal fillers are a gel-like substance that when injected subcutaneously, intradermal and supraperiosteal restore volume, smooth lines and creases, and enhance the overall facial contour. This rejuvenation can be achieved through products consisting of either hyaluronic acid (HA), calcium hydroxylapatite (CaHA), and poly-L-lactic acid. Products compromised of HA, such as the Juvederm, Restylane, and Revanesse can keep the skin plump and hydrated anywhere from 6 to 12 months. CaHA products, such as Radiesse· last longer and assist in stimulating natural collagen production. However, unlike HA fillers, there is no reversal agent for calcium-based dermal fillers. Poly-L-lactic acid products, such as Sculptra, can last up to 2 years and also stimulates natural collagen production.

Adipocytolic agents are the third class of injectables, with Kybella being the only FDA-approved product currently on the market. Kybella contains deoxycholic acid which is a naturally occurring molecule in the body that aids in the breakdown and absorption of dietary fat. When injected, the fat cells lyse, prompting the inflammatory cascade to begin the skin tightening component. Kybella was approved by the FDA to treat submental fat in 2015, and in 2018 alone 63,993 patients were injected with the product.[94] Patients typically need two to three treatments spaced 6 weeks apart in order to achieve the ultimate satisfactory outcome and will experience swelling of up to 7 days (**Figs. 107.43** and **107.44**).

Figure 107.44 A 45-year-old male presented to the clinic with a desire to get rid of his "double chin." **A–C**: He was not interested in having a surgical procedure and wanted a "cleaner neck line." He is pictured here right before deoxycholic acid (Kybella) injection and 3 months after his second treatment (**D–F**).

SUMMARY

The surgical specialty of Plastic and Reconstructive Surgery is perhaps the most far reaching surgical field. The scope of practice is not limited by patient age, sex, anatomic body part, or mechanism of disease. Hospitals cannot function as state-of-the-art medical centers of the 21st century without a robust group of plastic and reconstructive surgeons. Congenital anomalies, trauma victims, oncology patients, and many others all have improved quality of life, return to normal function, and improved self-esteem because of the advances made by modern plastic and reconstructive surgery. This dynamic field will continue to develop new approaches to issues such as wound healing, composite tissue allotransplantation, gender reaffirmation, autologous tissue transfers for complex reconstructive questions and peripheral nerve reconstruction and healing as well as many other complex questions that need innovative answers.
