Principles of Total Mesorectal Excision

The principle of rectal cancer treatment is the eradication of the primary tumor and its lymphatic drainage by en bloc removal of the rectum and the mesorectum, following well-defined anatomical planes. This operation, known as total mesorectal excision, or TME, requires dissection under direct vision along the areolar tissue plane situated between the MRF and the presacral fascia. A sharp dissection along this plane is associated with a higher probability of achieving a negative CRM, lower risk of bleeding from inadvertent tearing of the presacral veins, and reduced risk of injuring the hypogastric nerves.

Adequate lymphadenectomy requires division of the lymphovascular pedicle at the origin of the superior rectal vessels, caudal to the branching of the left colic artery from the inferior mesenteric artery. In patients with clinically

suspicious nodes at the origin of the inferior mesenteric artery, the lymphovascular control should be extended proximally by dividing the inferior mesenteric artery close to the origin (high tie). In both cases the sigmoidal branches are included in the surgical specimen; therefore, the proximal division of the bowel should ideally be performed at the junction of the descending and the sigmoid colon, incorporating most of the sigmoid colon in the surgical specimen.[217] As distal tumor extension along the rectal wall is limited, a distal margin of 2 cm of normal bowel wall is considered adequate for most tumors. However, distal spread in the mesorectum may extend farther than intramural spread. Not infrequently, mesorectal deposits are found 3 to 4 cm distal to the lower edge of the tumor. Therefore, for tumors of the upper rectum, the mesorectal excision should be extended to 5 cm distal to the lower edge of the tumor. In these patients the mesorectum should be divided perpendicular to the axis of the rectum. As some of the distal mesorectum is left in the pelvis along with the distal rectal stump, this operation is known as tumor-specific TME (TSME), to distinguish it from the TME performed with dissection carried to the pelvic floor, the rectum divided distal to the end of the mesorectum, and the entire mesorectum included in the surgical specimen.

Sphincter Saving Procedures

A TSME or a TME is compatible with sphincter preservation by anastomosing the divided end of the descending or the sigmoid colon to the rectal stump. This operation is known as a low anterior resection or LAR (**Fig. 68.13**). In this operation the rectum is divided distal to the tumor using a stapling device that simultaneously staples and divides the rectum, leaving a short rectal stump. The anastomosis is completed with a circular stapler that brings together the end of the colon to the rectal stump. The reestablishment of the large bowel's continuity by suturing the colon to the anal canal, working through the anus, is known as coloanal anastomosis or CAA (**Fig. 68.13**). The connection of the colon to the rectum or anal canal can be performed by an end-to-end or a side-to-end connection, or with the creation of a J-pouch reservoir. A tension-free, well-vascularized low colorectal or coloanal anastomosis requires a complete mobilization of the entire left colon with take-down of the splenic flexure, including division of the inferior mesenteric vein close to the ligament of Treitz. Following ligation of the IMA, the blood supply to the entire left colon is based on the left branch of the middle colic vessels through the marginal artery.

Many patients undergoing a sphincter-saving procedure report high bowel frequency, urgency, soiling, and inability to defer defecation for 15 minutes.[218] This constellation of symptoms is commonly known as low anterior resection syndrome (LARS).[219] The frequency and severity of these symptoms is variable and depends, to some degree, on the location of the tumor and the anastomosis, the patient's prior bowel function, and the use of neoadjuvant or adjuvant therapy.[220] Pelvic irradiation, before or after surgery, increases significantly the risk of bowel dysfunction.[221,222] The anatomical and physiologic factors that contribute to LARS are not completely understood. Anal sphincter pressures are not different in patients with or without LARS. What appears to be different is an exaggerated anal sphincter relaxation to even small volumes of stool within the neorectum.[223] Surgeons have tried to overcome this low capacitance of the neorectum—which results from an end-to-end anastomosis—by creating a colonic reservoir: either a colonic J-pouch, or a side-to-end anastomosis. A number of studies have compared the functional outcomes after straight end-to-end anastomosis and a colonic J-pouch. A systematic review of reconstructive techniques after LAR identified 9 trials that randomized a total of 473 rectal cancer patients to either colonic J-pouch or straight end-to-end anastomosis, reporting that short-term bowel function was better for J-pouch compared to straight anastomosis.[224] Frequency and urgency were less prevalent in patients with a colonic J-pouch, but the rate of fecal incontinence was similar in both groups. The only two trials that followed patients for more than 118 months found minimal or no long-term differences between groups. Although the methodology of these studies was very heterogeneous, they do indicate that a colonic J-pouch is associated with a short-term improvement in frequency and urgency, but no apparent long-term benefit, compared to end-to-end anastomosis. The same systematic review found no differences in anastomotic leak rate, or other complications, between groups. Of note, almost one-third of patients with colonic J-pouches often complained of long-term difficulty emptying the rectum, requiring use of laxatives or suppositories.[225,226] These symptoms are more prevalent when larger pouches are created; therefore, pouch size should be limited to 5 to 6 cm.[227,228]

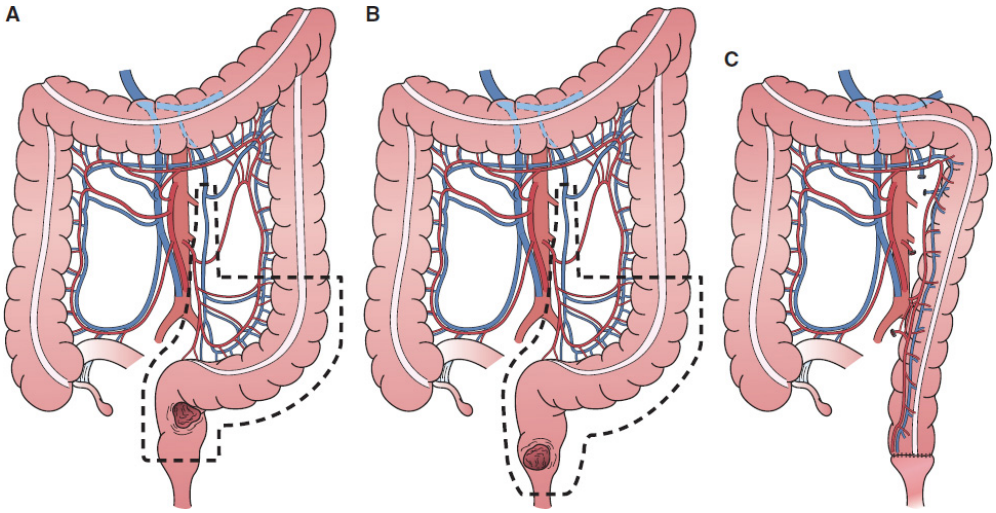

Figure 68.13 **A:** Low anterior resection, section in the distal third of the rectum, candidate for colorectal anastomosis. **B:** Low anterior resection, section above the sphincteric complex, candidate for coloanal anastomosis. **C:** Colorectal anastomosis.

The side-to-end anastomosis (created by inserting the anvil of a circular stapler 3 to 4 cm from the end of the mobilized descending colon) can also potentially increase the reservoir capacity of the anastomosis. It has similar functional results, but is easier to construct than the colonic J-pouch; although it, too, is associated with defecatory problems.[229] The creation of a transverse coloplasty proximal to an end-to-end anastomosis is another option used to increase the capacity of the neorectum, but is associated with a higher anastomotic leak rate.[224]

In summary, colonic reservoirs are associated with a temporary improvement in bowel frequency and urgency, but have the risk of long-term defecatory problems. In general, the authors prefer an end-to-end anastomosis using the larger descending colon, rather than the sigmoid colon, for creation of the neorectum.

The integrity of the anastomosis should be tested intraoperatively with a pneumatic test, or by endoscopy, with distension of the bowel while submerging the anastomosis in water. Air leaks thus detected may be treated with suture repair, redo of the anastomosis, and/or the creation of a proximal diverting stoma. Testing the integrity of the anastomosis during surgery has been associated with a lower risk of clinical postoperative anastomotic leak.[230]

Low colorectal and coloanal anastomoses have a risk of leakage ranging from 3% to 34%, depending on the patient population, the use of neoadjuvant radiation, the distance of the anastomosis from the anal verge, and the surgical

technique.[231,232] An anastomotic leak can cause pelvic sepsis, which may not only preclude sphincter preservation, but may also be associated with an increased risk of local recurrence and poorer survival, although more recent data have questioned this association.[233–235] To prevent these possible complications, a diverting stoma is recommended for patients having a TME, and for patients receiving neoadjuvant radiation.[236] Diverting stomas do not prevent complications, but mitigate the consequences of a leak and reduce the need for urgent reoperation in patients developing a leak.[237,238] A loop ileostomy is preferred over a transverse loop colostomy because it is easier to create and close.[239] However, loop ileostomies are associated with postoperative dehydration and electrolyte abnormalities requiring hospital readmission.[240,241] Prevention of these complications requires adequate patient education and training about stoma management.

Abdominoperineal Excision

For many cancers located in the distal rectum, particularly those infiltrating the levator muscles or the anal sphincter, an oncologically safe circumferential and/or distal resection margin is not compatible with sphincter preservation. In these patients an R0 resection requires a TME with en bloc excision of the levator muscles and the anal canal, and the creation of a permanent end colostomy. This operation is known as abdominoperineal excision of the rectum or APE (**Fig. 68.14**). As the name indicates, the APE has two parts: an abdominal part and a perineal part. During the abdominal part, the proximal lymphovascular control, division of the colon, and dissection along the mesorectal plane are similar to those in LAR, except that the mesorectal dissection should stop at the upper level of the levators, to avoid disturbing the portion of the rectum resting on the levator muscles. During the perineal part, the anal canal with the sphincter complex and the levator muscles are dissected off the ischiorectal fat, all the way to the apex of the ischiorectal fossa. The levators are divided close to their insertion in the white line near the obturator internus and coccygeus muscles. The levator muscles are left attached to the rectum, and the resulting surgical specimen has a cylindrical appearance; therefore, this procedure is called cylindrical APE or extralevator APE (ELAPE) (**Fig. 68.14**).[242] However, some surgeons question the need to entirely remove both levator muscles in every rectal cancer patient, and recommend removing only the portion of the levators required to clear the tumor. This

operation has been called the standard APE (SAPE).[243] The choice between an ELAPE and SAPE is controversial. The potential oncologic benefit of larger tissue removal needs to be weighed against the increased morbidity potentially associated with a larger perineal defect, particularly in patients treated with neoadjuvant therapy.[244] A recent meta-analysis with 949 patients from 1 randomized trial, 1 prospective case-control study, and 6 retrospective case series, indicated that ELAPE is associated with lower intraoperative rectal perforation, lower positive CRM, and lower risk of local recurrence, but with similar complication rates, compared to SAPE.[245] At the present time, the hypothetical benefit of the ELAPE over the SAPE has not been proven conclusively. It is possible that both techniques—the total or the tumor-specific excision of the levator muscles—may be equivalent as long as an R0 resection, with an intact rectal specimen, is achieved.

Many surgeons will perform both parts of the APE operation with the patient in modified lithotomy, also known as the Lloyd–Davis position. It provides relatively good access to the perineum and allows two teams to work simultaneously—one in the abdomen, and one in the perineum. Others perform the abdominal part in the supine position, and the perineal part with the patient prone over a hip roll and padding of the bony prominences. The prone position, also known as jackknife position, provides better exposure of the perineum, and facilitates assistance and teaching. It requires turning the patient, which takes time, and does not allow a two-team approach. Results seem to be similar with both approaches, and the selection is based on surgeon preference.[246]

Minimally Invasive Surgery for Rectal Cancer

Open surgery for rectal cancer requires long abdominal incisions. An APE can be performed though a midline infraumbilical or low transverse incision. Most sphincter-preserving procedures (SSPs) require a long midline incision, extending from the epigastrium to the symphysis of the pubis, in order to permit access to the entire left side of the large bowel from the splenic flexure to the lower rectum. These abdominal incisions are a source of patient discomfort, and short- and long-term morbidity. The goal of minimally invasive surgery in rectal cancer is to reduce the size of the abdominal incision, thus expediting recovery, without compromising the completeness of the mesorectal excision or the oncologic outcomes. However, the adoption of minimally invasive surgery for rectal cancer has been slow due to the difficulty of working in the relatively

deep and narrow pelvic space using long, rigid, nonarticulated laparoscopic instruments. According to a number of retrospective case series and small randomized controlled trials, laparoscopic TME is associated with less postoperative 5 pain, less surgical morbidity, and shorter length of hospital stay, but equivalent completion of the mesorectal excision, CRM positivity, and even LR, compared to open TME.[247–249] While these studies have shown that laparoscopic TME is feasible, less than 25% of all rectal cancer operations are performed laparoscopically in the United States.[250]

Five large multi-institutional prospective, randomized trials have compared open and laparoscopic TME for rectal cancer (**Table 68.7**).[251–255] The combined experience of these trials indicates that laparoscopic TME results in longer operative time, less blood loss, faster bowel recovery, and shorter hospital stay compared to open TME. Operative mortality and intraoperative and postoperative complications were not different between groups. When investigating successful oncologic resection comprised of positive distal margin, positive circumferential margin and completeness of TME, ALACART and Z6051 both failed to demonstrate noninferiority of laparoscopic resection. In addition, although not all of them powered to demonstrate differences in oncologic outcomes, these five studies have shown that LR, distant metastasis (DM), and survival were not different between groups. The combined experience of these studies suggests that with the noninferiority margin for the quality of the surgical resection in some studies, the long-term oncologic outcomes are equivalent for patients treated with open or robotic TME. However, patients in these trials were treated at high-volume centers and operated by surgeons experienced in minimally invasive techniques. Whether similar results can be achievable in the community is still debatable.

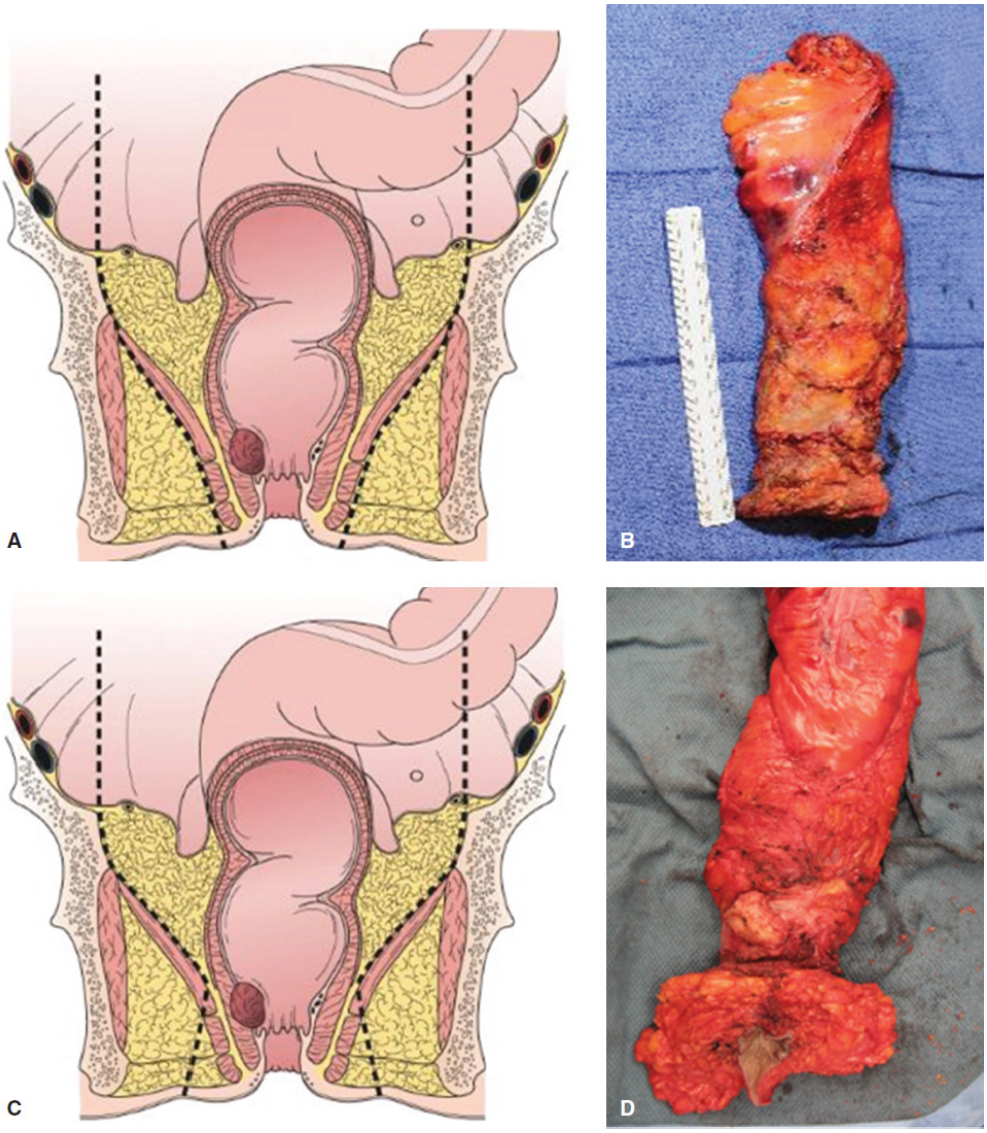

Figure 68.14 Total mesorectal excision. Following correct anatomical planes and avoiding entry into the mesorectum or sphincter muscles (extralevator approach) results in a surgical specimen that has a cylindrical appearance with no mesenteric "waist" or narrowing. **A:** Planes of dissection for ELAPE. **B:** ELAPE specimen. **C:** Planes of dissection for SAPE. **D:** SAPE specimen with mesenteric "waist."

Many surgeons currently perform a hybrid approach consisting of the laparoscopic lymphovascular control and colon mobilization, and the open mesorectal dissection and anastomosis through a lower abdominal transverse incision. The hybrid approach is aimed at facilitating the most technically challenging portion of the operation: the dissection of the distal rectum and the creation of the anastomosis. With this approach the size of the abdominal wall incision is smaller compared with a totally open procedure, but larger than with

a totally laparoscopic procedure. Although there is some evidence of short-term advantages to this approach compared to open surgery, long-term benefits compared to the totally open or laparoscopic approaches are unknown.[256]

The robotic platform (da Vinci) was introduced to the surgical armamentarium to facilitate the minimally invasive approach to procedures such as prostatectomy, hysterectomy, and TME, which require optimal visualization and dexterity in the narrow pelvic space. The experience accumulated thus far—based on retrospective institutional case series—suggests that robotic TME is equivalent to laparoscopic TME in terms of completeness of the mesorectal excision, CRM positivity, and short-term oncologic outcomes. Conversion rates appear to be lower compared to laparoscopic TME, but hospital charges are higher.[257] A prospective, randomized study comparing laparoscopic and robotic TME—the Robotic Versus Laparoscopic Resection for Rectal Cancer (ROLARR) trial—demonstrated no difference in conversion or circumferential margin positivity between the two surgical approaches.[258] However, as laparoscopy has not become standard in locally advanced rectal cancer (LARC), it is likely that the controversy regarding the benefit of robotic TME will continue for years.

Table 68.7 Open versus Laparoscopic Rectal Resections: Results of the Most Representative Series

The transanal–total mesorectal excision (TaTME), or down-to-up TME, is a transanal, minimally invasive approach for the dissection of the distal rectum in patients with a narrow pelvis.[259,260] With this approach, lymphovascular control, the entire colonic mobilization, and dissection of the upper rectum are performed using conventional transabdominal laparoscopy. The dissection of

the distal rectum is performed through the anus, using either conventional transanal equipment for very distal tumors, or endoscopic equipment (TEMS, TEO, TAMIS) for higher tumors. The rectal wall is incised circumferentially, distal to the tumor, and the MRF is identified. The lumen of the colon is closed with a purse-string suture to avoid contamination. The dissection is carried cephalad in the proper plane until the abdominal field is reached. The specimen is then removed, and the anastomosis performed through the anus. This approach is particularly useful for patients with very distal rectal cancers treated with chemoradiation therapy, in which the surgeon has no anatomical cues about where to transect the rectum in order to achieve a negative distal margin. The transanal approach allows the surgeon to choose precisely the point for transecting the rectum while visualizing the distal edge of the tumor. The benefit of the down-to-up approach for higher rectal cancers that could be treated with a conventional transabdominal dissection and a double-stapled anastomosis are uncertain. A multicenter matched comparison of robotic resection and TaTME of 730 patients with mid to distal rectal cancer did not show differences in specimen quality or conversion rate between these surgical approaches.[261] Outcomes of all patients that underwent TaTME in Norway were compared to outcomes of patients that underwent TME in a national database. TaTME patients experienced more local recurrences and anastomotic leaks. These reports were alarming enough to halt all TaTME in Norway.[262] TaTME is technically challenging, has a long learning curve and should be considered a treatment option for rectal cancer only in very experienced hands.

Adjuvant and Neoadjuvant Radiation and Chemotherapy for Locally Advanced Rectal Cancer

Several randomized, controlled trials conducted in the pre-TME era demonstrated that radiation therapy (RT) given before or after surgery reduced the rate of LR, compared to surgery alone.[263–265] However, the relevance of these trials was later questioned, because surgery was not standardized and the LR rates reported in the control arms—approximately 25%—were considered too high compared to that of patients treated in later years with surgery alone according to TME principles. The efficacy of RT in the setting of quality TME surgical resection was investigated in the Dutch Colorectal Cancer Group trial, which randomized 1,861 patients with resectable disease to TME alone or

short-course RT (SCRT) (5 Gy a day × 5 days, for a total dose of 25 Gy), followed by TME within 2 to 7 days. The study showed that SCRT reduced the rate of LR in resectable rectal cancer treated by TME, compared to TME alone; however, SCRT did not provide a significant survival benefit.[266] This trial proved that preoperative RT decreases the rate of LR in LARC patients treated with TME surgery.

The benefit of combining chemotherapy with RT was proven by several randomized trials that compared postoperative RT combined with 5-FU, administered as a bolus or as continuous venous infusion (CVI), to postoperative RT alone, in patients with pathologic stage II and III rectal cancers.[267,268] The results proved that combined 5-FU and radiation was more effective than radiation alone in reducing the risk of LR, and that CVI 5-FU was associated with lower toxicity compared to bolus 5-FU.

The European Organization for Research and Treatment of Cancer (EORTC) protocol 22921 was developed to assess the effect of adding chemotherapy to preoperative RT, and the subsequent value of postoperative chemotherapy in rectal cancer patients.[269] At the 5-year mark, LR was significantly lower in all three arms receiving any chemotherapy (pre- or postoperative) compared to preoperative RT alone, indicating a benefit of chemotherapy in reducing the risk of LR, regardless of when it was administered. The addition of chemotherapy to RT did not impact survival. Additional work by the Federation Francophone de la Cancerologie Digestive corroborated these findings.[270] These studies showed that, similar to what was found using postoperative radiation, adding chemotherapy to preoperative RT also reduced the rate of LR, compared to preoperative RT alone.

The German Rectal Cancer Group (CAO/ARO/AIO 94) compared preoperative versus postoperative CRT in 823 patients with clinical T3–4/N+ rectal cancer.[271] RT in this trial consisted of 50.4 Gy in 25 fractions with bolus 5-FU as a radiosensitizer. In the preoperative treatment group, surgery was performed 6 weeks after completion of CRT. Both groups had surgery according to TME principles, and received postoperative adjuvant chemotherapy. The preoperative CRT group had less toxicity and lower 5-year LR rates compared to the postoperative CRT group (6% vs. 13%). This study found no differences in the rates of DR, DSS, or OS. The NSABP R-03 study also compared the use of preoperative versus postoperative 5-FU/LV, using 45 Gy in 25 fractions in T3/4, N+ patients, to evaluate differences in DFS, LR, or OS.[272] Despite stopping the study early due to limited accrual, the R-03 study

reported better DFS in the preoperative CRT group, compared to the postoperative group, with a near-significant difference ($p = 0.065$) in OS and no difference in LR. The results of these two trials established preoperative CRT as the preferred treatment for LARC in both Europe and the United States.

More recently, it has been shown that capecitabine is noninferior to infusional 5-FU as a radiosensitizer for LARC, in both the NSABP R-04 trial and the German Cancer Research Center multi-center trial.[273,274] Several large, prospective trials have failed to prove that the addition of oxaliplatin to a fluoropyrimidine (5-FU or capecitabine) is superior to fluoropyrimidine alone as a radiosensitizer in patients with LARC.[274–277] Therefore, based on the current evidence, oxaliplatin is not recommended as a radiosensitizer added to a fluoropyrimidine in patients with LARC.

Alternatively to the standard hypofractionation (180 to 200 cGy a fraction) commonly delivered during the standard long-course CRT over a 6-week period, radiation therapy may be delivered as short course (SCRT) using fewer, larger fractions (5 Gy daily fractions for 5 consecutive days and a total dose of 25 Gy). In these patients, surgery is performed within 7 days of completion of the radiation. Both schemes are biologically equivalent in eradicating cancer cells, but SCRT has the potential benefits of shorter duration of treatment, more efficient utilization of resources, and reduced cost compared to CRT. However, higher dose per fraction increases the risk of delayed toxicity, and tumor regression is lower with SCRT. Two prospective, randomized trials comparing SCRT with CRT have reported equivalent local tumor control with both regimens, and the selection between CRT and SCRT is based on doctor and patient preferences.[278,279] In general, tumor regression is lower with SCRT when surgery is performed within 7 days of the last dose of radiation. For that reason, CRT has been the preferred radiation modality in the setting of large tumors that may benefit from maximal tumor regression before surgery. However, recent data suggest that the tumor response rate increases if surgery is delayed for 6 to 8 weeks after SCRT.[280]

Current guidelines recommend CRT or SCRT with the aim of reducing the risk of LR for all patients with stage II and III rectal cancers. However, the risk of LR depends on the distance of the tumor from the anal verge, the risk being lower for tumors located in the upper rectum compared to those in the lower rectum. It is possible that some patients with high rectal cancers, specifically those with T3N0 tumors and a clear CRM, may not actually benefit from preoperative radiation but may simply be exposed to radiation-associated

toxicity. A current trial in the United States seeks to address this question by comparing the outcomes of rectal cancer patients treated with neoadjuvant chemotherapy, with or without radiation, before TME.[281]

Chemotherapy for Locally Advanced Rectal Cancer

In the past, LR was the dominant problem in patients with LARC, but in the modern era more patients develop distant metastasis than LR. Consequently, patients with LARC treated with neoadjuvant CRT and TME are recommended for postoperative adjuvant chemotherapy, with the aim of reducing distant metastasis and improving survival. However, the data supporting this recommendation are limited, and based heavily on experience using adjuvant therapy for resected colon cancers. A meta-analysis of 21 controlled trials in patients receiving potentially curative surgery, including a total of 4,854 patients randomized to surgery plus fluoropyrimidine-based postoperative chemotherapy, and 4,367 patients to surgery and observation, has shown a significant reduction in the risk of death (17%) (HR = 0.83, CI: 0.76–0.91) and a reduction in the risk of DR (25%) (HR = 0.75, CI: 0.68–0.83) among patients undergoing adjuvant chemotherapy, compared to those undergoing observation.[282] A review of the experience of a large national database suggests that there is a survival benefit for rectal cancer patients receiving chemotherapy after CRT and TME.[283] On the other hand, a pooled analysis of four prospective randomized trials suggests a minimal improvement in DFS from postoperative 5-FU–based adjuvant chemotherapy in patients with rectal cancer treated with preoperative chemoradiation.[284] Despite these conflicting results, current guidelines recommend 4 months of postoperative adjuvant chemotherapy (5-FU or capecitabine plus oxaliplatin) for patients with locally advanced rectal cancer treated with neoadjuvant chemoradiation and TME surgery.

Postoperative adjuvant chemotherapy is often cancelled or delayed in many rectal cancer patients due to surgical complications or slow recovery from surgery. This is particularly relevant, as the delay in the initiation of adjuvant chemotherapy reduces the probability of survival.[285] Delivering systemic chemotherapy before surgery has the potential advantages of increasing treatment compliance, treating micrometastatic disease early, enhancing the response of the primary tumor, and shortening the time to temporary ileostomy

reversal. In this new treatment approach, in which all radiation and chemotherapy is delivered before surgery, known as total neoadjuvant therapy (TNT), systemic chemotherapy can be given before chemoradiation or after chemoradiation, but in both cases before surgery. Patients treated with TNT experience a greater grade of primary tumor response compared to patients treated with chemoradiation and surgery, but a beneficial effect in terms of survival has not been proven yet.[286–289]

Outcomes of Multimodality Treatment in Patients with Locally Advanced Rectal Cancer

Perioperative mortality in patients undergoing multimodality therapy, including total mesorectal excision for LARC, ranges from 1% to 3.5%, and between 23% and 48% of patients develop perioperative complications.[290] Sepsis is the most common complication after rectal cancer surgery. A recent systematic review of the literature, including 53 prospective cohort studies and 45 randomized trials, found a 2% postoperative death rate, 7% rate of surgical wound infection, 11% rate of anastomotic leakage, and a 12% rate of pelvic sepsis.[291] In addition to pelvic sepsis, perineal wound dehiscence is the most common complication after APE. In a large systematic review of 45 studies, the rate of perineal wound complication after SAPE was 15.3% for patients treated with surgery alone, and 32% in those treated with surgery and RT.[292] Many of these patients also had pelvic sepsis. The proportion of patients with perineal complications was similar for those who had ELAPE: 14.8% for surgery alone and 37.6% for surgery and radiation. The rate of perineal hernia was also similar for patients treated with SAPE and ELAPE: 1.8% versus 2%. Other common postoperative complications include urinary retention, pneumonia, and thromboembolic disease.

Surgery for rectal cancer, particularly when combined with CRT or SCRT, has iatrogenic long-term consequences including urinary, sexual, and bowel dysfunction. Up to 39% of patients develop urinary complications, 45% sexual dysfunction, and even a larger proportion, bowel dysfunction.[293,294] A recent population-based study found a 26% rate of moderate bowel problems, 17% urinary dysfunction, and 25% severe problems with sexual function among patients treated for rectal cancer. Patients with a stoma were more likely to have difficulty with body image and sexual activity compared to patients with no stoma. Less than 30% of rectal cancer patients reported perfect health; rectal

cancer patients were more likely to report problems, compared to patients with colon cancer. A follow-up study of the Dutch TME trial recently reported that these treatment-related symptoms persist 14 years after treatment; they reported increased sexual dysfunction, and a small decrease in overall functioning, as measured by a variety of quality-of-life questionnaires distributed to the general population.[295]

Contemporary cohorts of stage II and III rectal cancers treated with neoadjuvant CRT, TME, and postoperative chemotherapy have mostly reported 5-year LR rates between 5% and 10%, 5-year DFS of around 60%, and 5-year OS around 70%.

Treatment Selection in Patients with Localized Rectal Cancer

Unlike patients with localized colon cancer, who all require oncologic resection as the initial form of therapy, patients with rectal cancer have multiple treatment options. The selection among different options depends primarily on the clinical stage of the tumor, as determined by DRE, proctoscopy, and imaging studies, on the distance of tumor from the anal verge, and on patient performance status and expectations.

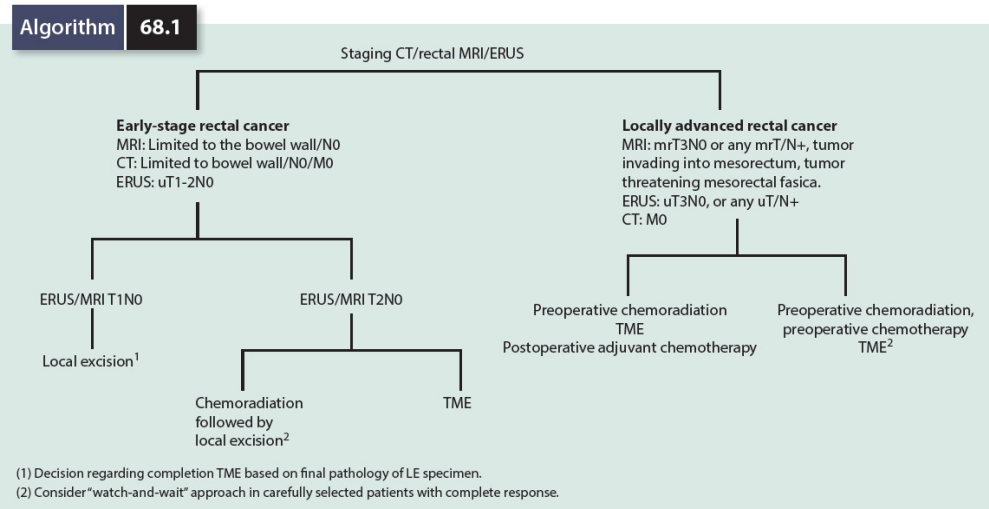
The standard treatment for patients with stage I rectal cancer (T1N0 or T2N0) is TME, but LE has increasingly been chosen as a reasonable and acceptable alternative for patients with distal T1N0 tumors. CRT and LE may also be considered as an alternative to TME in patients with T2N0 tumors interested in sphincter preservation, in whom a TME would require a permanent colostomy.

More advanced tumors—those penetrating beyond the muscularis propria (T3–4, any N) and/or involving the regional lymph nodes (any T, N+), and without evidence of distant metastasis—have several treatment options. In the United States and many other countries, where decisions regarding the treatment of rectal cancer are based on clinical TNM staging, patients with locally advanced disease are treated with 5-FU or capecitabine-based CRT, followed by TME, with consideration given to FOLFOX prior to CRT as an acceptable option (**Algorithm 68.1**).

In Europe and Scandinavia, where rectal cancer patients are stratified into different risk categories based on MRI features, patients are recommended for different treatment approaches according to their individual risk category

(**Algorithm 68.2**). The MRI-based risk stratification system uses a number of features, such as the proximity of the primary tumor to the MRF, the depth of tumor penetration into the mesorectum, the presence of large venous invasion, and the presence of metastatic lymph nodes. Based on these features, they have developed a three-tier classification scheme that includes low risk (the good), intermediate risk (the bad), and high risk (the ugly); each group has a different risk of relapse, and therefore requires different treatment strategies.[187,296] The low-risk group is recommended TME alone. The intermediate group is recommended SCRT followed by TME, while the high-risk group is recommended neoadjuvant CRT followed by TME. This treatment approach, guided by MRI risk categorization, is based mainly on results of prospective observational studies conducted in institutions with significant expertise in rectal cancer, but has not yet been tested in prospective, randomized trials.

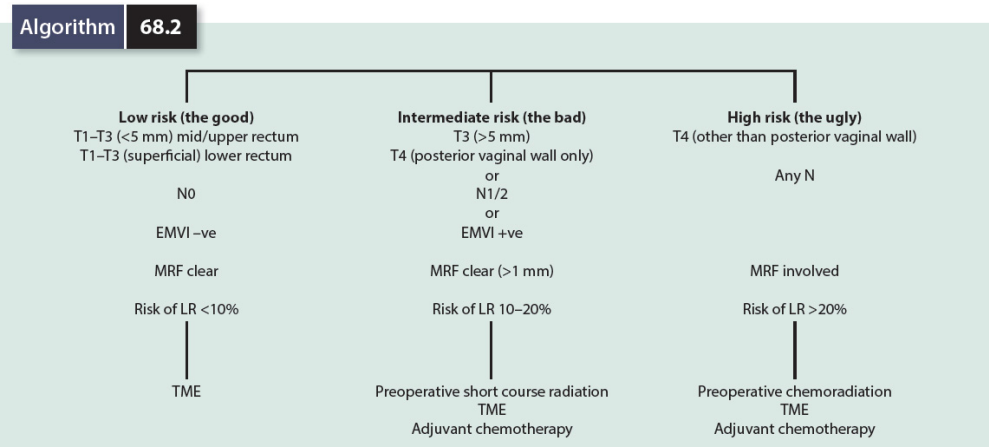
For patients requiring a TME, the decision between an APE and a sphincter-preserving low anterior resection depends on the relationship of the tumor with the anal sphincter and the levator muscle. In general, an APE is required when the tumor directly involves these structures, or is so close to the sphincter that resection with a negative resection margin will result in a loss of sphincter function. In borderline cases, baseline anal sphincter and bowel function, as well as patient wishes and desires should be taken into consideration. The patient should be counseled about LR rates and expected long-term surgical outcomes.



Algorithm 68.1 Approach to rectal cancer according to clinical staging.

Watch and Wait

Rectal adenocarcinomas display a variable degree of response to radiation and chemotherapy. A significant proportion of patients undergoing neoadjuvant chemotherapy and radiation have no viable cancer cells in the rectal specimens after TME surgery. Patients with such a pathologic complete response, have a low risk of tumor recurrence and excellent long-term survival.[297] Based on this observation, surgeons are now questioning the need for TME surgery in patients without apparent residual viable tumor based on DRE, endoscopy, and MRI.[298] Patients with such a clinical complete response are now followed in a close surveillance protocol known as watch and wait (**Fig. 68.15**). While some patients have developed local tumor regrowth requiring TME surgery, some have achieved long-term organ preservation. This approach is particularly appealing to patients with distal rectal cancer who otherwise will require an abdominoperineal excision of the rectum and an end colostomy. The evidence supporting the watch-and-wait strategy for patients with a clinical complete response to neoadjuvant CRT is limited to retrospective institutional case series.[299] While the combined experience of those studies suggests that watch and wait may be safe, at the present time, it should be considered an experimental approach deserving further investigation.[190]



Algorithm 68.2 Approach to locally advanced rectal cancer based on a three-tier risk stratification system ("the good, the bad, and the ugly").

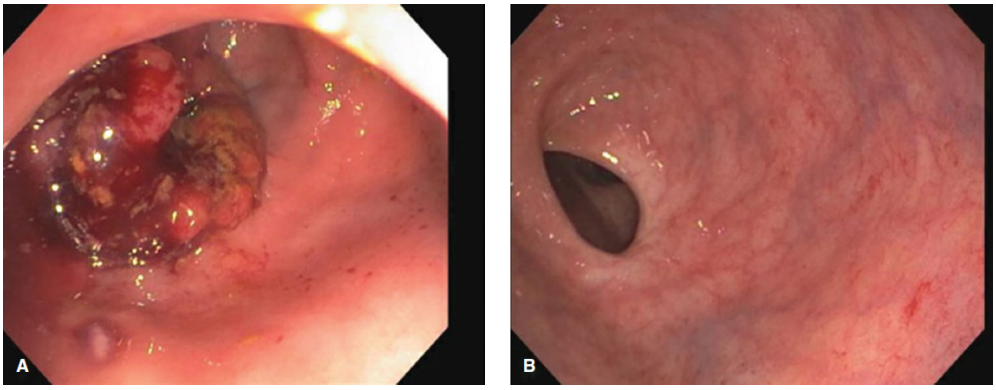


Figure 68.15 Neoadjuvant treatment including chemoradiation and chemotherapy in rectal cancer can lead to a complete response, and selected patients with such response can potentially avoid surgery. This nonoperative management strategy is referred to as the "watch-and-wait" approach. Recent data suggest that watch-and-wait can be a reasonable option in carefully selected and closely followed patients. **A:** Low rectal cancer invading sphincter muscles, proctectomy would require a permanent stoma. **B:** No evidence of tumor regrowth, 3 years after completion of neoadjuvant therapy the patient remains cancer free with a rectum-preserving watch-and-wait approach.

TUMOR-RELATED EMERGENCIES

Between 15% and 30% of all CRC patients present as surgical emergencies, obstruction (78%) being the most common presentation, followed by perforation (10%) and bleeding (4%).[300–302] Chronic bleeding leading to severe anemia is common, particularly in right-sided tumors; but acute hemorrhage requiring surgical or endovascular intervention is infrequent. Obstruction is the presenting symptom in more than 15% of patients diagnosed with CRC, and CRC is responsible for more than 50% of all cases of acute colonic obstruction.[303] Rectal cancers seldom present as an emergency (5.9%); this is much more likely with colon cancers (21.7%), most of which are in the left colon where the feces are solid, the lumen is smaller, and tumors are more likely to be annular.[301] Large-bowel obstruction may be secondary to other conditions such as diverticular disease and volvulus, which are the differential diagnosis of CRC.

The obstructed bowel undergoes significant changes in motility, secretion, and blood flow, which are responsible for the clinical manifestations. Proximal to the obstructed segment, particularly in left-sided obstructions, the colon develops mass action contractions, which cause colic pain. Persistent

obstruction and progressive distension lead to colonic hypomotility. Colonic obstruction causes progressive abdominal distension as a result of the accumulation of gas (mostly nitrogen from swallowed air), increased fluid secretion, and hyperproliferation of anaerobic bacteria. The accumulation of fluid in the distended colon can lead to dehydration. Progressive distension in the presence of a competent ileocecal valve results in a closed-loop obstruction. The increase in intraluminal pressure can compromise the mucosal blood flow and lead to irreversible ischemia. Tension in the wall of the distended bowel increases in proportion to the fourth power of the radius; the risk of ischemia and subsequent perforation is therefore high, particularly in the cecum, the segment of colon with the largest diameter.[304] The risk of perforation is related not only to the caliber of the colon, but also to the onset of obstruction (higher risk when acute) and the duration of the obstruction. Mucosal ischemia has been implicated as the cause of a nonspecific form of colitis that, in some patients, develops proximal to the site of obstruction. The presence of ischemia, which can only be diagnosed at the time of surgery, should influence the extent of resection.

Acute colonic obstruction manifests as abdominal discomfort or frank pain (depending on the onset of the obstruction), reduction or complete cessation of the passage of flatus and feces, and progressive abdominal distension. Abdominal tenderness, particularly if associated with fever and leukocytosis, requires immediate evaluation to exclude perforation or ischemia. DRE reveals an empty rectum in most patients with large-bowel obstruction.

Colonic obstruction must be distinguished from pseudo-obstruction. While the symptoms are similar, colonic pseudo-obstruction often presents in a specific clinical setting (patient immobilization, use of opioids, electrolyte imbalance), is still associated with passage of small amounts of stool and flatus, and is not associated with tenderness.[305] However, definitive diagnosis often requires specific radiologic tests, such as CT or water-soluble contrast enema.

A plain abdominal film demonstrates colonic distension, with air-fluid levels, and a cut-off at the site of obstruction. The absence of small-bowel distension indicates a competent ileocecal valve, with an increased risk of cecal perforation. The presence of gas in the small bowel and rectum raises the possibility of ileus or colonic pseudo-obstruction, but radiologic findings can be misleading. The presence of intramural gas indicates advanced ischemia. A

chest radiograph should always be obtained to exclude the presence of pneumoperitoneum.

A water-soluble contrast enema may help to determine the degree and level of obstruction. The flow of contrast to the cecum and the absence of mucosal abnormalities suggest pseudo-obstruction. The osmotic effect of the water-soluble contrast material may have a therapeutic effect in decompressing the colon in these patients.[306] The mucosal detail at the site of obstruction may help to define the cause of obstruction. However, endoscopy is a better alternative to contrast enema when confirming the presence of cancer. CT of the chest, abdomen, and pelvis often locates the transition point between the distended bowel above the obstruction and the collapsed bowel distal to that point. It also helps define the cause of the obstruction and, if malignant obstruction is confirmed, it is useful in staging the tumor.[307]

When compared with elective surgery, patients requiring emergency surgery tend to have more advanced disease. Even when stratified by stage, however, survival is worse for patients undergoing emergency surgery.[301,308] Also, an R1 or R2 resection is 10 times more likely for patients receiving emergency surgery.[309]

Patients presenting with obstructing CRC have higher operative mortality and morbidity and a poorer long-term prognosis than patients undergoing elective resection.[302,310] Perioperative mortality is three times higher in surgery performed for obstruction, compared with elective surgery.[302] Cardiopulmonary complications and abdominal sepsis are the major causes of in-hospital mortality and morbidity. The aim of surgery is therefore to minimize morbidity while obtaining functional results similar to those obtained for patients undergoing elective resection.

Patients with colonic obstruction are often dehydrated, and require preoperative fluid resuscitation and correction of electrolyte imbalances before surgery. A urinary catheter facilitates fluid management. Unstable patients should be monitored appropriately in the intensive care unit. A nasogastric tube prevents accumulation of swallowed air. Given the large fecal load proximal to the point of obstruction, antibiotic prophylaxis with a second-generation cephalosporin or a combination of an aminoglycoside and metronidazole should be given at the time of surgery.

The surgical management depends on the location of the obstruction. Lesions proximal to the splenic flexure are commonly treated by an extended right hemicolectomy, with primary anastomosis between the terminal ileum and the

nonobstructed colon distal to the lesion. This is a single procedure that removes the entire segment of distended and potentially ischemic bowel, and eliminates the risk of leaving a synchronous tumor in the obstructed colon. Some of these patients develop mild diarrhea, which is usually temporary.

The management of a lesion located distal to the splenic flexure is more controversial. The earlier described three-stage procedure (1—Diverting colostomy, 2—Tumor resection and anastomosis, 3—Colostomy closure) is rarely used today. A safe choice is the two-stage procedure, with initial resection of the segment containing the tumor, closure of the rectal stump as a Hartmann pouch, and construction of an end colostomy, followed by bowel anastomosis at a later date. However, the cumulative mortality and morbidity of both procedures is significant, and at least 30% of patients are left with a permanent colostomy.[311] In most tertiary centers, this operation is now limited to situations in which a primary anastomosis is contraindicated (e.g., extensive peritoneal contamination and/or severe sepsis).

The goal of surgery today is to relieve the obstruction and treat the cancer in a single operative procedure. Options include: (1) self-expanding metallic stents (SEMS) as a bridge to elective segmental colon resection, (2) subtotal colectomy and ileorectal anastomosis, (3) segmental colon resection, intraoperative colonic lavage, and primary anastomosis.

The rationale for the use of SEMS is temporary relief of the obstruction, avoiding the morbidity associated with an emergency operation, allowing medical stabilization, full staging work-up, one-stage surgery with primary anastomosis, and a minimally invasive approach. Most of the experience with this method comes from retrospective case-series studies; the success in relieving the obstruction ranges from 40% to 100%.[312] SEMS also has associated complications, such as reobstruction (12%), migration (11%), and perforation (4.5%).[312]

Several randomized, controlled trials comparing SEMS with emergency surgery have been published, with conflicting results.[313–317] Overall, the clinical success rate of relieving obstruction with SEMS ranges from 40% to 97%. It is important to recognize that the overall complication rate across these trials is variable (8.3% to 35%) and a recent prospective trial conducted in the Netherlands was stopped prematurely, due to an increased number of colonic perforations in the SEMS arm.[317] Perforation from the use of stents may result in a shorter DFS.[318] A Dutch population-based cohort study compared decompressing stoma and SEMS as a bridge to surgery for left-sided

obstructive colon cancer and found no difference in intermediate-term oncologic outcomes and similar complication rate.[319]

A subtotal colectomy with ileorectal anastomosis is a quick operation in which nondistended bowel is used for the anastomosis. This procedure minimizes the risk of fecal spillage, eliminates the risk of missing a synchronous tumor in the obstructed portion of the colon, and facilitates surveillance. The disadvantages, however, include a higher incidence of bowel obstruction after ileorectal anastomosis and the development of postoperative diarrhea, which may become incapacitating in elderly patients.[320]

A segmental resection with intraoperative colonic lavage and primary anastomosis avoids the risk of postoperative diarrhea, but carries a risk of fecal spillage and missing synchronous tumor. In addition, it requires using previously obstructed bowel for the construction of the anastomosis. Surgical tradition has condemned the performance of an anastomosis in an unprepared colon. Experience accumulated from the management of patients with civilian colon trauma has demonstrated that, under specific circumstances, a primary anastomosis can be performed safely in an unprepared colon, provided the bowel appears healthy and there is no extensive soiling in the peritoneal cavity. This experience has been transferred to the treatment of malignant colonic obstruction. Therefore, a segmental resection with colonic lavage and primary anastomosis is a viable option, as long as the colon is not ischemic and there is in no spillage during the operation. The use of a temporary diverting ileostomy may be necessary, but when the safety of a primary anastomosis is questionable, a staged procedure with a segmental resection, a Hartmann pouch, and an end colostomy, may be preferable.[321]

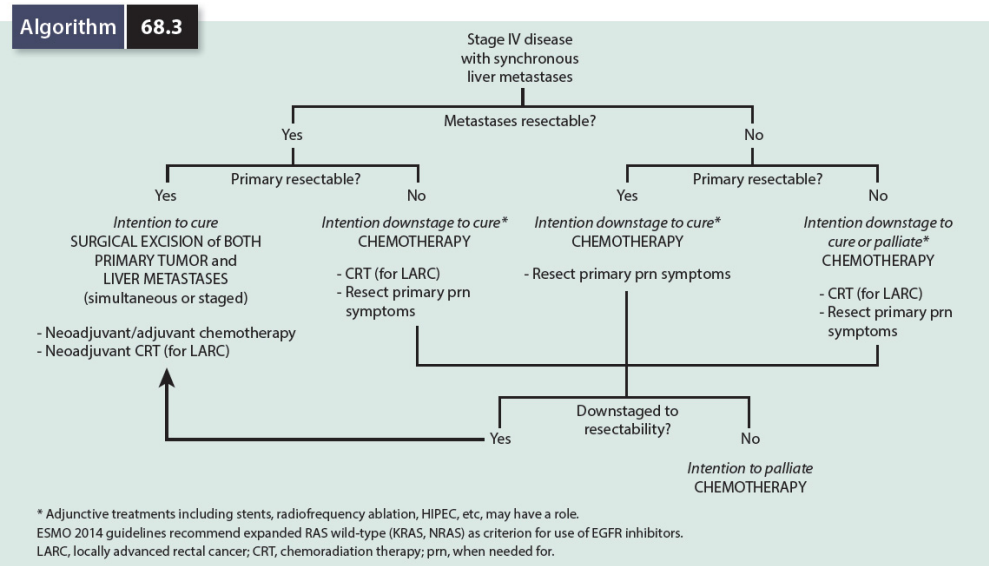
SURVEILLANCE AFTER CURATIVE RESECTION FOR COLON AND RECTAL CANCER

Of the almost 1 million patients diagnosed with CRC worldwide every year, two-thirds have curative intent surgery, but ultimately one-third of them will develop recurrence of disease or a second colorectal primary. Most recurrences arise within 3 years of the initial treatment, and almost all arise within 5 years. Recurrences are usually diagnosed at an advanced stage and

have an ominous prognosis. Surveillance regimens aim to identify recurrences before they become symptomatic, and while they are still potentially resectable.[322,323] Several meta-analyses of prospective, randomized trials comparing intensive or minimal surveillance after curative resection in patients with stage I to III CRC suggest that recurrences were diagnosed earlier and surgical salvage was more likely in patients undergoing intensive surveillance.[324] The survival benefit can only be partly attributed to the improved ability to resect recurrences; other elements such as increased psychological support, behavior modifications, and better treatment of comorbid conditions that accompany intensive surveillance regimens are also thought to contribute to improved survival. Based on this evidence, cancer organizations have established guidelines for surveillance after curative resection of CRC. All of them include a combination of regular history and physical examination, determination of CEA level, endoscopy, and imaging of the chest, abdomen, and pelvis. Some clinicians recommend surveillance for stage II and III diseases, while others also include stage I. In the future, surveillance will be risk adapted, targeting patients more likely to benefit from intensive surveillance based on clinical and molecular prognostic factors. Despite these recommendations, a recent population-based cohort study of 57 patients concluded that 70% were diagnosed between scheduled examinations.[323]

TREATMENT OF STAGE IV COLON AND RECTAL CANCER

Between 20% and 34% of all CRC patients are metastatic at the time of diagnosis; these are known as synchronous metastases. Another one-third of patients will develop metastasis sometime after undergoing treatment of the primary disease; this is known as metachronous metastasis. Synchronous metastases are usually more extensive and, in general, carry a worse prognosis compared to metachronous metastases.



Algorithm 68.3 Stage IV rectal cancer treatment algorithm.

The liver is the most common site of CRC metastasis, and liver metastasis is the most common cause of cancer death in patients with CRC. Autopsy studies have revealed that 50% of patients dying from CRC have liver metastasis and, in one-third of them, the liver is the only site of metastatic disease.[325] Some patients with liver-only metastatic disease are resectable at the time of diagnosis. Others are not resectable, due to the involvement of critical structures by large volume of metastatic disease. The treatment of stage IV CRC patients is complex, and requires consideration of the number of organs involved, the number and size of the metastasis, the location, the symptoms related to the primary in the colon or rectum, whether the tumor is resectable or not, and the patient's performance status. Treatment decisions should be made after discussion in a multidisciplinary tumor board.[326] A simplified algorithm for the treatment of patients with stage IV CRC is presented in **Algorithm 68.3**. The discussion is centered on patients with liver metastases, but these principles are equally applicable to patients with lung metastasis. Surgery is the only curative treatment for patients with colorectal metastases. Other forms of local therapy, such as radiation therapy or ablation, may improve survival. Most patients with metastatic disease benefit from systemic chemotherapy, either as adjuvant treatment to surgery or as the sole form of treatment.

Treatment of the Primary Tumor in Stage IV CRC

In the past, all patients presenting with synchronous metastasis were recommended to have resection of the primary tumor, to avoid complications such as obstruction or perforation during treatment of the metastatic disease. However, recent data suggest that patients with unresectable metastasis and an asymptomatic primary are unlikely to develop complications related to the primary tumor that require surgical intervention while the patient is receiving systemic chemotherapy. Currently, primary tumor resection is recommended for patients undergoing curative-intent resection of all metastatic disease, or for patients with unresectable metastasis and a symptomatic primary tumor. The treatment of patients with unresectable metastasis and an asymptomatic primary tumor is controversial. The benefit of avoiding complications related to tumor progression should be balanced against the mortality and morbidity associated with a noncurative resection, and the delay in starting systemic chemotherapy.

Observational studies and secondary analysis of prospective trials have reported an association between primary tumor resection and improved survival. A recent meta-analysis found a difference of 6.4 months in survival in patients undergoing resection.[327] However, these studies are limited by strong patient selection bias and outdated chemotherapy regimens. Patients undergoing resection are more likely to have liver-only disease, single metastasis, and tumors located in the colon. Rectal cancer patients are less likely to undergo primary tumor resection compared to patients with colon cancer, probably due to the higher complexity of rectal surgery, the possibility of using palliative CRT, and the fear of a colostomy.

Resection of asymptomatic tumors in stage IV disease has not consistently shown improvements in survival, nor does it necessarily reduce the risk of complications.[328] A recent analysis of the SEER database revealed that the proportion of patients with stage IV CRC undergoing primary tumor resection has been progressively decreasing in the last decade.[329] Despite this decrease in primary tumor resection, relative survival has been increasing during the same period of time. The improvement in survival has coincided with the introduction of more effective chemotherapy agents. However, the relative contribution of the declining rate of primary resection and the more active chemotherapeutic agents is unknown. In this SEER data analysis, more than half of patients diagnosed with stage IV CRC in 2009 had resection of the primary tumor, suggesting that current treatment practice lags behind evidence-based treatment guidelines. These data lend support to current guidelines that do not

recommend primary tumor resection in asymptomatic patients with unresectable metastases as noted in consensus guidelines.

Surgical Treatment of Colorectal Metastases

Overall, only 6% of CRC patients with liver metastases survive beyond 5 years, but in patients with resectable liver metastases the reported 5-year survival rate ranges from 25% to 40%. Patients with a single, isolated liver metastasis have 5-year overall survival rates as high as 71%. Liver metastases are considered resectable with curative intent if all disease can be removed with negative resection margin while preserving adequate liver reserve. Incomplete resection or tumor debulking is not recommended because it is associated with morbidity without impacting survival. The size of the metastasis is not a contraindication for surgery. When a curative liver resection may potentially result in insufficient liver remnant, portal vein embolization of the involved liver lobe is recommended to induce hypertrophy of the contralateral lobe of the liver. Repeated resection of recurrent liver metastases is feasible, but the probability of survival decreases with each subsequent resection. Simultaneous liver and colon resection is safe and efficient in a selected group of patients. Overall complication rate and hospital stay are lower as a second laparotomy can be avoided.[331,332]

The role of nonsurgical liver-directed therapy for the treatment of liver-only or liver-dominant metastatic disease is controversial. Tumor ablation is indicated in patients who are amenable to local therapy but are not candidates for surgical resection due to comorbidities. It can also be combined with surgery in patients with mixed resectable and unresectable lesions due to their anatomical location or insufficient liver remnant.[333] Other liver-directed therapies for which there is no consensus regarding efficacy are transarterial hepatic chemoembolization/radioembolization, liver-directed radiation, and hepatic arterial infusion (HAI) therapy. HAI was first developed over 45 years ago and has shown to be appropriate adjuvant treatment for patients with liver-dominant metastatic disease.[334] Patients with liver metastases refractory to all standard lines of chemotherapy may respond to HAI with 5-Fluorodeoxyuridine (5-FUDR).[335] Additionally, selected patients with strictly defined unresectable CRLM can experience enough response after combination treatment with HAI and systemic therapy to become resectable.[336]

Colorectal lung metastases can also be surgically removed following the same principles outlined for liver metastasis. Resection must be complete, based on the anatomic location of the disease, and with maintenance of adequate respiratory function. Resection of both liver and lung metastases is feasible in selected cases, but resection in the presence of nonhepatic extrapulmonary disease should be reserved for carefully selected patients. Ablation and radiation are also options for patients with nonresectable lung metastases as noted in consensus guidelines.

Chemotherapy for Metastatic Disease

Principles of Chemotherapy

A number of antineoplastic agents such as 5-FU or capecitabine, oxaliplatin, and irinotecan, and new biologic agents, such as bevacizumab, ziv-aflibercept, cetuximab, panitumumab, and regorafenib, are currently used in combination or as single agents in patients with metastatic CRC. The putative mechanism of action and the toxicity profile of each drug are presented in **Table 68.8**. The choice of the treatment regimen is based on the goals of therapy, the type and time of previous therapy, and the toxicity profile of the constituent drugs as noted in consensus guidelines. The chemotherapy regimens commonly used as first-line therapy in patients appropriate for intensive therapy include: FOLFOX (5-FU/LV/oxaliplatin), FOLFIRI (5-FU/LV/irinotecan), CapeOx (capecitabine/oxaliplatin), infusional 5-FU/LV, capecitabine as a single agent, or FOLFIRINOX (5-FU/LV/oxaliplatin/irinotecan). Cetuximab or bevacizumab can be added to first-line therapy in patients with KRAS/NRAS wild-type CRC, and other combinations such as FOLFOXIRI with bevacizumab have shown promising results.[337,338] The role of maintenance therapy after first-line therapy, and treatment after progression of metastatic disease on first-line therapy, is beyond the scope of this chapter. Median survival of patients with unresectable metastatic CRC, which 6 previously rarely exceeded 12 months, now exceeds 30 months when these agents are used. Increasing evidence suggests that the selection of chemotherapeutic agents will continue to be guided by molecular and genomic characterizations. Early reports have indicated that combined therapy with BRAF and EGFR inhibitors may be effective in treating BRAF V600E metastatic CRC specifically.[339]

Adjuvant Chemotherapy in Resectable Disease

The majority of patients who undergo resection for CRC liver metastasis ultimately relapse in the liver. It is theorized that the addition of systemic therapy provides treatment of occult micrometastatic disease, reducing the risk of relapse. A number of randomized controlled trials have found a modest improvement in RFS, but not in OS, with chemotherapy delivered before or after liver resection, compared with resection alone. The optimal timing of chemotherapy remains unknown.[340] The potential advantages of preoperative therapy include earlier treatment of micrometastatic disease, evaluation of tumor responsiveness, and the possibility of avoiding resection in patients with tumor progression during therapy. The main disadvantages of preoperative chemotherapy are the progression of nonresponsive tumors that become unresectable during systemic chemotherapy, and the increase in perioperative morbidity due to chemotherapy-induced liver toxicity. The EORTC Intergroup Trial—the only randomized trial evaluating the role of perioperative FOLFOX (3 months before and 3 months after liver surgery) in the management of resectable liver metastases—demonstrated an absolute increase of 7.3% in 3-year progression-free survival in the combined treatment group, compared with the resection-alone group.[341,342] This trial demonstrated an increased rate of postoperative complications in the chemotherapy group (25%) compared with surgery alone (16%), specifically showing a doubling in biliary fistula and hepatic failure rates. The study concluded that perioperative chemotherapy may improve cancer-specific outcomes, but at the cost of increased rates of postoperative complications, including liver dysfunction. Long-term follow-up has revealed the same benefit in progression-free survival, but no difference in OS with the addition of perioperative chemotherapy. The chemotherapy regimens used in the adjuvant setting are the same as those used in first-line therapy. However, bevacizumab can be added as long as it is discontinued at least 6 to 8 weeks before surgery and not restarted for 8 weeks after surgery, because it interferes with wound healing.[343] Cetuximab and panitumumab have been added to first-line regimens in patients with KRAS/NRAS wild type, but the benefits have been inconsistent. In fact, recent data suggest these could even be detrimental; therefore, they are not recommended at this time.[344]

Table 68.8 Main Chemotherapeutic Agents

Agents	Mechanism	Common Side Effects
5-FU	Pyrimidine analog, thymidylate synthase (TS) inhibitor	Hematologic: thrombocytopenia. GI: mucositis. Hepatic steatosis (yellow liver). Photosensitivity
Folinic acid (leucovorin)	Enhances 5-FU effects and contributes to TS inhibition	—
Irinotecan	Topoisomerase I inhibitor	Hematologic: myelosuppression. GI: diarrhea. Hepatic steatosis
Capecitabine	Pro-drug of 5-FU	GI: mucositis
Oxaliplatin	Platinum-based agent, DNA cross-linking	Peripheral neuropathy GI: sinusoidal congestion (blue liver)
Cetuximab/Panitumumab	Anti-EGFR monoclonal antibody (for use with KRAS wild-type tumors only)	Acneiform skin rash
Bevacizumab	Anti-VEGF monoclonal antibody	Compromised wound healing

Chemotherapy in Borderline Resectable Disease

A few patients present with liver-only metastases that are not amenable to a complete resection, due to close proximity to essential anatomical structures.

Systemic chemotherapy in this setting aims to convert an unresectable patient to resectable status. The duration of treatment in these patients is important. There is a need to balance the minimum time required to achieve a response that will make the patient resectable, while avoiding hepatotoxicity from the chemotherapeutic agents. Both FOLFOX and FOLFIRI increase resectability in 12.5% to 40% of patients initially considered unresectable. A study has shown that adding irinotecan to FOLFOX (FOLFIRINOX) in patients with initially unresectable metastasis increased the resection rate compared to FOLFOX alone.[345] Adding EGFR inhibitors to FOLFOX or FOLFIRI increased the resectability rate in patients with wild-type KRAS/NRAS tumors and initially unresectable liver metastasis.[346,347] Angiogenesis inhibitors combined with FOLFIRI modestly increase resectability of initially unresectable liver metastasis compared to FOLFIRI alone, but have no effect when combined with oxaliplatin-containing regimens.[348,349] To limit FOLFOX- and FOLFIRI-associated toxicity, patients receiving systemic chemotherapy to increase resectability should be evaluated for response every 2 months, and undergo surgery as soon as they become resectable.

Treatment of Peritoneal Carcinomatosis

Most patients with peritoneal carcinomatosis have widespread metastatic disease and are treated with systemic chemotherapy. The treatment of patients with the peritoneum as the only site of metastasis is controversial.[350,351] Complete cytoreductive surgery (CRS), with removal of all visible abdominal and pelvic disease, and hyperthermic intraperitoneal chemotherapy (HIPEC) are now commonly used in patients with peritoneum-only metastatic CRC. The most commonly used drug for intraperitoneal chemotherapy is mitomycin C, which is minimally active against CRC. As experimental data do not support any biologic benefit from the hyperthermia component, the role of HIPEC has been questioned. Oxaliplatin, irinotecan, doxorubicin, paclitaxel, and carboplatin have also been tested. Comparative studies have not shown a conclusive advantage of mitomycin C over oxaliplatin.[352] This aggressive treatment is associated with significant mortality (0.9% to 5%) and morbidity (12% to 52%), with the most common complications being SSI, hematologic toxicity, and intestinal fistula. Many single-institution case series have reported improved survival in patients treated with CRS and HIPEC followed by systemic chemotherapy, compared to systemic chemotherapy alone. A recent

review of 19 studies conducted from 1999 to 2009 reported a median survival of 33 months for patients treated with CRS and HIPEC versus 12.5 months for patients undergoing palliative surgery and/or systemic chemotherapy.[353] These studies have been criticized because of strong patient selection bias favoring peritoneum-only disease in the CRS/HIPEC group, an undefined role for palliative treatment, and suboptimal chemotherapy in the nonsurgical group. The only prospective trial published so far randomized patients to 5-FU/LV with palliative surgery versus CRS, HIPEC, and postoperative 5-FU/LV. OS was 12.6 months in the standard arm versus 22.2 months in the HIPEC group.[354] This study has been criticized because it also included patients with pseudomyxoma peritonei of appendiceal origin, and because it was conducted before most of the drugs currently used in metastatic disease were available. In the French PRODIGE-7 randomized trial, CRS-HIPEC showed no overall survival benefit over CRS alone and suggests that HIPEC should be abandoned in patients with resectable peritoneal carcinomatosis.[355] However, this study has been criticized because of its small sample size and for using oxaliplatin as a HIPEC regimen. In spite of this criticism, CRS and HIPEC are commonly performed regimens for patients with peritoneum-only colorectal metastases.[356]

The selection criteria for this complex and potentially morbid treatment are not well defined. The most important prognostic factors in patients undergoing CRS and HIPEC are the Peritoneal Cancer Index (PCI), a grading of tumor burden at the time of surgery, and the completeness of cytoreduction (CC) score. Unfortunately, the determinants of these scores are only available at the time of abdominal exploration during surgery. Therefore, they have not been useful in selecting those patients more likely to benefit from CRS and HIPEC. Recently, a Peritoneal Surface Disease Severity Score (PSDSS) that includes patient symptoms, extent of peritoneal dissemination, and primary tumor histology has been developed to stratify patients at the time of diagnosis, without the need of an operation.[357] The PSDSS score system has been found to be an independent prognostic factor in multivariate analysis, not only for patients undergoing CRS and HIPEC, but also for patients treated with systemic chemotherapy. This score may help eliminate selection bias in future comparisons of different treatments, in patients with peritoneum-only metastatic CRC.

Immunotherapy for CRC

In the last few years immune checkpoint inhibition—targeting inhibitory signal that tumors use to scape immune recognition—has become new treatment modality for MMRd/MSI-H metastatic CRC.[358] Antibodies targeting PD1 (Pembrolizumab, Nivolumab), PDL1 (Atezolizumab), and CTL4 (Ipilimumab) are now used in clinical practice in patients with metastatic disease and are being tested in the adjuvant setting for nonmetastatic MMRd/MSI-H colon and rectal cancers, alone or in combination with other chemotherapy agents and radiation therapy.[177,359–363] While highly effective in achieving durable responses, immune checkpoint inhibition is also associated with specific toxicity such as diarrhea and colitis, skin rashes, elevation of liver enzymes and fatigue.

TREATMENT OF LOCALLY RECURRENT CRC

LR after curative-intent surgery is defined as a relapse of tumor in the surgical field of the initial procedure, including the anastomosis, regional nodes, surgical scars, and drain tracts.[361] While most patients with LR also have distant metastasis, a few have isolated LR. A complete surgical resection is the only curative option for patients with isolated locally recurrent CRC, but is associated with considerable morbidity and mortality.[364]

The risk of LR is higher for rectal cancer compared to colon cancer, for advanced stage tumors (T4), for tumors with high-risk histologic features (lymphovascular and perineural invasion, grade III or IV, signet ring cell histology), perforating or obstructing tumors, and patients with close or involved CRM. Most local recurrences present within 3 years after the primary surgery, but LR tends to occur later in patients treated with CRT and surgery, compared to those treated with surgery alone. In the Dutch TME trial, 10% of LRs occurred more than 3 years after surgery in patients treated with TME, versus 31% in patients treated with preoperative RT and TME.[365]

While some LRs are detected though surveillance, while asymptomatic, most are diagnosed after they become symptomatic. Symptoms of local recurrence include bowel obstruction, abdominal distension, rectal or vaginal bleeding, and urinary problems.[366] Pelvic pain is common, and is a predictor of reduced long-term survival.[367] A common manifestation of recurrence in patients who have had abdominoperineal resection (APR) is a nonhealing perineal wound. Whenever symptoms suggestive of recurrence arise, a detailed history and

complete physical examination must be done. This includes DRE in patients who have undergone sphincter-preserving surgery, and a pelvic examination in females. If recurrent tumor is identified, endoscopy and imaging studies will help assess extent of disease and surgical risk. A complete colonoscopy should be performed if possible. Intraluminal recurrences are easily diagnosed with endoscopy and biopsy. Cystoscopy is required for patients who present with urogenital symptoms, as these strongly indicate tumoral invasion of the ureters and bladder.[368] CEA is routinely measured during follow-up surveillance after primary rectal cancer resection. Elevation of this tumor marker is frequently the first sign of recurrence.[369] However, elevated CEA is present in only about 50% of patients. Patients with elevated CEA should undergo further work-up with imaging studies.

A CT scan of the chest, abdomen, and pelvis is the primary imaging modality used in these patients, and it is especially helpful in identifying metastases in the liver, lung, and peritoneum, and evaluating regional adenopathy.[370] MRI is more accurate than CT in detecting and staging pelvic LR[371]; although it has been ineffective when added to routine follow-up, ERUS may be useful in diagnosing LR after LE of distal rectal cancer.[372] Positron emission tomography (PET) using the glucose analog fluorodeoxyglucose (FDG), particularly when combined with a CT scan, is helpful in distinguishing between postsurgical changes and tumor recurrence. In a recent meta-analysis comparing FDG-PET, FDG-PET/CT, CT, and MRI in the detection of recurrent CRC in patients with high suspicion of recurrent disease, based on symptoms or elevated CEA, FDG-PET and FDG-PET/CT performed more accurately than CT scan.[373] PET/CT also demonstrated greater accuracy than MRI in identification of lymph node recurrence in a lesion levels analysis.[374] Overall accuracy of FDG-PET/CT is slightly higher than FDG-PET: 92.3% (94% sensitivity, 77.2% specificity) versus 89% (90.3% sensitivity, 80% specificity).[375] However, lesions measuring less than 1 cm in diameter are more difficult to detect with PET scanning, as are mucinous tumors, due to poor FDG uptake. Finally, FDG-PET cannot be used to detect or evaluate LR if there is residual inflammation of the tumor bed secondary to chronic leaks. Regardless of the imaging studies used to help diagnose LR, histologic confirmation is imperative. Anastomotic recurrences should be biopsied endoscopically; extraluminal recurrences can usually be biopsied percutaneously, under radiologic (CT) guidance.

The treatment of locally recurrent CRC should be discussed in a multidisciplinary setting, since it often involves colorectal surgical

oncologists, radiation oncologists, medical oncologists, and other specialists. Patients with multifocal LR should be treated with systemic chemotherapy, as in metastatic disease. Only patients with localized LR and good performance status are candidates for surgical resection. Even these patients may benefit from additional systemic chemotherapy or chemoradiation, if they did not receive it at the time of treatment of the primary tumor.[376] Some patients with recurrent rectal cancer treated initially with standard doses of radiation (50.4 Gy in 180 cGy fractions, or biologically equivalent total dose) can be reirradiated to the gross tumor volume using small fractions (180 to 200 cGy), with or without sensitizing chemotherapy.[376] Reirradiation seems to increase the possibility of an R0 resection in patients with resectable disease, or provides good palliation in unresectable patients. Following preoperative chemotherapy and/or radiotherapy, restaging should be done to exclude interim development of distant metastasis and to ascertain the extent of the LR.

Surgery is the only curative option for patients with locally recurrent rectal cancer. Without treatment, median survival is typically 6 to 7 months[377]; systemic chemotherapy can prolong survival, similar to patients with systemic recurrence. Only patients with good performance status, with recurrences that, based on anatomical location, are amenable to an R0 resection, should be considered surgical candidates. A resection with gross positive margins (R2) should not be attempted, because it provides no oncologic advantage to the patient and is associated with significant morbidity. Patients found to have microscopic positive margins (R1) may benefit from intraoperative radiation. However, this modality is only available at some institutions, and requires preoperative planning. Therefore, the treatment of locally recurrent CRC should be limited to institutions with appropriate expertise and equipment.

Only about one-third of patients with isolated locally recurrent CRC are candidates for surgical salvage with curative intent. In the Intergroup Study 0114, which investigated several chemotherapy regimens in patients with locally advanced rectal cancer, only 159 (35%) of the 448 patients with single-site first recurrences in the liver, lung, or pelvis had curative-intent surgery.[366] The proportion of patients undergoing resection was similar for liver, lung, or local recurrences. OS differed significantly between the resected and nonresected groups, with 5-year OS of 27% and 6%, respectively ($p < 0.001$). The 5-year DFS was in the range of 30% for patients undergoing resection of tumors in solitary sites of the liver or lung, and 20% for those undergoing resection of LRs. Retrospective case series from institutions with experience in

the treatment of locally recurrent CRC report 5-year survival rates close to 35% for patients with R0 resections, compared to 21% for patients with R1 resections.

Palliation is an important aspect of the treatment of patients with unresectable LR. Bowel obstruction often requires palliative surgery, stomas, endoluminal stents, or percutaneous gastrostomy tubes. Urinary obstruction is common, requiring stents or percutaneous nephrostomies. Pain is a common symptom in these patients, often requiring the assistance of pain specialists and specialists in palliative care. Carefully selected rectal cancer patients who are unable to or unwilling to undergo palliative resection due to extensive comorbidity, can be treated with aggressive palliative radiation.[378]

Diverticular Disease

Lillias H. Maguire

Key Points

1. Although a minority of patients become symptomatic, the high prevalence of diverticulosis leads to a large and increasing burden of disease including diverticulitis, perforation, stenosis, fistula, and hemorrhage.
2. The prevalence of diverticulosis varies greatly across global populations. It is ubiquitous in older adults in North America and Europe.
3. The etiology of diverticulitis is incompletely understood, but includes both inherent and environmental risk factors.
4. Diverticulitis can be effectively diagnosed and its severity classified with cross-sectional imaging.
5. Acute uncomplicated diverticulitis may often be treated in the outpatient settings. Antibiotics may be omitted.
6. Acute complicated diverticulitis may be successfully treated with percutaneous abscess drainage or require urgent laparotomy and colectomy depending on disease severity.
7. Clinical guidelines for treatment of diverticulitis have changed meaningfully over a relatively short period of time reflecting improved understanding of the natural history of the disease.
8. The decision to operate electively for secondary prevention of diverticulitis should be individualized based on patient and disease-specific factors.

INTRODUCTION

Diverticular disease is one of the most common colorectal conditions evaluated and treated in the United States. The precursor 1 lesion, diverticulosis, is ubiquitous and its most common resultant pathology, diverticulitis, causes millions of outpatient visits, tens of thousands of surgeries, and results in billions of dollars in expense every year. Patient

presentations vary, including mild, self-limited disease, life-threatening abdominal sepsis, chronic complications, and recurrent disease. Recently, improved understanding of diverticulitis has meaningfully changed clinical guidelines over a short period of time. Traditional dogmas have fallen under increased scientific scrutiny. Today, diverticulitis patients may avoid antibiotics, are less likely to require inpatient admission or emergency surgery, less likely to undergo elective colectomy, and more likely to have percutaneous procedures and minimally invasive surgery. However, despite this progress, fundamental questions and clear opportunities for discovery remain.

TERMINOLOGY AND ANATOMY

Diverticulosis coli describes the presence of colonic pseudodiverticula, discrete sacs of mucosa and submucosa penetrating through the muscular layers of the colon wall (**Fig. 69.1**). Diverticula herniate through colonic circular muscle adjacent to penetrating mesenteric vessels, emerging between the tenia coli on the antimesenteric aspect of the colon.[1] With rare exception, diverticulosis is an acquired condition of adults that increases in frequency with advancing age.[2] Incidental diagnosis of this asymptomatic lesion can be made at the time of colonoscopy (**Fig. 69.2**), barium enema, or cross-sectional imaging. In Europe and North America, diverticulosis is most prominent in the sigmoid colon, effected in 95% of patients with diverticulosis.[3] Isolated sigmoid diverticulosis is present in 60% of cases and the pattern of involvement progresses proximally. Total colonic diverticulosis is present in up to 10% of cases. Much less common than colonic diverticulosis, small bowel and rectal diverticula are not included in this text.

The term "diverticular disease" encompasses pathology due to diverticula. The two most common diverticular diseases are diverticular hemorrhage and diverticulitis (inflammation of the diverticula) and its many sequelae. Two less common manifestations include segmental colitis associated with diverticulosis (SCAD) and symptomatic uncomplicated diverticular disease (SUDD). These entities have clinical overlap with inflammatory bowel disease (IBD) and irritable bowel syndrome, respectively.[4,5] Diagnosis is

controversial and the role of surgery even more so. For the purposes of this chapter they will not be considered further.

EPIDEMIOLOGY

North America and Europe

2 Diverticulosis is ubiquitous in older adults in Western Europe and North America. Endoscopic studies indicate that >50% of individuals over age 60 have diverticula.[3] Incidence increases with age, demonstrates a male predominance under age 60 and a female predominance thereafter.[6] Although only 4% of patients with incidentally discovered diverticulosis develop diverticular disease,[2] the high prevalence of diverticulosis leads to a substantial burden of disease. Nearly 200,000 inpatient admissions, 340,000 emergency room visits, and 1.9 million clinic visits a year are attributed to diverticulitis, resulting in billions of dollars in expense.[7] Diverticulitis is considered a disease of older adults in industrialized societies, but even within the modern era incidence continues to increase rapidly, particularly among young adults; between 1980 and 2007, diverticulitis increased 132% in Americans under age 50.[6] Within the United States, hospitalization for diverticulitis is more common in Northern latitudes and in urban areas.[8] Incidence is highest in the white population (62/100,000), lower in blacks and Hispanics (32/100,000), and lowest among Asians (10/100,000).[9]

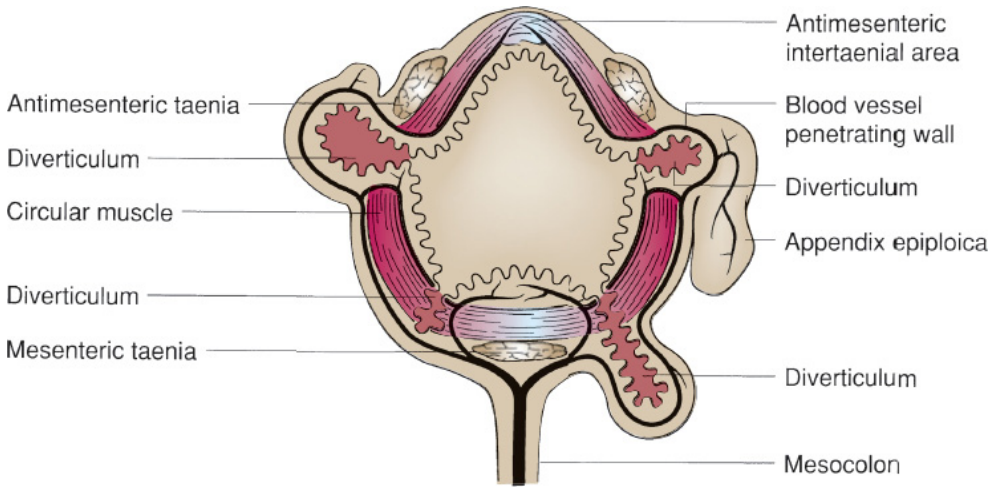

Figure 69.1 Cross section of the colon illustrating the relation of diverticula to the blood vessels penetrating the circular muscle layer, the taeniae, and the appendices epiploicae.

Africa

The observed low incidence of diverticular disease in Africa in the 1960s led to lasting etiologic theories.[10] In Sub-Saharan Africa, lack of routine screening endoscopy makes the true rate of asymptomatic diverticulosis impossible to know. However, in small endoscopic series of patients with hematochezia, presumably enriched for pathology, incidence of colonic diverticulosis is <5%.[11] Despite this low incidence, diverticular disease is reported with increasing frequency in some African hospitals.[12]

Asia

Incidence of diverticulosis in Asia is lower than in Europe and the United States. Reported incidence ranges from <5% in mainland China,[13] 12% to 14% in Korea and Taiwan,[14,15] 28% in Thailand,[16] and 32% in older adults in India.[17] Diverticulosis in Asia is anatomically distinct. Unlike European-ancestry populations, diverticulosis in Asians is right sided in up to 80% of cases.[13] The reason for this anatomic variation is unknown.

ETIOLOGY

3 The causes of diverticulosis and the triggers that produce diverticulitis are incompletely understood, but compelling associations between inherent and environmental risk factors have been observed (**Table 69.1**). The ubiquity of diverticulosis, difficulty in separating diverticulosis-risk from diverticulitis-risk, and the lack of model organisms are challenges for testing the causal relationships of these observations.

Figure 69.2 Endoscopic image of diverticulosis coli. Multiple diverticula are visible without evidence of inflammation of bleeding.

Inherent Risk Factors: Genetic Background

Traditionally considered a purely environmental condition, recent evidence indicates that an individual's genetic background also influences the development of diverticular disease. Two twin studies performed in Scandinavian populations identified increased disease concordance between monozygotic twins as compared to dizygotic twins and siblings. These

studies estimated that 40% to 53% of individual risk for diverticular disease is due to heritable factors.[18,19] Disease concordance was higher for more severe disease. Additionally, family history has been recognized as an independent risk factors for recurrence and complications.[20] Three recent genome-wide association studies[21–23] performed in European-ancestry populations have begun to define the genetic architecture of the disease, identifying associations with genes with known roles in immunity, connective tissue, and intestinal motility, among others. These data suggest that like most common diseases, diverticulitis is a complex trait with both environmental and genetic risk factors.

Table 69.1 Inherent and Environmental Risk Factors Associated with Diverticular Disease

Risk Factors Associated with Diverticular Disease	
Inherent	**Environmental**
▪ Age ▪ Sex ▪ Genetic background *Family history, ethnicity* ▪ Mendelian syndromes *Ehler–Danlos syndrome, Marfan syndrome, polycystic kidney disease, Williams syndrome* ▪ Acquired connective tissue disorders *Aneurysm, rectal prolapse, hernia, senescent collagen cross-linking* ▪ Altered colonic motility	▪ Geography *Country of birth, country of residence, Northern latitude, urban environment* ▪ Diet *Low fiber, high red meat intake* ▪ Lifestyle factors *Obesity, smoking, low physical activity* ▪ Microbiome ▪ Other *Medication use, UV light exposure, vitamin D*

Inherent Risk Factors: Changes in Colonic Structure and Function

The acquired, age-related nature of diverticulosis has led to the theory that connective tissue generation is involved in its pathophysiology. Observed associations with rare connective tissue disorders such as Ehlers–Danlos syndrome, Marfan syndrome, and Williams syndrome support this theory,[24,25] as does the association of diverticular disease with more common acquired connective tissue traits such as hernia, rectal prolapse, and aneurysm.[26] At the histologic level, natural connective tissue senescence is increased in patients with diverticulosis, as noted by cross-linking of collagen fibrils.[27] Increased elastin deposition is observed in the tenia coli, leading to the thick walls and foreshortened haustral folds frequently appreciated in diverticulitis patients.[28]

The Western predominance of diverticulosis in the relatively narrow noncompliant sigmoid colon led to the theory of diverticula being secondary to increased intraluminal pressure. Motility studies have overall demonstrated increased contractility in patients with diverticulosis compared to controls.[29] Histopathologic studies comparing patients with diverticular disease to controls have noted alterations in enteric and somatic innervation and disruption of signaling molecules including serotonin, vasoactive intestinal peptide, and acetyl choline,[30,31] but it is unknown if these alterations are causal, correlated, or reactive to the disease state.

Environmental Risk Factors: Diet and Lifestyle

Multiple modifiable lifestyle risk factors have been associated with diverticular disease. Dietary fiber was first identified in the 1960s. Working in Uganda, Painter and Burkitt observed the high-fiber diets and low disease prevalence among Africans compared to their British counterparts.[32] Modern work confirms that prudent diets low in red meat and high in vegetable and whole grain intake are associated with significantly lower risk of incident diverticulitis.[33] Obesity, smoking, and low physical activity are associated with incident diverticulitis.[15,34,35] Assuming these associations are causal, widespread adoption of a healthy lifestyle including <4 servings of red meat a week, 23 g of daily fiber, vigorous physical activity, body mass index <25, and abstaining from smoking could prevent 50% of diverticulitis cases.[36]

Other associations including vitamin D level, UV light exposure, seasonality, medication use, and others have been observed, but whether these relationships are causal or correlative is unknown.

Environmental Risk Factors: Microbiome

Multiple lines of reasoning suggest a role for the microbiome in diverticular disease. The colonic microbiome may link diet and disease through the bacteria that process dietary fiber into the short chain fatty acids (SCFAs) critical for intestinal epithelial proliferation and barrier function.[37] Western diet is associated with both decreased diversity of the gut microbiome and diverticular disease. However, the data are to date less compelling than the theory. Studies of the microbiome in diverticulitis have been limited to date by clinical reluctance to perform colonoscopy (and harvest samples) during acute diverticulitis, pretreatment with antibiotics, and a preponderance of studies in the controversial clinical entity SUDD. Despite these limitations, changes in the microbiome have been observed in patients with a history of diverticulitis, but it is unknown whether these changes predate or follow diverticulitis.[38,39] Nonetheless, the microbiome remains a compelling area of diverticulitis research.

ACUTE DIVERTICULITIS

Presentation and Differential Diagnosis

Acute diverticulitis presents with local inflammatory symptoms and systemic septic physiology depending on the severity of disease. 4 The modified Hinchey classification (**Table 69.2**) provides ordinal categorization to the severity of acute inflammatory diverticulitis correlated with associated CT findings.[40,41] Initial treatment strategy is guided by Hinchey stage. Stage 0–I disease typically presents with local inflammatory symptoms and signs alone. Patients complain of left lower quadrant pain, fever, altered bowel habit, malaise, and may have nausea and vomiting or urinary symptoms. Duration of symptoms on presentation is typically 12 to 48 hours. When taking a history, patients should be asked about prior surgeries and

endoscopies, family history of colorectal cancer, bowel habit, and continence. Review of systems should ascertain the presence or absence of fecaluria, pneumaturia, frequent urinary tract infections, foul vaginal discharge, and stool per vagina which suggest the presence of a fistula.

Table 69.2 Modified Hinchey Classification, Expected CT Imaging Findings, and Likely Initial Treatment Strategy for Increasingly Severe Presentations of Diverticulitis

Modified Hinchey Classification	CT Findings	Initial Treatment
0 Mild clinical diverticulitis	Diverticuli, colonic wall thickening	Supportive care or antibiotic treatment
Ia Pericolic inflammation	Diverticuli, wall thickening, pericolic soft tissue changes, small extraluminal gas locules	Supportive care or antibiotic treatment
Ib Pericolic or mesocolic abscess	Ia Changes with local fluid collection(s)	<3 cm abscess—antibiotics >3 cm abscess—antibiotics and percutaneous drainage
II Pelvic, retroperitoneal, distant abscess	Ia Changes with remote fluid collection(s)	<3 cm abscess—antibiotics >3 cm abscess—antibiotics and percutaneous drainage
III Purulent peritonitis	Pneumoperitoneum, ascites, peritoneal thickening, possible extravasation of oral contrast	Operative exploration, antibiotics, potential need for critical care
IV Feculent peritonitis	Same as III	Same as III

Modified from Klarenbeek BR, de Korte N, van der Peet DL, et al. Review of current classifications for diverticular disease and a translation into clinical practice. *Int J Colorectal Dis* 2012;27(2):207–

History should also seek evidence of other etiologies. Profuse diarrhea and history of travel, sick contacts, or suggestive food exposures should prompt consideration and evaluation of gastroenteritis. Chronic abdominal pain, weight loss, subacute change in bowel habit, and history of melena or hematochezia are not typical of acute diverticulitis and should arouse suspicion for an alternative diagnosis such as IBD or colorectal cancer. Because diverticular hemorrhage is typically painless, acute diverticulitis with hematochezia is unusual. Other causes such as IBD, malignancy, or ischemic colitis should be suspected and interrogated with sigmoidoscopy in this setting.

Physical examination in stage 0–II disease reveals focal tenderness or local peritonitis in the left lower quadrant. Rectal examination may demonstrate pelvic tenderness. Fever may be present but hypotension, tachycardia, and signs of septic physiology are typically absent. At these stages, differential diagnosis includes colitis, constipation, and genitourinary pathology. Stage III and stage IV diverticulitis presents with peritonitis and attendant septic physiology, which may range from fever and tachycardia to septic shock with multiple organ failure. Patients demonstrate diffuse peritonitis on examination. Differential diagnosis at this stage includes pancreatitis, perforated peptic ulcer disease, perforated appendicitis, perforated colon cancer, acute ischemic colitis, and flare of IBD among others.

Diagnosis

Standard laboratory investigations of abdominal pain including complete blood count, basic serum chemistries, amylase, lipase, pregnancy testing, and urinalysis should be performed. Nonspecific inflammatory markers including C-reactive protein (CRP), fecal calprotectin, and procalcitonin are frequently elevated in diverticulitis, more so in severe disease. Studies have demonstrated the potential of these tests to discriminate between complicated and uncomplicated diverticulitis,[42–44] but this has yet to be incorporated into routine diagnostic algorithms.

CT scan is the most common and useful radiologic test for acute diverticulitis. Ideally performed with intravenous and oral contrast, CT sensitivity and specificity for diverticulitis are greater than 95% even without contrast media.[45] CT scan findings can be used to stratify patients into Hinchey stages and exclude mimicking pathology. Typical findings in stage 0–I disease include the presence of diverticula, colonic wall thickening, pericolic inflammatory changes and abscesses, and even small pericolic locules of gas consistent with "microperforation." Stage II disease includes the same findings with the addition of pelvic or remote abscesses and stages III and IV are marked by free air, free fluid, peritoneal thickening, and potentially extravasation of enteric contrast. Aside from confirming and categorizing the diagnosis of diverticulitis, CT scan has other uses. CT evaluation of diverticular abscesses can predict the likelihood of antibiotic failure based on size and location, guide percutaneous abscess drainage, and predict recurrent abscess formation. Air in the bladder or vagina may suggest an occult fistula. For the surgeon, CT scan can also be useful for operative planning in evaluating the degree of inflammation, particularly adjacent to pelvic sidewall structures, and gauging the colon redundancy and height of the splenic flexure. However, a notable limitation of CT scan is its inability to distinguish inflammatory from malignant pathology. In patients who cannot undergo CT, MRI is similarly useful. In the setting of peritonitis, abdominal x-ray demonstrating pneumoperitoneum may appropriately prompt operative exploration without further diagnostic testing. Endoscopy is not a routine component of the acute diagnostic algorithm but should be used judiciously when other diagnoses, such as malignancy, IBD, and ischemia are seriously considered.

TREATMENT

Acute Uncomplicated Diverticulitis

Although less formal than the Hinchey classification, uncomplicated diverticulitis refers to inflammation limited to the colon and pericolic tissues without pelvic abscess or peritonitis. Traditional treatments of acute diverticulitis are inpatient admission, bowel rest, and antibiotics, but all of

these therapies lack an evidence base and have come under scrutiny. It is clear that patients with uncomplicated diverticulitis can be managed as outpatients with a failure rate <5%.[6] Acceptance of outpatient treatment is clear from national trends. Between 2006 and 2013, rates of hospital admission after emergency room 5 visits for diverticulitis fell from 58% to 46%.[46] Outpatient treatment is most prudently applied to otherwise healthy, reliable individuals with relatively mild local symptoms and no systemic systems.

Antibiotics have long been standard of care medical therapy for acute diverticulitis. However, randomized controlled trials and systematic reviews have failed to demonstrate a benefit. The Swedish AVOD trial randomized 623 patients to inpatient antibiotics or inpatient IV hydration alone. Short-term follow-up revealed no differences in complications, recurrence, or time to recovery. At a median follow-up of 11 years, the two groups remained equivalent in terms of recurrence and GI-specific quality of life.[47] The Dutch DIABOLO trial is more relevant to current clinical management. Participants with first episode, uncomplicated sigmoid diverticulitis were randomized to 10 days of outpatient antibiotics or observation alone. Time to recovery was equivalent between groups and no differences in recurrence or complications were observed, other than an 8% rate of antibiotic-related adverse events.[48] Systematic reviews of these and other studies have supported the findings. In 2020, the American Society of Colon and Rectal Surgeons incorporated these data into its clinical practice guidelines, including omission of antibiotics as a strong treatment recommendation in otherwise healthy patients with early diverticulitis.[49]

Following resolution of a first episode of diverticulitis, 10% to 30% of patients will recur.[2] Physicians commonly recommend adoption of lifestyle modifications associated with reduced incident diverticulitis: weight loss, high fiber diet, and smoking cessation, although it is unknown if these measures prevent recurrence. It is unclear whether patients with uncomplicated diverticulitis harbor increased risk for occult colorectal neoplasia, but colonoscopy is generally recommended[49] after resolution of a first episode and should be strongly considered if CT imaging demonstrates lymphadenopathy or colonic wall “shouldering,” symptoms are suggestive of malignancy, or complete recovery is not achieved.

Acute Complicated Diverticulitis

Intra-Abdominal Abscess

Diverticular abscess is present in 10% to 25% of hospitalized diverticulitis patients. Abscesses may be intramural, pelvic, pericolic, hepatic, or retroperitoneal (**Fig. 69.3**). The underlying etiology is assumed to be contained diverticular perforation and associated flora are enteric in nature. Small abscesses <3 cm may often be treated successfully with antibiotics alone, but larger collections fail medical management up to 34% of the time.[50] Image-guided percutaneous drainage is the mainstay 6 of therapy. Drainage is most likely to be successful in the hands of a skilled interventional radiologist approaching a unilocular collection via a transabdominal route. Multifocal or loculated abscesses are less likely to be well drained percutaneously and transgluteal drainage routes are painful and poorly tolerated. Overall, nonoperative therapy is successful in 80% of cases,[51,52] but urgent surgical intervention is indicated if septic symptoms worsen or fail to improve.

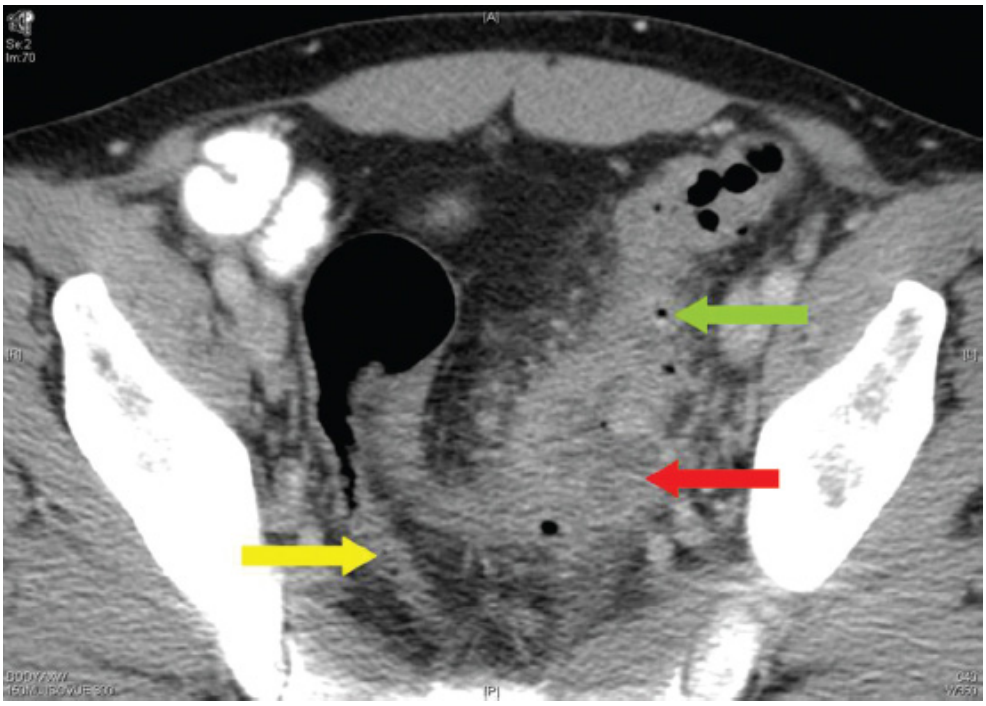

Figure 69.3 Sigmoid diverticulitis with pericolic abscess (*arrows*).

Following an episode of complicated diverticulitis, patients should undergo colonoscopy. Reported rates of occult malignancy range from 7.9% to 11%.[53,54] Until recently, surgical guidelines advised elective colectomy after an episode of complicated diverticulitis, but mandate is relaxing somewhat. Prior to widespread use of percutaneous drainage, the rate of recurrent abscess was considered unacceptably high and approached 40%. However, after percutaneous drainage, reported rates of recurrent complicated disease are lower, ranging from 15% to 25%.[55–59] Data are varied, in some series, all recurrent episodes were managed percutaneously without surgery[57] and in others, substantial minorities required urgent operation.[58] These data are heterogeneous, retrospective, and limited, speaking to the challenge of studying relatively rare events prospectively. Additionally, varied conclusions drawn from the same data reveal that surgeons do not agree on an acceptable rate 7 of abscess recurrence. However, the observation that recurrence and surgery are not inevitable consequences of diverticular abscess has led to a relaxation of guidelines from advising colectomy to advising consideration of colectomy.[49] Patients should be seen in consultation with a surgeon and the risks of recurrence balanced against patient preferences and anticipated surgical morbidity. When counseling patients on risk of recurrence, it should be noted that large abscesses (>5 cm) and pelvic abscesses are more likely to recur.

Perforated Diverticulitis with Peritonitis

Emergency surgery is required in 1% of diverticulitis patients overall, but may be required in 15% to 32%[52] of hospitalized patients. Hinchey III and IV disease presents with peritonitis and requires urgent operative intervention. Patients should be given broad-spectrum antibiotics, rapidly hemodynamically stabilized as needed, and explored. The goal of the operation is to achieve infectious source control by resecting the affected bowel and evacuating intraperitoneal pus and feces. Emergency colectomy for diverticulitis is morbid, potentially fatal, and care of unstable, elderly, or frail patients should be rapid and meticulous. Overall 30-day mortality is 5.1%. Patients >80 years of age, with serum creatinine >1.2 mg/dL, ASA class 4/5, or albumin <2.5 g/dL are increased risk of mortality and patients with four of these predictors have a 30-day mortality rate >50%.[60]

The most common approach to Hinchey III and IV diverticulitis is a Hartmann procedure: resection of the diseased bowel to soft compliant proximal colon, stapled or suture closure of the distal stump, and creation of an end colostomy. The major downside of this approach is the need for a second major operation to restore intestinal continuity. Hartmann reversal most often requires repeat laparotomy, can entail a challenging lysis of adhesions and pelvic dissection to "dig out" the rectal stump, and is associated with significant operative morbidity. Because of this, at least one-third of "temporary" urgent colostomies are permanent.[61] Therefore, creation of a primary anastomosis with diverting loop ileostomy (DLI) is an attractive alternative. Three randomized controlled trials, ColonPerfRCT (n = 62), DIVERTI (n = 102), and the DIVA arm of the LADIES trial (n = 133) randomized Hinchey III or IV patients to Hartmann procedure or sigmoid colectomy with DLI.[62–64] The three trials reached similar conclusions: morbidity and mortality of the primary operation were the same between the two approaches, but stoma-free survival was higher with primary anastomosis. Hartmann procedure at the initial operation led to greater morbidity at the time of ostomy takedown. Although compelling, these results have not changed clinical practice. In the United States >90% of urgent colectomies for diverticulitis are performed with end colostomy. In contrast to the results of randomized controlled trials, observed inhospital morbidity (32% vs. 23%) and mortality (16% vs. 6.4%) seem to be significantly higher for patients undergoing primary anastomosis than patients undergoing Hartmann procedure, respectively.[65] In clinical practice, the surgeon should decide to perform a colostomy or an anastomosis on an individual basis, evaluating the acute and chronic condition of the patient, the quality of the tissues, and the degree of contamination. Other considerations include baseline renal insufficiency, which could worsen with an ileostomy and continence, which is likely to be impaired after sigmoid colectomy.

An alternative approach to Hinchey III diverticulitis, laparoscopic lavage garnered serious clinical and academic interest as a potential alternative to resection. In laparoscopic lavage, the patient undergoes laparoscopic irrigation and drainage of intraperitoneal pus without mobilization or resection of the colon. Three heterogeneous randomized trials of laparoscopic lavage versus sigmoid resection did demonstrate some advantages of laparoscopic lavage including shorter operative times,

reduced superficial wound infections, and decreased stoma creation rates.[66–68] However, higher than expected rates of deep space infection and urgent reintervention occurred, forcing the early closure of one trial. Additionally, the occurrence of some unusual complications such as conversion of purulent to fecal peritonitis, fecal fistula, and missed adenocarcinomas dimmed enthusiasm for laparoscopic lavage. Colectomy remains the preferred approach to Hinchey III and IV diverticulitis.[49]

Surgical Technique—Urgent Operation for Perforated Diverticulitis

Preoperatively, the patient should be marked bilaterally for a potential ostomy while sitting up if possible, avoiding skin folds and creases. Operative approach may be open or minimally invasive considering the condition of the patient, anticipated severity of contamination, and skill of the operating surgeon. The patient should be placed in the lithotomy position to allow creation of circular stapled anastomosis if possible, perform colonoscopy if necessary, and assist in identification of structures in the inflamed pelvis. After clearing stool and pus from the operative field, the small bowel is swept free of the pelvis. Purulent rinds and adhesions may be broken up bluntly. Areas of perforation may be quickly oversewn to control contamination. The colon is divided just proximally to the diseased area and dissection carried to the sacral promontory. Sidewall structures are identified (**Fig. 69.4**) and dissection is kept close to the inflamed colon. The distal noninflamed sigmoid or upper rectum is transected and the specimen passed from the field. Any remaining contamination is irrigated to clear. If the patient is in shock after contamination is controlled, it is reasonable to stop at this point, leave the abdomen open, the bowel in discontinuity and proceed to the intensive care unit for resuscitation. However, if the patient is stable, the colon is mobilized for either creation of a colostomy or anastomosis. Due to inflammatory foreshortening of the mesentery, either approach may require takedown of the splenic flexure (**Fig. 69.5**), division of the inferior mesenteric artery (IMA), and possibly division of the inferior mesenteric vein (IMV) to achieve adequate colonic reach for a tension-free anastomosis or appropriately spouted colostomy. If the patient and bowel are judged by the surgeon to be suitable for an anastomosis, full mobilization and

careful assessment should be employed to assure that the anastomosis is tension-free, straight, and viable.

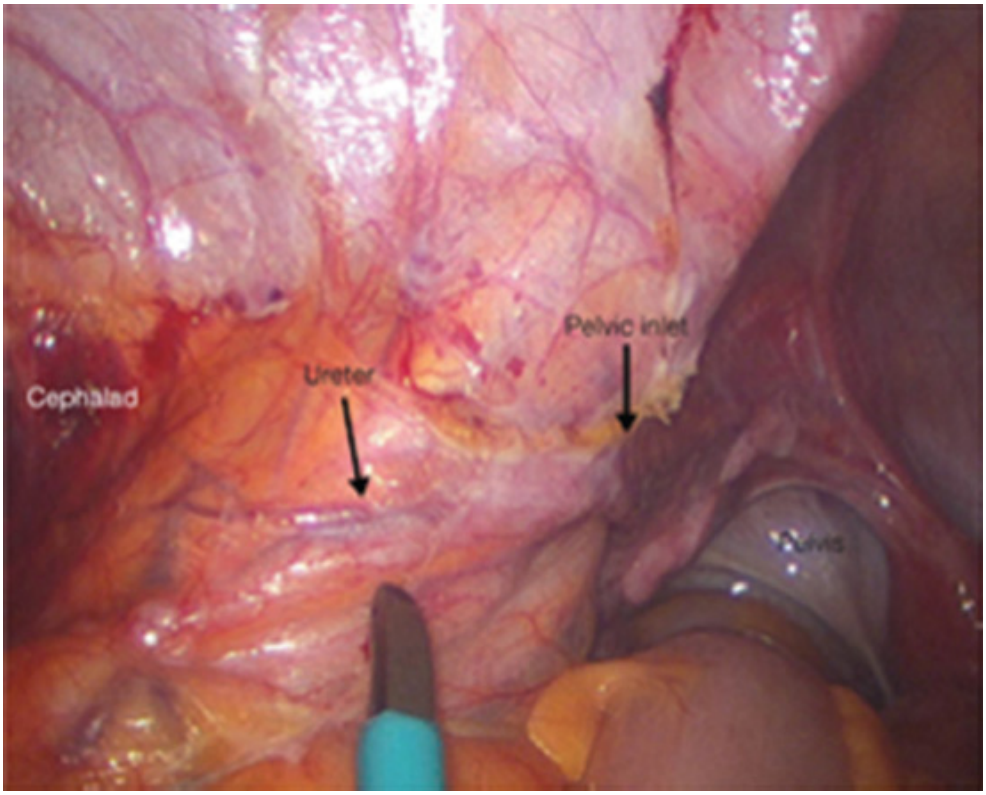

Figure 69.4 Surgical view of the left-sided pelvic sidewall structures demonstrating the ureter and iliac vessels.

If a Hartmann procedure is performed and a reversal is desired, the patient should be allowed to recover for at least 3 to 6 months. Colostomy reversal is elective and time should be taken to recover the patient from their acute perforation and optimize functional status through management of comorbid conditions, increased physical activity, smoking cessation, nutritional support, and weight loss as necessary. Thorough review of the operative note is key to understand the handling of the rectal stump and mesenteric vasculature. Colonoscopic screening should be updated if necessary. Preoperative continence should be queried and can be evaluated formally by manometry and defecography, or informally by examination and asking the patient to hold an enema in the rectum. Hartmann reversal can be undertaken by an open or minimally invasive approach. The rectal stump should be freshened to healthy compliant rectum and any residual sigmoid removed.

The stump can be foreshortened and shrunken with disuse, placement of an EEA sizer per anus may assist in identification.

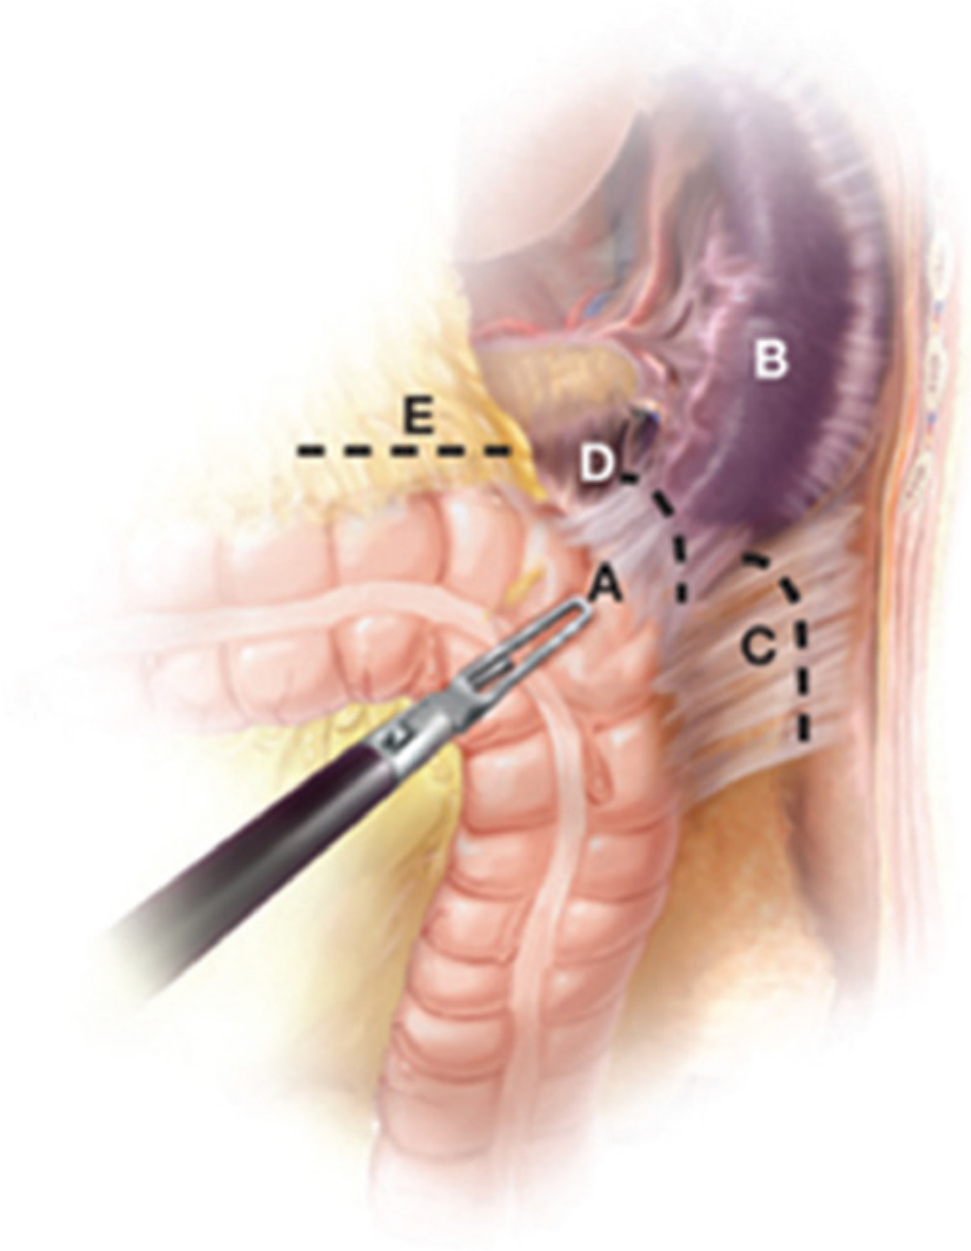

Figure 69.5 Illustration of the relationship of the splenic flexure of the colon (**A**) to the spleen (**B**). Full mobilization requires division of the abdominal (**C**), lienocolic (**D**), and omental (**E**) attachments.

If, at the index operation, a primary anastomosis is performed with a DLI, the patient should typically be allowed to recover for 3 months, the

anastomosis evaluated with barium enema and/or sigmoidoscopy, and the ileostomy reversed electively.

DIVERTICULITIS—RECURRENT AND CHRONIC INFLAMMATORY PRESENTATIONS

Recurrent Diverticulitis

After recovering from acute, uncomplicated diverticulitis 13% to 33% of patients will have recurrent attacks.[2] After one inpatient admission, the chance of a second admission is 9% and the risk of a subsequent attack increases thereafter. After two admissions, 23% have a third admission and 36% a fourth.[69] Physicians cannot predict or prevent recurrent attacks. For decades, the mechanistic assumption that every uncomplicated diverticulitis attack added up incrementally to an individual's risk of free perforation led the recommendation for routine, elective sigmoid colectomy for secondary prevention after two hospitalizations. However, improved understanding of the natural history of the disease has demonstrated that 80% to 90% of emergency colectomies happen on index admission.[70,71] Therefore, colectomy should not be routinely performed to prevent free perforation and colostomy after uncomplicated diverticulitis. Current practice guidelines recommend a case-by-case 8 decision for each recurrent diverticulitis patient, balancing the burden of disease, patient preferences, and surgical morbidity.[49] Patient factors influencing the decision might include frequency and severity of episodes, missed work and activities, health care expense, persistent symptoms between attacks, and antibiotic intolerance. These should be balanced against surgical candidacy, likelihood of operative morbidity, and predicted postoperative functional outcome using a framework of shared decision making.

Sufficient equipoise exists in recurrent diverticulitis that a randomized clinical trial of colectomy versus observation was performed. The DIRECT trial randomized a total of 108 recurrent diverticulitis patients to elective sigmoid colectomy versus observation. A total of 46% of conservatively treated patients crossed over to the surgical arm over 5 years of follow-up. Despite early termination due to high rates of stoma creation and anastomotic

leak, surgical patients still had higher gastrointestinal quality of life at 5-year follow-up.[72] The results of this trial suggest that although most surgeons focus on ostomy and operative morbidity, other factors may be more important to patient quality of life. There has been little research on patient-reported outcomes in diverticulitis compared to other common diseases. Further study could assist in improving shared decision making and patient counseling.

Surgical Technique—Elective Sigmoid Colectomy for Recurrent Diverticulitis

Sigmoid colectomy may be performed open or in a minimally invasive fashion using "straight stick" laparoscopy, hand assist technique, or robotics. When surgical expertise allows, a minimally invasive approach has several advantages and is preferred. As with other abdominal operations, minimally invasive surgery, particularly when coupled with enhanced recovery pathways, can shorten length of stay, decrease pain, and minimize wound complications.[73] Surgery for diverticulitis, including for complicated disease, urgent indications, and ostomy reversal is increasingly performed laparoscopically.[74] National trends indicate use of laparoscopy for elective diverticulitis surgery increased from 48% to 70% between 2006 and 2013.[75] Laparoscopic conversion rates are reported between 4% and 26% of cases and are higher with complicated disease.[76,77] Robotic surgery demonstrates equivalent outcomes with respect to length of stay and patient outcomes, with the exception of a decreased conversion rate compared to laparoscopy and increased overall hospital charges.[78,79]

Regardless of approach, the goal of the operation is not to remove all diverticula but all affected bowel. Proximal margin should be soft, pliable, and healthy left colon. Distal margin of resection is at the upper rectum, identified by its partially extraperitoneal location, splaying of the tenia, and loss of haustral folds. Transection in the distal sigmoid can be associated with recurrent diverticulitis postsurgically. Dissection may proceed from medial to lateral or vice versa. The ureter should be clearly seen and protected. The lateral attachments and mesentery of the colon should be divided and mobilized until a tension-free anastomosis is created. Typically, this requires high ligation of the IMA and mobilization of the splenic flexure.

Occasionally, division of the IMV and complete release of the greater omentum may be required. The anastomosis is created in a hand-sewn or stapled fashion according to the principles of a tension-free, straight, viable, and patent anastomosis and the surgeon's preference.

Fistula, Stenosis, and Obstruction

Fistula is a rare complication of diverticular disease and presumably occurs when a contained diverticular perforation erodes into an adjacent viscera or the abdominal wall. Some patients have a provocative presentation of building abdominal pressure followed by relief and discharge of gas and pus via the bladder, vagina, or skin. Although the fibrotic inflammation found at operation speaks to chronic inflammation, presentation of a fistula is not necessarily preceded by recurrent attacks of diverticulitis.

Colovesical fistulas are the most common type of diverticular fistula (65%) and are more common in men than women.[80] They present with pneumaturia, fecaluria, frequent urinary tract infections, renal impairment, or urosepsis. "Dirty" urinalysis and gas in the urinary bladder are appreciated on imaging and suggest the diagnosis. Differential diagnostic concerns include emphysematous cystitis and rectourethral fistulas, particularly in patients who have had prostate surgery or radiation. Cystoscopy and colonoscopy should be performed to exclude a locally advanced colonic or bladder malignancy.

Colovaginal fistulas are the next most common (25%) present with foul vaginal discharge and gas per vagina, typically in women who have had a hysterectomy. Many patients are referred from gynecologists and an area of inflammation and granulation tissue at the vaginal cuff is commonly seen on speculum examination. Colonoscopy should be performed to exclude malignancy. Differential diagnosis includes vaginal infection, anovaginal fistulas, and erosion of pelvic mesh in women with a history of proctopexy or sacrocolpopexy. Rare diverticular fistula types include colouterine, coloenteric, and colocutaneous. Principles of surgical repair for all fistulas broadly are resection of the diseased colon, repair of the attached normal organ, and separation of the two repairs with healthy tissue.

Colonic stenosis and large bowel obstruction can occur as sequelae of chronic diverticular inflammation. Patients may present urgently with a large

bowel obstruction or subacute symptoms including cramping pain, change in bowel habit, and bloating. Obstruction can be secondary to inflammatory phlegmon or abscess and therefore may respond to antibiotics, percutaneous drainage, and observation, obviating the need for emergent resection. However, completely obstructing fibrotic strictures risk perforation and require surgical intervention. Interval endoluminal stent placement as a bridge to surgery can be considered. Successful stent placement is less likely in diverticular disease than colorectal cancer and has a reported perforation rate up to 30%,[81] and can make subsequent colectomy more challenging. Endoluminal stent placement as definitive treatment should only be considered in very poor surgical candidates. Urgent presentation of large bowel obstruction may preclude endoscopic diagnosis and the fibrotic, thick inflammation can make differentiating diverticular strictures impossible to distinguish from malignancy on table. The cecum should always be assessed for viability as a first step in the operation. Inflammatory fibrotic strictures and tensely dilated colon may make for prohibitively challenging urgent pelvic operations. Surgical options include diversion with a loop or end-loop colostomy if inflammation precludes safe resection. Hartmann procedure or primary anastomosis with or without DLI are both options depending on the condition of the bowel and patient. Often completely obstructed patients are too deconditioned and bowel too dilated to permit consideration of an anastomosis. In the case of the tensely distended, obstructed colon, on table decompression may assist in safe handling of the bowel and decrease the chance of uncontrolled stool spillage. This can be performed using saline lavage delivered via the appendix and collected off the field. The author prefers to select a site for proximal transection, place a double purse string around a colotomy and carefully pass a 36-Fr Argyle chest tube proximally to evacuate stool and gas.

Surgical Technique—Operation for Diverticular Fistula

Chronic inflammation can alter anatomy and create challenging pelvic dissections in these patients. Patients should be placed in lithotomy and consideration given to use of ureteral stents. Minimally invasive approaches are appropriate if within the skill set of the surgeon. Minimally invasive mobilization of the splenic flexure in particular is useful as it reduces the

incision needed to appropriately mobilize the colon. Dissection can proceed in a lateral to medial or medial to lateral fashion and the IMA need only be taken high on the aorta to achieve appropriate colonic mobilization. Care should be taken to identify and preserve the ureters. In the area of the fistula, woody inflammation often makes laparoscopic dissection tedious, although use of hand-assisted technique, sponge sticks, or suction may mimic manual blunt dissection well. In the open technique, the colon can be bluntly pinched apart from the bladder or vagina. It is critical to exclude malignancy preoperatively in these patients to avoid "cracking through" a locally advanced malignancy that requires a multivisceral resection.

Colonic dissection is carried to the top of the rectum and sometimes lower, if necessary, to identify soft pliable bowel. The colon anastomosis is typically carried out with a circular stapling device. Colovesical fistulas are typically to the dome of the bladder, but urologic help may be advisable if they involve the trigone. Repair of the vaginal or bladder is typically unnecessary. It is the author's practice to fill the bladder and repair only if urine is leaking and place an EEA sizer in the vagina and repair only if the tissues are quite attenuated. A flat of viable omentum can be interposed between anastomosis and bladder or vagina. Alternatively, a peritoneal flap can be positioned in the space. Postoperatively after colovesical fistula repair, a urinary catheter is typically left in place for 7 to 10 days and a cystogram performed prior to removal.

Less Common Presentations of Diverticular Disease

Giant Diverticula

Giant diverticula are rare, commonly found in the sigmoid colon, and have been described to grow to 44 cm.[82] The etiology is unknown, but hypotheses include physical air trapping and gaseous overproduction by bacteria. Symptoms may cause mass effect, but asymptomatic presentation is common. Treatment is by sigmoid colectomy.

Right-Sided Diverticulitis

Right-sided diverticulitis is rare among European-ancestry populations, but more common in Asia and in Asian immigrants. Clinical presentation includes right-sided pain, fevers, chills, and gastrointestinal distress. Given the location, the differential diagnosis included terminal ileitis, cholecystitis, epiploic apendagitis, mesenteric adenitis, genitourinary pathology, and, of course, appendicitis, which may be clinically indistinguishable and radiologically confusing. Similar to sigmoid diverticulitis, patients with uncomplicated inflammation and a clear diagnosis can be managed with antibiotics. Recurrent disease, unclear diagnoses, and perforation should be treated with right hemicolectomy.[83,84]

Diverticular Hemorrhage

Diverticular hemorrhage is a noninflammatory diverticular pathology caused by erosion of the mesenteric vessels by an adjacent herniating diverticulum. Diverticular bleeding is the most common source of lower GI hemorrhage.[85] Hemorrhage is classically bright red, painless, and brisk. Differential diagnosis includes rapid upper gastrointestinal hemorrhage, arteriovenous malformations, neoplasms, colitis, and anorectal hemorrhage. Patients should be stabilized, blood made available, nasogastric lavage performed, and a thorough rectal examination performed to exclude pathology. Bleeding ceases spontaneously in 80% of cases.[86] Diagnosis is made via colonoscopy demonstrating sigmoid diverticulosis. In the absence of other pathology, the presumptive diagnosis of diverticular hemorrhage is made. When a bleeding lesion is seen, endoscopic treatments include epinephrine injection, cautery, and clips. Rebleeding occurs in a minority of patients and surgery is rarely required. In one large modern cohort of 14,925 patients with diverticular hemorrhage, 1,368 had a second episode, but only 64 required colectomy.[87] Segmental resection may be necessary in diverticular hemorrhage that is massive, recurrent, or fails endoscopic control.

SUMMARY

Diverticular disease is a common colorectal disease with a spectrum of presentations, treatments, and prognoses. Due to its high incidence, the practicing general, colorectal, or acute care surgeon is likely to see multiple manifestations throughout their career. Emerging basic research suggests that diverticulitis is a complex trait with both environmental and inherent risk factors, although its exact pathophysiology remains incompletely understood. Diagnosis is frequently suspected on the basis of symptoms and signs and confirmed with CT imaging. Treatment parallels the Hinchey severity classification system. Current treatment guidelines have changed with improving clinical understanding of the disease. Uncomplicated disease may be treated with or without antibiotics. Indications for elective surgery have changed and minimally invasive approaches adopted. Complex presentations including recurrence, free perforation, fistula, and obstruction remain challenges for the surgeon to pick the right operation for the right patient at the right time. Scientific understanding of the disease remains limited with many fundamental questions unanswered. For instance, global anatomic variation remains a mystery, the triggers of diverticulitis remain unknown, recurrence cannot be predicted or prevented, and the complex interplay between the individual and his environment that produces diverticular disease remains to be completely understood.

Anorectal Disorders

Amy L. Halverson and Vitaliy Y. Poylin

Key Points

1 The most common manifestation of internal hemorrhoids is painless, bright red rectal bleeding associated with bowel movements. A high-fiber diet supplemented with bulk-forming agents may reduce symptoms of hemorrhoids and is ideal for first- and second-degree hemorrhoids.

2 Rubber band ligation is suitable for symptomatic first- and second- and some third-degree internal hemorrhoids that do not respond to bulk-forming agents. Hemorrhoidectomy is required in only a few patients with symptomatic hemorrhoids.

3 An anal fissure is an ischemic ulcer in the lower portion of the anal canal. Treatment, both medical and surgical, involves relaxing the internal anal sphincter.

4 The basic principles of anal fistula treatment are to limit the access of fecal contents into the tract while preserving the anal sphincter.

5 Pilonidal disease results from hair in the subcutaneous tissue as the nidus for a chronic foreign body reaction. Treatment aims to remove the offending tuft of hair.

6 Rectal prolapse results from intussusception that extends beyond the anal verge. Fit patients are best treated with transabdominal rectopexy. Patients with significant medical comorbidities are best treated using a perineal approach.

7 Anal condylomata acuminata are caused by human papillomavirus, as are anal intraepithelial neoplasia and anal cancers.

8 Palpable lesions of the anal canal are not hemorrhoids and might be cancers; examination under anesthesia and biopsy allow for correct diagnosis.

ANATOMY AND PHYSIOLOGY

The Rectum

The rectum begins at the level of the sacral promontory and measures approximately 15 cm in length. At the proximal colon, the tinea of the colon splays to form a uniform layer of muscle in the rectal wall. The rectum descends along the curvature of the sacrum and passes through the levator ani muscles, where it becomes the anal canal (**Fig. 70.1**). The mesentery of the rectum (mesorectum) is surrounded by a thin investing fascia that is distinct from the presacral fascia and serves as a dissection plane in rectal cancer surgery. The endopelvic fascia that covers the sacrum posterior to the rectum is referred to as Waldeyer fascia; anteriorly, Denonvilliers fascia lies between the rectum and the vagina in females and between the rectum and seminal vesicles in males.[1]

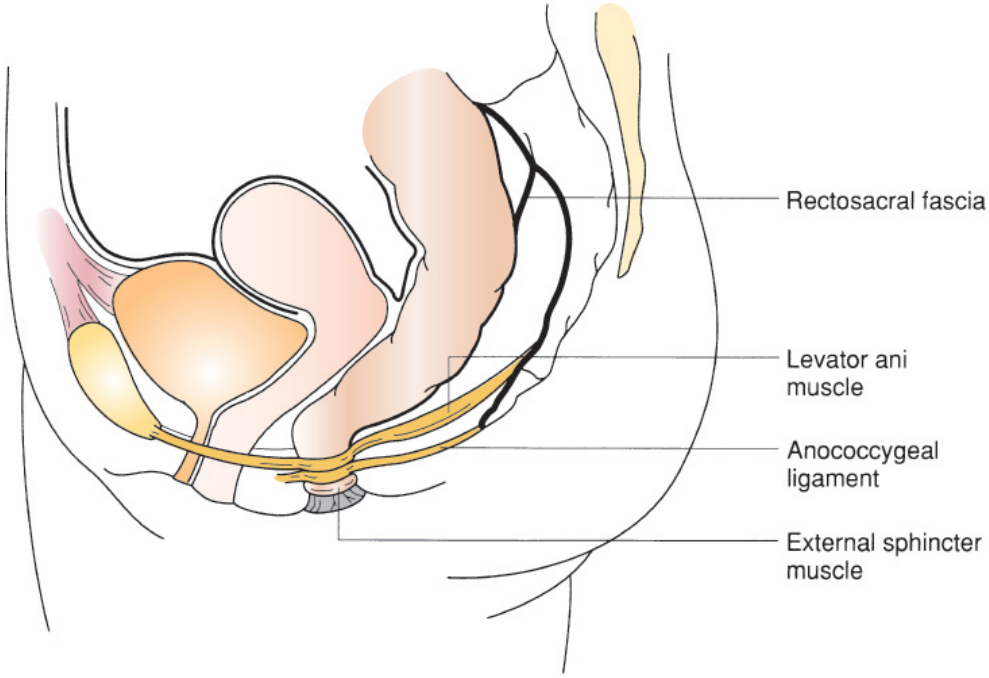

Figure 70.1 Pelvic anatomy.

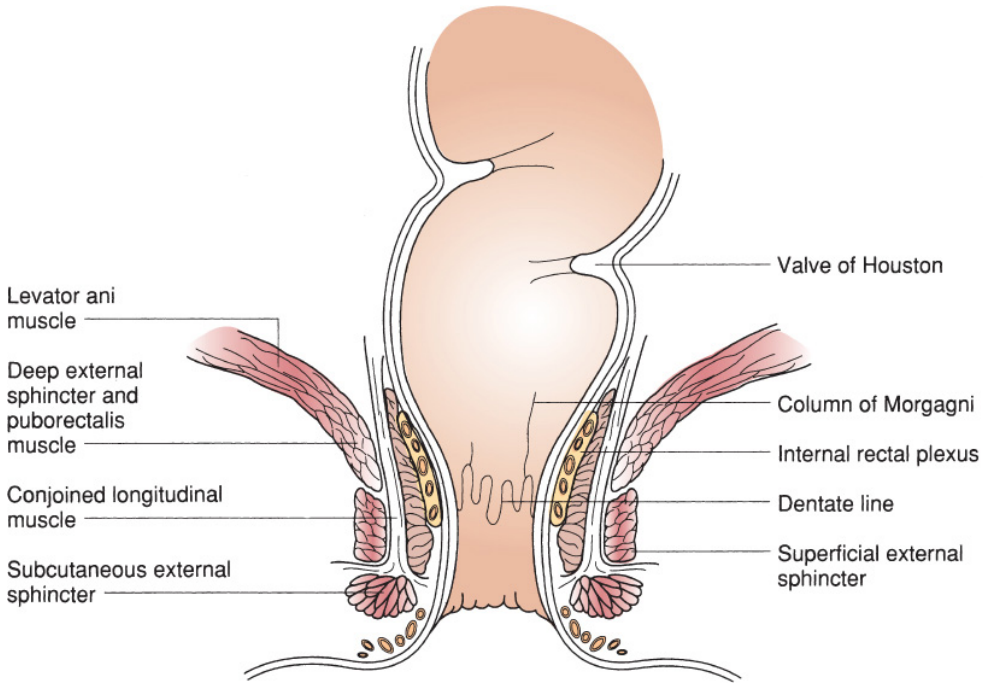

Figure 70.2 Anatomy of the anal canal.

The Anal Canal and Pelvic Floor

Anal Canal

The anal canal is the terminal portion of the intestinal tract. It continues from the rectum 4 to 5 cm through the pelvic floor musculature to the hair-bearing skin of the anal margin. Understanding the various types of anal epithelium helps to elucidate the diagnosis of both benign and malignant conditions. At the anal verge, skin becomes anoderm, a squamous epithelium without hair. The anoderm extends to the dentate line, which represents the division between embryonic endoderm and ectoderm (**Fig. 70.2**). Folds of tissue at the dentate line form anal papillae. Between the papillae lie the anal crypts, which house the anal glands. These glands are the structures from which anal abscesses and fistulae commonly originate. The endoderm in the first 1 to 2 cm proximal to the dentate line is called the transition zone and represents a gradual change from squamous epithelium to the columnar epithelium lining the rectum.

The muscularis propria of the rectum continues distally to form the internal anal sphincter. The pelvic floor is composed of the levator ani muscle (which has three parts, puborectalis, pubococcygeus, and Iliococcygeus) and

external anal sphincter. Together, these muscles and their connections are responsible for both continence and defecation. The puborectalis muscle forms a sling that extends from the posterior pubis around the rectum and maintains an acute angle at the anorectal junction, which contributes to the continence mechanism (**Fig. 70.3**). The external anal sphincter is a striated muscle that surrounds the internal anal sphincter. It is contiguous with the levator ani and attaches to the coccyx with the anococcygeal ligament. In addition to its role in maintaining continence, the anococcygeal ligament plays a role in the development of fistulas—posterior abscesses that cannot break through this tuft of connective tissue, can extend to both ischiorectal fossae, creating a horseshoe abscess.

Anorectal Spaces

There are several anorectal spaces created by myofascial relationships in the pelvis (**Fig. 70.4**). The perianal space contains external hemorrhoids, the subcutaneous component of the external sphincter, and the most distal portion of the internal sphincter. It communicates with the intersphincteric space located between the internal and external sphincters. It is the most common path for cryptoglandular infections, which include abscesses and fistulas. The ischioanal and ischiorectal spaces are the largest potential spaces, extending from the skin caudally to the levator ani and obturator fascia cranially. Horizontally these spaces lie between ischial tuberosities and the anus/rectum. These spaces communicate with the postanal/postrectal spaces and can be a common path by which infections spread. Posterior to the anus and rectum, the postanal and postrectal spaces are limited by the anococcygeal ligament and levator muscles. If an infection develops in this area, the above structures often limit the spread of the infection distally or proximally, forcing the infection to spread laterally to the ischioanal/ischiorectal space creating horseshoe abscesses.

Blood Supply and Innervation

The rectum and anus receive abundant blood supply from the superior, middle, and inferior rectal arteries (**Figs. 70.5** and **70.6**). The superior rectal (hemorrhoidal) artery starts as the terminal branch of the inferior mesenteric artery, descending posterior to the rectum where it bifurcates to supply the

rectum and upper anal canal. The middle rectal arteries (present as a distinct vessel in <15% of people) arise from the internal pudendal or inferior gluteal arteries (branches of the internal iliac artery). The inferior rectal arteries also arise from the internal pudendal arteries to supply the anal sphincters and anal canal. The venous drainage of the anus is via both the portal and systemic venous systems. The superior rectal vein drains the rectum and upper anal canal into the portal venous system through the inferior mesenteric vein. The middle and inferior rectal veins drain into the systemic venous system via the internal iliac veins. Because of the rich communication between these veins, patients with portal hypertension may develop portosystemic shunts resulting in bleeding rectal varices. Hemorrhoids are submucosal sinusoids that contain both arterial (typically terminal branches of the superior hemorrhoidal artery) and venous (usually superior, middle, and inferior hemorrhoidal veins) supply. Sinusoids differ from veins in that histologically, the walls of these vascular structures do not contain muscles.

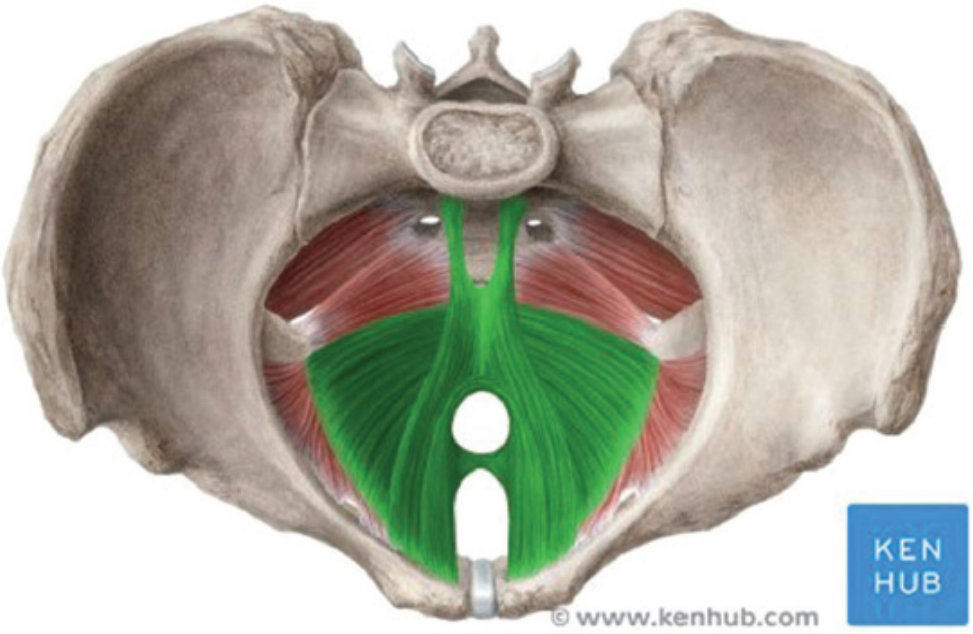

Figure 70.3 Muscles of the pelvic floor.

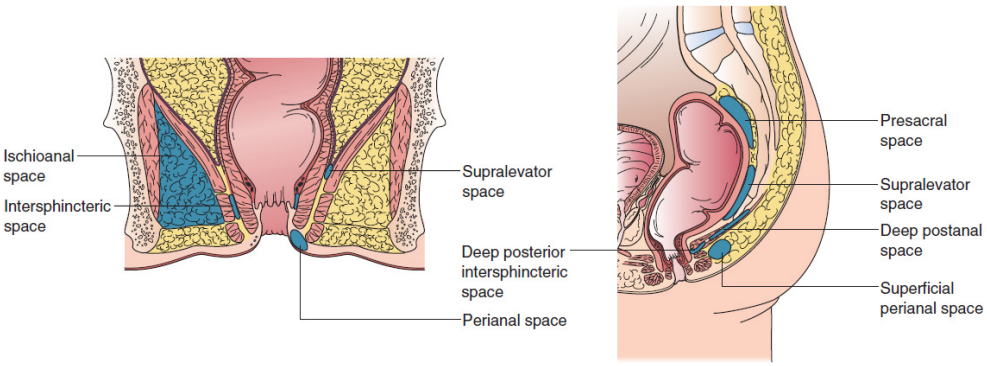

Figure 70.4 Anorectal spaces.

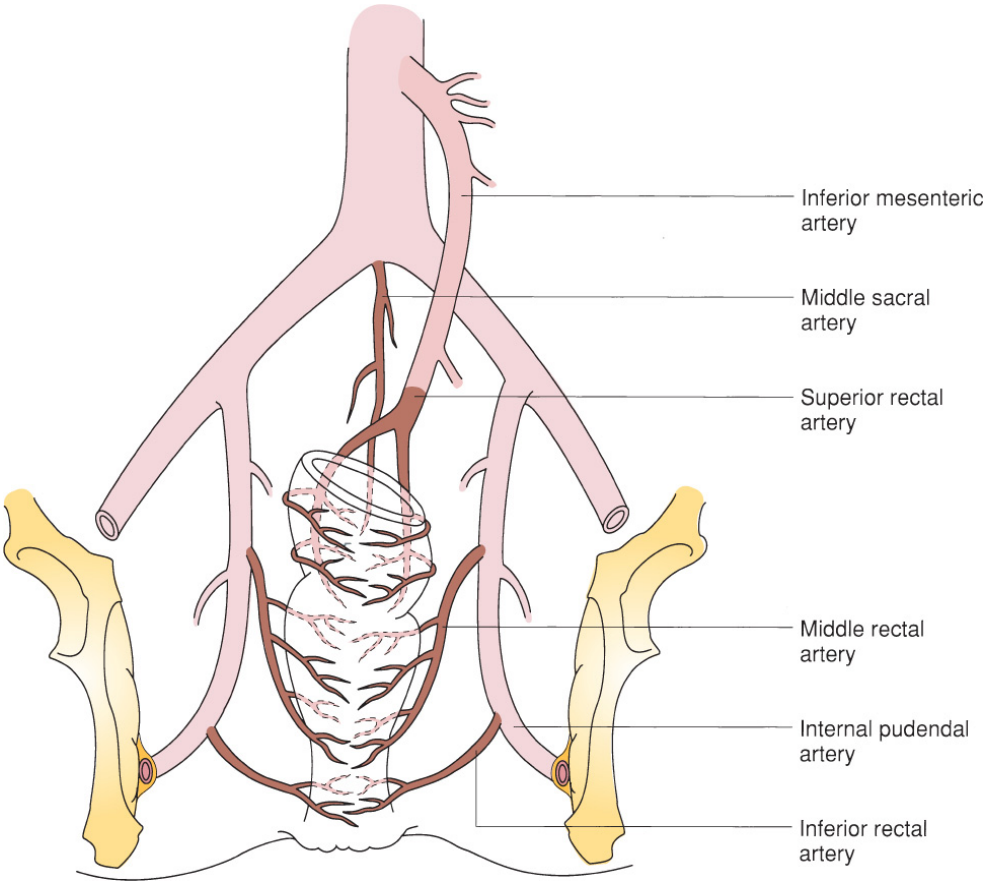

Figure 70.5 Arterial supply.

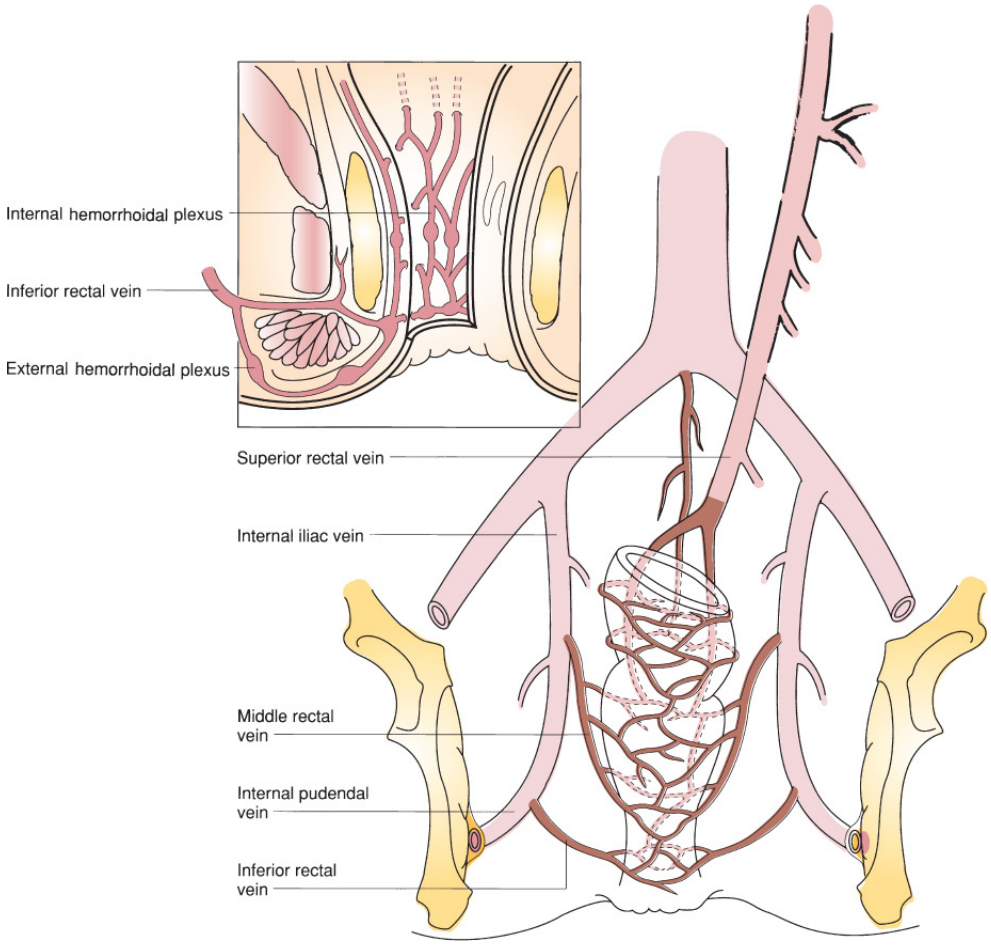

Figure 70.6 Venous supply.

Lymphatic drainage of the rectum and anus mirrors the arterial supply (**Figs. 70.7** and **70.8**). Drainage from the upper and middle rectum flows to the inferior mesenteric lymph nodes. The lower rectum and upper anal canal may drain to the inferior mesenteric nodes or may drain laterally to the internal iliac nodes. Lymph from the anus below the level of the dentate line typically drains to the inguinal lymph nodes. However, drainage may also occur to the inferior mesenteric and internal iliac nodes. Clinically this drainage pattern is relevant in cancer patients to identify the extent of their disease. For example, lymph node metastases from anal cancer often develop in the inguinal lymph nodes.

Sympathetic innervation of the rectum originates from the first three segments of the lumbar spinal cord and synapse at the preaortic plexus (**Fig. 70.9**). The nerves bifurcate to form the hypogastric plexus, which, during anterior resection, can be routinely observed overlying the top of the sacrum

before extending laterally and joining the pelvic plexus. Parasympathetic innervation (nervi erigenti) originates from the second, third, and fourth sacral nerve roots and eventually extends medially along Denonvilliers fascia. In men, nervi erigenti are responsible for erection, and damage to these nerves during rectal or prostate surgery would lead to impotence.[2] Sympathetic nerves are responsible for ejaculation, and damage to these structures during surgery (sigmoid colectomy or anterior resection) would lead to retrograde ejaculation. Injury to the pelvic nerves may also lead to bladder dysfunction. In women, dysfunction following nerve injury is less well understood. Some patients do report dyspareunia and decreased lubrication during intercourse following pelvic surgery.

The internal anal sphincter receives both sympathetic and parasympathetic innervation and maintains tonic contraction at rest. The inferior rectal branch of the pudendal nerve and perineal branch of the fourth sacral nerve innervate the external anal sphincter. The inferior rectal nerve also carries sensory information from the anal canal. The majority of sensory nerve endings within the anal canal are located distal to the dentate line. However, patients may sense painful stimuli up to 1.5 cm proximal to the dentate line. This pattern of innervation has clinical implications on planning, counseling, and establishing expectations for pain during and after anorectal procedures.

Physiology

The primary function of the rectum is to serve as a distensible reservoir for stool. The principal function of the anus and pelvic floor is the maintenance of continence and regulation of defecation. Continence and defecation involve a combination of voluntary and involuntary muscular activities. At baseline, both internal and external sphincters are closed and the puborectalis is tightened, pulling the rectum forward and providing extra support. Hemorrhoids are also thought to contribute to continence, especially of mucus and gas. Defecation starts with rectal distention that causes the internal anal sphincter to relax and external sphincter to tighten—the rectoanal inhibitory reflex. This process, which presents a small amount of stool into the anal canal, is called sampling. If the call for defecation is not answered, both sphincters and the puborectalis maintain control by further tightening and making the anorectal angle more acute.

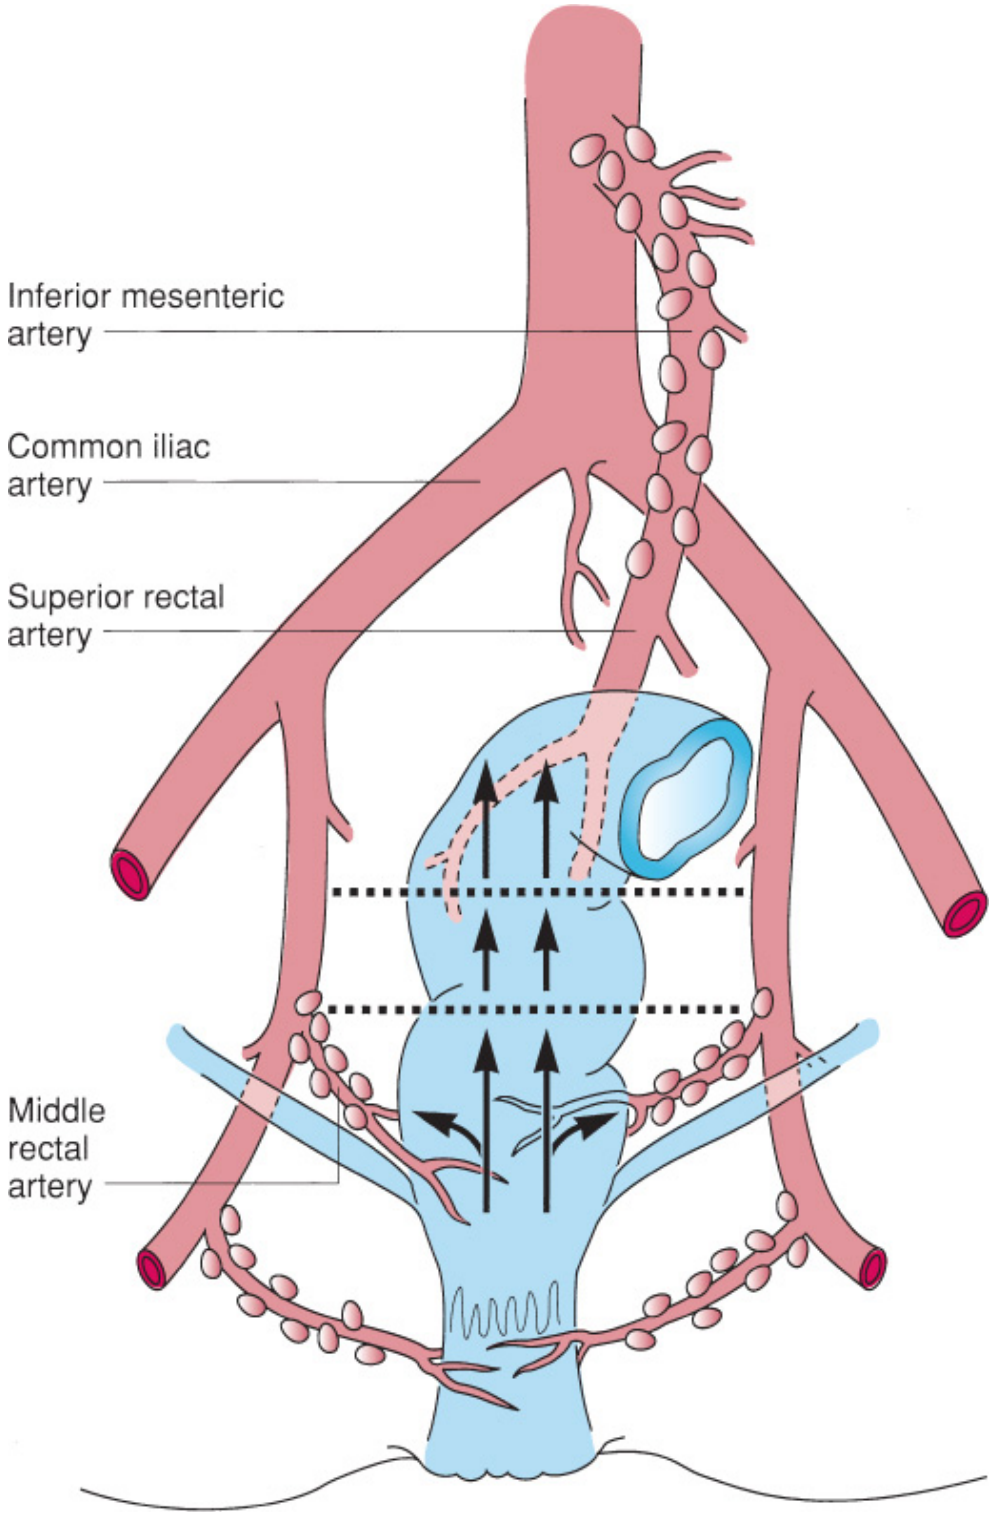

Figure 70.7 Lymphatic drainage of the rectum.

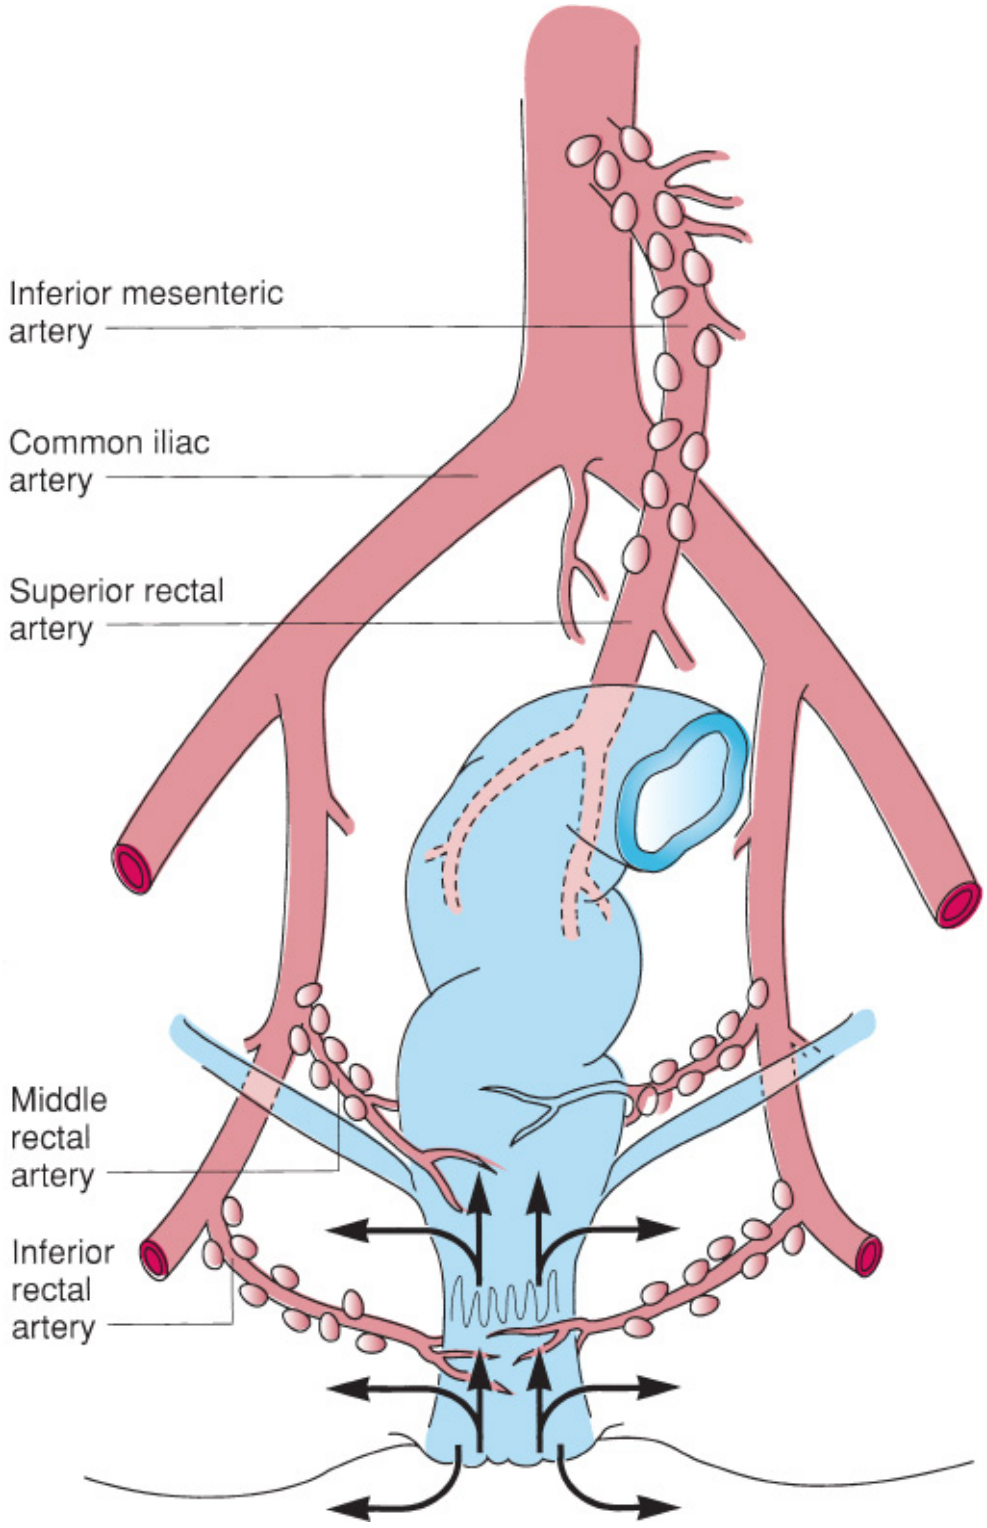

Figure 70.8 Anal canal.

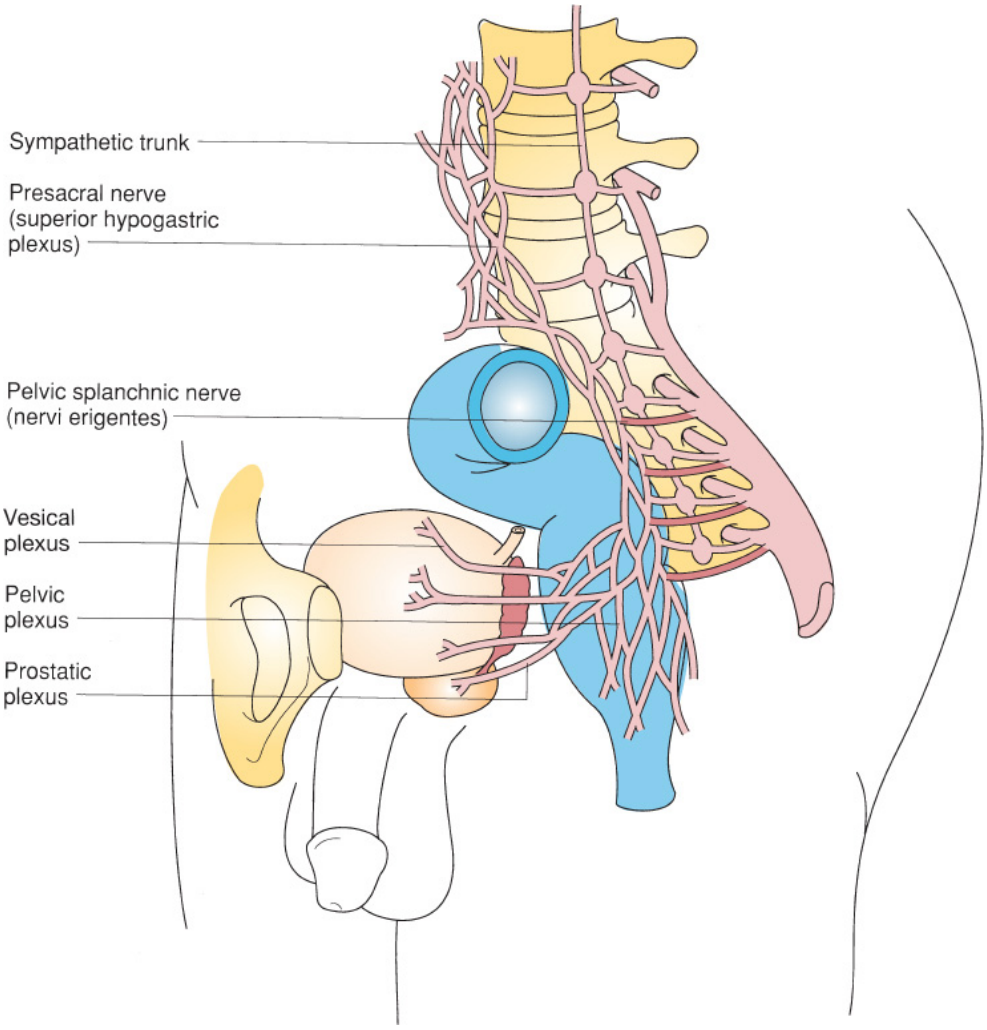

Figure 70.9 Innervation.

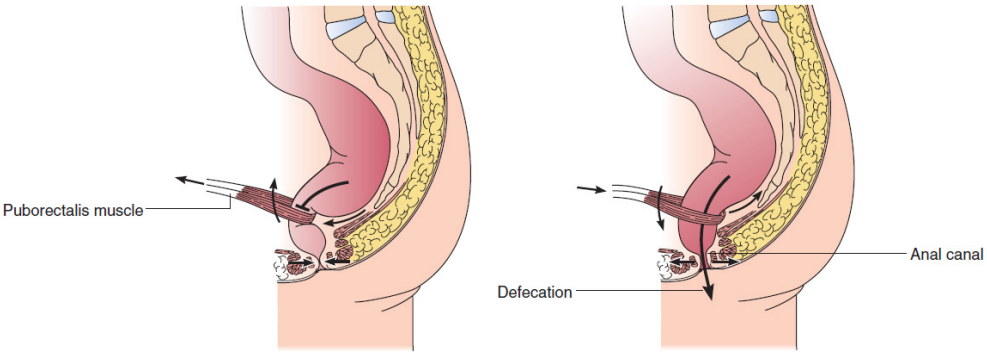

Figure 70.10 Mechanism of defecation.

Contraction of the external anal sphincter will often more than double the intra-anal pressure. This muscle can typically be contracted voluntarily for only 30- to 60-second periods. If the call to defecate is answered, either the

sitting or squatting position is assumed, thereby helping to straighten the anorectal angle. Defecation occurs through the coordinated effort of increasing the intra-abdominal pressure (Valsalva) and relaxing the puborectalis muscle, which further opens the anorectal angle and shortens the anal canal (**Fig. 70.10**). Subsequently, both the internal and external anal sphincters relax, the pelvic floor descends, and a funneling occurs, allowing the rectal contents to pass. After completion of rectal evacuation, a "closing reflex" occurs, where transient contraction of the external anal sphincter and puborectalis help to restore the tonic contracture of the internal anal sphincter.

DIAGNOSTIC EVALUATION OF THE ANUS

An accurate and detailed history is essential to diagnosing anorectal disorders. Common presenting symptoms of anorectal problems include pain, bleeding, and the presence of prolapse or a mass. Symptoms may be acute or chronic. Painless bleeding is characteristic of internal hemorrhoids. Pain is indicative of pathology distal to the dentate line. Common etiologies of pain include thrombosed external hemorrhoids, abscesses, and anal fissures. Anal fissures may cause bleeding, and fissure pain is typically worse with bowel movements rather than constant and often described by patients as, "it feels like I am passing glass." A perirectal abscess often has associated fever. Patients may also report itching and incontinence. Many diagnoses are evident by history alone and are confirmed with physical examination (**Table 70.1**).

Table 70.1 Symptoms of Common Benign Pathology

	Pain	
Bleeding	+	−
+	Fissure	Internal hemorrhoid
−	Thrombosed external hemorrhoid Abscess	Residual hemorrhoidal tag Condyloma

Alternations in bowel habits are often a contributing factor to anorectal pathology. Although there is a wide range of what is considered a normal frequency of bowel movements—between one bowel movement every 3 days and three times a day, patients with extremes in bowel movement frequency are more likely to develop symptoms. Frequency, consistency of stool, straining with evacuation, and time spent defecating should be assessed. Other relevant components of history include trauma (including injuries and episiotomies during childbirth in women), prior surgery, travel history, sexual history, and in women, a history of prior cervical dysplasia is helpful to assess the risk of anal dysplasia.

Physical examination of the anus should include a visual inspection of the perianal area as well as a digital examination (**Table 70.2**). Patients may be examined in either the left lateral decubitus or prone jack-knife position. Providing the patient with a simple explanation and reassurance regarding the planned examination helps to ensure cooperation and minimize anxiety. Inspection of the anus may demonstrate skin tags or external hemorrhoids, fissures, scars, or excoriation of the skin. Straining during inspection may help to demonstrate rectal mucosal or full-thickness prolapse and assess the degree of perineal descent. Digital examination with a gloved, well-lubricated index finger assesses for tenderness, the tone of the anal sphincters, and the presence of a rectal mass. A more detailed evaluation of the anus includes anoscopy and rigid or flexible proctosigmoidoscopy, which patients usually tolerate in the office setting.

BENIGN ANORECTAL DISEASE

1 Hemorrhoids

Hemorrhoids are cushions of vascular tissue and are a normal part of the anal canal. The number and location of hemorrhoids may vary, however. Most commonly, there are three pillars located in the left lateral, right anterior, and right posterior quadrants. Hemorrhoids are generally classified as internal (proximal to the dentate line), external (distal to the dentate line), and mixed (most commonly seen). Additionally, internal hemorrhoids are classified by the degree of prolapse (**Table 70.3**).

Clinical Manifestations

Internal Hemorrhoids

As there is no somatic innervation above the dentate line, internal hemorrhoids do not cause pain. The most common presenting symptom is painless bleeding with bowel movements, which can manifest as either blood on the toilet paper to blood dripping into the toilet bowl. Bleeding may be associated with firm bowel movements and may persist for a few days, followed by a period of no symptoms. Hemorrhoidal bleeding rarely leads to anemia, but may be of increased concern in chronically anticoagulated patients. Prolapsing tissue that retracts either spontaneously or with manual reduction may cause fecal soiling or itching.

Table 70.2 The Complete Digital Rectal Examination

Preparation
Enema
Left lateral decubitus position
Lighting, gloves, lubrication, anoscope

Visualization
Retract the buttocks
Inspect for:
- Soiling
- Excoriation or abrasion
- Scarring
- Patulous anus, deformity, or flattening of folds
- Fissure
- External fistula opening
- Anal wink reflex
- Prolapse through anus with strain
- External hemorrhoids

Palpation
Slow insertion of gloved, lubricated finger
Pain with examination
Palpable sphincter defect
Perineal body scarring
Anal stenosis
Relaxed or increased tone
Prostate abnormalities (men) or anterior rectocele (women)
Gross blood present
Muscle function: squeeze
- Adequate
- Accessory muscle use

Strain
- Adequate
- Puborectalis relaxation
- Prolapsing tissue
- Other organ prolapse

External Hemorrhoids

External hemorrhoids present with the acute onset of pain and swelling. The pain is highest in the first 48 hours after the onset of the thrombosis and gradually subsides over the next few days. The clot may resorb or erode through the epithelium, causing spotting of blood.

Table 70.3 Hemorrhoidal Classification

Degree	Description
First	Hemorrhoids bleed but do not prolapse
Second	Hemorrhoids prolapse on straining but reduce spontaneously
Third	Hemorrhoids prolapse and require manual reduction
Fourth	Prolapsed hemorrhoids cannot be manually reduced

Evaluation

On physical examination, hemorrhoids may present with prolapsed mucosa, as edematous external tags or soft, residual hemorrhoidal skin tags. Thrombosed external hemorrhoids appear as tender, firm, and often bluish masses. Having patients strain may be useful to demonstrate hemorrhoid prolapse. The digital examination allows for assessment of sphincter tone and the presence of a mass. Anoscopy is used to inspect internal hemorrhoids and assess the appropriateness of office-based treatment. Colonoscopy is indicated when patients have bleeding that is not consistent with physical examination findings, or when symptoms do not respond to initial treatment.

Treatment

Treatment should be tailored to the patient's symptoms, which do not always correlate with physical examination findings. One should clarify the patient's goals in seeking treatment. Patients may only want evaluation and reassurance that their condition is benign. Treatment of internal hemorrhoidal bleeding may not satisfy patients who are bothered by residual hemorrhoidal

tags. Treatment options include nonoperative measures alone, office-based procedures, or operative procedures.

Nonoperative Management

Excessive straining during defecation or prolonged sitting on the toilet, for example, while reading, contribute to hemorrhoidal problems. Symptoms can be reduced or eliminated in many patients by altering their dietary intake and lifestyle. Increasing fiber and fluid intake eliminates a large proportion of problems with grade I and II hemorrhoids and can significantly improve symptoms with higher-grade hemorrhoids. Fiber can be either dietary or supplemental and works by increasing bulk and moisture in the stool. Suppositories and topical ointments may provide temporary relief, but do not address the cause of the problem. Since most formulations include corticosteroids, long-term use can lead to issues with thinning of the skin and itching. Sitz baths soothe symptoms, but do not address the underlying cause of the problem. However, in patients with external hemorrhoid problems, using water for cleaning can be a useful adjunct to improving itching and avoiding overcleaning.

Office-Based Treatments

2 Rubber band ligation can be performed through an anoscope in the office without the use of anesthesia. It is essential to clarify expected outcomes with the patient, and that the office-based procedures might require repeat treatments. However, these procedures are quick and usually painless alternatives to surgery.

The band is placed around the hemorrhoid two to three cm above the dentate line, causing localized ischemia of the intervening tissue. Placement of the band too close to the dentate line will result in pain and is unlikely to help with symptoms (**Fig. 70.11**). Placing more than two bands at once may increase discomfort and is generally not recommended. Approximately 1 to 2 weeks after rubber band placement, the hemorrhoid tissue will slough, and the patient may experience spotting of blood. Rarely, significant bleeding requiring urgent intervention may occur. Fibrosis that occurs at the site of the banding causes fixation of the remaining hemorrhoidal tissue, which helps to prevent further prolapse and bleeding. Improvement or complete disappearance of symptoms may be achieved in more than 80% of grade I

and II hemorrhoids, but less than 30% of more advanced hemorrhoids.[3] Complications are rare and include pain and thrombosis, but a few cases of pelvic sepsis have been reported. Sclerotherapy involves the injection of a sclerosing agent (such as 5% phenol solution) into the submucosa that leads to fibrosis of the surrounding tissue. Injection is performed through an anoscope, and is an option for symptomatic hemorrhoids that are too small to band. It is important not to inject the sclerosant directly into the hemorrhoids, or thrombosis may ensue.

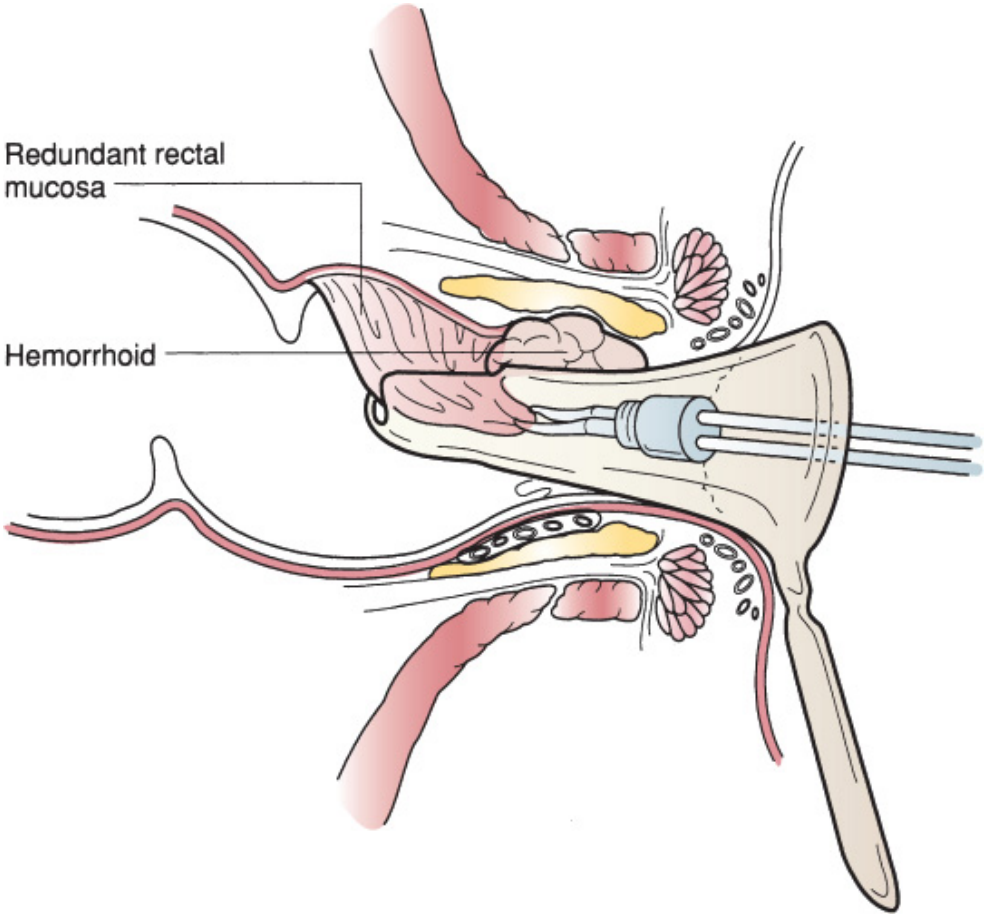

Figure 70.11 Rubber band ligation.

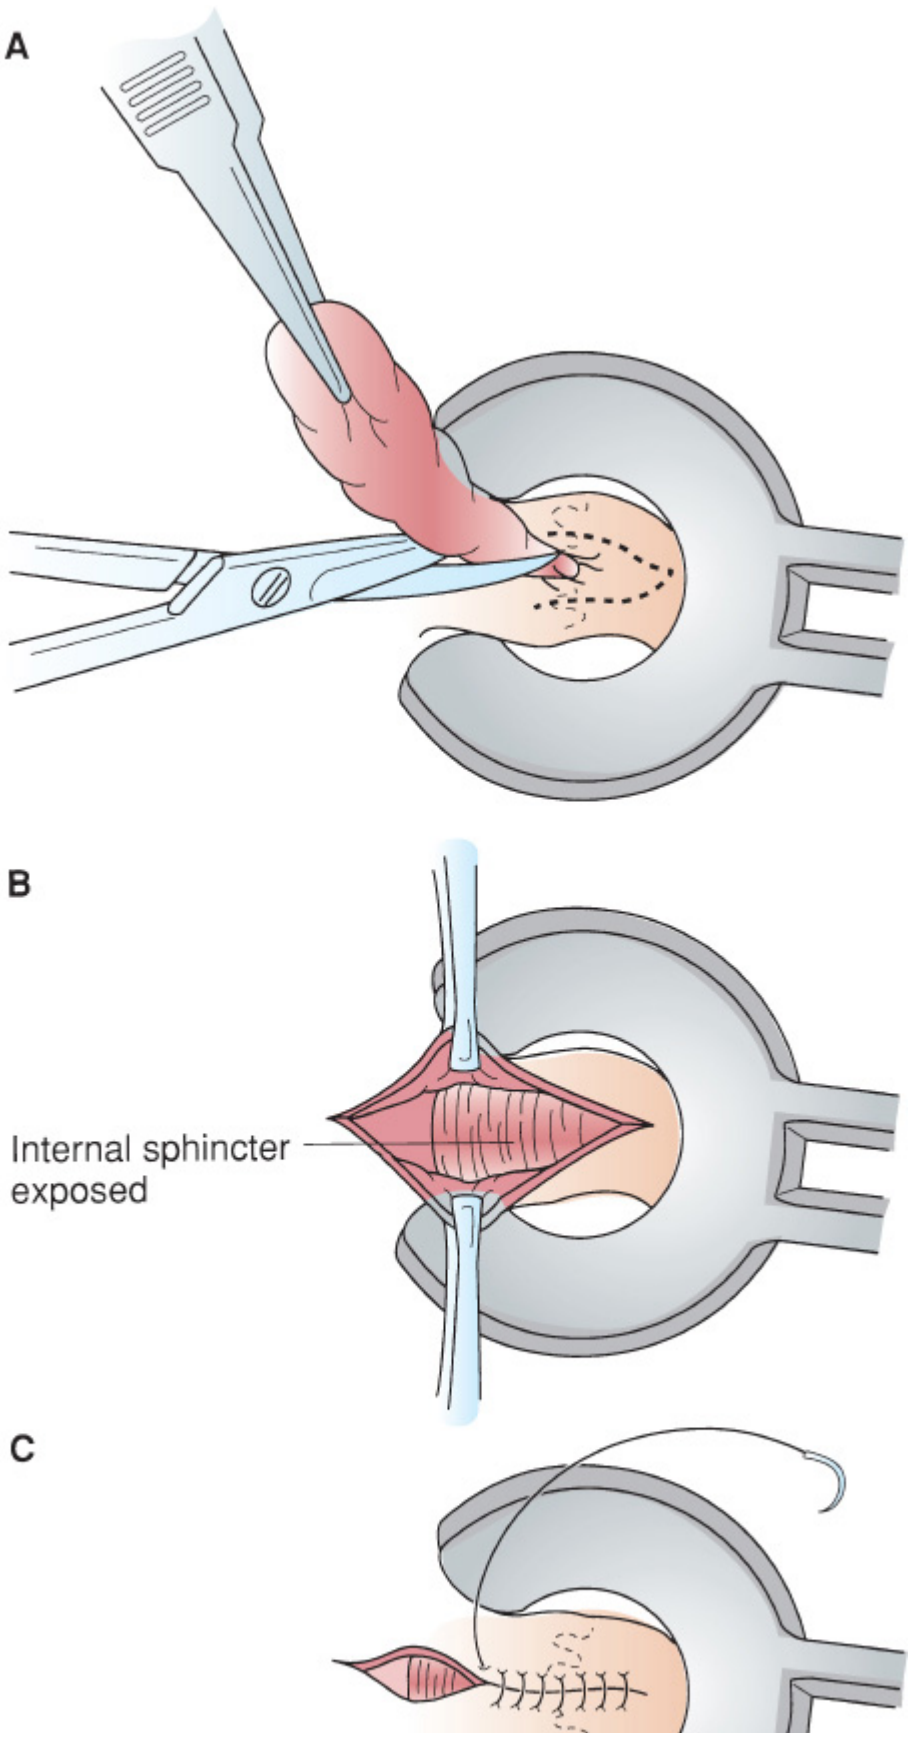
Operative Treatment

Excisional hemorrhoidectomy is the most definitive treatment for hemorrhoid-related symptoms and is indicated in patients who fail conservative or office-based procedures. Hemorrhoidectomy is typically an outpatient procedure, and in most cases performed under monitored

anesthesia care (MAC) and local or regional (spinal) anesthesia. The patient is placed in the prone jack-knife position with the buttocks taped apart. Initial ligation of the apex of the hemorrhoidal tissue helps to decrease bleeding during dissection. The skin is incised at the distal extent of the hemorrhoid and the hemorrhoidal tissue is carefully separated off of the underlying internal sphincter. The dissection may be undertaken with the use of a scalpel, scissors, electrocautery, or controlled electrical energy such as ultrasonic shears or a bipolar vessel-sealing device (**Fig. 70.12**). Vessel-sealing devices should be used with caution so as to not excise too much tissue. If more than one hemorrhoidal bundle is excised at once, it is also critical to ensure that at least 2 cm of normal anoderm is left between the excision sites to avoid postoperative anal stenosis. It is critical to preserve the underlying internal anal sphincter muscle. The wound may be left open or, more commonly, may be closed with absorbable suture. When closing the mucosa and anoderm, the dentate line should be reapproximated to avoid mucosal ectropion. Additionally, limiting intravenous fluids to <700 cc may help to decrease postoperative urinary retention, which occurs after approximately 15% of procedures.[4] Excisional hemorrhoidectomy is superior to office-based therapies in achieving complete remission. Surgery is associated with significant postoperative pain.[5] Multimodal analgesia including acetaminophen, NSAIDs, and minimal use of opioids is recommended. Gabapentin can also be added safely in most patients.

Stapled hemorrhoidopexy, known as procedure for prolapse and hemorrhoids (PPH), involves excision of a circumferential sleeve of mucosal and submucosa, thus interrupting hemorrhoidal vessels and pulling up the tissue. Enthusiasm for this procedure has waned due to rare but severe complications, including rectovaginal fistula, debilitating chronic pain, and pelvic sepsis. Long-term follow-up of hemorrhoidopexy compared to excisional hemorrhoidectomy show inconsistent results. Aytac et al. found similar rates of recurrent symptoms in both groups.[6,7]



A
B
Internal sphincter
exposed
C

Figure 70.12 Technique of closed hemorrhoidectomy.

Doppler-guided transanal hemorrhoid devascularization involves suture ligation of each hemorrhoidal column without resection of the hemorrhoid. A specific anoscope that includes a Doppler probe is used to identify the signal of the vessel feeding each hemorrhoidal column, typically above or just at the top of the column. Once the vessel is identified, it is then ligated with a suture and the Doppler probe is again used to confirm the disappearance of the signal. Typically, the hemorrhoidal column is then also oversewn with this suture. The purported benefit of this procedure is that because the ligation occurs above the dentate line, postoperative pain should be significantly lower than with an excisional hemorrhoidectomy. This procedure requires the purchase of specific equipment and supplies and thus can have cost limitations.[8]

Special Hemorrhoid Situations

Thrombosed External Hemorrhoids

Thrombosed external hemorrhoids are a relatively common complication of hemorrhoidal disease. The exact etiology is unknown. Their occurrence is often associated with physical exertion or straining as well as severe diarrhea. Patients typically present with a painful, tender mass in the perianal area. Pain peaks at 48 to 72 hours and subsides over 3 to 5 days. This condition is self-limited and usually resolves on its own over a few weeks without any significant issues, although some patients are bothered by residual skin tags. Management is typically conservative and includes pain control with mild oral analgesia, warm sitz baths, and a bulk-producing agent. If a patient presents within 72 hours, when pain is still rising or at its peak, consider performing a thrombectomy. This procedure can usually be done in the office using local anesthesia and tends to decrease the intensity of pain, but not overall duration of symptoms. After administration of local

anesthetic (typically lidocaine with epinephrine) an incision is made in the anoderm overlying the thrombus and the clot evacuated with gentle pressure.[9]

Incarcerated Hemorrhoids

Rarely, patients present with prolapsed fourth-degree hemorrhoids that have become incarcerated. While internal hemorrhoids do not typically cause pain, patients with incarcerated hemorrhoids often have severe pain. On inspection, edematous prolapsed mucosa, with occasional thrombosis is seen. Although these hemorrhoids may look impressive, conservative management with analgesia, stool softeners, and sitz baths is preferred.

Gangrenous Hemorrhoids

Rarely, incarcerated hemorrhoids may necrose. This situation constitutes a surgical emergency, especially in high-risk patients with diabetes or immunosuppression. Precautions including leaving generous anoderm bridges between hemorrhoidectomy sites and avoiding injury to the sphincters should be undertaken to minimize the risk of the long-term complications.

Anal Fissure

An anal fissure is a tear in the mucosal lining of the distal anal canal. Although more commonly found in younger patients, fissures can occur at any age and equally afflict male and females. Fissures are classified as acute or chronic based on the duration of symptoms (with the 8-week mark distinguishing acute from chronic). The vast majority of the fissures (90%) are located in the anterior or posterior midline and are theoretically associated with a watershed area of blood supply.[10] Fissures may occur with trauma from passing hard stool or from diarrhea. Lateral fissures are less common and should alert the clinician to the possibility of infection, HIV, Crohn disease, or malignancy.

Clinical Manifestations

Anal fissure typically presents with sharp pain during defecation. Some individuals experience a persistent throbbing pain lasting from minutes to

hours after defecation. Rectal bleeding is typically minimal and limited to spotting on toilet paper.

Because most patients come in with severe pain, one should reassure the patient and limit the initial evaluation to avoid further pain and trauma. Gently spreading the buttocks apart to visualize anal verge and observing even part of the tear, often with an associated anal skin tag, is generally sufficient. Fibers of the internal anal sphincter are often visible at the base of the chronic fissure. Adding a digital examination or anoscopy exacerbates pain and is unlikely to provide additional information. If there is a concern for other issues, the patient should be taken to the operating room to be examined under anesthesia or return to the clinic within 6 to 8 weeks after treatment starts to allow for a more thorough examination. Some patients have superficial fissuring on the perianal skin, often accompanied by itching after a bowel movement, which is associated with perianal irritation/dermatitis. These fissures are more distal, superficial, and often multiple with associated skin irritation.

3 Management

Medical Management

Treatment of anal fissures concentrates on symptom relief. The presence of a fissure without any symptoms (once other causes are ruled out) is not an indication for treatment. Most patients experience improvement or complete disappearance of symptoms with a bowel management program consisting of increased dietary fiber, oral liquid intake, and stool softeners.[11] Topical application of 0.2% nitroglycerin ointment or a calcium channel blocker such as 2% nifedipine or diltiazem can also facilitate healing fissures. All formulations are applied superficially and have similar success rates of 50% to 60%. Nearly 30% of individuals treated with topical nitroglycerine report headaches.[12,13]

Botulinum Toxin Injection

Injection of endopeptidase blocks acetylcholine release, thus causing temporary paralysis of the muscle. Effects last for up to 3 months. The technique, dose, and success rate vary widely in the literature. Generally, 100 Units of botulinum toxin are injected directly into the internal sphincter in four to five aliquots. Recent studies show similar effectiveness between

Botox and topical nitrates.[14] Treatment with Botox may result in short-term incontinence to gas or rare infection from the injection itself. No significant long-term complications have been reported. Botox is an option for patients with continence problems, or when the use of a more definitive procedure is associated with a higher chance of complications. Although Botox can be injected in the office with local anesthesia, if the patient cannot tolerate anoscopy and diagnosis is uncertain, then anoscopy with sedation should be undertaken.

Surgical Management

Lateral internal sphincterotomy (LIS) is considered the gold standard for treating anal fissures and has a 98% success rate. LIS is an outpatient procedure associated with minimal postoperative discomfort. LIS is performed by incising anoderm overlying the internal sphincter and sharply dividing internal sphincter muscle extending cephalad with electrocautery under direct vision. Alternatively, using a closed technique, a scalpel is inserted in the intersphincteric groove, turned toward the anal canal and a portion of the muscle is divided toward, but not including mucosa. With both approaches, a divot in the internal sphincter should be easily palpated afterward. The defect in the anoderm is closed with absorbable suture (**Fig. 70.13**). The amount of sphincter muscle divided should be limited to the length of the fissure (tailored sphincterotomy) to decrease the chance of incontinence without significantly compromising the success rate. Sphincterotomy is associated with a 5% risk of incontinence and should not be offered to patients with baseline continence problems.[13] Sphincterotomy should not be performed in the anterior or posterior midline since this can result in a keyhole deformity leading to leakage of mucus and stool. If sphincterotomy is not successful, one may proceed with a repeat lateral sphincterotomy on the opposite side. In patients with resistant fissures or continence problems, advancement flaps such as house or V-Y flaps can be performed. Healing rates following fissurectomy and advancement flap are comparable to those following sphincterotomy.[15]

Anorectal Abscess

Anorectal abscesses typically result from infection of the glands that empty into the anal crypts within the anal canal. Anorectal abscesses may also occur following iatrogenic trauma or malignancy. Rarely, infections such as tuberculosis and actinomycosis may result in a perianal abscess. The glands lie within the intersphincteric space. Therefore, when the glands become infected, an abscess originates within the anal space and may extend to other perianal spaces (**Figs. 70.14** and **70.15**).

Clinical Manifestations

Abscesses present with acute onset of perianal pain, often accompanied by fever. Superficial perianal or ischiorectal abscesses may have associated external induration, fluctuance, or erythema, whereas deeper abscesses may lack external manifestations. Tenderness and fullness may be palpable on digital rectal examination. Associated symptoms may include tenesmus and difficulty voiding.

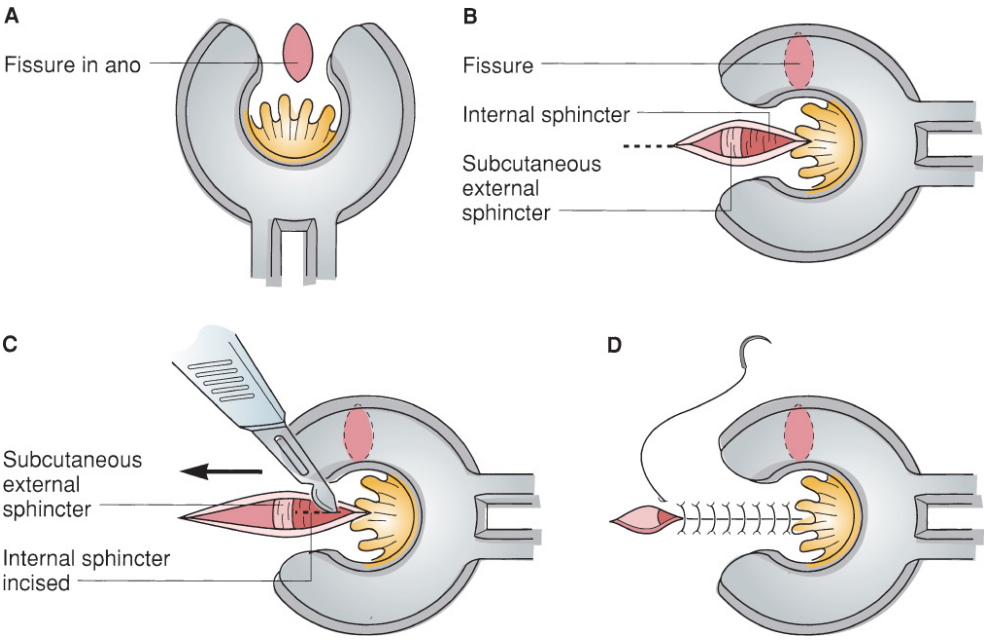


Figure 70.13 Lateral internal sphincterotomy.

Evaluation

When a perianal abscess is suspected, but physical examination findings are limited, a computed tomography (CT) scan or pelvic MRI is helpful to identify underlying pathology.

Management

The key to managing an anorectal abscess is adequate incision and drainage. Superficial abscesses may be amenable to drainage in the outpatient setting. One approach to draining an abscess is to make a 1-cm incision over the abscess cavity at the point of most tenderness or fluctuance. When choosing the site for incision, consider the potential for subsequent fistula formation. An external fistula opening may occur at the site of the incision site. Therefore, one should choose an incision site as close as possible to the anal verge that still allows for adequate drainage. A 10-F to 16-F drainage catheter (Pezzer or Malecot) is inserted through the incision into the abscess cavity (**Fig. 70.16**). Alternatively, a larger elliptical or cruciate incision may be made over the abscess cavity. If using a cruciate incision, excise the skin edges to allow for ongoing drainage. Patients should irrigate or soak the wound and cover it with dry gauze. Anoscopy with examination of the dentate line may reveal an internal fistula opening. Probing to identify a fistula tract at the time of abscess drainage should be done with caution as aggressive probing may create a false tract. A superficial fistula tract identified at the time of abscess drainage may be treated with primary fistulotomy. For deeper fistulas, a draining seton, consisting of a silastic band or nonabsorbable suture, should be placed in the fistula track.[16] Antibiotics are not used routinely after adequate drainage, but are indicated when there is extensive surrounding cellulitis or in patients with diabetes or who are immunocompromised.

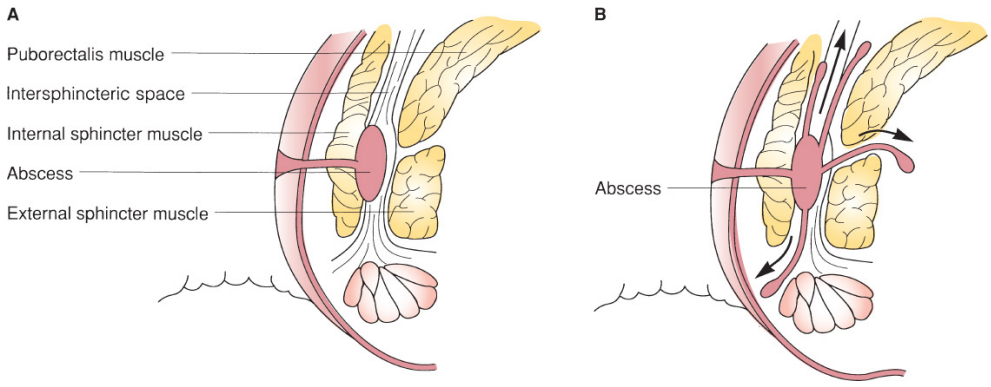

Figure 70.14 **A, B:** Pathways of infection.

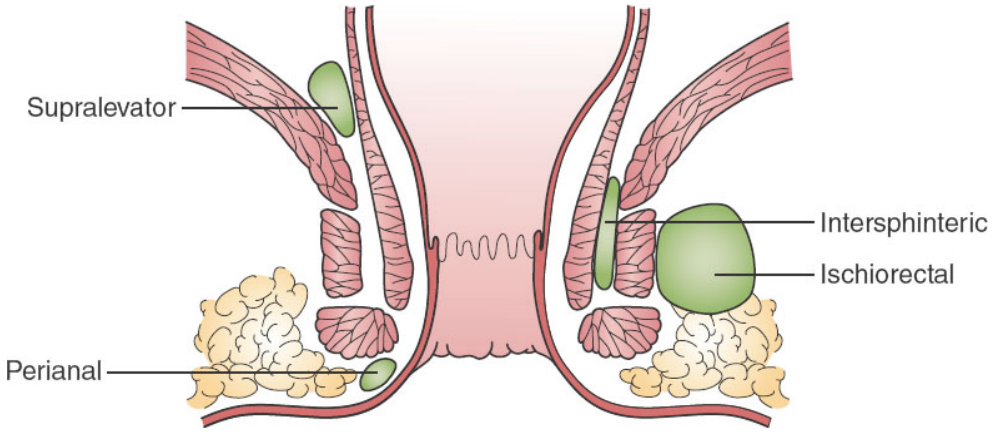

Figure 70.15 Classification of anorectal abscesses.

Deeper abscesses may require drainage in the operating room with sedation or general anesthesia. An abscess involving bilateral ischioanal spaces is referred to as a horseshoe abscess. These infections originate in the posterior midline and extend to both ischioanal spaces. Treatment may require bilateral incisions overlying the ischioanal areas. Supralevator abscesses are less common and can be difficult to diagnose. Because the location of the abscess is adjacent to the abdominal cavity, patients may present with abdominal or pelvic pain. Digital examination may demonstrate induration or a tender mass located in the distal rectum above the level of the anorectal ring. The etiology of a supralevator abscess dictates its management. These abscesses may result as an extension of an intersphincteric abscess, extension of an ischioanal abscess, or may result from an intra-abdominal abscess from perforated diverticulitis, appendicitis, or Crohn disease. A supralevator abscess secondary to extension from an ischioanal abscess should be drained through the ischioanal area. A supralevator abscess secondary to extension from an intersphincteric abscess should be drained into the rectum, as drainage through the ischioanal area may result in a complex suprasphincteric fistula. Percutaneous, image-guided, drainage may be an option in patients with a supralevator abscess secondary to an intra-abdominal source.

Rarely, anorectal abscesses can result in necrotizing infection and death, a condition referred to as Fournier gangrene. This situation may result from a delay in diagnosis and management of an anorectal abscess, infection with a highly virulent organism, or may be due to patient factors such as diabetes or compromised immune function. The infection superficially spreads around

the perineum, causing necrosis of the skin and underlying muscle and fascia. Treatment includes empiric broad-spectrum intravenous antibiotics and prompt surgical debridement of the necrotic tissue until healthy tissue is encountered.

After adequate drainage, approximately half of patients heal.[16] Alternatively, patients may experience a recurrent abscess or develop an anal fistula.

Anal Fistula

Clinical Manifestations

A recurrent abscess is usually indicative of a cryptoglandular fistula arising from the glands in the anal crypts. Fistulas may occur without a prior history of an abscess. Fistulas present as a perianal nodule, often with persistent or intermittent purulent drainage. On physical examination, there may be an external opening with granulation tissue. Sometimes the external opening closes over superficially, making the fistula challenging to identify.

The differential diagnoses of cryptoglandular fistulae include hydradenitis, which is inflammation of the apocrine sweat glands with resulting subcutaneous fistula tracts. In hydradenitis the fistulae are superficial and do not extend into the anal canal. A second differential is pilonidal disease. The origin of inflammation of pilonidal disease is a tuft of hair in the gluteal cleft creating a foreign body reaction.

Evaluation

A thorough history should include information about the duration of symptoms, a history of prior anorectal surgery, sphincter function, and associated urogenital symptoms. Additionally, one should inquire about a change in bowel habits or abdominal symptoms that may suggest Crohn disease.

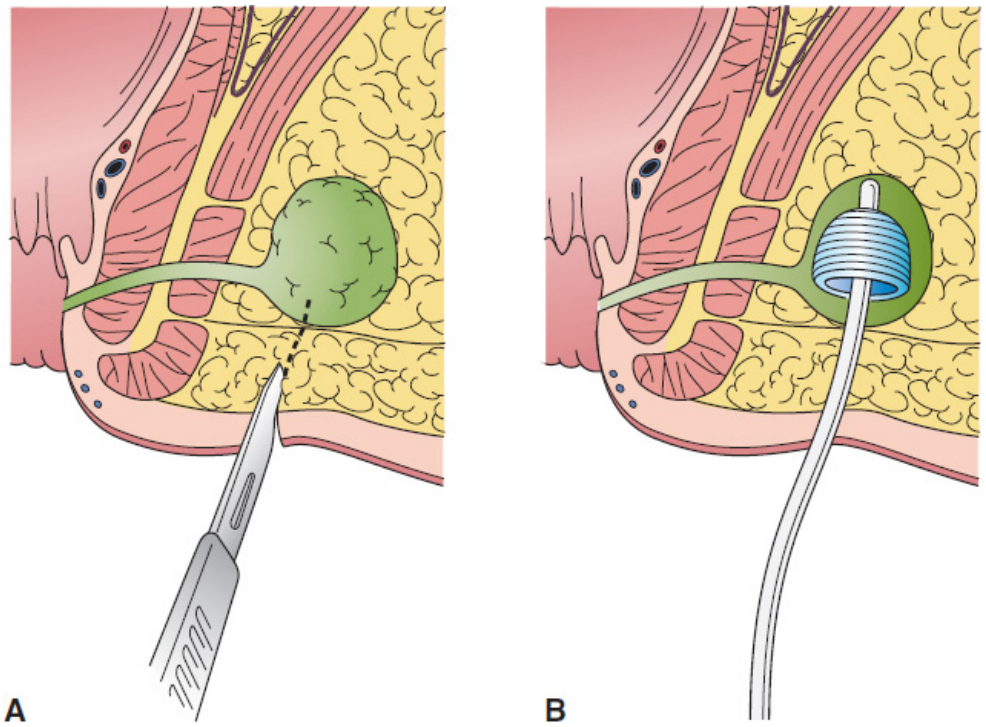

Figure 70.16 Abscess drainage with drain placement.

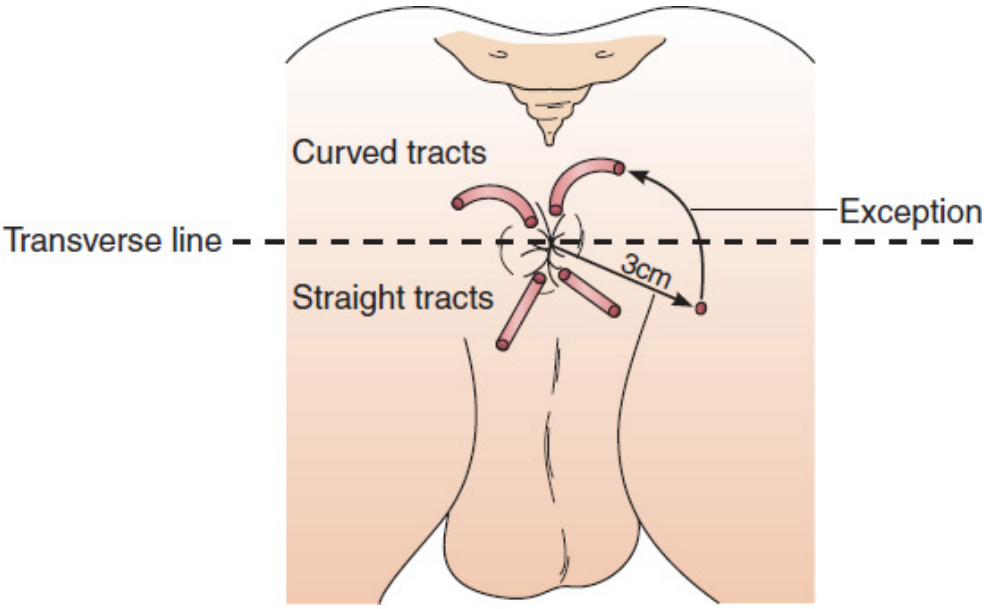

Figure 70.17 Goodsall rule.

Goodsall rule states that if an imaginary line is drawn transversely across the anus, an external fistula opening seen posterior to this line originates from an internal opening in the posterior midline, whereas an opening anterior to this line originates from the closest anal crypt (**Fig. 70.17**). Locating the

internal opening is not always possible with a fistula probe, and in this situation other diagnostic maneuvers may be necessary. Injection of the external opening with hydrogen peroxide, with or without the use of endoanal ultrasound, may help identify smaller fistulas. For patients with complex fistulas, including multiple fistulas, recurrent fistula, and fistulas associated with Crohn disease, ultrasound, MRI or fistulography with a water-soluble contrast and fluoroscopy may help to delineate a fistula tract.

Management

The first step in treating a fistula is to identify the entire length of the fistula tract. During an examination under anesthesia with the patient under MAC in the prone or lithotomy position, a probe is passed along the course of the fistula tract and assessed relative to the degree of sphincter muscle proximal and distal to the fistula tract. The fistulotomy, that is, unroofing of the fistula tract, is performed for the portion of the fistula peripheral to the anal sphincter. Simple, superficial fistulas may be treated with primary sphincterotomy. In general, involvement of less than 30% of the sphincter muscle is considered amenable to primary sphincterotomy. In women, the anterior anal canal is shorter, and one should be cautious about performing an anterior fistulotomy. Primary fistulotomy is associated with fistula healing rates as high as 90%.[16] For fistulas involving more sphincter muscle than is prudent to divide, place a seton and plan for a definitive interval procedure.

4 There are numerous options for treating fistulas. Regardless of technique, the goal is to obliterate the fistula tract while preserving sphincter function. Treatment options include primary fistulotomy, seton placement, advancement flaps, and ligation of intersphincteric fistula tract (LIFT). Instillation of fibrin glue and the use of a fistula plug are associated with high recurrence rates and are not recommended as primary treatment for fistulas.[16]

After initial placement, a seton may be sequentially tightened at 2- to 4-week intervals to form a “cutting” seton where the seton gradually erodes through the sphincter muscle. When the seton is deemed to be superficial enough, a second-stage fistulotomy is performed to remove the seton. The cutting seton is associated with success rates as high as 94%. The disadvantage of using a cutting seton is the risk of compromise of the

sphincter function. There is a wide range of rates of reported incontinence following the use of the cutting seton ranging between 23% and 22%.[17,18]

An endoanal advancement flap is commonly used for more complex fistulas. This procedure involves raising a flap of mucosa with the underlying internal sphincter muscle (**Fig. 70.18**). The fistula tract is curetted, and the internal fistula tract opening is sutured closed with absorbable suture. The raised flap of tissue is placed over the internal opening and sutured in place. The success rate of the advancement flap ranges from 66% to 87%.[16,19] In the case of a failed advancement flap, one may perform a repeat flap repair after an interval to allow for resolution of inflammation.

Another treatment for an anal fistula is the LIFT procedure (**Fig. 70.19**). After a seton has been in place long enough for fibrosis around the seton to form, the fistula tract is ligated and divided. An incision is made over the intersphincteric groove and deepened down to the fistula tract. Both ends of the exposed length of the fistula tract are ligated, and the tract is sharply divided. Reported success rates after the LIFT procedure range from 40% to 95%.[20,21]

Anal Fistula and Crohn Disease

Anal fistulas occur in 13% to 54% of individuals with Crohn disease.[22] Asymptomatic fistulas in the setting of Crohn disease do not need to be treated.[16] Crohn-related fistulas may be complex with more than one external opening. The first step in treating these fistulas is to unroof the branching tracts to create a single track at the internal opening. Patients may experience adequate symptomatic control with medical management using an anti-TNF medication.[23] Once a single fistula without inflammation is achieved, the techniques for treating fistulas described previously are applicable to patients with Crohn-related fistula. Before attempting a fistula repair procedure, examination should assess for anal canal fibrosis and acute mucosal inflammation. Crohn-related anal fistulae may be controlled with long-term seton placement and medical management. Temporary diversion may facilitate fistula healing, and proctectomy may be necessary for severe perianal disease (**Box 70.1**).[24]

Anovaginal and Rectovaginal Fistulae

Clinical Manifestations

A rectovaginal fistula is a communication between the anterior anus or rectal wall and the posterior vagina. Such fistulae can be debilitating due to the passage of gas or stool into the vagina resulting in incontinence and skin excoriation. An anovaginal fistula may occur as a complication from cryptoglandular disease with or without associated Crohn disease. Anovaginal fistulae may also result from obstetric injury, iatrogenic injury from stapled hemorrhoidopexy, low anterior resection, or other perineal trauma.

Box 70.1 Classification of Anal Fistulas

Intersphincteric Fistula. The tract of the fistula lies within the intersphincteric space and the external opening lies close to the anal verge. These fistulas are the most common, and typically result following a perianal abscess.

Transsphincteric Fistula. The fistula tract begins in the intersphincteric space and then traverses through a portion of the external sphincter muscle. The external opening typically lies over the ischioanal fossa.

Suprasphincteric Fistula. The fistula tract begins in the intersphincteric space and then passes upward above the external sphincter and then perforates the levator ani muscles to drain through the ischioanal fossa.

Extrasphincteric Fistula. The fistula tract begins in the distal rectum rather than the anal canal and perforates the levator ani muscles to drain through the ischioanal fossa. These fistulas are rare and develop typically from Crohn disease or rectal trauma.

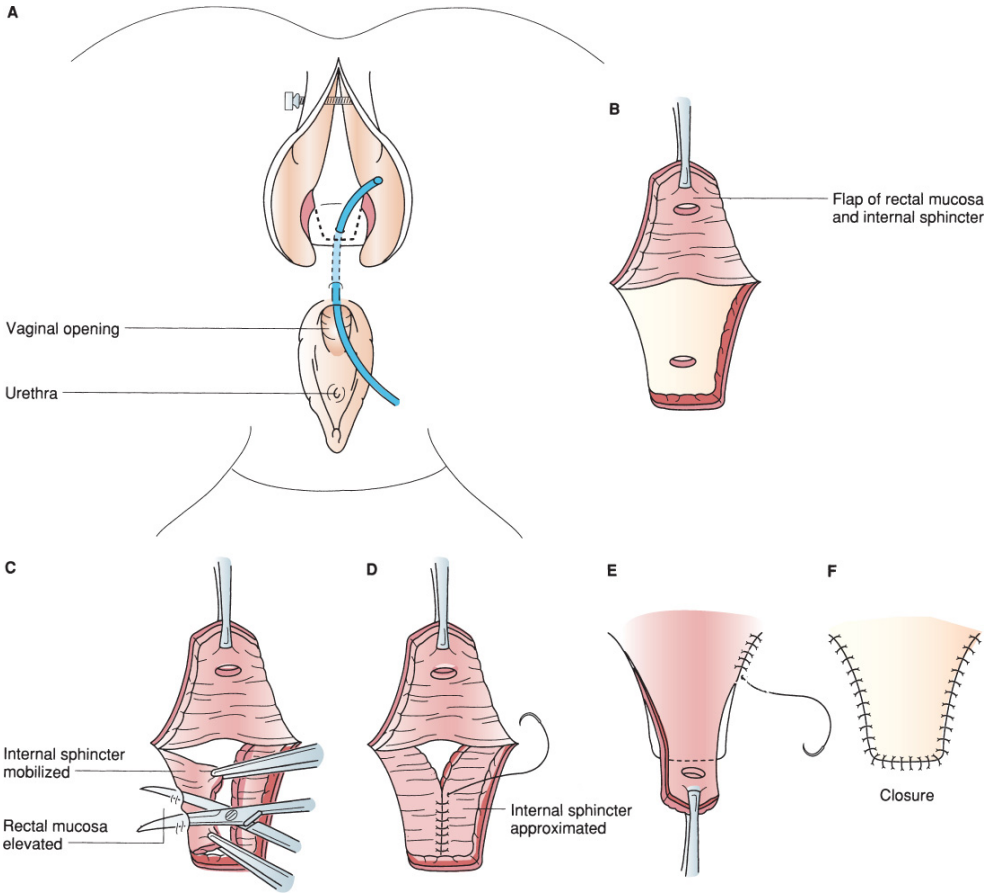

Figure 70.18 Mucosal advancement flap.

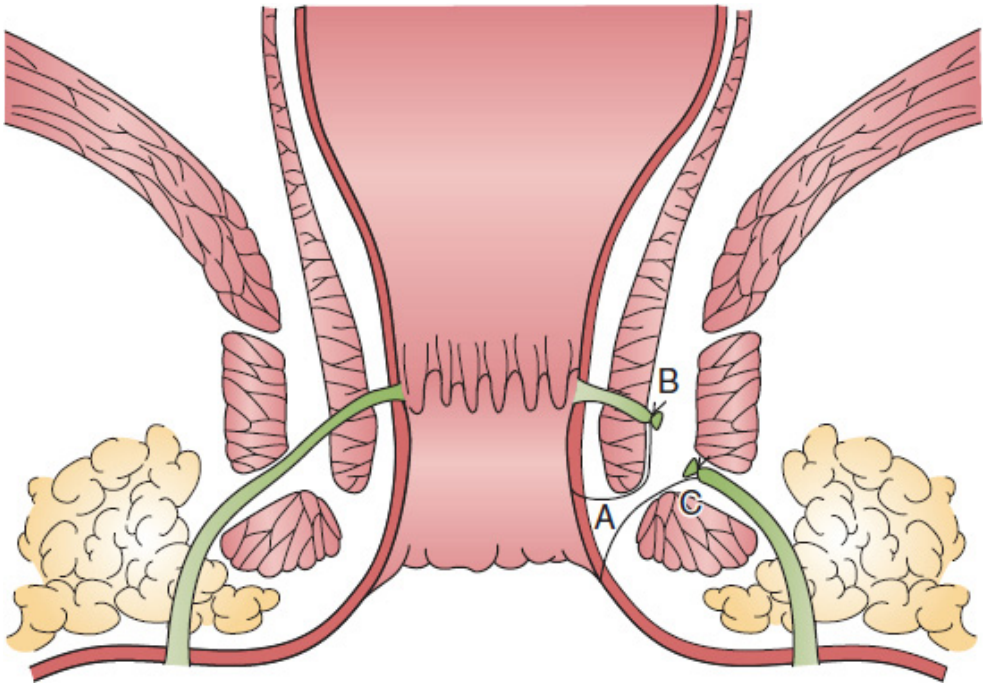

Figure 70.19 Anal fissure: ligation of intersphincteric fistula tract.

Evaluation

The clinician should ask about the patient's obstetric and surgical history. Obstetric injury may result in a fourth-degree (full thickness) tear of the rectovaginal septum. In addition to leakage of stool per the vagina, individuals may experience anal incontinence due to sphincter compromise. Physical examination should include inspection of the perianal skin and introitus. A digital rectal examination allows for assessment of sphincter tone, the thickness of the perineal body, and possible palpation of an anterior rectal wall defect. Anoscopy may help to visualize the opening in low fistulas, while proctoscopy or flexible sigmoidoscopy may be necessary to identify mid or high fistulas. If a rectovaginal fistula is suspected clinically, but no defect can is seen, a rectal enema of saline or water with methylene blue after vaginal tampon insertion can be useful. Staining on the tampon is indicative of a fistula. A contrast enema under fluoroscopy may be needed in complex cases to identify the fistula. In the setting of a low fistula occurring after obstetric injury, evaluation should include an assessment of the anal sphincter using ultrasound.

Management

In patients with small fistulas and minimal symptoms, medical treatment with bulking agents such as fiber may be sufficient in controlling symptoms. Fistula repair following an obstetric injury should be delayed 3 to 6 months to allow for resolution of inflammation. Similarly, repeat surgery after a prior failed repair should be delayed 3 to 6 months following the prior repair.[25]

Treatment of low rectovaginal or anovaginal fistulas with an intact sphincter may be accomplished by endorectal advancement flap or vaginal advancement flap. Most colorectal surgeons prefer to perform an advancement flap transanally rather than vaginally as the repair is to the high-pressure side. The opening in the vagina may be left open to drain. Success rates of endorectal advancement flaps for simple low rectovaginal fistulas range from 41% to 78%.[16]

If a low rectovaginal fistula is associated with incontinence secondary to a defect in the anal sphincter, repair with an overlapping sphincter repair has been shown to have good results. Episioproctotomy (perineoproctotomy) involves dividing the tissue distal to the fistula. The rectal mucosa is then repaired followed by an overlapping sphincter repair to form a buttress between the rectal and vaginal defects. Finally, the vaginal mucosa and anoderm are reapproximated. Hull et al. compared the outcomes of 50 women with rectovaginal fistulas treated with episioproctotomy and 37 who underwent rectal advancement flap for anovaginal fistulas. The success rates for fistula healing were similar for both procedures—78% for episioproctotomy and 62% for mucosal advancement flap. Episioproctotomy was associated with significantly better fecal continence ($P < 0.01$) and sexual ($P = .04$) function.[26]

High rectovaginal fistulas are treated with an abdominal procedure based on the etiology of the fistula and the condition of surrounding tissues. The principles of fistula repair include identifying healthy, well-vascularized tissue and utilizing interposition grafts such as omentum or rectus muscle to decrease the risk of recurrent fistulization.

Pilonidal Disease

Clinical Manifestations

Pilonidal disease is subcutaneous inflammation caused by embedded hair resulting in a foreign body reaction. Pilonidal disease may present as an acute abscess with pain, induration, erythema, or fluctuance adjacent to the gluteal cleft. Pilonidal disease may also manifest as a series of one or more chronic sinus tracts or "pits" in the gluteal cleft.

Evaluation

Physical examination is usually adequate for evaluating a pilonidal sinus tract. MRI may be helpful to differentiate a pilonidal sinus from a cryptoglandular fistula.

5 Management

An acute pilonidal abscess is managed by incision and drainage. Definitive treatment of chronic pilonidal disease involves excising the nidus of infection, commonly with excision of the skin and subcutaneous tissue to incorporate all of the residual pits. The wound can then be left open or closed. There are various described techniques for wound closure.

Midline closure is associated with a relatively high recurrence rate.[27] The alternative closure techniques involve incision placement lateral to the gluteal cleft and skin advancement or rotational flaps that result in an asymmetric closure off of the midline (**Fig. 70.20**). Less-invasive techniques, including pit excision alone using a punch biopsy and phenol instillation to obliterate the sinus tract, are associated with higher recurrence rates (**Table 70.4**).[28]

Fecal Incontinence

Clinical Presentation

Fecal incontinence is, "the uncontrolled passage of feces or gas over ≥1 month's duration, in an individual of ≥4 years of age, who had previously achieved control."[29] The severity of incontinence may range from minor soiling to complete incontinence of solid stool. Fecal incontinence affects up to 18% of the population.[30]

Anal continence depends on the reservoir function of the rectum, the individual's ability to sense the presence of stool in the rectum, and the

coordinated function of the anal sphincters and pelvic floor. (See section on Physiology.) Fecal incontinence is a symptom that may result from a variety of clinical conditions. Alterations in stool consistency or changes in rectal compliance due to inflammatory bowel disease or following pelvic radiation may overwhelm normal anal sphincter continence mechanisms. Neurologic disorders may affect both rectal sensation and muscle coordination. Iatrogenic injury to the sphincter can occur with anal surgery such as fistulotomy, sphincterotomy, or hemorrhoidectomy. In women, obstetric injury is a common cause of anal incontinence. Approximately 5% of vaginal deliveries result in sphincter injury. The effects of an obstetric sphincter injury may not manifest until decades following the injury. Risk factors for obstetric sphincter injury include nulliparity, increased birth weight, Asian race, use of instrumentation such as vacuum-assisted birth, and a prolonged second stage of labor.[31]

Evaluation

A thorough history should identify potential causes of incontinence and delineate the nature of the patient's symptoms, including frequency of bowel movements, the presence of tissue prolapse with bowel movements as well as the frequency of incontinence episodes, and whether the incontinence is to flatus, liquid stool, or solid stool. The initial evaluation should also assess the extent to which a patient's symptoms affect their quality of life.[29] When evaluating a patient with incontinence, differentiating between incontinence related to a compromised sphincter, soiling due to mucosal prolapse, or overflow incontinence related to underlying constipation is necessary. Fecal incontinence in the absence of urgency or incontinence to flatus is suggestive of soiling related to mucosal prolapse. Straining with bowel movements or a sensation of incomplete evacuation raises the suspicion of pelvic floor dysfunction.

Physical examination should include inspection of the perianal skin for scars from previous surgery or obstetrical injury and excoriation from chronic soiling. Separation of the buttocks may demonstrate gaping of the anus in individuals with a compromised sphincter. Digital examination can provide a gross assessment of both resting tone and squeeze effort. Anoscopy may identify mucosal inflammation or enlarged internal hemorrhoids.

The structural integrity of the anal sphincters is commonly assessed using endoanal ultrasound. Transperineal ultrasound or MRI can also assess sphincter anatomy. Defecography, dynamic MRI, and anal manometry are useful to assess anal sphincter and pelvic floor muscle function. Manometry measures anal pressure using a transducer catheter placed in the anal canal. Pressures are recorded with the patient at rest, when squeezing, and during simulated defecation. Evaluation of rectal sensation is performed by placing a balloon catheter above the anorectal ring and then gradually inflating the balloon with air. There are wide ranges of manometric values in asymptomatic individuals and variability with age and sex (see **Table 70.5**).

Management

Bowel Management Program

Patients with loose stool may benefit from a bowel management program that includes increased dietary fiber to bulk the stool and absorb excess liquid, making the stool easier to sense and control. Medical management may include constipating agents such as loperamide or diphenoxylate atropine. Bile acid binders can also thicken the stool and decrease stool frequency. Taking an enema after a bowel movement helps to empty the rectum, thereby decreasing the leakage between bowel movements.

Pelvic Floor Physical Therapy

Pelvic floor physical therapy helps to optimize sphincter and pelvic floor function. Therapy is targeted to the patient's need and may include sphincter strengthening, coordination of pelvic floor relaxation during defecation, and improving rectal sensation. Biofeedback typically employs the use of a pressure-sensitive probe placed into the anal canal to measure the strength and coordination of the anal sphincter and pelvic floor musculature. Data is transmitted to a monitor, where the patient can watch the manometric tracings. Through a series of coached exercises and visual feedback, patients can improve abdominal wall and pelvic floor muscle coordination. Reported rates of improvement with biofeedback range from 50% to 90%.[32] Successful therapy depends on the knowledge and skills of the therapist and patient motivation.

Sacral Neuromodulation

Interventions to treat fecal incontinence consistent of neuromodulation and techniques of sphincter augmentation. Sacral neuromodulation involves stimulation of a sacral nerve with an implantable stimulator (**Fig. 70.21**). The exact mechanism of this technique is not known. Studies have demonstrated improvement in symptoms even with an existing sphincter defect. This technique involves placing an electrode into the foramen of the sacral vertebrae, most commonly S3. The electrode is initially connected to an external neurostimulator. If the patients experience improvement in function, a long-term neurostimulator is placed subcutaneously. Complications following neurostimulator implantation include infection, pain, either at the stimulator site or painful stimulation and loss of efficacy over time. Reoperation rates, including replacement of a lead, battery, or explant of the device range up to 39%.[33]

Table 70.5 Anal Manometric Parameters

Measurement	Definition	Normal Range
High-pressure zone	The length of the anal canal with resting pressures ≥30% higher than rectal pressure	3–5 cm
Resting pressure	The pressure in the high-pressure zone at rest after a period of stabilization	40–70 mm Hg
Maximum voluntary pressure	The highest pressure recorded above the baseline (0) at any level of the anal canal during maximum squeeze effort by the patient	>70 mm Hg
Squeeze pressure	Calculated difference between the maximum voluntary pressure and the resting pressure	>100 mm Hg
Sphincter endurance	The length of time that the patient can maintain a squeeze pressure above the resting pressure	>10 sec
Rectal pressure	Pressure generated by the rectum with rest, squeeze, and push	60–70 mm Hg
Sensory threshold	The minimum rectal volume perceived by the patient	20–40 mm Hg
Urge sensation	*Sensation* is the volume associated with the initial urge to defecate	80–140 mm Hg
Maximum tolerated volume	The volume at which the patient experiences discomfort and an intense desire to defecate	130–150 mm Hg

Balloon expulsion test	Evaluates the ability of the patient to expel a balloon inflated with 50–60 mL of water	Patients with normal anorectal function are expected to expel the balloon

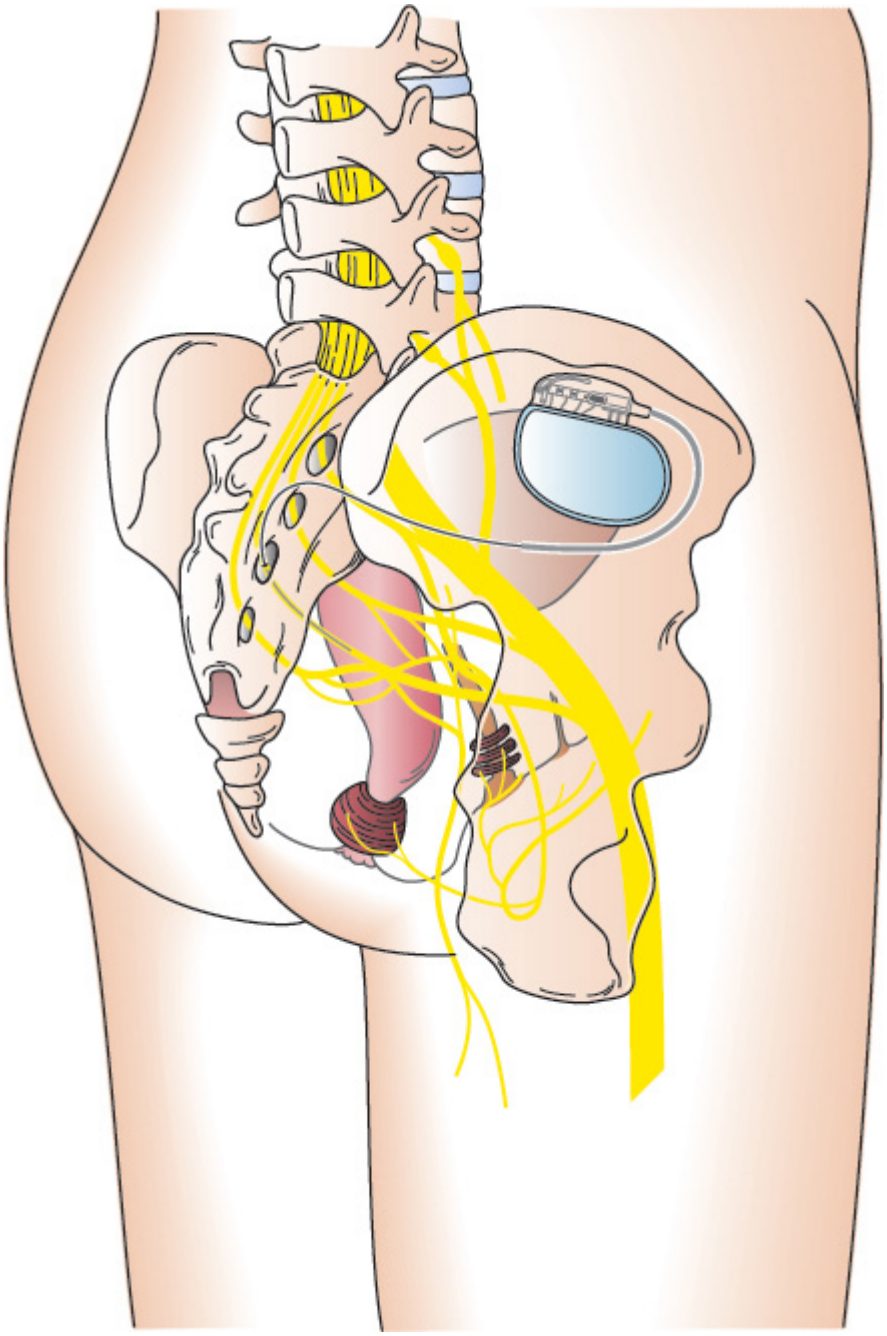

Figure 70.21 Fecal incontinence: sacral neuromodulation.

Sphincter Repair and Augmentation

An overlapping sphincter repair is an option for patients with significant external sphincter defects. The fibrotic scar tissue at the site of the defect is divided, and the two ends of the sphincter muscle are identified and are mobilized laterally. The ends of the muscle are sutured in an overlapping fashion (**Fig. 70.22**). While this procedure is associated with an initial success rate of greater than 80%, the durability of the repair is limited with nearly half of patients developing recurrent incontinence after long-term follow-up.[34] Less common treatments include the Secca procedure, which involves the use of radiofrequency delivered to the anal sphincter, results in tissue remodeling.[35] Several case series have demonstrated the short-term efficacy of this procedure, with more than half of patients treated reporting improvement in their symptoms. More recent studies show varied results regarding the long-term effectiveness of the Secca procedure.[36,37] Another option for treating mild incontinence is the injection of a bulking agent (silicone or carbon-coated microbeads) into the anal submucosal or intersphincteric space to increase resting pressures by augmenting the anal cushions or restoring anal canal symmetry.[38]

In rare instances, sphincter replacement with a prosthetic device may be considered (**Fig. 70.23**). Durable 5-year results have been reported, with 89% of patients reporting improvement and 36% reporting full continence.[39] In patients with severe incontinence for whom alternative methods have failed, the creation of a sigmoid colostomy may improve quality of life and allow them to resume normal daily activities.

Rectal Prolapse

Clinical Manifestation

Rectal prolapse is the full-thickness protrusion of the rectum through the anal canal. Rectal prolapse occurs in approximately 0.5% of the general population and is more common in women.[40] Although typically seen in women over age 50 years old, rectal prolapse may be seen in younger individuals with developmental delay or psychiatric comorbidities. Rectal prolapse may be associated with chronic constipation in up to 50% of

individuals.[40] The chronic traumatic stretch of the anal sphincter results in fecal incontinence in the majority of patients.

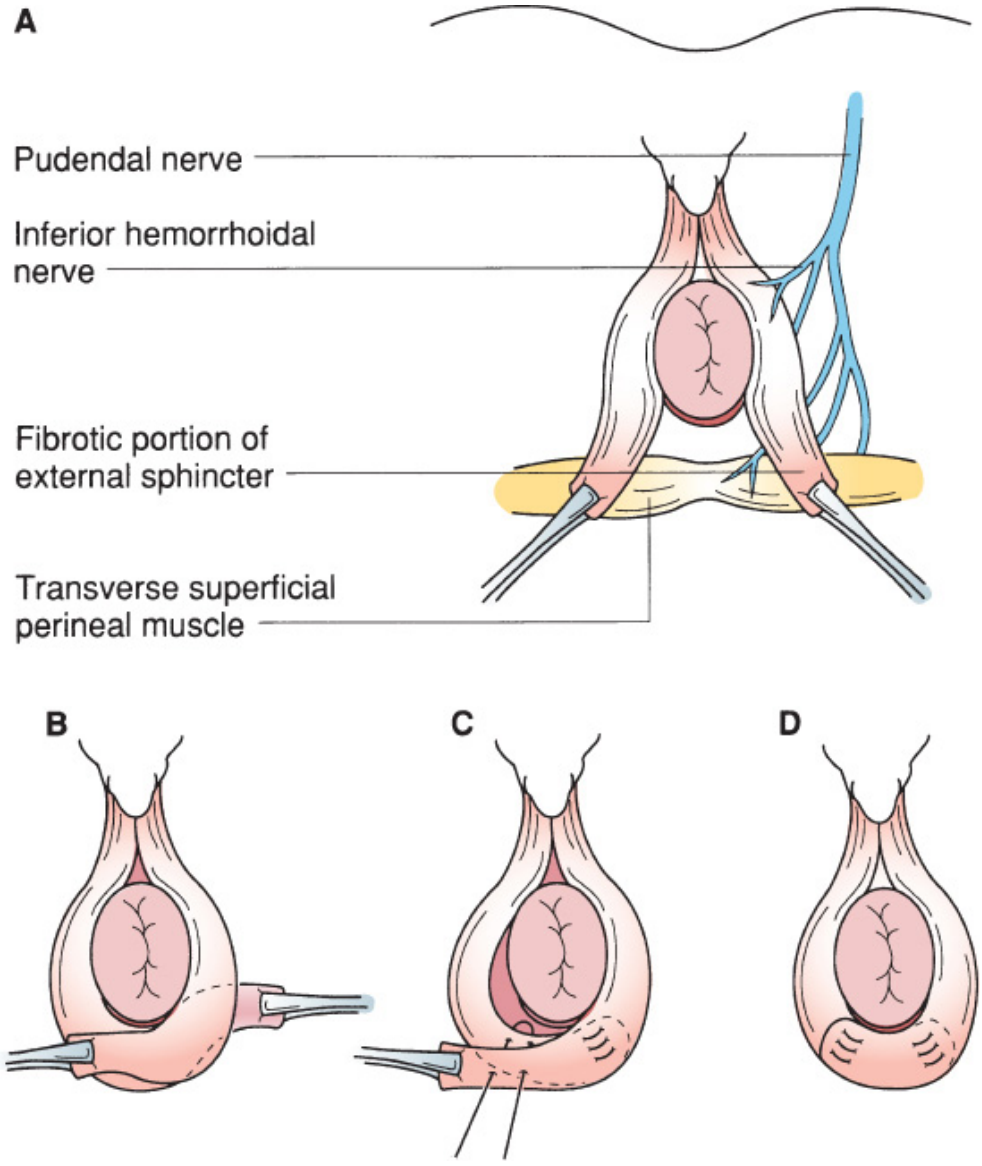

Figure 70.22 Overlapping sphincteroplasty.

Evaluation

Patients report protrusion of tissue that occurs with defecation or, in more advanced prolapse, may occur with moderate activity such as ambulating. The prolapse may reduce spontaneously or require manual reduction. Patients may experience fecal soiling and symptoms of incontinence. A complete history should include information about bowel habits and any

associated genitourinary dysfunction such as urinary incontinence or vaginal vault prolapse. On digital rectal examination, there may be decreased sphincter tone. An enterocele appears as smooth prolapse limited to the anterior rectal wall. It is crucial to differentiate full-thickness rectal prolapse, with concentric folds of tissue from mucosal prolapse, with radial folds of tissue (**Figs. 70.24** and **70.25**). Examination of the prolapsed tissue is facilitated by having the patient Valsalva while seated on a commode (**Fig. 70.26**). Endoscopy often shows edematous mucosa. Patients should be evaluated with colonoscopy to rule out a mass, which could serve as the lead point of intussusception. Ten percent to 15% of patients have an anterior ulcer identified on proctoscopy.[40] Defecography is helpful to clarify the diagnosis when prolapse is suspected, but cannot be demonstrated on examination. Additionally, defecography can reveal intussusception and concomitant pathology such as enterocele and pelvic floor dysfunction. Anorectal manometry may also be useful to evaluate for associated pelvic floor dyssynergia.

Patients may present with full-thickness rectal prolapse that is not reducible. If the prolapsed bowel appears viable, then the application of table sugar directly to the exposed mucosa may facilitate manual reduction. If the prolapsed tissue has advanced ischemia, then prompt, transperineal resection is indicated.

6 Management

Treatment of rectal prolapse requires surgical intervention. The choice of procedure depends on a history of previous procedures and the patient's overall medical condition.

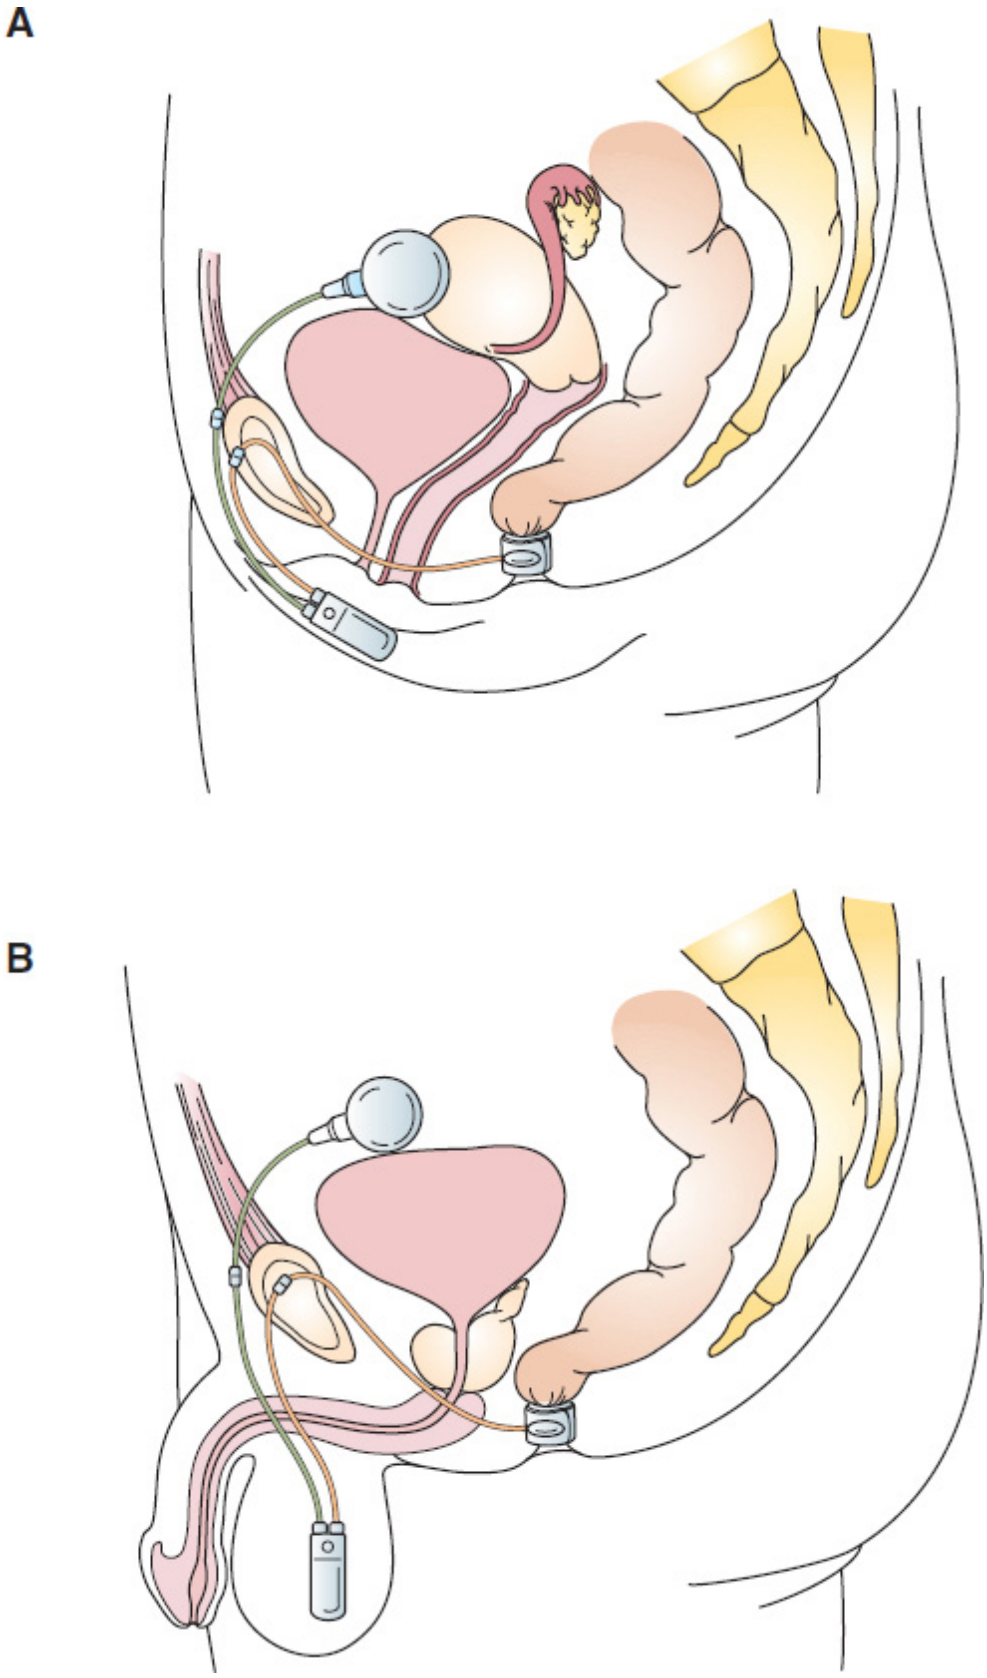

Figure 70.23 Implanted artificial sphincter.

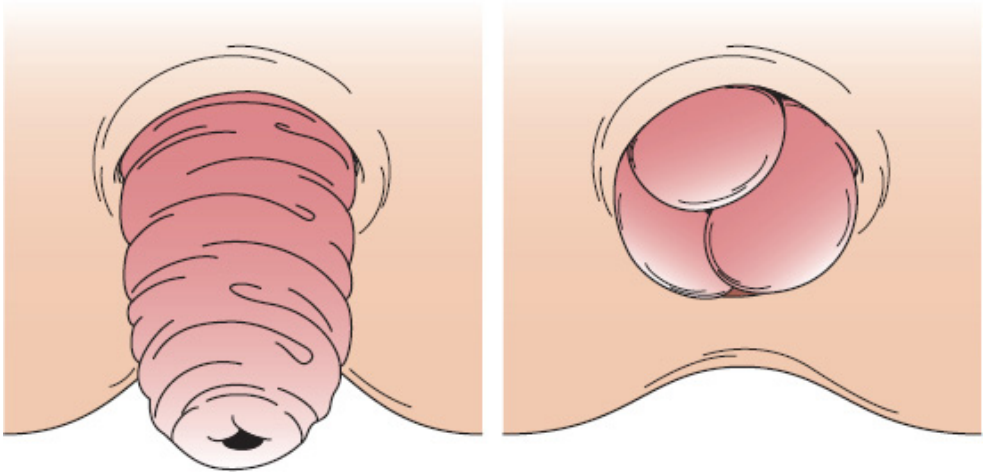

Figure 70.24 **A:** circumferential folds and **B:** radial folds.

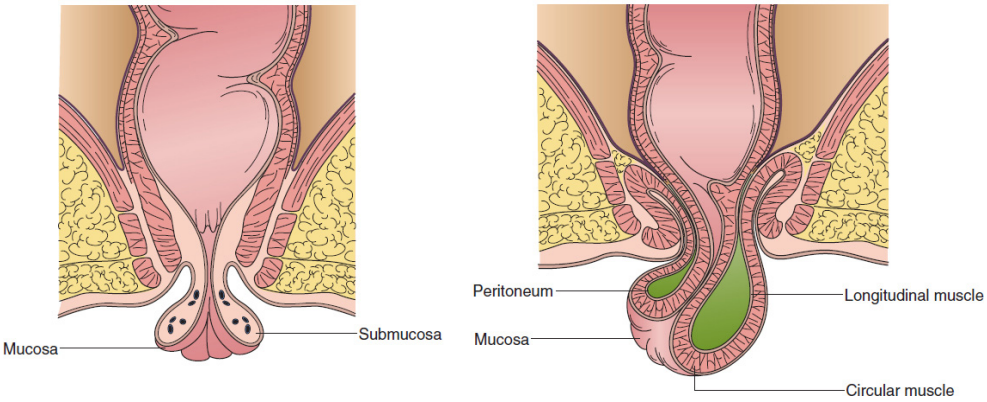

Figure 70.25 **A:** rectal mucosal prolapse and **B:** full thickness rectal prolapse.

Abdominal Operations for Rectal Prolapse

Transabdominal fixation of the rectum is the procedure of choice due to comparable or lower recurrence rates and better functional outcomes. A transabdominal repair involves mobilization and fixation of the rectum. Historically this involved posterior and anterior mobilization of the rectum and fixation of the rectum to the sacral promontory, with or without concomitant sigmoid colon resection. One problem with this approach is that posterior mobilization of the rectum may worsen constipation. In one report 50% of individuals with baseline constipation reported worsening constipation and 15% of patients reported de novo constipation.[41] In theory, the increased constipation could be related to disruption of rectal innervation. A newer technique involves only limited anterior mobilization

of the rectum and fixation of the rectum to the sacrum with synthetic or biologic mesh. Early reported outcomes of this anterior rectopexy technique indicated improvement in patients with preoperative constipation and no patients reporting new constipation (**Fig. 70.27**). Subsequent studies reported recurrence rates up to 14%, and de novo constipation was reported in 6%.[42,43]

Figure 70.26 Photo of full-thickness rectal prolapse.

Perineal Operations for Rectal Prolapse

A transperineal approach for rectal prolapse is indicated for ischemic, nonreducible prolapse. This approach has the advantage that it may be performed under regional anesthesia. The patient is positioned in the prone position. Excess rectum is excised, and the colon is anastomosed to the distal rectum, just proximal to the dentate line (**Fig. 70.28**). Levator muscle

imbrication prior to colonic anastomosis may ameliorate postoperative incontinence. The Delorme procedure is an alternative perineal approach that is appropriate for individuals with limited prolapse of 5 cm or less. This procedure involves stripping the mucosa of the prolapsed rectum from the muscularis propria, followed by plication of the muscularis propria and reanastomosis of the mucosa. This technique has a high recurrence rate but has very low associated morbidity, and may be appropriate for frail, older patients.

SEXUALLY TRANSMITTED DISEASES OF THE ANORECTUM

Gonorrhea

Gonorrhea is caused by the gram-negative intracellular diplococcus *Neisseria gonorrhoeae,* with an incubation period that ranges from 3 days to 2 weeks.

Clinical Manifestation

Symptomatic anorectal gonococcal infection results in pruritus or tenesmus, accompanied by a mucoid and sometimes bloody rectal discharge. Anorectal gonorrhea results in a thick yellow mucopurulent discharge from the anus.

Evaluation

Anoscopy or sigmoidoscopy may reveal a proctitis extending to no more than about 10 cm from the anal verge. Although these findings may be mistaken for ulcerative or nonspecific proctitis, abscesses, fistulae, and ulcers are not typical. Diagnosis is confirmed by culture on a Thayer–Martin medium plate incubated in a carbon dioxide environment.

Treatment

First-line treatment is a single intramuscular injection of 250 mg of ceftriaxone. Alternative treatments that have been proposed include single oral dose of 500 mg of cefixime or a single oral dose of a fluoroquinolone.

Because of the high rate of concomitant infection with Chlamydia, patients should be given appropriate treatment for Chlamydia as well. Sexual partners from the past 60 days should also be treated.

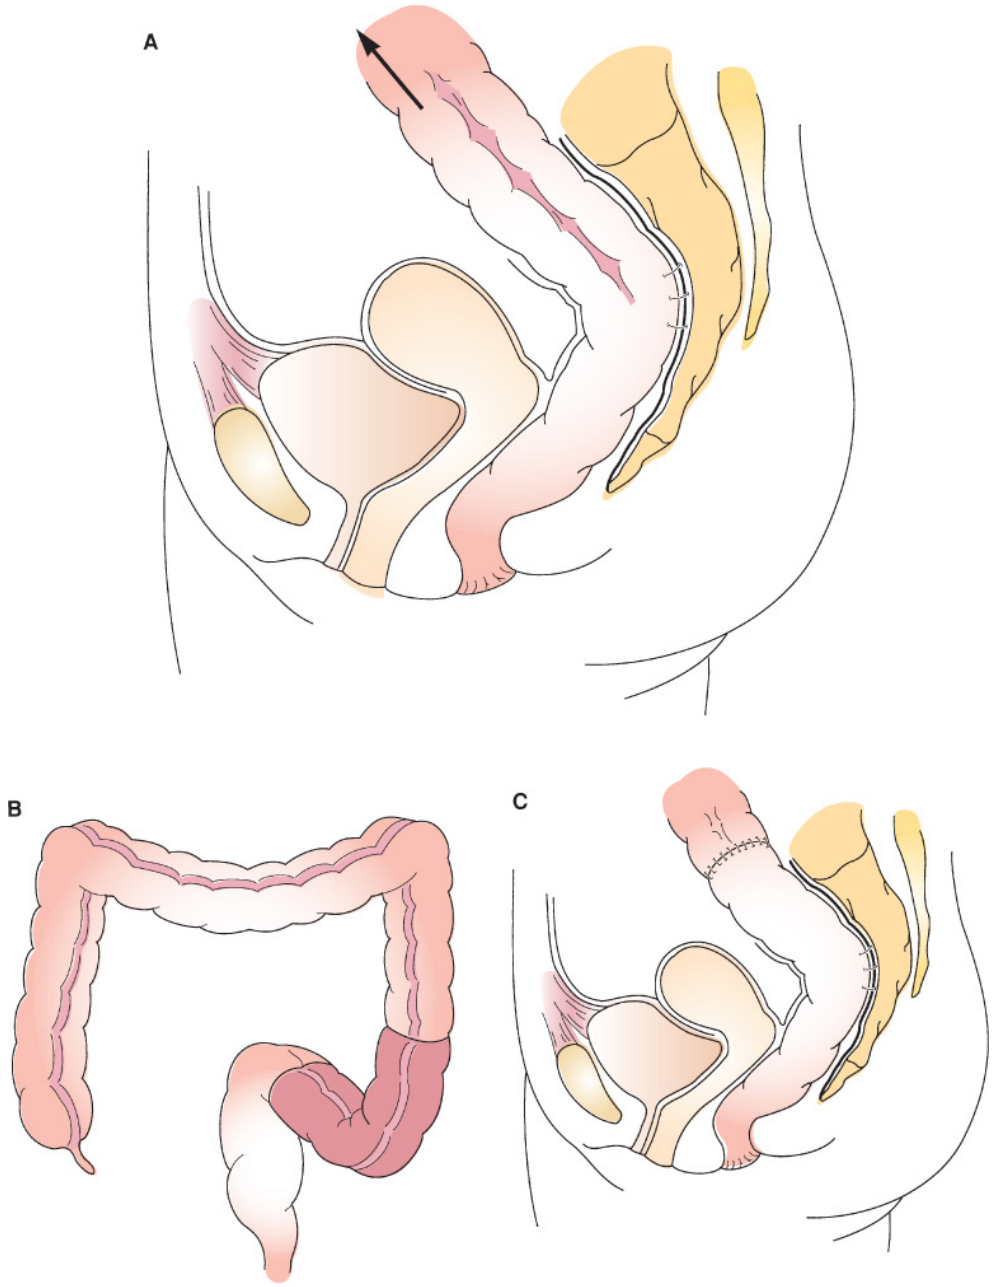

Figure 70.27 Ventral rectopexy. Mesh is sutured to the anterior rectum and sacral promontory.

Chlamydia/Lymphogranuloma Venereum

Chlamydia trachomatis is the most common sexually transmitted bacterial infection worldwide. With 15 known serotypes, anorectal Chlamydia infection can cause proctitis (serotypes D–K) or lymphogranuloma venereum (LGV) (serotypes L1–L3). Transmission of disease is through anoreceptive intercourse, with an incubation period ranging from 5 days to 2 weeks; secondary involvement can also occur as a late manifestation of genital infection.

Clinical Manifestations

Symptoms of non-LGV anorectal infection include rectal pain, tenesmus, and fever, although a substantial number of infected patients will be asymptomatic.

Evaluation

Examination reveals enlarged, matted inguinal lymph nodes, and proctosigmoidoscopy shows an erythematous rectal mucosa without frank ulcerations. Patients with LGV also complain of pain, fever, and tenesmus but often have a slight mucopurulent discharge and hematochezia. The inguinal lymph nodes in LGV are often more enlarged as they fuse into a large indurated mass with overlying erythema. Evaluation of the rectal mucosa reveals a more severe granular proctitis with mucosal friability and frank ulceration. If left untreated, the disease may progress to fistulae, abscesses, and late rectal strictures. In this setting, LGV may be confused for perianal Crohn disease. The marked inguinal lymphadenopathy may help distinguish LGV from Crohn.

Treatment

Chlamydia infection is treated with a single oral dose of azithromycin (1 g) or doxycycline (100 mg) twice a day for 7 days. Alternative therapy includes erythromycin or a fluoroquinolone. Treatment of LGV is a 21-day course of either erythromycin or doxycycline. Sexual partners also require treatment to prevent reinfection.

Herpes Simplex Virus

An estimated 20% of the general population are affected by herpes. The majority of anorectal herpes infections are caused by HSV-2 with only about 10% being caused by HSV-1. Transmission is through autoinoculation or direct contact with an infected individual who is shedding the virus. The clinical infection may begin 4 to 21 days following anoreceptive intercourse.

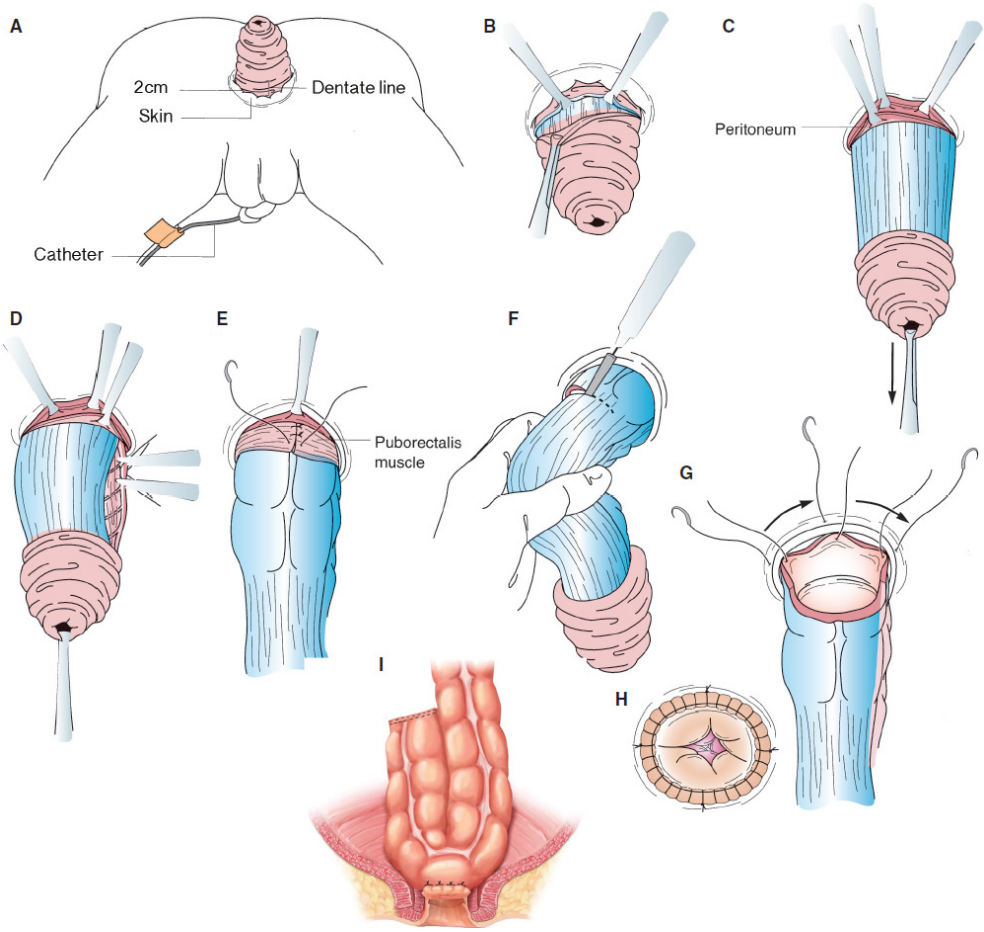

Figure 70.28 Perineal proctosigmoidectomy.

Clinical Manifestations

Patients present with small red vesicles, which may be clustered or scattered in the perianal skin, anal canal or perineum. These lesions are extremely painful to touch. Mucus discharge occurs in some patients with proctitis.

Evaluation

Proctoscopy reveals friable mucosa, ulceration, and mucopurulent discharge. These findings are limited to the distal 10 cm on proctoscopy. Tender

inguinal adenopathy occurs in up to 50% of patients with HSV proctitis. Diagnosis is made on clinical examination, finding multinucleated giant cells with intranuclear inclusion bodies on Pap smear, a positive Tzanck preparation or a positive culture.

Treatment

Acute infection is self-limited; treatment includes warm sitz baths and oral analgesics. The use of antiviral medications has been shown to shorten the length of symptoms but does not affect recurrence rates. Acyclovir (400 mg five times/day for 10 days) is most commonly used for initial infection. Recurrent attacks may be treated with acyclovir (200 mg five times/day) or valacyclovir (500 mg twice/day).

HIV and AIDS

Surgery for anorectal diseases is the most common indication for surgery in HIV infected. With significantly improved life expectancy for patients with HIV it is important to be cognizant of a number of conditions associated with this disease. Primary manifestations of HIV (anal ulcers) are rare and usually limited to patients with AIDS. However, these patients have high rates of other problems such as human papilloma virus (HPV), HSV, and anal fissures. Some of these problems are related to immunosuppression and concomitant infections, while others likely arise from treatment (HAART therapy) that can cause diarrhea. Treating these conditions is not significantly different when compared to other patients, but potential issues with healing, infection, and a higher chance of recurrence should be taken into consideration.

Condyloma 7 Acuminata and Squamous Intraepithelial Lesions

Anal condylomata acuminata or “warts” are caused by the HPV. HPV is a papovirus of which more than 130 subtypes of HPV have been identified. The prevalence of any genital HPV is estimated to be approximately 43%.[44] Inoculation of the anal epithelium allows entry of the HPV into the basal cell

layers. As these cells proliferate, viral replication occurs in the nucleus. The basal cells then migrate toward the surface, and infective particles are released in the form of visible warts.

HPV changes are classified into three grades of dysplasia: condyloma (no dysplasia), low-grade, and high-grade squamous intraepithelial lesions (LSILs and HSILs). Select serotypes are implicated in oncogenic cellular transformation; HPV serotype 16 is associated with 89% of anal squamous cell cancers (SCCs).[45] Individuals at increased risk for anal dysplasia include women with a history of cervical neoplasia, men who have sex with men (MSM), and individuals who are immunosuppressed. The mechanism for oncogenesis involves the inactivation of the P53 tumor suppressor gene by viral proteins.

Clinical Manifestations

Patients with anal dysplasia may experience pain, bleeding, or pruritis, although the majority of patients are asymptomatic.[46]

Evaluation

Condyloma acuminata are easily recognized as epithelialized cauliflower-like projections. They may be flat, raised, sessile or pedunculated, and range in size from millimeters to a large fungating lesions. They may be in clusters or grow to cover the perineum and anal canal in a "carpet-like" fashion. Anoscopy is used to identify lesions within the anal canal. Visualization of anal dysplasia is enhanced with the topical application of 4% acetic acid. Irregular and white blanching areas are suggestive of dysplasia. High-resolution anoscopy (HRA) can be used in high-risk patients and allows for better visualization and often simultaneous treatment of the lesions. It is not clear that HRA provides better screening then regular anoscopy. None of the above techniques have been clearly shown to be superior in preventing anal cancer.

Treatment

Treatment of a few easily accessible lesions can be done in the office by tangential excision, fulguration, cryotherapy, or chemical therapy (trichloroacetic acid). Larger or multiple lesions are treated in the operating

room by electrodesiccation, laser, or excision in the operating room. Topical agents such as podofilox, imiquimod, and fluorouracil applied by the patient on the perianal skin and in the anal canal may slow the progression of the disease and decrease the need for reintervention.[47] Vaccination against more virulent strains of condyloma (Gardasil) is currently available. The vaccine is effective in lowering rates of cancer when administered before initiation of sexual activity. The utility of giving this vaccine to adults after the diagnosis of condyloma is uncertain.

Since HPV and anal dysplasia are currently not curable and are often asymptomatic, individuals with anal dysplasia should be evaluated. Surveillance with anal cytology (anal Papanicolaou [Pap] test) smears every 1 to 2 years can be used, although sensitivity and specificity is low.[48] Recent studies found the 5-year incidence of progression from high-grade dysplasia to invasive SCC to be 6% to 9%.[49,50]

NEOPLASTIC ANORECTAL DISEASE

Neoplasms of the anal region are relatively rare, and include both benign and malignant tumors. Defining the location of the tumor is essential in the diagnosis and management of these conditions. The American Joint Commission on Cancer has developed standardized terminology and has recognizes the anal verge as the line dividing between the anal canal and anal margin. Practically, lesions that can be visualized by opening patient's buttocks are anal margin lesions. It may be sometimes challenging to determine primary location of large, bulky tumors, history of symptoms, examination, and histology can often serve as a guide.

Squamous Cell Carcinoma

Historically anal cancer was most common in women aged 50 to 70. Over the past three decades, the incidence of anal cancer has increased in women and at an even higher rate in MSM. Recent data shows that the rate per 100,000 is 1.6 for men and 2.2 for women.[51] Fewer than half of patients present with localized disease.[51]

8 Clinical Manifestations

Squamous cell carcinoma may occur on the perianal skin and in the anal canal. Patients often present with symptoms of pain and bleeding, similar to symptoms of hemorrhoids or an anal fissure. The gross appearance is typically a firm, ulcerated mass with rolled, everted edges.

Evaluation

While symptoms may mimic other conditions such as fistula, hemorrhoids, or chronic pruritus, any chronic unhealed or indurated ulceration in the perianal area should be biopsied. A digital examination and anoscopy should be performed to evaluate the location and size of an intra-anal tumor. Physical examination should include careful evaluation of inguinal lymph nodes as the most common sites of locoregional disease. Suspicious nodes may be evaluated further with fine-needle aspiration. A chest and abdominal CT scan along with CT or MRI of the pelvis are indicated for disease staging. Additional workup includes HIV testing and evaluation for cervical dysplasia in women. Also, one should discuss fertility preservation in appropriate patients per consensus guidelines.

Treatment

Anal Margin Tumors

T1 (<2 cm) and T2 (2 cm to 5 cm) well-differentiated lesions that do not invade the sphincter muscle may be treated with local excision with a 1-cm margin. More advanced lesions are best treated with a combination of 5-fluorouracil, mitomycin C, and radiation. Patients generally receive 50.4 Gr with an additional boost to inguinal lymph nodes if lymph node metastases are suspected. Abdominoperineal resection (APR) is indicated for persistent or recurrent disease and in the setting of significant functional issues related to tumor or consequences of treatment (incontinence). This surgery may require excision of a large portion of the perineum and flap closure.

Anal Canal Tumors

The standard treatment for anal canal lesions is chemotherapy and radiation per consensus guidelines. According to SEER data, overall 5-year survival is 68%, ranging from 82% for localized disease to 32% for distant disease.[51]

Recent studies have suggested that local excision alone may be considered for select T1 tumors.[53] The decision to proceed with local excision must consider the resectability of the lesion based on the potential for sphincter preservation and avoidance of anal canal stricture. APR (usually with omental or myocutaneous flap closure of the perineum) is reserved for patients with persistent or recurrent disease. Tumors may continue to regress for up to 6 months. Unless there is a clear growth of tumor at the end medical treatment, tumor response should be closely monitored up to 6 months before proceeding with APR.[54]

ADENOCARCINOMA

Paget Disease

Paget disease is an intraepithelial adenocarcinoma of the perianal skin. While this disease was initially described in the breast, it may also occur in the axilla and anogenital region. The exact origin of Paget cells is unknown. However, authors have hypothesized that they arise from apocrine or sweat glands, or are metastatic from an underlying adenocarcinoma. Perianal Paget disease begins as a benign in situ neoplasm but may eventually become invasive as an adenocarcinoma. Paget disease is a rare disease and occurs most commonly in elderly patients.

Clinical Manifestations

The typical appearance is an erythematous, sometimes sharply demarcated rash that may ooze or scale. Paget disease must be differentiated from other dermatologic conditions such as eczema, lichen sclerosis, and hyperkeratosis; these conditions tend to present in a circumferential pattern, whereas Paget disease tends to be unilateral.

Evaluation

The diagnosis is made by biopsy, which demonstrates the presence of periodic acid–Schiff positive Paget cells. Patients with Paget disease should also undergo a colonoscopy as perianal Paget disease may occur with synchronous colonic neoplasia.[55]

Treatment

The treatment of perianal Paget disease in the absence of invasive carcinoma is wide local excision. Because the disease may extend beyond the grossly visible margin, mapping biopsies at least 1 cm from the edge of the lesion in all four quadrants is recommended and consideration for flap closure for larger defects should be given. Patients with underlying cancer are generally treated based on the type of cancer they develop but often require radical resection after neoadjuvant treatment.

Anal Canal Adenocarcinoma

Anal canal adenocarcinomas are relatively rare, accounting for less than 10% of all anal carcinomas. Histologic studies show that these neoplasms arise from either the colonic mucosa or the anoderm and arise via HPV-dependent and independent pathways.[56]

Clinical Manifestations

The presentation of adenocarcinoma is similar to SCCs of the anal canal, with pain, bleeding, pruritus, and a palpable mass. These tumors tend to have a more aggressive natural history than SCC. Workup should include CT of the chest and abdomen as well as MRI pelvis with rectal cancer protocol and carcinoembryonic antigen (CEA). Colonoscopy should be performed if not recently done.

Treatment

These tumors are treated similar to rectal cancer, with chemoradiation followed by APR.

Basal Cell Carcinoma

Basal cell carcinomas of the perianal skin are rare. This condition is more common in men than women, and one-third of patients have basal cell cancers on other cutaneous sites.

Evaluation

Similar to basal cell cancers of the skin elsewhere on the body, these tumors typically appear as an ulcer with irregular and raised edges.

Treatment

These tumors are treated with local excision followed by close surveillance.

Melanoma

Melanoma occurs most commonly in the skin and eyes, but can also develop from the transitional epithelium within the anal canal or the anoderm at the anal verge. This tumor is more common in females than in males and is relatively rare, accounting for less than 4% of all anal malignancies.[57]

Clinical Manifestations

Symptoms include pain, pruritus, and bleeding. Some anal melanomas may not contain pigment and can be challenging to differentiate from SCC. Anal canal melanomas spread submucosally into the rectum, but do not typically invade other organs. Lymphatic spread to mesenteric lymph nodes is present in up to 32% and distant spread in 13% of patients at the time of diagnosis.[51]

Evaluation

The initial evaluation should include CT of the chest and abdomen and MRI of the pelvis. Careful evaluation of lymph node and anal sphincter involvement should be done by physical examination and imaging. Further genetic analysis of tumors can identify specific mutations in molecular pathways that can be targeted by systemic therapies.

Treatment

Melanomas of the anal canal do not respond to chemotherapy or radiation, making surgery the only chance for cure. Options include wide local excision or APR. With either option, the prognosis is poor, and recurrences are common. A recent review by Matsuda et al. found that APR provided better local control, but overall survival and relapse-free survival did not differ between local excision and APR.[57] Consideration should be given to palliation of symptoms and maintaining adequate function. If the presenting

lesion is not amenable to local excision without sacrificing function, then APR is warranted. Recent studies using targeted systemic therapy and immunomodulators have shown prolonged survival in patients with cutaneous melanoma; however, data on their effects on mucosal melanomas is still lacking.[58]

Appendiceal Diseases

Arden M. Morris

Key Points

1. Recent data indicate an immune-related role for the appendix as a repository for beneficial bacteria of the microbiome.
2. Acute appendicitis, one of the most common urgent abdominal conditions in high income countries, is considered to be the result of a closed loop obstruction due to fecolith, inflammation of lymphoid aggregates, or other blockage at the appendiceal orifice.
3. Seasonal and geographic variation in the incidence of uncomplicated but not in the incidence of complicated or perforated appendicitis support potentially different etiologic mechanisms.
4. Signs and symptoms of appendicitis may be especially vague in the early stages, due to autonomic innervation, and become more pronounced with progressive inflammation of the somatically innervated parietal peritoneum.
5. An abdominal computed tomography scan is the imaging test of choice among patients with clinical signs of appendicitis.
6. Complicated appendicitis refers to the presence of abscess or perforation and occurs in about 10% of cases in the United States.
7. Controversy persists about the role for interval appendectomy among patients with complicated appendicitis. Adults with complicated appendicitis who do not undergo interval appendectomy should at least undergo a follow-up CT scan and/or colonoscopy to rule out other pathology.
8. Substantial randomized controlled trial data support using antibiotics first among patients with uncomplicated appendicitis, absence of fecolith, and the ability to follow up; still, about 27% of patients can expect to fail non-operative management in the first year after diagnosis.
9. Appendicitis is the most common non-obstetrical abdominal condition of pregnancy and should be treated by appendectomy due to high risk for premature delivery or fetal demise.

ANATOMY AND PHYSIOLOGY

The vermiform appendix is a finger-like, antimesenteric projection of bowel, approximately 6 mm in diameter and up to about 9 cm long, attached at the cecum as a closed tube. It sits adjacent to the ileocecal valve at the proximal convergence of the taeniae coli. Its free end is mobile and can extend in any direction. In a postmortem analysis of 10,000 cases in England,[1] Wakeley described its location primarily in relation to the cecum and ileum: retrocecal, 65.3%; pelvic, 31%; subcecal, 2.3%; preileal (anterior), 1%; and right paracolic gutter and postileal (posterior), 0.4%. As with the small intestine and colon, the wall of the appendix consists of mucosa, submucosa, muscularis externa, and serosa. The appendix is innervated by the autonomic nervous system and thus lacks somatic pain fibers. The appendiceal artery, a branch of the ileocolic artery, provides the blood supply, and is encased in the mesoappendix, a short extension of ileal mesentery. Similar to the terminal ileum, the submucosa harbors numerous lymphoid follicles.

Most nonhuman mammals have no appendix, which was considered support for the long-standing theory that it was a vestigial organ that may have assisted with cellulose digestion but 1 had no current function. More recently, however, investigators have proposed an immune-related role as a repository for beneficial bacteria of the microbiome and a site of defense against pathogens.[2] The gut microbial biofilm is an extracellular matrix of mucin and immunoglobulins, produced by mucous cells and abundant lymphoid tissue of the appendix, containing densely packed bacterial communities that line the gut lumen.[3] The microbiome is thought to aid in digestion, provide a barrier, elaborate immune responses to pathogens, interact with hormones such as insulin, and to play a role in obesity and cardiovascular health.[4,5] Theoretically, if an enteric pathogen were to destroy the colonic microbiome, the size and shape of the appendix would facilitate a protected space for normal flora that could then repopulate the colon.

APPENDICITIS

Etiology and Pathophysiology

At more than 270,000 cases annually, acute appendicitis is one of the most common urgent abdominal conditions in the United States with a lifetime risk of 6% to 9%.[6] Due to its 2 unique structure, inflammation of the appendix or acute appendicitis generally is considered the result of a closed loop obstruction, either by a foreign body such as a fecolith or alternatively by inflammation of lymphoid aggregates, effectively blocking the appendiceal orifice. The ensuing bacterial entrapment causes further activation of lymphoid cells, cytokines, and edema; all the while, mucus accumulates contributing to luminal pressure. The resultant dilation leads to increased mural pressure, venous congestion, ischemia, and ultimately necrosis and perforation. This convenient etiologic explanation is likely accurate in many cases. The common finding of a fecolith could explain the higher prevalence of appendicitis among persons who consume a Western diet.[7] The finding of lymphoid hyperplasia could explain the higher prevalence of appendicitis among persons between the ages of 10 and 20, who have substantially more lymphoid tissue in the appendiceal submucosa.

There is also evidence, however, that appendicitis occurs in the absence of luminal obstruction.[8] Several hypotheses have been advanced to explain this phenomenon but most remain speculative. The "hygiene hypothesis"[9] proposed that adaptive immunity after early pathogen exposure conveys a protective effect, reducing the risk of lymphoid hyperplasia in the appendix. With progressively better living conditions in the early 20th century, young children were exposed to fewer enteric pathogens and therefore presumably became more prone to aberrant immune responses (nonobstructing lymphoid hyperplasia) with concomitant increased incidence of appendicitis. Recent evidence that acute appendicitis is actually less common among those with higher socioeconomic status[10] contradicts the hygiene hypothesis, but the study authors did not address the difference in antigen exposures among those of low socioeconomic status in the early 20th century versus the early 21st century. Although there is little evidence to support the hygiene hypothesis in appendicitis, allergists and immunologists are actively investigating variations of it related to inflammatory bowel disease and other autoimmune diseases. Another hypothesis to explain appendicitis in the absence of obstruction is that specific bacterial or viral pathogens induce ulceration of the appendiceal mucosa, permitting bacterial invasion of the wall and inciting an inflammatory cascade.[8] While a number of bacterial pathogens

have been identified and associated viral agents include Coxsackie, adenovirus, measles, and cytomegalovirus, most study sample sizes are too small to draw reliable conclusions.

3 Although appendicitis traditionally was thought to progress steadily until perforation, a more recent theory posits that complicated (perforated) and uncomplicated appendicitis may have different etiologies, suggesting that they should be treated as different entities. An analysis of the National Hospital Discharge Survey between 1975 and 2006 described outbreaks and seasonal variation in the diagnosis of uncomplicated appendicitis,[11] supporting an infectious etiology, and noted epidemiologic similarities between uncomplicated appendicitis and influenza that were not identified for *perforating* appendicitis.[12] A more recent study identified geographic clustering of uncomplicated appendicitis cases that was not present for cases of complicated, or perforating, appendicitis.[10] Still others[8,13] have identified specific bacteria that may play a role in perforating versus nonperforating appendicitis but these studies are subject to serious sample size limitations and require confirmation through larger studies. One such study, the Microbiology APPendicitis ACuta (MAPPAC) trial, is currently accruing patients with CT-confirmed perforated and nonperforated appendicitis to study microbiologic and immunologic characteristics at the time of diagnosis and 12 months after treatment.[14] While the MAPPAC trial study design is complex, drawing from multiple existing clinical trials, it may shed light on high-risk versus protective bacteria within the gut lumen and may clarify the unintended outcomes of treatment on the microbiome.

Diagnosis

History and Physical Examination

4 Vague periumbilical pain, the most common symptom of early appendicitis, can be attributed to the embryologic origin of autonomic fibers in the midgut. As the appendix becomes increasingly inflamed, it activates somatic pain fibers in the parietal peritoneum. Most often, this will be at McBurney point, one-third of the distance from the anterior superior iliac spine to the umbilicus. The numerous potential locations of the middle and tip of the appendix can result in a confusing array of possible symptoms, as

reflected by the variety of signs associated with different anatomic sites (**Table 71.1**). Additional symptoms can include nausea, vomiting, diarrhea, constipation, and even burning with urination, although all are unlikely to be as severe or as progressive as pain.

Table 71.1 Signs of Acute Appendicitis on Physical Examination

Name	Description	Implication
McBurney Sign	Pain with pressure to McBurney point	Right lower quadrant inflammation
Dunphy Sign	Right lower quadrant abdominal pain with abdominal wall flexion, for example, cough	Inflammation of the parietal peritoneum
Rovsing Sign	Referred pain at the right lower quadrant after pressure to the left lower quadrant abdomen	Right lower quadrant inflammation
Psoas Sign	Right lower quadrant abdominal pain upon tapping the right heel	Retrocecal inflammation
Obturator Sign	Pain with internal and external rotation of the right hip	Pelvic inflammation

Physical examination signs can be just as ambiguous as the clinical history. Patients may have a low-grade fever that is rarely higher than 102°F and may or may not have mild tachycardia. Although tenderness to pressure at McBurney point is highly suggestive, it is not entirely reliable, especially among women who may be experiencing ovarian torsion or cystic disease. Conversely, cervical motion tenderness during a pelvic examination may indicate an inflamed pelvic appendix rather than a gynecologic condition.

Rebound tenderness and involuntary guarding, or contraction of the abdominal wall in response to pressure, can help to clarify peritoneal irritation. To establish retrocecal appendicitis, stimulating the iliopsoas muscle by tapping the heel or extending the right hip may be helpful.

Laboratory and Imaging Studies

The white blood count and a urine analysis are the most important laboratory values in the diagnosis of appendicitis, although obtaining C-reactive protein is becoming more common. While the white blood count may be normal, it is more likely to be in the slightly high range from 10 to 14,000 white blood cells per mL. Urine analysis may show increased leukocytes or microscopic hematuria. In the setting of a suspicious history and physical examination, a C-reactive protein level >10 mg/mL is suggestive of acute appendicitis and >50 mg/mL suggests complicated appendicitis.

Given the imprecision of clinical history, physical examination, and laboratory signs, several authors have proposed grading schemes to assist with diagnosis (**Table 71.2**). The rationale for a scoring system rather than simply relying on imaging is based on concerns for radiation associated with CT scan, especially among children, the inaccuracy and operator dependency of ultrasound, and the absence of a role for plain radiographic imaging. In a retrospective study of 747 consecutive children who presented to a Dutch hospital with symptoms concerning for appendicitis, a head-to-head comparison of the three grading schemes was performed. Thirty-six percent of patients overall were diagnosed with acute appendicitis. The area under the receiver-operator curve of the appendicitis inflammatory response (AIR) score was 0.90, the Alvarado score was 0.87, and the pediatric appendicitis score was 0.82. In a study of adult patients, the AIR continued to outperform the Alvarado score.[15]

Table 71.2 Grading Schemes to Assess Risk of Acute Appendicitis

Scoring System	Symptoms (Points)	Signs (Points)	Laboratory Values (Points)	Score (Sum of Points)	Recommendation
Alvarado Score	Migration of pain (1) Anorexia (1) Nausea/ vomiting (1)	Right lower quadrant tenderness (2) Rebound pain (1) Elevated temperature ≥37.3°C or 99°F (1)	Leukocytes ≥10,000 (2) Differential ≥75% polymorphonuclear cells (1)	5–6 7–8 9–10	Compatible with appendicitis; observation Probable appendicitis; surgery High probability of appendicitis; surgery
Pediatric Appendicitis Score (PAS)	Migration of pain (1) Anorexia (1) Nausea/ vomiting (1)	Right lower quadrant tenderness (2) Cough/hopping/ percussion/tenderness in the right lower quadrant (2) Elevated temperature ≥37.3°C or 99°F (1)	Leukocytes ≥10,000 (2) Differential ≥75% polymorphonuclear cells (1)	≤5 ≥6	Not appendicitis; observation Appendicitis; surgery
Appendicitis Inflammatory Response Score (AIR)	Nausea/ vomiting (1)	Right lower quadrant tenderness (1) Rebound tenderness (1, 2, 3) Elevated temperature ≥38.5°C	Leukocytes 10,000–15,000 (1); ≥15, 000 (2) Differential polymorphonuclear cells 70–84% (1); ≥85% (2) C-reactive protein 10–49 mg/ mL (1); ≥50 mg/mL (2)	0–4 5–8 9–12	Low probability of appendicitis Indeterminate group; inhospital observation with additional imaging or diagnostic laparoscopy High probability of appendicitis; surgery

Adapted from Macco S, Vrouenraets BC, de Castro SMM. Evaluation of scoring systems in predicting acute appendicitis in children. *Surgery* 2016;160(6):1599–1604.

The diagnostic utility of imaging studies was previously subject to some debate. Ideally, imaging studies should be sufficiently accurate to help the clinician to balance timeliness of treatment with a reduction in unnecessary operations. As noted, ultrasound is operator dependent and not reliably accurate but may still be favored among children as a means to spare radiation exposure. Signs of appendicitis by ultrasound include a target lesion (thick-walled, noncompressible lumen), peritoneal fluid, or abscess.

Arguments against the use of CT were based on the now-refuted belief that appendicitis inexorably progressed to perforation and therefore mandated a rapid operation; CT scans were seen as time consuming and unnecessary since a negative appendectomy rate of 15% to 20% was acceptable. Although early CT scans did not have the precision necessary to reduce 5 the rate of negative appendectomies,[16] technologic advances and a paradigm shift in surgical culture over the past 15 years have led to standard use of helical CT with thin-cut slices and intravenous contrast for suspected appendicitis in adult patients.[17] Oral and rectal opacification are now

believed to improve neither sensitivity nor specificity. Signs of appendicitis on CT scan include appendicolith, mesenteric fat stranding, diameter >10 to 13 mm, appendiceal wall thickening >3 mm, and phlegmon (**Fig. 71.1**); complicated or perforated appendicitis can be identified through periappendiceal gas or abscess. Because radiation exposure is an increasing concern with CT scan, a single-institution randomized controlled trial powered for noninferiority compared low-dose and standard-dose CT scans among 891 adults with suspected appendicitis.[18] The study demonstrated similar rates of negative appendectomy (3.2% and 3.5%) and similar rates of perforation (26.5% and 23.3%), concluding that low-dose CT is not inferior to standard-dose CT for the diagnosis of appendicitis in young adults. Although uptake of a low-dose protocol has been slow, additional randomized controlled trials have supported these findings.[19] While magnetic resonance imaging (MRI) has high sensitivity and specificity, it is currently an expensive and uncommon approach for diagnosing appendicitis.

Differential Diagnosis

The differential diagnosis must be considered during the preliminary workup and should include enteritis, pyelonephritis, nephrolithiasis, gynecologic issues such as ovarian torsion or cyst, tubo-ovarian abscess or tubal pregnancy, small bowel or cecal obstruction or perforation, Meckel diverticulitis, and cecal diverticulitis or cancer. Clinical examination, laboratory studies, and CT scan can help to distinguish most but not all of these conditions as demonstrated by a low but ongoing negative appendectomy rate.

Management

Complicated Appendicitis

Traditional management of appendicitis has focused on performance of surgical resection as rapidly as possible after diagnosis, and appendectomy remains the most common urgent abdominal operation in the United States. As noted above, much of the rationale for urgent surgery was related to a perceived risk of impending perforation and a desire to avoid sepsis. 6 Complicated appendicitis refers to appendicitis accompanied by gangrene,

abscess, or phlegmon, indicating an extant micro- and macroperforation, and occurs in up to 10% of acute appendicitis cases.

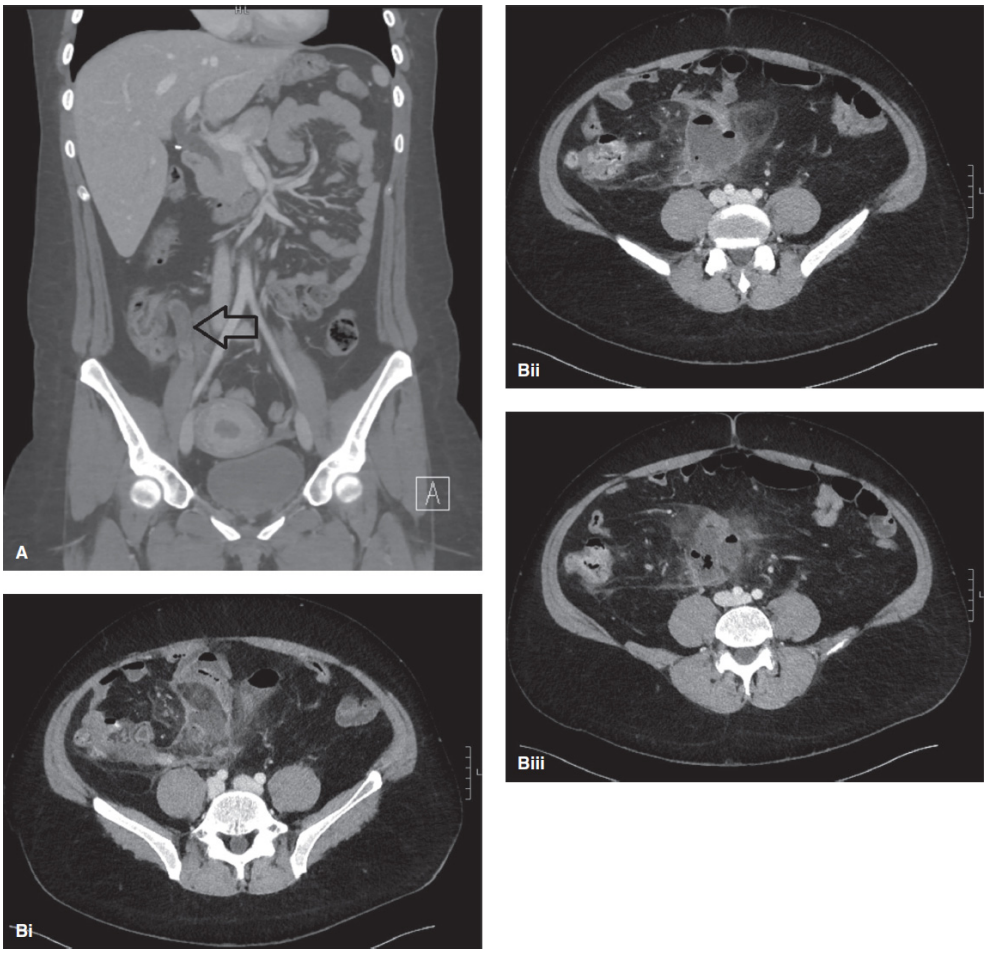

Figure 71.1 Computed tomography displaying (**A**) nonperforated appendicitis with a distended, thick-walled appendix; (**B**) perforated appendicitis with an adjacent abscess.

In the setting of complicated appendicitis, there are essentially three management options. First, an operation to remove the appendix can be performed urgently either open or laparoscopically. The second management option entails controlling infection and reducing inflammation using antibiotics, percutaneous drainage if possible, and supportive measures such as bowel rest and intravenous hydration. After a 6- to 12-week interval, laparoscopic or open appendectomy is performed. The rationale for interval appendectomy rather than urgent appendectomy is that nearby structures are less likely to be injured when inflammation has subsided. Interval

appendectomy was first described in the mid-20th century and gained traction in the early 2000s as preoperative CT scans became common practice, enabling preoperative identification of appendiceal abscesses.

As interval appendectomy became an accepted management strategy, surgeons began to question the need for any appendectomy thereby giving rise to the third treatment option for complicated appendicitis: antibiotics, drainage if possible, and supportive measures followed by no appendectomy. Proponents of no further treatment cite a low rate of previously unrecognized pathology, low rate of recurrent appendicitis, and a high operative complication rate. By contrast, advocates of interval appendectomy for complicated appendicitis cite the concern for possible cystadenoma or malignancy, early recurrence, and low complication rate. To be fair, the complication rate is generally less than 10% and complications are often limited to wound infection or abdominal abscess; the sheer volume of appendectomies, however, makes the absolute complication rate higher than many other types of operations.[20] Surgeon investigators on each side of the debate support their positions with single-institution case series for the most part,[21] and indeed practicing general surgeons have been shown to make clinical decisions based on heuristic-based concern for adverse outcomes more than deliberative evaluation of the data.[22] Regardless, 7 adult patients with perforated appendicitis who do not undergo an immediate or interval appendectomy must be evaluated with a follow-up CT and/or colonoscopy in order to ascertain the absence of other pathology such as Crohn disease or cancer.

Surgical Approaches

The classic open appendectomy operation starts over McBurney point with an oblique incision of the skin in Langerhans lines, incision of the external oblique aponeurosis, and a muscle-splitting incision before opening the peritoneum. If the appendix is not immediately apparent, the terminal ileum is grasped and followed to the cecum. At times, depending on the location of the appendix and the patient's body habitus, it may be necessary to mobilize the cecum laterally to locate the appendiceal base. If the base is obscured by substantial inflammation, following the teniae proximally can be helpful. The appendiceal artery is divided and the appendiceal base is ligated usually

with a stapler or suture. The appendix is amputated just distal to ligation and removed. Previously, the appendiceal stump was inverted with suture to prevent mucocele formation or fistula but there are no data to support this step. The peritoneum and pelvis then should be irrigated and the abdominal wall is closed in layers. Recent data indicate no benefit of leaving a drain or of delayed skin closure.[23]

Laparoscopic appendectomy, first described in 1983,[24] is essentially the same operation as open appendectomy, usually performed through three laparoscopic ports instead of an open incision. With the exception of the laparoscopic specific procedures such as insufflation of the abdomen, each step is the same and the major potential risk categories (bleeding, abscess, wound infection, damage to nearby structures) are also the same. Compared with open appendectomy, the laparoscopic approach leads to fewer wound infections, reduced hospital stay, and reduced pain, and is an advantageous approach in the setting of uncertainty or unexpected operative findings with a normal appendix.[25] Both randomized trials and case series have demonstrated that the laparoscopic approach confers about 35% higher odds of organ space surgical site infection than the open approach, but the risk remains well under 10%. A 2010 cohort study[26] that included over 32,000 patients from 222 U.S. hospitals demonstrated that, in spite of these benefits, open appendectomies are still performed in about 20% of cases, largely among elderly patients or those who were at higher risk due to comorbid disease.

Single-incision laparoscopic surgery (SILS), in which a single port site scar is hidden in the umbilicus, has garnered interest for it is a cosmetic advantage over conventional laparoscopic appendectomy. Although case duration and expense can be much higher, the single-incision approach in pediatric surgery is increasingly accepted. A large single-institution cohort study found that the need for conversion to conventional laparoscopy was associated with obesity, male sex, or complicated appendicitis.[27] Another study of 970 pediatric patients with appendicitis found that an adaptive approach utilizing one, two, or three ports depending on operative difficulty was associated with substantial cost savings.[28]

In the event that an open or laparoscopic operation is performed and a normal appendix is identified, a search for other pathology should be conducted. Specifically, the surgeon should examine the terminal ileum for

evidence of Crohn disease or more proximally a Meckel diverticulum, the cecum for diverticulitis, Crohn disease, or neoplasm, the sigmoid colon (if redundant) for evidence of diverticulitis, Crohn disease, or neoplasm, and in a woman, the adnexal structures for evidence of cysts, inflammation, infection, neoplasm, or other mass. A major advantage of the laparoscopic approach is the ease of examination of and potentially intervention on nonappendiceal structures.

Nonoperative Management of Uncomplicated Appendicitis

Traditional management of appendicitis has been based on the poorly supported hypothesis that appendicitis is a progressive disease—that is, a disease that will culminate in appendiceal perforation and pelvic abscess if untreated surgically. This hypothesis was so widely accepted that, throughout the 20th century, an unnecessary or negative appendectomy (i.e., no histologic evidence of appendicitis) rate of 15% was considered acceptable within the surgical community.[16] Even in the best case scenario, an appendectomy is painful and requires several weeks of recovery (3 to 4 weeks for laparoscopic and 4 to 6 weeks for open surgery) before return to usual activity. Recovery time is especially pertinent because appendicitis is more common among active young adults[29] who are more likely than their older counterparts to hold physically demanding jobs, to have a high deductible health insurance plan, and to lack paid sick leave. Appendectomy also has a complication rate from 3% to 21%[20,29,30] and is costly at a median charge per case of $33,000 in 2012.[31]

Noting circumstances in which delayed or omitted appendectomy has *not* resulted in peritonitis, or even in progression of disease, many surgical investigators have proposed that nonoperative management is a viable option among selected patients.[32] Thus far, five randomized trials suggest that use of broad-spectrum antibiotics may change what was perceived as the natural history of acute appendicitis and that many adult patients can be treated with antibiotics only[30,33–36] and one U.S. study 8 is currently underway.[37] The largest and most recent, the APPendicitis ACuta (APPAC) trial,[30] compared antibiotic therapy with appendectomy and found that among 257 adults with computed tomography (CT) confirmed uncomplicated appendicitis who were

treated with antibiotics, 73% did not require appendectomy within 1 year of initial presentation. Among the 27% in the nonoperative management arm who had appendectomy following failure of antibiotics alone, the surgical complication rate was no higher than among patients who underwent appendectomy initially. The trial was designed as a noninferiority trial, meaning that it was powered to detect whether nonoperative management with antibiotics was inferior to the gold standard, that is, appendectomy. The study team assigned the minimal clinically important difference (MCID) to be less than or equal to 24% "failure." That is, if nonoperative management failed in less than or equal to 24% of cases, it would be deemed noninferior to appendectomy. Based on the assigned MCID, the authors had to conclude that nonoperative management with antibiotics had not been shown to be noninferior.

Critics of the study pointed out that patients were highly selected (nonpregnant adults aged 19 to 60 with CT-demonstrated uncomplicated appendicitis and no evidence of an appendicolith), were treated with 3 days of a selected antibiotic not commonly used in the United States, and underwent open appendectomy which is also increasingly uncommon; others questioned the assignation of MCID.[38] The implications were that the patient cohort and the treatment delivered was not representative of U.S. practice. Another Finnish study, the Peri-Appendicitis Acuta (peri-APPAC) trial,[39] in which patients with complicated appendicitis who had been treated with antibiotics and drainage if necessary were randomized 3 months later to appendectomy versus MRI. This study was terminated prematurely on ethical grounds due to 20% rate of malignancy, about tenfold higher than expected from a meta-analysis of 61 studies.[40] Finally, recently published 5-year results of the APPAC study[41] indicated that another 12% of patients eventually underwent appendectomy more than 1 year after the initial presentation.

Taken together, these findings added fuel to the hot debate in the surgical community about the safety of nonoperative management[42]—and lent credence to the criticism that patients and surgeons in Finland may differ in fundamental ways from those in the United States and other countries. There is one aspect of nonoperative management upon which all agree, however: no studies to date support a nonoperative approach for every patient who presents with signs and symptoms of acute appendicitis. Identifying

appropriate patients for nonoperative management—and importantly those for whom such an approach is likely to fail—is an area of keen interest among surgical researchers. Among the currently open questions are how to compare the relative benefits, harms, and costs of each treatment option and under what circumstances they differ. The risk of postoperative complications, for example, varies widely by patient age, comorbid disease, and clinical presentation. Moreover, the potential harms of broad-spectrum antibiotics, radiation exposure, and appendicitis recurrence are not easily quantified. The COVID pandemic may provide a natural experiment that will clarify clinical features or baseline patient characteristics to better guide nonoperative management.[43]

Special Populations

Pregnancy

Appendicitis is the most common nonobstetrical urgent abdominal condition among pregnant women, followed closely by cholecystitis. Both can be difficult to diagnose, especially in late pregnancy, due to common pregnancy symptoms of general nausea, mild leukocytosis, and compression or relocation 9 of structures by the enlarging uterus. Consequently, appendicitis in pregnancy is associated with late presentation, maternal morbidity, and fetal mortality. In a cohort analysis of 3,133 pregnant women who underwent appendectomy,[44] fetal loss and preterm delivery occurred in 6% and 11% of those with complicated appendicitis compared with 2% and 4% of those with uncomplicated appendicitis. Given the risk, nonoperative management is not considered an acceptable option among pregnant women. While there has been some debate about the safety of a laparoscopic versus open approach, several systematic reviews[45–48] indicate that in experienced hands, there is no elevated risk of fetal loss or preterm labor based on surgical approach.

Elderly Patients

The diagnosis of appendicitis in frail or elderly patients may be challenging and is often delayed. Elderly patients are much more likely to present with complicated and specifically perforated appendicitis. In contrast to younger

patients, a precipitous leukopenia may be identified rather than leukocytosis. In addition to perforation, the rate of unexpected malignancy is substantially higher as patient age increases. In the Peri-APPAC trial noted above,[39] all cases of malignancy occurred in patients aged >40 years. Among elderly patients with apparently perforated appendicitis, antibiotic treatment alone is inadequate and a planned resection should follow. In the setting of suspected cancer, a very conservative approach traditionally would include open appendectomy through a midline incision. A recent meta-analysis compared morbidity and mortality among 12 observational studies of 126,000 elderly patients who had undergone laparoscopic and open approaches.[49] Although the meta-analysis was limited by selection bias within studies and heterogeneity between them, it persuasively reported only one-third of the mortality and two-thirds the morbidity using laparoscopy compared with open surgery.

Low- and Middle-Income Countries

Population based studies of disease in low- and middle-income countries present a particular challenge, partly due to lack of reliably recorded health data that can be compared with high-income countries. Nonetheless, appendicitis typically has been considered a phenomenon of industrialized countries. A systematic review[7] of 120 population-based studies over the last 100 years found that in Western industrialized countries rates of both uncomplicated and complicated or perforated appendicitis have stabilized, while rates of surgery are in decline. The authors surmise that nonoperative management is increasingly accepted and being deployed. They note as well that, among currently industrializing countries in Asia, the Middle East, South America, and Africa, the incidence of acute appendicitis has been increasing, much as the United States did in the mid-20th century. The authors concluded based on these data that early industrialization contributes to increased incidence which later can be expected to plateau. A multicenter international cohort study[50] by the National Institute for Health Research's Global Health Research Unit in the United Kingdom tracked outcomes of surgery prospectively over 6 months with 30-day follow-up. Although the availability of laparoscopy was related to the Human Development Index (HDI), even among low-HDI countries, a laparoscopic approach was

associated with about three- to fourfold reduction in 30-day perioperative complications and surgical site infections.

APPENDICEAL NEOPLASMS

Neuroendocrine Tumors

About two-thirds of all appendiceal neoplasms originate from neuroendocrine tissue and about half of all neuroendocrine neoplasms in the gut are located within the appendix. Neuroendocrine tumors of the appendix are usually diagnosed incidentally after appendectomy. Most are low grade, confined to the appendix, and small at the time of diagnosis. Appendiceal neuroendocrine tumors <2 cm in size and without the advanced features of high mitotic index, mesoappendiceal invasion, or positive margin can be managed by appendectomy alone.[51,52] Follow-up right colectomy is recommended for neuroendocrine tumors with advanced features or size ≥2 cm due to concern for lymphatic spread. Hematogenous metastasis to the liver is also possible but extremely rare. So-called goblet cell carcinoid tumors have been reclassified as adenocarcinoma as they are not of neuroendocrine origin.[53]

Appendiceal Mucinous Neoplasms

Low-grade appendiceal mucinous neoplasms (LAMNs) and high-grade appendiceal mucinous neoplasms (HAMNs) are characterized by a dilated, mucus-filled appendiceal lumen. The term mucocele is no longer considered a pathologic diagnosis. LAMN and HAMN do not metastasize hematogenously or lymphatically and rarely invade structures; instead, in a phenomenon known as "pushing invasion," the wall of the appendix is dissected by acellular mucin which can then spread over surfaces.[53] An appendix in which LAMN is entirely contained without spillage into the peritoneal cavity can be safely followed with imaging. In the presence of intraperitoneal spillage, however, pseudomyxoma peritonei, a condition in which mucin inexorably accumulates within the abdominal cavity is a real concern. Pseudomyxoma peritonei, while not invasive, entraps structures and

fills the paracolic gutters, diaphragmatic peritoneum, pelvic peritoneum, and omentum. In the setting of perforated mucinous neoplasm, peritoneal stripping and potentially hyperthermic intraperitoneal chemotherapy (HIPEC) should be strongly considered. HAMN contains high-grade dysplasia but no infiltrative features. As a newly characterized diagnosis, its behavior is not well understood but it is believed to be more likely to contribute to aggressive pseudomyxoma peritonei than LAMN. Mucinous adenocarcinomas are similar to HAMN but also infiltrate surrounding structures and histologically display tumor budding surrounded by desmoplastic stroma. If the patient can tolerate it and disease is not too far advanced, HIPEC is appropriate in these cases.

Adenocarcinomas

Adenocarcinomas of the appendix are extremely rare and are characterized essentially identically to those of the colon. Identification of a nonmucinous adenocarcinoma should be followed by a right colectomy. Goblet cell adenocarcinomas have been recently reclassified, as noted above, and can exhibit a range of tumor biology including transmural spread. These tumors can be hard to distinguish pathologically from signet cell carcinoma. In both cases, aggressive treatment with right colectomy and a search for transmural, lymphatic, and hematogenous spread is warranted.

Abdominal Wall Hernias

Benjamin K. Poulose, Jeremy A. Warren, and Robert J. Fitzgibbons Jr

Key Points

1 The concept of the “abdominal core” aims to capture the complex relationships of the circumferential soft tissues of the diaphragm superiorly, abdominal wall and flanks anterolaterally, and pelvic floor inferiorly. Maintenance of abdominal core health may include surgical (e.g., hernia repair) and nonsurgical interventions (e.g., physical therapy) with an emphasis on maximizing core stability and function.

2 Major risk factors for the development of abdominal wall hernias include chronic obstructive pulmonary disease, smoking, high intra-abdominal pressure, collagen vascular disease, thoracic or abdominal aortic aneurysm, peritoneal dialysis, abnormalities in the regulators of collagen homeostasis matrix metalloproteinases (MMPs) and their tissue inhibitors (TIMPs) in association with local cytokine induction, and an increased type I: type III collagen ratio.

3 Inguinal hernias constitute approximately 75% of abdominal wall hernias, with femoral hernia accounting for 5%. Femoral hernias are more common in women, but a woman with a groin hernia is still five times more likely to have an inguinal hernia (usually indirect) than a femoral. Incisional, umbilical, and epigastric hernias account for 15%, and miscellaneous hernias make up the other 5%.

4 Watchful waiting is an acceptable alternative to routine repair for male inguinal hernia patients with minimal symptoms. This does not apply to females because of the higher risk of a hernia accident. Patients in the watchful waiting group should be aware of the likelihood of long-term crossover into treatment group.

5 The performance of a “tension-free” inguinal hernia repair reduces the risk of recurrent hernia to a rate generally reported to be less than 2%.

6 The literature dealing with groin hernia in women is insufficient making management decisions difficult. In general, a laparoscopic approach is recommended if expertise is available.

7 The frequency of at least some long-term groin pain after inguinal herniorrhaphy is approximately 10% at 1 year with moderate to severe pain in 1% to 2%.

8 Abdominal wall dynamics are better addressed with muscles reapproximated, contributing to improved quality of life and patient satisfaction.

9 Abdominal wall reconstruction and myofascial release (separation of an abdominal wall fascial layer from a muscular layer) are useful tools in the armamentarium of the hernia surgeon.

INTRODUCTION

One of the most frequently performed operations by general surgeons worldwide is the repair of an abdominal wall hernia. According to the National Institute of Diabetes and Digestive and Kidney Diseases (NIDDK), in the years 2009–2010, abdominal wall hernias were responsible for 3.6 million ambulatory care visits, 380,000 hospitalizations, and 1,322 deaths in the United States.[1] In the past, most training programs relegated the repair of abdominal hernias to the junior members of the surgical team with little regard for results.[2] However, as we being to understand the complexities and relationships of the abdominal wall to other components of the abdominal core and its overall function, this is changing rapidly. Interest by the academic community in the science behind hernia repair as well as an explosion in device development by industry has resulted in significant changes to many surgeons' practices. In this chapter, we have provided a detailed description of the abdominal wall anatomy, an understanding of which is key to successful hernia repair.[3] We have then described the different treatment options with their available evidence and have included some of the newer developments in the field of hernia surgery.

ANATOMY OF THE ABDOMINAL CORE

The concept of the "abdominal core" aims to capture the complex relationships of the circumferential soft tissues of the diaphragm superiorly, abdominal wall and flanks anterolaterally, and pelvic floor inferiorly. Maintenance of abdominal core health includes exercise, physical therapy, medical therapy (including compression garment/truss use), alternative medical therapies, surgical intervention (e.g., hernia repair), and measures to prevent disease (e.g., hernia prophylaxis). Disease processes 1 involving abdominal core health include intrinsic diseases of the abdominal wall (e.g., hernia, diastasis, athletic pubalgia or core muscle injury, benign and malignant tumors) and extrinsic diseases of the abdominal wall (e.g., prosthetic and intervention-associated complications, benign and malignant tumors).[4] Most pertinent to abdominal core surgeons, the anatomy of the abdominal wall and the inguinal region are presented, first from the viewpoint of the surgeon using open techniques and subsequently from the perspective of the surgeon utilizing a minimally invasive approach. Anatomic terms for which synonyms and eponyms are commonly used are listed in **Table 72.1**. Specific anatomic nomenclature can now be found in *Terminologia Anatomica,* the successor to *Nomina Anatomica.*

Table 72.1 Anatomic Terms with Common Synonyms and Eponyms

Fascial Structures/Spaces
Fatty layer of superficial fascia; panniculus adiposus; Camper fascia
Investing fascia of external abdominal oblique; fascia innominata
Membranous layer of superficial fascia; Scarpa fascia
Retroinguinal space; space of Bogros
Retropubic space; space of Retzius
Ligamentous Structures
Iliopectineal ligament; iliopectineal arch
Iliopubic tract; Thompson ligament (band)
Inguinal ligament; Poupart ligament
Lacunar ligament; Gimbernat ligament
Pectineal ligament; Cooper ligament
Aponeurosis-Derived Structures
Arcuate line; semicircular line; linea semicirculars; line of Douglas
Falx inguinalis (often incorrectly referred to as *conjoined tendon*)
Reflected inguinal ligament; reflex ligament; Colles ligament
Semilunar line; linea semilunaris

The sheets of relatively thin muscles and aponeuroses that make up the abdominal wall would, individually, seem to predispose to visceral eventration. However, the laminar layout of these sheets over most of the wall precludes this in most cases. The most common sites of hernia formation are found between laminations, where only peritoneum and fascia are found between the viscera and skin. These weak areas are most important to the hernia surgeon and are described in detail in the subsequent sections dealing with the anterior and posterolateral abdominal wall and the inguinal region.

Diaphragm

The diaphragm forms the cranial "ceiling" of the abdominal core and separates the thoracic cavity from the abdominal cavity. The skeletal muscle of the diaphragm originates from the caudal aspect of the sternum, lower ribs,

and vertebrae forming a dome-shaped structure with a central membranous tendon. Unlike most other skeletal muscles, several vital structures pass through openings within the diaphragm including the esophagus, aorta, and inferior vena cava. The main arterial supply to the diaphragm include the musculophrenic and inferior phrenic arteries; venous drainage is obtained via the superior and inferior phrenic veins. Generally, vasculature of the diaphragm projects radially from the hiatal openings. The right and left phrenic nerves, originating from cervical roots C3–C5, enter the diaphragm mostly medially and branch radially outward. The esophageal hiatus has particular significance as it is a common site of herniation of intra-abdominal contents into the mediastinal space. The muscular right crus of the diaphragm, a critical landmark in hiatal hernia repair, has two components: a right and left pillar that form the esophageal hiatus itself. The left crus of the diaphragm itself typically does not encircle the esophagus. Functionally, the diaphragm is critical to breathing. As the diaphragm contracts, the thoracic cavity increases in volume, enabling inspiration. As the diaphragm relaxes, the recoil of the lungs and thorax allows for expiration. The diaphragm is also critical to forced expiratory functions such as coughing and sneezing.

Anterior Abdominal Wall and Flanks

Superficial Fascia, Vessels, and Nerves

The anterior abdominal wall does not consist solely of muscle and aponeurosis; it can also be the repository for copious amounts of adipose tissue (panniculus adiposus) in its superficial fascial layer, often called *Camper fascia.* This layer, which is continuous inferiorly with the outer layer of fascia covering the perineum and genitalia, also contains the dartos muscle fibers of the scrotum. The major blood vessels of the superficial fatty layer are the superficial epigastric vessels and superficial circumflex iliac vessels, which are tributaries of the femoral vessels. The superficial fascia is also replete with lymphatic vessels that drain into the inguinal lymph nodes inferior to the umbilicus. The lymphatic structures cross the inguinal ligament, so that they are potentially placed in the surgical field during open herniorrhaphy.

A second fascial layer in the superficial abdominal wall is the deep fascia of Scarpa. Although most commonly considered a distinct anatomic layer, Scarpa fascia actually consists of compressed fibrous components of the superficial fascia.[5] The deeper fibrous tissue of the superficial fascia forms the fundiform ligament of the penis (suspensory ligament of the female clitoris), continues onto the penis and scrotum, and ultimately fuses with the superficial fascia of the perineum.

The superficial fascia also fuses with the layer of fascia (fascia innominata) investing the external abdominal oblique muscle. This fascia is bound inferiorly to the inguinal ligament and pubis before continuing onto the thigh, where it blends with the fascia lata to seal the space beneath and inferior to the inguinal ligament, which is the inferior portion of the myopectineal orifice (**Fig. 72.1**). This portion of the inguinal region includes Hesselbach (inguinal) triangle superiorly and therefore constitutes the weakest aspect of the groin.

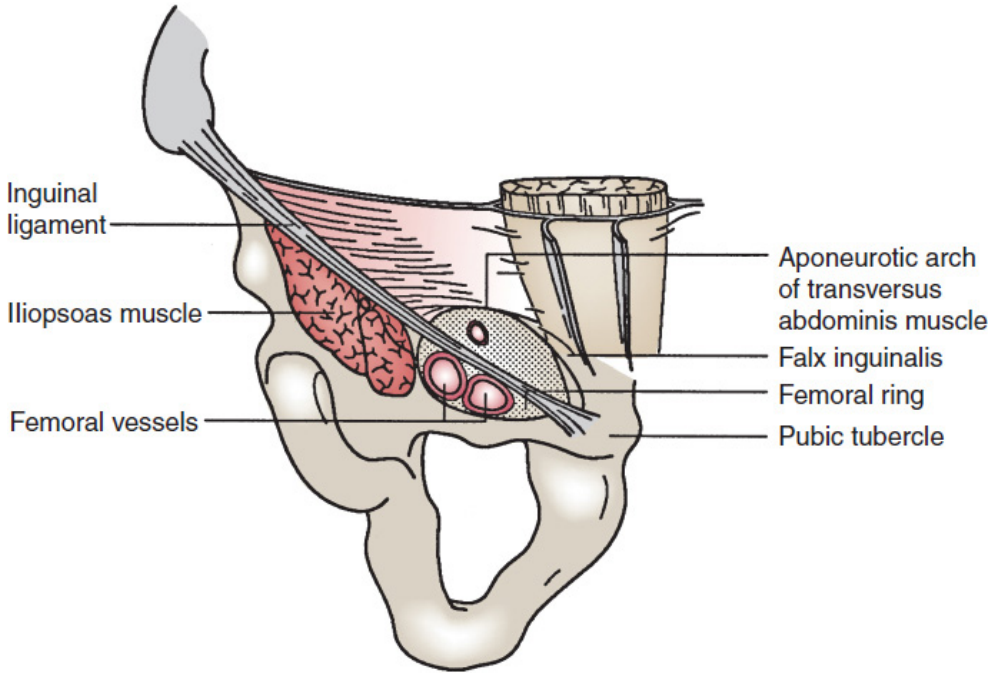

Figure 72.1 The myopectineal orifice. Superior to the inguinal ligament, this area includes the inguinal (Hesselbach) triangle. Inferior to the ligament, the orifice transmits the iliopsoas muscle, the femoral nerve and vessels, and the femoral canal and sheath. (Reproduced with permission from Wantz GE. *Atlas of Hernia Surgery*. New York: Raven Press; 1991:4.)

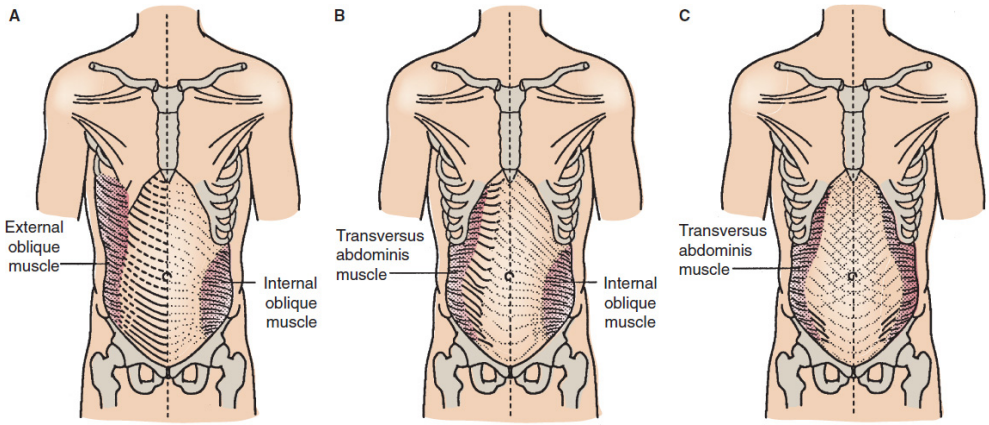

Figure 72.2 Pattern of crossing of the aponeurotic fascicles of the abdominal wall musculature. **A:** Fascicles from the right external oblique and anterior lamina of the left internal oblique. **B:** Fascicles from the right transversus abdominis and posterior lamina of the left internal oblique. **C:** Fascicles between the right and left transversus abdominis muscles.

The skin of the anterior abdominal wall is segmentally innervated in the familiar dermatome pattern. The nerve branches to this area are derived from the anterior and lateral cutaneous branches of the ventral rami of the 7th to 12th intercostal nerves and from the ventral rami of the first and second lumbar nerves. Disruption of one of these nerves is rarely noted by the postoperative patient because the dermatome fields overlap significantly. The anterior and lateral cutaneous branches reach the subcutaneous layer by coursing between the flat lateral muscles and by piercing the sheath of the rectus abdominis.

Anterior Musculature and Ligaments

The division of the wall into anterior and posterior segments is somewhat artificial because the anterior muscles, with the exception of the rectus abdominis, arise posteriorly and also form part of the posterior wall.

The three muscles of the lateral aspect of the anterior abdominal wall (**Fig. 72.2**) are composed of a variable amount of muscle with a large aponeurosis. The aponeurosis is the tendon of insertion for the lateral muscles, and it also forms the sheath of the rectus abdominis. The midline decussation of the three aponeuroses forms the linea alba. Fibrous tissue layers are of great importance to the hernia surgeon because of their ability to support sutures. *Fascia* and *aponeurosis* are terms commonly used to describe these fibrous

structures, but are often confused and used interchangeably. In this chapter, an aponeurosis is defined as the non–muscle-fiber-containing portion of a muscle usually present at insertion points. Muscle fibers are said to "give way" to the corresponding aponeurosis. Fascia, on the other hand, is the fibrous tissue that lines or envelops muscles.

External Abdominal Oblique Muscle and Associated Ligaments

The external abdominal oblique muscle (**Figs. 72.2** and **72.3A,B**) is the most superficial of the three lateral abdominal muscles. The external abdominal oblique arises from the posterior aspects of the lower eight ribs and interdigitates with both the serratus anterior and the latissimus dorsi at its origin. The direction of the muscle fibers varies from nearly horizontal in its upper portion to oblique in the middle and lower portions. The mostly horizontal fibers, which originate posteriorly, insert onto the anterior portion of the iliac crest. The obliquely arranged anteroinferior fibers of insertion fold on themselves to form the inguinal ligament. The remaining portion of the aponeurosis inserts into the linea alba after contributing to the anterior portion of the rectus abdominis sheath. Some fibers cross the linea alba to reinforce further the anterior rectus sheath of the opposite side.

The more medial fibers of the aponeurosis of the external oblique divide into a medial and a lateral crus to form the external or superficial inguinal ring. The spermatic cord (or round ligament) and branches of the ilioinguinal and genitofemoral nerves pass through this opening. The *inguinal ligament* (**Fig. 72.4**) is worthy of special consideration because of its important role as both a landmark and an integral component of many groin hernia repairs. The inguinal ligament is formed by obliquely oriented anteroinferior aponeurotic fibers of the external abdominal oblique. The ligament is formed when the aponeurosis folds beneath itself. Its lateral attachment is to the anterior superior iliac crest; its medial insertion is primarily on the pubic tubercle.

The medial insertion of the inguinal ligament in most persons is dual. One portion runs along the superior surface of the pubic tubercle and symphysis to form (or at least reinforce) the superior pubic ligament. The other portion is fan shaped and spans the distance between the inguinal ligament proper and

the pectineal line of the pubis. This fan-shaped portion of the ligament is called the *lacunar ligament* (**Fig. 72.4**). It blends laterally with the pectineal (Cooper) ligament.

Internal Abdominal Oblique Muscle and Aponeurosis

The middle layer of the lateral abdominal group is the internal abdominal oblique muscle (**Figs. 72.2** and **72.3B,C**). This muscle primarily arises from the iliac fascia along the iliac crest and forms a band of iliac fascia fused with the inguinal ligament. The uppermost fibers course obliquely toward the distal ends of the lower three or four ("floating") ribs. The muscle fibers of the internal oblique fan out following the shape of the iliac crest so that the lowermost fibers are directed inferiorly. These fibers arch over the round ligament, or spermatic cord. Some of the lower muscle bundles in the male join fibers of the transversus abdominis to form the cremaster muscle. The aponeurosis of the internal oblique (**Fig. 72.5A**) above the level of the umbilicus splits to envelop the rectus abdominis, reforming in the midline to join and interweave with the fibers of the linea alba. Below the level of the umbilicus (**Fig. 72.5B**), the aponeurosis does not split but rather runs anterior to the rectus muscle, continues medially as a single sheet, joins the anterior rectus sheath, and finally contributes to the linea alba. The aponeurotic portion of the internal oblique is widest at the level of the umbilicus.

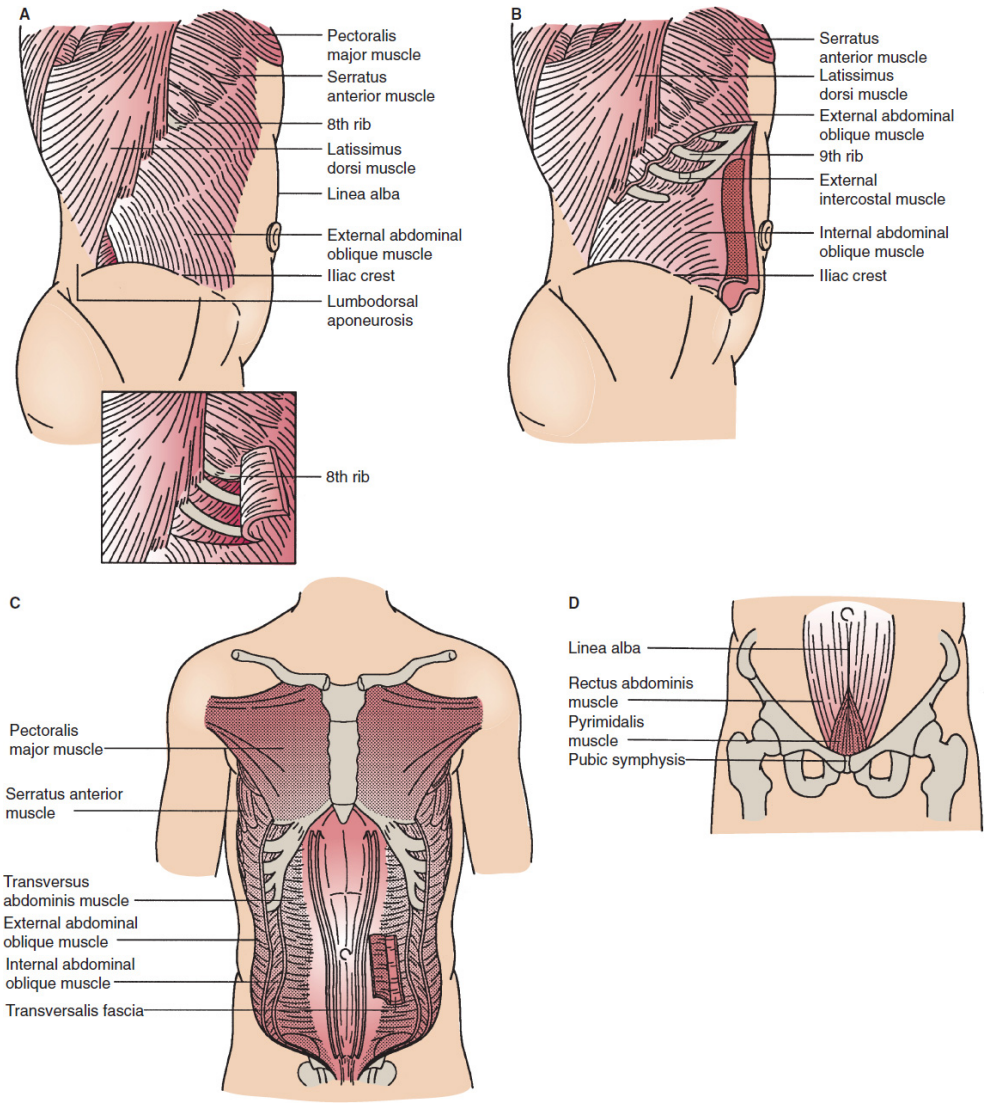

Figure 72.3 **A:** External oblique muscle and aponeurosis. **B:** Internal oblique muscle and aponeurosis. **C:** Transversus abdominis muscle and aponeurosis. **D:** Lower rectus abdominis and pyramidalis muscle. The linea alba is formed by the intermeshed fibers of the aponeuroses of the lateral muscle layers; it is tensed by the pyramidalis, which inserts into it.

Transversus Abdominis Muscle and Aponeurosis

The transversus abdominis muscle (**Figs. 72.2** and **72.3C**) arises from the fascia along the iliac crest and inguinal ligament and from the lower six costal cartilages and ribs, where it interdigitates with the lateral diaphragmatic fibers. The muscle bundles of the transversus abdominis for the most part run horizontally. The lower medial fibers, however, may

continue in a more inferomedial course toward the site of insertion on the crest and pecten of the pubis.

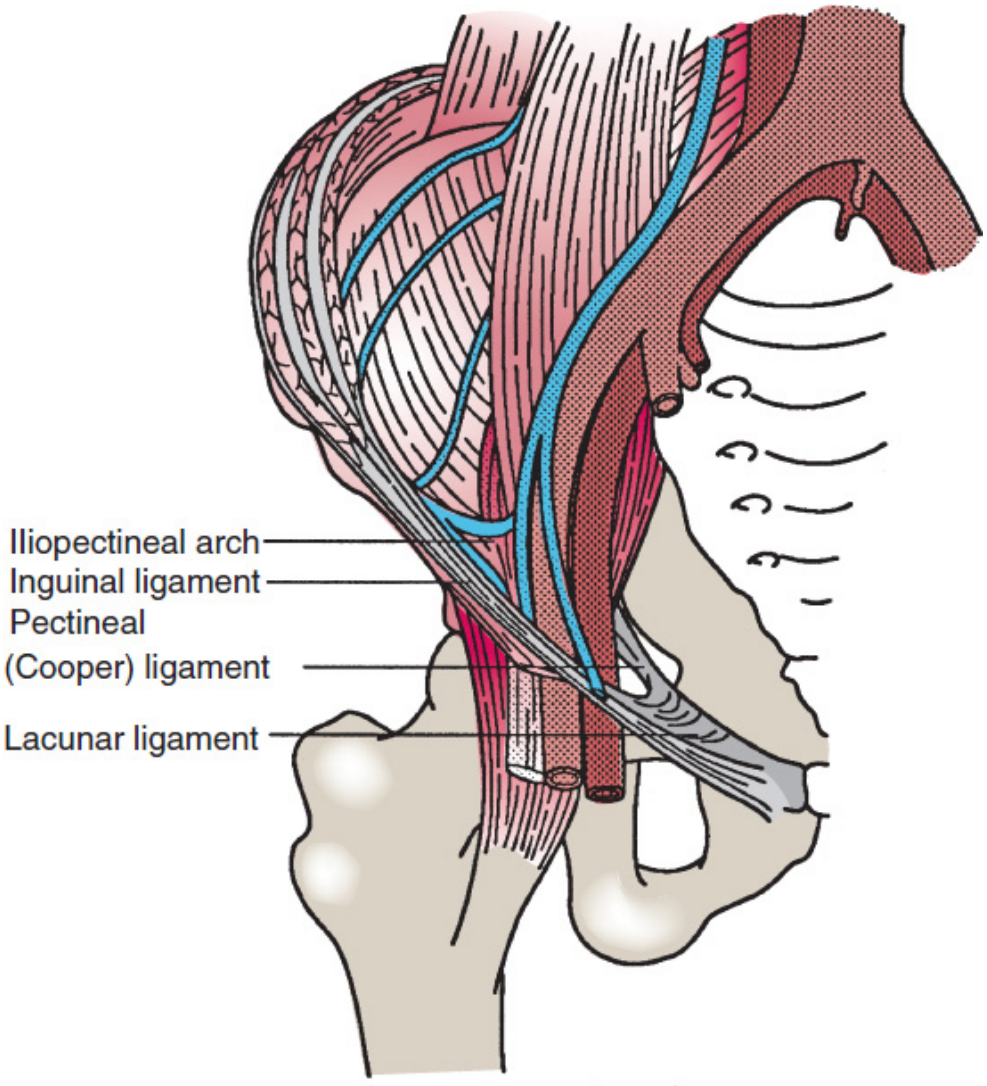

Figure 72.4 Ligamentous structures of the inguinal region. The iliopubic tract is not seen in this view because it is obscured by the inguinal ligament. The lacunar ligament is the expanded medial end of the inguinal ligament; on the pecten pubis, it blends with the inguinal (Cooper) ligament.

The aponeurosis of the transversus abdominis joins the posterior lamina of the internal abdominal oblique, forming above the umbilicus a portion of the posterior rectus sheath. Below the umbilicus, the transversus abdominis aponeurosis is a component of the anterior rectus sheath. The gradual termination of aponeurotic tissue on the posterior aspect of the rectus abdominis forms the arcuate line (of Douglas) (**Fig. 72.6**). The transversus

abdominis muscle and aponeurosis extend medial to the semilunar line. The medial aponeurotic fibers of the transversus abdominis insert on the pecten pubis and the crest of the pubis to form the falx inguinalis. These fibers infrequently are joined by a portion of the internal oblique aponeurosis; only then is a true conjoined tendon formed.[6]

The arch formed by the termination of the aponeurotic fibers of the transversus abdominis is called the *aponeurotic arch* (**Fig. 72.6**). The area beneath the arch varies. A high arch may be a predisposing factor in direct inguinal hernia. Contraction of the transversus abdominis causes the arch to move down toward the inguinal ligament in a kind of shutter mechanism, which reinforces the weakest area of the groin when intra-abdominal pressure is raised.

Rectus Abdominis

The rectus abdominis (**Figs. 72.3D** to **72.5**) forms the central and anchoring muscle mass of the anterior abdomen. The rectus muscle arises from the fifth to the seventh costal cartilages and inserts on the pubic symphysis and pubic crest. Each rectus muscle is segmented by tendinous intersections at the levels of the xiphoid process and the umbilicus and at a point midway between these two. The principal blood supply reaches the muscle from the superior and inferior epigastric arteries (**Fig. 72.5**), which anastomose just superior to the umbilicus. Other vessels are anterior branches of the intercostal arteries; these reach the muscle by entering the lateral aspect of the rectus sheath. The innervation of the muscle is from the 7th to the 12th intercostal nerves, which laterally pierce the aponeurotic sheath of the muscle. The lateral edge of the muscle is demarcated by a slight depression in the aponeurotic fibers coursing toward the muscle; this depression is the *semilunar line.*

The small pyramidalis muscle (**Fig. 72.3D**) accompanies the rectus abdominis at its origin in a minority of people. The pyramidalis arises from the pubic symphysis. It lies within the rectus sheath and tapers to attach to the linea alba, the conjunction of the two rectus sheaths and the major site of insertion of three aponeuroses from all three lateral muscle layers.

Rectus Sheath

Although the components of the rectus sheath individually have been discussed in relation to the three lateral abdominal muscles, it should also be considered as a distinct entity. Three features of the rectus muscle and its sheath can be observed even topographically in well-muscled or very thin subjects:

1. The semilunar line is a slight depression in the aponeurotic fibers corresponding to the lateral edge of the rectus muscle. It marks the site of initial lateral insertion of the aponeurotic tendons of the lateral abdominal muscles.
2. The tendinous inscriptions divide each muscle into three parts.[7] These are the basis of the expression "six pack," popularized by bodybuilders.
3. The linea alba is the midline confluence of the aponeuroses of the rectus muscles and also the internal and external oblique muscles.

The composition of the rectus sheath varies depending on the level sampled. The anterior sheath superior to the umbilicus is composed of the aponeurosis of the external abdominal oblique and the anterior lamina of the internal abdominal oblique. The transversus abdominis aponeurosis does not participate in the formation of the anterior sheath at this level. At a variable level inferior to the umbilicus, the anterior sheath is a composite of all the aponeurotic layers.

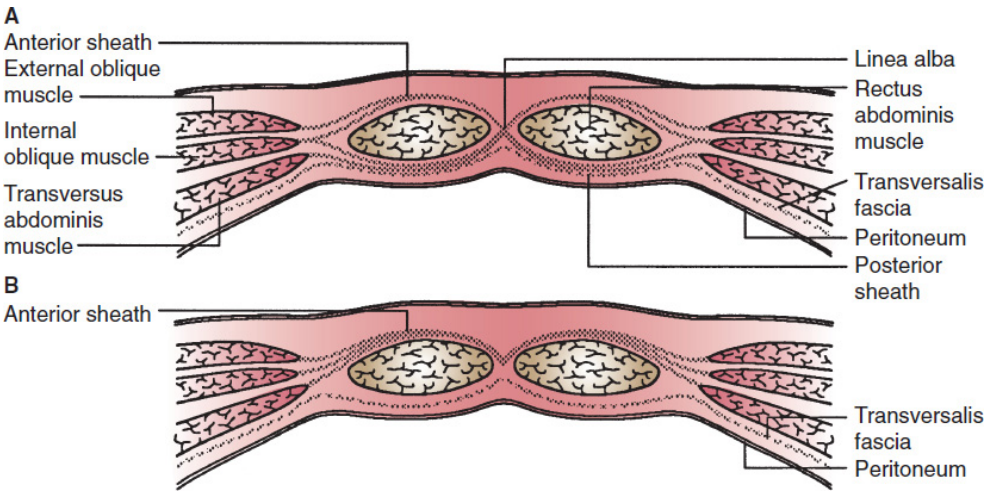

Figure 72.5 **A:** Immediately superior to the umbilicus, the rectus sheath consists of anterior and posterior components. The anterior sheath is composed of the aponeuroses of the external and internal abdominal oblique muscles, and the posterior sheath consists of the posterior aponeurotic lamina of the internal oblique and the aponeurosis of the transversus abdominis muscle. **B:** The rectus sheath inferior to the arcuate line (of Douglas) consists of an anterior portion made up of fibers from all aponeurotic layers; the posterior portion at this point comprises only transversalis fascia covered internally by peritoneum.

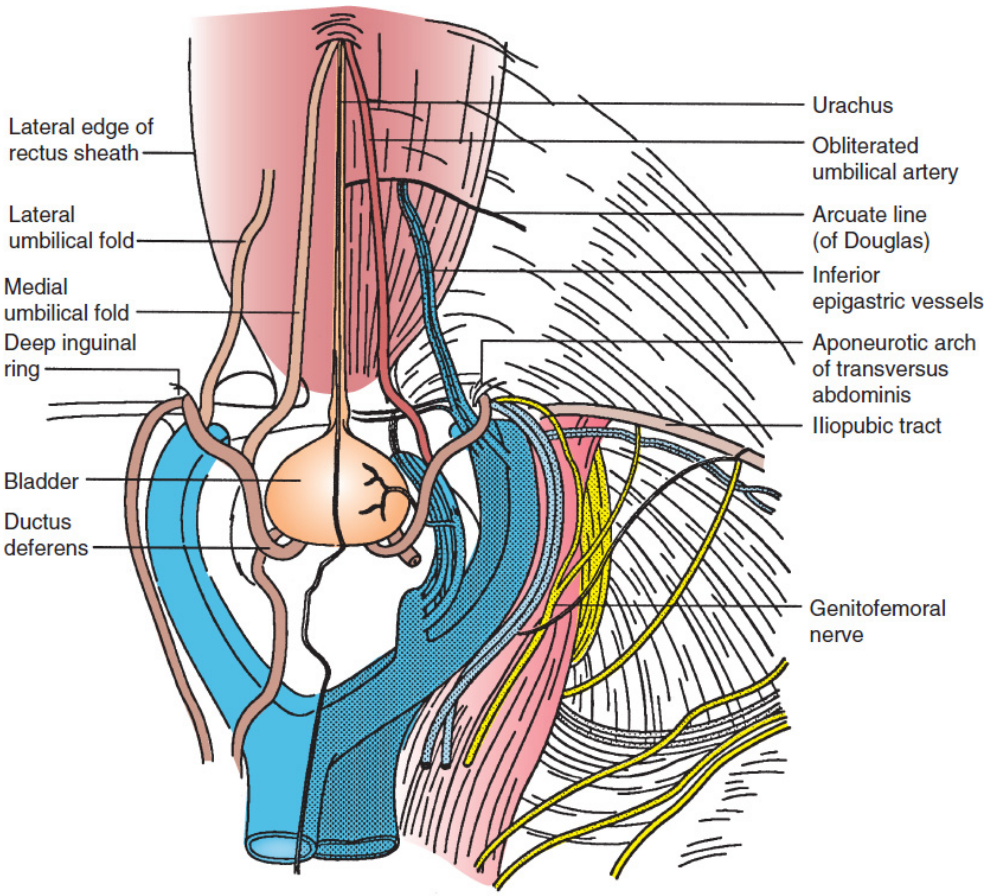

Figure 72.6 The deep inguinal region, pelvis, and anterior abdominal wall from the viewpoint of a surgeon using a laparoscopic technique. The anterior wall folds upward approximately at the iliopubic tract in this illustration.

The posterior sheath of the rectus muscle superior to the umbilicus is a lamination of the posterior lamina of the aponeurosis of the internal abdominal oblique and the transversus abdominis aponeurosis, while the transversalis fascia and peritoneum underly the aponeurotic layers. The external abdominal oblique does not participate in the formation of the posterior portion of the rectus sheath. At a highly variable site inferior to the umbilicus, all the aponeurotic tendons pass anteriorly to form the anterior rectus sheath. The fibers of the posterior sheath are seen to attenuate gradually. The aponeurotic fibers do not end abruptly at the arcuate line. This transfer of connective tissue away from the posterior rectus sheath causes the arcuate line (of Douglas) to form on the posterior surface of the muscle (**Fig. 72.6**). The tissue covering the deep surface of the rectus muscle inferior to the arcuate line is primarily the transversalis fascia and peritoneum.

Some have questioned this traditional scheme of rectus sheath composition, contending that each of the aponeurotic layers superior to the umbilicus is actually bifid, with both contributing to the anterior and posterior sheaths.[8] The fibers of the posterior sheath are seen to attenuate gradually. The concept of rectus sheath composition favored by most is shown in **Figure 72.7**.[9]

Innervation and Blood Supply of the Anterior Abdominal Wall

The innervation of the anterior wall muscles is multiple. The lower intercostal and upper lumbar nerves (T7 to T12, L1, L2) contribute most of the innervation to the lateral muscles, the rectus abdominis, and the overlying skin. The nerves pass anteriorly in a plane between the internal abdominal oblique and the transversus abdominis, eventually piercing the lateral aspect of the rectus sheath to innervate the muscle therein. The external oblique muscle receives branches of the intercostal nerves, which penetrate the internal oblique. The anterior ends of the nerves form part of the cutaneous innervation of the abdominal wall. The first lumbar nerve divides into the ilioinguinal and iliohypogastric nerves. These may divide within the psoas major muscle or between the internal oblique and transversus abdominis muscles. The ilioinguinal nerve may communicate with the iliohypogastric nerve before innervating the internal oblique. The ilioinguinal nerve then passes through the external inguinal ring to run with the spermatic cord, whereas the iliohypogastric nerve pierces the external oblique to innervate the skin above the pubis. The cremaster muscle fibers, which are derived from the internal oblique muscle, are innervated by the genitofemoral nerve (L1, L2).

The blood supply of the lateral muscles of the anterior wall is primarily from the lower three or four intercostal arteries, the deep circumflex iliac artery, and the lumbar arteries. The rectus abdominis has a complicated blood supply derived from the superior epigastric artery (a terminal branch of the internal thoracic, or internal mammary, artery), the inferior epigastric artery (a branch of the external iliac artery), and the lower intercostal arteries. The latter arteries enter the sides of the muscle after traveling

between the oblique muscles. The superior and inferior epigastric arteries enter the rectus sheath and anastomose near the umbilicus.

Posterolateral (Lumbar) Abdominal Wall

The posterolateral or lumbar portion of the abdominal wall (**Fig. 72.8**) is often overlooked in discussions of abdominal hernia, perhaps because of the much more common occurrence of groin and femoral hernias. The configuration of the muscle layers in the lumbar area also predisposes to hernia formation. For the purposes of this discussion, the lumbar portion of the abdominal wall is defined as the area bounded superiorly by the 12th rib, inferiorly by the iliac crest, and medially by the erector spinae group. Eight muscles arrayed in three layers constitute the posterolateral or lumbar portion of the abdominal wall.

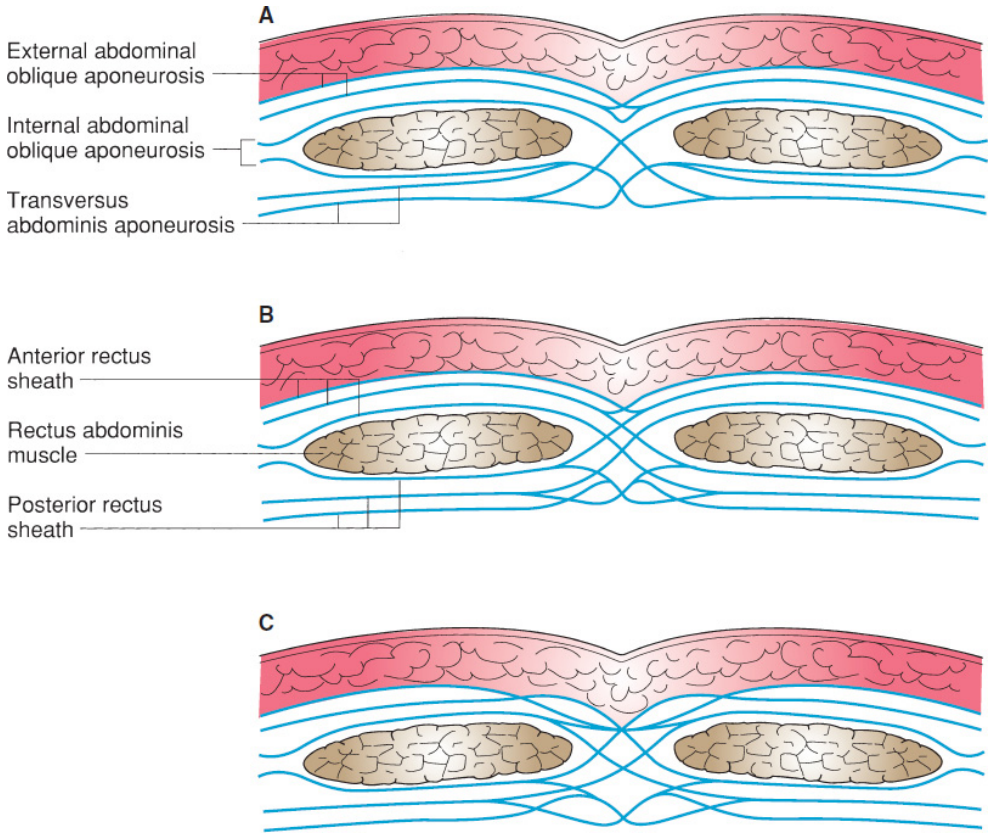

Figure 72.7 Patterns of midline decussation of the aponeuroses. **A:** Single anterior and posterior lines of decussation. **B:** Single anterior and triple posterior lines of decussation. **C:** Triple anterior and posterior lines of decussation.

The most superficial layer is composed of the external abdominal oblique muscle, which arises from the posteroinferior portion of the lower ribs and inserts in part along the posterior iliac crest. Closely associated with the external oblique in this area is the latissimus dorsi, which arises from the posterior iliac crest, the spinous processes of the sacrum and lumbar vertebrae, and the lumbodorsal fascia. The muscle courses obliquely toward its insertion on the medial aspect of the intertubercular groove of the humerus. The triangular space formed by the two muscles just described and the iliac crest is called the *inferior lumbar (Petit) triangle* (**Fig. 72.8A**).

The middle layer of lumbar abdominal muscles consists of the erector spinae, the internal abdominal oblique, and the extremely thin insignificant serratus posterior inferior. The erector spinae forms a significant portion of the abdominal wall in the lumbar region, with fibers extending nearly the length of the spinal column. The internal abdominal oblique muscle forms the remainder of the layer. The serratus posterior inferior arises from the lumbodorsal fascia and inserts on the lower four ribs. The middle layer of lumbar muscle is associated with the superior lumbar triangle, a more common site of hernia than the inferior lumbar triangle described previously. The superior triangle (**Fig. 72.8B**) is formed superiorly by the 12th rib, the serratus posterior inferior, and the superior lumbocostal ligament; inferiorly by the upper border of the internal abdominal oblique; and medially by the erector spinae.

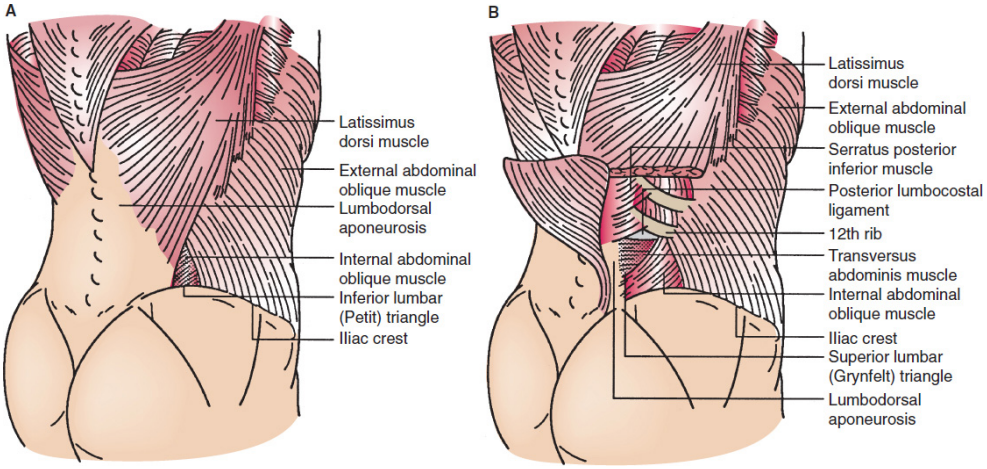

Figure 72.8 The lumbar abdominal wall with the inferior lumbar triangle (**A**) and the superior lumbar triangle (**B**).

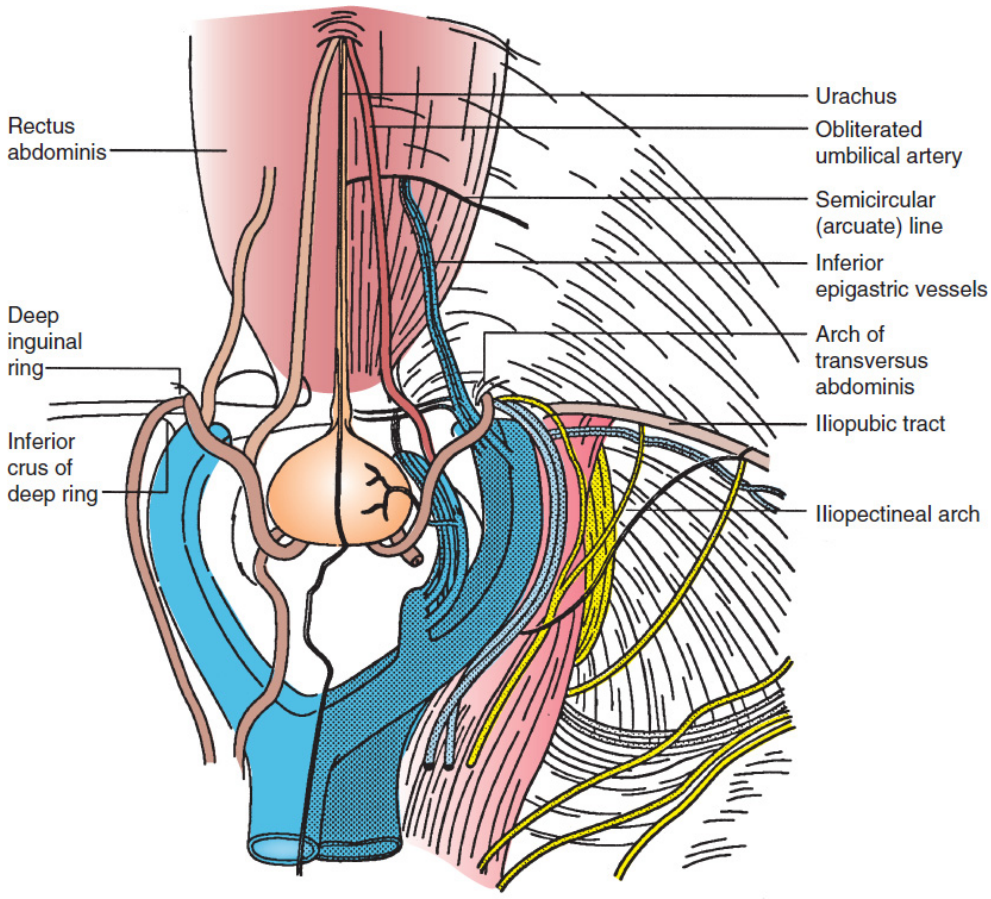

Figure 72.9 The deep inguinal region and the anterior abdominal wall seen from within the abdomen. The urachus, the obliterated portion of the umbilical artery, and the inferior epigastric vessels are covered by peritoneal folds, respectively called the median, medial, and lateral umbilical folds.

The deep layer of the lumbar abdominal wall includes three muscles: the quadratus lumborum, the psoas major, and the transversus abdominis. The quadratus lumborum primarily arises from the posterior iliac crest and inserts on the 12th rib. The psoas major arises from vertebrae T12 through L5 and passes beneath the inguinal ligament to insert on the lesser trochanter of the femur.

Deep Inguinal Region

Minimally Invasive View

Deep Aspect of the Anterior Abdominal Wall, Peritoneal Folds, and Associated Structures If one creates a space in the abdominal cavity by distending it with gas, an excellent view of the anterior wall can be obtained.

The umbilical peritoneal folds (**Fig. 72.9**) in most subjects are very prominent and provide easily identified landmarks. The folds (ligaments) primarily exist because the peritoneum covers underlying structures.

The single median umbilical fold extends from the umbilicus to the urinary bladder and covers the urachus, the fibrous remnant of the fetal allantois. The urachus may be patent for a short distance in adults or may open into the umbilical scar in newborns. The medial umbilical fold is formed by the underlying obliterated portion of the fetal umbilical artery. This normally cordlike structure, like the urachus, may be patent for a portion of its length. Indeed, the proximal, patent portion of the artery normally supplies the superior vesicular arteries to the bladder. The lateral fold covers the inferior epigastric arteries as they course toward the posterior rectus sheath, which they enter approximately at the level of the arcuate line.

Between the median and the medial ligaments, a depression is usually found that is called the *supravesical fossa.* This is the site of hernias of the same name. The fossa formed between the medial and lateral ligaments is the medial fossa; this is the site of direct inguinal hernias. The lateral fossa is less well delineated than the others. The medial border of the fossa is formed by the lateral umbilical ligament and the rectus abdominis. This fossa does not have a lateral border; rather, the concavity slowly attenuates. The deep inguinal ring is located in the lateral fossa and therefore is the site of the congenital or indirect inguinal hernia.

Transversalis Fascia

The transversalis fascia (endoabdominal fascia) is perhaps the most commonly misunderstood structure in the literature devoted to groin hernia. Confusion results because surgeons may actually be referring to very different anatomic structures when discussing various hernia repairs; however, each may use the same anatomic term or eponym. Indeed, perhaps the biggest reservation among surgeons intent on performing a Shouldice repair is a precise definition of what is being sewn to what.

The transversalis fascia proper is a continuous sheet that extends throughout the extraperitoneal space. The term *transversalis fascia* is generally defined as the deep or endoabdominal fascia covering the internal surface of the transversus abdominis, the iliacus, the psoas muscles, and the

obturator internus and portions of the periosteum. One variant of this convention is the use of terms specific to the muscle covered by the fascia (e.g., iliac fascia).

Most authors feel that only one layer of transversalis fascia exists, whereas others maintain that the transversalis fascia comprises two layers, or laminae.[10] The posterior lamina is a layer of fibrous connective tissue that widely varies in density and continuity and is interspersed with adipose tissue, as seen in **Figure 72.10**. This layer is often referred to simply as the *preperitoneal fascia.* The anterior lamina is more uniform and is adherent to the deep surface of the transversus abdominis and the rectus abdominis. The posterior lamina is contained within the preperitoneal space, which is defined as the space between the peritoneum and the anterior lamina of the transversalis fascia. The inferior epigastric vessels are enclosed by, or interspersed with, the adipose tissue and the fibrous tissue of the posterior lamina of the transversalis fascia. The vessels are in contact anteriorly with the anterior lamina of the transversalis fascia as they course upward to enter the rectus abdominis sheath.

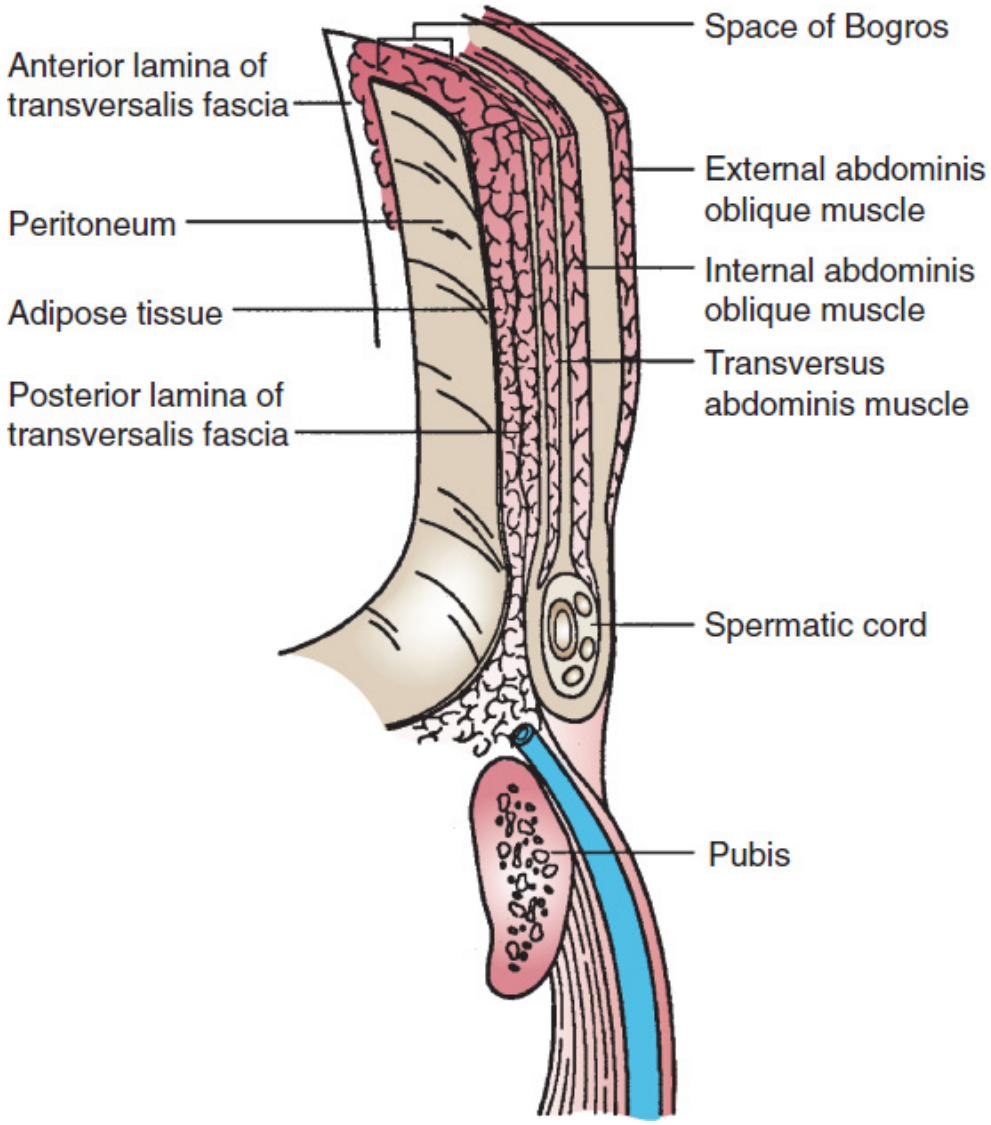

Figure 72.10 A parasagittal section through the layers of the anterior abdominal wall and groin. Observe that the transversalis fascia is depicted as a bilaminar structure.

Transversalis Fascia Derivatives

The transversalis fascia analogs or derivatives are the iliopectineal arch, iliopubic tract, and crura of the deep inguinal ring. The superior and inferior crura form a transversalis fascia sling, a structure shaped like a "monk's hood," around the deep inguinal ring (Fig. 72.9). The transversalis fascia also contributes the internal spermatic fascia to the spermatic cord at this point. This "sling" has functional significance; when the transversus abdominis contracts, the crura of the ring are pulled upward and laterally,

which results in a valvular action that helps to prevent the indirect formation of a hernia.

The iliopubic tract (**Figs. 72.9** to **72.11**) has become an increasingly important landmark for surgeons as the use of laparoscopic technology has increased.[11,12] The iliopubic tract is the thickened band of transversalis fascia formed at the zone of transition between the deep surfaces of the iliac and transversus abdominis muscles. The structure courses parallel to the more superficially located inguinal ligament, is attached to the iliac crest laterally, and inserts on the pubic tubercle medially. The tract forms along its course a portion of the inferior crus of the deep inguinal ring and then contributes to the anterior and medial walls of the femoral sheath. The tract fuses with the inguinal ligament to form a component of the inferior wall of the inguinal canal. At its insertion on the pubic tubercle, it curves backward slightly to blend with Cooper's pectineal ligament. The pectineal ligament is actually a condensation of periosteum and is not a true analog of the transversalis fascia, but it is reinforced by fibers from the iliopubic tract and inguinal ligament.

The iliopubic tract contains not only fibrous connective tissue but also some elastic fibers.[13] In one series, the iliopubic tract was a substantial structure, suitable for use in hernia repairs, in 42% of the specimens examined. The tract, whether substantial or not, can be used as a readily identified landmark.

The iliopubic tract has particular significance because of its importance as a landmark to the laparoscopic surgeon. Many of the branches of the lumbar plexus run inferior to the tract, and damage to these nerves may be the result of aggressive dissection or the placement of tacks or staples to affix a prosthesis below this structure. The tract is not obviously visible in every patient from a laparoscopic view, but its location should always be immediately known to the surgeon because of its constant relationship to the other landmarks in this area.

The iliopectineal arch (**Fig. 72.9**) is also a condensation of the transversalis fascia. The iliopectineal arch commences at the medial border of the iliacus muscle, where it is continuous with the iliac fascia, itself a portion of the transversalis (endoabdominal) fascia. The arch separates the vascular compartment containing the femoral vessels from the neuromuscular compartment containing the iliopsoas muscle, femoral nerve, and lateral

femoral cutaneous nerve. The iliopectineal arch also contributes to the proximal portion of the femoral sheath, thereby joining the iliopubic tract in the formation of the femoral sheath.

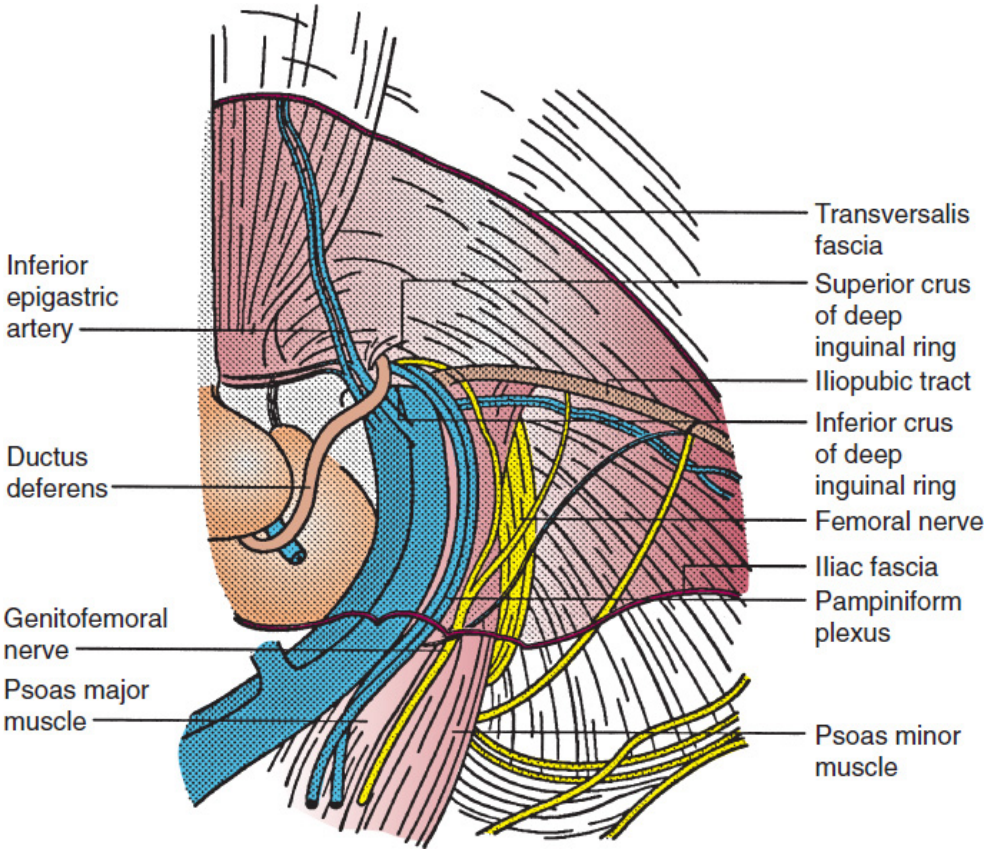

Figure 72.11 A schematic representation of the deep inguinal region. The iliopubic tract is shown as a thickening of the transversalis fascia, inferior to which many of the branches of the lumbar plexus exit the pelvis.

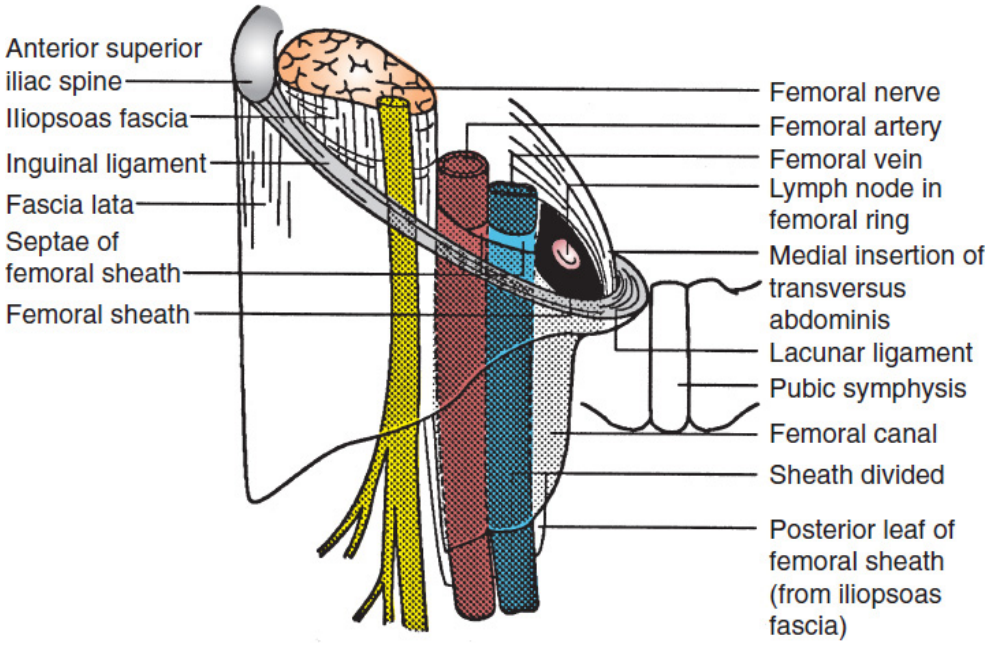

Figure 72.12 Schematic view of the femoral sheath, ring, and canal. The transversalis fascia forms the anterior portion of the sheath, and the iliopsoas fascia forms the posterior portion. Septae separate the vessels from each other and the vein from the femoral canal. The femoral ring contains a lymph node. The ring is formed medially by the aponeurosis of the transversus abdominis aponeurosis, anteriorly by the inguinal ligament, posteriorly by the pubic bone, and laterally by the femoral sheath.

Femoral Sheath, Canal, and Ring

The femoral sheath (**Fig. 72.12**) is primarily composed of extensions of the transversalis fascia. The sheath is best understood in terms of the structures contained within. As the external iliac artery and vein pass beneath the inguinal ligament to become the femoral vessels, they are covered anteriorly by the transversalis fascia proper. This fascial layer is posteriorly and laterally joined by portions of the iliopsoas fascia, which themselves are continuations of the transversalis fascia. At the inguinal ligament, the iliopsoas fascia forms the iliopectineal arch. This arch divides the vascular compartment (lacuna vasorum), containing the femoral vessels, from the muscular portion (lacuna musculorum), which contains the iliopsoas muscle, femoral nerve, and lateral femoral cutaneous nerve. The vascular lacuna is further divided by septa into compartments for the vessels and the femoral branch of the genitofemoral nerve.

The medial border of the femoral sheath follows the transversus abdominis aponeurosis to its insertion just lateral to that of the lacunar ligament and extends inferiorly to fuse eventually with the medial septum and adventitia of the femoral vein. The resultant cone-shaped cul-de-sac is the femoral canal. The canal normally contains only wisps of connective tissue and small lymphatic nodes. The wider proximal part of the canal, the femoral ring, contains a large node, which is often referred to as *Cloquet node.*

The femoral ring is the extraperitoneal opening of the canal. The boundaries of the ring are formed medially by the curved edge of the transversus abdominis aponeurosis, not the lacunar ligament, which inserts more medially.[14] Laterally, the ring is bounded by the connective tissue septum and the adventitia that is interposed between it and the femoral vein. The anterior boundary is the inguinal ligament; posteriorly, the ring is reinforced by the iliopubic tract and iliopectineal ligament. The canal is not in direct communication with the pelvic cavity. The transversalis fascia is not a component of the roof of the canal because it is diverted at this point to form the femoral sheath. This weakened area is therefore quite prone to hernia formation, especially in female subjects.

Inguinal (Hesselbach's) Triangle

The inguinal triangle is the site of direct inguinal hernias. This triangle is most often described from the anterior aspect (**Fig. 72.13**), in which case the inguinal ligament forms the base of the triangle, the rectus abdominis forms the medial border, and the inferior epigastric vessels form the superolateral border. The triangle as originally described by Hesselbach had the pectineal ligament as its base. The latter description is quite useful to the surgeon viewing the abdomen from within because the inguinal ligament cannot be seen from this viewpoint. When the inguinal triangle is transilluminated, the thinness and translucency of the area of abdominal wall within the triangle underscores its importance in hernia development and repair. In the most translucent area, little or no muscle is present. Only the peritoneum and the transversalis fascia cover the triangle here. The aponeurotic arch of the transversus abdominis crosses the triangle just below the apex in most people. A high aponeurotic arch affords less reinforcement to the triangle and

may therefore predispose a person to the formation of a direct inguinal hernia.

Components of the Spermatic Cord

The spermatic cord (**Figs. 72.11** to **72.14**) is closely associated with the deep inguinal ring. The spermatic cord is most appropriately described at this point because the deep ring itself is formed by derivatives of transversalis fascia, as is the innermost covering layer of the spermatic cord, the internal spermatic fascia. The middle covering layer is called the *cremasteric fascia* and contains the cremasteric muscle bundles; both are derived from the internal abdominal oblique muscle and fascia. The outermost covering of the spermatic cord is the external spermatic fascia, which is continuous with the investing fascia of the external abdominal oblique muscle.

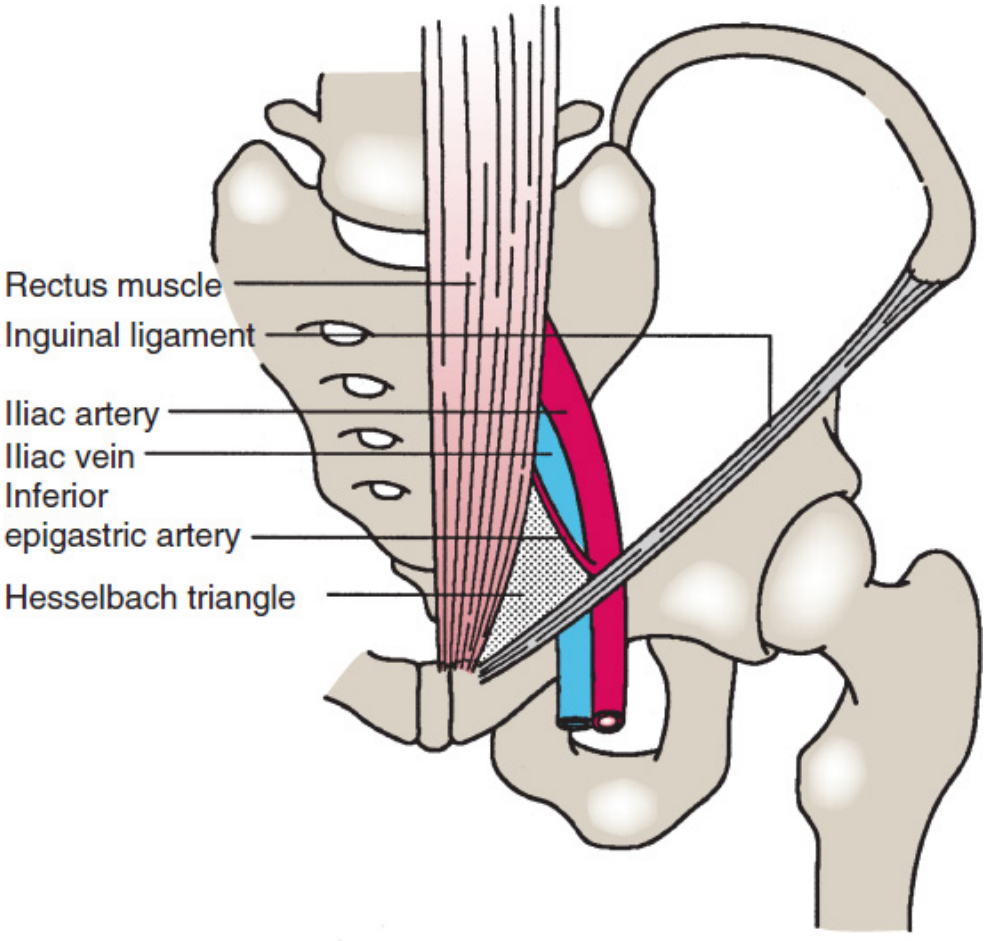

Figure 72.13 The inguinal (Hesselbach) triangle.

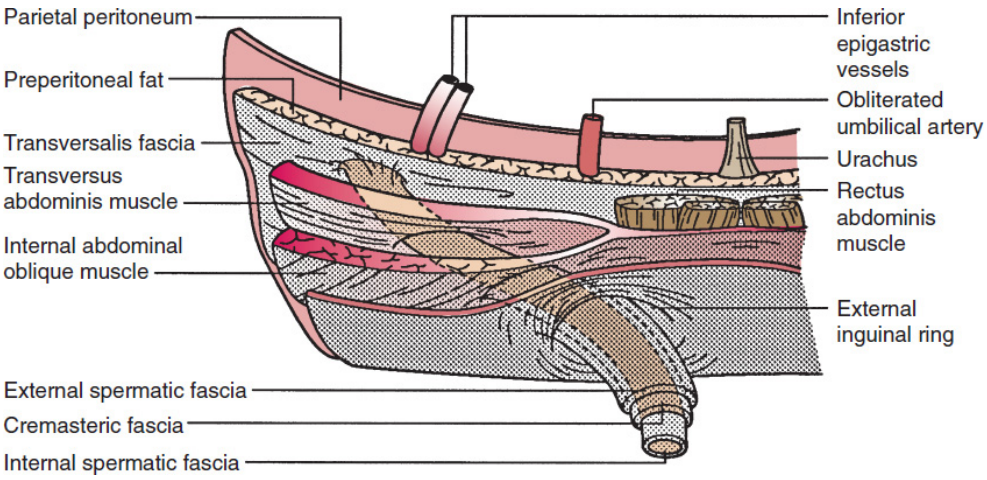

Figure 72.14 The component layers covering the contents of the spermatic cord.

The tunica vaginalis is initially a component of the cord, but normally it atrophies and closes early in neonatal life. This structure is an evagination of peritoneum. The testicle descends retroperitoneally in fetal life and is merely in contact with the posterior aspect of the tunica. An indirect congenital hernia enters the patent tunica vaginalis.

The cord structures enclosed by the coverings described earlier are the ductus (vas) deferens, the pampiniform venous plexus, the testicular artery, and the genital branch of the genitofemoral nerve, a branch of the lumbar plexus (**Figs. 72.9**, **72.11**, and **72.15**).

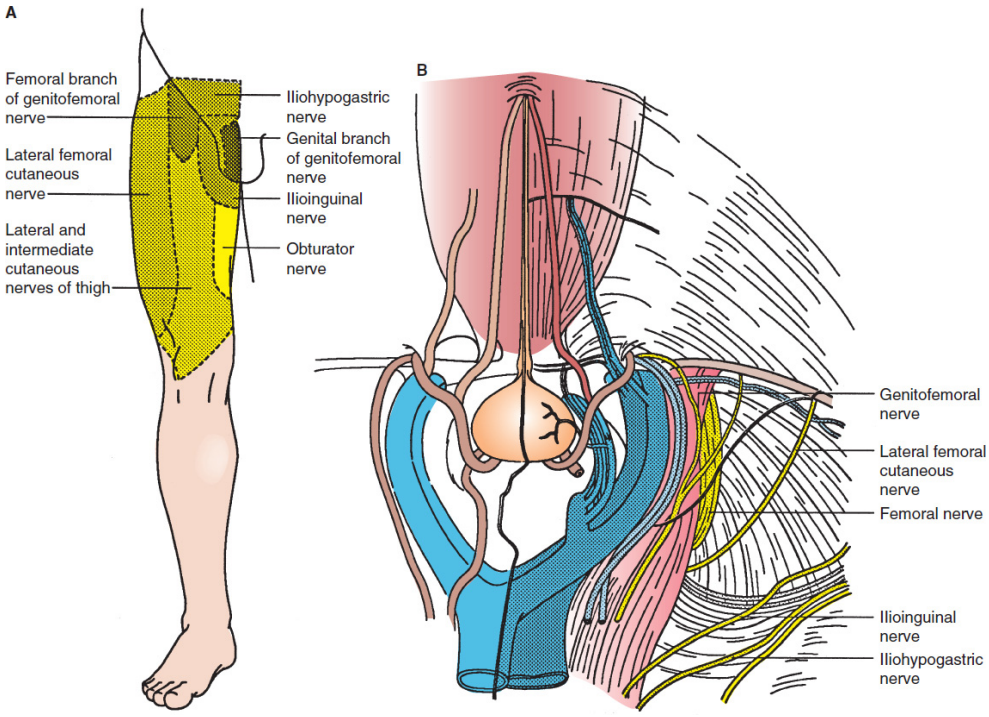

Figure 72.15 **A:** The cutaneous territories innervated by several branches of the lumbar plexus. **B:** Some of the branches of the lumbar plexus seen from within the abdomen.

Branches of the Lumbar Plexus

The nerves crossing the iliac fossa are some of the most variable in the body. This variability may be the cause of frequent intraoperative injury to the fragile nerves. The lumbar plexus is formed by roots from the 12th thoracic nerve and the first through fourth lumbar nerves. Cutaneous territories innervated by branches of the lumbar plexus are seen in **Figure 72.15A**. The five terminal branches commonly encountered in laparoscopic herniorrhaphy can be discerned in many people as they course across the iliacus muscle covered by peritoneum and the iliac fascia (a portion of the transversalis–endopelvic fascia). The nerves form within or deep to the psoas major muscle (**Fig. 72.15B**), often ramifying with other nerves within or close to the muscle. The nerve branches initially lie within the so-called triangle of pain,[15] bordered medially by the psoas muscle, anteriorly and inferiorly by the iliopubic tract, and laterally by the iliac crest. With the exception of the genital branch of the genitofemoral nerve, the branches of the lumbar plexus destined for the thigh run beneath the iliopubic tract.

The most anterior of the nerves encountered, the genitofemoral nerve, is also the most variable. This nerve may occur as a single trunk lying deep to the peritoneum and fascia on the anterior surface of the psoas muscle. The nerve may also divide into its component genital and femoral branches within the muscle. The genital branch travels with the spermatic cord, entering at the deep inguinal ring; it ultimately innervates the cremaster muscle and the lateral scrotum. The femoral branch of the nerve innervates the skin of the proximal mid-thigh.

The lumbar plexus branch encountered immediately deep to the lateral aspect of the psoas muscle is the large femoral nerve. Although not routinely encountered during laparoscopy, the femoral nerve has been injured in some cases.[16] The lateral femoral cutaneous nerve crosses the iliac fossa under the iliac fascia to run deep to the iliopubic tract and the inguinal ligament, which it pierces to enter the thigh.

The iliohypogastric nerve typically arises with the ilioinguinal by a common trunk from the first lumbar nerve. They may exchange fibers within the muscle, but they usually diverge immediately to form individual nerves. The iliohypogastric nerve crosses the iliac fossa just inferior to the kidney and pierces the transversus abdominis. The subsequent course of the nerve carries it between the transversus and the internal abdominal oblique until it pierces the aponeuroses of both obliques just above the external inguinal ring.

The ilioinguinal nerve normally crosses the iliac fossa just inferior to the iliohypogastric nerve. In its typical further course, the nerve pierces the transversus abdominis and internal abdominal oblique above the iliac crest and eventually enters the inguinal canal. The nerve may run more diagonally through the iliac fossa and then pierce the iliopubic tract to reach the inguinal canal.[17] This path "can obviously render the nerve more vulnerable to iatrogenic injury."

Vasculature of the Abdominal Wall and Deep Inguinal Region

The vasculature of the deep inguinal region and anterior abdominal wall has been analyzed by surgeons for well over 100 years. The importance and

variability of these vessels have been underscored by the ominous mnemonics used to refer to them—"crown of death" (*corona mortis*) and "triangle of doom." The primary blood supply to the deep anterior wall is from the inferior epigastric artery. This artery is a branch of the external iliac artery. In many cases, an artery called the "aberrant" obturator artery arises from the inferior epigastric, which joins the "normal" obturator artery and thereby forms a circle—the corona mortis—before entering the obturator foramen. Injury to the circle, usually sustained while the surgeon is working in the area of the Cooper ligament, causes copious bleeding. Recent studies have indicated that aberrant obturator vessels are present in between 60% and 90% of the whole pelves studied.[18,19]

The veins in this area are also prone to injury because many, especially the iliopubic veins and obturator veins and their tributaries, may be much larger than their accompanying arteries. One network of veins in the area is situated on the inferior deep surface of the rectus muscles. The veins of this network, which anastomose with the pubic branches discussed earlier, have been called the *rectusial veins*.[20]

The vessels in the vascular compartment of the deep inguinal region are the external iliac artery and vein. They arise within a triangular area bordered laterally by the gonadal vessels and medially by the ductus deferens. The primary continuations of the external iliac vessels are the femoral artery and vein. The inferior epigastric artery is a branch of the external iliac. The obturator artery may arise from either of these arteries as a replacement or accessory to the obturator branch of the internal iliac artery.

A final vessel to consider in this review is the deep circumflex iliac artery (**Fig. 72.10**). The origin of this artery is extremely variable, but its course is predictable along the iliopubic tract. It pierces the transversalis fascia and runs along the iliac fossa to anastomose eventually with a deep lumbar artery. Because the deep circumflex artery runs along the iliopubic tract, it can inadvertently be stapled or otherwise injured during laparoscopic herniorrhaphy.

Pelvic Floor and Obturator Muscles

The pelvic musculature normally affords remarkable support to the structures within the true pelvis and form the caudal most aspect of the abdominal core.

Although a myoaponeurotic hammock-like sheet forms the pelvic diaphragm, obturator muscles and membrane, and urogenital diaphragm, herniation of fat or viscera through or around any of these layers occurs. The potential for hernia formation is increased because of the openings through which many structures exit or enter the pelvis.

The Latin term *obturator* is translated as "stopper for a bottle." The aptly named obturator internus, along with its membrane and the obturator externus, closes off nearly all the large obturator foramen. The small superolateral aperture through which the obturator vessels and nerve pass is the site where obturator hernias form. The obturator internus arises from the deep surface of parts of all three pelvic bones. The muscle fibers converge on a tendon, which leaves the pelvis through the lesser sciatic foramen to insert on the greater trochanter. The dense internal obturator fascia covers the muscle and is thickened to form the arcuate ligament, from which the levator ani muscles (the pelvic diaphragm) are in part suspended. The obturator internus fascia splits to enclose the pudendal vessels in the pudendal canal. The external obturator muscle arises from the pelvic bones surrounding the obturator foramen and from the anterior portion of the obturator membrane. The external obturator muscle is supplied by the obturator nerve and vessels.

The component muscles of the bowl-shaped pelvic diaphragm, the pubococcygeus, iliococcygeus, and puborectalis, along with the coccygeus form the floor of the pelvis. The pubococcygeus arises from the posterior aspect of the pubis and the thickened portion of the internal obturator fascia, called the *tendinous arch* (**Fig. 72.16**), that spans the distance between the pubis and ischial spine. The puborectalis, the midportion of the diaphragm, arises from the pubis and loops around the rectum as the puborectal sling. The iliococcygeus is suspended at its origin from the tendinous arch and inserts on the coccyx. The coccygeus muscle completes the diaphragm posteriorly, arising from the ischial spine and inserting on the sides of the coccyx.

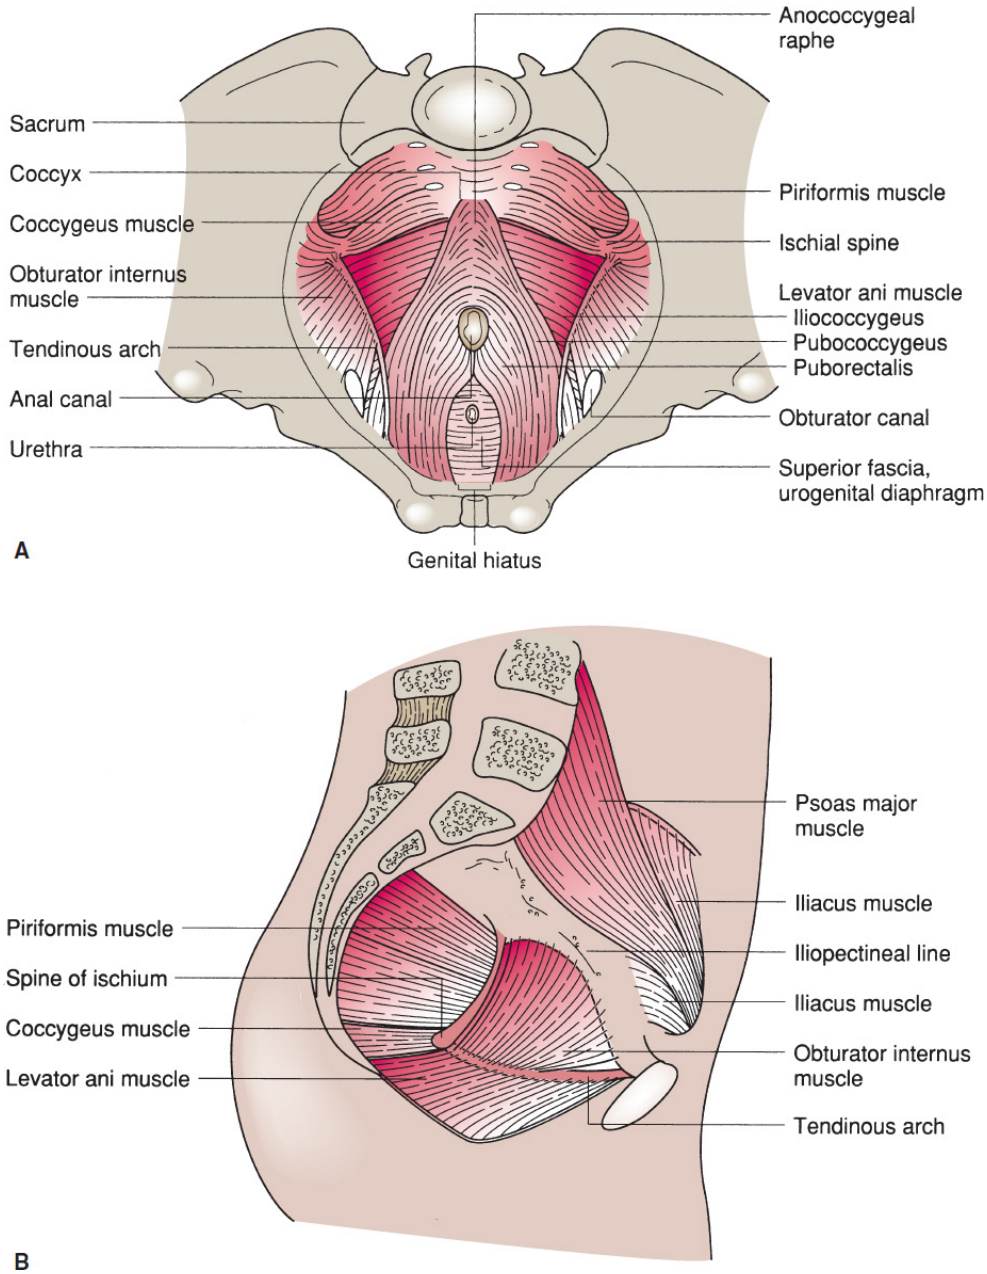

Figure 72.16 **A:** The pelvic diaphragm (levator ani and the piriformis) and the urogenital diaphragm viewed from within the pelvis. **B:** Hemisection of the pelvis revealing the levator ani, piriformis, obturator internus, and psoas muscles.

The area remaining between the sacrum and the greater sciatic foramen is filled for the most part by the piriformis muscle. The piriformis arises from the anterior surface of the second through fourth sacral vertebrae and the sacrotuberous ligament. This muscle exits the pelvis through the greater sciatic foramen, which is thereby divided into suprapiriform and infrapiriform portions (**Figs. 72.16** and **72.17**). The superior gluteal nerves

and vessels pass through the suprapiriform foramen, whereas the inferior gluteal nerves and vessels in company with the sciatic nerve pass through the infrapiriform foramen.

The most pronounced deficit in the pelvic diaphragm is situated anteriorly, where an aperture must allow the urogenital structures to pass out of the pelvis. This area is reinforced by the urogenital diaphragm, a structure primarily consisting of the superficial and deep transverse perineal muscles. The deep transverse perineal muscle is enclosed by a weak superior fascia and a sturdier inferior perineal fascia. The urogenital diaphragm recently has been shown to be more funnel shaped than sandwichlike, as previously depicted in many atlases. The urogenital diaphragm exists only in humans because the human pelvic outlet faces inferiorly, unlike that of quadrupeds.

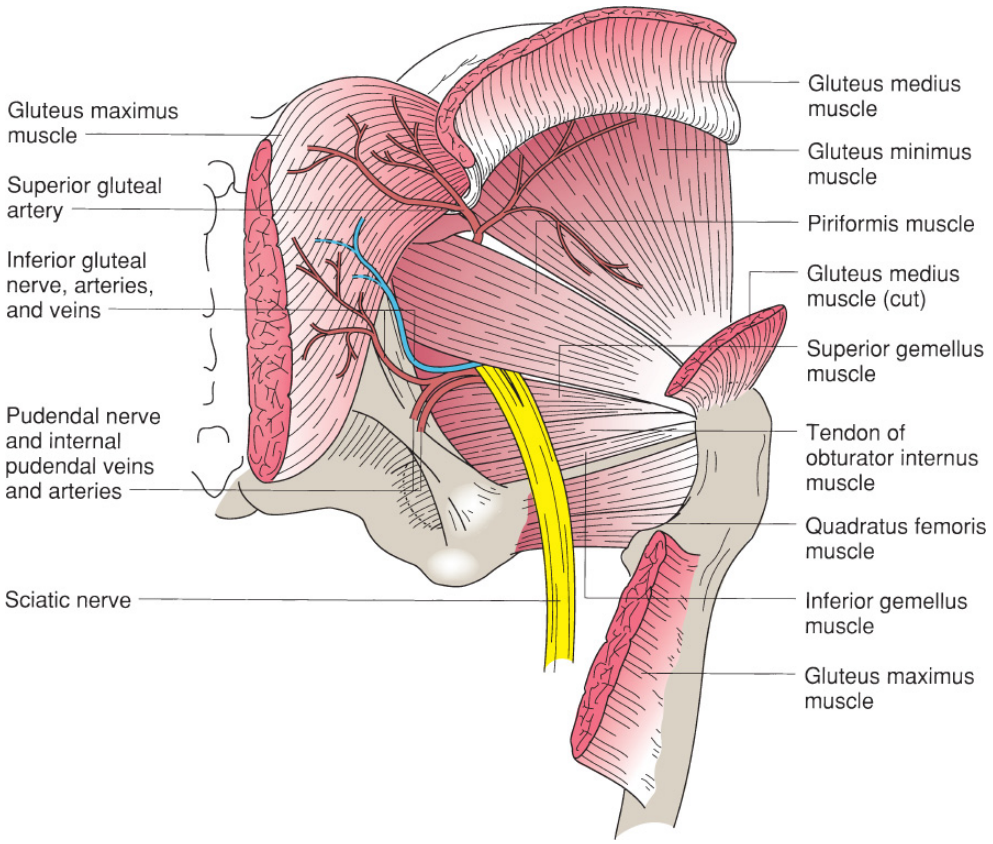

Figure 72.17 The gluteal muscles and lateral rotators of the hip. External relations of the sciatic foramen are also evident.

WHY DO HUMAN BEINGS DEVELOP ABDOMINAL WALL HERNIAS?

The most common hernias develop at sites where the abdominal wall has natural openings such as the internal inguinal ring, the umbilicus, and the esophageal hiatus. Previous surgical entry sites (incisional hernia) are also common areas where hernias develop. Factors that increase the pressure in the abdominal cavity, such as obesity, heavy lifting, coughing with chronic lung disease, straining during a bowel movement or urination (prostatism), chronic lung disease, and ascites, have traditionally been considered important in the etiology, especially at these natural openings. Developmental phenomena also play a role. For example, in the evolution from a quadruped to a biped, the unprotected groin is more vulnerable to changes 2 in intra-abdominal pressure, predisposing to inguinal herniation. Major risk factors for the development of an abdominal wall hernias include chronic obstructive pulmonary disease, smoking, high intra-abdominal pressure, collagen vascular disease, thoracic or abdominal aortic aneurysm, peritoneal dialysis, matrix metalloproteinase (MMP) abnormalities, and an increased type I: type III collagen ratio.

The role of heavy lifting, especially a single strenuous event, is an unsettled question and has considerable medical–legal ramifications. There is minimal evidence that vigorous abdominal wall activity is an independent risk factor for abdominal wall hernia development despite the overwhelming opinion to the contrary in the lay literature.[21–23] In a systematic review of existing evidence performed by Svendsen and colleagues, regarding the effects of occupational and mechanical exposures in relation to inguinal hernias, a causal relationship could not be established between specific mechanical insults and occurrence of inguinal hernia, hernia recurrence, and persistent pain after inguinal hernia repair.[24,25] According to the results of another register-based male cohort study in Denmark, increasing cumulative exposure to daily lifting activities and prolonged standing or walking at work was associated with an increased risk of having an indirect inguinal hernia repair.[24,25] The authors hypothesized that patent processus vaginalis may be more susceptible to changes in intra-abdominal pressures, whereas in a direct hernia, other mechanisms may be involved in connective tissue

degradation and weakening of the transversalis fascia. Still, the role of mechanical activity in the development of abdominal wall hernia is not completely clear, and further research is needed to determine if inguinal hernias can be prevented and if the postoperative prognosis can be improved by reducing occupational mechanical exposures.

Familial predisposition and the role of connective tissue diseases in hernia development have received considerable attention in recent years. Particularly important for inguinal hernia is a family history as it has been reported to increase the risk up to 8 times.[26,27] Various connective tissue disorders, such as osteogenesis imperfecta, Marfan syndrome, Ehlers–Danlos syndrome, and congenital hip dislocation, are associated with hernias. Imbalances in collagen, the basic building block of the abdominal wall, are believed to contribute to hernia disease. While type I collagen confers predominantly tensile strength, type III collagen consists of thinner fibers and is regarded as a temporary matrix during tissue remodeling. A decreased ratio of type I to type III collagens can be detected in fascial and skin specimens obtained from patients with hernias. A similar phenomenon was discovered by Cannon and Read in smokers when they performed biopsies of the rectus sheaths from adult smokers with inguinal hernias and coined the term "metastatic emphysema."[28] The investigators also demonstrated significantly greater levels of circulating serum elastolytic activity in patients who smoke.

Aside from primary defects in collagen synthesis, the imbalances in collagen in patients with hernia can be attributed to altered extracellular matrix (ECM) which is maintained in a dynamic balance of synthesis and degradation by a complex set of enzymes. MMPs,[29] which are a group of 23 structurally related zinc-dependent enzymes, protease with collagenolytic activity and have a pivotal role in the integrity and composition of the ECM.

The association between MMP overexpression and abdominal wall hernia was initially demonstrated by Bellon and colleagues, who studied the expression of MMP-1 and MMP-2 in the transversalis fascia of patients with direct and indirect inguinal hernia. Since then, several studies have been conducted, aiming at elucidating the role of MMPs in the development of primary and recurrent abdominal wall hernias. For this purpose, MMP levels in fascia, skin, hernia sac, and blood specimens of patients with inguinal, incisional, and recurrent abdominal wall hernias have been measured. The

expression of MMP mRNA in cultured fibroblasts has also been investigated to evaluate cell–cell and cell–matrix interactive mechanisms as causative factors for abnormal MMP production. In addition to this, in vitro studies have been performed to study the effect of different mesh materials on MMP expression on cultured fibroblasts; in one such study, polypropylene has been shown to induce less MMP2 expression than polygalactin. The function of MMPs is further regulated by a variety of endogenous regulators, the most important ones are known as tissue inhibitors of MMPs (TIMPs).[30–32] Studies have shown that an imbalance between MMP and TIMP activity may have a role pathogenesis of abdominal wall hernias.[33]

Despite the increasing knowledge regarding MMPs in incisional and inguinal hernia, the exact role of MMPs in the pathogenesis of hernia formation remains unclear. Most studies are small and not completely controlled; and there is a remarkable heterogeneity among studies concerning the characteristics of the study populations, the examined tissue specimens, and the biochemical assays used. In addition to MMP and TIMPs, factors that have been implicated in hernia development include deficiency of the elastic fiber system of the transversalis fascia, decreased tropoelastin and lysyl oxidase-like 1 synthesis, elastase overexpression and TGF-beta1 overexpression. It remains unclear whether these alterations in hernia patients are a part of the "cause-or-effect" phenomenon. Another interesting area of research are drug classes that can suppress MMP expression (e.g., tetracyclines, especially doxycycline, aspirin, statins, and thiazolidinediones) and understanding their role in hernia prevention and treatment.[34]

COMPLICATIONS OF HERNIAS

Hernia Accident

For years, surgeons have been taught that all hernias should be repaired at diagnosis to prevent a hernia accident, which is defined as a bowel obstruction or incarceration with strangulation, because of the perception that patients presenting with these complications have an unacceptable increase in mortality. This thinking, however, has not stood up when tested in

randomized controlled trials. For example, for men with asymptomatic inguinal hernias, randomized controlled trials have shown that a strategy of watchful waiting is safe.[35]

Incarceration

Incarcerated means "trapped" or "imprisoned." Clinically, an incarcerated hernia is an irreducible hernia. An incarceration is not in and of itself a surgical emergency. Many hernias are chronically incarcerated due to adhesions of contents (e.g., omentum, bowel, ovary, etc.) to the hernia sac. The hernia itself is not necessarily tense to palpation, and the overlying skin appears normal. Normal bowel sounds may be heard within the hernia. It is important to differentiate an incarcerated hernia from a hydrocele of the cord. One can get above the hydrocele with the examining fingers. One cannot get above a hernia, however, as it communicates with the abdominal cavity. Hydroceles will transilluminate clearly, but a hernia will not.

An acutely incarcerated, painful hernia must be managed carefully. An attempt at reduction is reasonable unless there are signs of strangulation, which is not always obvious by clinical examination. Immediate surgical exploration is the safest approach when the diagnosis is not clear. The advantage of reduction followed by elective repair is that edematous tissue associated with an acute incarceration can return to normal, which presumably will translate into a better repair with less chance of infection.[36] If an attempt at reduction seems reasonable, the patient is sedated and placed in bed. The Trendelenburg position should facilitate reduction of a groin hernia. An attempt should be made at the initial examination to reduce the hernia. The maneuver of taxis entails grasping the neck of the hernia with the fingers of one hand and then applying intermittent pressure on the most distal part of the hernia with the other hand. Taxis has the effect of elongating the neck of the hernia so that the contents of the hernia may be guided through this area back into the abdominal cavity with a rocking movement. Mere pressure on the most distal part of the hernia causes bulging of the hernia sac around the neck, which can occlude the neck and prevent it from being reduced (**Fig. 72.18**). The maneuver of taxis should not be performed with excessive pressure or too vigorously. If the hernia is strangulated, gangrenous bowel might be reduced into the abdomen or perforated in the process. One or two

gentle attempts should be made at taxis. If they are unsuccessful, this procedure should be abandoned. Rarely, the hernia together with its peritoneal sac and constricting neck may be reduced into the abdomen (reduction en masse). The patient would then have persistent obstruction after reduction of the hernia.

Intestinal Obstruction

One hundred years ago, the most common cause of intestinal obstruction was a hernia. At the present time, hernia is third, after adhesive obstructions and cancer. Hernia is an important cause of obstruction that is not infrequently missed on clinical examination. When a patient with an intestinal obstruction is examined, great emphasis should be placed on adequate exposure of the entire abdominal wall and groin area (from nipples to knees). Proper lighting is essential because previous scars can fade with time and become barely perceptible. The patient with intestinal obstruction as a result of a hernia will have a tense hernia that is irreducible. The abdomen itself will be distended, and high-pitched bowel sounds with frequent rushes will be heard. If the process continues to the complication of strangulation, these signs will disappear. Unlike adhesive small-bowel obstructions, partial small-bowel obstructions secondary to hernia are rare. Most patients will have had vomiting and obstipation.

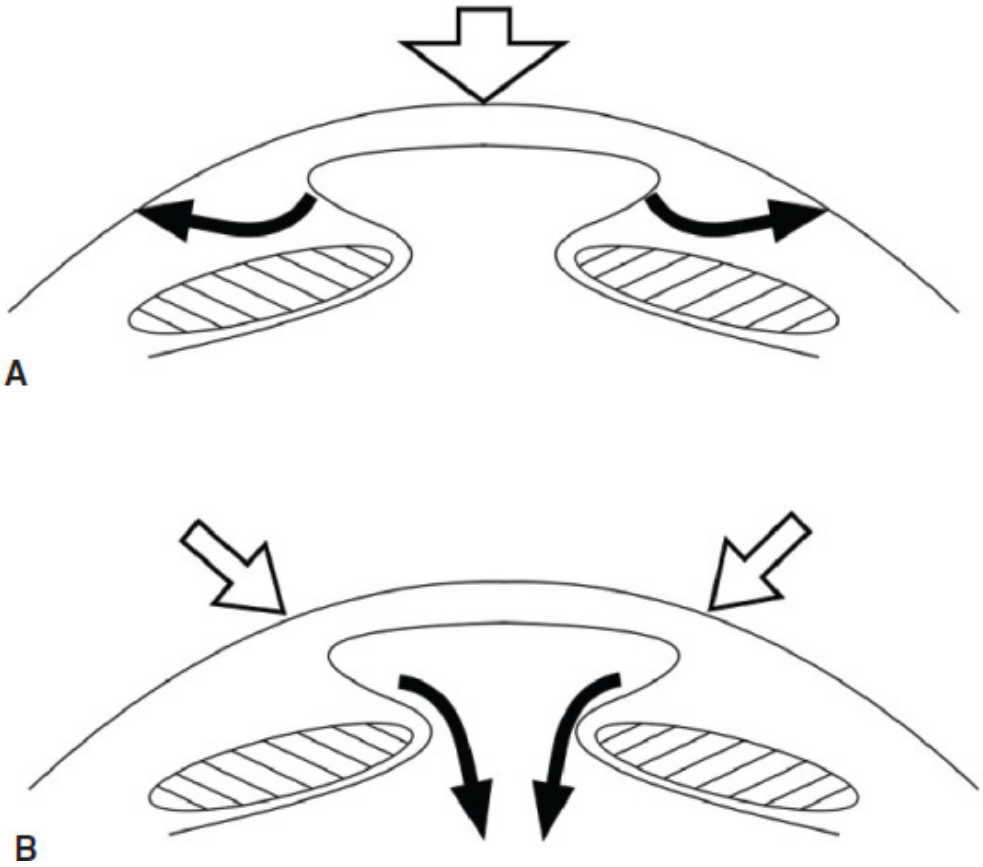

Figure 72.18 Reduction of a hernia by taxis. **A:** Applying pressure on the hernia directly occludes the neck. **B:** Elongating the neck of the hernia while applying pressure allows reduction.

Figure 72.19 Computed tomogram showing a left-sided inguinal hernia.

A plain roentgenogram of the abdomen will reveal the signs of an intestinal obstruction—dilated loops of bowel with air–fluid levels and no bowel gas distal to the obstruction. Frequently on a plain roentgenogram, one can see bowel shadows in the region of the hernia. A lateral view is often useful to demonstrate this feature more clearly. Contrast studies are not usually necessary in this instance. Computed tomography (CT) reliably demonstrates the hernia with characteristic features of obstruction and should be considered if the clinical diagnosis is not certain (**Fig. 72.19**) because a distal intestinal obstruction secondary to another cause (e.g., adhesions) may result in significant distention of a coincidental nonobstructing hernia of the abdominal wall. Should the examiner focus attention exclusively on the hernia, the real cause of the obstruction may be missed when the hernia is repaired.

The next steps in management include resuscitation followed by urgent surgery. At surgery, an approach directly over the hernia is used. In all patients, the entire gastrointestinal tract must be assessed to eliminate causes of obstruction other than the hernia itself. Diagnostic laparoscopy is a very useful adjunct to evaluate the bowel in these situations. This is done before the hernia is repaired. The bowel, if viable, is reduced into the abdomen. If

difficulty is encountered in reducing the hernia, the neck of the hernia can be widened. In the case of an inguinal hernia, division of the neck with or without ligation and division of the inferior epigastric vessels is safe, and the hernia contents can be reduced into the abdomen. In the case of a femoral hernia, the inguinal ligament can be split anteriorly and the hernia contents reduced into the abdomen. If the bowel is nonviable, then a bowel resection can be performed with anastomosis. The hernia is then repaired.

Strangulation

Strangulation of a hernia is a serious and life-threatening condition in which the hernia contents become ischemic and nonviable. The pathogenesis of this condition involves intra-abdominal contents within the hernia sac. Straining may push more contents into the sac, and the tense sac then causes pressure at the neck. This pressure initially produces venous congestion, resulting in edema. Eventually, the pressure is so great that the arterial supply is obstructed and the contents become gangrenous.

When intestine is involved, in addition to having an irreducible hernia and intestinal obstruction, the patient is toxic, dehydrated, and febrile. Examination of the abdomen reveals the signs of an intestinal obstruction, with distention and increased bowel sounds. Absolute constipation and vomiting are other manifestations. The hernia itself is tense, irreducible, and very tender, and the overlying skin may be discolored with a reddish or bluish tinge. No bowel sounds are heard within the hernia itself. The patient commonly manifests a leukocytosis with a predominance of polymorphonuclear leukocytes. Blood gases may reveal metabolic acidosis.

Management of these patients requires urgent attention to detail. No attempt should be made to reduce the hernia. Rapid resuscitation should commence immediately, with nasogastric suction and replacement of fluids and electrolytes. The patient should be given antibiotics. Once the patient is resuscitated, urgent surgery commences to expose the hernia, open the sac, and assess the viability of the bowel. More bowel can be pulled into the hernia so that viable bowel can be transected and the gangrenous portion removed. An anastomosis should be performed and the bowel then reduced into the abdominal cavity. The hernia is then repaired.

Richter Hernia

August Gottlieb Richter in 1785 described a hernia type that bears his name in which the antimesenteric border of the intestine protrudes into the hernia sac without involving the entire circumference of the intestine so that intestinal obstruction does not occur (**Fig. 72.20**). The most common site is the femoral ring (36% to 88%), followed by the inguinal canal (12% to 36%), and an abdominal wall incision (4% to 25%). Miscellaneous locations include umbilical, obturator, supravesical, Spigelian, triangle of Petit, sacral foramen, Morgagni, internal, and diaphragmatic.[37] The routine use of laparoscopy by general surgeons has resulted in an increased incidence at trocar sites such that most surgeons will repair the fascia for trocar sleeves greater than 5 mm. The surgical treatment is to expose the herniated bowel by opening the sac. The neck of the sac is enlarged to allow delivery of the bowel into the wound. Any areas of gangrene are excised and the bowel wall reconstituted. The hernia is then repaired.

Prosthetic Materials Used in Hernia Repair

The development of a wide variety of materials for inguinal and ventral hernia repair and abdominal core surgery makes it possible to individualize the selection of prostheses to a variety of clinical settings.[38,39] However, lack of clear data on optimal mesh selection, the sheer variety of options, and generally poor information and knowledge of specific mesh properties can make mesh selection quite daunting. It is important to note that there is little high-quality data regarding optimal mesh type for a given clinical scenario, and almost no direct comparative data between mesh types, let alone specific mesh brands or constructs. The choice of mesh is left largely to the judgment and experience of the operating surgeon. This section should serve as an overview to understanding mesh characteristics and some potential advantages or disadvantages of various mesh options in hernia repair. **Figure 72.21** summarizes mesh characteristics and key properties.

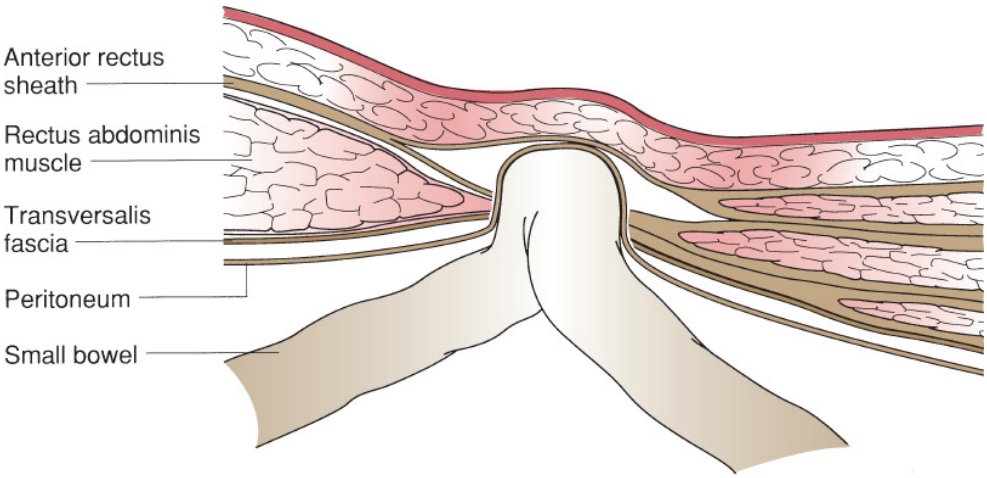

Figure 72.20 Richter hernia. Part of the bowel wall herniates through the defect in the abdominal wall.

Biologic Mesh

Broadly, mesh can be categorized as biologic, those meshes derived from some organic material, or synthetic. Biologic mesh comes from several possible sources including human, bovine, ovine, and porcine. Porcine is currently the most commonly used biologic mesh in hernia repair and has the largest volume of literature to support its use in various settings. In theory, all of these materials provide an acellular, biologically derived scaffold to allow nascent tissue ingrowth or remodeling that strengthens the abdominal wall repair. The actual behavior of these meshes is not entirely clear, however, and may behave quite differently from each other or in different clinical scenarios and in different patients.[40] The construct and processing of various biologic meshes, most of which are proprietary, vary greatly, and likely influences their behavior in vivo. Biologic mesh widely proliferated after their initial introduction, primarily for complex hernia repair and in the setting of contamination. No high-level clinical trials have yet demonstrated superiority of these materials in terms of infection, mesh removal, or hernia recurrence. In fact, many studies indicate a higher risk of hernia recurrence with biologic mesh repair compared to synthetic. Additionally, biologic mesh is quite expensive, as much as 200 times the cost of a comparable sized synthetic mesh. The very high cost and poor-quality data have led many away from routine use of biologic mesh in recent years.[41–44] However, the role for biologic meshes is yet to be determined as long-term catastrophic infection

rates associated with permanent synthetic meshes become better known and the cost-effectiveness tradeoff is better analyzed.[45]

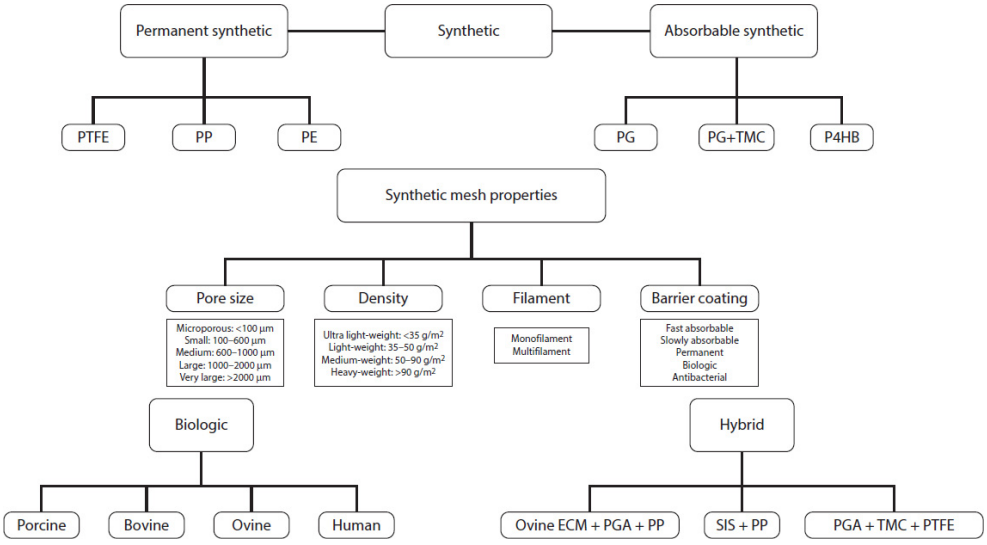

Figure 72.21 Classification of Materials Currently Available for Hernia Repair.

Absorbable Synthetic Mesh

Synthetic mesh can be further divided into absorbable and permanent synthetic mesh. Absorbable synthetic meshes, commonly referred to as biosynthetic, are recent additions to the available armamentarium. These are most often used in place of a biologic mesh in cases where there is a relative contraindication to the use of permanent synthetic mesh, as they are generally significantly cheaper. Early clinical data are conflicted, but seem to indicate acceptable clinical outcomes in terms of infection for absorbable synthetic meshes with a faster resorption profile. Longer-term resorption products tend to behave like heavyweight permanent synthetic meshes in the short term-appropriate caution should be employed when using these absorbable synthetic meshes in contaminated situations. No study has greater than 2-year follow-up to date, and there are scant comparative data of absorbable synthetic to biologic or permanent synthetic mesh for comparison.[46–48]

Permanent Synthetic Mesh

Permanent synthetic meshes are largely composed of one of three materials: polypropylene (PP), polyester (PE), or polytetrafluorethylene (PTFE). These can be further subdivided by their structural and physiomechanical properties. This is perhaps among the most misunderstood aspects of mesh,

while simultaneously being of the utmost importance in understanding how a mesh will perform in a given situation. While a comprehensive review of these characteristics is beyond the scope of this chapter, the key properties that appear to correlate with clinical performance are summarized here.

Mesh Properties

Pore Size Pore size, or the space between filaments of a mesh, is increasingly recognized as among the most important characteristics of a mesh, particularly in the setting of infection. This is characterized as microporous (<100 um), small-pore (100 to 600 um), medium-pore (600 to 1,000 um), large-pore (1,000 to 2,000 um), or very large pore (>2,000 um).[49] Smaller interstices and greater overall surface area may allow increased bacterial adherence and impede the ability of host immunity to fight infection should it occur. Conversely, large-pore mesh confers greater bacterial clearance and ability to avoid mesh explantation should infection occur.[50] Additionally, normal healing around a permanent mesh produces a granuloma around each fiber. In the case of microporous mesh, this can create a bridging fibrosis, increasing the overall stiffness of the mesh and potentially increasing the risk of chronic pain. Pore size of >1,000 um minimizes this possibility.[51]

Density Mesh density, defined as the material mass divided by area, is a function of fiber thickness and the construct (multifilament vs. monofilament, type of weave structure), and the pore size. Mesh density <35 g/m^2 is considered ultra light-weight, 35 to 50 g/m^2 light-weight, 50 to 90 g/m^2 mid-weight, and >90 g/m^2 heavy-weight.[49] Density has much to do with the strength of a mesh, but is not the sole determining factor. The strength of a mesh is measured by a few key metrics: suture retention strength, tear resistance testing, uniaxial tensile testing, ball-burst testing, and repetitive loading.[49,52] As density is partly determined by pore-size, these two parameters are intimately linked. Currently, all available heavy-weight meshes are also small-pore. Though quite strong, this has the potential disadvantage of creating bridging fibrosis and mesh contracture and poor tolerance of infection. Light-weight and ultra light-weight mesh, on the other hand, is more tolerant of infection, but has been shown in several studies to have a higher risk of hernia recurrence for ventral hernia repair.[53–55]

Structure Much of a mesh structure is determined by the material, but each material can be constructed differently, and this confers different properties. For example, PTFE has traditionally consisted of a laminar microporous structure. While this mesh provides probably the best available adhesion barrier, it cannot withstand infection and typically must be removed should mesh infection occur. A newer monofilament knitted PTFE hybrid mesh has recently become available as well, and while no clinical data are yet available, this appears to behave more like a monofilament polypropylene or polyester mesh. Similarly, multifilament mesh, common with polyester, is unable to withstand infection in most cases. Composite meshes, those composed of more than one distinct layer compressed into a single mesh, usually in order to provide and adhesion barrier, are similarly unable to withstand infection. Monofilament, large-pore material, however, generally tolerates infection without requiring mesh removal.

Barrier Coating A variety of substances and materials can be used to create barrier coated mesh, sometimes referred to as adhesive barrier or tissue-separating mesh, to make them suitable for intraperitoneal placement. Broadly, these barriers may be permanent or resorbable, synthetic or biologic, comprised of a second material layer or intrinsic to the mesh material itself, and may additionally have antimicrobial activity. No mesh is able to completely and consistently prevent adhesions to the viscera, and there are little clinical data to indicate the optimal barrier coating. In theory, a barrier should be present long-enough to allow neoperitonealization over the mesh, thus allowing native tissue to provide the ultimate barrier to adhesion. However, adhesion-related complications are a known, albeit uncommon, long-term risk of intraperitoneal mesh, including adhesive bowel obstruction, mesh-bowel fistula, or delayed infection, and the presence of intraperitoneal mesh can complicate subsequent abdominal operations, resulting in potentially high rates of enterotomy or secondary mesh infection.[50,55–57] As they are designed to prevent tissue ingrowth, barrier-coated meshes should not be used in extraperitoneal position.

Hybrid Mesh

A final category of mesh is the hybrid construct, comprised of a permanent synthetic and an absorbable synthetic or biologic component. There are

currently little data regarding the use of the meshes for various hernia repairs.

GROIN HERNIAS

Groin hernias are described as inguinal and femoral, the inguinal hernias being further subdivided into direct and indirect hernias (some authorities refer to these as medial and lateral hernias, respectively). Groin hernias may be primary or recurrent. An indirect hernia occurs as a protrusion of abdominal contents through the internal ring, lateral to the inferior epigastric vessels, into the inguinal canal. Indirect inguinal hernias (lateral hernias) are situated within the spermatic cord and therefore may extend into the scrotum. In female patients, the hernia follows the round ligament and may present as a swelling in the labium. A direct hernia (medial hernia) is a protrusion through the triangle of Hesselbach medial to the inferior epigastric vessels. These hernias develop through an area where the endoabdominal fascia is not protected by overlying muscle. Direct hernias do not usually involve the cord, as they tend to protrude forward. However, they occasionally track alongside the cord down the entire length of the inguinal canal and even enter the scrotum. For this reason, the only absolute distinction between a direct and an indirect hernia is the relationship to the inferior epigastric vessels. Inguinal hernias are more common in men (with a 15% lifetime risk among men aged >25 years) with a male to female age-adjusted ratio of 7.5:1.[58] A femoral hernia protrudes through the femoral canal, which is bordered by the inguinal ligament superiorly, the lacunar ligament medially, Cooper ligament inferiorly, and the femoral vein laterally. This hernia presents below the inguinal ligament (**Fig. 72.22**). In a sliding hernia, part of the sac is formed by the viscera, on the left side the sigmoid colon or bladder, and on the right side the cecum or bladder (**Fig. 72.23**).

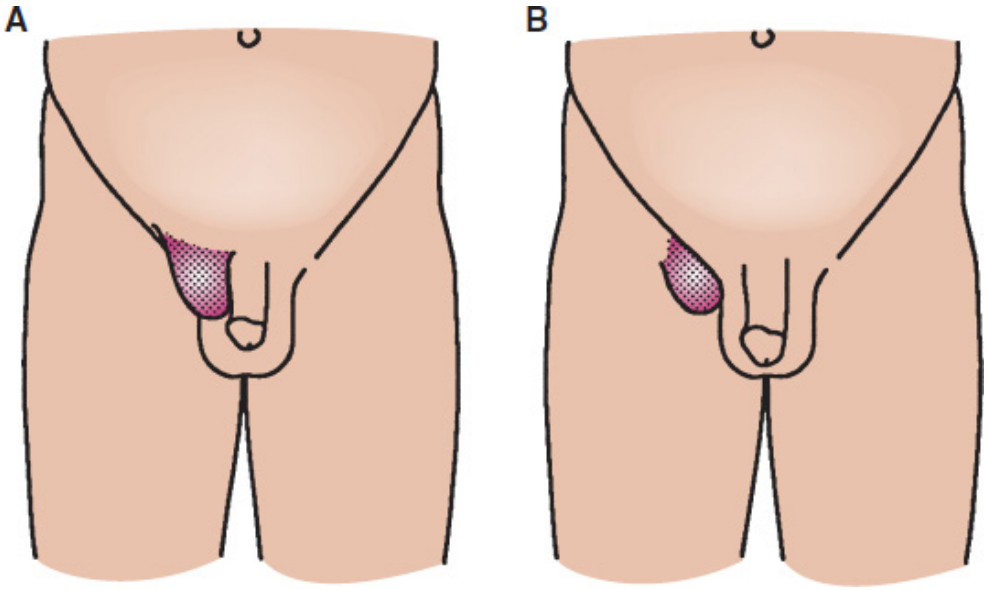

Figure 72.22 **A:** Inguinal hernia. This presents above the inguinal ligament and extends below it. **B:** Femoral hernia. This presents below the inguinal ligament.

Epidemiology

1. Inguinal 3 hernias occur in persons of all ages, from the neonate to the elderly. Inguinal hernias constitute approximately 75% of abdominal wall hernias, with femoral hernia accounting for 5%. Femoral hernias are more common in women, but a woman with a groin hernia is still five times more likely to have an inguinal hernia (usually indirect) than a femoral. Incisional, umbilical, and epigastric hernias account for 15% and miscellaneous hernias make up the other 5%. The lifetime risk of developing a groin hernia is approximately 25% in males and 5% in females. Inguinal hernias are more common on the right than the left and are 10 times more likely in males than in females.[59] Indirect inguinal hernias are twice as common as direct hernias. The reported prevalence of inguinal hernia in the general population varies widely in the literature primarily due to a lack of a consistent reporting mechanism; for example, questionnaire versus actual physical examination. The most reliable data use hernia repair as a surrogate for the prevalence.[60] For example, in a study using the Danish Hospital registry, the country's population of 5,639,885 people was studied. There were 46,717 groin hernia repairs

reported between 2005 and 2010 making it possible to estimate prevalence for various age groups as shown in **Figure 72.24**.

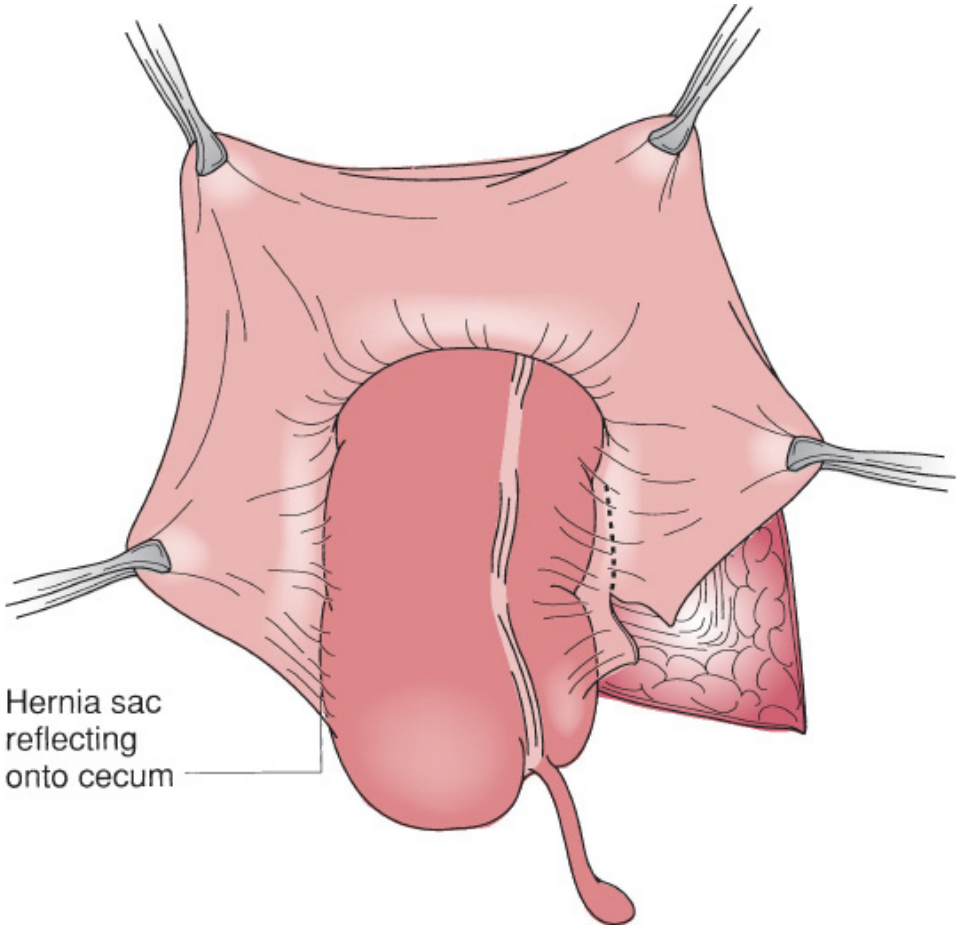

Figure 72.23 Sliding hernia (right indirect inguinal).

2. The figure confirms a bimodal incidence pattern peaking at the extremes of life with an initial peak at 0 to 5 years followed by a second peak at 70 to 80 years.[60] Right-sided inguinal hernias are more common than left. In men, indirect inguinal hernias outnumber direct by about 2:1, with femoral hernias making up a much smaller proportion. The literature dealing with groin hernia in women is insufficient making management decisions difficult. For females, indirect inguinal hernias are the most common which are five times more common than femoral hernias, with direct hernias occurring rarely. Overall, femoral hernias account for fewer than 10% of all groin hernias and the prevalence is higher in females than in males. Femoral hernias are especially dangerous as 40% of all femoral hernias

present as emergencies, with incarceration or strangulation and need emergency repair which is associated with high mortality. A study from the Swedish Hernia Registry analyzing 90,648 inguinal hernia operations (83,753 males, 6,895 females) between 1992 and 2003 revealed a higher percentage of emergency operations in women (16.9%) than in men (5%).[61] Femoral recurrences are particularly common in women in whom the diagnosis at the time of the primary repair was a direct inguinal hernia, strongly suggesting a missed femoral hernia at the original procedure since direct hernias are very rare in women. Femoral hernias are also more common in older patients and in those who have previously undergone inguinal hernia repair. Risk factors for the development of an inguinal hernia are listed in **Table 72.2**.

Classification

The primary purpose of a classification system for any disease is to stratify for severity so that reasonable comparisons can be made between various treatment strategies.[62] However, with the multiplicity of operative techniques and approaches for repair of groin hernias, no one classification system has been accepted by all practitioners. The reason why it is so difficult to develop a classification system that all surgeons can agree on is that in the final analysis, the physical examination represents an important component and no one has been able to eliminate its subjectivity. The European Hernia Society, Nyhus, Gilbert, Schumpelick, Harkins, Casten, Halverson and McVay, Lichtenstein, Bendavid, Stoppa, Alexandre, and Zollinger have developed groin hernia classification systems. The European Hernia Society classification is a simple system using three variables, location (M = medial, L = lateral, and F = femoral) and size of the defect (1 [≤1 finger], 2 [1 to 2 fingers], and 3 [≥3 fingers]) and status (P = primary, R = recurrent, and X = unknown) (**Table 72.3**).[63] The Nyhus system which is shown in **Table 72.4** remains popular among many surgeons in the Unites States.

Clinical Diagnosis

Groin hernias present with a swelling that has a cough impulse. With indirect hernias, the swelling may extend down into the scrotum. The swelling

typically reduces when the patient lies down, though sometimes requires manual reduction. Applying pressure over the mid-inguinal point (midway between the anterior superior iliac spine and the pubic tubercle and just above the inguinal ligament) with the fingertip will control an indirect hernia and prevent it from protruding when the patient strains. A direct hernia will not be controlled with this maneuver. Similarly, if the scrotum is invaginated with the index finger and the tip of the finger is placed through the external inguinal ring into the canal, and the patient is then asked to strain, an indirect hernia will push against the fingertip, whereas a direct hernia will push against the pulp of the finger. It should be noted that the accuracy of this clinical assessment is questioned by many authorities. A femoral hernia presents as a swelling below the inguinal ligament and just lateral to the pubic tubercle (**Fig. 72.22**).

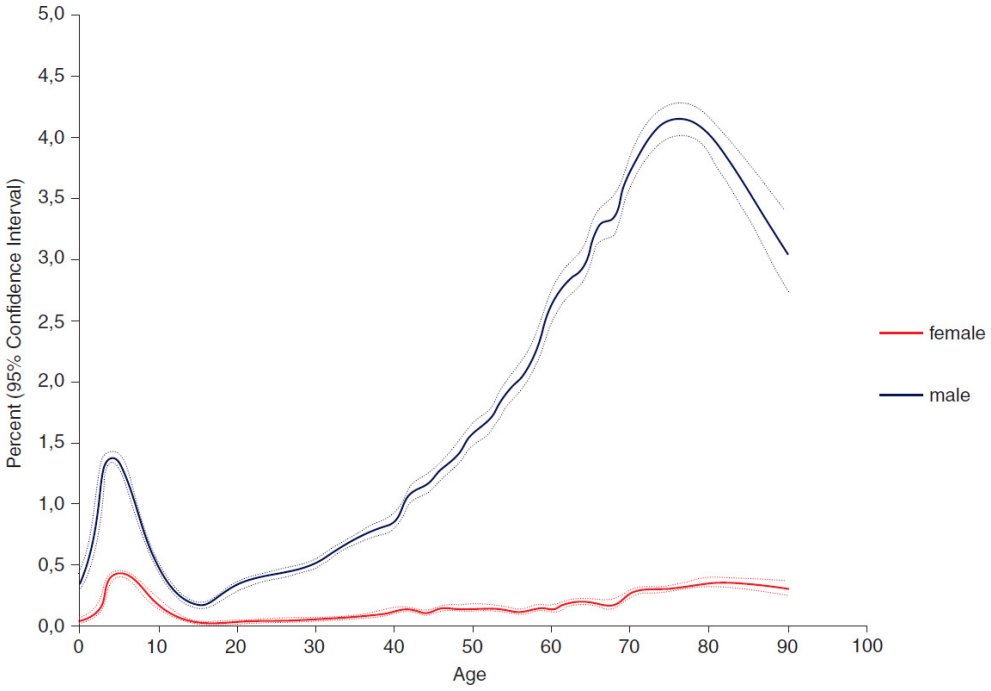

Figure 72.24 Prevalence of combined inguinal and femoral hernia repair (i.e., all groin hernias), stratified by age and gender. The results indicate the percentage of persons at a given age in the population who were operated for a groin hernia during the study period. Example: 4.19% CI 4.04% to 4.34% of all males aged 75 to 80 years in Denmark were operated for a groin hernia at least once during the study period. (From Burcharth J, Pedersen M, Bisgaard T, et al. Nationwide prevalence of groin hernia repair. *PLoS One* 2013;8(1):e54367, with permission.)

Differential Diagnosis

The clinical presentation of a groin hernia, especially when large, is frequently obvious to the examiner. Smaller hernias and recurrent hernias can be confused with a number of different conditions that can be mistaken for a hernia (**Table 72.5**).

Table 72.3 EHS Classification of Groin Hernias

		Primary (P)		Recurrent (R)

Lateral (L)					
Medial (M)					
Femoral (F)					

Table 72.4 Nyhus Classification of Groin Hernias

Type	Description
I	Indirect hernia Normal-sized internal ring Typically in infants, children, small adults
II	Indirect hernia Dilated internal ring Posterior wall intact Inferior epigastric vessels not displaced Does not extend to the scrotum
III	Posterior wall defect
IIIA	Direct hernia Size not taken into account
IIIB	Indirect hernia Dilated internal ring encroaching on Hesselbach triangle (massive scrotal, sliding, or pantaloon type)
IIIC	Femoral hernia
IV	Recurrent hernia
IVA	Direct
IVB	Indirect
IVC	Femoral
IVD	Combined

A hydrocele extending into the scrotum or an encysted hydrocele of the cord can involve the groin area. The distinguishing features are that the examining hand can get above a hydrocele but not above a hernia and that a hydrocele transilluminates very clearly. A varicocele does not transilluminate, has the characteristic feel of a "bag of worms," and is more

tube-like in conformation. Lesions of the testicle may sometimes mimic a hernia, particularly in inflammatory conditions, such as epididymo-orchitis. The distinguishing features are intense pain extending down into the scrotum. The testicle itself is enlarged and tender, as is the epididymis. On rectal examination, the seminal vesicles are tender. This condition may be bilateral. Torsion of the testicle is distinguished by the fact that the testicle is absent from the scrotum and the swelling in the groin feels firm. A sonogram reveals a solid mass in the testicle, which has been pulled up because of the torsion. Testicular tumors, if large enough, may extend up to the groin area, but they have a solid feel and sonography can distinguish them. An aneurysm of the femoral artery may present as a groin swelling but with an expansile impulse and sometimes a bruit. If thrombosis develops in the aneurysm, pulsation may be lost. In this instance, the aneurysm becomes tender. Femoral aneurysms move from side to side but not up and down. A saphena varix usually presents below the inguinal ligament and represents a varicosity of one of the branches of the long saphenous vein as it emerges from the hiatus. It is particularly common in pregnancy. Like a hernia, the varix has a cough impulse and becomes more prominent when the patient is standing. Compression over the femoral hiatus obliterates this lesion. The varix is sometimes associated with varicose veins farther down the lower limb. The overlying skin has an associated bluish discoloration. A lipoma within the spermatic cord is a very common condition and, from anatomic studies and surgical dissection, is now regarded as a hernia of the extraperitoneal fat.[64] If found at surgery, the lipoma is removed to avoid a persistent bulge in the inguinal region despite a successful hernia repair.

Table 72.5 Differential Diagnosis of a Groin Hernia
Hydrocele
Encysted hydrocele of the cord
Varicocele
Epididymo-orchitis
Torsion of the testis
Undescended testis
Ectopic testis
Testicular tumor
Pseudohernia
Femoral artery aneurysm
Saphena varix
Lipoma of spermatic cord
Inguinal lymphadenopathy
Psoas abscess
Cutaneous lesions (e.g., sebaceous cyst and skin tumor)

Enlargement of inguinal lymph nodes may also be mistaken for herniation. Inflammatory nodes are usually tender; metastatic lymphadenopathy is usually not tender. If inguinal lymph nodes are replaced by metastasis, a primary lesion should be looked for in the skin in any part of the lower limb. The perineum and anal canal should also be examined. Lymphadenopathy can also be caused by lymphoma, and groin nodes may be the only site. Lymphadenopathy characteristically appears as a well-circumscribed mass below the inguinal ligament that one can get above with the examining hand.

Lymph nodes are solid on ultrasonography, and for this reason, it may be difficult to differentiate nodes from a femoral hernia containing omentum.

Surgical Indications

Historically, surgeons have recommended repair of inguinal hernias at diagnosis unless specific contraindications are present. This recommendation was based on the presumption that the morbidity and mortality associated with a bowel obstruction and/or strangulation was greater than the risks of operation. 4 This concept was challenged for asymptomatic or minimally symptomatic male patients based on several randomized controlled trials in the early part of this century which demonstrated that watchful waiting for minimally symptomatic inguinal hernias was safe.[35] However, long-term follow-up from these randomized controlled trials have demonstrated a crossover rate of up to 70% by 10 years for patients in the watchful waiting group, with crossover being much higher for patients older than 65 years of age. The most common reason for crossover is increasing pain. Patients who opt for this strategy should be informed that it is safe to delay surgery for several years, but increasing symptoms will more than likely make them choose to have their hernia repaired over the next 10 years.

An alternative to surgical repair is a mechanical device known as a truss which consists of a belt with a pad that is applied to the groin after spontaneous or manual reduction of a hernia and has been used for centuries. It serves to maintain reduction and possibly prevents enlargement of the hernia. There are insufficient studies to determine how effective trusses actually are and whether they are as good as surgery for the control of symptoms.[65] Most patients find them cumbersome to use and difficult to keep clean. With prolonged usage, atrophy of the spermatic cord has been reported and eventual surgical repair is made more difficult due to fibrosis of the tissues. However, some patients do achieve symptomatic relief. **Table 72.17** summarizes the International Guidelines for Groin Hernia Management.[66]

Preoperative Considerations

Most elective groin hernias can be repaired on outpatient basis. Local anesthesia is sufficient for most cases of open inguinal hernia repairs with or

without supplemental intravenous sedation. Its greatest advantage is the virtual elimination of urinary retention when compared to regional or general anesthesia.[67] Additionally, recovery can be quicker than techniques utilizing general anesthesia especially in the elderly population. General anesthesia is an acceptable alternative and is preferred by many surgeons in patients with acceptable perioperative anesthesic risk. Indeed, epidemiologic information from databases primarily in Europe discloses that local anesthesia is used in only about 10%.[68] Regional anesthesia has the highest incidence of cardiovascular complications and should be avoided.[68] Laparoscopic hernia repairs require general anesthesia and can only be performed in patients who can safely tolerate general anesthesia and a pneumoperitoneum. Antibiotic prophylaxis has not been shown to be of any value except in patients at high risk for infection.[66] Nevertheless, it is routinely used in the United States because of medicolegal considerations when placing a prosthesis.

Surgical Treatment of Groin Hernias

Four developments in the latter half of the 20th century significantly decreased morbidity and favorably influenced the recurrence rate to the currently accepted level of less than 2%: (a) the routine use of prosthetic materials, (b) the widespread acceptance of the "tension-free" concept, (c) the realization that the preperitoneal space can be used for hernia repair, and (d) therapeutic laparoscopy (**Algorithms 72.1** and **72.2**). These concepts are discussed in this section; the treatment strategies are divided between an open approach in the conventional anterior space and a preperitoneal approach, either open or laparoscopic.

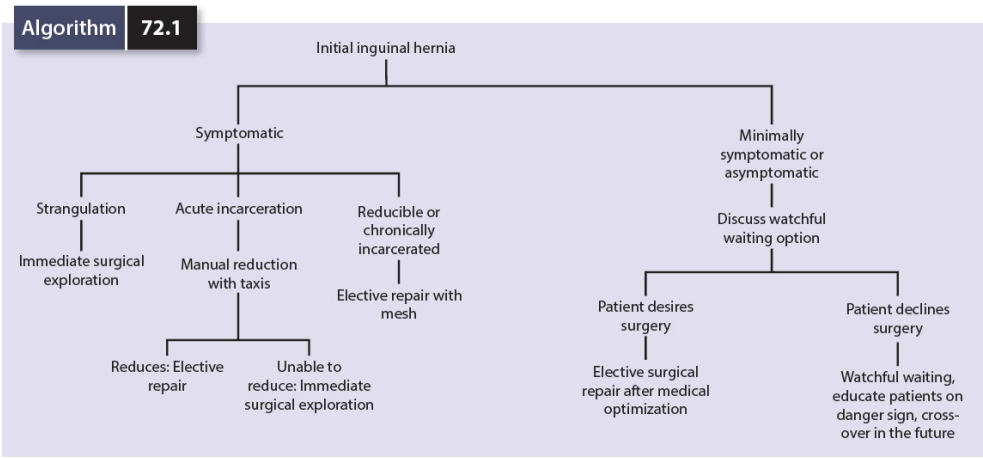
Open Approach

The simplest Nyhus type I indirect inguinal hernias, which include most inguinal hernias in children, are adequately treated by obliteration of the congenital patent processus vaginalis alone. Since the inguinal floor is otherwise normal, reconstruction is not required. Classically, the hernia sac is dissected from the cord structures, ligated, and removed at its origin at the internal ring, the so-called high ligation of the sac, thus the term *herniotomy.* The skin incision starts at the pubic tubercle and is extended laterally. The

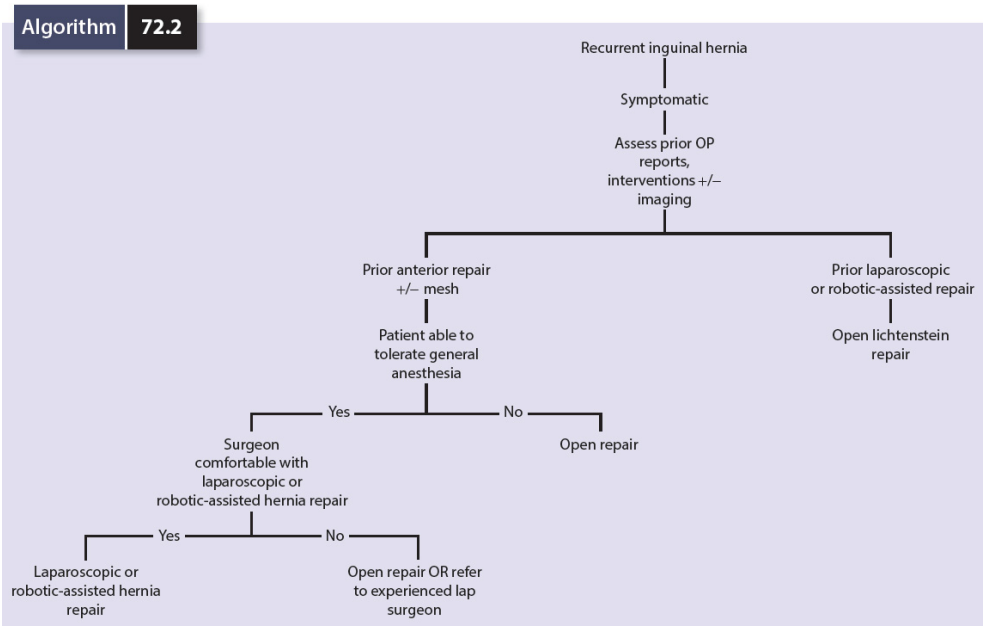
external oblique aponeurosis is opened in the line of its fibers through the external ring and the lower leaf is freed from the spermatic cord. The spermatic cord is freed from the floor of the inguinal canal and the pubic tubercle. Mobilization of the cord structures is completed by means of blunt dissection, and a Penrose drain is placed around them so that they can be retracted during the procedure.

The genital branch of the genitofemoral nerve and the spermatic vessels are included with the cord. The ilioinguinal and iliohypogastric nerves are usually preserved. The cremasteric fibers are separated, and the hernia sac is dissected from the cord structures to a point proximal to the internal ring. Ligation can be performed at this point (high ligation), followed by division of the neck of the sac. Prior to this, the sac can be opened to allow a digital examination of the abdominal cavity and femoral ring. Alternatively, the sac may be simply inverted. The proponents of not opening the sac feel that with this method the patient experiences less pain because the highly innervated peritoneum has not been violated. Notably, herniotomy is rarely utilized solely as a means of repair in adults.

The terms *herniorrhaphy* or *hernioplasty* are used when a procedure to reconstruct the inguinal floor is added. For indirect hernias, the sac is first dealt with in an identical manner as for a herniotomy. The only exception is large indirect inguinal scrotal hernias where complete removal of the sac might result in too high of an incidence of cord and testicular complications because of the extensive dissection required to completely separate them from the cord. Most authorities believe that these large sacs are best transected at the midpoint of the canal, and the distal sac is left in situ. Direct hernia sacs are almost never removed but instead are dissected from surrounding structures and reduced into the preperitoneal space. Dividing the transversalis fascia circumferentially at the neck (base) of the sac will aid in this reduction in some cases. The defect may be closed primarily at this point to maintain the reduction while a formal repair is being performed. The latter is considered a matter of convenience and adds nothing to the strength of the final outcome. The area of weakness in the posterior wall is then reinforced with the patient's own tissues or a mesh prosthesis.



Algorithm 72.1 Management of initial inguinal hernia.



Algorithm 72.2 Management of recurrent inguinal hernia.

The next step is to reconstruct the inguinal floor. There are two ways to do this. The first is a tissue repair, so named because only the patient's native tissue is used without foreign 5 prosthetic material. The second is the tension-free repair (TFR). This implies the use of a prosthesis to repair the weakened inguinal floor, eliminating the need to reapproximate tissues that were not in apposition naturally. Edoardo Bassini (1844–1924) is considered the father of modern inguinal hernia surgery because in the latter part of the 19th century he introduced the first tissue repair based on solid anatomic principles, which became the "gold standard" for inguinal hernia

repair for most of the 20th century. His scientific approach led to the development of several distinct steps essential for the procedure (**Table 72.6**). Before Bassini's achievements, elective herniorrhaphy was almost never recommended because the results were so bad.

Today, there are at least 70 named tissue repairs described in the literature.[69] Most are relatively minor modifications of the Bassini, Shouldice, and McVay repairs. In the Bassini repair, the transversus abdominis aponeurosis together with the transversalis fascia is sutured to the shelving edge of the inguinal ligament with nonabsorbable interrupted sutures (**Fig. 72.25**). In the Shouldice repair, the transversalis fascia is divided from the internal ring to the pubic tubercle. The musculofascial elements laterally are then sutured to different levels of the inferior flap of the external oblique aponeurosis with four rows of running sutures (**Fig. 72.26**). Although the suture material originally used for this repair was stainless steel wire, other nonabsorbable materials, such as Prolene, are now used. The McVay repair (**Fig. 72.27**) addresses both inguinal and femoral hernias. The central attenuated portion of the inguinal floor is excised. Cooper ligament must be clearly identified. The inguinal floor is then repaired by approximating the transversus abdominis aponeurosis and transversalis fascia to Cooper ligament between the pubic tubercle and the femoral vein. A so-called transition stitch is then necessary between the transversalis fascia, Cooper ligament, and inguinal ligament to bring the repair above the femoral vessels. The repair is then continued laterally along the inguinal ligament.

Table 72.6 Essential Steps for Open Inguinal Hernia Repair

1. Complete division of the external oblique aponeurosis and the transversalis fascia
2. Differentiation between indirect and direct defects
3. Isolation of the spermatic cord or round ligament
4. Ligation and removal of the sac at the deep inguinal ring flush with the peritoneum
5. Oblique reconstruction of the inguinal canal with an anterior and posterior wall and an internal and external ring

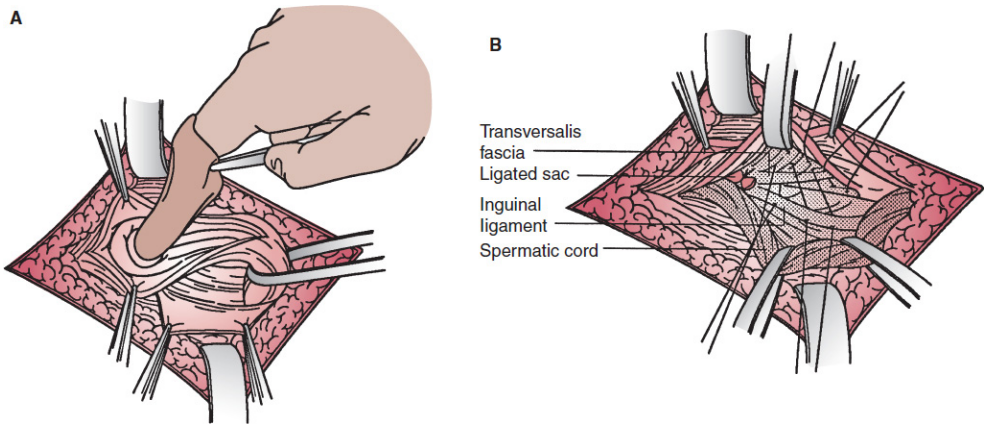


Figure 72.25 Bassini repair.

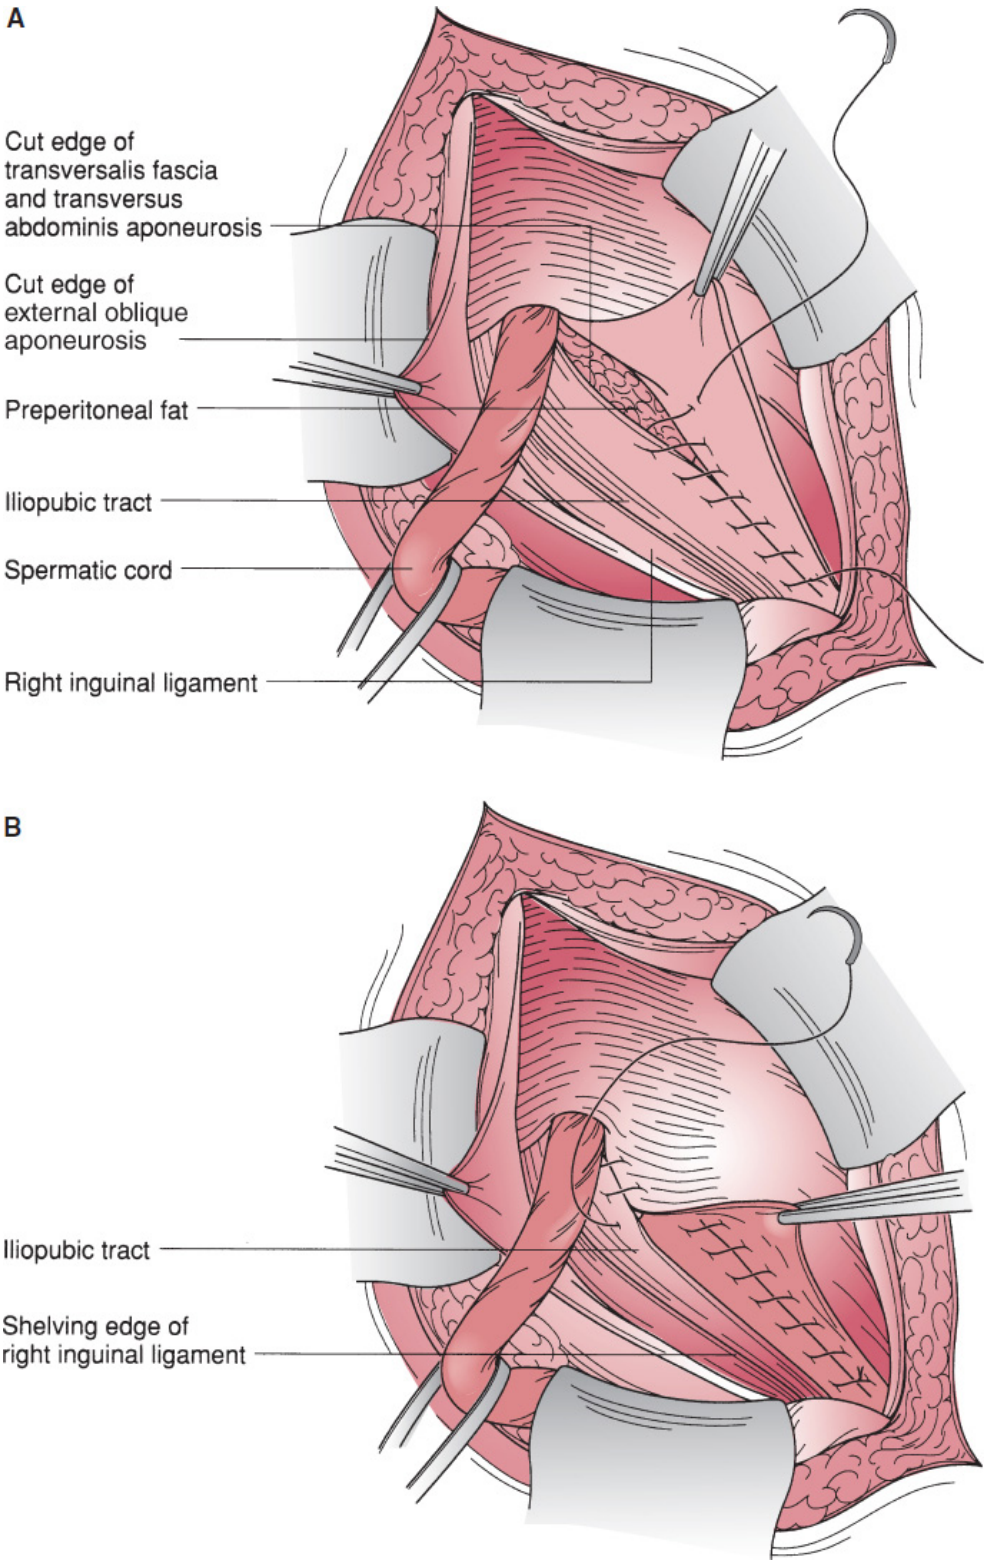

Figure 72.26 Shouldice repair.

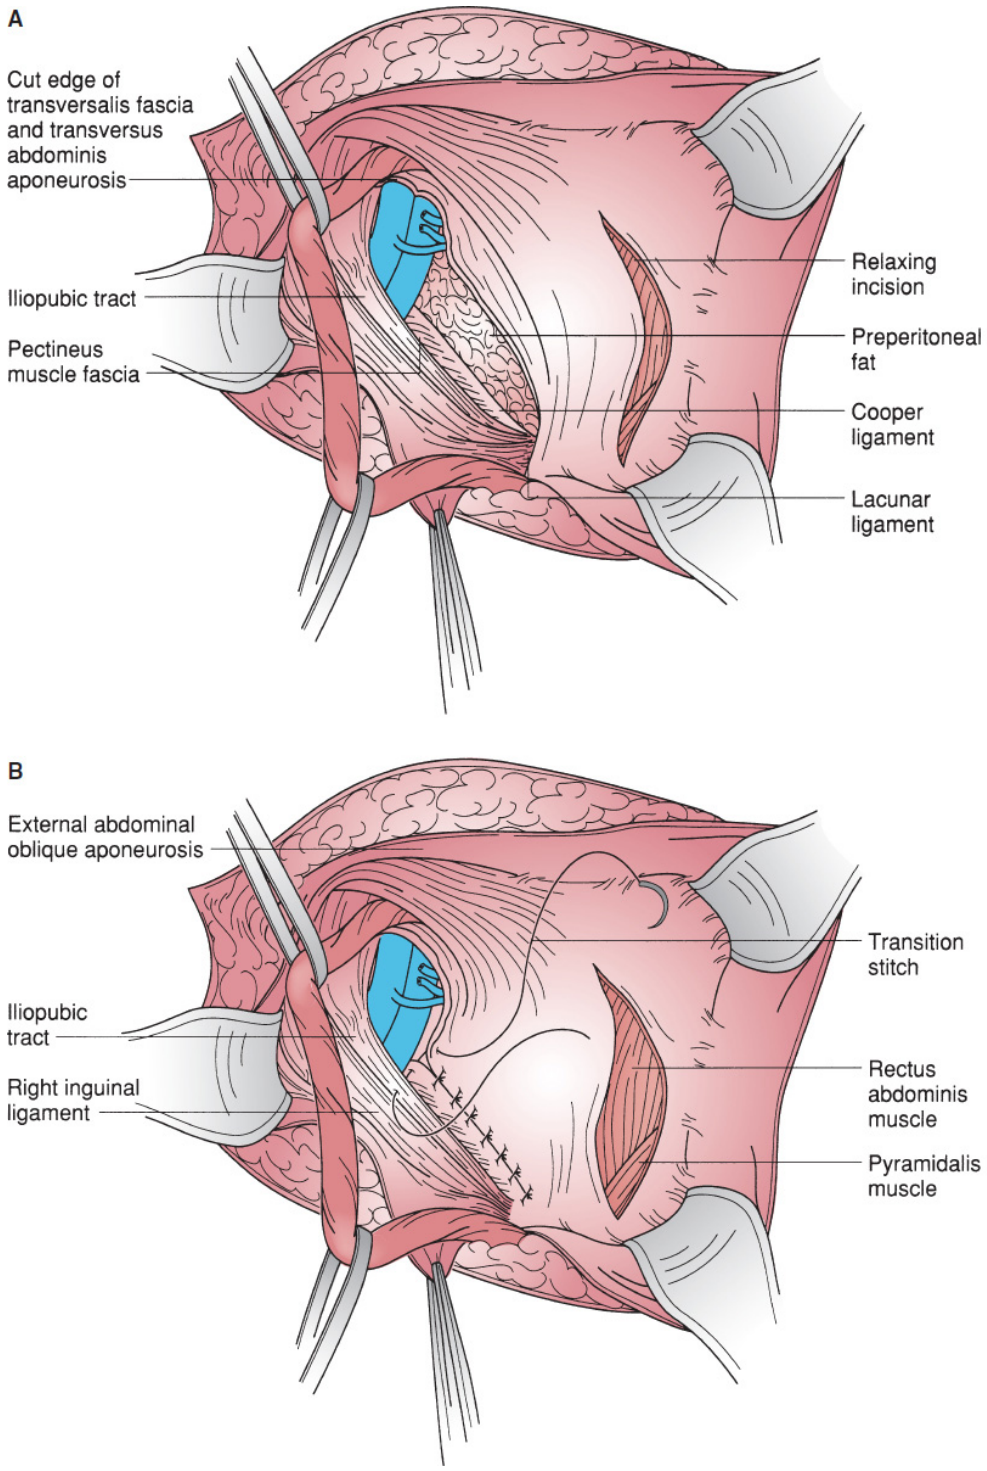

Figure 72.27 McVay (Cooper ligament) repair.

A relaxing incision is necessary for repairs of large indirect hernias and whenever the McVay repair is used. Failure to make a relaxing incision has been implicated in a greater incidence of recurrence. The relaxing incision is

made in the anterior rectus sheath in a vertical direction and is extended 3 to 4 cm above the pubis to a level opposite the internal ring (**Fig. 72.27**). The resulting defect in the sheath is protected posteriorly by the body of the rectus muscle, which prevents herniation at that site.

As population-based studies began to supplant personal series, it became obvious that the recurrence rate for tissue repairs with the exception of the Shouldice repair approached 10% to 15% in the general surgical practice.[70] In the 1990s, widespread adoption of the routine use of prosthesis (usually a mesh material) as popularized by Lichtenstein has resulted in the near elimination of the Bassini approach in the United States with recurrence rates decreasing by 50% to 75%.[71] The Lichtenstein operation or open mesh herniorrhaphy, which is considered the "gold standard" operation for inguinal hernias with a recurrence rate of 1% to 1.6% (**Fig. 72.28**).[72] The initial dissection is identical to the tissue repairs described. A useful adjunct to this approach is to separate the subcutaneous fat from the inguinal ligament exposing the femoral sheath. The femoral artery can usually be easily palpated and the typical space for femoral hernia palpated medial to the femoral vein. This allows assessment of the femoral space without division of the transversalis fascia. Care is taken to minimally disrupt the spermatic cord and its contents, dissecting only what is necessary to achieve each step of the operation. Attempts are made to identify and preserve in situ the ilioinguinal nerve, iliohypogastric nerve, and genital branch of the genitofemoral nerve. If a femoral hernia is present, the inguinal floor is incised, exposing the preperitoneal fat, femoral space, and Cooper ligament. Once the sac has been dealt with and any sizable cord lipoma resected, a 15- × 7-cm sheet of mid-weight polypropylene mesh is used, the medial end of which is rounded to the shape of the medial corner of the inguinal canal. This medial end is allowed to extend 2 cm medial to the pubic tubercle. The first running permanent suture approximates the inferior aspect of the mesh to the shelving edge of the inguinal ligament just adjacent to, but not through, the pubic tubercle. The periosteum of the bone is avoided to prevent osteitis pubis. This is continued just proximal to the internal ring and tied to itself. Next, superior absorbable sutures are placed in an interrupted fashion approximating the mesh to the conjoined tendon, taking care to avoid the iliohypogastric nerve. For a femoral hernia, a posterior "extension" of the mesh is added when shaping the mesh and approximated to Cooper ligament

after the inferior edge has been attached to the inguinal ligament. Alternatively, the inferior edge of the prosthesis is sewn directly to Cooper ligament medially and then transitioned to the inguinal ligament over the femoral vessels. Both techniques close the femoral canal. A slit is cut in the lateral end of the mesh to produce a narrow (one-third width) tail below and a wider (two-thirds width) tail above. The spermatic cord is positioned between the two tails. The wider tail is placed over the narrow one and a so-called shutter valve stitch placed just lateral to the cord including the inferior surface of the superior tail, the inferior surface of the inferior tail, and the inguinal ligament. The tails are then tucked under the external oblique aponeurosis to the level of the anterior superior iliac spine. The external oblique aponeurosis is closed to recreate the external ring. The wound is closed in layers.

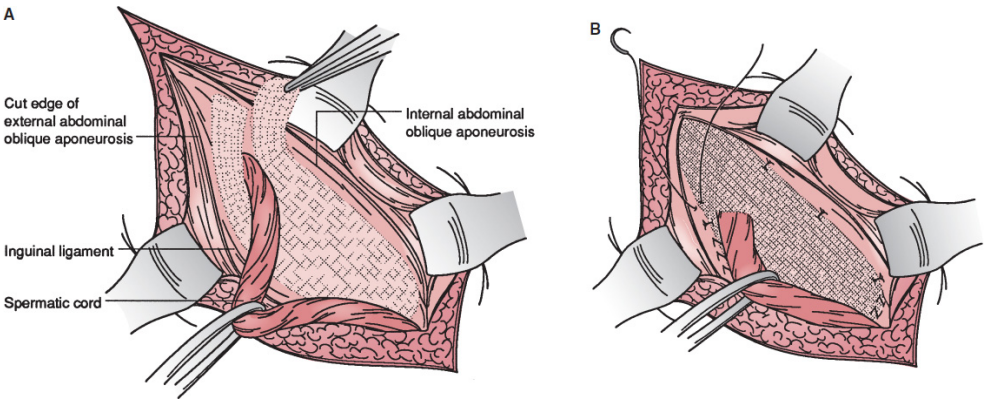

Figure 72.28 The Lichtenstein hernioplasty, showing placement of the mesh.

A popular modification of the Lichtenstein operation has been termed the plug-and-patch repair. As the name implies, a plug usually constructed from polypropylene is inserted in the defect and secured with interrupted sutures to either the internal ring (for an indirect hernia) or the neck of the defect (for a direct hernia). The patch is then placed over the plug to cover the inguinal floor as in the Lichtenstein. One might argue that this operation is nothing more than a Lichtenstein on top of a plug, and in fact the term "plugstenstein" has been used to describe it. However, the difference with a plug-and-patch repair is that only one or two sutures—or, sometimes, no sutures—are used to secure the flat prosthesis to the underlying inguinal floor. This results in an operation that is fast and very easy to teach. However, based on trials

comparing the plug and patch to the Lichtenstein technique, no benefit with respect to recurrence rate and/or chronic pain has been demonstrated.[66] The downside of this operation is the mesh burden placed in the inguinal region, including a dense plug that can migrate. In addition, plugs can make repairs for recurrence very challenging later in a patient's course.

A hybrid procedure described by Desarda combines elements of the Lichtenstein repair with a pure tissue repair avoiding the need for allogeneic material.[73] The initial steps are identical to Lichtenstein but then instead of using a synthetic prosthesis to reinforce the inguinal floor, the medial edge of the divided external oblique aponeurosis is approximated with a continuous suture to the inguinal ligament beginning at the pubic tubercle and extending to the internal ring. The external oblique aponeurosis is then divided again one to two CMs cranially parallel to the inguinal canal in effect creating a vascularized flap of external oblique which serve as an autologous patch to reinforce the inguinal floor. The cranial edge of this flap is then sutured to the internal oblique muscle from the pubic tubercle to the internal ring. The cord structures are returned to the inguinal canal and the two remaining cut edges of the external oblique aponeurosis are reapproximated to reconstruct the anterior surface of the inguinal canal and the external ring.

Preperitoneal Approach

The preperitoneal space is situated between the transversalis fascia and the peritoneum. The final common denominator in all groin hernias is failure of the transversalis fascia to retain the intra-abdominal contents. Repairs performed in this space make the distinction between direct, indirect, and femoral irrelevant because the repair is accomplished behind the defective transversalis fascia, addressing the entire myopectineal orifice.

For a conventional, open operation, the preperitoneal space can be entered via a lower midline incision or a transverse incision placed slightly higher than usual. The rectus muscle is retracted medially and the preperitoneal space entered. A large prosthesis is used that extends far beyond the margins of the myopectineal orifice and envelops the visceral sac. The mesh is held in place by intra-abdominal pressure, which pushes outward toward the undersurface of the transversalis fascia. If the hernia sac is large, it is amputated or inverted beneath a purse-string suture to smooth the external

surface of the visceral sac. The distal peritoneal sac is left in place, undissected, and attached to the cord. With a sliding indirect hernia, the sac is easily dissected away from the cord. For a bilateral repair, one large chevron-shaped mesh can be used for both sides as described by Stoppa. One disadvantage of this technique is the need for a larger incision and substantial amount of dissection and the associated pain. Laparoscopic hernia repairs avoid the disadvantages of a large incision while providing the advantages of preperitoneal repair.

Several newer, less invasive preperitoneal techniques have been developed to place a mesh in the preperitoneal space. For example, in the Kugel procedure, a small incision is made over the deep inguinal ring and the preperitoneal space is developed bluntly followed by the use of a prosthesis with an incorporated reinforcing ring. This ring can be deformed to allow the prosthesis to be introduced into the preperitoneal space and then the ring causes it to spring back to its original shape, providing wide overlap of the myopectineal orifice.[74] The procedure works well in experienced hands but because it is partially blind, considerable training is required. In addition, in earlier designs, the peripheral memory recoil ring was made of polyethylene terephthalate which had a tendency to fracture over time occasionally resulting in injury to nearby viscera.[75] In addition to the Stoppa and Kugel procedures, other preperitoneal repairs have been described including the Trans Rectus sheath Pre Peritoneal technique, the Trans Inguinal Pre Peritoneal, the Onstep technique and the Ugahary technique. A detailed description of each of these operations is beyond the scope of this chapter but a thorough discussion of them is provided in the reference.[76]

Another approach is to take advantage of both the preperitoneal space and the conventional anterior space using a bilayered prosthesis in which a cylinder of prosthetic material connects the two layers through the hernia defect or the internal ring.[77] One such prosthetic is the Prolene Hernia System (PHS) where both an onlay and sublay mesh is placed. Trials comparing PHS to the Lichtenstein technique have not shown any difference with respect to recurrence rate and chronic pain.[66] The objection to this system is that both the conventional anterior and the preperitoneal spaces are dissected making the repair of a recurrence more difficult.

Laparoscopic Approach

The terminology to describe a laparoscopic inguinal herniorrhaphy can be confusing. A laparoscopic preperitoneal hernia repair, in which a laparoscopy is performed and the preperitoneal space is entered with a second incision in the peritoneum, is called a *transabdominal preperitoneal repair,* or TAPP repair. An inguinal hernia repair in which prosthetic material is placed intraperitoneally over the defect under laparoscopic guidance is referred to as an *intraperitoneal onlay mesh repair,* or IPOM repair. The third general type of laparoscopic approach is the *totally extraperitoneal laparoscopic repair,* or TEP repair. Laparoscopy, by definition, implies that the peritoneal cavity has been entered. To refer to this technique as *extraperitoneal* therefore represents a contradiction in terms. However, because a laparoscope and related instruments are used, it is fitting to discuss the extraperitoneal approach along with the other laparoscopic inguinal herniorrhaphies.

The TAPP and the TEP laparoscopic inguinal herniorrhaphies are the most popular. Both are modeled after the conventional preperitoneal operations. The major difference is that the preperitoneal space is entered through three trocar sites rather than through a large conventional incision. The ensuing radical dissection of the preperitoneal space with placement of a large prosthesis is similar to the conventional preperitoneal operation.

Laparoscopic versus Conventional Herniorrhaphy; Mesh versus Non-Mesh

Randomized controlled trials as well as meta-analysis of pooled data from these trials have shown that on average, patients undergoing laparoscopic herniorrhaphy have less pain initially than open, tension-free herniorrhaphy and return to normal activities sooner with a lower incidence of wound infection and hematoma and less chronic pain/numbness.[66,78] These advantages of laparoscopic hernia repair must be interpreted in light of the disadvantages, which include longer operative time and complications related to the laparoscopy such as bowel perforation or major vascular injury, potential adhesive complications at sites where the peritoneum has been breached or prosthetic material has been placed, the need for a general anesthetic, and increased cost because of the expensive equipment. On the other hand, the conventional operation can be performed under local anesthesia on an outpatient basis, with minimal risk of intra-abdominal

injury, and the cost is less. The best indications are a recurrent hernia after an open conventional procedure or for bilateral hernias. The most important final determinate about the best procedure for an individual patient should be based on local factors such as surgeon expertise, size and degree of incarceration of the hernia and the patient's comorbid conditions. In general practice a mesh repair is recommended because of its dramatic decrease in recurrence rate when compared to tissue repair, realizing that there are specialty centers performing pure tissue repairs with results equaling a mesh repair.

Robotic-Assisted versus Laparoscopic Inguinal Herniorrhaphy

There have been several inconclusive evaluations comparing a robotic-assisted approach to inguinal hernia repair to a laparoscopic approach. Representative retrospective studies have not shown significant benefit.[79] The only prospective trial to date is the Transabdominal Laparoscopic Inguinal Repair (RIVAL) study.[75] In this randomized controlled clinical trial, 102 patients were randomized to either robotic-assisted or laparoscopic approach to inguinal hernia repair. No difference was noted for the primary outcomes of postoperative pain, quality of life, mobility, wound morbidity, or cosmesis. The robotic-assisted approach was associated with longer operative times (76 minutes vs. 41 minutes) and higher mean frustration levels as measured by the NASA Task Load Index Scale. No differences in ergonomics were noted between the groups. Higher median cost per case was noted for the robotic-assisted approach ($3,258 vs. $1,421) not accounting for capital equipment costs in either group.[80]

Patient and Procedure Selection

6 Assuming equivalence for recurrence and complication rates between laparoscopic and open tension-free hernia repair for a given surgeon, all adult patients with inguinal hernias who are candidates for general anesthesia can be considered candidates for laparoscopic inguinal hernia repair.[66] Certain hernia types, such as those that are recurrent, bilateral, or otherwise complicated, are particularly suited for the laparoscopic approach.[81,82] In addition, women may be better served with a laparoscopic operation because the femoral space is addressed, which should eliminate the excessive incidence of femoral recurrence observed with conventional

operations such as the Lichtenstein.[61] Contraindications to laparoscopic inguinal hernia repairs include intra-abdominal infection and coagulopathy. Relative contraindications for laparoscopic inguinal hernia repair include intra-abdominal adhesions from previous surgery, ascites, or previous retropubic space surgery, because of the increased risk for bladder injury. Severe underlying medical illness is also a relative contraindication because of the added risk of general anesthesia and these patients are better suited for a conventional operation under local anesthesia. An incarcerated sliding scrotal hernia is a relative contraindication, especially when it involves the sigmoid colon, because of the high risk for perforation during the dissection.

Operative Techniques

Transabdominal Preperitoneal Repair

The TAPP repair can be performed either via robotic-assisted or traditional laparoscopic approach. The procedure is begun with a thorough diagnostic laparoscopy done through an umbilical or periumbilical cannula to rule out unrelated pathology and carefully inspect both myopectineal orifices. Two additional cannulas are placed just lateral to the rectus sheath on either side of the umbilicus (**Fig. 72.29**). For a unilateral hernia, a transverse incision is begun at the lateral side of the medial umbilical ligament and extended to the anterior superior iliac spine. It is quite important to enter the true preperitoneal plane and not the retromuscular plane (anterior to the transversalis fascia) which leads to a bloodier dissection. Conversely, the retromuscular plane can be preferentially entered in situations where previous pelvic operations have been performed (i.e., prostatectomy, Pfannensteil incision, rectal surgery, open appendectomy). In these situations, the operation should be performed by surgeons with much experience with laparoscopic or robotic-assisted approaches. If the medial umbilical ligament appears to compromise exposure, it can be divided. Electrosurgical current is used to minimize bleeding from the remnants of the embryologic umbilical artery. A radical dissection of the preperitoneal space is then performed with mostly blunt dissection and generous use of electrosurgical current, as bleeding in this area is particularly troublesome if it interferes with illumination. The ipsilateral inferior epigastric vessels, Cooper ligament, and iliopubic tract are identified (**Fig. 72.30**). The cord structures

are mobilized, and the peritoneal flap is dissected well proximal to the bifurcation of the vas deferens and the internal spermatic vessels. Recurrences have been attributed to inadequate mobilization of the peritoneal flap, which does not allow the prosthesis to lie flat in this area. If small, an indirect sac is mobilized away from the cord structures and reduced. If large, the sac can be divided at a convenient point distal to the internal ring and only the proximal portion mobilized. A direct sac readily reduces during the preperitoneal dissection. An easily visible layer of fatty tissue separates the attenuated transversalis fascia lining the defect and the peritoneum.

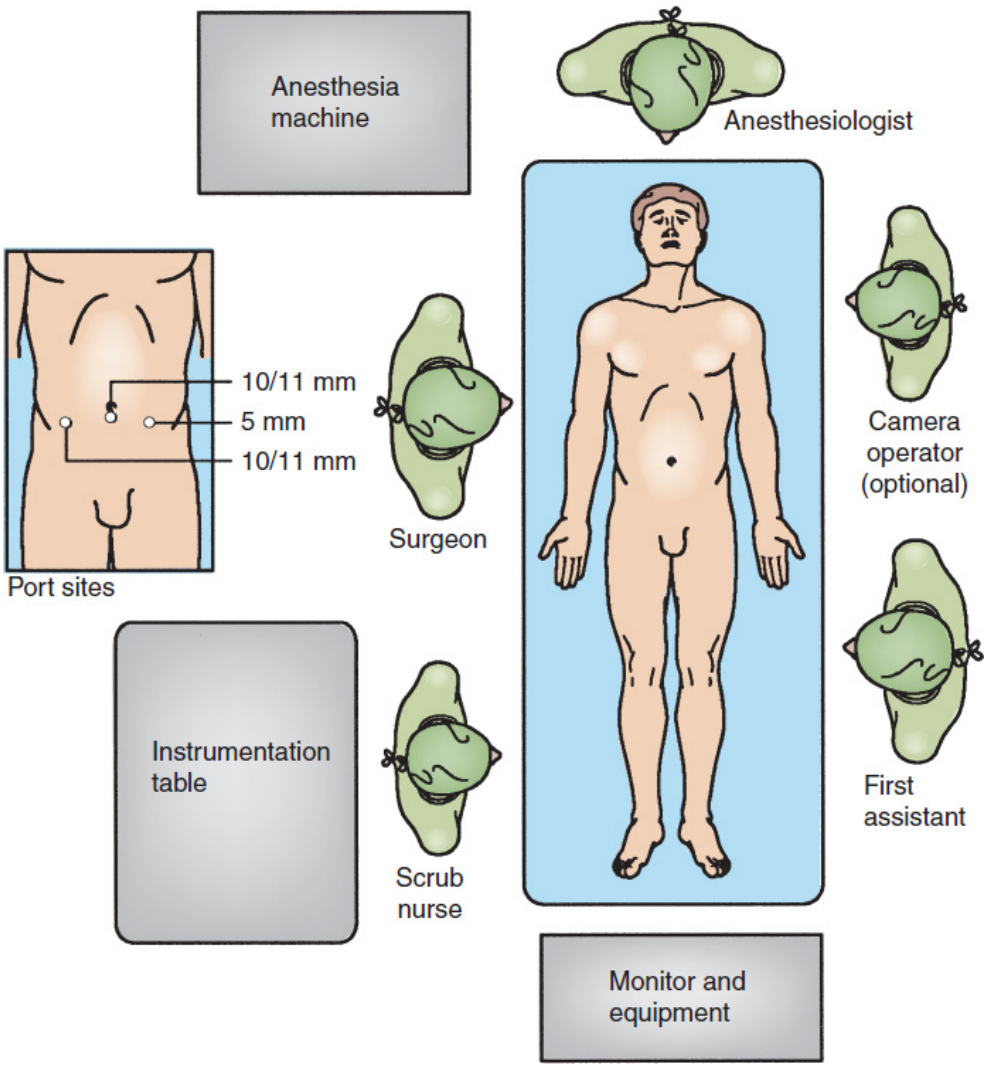

Figure 72.29 Typical operative setup and cannula site selection for a transabdominal preperitoneal (TAPP) laparoscopic inguinal herniorrhaphy.

A large piece of permanent mesh (at least 14 × 11 cm) is placed in the preperitoneal space to cover the entire myopectineal orifice and extending onto the anterior abdominal wall superiorly at least 2 cm above the hernia defect, to the anterior superior iliac spine laterally, and to Cooper ligament medially. Most surgeons prefer to fasten the prosthesis with staples, tacks, or glue, but there is increasing evidence that fixation is not necessary when a large prosthesis is used that widely overlaps the entire myopectineal orifice. Staples or tacks are never placed below the iliopubic tract when lateral to the internal spermatic vessel because of the danger of damage to the important nerves in this area. The last step is to cover the prosthesis by closing the peritoneum with sutures, tacks, staples, or glue.[66] The goal is to isolate the prosthesis from the abdominal viscera rather than to always achieve precise approximation of the peritoneal edges. This is because gaps can form if the peritoneum is closed under tension allowing bowel to migrate into the preperitoneal space. A better option is to secure the inferior peritoneal flap to the transversalis fascia above the prosthesis and leave the superior flap alone.

For bilateral inguinal hernias, two different approaches are commonly used. A separate peritoneal flap can be created similar to a unilateral approach. The advantage of this is easier handling of the peritoneal flap closure. Alternatively, the symphysis pubis is completely exposed so that both preperitoneal dissections communicate with each other. This exposure allows the placement of one large prosthesis (at least 25 × 11 cm) that essentially covers the entire lower pelvis.

Totally Extraperitoneal Repair

An incision is made at the umbilicus and the rectus sheath is opened on one side and the rectus muscle is retracted laterally. Blunt dissection is then begun in the space between the rectus muscle and the posterior rectus sheath. Once the space is large enough, two additional cannulas are placed in the midline, one approximately 5 cm above the symphysis pubis and the other midway between the umbilicus and the symphysis pubis. The dissection of the retrorectus and preperitoneal space immediately posteriorly is completed under direct vision. The rest of the operation is identical to the TAPP procedure described previously except that peritoneal closure is not necessary. Popular alternatives are to use a water- or air-filled balloon

dissector to perform the preperitoneal dissection and to place the two accessory cannulas on either side of the umbilicus, as in the TAPP procedure, instead of in the midline.

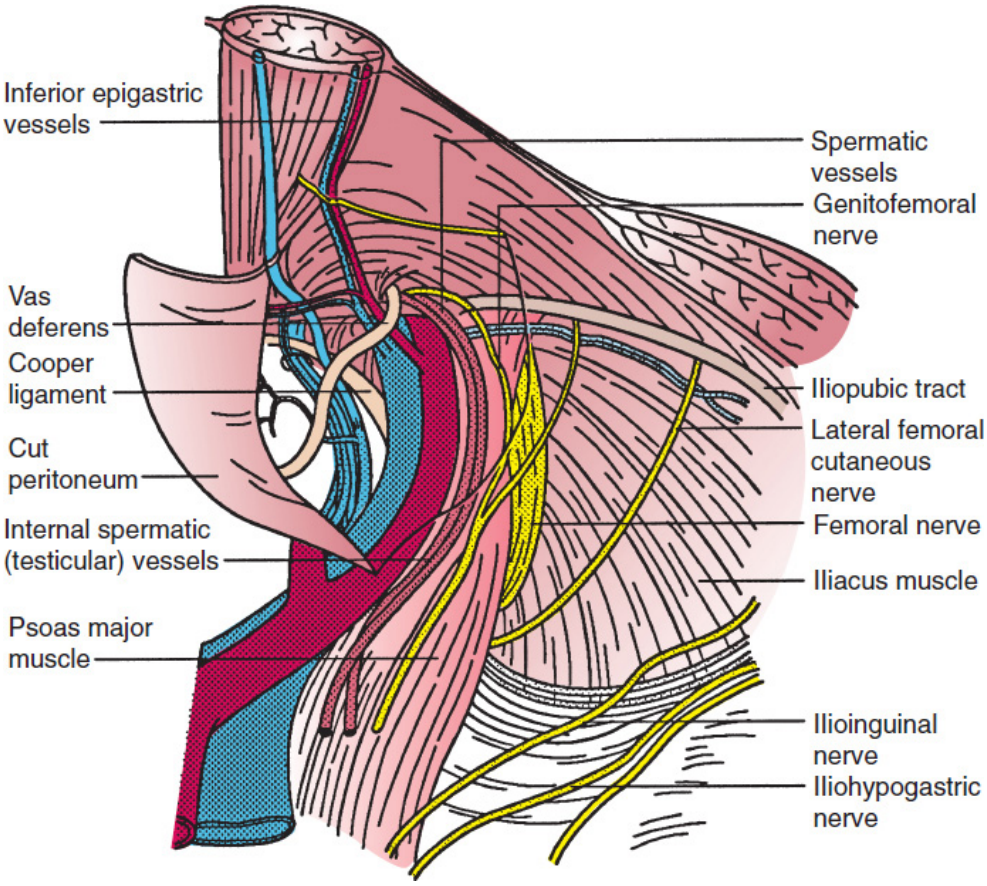

Figure 72.30 Important structures that must be identified after a preperitoneal dissection: inferior epigastric vessels, Cooper ligament, spermatic vessels, vas deferens, iliopubic tract, genitofemoral nerve, femoral nerve, lateral femoral cutaneous nerve, ilioinguinal nerve, iliacus muscle, and psoas major muscle.

The presumed advantages of the TEP procedure are that the inherent complications of entering the peritoneal cavity, such as intra-abdominal organ injury or postoperative bowel obstruction secondary to adhesions or trocar site herniation, are avoided. However, the operative space is limited, and considerable experience is required to become familiar with the anatomy from this perspective. Great care should be taken in reoperative fields or when prior mesh prosthesis is present. In addition, it is not yet clear whether inadvertent breaches in the peritoneal cavity that are difficult to visualize

because of the direction of the optics might negate the potential benefits of this approach.

Intraperitoneal Onlay Mesh Repair

The IPOM procedure which will be discussed in more detail in the incisional hernia section has never gained popularity for the treatment of an inguinal hernia. Nevertheless, it can be useful in patients with multiply recurrent inguinal hernias when dissection in both the conventional anterior space and the preperitoneal space has been made nearly impossible because of excessive scaring.[81] Often times in this situation, peritoneal closure is impossible and the adhesion barrier prosthetics developed for ventral hernia repair can be used.

Special Considerations: Pediatric Hernias

Given the high incidence of indirect inguinal hernias due to a patent processus vaginalis in pediatric patients, hernia repairs are completed using a high ligation technique. Concerns exist with the use of mesh in adolescents with respect to effect on fertility, long-term groin pain, and infection risk.[83,84] Postpubertal males have a similar anatomy to the adult population with a larger inguinal ring diameter and variations on transverse fascia defects. It is unclear as to which age/size does a child become an adult with respect to principles of hernia repair. Longitudinal studies comparing different hernia repair techniques in adolescents are needed before we can determine optimal treatment for adolescents especially those with weak inguinal floors and direct hernias.

Femoral Hernias

Femoral hernias are much more rare, accounting for 2% to 4% of groin hernia repairs, and can present a challenge to even the most experienced surgeon. Femoral hernias are more common in women and often present with an acute episode of incarceration, intestinal obstruction, or strangulation, so that emergency surgery is necessary. It can be difficult to reduce the hernia at surgery, and it is not uncommon to have to divide the inguinal ligament to obtain greater freedom to perform this reduction. Femoral hernias can be repaired from a lower “crural” approach, in which a transverse incision is

made over the femoral triangle in the upper thigh. The hernia is approached from below the inguinal ligament and reduced, and then the defect is closed by suturing the inguinal ligament to Cooper ligament from below. An alternative is to insert a small mesh plug into the defect and suture the periphery to the inguinal ligament and Cooper ligament.[72] If this technique is used, it is important to leave a layer of adventitial tissue between the femoral vein and the plug. The femoral vein should not be skeletonized. The repair can also be carried out from above via an inguinal approach, as in the McVay repair. The posterior floor of the inguinal canal is dissected out, and Cooper ligament is repaired after the hernia has been reduced. A third type of femoral hernia repair is the preperitoneal repair. Access to the preperitoneal space is gained through an abdominal incision or laparoscopy. A study based on the Swedish national register revealed that preperitoneal mesh techniques (both laparoscopic and open) are a better choice for women with femoral hernias.[85] For patient undergoing a Lichtenstein approach, modifications should be made to ensure evaluation of the femoral space and to address a femoral hernia if present. Prior to incising the external oblique aponeurosis, the subcutaneous tissue can be further separated from the inguinal ligament easily exposing the femoral canal. A femoral hernia from this approach will be palpated typically as a hard mass just medial to the femoral vein; reduction and repair can proceed as described above for the crural approach. Alternatively, the transversalis fascia can be incised exposing the preperitoneal fat and Cooper ligament. A femoral hernia can be reduced through this exposure and the flat sheet Lichtenstein prosthesis modified to include an inverted “triangle” that extends posteriorly overlapping Cooper ligament. This mesh extension is then suture to Cooper ligament covering the femoral space. Preperitoneal herniorrhaphies result in coverage of the entire myopectineal orifice and thus both femoral and inguinal hernias are treated. Indeed, in the Swedish study a much higher femoral recurrence rate was observed in women compared to men especially after the repair of a direct inguinal hernia. This is significant because direct hernias are rare in women providing strong evidence that the femoral hernia was actually missed at the index operation.[61]

SPORTS HERNIA/ATHLETIC PUBALGIA

The term *sports hernia* is confusing because, by definition, these patients do not actually have a hernia but rather a weakness of the posterior inguinal floor. This condition has received considerable attention in the lay press because of its prevalence in high-profile athletes involved in sports who require rapid changes in direction of the hip area such as soccer, football, basketball, track and field, tennis, and hockey. Alteration in the complex balance that must be maintained between the lower abdominal muscles and the leg adductor muscles and tendons, all revolving around the area of the pubic bone, is the final common denominator for many of the conditions that cause groin pain in up to 5% of athletes (**Fig. 72.31**).[86] The first step in approaching these patients is to make sure that one is not dealing with a cause outside of the groin with referred pain, such as lumbosacral radiculopathic pain, prostatitis, hip disease, and a gastrointestinal cause. The differential diagnosis is listed in **Table 72.7**.

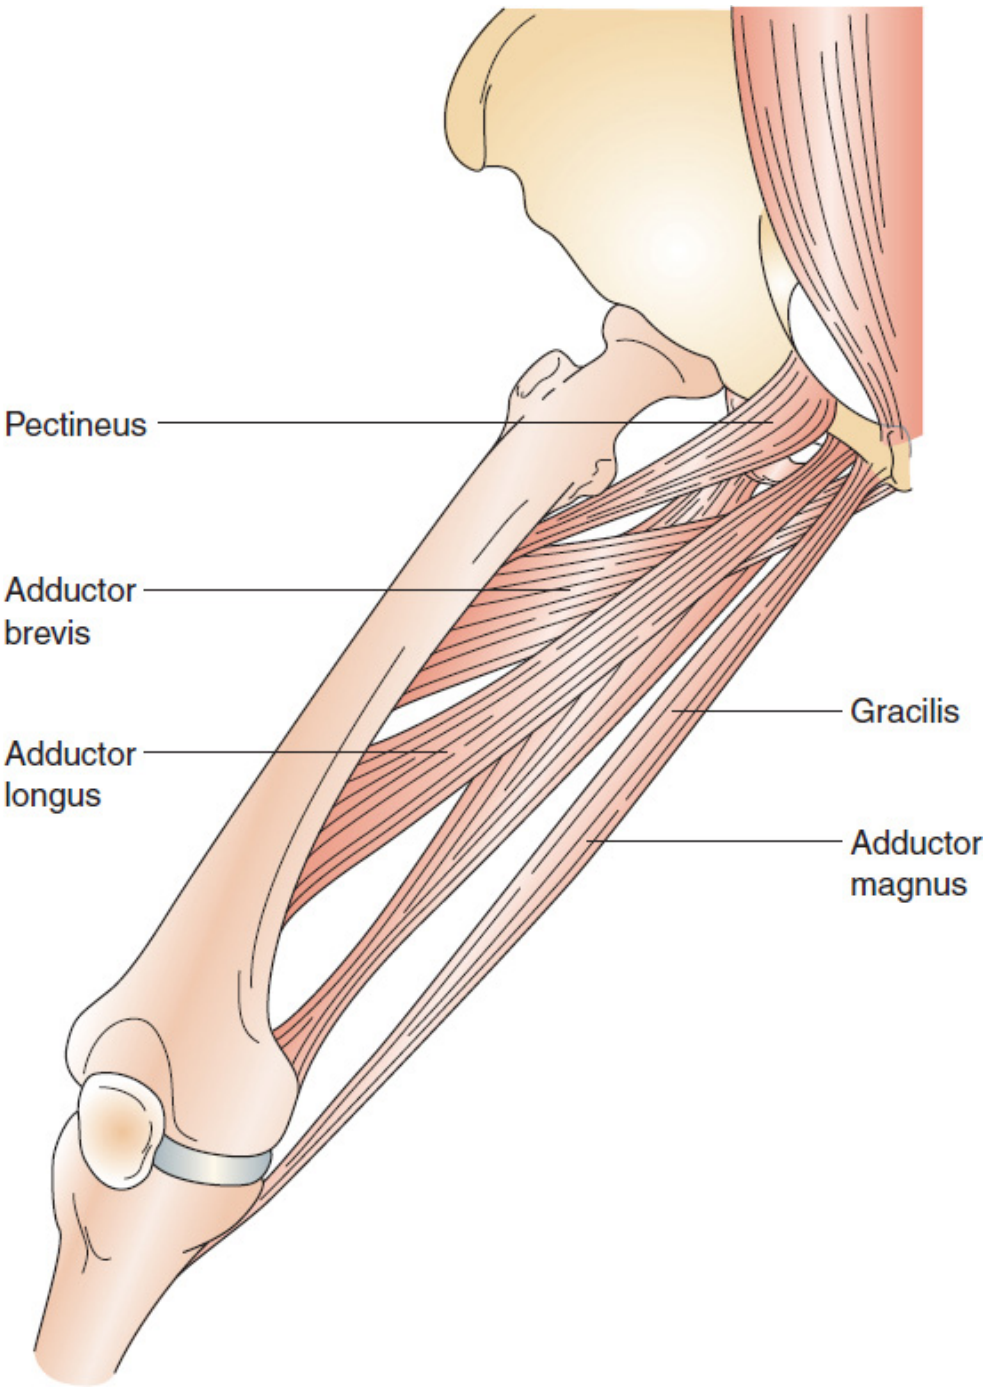

Figure 72.31 Complicated arrangement of muscle pulling in different directions that attach to the pubic bone.

Table 72.7 Conditions Other Than a Hernia Associated with Groin Pain

- Nerve entrapment
- Adductor tenoperiostitis
- Pelvic stress fractures
- Osteitis pubis
- Symphysis syndrome
- Gilmore groin (groin disruption)
- Iliopsoas bursitis
- Tendinopathies
- Posterior inguinal wall insufficiency or avulsion fractures
- Synovitis
- Osteoarthritis
- Legg–Calvé–Perthes disease
- Slipped femoral capital epiphysis
- Osteochondritis dissecans or avascular necrosis of the femoral head
- Acetabular labral tears
- Prostatitis
- Epididymitis
- Nephrolithiasis
- Urinary tract infection
- Lymphadenitis

Some authorities prefer to refer to this condition as "athletic pubalgia," as this conveys the concept that the physical examination is inconclusive and the cause of groin pain is unclear. Imaging may be performed by ultrasound, but cross-sectional imaging (CT or magnetic resonance imaging [MRI]) is the most useful diagnostic modality in the absence of a highly experienced ultrasonographer.[87] Compared to CT, MRI provides excellent overall anatomic detail especially with the development of fast imaging scanners that will allow dynamic imaging (i.e., performed during straining) with or without the addition of intraperitoneal contrast agents.

The initial treatment is conservative with mandatory inactivity, elastic immobilization bandages, ice/massage, nonsteroidal anti-inflammatory

analgesics, and occasional steroids (systemic and/or local). Physical therapy performed by a specialized practitioner can often improve symptoms. Surgery should be reserved after non-operative interventions have been performed. Although lacking clear-cut anatomic justification, a mesh hernia repair similar to either an anterior Lichtenstein or a TEP laparoscopic operation is the most popular procedure, sometimes combined with a variety of muscle reattachment procedures and tenotomies. The best results are obtained with a multidisciplinary approach including a surgeon, an orthopedist, a physical therapist, and a sports medicine physician. Not surprisingly, the results are variable given the lack of objective criteria to recommend operation but can be gratifying in some in this motivated group of patients.[88]

Complications of Inguinal Hernia Repair

Complications Related to the Patient

Urinary Retention

The most common predisposing factor for urinary retention after a hernia repair is the use of general or regional anesthesia.[67] Meta-analyses of randomized controlled trials comparing various hernia techniques performed under general anesthesia have not shown a difference in urinary retention rates.[89–92] Predisposing factors for urinary retention include overhydration with intravenous fluid during surgery, use of opioid analgesics, older age, prostatic symptoms, and prolonged operative time.[93,94] Intermittent catheterization or temporary placement of an indwelling urinary catheter is usually adequate therapy. Prophylactic and therapeutic use of alpha-adrenergic blockers including prazosin and tamsulosin has been shown in some studies as an effective strategy to prevent postoperative urinary retention.[95,96]

Ileus

Ileus can be seen with either the conventional or the laparoscopic procedure but is more common with the latter. Treatment is symptomatic, and spontaneous resolution is the rule. Nasogastric decompression is occasionally needed.

Complications Related to the Herniorrhaphy

Recurrence

The accuracy of reported recurrence rates after inguinal hernia repair comes in to question because recurrence can occur many years after the index operation (50 years or greater) making precise follow-up impossible.[97] A lower risk for recurrence with the use of prosthetic material for the repair of an inguinal hernia has been clearly proven by meta-analysis with relatively short-term follow-up.[66] Recurrence rates of 2% or less are now routinely reported from specialty centers performing either laparoscopic or conventional tension free repairs. Although the recurrence rate for hernia repairs is less than 1% at the Shouldice Clinic, others have not been able to duplicate this outstanding record with this or any of the other nonprosthetic repairs.[98] Complications during the first month after surgery; operation for recurrence; and sutured repairs without mesh, with either anterior or preperitoneal techniques, are associated with an increased recurrence rate. However, an increasing number of patients are seeking a tissue-based repair to avoid potential mesh-related complications even with higher recurrence. Formerly, a laparoscopic approach was thought to be associated with a higher chance of recurrence. This was felt to be the most likely reason for a higher recurrence rate at 2 years in a Veterans Affairs study for the laparoscopic approach (10%) compared to an open TFR (4% for the Lichtenstein repair).[99] Since that trial was performed, refinements and expertise in a laparoscopic approach to inguinal hernia repair have shown equivalent recurrence rates with possible decreased rates of chronic groin pain.[100]

A consistent definition of a recurrent hernia does not exist because of the difficulty in differentiating a lipoma of the cord, a seroma, or an expansile bulge of the internal oblique muscle from a true hernia recurrence. It may be that reoperation rates as a surrogate provides a reasonable estimate of recurrence.[101] From a clinical standpoint, a hernia should not be classified recurrent unless there is a visible bulge or there is unequivocal evidence of a hernia by an imaging modality such as ultrasound, CT, or MRI. This is especially important for patients who present with pain after their hernia repair because their pain is likely due to a preoperative condition other than the hernia or a postinguinal herniorrhaphy pain syndrome which might be

exacerbated by further groin surgery. Femoral recurrences are seen after a Lichtenstein repair because the femoral canal is not routinely closed with the classic technique.[61,97,102]

The general principle for managing recurrent hernias depends on the original repair.[103] The logical approach is to perform the herniorrhaphy in the space that has not been dissected. If the patient had a previous conventional repair, then a preperitoneal repair is best chosen. On the other hand, if the index operation was a preperitoneal one, then a repair that is performed in the conventional inguinal space is best. The dissection of the preperitoneal space after a failed herniorrhaphy has been performed is particularly challenging, with significant risk for vascular, neurologic, and bladder injury.

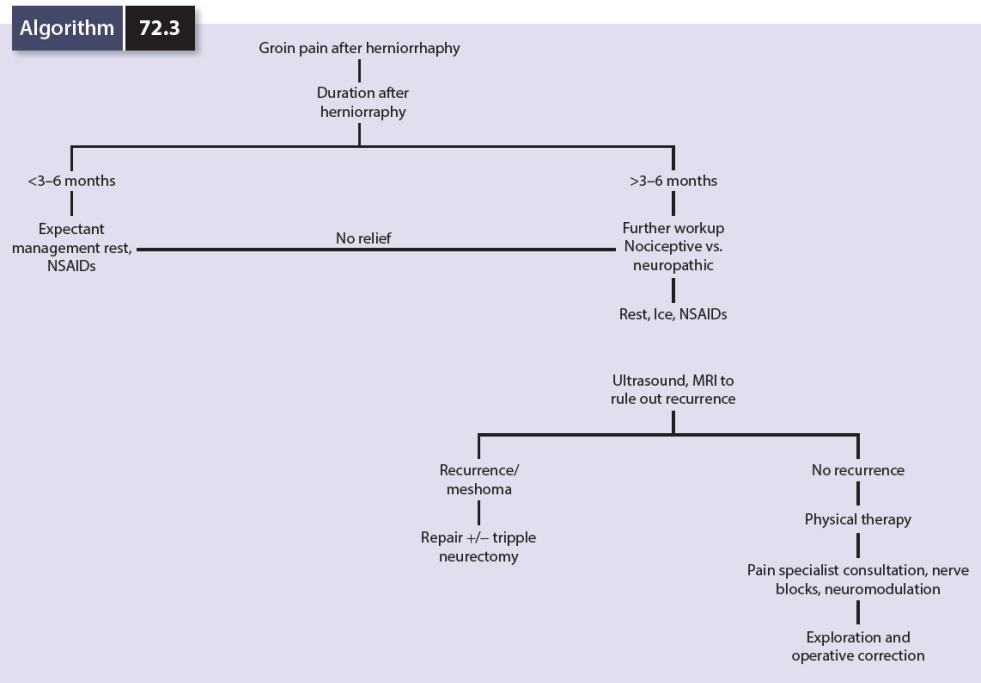
7 *Postherniorrhaphy Groin Pain*

Now that the recurrence rate has been brought down to a minimum using modern hernioplasty techniques, chronic postoperative groin pain syndromes (persisting >3 to 6 months post-surgery) have emerged as the biggest issue facing inguinal hernia surgeons (**Algorithm 72.3**). Poobalan and colleagues published a critical review of inguinal herniorrhaphy studies between 1987 and 2000.[104] The frequency of at least some long-term groin pain was as high as 53% at 1 year (range, 0% to 53%). On average, moderate or severe postherniorrhaphy groin pain probably occurs in about 10% of patients. Several factors have been suggested to be related to the development and intensity of postherniorrhaphy including psychological status, presence of preoperative pain at surgical site, nerve injury, intraoperative nerve handling, surgical technique (open vs. laparoscopic), and acute postoperative pain. Risk prediction model for persistent postoperative pain–based preoperative, intraoperative, and postoperative factors can be helpful in predicting which patients will be more likely to suffer from postherniorraphy pain.[83]

Perhaps the most important determination for patient's with chronic postherniorraphy pain is to determine if the pain is similar to that experienced before repair. There are a variety of conditions that cause groin pain (**Table 72.7**). CT, ultrasonography, herniography, laparoscopy, and MRI all have their place in the evaluation of these patients. MRI is perhaps the most beneficial because of its ability to differentiate between muscle tear,

osteitis pubis, bursitis, and stress fracture. Strain of the adductor muscle complex (adductor longus, brevis, magnus, and gracilis muscles) is commonly overlooked in this group.

True postherniorrhaphy groin pain should be divided into two types: (a) nociceptive pain, which is caused by tissue damage, is further subdivided into somatic and visceral pain, and (b) neuropathic pain due to direct nerve damage. Somatic pain is the most common and is usually caused by damage to ligaments, tendons, and muscles. Visceral pain refers to that which is related to a specific visceral function such as urination or ejaculation (see dysejaculation syndrome, later). Neuropathic pain is much less common but is important to recognize because surgical treatment is possible if the cause is incorporation of a nerve in staples or suture material. The nerves that are usually involved are the ilioinguinal nerve, the iliohypogastric nerve, both the genital and femoral branches of the genitofemoral nerve, and the lateral cutaneous nerve of the thigh. The former two are especially prone to injury during a conventional herniorrhaphy, whereas the latter are most likely damaged during laparoscopy. A femoral nerve injury is extremely rare and is usually the result of a gross technical misadventure. Pain and/or paraesthesia in their distribution characterize patients' symptoms for the more common nerves. There is significant overlap of these nerves, and therefore, it is commonly difficult to sort out exactly which nerve is damaged. Both nociceptive and neuropathic pain is best treated initially with reassurance and conservative treatment with anti-inflammatory medications and local nerve blocks because these will frequently resolve spontaneously. An exception is the patient who complains of severe pain immediately (i.e., in the recovery room). This patient may be best served by immediate reexploration before scar tissue develops. When groin exploration is required, triple neurectomy and neuroma excision, adhesiolysis, and foreign body removal (i.e., mesh or suture) are options for treatment. The patients reoperated for persistent pain after hernia surgery often experience a reduction in pain, but a small percentage of patients experience no relief or even worsening of their symptoms.[105] Given the heterogeneity of the problem, further well-designed studies are necessary to identify patient population that may benefit the most from surgical intervention. It cannot be overemphasized that these complex patients should be evaluated and treated at centers with specific multidisciplinary expertise in this area.



Algorithm 72.3 Management of groin pain after herniorraphy.

Cord and Testicles

Infertility

Infertility caused by inguinal hernia surgery is a recognized complication. The cause of infertility can be related to either the vas deferens or the testicle. The incidence of injury to the vas deferens during inguinal herniorrhaphy has been estimated at 0.3% for adults and between 0.8% and 2% for children.[106] Injury to the testicle, which eventually leads to atrophy, is estimated to occur in about 0.5% for primary hernia repairs but increases 10-fold to 5% for recurrent repairs. Injuries to the vas deferens that may present as an obstruction include division, ligation, clipping, stapling, electrocauterization, devascularization, and scarification. In addition, there is evidence that there is a small subset of patients whose inflammatory response to mesh is so severe that vasal obstruction results.[107] In addition to obstruction, traction injuries during normal cord mobilization may damage the muscular layer of the vas deferens, which then interferes with rapid sperm transfer during ejaculation.[108] Sperm antibodies may develop as a result of extravasation of sperm at an injury site, which is why a unilateral injury can also result in infertility. The role of mesh in the causation of infertility has been implicated by some small case series and case reports.

Ironically, one of the major arguments for the routine use of mesh in inguinal hernia surgery is to preserve fertility. The theory is that by decreasing the generally accepted recurrence rate in the general population from 10% to 15% seen with Bassini and its variants to less than 5% with the mesh tension-free approach, reoperative surgery, with its heavy toll of testicular loss, is avoided.[109]

Ischemic Orchitis

Damage to the blood supply of the testicle can cause ischemic orchitis and testicular atrophy.[108] Ischemic orchitis occurs in about 1% of primary hernioplasties but is much more common with operations performed for recurrent hernias.[110] It manifests as postoperative inflammation of the testicle developing within 1 to 2 days after surgery. The patient has a painfully enlarged testicle that is hard in consistency and associated with low-grade fever. Pain is severe and may last several weeks. Ischemic orchitis is caused by thrombosis of the veins draining the testicle after extensive dissection of the spermatic cord. It is generally accepted that the incidence can be decreased by division of large inguinal–scrotal sacs leaving the distal sac open in situ rather than excising it.[111] The majority of patients with testicular swelling as an immediate complication of herniorrhaphy recover without testicular atrophy. In one report, testicular atrophy developed in 19 patients among 52,583 primary inguinal hernia repairs (0.036%) and 33 patients among 7,169 recurrent inguinal hernia repairs (0.46%).[112] A substantial number of patients who develop testicular atrophy after inguinal herniorrhaphy have no history of a testicular problem at the time of the index operation. The management of a patient with ischemic orchitis is usually conservative with elevation and anti-inflammatory medication. Antibiotics and steroids have been used but their value is unproved.

Miscellaneous

Hydroceles occasionally develop after inguinal herniorrhaphy, but the cause is not known and therefore a preventative measure is not possible. The urologic literature suggests that the practice of leaving the distal aspect of an indirect inguinal sac in situ rather than removing it should be incriminated, but this is not accepted by most experienced hernia surgeons. The treatment is the same as for any other hydrocele. Testicular descent is a complication

felt to be related to complete division of the cremasteric muscle, but the occurrence is variable. The cord structures lose their tethering effect, allowing the testicle to descend into the most dependent portion of the scrotum. Due to the elasticity of the scrotum, with time, gravity causes the scrotum to elongate. Patients complain their testicle "drops into the toilet" and can be quite unhappy. Few hernia surgeons now routinely completely divide the cremasteric muscle, so it is hoped that this will become a rare phenomenon. The dysejaculation syndrome is characterized by searing, burning, painful sensations throughout the groin around the time of ejaculation. The incidence is approximately 0.04%.[111]

Wound Infection

This is a surprisingly rare complication of groin herniorrhaphy (<5%) and the reason for the "protected" status, especially when compared to prosthetic ventral herniorrhaphy, is not known.[111] Most cases of necrotizing fascitis following inguinal hernia repair have been associated with either strangulated bowel or appendicitis in the hernia sac. Necrotizing fasciitis has only previously been reported in a few cases following elective hernia repair. Other factors leading to infection are pre-existing infection or ulceration of the skin over the hernia, obesity, incarcerated or obstructed bowel within the hernia, and perforation of the bowel at the time of hernia repair. Untreated seromas can become secondarily infected. It is not always necessary to remove the mesh prosthesis in the presence of infection. A trial of local wound care after opening of the incision and debridement is warranted.

Seromas

Seromas are common with extensive flap dissection in large hernias and with the use of synthetic mesh in laparoscopic hernia repairs and are possibly related to the size of the mesh used. The fluid eventually resorbs spontaneously. Aspiration is performed for symptomatic relief only in rare instances of severe pain. Strategies to prevent and manage seromas are largely based on empiricism and personal opinion, as objective data are nearly absent.

Bleeding

Hemorrhage can occur from the cremasteric, internal spermatic, or inferior epigastric vessels. Conservative treatment with reassurance is preferred for a stable hematoma. Evacuation is rarely required. Injuries to the deep circumflex artery, the corona mortis, or the external iliac vessels may result in a large retroperitoneal hematoma.

Prosthetic Complications

Shrinkage of polypropylene and other meshes should be considered by surgeons when performing prosthetic repairs. The decrease in size is felt to be due to scarification of the recipient's tissue. Intestinal obstruction or fistulization is possible by erosion, especially if there is physical contact between intestine and the prosthesis. Rejection because of an allergic response is possible but extremely rare. What patients cite as "rejection" of the mesh is usually the result of infection. Local erosion into the cord structures has also been reported.[113]

Complications Related to Laparoscopy

Vascular Injury

These are for the most part related to access. The most serious injuries occur to vessels that reside in the retroperitoneum. For all laparoscopic procedures, the risk for major vascular injury that requires operative intervention is 0.9 per 1,000 cases.[114] The vessels most at risk are the distal aorta, common iliac arteries and veins, and inferior vena cava and the inferior epigastric vessels. Injuries to the renal vessels have also been reported. These vessels are fixed and may be penetrated even if the safety mechanisms of the needle or trocar are working properly. The mesenteric and omental vessels are also at risk, especially in the presence of adhesions. The epigastric arteries may be injured with secondary cannula placement.

The insufflation needle is the most common cause of vascular injury but may be self-limiting; on the other hand, injuries caused by a trocar are usually more obvious and catastrophic. The mortality associated with retroperitoneal injury secondary to trocar insertion ranges from 9% to 36%, even with rapid identification and repair. When retroperitoneal trocar injury is suspected, immediate conventional laparotomy is almost always indicated. Most abdominal wall vascular complications occur during the placement of secondary cannulas. Usually, pressure can be applied to bleeding at the

trocar site with the cannula. Occasionally, suture ligation is required, which has been simplified by the development of disposable "exit devices" designed to facilitate the placement of fascial sutures. Most of these complications can be avoided by placing the secondary trocars under direct vision.

Gas Embolism

This is caused by intravascular insufflation.[115] It is an uncommon complication, unique to the needle insufflation technique. Careful attention to tests confirming proper peritoneal needle placement will keep the incidence of this complication low.

Visceral Injury

Visceral injuries are uncommon, occurring in 1.8 per 1,000 cases of all laparoscopic procedures, but they have a mortality rate of 5%.[114] The most common means of injury is the insufflation needle. Simple repair laparoscopically is usually possible as most are self-limiting. If the injury is caused by a trocar, formal repair of the injury will be needed. The injury can be repaired laparoscopically if the skill of the laparoscopic surgeon is sufficient. Otherwise, laparotomy is mandatory. Quite often, these injuries go unnoticed at the time of insult, so that visceral injury is the most common cause of late morbidity and mortality associated with laparoscopic access. Patients typically present with peritonitis and sepsis 2 days to 1 week after surgery.

Bladder Injury

Bladder injury can be the result of a laparoscopic misadventure or can be directly related to the herniorrhaphy. Laparoscopic peritoneal access can result in a bladder perforation, usually the result of failure to decompress a distended bladder. Less commonly, injury is associated with a congenital bladder abnormality. Bladder injury has not been reported with the open access technique. Injury to the bladder can also occur during secondary suprapubic trocar placement during the course of an operation. When bladder injury occurs, it is usually obvious. After Veress needle insertion, urine is withdrawn into the syringe, or blood and gas are noticed in the urine if the patient is catheterized. In questionable cases, methylene blue dye may be instilled into the bladder to look for leakage. Bladder injury recognized

during laparoscopy should be repaired laparoscopically provided the experience of the surgeon is sufficient. This should be followed by bladder drainage for 7 to 10 days.

Bladder injury may present in a delayed fashion with hematuria and lower abdominal discomfort. A retrograde cystogram usually confirms the diagnosis. Small defects may be managed with postoperative decompression via an indwelling catheter for urinary drainage, while larger defects necessitate repair. The bladder is especially prone to injury during preperitoneal herniorrhaphies or when the preperitoneal space has previously been dissected (e.g., previous preperitoneal hernia repair or prostatectomy).[116]

Bowel Obstruction

This problem plagued the developmental stages of laparoscopic inguinal herniorrhaphy for two reasons. First, the importance of closing trocar sites at the fascial level if greater than 5 mm was not appreciated, resulting in the occasional patient with an incarcerated or strangulated ventral hernia at the trocar site, leading to the clinical presentation of a bowel obstruction. There are now several different types of reusable and disposable appliances designed to facilitate trocar site fascial closure, which should minimize the incidence of these hernias. The second is inadequate peritoneal closure over the prosthesis, which allows bowel to migrate into the preperitoneal space, also resulting in intestinal obstruction. Steps taken to avoid tension at the peritoneal closure site (see TAPP technique section) have decreased this problem. Theoretically, the TEP procedure eliminates the possibility of this complication because the abdomen is not entered. However, inadvertent breaches of the peritoneum during a TEP herniorrhaphy are common, especially in patients with thin peritoneum or those who have scar tissue associated with previous lower abdominal surgery. These peritoneal lacerations can be difficult to recognize because they are not in the visual field of the limited working space, and indeed, intestinal obstruction has been reported.[117]

Diaphragmatic Dysfunction

Phrenic nerve palsy has been reported with a variety of laparoscopic procedures; it is usually transient but has been known to require a short

period of mechanical ventilation. Stretching during the pneumoperitoneum probably causes this complication.

Hypercapnia

This is the result of inadequate compensatory ventilation given the fact that, in the vast majority of laparoscopic procedures, carbon dioxide is used as the insufflating agent.

VENTRAL ABDOMINAL WALL HERNIAS

Repair of ventral abdominal wall hernia is one of the most common procedures performed by a general surgeon. Ventral hernias comprise a diverse group of hernias and are best divided into their various subtypes when discussing surgical management because the natural history as well as results of operations varies depending on the specific hernia. Ventral hernia should be distinguished from pseudohernia which is a condition that occurs in patients with denervation of the abdominal wall musculature (e.g., after polio or flank incisions). The abdominal wall muscles bulge forward on straining and have the appearance of a hernia but no frank fascial defect can be discerned on physical examination or cross-sectional imaging. **Table 72.8** uses the common terminology familiar to all surgeons for classifying abdominal wall hernias. **Table 72.9** is a classification system published by Zollinger that expands upon **Table 72.8** by further subdividing ventral hernias based on etiology.[117] An expert panel of European Hernia Society proposed a grid classification system of incisional hernias based on localization, size, recurrences, and symptoms (**Table 72.10**)[118,119] and the Ventral Hernia Working Group (VHWG)[119] (**Table 72.11**) has proposed a grading system for ventral hernias based on risk of postoperative surgical site occurrences (SSOs).

UMBILICAL AND PERIUMBILICAL HERNIAS

Umbilical and periumbilical hernias are usually congenital, caused by arrest of the normal spontaneous closure of the umbilical ring through which umbilical blood vessels pass in the developing fetus, which results in a defect in the fascia covered by skin. In infants, the fascial defect varies in size but is most commonly 1 to 2 cm. A large proportion of pediatric umbilical hernias heal spontaneously, and 80% of them close by the time the patient is 2 years old. This is the only abdominal wall defect genetically programmed to close. Persistent umbilical hernias require surgery. In older patients, the onset is often sudden and the defect is relatively small. There are several syndromes associated with umbilical hernias such as mucopolysaccharide storage diseases, Beckwith–Wiedemann syndrome, and Down syndrome. Predisposing factors for the development of umbilical hernias in adults are multiple pregnancies, obesity, cirrhosis with ascites, and large abdominal tumors, all of which cause an increase in intra-abdominal pressure.[120] Male gender is also a risk factor with the peak incidence of repair at about age 60 years.[121] The differential diagnosis includes the varicosities that extend radially from the umbilicus in persons with portal hypertension, the so-called caput medusae (**Fig. 72.32**). The varicosities have a bluish discoloration and fill when the patient is straining. A metastatic deposit of intra-abdominal cancer at the umbilicus may mimic umbilical herniation. Cancer cells reach this area via lymphatics in the falciform ligament. Metastasis presents as a hard nodule, and biopsy is diagnostic. Other periumbilical masses that can be confused with an umbilical hernia include umbilical granulomas, epidermal inclusion cysts, omphalomesenteric duct remnant cysts, and urachal cysts.

The management of umbilical hernias is nonoperative in children up to the age of 2 or 3 years because spontaneous closure is the rule. In those who require surgery, adults or children, several repair options are available. For open repairs, an infraumbilical semilunar incision is made and the hernia identified. There may or may not be a true peritoneal sac, as smaller hernias usually consist of preperitoneal fat only. If a sac is present, it can be opened and the contents reduced into the abdomen. Alternatively, the hernia can be dissected circumferentially to the fascial opening and reduced without entering the peritoneal cavity. The dissection can be continued beneath the

fascia creating a preperitoneal space for the placement of a prosthesis, if needed. Several techniques can be used to close the fascial defect. Simple suture repair with interrupted, running, or figure-8 sutures, either absorbable or permanent is commonplace, accounting for more than 50% of umbilical hernia repairs.[122] There is no clear evidence as to which of these suture techniques is optimal. There is evidence of lower recurrence rate with permanent suture repair compared to fast-absorbing suture.[123] Slow-absorbing suture is acceptable and has the benefit of no residual foreign body presence that can lead to subsequent infection/granuloma. In 1901, James Mayo described the classic overlapping, vest-over-pants (double-breasting or waistcoat) technique, which bears the name of his clinic, in which the upper edge of the linea alba overlaps the lower edge (**Fig. 72.33**).[124] The operation is losing popularity now because it is generally not consistent with the tension-free concept popular in hernia surgery today.[125] It requires more dissection than other procedures to create the flaps and is therefore more painful. Suture herniorrhaphy is the easiest procedure for repair, but has the highest recurrence rate. Factors known to increase recurrence include high body mass index (BMI), diabetes, smoking, and hernia size. Despite the higher recurrence rate for suture repair compared to mesh repair, the rate of recurrence is still relatively low; 10% for umbilical hernias smaller than 1 to 2 cm.[126] Conversely, 90% of patients do well with a suture repair long term without mesh prosthesis. Recurrence, if encountered, can usually be easily addressed at a subsequent operation typically using mesh.

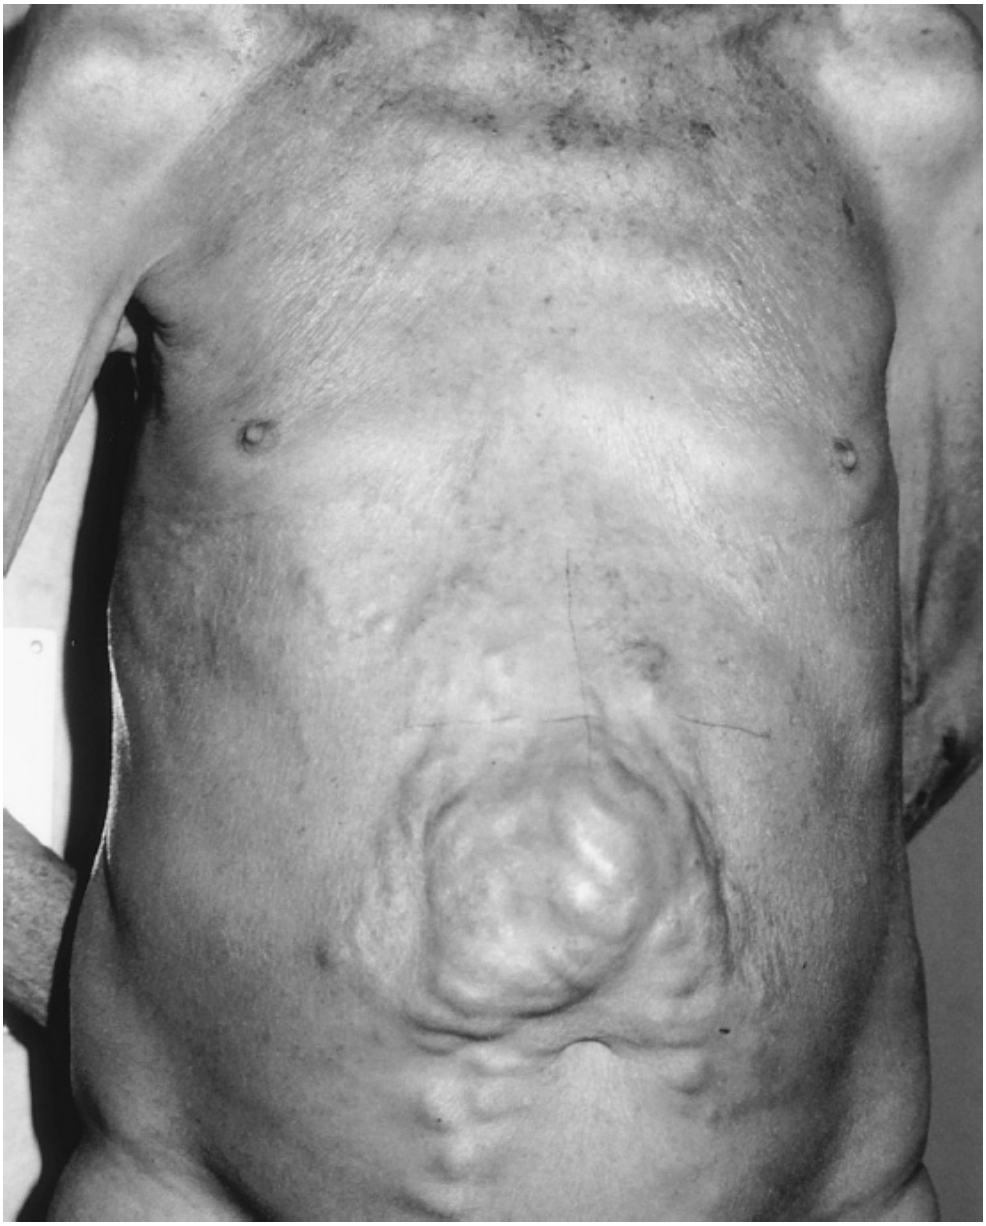

Figure 72.32 Caput medusae. Large periumbilical collaterals in a patient with portal hypertension.

For larger hernias, particularly in adults, the preperitoneal space can be exploited by bluntly dissecting the peritoneum from the undersurface of the posterior rectus sheath for enough distance to be able to place an appropriate prosthesis. A mesh prosthesis is placed in the preperitoneal space and then the fascial edges defect closed. Alternatively, intraperitoneal placement using a barrier-coated mesh (see prosthetic materials section) can be performed in the event of small defects through which preperitoneal

dissection is difficult, if the preperitoneal space plane cannot be maintained, or surgeon preference. It is still important to dissect the preperitoneal fat of the falciform ligament and median umbilical ligament to ensure proper seating of the mesh against the abdominal wall and prevent reherniation of the preperitoneal fat. Recent results from a multicenter randomized control trial suggest a higher complication rate for intraperitoneal versus preperitoneal mesh for umbilical hernia,[127] which has been seen in some other retrospective studies of intraperitoneal mesh as well.[55,57,128]

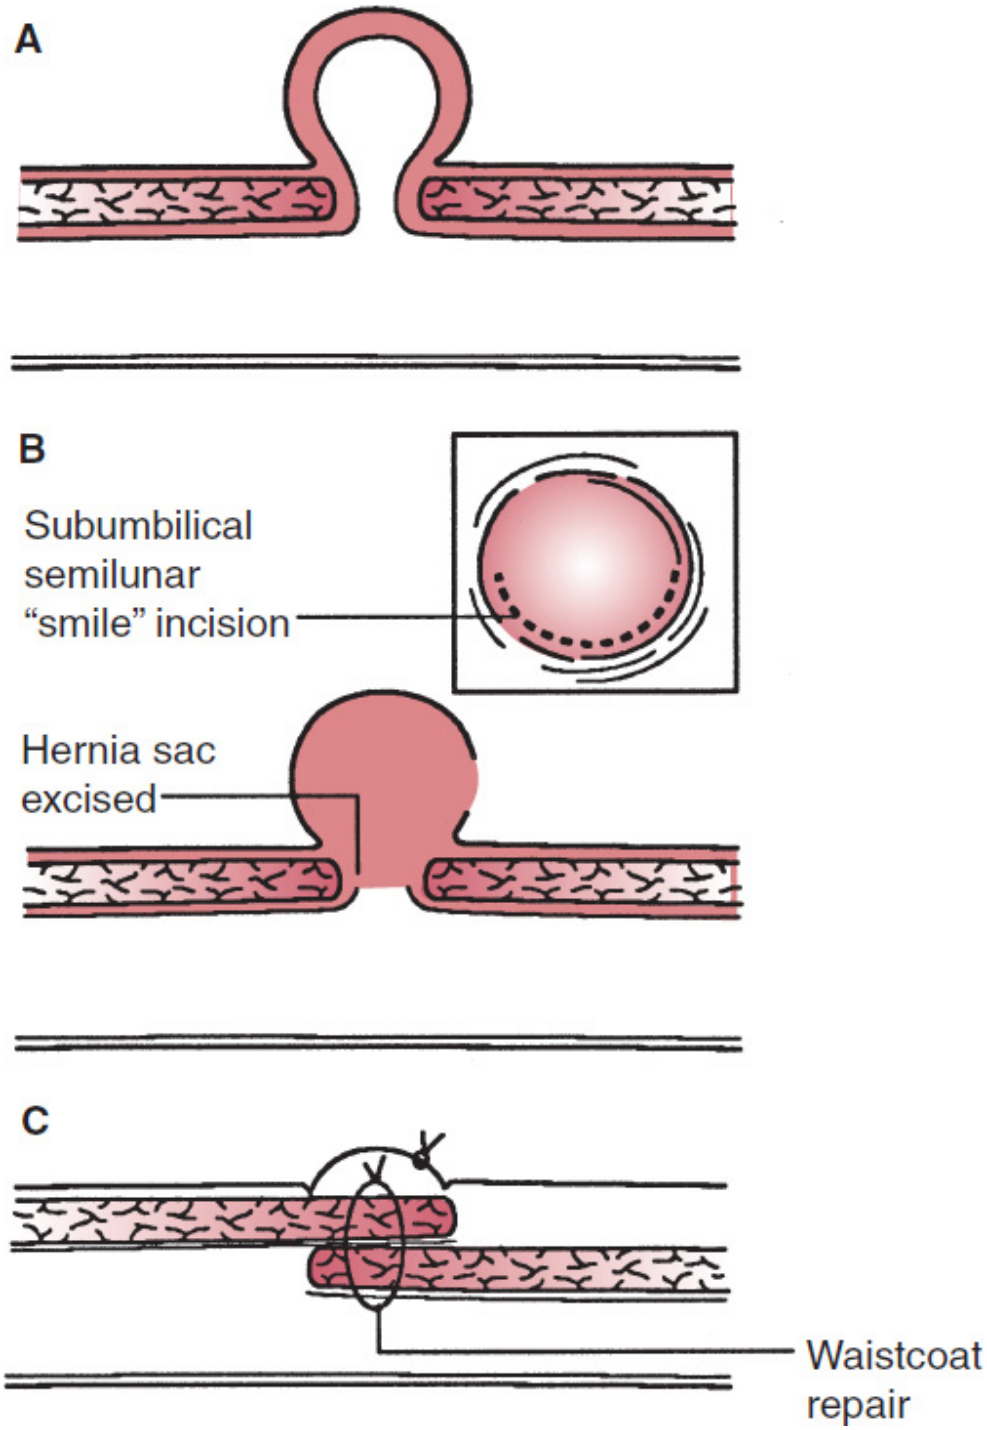

Figure 72.33 Mayo repair of an umbilical hernia. **A:** Diagram of longitudinal section through the hernia. **B:** Subumbilical "smile" incision. The hernia sac is excised. **C:** Waistcoat type of closure.

A laparoscopic or robotic approach for umbilical hernias is a good option as well, particularly for recurrent defects or hernias with larger than 3 cm.

There may be some benefit to this approach, including decreased operative time and faster return to normal activity. The technical details are similar to those of a laparoscopic incisional hernia repair (see incisional hernia section). With the advent of robotic-assisted surgery, a TAPP approach is increasingly popular, emulating the open preperitoneal repair in a minimally invasive fashion. While this can be performed either laparoscopically or robotically, a robotic-assisted repair may facilitate more reliable defect closure.[129–131]

EPIGASTRIC HERNIAS

Epigastric hernias occur through a defect in the linea alba. In the majority of these patients, only a single decussation of the fibers of the linea alba is present rather than the usual triple decussation (**Fig. 72.7**). The incidence of epigastric herniation reported varies from less than 1% to as high as 5%. Epigastric hernias are more common in woman than men with a peak incidence of repair around age 40 years.[121] About 50% of them are asymptomatic. Most are less than 1 cm and contain only incarcerated preperitoneal fat without a peritoneal sac. For this reason, epigastric hernias commonly cannot be visualized with laparoscopy. Patients complain of a painful nodule in the upper midline. Repair by reduction of the preperitoneal fat and simple closure of the defect is curative. These hernias are prone to recur, with rates as high as 10%, which has led many surgeons to routinely include a prosthetic underlay just as in umbilical or incisional hernias.

Left untreated, an epigastric hernia can become large enough for a peritoneal sac to form, into which the intra-abdominal contents can protrude. The sac is usually wide, and serious complications are not common. About 20% are multiple, and this needs to be ascertained prior to operation if all the defects are to be addressed, because after anesthesia induction, they can be difficult to identify.

In *diastasis recti,* the two rectus muscles are widely separated, with an intact, but stretched linea alba that protrudes like a fin. The condition rarely produces surgical complications and therefore surgical correction is not routinely recommended. However, many patients find the defect affects their self-image, abdominal core stability, and quality of life and request

treatment. They should be cautioned that many insurance companies consider this a cosmetic defect and will not reimburse. Surgery involves removal of a strip of the weakened linea alba and reapproximation, plication, of the widened linea alba, or mesh reinforcement in a sublay fashion, typically the retromuscular space. An alternative is a mesh repair performed laparoscopically. The management of diastasis, especially in our postpartum patients, needs additional research to gain information on appropriate therapies. These problems can greatly affect core stability similar to ventral hernia. Olsson et al. have demonstrated a link between surgical intervention for postpartum diastasis and improvement in pelvic floor function.[132] This is the first empiric evidence that elements of the abdominal core musculature function in an interdependent fashion as a cohesive unit. Importantly, this lends evidence that diastasis represents a diseased anterior abdominal wall with functional implications; it is not solely an issue of cosmesis.

INCISIONAL HERNIAS

Incisional hernias can complicate any type of abdominal surgery, regardless of the type of incision. The highest incidence is with midline laparotomy incisions when compared to, transverse incisions, paramedian incisions, pfannensteil incisions, and laparoscopic trocar sites.[133,134] Despite this fact, surgeons continue to prefer midline laparotomies because it provides better access to the entire abdomen.. More than 2 million laparotomies are performed yearly in the United States, with an estimated incidence of an associated IH on average felt to be between 10% and 20%, but higher incidence rates of up to 69% have been reported depending upon the patient population being studied.[135] The variability in the incidence rates is due to many contributing factors including patient-related comorbidities and technical factors during the surgery. Patients with certain diseases, such as diverticulitis and abdominal aortic aneurysm (AAA), are more prone to develop an incisional hernia when they require surgical intervention.[136,137]

The cumulative incidence of incisional hernias is linear, as they can present after considerable delay following the index operation. Poor surgical technique, rough handling of tissues, use of rapidly degraded absorbable suture materials, closure of the abdomen under tension, and infection of the

wound are technical causes of incisional hernias. Morbid obesity, cigarette smoking, pulmonary disease, debilitation from cancer, chemotherapy, the use of steroids, hypoalbuminemia, and other pre-existing comorbid conditions are patient factors that have been incriminated. Patients with a history of aortic aneurysm or a proven defect in collagen metabolism also exhibit an increased incidence of incisional hernias.[138] Read and Yoder in a retrospective review found that 17% of incisional hernias are incarcerated or strangulated at presentation.[139] The consequences of unrepaired enlarging symptomatic hernias include loss of abdominal domain; significant biomechanical alterations that affect posture; compromise of activities of daily living, including lifting and straining; and poor cosmetics. Most of the published literature on treatment options addresses midline defects. The management of nonmidline incisional hernias (i.e., subcostal, transverse, or gridiron incisions) to some extent must be extrapolated.[140]

At least some ventral hernias can be prevented by proper abdominal closure after a laparotomy. Slowly absorbable monofilament should be placed in the aponeurosis only 5 to 8 mm from the wound edge, not to include muscle, 4 to 5 mm apart in a single layer, creating at least a 4:1 suture length to wound length ratio. Two recent randomized control trials demonstrate the superiority of this small-bite technique compared to traditional large-bite technique in the prevention of incisional hernia.[141,142] Studies have shown that nonabsorbable sutures result in a lower incidence of incisional herniation but at the cost of increased wound pain and chronic suture sinuses when they become infected.[116] These suture sinuses tend to be multiple and take years to eradicate by probing the sinus tracks and removing deep sutures. The development of better monofilament absorbable sutures has caused most surgeons to use a slowly absorbable monofilament suture.[111] Using small needles is recommended to avoid including excessive amounts of tissue. By measuring the suture remnants in relationship to the total length of the suture, one can calculate a suture length to wound length ratio which should never be less than 4.[143] Several studies have also demonstrated the benefit of prophylactic mesh at the time of initial laparotomy, which can be placed in the retromuscular sublay or onlay position.[144–147] While this approach does significantly reduce the risk of incisional hernia, adoption is slow, likely due to concern for mesh-related complications, lack of reimbursement for the procedure, and medicolegal concerns.

Another common practice after laparotomy is to prescribe abdominal binders. Although most surgeons prescribe abdominal binders following laparotomy, there is no evidence that these devices decrease pain; improve respiratory function; or prevent incisional hernias, seroma formation, or wound complications. The use of a binder may provide some comfort in the immediate postoperative period to some patients and should be recommended for this purpose only.[148,149]

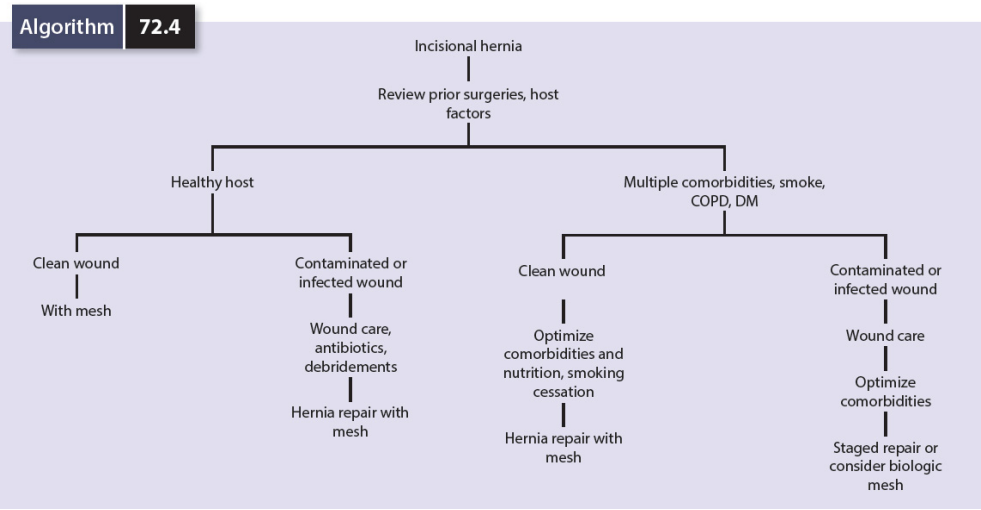
Treatment of Ventral Hernias

General Principles

As described above, the abdominal wall is a complex unit of the abdominal core and plays an important role in respiration, defecation, micturition, movement of the trunk, and protection of intra-abdominal organs (**Algorithm 72.4**). It has been shown that health-related quality of life improves after ventral incisional hernia repair, presumably related to improved abdominal 8 wall function.[150] Additionally, there is some risk of acute incarceration or strangulation, though this risk is likely fairly low and watchful waiting is appropriate for many patients. A variety of surgical techniques can be used to repair abdominal wall defects. There is considerable debate as to the gold standard for repair, in part due to the lack of prospective randomized trials comparing surgical techniques, but also due to the significant heterogeneity that is inherent to hernia repair. Considering the choice of surgical approach (open, laparoscopic, or robotic), the massive catalog of available mesh, the choice of position in the abdominal wall (onlay, retromuscular, preperitoneal, or intraperitoneal), and the number of mesh fixation options, combined with widely varied hernia morphology and patient comorbidities, it is no surprise the optimal repair has not yet been determined in the literature. Many experts believe that reapproximation of rectus muscles in the midline restores functional abdominal wall anatomy and is recommended if it can be performed without excessive tension.

Preoperative Preparation

Successful management of ventral hernias begins with appropriate preoperative evaluation and optimization. Many of these patients have had multiple prior surgeries, including previous attempts at hernia repair and it is important for the surgeon to obtain and review all the previous operative reports and evaluate the nature of previous surgeries, incision types, and closure techniques. Preoperative imaging may be necessary to delineate the extent of the hernia, the defect size, the morphology of the hernia and the abdominal wall musculature, or estimate the volumes of the hernia and the abdominal cavity in the case of loss of domain. Ultrasound and CT imaging is appropriate, though CT is generally preferred for more complex hernias.



Algorithm 72.4 Management of incisional hernia.

Patient factors, such as smoking, obesity, COPD, and diabetes are major contributors to failure of ventral hernia repair and perioperative complications. Smoking cessation is advocated by most surgeons for at least 4 weeks prior to complex ventral hernia repair. Obesity increases both the wound complications and risk of hernia recurrence, and many surgeons recommend against repair at BMI >40 kg/m^2.[151,152] Options include concurrent hernia repair with bariatric surgery, neoadjuvant bariatric surgery with delayed definitive repair of the abdominal wall, waiting for self-directed or medically supervised weight loss, or proceeding with a higher risk repair. The optimal strategy for these patients is difficult, as the surgeon must weigh the patients ability to lose weight, access to bariatric surgery, and the symptoms and risk of the hernia itself. Diabetes should be well

controlled, through there are currently no clear guidelines on optimal control before proceeding with hernia repair. Cardiopulmonary risk stratification is often needed in high-risk patients as well. Finally, there is increased attention given to preoperative nutritional optimization prior to hernia repair, with may improve perioperative morbidity, but evidence of improved hernia outcomes is lacking.

On the day of surgery, special attention must be paid to the administration of thromboembolism prophylaxis and preoperative antibiotics. An iodophor skin barrier may be used to decrease mesh contact with the skin. In the operating room, sharp debridement of devitalized or infected tissues is recommended and sometimes a staged approach for hernia repair is necessary. Prior to abdominal wall closure, attention should be paid to ventilator mechanics as rising peak and plateau pressures can be early signs of abdominal compartment syndrome.

Surgical Techniques

This section outlines several specific options for hernia repair. Detailing all possible manifestations and subtleties of each of these procedures, its complications, indications, and long-term outcomes is beyond the scope of this chapter, and much remains unsettled in the literature. As such, this should be considered a guide to the options available for repair. Complications specific to each surgical technique are discussed along with each section. Detailed definitions of these complications are discussed later in the chapter.

Nonprosthetic Repairs

Traditionally, the repair of an incisional hernia depended on the size of the hernia. If the defect was solitary and 3 cm or less, primary closure with nonabsorbable suture material was recommended. However, there is ample evidence, most notably the landmark prospective randomized trial by Luijendijk et al.,[153] and the 10-year completion of that study by Burger et al.,[154] that prosthetic mesh repair significantly decreases the risk of hernia recurrence compared to non-mesh repair, with rates of hernia recurrence after suture repair alone approaching 70%.[153,155] These investigators found a 50% reduction in the recurrence rate when a prosthesis was used, and this

even applied to small hernias (<10 cm^2). For this reason, a simple, nonprosthetic technique should be reserved for smaller hernias in patients with low-risk factors for further recurrence. With increasing recurrences observed over time regardless of mesh use, we are beginning to understand that ventral hernia is a chronic disease process. It may be simplistic to think of "recurrence rates" in the traditional sense with the implication that hernia recurrence is completely unanticipated. It may be more appropriate to think in terms of years of durability of a repair with an array of treatments needed for a particular patient over time. Some patients may be wish to undergo initial primary repair of even larger hernias without mesh especially considering the rate of long-term catastrophic complications with mesh use is largely unknown.

Prosthetic Repairs

The concept of prosthetic mesh repair of abdominal wall hernias was proposed by Usher and colleagues in 1958 using a polypropylene mesh.[156] Since that time, a massive proliferation of mesh products has occurred, particularly after the advent of laparoscopic repair. These are outlined above. The importance of understanding the physical properties of mesh and where it is positioned within the abdominal wall at the time of repair cannot be overstated (**Fig. 72.34**). The mesh material, fiber construct, pore size, fiber density and strength, barrier coating, and layer of the abdominal in which it is placed largely determine the risk of infection, mesh salvage in the event of infection, and the risk of hernia recurrence. Additional understanding of surgical technique, such as optimal mesh overlap beyond the borders of the hernia, appropriate mesh fixation, and choice of surgical approach are also critical. Details of mesh types and characteristics are discussed above. Here we focus on surgical technique and mesh utilization.

Onlay Prosthetic Technique

The onlay repair involves dissection of the subcutaneous fat away from the underlying anterior rectus fascia circumferentially around the hernia defect. The defect is closed, and mesh placed directly on the anterior rectus fascia. Typically a noncoated permanent synthetic mesh is used, and fixation techniques vary. Technically, this is probably the simplest repair, as the tissue planes are familiar and easy to identify, and has the potential

advantage of not requiring entry into the abdominal cavity. However, closure of larger defects with this approach may result in excessive tension, requiring some additional myofascial release for defect closure, increasing the complexity and risk of the operation. This technique has the highest rate of surgical site infection (SSI) and SSOs due to the subcutaneous dissection required. This space is inherently poorly vascularized, and dissection may further obliterate the periumbilical epigastric perforators, leading to increased risk of infection, seroma, or abdominal wall ischemia and necrosis. Patients should be well selected for this technique and have overall low preoperative wound risk. From a technical standpoint, care should be taken to preserve the vascular perforators in the subcutaneous space. Also, the thin layer of lymphatics immediately anterior to the fascial layer of the anterior abdominal wall should be preserved. Wound complications occur in up to 20% of traditional onlay repairs. With careful patient selection and using fibrin glue as an adjunct with midweight macroporous polypropylene, SSI and SSO rates are comparable to sublay placement of mesh.[157] Additionally, hernia recurrence appears to be higher after onlay repair. This may be explained by Pascal's law which states that pressure exerted on an enclosed fluid acts equally in all directions, and in the case of an onlay technique, this results in lifting forces against the mesh.[158] Further, SSI is a known risk factor for hernia recurrence. Though some advocate this technique, these factors should be considered.[159,160]

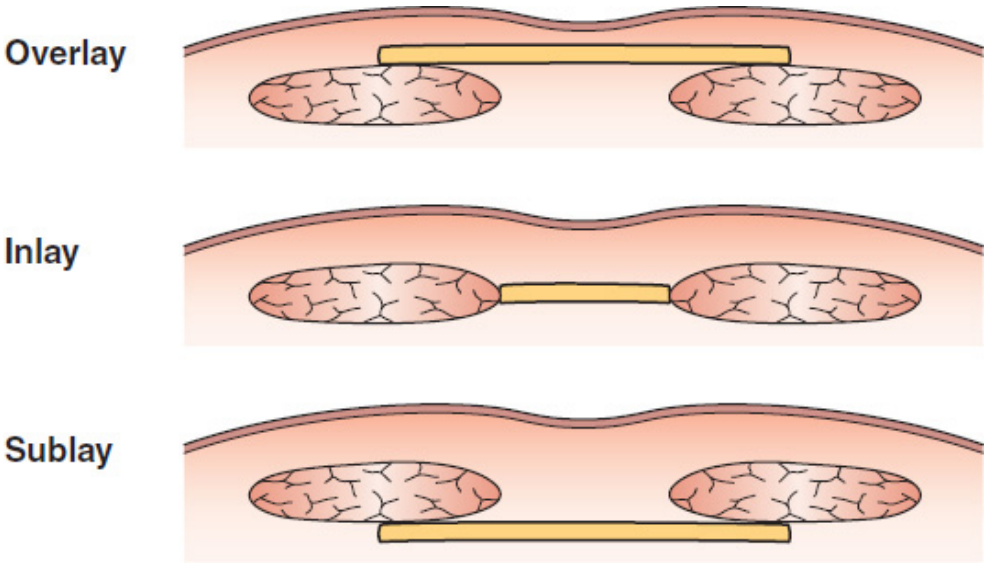


Figure 72.34 Potential spaces in the abdominal wall to place prosthetic material: onlay or on top of the anterior abdominal fascia; inlay placed within the defect at the level of the fascia; and sublay posterior to the fascia; three positions for sublay exist: retromuscular, preperitoneal, and intraperitoneal.

Prosthetic Bridging Technique

A bridged repair is one in which the hernia defect is left unclosed, instead placing mesh across the hernia defect with wide circumferential overlap, essentially replacing the defect with prosthetic and avoiding a high-tension closure. This became popular in the 1990s in keeping with the tension-free concept for inguinal herniorrhaphy and as laparoscopy became increasingly popular for ventral hernia repair. Laparoscopic repair is detailed below. Mesh selection depends on the approach. A barrier-coated, biologic, or absorbable synthetic mesh is required for intraperitoneal placement. If mesh is placed in an extraperitoneal position, a noncoated mesh may be used as long as there is some tissue layer between the mesh and viscera. Although this repair is theoretically attractive, it has not been as successful for incisional hernias as for inguinal hernias. The recurrence rate is especially high in obese patients and large hernia defects.

In the management of the open abdomen, a bridged mesh may be used to perform serial mesh excision. This is a technique whereby an open abdomen is closed by placement of a bridging ePTFE mesh, with serial visits to the operating room to tighten the mesh by serially excising a strip of the mid-portion of the mesh, thereby eventually bringing the native fascial edges into

apposition for closure. This approach allows for definitive abdominal wall closure after a mean of six visits to the operating room.[161]

Sublay Prosthetic Technique

The term sublay deserves specific definition. This can refer to any mesh position below the abdominal wall and includes intraperitoneal, preperitoneal, or retromuscular placement. As such, a thorough reading of the literature is necessary to determine the exact technique being discussed. Only recently has this term become more universally synonymous with the retromuscular repair, and will be used in this context here. First described by Rives, and commonly known as the Rives-Stoppa repair, this approach is characterized by the placement of a large prosthesis in the space between the abdominal muscles and the peritoneum (**Fig. 72.17**). It was popularized by Rives, Velamenta, Stoppa, and Wantz and is particularly suitable for large and multiply recurrent hernias when most of the abdominal wall must be reconstructed.[162–163] It is considered the most effective conventional incisional hernia repair and therefore the one against which other procedures must be measured.

The procedure is begun by excising the previous scar and dissecting the peritoneal sac of the hernia to the level of the fascia. Occasionally, the sac does not have to be opened and the procedure can be performed totally extraperitoneal. More commonly, the sac is thin and easily disrupted, making entrance into the peritoneal cavity inevitable. The myofascial release is begun by opening the posterior rectus sheath on each edge of the hernia defect just lateral to the linea alba and dissected away from the undersurface of the recti to the lateral edge of the rectus sheath, with care being taken to prevent damage to the perforating intercostal neurovascular bundles at the lateral side of the sheath (**Fig. 72.35**). Mobilization of the posterior sheath alone bilaterally has the effect of medializing the rectus-anterior sheath myofascial unit to facilitate primary fascial closure. The posterior rectus sheaths are then approximated to each other primarily (unless the peritoneum has not been opened). It is sometimes necessary to add additional myofascial release to further decrease the tension. In this case, a TAR is the preferred approach, though a posterior component separation or external oblique release may also be used. A large mesh prosthesis is then placed in this space outside the repaired posterior sheath but beneath the recti. The optimal

method of mesh fixation in this space has not been determined. Options include fixation to the costal margin or Cooper ligament, direct suture to the posterior rectus sheath, lateral percutaneous transfascial sutures, lateral tacks, adhesives, or no fixation at all. Suction drains are used by most surgeons which are typically removed prior to discharge in clean wound conditions.[164] The procedure is completed by reapproximating the anterior rectus sheaths, thus bringing the rectus muscles back to their normal configuration. The best long-term results are obtained when the anterior fascia can be closed bringing the muscles back together because of an improvement in abdominal wall mechanics. However, it is sometimes impossible to achieve this and the gap must be bridged with a prosthesis (**Fig. 72.36**).

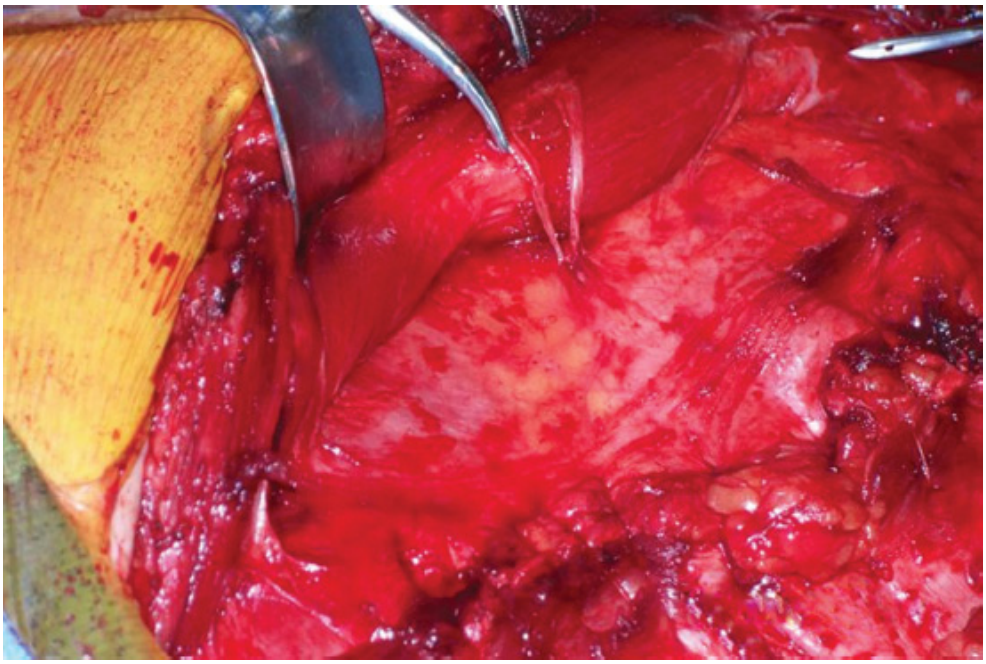

Figure 72.35 Neurovascular bundles in posterior rectus compartment supplying the rectus muscle.

Due to the well-vascularized compartment created for mesh placement during retromuscular repair, this approach has the lowest SSI and prosthetic-related complications of any open repair.[159,160] One unique complication deserves mention, however. Interparietal hernias may occur due to breakdown of the posterior rectus sheath closure. This can result in herniation of the viscera into the interparietal plane between the disrupted

posterior sheath and the intact mesh against the anterior abdominal wall. These often present acutely with small bowel obstruction. The surgeon must have a high-index of suspicious for this complication, as it will frequently be missed as the cause of SBO by radiology. This can be identified by typical signs of SBO along with visualization of the posterior rectus sheath below the herniated bowel. Repair is necessary, and the primary goal is obliteration of the potential space between the posterior sheath and mesh in which the bowel may be incarcerated.[165] This complication can occur with any procedure involving separation and closure of the posterior sheath, including a standard Rives-Stoppa repair, TAR, or posterior component separation.

Myofascial Release (i.e., Component Separation)

9 Abdominal wall reconstruction is defined as ventral hernia repair performed using a myofascial release technique. Myofascial release, in turn, is defined as separation of an abdominal wall fascial layer from a muscular layer, allowing medial advancement of the separated muscle layers in order to close the hernia defect and restore native abdominal wall anatomy. Previously this has been referred to as "component separation" which is a generic term describing a variety of myofascial release techniques. The main types of myofascial release techniques currently used are described below.

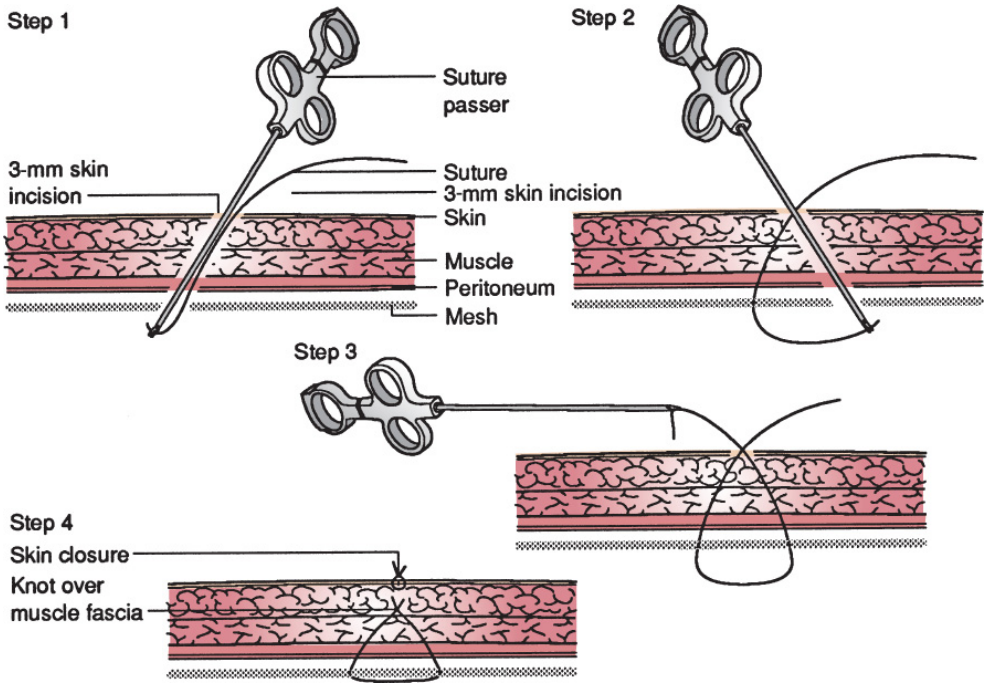

Figure 72.36 Fixation of prosthesis to the peritoneal surface of the abdominal wall with the use of a suture passer. **Step 1:** The suture passer device with a heavy nonabsorbable suture is passed through a 3-mm stab incision in the skin at an oblique angle. The device and suture traverse the entire abdominal wall and then the prosthesis. Once the peritoneal cavity is entered, the suture is released and the passer is withdrawn back into the subcutaneous tissue. **Step 2:** The device is redirected at a different angle through the abdominal wall and prosthesis and the suture is grasped. **Step 3:** The suture is pulled out of the abdominal cavity so that the two free ends are extracorporeal. **Step 4:** The suture is tied with the knot resting on the fascia. The skin is then closed.

Anterior Component Separation

The term component separation itself was initially used to describe a technique popularized in the early 1990s by Ramirez and colleagues which is based on lateral fasciotomies that allow sliding of the muscular fascia layers toward the midline providing coverage for large midline abdominal wall defects.[166] Originally, it was proposed as a tissue repair for patients with contaminated wounds to avoid use of prosthesis, but several modifications have been described since the original description. In this technique, the skin and subcutaneous fat are dissected free from the anterior sheath of the rectus abdominis muscle and the aponeurosis of the external oblique muscle. The aponeurosis and muscle belly of the external oblique muscle are transected longitudinally lateral to the semilunar line (**Fig. 72.37**). It is important to

extend the incision inferiorly to the inguinal ligament and superiorly onto the chest wall at least 5 to 7 cm cranial to the costal margin especially for defects close to the xiphoid. The external oblique muscle is separated from the internal oblique muscle, as far laterally as possible in a relatively avascular plane, beyond the area of skin undermining toward the midaxillary line. This step is safe because the neurovascular bundle (comprising the intercostal nerves and vessels) lies deep to the internal oblique muscle. Additionally, the rectus abdominis muscle is released from its encasing posterior fascia by incising the posterior rectus sheath and separating it from the overlying rectus muscle. The result of the combined posterior rectus release and the external oblique release is that the internal oblique-transversus abdominis muscle and the rectus abdominis complex slide medially for up to 10 cm in the mid-abdomen, allowing closure of defects up to 20 cm. In fact, release of the posterior rectus sheath alone results in mobilization of 5 cm in the mid-abdomen. Care must be taken not to damage the neurovascular bundles that runs between the internal oblique and transversus abdominis muscle to enter the rectus sheath posterolaterally. After advancement of the rectus complex toward the midline, the fascial closure is performed followed by layered closure of the subcutaneous tissues and skin with drains. Several modifications to the original technique have been described. The technique can also be used as an adjuvant to the prosthetic repairs described next.

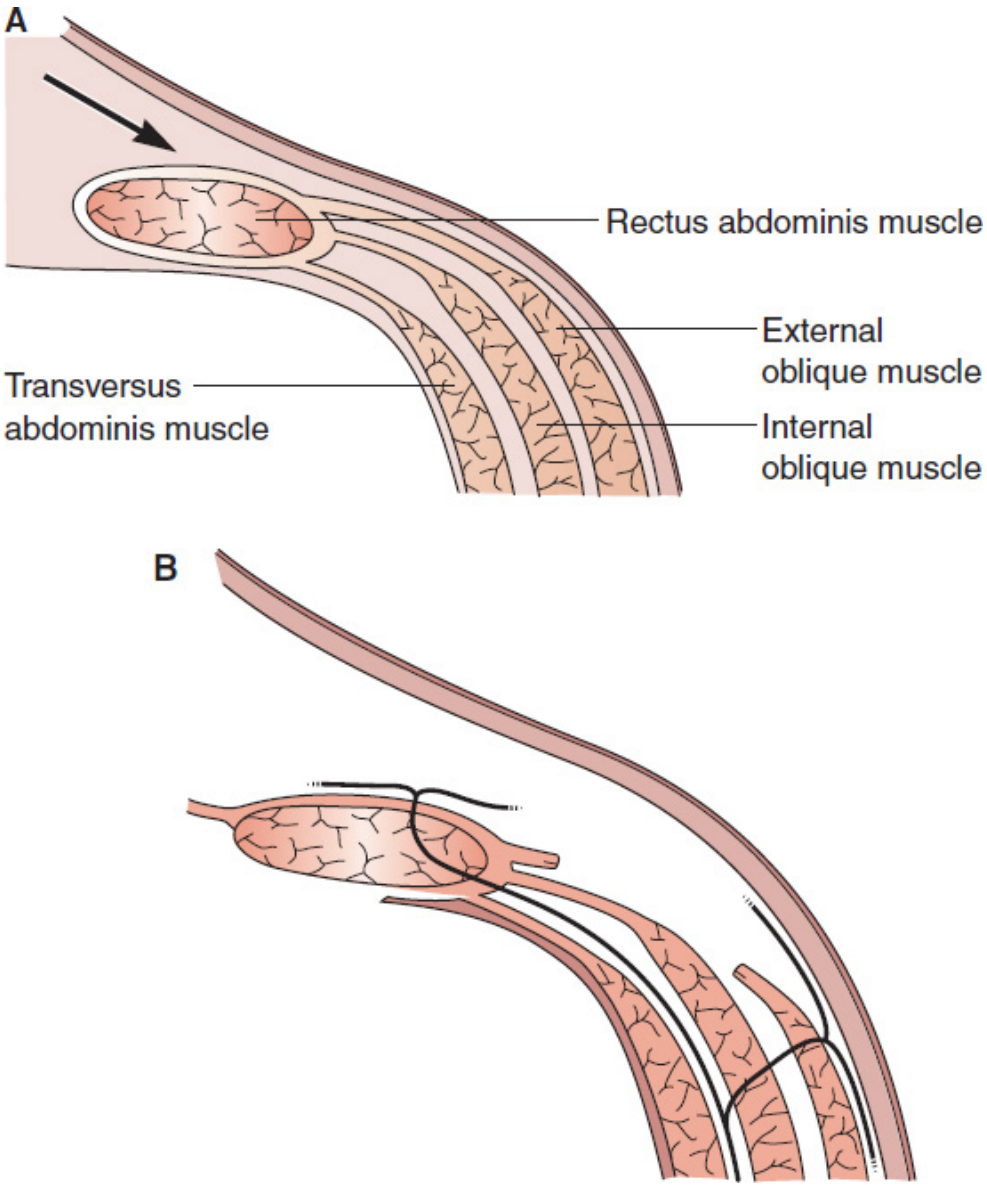

Figure 72.37 Component separation technique.

Unfortunately, SSO and SSI following anterior releases involving large subcutaneous dissections are significant, occurring in up to 50% of patients. This can range from simple seromas to full-thickness necrosis and loss of abdominal wall skin and soft tissue, creating potentially devastating chronic abdominal wall wounds. This results from division of the deep inferior epigastric perforators in the periumbilical region that are divided during the massive subcutaneous dissection required for this procedure, devascularizing the mid portion of the abdominal wall. Several modifications of the classic Ramirez component separation have been described to mitigate these

complications. The perforator preserving technique completes the subcutaneous dissection but identifies and preserves the periumbilical perforators, significantly reducing the risk of wound complications. Endoscopic component separation (discussed below) utilizes laparoscopy to dissect the interparietal plane between the external and internal obliques, thus eliminating the need for subcutaneous dissection and vascular disruption. The development of posterior approaches to lateral myofascial release (discussed below) offers an excellent alternative to the external oblique release with significantly lower wound complication rates while still gaining significant mobilization of the abdominal wall.

Endoscopic Component Separation This technique was developed to lessen the degree of abdominal dissection and potentially address the wound complications associated with open anterior component separation with the use of a balloon dissector and laparoscopic instruments. The technique involves making 2- to 4-cm incisions just below the costal margin in anterior axillary line (lateral to the attachment of the external oblique aponeurosis on the rectus sheath). The space between the external and internal oblique muscles is dissected and under camera guidance, dissector balloon is inflated which further aids blunt dissection in this layer. The external oblique aponeurosis is then divided. A Balloon dissector can be used in the subcutaneous space as well. This technique can be followed by either open, laparoscopic, or robotic-assisted hernia repair.[167–170] Potential limitation might be the adequacy of the myofascial advancements using this technique. Proponents of this technique claim reduction in postoperative stay by about 50% and a distinct advantage in the setting of stomas. The primary benefit, however, is the reduction in wound complications while still achieving significant myofascial advancement (**Fig. 72.33**). Care must be taken to ensure the proper interparietal plane is dissected, as disruption of more than just the external oblique may result in lateral bulging or hernia.

Transversus Abdominis Release/Posterior Component Separation

The transversus abdominis release (TAR) allows a posterior extension of the myofascial release after initial retrorectus dissection to achieve greater fascial mobilization and overlap of mesh placement.[171] This is done by incising the first layer of the posterior rectus sheath, which is the posterior

lamella of the internal oblique, just medial to the neurovascular bundles, followed by division of the transversus abdominis muscle (in the upper abdomen) or its aponeurosis (in the mid and lower abdomen) to enter either the "pretransversalis plane" or the preperitoneal plane. The pretransversalis plane is usually more robust and is readily entered superior to the arcuate line. Utilization of this plane near the costal margin minimizes extensive defects when mobilizing the preperitoneal space alone. Inferiorly, the preperitoneal space is typically entered and mobilized. This dissection continues laterally to at least the mid-axillary line, but can be carried as far posteriorly as the psoas muscle. Superiorly, this can extend under the diaphragm, dissecting the peritoneum away from the central tendon of the diaphragm. Inferiorly, this can extend into the Space of Retzius, exposing the symphysis pubis and Cooper ligament. This results in the disinsertion of the transversus abdominis from the rectus sheath and releases the circumferential tension it normally applies, allowing the medialization of the rectus abdominis across the midline defect (**Figs. 72.38** and **72.39**). After closure of the posterior elements, there remains a large retromuscular space for placement of prosthetic mesh to reinforce the anterior fascial closure.

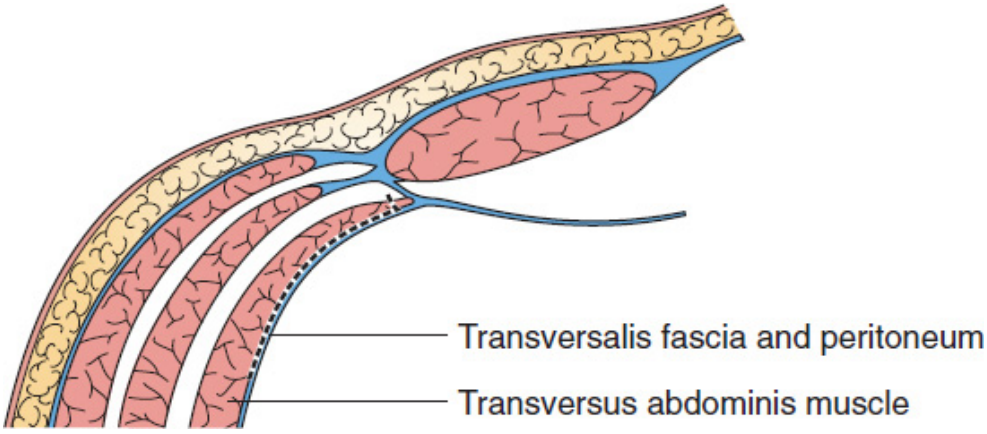

Figure 72.38 The posterior rectus sheath is incised about 0.5 to 1 cm medial to the anterior/posterior rectus sheath junction to expose the underlying transversus abdominis muscle. Note the perforator nerves that are preserved during retromuscular dissection and subsequent posterior component release.

As with the Ramirez external oblique release, significant myofascial advancement is possible with each incremental step of the retrorectus + TAR approach. In a cadaver study by Majumder et al., after midline laparotomy

and retrorectus dissection alone, the anterior fascia can be mobilized 4 to 7 cm, depending on the degree of tension. The addition of incision of the posterior lamella of the internal oblique, the first step in TAR, increased that release slightly, division of the transversus abdominis muscle by about 1 cm, and to a maximum of 5 to 10 cm after completion of the lateral preperitoneal dissection. Mobilization of the posterior sheath increased in similar fashion with each step of the procedure, but to an even greater degree, with maximal posterior medialization of 7 to 11 cm.[172]

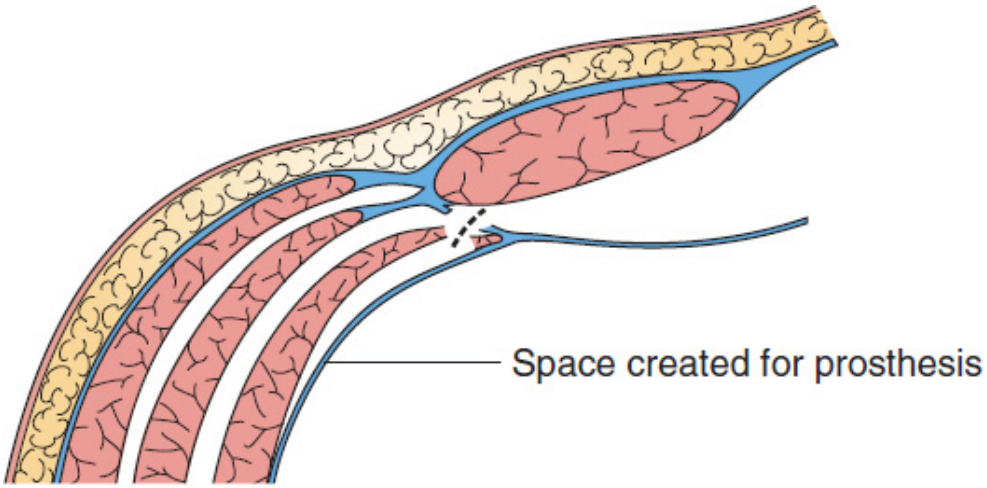

Figure 72.39 Division of the posterior rectus fascia just medial to the linea semilunaris and perforator nerves followed by division/release of the transversus abdominis muscle along its entire medial edge.

This technique is an important addition in the armamentarium of surgeons dealing with complex abdominal wall problems and has been shown to have favorable perioperative morbidity and acceptable recurrence rates compared to anterior component separation.[148] The technique is particularly suited for addressing recurrent hernias after a prior anterior component separation but probably should not be used simultaneously in combination with a concurrent anterior component separation. However, TAR is technically difficult because the transversalis fascia/peritoneum complex posteriorly can be extremely thin, tearing easily. In order to isolate the viscera from the prosthetic which will eventually be placed, these tears must be repaired. If this is not possible, an intervening fast absorbable mesh or biologic mesh can be used to separate the viscera from the retromuscular space. Alternatively, one of the adhesion barrier prostheses can be used.

Laparoscopic Ventral Hernia Repair

Laparoscopic ventral hernia repair was developed in the 1990s as a natural extension of the increasing application of this minimally invasive technology. The greatest value of laparoscopic surgery is the reduction in wound complications due to the small access incisions, and the ability to apply the "gold standard" sublay technique with mesh placed below the hernia defect in a tension-free manner, thus eliminating the need for the extensive abdominal wall dissection implicit in the conventional open operation.[62] Laparoscopic surgery provides several potential advantages including decreased blood loss, lower wound infection rates, decreased hospital stay, and patient preference.[173,174] Improvements in wound infection has been consistently demonstrated, though minor SSOs such as seromas are more commonly seen with laparoscopic repair. However, laparoscopic VHR has not clearly reduced hernia recurrence rate. As with any hernia repair technique, patient selection is key. This is most appropriate for patients at high risk for wound complications and small- to moderate-sized defects. Contraindications to laparoscopic VHR include patient intolerance of pneumoperitoneum or general anesthesia, and open abdominal wall wounds or other poor skin and soft tissue quality that requires resection. Relative contraindications include extensive intra-abdominal adhesions, COPD, heart failure, or large hernia defects >10 cm.

Entrance to the abdominal cavity followed by adhesiolysis can be problematic for a surgeon performing a laparoscopic ventral hernia repair and devastating complications resulting from visceral injury are possible. Typically, off-midline access is obtained via open cut-down (Hasson technique), Veress needle insufflation, or direct optical trocar entry into the abdominal cavity, typically at Palmer point in the left upper quadrant, or its corresponding point on the right side. This is left to the discretion and experience of the surgeon, as no one technique is clearly superior. Use of a Hasson open cut-down technique likely minimizes unrecognized enterotomies, especially in these complex settings. Once the abdomen has been safely entered, additional cannulae are placed according the size and location of the hernia, with at least one trocar typically placed on the contralateral side to assist in mesh fixation. Adhesiolysis is completed and the abdominal contents are reduced from the hernia defect. Once all the

hernia defects are identified, the operating surgeon must make a decision to either continue the procedure laparoscopically or convert to an open operation. Traditionally, laparoscopic VHR was a bridging repair, placing mesh with wide overlap around the hernia defect with no attempt to close the defect itself. In our opinion, multiple "swiss cheese defects" are the best indication for a laparoscopic repair. On the other hand, if there are only one or two defects with wide separation of the muscles, the laparoscopic repair is not as effective due to the risk of hernia recurrence for large bridged defects, and due to eventration or pseudorecurrence in which the mesh bellows out across the unclosed hernia defect, mimicking a hernia recurrence. This can be both painful and unsightly for patients.[175] Currently, most surgeons favor closure of the hernia defect during laparoscopic repair whenever possible, and the inability to do so is often a primary indication for conversion to an open procedure. Closure is typically performed using percutaneous transfascial sutures using a suture passer (**Fig. 72.36**). This closure can be aided by the addition of endoscopic component separation. More recently, robotic-assisted ventral hernia repair has grown in popularity due to the ability to suture reapproximate the fascial defect reliably. There is evidence that defect closure reduces seroma formation, but its effect on hernia recurrence and overall morbidity remains unclear.[176–178]

Mesh selection and placement is key to successful laparoscopic VHR. Mesh should have an antiadhesive barrier of some kind, often referred to as a tissue separating mesh, as it is in direct contact with the viscera. Several options exist as discussed above (**Figure 72.21**). The mesh should be sized after appropriately measuring the hernia defect and appropriate overlap. Ideal mesh overlap is 5 cm or greater, and likely increases with increasing defect size.[179,180] Measurements should be made intracorporeally in order to negate the effect of the insufflated abdominal wall.[181] Mesh should be placed through a trocar to avoid any potential contact with the skin, and unfurled against the abdominal wall. Fixation is a point of debate, with many surgeons increasingly avoiding transfascial sutures or any permanent fixation due to the concern for postoperative pain. While there is reliable evidence that tack fixation alone is adequate, absorbable fixation alone or the use of surgical adhesive alone appears to increase the risk of hernia recurrence. The International Endohernia Society published updated guidelines on laparoscopic ventral hernia repair in 2019 and is an invaluable resource into

surgical technique and the controversies in laparoscopic ventral hernia repair.[182]

Complications specific to laparoscopic VHR include those inherent to laparoscopy, such as inability to tolerate pneumoperitoneum or gas embolism. Of most concern is enterotomy. Though this is relatively low risk, typically reported around 1%, the limited field of view, off-screen instrument exchanges, and potential for thermal injury via direct contact or capacitive coupling increase the potential to miss these injuries. Additionally, because of the risk of mesh infection due to the mesh type and position in the abdominal cavity, an enterotomy during laparoscopic VHR typically requires a change of approach either to an open repair or aborting the case and delaying definitive repair. Long-term complications of intraperitoneal mesh are increasingly recognized and are inherent to the laparoscopic IPOM approach. Subsequent abdominal operations occur in up to 25% of patients, often for non–hernia-related pathology. Adhesions to intraperitoneal mesh can increase the risk of enterotomy, contamination, secondary mesh infection, or enterocutaneous fistula. Enteroprosthetic fistula may also occur due to erosion of mesh into the adjacent viscera.[56,57]

Robotic-Assisted Ventral Hernia Repair

In recent years, robotic technology has emerged as an alternative to traditional open and laparoscopic techniques in the repair of ventral hernias and its use is growing rapidly. Purported benefits of the robotic platform include enhanced three-dimensional visualization, articulating instruments, and improved surgeon ergonomics, particularly compared to traditional laparoscopic ventral hernia repair. This has also generated much controversy due to the high capital cost of the robotic system itself and few reported benefits in clinical outcomes. Robotic VHR can be divided into two broad categories. First is a simple extension of traditional laparoscopy, with standard transabdominal approach and intraperitoneal mesh placement. Second is conversion of traditional open techniques, such as preperitoneal or retromuscular repair, to the minimally invasive platform.

The majority of robotic VHR performed in a manner similar to traditional laparoscopy, consisting of transabdominal approach, lysis of adhesions, closure of the hernia defect, and placement of mesh in an intraperitoneal

position (IPOM). There are several potential benefits of the robot over traditional laparoscopy. First, the ability to achieve closure of the hernia defect is aided by the enhanced ability to suture the defect closed robotically. This is enabled by the articulating robotic needle drivers and avoids the often imprecise and painful transcutaneous methods of defect closure. Closure of the defect has been shown to decrease the risk of seroma formation and may decrease the risk of hernia recurrence, particularly for large hernias with a relatively lower area of mesh–tissue interface.[176,178–180] Secondly, the mesh is secured with intracorporeal suture rather than tacks or transfascial sutures, potentially reducing postoperative pain, though this benefit has little supportive clinical evidence to date.[183–185] There does seem to be a benefit in shortened length of hospital stay with robotic-assisted laparoscopic VHR, which has been consistently demonstrated in the published literature.[186,187] Finally, the ergonomic benefit to the surgeon has contributed to the proliferation of this approach. Laparoscopic VHR requires lateral trocar placement to work on the anterior abdominal wall, requiring downward external deflection of working instruments, often creating difficult and ergonomically unfavorable body position for the surgeon. Occupational injury involving the neck, back, and upper extremities is clearly associated with minimally invasive surgery, and this may be mitigated by robotic technology, preventing such injuries and potentially prolonging the operative career of the surgeon.[188–190]

The true benefit of robotic-assisted VHR may lie in its ability to convert traditional open VHR techniques, such as preperitoneal, retromuscular and component separation, to a minimally invasive platform. The robotic transabdominal preperitoneal repair (rTAPP) is a popular method for repair of small- to moderate-sized hernia defects. With this approach, intra-abdominal access is obtained similar to traditional laparoscopy, with lateral placement of trocars and instruments. Any necessary lysis of adhesions is completed, and the hernia reduced in standard fashion. A peritoneal flap is then created around the hernia defect, ideally to allow for at least 5 cm of mesh overlap. After completion of the peritoneal flap, the hernia defect is closed intracorporeally, mesh placed against the posterior rectus fascia, and the peritoneal flap closed below the mesh, completely excluding it from the visceral cavity. This approach is appealing, as it prevents the potential complications of intra-abdominal mesh and obviates the need for a barrier-

coated mesh and requires minimal mesh fixation, potentially reducing postoperative pain. There are currently limited published data on this approach, but it do appear to be safe and effective. Comparative data are lacking.[129,131]

For larger, more complex hernias, additional mobilization of the abdominal wall by way of myofascial release may be necessary to achieve fascial closure, limiting the applicability of the robotic IPOM or rTAPP techniques. However, using the robotic platform, release of the myofascial layers of the abdominal wall can be accomplished in order to medialize the rectus abdominis, close the hernia defect, and allow wide mesh reinforcement in the retromuscular plane. There are several variations in approach that can achieve this end result. The first description was a transabdominal approach. Trocars were placed in the lower abdomen, a transverse incision made in the posterior rectus sheath or peritoneum, and retromuscular dissection carried out in a cephalad direction. After adequate dissection, the defect is closed, mesh placed in the retromuscular position, and posterior layer closed. This approach works well for hernias in the upper abdomen via docking in the lower abdomen, or vice versa, but has limited applicability to infraumbilical hernias or longer defects.[181] Alternatively, incision of the lateral border of the ipsilateral rectus sheath can be performed, carrying the dissection medially to the linea alba, dropping down to the preperitoneal plane along the midline, and reentering the retromuscular plane on the contralateral side. This technique allows access to infraumbilical defects, but is limited by the width of the rectus sheath and the size of the hernia defect.[192]

The addition of a robotic TAR allows repair of large midline hernia defects. Trocars are placed transabdominally in the lateral abdominal wall. After necessary adhesiolysis and hernia reduction, the contralateral rectus sheath is opened. Retromuscular dissection is carried out along the length of the hernia, extending at least 5 cm above and below the defect, and continued laterally to the semilunar line. Of critical importance to this repair, as with the open approach, is the dissection of the midline above and below the hernia defect. The fascial elements coalesce to form the linea alba such that the retromuscular spaces are not continuous with each other. Thus, the midline peritoneum and preperitoneal fat must be dissected from the overlying linea alba, leaving it attached to the posterior sheath bilaterally

and with care taken to avoid damage to the intact linea alba, which may result in hernia recurrence. A TAR is then performed as described above by incising the posterior lamina of the internal oblique aponeurosis, dividing the transversus abdominis muscle and aponeurosis, and extending dissection laterally in the preperitoneal plane. This continues laterally to approximately the mid-axillary line, followed by placement of additional trocars in the contralateral abdomen directly into the dissected preperitoneal space. The robot is then docked from these new trocars ("double-dock" technique) and an identical retromuscular dissection and TAR performed on the opposite side, bringing the initial trocars into the dissected space. The posterior sheath is closed, along with any peritoneal defects, the anterior hernia defect is closed, and mesh placed in the retromuscular position. The bilateral myofascial release allows significant mobilization of the abdominal wall to accommodate defect closure, comparable to open repairs described above.[192–194]

This technique has one significant drawback in that it necessitates a bilateral TAR. Many patients with comparable hernias would likely not require this additional release if the repair was performed in an open fashion. The most recent iteration of robotic retromuscular repair is a modification of the totally extraperitoneal technique used for inguinal hernias, the extended totally extraperitoneal (eTEP) repair. It should be noted that this is not necessarily a new operation, but a modification of the above described techniques to allow a more tailored approach to ventral hernia repair. Using the eTEP approach, access to the retromuscular space is done directly, most often using an optical trocar, rather than first entering the abdominal cavity. After initial unilateral retrorectus dissection, a "crossover" is performed by which the rectus sheath in incised near the midline to enter the preperitoneal plane below the linea alba. This plane is dissected across the midline until the contralateral rectus sheath is identified, at which point it is incised to enter the contralateral retrorectus plane. Variations in this approach include placement of all trocars along the lateral aspect of one rectus sheath, performing crossover and ultimate repair from this lateral position, or placing the instruments in either the upper or lower rectus sheath bilaterally after the initial crossover is performed. In either case, bilateral retromuscular dissection is completed laterally to the semilunar line, and above and below the hernia defect at least 5 cm to allow

mesh overlap. The hernia defect is closed, as is any posterior sheath or hernia sac defects, and mesh is placed into the retromuscular plane. If needed, TAR can still be performed on one or both sides. Unlike the technique described above, however, this can be tailored to the need of the individual hernia defect, extending the dissection only as far as is necessary to achieve hernia closure.[195–197]

These robotic retromuscular techniques have demonstrated some clinical benefit, most notably shorter length of stay compared to both open retromuscular repair and standard laparoscopic IPOM VHR. There remains a fairly high rate of seroma, though typically clinically irrelevant. Though there seems to be a low rate of SSI with robotic retromuscular repair, this has not yet been clearly seen in the literature.[198,199] The double-dock procedures with bilateral TAR are limited to large defects, typically >10 cm, that are expected to require TAR even if performed open.

Massive Hernia with Loss of Domain

There is no consistent definition as to what constitutes a massive hernia. This term is often applied to large defects, >10 cm, or hernias with "loss of domain" in which the volume of herniated viscera exceeds the capacity of the abdominal cavity to accommodate its replacement into the visceral sac. Many of these hernias are recurrent and associated with morbid obesity, skin ulcerations, enterocutaneous fistulae, diverting stomas, and distortion of the abdominal wall from multiple prior repair attempts. Several physiologic changes such as alteration of ventilatory equilibrium and impairment of venous return results from long-standing massive hernias. Forced reduction of the hernia with replacement of contents into the abdominal cavity can increase intra-abdominal pressure considerably, resulting in respiratory insufficiency and cardiovascular compromise.[200] In extreme cases, it is impossible to return the contents to the abdomen and repair the hernia defect without resection of intra-abdominal contents, such as colectomy with omentectomy. Repair of massive ventral hernias with loss of domain is technically challenging and is associated with high morbidity, mortality, and recurrence rates. A good understanding of the abdominal wall anatomy and the nature of fascial defects is essential prior to repairing these ventral hernias. Complications of repair are common and include respiratory compromise, abdominal compartment syndrome, skin flap necrosis, and wound infection, in addition to the usual surgical complications. Therefore, repair should not be recommended unless there are overwhelming indications such as disabling symptoms, bowel obstruction or strangulation, or extensive skin ulceration caused by the hernia. These patients require complex abdominal wall reconstruction, and might best be seen in centers with special interest in this area where teams have been assembled to treat complex abdominal wall pathology.

Progressive Preoperative Pneumoperitoneum

Progressive preoperative pneumoperitoneum (PPP), which was first described by Goni Moreno for repair of massive incisional hernias, is a useful technique in patients with loss of domain, from incisional or massive

inguinal hernias, to expand the abdominal cavity by stretching the abdominal wall musculature and the diaphragm.[31,201–206] The maneuver involves injecting room air (or CO_2) via a needle or implantable catheter every 1 to 3 days for a prescribed period of time between 1 and 4 weeks. Volume of air injection varies but is most often administered to the degree the patient tolerates (development of shoulder pain, difficulty breathing, or subcutaneous emphysema). This can be performed by patients and families as outpatient, but is more often performed in a hospital setting. The effect of PPP is twofold. First, there is lengthening of the abdominal musculature and expansion of the abdominal cavity volume.[205,207] While the hernia sac expands as well, often more than the abdominal cavity, if the volume expansion of the abdominal cavity is equal or greater than the original hernia sac volume, the abdomen can typically accommodate the return of the herniated contents and allow fascial closure.[208] Second, the gradual expansion of the abdominal cavity seems to allow for physiologic adaptation that permits the massive abdominal wall reconstruction and increased abdominal pressure at the time of closure.[207]

Progressive preoperative pneumoperitoineum has been more commonly applied in Europe and South America with good results for large ventral hernias. Rate of fascial closure ranges from 50–100%, with reported recurrence rate of 3–37%.[206] Complications include extensive subcutaneous emphysema, surgical site infections, other non-infectious wound complications, abdominal wall soft tissue necrosis, venous thromboembolism (VTE), and cardiopulmonary complications. Complications tend to be higher than typical incisional hernia repairs owing to the more complex techniques usually required to achieve closure and the prolonged duration of hospitalization and/or abdominal insufflation. A variety of repair techniques are used in conjunction with PPP including external oblique release, retromuscular repair with or without additional posterior release, laparoscopic repair. Mesh reinforcement should be used due to excessively high recurrence rates with suture repair. Adjunctive measures such as chemical component separation (discussed below) may add benefit and improve the success rate of PPP.[209] Despite the relative success in reported series, this is a complex process reserved for only the most complex patients with large hernias and significant loss of abdominal domain

that have little chance of closure without some ability to expand abdominal volume.

Chemical Component Separation

A newer modality for expansion of the abdominal cavity utilizes chemical paralysis of the abdominal wall by botulinum toxin A (BTA) injection into the lateral abdominal wall musculature, often termed chemical component separation. The resultant flaccid paralysis of the oblique musculature, which peaks at approximately 3 weeks after injection, has been shown to elongate and decrease the thickness of the lateral abdominal muscles, which reduces the mean hernia defect size on subsequent imaging.[210,211] This potentially improves the ability to reapproximate the hernia defect or minimize the extent of other myofascial release techniques that may increase the operative risk. Indeed, all studies to date indicate the ability to close the hernia defect in all cases. In addition to the benefits of achieving fascial closure, BTA injection seems to provide significant postoperative pain control as well.[212]

There is significant heterogeneity in the literature on the use of BTA, however. The administered dose of BTA varies between studies, ranging from 200 to 500 units with dilutions between 2 and 100 units/mL, and injections sites vary from 3 to 5 per side. Additionally, the time between injection and attempted hernia repair varies from several weeks to intraoperative injection. Patient selection varies, with some studies done primarily in patients after open abdomen management,[213,214] which represents a significantly different pathology than typical incisional hernias. The complexity of incisional hernias ranges widely as well, making it difficult to discern the optimal patient that would benefit from BTA. Finally, surgical technique for hernia repair varies greatly in each study. These include simple suture repair, external oblique release (Ramirez component separation), retromuscular repair, laparoscopic repair, and concurrent progressive preoperative pneumoperitoneum. There is currently no comparative data of BTA versus other modalities of abdominal wall expansion, no randomized control trials, and no clear evidence that BTA injection ultimately effects the extend of myofascial release needed for closure. Despite these drawbacks in the current literature, BTA injection appears to be quite safe and warrants

further investigation to assess its efficacy in complex abdominal wall reconstruction.[210–217]

Tissue Expansion

Tissue expanders can also be used when either skin or the myofascial elements of the abdominal wall are deficient. They are implanted subcutaneously or subfascially and are gradually inflated until the desired amount of extra tissue is obtained. The limitation of the technique is the delay in definitive repair while the expansion is going on and the considerable amount of pain that patients complain of. The intra-abdominal placement of tissue expanders has also been described to address the issue of loss of domain, but this is primarily confined to the pediatric literature.

Visceral Reduction

The primary concern in hernias with loss of domain is the revisceration of the herniated contents back into the abdominal cavity. If the above measures to expand the abdominal cavity fail or are inadequate, consideration may be given to reducing the contents of the hernia itself by resection of the viscera. Options include omentectomy, colectomy, or small bowel resection. There are extremely limited data on this approach as a means to achieve fascial closure in complex hernia repair with loss of domain, and this should be considered only as a last resort in expert hands.[218,219]

Parastomal Hernias

Parastomal hernia is among the most common complications of permanent enterostomies and can have significant effects on the patients' quality of life, physical and psychological well-being, and health care resources.[220] The incidence of parastomal hernia varies with the type of the stoma (1.8% to 28% for ileostomy and 4% to 48% for colostomies).[221,222] Studies designed with very careful follow-up suggest that a paracolostomy hernia develops in more than 50% of patients followed for longer than 5 years with most occurring in the first 2 years. The true incidence of parastomal hernias has been difficult to quantify given the lack of uniform definition of what constitutes a hernia, variable follow-ups, and inadequacy of physical

examination to diagnose early occurrences.[223] Poor site selection or technical errors, such as making the fascial opening too large, excessive splitting and stretching of muscle fibers, epigastric nerve denervation, placing a stoma in an incision, or emergency rather than elective creation of stoma, account for some of these hernias. Placing a stoma lateral to the rectus sheath is widely touted as a cause, but this is now being challenged. Obesity, malnutrition, advanced age, collagen abnormalities, postoperative sepsis, abdominal distention, constipation, obstructive uropathy, steroid use, and chronic lung disease also contribute. Other techniques for stomal construction, such as extraperitoneal tunneling, stapled ostomy, and prophylactic mesh reinforcement for permanent colostomies especially in the posterior sublay position have been suggested. Currently, only prophylactic mesh reinforcement of permanent end colostomy has significant data to clearly warrant routine use.[224–226] A classification system for parastomal hernias has been recommended based on the size and presence of a concomitant incisional hernia by the European Hernia Society (**Table 72.12**) which will help standardize the definition of parastomal hernias for future studies.[227]

Most parastomal hernias are asymptomatic and therefore can be treated nonoperatively. Approximately one-third of patients will ultimately require repair, though life-threatening complications, such as bowel obstruction or strangulation, are rare. Routine repair is therefore not recommended. **Table 72.13** lists possible indications. The three general types of stomal hernia repair are fascial repair, stomal relocation, and prosthetic repair, which can be performed either laparoscopically, robotic-assisted, or open. Fascial repair involves a local exploration around the stoma site, with primary closure of the defect. This approach is associated with up to 75% recurrence rate[228] and should be considered of historical interest only. Stoma relocation[223] is usually indicated in patients with other stomal problems, such as skin excoriation or suboptimal stomal construction. Simple relocation, however, results in risk of parastomal hernia at the nascent site of 24% to 86%, as well as up to 50% hernia recurrence at the initial site, along with risk of midline incisional hernia if a laparotomy is required. The major drawbacks of stomal relocation are the fact that a laparotomy is required, which in and of itself causes more morbidity than some of the other techniques, and that it exposes the patient to the risk of three new incisional

hernias at (a) the old stoma site, (b) the laparotomy incision site, and (c) the new stoma site with reported recurrence rates ranging from 24% to 86%.

Whenever possible, a prosthetic repair should be considered as this appears to be the most effective. There are several potential options for repair.

1. Open onlay: Mesh is placed anterior to the anterior rectus aponeurosis. Incision may be midline or a curvilinear incision outside the boundaries of the patient's appliance (**Fig. 72.40**). The skin and subcutaneous tissue are then dissected from the underlying anterior fascia widely around the stoma and hernia defect. The defect is closed around the stoma, and a prosthetic

onlay placed around the stoma and fixed to the underlying fascia. The problem with this approach is that the undermining of subcutaneous tissue leads to wound complications due to the relative poor vascularity and potential disruption of perforating vessels during dissection. As with any onlay technique for ventral hernia repair, patients should be selected carefully to minimize wound risk. This approach is a reasonable one in patients with hostile abdomens and where intraperitoneal mesh is to be avoided. Recurrence rates of up to 26% have been reported with this technique with a mesh removal rate up to 23%.[229]

2. Open retromuscular or preperitoneal sublay: Mesh is placed posterior to the rectus muscle and anterior to the posterior rectus sheath (retromuscular repair) or mesh placement between posterior rectus sheath and peritoneum (preperitoneal repair) has been described in small case series. Posterior component separation with retromuscular mesh positioning is a technique that has been described in patients with complex parastomal hernias which uses mesh to reinforce all "at risk" areas for recurrence.[230,231] This approach allows any midline hernias to be easily addressed as well. Mesh may be cut as a keyhole, wrapping the mesh around the stoma left in situ and subsequent closure of slit cut in the mesh. If the stoma is revised or relocated, the stoma can be brought back through the mesh directly without requiring a long slit to be cut in the mesh. This can be also accomplished using a stapled technique, fixating the mesh to the posterior sheath with a circular stapler and bringing the stoma back through the mesh. An extraperitoneal Sugarbaker technique is also possible, lateralizing the stoma within the retromuscular space and placing an intact flat mesh below the stoma as described below.[232] This approach is feasible using a robotic approach, but is most often performed via midline laparotomy.

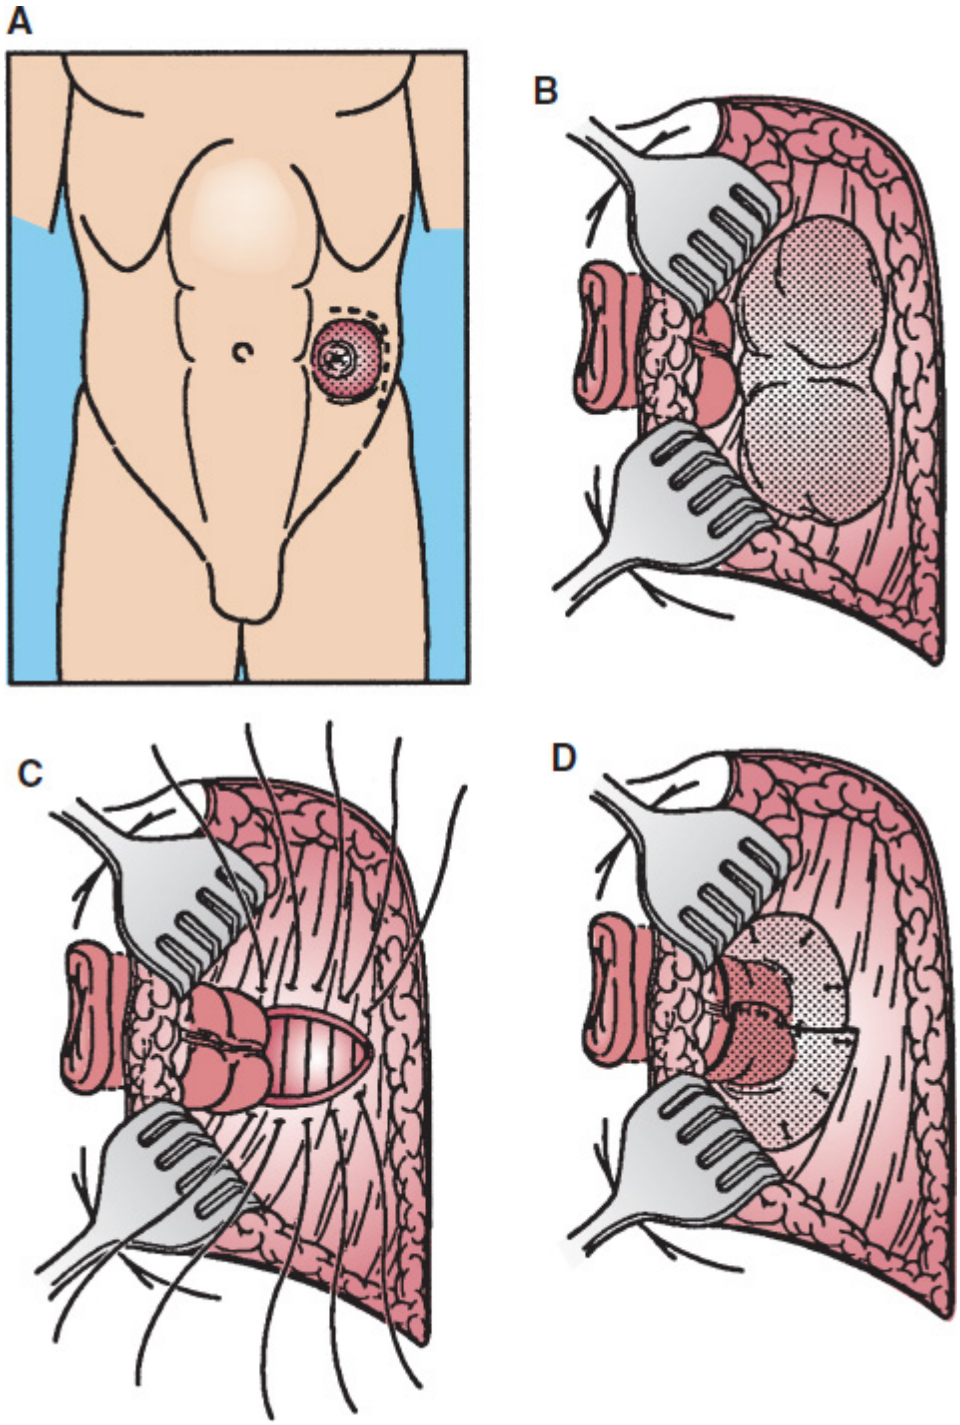

Figure 72.40 Repair of a parastomal hernia. **A:** Incision around hernia. **B:** Hernia sac is identified, the contents are reduced, and the peritoneum is closed. **C:** The edges of the fascial defect are reapproximated. **D:** The fascial repair is reinforced with polypropylene mesh, which is wrapped around the subcutaneous portion of the colon and sutured in place.

3. Open intraperitoneal sublay mesh (known colloquially as IPOM). An intra-abdominal prosthetic repair eliminates the need for the abdominal wall dissection. It also enlists the mechanical advantage of placing the prosthesis on the peritoneal side of the abdominal wall.[233] The intra-abdominal approach is particularly suited for laparoscopy or robotic surgery, which provide excellent visualization. Several techniques have been described.[234] This can be performed in two ways. (1) The Sugarbaker technique in which the bowel is first lateralized along the abdominal wall. The mesh is placed over the entire fascial defect and under the lateralized bowel, and fixated circumferentially except laterally where the bowel exits to create a mesh flap valve around the stoma. (2) The Keyhole technique requires a 2- to 3-cm cutout is made in the mesh for the ostomy while widely covering the defect. This can be tricky as too small of an opening can obstruct the enterostomy while too large of an opening can result in recurrence, the mesh must be slit, then reclosed, in order to place it circumferentially around the ostomy. Recurrence rate is lower with Sugarbaker repair compared to keyhole when mesh is placed intraperitoneally.
4. Laparoscopic repair of parastomal hernia. Laparoscopic repair of parastomal hernias has the advantage of avoiding a large incision while providing superior view of the defect and allowing for intraperitoneal mesh placement.[235] Currently descried techniques of laparoscopic repair include: (1) modified Sugarbaker technique, (2) Keyhole technique, and (3) Sandwich technique which combines both these approaches. Reported recurrence rates range from 0% to 47% with infection rates up to 16%, conversion rates range from 0% to 15% and 10% rate of mesh explantation. Optimal mesh for this approach has not been determined, but a barrier-coated mesh is necessary.
5. Robotic-assisted repair of parastomal hernias is an extension of both the laparoscopic and open approaches. Many surgeons prefer the enhanced three-dimensional visualization as well as the flexibility afforded by instrument articulation, which allows reliable hernia defect closure and mesh fixation using suture. Robotic parastomal hernia repair can follow the traditional laparoscopic approach identical to that described above. However, the potential benefit of the robotic platform is the ability to perform more complex operations, such as the retromuscular sublay repair,

in a minimally invasive fashion, which can be performed using a keyhole mesh or an extraperitoneal Sugarbaker approach.

Prophylactic Mesh Placement

Recent randomized controlled trials and a recent meta-analysis have shown that prophylactic implantation of both biologic and synthetic mesh in a preperitoneal or sublay position for both ileostomies and colostomies is safe and effective and may be associated with some of these studies showing a decreased incidence (15% vs. 52%) of parastomal herniation.[236,237] Synthetic meshes are cost effective without added morbidity or mortality. These studies have had limitations such as small sample size, heterogeneous population, and variable follow-up. Prospective multicenter randomized controlled study comparing standard stoma creation to reenforcement with porcine acellular dermal matrix showed similar incidence of parastomal hernia at 24 months in both groups. Early results of the Danish PREVENT-trial demonstrates significantly lower rate of parastomal hernia at 1 year when sublay light-weight polypropylene mesh is used.[226] Further large scale randomized controlled trials with long-term follow-up are necessary to identify specific group of patients in whom reenforcement is essential and cost effective, and to identify the optimal mesh type and location for prophylaxis.[237]

UNUSUAL HERNIAS

Spigelian Hernia

A Flemish anatomist, Adriaan van der Spieghel, first described the semilunar line, which is the lateral limit of the posterior rectus sheath. Also called the spontaneous lateral ventral hernia, a Spigelian hernia protrudes through an area of weakness just lateral to the rectus sheath most often below the arcuate line (**Fig. 72.41**). The hernia is usually interparietal, rarely penetrating the external oblique fascia, and therefore can be difficult to appreciate. This is an unusual hernia; only 744 cases have been described in the literature. The typical presentation is lower abdominal swelling or pain just lateral to the

border of the rectus muscle, and commonly occur in elderly female patients. They are usually small, about 1 to 2 cm in diameter, although large hernias up to 14 cm in diameter have been described. Omentum and small or large bowel may enter the sac. Incarceration and strangulation may occur. Because the hernia is deep to the external oblique fascia, the clinical presentation may not be obvious. Pain and tenderness may be the only signs. Plain roentgenograms may show a bowel shadow in this area, and CT can demonstrate the defect well. Treatment is operative repair. For open repair, a transverse incision is centered over the mass. The external oblique aponeurosis is split to reveal the protrusion. If a large sac is present, it is divided and sutured. The aponeurotic defect is triangular, with its base at or near the lateral border of the rectus muscle. The defect is closed by joining the separated transversus and internal oblique layers. As these hernias are often partial thickness, laparoscopy is probably the preferred choice for repair, as the defect is readily visualized. A preperitoneal mesh repair is preferred.

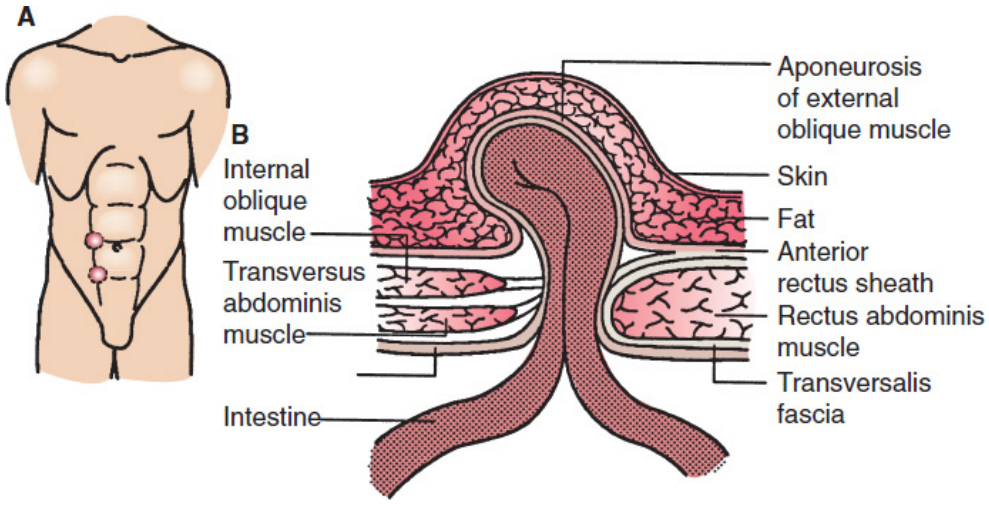

Figure 72.41 Spigelian hernia. **A:** Usual site of occurrence. **B:** Transverse section of abdominal wall showing site of defect.

Lumbar and Flank Hernias

The lumbar region is the area bounded inferiorly by the iliac crest and superiorly by the 12th rib, posteriorly by the erector spinae group of muscles, and anteriorly by the edge of the external oblique muscle as it extends from

the 12th rib to the iliac crest. The three varieties of primary lumbar hernia are described in **Table 72.14**. These hernias require repair if they are large or symptomatic, typically with mesh repair. A preperitoneal and retroperitoneal approach is most often used, and can be performed in an open, laparoscopic, or robotic fashion. For the inferior lumbar hernia, a rotation flap of fascia lata can be used (**Fig. 72.42**).[238,239]

Incisional hernias may also occur in the lateral abdominal wall when nonmidline incisions are required for various urologic, vascular, or neurosurgical procedures. This can lead both to true full-thickness incisional hernias, as well as partial-thickness defects or denervation and atrophy than appears clinically like a hernia, but without true anatomic defect. True incisional hernias are often larger than primary lumbar hernias and typically require repair. Options include a preperitoneal and retroperitoneal dissection to facilitate mesh reinforcement in this plane below the closed defect, and can be accomplished open, laparoscopically or robotically. For partial-thickness defects, a minimally invasive approach is sometimes helpful, as the external oblique layer is intact and the defect more difficult to identify from an open approach. For eventration in the absence of true hernia, nonoperative management is appropriate in most patients. If repair is desired due to significant size, abdominal wall and core instability, or patient young age, a similar approach with wide mesh reinforcement is appropriate, ideally in a sublay preperitoneal/retroperitoneal position, with plication of the redundant and atrophied overlying oblique musculature.[238,239]

Table 72.14 Types of Lumbar Hernia

Type	Description
Superior lumbar hernia of Grynfeltt	Occurs through a space between the latissimus dorsi, the serratus posterior inferior, and the posterior border of the internal oblique muscle
Inferior lumbar hernia of Petit	Occurs through a defect in the space bounded by the latissimus dorsi posteriorly, the iliac crest inferiorly, and the posterior border of the external oblique anteriorly
Secondary lumbar hernia	Develops as a result of trauma, mostly surgical (e.g., renal surgery), or infection; lumbar hernias were encountered relatively frequently in the past in cases of spinal tuberculosis with paraspinal abscesses

Obturator Hernia

This hernia is the result of abdominal contents protruding through the obturator canal in the pelvis. This canal is the opening in the superior part of the obturator membrane covering the foramen formed by the union of the pubic bone and ischium, through which the obturator nerve, artery, and vein pass from the pelvic cavity into the thigh. A recent history of profound asthenia and weight loss is not unusual, which is most likely due to the loss of the protective fat in the obturator canal.[240] This may account for the fact that women, more often than men, are afflicted with this hernia because their broader pelvis results in a larger obturator canal. The diagnosis of an obturator hernia is difficult because it is rare and physical examination is rarely helpful because the associated mass is concealed beneath the adductor muscles of the thigh. The main symptom is intermittent pain, however, this will classically present as bowel obstruction in the elderly patient in the absence of prior abdominal surgery. A helpful physical examination maneuver is the Howship-Romberg sign where inner thigh pain is experienced with internal rotation of the thigh. During repair, the defect is

approached transperitoneally; the hernia is reduced and mesh placed over the defect. Depending on the expertise of the responsible surgeon, either a conventional open or laparoscopic operation is reasonable, though laparoscopy offers the optimal visualization and ease of repair.

Sciatic Hernia

A sciatic hernia is a protrusion of a peritoneal sac through the major or minor sciatic foramen (**Fig. 72.43**). These very rare hernias present with a swelling on the buttock. The sciatic nerve may be involved. A ureter can become obstructed if it is included with the herniated tissues. The treatment of these hernias is surgical. Both transperitoneal and transgluteal approaches have been described. A combination of the two is sometimes used. The defect usually requires a prosthetic mesh repair.

Supravesical Hernia

This hernia is anterior to the urinary bladder and forms when the integrity of the transversus abdominis muscle and the transversalis fascia fail, both of which insert into Cooper ligament. The preperitoneal space is continuous with the retropubic space of Retzius, and the hernia sac protrudes into this area. The sac of the hernia is directed laterally, emerges at the lateral border of the rectus muscle, and presents in the inguinal, femoral, or obturator region. It can also be associated with an inguinal, femoral, or obturator hernia. Treatment of this hernia depends on recognizing it at the time of groin exploration and reinforcing the defect.

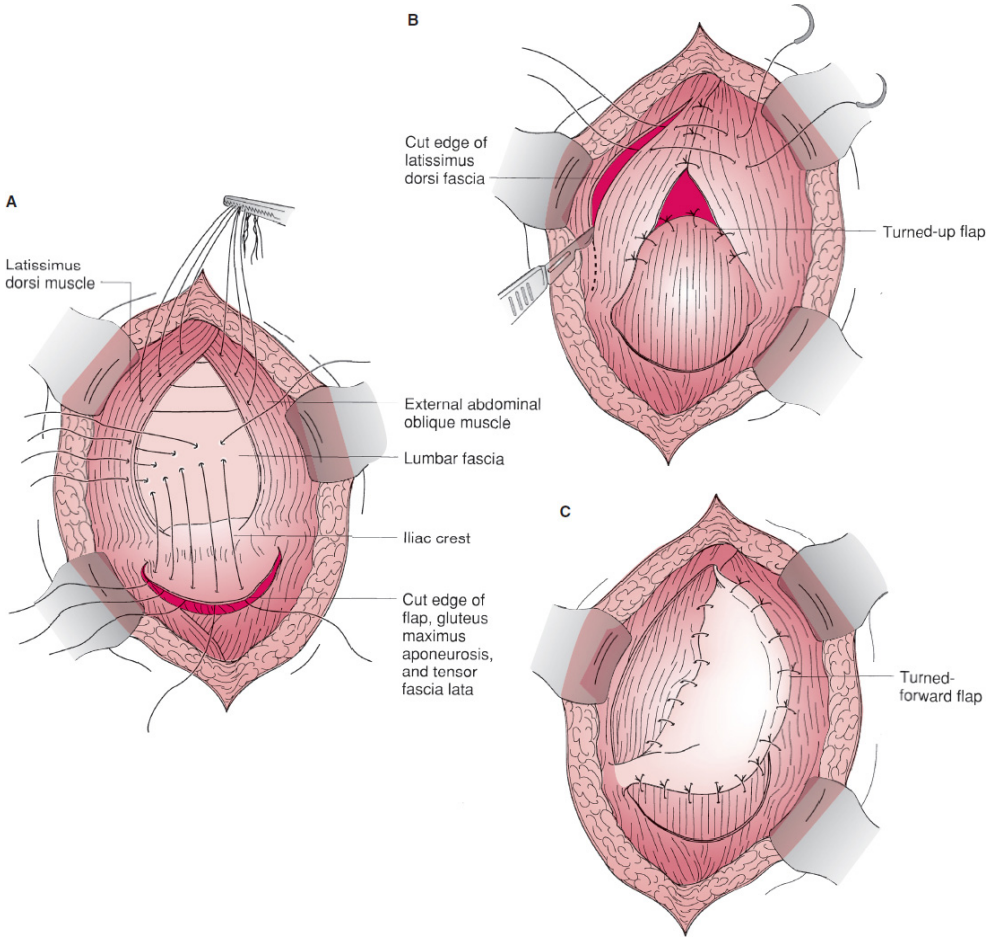

Figure 72.42 Technique of repair of inferior lumbar hernia.

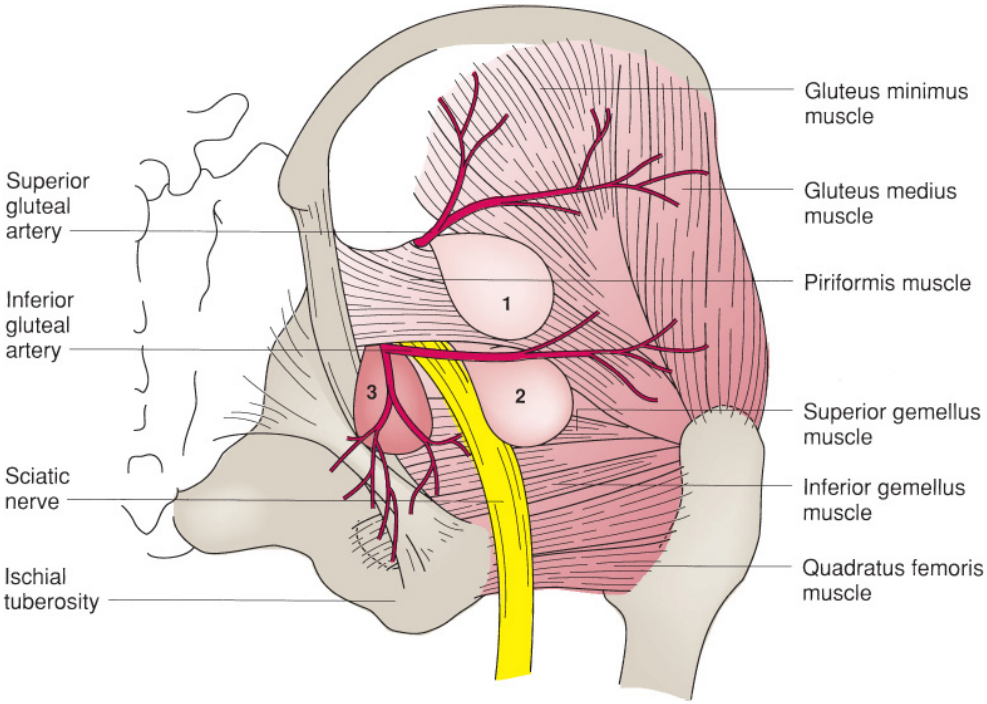

Figure 72.43 Sciatic hernia. **1:** Suprapiriform. **2:** Infrapiriform. **3:** Subspinous.

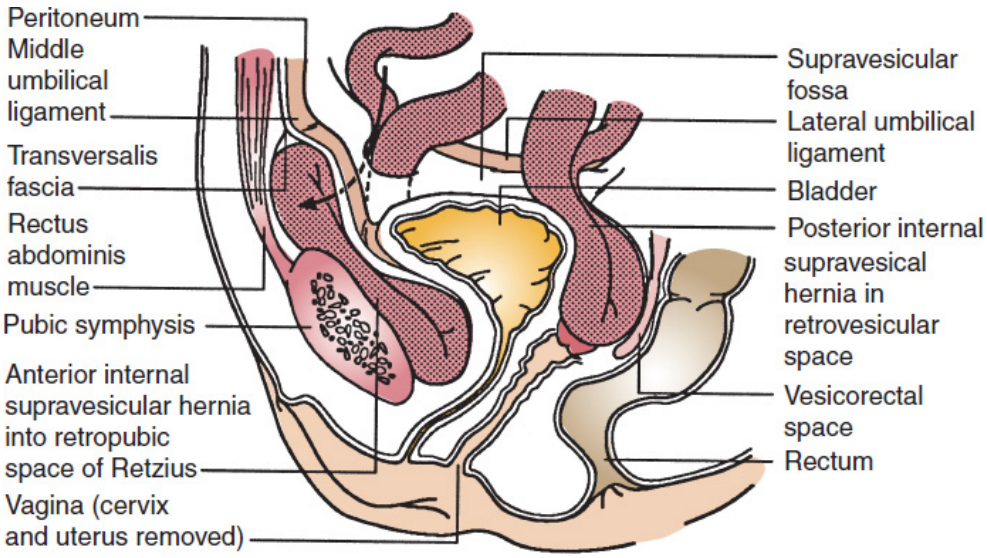

Figure 72.44 Internal supravesical hernias.

A second variety of these hernias is known as an internal supravesical hernia. They are classified according to whether they cross in front of, beside, or behind the bladder (**Fig. 72.44**). Bowel symptoms predominate in patients with these hernias, and urinary tract symptoms develop in up to 30%. The treatment is surgical, and a transperitoneal approach is used through a

low midline incision. The hernias can usually be reduced without difficulty. The neck of the sac should be divided and closed.

Interparietal Hernia

An interparietal, or interstitial hernia is a partial-thickness defect with herniation of visceral contents between layers of the abdominal wall. These may occur in the inguinal space, termed *inguinal interstitial* hernias. An *inguinal crural* hernia occurs when the sac passes behind the inguinal ligament in the region of the femoral ring. Spigelian hernias may be interparietal as well, as described above. The cause of these hernias appears to be related to congenital abnormalities; they have been associated with failure of the testis to descend, congenital pouches, and other abnormalities, such as absence of the cremaster and absence of the external abdominal ring. The diagnosis of these hernias is difficult because no swelling of the abdominal wall is obvious unless the hernia is large. Pain is commonly the only symptom, and it is not unusual for patients to present with intestinal obstruction secondary to incarceration. CT, ultrasonography, and laparoscopy can be helpful in making the diagnosis. Not infrequently, the correct diagnosis is made only at operation. The defect is repaired according to the principles described for inguinal and incisional hernias.

Acquired interparietal hernias are an uncommon but important complication of retromuscular hernia repairs, occurring after both open and robotic repairs. These occur due to disruption of the closed posterior rectus sheath or other defect in the peritoneum, allowing viscera to herniate through the posterior sheath, while the anterior fascia and mesh typically remain intact anteriorly. Incidence is approximately 1% and most often presents in the early post-operative period as a bowel obstruction. A high index of suspicion is needed to detect these defects, and CT is needed for diagnosis. Bowel can be seen against the abdominal wall with the disrupted posterior sheath angulated downward away from the abdominal wall, pinching the bowel at the neck of the hernia. Acute repair is needed and can be accomplished with laparoscopic exploration, reduction of the herniated contents, and obliteration of the potential space between the posterior sheath and anterior mesh. Tacks, transfascial sutures, or intraperitoneal mesh, either absorbable or barrier coated, are all viable options, the aim of which is to

prevent any subsequent herniation back into the retromuscular space. More chronic or subacute presentation does occur, and treatment is aimed at relief of presenting symptoms.[165,241]

Littre Hernia

Littre hernia is a groin hernia containing a Meckel diverticulum. These hernias sometimes also contain the appendix. If the diverticulum is symptomatic or strangulated, then it is mandatory to resect it at the time of the hernia repair.

Perineal Hernia

These hernias are more common in older female patients and are related to a lax pelvic floor. They are termed *anterior* or *posterior* according to their relationship to the transverse perineal muscle. The anterior hernias usually present as a swelling in the labium or lateral vaginal wall. The posterior hernias present between the rectum and the ischial tuberosity. Surgical repair requires a transperitoneal or posterior approach, and, if the opening is large, a prosthetic mesh repair is required.

Perivascular Hernia

These hernias present through defects between the inguinal ligament and the iliopubic bone. They are known by various eponyms according to their position. The hernia protruding through a defect in the lacunar ligament is *Laugier hernia.* The hernia protruding through the pectineal fascia is *Cloquet hernia.* The hernia extending anterior to the femoral vessels but behind the inguinal ligament is *Velpeau hernia.* The hernia behind the vessels is *Serafini hernia.* Lateral to the femoral artery are two hernias, the anterior one being *Hesselbach hernia* and the more posterior one *Partridge hernia* (**Fig. 72.45**).

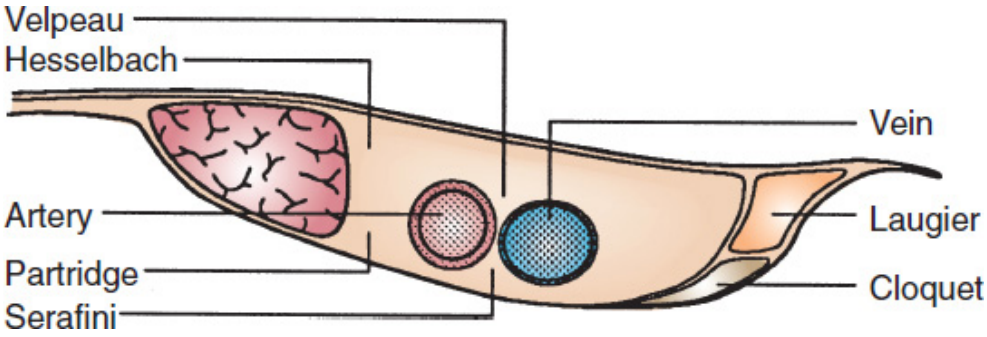

Figure 72.45 Perivascular hernias and their eponyms.

COMPLICATIONS OF VENTRAL HERNIA REPAIR

Ventral hernia repair and abdominal wall reconstruction is complex, and the incidence of complications depends on multiple factors including the complexity of the hernia repair, the technique used, mesh selection, and patient comorbidities. It is often difficult to parse and compare complications between different procedures and meshes in the literature due to the lack of comparative trials as well as nonstandardized nomenclature. The recently developed terminology of SSO, which includes both the commonly understood SSI as well as other noninfectious wound complications, provides a good framework for reporting and better comparison across hernia studies.[242] Several risk calculators are available to assist in optimizing patients for surgery, selection of the optimal surgical approach, and for informed consent. The American College of Surgeons National Surgical Quality Improvement Project (ACS NSQIP) risk calculator accounts for patient-related factors for morbidity and mortality. The Ventral Hernia Risk Score (VHRS), Hernia Wound Risk Assessment Tool (HWRAT), Ventral Hernia Working Group (VHWG), the Carolinas Equation for Determining Associated Risks (CeDAR), the Michigan Surgical Quality Collaborative (MSQC), and the Americas Hernia Society Quality Collaborative Outcomes Reporting App for Clinician and Patient Engagement (AHSQC ORACLE) are all available tools to assist the surgeon in predicting the risk of wound and general complications following VHR (**Fig. 72.46**, **Table 72.16**).[243,244] These scoring systems have been developed

using variable methodology, primarily based on retrospective or registry-based data, and none to date have been externally, independently validated.

General Complications

There are many complications inherent to abdominal surgery, and VHR is no exception. Postoperative ileus, early SBO, cardiac, pulmonary, and renal complications can all occur following any VHR. These can be mitigated somewhat by choice of technique, with open repairs tending to have a higher risk of ileus, SBO, or wound complications. Cardiac arrhythmias may complicate pneumoperitoneum during laparoscopic or robotic repair. Urinary retention may occur in complex cases, particularly if dissection is required around the bladder. Pulmonary complications may be increased with some complex VHR, particularly large hernia defects and those with loss of domain. Attempting to reviscerate the herniated contents into the abdominal cavity and close the hernia defect may require significant tension, resulting in significant increase in intra-abdominal pressure. This may result in early postoperative respiratory insufficiency or failure, pneumonia, prevent initial extubation, or in the extreme result in abdominal compartment syndrome. Attention must be paid to airway pressures and other ventilatory parameters, along with intra-abdominal pressure, in such cases. All ventral hernia patients should be considered high risk for venous thromboembolic complications and be prophylaxed accordingly.

Surgical Site Infection

SSI is defined by the Center for Disease Control (CDC) and is divided into three types by the depth of the infection. Superficial SSI involves only the skin and subcutaneous tissue of the associated incision, presenting within 30 days with typical signs of infection including tenderness, swelling, erythema, or heat. Diagnosis requires one of these signs along with purulent drainage, positive culture, or deliberate opening of the surgical wound. This does not include cellulitis, stitch abscess/granuloma, or infection at stab incisions. This is the most common type of SSI with most hernia repairs. Deep SSI involves the fascia or muscle layers, also presenting with typical signs of infection. Also included in the criteria are fever, spontaneous wound

dehiscence, or abscess. Infection occurring in the retromuscular compartment or preperitoneal space after abdominal wall reconstruction would be considered a deep space infection. Organ-space SSI can have differing definitions depending on the procedure performed. For the purpose of hernia repair, these occur deep the abdominal wall musculature in the intra-abdominal compartment. Diagnostic criteria include purulent drainage from organ-space drains, percutaneously placed drains in fluid collection/abscess cavity with positive culture, or intra-abdominal sepsis.

5	>19	812 (3.0%)	215 (26.5%)

Table 72.17 Summarizes the International Guidelines for Groin Hernia Management

Grade 3/4

- Mesh-based repair is recommended for adult inguinal hernias.
- Flat mesh Lichtenstein technique is recommended over 3-dimensional implants.
- Laparo-endoscopic (TEP or TAPP) technique is suggested for male primary unilateral hernias.
- Shouldice technique is recommended in nonmesh repair.

Grade 4/4

- Antibiotic prophylaxis is not recommended in average-risk cases.
- Local anesthesia is recommended for reducible open repair.
- Timely repair, laparoendoscopic technique, and consideration of femoral hernias are recommended in female groin hernias.
- Minimizing spermatic cord trauma reduces orchialgia.
- Laparoendoscopic repair is recommended after failed anterior repair.
- Anterior repair is recommended after a failed posterior repair.
- Considering cost-effectiveness, day-case laparoendoscopic repair is recommended.

The risk of SSI increases with increasing level of contamination of the operation, with dirty or infected wounds having the highest risk of infection at around 40%. Other factors also contribute to this risk including smoking, COPD, diabetes, obesity, immune compromise, history of infection, and surgical technique. As discussed above, many of these risk factors are modifiable and should ideally be addressed prior to surgery. Most SSIs require treatment of some kind, referred to as an SSI requiring procedural intervention (SSOPI). This can include the use of antibiotics, wound opening, wound debridement, suture excision, or percutaneous drainage. If the infection involves the prosthetic mesh, partial or complete mesh removal may also be required. The risk of SSI can be mitigated with preoperative optimization of patient comorbidities, choice of surgical approach, and meticulous sterile technique. Minimally invasive approach has been clearly demonstrated to lower the risk of SSI, but is not appropriate for all patients

for a variety of reasons. Other strategies such as use of antimicrobial mesh, minimal handling of the mesh itself (the "no-touch technique"), use of iodine impregnated drapes, and antibiotic irrigation have some support in the literature as well, though no level 1 data currently support any of these practices.

Surgical Site Occurrence

There are a variety of wound complications that can occur as a result of hernia repair and AWR that do not meet the criteria for SSI. Current nomenclature refers to these as Surgical Site Occurrences (SSOs), though this term is sometimes used as a broader term under which SSI is included. Included under SSO are seroma or serous wound drainage hematomas, cellulitis, skin and soft tissue ischemia or necrosis, exposed prosthetic mesh, or enterocutaneous fistula. This also allows specific descriptors of the origins of some types of SSI, such as infected seroma or hematoma, infected or contaminated prosthetic mesh, or purulent wound drainage. As with SSI, intervention is sometimes necessary for treatment (SSOPI), though often simple SSOs, such as seroma, can be managed expectantly without intervention. Noninfectious SSOs can be reduced with the use of drains, though their use does not confer protection against SSI.[245]

Mesh-Related Complications

Among the most feared complications of VHR is a complication related to the implanted prosthetic mesh. This can include mesh infection or periprosthetic infection, exposed mesh, extrusion of mesh through the skin, or enterocutaneous fistula. Mesh infection is typically reported in <1% of laparoscopic or robotic cases and <5% for open repair. The risk of mesh erosion or fistula is unknown, with data limited primarily to case reports or small case series. The risk of any of these complications and the treatment required varies greatly by presentation, mesh type, and mesh location. Generally speaking, no particular mesh seems to be a higher risk of infection when used in clean cases. However, the properties of the mesh and location within the abdominal wall seem to have significant impact on the treatment needed. Intraperitoneal mesh typically requires removal, though there are

reports of salvage. Treatment of extraperitoneal mesh infection, those placed in the preperitoneal, retromuscular or onlay position, varies more by mesh type. Generally, microporous, multifilament, laminar, or composite mesh requires complete removal, whereas monofilament, large-pore mesh is salvage in the majority of cases. In the event of enterocutaneous fistula, mesh removal is generally required. Fistula can occur as an acute complication after hernia repair, typically as a result of unrecognized enterotomy, or can present late due to mesh erosion into the viscera or a subsequent abdominal operation. Mesh removal is universally required for intraperitoneal mesh in both the acute and late setting. For mesh in an extraperitoneal position, there are reports of spontaneous closure despite presence of the mesh, though partial or complete mesh removal are frequently required (**Table 72.15**).[50,192]

Complications Related to Laparoscopy

These complications have been described above and include gas embolism, visceral injury, bladder injury, bowel obstruction, diaphragmatic dysfunction, and hypercapnia.

The Spleen

Oliver A. Varban and Anne P. Ehlers

Key Points

1. The spleen is a lymphatic organ with hematologic and immunologic function that is located in the left upper quadrant of the abdomen, relating to the diaphragm both superiorly and laterally and spans the 9th, 10th, and 11th ribs posteriorly.
2. Considered the second largest secondary lymphoid organ in the body, the normal size of the spleen is approximately 13 × 7 × 4 cm and the typical weight of a spleen is 150 to 200 g.
3. Accessory spleens are small nodules of splenic tissue that can be found in the tail of the pancreas, hilum of the spleen, gastrosplenic or splenorenal ligament, greater omentum, or in the pelvis.
4. The spleen removes senescent erythrocytes, remodels abnormal red blood cells (RBCs), recycles iron, and generates B- and T-lymphocytes in response to antigens.
5. The spleen facilitates opsonization and phagocytosis of encapsulated organisms including *Streptococcus pneumonia, Haemophilus influenzae, and Neisseria meningitidis*. Vaccines targeting encapsulated organisms can prevent overwhelming postsplenectomy infection.
6. Indications for splenectomy include trauma, hematologic and malignant disorders, cysts and infections and before allogenic hematopoietic stem cell transplant.
7. Physical enlargement of the spleen can occur as a result of neoplastic, infectious, inflammatory, congestive, infiltrative, and hematologic conditions.

INTRODUCTION

An understanding of splenic anatomy and physiology is important for both surgical decision making but also operative technique. Splenic diseases other than trauma have generally included hematologic or immunologic conditions. Historically, open total splenectomy was the only procedure applied for the

treatment of splenic disease, however current variations include a minimally invasive approach as well as spleen-preserving procedures. The surgical history of the spleen, its anatomy, physiology, indications for operative management, and techniques are reviewed.

HISTORY

The spleen has long been considered a mysterious organ with various descriptions of its function throughout history. Beginning in ancient Greece, Plato believed that the spleen's function was "to maintain the liver bright and pure."[1] Hippocrates described its role in producing one of the four vital humors—"black bile," which was later considered to be related to feelings of melancholy.[1] Terms such as "spleenful" and "spleenless" persisted even into the 17th century as a means to describe those with and without morose feelings, ill humor, malice, or spite.[2] The spleen has even been associated with the ability to run, with references to performing splenectomy in ancient literature as a means to allow men and horses to run faster. By the 14th century, descriptions of splenic anatomy improved and included Mondino De Liucci identification of short vessels from the stomach when studying splenic vascularization. In the early 16th century, Paracelsus rejected the black bile theory and began to question its physiologic function, reporting that the spleen was a superfluous organ that should be excised when diseased. During the same era, Versalius performed splenectomy in mice and other animals without adverse effects, supporting the theory that the spleen was not essential to life. It wasn't until 1911 when Micheli identified the spleen as the site of red cell destruction in autoimmune hemolytic anemia. In 1916, Paul Kaznelson, who was a Czech medical student, postulated that the removal of the spleen in patients with idiopathic thrombocytopenic purpura would be of benefit.

1 The first reported splenectomy was performed by Adriano Zaccaria in 1549, in Palermo Italy on a 24-year-old lady with malarial splenomegaly.[1] According to the report, the spleen weighed 1,340 g and the recovery from surgery was 24 days. Subsequent procedures were performed for a variety of indications. In 1826, Carl Frederick Quitterbaum performed a splenectomy for secondary hypersplenism due to cirrhosis. Meanwhile, Jules Pean

performed a splenectomy for a large cyst in France in 1865. By 1900, Bessel-Hagen reported on 360 splenectomies and noted a 40% mortality rate.[3] Conservative therapy for splenic disease was first explored during war-time periods, with Franciscus Roestti credited for performing the first successful partial splenectomy for trauma in 1590. By the 20th century, technical advances in hemostasis and blood transfusion as well as an understanding of the pathophysiology of splenic function led way to improved surgical outcomes.[4] The first laparoscopic resection was described in 1992 and has become well accepted, becoming the "gold standard" for surgical treatment for immune thrombocytopenia purpura.[5,6]

EMBRYOLOGY AND ANATOMY

The spleen develops as an outpouching from the mesogastrium during the 5th week of gestation.[4,7,8] The spleen's typical position in the left upper quadrant is the result of the natural rotation of the gut during development. In that location, the spleen relates to the diaphragm both superiorly and laterally, and it generally spans the 9th, 10th, and 11th ribs along the left mid to posterior axillary line (**Fig. 73.1**). The ventral surface of the spleen relates to the greater curvature of the stomach and the tail of the pancreas. The tail of the pancreas touches the splenic capsule in 30% of cases and is 1 cm away in 70% of cases. The inferior pole relates to the left kidney posteriorly and the splenic flexure of the colon anteriorly (**Fig. 73.3**).

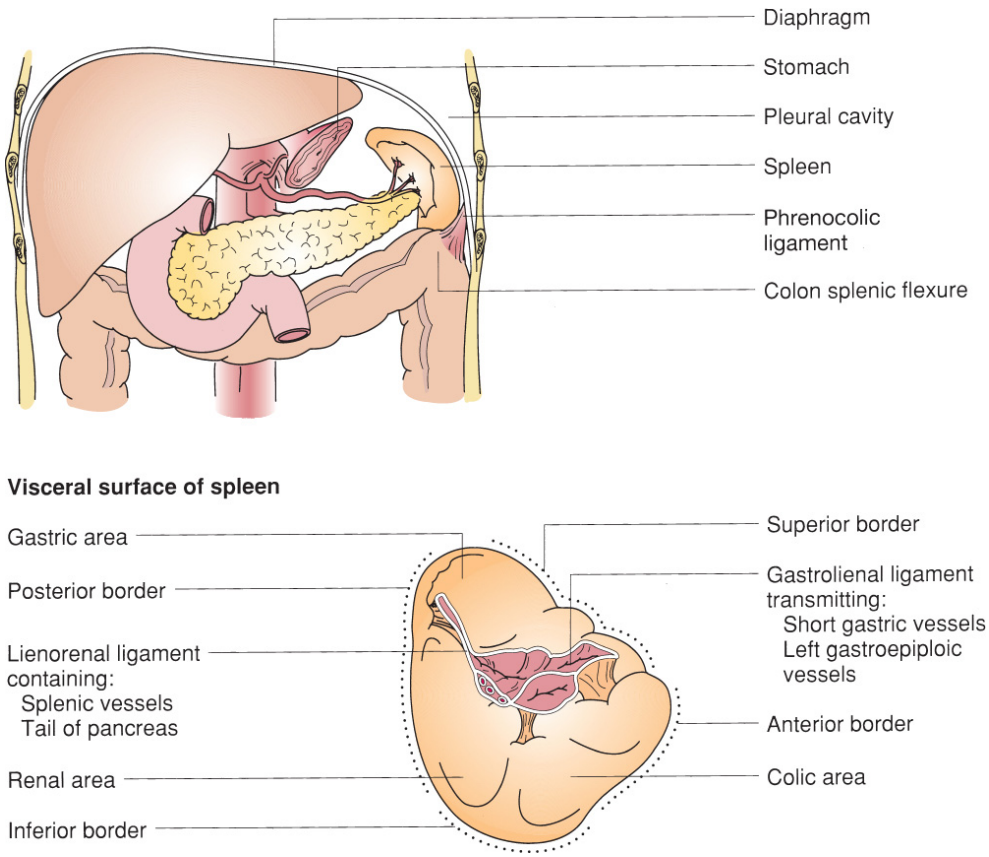

Figure 73.1 Anatomic relation of the spleen to the liver, diaphragm, pancreas, colon, and kidney. The stomach is sectioned to illustrate the anatomic relation in situ.

The typical spleen is 13 × 7 × 4 cm in size and weighs approximately 150 to 200 g.[7,8] In the elderly population the typical weight of a spleen decreases to approximately 100 g.[9] In general, the tip of the spleen can be palpated below the costal margin once it has doubled in size to range of 300 to 400 g.[10] The definition of massive splenomegaly has been arbitrarily set at 1,500 g or 10 times the average adult splenic weight. The spleen can also develop a significant cleft, which can be confused with splenic disruption on CT.

The vascular anatomy of the spleen includes the splenic artery, splenic vein, and short gastric vessels (**Fig. 73.2**).[11] The blood flow to the spleen in the typical adult is estimated to be 200 to 300 mL/min or approximately 5% of the cardiac output. The splenic artery is one of the major trunks branching off from the celiac axis and generally travels outside the parenchyma of the pancreas along the superior border. In some cases, the splenic artery is covered by the posterior surface of the pancreas and branches from splenic

artery are generally found in this location. The first major branch point along the splenic artery typically occurs between 2 and 3 cm from the hilum and it is called the superior polar artery. Subsequent branch points can vary from three and five segmental branches that enter along the trabeculae of the spleen. Additional blood supply from the short gastric vessels originates from the left gastroepiploic artery. The spleen is also capable of developing blood supply originating from the omentum, diaphragm, or the mesentery of the splenic flexure of the colon, particularly in the diseased state or when enlarged. Segmental venous branches that leave the trabeculae form the main splenic vein in the hilum of the spleen. The splenic vein is commonly associated with the posterior surface of the tail and body of the pancreas and forms a junction with the superior mesenteric vein prior to entering the portal vein. The inferior mesenteric vein may join the splenic vein directly at several areas along its course or may come together right at the junction of the superior mesenteric vein. In addition, there are again several pancreatic branches that directly enter this splenic vein. The lymph node drainage of the spleen follows the vasculature. Primary lymph nodes are located in the hilum of the spleen as well as along the splenic artery, typically located at the superior border of the pancreas and along the short gastric vessels.

The spleen remains fixed in position in the left upper quadrant primarily by the splenogastric, splenorenal, and splenocolic ligaments and mobilization of the spleen during splenectomy involves division of these ligaments (**Fig. 73.3**).[10] Ligaments are absent in the setting of "wandering spleen," in which the spleen may be found outside of the left upper quadrant and often in the pelvis.[12] The splenogastric ligament is a superior extension of the greater omentum along the proximal greater curvature of the stomach and the area includes short gastric vessels supplied by the left gastroepiploic vessels. The splenorenal ligament runs parallel to the posterolateral border of the spleen and attaches to the superior pole of Gerota fascia. The splenocolic ligament is short, associated with the splenic flexure of the colon and may be avascular or have small blood vessels that need to be controlled with ties or clips during mobilization of the splenic flexure. The splenoomental and splenophrenic ligaments are variably present and the greater omentum may be associated with the splenic capsule along the inferior pole. In order to avoid disruption of the inferior capsule of the spleen, it is imperative to investigate the extent of these attachments and divide them

prior to exerting vigorous traction along the omentum. Splenophrenic ligaments are more likely to be present when the spleen is enlarged or diseased and may be avascular or have branches of vessels that parasitized from the blood supply of the diaphragm.

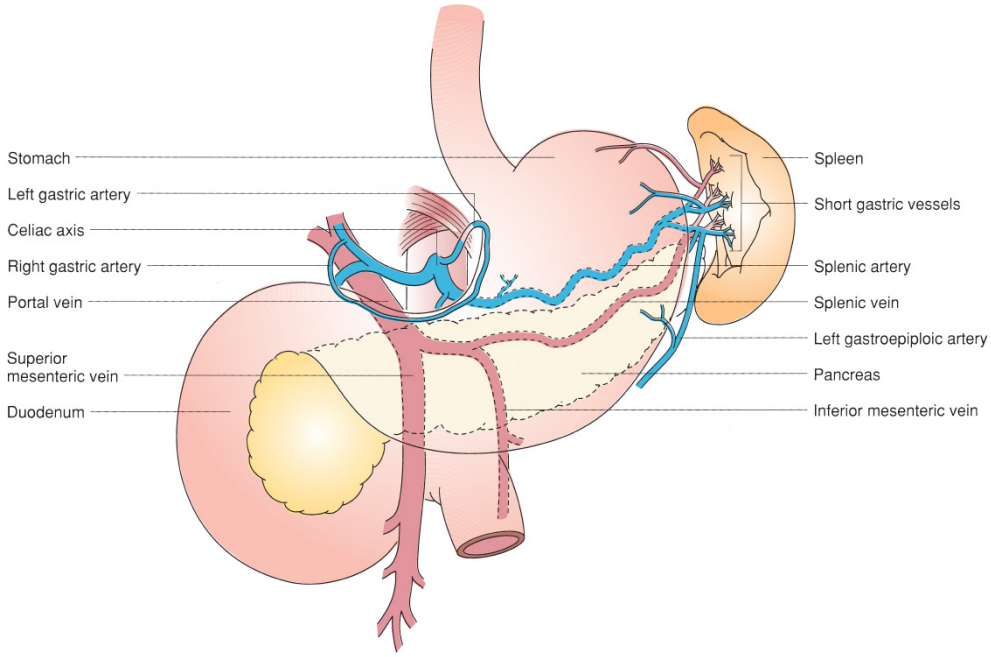

Figure 73.2 The arterial blood flow to the spleen is derived from the splenic artery, the left gastroepiploic artery, and the short gastric arteries (vasa brevia). The venous drainage into this portal vein is also shown.

2 The parenchyma of the spleen consists of white pulp, which surrounds the arteries, a marginal zone, and red pulp that comprises 75% of the spleen.[13,14] Arteries and veins feed the segmented anatomy of the spleen via trabecula, which are fibrous bands that attach to the splenic capsule.[11] The capsule of the spleen consists of a single layer of mesothelium and several layers of fibroelastic tissue. Trabecular arteries that enter the spleen are a continuation of the segmental arterial branches that form perpendicular branches and the central arteries (**Fig. 73.4**). Periarterial lymphatic sheath surround the central arteries and are composed of T lymphocytes and follicles with B cells at various stages of development. Secondary follicles form during antigenic stimulation. The marginal zone contains a mixture of lymphatics and macrophages, while the red pulp is made up of splenic cords, known as cords of Billroth as well as splenic sinuses. The splenic cords are a meshwork of fibroblasts and mature macrophages. The splenic sinuses are

an interconnective meshwork of thin-walled red cell spaces that are generally filled with erythrocytes.[14] Blood flow through the spleen can be both fast and slow.[15] Approximately 90% of the splenic blood flow is slow as erythrocytes travel through the fenestrated meshwork of the red pulp and relates to the role of clearing senescent erythrocytes. The fast flow pattern involves a greater volume of plasma and fewer erythrocytes allowing blood to flow through the splenic arteries and return rapidly to the splenic veins.

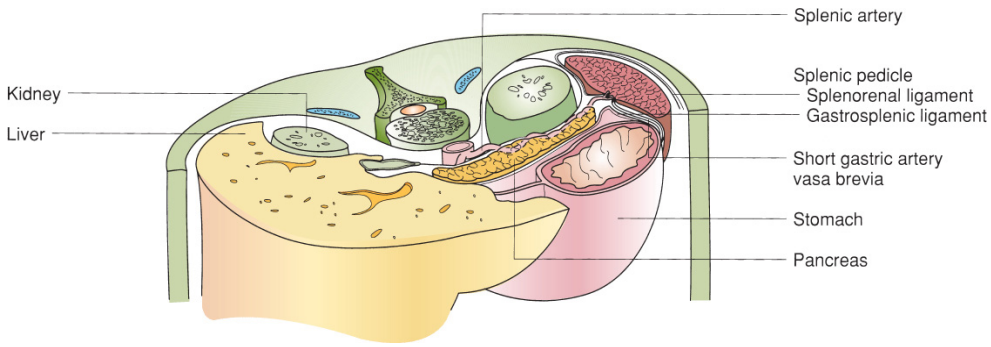

Figure 73.3 The relations of the spleen to the abdominal and retroperitoneal viscera are seen in a cross-section of the left-facing torso.

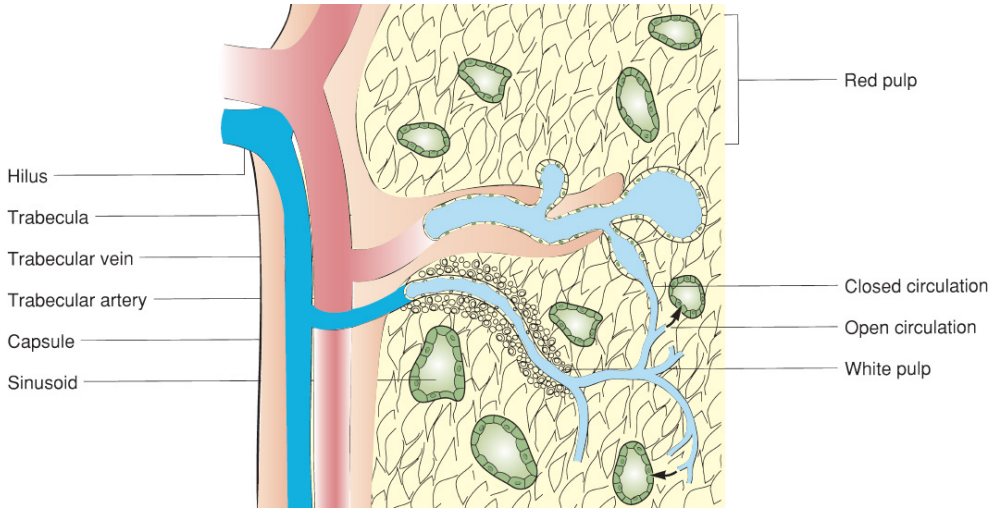

Figure 73.4 The splenic microanatomy is shown with depictions of both the open and closed circulations.

3 Accessory spleens are small nodules of splenic tissue (0.5 cm up to 3 to 4 cm) that are completely separate from the main body of the spleen and can be found in the splenic hilum, the omentum, small bowel mesentery, and less commonly in the retroperitoneum behind the spleen or in the pelvis. The

reported incidence of accessory spleens ranges between 10% and 20% and should be removed managing autoimmune disorders.[16] Nuclear scan of the spleen can be performed when trying to identify sources of residual splenic tissue and accessory spleens.[17]

PHYSIOLOGY

The spleen performs two major functions: hematologic and immunologic (**Table 73.1**).[14] The hematologic function involves destruction or clearance of the circulating blood cell elements as well hematopoiesis and storage of blood cells, consisting predominantly of platelets. In terms of the immunologic functions, the spleen generates cellular and humoral immune responses by producing specific antibodies, in particular to opsonized antigens and specific encapsulated microorganisms.

Hematologic Function of the Spleen

4 The hematologic function of the spleen includes removal of senescent erythrocytes, remodeling of abnormal red blood cells (RBCs), and recycling of iron by splenic macrophages (**Table 73.2**).[14] The average life span of a normal erythrocyte is estimated to be approximately 120 days.[18] Removal of erythrocytes occurs via phagocytosis performed by macrophages and is called culling. Hemoconcentrated erythrocyte-laden fluid enters the sinuses of the red pulp and flows slowly through a sinusoid network with adjacent cords filled with macrophages. The precise mechanism by which senescent red cells are identified for destruction in normal physiology is unclear. However, one hypothesis is that red cells become less compliant over time and are more prone to being trapped in the mesh of the sinusoids. Another hypothesis is that specific cell surface marker molecules are involved in identification of senescent cells targeted for destruction. Decreased pliability of erythrocytes occurs with conditions such as hereditary spherocytosis, elliptocytosis, and sickle cell anemia, resulting in destruction with clogging of the sinusoids and hypersplenism.

Erythrocytes can also undergo remodeling or pitting, which involves partial removal of the cell membrane typically associated with the

cytoplasmic inclusions, resulting in a larger size and thus will pass more slowly through the splenic red pulp.[14] Also, the nuclear remnant may be trapped passing through a small space in the spleen and pitting occurs when the solid particle that does not allow deformation gets pinched off. Intracytoplasmic inclusions include Howell–Jolly bodies that are nuclear remnants, Heinz bodies that are denatured hemoglobin, and Pappenheimer bodies that are iron granules.

Table 73.1 Normal Functions of the Spleen

Hematologic
Culling or destruction of senescent erythrocytes
Pitting or removal of cytoplasm inclusive in erythrocytes
Reservoir for platelets and granulocytes
Hematopoiesis—as fetus or in conditions with bone marrow destruction
Immunologic
Filtration and trapping of circulatory antigens
Lymphocyte stimulation and proliferation
Antibody production in germinal follicles
Production of opsonin: tuftsin and properdin
Opsonins: tuftsin and properdin

Table 73.2 Hematologic Changes Postsplenectomy/Hyposplenic Condition

1. Erythrocytes
    1. Howell–Jolly bodies (nuclear fragments)
    2. Heinz bodies (hemoglobin deposits)
    3. Pappenheimer bodies (iron deposits)
    4. Target cells
    5. Spur cells (acanthocytes)
2. Platelets
    1. Transient thrombocytosis
3. Leukocytes
    1. Transient leukocytosis
    2. Persistent lymphocytosis
    3. Persistent monocytosis

Destruction of circulating cellular elements in the blood (i.e., platelets and leukocytes) occurs in diseased states. If either platelets or white blood cells become coated with antibodies, the Fc portion of the immunoglobulin will interact with the Fc receptors on the macrophages in the splenic cords leading to phagocytosis of these cell types. Hypersplenism alone may also result in destruction of cells even without autoantibodies or defects in the cells.

During gestation, the spleen serves as a source for hematopoiesis of all cell types and in certain disease states, the spleen may develop the capacity for erythropoiesis and myelopoiesis. Germinal centers in the white pulp of the spleen produce reactive lymphocytes and the cords of the spleen are filled with macrophages. Finally, the spleen is also a reservoir of circulating cellular elements and it is estimated that 30% of all platelets resides in the spleen.[19]

Immunologic Function of the Spleen

The spleen is involved in generating an immune response to circulating opsonized antigens or specific encapsulated microorganisms so they may be

trapped by the spleen. Phagocytic cells, dendritic cells, T cells, and B cells can be found in the marginal zone of the white pulp in the spleen and can generate specific antibody responses. The cellular components and structure of the germinal follicles is anatomically similar lymphatic tissue and becomes enlarged in a similar fashion when simulated by antigens from microbes.

The spleen is also responsible for synthesizing opsonins, such as properdin and tuftsin. Tuftsin is a small peptide that binds to the surface of granulocytes and promotes phagocytic function by these cells.[20] Properdin can initiate the alternate pathway of complement activation, which results in destruction of abnormal cells or bacteria that are bound by antibodies. Since the spleen is not the only source of these nonspecific immune-enhancing proteins, splenectomy only leads to a modest alteration in this function.

PATHOPHYSIOLOGY

Hyposplenism and hypersplenism are broad categories that describe common pathophysiology of the spleen. These categories provide guidelines for deciding who should undergo splenectomy and also how to manage patients postoperatively.

Table 73.3 Causes/Disorders Associated with Hyposplenism
Splenectomy
Sickle cell anemia
Congenital asplenia (autosomal recessive disorder)
Autoimmune disorders (e.g., glomerulonephritis and SLE)
Celiac disease/inflammatory bowel disease
Tumor or cystic replacement of spleen
Amyloidosis
Splenic vascular accident
Radiation

SLE, systemic lupus erythematosus.

Hyposplenism

5 Causes for hyposplenism are listed in **Table 73.3**. While the most common cause is due to splenectomy,[21] congenital asplenia or autoimmune disorders resulting in the destruction of splenic tissue can be investigated by ^{99}Tc-labeled spleen scan or pitted RBC count.[17] Pathophysiologic consequences of hyposplenism includes an increase in Howell–Jolly bodies, Heinz bodies, and Pappenheimer bodies as well as an increase in circulating reticulocytes, platelets, and leukocytes. Platelet counts range between 500,000 and one million but may also be transient given the fact that the spleen may not be the primary area of platelet destruction and that platelets have a typical half-life of 10 days. The immediate increase of white cells reflects the storage of a large proportion of white cells in the spleen and as with thrombocytosis, the effect may also be transient. Given that the spleen is responsible for generating an immune response to circulating opsonized antigens, asplenic patients are also at risk for developing overwhelming sepsis by encapsulated microorganisms, which include *Streptococcus pneumonia, Haemophilus influenzae,* and *Neisseria meningitidis*.[21]

Hypersplenism

Hypersplenism is defined according to the following criteria: (1) documented anemia, thrombocytopenia, or leukopenia; (2) normal compensatory response by the bone marrow to correct the cytopenia; and (3) correction of this cytopenia by splenectomy.[22] Causes for hypersplenism are listed in **Table 73.4**, which are based on the primary disorder of the blood cells or of the spleen itself. Regardless of cause, the pathophysiology ultimately involves destruction of circulating blood elements within the splenic parenchyma. In some cases, the process may also result in splenomegaly, which can create a mass effect on the surrounding organs. When the stomach is compressed between an enlarged spleen and the liver, patient may experience early satiety and weight loss. Elective splenectomy is indicated in cases of hypersplenism, in order to reverse the cytopenia and also to relieve compressive symptoms from splenomegaly.[23]

SURGICAL TREATMENT FOR DISEASES RELATING TO THE SPLEEN

Approximately 25,000 splenectomies are performed in the United States for a variety of indications.[24] In a 2001 study evaluating 6 the indication for splenectomy over a 10-year period, the most common indication was therapeutic splenectomy, including for trauma (44%). The next most common indication was incidental to another procedure (26.3%) and for staging purposes (20.2%).[25] Splenectomy for diagnosis was the least common indication (9.5%). An updated report describing all splenectomies in Olmsted County, Minnesota, over a nearly 50-year period showed that the most common indication for splenectomy was malignancy (35%) followed by trauma (19%).[26] With practice changes both for therapeutic and diagnostic purposes, the landscape of indication for splenectomy is shifting. For example, trauma splenectomy is less commonly performed due to the increased understanding of the natural history of splenic trauma, and splenectomy for staging purposes is less commonly performed. In this section, we will discuss the indications for splenectomy as well as now these indications have changed over time. Similarly, splenectomy used to be

included as part of the staging work-up for lymphoma but has largely been replaced by imaging. A summary of indications for splenectomy is included in **Table 73.5**.

Table 73.4 Causes of Hypersplenism

I. Primary diseases of blood cells; normal spleen
    A. Congenital
        i. Erythrocyte abnormalities
            a. Hereditary spherocytosis
            b. Hereditary elliptocytosis
            c. Glucose 6-phosphate dehydrogenase deficiency
            d. Pyruvate kinase deficiency
        ii. Hemoglobin abnormalities
            a. Thalassemia major
            b. Sickle cell anemia (eventually results in splenic infarction and hyposplenism)
        iii. Platelet abnormalities
            a. Wiskott–Aldrich syndrome
    B. Acquired
        i. Autoimmune hemolytic anemia
        ii. Autoimmune neutropenia—Felty syndrome
        iii. Immune thrombocytopenia purpura
        iv. Thrombotic thrombocytopenia purpura
II. Primary disorders of the spleen
    A. Neoplastic
        i. Hairy cell leukemia
        ii. Chronic lymphocytic leukemia
        iii. Chronic myelogenous leukemia
        iv. Non-Hodgkin lymphoma
    B. Cellular infiltrative (hematopoiesis)
        i. Agnogenic myeloid metaplasia
        ii. Mastocytosis
        iii. Chediak–Higashi
    C. Metabolic infiltration
        i. Gaucher disease
        ii. Sarcoidosis
    D. Vascular
        i. Splenic vein thrombosis
        ii. Portal vein hypertension (cirrhosis)

Historically, the only available option was open splenectomy. The first laparoscopic splenectomy was described in 1991,[27] and now is the preferred approach in many centers. Similarly, robotic splenectomy is described as well for some indications. In addition to the technical advances in approach, there has also been an increased recognition of the immune function of the spleen. This has led to efforts to preserve the spleen when at all possible. We will begin by discussing specific conditions and indications for splenectomy then proceed to discuss the role of the spleen as a diagnostic or therapeutic specimen. The specific categories that will be discussed are trauma, autoimmune and erythrocyte disorders, hypersplenism, vascular abnormalities, as well as miscellaneous indications.

Table 73.5 Indications for Splenectomy in Two Large Series

	Kraus et al.	Hernandez et al.
N	1,280[25]	724[26]
Dates	1986–1995	1966–2011

Benign hematologic disease	219 (17%)	83 (11%)
Intraoperative iatrogenic injury or incidental	336 (26%)	90 (12%)
Other	172 (13%)	156 (22%)

Trauma to the Spleen

In the United States, the spleen is the most commonly injured abdominal organ due to blunt trauma, and approximately 8% of injuries are due to penetrating trauma.[28] Of the 1.5 million U.S. adults who suffer from blunt trauma, nearly 40,000 are diagnosed with a splenic injury.[29] The management

of traumatic injury to the spleen has evolved over time, mirroring general trends in trauma surgery. The first reported splenectomy reported in the United States was in fact for penetrating trauma. In 1816, a man was attacking a woman when she stabbed him in the left flank, resulting in splenic protrusion from the wound. The protruding spleen was successfully ligated and the patient reportedly recovered.[30] Since that time, splenectomy for trauma was the norm for more than 100 years. In 1962, a Brazilian surgeon, Dr. Campos Christo, reported a case of partial splenectomy with splenic salvage in cases of trauma.[31] As trauma systems evolved to become more sophisticated, and with the advances achieved in cross-sectional imaging techniques, there was a gradual shift from mandatory splenectomy for every patient with an injured spleen toward an emphasis on splenic preservation when possible.[28]

Splenic injury should be high on the list of suspected injuries for patients who sustain blunt trauma, particularly in those with left upper quadrant tenderness or peritonitis. Vital sign abnormalities, particularly hypotension, can be present and should heighten suspicion of an injury but are not required for the diagnosis of a splenic injury. The standard advanced trauma life support assessment of airway, breathing, and circulation should be applied to all patients at risk for a splenic injury. The diagnostic evaluation is predicated on the patient's underlying hemodynamic state. For hemodynamically normal patients, diagnostic evaluation should include a complete blood count, chest x-ray to evaluate for rib fractures, and CT scan which can diagnose splenic injury as well as other potential sources of intra-abdominal injury. CT scan will also allow for assessment of the severity of the splenic injury. The grading system for splenic trauma is summarized in **Table 73.6**.

According to guidelines from the Eastern Association for the Surgery of Trauma (EAST), patients who present after blunt trauma with hemodynamic instability or diffuse peritonitis should be brought the OR urgently for exploratory laparotomy.[32] The operative approach consists of a generous midline incision followed by abdominal packing to contain ongoing hemorrhage. Rapid mobilization of the lateral attachments of the spleen, typically accomplished using blunt dissection, should be performed to bring the spleen into the operative field. The hilar vessels can then be controlled

and ligated to stop hemorrhage. This will be discussed in more detail in the section describing operative approaches to the spleen.

Table 73.6 Grading of Splenic Injuries

Grade	Laceration	Hematoma
I	<1-cm depth	Subcapsular <10% surface area
II	1–3 cm not involving a trabecular vessel	Subcapsular 10–50% surface area or intraparenchymal <5 cm
III	>3-cm depth or any depth involving a trabecular vessel	Subcapsular, >50% surface area or ruptured subcapsular or intraparenchymal laceration ≥5 cm
IV	Segmental or hilar vessel involvement	
V	Shattered spleen or hilar vessel disruption	

The majority of patients with splenic injury (85% to 90%) are managed nonoperatively.[29] Patients with diagnosed splenic injuries who are managed nonoperatively must be closely monitored (such as in an intensive care unit) while adhering to institutional protocols to minimize morbidity. Importantly, nonoperative management should only be conducted in a setting where an operating room is rapidly available should the patient decompensate. Serial abdominal examinations in combination with serial complete blood counts will help to determine need for additional intervention such as laparotomy. A change in patient status (e.g., drop in hemoglobin, development of

hypotension, increased pain) should prompt immediate reevaluation to determine the need for additional diagnostic tests or intervention. Depending on the stability of the patient, this may warrant immediate transfer to the operating room.[29]

An important adjunct to nonoperative management of splenic injury is the availability of splenic artery embolization. Guidelines recommend consideration of angiography in patients with grade III or worse injury, those who have a contrast blush on their initial CT scan, patients with a moderate amount of hemoperitoneum, or in patients who demonstrate evidence of ongoing hemorrhage.[32] This technique can be especially useful for high-grade injuries (Grade IV/V), which have a high rate of failure with observation alone.[33] In a 2011 meta-analysis evaluating outcomes for more than 10,000 patients with blunt splenic injury, 68% were managed nonoperatively. Among patients who underwent observational therapy without splenic artery embolization, there was an overall failure rate of 8.3%, but varied based on the degree of injury with an 83.1% failure rate for grade V injury. For patients who underwent splenic artery embolization, there was an overall failure rate of 15.7% but no variation was seen in injury severity. The conclusion was that splenic artery embolization more frequently allowed for splenic preservation for high-grade injuries.[33] Splenic artery embolization is not standard of care and its use varies among centers. Among level I trauma centers, utilization rates vary from 1% to 19%. In a study of four level I trauma centers, patients treated at centers with higher utilization were significantly more likely to successfully undergo nonoperative management.[34] However, other studies have shown no difference in rates of splenic salvage, leading the EAST to describe splenic artery embolization and other interventional techniques as "important adjuncts to nonoperative management of splenic injuries" rather than endorsing it as a guideline.[32]

The feared complication of nonoperative management of splenic injuries is delayed splenic rupture that occurs in the outpatient setting. Several large observational studies demonstrate that the majority of patients who fail nonoperative management do so within the first 3 to 5 days after injury. In one study where patients were followed up to 6 months after their injury, the rate of rupture in the outpatient setting was 1.4%.[29] Patients who are discharged from the hospital after nonoperative management of splenic injuries should be counseled about the risk of delayed rupture.

Autoimmune and Erythrocyte Disorders

Autoimmune and erythrocyte disorders are two categories of disease that often lead to consideration for splenectomy. In cases of autoimmune disease, antibodies lead to destruction of circulating cells. One common example of this is immune thrombocytopenic purpura (ITP). In intrinsic erythrocyte disorders, cellular defects lead to a shortened half-life in the peripheral circulation due to premature elimination in the spleen. An example of this would be sickle cell disease. In this section, we will review some of the commonly encountered autoimmune and erythrocyte disorders in which splenectomy may be considered as part of the treatment algorithm. A summary of the diagnoses leading to splenectomy can be found in **Table 73.7**.

Immune Thrombocytopenic Purpura

ITP is typically a diagnosis of exclusion, and other potential etiologies of thrombocytopenia must first be ruled out. ITP may be idiopathic but can be secondary to other conditions such as systemic lupus erythematosus, HIV/AIDS, and lymphoma. There are two peaks in disease diagnosis, one between 20 and 30 years of age when females are slightly more affected than males, and one after 60 years of age where there is no difference in sex distribution.[35] The pathogenesis of ITP remains incompletely understood as there are likely several mechanisms leading to the clinical presentation. Traditional models of the disease suggest that antiplatelet antibodies lead to premature platelet destruction in the spleen, liver, or both. However, up to 50% of patients with ITP do not demonstrate antiplatelet antibodies. Other suggested mechanisms include T-cell–mediated abnormalities as well as involvement of CD8 cells.[35]

Table 73.7 Final Pathologic Diagnoses in 122 Spleens Removed for Diagnostic Purposes

Total Number of Diagnostic Splenectomies		122
Indication	**Diagnosis**	
Splenic mass		52

Categorize lymphoma		29
	Malignant (successful)	28
	Benign	1

Adapted from Kraus MD, Fleming MD, Vonderheide RH. The spleen as a diagnostic specimen: a review of 10 years' experience at two tertiary care institutions. *Cancer* 2001;91(11):2001–2009.

The hallmark of ITP is isolated thrombocytopenia (platelet count <100,000/mm^3). Patients rarely (<5%) present with life-threatening hemorrhage, but more commonly present with fatigue, easy bruising, and mucocutaneous bleeding.[35] Patients should be evaluated with complete history and physical examination to evaluate for other potential causes of

thrombocytopenia. Peripheral blood smear typically shows reduced numbers of otherwise normal-appearing platelets. Measurement of antiplatelet antibodies and bone marrow biopsy are not part of the routine diagnostic evaluation.

Treatment of ITP is predicated on the patient's clinical presentation. For patients who present with evidence of acute hemorrhage, the primary goal is to stop ongoing bleeding. The standard approach includes platelet transfusion in conjunction with corticosteroids and intravenous immune globulin (IVIG). Because of the ongoing platelet destruction, platelet transfusions are typically only helpful for a few hours at a time and thus ongoing transfusion may be necessary while the corticosteroids and IVIG start to work. In certain life-threatening situations, transexamic acid can help as well.[35] Many patients with ITP do not require any treatment. Severe bleeding typically does not occur until the platelet count is <30,000/mm^3. As such treatment is not initiated until platelet counts fall below this level. The mainstay of treatment is corticosteroids, but unfortunately 70% to 90% of patients will experience relapse when corticosteroids are stopped.[35] Other potential therapies include IVIG and Rh_0(D)-immune globulin but like corticosteroid treatment, it is uncommon to achieve sustained remission.

Several newer treatments have recently become available. These include thrombopoietin-receptor agonists (e.g., eltrombopag, romiplostim) and immunomodulators (e.g., rituximab). Thrombopoietin-receptor agonists are approved for patients with ITP who are refractory to other medical treatments. Randomized trials demonstrate that 70% to 95% of patients will see increased platelet counts and that this will be sustained in 40% to 60%. Similarly, immunomodulators have demonstrated success with up to 40% demonstrating complete response and up to 60% demonstrated some treatment effects. However, rituximab is not currently approved for treatment of ITP by the Food and Drug Administration (FDA).

For patients who do not respond to corticosteroids or other medical treatments, or who cannot tolerate therapy, splenectomy is the next option. While splenectomy is curative for most patients, up to 30% will experience relapse.[35,36] Given the success in development of treatments for ITP as well as the risks of postsplenectomy sepsis, splenectomy as a treatment for ITP has declined in frequency.[36]

Thrombotic Thrombocytopenic Purpura

Thrombotic thrombocytopenia purpura (TTP) is a syndrome characterized by microangiopathic hemolytic anemia and severe thrombocytopenia. This results in visceral ischemic symptoms, particularly in the central nervous system. Until recently, its etiology was poorly understood. However, the discovery of the cause of this disease, severe deficiency of a disintegrin and metalloprotease with thrombospondin type 1 repeats, member 13 (ADAMTS13), a protein that processes von Willebrand Factor (vWF) in the body, led to advancements in the understanding of this disease. vWF is known to be essential for platelet adhesion and aggregation. Patients who died from TTP were found to have large amounts of vWF within the microthrombi due to the inability of ADAMTS13 to effectively cleave vWF. Thrombocytopenia does not typically occur until levels of ADAMTS13 are <10%.[37,38] Deficiency of ADAMTS13 can be either hereditary or, more commonly, acquired through the development of autoantibodies.

Initial presentation of TTP may be nonspecific with symptoms such as fatigue and headache. Patients may then go on to develop petechiae as well as neurologic symptoms such as confusion and seizures. Rare symptoms of the disease may include myocardial infarction or stroke. Complete blood count will demonstrate thrombocytopenia and hemolytic anemia. Fragmented blood cells will be seen on blood smear.

Treatment of the condition depends on whether the deficiency is hereditary (genetic) or acquired. For hereditary deficiency, the treatment consists of serial infusions of fresh frozen plasma (as no autoantibodies are present). For patients with acquired deficiency and the presence of autoantibodies, the initial treatment consists of plasma exchange. Other immunosuppressive agents such as corticosteroids, rituximab, vincristine, and others have been employed to achieve resmission.[39] While used previously, anti-platelet agents such as aspirin and dipyridamole are less effective in preventing platelet aggregation in TPP. Ongoing work continues in the investigation of additional drugs to treat patients with TTP.

The role of splenectomy for treatment of TTP is not entirely clear as the evidence for its effectiveness varies. While some reports demonstrate relapse-free survival in up to 70% of patients who undergo splenectomy, other reports state that less than 10% achieve remission. The role of the

spleen is not completely known, but it is thought to be a significant site of ADAMTS13 autoantibody production, as well as ADAMTS13 removal in the body.[40]

Autoimmune Hemolytic Anemia

Autoimmune hemolytic anemia exists in two forms: warm autoimmune hemolytic anemia and cold autoimmune hemolytic anemia. It is important to distinguish between the two because the etiology and treatment differ.

In warm autoimmune hemolytic anemia, the primary abnormality is IgG antibodies directed against erythrocytes. Binding is maximal at 37°C which is why it is referred to as "warm." The erythrocytes are then removed in the spleen as the splenic macrophages carry receptors for the Fcγ portion of the heavy chain of IgG. Median age of onset is in the 50s and there is a slight female predominance for disease. About half of cases are primary and idiopathic, while the other half of cases are due to medications or other disorders. Typical presenting signs are often related to the underlying anemia (e.g., fatigue, dyspnea) but can include more severe findings such as venous thromboembolism in up to 15%. Diagnosis includes laboratory findings of anemia, reticulocytosis, hemolysis, and a positive Coombs test. Initial treatment may include transfusion of ABO- Rh-blood for patients with severe anemia (Hbg <6 g/dL). Long-term management includes corticosteroids, rituximab, or both. While splenectomy was historically performed as part of the treatment, guidelines now recommend medical management over splenectomy given the long-term risks associated with splenectomy and the variable effectiveness. Only half of patients will demonstrate remission following splenectomy, and of those 25% will relapse with 1 year.[41]

Cold autoimmune hemolytic anemia is characterized by IgM antibodies that bind to RBCs, ultimately leading to complement activation and RBC aggregation, and accounts for about 15% of autoimmune hemolytic anemia. Because of this mechanism, the spleen features less prominently in this form of the disease and therefore splenectomy is not effective. Diagnosis of cold autoimmune hemolytic disease is based on a combination of clinical presentation and laboratory testing. Laboratory evaluation will indicate evidence of chronic hemolysis, positive direct antiglobulin test, and an elevated cold agglutitin titer. Treatment consists of avoidance of cold

temperature, blood transfusion, and plasmapheresis in acute situations. Corticosteroids are generally not effective. Rituximab has been used with some success. As mentioned previously, splenectomy is not effective for this form of disease.[41]

Autoimmune Neutropenia (Felty Syndrome)

Felty syndrome is the clinical picture of neutropenia and splenomegaly in the setting of rheumatoid arthritis. Fewer than 1% of patients with rheumatoid arthritis go on to develop this syndrome. Abnormalities detected in patients with Felty syndrome include impaired production of neutrophils, increased sequestration and destruction of neutrophils, and excessive neutrophil margination. Patients with Felty syndrome suffer from a high rate of infections due to neutropenia, and up to 36% 5-year mortality rate. Treatment of Felty syndrome starts with antirheumatic drugs such as methotrexate. If this treatment fails, other options include colony-stimulating factor and splenectomy. Splenectomy can improve the degree of neutropenia and decrease the incidence of recurrent infection.[42]

Hereditary Spherocytosis

Hereditary spherocytosis is an autosomal dominant disease that is the most common of the congenital hemolytic anemias affecting 1 in 2,000 individuals. The primary defect is a defect in spectrin and ankyrin that lead to loss of the membrane surface area and decreased erythrocyte deformability. This then leads to increased destruction in the spleen because of the fact that the affected erythrocytes lack of deformability that impacts the passage of erythrocytes through channels of the spleen. Clinical manifestations include anemia, jaundice, gallstones, reticulocytosis, spherocytes on peripheral blood smear, and splenomegaly. Diagnosis is based on thorough history and physical examination in combination with laboratory findings. Because the spleen plays a dominant role in sequestration and destruction of erythrocytes, splenectomy will cure most patients. Patients should be assessed at the time of scheduling a splenectomy for the presence of gallstones and a laparoscopic cholecystectomy should be performed if stones are identified.[43]

Hereditary Elliptocytosis

Hereditary elliptocytosis is less common then hereditary spherocytosis but is similarly caused by defects in membrane proteins that lead to elliptical shaped erythrocytes resulting in reduced deformability. Most patients are asymptomatic and are only diagnosed when peripheral blood smear is performed for other reasons. However, patients may exhibit symptoms related to the disorder such as anemia, jaundice, and splenomegaly. Splenectomy can be considered, but should only be done for patients older than 5 years of age with severe symptoms.[44]

Hereditary Nonspherocytic Hemolytic Anemia

This is a heterogenous group of hemolytic anemias caused by inherited defects in various enzymes involved in glycolysis. The most common variants are glucose 6-phosphate dehydrogenase (G6PD) deficiency and pyruvate kinase deficiency. In G6PD deficiency, patients can be completely asymptomatic. Symptoms of hemolysis are typically brought on by infection, exposure to fava beans, or to oxidative drugs. Treatment is generally supportive and splenectomy is not recommended. Pyruvate kinase deficiency similarly presents with signs and symptoms of hemolysis, as well as complications such as hyperbilirubinemia and gallstones. 80% to 85% of patients have splenomegaly. Treatment consists of supportive therapy, and splenectomy may reduce some symptoms and decrease transfusion requirements.[45,46]

Thalassemia

Thalassemia is an inherited disorder characterized by various structural defects in the globin chains. Previously, thalassemias were divided into subtypes based on the underlying molecular defect, but the current classification system divides them into transfusion-dependent thalassemia (TDT) and non–transfusion-dependent thalassemia (NTDT) based on their need for ongoing blood transfusion to survive. The categories are not mutually exclusive and are based on clinical presentation. In addition, patients with NTDT may intermittently require transfusion, whereas patients with TDT generally require ongoing transfusion for survival.[47] The molecular defects in thalassemia lead to ineffective erythropoiesis and peripheral hemolysis. Clinically, patients may present with iron overload and

anemia. Ineffective erythropoiesis is also associated with bone disease, organomegaly due to extramedullary hematopoiesis, gallstones due to peripheral hemolysis, and hypercoagulability. All of these may result in end organ damage.[48]

Diagnosis of thalassemia is made by analysis of the peripheral blood smear. Erythrocytes will demonstrate variation in cell size and shape, microcytosis, and hypochromia. The specific findings will vary by molecular defect. Hemoglobin analysis is also important but must be performed with the clinical setting in mind. Definitive diagnosis is made by DNA analysis.[47]

Conventional treatment of the thalassemias includes transfusion, iron chelation, and splenectomy. Transfusion functions to not only treat the anemia but also suppress ineffective erythropoiesis. Iron chelation addresses the iron overload that occurs either due to increased intestinal absorption or the iron load from regular transfusion. Splenectomy is rarely used for patients with TDT due to the increased safety and availability of blood. For patients with NTDT, splenectomy may improve anemia and reduce their risk of infection. However, in addition to the standard risks brought on by splenectomy, for patients with NTDT it also confers a hypercoagulable state. Splenectomy is currently only recommended for patients who cannot receive transfusions or undergo iron chelation therapy, or who suffer from hypersplenism or symptomatic splenomegaly.[48]

Sickle Cell Disease

Sickle cell disease is an inherited disease characterized by a missense mutation in the sickle hemoglobin gene. It is increasing in frequency and more than 300,000 infants are born with this disease every year. It is more common in areas of the world with endemic malaria as heterozygosity for the sickle cell mutation is protective against malaria. The variation in the shape of the erythrocyte leads to hemolytic anemia and blockage of small blood vessels leading to vaso-occlusion. This can then lead to tissue ischemia, severe pain, and in some cases organ failure.[49]

While most patients with sickle cell disease are born with normal spleens, over time the spleen can exhibit both functional hyposplenism and splenomegaly. This is because the environment of the spleen promotes sickling which then increases adhesion of the sickled erythrocytes. Sickled

cells are also cleared more regularly by the spleen. While the precise mechanism is not known, splenic injury occurs early on for most patients. Because most patients develop hyposplenism over time, splenectomy is not often required. Most of the vaso-occlusive episodes do not result in sickle cell crisis. However, acute splenic sequestration can occur when RBCs become trapped in the spleen resulting in abdominal pain, distention, and signs of anemia and shock due to an acute drop in the hemoglobin level. Treatment consists primarily of transfusion as well as treatment of any inciting cause such as infection. For patients with recurrent sequestration, splenectomy can be considered.[50]

Treatment of sickle cell disease consists of prophylactic penicillin for children, hydroxyurea, and regular transfusion. Stem-cell transplant may be curative but is currently limited. As described above, most patients do not ever require splenectomy but it can be considered for those who develop hypersplenism. Laparoscopic splenectomy is preferred, and partial splenectomy may be considered for young children with the purpose of preserving immune function.[49,50]

Wiskott–Aldrich Syndrome

Wiskott–Aldrich Syndrome (WAS) is an X-linked immunodeficiency disorder characterized by recurrent infections, eczema, and bleeding diathesis. While males are most frequently affected, females can be carriers and in rare cases may exhibit symptoms. The syndrome has associated abnormalities in T and B cells and may result in hemorrhagic insults, autoimmune disease, as well as a propensity for lymphoma and other malignancies. The associated thrombocytopenia is incompletely understood, but may due to increased platelet destruction by the spleen as well as megakaryocyte dysfunction.[51]

All patients with WAS exhibit thrombocytopenia that typically manifests in the first year of life with easy bruising, spontaneous or prolonged bleeding (particularly after circumcision), as well as petechiae. The other features such as eczema and recurrent infections do not occur in all patients. WAS should be suspected in patients with thrombocytopenia but genetic testing is the gold standard for diagnosis.[52] The definitive treatment for WAS is hematopoietic stem cell transplantation or stem cell gene therapy, ideally

within the first 2 years of life. For adults who have not been treated, hematopoietic stem cell transplantation may also be an option. Additionally, supportive therapy consists of infection prophylaxis, management of thrombocytopenia, and managing other symptoms related to associated autoimmune or other diseases. Because of the potential role of the spleen in thrombocytopenia, splenectomy has been recommended for patients with severe thrombocytopenia such that avoidance of activity (for prevention of bleeding) interferes with their quality of life, particularly for patients with the milder form of WAS termed X-linked thrombocytopenia as this group has lower risk of infection.[52]

Hypersplenism

7 Hypersplenism, or splenomegaly, is enlargement of the spleen. While there are many causes for hypersplenism to occur, these causes can be broadly categorized into neoplastic, hematopoietic, and metabolic or storage disorders. Typical symptoms include abdominal discomfort and tenderness, early satiety, bloating, and other symptoms related to the mass effect of the spleen on adjacent organs. Cytopenias are frequently present due to sequestration.

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia (CLL) is the most common type of leukemia in developed countries. Males are more commonly affected, and the median age at diagnosis is 72 years. The disease is caused by a clonal proliferation and accumulation of mature B cells in the spleen, blood, lymph nodes, and bone marrow. Patients are commonly diagnosed incidentally after complete blood count demonstrates lymphocytosis. Symptoms include anemia, thrombocytopenia, neutropenia, lymphadenopathy, and B symptoms. Diagnosis is confirmed with immunophenotyping. Treatment choices are dictated by stage as well as symptoms. Findings that indicate the need for treatment include progressive anemia or thrombocytopenia, autoimmune anemia or thrombocytopenia that does not respond to steroids, enlarging of symptomatic lymphadenopathy, and enlarging or symptomatic splenomegaly. The standard chemotherapy regimen is fludarabine plus cyclophosphamide

(FCR) which will lead to remission for many patients. Alternative regimens are available for patients who do not tolerate FCR.

The spleen is the third-most affected organ in CLL. Both the white and red pulp are diffusely infiltrated. Splenomegaly is common due to the infiltrative nature of the disease (as demonstrated in Figure 73.7) but splenectomy is rarely necessary. It may be indicated for patients with advanced CLL and refractory pancytopenia. Up to 90% of patients who undergo splenectomy demonstrate improvement in thrombocytopenia as well as hemoglobin. For patients who are not surgical candidates, splenic irradiation can be considered. In a review of 27 studies, splenic irradiation was found to be effective for splenic reduction (72% of patients), relief of pain (59% of patients) and improved cytopenia (78% of patients).[53–55]

Chronic Myelogenous Leukemia

Chronic myelogenous leukemia (CML) accounts for approximately 15% of adult leukemias and is characterized by the Philadelphia chromosome (Ph). This chromosome results from a translocation that gives rise to BCR-ABL1, a protein with deregulated tyrosine kinase activity. While CML can occur in three phases (chronic, accelerated, and blast), most patients are diagnosed in the chronic phase. Diagnosis is made by history and physical (including palpation of the spleen), complete blood count, chemistry, and liver function tests. Spleen size is used as part of the staging as larger spleens confer higher likelihood of dying from CML. A bone marrow biopsy to confirm the presence of the BCR-ABL1 gene is also recommended to confirm the diagnosis. Clinical features include leukocytosis, thrombocytosis, and splenomegaly in more than half of patients. The standard treatment for CML is with tyrosine kinase inhibitors (TKIs). Second-generation TKIs (e.g., dasatinib, nilotinib, bosutinib) have demonstrated superior outcomes compared to first-generation TKIs such as imatinib, but drug selection should be individualized based on the presenting patient. While not curative, splenectomy can be performed to relieve symptoms associated with splenomegaly and thrombocytopenia, and to reduce transfusion requirements.[56,57]

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma is a heterogeneous disease arising from primarily mature B cells, and in some cases T lymphocytes or natural killer cells. The disease arises from DNA mutation and can be associated with specific mutations, as in the case of the MYC oncogene in Burkitt lymphoma, or due to underlying infections such as Epstein–Barr.[58] Common presenting signs include lymphadenopathy and splenomegaly, and a third of patients will have extranodal disease. Systemic symptoms including B symptoms are present in about half of patients while many patients are asymptomatic. Diagnosis is made with routine blood tests, which can be normal or may exhibit anemia, thrombocytopenia, or neutropenia due to bone marrow involvement. A biopsy of the affected lymph node or organ is required for diagnosis. Staging is based on the number an extent of involved lymph nodes, as well as the presence of B symptoms or extranodal disease. CT scan is the primary method used to assess extent of disease which is important for staging.[59] For most patients with indolent or low-grade lymphoma, chemotherapy is not curative. These patients are followed clinically and many never require treatment.[58] For patients with high-grade lymphoma, immunochemotherapy with R-CHOP (rituximab, cyclophosphamide, doxorubicin, vincristine, and prednisolone) is standard and results in cure for 60% to 70%. For patients who have symptoms related to splenomegaly as described above, or with progressive cytopenia, splenectomy can be considered. While splenectomy was previously used as a diagnostic or staging tool, this is less commonly the case due to advances in imaging.[58,59]

Hairy Cell Leukemia

Hairy cell leukemia is a rare B-cell leukemia so named because of the characteristic appearance of "hairy cells" on peripheral blood smear in 90% of patients. While many patients with hairy cell leukemia are asymptomatic, most patients present with splenomegaly or symptoms related to cytopenia. Splenectomy was previously the mainstay of treatment, leading to complete response in 40% to 62% of patients and 5-year survival of 61% to 68%. Splenectomy continues to play a role for patients with symptomatic splenomegaly, complications related to cytopenias, infections, or pregnancy. However, other therapies have largely replaced splenectomy. Some patients who present with indolent disease do not require treatment at all. For

patients with symptomatic splenomegaly or severe cytopenia, standard treatment includes cladribine and pentostatin.[60]

Myelodysplastic Syndrome

Myelodysplastic syndrome (MDS) is a clonal stem cell disorder that primarily occurs in older adults with a median age at diagnosis of 65 to 70 years. Multiple steps involving gene mutations and/or cytogenetic changes resulting in ineffective hematopoiesis. As a result, patients develop cytopenias with a third of patients going on to develop acute myeloid leukemia. The exact cause of MDS is determined in only 15% of cases with linkage to heritable, environmental, or occupational factors for most others. Patients present with nonspecific symptoms related to anemia or thrombocytopenia, as well as increased risk of infection due to neutropenia. Peripheral blood smear will demonstrate small numbers of circulating blasts. Bone marrow analysis is required for diagnosis. Cytogenetic analysis may be useful for cases in which the diagnosis is not clear but also serves to provide valuable prognostic information. Treatment is based on the international prognostic scoring system. For lower-risk patients, the goal of treatment is to reduce consequences of cytopenia, reduce need for transfusion, and improve quality of life. For these patients, treatment includes erythropoiesis-stimulating agents as well as hypomethylating medications in some countries. Some patients also require transfusions to treat cytopenia. Treatment for higher-risk patients aims to extend survival while preventing progression to acute myeloid leukemia. Treatment options include allogeneic stem-cell transplantation, intensive chemotherapy, and hypomethylating agents.[61] As with the other neoplastic processes, patients with MDS can develop significant and symptomatic splenomegaly. Splenectomy can be considered but carries a high risk of morbidity and mortality without demonstrated improvements in survival.[62]

Metastatic Disease to the Spleen

Metastasis to the spleen is thought to occur in less than 10% of patients with cancer, but due to improvements in imaging and follow-up the incidence is increasing. Metastases can be either solitary or as part of a multivisceral presentation. For solitary lesions, the most common primary cancers are

colorectal and ovarian. For multivisceral lesions, the most common primary cancers are breast, colorectal, ovarian, lung, and melanoma. Imagine-guided biopsy of the spleen is preferred for diagnostic purposes, but in some cases splenectomy can be performed to relieve symptoms associated with splenomegaly. Particularly for solitary lesions occurring late after the primary is diagnosed, there is evidence that splenectomy may lead to long-term remission.[63]

Gaucher Disease

Gaucher disease is the most common of the lysosomal storage disease and has three described variants. It is inherited in an autosomal recessive fashion and leads to insufficient activity of the lysosomal enzyme acid β-glucosidase which leads to accumulation of its main substrate, glucosylceramide. Glucosylceramide than accumulates in macrophages in affected organs which can cause bone involvement, hepatomegaly, splenomegaly, as well as anemia and thrombocytopenia. While the underlying abnormality is understood, the mechanism by which this causes disease in specific organs is poorly understood. There are three subtypes. Type I is most common and is usually diagnosed in adults particularly from specific populations such as the Ashkenazi Jewish population; types II and III are diagnosed in infancy or childhood and are more severe. The gold standard of diagnosis is the detection of insufficient enzyme activity. The mainstay of therapy is enzyme therapy, with the goal being to reduce the signs and symptoms caused by the disease. Prior to this, partial splenectomy was a common treatment recommendation but with the development of enzyme therapy, patients can experience reduction in spleen volume of 50% to 60% after 2 to 3 years of treatment.[64]

INCIDENTAL SPLENECTOMY

Incidental splenectomy, or removal of the spleen during the course of another operation, it not uncommon. While these operations are explained in detail in other portions of this textbook, here we make some comments about the reasons why this may occur.

Incidental splenectomy often occurs during distal pancreatectomy due to the intimate association of the splenic vein to the undersurface of the pancreas, as well as the many venous branches to the pancreatic parenchyma. With an increased understanding of the risks associated with splenectomy, there has been renewed interest in distal pancreatectomy without splenectomy. This can be achieved either through the preservation or resection of the splenic vessels. In cases where the splenic vessels are divided, the short gastric vessels are carefully preserved to maintain blood flow to the spleen. It should be noted that these approaches should only be employed when anatomically and oncologically appropriate.[65,66]

Splenectomy may also be employed in conjunction with resection of proximal gastric cancers, tumors involving the left kidney or adrenal gland, and retroperitoneal masses invading the spleen. The purpose of splenectomy in these cases is often to provide adequate exposure to dissect bulky disease posterior to the spleen. It should be recognized that despite the risk that asplenia confers to patients, the spleen can be safely removed to facilitate a complete resection.

IATROGENIC SPLENECTOMY

Because of its proximity to organs in the left upper quadrant of the abdomen, the spleen can be injured during the course of other operations, sometimes requiring removal. This scenario is undesirable not only because the patient will be left asplenic, but they also have not had the opportunity for prophylactic vaccines prior to the operation. While the best method to protect against this is not to injure the spleen at all, understanding the operations that put the spleen most at risk can give a sense of when to be especially cautious.

In a 2019 retrospective study describing all splenectomies at a single hospital over a 17-year period in England, nearly half of all splenectomies were unplanned. Of the unplanned splenectomies, 36% were iatrogenic (vs. emergency for trauma or rupture). Of the 26 iatrogenic splenectomies, 11 occurred during a procedure for benign disease and 15 during a procedure for malignant disease. The most common operation leading to iatrogenic splenectomy was elective open colon resection (n = 12, 46%) followed by

emergency open colonic resection (n = 7, 27%).[67] While the spleen can be damaged due to a variety of factors in colorectal surgery, it is especially high risk in cases where the splenic flexure must be mobilized. A 2018 report from the Cleveland Clinic reported on their series of 2,336 colorectal operations that required splenic flexure mobilization. They reported a 1.1% risk of splenic injuries, most of which (64%) were managed with topical hemostatic agents. Splenorrhaphy was used in 16%, and the remaining 20% underwent splenectomy. The rate of splenic injury was much lower in laparoscopic cases (0.25% vs. 1.5%, p = 0.005), leading the authors to conclude that laparoscopic colon resection may result in fewer iatrogenic spleen injuries due to the increased visualization.[68]

Other operations that place the spleen at risk for injury include left nephrectomy, left adrenalectomy, antireflux procedures, and colonoscopy. In a 2013 study of 4,323 patients undergoing nephrectomy at the Mayo Clinic, they reported iatrogenic splenectomy in 33 patients (0.8%). Of these patients, 94% underwent a radial open left nephrectomy. Iatrogenic splenectomy was associated with longer operative time, more blood loss, higher rate of complications, and longer hospital length of stay.[69] As in this example, understanding risk factors prior to operating is important, but being prudent to avoid injury to the spleen is this most important guiding factor when considering this topic.

DIAGNOSTIC SPLENECTOMY

Diagnostic splenectomy has historically been used in cases when a patient has a splenic mass diagnosed on imaging in which definitive diagnosis was necessary, or in cases where a patient had splenomegaly on physical examination without any clear underlying disorder. In a 2001 series of more than 1,200 patients undergoing splenectomy, diagnostic splenectomy accounted for only 9.5% of the cases.[25] In the 1980s and 1990s, splenectomy was also used to reduce tumor burden in patients with leukemia or to diagnose or stage lymphoma.[70] While most patients can be diagnosed with imaging, laboratory studies, blood smears, and in some cases less-invasive biopsy methods, in some cases of lymphoma the diagnosis is still unclear. Furthermore, studies demonstrate that 37% to 57% of patients with

idiopathic splenomegaly harbor lymphoma. In a 2019 study of 113 patients undergoing diagnostic splenectomy at the Mayo Clinic Arizona, 35 (40%) had an unknown diagnosis prior to surgery. Of these patients, 16 (46%) received a definitive diagnosis following the operation. However, more than half of these patients (56%) underwent a change in their medical management as a result of the findings and 54% reported that their symptoms resolution. Given these findings the authors suggest that for patients who present with equivocal findings, diagnostic splenectomy can be a useful adjunct in their evaluation.[71]

Recognizing the significant morbidity that can accompany splenectomy, less-invasive options for diagnosis such as percutaneous image guide biopsy have been developed. As with indications for diagnostic splenectomy, splenic biopsy is indicated in cases of an indeterminant splenic mass where diagnosis cannot be determined by clinical or other diagnostic methods. Splenic biopsy is successful in more than 90% of cases and is significantly less invasive compared to splenectomy.[72]

VASCULAR DISORDERS OF THE SPLEEN

Vascular problems with the spleen that can lead to splenectomy include both venous and arterial problems. The most common situation would be splenic vein thrombosis and splenectomy in this setting is curative for the patient. Splenic artery aneurysms are one of the more common visceral aneurysms and can be an indication for splenectomy.

Splenic Vein Thrombosis

Splenic vein thrombosis typically occurs secondary to pancreatic disorders due to the close relationship between the splenic vein and the pancreas. It may present in up to 12% of patients with chronic pancreatitis and 22% of patients with acute pancreatitis. It can also occur in cases of pancreas cancer due to invasion of the vein. Splenic vein thrombosis leads to left-sided or “sinistral” portal hypertension. This localized area of venous hypertension can lead to the development of gastric varices (53% to 77% of patients) due to increased pressure in the gastroepiploic system. Clinically, patients with

sinistral portal hypertension may present with upper gastrointestinal bleeding due to rupture of gastric varices in 4% to 12%. In the setting of acute hemorrhage, upper endoscopy may demonstrate gastric varices. The presence of gastric varices in the absence of esophageal varices is also suggestive. Various imaging techniques can then be used to confirm the thrombus within the splenic vein. Because the majority of patients do not experience acute bleeding, most patients are diagnosed via CT, MRI, or ultrasound.

For patients without acute bleeding, anticoagulation should be considered as initial therapy. Splenectomy is typically employed for patients with uncontrollable episodes of bleeding.[73] By removing the spleen, the collateral flow is reduced, releasing the hypertension causing development of gastric varices. Splenectomy was previously recommended for all patients with splenic vein thrombosis to prevent future bleeding episodes, but due to advances in imaging and the realization that a minority of patients present with acute hemorrhage, observation is safe for most patients.[74]

Splenic Artery Aneurysm

Of all the visceral arterial aneurysms, splenic artery aneurysm is the most common and accounts for approximately 60% of such aneurysms. Most splenic artery aneurysms are asymptomatic and are diagnosed incidentally on imaging for other reasons. Women are affected four times more often than men, and there is some thought that this is potentially related to the increased frequency of abdominal ultrasound for women during pregnancy. Women also more frequently have true aneurysms, while men more frequently have pseudoaneurysms, which are more prone to rupture. Typical symptoms include abdominal pain, and aneurysmal rupture should be suspected when patients present with abdominal pain in the setting of anemia. Treatment of splenic artery aneurysms is determined by the size of the aneurysm. Risk of rupture increases substantially when the aneurysm size exceeds 2 cm. Patients who are asymptomatic and have aneurysms smaller than 2 cm can be followed with serial imaging. The special case is in women of child-bearing age who are planning pregnancy, or for women who are already pregnant. There is a high risk of rupture during pregnancy and therefore it is recommended that they be treated even if smaller than 2 cm. Reasons for the increased risk during pregnancy are thought to be related to increased levels

of circulating hormones that lead to increased blood flow and pressure in the splenic artery. Pseudoaneurysms should also be repaired, regardless of size.[75]

For patients that do require treatment, there are a variety of approaches. Aneurysms can be surgically resected or ligated, and endovascular approaches that can be used as well. Splenectomy can be used as an adjunct to aneurysm resection. Both surgical and endovascular options are safe and effective, but endovascular repairs may result in a faster recovery and shorter length of stay.[76]

MISCELLANEOUS INDICATIONS FOR SPLENECTOMY

Less commonly encountered indications for splenectomy include cysts, abscesses, as well as the "wandering spleen." The indications are discussed here.

Cysts of the Spleen

Splenic cysts are typically classified as either parasitic or nonparasitic, as first described by Fowler in 1913. Parasitic cysts are almost always hydatid cysts caused by Echinococcus. Fewer than 5% of all patients with echinococcal infection will develop hydatid cyst of the spleen. Many patients are asymptomatic, but mass effect from an enlarging cyst can cause pain or discomfort due to mechanical displacement of other abdominal organs. Diagnosis is made through a thorough history and physical examination in conjunction with serology and imaging. Ultrasound and CT scan may demonstrate peripheral calcification, daughter cysts within the larger cavity, or additional cysts in the liver. Splenectomy is the most common treatment, and care should be taken intraoperatively to avoid spillage from the cyst which can cause anaphylactic shock. The cyst can be carefully aspirated if it is sufficiently large to prevent adequate mobilization of the spleen. Partial splenectomy may also be considered based on the location of the cyst. Medical therapy such as albendazole is used as an adjunct.[77]

Nonparasitic cysts are classified into several different categories, often based on whether the cyst is primary or secondary. Primary cysts (20% to 30% of all nonparasitic cysts) include congenital cysts and neoplastic cyst. Neoplastic cysts include hemangiomas, lymphangiomas, and dermoid cysts. Secondary cysts (70% to 80% of all nonparasitic cysts) are either traumatic or necrotic.[78] Within the designation of nonparasitic cysts, there are many debates regarding the overall classification without a single accepted classification scheme. For asymptomatic cysts smaller than 5 cm in diameter with typical imaging findings, nonoperative treatment is recommended. Typical findings on imaging include the absence of solid components, regular appearance of the cyst wall, and lack of any contour defect. For larger or more symptomatic cysts there are several proposed approaches. Total splenectomy has historically been the most common treatment but has given way to other treatments. Aspiration has been described but is not generally recommended. Marsupialization can lead to recurrence of the cyst and is therefore not recommended. Total or subtotal cyst resection can prevent the need for partial or total splenectomy and laparoscopic methods are currently described both for cyst removal and partial splenectomy with good success.[79]

Abscess of the Spleen

While uncommonly encountered, splenic abscess carries significant risk of mortality if not adequately treated. Causes of splenic abscess include hematogenous spread of bacteria either due to infectious endocarditis or intravenous drug use; ischemia secondary to trauma; secondary infection from adjacent organs (e.g., pancreas, bowel); and in certain immunocompromised states. Commonly encountered bacteria are *Streptococcus species* and *Escherichia coli*. Typical symptoms include fever and left upper quadrant pain, as well as splenomegaly in some patients. Imaging such as ultrasound or CT scan will show findings of a rim enhancing fluid collection, and treatment consists of appropriate antibiotics followed by source control. While splenectomy was traditionally advocated for source control, percutaneous drainage of splenic abscess has demonstrated success of 67% to 100%. For patients who fail percutaneous drainage, subtotal or total splenectomy is an option.[80]

Ectopic Spleen (Wandering Spleen)

Ectopic, or "wandering," spleen is a condition in which the spleen is located in the lower abdomen or pelvis, rather than the left upper quadrant. The abnormality is due to laxity of the peritoneal attachments. This condition is more commonly encountered in children and is 10 times more common in females. About half of patients with this condition are asymptomatic. Symptoms associated with wandering spleen are typically due to acute torsion, or rupture after trauma. For patients with life-threatening hemorrhage, splenectomy is recommended. For patients who are incidentally found to have wandering spleen, laparoscopic splenopexy has been described.[81,82]

SPLENECTOMY: OPERATIVE TECHNIQUE

Splenectomy remains the mainstay of treatment for many conditions affecting the spleen as described earlier in this chapter. An important decision to make early on is which approach to plan for. For example, a patient presenting in acute trauma with splenic laceration will require an open approach, where a patient with underlying hematologic abnormality may be a good candidate for a laparoscopic or robotic approach. Secondarily, some patients may be a good candidate for a partial splenectomy. In this section we will describe the preoperative considerations, the steps of the operation, and the postoperative care for patient undergoing splenectomy.

Preoperative Evaluation

For patients who are undergoing urgent splenectomy for hemorrhagic shock related to trauma or splenic rupture, rapid evaluation and management should take care following advanced trauma life support approaches.

For all other patients, standard evaluation should include careful history and physical examination. History should include a complete medical history to determine their fitness for undergoing general anesthesia, as well as a more nuanced understanding of the indication for splenectomy. The surgeon should inquire as to prior operative history which may help determine the

approach. Imaging will help determine the size of the spleen as some approaches may not be suitable for extremely large specimens. Importantly, all patients undergoing elective splenectomy should undergo routine vaccination with vaccines to prevent against overwhelming postsplenectomy sepsis from pneumococcus pneumonia, *H. influenzae* type B, meningococcus, and seasonal flu. Ideally these would be administered at least 2 weeks prior to a scheduled splenectomy, but there is debate around the optimal time frame.[24] This will be discussed in detail in the section entitled "Sequelae of Splenectomy and Hyposplenism."

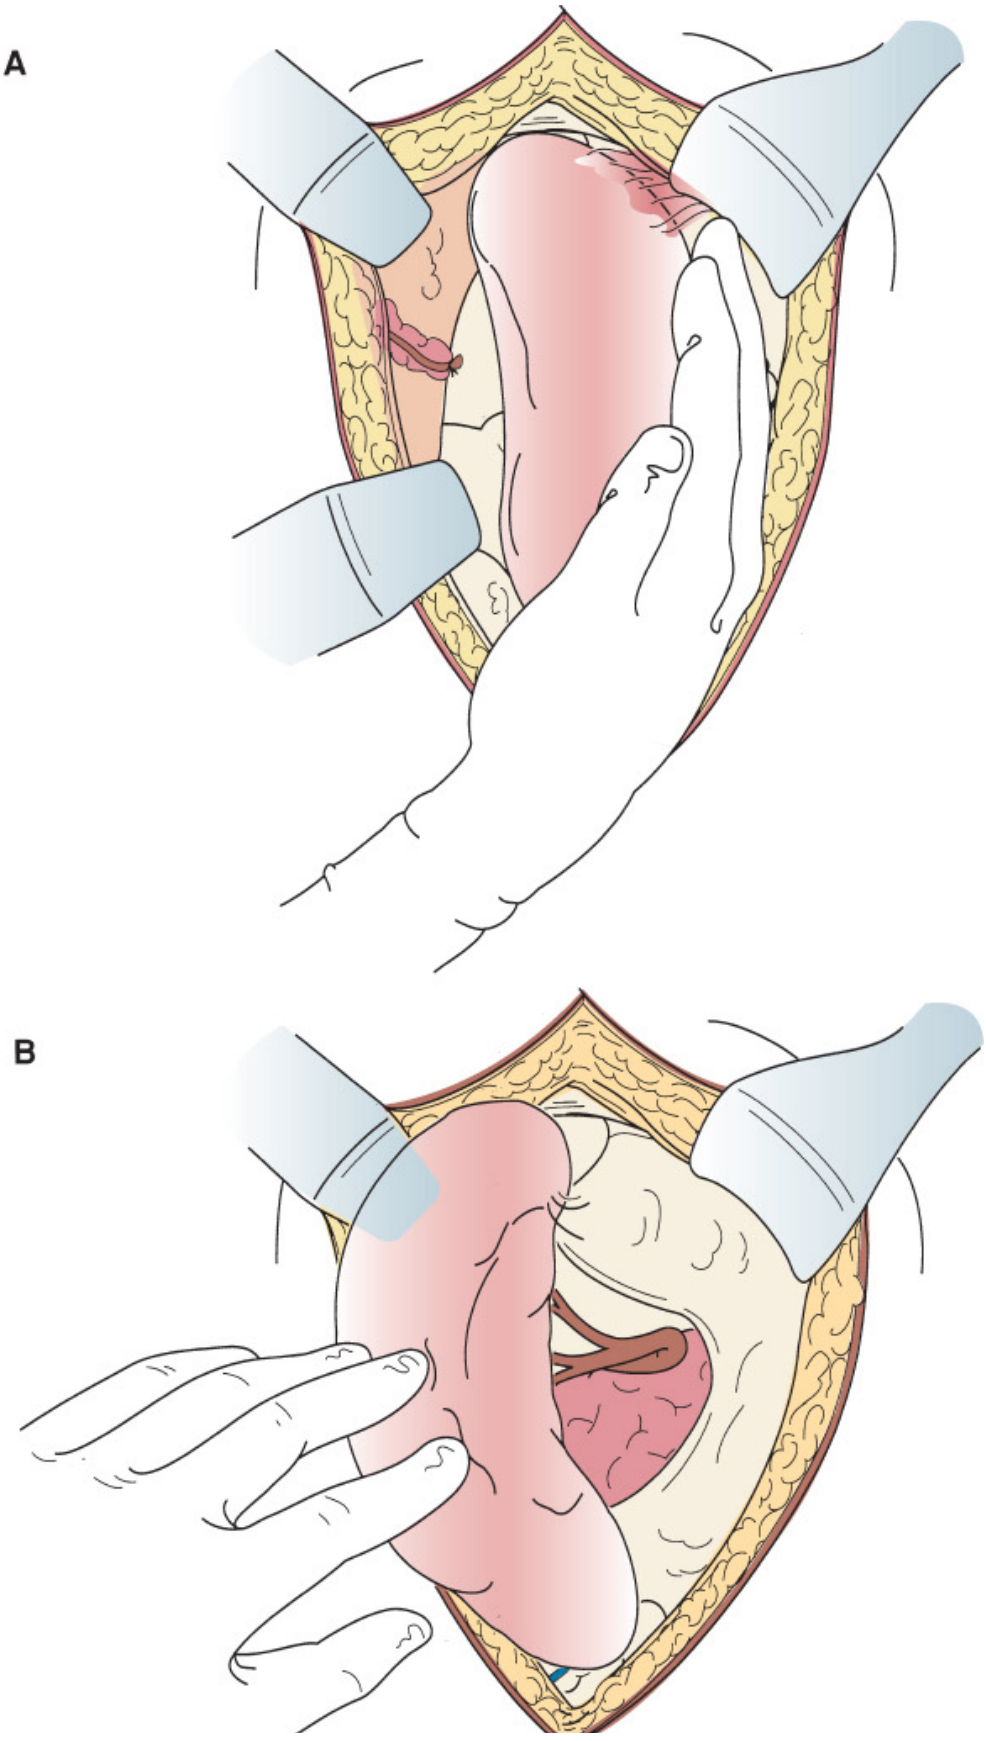
Description of Procedure

Open Splenectomy—Nontraumatic

The patient is positioned supine on the operating room table. The operation begins with either a midline laparotomy incision or a left subcostal incision. Once the abdominal cavity is safety entered, a self-retaining retractor system should be employed to facilitate exposure of the spleen. Retract the stomach medially to gain access to the gastrosplenic ligament and identify an avascular space for entry into the lesser sac. Using an energy device, serially ligate the vessels in the gastrosplenic ligament to gain access to the splenic hilum. Identify the course of the splenic artery and carefully incise the overlying peritoneum to fully expose the vessel. After gaining proximal and distal control, the artery can then be ligated either with silk sutures or a vascular stapler. It is important to ligate the artery before the vein as it allows for drainage of the organ prior to removal, possibly lessening blood loss.

Continue to divide the gastrosplenic ligament to fully mobilize the spleen from the stomach. Care should be taken near the upper pole of the spleen as the stomach is in close proximity, and sometimes completely adherent, to the spleen. Continue to mobilize the spleen by dividing the posterior and lateral attachments to deliver the organ into the surgical field. Take care not to injure the capsule of the spleen as this can cause significant hemorrhage. Finally, divide the splenocolic ligament to fully mobilize the spleen. Once the hilum is visible, the vessels can be serially ligated either with clamps and ties, or with a vascular stapling device. After removing the specimen and

meticulously achieving hemostasis, maintain vigilance for the possibility of an accessory spleen which must also be removed before completing the operation. A schematic of this approach is demonstrated in **Figure 73.9**.



A
B

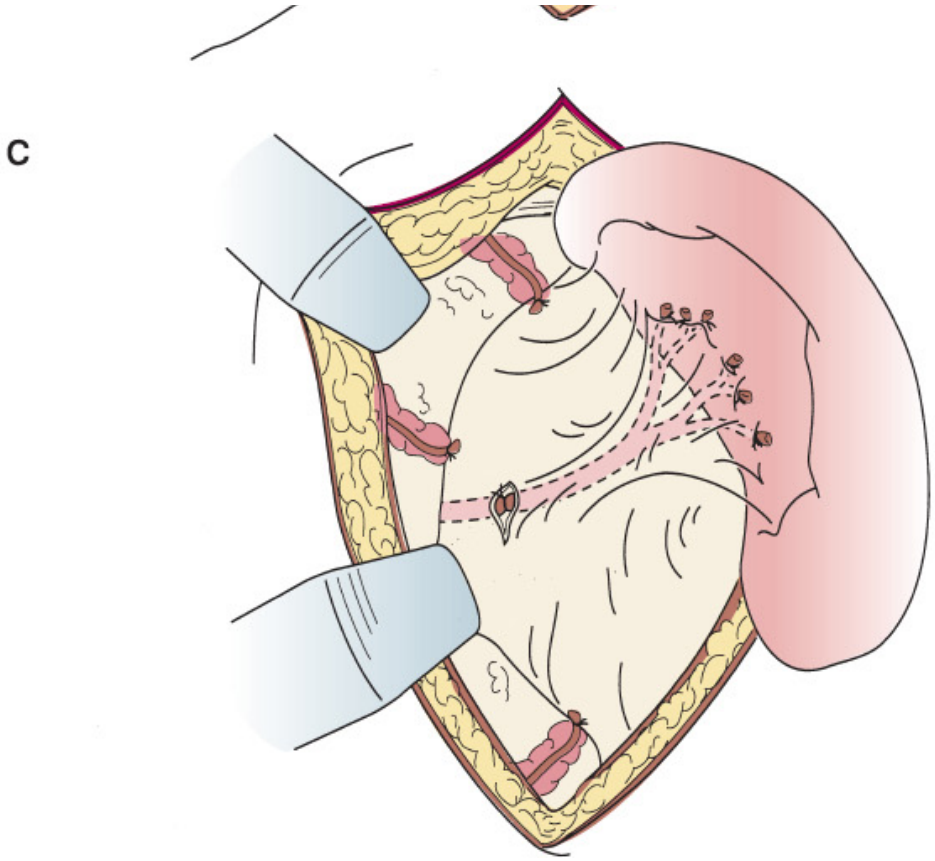


Figure 73.5 **A, B:** Rapid mobilization of a bleeding spleen can be accomplished in most patients by blunt dissection of the lateral attachments. **C:** The splenic hilum can then be quickly controlled.

Open Splenectomy—Traumatic

Open splenectomy for trauma takes place during an exploratory laparotomy. The patient is supine on the operating room take, prepped from neck to knees with arms extended. A generous midline laparotomy is made, immediately packing all four quadrants of the abdomen. Once any ongoing hemorrhage has been controlled, begin a thorough examination to determine the source. If the spleen is determined to be injured and bleeding, elevate the spleen medially using a combination of rolled laparotomy packs and blunt dissection as demonstrated in Figure 73.8. Once in the surgical field, serially clamp and ligate all vessels of the splenic hilum to control bleeding and remove the organ. Unlike the situation for an elective or planned splenectomy, the hemoperitoneum has often facilitated much of the dissection. Once the organ is removed, again meticulously check for ongoing bleeding as missed bleeding from the short gastric vessels can be a significant of ongoing

hemorrhage. A schematic of this approach is demonstrated in **Figure 73.5**. A schematic of techniques to repair superficial splenic lacerations is demonstrated in Figure 73.6.

Laparoscopic Splenectomy

In the elective setting, laparoscopic splenectomy is the preferred approach in many centers. First introduced in the early 1990s, the laparoscopic approach was found to be associated with less blood loss intraoperatively, less pain, shorter hospital length of stay, and lower morbidity.[83] Initially, laparoscopic splenectomy was contraindicated for cases of splenomegaly but as the technology developed and surgeons gained experience it became more common. However, some of the previously cited benefits may not apply for patients with splenomegaly. In a 2019 matched case study, the authors found that for patients with moderate splenomegaly (splenic weight 500 to 1,000 g), the laparoscopic approach was associated with a significantly longer operating time and 14% conversion rate. There was no difference in length of stay, morbidity, or mortality. However, for patients with massive splenomegaly (>1,000 g), the laparoscopic approach was associated with longer operating room time, 35% conversion rate, and a higher rate of readmission compared to open surgery. The authors conclude that for patients with splenomegaly, it is not clear whether the laparoscopic approach is superior.[83]

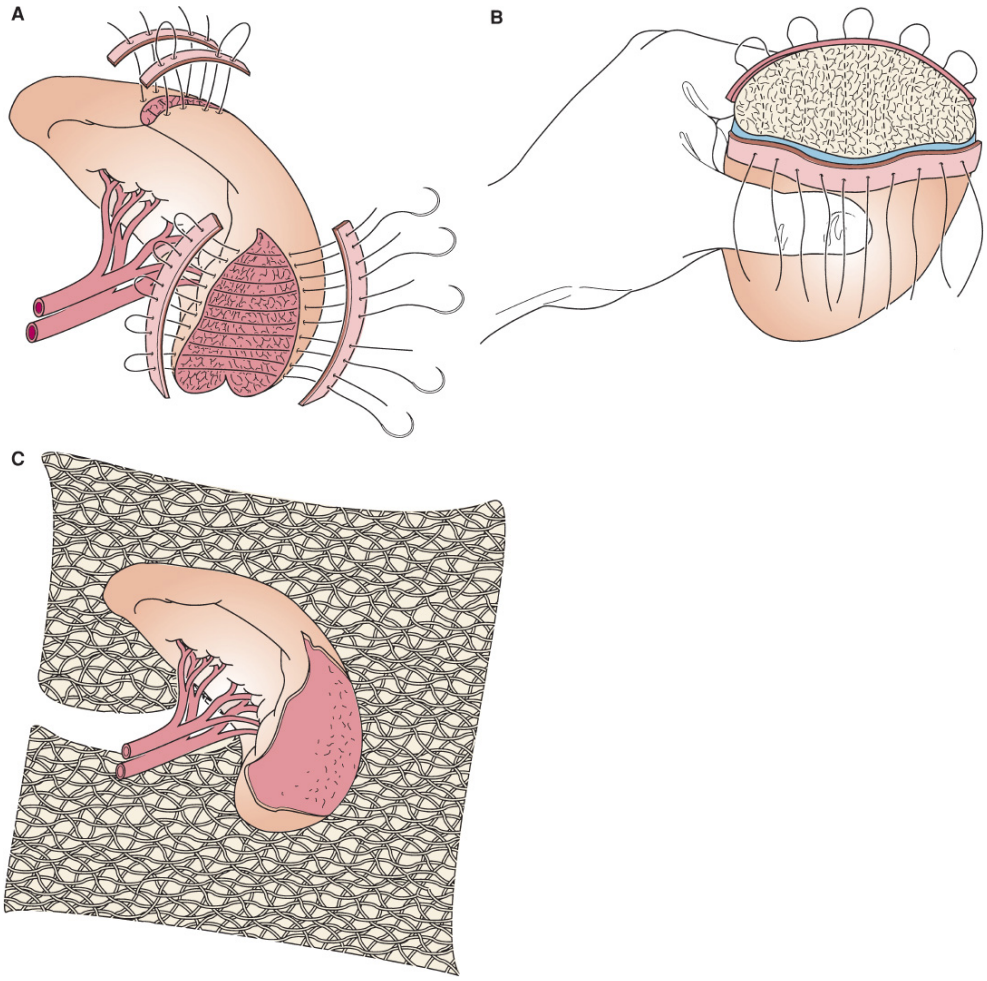

Figure 73.6 **A:** Techniques to suture superficial splenic lacerations. **B:** Technique to control bleeding after hemisplenectomy. The sutures can be interlocked. **C:** Polyglycolic acid mesh sheets or mesh bags can be applied to spleens that have had the capsule stripped away.

Figure 73.7 A massively enlarged, 2.2-kg spleen from a patient with chronic lymphocytic leukemia. Superficial areas of infarction are indicated by *thin arrows* and splenic infarction by the *thick arrow*.

The procedure begins with the patient in a right lateral decubitus position with a flexed table to optimally expose the left flank. Port positions and selection may vary slightly between surgeons, but a commonly described method is to place four to five ports in the left subcostal plane. Entry can be gained either via Hasson or Veress technique. The entry port is placed in either in the periumbilical location or just lateral to Palmer point. After

visual inspection of the abdomen and assessment of the size of the spleen, additional ports are placed just below the left subcostal margin to allow appropriate triangulation of the spleen. Begin by mobilizing the splenic flexure of the colon using an energy device. Carry this dissection medially to enter the lesser sac and divide the short gastric vessels. As in open splenectomy, take care at the upper pole of the spleen as the stomach may be very adherent at this point. Next visualize the splenic artery to allow for dissection. As dissection continues, small branches may be encountered that can be serially clipped and ligated. Once the splenic artery is dissected circumferentially, it is doubly clipped and ligated. Alternatively, a surgical stapling device can be used to divide the artery.

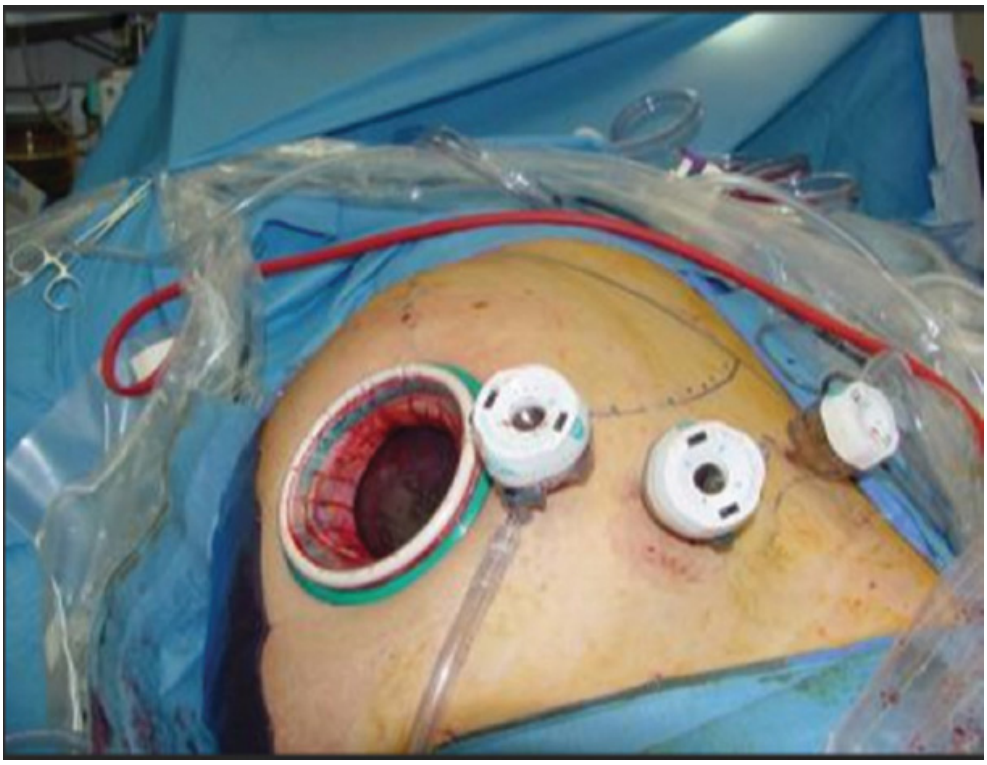
Continue dissection on the medial aspect of the spleen to expose the hilar vessels. Meticulous dissection ensues, clipping and ligating small vessels as the operation proceeds. Further mobilize the spleen by dividing the hilar attachments. Continue to dissect until the splenic vein is identified and encircled. Divide the vein with an endoscopic stapler with a vascular load. Alternatively, the entire vascular pedicle can be divided with an endovascular stapler rather than separately dividing the artery and vein. Once the vessels are ligated, continue dissection around to organ to free any remaining attachments so that the spleen can be removed. A specimen removal bag is then inserted to facilitate removal, brought to skin level, and the spleen is then morcellated to allow for removal. Carefully inspect the splenic fossa for hemostasis before closing the abdomen.

Hand-Assisted Laparoscopic Splenectomy

For cases in which splenomegaly would otherwise preclude the laparoscopic approach, the use of a hand port can help to facilitate laparoscopic splenectomy. In this technique, an additional incision is made to allow for insertion of the surgeon's nondominant hand into the abdomen. Reports of this technique describe a 7- to 8-cm incision (or slightly smaller than the surgeon's hand) located 2 to 4 cm caudal to the lower pole of the spleen. It can be made in the midline, or on the right subcostal area.[84,85] A hand port is then placed in the wound. The use of the hand port allows the nondominant hand to assist in retraction of the spleen. Additionally, the spleen can be

removed through this incision without the need for morcellation in some cases.

The advantage of hand-assisted laparoscopic splenectomy is that it allows for removal of larger spleens that would otherwise require open surgery while still maintaining the benefits associated with standard laparoscopic splenectomy. The additional tactile feedback afforded also may result in a lower incidence of hemorrhage as the vascular pedicle can be directly palpated and controlled.[85] In a meta-analysis of 16 studies with 754 patients undergoing laparoscopic splenectomy and hand-assisted laparoscopic splenectomy, the hand-assisted approach was found to be associated with shorter operative time, less blood loss, and a lower rate of conversion for open surgery in cases of splenomegaly. There was no significant difference in outcome metrics such as complications, hospital length of stay, or mortality, leading the authors to conclude that in cases of splenomegaly the hand-assisted approach is ideal.[86]



Schematic of port placement for hand-assisted laparoscopic splenectomy.

Robotic Splenectomy

Robotic approach to splenectomy is described and is similar in procedure to laparoscopic splenectomy. For normal-sized spleens, the robotic approach in results in longer operating time and higher costs, but no difference in safety, compared to laparoscopy. For splenomegaly, the robotic approach is associated with less blood loss and longer operative time without significant differences in safety.[87] Given the technical challenges presented by splenomegaly, some argue that the best approach in that circumstance remains hand-assisted laparoscopic splenectomy.[88]

Partial Splenectomy

Partial splenectomy has been advocated because it allows for removal of pathology while still preserving the immune function of the spleen and preventing overwhelming postsplenectomy sepsis. Indications for partial splenectomy include cysts, intraparenchymal lesions, hematologic disease, abscess, as well as others. The operation begins with division of the gastrocolic ligament followed by the gastrosplenic ligament to enter the lesser sac. Short gastric vessels are divided to allow visualization and temporary occlusion of the splenic artery. The spleen is then completely mobilized and segmental vascular control at the splenic hilum is achieved. Once the vessels are controlled, the splenic artery is then unclamped to allowed for visualization of the newly created ischemic zone, which can then be resected. That portion of the spleen is transected using an energy device, and subsequently removed. Given the potentially large surface area of splenic parenchyma now exposed, meticulous hemostasis must be achieved before closure. This can be accomplished with energy or hemostatic agents.[89]

SEQUELAE OF SPLENECTOMY AND HYPOSPLENISM

Postsplenectomy Sepsis

For patients who are asplenic, either due to surgical removal or functional asplenia, postsplenectomy sepsis is a significant concern. Hyposplenism, or impaired splenic function, may also occur in patients with HIV infection,

chronic graft-versus-host-disease, and severe celiac disease. Asplenic or hyposplenic patients are at particularly high risk of infection from encapsulated bacteria such as *Streptococcus pneumoniae* and *H. influenzae* type b. Other common high-risk organisms include *N. meningitidis, E. coli, and Staphylococcus aureus*. The reason for this is that the spleen is the organ best suited for removal of IgG-coated bacteria and encapsulated bacteria as these are not effectively opsonized by other methods. It is important to remember that patients who have not undergone surgical splenectomy may be functionally asplenic due to underlying disease, and thus may still be at risk for these infections.[24]

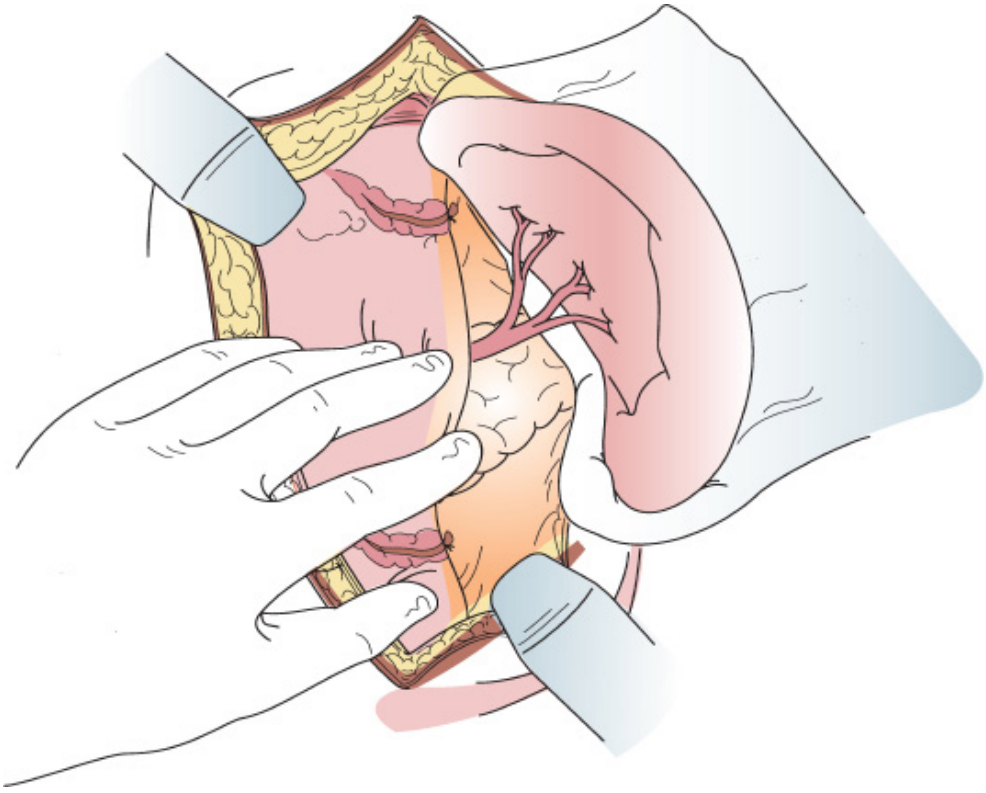


Figure 73.8 Lateral mobilization permits the spleen to reach the surface of a midline wound despite the presence of intact hilar vessels.

B
Peritoneum

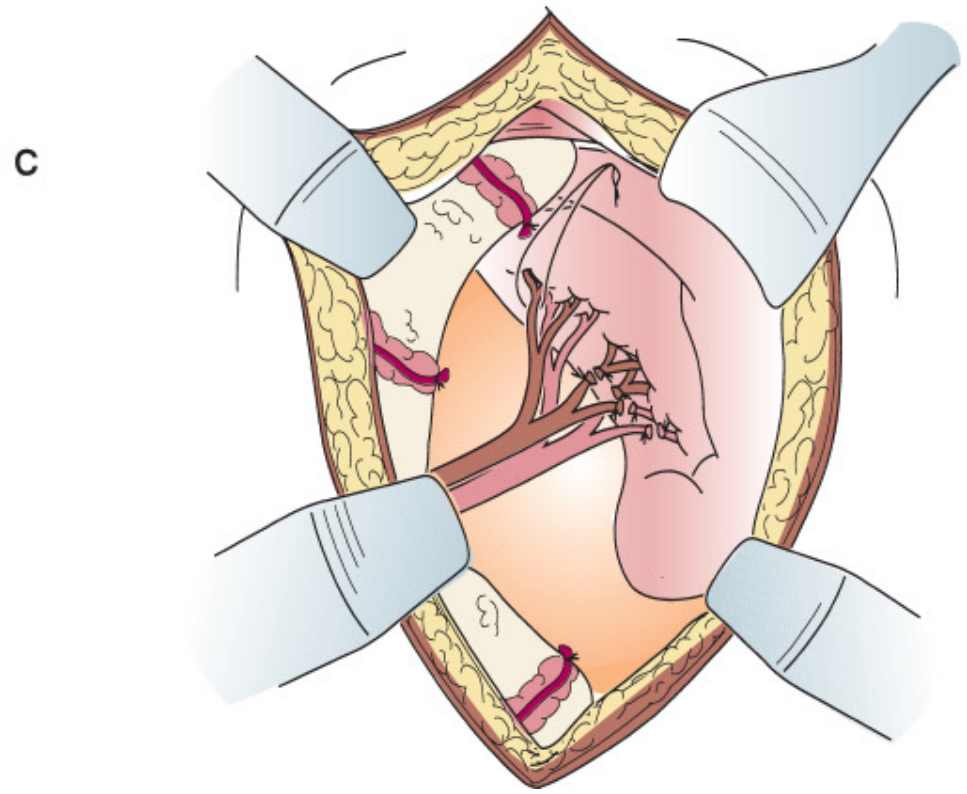

Figure 73.9 Technique for elective splenectomy. **A:** The inferior pole is reflected laterally by the assistant's fingers, exposing the lower edge of the hilar peritoneal envelope. **B:** The hilar peritoneum is opened, here shown progressing from inferior to superior. **C:** Individual vessels are identified and suture is ligated.

The risk of postsplenectomy sepsis depends on the indication for splenectomy. Healthy patients undergoing trauma splenectomy have the lowest risk while patients with surgical asplenia due to sickle cell disease, thalassemia, or portal hypertension are highest risk. Patients with hereditary spherocytosis or ITP are intermediate risk. Children, particularly infants, are at highest risk. The risk of postsplenectomy sepsis is highest in the first year following splenectomy but remains high for at least 10 years or longer. While the overall risk of postsplenectomy sepsis is low, mortality is high. Prior to the availability of effective vaccines, the incidence of postsplenectomy sepsis was 3.2% and led to death in up to two-thirds of affected patients.[24] A 2014 study of more than 20,000 splenectomized patients from 1970–2009 in Sweden indicated that there was a nearly six-fold higher risk of sepsis compared to the general population. As previously described, patients who underwent splenectomy for trauma has a lower risk than patients with

hematologic malignancy. Overall mortality for patients with sepsis was 17%.[90]

Given the high risk of postsplenectomy sepsis and associate mortality routine prophylaxis is recommended. Ideally, these vaccines can be given prior to splenectomy but in many cases (e.g., trauma) this may not be possible. While the exact timing is debated, there is some evidence that vaccination is less effective if administered in the 2 weeks before or after splenectomy. For *S. pneumoniae,* there are two vaccines (PCV13 and PPSV23) given 8 weeks apart. *H. influenzae* type b is a single vaccination while *N. meningitidis* requires two doses. In addition, it is recommended that patients undergo vaccination for the seasonal influenza virus.[24] However, in a 2019 study describing vaccination rates in Minnesota over a nearly 50-year period, only 62% of patients received adequate vaccination with only 32% received booster vaccines. Furthermore, patients who did not receive appropriate vaccination more frequently presented with sepsis and developed sepsis at a shorter time interval following surgery compared to those who were vaccinated.[26]

Initial symptoms of postsplenectomy sepsis include nonspecific viral symptoms such as fever, chills, rigors, diarrhea, and vomiting. However, these symptoms can rapidly progress to fulminant sepsis in 1 to 2 days. Effective treatment begins with early recognizing that a patient might be at risk so that diagnosis can be made quickly. Treatment including blood cultures and early initiation of broad spectrum antibiotics follows standard sepsis bundles.[91]

Vascular Complications Following Splenectomy

A less commonly recognized complication following splenectomy is arterial and venous thrombosis, as well as vascular remodeling leading to pulmonary hypertension. These complications vary by indication and are most common following splenectomy for thalassemia. While the exact mechanism is not well understood, it is thought to be related to a combination of platelet activation, altered lipid profile, hypercoagulability, and changes to vascular endothelium. This may be because damaged cells and particulate matter that

would otherwise be filtered by the spleen are left circulating in the blood. Because the mechanisms underlying this phenomenon are still being explored, there is no universally endorsed strategy to treat or prevent this. Some advocate for thromboprophylaxis or anti-platelet therapy in high-risk patients but this has not been validated in prospective studies.[92]

One specific example of thrombotic disease following splenectomy is portal vein thrombosis. This occurs not only due to the hypercoagulable state induced by splenectomy, but also due to stasis within the splenic vein stump that leads to turbulent blood flow. This is a rare complication of splenectomy (<1%) but can be fatal. Patients may be asymptomatic or show symptoms of abdominal pain and fever. Anticoagulation is the mainstay of treatment.[93]

Section K: SURGICAL ENDOCRINOLOGY

74

Breast Disease

Thanh U. Barbie and Julie A. Margenthaler

Key Points

1. Any clinically suspicious mass, even in the absence of an imaging abnormality, needs to be biopsied.
2. Core needle biopsy is the preferred strategy for breast cancer diagnosis. Core needle biopsy is less invasive and less expensive than excisional biopsy and facilitates definitive breast cancer treatment planning.
3. The upgrade of lobular neoplasia diagnosed on core biopsy at time of surgical excision to malignancy is 1% to 3% and as such surgical excisional biopsy is no longer indicated if there is radiographic-pathologic concordance.
4. All women should undergo risk assessment by age 35 to determine the best approach for breast cancer screening.
5. Surgical options for the treatment of DCIS include breast-conserving surgery as a component of breast conservation therapy (partial mastectomy and postoperative radiation therapy) or simple mastectomy.
6. Sentinel lymph node biopsy has replaced axillary lymph node dissection for axillary staging, and the therapeutic impact of axillary lymph node dissection may be limited to specific subsets of breast cancer patients.
7. Local regional management of invasive breast cancer consists of breast conservation therapy (partial mastectomy with radiation therapy) or mastectomy, noting that the choice in locoregional management does not typically impact the recommendation for adjuvant medical therapy.
8. Among patient's undergoing partial mastectomy, performing cavity shave margins halved the rates of positive margins and reexcision.
9. A negative surgical margin for invasive breast cancer is now defined as no tumor at the ink margins. Given the potential for gaps between lesions in DCIS, a negative surgical margin is still defined as ≥2 mm, understanding that this practice may evolve pending more study results.

10 Nipple-sparing mastectomy is a safe option for BCRA mutation carriers, with no local regional recurrences at the nipple or areola at up to 37 months of follow-up.

11 Axillary radiation therapy may result in less morbidity than axillary lymph node dissection in patients with early stage breast cancer with clinically negative axillary examinations who have ≤2 positive sentinel lymph nodes.

ANATOMY

Surgical Anatomy of the Breast

The boundaries of the mature adult breast are the 2nd rib superiorly, the 6th rib inferiorly, the sternal edge medially, and the midaxillary line laterally. Breast tissue also extends into the axilla. Posteriorly, the breast lies on top of portions of the deep investing fasciae of the pectoralis major muscle, the serratus anterior muscle, the external abdominal oblique muscles, and the upper extent of the rectus sheath (Fig. 74.1). The breast is composed of skin, subcutaneous tissue, and breast parenchyma. The skin overlying the breast is thin and contains hair follicles, sebaceous glands, and exocrine sweat glands. The subcutaneous tissue is composed of fat, vasculature supplying the skin, lymphatics, and nerves. The breast parenchyma consists of parenchymal components and stroma.

Breast tissue is located within the superficial fascia of the anterior thoracic wall and consists of 15 to 20 lobes of glandular tissue that are divided by connective tissue with adipose tissue filling the space between the lobes (Fig. 74.2). Each lobe is composed of 20 to 40 lobules, which are themselves composed of 10 to 100 alveoli. Each lobe ends in a lactiferous duct that dilates into lactiferous sinuses, which then open through constricted orifices into the nipple. The suspensory ligaments of Cooper are fibrous connective bands that extend from the deep fascia to connect to the dermis, providing the breast with both support and mobility. There is significant variation in breast size with the average nonlactating breast weighing between 150 g and 225 g, whereas the lactating breast may exceed 500 g.[1]

The left breast is commonly slightly larger than the right.[2] The upper outer quadrant of the breast contains more breast parenchyma and is the most frequent site of both benign and malignant breast disease.

The skin of the nipple and areola is highly pigmented and somewhat wrinkled, composed of stratified squamous epithelium. Deep to the nipple and areola are bundles of smooth muscle fibers that are arranged radially, circumferentially, and longitudinally, allowing for erection of the nipple from stimuli. Along the margin of the areola are sebaceous glands and sweat glands. Accessory glands known as Montgomery glands have nodular elevations (tubercles of Morgagni) that open onto the surface of the areola. The nipple and areola are highly innervated, with the nipple containing numerous free sensory nerve endings and Meissner corpuscles, whereas the areola contains both Ruffini-like endings and Krause-end bulbs.[3] The sensory innervation of the breast is mainly the lateral and anterior cutaneous branches of the second through sixth intercostal nerves. There is also a small region of skin over the upper portion of the breast that is supplied by the anterior or medial branches of the supraclavicular nerve that arises from the cervical plexus.

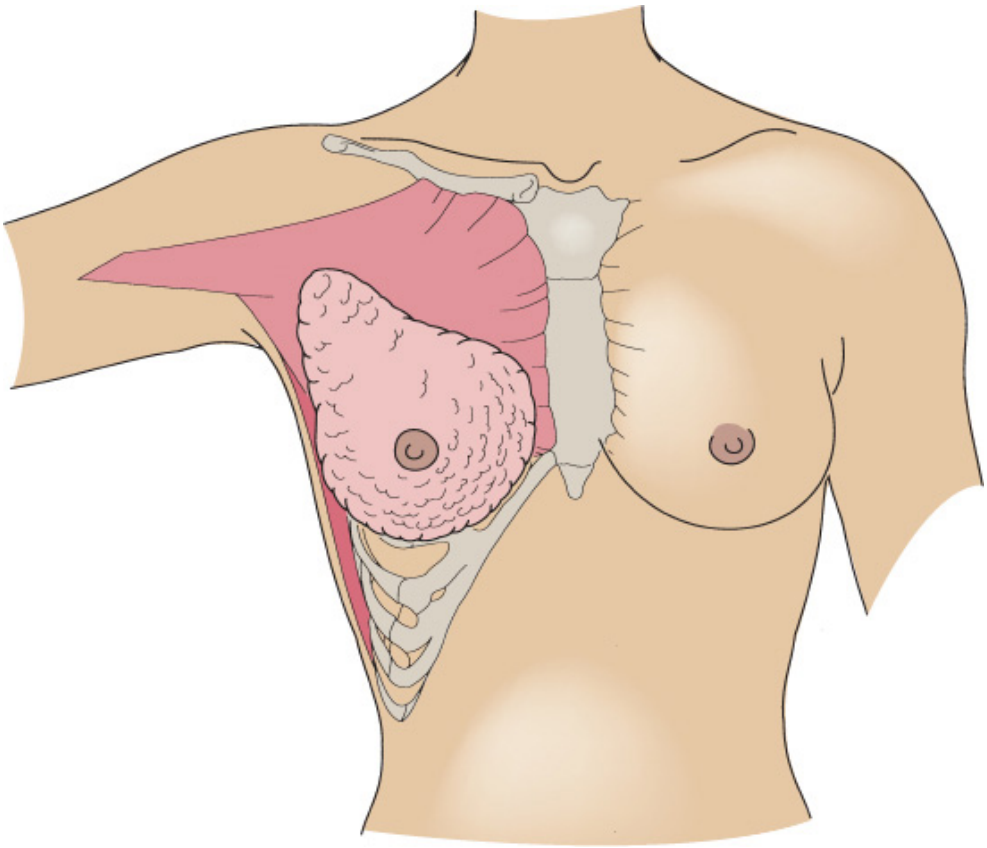

Figure 74.1 The adult female breast. The upper and medial portions of the breast rest on the pectoralis major muscle, and the inferolateral portion rests on the serratus anterior.

The arterial blood supply to the breast consists of the internal mammary artery (perforating branches), the posterior intercostal artery (lateral branches), and several branches of the axillary artery including the superior thoracic artery, the lateral thoracic artery, and the pectoral branches of the thoracoacromial artery. The breast's venous system parallels its arterial system, consisting of the internal mammary veins, the posterior intercostal veins, and the axillary vein tributaries.[4]

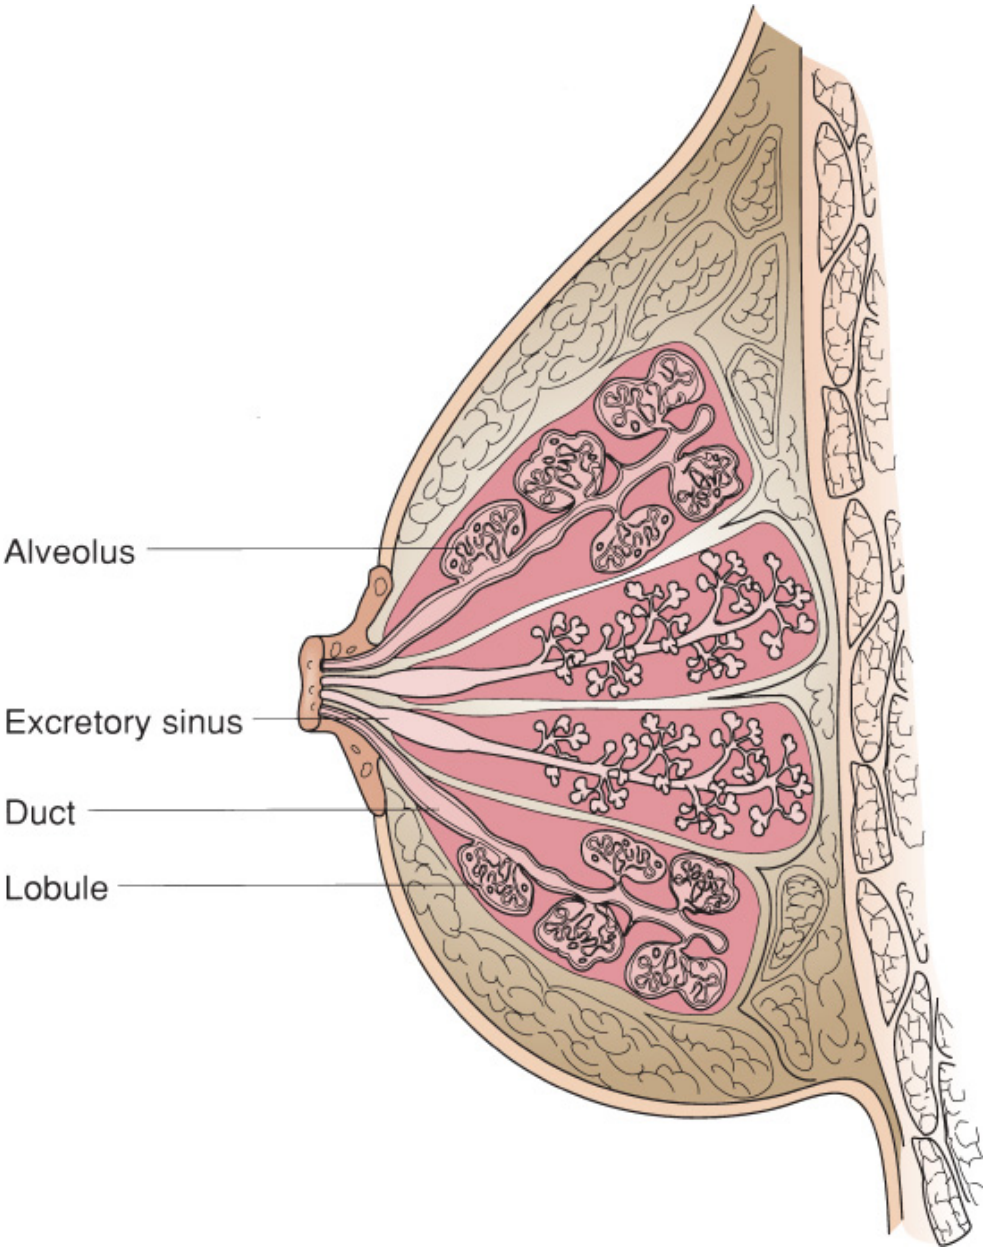

Figure 74.2 The breast consists of 15 to 20 lobes of glandular tissue. Within each lobe, the lobules are composed of branched tubuloalveolar glands. Each lobule ends in a lactiferous duct. These ducts dilate into lactiferous sinuses beneath the nipple.

Lymphatic Drainage

The lymphatic flow from the breast is unidirectional through thin-walled, valveless vessels that are interconnected through three groups. The primary group of lymphatic vessels comes from within the gland in the interlobular spaces and along the lactiferous ducts. The lymphatic vessels that drain the

skin, nipple/areola, and the central portion of the gland constitute the subareolar plexus. The third plexus is on the deep surface of the breast and communicates with small vessels in the deep fascia underlying the breast. More than 75% of the lymph from the breast passes to the axillary lymph nodes, whereas the remainder passes to parasternal nodes. The flow of lymph to either the axillary or the parasternal nodes is independent of the quadrant from where the lymph originated.[5] Occasionally, lymph flow can be found outside of these three interconnected plexuses, occurring along the lateral cutaneous branches of the posterior intercostal arteries, within the rectus sheath or subperitoneal plexus by following branches of the intercostal and musculophrenic vessels, or directly to subclavicular or apical nodes.[6]

The axilla is a pyramidal compartment between the upper extremity and the thoracic walls, which can be thought of as consisting of four walls, an apex, and a base. The anterior wall consists of the pectoralis major/minor and its associated fasciae. The supscapularis muscle, teres major muscle, latissimus dorsi muscle, and associated tendons form the posterior wall. The medial wall consists of the serratus anterior muscle and associated intercostal muscles of the upper four or five ribs. A thin strip of the humerus and the bicipital groove, which is between the insertion of the muscles of the anterior and posterior walls, forms the lateral wall. The apex is an aperture that extends into the posterior triangle of the neck through the cervicoaxillary canal, which is bounded by the clavicle anteriorly, the scapula posteriorly, and the 1st rib medially. The base of the axilla is the axillary fascia and skin.[6]

The axillary lymph nodes have traditionally been divided into three levels, corresponding to their location relative to the pectoralis minor (Fig. 74.3). Level 1 nodes (external mammary, axillary vein, and scapular lymph node groups) are inferior and lateral to the pectoralis minor; level 2 nodes (central lymph node and some subclavicular lymph node groups) are behind the pectoralis minor; and level 3 nodes (subclavicular lymph node group) are medial to the pectoralis minor. The interpectoral nodes (Rotter nodes) are located between the pectoralis major and minor muscles along the lateral pectoral nerve. The supraclavicular nodes are contiguous with the apex of the axilla. The internal mammary nodes are located in the first six intercostal spaces within 3 centimeters of the edge of the sternum, with the highest concentration of nodes found in the first three intercostal spaces.[7,8]

BREAST PHYSIOLOGY

Breast Development

As epidermal appendages, mammary glands likely evolved from ancient apocrine glands that were associated with hair follicles.[9] The mammary gland is a complex secretory organ consisting of multiple different cell types. Epithelial cells form the ductal network of the gland, which is embedded within a fat pad composed of adipocytes. In addition, there are vascular endothelial cells that make up the blood vessels, stromal cells including fibroblasts, and immune cells. During the three stages of mammary development (embryonic, pubertal, and pregnancy/lactation), these cells undergo an intricate series of changes under the regulation of hormones and regulatory factors, resulting in permanent changes to the mammary gland that both modify its architecture and biologic characteristics.[10] Understanding breast development and morphology is extremely important to the study of both premalignant and malignant conditions.

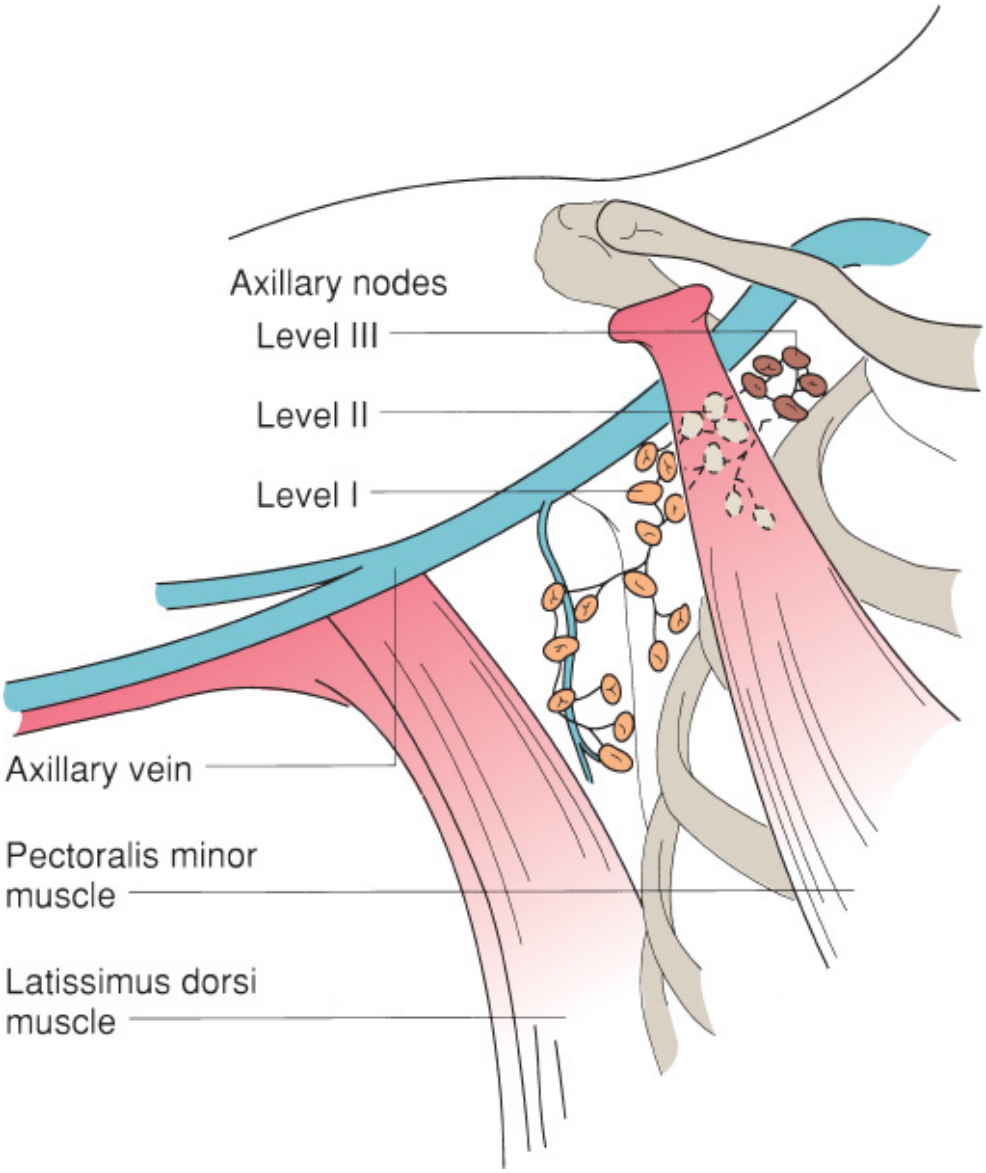

Figure 74.3 The axillary lymph nodes are divided into three levels by the pectoralis minor muscle. The level I nodes are inferior and lateral to the pectoralis minor, the level II nodes are below the axillary vein and behind the pectoralis minor, and the level III nodes are medial to the muscle against the chest wall.

In humans, mammary gland development starts in the sixth week of fetal life with the formation of bilateral milk lines or ectodermal thickenings that extend from the axilla to the groin. These ridges rapidly regress except for those of the thorax, where invagination of ectoderm cells into the mesenchyme results in mammary bud formation. In the human embryo, at about 5 months, the deep layer of the mammary bud epithelium starts to proliferate and produces about 10 to 25 secondary buds, which will later

correspond to lactiferous ducts. Canalization, or the formation of lumens within the solid core of these epithelial structures, occurs later in development. By birth, six to eight of these ducts are patent and empty into the nipple.[11–15] A parallel bundle of an additional 25 smaller ducts also appear and are the precursors to the milk-producing units of the breast.[16] The subareolar lymphatic plexus also develops from the ectoderm in a similar fashion,[17] while the nipple forms from the proliferation of the mesenchyme under the areola.[14]

In infants, only small ductal structures are seen within the stroma and during childhood these structures continue to grow isometrically at a rate similar to the rest of the body until puberty.[18] These initial stages of breast development are not dependent on sex steroids but are likely governed by numerous growth factors that regulate the epithelial-mesenchymal interaction, including Lef-1,[19] parathyroid hormone–related protein, and the type 1 parathyroid hormone/parathyroid hormone–related protein receptor.[20]

During puberty, the female glands enlarge rapidly secondary to maturation of the ductal system into a lobuloalveolar system. This is characterized by thickening of the ductal epithelium, elongating ducts, and an increasing amount of periductal connective tissue. In addition, stem cells at the tips of the ductal tree form terminal end buds, which are highly proliferative and give rise to alveolar buds. In early puberty, these alveolar buds empty into a terminal ductal lobular unit and are referred to as lobules type 1. Under the influence of ovarian hormones (estrogen and progesterone), lobules type 1 will differentiate into lobules type 2, which are characterized by smaller but more numerous buds that are noted as ductules or alveoli. It has been postulated that each menstrual cycle fosters new budding that never fully returns to the baseline of the prior cycle.[21,22] In addition to estrogen and progesterone, pubertal breast development is also dependent on other hormones and regulatory factors including prolactin, growth hormone, glucocorticoids, growth factors (hepatocyte growth factor, IGF-1, IGF-2, FGF, neuregulins especially heregulin), vitamin D receptor, metalloproteinases, and PTEN.[23–28]

As these developmental events are occurring, physical changes in the breast contour and the appearance of the nipple become evident and are illustrated as the five Tanner stages of breast development (Fig. 74.4).[29]

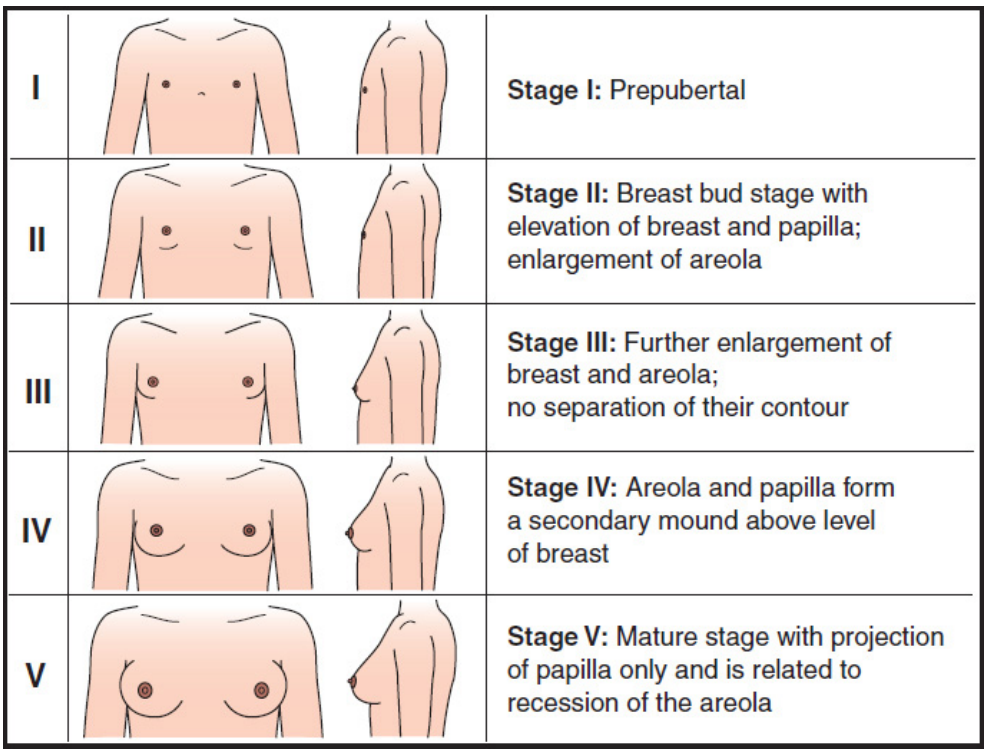

Figure 74.4 Tanner stages of breast development.

Pregnancy and Lactation

Although the pubertal phase is marked by significant lobular development, the mammary gland does not achieve full differentiation until after pregnancy and lactation. In early pregnancy, the distal ducts continue to proliferate resulting in more lobules and more alveoli within each lobule. However, by mid-pregnancy, proliferation of the lobules ceases and instead alveolar cells begin to differentiate into acini by hypertrophy and the ability to secrete colostrum into the lumina of the ductules. By the third trimester, the acini become distended with colostrum and the breast's connective tissue and fat become largely replaced by glandular proliferation. In addition, the connective tissue becomes infiltrated with plasma cells, lymphocytes, and eosinophils. There is also a marked increase in vascularity. The stage of lactogenesis or the ability to synthesize and secrete milk marks the final stage of maturation of the mammary gland (lobule type 4).[30,31] Following lactation or during weaning, the mammary gland involutes with lobules type 4 returning to the prepregnancy state as lobules type 2 and 3.[32,33]

The hormones and regulatory factors that govern mammary development during pregnancy and lactation overlap with those previously discussed for pubertal breast development, with estrogen, progesterone, and prolactin playing chief roles. Other hormones and regulatory factors include intracellular signaling molecules (c-erbB, hox genes, cell–cell adhesion molecules such as E-cadherin, cell cycle protein cyclin D1, RANK-L, slug transcription factor), activins and inhibins including STAT5, hypothalamic peptides, thyrotropic-releasing hormone, and lactogenic hormones.[34–41]

Menopause

By menopause, the mammary gland is mainly replaced by fat as the glandular epithelium undergoes apoptosis. As such, the postmenopausal phase is characterized by both a decrease in lobules and ducts.[42,43]

In summary, human breast development is a progressive process that is initiated during embryonic life, with glandular maturation starting at puberty, and attainment of full breast differentiation only with subsequent pregnancy and lactation.

CLINICAL EVALUATION OF THE PATIENT WITH BREAST DISEASE

Breast disease is an extremely common clinical problem. Most women who present to a breast health specialist will have benign breast disease. One of the primary goals of the evaluation is to determine whether the breast problem represents benign or malignant breast disease. With benign conditions, the goals are to reassure the patient and if indicated provide symptomatic treatment. With a malignant condition, prompt evaluation and treatment should be undertaken, typically involving a breast surgeon, medical oncologist, and radiation oncologist. In this section, clinical breast examination (CBE), diagnostic imaging studies, and biopsy procedures used to evaluate the patient with breast disease are discussed.

During the CBE, it is important to discuss with the patient whether she has any breast concerns and to elicit a gynecological history including

menopausal status (for premenopausal patients, the time in their menstrual cycle) and the use of any hormonal therapies. If a woman has any breast problems, a thorough history needs to be obtained (Table 74.1).

Clinical Breast Examination

Clinical breast examination (CBE) is performed in both the sitting and supine positions. The patient is disrobed from the waist up and then provided a front-opening gown. Visual inspection is first accomplished with the patient sitting upright with the arms relaxed to her side. The bilateral breasts are compared for size and shape. It is normal to find slight differences in breast size, with the left breast often slightly bigger than the right. Breast shape is also contrasted. Recent changes to breast size or alterations in breast shape can be concerning signs and need to be evaluated by the provider, as tumors located superficially can cause changes to the breast contour. The skin of the breasts is inspected for dimpling, edema (peau d'orange), and/or erythema. In cases of significant erythema and peau d'orange, the provider needs to consider the diagnosis of an inflammatory breast cancer (IBC) versus an infectious etiology. This is followed by close inspection of the nipples for symmetry. Although some women have a lifelong history of nipple inversion, any new history of nipple inversion needs to be regarded with a high index of suspicion. Next the nipple–areola complex is evaluated for any eczematous changes or ulcerations (to suggest conditions such as Paget disease of the breast [PDB]). The patient is then asked to raise her arms to allow for a more complete visual inspection of the lower aspect of the breasts bilaterally. The visual examination is completed when the patient is asked to place her hands on the hips and then to contract the pectoral muscles. This allows for a final visual assessment of breast symmetry. Furthermore, tumors deep within the substance of the breast involving Cooper ligaments can result in skin retraction and can sometimes be seen best with contraction of the pectoral muscles.

Table 74.1 Medical History of a Breast Problem

General
Age at menarche
Number of pregnancies
Number of live births
Age at first birth
Family history of ovarian cancer, gynecologic cancers, and other cancers, including affected relative, age of onset, and presence of bilateral disease
History of breast biopsies (and histologic diagnosis, if available)
Premenopausal women
Date of last menstrual period
Length and regularity of cycles
Use of oral contraceptives
Postmenopausal women
Date of menopause
Use of hormone replacement therapy
Specific
Onset
Duration
Frequency
Severity
Relationship to menstrual cycle or use of hormone replacement therapy

With the patient remaining in the sitting position but now with the pectoral muscles relaxed, palpation of the regional lymph nodes of the neck, clavicles (infraclavicular and supraclavicular), and axilla is then performed. To best delineate the axillary lymph nodes, the patient should be examined with the ipsilateral arm supported (Fig. 74.5). Attention is paid to evaluate the size, consistency (soft or firm), and characteristics (mobile or matted, tender or nontender) of the lymph nodes. Bimanual palpation of the breasts for masses and asymmetry completes the sitting examination.

The patient is then placed in the supine position with the ipsilateral arm raised above the head and the contralateral breast covered with the gown. The breast tissue is carefully palpated to evaluate for masses and asymmetry. It must be noted that generalized lumpiness is not a pathologic finding, with most normal breasts having more nodularity in the upper outer quadrants, at the inframammary ridge, and in the subareolar region. Comparing the breasts for symmetry by palpation may help discriminate benign findings from those that require additional evaluation. The area examined extends from the clavicle to the lower rib cage and medially from the sternal border to the midaxillary line. In addition, the axillary tail of the breast should be carefully palpated. The three search patterns that have been described are concentric circles, radial spoke method, and the vertical strip pattern (Fig. 74.6). As the first two methods can result in a less than thorough examination of the nipple–areola complex, we prefer the vertical strip pattern as it incorporates this area. Otherwise, with the other two search patterns, a separate examination of the nipple–areola complex needs to be performed.

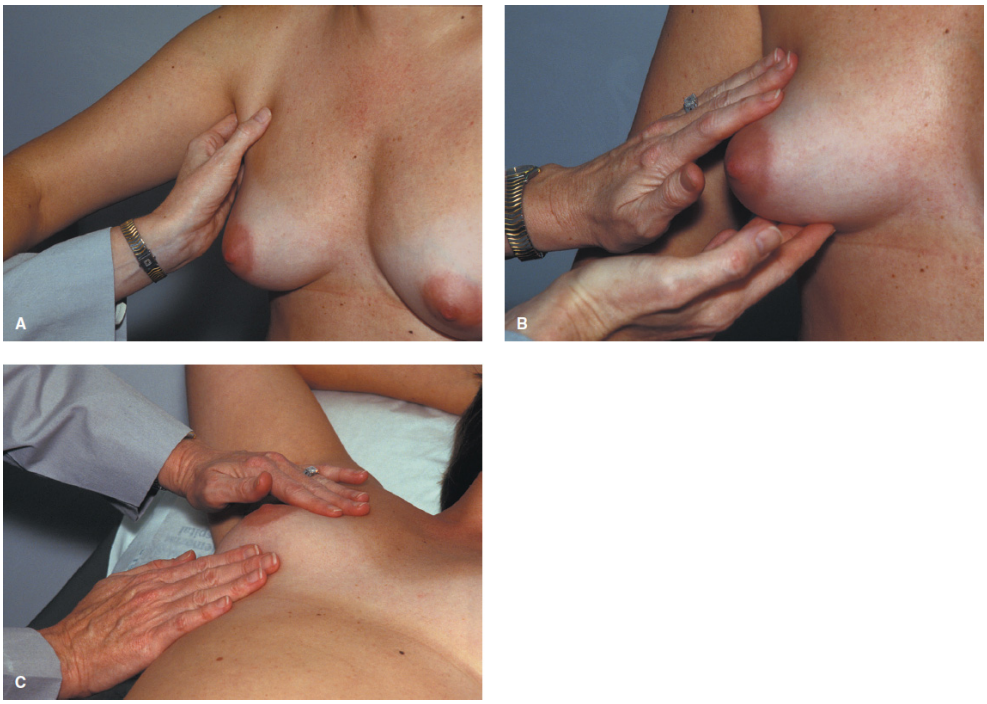

Figure 74.5 Breast examination. **A:** The patient's ipsilateral arm is supported by the examiner to relax the pectoral muscle while the axillary nodes are examined. **B:** Bimanual examination of the breast in the upright position. **C:** Bimanual examination in the supine position with the arm raised over the head.

Figure 74.6 Clinical breast examination search patterns: vertical strip, radial spoke, and concentric circles.

Diagnostic Mammography and Breast Ultrasound

A woman who has an indeterminate or abnormal CBE will typically benefit from a diagnostic imaging evaluation, which can include mammography, targeted ultrasound, and/or MRI. *It is important to note that any clinically suspicious mass, even in* 1 *the absence of an imaging abnormality, needs to be biopsied as up to 15% of breast cancers are mammographically occult.*[44]

Soft tissue densities and clustered microcalcifications are two common mammographic findings suggestive of breast cancer. Soft tissue densities can appear as well-defined round/oval/lobulated masses, spiculated masses, irregular masses, or as areas of architectural distortion without an obvious mass (Fig. 74.7). Nearly 90% of spiculated soft tissue masses are associated with invasive cancer whereas well-defined solid masses are less commonly predictive of malignancy. Microcalcifications can have benign or malignant features, with benign calcifications often appearing rim-like, large, coarse, smooth, round and/or oval in appearance. Calcifications that are associated with malignancy tend to be smaller in size ranging between 0.1 to 1 mm in diameter. They are typically clustered, numbering four to five per cubic centimeter. Histologically, these represent intraductal calcifications in areas of necrotic tumor or calcifications within mucin-secreting tumors. In addition, malignant microcalcifications can often appear in a granular or linear branching pattern, with the linear branching pattern being highly associated with malignancy (Fig. 74.8).

Breast ultrasound is another important diagnostic imaging modality for the evaluation of breast masses and/or mammographic abnormalities. Breast ultrasound is complementary to mammography, and is particularly valuable for the evaluation of breast masses. Breast ultrasound can increase the sensitivity and specificity of mammography for detection of breast cancer.[45] Ultrasound can differentiate a cystic mass from a solid one, characterize a palpable lesion that is not seen on mammography, and can assist with determining the actual size of a lesion. Ultrasonographic features that are used to characterize a lesion include shape (oval, round, lobular, irregular); margin (circumscribed, obscured, microlobulated, ill-defined, speculated); orientation (parallel or not parallel to skin); matrix echogenicity (anechoic, hypoechoic, hyperechoic); homogeneity (homogeneous, heterogeneous); and attenuation (indifferent, shadowing, enhancement).

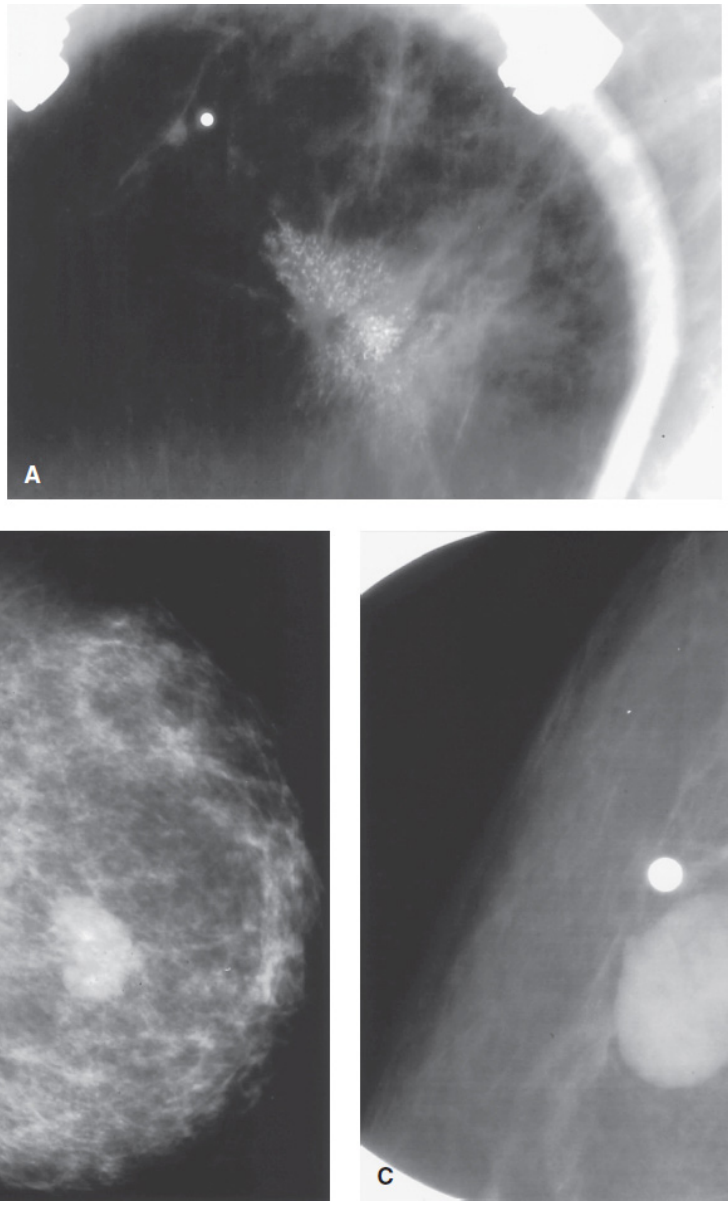

Figure 74.7 Mammographic masses. **A:** Spiculated mass with calcifications. **B:** Lobulated mass with indistinct posterior margin. **C:** Well-circumscribed mass.

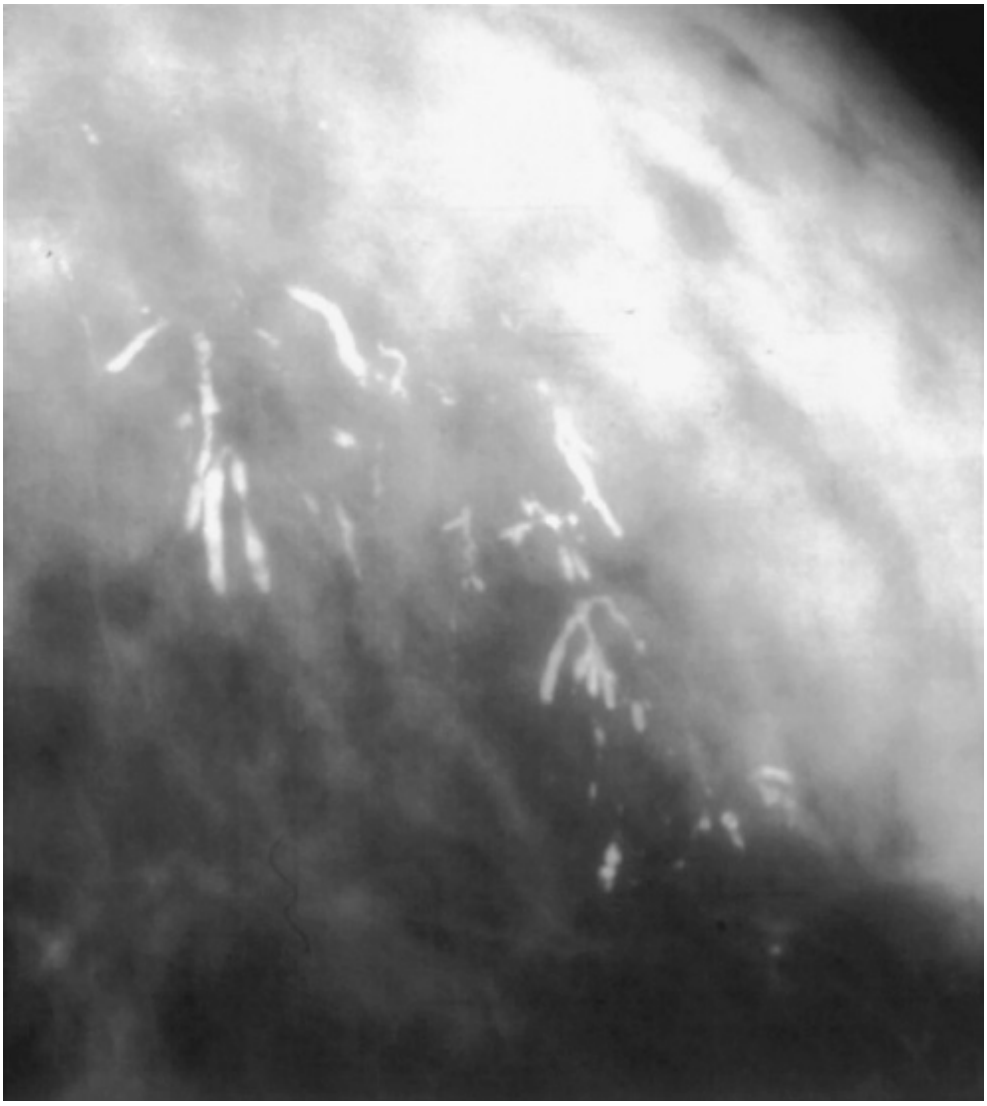

Figure 74.8 Microcalcifications. The branching, irregular appearance is classic for ductal carcinoma in situ.

Diagnostic MRI

Gadolinium contrast-enhanced MRI is complementary to mammography and breast ultrasound. It is not typically used for the evaluation of benign breast masses, but does have a high sensitivity for detection of breast cancer. As such, MRI is most commonly used to evaluate extent of disease and exclude occult breast cancers in patients with newly diagnosed breast cancer. In a meta-analysis of 44 studies, the sensitivity and specificity of diagnostic breast MRI was determined to be 90% and 72%, respectively.[46] The role of

MRI in the evaluation of newly diagnosed breast cancer patients is discussed in ***Evaluation of the Patient with Breast Cancer***.

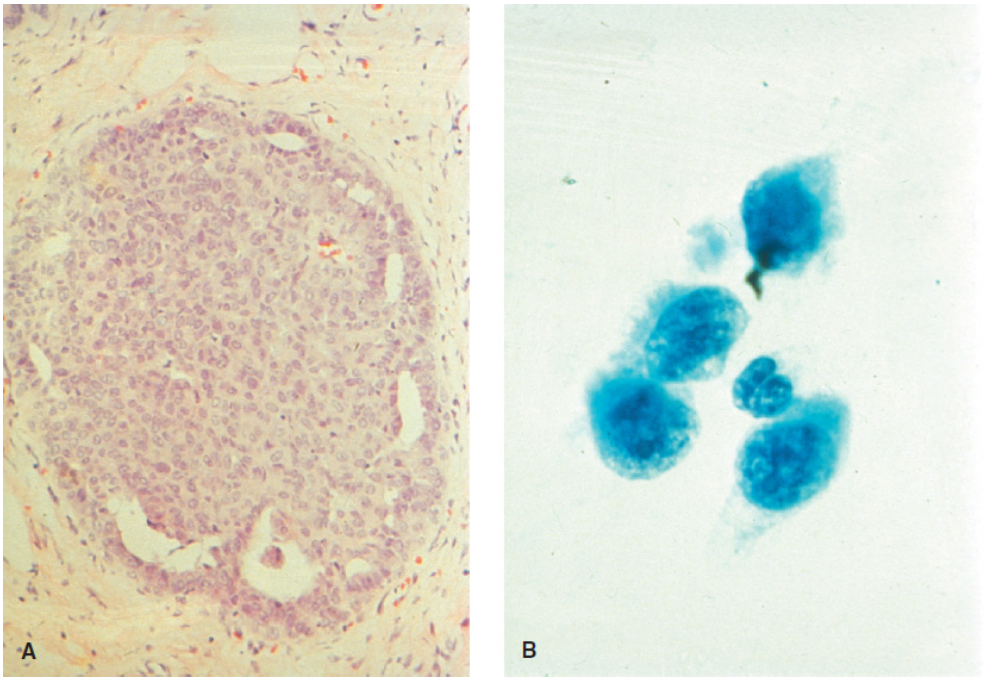

Figure 74.9 Comparison of core needle biopsy specimen (**A**) and fineneedle aspiration specimen (**B**). Only the core specimen can demonstrate the architectural detail.

Biopsy Procedures

Breast biopsy is one of the most common general surgery procedures performed in the United States. There are multiple different types of breast biopsy ranging from fine-needle aspiration (FNA) biopsy to excisional biopsy. The different types of breast biopsy are discussed below.

Fine-Needle Aspiration (FNA)

Fine-needle aspiration of the breast is the least invasive breast biopsy procedure. FNA can be used for both diagnosis and treatment, and can be performed using palpation or image guidance. FNA is commonly used to sample suspicious breast and axillary lesions especially those that are palpable. Other indications include drainage of simple cysts, and small abscesses. In institutions with experienced cytopathologists, diagnostic FNA has a reported sensitivity of 98% and a specificity of 97%.[47] However, as

the tissue architecture cannot be evaluated by FNA, a definitive diagnosis of invasive cancer cannot be made. In the past, FNA was commonly used to sample palpable breast masses as part of the Triple Test for evaluation of palpable masses. Currently, ultrasound can more accurately assess these lesions and low-suspicion lesions are followed with serial imaging. High-suspicion lesions are best sampled by core needle biopsy to allow assessment of tissue architecture (Fig. 74.9).

Core Needle Biopsy

2 Core needle biopsy is also a minimally invasive strategy for breast biopsy. Given the limitations of FNA, core needle biopsy allows for more tissue to be sampled, permitting a histologic diagnosis, and offering the ability to discriminate between invasive and noninvasive breast cancer. Core needle biopsy can be performed by palpation, but ultrasound-guided core needle biopsy typically offers superior results. Ultrasound imaging and patient preparation are similar to that described for patients undergoing FNA.

For nonpalpable lesions that cannot be imaged by ultrasound but are present on mammography (most commonly microcalcifications), stereotactic core biopsy can be performed. Stereotactic techniques use the principle of triangulation, which allows the precise location of a breast lesion to be determined in three dimensions.[48] The patient can be upright or prone depending on the machine. More commonly, the patient is placed in the prone position on the stereotactic table, which has an opening for the breast. A mammography unit is attached beneath the table and compresses the dependent breast. An initial scout image is obtained perpendicular to the compressed breast and evaluated. Following biopsy, repeat images are obtained to ensure the area of concern has been adequately biopsied. The procedure may be repeated to obtain additional cores. Most stereotactic core biopsies are performed with vacuum assistance allowing for greater accuracy. If suspicious microcalcifications are biopsied, the samples can be examined with specimen imaging to ensure the presence of microcalcifications within the biopsy samples.

Failure to obtain an adequate sample can result in a false-negative diagnosis, although the false-negative rate is very low. In some instances the

results of the core biopsy may not be definitive and a surgical excision is required. If the core biopsy demonstrates atypical ductal hyperplasia (ADH), atypical lobular hyperplasia (ALH), radial scar, or lobular carcinoma in situ (LCIS) surgical excision is required to exclude a diagnosis of malignancy. In the clinical context of persistent suspicious physical or imaging abnormalities (discordance between clinical and/or imaging findings and pathology results), surgical excision is required. Please see Table 74.2 for indications for surgical excision after core biopsy.

Incisional Biopsy

Incisional biopsy typically involves surgical removal of part of a large mass for diagnosis. With the advent of core needle biopsy techniques, incisional biopsy is rarely required. However, if a core needle biopsy is nondiagnostic and the mass is too large to remove without significant cosmetic compromise, an incisional biopsy can be performed for definitive diagnosis.

INDICATIONS/CONTRAINDICATIONS

Table 74.2 Indications for Surgical Biopsy after Core Biopsy

- Atypical ductal hyperplasia
- Radial scar
- Columnar cell hyperplasia with atypia
- Papillary lesions
- Lack of concordance between appearance of mammographic lesion and histologic diagnosis
- Nondiagnostic specimen (including absence of calcifications on specimen radiograph when biopsy is performed for calcifications)

Excisional Biopsy

Excisional biopsy of the breast is the surgical removal of a breast lesion. Although core needle biopsy has largely obviated the need for excisional biopsy for diagnostic considerations, indications for this procedure still remain. Indications include breast lesions that are presumed to be benign but require excision, discordance between clinical evaluation/diagnostic imaging and pathology requiring further tissue sampling, high-risk lesions

(including atypical hyperplasia, radial scar, papilloma, LCIS) identified on core biopsy, abnormalities that are close to the nipple or chest wall, small breasts that are not amenable to core biopsy (given the needle excursion is often 2 cm), and for patients who cannot tolerate stereotactic core needle biopsy. In addition, excisional biopsy may be considered for complex cysts, aspirated cysts that do not completely resolve, and when follow-up imaging for a lesion with previous benign pathology from a core biopsy shows an increase in size or has suspicious changes. Excisional biopsies may also be performed for likely benign lesions that are greater than 2 cm, painful, or recurring, or where the mass represents growing cysts or fibroadenomas. Patient preference for complete removal of a benign lesion may also be an indication for excisional biopsy.

For nonpalpable lesions, the abnormality can be localized preoperatively using a needle localization wire that is placed with the patient in a sitting position with the breast compressed by a labeled grid plate. Various needles used include the Kopans needle (checkmark wire), the Hawkins needle (multiple barbs and the only retractable wire for repositioning), and the Homer needle (J wire and nontransectable needle). For lesions that are superficial and can be readily imaged by ultrasound, needle localization can be performed under ultrasound guidance. Alternatively, there are other localization techniques including radioactive seeds, magnetic seeds, and radar seeds. There are additional methods in development. The patient is then taken to the operative setting, where excision of the lesion can be performed under local anesthesia (mixture of short- and long-acting anesthetics with epinephrine) with sedation or general anesthesia. In the operating room, the patient is placed in the supine position with the arm ipsilateral to the index lesion positioned at 90 degrees. Appropriate padding of the arm and wrists should be undertaken. The operative site is then prepped and draped in a sterile fashion. Intraoperative localization is performed by evaluating the imaging studies and palpating the needle (for nonpalpable lesions) or by direct palpation. For lesions located in the upper half of the breast, transverse or curvilinear incisions are made along Langer lines. If an incision is needed in the lower half of the breast, radial incisions are used. When possible, periareolar or inframammary incisions are made as they result in the best cosmesis. Prior to incision, an anesthetic of short- and long-acting local anesthesia with epinephrine is injected into the skin and

along the path of the needle localization wire. The incision is then typically made directly above the palpable mass or the tip of the needle (Fig. 74.10). Alternatively, an incision can be made next to the needle and then followed down to its tip to find the target lesion. Once the skin incision is made, the thickest possible flaps, which would still result in fully removing the lesion anteriorly, are developed. The specimen is then excised with electrocautery. The specimen is oriented with sutures, with the short stitch designating the superior margin and the long stitch designating the lateral margin. Palpation of the cavity is performed to ensure complete removal of the lesion. Specimen imaging is performed to confirm excision of the lesion of interest. Hemostasis is then achieved with electrocautery and the cavity is irrigated with saline. The cavity is examined again to confirm hemostasis. The skin is closed in two layers. The dermis is reapproximated with interrupted sutures of 3-0 vicryl and the skin is closed with a subcuticular running stitch of 4-0 monocryl. Cyanoacrylate tissue adhesive is then applied, allowing the patient to take a shower within 24 hours. For allergies to skin glue, adhesive strips can be applied. No pressure dressing is needed. A sports bra may be worn to stabilize the breast for the first 48 hours.

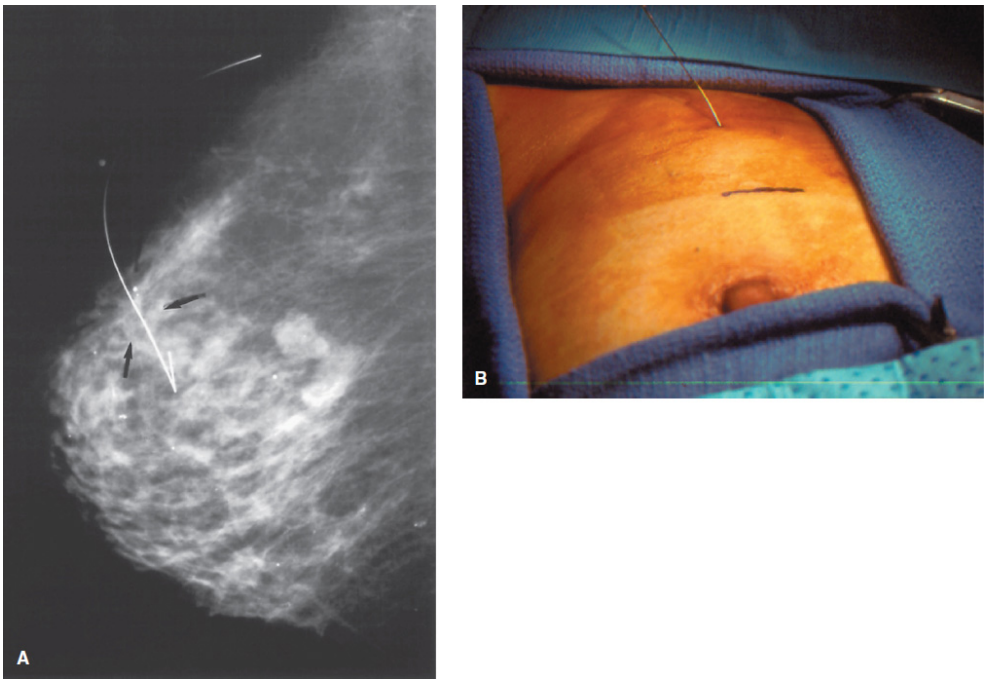

Figure 74.10 Incision placement for needle localization biopsy. **A:** The mammogram demonstrates that the lesion (*arrow*) is inferior to the point of wire entry. **B:** Incision placement inferior to wire entry to allow access to the lesion.

Skin Punch Biopsy

For any suspicious cutaneous lesion of the breast or chest wall, a biopsy can be obtained using a punch biopsy device, which consists of a circular blade. Punch biopsy devices are available in various sizes ranging from 1 mm to 8 mm, with the 4-mm size most commonly used in breast biopsies. The area to be biopsied is first selected. Common sites are the most abnormal-appearing site within a lesion or the edge of an actively growing lesion. The involved skin is cleansed and infiltrated with 2 to 3 mL of 1% lidocaine. The punch device is held vertically over the skin and rotated downward using a twirling motion until the subcutaneous fat or the hub of the device is reached. The specimen is then transected at the base with iris scissors. The skin is approximated with an interrupted stitch or U-stitch of 4-0 monocryl.

COMMON CLINICAL PROBLEMS AND MANAGEMENT ALGORITHMS

The most common clinical breast problems include breast masses, breast pain, nipple discharge, and breast infections. Clinical algorithms for the evaluation of these common breast problems have been developed to facilitate optimal care.

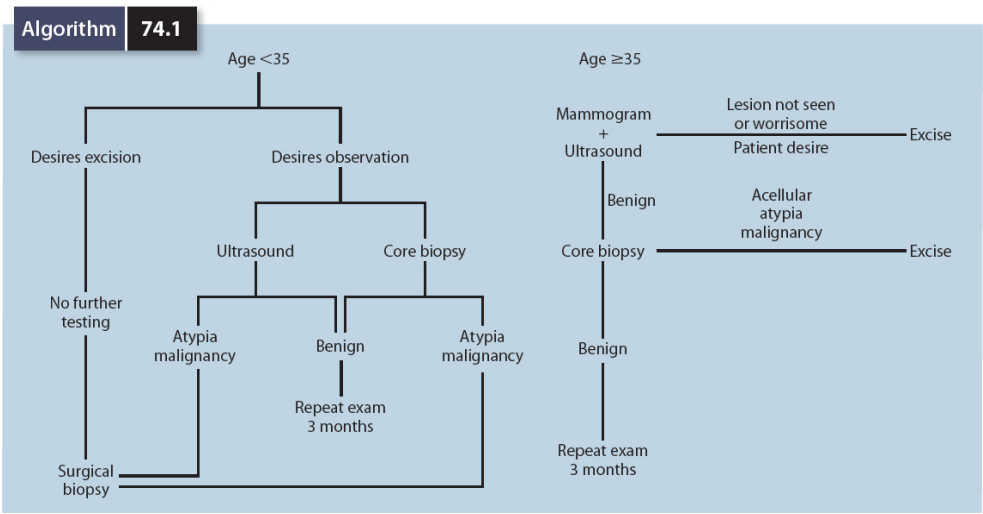
Breast Mass

A breast mass is defined as a palpable area in the breast that may be either benign or malignant. When a woman presents with a palpable breast finding, a thorough history and physical examination needs to be performed. The history should include a thorough review of the patient's medical problems and any risk factors associated with breast cancer (see ***Management of Patients at High Risk for Breast Cancer***).

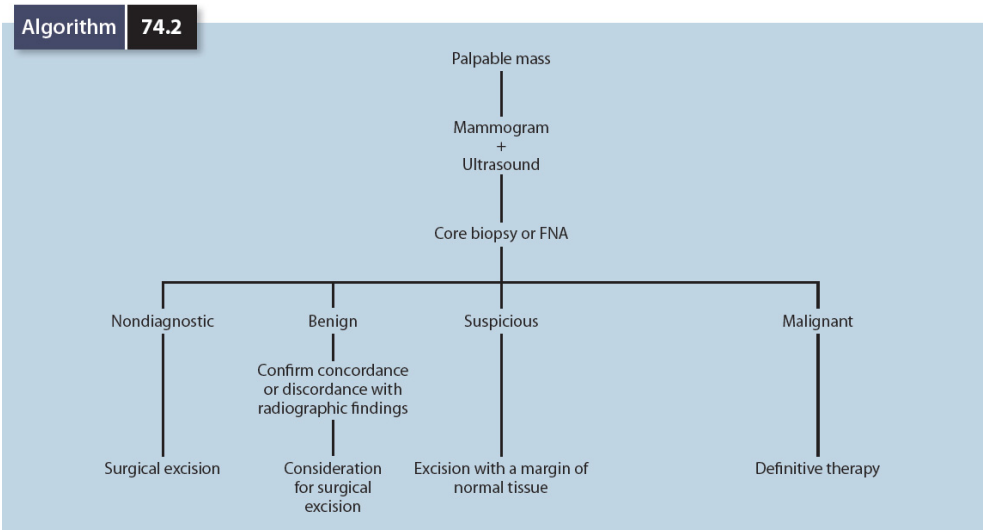
In women less than 40 years old with no family history of premenopausal breast cancer or other risk factors, a targeted ultrasound is an appropriate initial imaging approach for a breast mass that appears clinically benign (Algorithm 74.1). The ultrasound is used to determine if a dominant mass is indeed present, as normal glandular tissue of the breast, especially in young

women, may feel nodular. In a review of 605 women younger than 40 years of age who were referred for evaluation of a breast mass, only 36% of the masses detected by patients had a surgical correlate. Furthermore, only 29% of the masses detected by primary care providers were confirmed.[49] Consideration can then be made regarding the need for additional imaging such as mammography or an MRI. In women aged 40 or older, the initial imaging approach to a palpable mass should include a mammogram and ultrasound. These studies should be obtained prior to any biopsies are performed as post-biopsy changes can distort subsequent imaging evaluation. Of note, all clinically suspicious palpable masses need to be biopsied even in the absence of imaging findings as 15% of breast cancers can be mammographically occult (Algorithm 74.2).[44] Ultrasound also provides important information about the etiology of a breast mass, and can further categorize the mass as either cystic or solid. Workup of a cystic lesion typically involves aspiration of the cyst, with further evaluation based on the results of the aspiration (Algorithm 74.3). The definitive diagnosis of a breast mass is often confirmed by a core needle biopsy, although FNA is an appropriate alternative (Table 74.3). Core needle biopsy is typically preferred to excisional biopsy.

Breast cysts are common causes of dominant masses in premenopausal and perimenopausal women. If a cyst is found in a postmenopausal woman in the absence of hormone therapy use, it should be regarded with a high degree of suspicion. Palpable masses that present as benign solid masses include fibroadenomas, fibrocystic disease, and fat necrosis. Fibrocystic breast disease has been used to describe a variety of benign breast disorders associated with nodular breast tissue. This term, however, should be reserved for women who have a biopsy consistent with one of the histologic components of fibrocystic change. Breast surgery, blunt trauma, injection of native or foreign substance such as fat and silicone, and radiation therapy can result in fat necrosis. On clinical exam and mammographic imaging, fat necrosis can mimic a malignancy, often leading to a biopsy. However, when oil cysts, which are circumscribed masses of mixed soft tissue density and fat with a calcified rim, are present radiographically, a definitive diagnosis of fat necrosis can be made (Fig. 74.11). Please see the section ***Benign Breast Disease***.



Algorithm 74.1 Diagnosis and management of the patient with a clinically benign breast mass. The use of imaging studies varies according to age because breast carcinoma is infrequent in women younger than 35 years old.



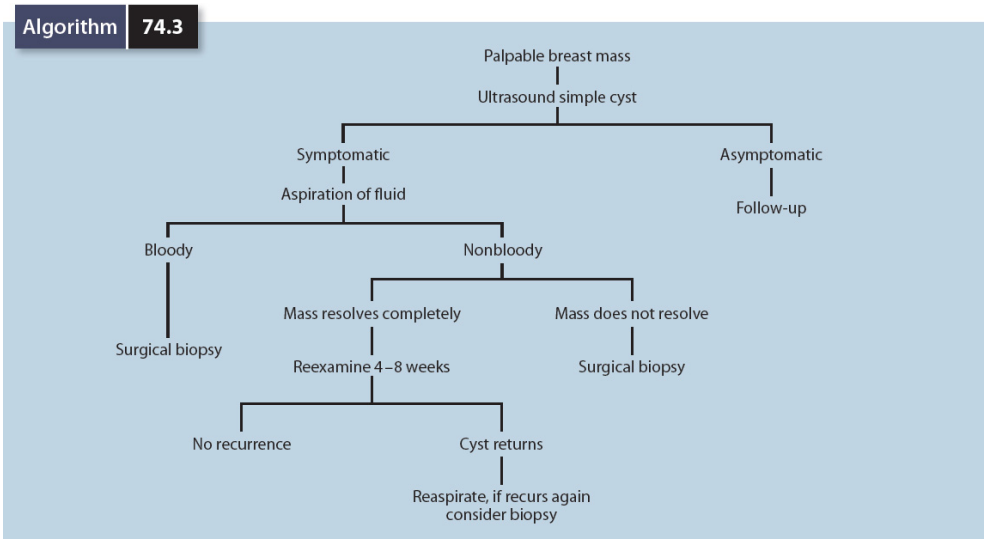
Algorithm 74.2 Diagnosis and management of the patient with a clinically indeterminate or suspicious solid breast mass. In this circumstance, imaging studies are insufficient to exclude malignancy, and tissue sampling is required.

Breast Pain

Breast pain (mastalgia, mastodynia, idiopathic breast pain) is a common concern and is rarely (0.5% to 3.3%) representative of a breast cancer. It is noted that some IBCs can present with pain. While two-thirds of patients present with cyclical breast pain, another one-third has pain that is unrelated

to the menstrual cycle and more likely to be secondary to a breast or chest wall lesion.[50]

Cyclical breast pain is associated with hormonal changes during the menstrual cycle and often occurs the week prior to the onset of menses and often dissipates once menstrual flow is established. During the menstrual cycle, the breast undergoes significant histologic changes as described by Vogel (see ***Menstrual Cycle***).[51] During the secretory phase, luminal cells produce apocrine secretions and the stromal cells become edematous, which may contribute to the pathogenesis of breast pain. However, the exact physiologic events are not understood completely. Furthermore, while most women do experience mild cyclical breast pain, it is not clear why others have more pronounced pain. Cyclical breast pain is typically bilateral and involves the upper outer aspect of the breasts with radiation to the axillae or down the arms.



Algorithm 74.3 Diagnosis and management of the patient with a cystic lesion. Bloody fluid on aspiration, failure of the mass to resolve completely, and prompt refilling of the same cyst are indications for surgical biopsy.

Table 74.3 Management of Breast Masses Based on Core Biopsy Diagnosis

FNA Diagnosis	Treatment
Malignant	Definitive therapy
Suspicious	Surgical biopsy
Atypia	Surgical biopsy
Benign	Possible observation[a]
Nondiagnostic	Surgical biopsy

[a]See discussion in text on clinical approach to the patient with a solid breast mass.

Noncyclical breast pain is more frequently unilateral and variable in its location in the breast. Possible etiologies include large pendulous breasts with pain resulting from stretching of the Cooper ligaments, duct ectasia, macrocysts, medications (including antidepressants, hormones and antibiotics), and infections.[52,53] Thrombophlebitis of the lateral thoracic or superior thoracoepigastric vein (Mondor disease) is an uncommon presentation for breast pain characterized by a tender subcutaneous cord in the lateral aspect of the breast (Fig. 74.12). Mondor disease may result from trauma, radiation to the breast, and/or breast surgery. It can also occur in women with nonpalpable breast cancers, and a mammogram should be obtained when diagnosed.[54] For symptomatic relief, a patient can use anti-inflammatory medications, although Mondor disease often resolves spontaneously without the need for a specific therapy. Referred pain to the breast from the chest wall or ribs can also occur. Spinal or paraspinal problems and medical conditions (biliary, pulmonary, esophageal, and cardiac disease) can also result in referred pain.

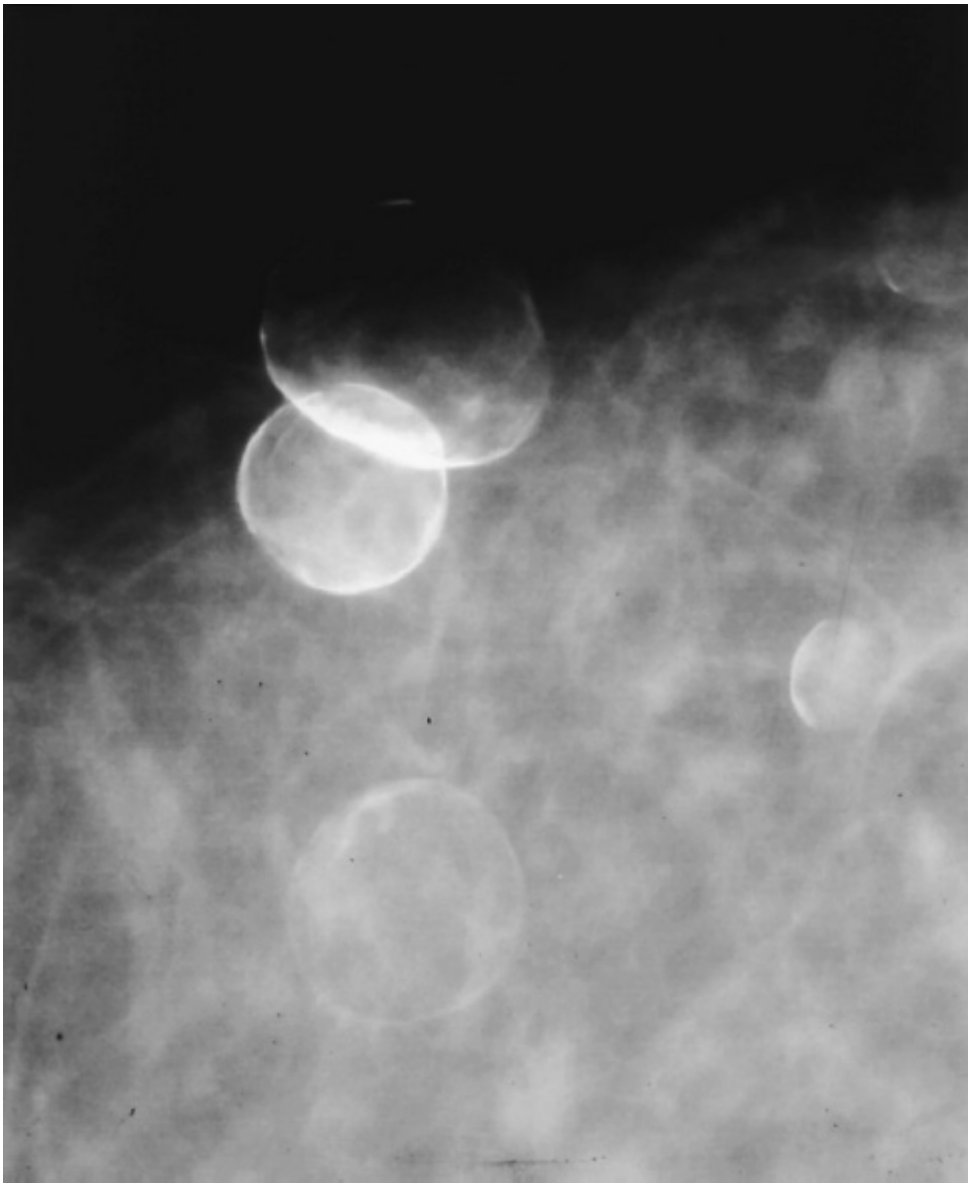


Figure 74.11 Oil cysts. The calcified rims of these cysts in a patient with a history of trauma are diagnostic.

Figure 74.12 Mondor disease. Thrombophlebitis of the thoracoepigastric vein causes retraction of the lateral portion of the breast, which crosses to the midline at the inferior areolar margin and is accompanied by a palpable cord.

The workup for breast pain should include a careful history, including questions related to the menstrual cycle, a thorough physical examination, and in women 35 years and older, a mammogram. If a malignancy is suspected, biopsy should be performed. If the CBE and diagnostic imaging studies are normal, reassurance that the symptoms are not consistent with breast cancer often provides significant relief for the patient.

Initial therapy for idiopathic breast pain includes lifestyle changes, the use of supportive garments such as a well-fitting brassiere with a steel underwire, a low fat–high-carbohydrate diet, and elimination of caffeine and nicotine. Oral analgesics with acetaminophen or nonsteroidal anti-inflammatory drugs (NSAIDs) should be initiated. Topical analgesic gels containing diclofenac or salicylate can be applied to the affected breast areas. If a patient is on oral contraceptives or hormone replacement therapy, discontinuation of these medications may improve pain. However, in women not using oral contraceptives with cyclical breast symptoms, the initiation of

this therapy has been shown to reduce breast pain severity and duration. Although inconclusive evidence exists for the role of evening primrose oil (3,000 mg daily),[55,56] it is often part of the initial therapeutic approach. Evening primrose oil needs to be taken for at least 4 to 6 months to achieve a positive effect.

Approximately 5% of women will still have debilitating breast pain despite lifestyle changes and the initial therapies described above. For these women, therapies such as danazol, tamoxifen, bromocriptine, and GNRH agonists can be considered. However, only danazol has been approved by the FDA for the treatment of idiopathic breast pain. Danazol (100 mg to 400 mg daily) is an antigonadotropin that results in a hypoestrogenic state. However, its use is often discontinued as it also induces a hyperandrogenic state, with most women having side effects of increased facial hair, acne, deepening of the voice, and adverse blood lipid profiles.[57] Tamoxifen (10 mg daily) has also been shown to be effective although side effects, including the risk of blood clots, endometrial cancer, and hot flashes limit its use.[58] As both danazol and tamoxifen have significant teratogenic effects, women on these therapies must be counseled to use an effective birth control method. Although bromocriptine and GNRH agonists have been studied for use in breast pain, they are not currently recommended because of significant side effects. Therapies that have been proven to be ineffective include diuretics, progesterone, and vitamins. Surgery to excise trigger spots (in the absence of an identifiable lesion) is not recommended, as the affected area is often by a painful scar.

Nipple Discharge

Nipple discharge is a common breast symptom that often results in surgical consultation. The most common cause of pathologic nipple discharge is an intraductal papilloma, but breast cancer can also present as a pathologic nipple discharge. The first step in evaluation of nipple discharge is to determine whether the nipple discharge is pathologic or physiologic. Physiologic discharge is nonspontaneous or is elicited by manual compression of the nipple. It often involves multiple ductal orifices in the nipple and is present in both breasts. The discharge is commonly white or clear (although it can also present as yellow, green, brown, or gray fluid) and

is negative on occult blood test. In contrast, pathologic nipple discharge is spontaneous, is present in a single breast/ductal orifice, and is often positive on occult blood test. However, any nipple discharge that is spontaneous is considered pathologic. Age is also predictive of breast cancer risk in women with nipple discharge. In a study involving women with pathologic nipple discharge, breast cancer was present in 3% of women <40 years old, 10% in those 40 to 60 years old, and 32% in those over 60 years old.[59]

Clinical evaluation of nipple discharge includes a careful history and physical examination. The history includes questions regarding whether the discharge is spontaneous or elicited, unilateral or bilateral. The patient should be questioned regarding any recent trauma to the breast. The past medical history and medications are reviewed. Medications such as oral contraceptives, metoclopramide, phenothiazines, and selective serotonin reuptake inhibitors can be associated with nipple discharge. A premenopausal woman presenting with milky fluid discharge bilaterally or galactorrhea, should be evaluated for endocrine disease. Hypogonadism as suggested by amenorrhea or hot flashes/vaginal dryness should prompt a workup for hyperprolactinemia. In addition, hypothyroidism, pituitary adenoma and chest trauma (including thoracotomy) can result in galactorrhea. When endocrine disease is suspected, patients should undergo laboratory evaluation including quantitative hCG, prolactin level, and thyroid function tests. The physical examination should include a visual field test as often these patients may show signs of bitemporal field loss or chiasmal syndrome. A careful breast examination is performed to evaluate for any dominant masses, skin changes such as eczema/infections, nipple changes such as Paget disease, or adenopathy. Each of the quadrants of the involved breast is massaged from the periphery to the nipple areolar complex and then pressure is applied to the base of the nipple areolar complex to elicit discharge. This will help define the involved quadrant of the breast and whether the discharge is from a single ductal orifice. The color of any nipple discharge should be noted, and an occult blood test should be performed.

After initial evaluation, no further workup is required in women who have physiologic discharge, and these women should be advised to avoid manual compression of the nipples.

Imaging evaluation is indicated for patients with pathologic nipple discharge and includes an ultrasound, and for patients >30 years old, a

mammogram is also recommended. In patients with an imaging abnormality, a biopsy should be considered. Additional diagnostic tests that may be helpful include ductography and ductoscopy. Ductography is performed by instilling contrast medium into the involved duct to identify any lesions in the ductal system. Lesions will appear as either a complete ductal obstruction, irregularities in the duct wall, or as an intraductal filling defect (Fig. 74.13). However, the absence of a lesion on ductography does not rule out a cancer.[60] Ductoscopy is often performed in the operating room and involves the use of a small fiberoptic ductoscope that is placed into the involved duct. The benefit of ductoscopy is that it allows for direct visualization of any potential lesions, which may result in more precise excision.

The most common etiology of pathologic nipple discharge is a papilloma, which is a benign epithelial lesion with supporting stroma that grows within a duct. When a papilloma is diagnosed by core biopsy, the standard recommendation is to proceed with surgical excision as it may be associated with atypia or ductal carcinoma in situ. Other causes for pathologic nipple discharge include malignancy (most commonly DCIS, 5% to 15% of cases), and ductal ectasia, which is characterized by ductal dilatation with loss of elastin in the duct walls and the presence of chronic inflammatory cells. It is not known however, whether the inflammatory cells result from a primary or secondary infection and antibiotics are not recommended.

If a malignancy is identified as the etiology of a pathologic nipple discharge, it should be managed accordingly, with appropriate cancer surgery typically the first treatment. In the absence of a known malignancy, pathologic nipple discharge should be treated with terminal duct excision. Prior to excision, the patient should refrain from any nipple stimulation. If the involved duct can be identified intraoperatively, a lacrimal duct or instillation of methylene blue may aid with the ductal excision. Terminal duct excision is commonly performed with a circumareolar incision and involves removal of the duct from its proximal to distal extent, which is often a distance of 2 to 3 cm. Alternatively, ductoscopy can be performed as previously prescribed and then the outer sheath of the cannula can be left in place as a guide for surgical excision of the involved duct. If there is difficulty isolating the involved duct or multiple ducts are involved, central or total terminal duct excision may be indicated. The potential risks of

terminal duct excision include inability to breastfeed and hyposensitivity or hypersensitivity of the nipple.

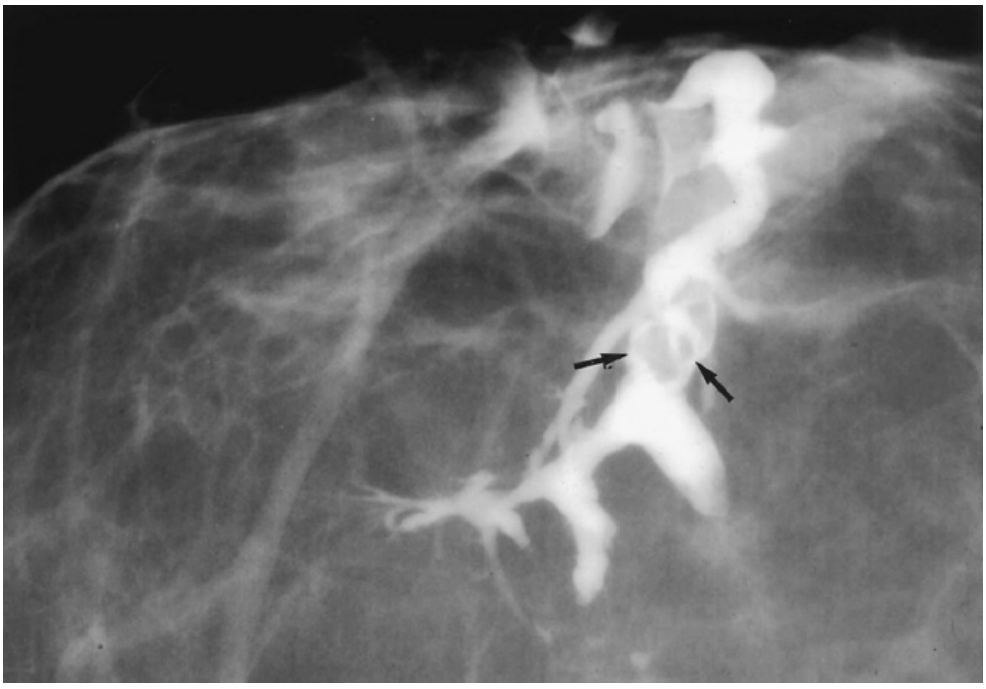

Figure 74.13 Ductogram. A large defect (*arrows*) represents an intraductal papilloma.

Breast Infections

Breast infections are less common outside of the postpartum period. As such, breast infections can be classified as lactating or nonlactating infections. Lactating infections occur commonly during the initial 6 weeks of breastfeeding and during the process of weaning. In the initial stages of infection, a mastitis or cellulitis is typically found, with associated pain, erythema, induration, and fever. A woman should not be counseled to discontinue breastfeeding. Commonly the cellulitis results from *Staphylococcus aureus*. Treatment includes pain management (acetaminophen, NSAIDs) and an antibiotic such as dicloxacillin. Alternative antibiotics include cephalexin and erythromycin. The mastitis should improve within 24 to 48 hours after initiation of antibiotics. If symptoms or fever persists, an abscess should be ruled out. For small or superficial abscesses, needle aspiration may be attempted. However,

incision and drainage should be considered for large or complex abscesses, understanding the risks associated with milk fistula formation.

Nonlactating breast infections can present as periareolar abscesses or less commonly as peripheral abscesses. For small or moderate size abscesses, needle aspiration is the first line of treatment and a drain can be placed if indicated. However for larger and/or deeper abscesses, incision and drainage may be indicated. This is commonly performed in the operating room under general anesthesia, although if the anterior aspect of the abscess is close to the skin it may be possible to perform the incision and drainage at the bedside with infiltration of a local anesthetic. A preoperative ultrasound can be obtained to better evaluate the size and location of the abscess. Often the abscess is not located directly under the area of greatest erythema, and careful breast examination should be performed to localize the area of greatest fluctuance. *Biopsy of the cavity should always be considered, as breast infection may be an unusual breast cancer presentation.* For a subareolar abscess, removal of the sinus tract as well as the segmental duct should be considered. Antibiotics, such as cephalexin 500 mg QID, are commonly prescribed for 7 to 10 days postoperatively, although once a wound is properly drained and cellulitis subsides, the patient can discontinue all antibiotics. For chronic subareolar abscesses, it may be necessary to completely excise the involved duct.

In the setting of recurrent or persistent abscess formation or inflammatory changes despite adequate surgical management, other etiologies need to be considered including idiopathic granulomatous mastitis, Wegener granuloma, sarcoidosis, tuberculosis, and histoplasmosis.

BENIGN BREAST DISEASE

Benign breast lesions can be classified into three groups: (1) nonproliferative breast lesions, (2) proliferative breast lesions without atypia, and (3) proliferative breast lesions with atypia (Table 74.4).

Table 74.4 Classification of Benign Breast Disease

Nonproliferative: No Increase In Risk
Cysts: micro or macro
Ductal ectasia
Simple fibroadenoma
Mastitis
Fibrosis
Metaplasia: squamous or apocrine
Mild hyperplasia
Proliferative: RR 1.5–2.0
Complex fibroadenoma
Papilloma
Sclerosing adenosis
Hyperplasia: moderate or severe
Proliferative with Atypia: RR 4.5–5.0
Atypical ductal hyperplasia
Atypical lobular hyperplasia

RR, relative risk.

Nonproliferative Breast Lesions

Nonproliferative breast lesions include breast cysts, papillary apocrine change, epithelial-related calcifications, and mild hyperplasia of the usual type. These lesions are not associated with an increased risk of breast cancer.[61] Papillary apocrine change is characterized by proliferation of ductal epithelial cells showing apocrine features and has eosinophilic cytoplasm. Benign calcifications found in normal ducts, lobules, breast stroma, and blood vessel walls are referred to as epithelial-related calcifications. Mild hyperplasia of the usual type occurs when the number of epithelial cells within a duct is more than two but not more than four cells in depth, and the epithelial cells do not cross the lumen of the involved space.[62]

The most common nonproliferative lesions of the breast are cysts, which often present clinically as solitary masses that can be associated with pain. They are fluid-filled round or ovoid structures arising from the terminal duct lobular unit when fluid accumulates because of distension and obstruction of the efferent ductule.[63] Given that cysts arise from lobular pathology, they occur mainly during lobular development, menstrual cyclic changes, and lobular involution in pre- and postmenopausal women, with peak incidence between 35 and 50 years of age.[64,65]

The three types of cysts are simple, complicated, and complex. Simple cysts are well circumscribed and on ultrasound have posterior acoustic enhancement. In addition they are anechoic and do not have solid components or Doppler signals. If simple cysts are diagnosed by ultrasound, they are by definition benign and do not require further intervention, although cyst aspiration can be performed if the patient is symptomatic. Alternatively, FNA can also be used to diagnose simple cysts. If the aspirated fluid is nonbloody and the palpable mass completely resolves this is also diagnostic of a simple cyst and no further diagnostic evaluation is required. A follow-up CBE +/– ultrasound can be performed in 3 to 6 months to document stability and the patient may resume routine breast cancer screening.

Unlike simple cysts which are not associated with malignancy, complicated and complex breast cysts are associated with malignancy in <1% and 1% to 23% respectively.[66–68] On ultrasound, complicated cysts appear as masses with homogenous low-level internal echoes due to echogenic debris. However, there are no solid components, thick walls, or thick septa. Complex cysts are defined as cysts with solid components, thick walls, or thick septa. Complex cysts are characterized on ultrasound by the absence of posterior wall enhancement and the appearance of anechoic and echogenic components. Complicated cysts can be confirmed as benign by biopsy, either through FNA, core biopsy, or excisional biopsy. Alternatively, ultrasound imaging and mammography (if the lesion was visualized on mammography) with CBE every 6 months for 2 years can be performed to document stability. If complicated cysts develop any concerning changes such as an increase in size or development of a solid component, biopsy should be performed per consensus guidelines. Complex cysts mandate biopsy. If no fluid is aspirated by FNA, then core biopsy under image guidance should be performed with care to biopsy the solid component. A metallic clip marking

the biopsy site facilitates surgical excision if necessary and facilitates follow up imaging. If pathology is concordant with imaging findings, then follow up with CBE and ultrasound imaging every 6 to 12 months for 1 to 2 years can be performed to document stability. For any concerning changes in the appearance of the lesion or increase in size, excisional biopsy should be performed. In patients that may be noncompliant with follow-up care, surgical excision should be considered for complicated and complex breast cysts per consensus guidelines.

Proliferative Breast Lesions without Atypia

Proliferative breast lesions without atypia include ductal hyperplasia, intraductal papillomas, sclerosing adenosis, radial scars, and fibroadenomas. Ductal hyperplasia is often an incidental finding noted on biopsies obtained for mammographic abnormalities or for breast masses. Ductal hyperplasia is characterized by an increased number of cells within the ductal space, however the cells retain the cytological features of benign cells. Ductal hyperplasia is not associated with a significant risk for subsequent breast cancer and no additional treatment is necessary.[62,70] Women with intraductal papillomas often present with pathologic nipple discharge (see section on ***Nipple Discharge*** above). These lesions consist of a monotonous array of papillary cells that grow from the wall of a duct or cyst into its lumen. Given that intraductal papillomas can harbor areas of atypia or ductal carcinoma in situ (DCIS), surgical excision is recommended when intraductal papillomas are diagnosed by core needle biopsy. If no atypia or DCIS is found at the time of excision, then no further treatment is necessary.[71–75] Sclerosing adenosis typically presents as a mammographic abnormality or a mass and requires no further treatment following biopsy, as it is a benign lobular lesion resulting from increased fibrous tissue and interspersed glandular cells.[76,77] Complex sclerosing lesions or radial scars are often found incidentally when a breast mass or radiologic abnormality is biopsied or excised. These lesions are characterized by a fibroelastic core with radiating ducts and lobules, and radial scars can appear spiculated on mammography.[78] When diagnosed on core biopsy, radial scars should be excised as 8% to 17% are associated with malignancy at surgical excision.[79–81] If the surgical excisional confirms a radial scar, no additional treatment is needed.

Fibroadenomas typically present as well-circumscribed mobile masses that are not fixed to the surrounding breast tissue. They are benign solid tumors made of glandular as well as fibrous tissue, and are found most commonly in women between the ages of 15 and 35 years.[82] Fibroadenomas with benign imaging characteristics can be followed with serial CBE and ultrasound imaging to ensure stability. Alternatively, core needle biopsy can be performed to confirm the diagnosis. If a fibroadenoma is asymptomatic, surgical excision is not necessary. However, if the presumed fibroadenoma is symptomatic or increases in size, excision can be performed for symptomatic relief or to rule out a malignancy such as a phyllodes tumor.[83] Fibroadenomas that are associated with proliferative changes such as sclerosing adenosis, ductal epithelial hyperplasia, epithelial calcification, or papillary apocrine changes are referred to as complex fibroadenomas. Surgically excision of these lesions is often recommended to exclude a diagnosis of breast cancer,[84,85] although this is controversial as some advocate that these lesions can be followed similarly as simple fibroadenomas.[86]

A fibroadenoma that is greater than 10 cm in size is referred to as a giant fibroadenoma and excision is recommended, as these lesions are hard to differentiate from a phyllodes tumor.[62] Juvenile fibroadenomas occur in young women between the ages of 10 and 18 and can vary in size from 5 to 20 cm in diameter. Surgical excision is recommended as these lesions can be cosmetically distressing for the young patient and are difficult to differentiate from a phyllodes tumor, although risk to the prepubertal breast bud is a potential complication.[87]

Proliferative Breast Lesions with Atypia

Proliferative breast lesions with atypia include ADH, ALH, flat epithelial atypia (FEA), and LCIS. Although these lesions are not considered premalignant, they are associated with an increase in the patient's future risk of developing breast cancer (Fig. 74.14).

ADH is characterized by a proliferation of uniform epithelial cells with monomorphic round nuclei filling part, but not all, of the involved duct. ADH often presents as suspicious microcalcifications seen on mammography. In contrast, ALH is often an incidental finding found on breast biopsies

performed for other reasons, such as an abnormal mammogram or breast mass. ALH is characterized by a proliferation of monomorphic, evenly spaced, dyshesive cells filling part, but not all, of the involved lobule.[62] Atypical hyperplasias are associated with an increased risk of subsequent breast cancer (relative risk 3.7 to 5.3) in both the ipsilateral and contralateral breast.[88–92] Atypical hyperplasias are often diagnosed on core needle biopsy, and in this clinical context surgical excision is indicated to exclude a diagnosis of malignancy. Atypical hyperplasias are upgraded to DCIS or invasive breast cancer in 10% to 20% of cases. If the diagnosis of atypical hyperplasia is made by excisional biopsy and the area is adequately sampled, reexcision is not necessary or recommended. Instead, the patient should be counseled toward risk reduction strategies which include CBE every 6 to 12 months, annual screening mammography, and consideration for chemoprevention with a selective estrogen receptor modulator (SERM) or an aromatase inhibitor (AI) per consensus guidelines. In addition, the patient should be counseled to perform consistent breast self-examinations such that she will become familiar with her breasts and report changes promptly to her provider (please see the section on ***Management of Patients at High Risk for Breast Cancer*** below).

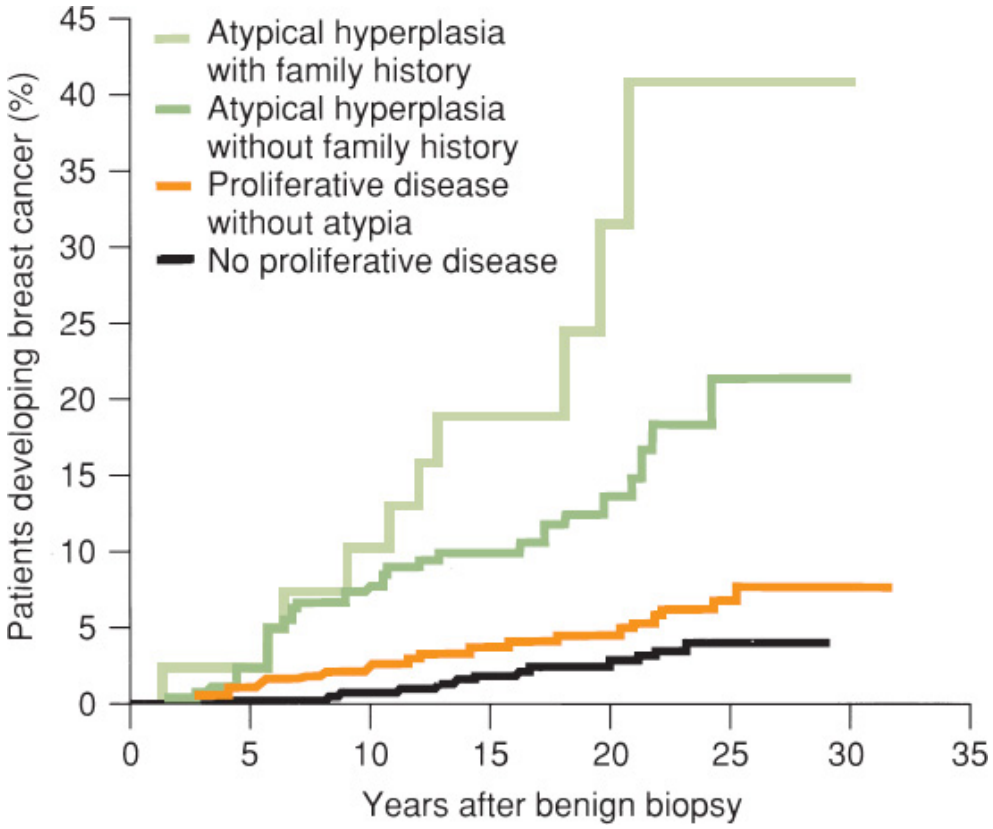

Figure 74.14 Cumulative risk for the development of invasive breast cancer after a biopsy for benign breast disease. Women with atypical hyperplasia (ductal or lobular type) are at a significantly increased risk for the development of breast cancer. (Reproduced with permission from Page DL, Dupont WD. Anatomic markers of human premalignancy and risk of breast cancer. *Cancer* 1990;66:1326.)

Lobular Carcinoma In Situ (LCIS)

LCIS is a noninvasive lesion that arises from the lobules and terminal ducts of the breast. It is characterized by solid proliferation of small cells, with small, uniform, round to oval nuclei, and variably distinct cell borders. The cytoplasm of the cells is clear to lightly eosinophilic and occasionally there are intracytoplasmic vacuoles that may be large enough to produce signet ring cell forms. LCIS tends to have a very low proliferative index and are estrogen-receptor positive.[93] LCIS is more prevalent in premenopausal women and white women.[94,95]

LCIS is often diagnosed as an incidental finding on a breast biopsy that has been performed for another reason, such as an 3 area of fibrocystic change or mammographic abnormality. If LCIS is identified on core biopsy, in the

past excisional biopsy was always recommended given the possible upgrade to DCIS or invasive cancer that was presumed to occur in 15% to 38% of patients.[96–100] However, more recently this risk of an upgrade to malignancy is found to be much lower at a rate of 1% to 3% if LCIS is found as an incidental finding on core biopsy.[101–105] As such, if radiographic and pathologic concordance exists, a possible alternative to surgical excision is imaging and clinical follow-up. If LCIS is found on excisional biopsy, no further surgical intervention is needed. However, if *pleomorphic* LCIS is identified at a surgical margin on excisional biopsy, wide excision with negative margins is recommended as pleomorphic LCIS can be hard to differentiate from DCIS.[106–108]

Although it is not a premalignant lesion, LCIS conveys a substantial increased risk for breast cancer. The relative risk of developing an invasive cancer in women with LCIS is approximately two to three folds higher than for women without LCIS (Table 74.5).[109] LCIS also conveys an increased risk for breast cancer to the contralateral breast. Historically, women diagnosed with LCIS were treated with bilateral prophylactic mastectomies. However this approach has been proven to be too aggressive given that *most* women with LCIS who do not have other contributory factors (e.g., family history of premenopausal breast cancer) will not develop an invasive breast cancer. Instead, a careful lifetime surveillance protocol similar to that described above for atypical hyperplasias can be followed. Chemoprevention with a SERM and/or AI can also be discussed with the patient. There are currently no randomized trials to compare the efficacy of surveillance protocol versus prophylactic mastectomy in women with LCIS.

FEA is an intraductal finding that is characterized by the replacement of native epithelial cells by a single layer, or up to three to five layers of mildly atypical cells (World Health Organization definition).[110] When diagnosed at core biopsy, the risk of upgrade to a malignancy at surgical excision is 5% to 15%.[111–113] When FEA is diagnosed by excisional biopsy, no further surgery is warranted. However, if FEA is diagnosed by core needle biopsy, excisional biopsy should be performed. Alternatively, radiologic surveillance can be performed and if there is absence of a residual mammographic abnormality and core biopsy was felt to be adequate, no further surgery is needed. Excisional biopsy must be performed for any residual lesions seen. When FEA is found at the margins, wider excision is

not needed.[111–114] Although FEA is an atypia, it conveys the same risk of breast cancer that is associated with benign proliferative disease without atypia and as such, patients should continue routine surveillance.[115] There is also no data to support the use of chemoprevention.

MANAGEMENT OF PATIENTS AT HIGH RISK FOR BREAST CANCER

Risk Factors

Breast cancer is the most common cancer in women in the United States. Approximately 200,000 women and 2,000 men are diagnosed with invasive breast cancer each year.[116] Breast cancer is the most common cancer in women of every major ethnic group, and the highest rate is among Caucasian women, with 122 newly diagnosed breast cancer cases per 100,000 women each year.[117] Understanding the risk factors for breast cancer is important, as some of these risks can be modified to decrease a patient's risk either through lifestyle/behavioral changes and/or the use of chemoprevention.

Increasing Age

As a woman ages, her risk for breast cancer increases: birth to age 49, 1.9% probability of developing invasive breast cancer (1 in 53); age 50 to 59, 2.3% (1 in 43); age 60 to 69, 3.5% (1 in 29); age 70 and older, 6.7% (1 in 15). From birth to death the probability of developing invasive breast cancer is 12.3% or 1 in 8.[116]

Estrogen Exposure

A woman's lifetime exposure to estrogens appears to correlate with her risk for breast cancer.[118] Exposure to estrogens can be approximated by age of first menarche, age of menopause, and age of first live birth, with nulliparous women who have an early menarche and a late menopause having the highest risk. Premenopausal women who undergo bilateral oophorectomy are at decreased risk. Given that high endogenous levels of estrogen is known to increase the risk of breast cancer in both premenopausal and postmenopausal

women, the use of exogenous hormones and their associated risk for breast cancer has been studied and debated. The use of hormonal contraceptives does not appear to significantly increase the risk of breast cancer.[119] However, the use of hormone replacement therapy in postmenopausal women has been associated with an increased risk of breast cancer as reported in the Women's Health Initiative Estrogen Alone and Estrogen-Plus-Progestin Studies, which were stopped early secondary to this and other concerns.[120] In the Estrogen-Plus-Progestin study, the HRT used was a combined estrogen-progestin therapy (EPT) that was given to postmenopausal women with an intact uterus. The risk of breast cancer is relatively low as EPT would result in an additional eight cases of breast cancer if 10,000 women took EPT for a year. More recently, it was determined that the rate of death from breast cancer among those taking EPT was 2.6 per 10,000 women per year, compared with 1.3 per 10,000 women per year among those taking placebo.[121] Short-term use of less than 3 years does not appear to significantly increase the risk of breast cancer and after the cessation of EPT use for 3 years a woman's risk returns to baseline.

RESULTS

Table 74.5 Risk for Breast Cancer Development after Lobular Carcinoma in Situ

[a]Includes intraductal and invasive cancer.

Given that lactation interrupts ovulation and modifies pituitary and ovarian hormone secretion, it has been postulated that breastfeeding can reduce breast cancer risk. This finding remains inconclusive. Limited data suggest that longer duration of lactation in premenopausal women may reduce risk.[122] A pooled analysis consisting of over 50,000 women with breast cancer and 96,000 controls concluded that for every 12 months of breastfeeding there was an associated 4.3% reduction in the relative risk of breast cancer.[123]

Environmental and Lifestyle Factors

Women who were subjected to ionizing radiation of the chest, such as for treatment of Hodgkin lymphoma or through exposure from nuclear plant accidents or the atomic bomb, have an increased risk of breast cancer. The prepuberty stage (age 10 to 14) appears to be the most vulnerable time for exposure, with little associated risk when exposure occurs after age of 45.[124–126] Alcohol use is associated with an increased risk of breast cancer and correlates with the amount of consumption, with differences noted with alcohol intake as low as three drinks per week versus those who abstain from alcohol. A meta-analysis of 110 studies shows a small but significant association (RR 1.05, 95% CI 1.02–1.08).[127,128] The relationship between cigarette use and breast cancer risk remains controversial because of unresolved issues of confounding and dose response, however a recent meta-analysis found that smoking before menarche and before the first birth was associated with an increased risk for breast cancer.[129] Furthermore, in women diagnosed with breast cancer, lifetime cigarette smoking (≥20 pack-years) was associated with an increased risk of recurrence and all-cause mortality.[130] The role of dietary factors such as fat intake, red meat and processed meat, phytoestrogens, calcium/vitamin D, and antioxidants in modifying breast cancer risk remains inconclusive. Regular physical exercise and a diet composed mainly of fruits and vegetables likely provide protection against breast cancer.

Family History

The number of first-degree relatives with breast cancer is strongly associated with a woman's risk for the future development of breast cancer. If one first-degree relative is affected, the risk of breast cancer increases by

approximately twofold, and if two first-degree relatives are affected, the risk of breast cancer is increased by approximately threefold. The age at diagnosis of the first-degree relative is also important, as a women's risk is approximately threefold higher when the diagnosis occurs before age 30 but only 1.5-fold higher if the diagnosis is after age 60.[131]

When evaluating family history, it is important to note that the majority of breast cancers are caused by sporadic mutations (mutations that occur in somatic cells that cannot be inherited). When studying the family tree of women with *sporadic breast cancer*, these women typically have no family history of breast cancer through two generations, including siblings, offspring, parents, and both maternal and paternal aunts, uncles, and grandparents. Less than 10% of breast cancers are hereditary. In families with *hereditary breast cancer*, the family tree is characterized by earlier onset of breast cancer, bilateral breast cancer, a greater frequency of primary cancers such as breast and ovary, and an autosomal dominant inheritance pattern (Fig. 74.15).[132] For women who have first- or second-degree relatives with breast cancer but do not meet the hereditary breast cancer definition noted above, these women have *familial breast cancer* where it is likely that both genetic and environmental factors play a role in their susceptibility.[131]

Most patients with hereditary breast cancer have mutations in the *BRCA1* or *BRCA2* genes which are localized to chromosome 17q21 and chromosome 13q12.3, respectively. Both serve as tumor suppressor genes and function as gatekeepers in controlling gene transcription, regulating repair of DNA damage (especially double strand breaks during cell replication), and may play a role in the maintenance of genomic stability.[133–135] Founder mutations exist in the Ashkenazi Jewish population with specific mutations in *BRCA1* (185delAG, 5382insC) and *BRCA2* (617delT).[136] Other BRCA-specific mutations have been identified in Dutch, Scandinavian, French-Canadian, and Belgian populations.[137,138]

The lifetime risk of breast cancer in *BRCA1* and *BRCA2* mutation carriers is estimated to be as high as 85%, which is markedly elevated from a baseline risk of 12% in the general population (Table 74.6). Ovarian cancer risk is higher in *BRCA1* carriers with an estimated risk of 40% to 60% whereas *BRCA2* carriers have a risk of 15%. Among male patients with breast cancer who have a *BRCA* mutation, one-third of mutations involve

BRCA1 and two-thirds involve *BRCA2*. The risk of breast cancer in males is 1% to 5% with a *BRCA1* mutation, and 5% to 10% with a *BRCA2* mutation, versus a risk of 0.1% in the general population.[139–141] In addition prostate and pancreatic cancer is more common in patients with *BRCA2* mutations.[142,143]

Several commercial tests exist for *BRCA1* and *BRCA2* testing. Prior to genetic testing, patients should undergo genetic counseling where the complexities of testing are discussed along with potential emotional and financial ramifications that can result from positive test results. Ideally, genetic testing should start with a family member affected with breast or ovarian cancer or both. If that individual tests negative, further testing on an unaffected relative is unlikely to be informative. Candidates for gene testing include those with a known *BRCA1* or *BRCA2* gene mutation in the family, a personal history of breast cancer at age 45 or younger, a personal history of breast cancer at age 50 or younger and a family member (parent, sibling, child, grandparent, grandchild, uncle, aunt, nephew, niece or first cousin) diagnosed with breast cancer at any age, a personal history of triple negative breast cancer (TNBC) diagnosed at age 60 or younger, a personal history of ovarian cancer, a personal or family history of male breast cancer, and Ashkenazi Jewish heritage and a personal or family history of breast or ovarian cancer per consensus guidelines. Once an individual tests positive for a mutation, she should inform her first- and second-degree relatives of their risk status and the potential for DNA testing.

Other breast cancer susceptibility genes include *p53*, *ATM*, *CDH1*, and *PTEN*. The Li-Fraumeni or SBLA syndrome corresponds with *p53* mutations and includes a broad spectrum of cancers including sarcoma, breast cancer and brain tumors, lung and laryngeal cancer, leukemia, lymphoma, an adrenal cortical carcinoma.[145] The *ATM* gene mutation results in a childhood neurologic disorder referred to as ataxia-telangiectasia which is characterized by progressive cerebellar and neuromotor deterioration, telangiectasia of the conjunctivae and facial skin, and growth retardation. Females with the *ATM* mutation have a five times higher risk for developing breast cancers than the general population.[146] Females with the *CDH1* or E-cadherin gene mutation have a 70% lifetime risk for diffuse gastric cancer and a 40% risk for lobular breast cancer.[147] Distinctive mucocutaneous lesions referred to as trichilemmomas characterize Cowden disease, which

is associated with an increased risk of breast, thyroid, and genitourinary tract cancers in women, resulting from the *PTEN* gene mutation.[148]

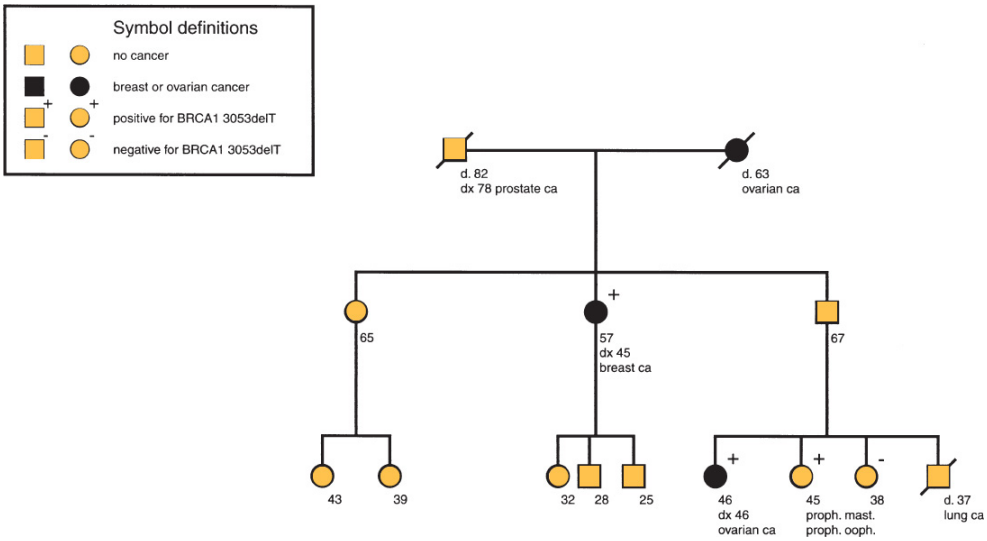

Figure 74.15 Pedigree of genetic breast cancer. The family illustrated in the pedigree carries a mutation of the BRCA1 gene; multiple relatives are affected with breast and ovarian cancer.

Clinical Risk Assessment

4 Through large population studies, numerous factors that can increase breast cancer risk have been identified as summarized in Table 74.7. In an effort to quantitate these potential risks such that preventive strategies can be better tailored, multiple risk assessment tools have been developed including the BCRAT or the Gail model 2,[149] BRCAPRO,[150] BOADICEA,[151] Tyrer–Cuzick,[152] and the Breast cancer surveillance consortium.[153] The Gail model calculates risk over a defined time interval and predicts risk accurately in groups of women 35 years of age and older who undergo annual mammography. The model is not for women who have a strong family history of breast cancer (such as genetic mutation carriers) or those with LCIS. The components of the Gail model include current age, age at menarche, age at time of first live birth, number of first-degree relatives with breast cancer, number of prior breast biopsies, prior breast biopsy with atypia, and race. A sample risk calculation is shown in Figure 74.16. Women are considered to be high-risk if their 5-year risk is >1.7%, or if their lifetime risk of breast cancer is at least 20%.

Management

All women at high risk for breast cancer should undergo genetic counseling, with education provided about the risk factors, genetics and natural history of breast cancer. These women should be followed with enhanced surveillance, and chemoprevention or prophylactic surgery should be considered. For women who have a genetic predisposition, such as those with a *BRCA1* or *BRCA2* mutation, many experts support aggressive surveillance including CBE biannually beginning at age 20, and annual mammography and MRI screening performed in a staggered fashion such that imaging occurs every 6 months starting at age 25. The use of screening MRI for women at high risk is supported by numerous studies. Prophylactic mastectomies can be considered at any age; many women prefer to defer this until after childbearing as they would like to breastfeed. Ovarian cancer screening for *BRCA1* and *BRCA2* carriers includes transvaginal ovarian ultrasound, serum CA-125, and annual pelvic exams starting at age 30. When childbearing is complete, prophylactic oophorectomies should be considered. In women with a family history but no known genetic abnormality, screening mammography should begin 10 years before the age of onset in the youngest diagnosed first-degree relative or at age 40. Furthermore, in the absence of a genetic abnormality, women who have a lifetime risk of breast cancer >20% should also be monitored with annual screening MRI.

Table 74.6 Estimated Lifetime Cancer Risks for BRCA1 and BRCA2 Mutations (To Age 70)

Type of Cancer	General Population (%)	BRCA1 Carrier (%)	BRCA2 Carrier (%)
Breast cancer	8.0	40–85	40–85
Contralateral breast cancer	0.5–1/yr	40–65	40–65
Male breast cancer	0.1	1–5	5–10
Ovarian cancer	1.4	30–45	10–20

Table 74.7 Magnitude of Known Breast Cancer Risk Factors

Relative Risk <2
Early menarche
Late menopause
Nulliparity
Proliferative benign disease
Obesity
Alcohol use
Hormone replacement therapy
Relative Risk 2–4
Age >35 first birth
First-degree relative with breast cancer
Radiation exposure
Prior breast cancer
Relative Risk >4
Gene mutation
Lobular carcinoma in situ
Atypical hyperplasia

In addition to its role in the treatment of breast cancer, endocrine therapy (chemoprevention) can reduce the risk of invasive and/or in situ breast cancers in women at high risk for breast cancer. Women who are known to benefit from chemoprevention include those >35 years with a history of LCIS, DCIS, or atypical proliferative lesions of the breast, women between 35 and 59 years with a Gail model risk of breast cancer >1.7% over 5 years, and women with known *BRCA1* or *BRCA2* mutations who do not undergo bilateral prophylactic mastectomies. Currently, there is no data regarding the risks and benefits of chemoprevention in male patients with breast cancer and as such, the use of these agents in men is not recommended.

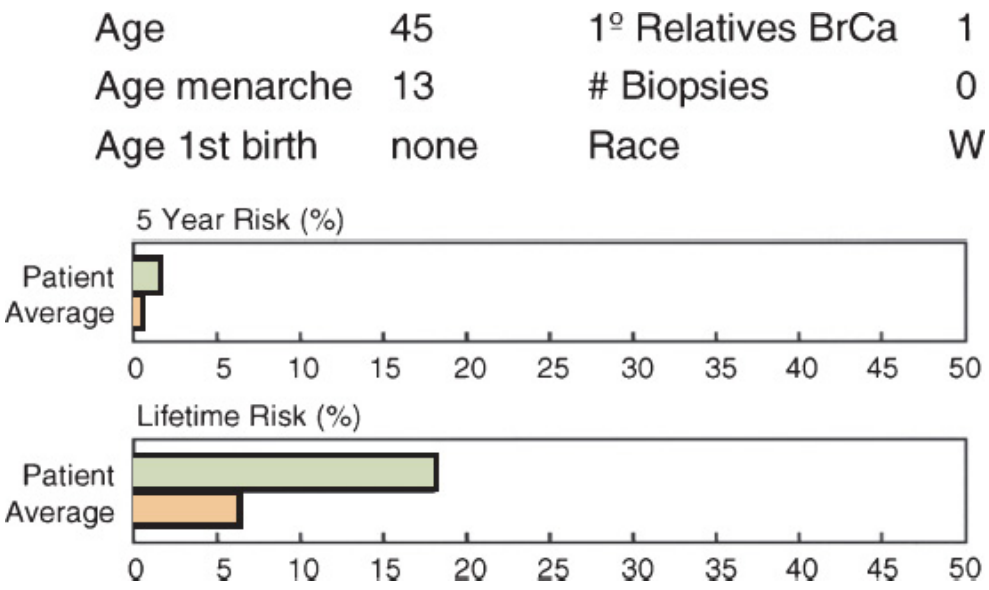

Figure 74.16 Breast cancer risk assessment according to the Gail model. This woman's 5-year risk for the development of breast cancer is 1.6%, and her lifetime risk is 18%.

For pre- and postmenopausal women at increased risk of breast cancer, both tamoxifen and raloxifene can be used. As SERMs, both agents block the effects of endogenous estrogen on normal breast tissue and breast cancer. Using data from four trials in the 2013 U.S. Preventive Services Task Force (USPSTF) meta-analysis, tamoxifen has been shown to reduce the risk of estrogen receptor-positive breast cancer (RR 0.70, 95% CI 0.59–0.82). Similarly, using data from two trials in the 2013 USPSTF meta-analysis, raloxifene reduced the risk of estrogen receptor-positive breast cancers (RR 0.44, 95% CI 0.27–0.71).[154,155] In terms of the choice between tamoxifen and raloxifene, the STAR trial directly compared tamoxifen with raloxifene and showed that the former was slightly more effective at preventing invasive breast cancer (Fig. 74.17). However, neither resulted in a reduction in breast cancer-specific, or all-cause mortality rates.[156]

Both tamoxifen and raloxifene have estrogenic activity on the bone resulting in a decreased incidence of fractures, while only tamoxifen has estrogenic activity on the uterus and coagulation pathways. Therefore, tamoxifen use is associated with an increased risk of endometrial cancer (4 cases in 1,000 women, RR 2.13, 95% CI 1.36–3.32) and thromboembolic events (4 cases in 1,000 women, RR 1.93, 95% CI 1.41–2.64),[154] with a trend toward higher stroke rates and pulmonary embolism.[157] Despite these

risks, quality of life measures (depression, anxiety, major psychosocial outcomes) show no differences in women receiving the drug versus placebo. However, an increase in vasomotor symptoms, gynecologic symptoms, and problems of sexual functioning was noted.[158,159] As congenital anomalies have been associated with tamoxifen, women with childbearing potential must implement an effective contraceptive method. For women desiring a pregnancy, tamoxifen should be discontinued for at least 2 months prior to attempt at pregnancy.

In postmenopausal women, studies show that aromatase inhibitors (AIs) are a reasonable alternative to tamoxifen and raloxifene. AIs suppress plasma estrogen levels by inhibition of aromatase, an enzyme that converts androgens to estrogens. Although AIs are commonly used for breast cancer treatment, they are not approved in the United States for breast cancer prevention at this time. Also, while both the USPSTF and ASCO support the use of SERMs for both premenopausal and postmenopausal women, only ASCO considers the use of exemestane as a reasonable alternative to SERMs for postmenopausal women.[160] More recently, the International Breast Cancer Intervention Study (IBIS-II trial) showed that high-risk postmenopausal women who took the AI anastrozole had a 50% reduction in the number of invasive breast cancers and DCIS compared to placebo. The side effects of anastrozole include musculoskeletal problems, hypertension, vaginal dryness, and vasomotor symptoms.[161] AIs may also be associated with a loss of bone density.

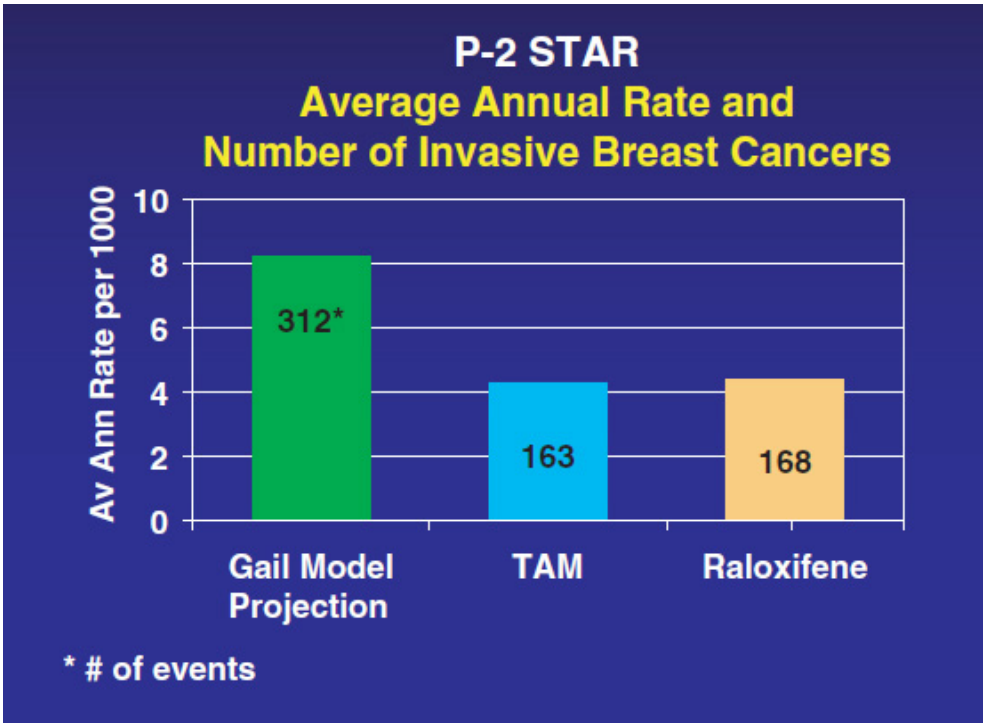

Figure 74.17 Both tamoxifen and raloxifene when taken for 5 years in the National Surgical Adjuvant Breast and Bowel Project P-2 (STAR trial) were equally effective at reducing the risk of invasive breast cancer.

The decision to proceed with endocrine therapy chemoprevention must be individualized. In general, the data support the use of endocrine therapy versus observation. For premenopausal and postmenopausal women, tamoxifen or raloxifene are both reasonable options. If a woman's primary concern is breast cancer prevention, then tamoxifen should be chosen. However, if there are risk factors for uterine cancer and/or thromboembolic complications, raloxifene is a reasonable alternative. If a postmenopausal woman does not want to take a SERM, then an aromatase inhibitor can be prescribed.

DUCTAL CARCINOMA IN SITU (DCIS)

Ductal carcinoma in situ (DCIS) is commonly defined as the proliferation of malignant epithelial cells within the mammary ductal system with no evidence of invasion into the surrounding stroma on routine light microscopic examination (Fig. 74.18). It is further categorized by its size, nuclear grade,

presence and extent of comedo necrosis, and architectural pattern. Common histologic subtypes of DCIS include comedo, cribriform, micropapillary, papillary, and solid.[162] DCIS is designated as Tis (DCIS) by the TNM staging system and considered a Stage 0 breast cancer.[163] The incidence of DCIS increases with age and is uncommon in women younger than 30 years. In women aged 50 to 64 years, the risk is as high as 88 per 100,000 women.[164] Among the breast cancers diagnosed in the United States, 25% are DCIS.[165] The risk of development of metastases and/or death in women with DCIS is rare (<1%).[166]

Most patients with DCIS will present with no breast-related symptoms or findings on physical examination. More than 90% of all cases of DCIS are detected on imaging studies—commonly as microcalcifications on mammography.[167,168] Prior to routine screening mammography, DCIS presented as a palpable mass, in association with nipple discharge, or as Paget disease.[169,170] Although most patients with DCIS have microcalcifications of indeterminate morphology, patterns that are highly suggestive of DCIS include linear branching or segmental types of pleomorphic microcalcifications.[168]

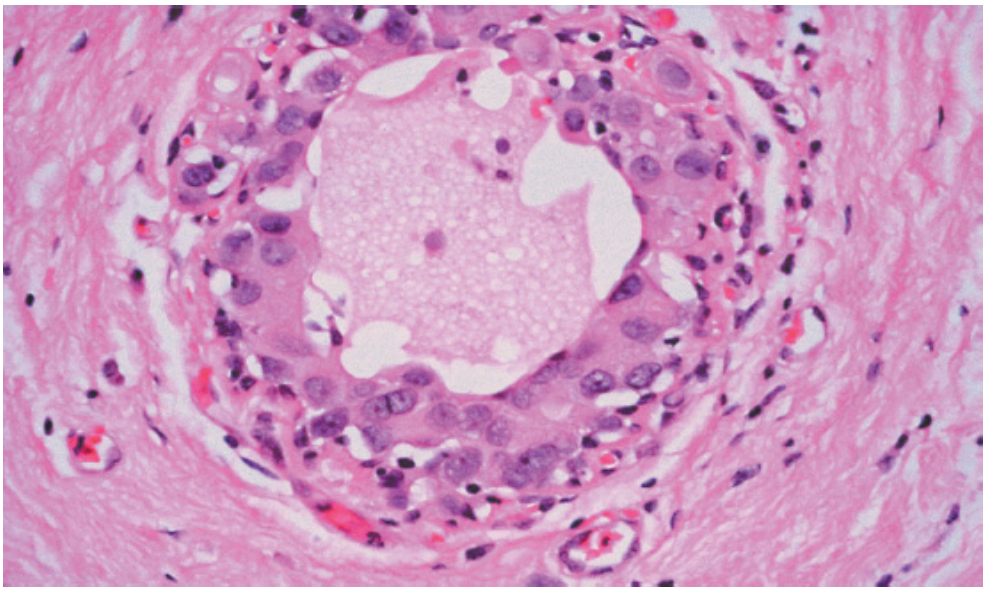

Figure 74.18 Photomicrograph of ductal carcinoma in situ. The abnormal cells do not cross the ductal basement membrane. The necrotic debris in the center of the duct is responsible for the calcification visible on mammography.

Once an abnormal lesion is detected by diagnostic imaging, the diagnosis of DCIS is typically confirmed by breast biopsy. Of note, when DCIS is diagnosed initially by core biopsy, 15% to 20% of lesions will be upgraded to invasive cancer at the time of definitive resection. Large, high-grade DCIS lesions are more likely to have an invasive component.[171]

5 Surgical options for the treatment of DCIS include breast-conserving surgery as a component of breast conservation therapy (BCT) (partial mastectomy and postoperative radiation therapy) or simple mastectomy. Although there is no randomized trial that has ever compared the treatment of DCIS by mastectomy with treatment by BCT, a large number of clinical studies have shown that the local recurrence rate of BCT is 10% to 15% after 10 years and that approximately half of the local recurrences are invasive carcinoma.[172–176] Mastectomy is curative in 98% of patients with DCIS, regardless of the tumor grade or the size of the lesion.[172,173] However, both surgical treatment options are associated with equivalent long-term survival as shown in both retrospective and prospective analyses.[177–179] Given that partial mastectomy is a much less invasive surgical procedure, BCT is typically recommended over mastectomy. Mastectomy should be performed if BCT is contraindicated, or based on patient preference. BCT is contraindicated with multicentric disease, extensive disease where resection would result in poor cosmesis, and in patients who cannot receive radiation therapy. For patients undergoing mastectomy, immediate breast reconstruction options should be reviewed.

BCT typically includes a partial mastectomy with negative surgical margins, followed by radiation therapy to eradicate any residual disease. Radiation therapy is typically recommended, except in rare circumstances (see ***Breast Cancer in the Elderly***). Four prospective, randomized clinical trials—NSABP B-17 (1998, 2001),[175,176] EORTC 10853 (2006),[180] United Kingdom (2003),[181] and the SweDCIS (2008)[182] have focused on the role of radiation therapy in the treatment of DCIS (Table 74.8). Despite differences in study design, the results are very similar, demonstrating a 50% to 60% reduction in local recurrence with surgical excision and radiation therapy compared to surgical excision alone. Furthermore, the results of NSABP B-17 confirm that the reduction in local recurrence persists through 12 years of follow-up. However, no survival benefit from radiation therapy was

observed. Patients with comedo necrosis, uncertain margins, and/or those at highest risk for recurrence appear to benefit most from radiation therapy.[183] However, even in the most favorable subgroup (absent or slight comedo necrosis, clear margins), radiation therapy was associated with a reduction in the absolute incidence of breast recurrence by 7% at 8 years.

Given the risks, inconvenience and cost associated with radiation therapy, attempts have been made to define a subgroup of patients with DCIS who may not require radiation therapy. The ECOG 5194 study investigated patients undergoing local excision alone in women with low-risk DCIS (low- to intermediate-grade DCIS lesions were <2.5 cm, and high-grade DCIS lesions were <1.0 cm). Margins were at least 3 mm and a postexcision mammogram was obtained for all patients to document the adequacy of surgical resection. Tamoxifen following excision was allowed but not required. At a median follow-up of 6.7 years, the local recurrence rate at 5 years was 6.1% (95% CI 4.1% to 8.2%) for patients with low- to intermediate-grade DCIS (n = 565), and 15.3% (95% CI 8.2% to 22.5%) for patients with high-grade DCIS (n = 105).[184] These findings suggest that local excision alone may be sufficient for select patients with low- to intermediate-grade DCIS. However, identifying these patients remains a challenge.

RESULTS

Table 74.8 Results of Randomized Trials of Radiotherapy in Ductal Carcinoma in Situ

			IBTR (%)	
Study	Patients (No.)	Median Follow-up (mo)	E	RT
NSABP B-17[175,176]	813	44	40	17
EORTC 10853[180]	1,010	126	26	15
United Kingdom[181]	1,030	53	14	6
SweDCIS[182]	1,046	96 (mean)	27	12

DCIS, ductal carcinoma in situ; E, excision alone; EORTC, European Organization for Research and Treatment of Cancer; IBTR, ipsilateral breast tumor recurrence; NSABP, National Surgical Adjuvant Breast Project; RT, radiation therapy.

Other models which have attempted to predict the likelihood of local recurrence following excision alone in patients with DCIS include the Van Nuys Prognostic Index (VNPI)[185] and its updated version the University of Southern California Van Nuys Prognostic Index (USC/VNPI).[186] Patients are classified into three groups based on pathologic classification: (1) non–high-grade DCIS without comedo type necrosis, (2) non–high-grade DCIS with comedo type necrosis, and (3) high-grade DCIS with or without comedo type necrosis. The USC/VNPI score (range is 4 to 12) is then calculated based on the pathologic classification score and points given for margins, tumor size, and the patient's age. The study's conclusion is that women with an overall low score (4, 5, 6) did not require radiation therapy. However, attempt to replicate and validate the USC/VNPI score in other datasets have had varying success[187–189] and as such it is not commonly used.

More recently gene expression analysis has been explored in an attempt to distinguish patients who may omit postexcision radiation therapy. The DCIS Recurrence Score is a multigene assay that was developed using tumors from 327 patients who participated in the ECOG5194 trial as described previously.[190] The DCIS Recurrence Score is designed to stratify patients into three groups corresponding to the 10-year risk of developing ipsilateral DCIS or invasive breast cancer. Those with a low score (<39) had a risk of ipsilateral recurrence of 12% and 5% respectively; intermediate score (39–54) had a risk of ipsilateral recurrence of 25% and 9%; and high score (>55) had a risk of ipsilateral recurrence of 27% and 19%. It must be noted that for some patients a 12% risk of an ipsilateral recurrence at 10 years may not justify omission of radiation therapy. Furthermore, validation of this multigene assay is required prior to its implementation into clinical practice.

Axillary lymph node involvement in DCIS is rare, and sentinel lymph node biopsy is not indicated during breast-conserving surgery. In the NSABP B-17 and B-24 trials, the axillary recurrence rates, irrespective of treatment, were 0.83 and 0.36 per 1,000 patient-years of follow-up.[191] If a patient is undergoing a mastectomy following core needle biopsy, SLN biopsy should be considered as it is possible that an occult invasive breast cancer will be identified, and SLNB is often not feasible after mastectomy. Of note, SLNB after a mastectomy has been explored through skin mapping. Radiocolloid with or without blue dye is injected superior to the mastectomy incision into the skin flap, with successful identification of a sentinel lymph node in 13 out

of 20 patients (65% success rate).[192] Our institution has had slightly higher success rates with the injection of both radiocolloid and blue dye.

After breast-conserving surgery, a postexcision mammogram should be performed prior to the initiation of radiation therapy to ensure that there are no persistent residual suspicious calcifications. Treatment for DCIS after breast-conserving surgery is not considered complete without adjuvant radiation therapy (see ***Radiation Therapy***).

There is no role for chemotherapy in DCIS. However, endocrine therapy is commonly recommended. Fifty to 75% of DCIS specimens express estrogen and progesterone receptors.[193,194] In the United States, only tamoxifen has been approved to prevent breast cancer recurrences in women with DCIS. Currently, no data exist to support the use of aromatase inhibitors in this population. The benefit of tamoxifen therapy in decreasing local recurrence rates is supported by both a meta-analysis of two randomized trials and by NSABP B-24. The meta-analysis consists of 3,375 women and shows that tamoxifen after surgery for DCIS reduces recurrence of both ipsilateral DCIS (HR 0.75; 95% CI 0.61 to 0.92) and contralateral DCIS (HR 0.50; 95% CI 0.28 to 0.87) (Fig. 74.19). There is also a trend toward decreased ipsilateral invasive cancer (HR 0.79; 95% CI 0.62 to 1.01) and reduced contralateral invasive cancer (HR 0.57; 95% CI 0.39 to 0.83). The number needed to treat in order for tamoxifen to have a protective effect against all breast events was 15. However, there was no difference in all-cause mortality (RR 1.11; 95% CI 0.89 to 1.39).[195] In a retrospective review of NSABP B-24, it was found that at 10 years of follow-up, patients (n = 732) with ER-positive DCIS treated with tamoxifen had significant decreases in any subsequent (invasive and/or noninvasive; ipsilateral and/or contralateral) breast cancer events compared with those who received placebo (HR 0.58, 95% CI 0.42 to 0.81, $p < 0.0015$).[196]

Management of patients with DCIS who have not undergone bilateral mastectomies include consideration of tamoxifen for 5 years rather than observation, recognizing that although there is an improvement in recurrence rates, there is no proven survival benefit per consensus guidelines. In women who have undergone bilateral mastectomies, the risks associated with tamoxifen use likely outweigh the benefits. Furthermore, tamoxifen is not typically recommended for patients with ER-negative DCIS.

EVALUATION OF THE PATIENT WITH BREAST CANCER

Breast cancer is a heterogenous disease that can be characterized further based on clinical and pathologic features. Further characterization and staging of breast cancer in newly diagnosed breast cancer patients can facilitate definitive treatment. Pathologic, biologic and anatomic characteristics are used in combination to predict prognosis and response to therapy.

AJCC TNM Staging

The eighth edition of the AJCC TNM staging system for breast cancer is an internationally accepted system used to characterize the extent of disease, predict prognosis, and facilitate medical decision-making (Table 74.9).[198] Unlike the seventh edition, this new staging system is no longer just based on anatomic findings (TNM anatomic stage groups) but now includes pathologic prognostic (TNM pathologic prognosis stage groups) and clinical prognostic (TNM clinical prognostic stage groups) factors by incorporating such things as tumor grade and receptor status (esterogen, progesterone, HER2 amplification). The system we will discuss in detail is the TNM anatomic staging system, where breast cancer is classified on the basis of the primary tumor type (invasive or in situ) and size (T), the presence or absence of regional lymph node involvement (N), and the presence or absence of distant metastases (M).

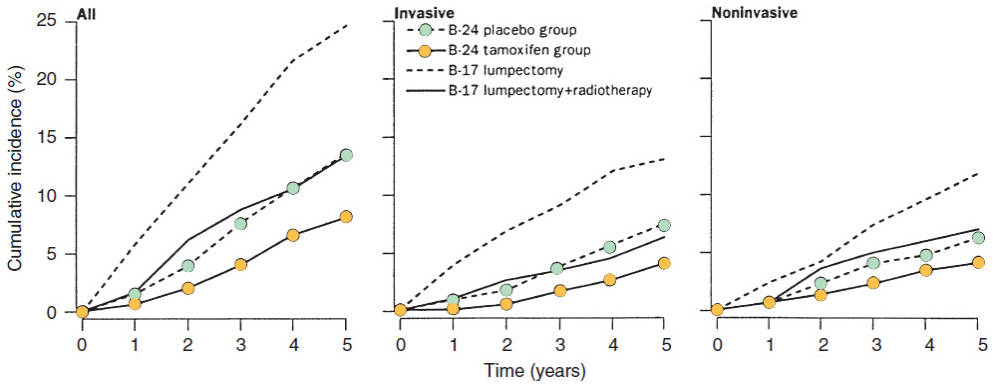

Figure 74.19 Benefits of radiation therapy and tamoxifen in ductal carcinoma in situ. The cumulative incidence of breast cancer events in the ipsilateral and contralateral breasts for patients treated in the National Surgical Adjuvant Breast and Bowel Project B-17 and B-24 trials is shown. The reduction in recurrence is greatest for patients receiving radiotherapy and tamoxifen.

Noninvasive breast cancers are noted as Tis and further classified into Tis (DCIS) and and Tis (Paget). LCIS is now considered a benign entity and as such not classified as Tis. T1 tumors are invasive cancers ≤20 mm; T2 tumors are >20 mm but ≤50 mm; whereas T3 tumors are >50 mm. T4 tumors are any size with direct extension to the chest wall and or the skin, resulting in nodules or ulcerations. Invasion of cancer into the dermis alone does not qualify as T4. IBC, which is defined by typical skin changes involving a third or more of the skin of the breast, is classified as T4d.

Lymph node classification criteria differ depending on whether the lymph nodes were clinically or pathologically assessed and as such are designated as cN or pN respectively. When possible, pathologic classification is preferred. Regional lymph nodes are defined as those of the ipsilateral axilla, ipsilateral intramammary, internal mammary nodes, and supraclavicular nodes. Metastasis to any other lymph node, including cervical or to the contralateral axillary lymph node is classified as distant disease (M1). In regards to the clinical classification of the regional lymph nodes, cN0 refers to no regional lymph node metastases. Mobile level I and II axillary lymph nodes containing metastases that are ipsilateral are considered cN1, whereas fixed or matted nodes are cN2. When metastases occur in the infraclavicular lymph nodes, ipsilateral internal mammary lymph nodes *and* axillary lymph nodes, or to the ipsilateral supraclavicular lymph nodes, it is classified as cN3.

In order to discuss the pathologic classification of regional lymph nodes, it is important to note that breast cancer metastases must be greater than 0.2 mm and exceed 200 cells in a single histologic lymph node cross section to be considered clinically relevant. As such pN0 refers to no regional lymph node metastases, pN1mi is used to describe micrometastases (greater than 0.2 mm or more than 200 cells, but none greater than 2.0 mm), and pN1 is used to describe metastases in one to three lymph nodes, and/or internal mammary nodes with metastases detected by SLN biopsy but not clinically detected. pN2 disease occurs when metastases are present in four to nine axillary lymph nodes or in clinically detected internal mammary lymph nodes in the absence of axillary lymph node metastases. pN3 disease includes metastases in 10 or more axillary lymph nodes, metastases to the infraclavicular (level III axillary) lymph nodes, in clinically detected ipsilateral internal mammary lymph nodes in the presence of 1 or more positive level I, or II axillary lymph nodes, in more than three axillary lymph nodes and in internal mammary lymph nodes with micrometastases or macrometases detected by SLN biopsy but not clinically detected, or in ipsilateral supraclavicular lymph nodes.

Distant metastasis (M1) is defined as detectable metastases as determined by classical clinical and radiographic means and/or histologically proven larger than 0.2 mm. When no clinical or radiographic evidence of distant metastases is present, but deposits of molecularly or microscopically detected tumor cells are found in circulating blood, bone marrow or other nonregional nodal tissue that are no larger than 0.2 mm in a patient with no symptoms of metastases the designation used is cMO(i+).

The particular combination of the T, N, and M characteristics defines the overall breast cancer stage. Although the TNM staging system estimates predicted survival, it should not be used alone to dictate treatment.

Histologic Subtype and Tumor Grade

Most invasive breast cancers arise from epithelial elements and are categorized as carcinomas, consisting of several histologic subtypes. Based on the Surveillance Epidemiology and End Results (SEER) database of the National Cancer Institute between 1992 and 2001, estimated percentages of each histologic subtype of breast cancer in a series involving 135,157

women showed infiltrating ductal carcinoma (IDC) as the most common (76%), followed by invasive lobular (8%), ductal/lobular (7%), mucinous/colloid (2.4%), tubular (1.5%), medullary (1.2%), and then papillary (1%).[199]

IDC is the most common type of invasive breast cancer. On gross pathologic evaluation, these lesions are typically firm, gray-white, gritty masses. Cytologic features of these cells range from low grade to highly malignant. Microscopically these cancers are characterized by cords and nests of tumors cells with varying amounts of gland formation. As these cancer cells infiltrate the breast parenchyma, they induce a fibrous response, resulting in their characteristic irregular, stellate shape. Often IDC is associated with a variable amount of DCIS.

Table 74.9 Tumor, Node, Metastasis (TNM) Classification for Breast Cancer Staging

TNM Definitions

Primary Tumor	
Tx	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ, ductal or lobular or Paget disease of the nipple with no tumor
T1	Tumor 2 cm or less in greatest dimension
T2	Tumor more than 2 cm but not more than 5 cm in greatest dimension
T3	Tumor more than 5 cm in greatest dimension
T4	Tumor of any size with direct extension to the chest wall (not including pectoralis muscle), skin edema, skin ulceration, satellite skin nodules, or inflammatory carcinoma
Regional Lymph Nodes (Pathologic)	
Nx	Nodes cannot be assessed
N0	No regional node metastases histologically, no additional examination for isolated tumor cells (ITCs)
N1	Metastasis to one to three axillary nodes or in internal mammary (IM) nodes with microscopic disease detected by sentinel node biopsy, which is not clinically apparent
N2	Metastases in four to nine axillary nodes or in clinically apparent IM nodes in the absence of axillary node metastasis
N3	Metastases in 10 or more axillary nodes, or in infraclavicular nodes, or in IM nodes in the presence of one or more positive axillary nodes; or in more than three axillary nodes with IM metastases, or in supraclavicular nodes
Distant Metastases	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis

M0 M1	Distant metastasis		
Stage Grouping			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage IIA	T0 T1 T2	N1 N1 N0	M0 M0 M0
Stage IIB	T2 T3	N1 N0	M0 M0
Stage IIIA	T0 T1 T2 T3 T3	N2 N2 N2 N1 N2	M0 M0 M0 M0 M0
Stage IIIB	T4 T4 T4	N0 N1 N2	M0 M0 M0
Stage IIIC	Any T	N3	M0
Stage IV	Any T	Any T	M1

Infiltrating lobular carcinomas (ILC) are the second most common type of breast cancer. The incidence rate of lobular carcinoma is rising faster than the rate of ductal carcinoma in the United States. Furthermore, postmenopausal hormone therapy use may be more strongly associated with lobular carcinoma that ductal carcinoma. Although some ILC may appear similar to IDC macroscopically, others may not show a mass lesion with the excised tissue appearing normal or having only a slightly firm consistency. As such, the microscopic size of ILC may be much greater than what is measured grossly. Unlike IDC, ILC induces only a minimal fibrous reaction.

Microscopically, these tumors are characterized by small cells that insidiously infiltrate the mammary stroma and adipose tissue individually and in a single file pattern, often growing in a target-like configuration around normal breast ducts. LCIS or DCIS may be present with ILC. There is a higher frequency of bilateral and multicentric disease with ILC than IDC.[200,201] ILC are more common in older women, and are typically larger but more differentiated than IDC. ILC are almost always estrogen receptor-positive. The prognosis for ILC and IDC appears to be similar, however, recent reports suggest that the short-term prognosis for ILC may be more favorable.[202,203] ILC tend to metastasize later than IDC and spread to unusual locations such as the peritoneum, meninges, and the gastrointestinal tract.[204] Furthermore, lobular breast cancers have been observed in families that carry germline mutations in *CDH1*, the gene that encodes for the E-cadherin protein. The lack of E-cadherin can be used to distinguish ILC from IDC.[205,206]

Mucinous (colloid) carcinoma is a less common histologic subtype that is more common in older patients. On gross examination, these tumors have a soft gelatinous appearance and tend to be well circumscribed. Microscopically, they are characterized by nests of tumor cells, with uniform and low grade nuclei, dispersed in large pools of extracellular mucus. These lesions have a favorable prognosis.[207,208] Another histologic subtype with favorable prognosis is tubular carcinoma, which is characterized by the presence of well-formed tubular or glandular structures infiltrating the stroma. The tumor cells are low grade and are often associated with low-grade DCIS. Metastatic disease is rare with tubular carcinoma.[209]

Medullary carcinomas are well circumscribed, soft, tan masses with areas of hemorrhage and necrosis. Microscopically, the tumor cells are poorly differentiated, grow in a syncytial pattern, and have an intense lymphoplasmacytic infiltrate.[210] These cancers occur more frequently in younger patients and are more frequent in women with *BRCA1* mutations, although the majority of breast cancers in patients with *BRCA1* mutation are not medullary.[211] Despite, their aggressive histologic appearance, medullary carcinomas are associated with a more favorable prognosis than IDC.[212,213]

Other breast cancer subtypes include macropapillary carcinomas which are highly aggressive and have a tendency for lymph node metastasis even when small in size.[214] Also likely associated with a worse prognosis,

metaplastic carcinomas are well circumscribed tumors that contain various combinations of poorly differentiated ductal adenocarcinoma, mesenchymal (sarcomatous), and other epithelial (e.g., squamous cell) components.[215] When the squamous cell component predominates, the tumors tend to be more aggressive and are frequently refractory to treatment when compared with IDC.[216,217] Unlike IDC, metaplastic breast cancers tend to have fewer T1 tumors, more node-negative tumors, more poorly differentiated or undifferentiated tumors, and have fewer estrogen receptor positive tumors.[215] Metaplastic breast cancers are treated similarly to other invasive breast cancers.[218–220]

The grade of a breast cancer is determined by a combination of the architectural and cytologic features, usually assessed by utilizing the Ellston–Ellis modification of the Scarff–Bloom–Richardson scoring system. This system is based on three parameters including tubule formation, nuclear pleomorphism, and mitotic activity. Each category is assigned a score of 1 to 3 and then a summation score of 3 to 9. The lowest possible score is 3 with scores of 3 to 5 defined as grade 1, 6 or 7 as grade 2, and 8 or 9 as grade 3. Cells that infiltrate the stroma as solid nests of glands and where the nuclei are relatively uniform with little or no evidence of mitotic activity are referred to as well differentiated or grade 1 tumors. When the tumor cells infiltrate as solid nests with some glandular differentiation and nuclear pleomorphism is present, the tumor is categorized as grade 2 or moderately differentiated. In addition, the mitotic activity is moderate. In poorly differentiated or grade 3 tumors, solid nests of neoplastic cells without evidence of gland formation are present. In addition, there is marked nuclear atypia and high mitotic activity.[221]

Biomarker Profile (ER, PR, HER2)

As targeted therapies exist targeting breast cancers that express the estrogen receptor (ER), progesterone receptor (PR), and/or the HER2 protein, these biomarkers have significant treatment implications. As such, when an invasive breast cancer is diagnosed, expression of these biomarkers is determined. Using immunohistochemistry and image analysis, ER and PR are considered positive if greater than or equal to 10% of cells stain positive. The Allred score is another method to quantify ER and PR expression. The

Allred score integrates the percentage of cells that stain positive, with the intensity of staining to give a score of 0 to 8.[222] The goal of the Allred score is to quantify ER expression based on the likelihood that a breast cancer patient will respond to endocrine therapy. One of the benefits of the Allred score is that by integrating both the percentage and intensity of staining, patients with <10% staining may be identified who benefit from endocrine therapy.[223] The receptor tyrosine kinase protein HER2 is a member of the epidermal growth factor receptor family and its amplification or overexpression has been shown to contribute to breast cancer development and progression. HER2 can now be targeted using monoclonal antibodies and small molecule inhibitors. Using immunohistochemistry and image analysis, HER2 is scored 0, 1+, 2+, and 3+. Positivity is noted as 3+, whereas scores of 0 and 1+ are considered negative. A score of 2+ is considered indeterminate and further testing for gene amplification can be performed using either FISH (fluorescence in situ hybridization) or CISH (chromogenic in situ hybridization). The HER2 FISH assay is based on the gene copy number and the ratio between the number of HER2 and chromosome enumeration probe 17 (CEP17) sequences, with positivity defined as a HER2/CEP17 ratio ≥2.0. Positivity is also defined as HER2 copy number ≥6.0 signals/cell even if the HER2/CEP17 ratio is <2.0.[224] Alternatively, a more cost effective and comparable method to FISH testing is the HER2 CISH assay.[225,226]

An emerging biomarker is the Ki-67 index. The Ki-67 antigen is present in all phases of the cell cycle except for the G0/resting phase and reflects of the proliferative potential of a breast cancer. Ki-67 is determined by IHC and noted as a percentage, where <10% is considered a low proliferative index, 10% to 20% is considered borderline, and >20% is considered high. The Ki-67 index can also be used to measure the response to endocrine therapy.

Molecular Subtyping

Recent advances in molecular biology, including the development of sophisticated techniques for gene expression profiling, have established a new taxonomy of breast cancer, defining molecular subtypes of breast cancer. This new taxonomy has had a profound impact on the clinical management of breast cancer, as the molecular subtypes differ markedly in prognosis and

response to therapy. As gene expression profiling is not routinely performed on clinical specimens, molecular subtypes have been approximated based on expression of the estrogen receptor, progesterone receptor, HER2 expression, and other biomarkers. Commonly defined subtypes include luminal A (ER+, PR+, HER2–, Ki-67 <14%), luminal B (ER+ and or PR+, HER2+/–, Ki-67 ≥ 14%), HER2 (ER and PR–, HER2+), and basal-like (ER, PR, and HER–).[227–229] Luminal A and B subtypes have estrogen receptor expression, however the former group has a much better overall survival.[230] Luminal B HER2+ and HER2 subtypes benefit from targeted therapies against HER2. Furthermore, both HER2 and basal-like breast cancers are known to have higher initial responses to anthracycline-based chemotherapy than the luminal subtypes but are associated with a decreased disease-free survival.[231]

Table 74.10 Approach to the Axillary Nodes

Finding	Approach
Clinically negative	Sentinel lymph node biopsy
Radiographically suspicious	Fine-needle aspiration (image guided) If no metastatic disease identified, then sentinel lymph node biopsy If metastatic disease is identified, consideration for axillary lymph node dissection
Clinically suspicious	Fine-needle aspiration (image or hand guided) Follow-up management as for radiographically suspicious

Breast MRI

Although there is no data from prospective randomized trials demonstrating improved outcomes with the addition of MRI to the diagnostic evaluation of

newly diagnosed breast cancers, the consensus guidelines suggest that diagnostic MRI should be considered in patients with newly diagnosed breast cancer when (1) the clinical extent of disease appears larger than what is observed on mammography, (2) there is concern about pectoralis muscle involvement, (3) there is no evidence of a breast primary in the presence of axillary lymph node metastases, (4) there is no disease identified on physical examination or mammography in the presence of PDB, (5) in women at very high risk for contralateral breast cancers such as those with *BRCA1/2* mutations, and (6) to help determine the extent of disease prior to treatment. Of note, MRI is associated with a high false-positive rate, and many MRI-detected abnormalities will need to be biopsied in order to meaningfully interpret the results of the MRI.

Sentinel Lymph Node Biopsy

Breast cancer spread to ipsilateral axillary lymph nodes is common, occurring in 15% to 30% of patients. The presence of axillary lymph node metastases has important prognostic implications, and can impact medical, surgical and radiation oncology decision making. However, ALND has significant risks, and the therapeutic impact of axillary surgery remains to be clearly defined.[232–234] Currently SLNB is the procedure of choice for staging of the axilla in breast cancer. Axillary ultrasound has also been used, and can facilitate evaluation of patients with an equivocal physical examination (Table 74.10).

6 The SLN hypothesis predicts that breast cancers metastasize to one or a few lymph nodes prior to involving other lymph nodes in the corresponding lymph node basin. Prospective studies have confirmed this hypothesis, demonstrating that the pathology of the SLN accurately predicts the pathology of the corresponding axillary lymph node basin (Table 74.11). SLNB has significantly fewer complications than ALND, with the risk of lymphedema being significantly lower (2% after SLNB vs. 13% after ALND at 12 months).[235]

The SLNB procedure begins with localization of the SLN through injection of radioactive colloid and/or blue dye. Given that the combined use of both tracers appears to be complementary and that failed SLN identification is minimized when both tracers are used, this is our recommended approach. A

systematic review by an expert panel convened by ASCO concluded that the use of both blue dye and radioactive colloid was associated with a trend toward a lower false-negative rate.[236]

Prior to surgery, radioactive technetium sulfur colloid is injected either peritumorally, intradermally, or into the subareolar plexus. Lymphoscintigraphy can be performed to identify areas of increased radioactivity. Alternatively, a handheld gamma probe can be used to survey the axilla and identify hot spots. The patient is then brought to the operating room and positioned with the ipsilateral arm abducted up to 90 degrees. The breast, anterior chest wall, and axilla are prepped and draped in the usual standard sterile fashion. Five milliliters of blue dye (isosulfan or methylene blue dye) is injected either around the tumor periphery, at the palpable edge of the biopsy cavity, or into the subareolar plexus. Blue dye should not be injected directly into the tumor itself as the lymphatics may be occluded by tumor. Likewise, blue dye should not be injected into the seroma cavity following breast surgery as the seroma cavity may not have sufficient lymphatic drainage. For these reasons, we typically inject into the subareolar plexus. Breast massage is performed for 5 minutes to dilate the breast lymphatics and facilitate lymphatic drainage.

Isosulfan blue can be used for SLNB, however anaphylaxis requiring resuscitation can occur in 0.7% to 1.1% of cases.[237,238] Alternatively, methylene blue can be used. The risks associated with methylene blue include skin necrosis if injected intradermally, pain secondary to caustic reaction, and pulmonary edema.[239–241] These risks can be minimized by diluting the methylene blue, with common dilutions ranging from 2:3 (2 mL of methylene blue mixed with 3 mL of saline, injecting 5 mL total) to 1:4 (1 mL of methylene blue mixed with 4 mL of saline, injecting 5 mL total). In patients taking serotonergic psychiatric mediations, methylene blue should be used with caution as the dye can prevent the action of monoamine oxidase A, resulting in toxic levels of serotonin or serotonin syndrome. This is characterized by mental status changes, muscle twitching, excessive sweating, shivering, diarrhea, trouble with coordination, and/or fever.[242]

Table 74.11 Results of Prospective, Multi-Institutional Studies of Lymphatic Mapping and Sentinel Node Biopsy

Study	No. Patients	% SN Identification	% False Negative

Using a handheld gamma probe the axilla is systematically surveyed and the skin is marked at the location of the hottest spot. A small incision is then made below the hair-bearing area of the axilla and carried down through the subcutaneous tissue. The clavipectoral fascia is incised with care to visually identify any blue lymphatics. The blue lymphatics are then followed toward the axilla to identify the sentinel lymph node(s). Successful SLN identification by blue dye is defined as the identification of any blue node or nonblue node with a blue afferent lymphatic. These lymph nodes are also evaluated with the gamma probe and the associated counts are recorded. The dissection is continued until all lymph nodes associated with a blue afferent lymphatic are removed and any remaining lymph nodes have less than 10% radioactivity compared to the most radioactive lymph node.[243–245] This often results in more than one SLN being identified and removed. Finally, palpation of the axilla is performed and any suspicious lymph nodes are also removed as gross tumor involvement can interfere with uptake of both radioactive colloid and blue dye. In the case of gross tumor involvement the radioactive colloid and blue dye are may be diverted to a lymph node other than the true SLN, giving rise to a false-negative result if palpation of the axilla and removal of suspicious lymph nodes is not performed.[246,247] Once all SLN have been identified and removed, hemostasis is obtained, and the

clavipectoral fascia is reapproximated with interrupted vicryl stitches. The deep dermal layer is reapproximated with interrupted 3-0 vicryl stitches and the skin closed with a running subcuticular stitch.

TREATMENT OF THE PATIENT WITH BREAST CANCER

Breast cancer is currently treated with a multidisciplinary approach. Most patients benefit from a combination of therapies which may include surgery, medical therapy, and radiation therapy. This multidisciplinary approach has resulted in a significant reduction in breast cancer mortality.[248] One important consideration is optimal coordination of surgery with the other treatment modalities. In the discussion below we will first provide an overview of how the different treatment modalities are coordinated in early stage, locally advanced and metastatic 7 breast cancer. After this overview, surgery, medical therapy and radiation therapy will be discussed in more detail.

Overview

Most patients with newly diagnosed breast cancer have no evidence of metastatic disease and are diagnosed with *early stage* breast cancer. This includes patients with clinical stage I (T1N0), IIA (T1N1 or T2N0), or IIB (T2N1) disease. Local regional management often consists of BCT (partial mastectomy with radiation therapy) or mastectomy, noting that the choice in locoregional management does not typically impact the recommendation for adjuvant medical therapy. For patients with clinical T1N0 disease, surgery is typically the first treatment modality. For patients with clinical T2N0 or T2N1 disease, neoadjuvant chemotherapy or endocrine therapy is often the first treatment modality. The goal of neoadjuvant therapy is to shrink the primary breast cancer prior to surgery, facilitating BCT. For patients with a clinically suspicious axilla, an ultrasound guided FNA may be helpful to determine whether there is metastatic spread to the axilla. If the FNA is negative, then the patient should undergo a SLNB at the time of surgery. For

patients with a clinically negative axilla, a SLNB should be planned at the time of surgery with a decision about further management of the axilla, if any, pending the results of the SLNB. The decision to recommend chemotherapy for patients with early breast cancer is primarily dependent on tumor characteristics but also integrates the patient's overall health status and personal preference. Adjuvant chemotherapy is typically recommended when high-risk features are present such as high-grade tumor, large tumor size (≥1.0 cm), unfavorable biomarker profile, or lymph node involvement. In addition, an Oncotype DX can be obtained in patients with ER+/HER2- negative breast cancers and negative lymph nodes. A score of ≥31 often suggests that adjuvant chemotherapy will be beneficial. For patients with breast cancers that are hormone receptor-positive, endocrine therapy is typically recommended postoperatively. If adjuvant chemotherapy is recommended, then endocrine therapy is given after completion of chemotherapy. For patients with TNBC, adjuvant chemotherapy is commonly given if the tumor size is ≥0.5 cm. Patients who have HER2-positive breast cancers that are ≥1.0 cm are treated with adjuvant chemotherapy plus HER2-directed therapy. The management of HER2-positive breast cancers that are <1.0 cm is controversial and should be decided by the patient and her provider after a discussion of the risks and benefits of treatment. Adjuvant radiation therapy is typically recommended for all patients who are treated with BCT, and a subset of patients who are treated with mastectomy (see ***Radiation Therapy***).

Patients with *locally advanced disease* (clinical stage IIB [T3N0], or stage IIIA–IIIC [T1–T3N2 disease or T4 disease]) are at a higher risk for recurrence and distant metastases, and neoadjuvant and/or adjuvant chemotherapy and radiation therapy are typically recommended (Fig. 74.20). Benefits of neoadjuvant chemotherapy in this clinical context include the ability to treat any potential systemic disease immediately, and the ability to directly assess the response to treatment by physical examination and imaging, allowing for suboptimal regimens to be discontinued and other regimens to be prescribed. In patients with hormone receptor-positive disease, neoadjuvant chemotherapy is associated with a higher response rate in a shorter period of time than endocrine therapy. Endocrine therapy in the neoadjuvant setting is often reserved for postmenopausal women who have

contraindications to chemotherapy. For patients with HER2-positive breast cancer, HER2-directed therapy such as trastuzumab with or without pertuzumab should be given in addition to chemotherapy. If a patient has a limited response or cannot tolerate the neoadjuvant regimen, she should proceed with surgery. Even if patients have an excellent clinical response, they should undergo surgery to remove the area of involvement. Although BCT is an option for patients with locally advanced breast cancer (LABC) who have a significant clinical response to neoadjuvant chemotherapy, mastectomy is typically recommended for those who initially present with breast cancers that are greater than 5 cm.

Figure 74.20 Locally advanced breast cancer. The breast is lifted and the upper half is bulging because of the large tumor. Distortion in the inferolateral contour is evident. The medial skin changes are caused by dermal tumor satellites.

Approximately 5% of patients with newly diagnosed breast cancer will present with stage IV disease, and up to 30% of patients who present with early stage breast cancer at diagnosis will develop distant metastatic disease.[249] The approach to patients with metastatic breast cancer is focused on prolonging survival and improving quality of life by minimizing cancer-related symptoms. As such the treatments plans for these patients are highly individualized.

For patients with hormone receptor-positive, HER2-negative disease, the preference is for endocrine therapy alone. However for patients with rapidly progressing disease, endocrine-resistant disease, or a large tumor burden involving visceral organs, chemotherapy should be considered.[250,251] For patients with $HER2^+$ disease, HER2-directed therapies should be administered along with chemotherapy. For patients with TNBCs, chemotherapy is the only option for treatment of metastatic disease.

When chemotherapy is indicated, the preference is for sequential single agent therapy, which includes taxanes and anthracyclines. Other options, especially for patients with bone-predominant ER^+ metastatic disease that have failed two trials of endocrine therapy, include capecitabine, which is derived from the antimetabolite fluorouracil. Capecitabine also may be indicated for metastatic disease to the brain as it appears to cross the blood–brain barrier.[252–254] Other agents include eribulin, gemcitabine, ixabepilone, etoposide, and platinum agents.

Although combination chemotherapy conveys a higher risk of toxicity, its use is indicated when tumor burden is large or when patients have significant symptomatic disease. This includes anthracycline-containing regimens, nonanthracycline taxane-based regimens, and combination regimens incorporating platinum salts. It is important to note that no prospective study has shown that combination chemotherapy improves overall survival compared with single-agent sequential chemotherapy.

For women with metastatic breast cancer, data exist that extending chemotherapy duration is associated with improved progression-free and overall survival. However, prolonged chemotherapy can be associated with more serious toxicities such as neutropenia and neuropathy.[255,256] As such, an individualized approach should be undertaken weighing tumor response against side effects. During treatment for metastatic disease, the patient needs to be monitored for treatment failure, which includes clinical deterioration during treatment, evidence of new metastatic disease, and increasing size of previously documented metastatic lesions.

Table 74.12 Recommendations for Adjuvant Therapy

Patient Group	Recommended Treatment
Node Negative, Low Risk	
Tumor <0.5 cm	No treatment or endocrine therapy if ER+
1–2 cm, grade 1, ER+	
Special histologic types	
Node Negative, Higher Risk	
ER+	Endocrine therapy OR chemotherapy + endocrine therapy
ER–	Chemotherapy
Any HER2+	Add trastuzumab to chemotherapy
Node Positive	
ER+	
Premenopausal	Chemotherapy + endocrine therapy
Postmenopausal	Chemotherapy + endocrine therapy OR endocrine therapy alone
ER–	Chemotherapy
Any HER2+	Add trastuzumab to chemotherapy

ER+, estrogen receptor positive; ER–, estrogen receptor negative.

The recommendations for adjuvant therapy are summarized in Table 74.12.

Surgical Therapy

Partial Mastectomy

Breast conservation therapy (BCT) consists of breast-conserving surgery (partial mastectomy) followed by radiation therapy (RT) (Fig. 74.21). The use of BCT is supported by six prospective randomized clinical trials demonstrating that partial mastectomy plus radiation therapy offers equivalent survival to mastectomy with a low rate of local recurrence

(Table 74.13).[257–265] The local recurrence rate with BCT is 5% to 22% versus 4% to 14% with mastectomy. Of note, most recurrences after mastectomy occur within the first 3 years, but recurrences after BCT tend to occur later.[266–268] Factors that increase local recurrence rate following partial mastectomy include young age, lymph node involvement, ER^- disease, and absence of radiation therapy.[269] The American College of Surgeons, the American College of Radiology, the College of American Pathologists, and the Society of Surgical Oncology have developed consensus standards of care for BCT.[270] Most patients can be offered BCT except for those with (1) multicentric disease, (2) diffuse suspicious microcalcifications on mammography, (3) a history of radiation therapy that includes a portion of the affected breast such that when combined with the current proposed treatment would result in an excessively high total radiation dose to the chest wall, (4) pregnancy (although if in the third trimester, partial mastectomy can be performed with planned breast irradiation deferred postpartum), (5) IBC, and (6) persistently positive margins after multiple attempts at breast-conserving surgery (Table 74.14).

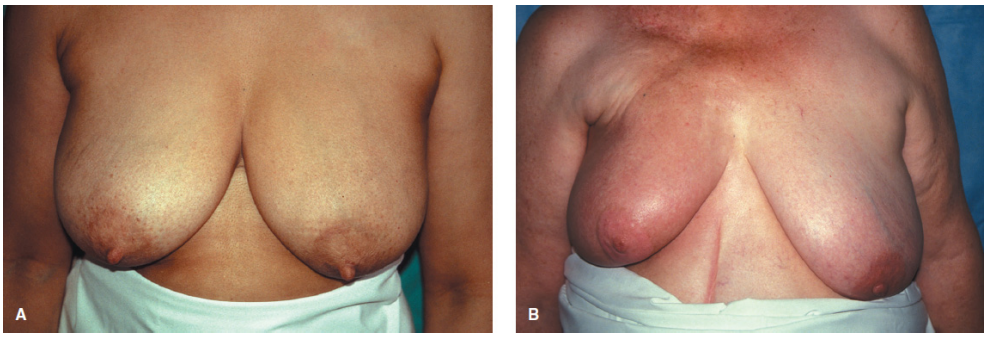

Figure 74.21 Cosmetic outcome after breast-conserving therapy with radiation. **A:** Excellent cosmetic outcome. The treated breast (**left**) is identical to the untreated breast. **B:** Fair cosmetic outcome. Significant shrinkage and loss of ptosis is evident in the treated right breast.

Table 74.13 Survival in Prospective Randomized Trials Comparing Breast-Conserving Therapy with Mastectomy

		Overall Survival		Local Recurrence	
Trial	Follow-Up (Yrs)	BCT (%)	Mastectomy (%)	BCT (%)	Mastectomy (%)
Institut Gustave-Roussy[264]	15	73	65	9	14
Milan I[259]	20	42	41	7	2
NSABP B-06[258]	20	46	47	14	10
NCI[263]	20	54	58	31	6
EORTC[261]	10	65	66	20	12
Danish[265]	6	79	82	3	4

BCT, breast-conserving therapy; EORTC, European Organization for Research and Treatment of Cancer; NCI, National Cancer Institute; NSABP, National Surgical Adjuvant Breast and Bowel Project.

The operative approach for a partial mastectomy is very similar to an excisional biopsy and is sometimes referred to as a wide excision, lumpectomy, or segmental mastectomy. The considerations for placement of the incision are similar to those for excisional biopsy, however it is best to keep the incision within the boundaries of a potential mastectomy incision, and the incision should be made directly over the lesion rather than at the wire insertion site to minimize tunneling. As negative margins are associated with lower rates of recurrence, many techniques have been developed to ensure negative margins at the time of the initial surgery. One common 8 technique is to remove the breast cancer with surrounding normal tissue, and then obtain additional shave margins. Each shave margin is labeled and oriented in relationship to the primary cancer.[271–276] Approaches to evaluate intraoperative margin status include frozen section, cytologic touch prep analysis, and intraoperative ultrasound. However, no method has proven superior and there is no established standard of care. In patients undergoing breast-conserving surgery, it is important to discuss the potential need for re-excision. A histologically positive margin is defined as a margin that has tumor present at the inked margin. Patients with a positive margin have at least a twofold increase in ipsilateral local breast cancer recurrence. As such, controversy has centered on the optimal amount of normal tissue that should be excised around the cancer to minimize local recurrence risk. A recent 9 multidisciplinary consensus panel supports the use of "tumor at

ink" as the criteria for positive margin/re-excision based on a meta-analysis that included 33 studies with 28,162 patients and 1,506 ipsilateral recurrences.[277] Like most other institutions, we have adopted this new definition of a positive margin for invasive breast cancers to guide decisions about reexcision. However, given the concern for gaps between lesions or skip lesions in DCIS, we continue to define a negative margin for this pathology as ≥2 mm, understanding that this practice may evolve pending more study results.

Axillary Lymph Node Dissection

Until recently, axillary lymph node dissection (ALND) was performed in all newly diagnosed breast cancer patients to facilitate staging, medical decision making and minimize locoregional recurrence. More recently, SLNB has replaced ALND for axillary staging, and the therapeutic impact of ALND may be limited to specific subsets of breast cancer patients. In the American College of Surgeons Oncology Group Z0011 trial, eligible patients had T1–T2 invasive breast cancers, no palpable adenopathy, and 1 to 2 SLNs containing metastases identified by frozen section, touch preparation, or H&E staining. Patients were randomized to undergo ALND or no further axillary treatment. Systemic therapy was at the discretion of the treating physician. Patients ineligible for the trial included those with matted lymph nodes, ≥3 positive nodes, gross extranodal disease, and those treated with neoadjuvant therapy.[278] After 6 years of follow-up, SLNB alone was not inferior to ALND in patients with limited sentinel lymph node involvement treated with BCT. Of note, these findings have been compared with those of the NSABP B04 trial that was conducted over a decade ago, which randomized women with clinically negative nodes to treatment with radical mastectomy, total mastectomy plus axillary radiation, or total mastectomy with delayed ALND if nodal recurrences were observed. No statistically significant survival differences were observed between any of the groups initially, or at any of the analyses up to 25 years of follow-up.[232] These studies suggest that for contemporary women, ALND may not provide a survival benefit in patients who are clinically node-negative. Currently, ALND is limited to patients with positive sentinel lymph nodes who do not meet Z0011 criteria, those with a contraindication to SLNB such as pregnant

women, those with clinically palpable pathologic lymph nodes, and patients with IBC.

INDICATIONS/CONTRAINDICATIONS

Table 74.14 Contraindications to Breast-Conserving Therapy in Invasive Carcinoma

Absolute Contraindications

- Two or more primary tumors in separate quadrants of the breast
- Persistent positive margins after reasonable surgical attempts
- Pregnancy is an absolute contraindication to the use of breast irradiation. When cancer is diagnosed in the third trimester, it may be possible to perform breast-conserving surgery and treat the patient with irradiation after delivery
- A history of prior therapeutic irradiation to the breast region that would result in retreatment to an excessively high radiation dose
- Diffuse malignant-appearing microcalcifications

Relative Contraindications

- A history of scleroderma or active systemic lupus erythematosus
- Large tumor in a small breast that would result in cosmesis unacceptable to the patient. In this circumstance, preoperative chemotherapy should be considered.
- Very large or pendulous breasts if reproducibility of patient setup and adequate dose homogeneity cannot be ensured

The boundaries of an ALND are the axillary vein superiorly, the serratus anterior muscle and long thoracic nerve medially, and the latissimus dorsi muscle and thoracodorsal nerve laterally. Contemporary axillary dissection in breast cancer involves removal of the level 1 and 2 lymph nodes (Fig. 74.22).[279] Level 3 nodes are palpated and only in the presence of gross disease is dissection performed, as removal of these nodes greatly increase the risk of lymphedema and are rarely (<1%) involved in the absence of level 1 and 2 disease.[280,281] Typically, a yield of ≥10 axillary lymph nodes is achieved with ALND.

The procedure is performed under a general anesthetic that does not include a muscle relaxant as identification of the long thoracic and thoracodorsal nerves are critical to the dissection. Preoperative antibiotics and deep venous thrombosis prophylaxis with sequential compression devices are employed. The patient is placed in the supine position with the ipsilateral arm abducted ≤90 degrees. Use of a stockinette allows for mobilization of the arm during dissection. If the ALND is performed through a mastectomy incision (modified radical mastectomy), no additional incisions are required. Also, for partial mastectomies performed in the upper outer quadrant, the partial mastectomy incision can be extended to the axilla. For palpable nodes that close to, or have eroded the skin, it is important to take the overlying skin during the dissection.

For an ALND performed during a partial mastectomy or as a separate procedure, a curvilinear skin incision is made 1 to 2 cm below the hair-bearing area of the axilla, following Langer lines from the border of the pectoralis major muscle to the latissimus dorsi muscle. Although flaps can be developed superiorly, inferiorly, laterally, and medially, most surgeons find that this is not necessary. Once the skin incision is made, the lateral edge of the pectoralis major muscle (PM) is palpated and the PM fascia is then opened with electrocautery. The lateral edge of the PM is then retracted medially to expose the pectoralis minor muscle (PMi), with care to avoid injury to the medial pectoral nerve, which innervates both the PM and the PMi. The tissue at the border of the PMi is then incised with care to avoid injury to the axillary vein or brachial plexus superiorly. If the arm is in a stockinette, it should be flexed medially and anteriorly to relax the PMi. The PM and PMi are then retracted and using blunt dissection, the axillary vein at the medial extent of the dissection can be identified. Further blunt dissection can be performed just below the medial aspect of the axillary vein and just lateral to the chest wall to identify the long thoracic nerve. The long thoracic nerve can also be palpated along the chest wall and once it is identified, the nerve is dissected free of surrounding tissue inferiorly to the insertion. To avoid injury, the fascial layer on the serratus anterior muscle which holds the nerve in place should not be opened. Attention is now turned to identification of the thoracodorsal nerve. Dissection is initiated mid-axilla just inferior to the axillary vein. Anterior to the bundle is often the thoracoepigastric vein, which is a large superficial venous tributary arising from the axillary vein.

Although the thoracoepigastric vein may need to be transected to allow for completion of the dissection, it is important to first identify the thoracodorsal nerve. The axillary fat pad/contents can then be dissected away from the thoracodorsal bundle using blunt dissection from superiorly to inferiorly with a long fine tonsil clamp. Once the long thoracic and thoracodorsal nerves are identified and dissected free of surrounding tissue, the axillary contents can be mobilized and removed. Of note, there are usually three to five intercostobrachial nerves that supply sensation to the medial-posterior aspect of the arm and run medial to lateral in the field of dissection. An attempt should be made to spare these nerves but only if they do not directly interfere with the dissection. The axillary contents are retracted inferiorly, and using electrocautery or sharp dissection, it is freed from the teres major posteriorly. The axillary contents are then sent en bloc to the pathologist. The wound is suction irrigated with sterile saline and hemostasis is achieved. A single 19 French round Blake drain can be placed above or below the bra line. However, some surgeons do not place drains for ALNDs, as in the absence of an associated mastectomy, the drainage is often scant. The skin is closed with interrupted 3-0 vicryl sutures and a 4-0 subcuticular stitch. If a drain is placed, it is removed when drainage is less than 30 mL per 24 hours. No antibiotic prophylaxis is necessary.

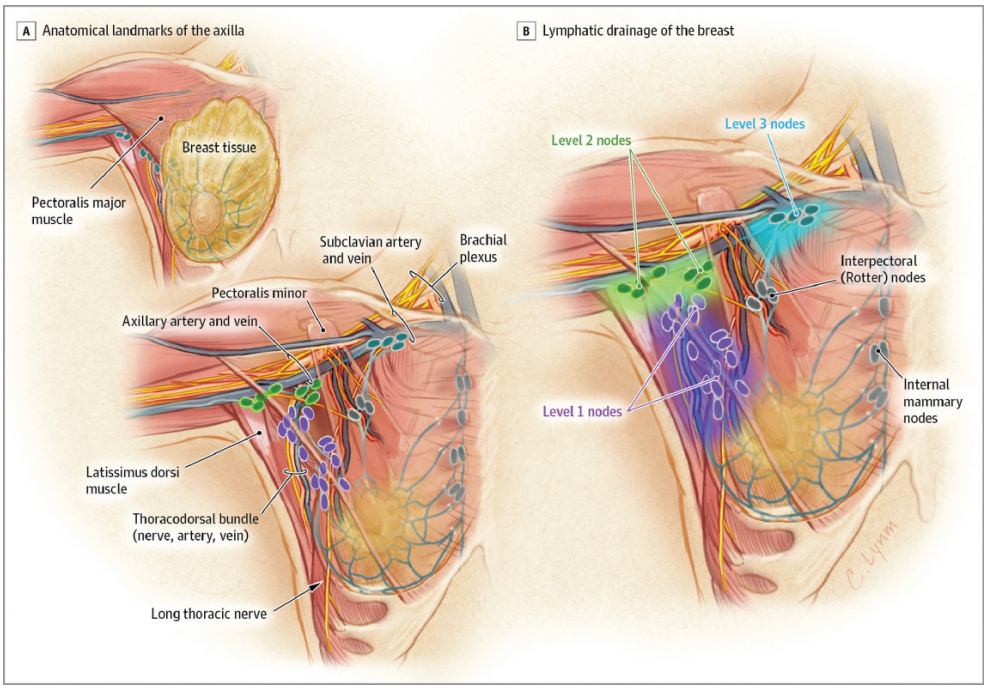

Figure 74.22 **A:** Anatomical landmarks of the axilla. The boundaries of the axillary lymph node dissection are the axillary vein superiorly, the latissimus dorsi and thoracodorsal bundle laterally, and the serratus anterior muscle and long thoracic nerve medially. **B:** Lymphatic drainage of the breast. During an axillary lymph node dissection, level 1 and 2 lymph nodes are removed.

The approach to axillary lymph node dissection described above is a medial to lateral approach with the long thoracic nerve, axillary vein, and thoracodorsal nerve identified in sequence. Alternatively, one can approach the dissection through a lateral to medial approach. With this method, once the clavipectoral fascia is incised to enter the true axilla, the anterior surface of the latissiumus dorsi is identified at the lateral extent of the axillary dissection. The clavipectoral fascia is then incised along the superior and medial aspects of the axilla. Dissection is then performed to first identify the thoracodorsal nerve, then the axillary vein superiorly, and then the long thoracic nerve medially. Once all the nerves and vascular structures are identified, the axillary contents are mobilized and removed.

Complications from ALND include motor and/or sensory nerve injury. Injury to the long thoracic nerve may result in winged scapula, whereas injury to the thoracodorsal nerve leads to weakness of internal rotation and extension, characterized by the functional inability to hold a book under the

arm. Other risks include seroma formation, infection, and lymphedema.[282–284] The risk of lymphedema is lifelong and is as high as 30%.

Simple Mastectomy

A mastectomy is performed for patients with breast cancer who are not candidates for BCT or for patients who prefer a mastectomy. For women at high risk for the development of breast cancer, it can be performed as a prophylactic procedure. The goal of mastectomy is complete removal of the breast tissue while preserving muscle function, and viable skin flaps for primary closure. Preoperatively, the patient is examined in the holding area, where the breast is marked and the correct site of surgery is confirmed. An intravenous antibiotic that covers skin flora, such as cefazolin, given before skin incision has been shown to significantly decrease the risk of infection in patients undergoing mastectomy (relative risk 0.60, 95% CI 0.45 to 0.81).[285] The patient is then placed in the supine position with the arms abducted up to 90 degrees with padding placed beneath the arms and wrist to avoid brachial nerve and radial nerve injury. The skin is then cleansed with a preparation of chlorhexidine gluconate/isopropyl alcohol or betadine solution and the patient is draped in a sterile fashion. The most common skin incision used is an elliptical incision in the horizontal (Stewart Incision) or diagonal plane (Orr Incision), although historically a vertical plane incision for high lying or infraclavicular lesions has also been used (Fig. 74.23). The medial border of this incision is 2 cm from the sternal edge and the lateral border is at the midaxillary line. The elliptical incision should include the skin directly over the tumor, especially if the tumor is superficial. Once the incision is made, a superior skin flap is developed in the relatively avascular plane between the skin and the breast parenchyma, to the level of the clavicle. The fascia of the pectoralis major muscle is then incised from the sternum to the edge of the lateral edge of the muscle with care to preserve the internal mammary perforators. The inferior flap is then developed to the level of the rectus muscle (just at or below the level of the inframammary fold). The underlying fascia is then incised from the sternum to the mid axillary line. The medial flap is then developed similarly, connecting the superior and inferior flaps, with attention to the internal mammary perforators in this area. As these vessels tend to retract, a stick tie should be used to ligate any bleeding

vessel. Unlike the other skin flaps, the lateral dissection tends to be less well defined and slightly thicker. The flap is taken down to the level of the latissimus muscle. Care should be taken to avoid the axillary contents and sensory nerves. The breast is then removed en bloc with the fascia of the pectoralis muscle by retracting the breast downward and dissecting the plane between the muscle fibers and the fascia. The wound is then irrigated with warm sterile saline, and the flaps and chest wall are then systematically inspected to ensure hemostasis. A drain is then placed to prevent seroma formation. Skin closure can be performed in different ways, such as with a 3-0 running polydioxanone suture (PDS) with a 4-0 subcuticular stitch or with interrupted 3-0 vicryl sutures with a 4-0 subcuticular stitch. Post mastectomy, the patient is admitted to the hospital overnight to ensure adequate pain control, and to monitor for acute bleeding. When drain output is less than 30 mL for two consecutive days, the drain is removed (typically between postoperative days 7 and 14). No antibiotic coverage is necessary while drains are in place. In less than 1% of cases, hematomas can occur and if small can be observed. For large or enlarging hematomas (encompassing greater than one-fourth of the chest wall), surgical exploration is required to evacuate the hematoma and stop any sources of bleeding. Other complications associated with mastectomy include skin flap necrosis, pneumothorax, cellulitis, neuropraxia, and lymphedema.

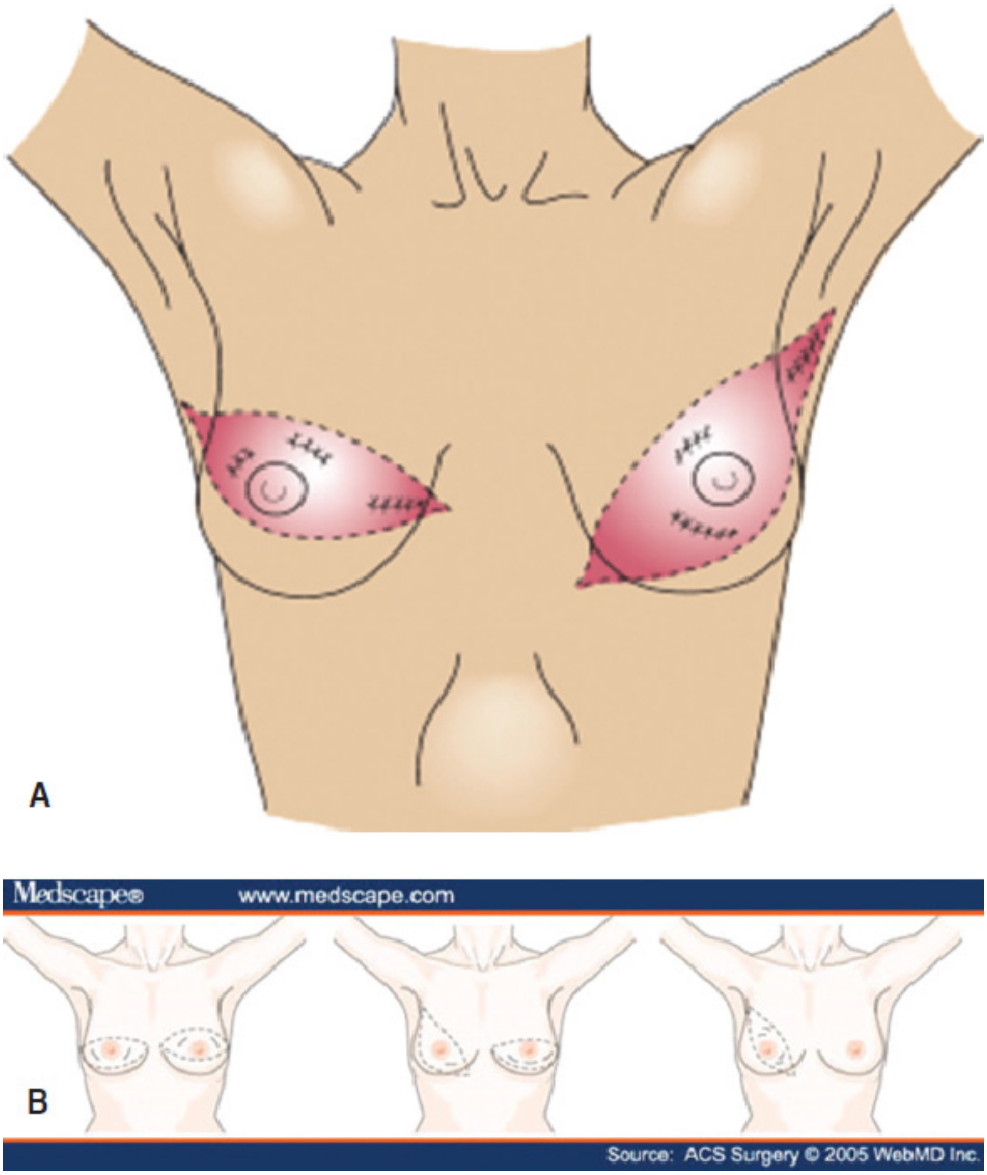

Figure 74.23 Incision placement for modified radical mastectomy. The incision should include the nipple–areola complex, biopsy scar, and excess skin of the breast.

If immediate reconstruction is planned, a *skin-sparing* incision is made, which often consists of making either a smaller horizontal ellipse around the nipple–areola complex, a circular incision just encompassing the nipple–areola complex, or a lollipop incision (Fig. 74.24). In some circumstances, the patient may be a candidate for a *nipple-sparing mastectomy* if her breasts are small to moderate in size, often no larger than a C cup, with minimal ptosis, and the breast cancer is at least 2 cm from the nipple. Tumor size, histology, or lymph node status are no longer considered exclusion

criteria for nipple-sparing mastectomy, and current exclusion criteria include clinical involvement of the nipple areolar complex, PDB, bloody nipple discharge, multicentric disease[286] and/or inflammatory carcinoma.[287] Nipple-sparing mastectomies are often performed through an inframammary fold incision or a radial lateral incision. More recently, a lateral vertical incision has been described. This incision is associated with a significant reduction in hypertrophic scar formation versus the radial lateral incision.[288] Intraoperatively, a biopsy of the retroareolar margin is performed and must be histologically negative 10 for malignancy. BRCA mutation carriers are also candidates for nipple-sparing mastectomies. In a study of 26 patients with BRCA mutations undergoing prophylactic mastectomies, DCIS was identified in one patient compared with two cases of DCIS in the matched control group. There were no locoregional recurrences in the patients with BRCA mutations at 37 months of follow-up.[289] These findings support that nipple-sparing options are reasonable for patients with BRCA mutations.

Although the goal of a mastectomy is to completely remove the breast cancer and normal breast tissue, local recurrence remains a risk. The risk of local recurrence is 6% at 5 years in patients with no lymph node involvement, and 16% at 5 years in patients with one to three lymph nodes involved. With the addition of radiation therapy the risk of local recurrence decreases to 2%. When four or more lymph nodes are involved, the risk of recurrence is 26% at 5 years, decreasing to 6% with the addition of radiation therapy.[290]

In women with a personal history of breast cancer, the absolute risk of contralateral breast cancer is estimated to be 0.5% to 1.0% per year or 5% to 10% during the 10 years following diagnosis.[291] As such, most women will not develop a contralateral breast cancer. As no randomized clinical trials have been performed, it is not known if contralateral prophylactic mastectomy (CPM) is associated with a survival benefit in women with a personal history of breast cancer. However, a survival benefit for CPM has been shown for patients with a deleterious *BRCA1* or *BRCA2* mutation.[292–295] The decision to perform a CPM must be individualized with each individual patient. Of note, a twofold increased risk of major complications exists with CPM when compared with unilateral mastectomy.[296,297]

Breast Reconstruction

All patients undergoing mastectomy should be offered consultation with a plastic surgeon for consideration of breast reconstruction, recognizing that some women may choose to forego this procedure and prefer the use of breast prosthesis. The two main types of breast reconstruction include implant-based and autologous tissue breast reconstruction. Implants include silicone or saline implants. Autologous tissue techniques used for breast reconstruction often include either the transverse rectus abdominus myocutaneous (TRAM) flap or the deep inferior epigastric perforator (DIEP) flap.

Breast reconstruction can be performed immediately after a mastectomy procedure (immediate reconstruction) or at a later time (delayed reconstruction). For implant-based breast reconstruction, the most common technique involves a two-stage method with placement of a tissue expander under the pectoralis major muscle at the time of the mastectomy (Fig. 74.25). The tissue expander can then be filled incrementally with saline with the first fill typically occurring 1 to 3 weeks postoperatively with additional fills every 1 to 2 weeks until the desired expansion is achieved. The tissue expander is then left in place for several months to allow for maximal skin remodeling. During the second stage, the tissue expander is removed and is replaced with a silicone or saline implant. This two-stage reconstruction method is particularly beneficial for women who will need adjuvant radiation therapy as radiation can result in flap necrosis, fibrosis and shrinkage resulting in poor cosmetic outcomes after immediate implant and/or tissue flap reconstruction. Instead, the tissue expander allows for skin preservation and the ability to then proceed with either an implant or autologous reconstruction at a later date. The complications associated with tissue expander placement include infection requiring removal. This occurs at a rate of 1.2%, but may be higher in women being treated with chemotherapy and/or radiation therapy.[298]

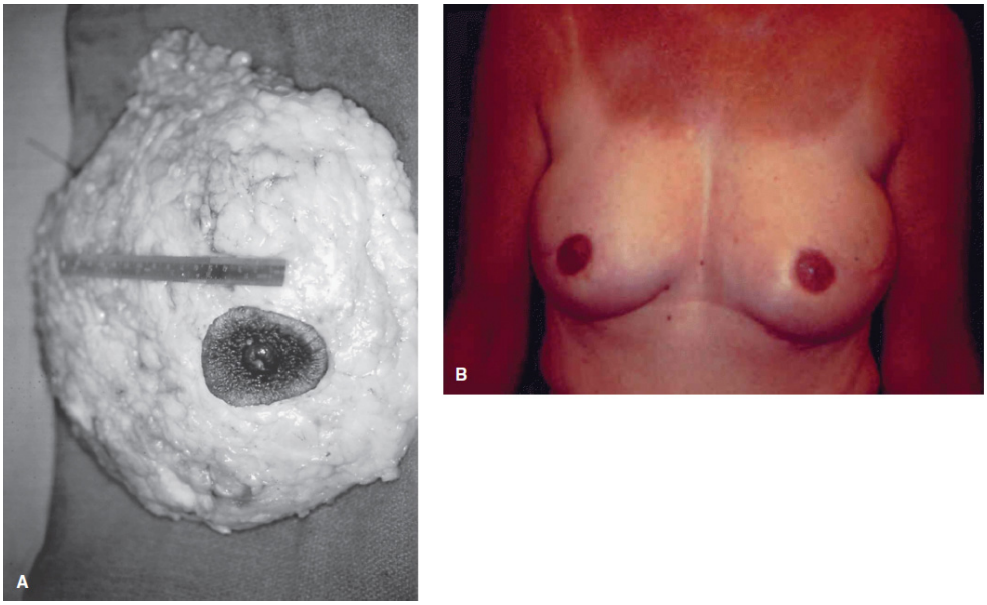

Figure 74.24 Skin-sparing mastectomy. **A:** The only skin removed was the nipple–areola complex. **B:** Cosmetic outcome after bilateral skin-sparing mastectomy and transverse rectus abdominis myocutaneous (TRAM) flap reconstruction.

Figure 74.25 Breast reconstruction with tissue expanders. Although the breasts are not identical, this is not evident when a bra is worn.

Although silicone gel implants are superior to saline implants in terms of offering a more natural contour and texture, the use of silicone implants remains controversial secondary to unsubstantiated claims of a link between silicone implants and autoimmune disease first reported in 1992. Since that time, no studies have shown a causative relationship and the American College of Rheumatology and the FDA have concluded that there is no additional risk of connective tissue disease in patients with silicone implants.[299–301]

A few case reports have noted an association between breast implants (saline or silicone) and anaplastic large cell lymphoma of the breast. There have been 60 cases of ALCL reported among an estimated 5 to 10 million women with breast implants. Although a causal relationship is not proven and the potential risk is extremely low, the FDA does require breast implant manufacturers to include this finding in the product labeling.[302]

The primary benefit of autologous tissue breast reconstruction is that the reconstructed breast appears and feels more natural than following implant-based breast reconstruction. In addition, autologous tissue breast reconstruction may be the only option in patients who have undergone chest wall radiation, as skin fibrosis may preclude implant-based breast reconstruction. A common procedure is the free TRAM flap, which involves removing skin, subcutaneous fat, muscle and associated blood supply from the lower abdomen. The blood supply includes the deep inferior epigastric artery and vein, which are anastomosed to the internal mammary or thoracodorsal arteries and veins. The TRAM flap is contoured to replicate the native breast. Similar to the TRAM flap, the DIEP perforator flap uses the same lower abdominal skin and subcutaneous fat but spares the rectus abdominis muscle. In both methods, the donor site is closed as a modified abdominoplasty.

Radical Mastectomy

In 1907, Halsted presented to the American Surgical Association his results of 232 patients who underwent his radical mastectomy at Johns Hopkins. Halsted's radical mastectomy involved wide excision of skin via a teardrop incision extending across the deltopectoral groove, excision of the entire pectoralis major muscle, resection of the pectoralis minor muscle to expose the axillary contents for dissection, and excision of the supraclavicular lymph nodes. In certain cases, he also removed the mediastinal nodes. Immediate skin grafting was performed to close all of the wounds.[303] With advances in breast cancer screening, adjuvant medical therapy, and radiation therapy, a concomitant evolution toward less radical surgery has ensued. A report by the American College of Surgeons Commission on Cancer demonstrated a dramatic decline in the use of the radical mastectomy from 47.9% of breast cancer cases in 1972 to 3.4% of cases in 1981.[304] Further, the **modified**

radical mastectomy, which consists of a simple mastectomy and axillary lymph node dissection, was considered a satisfactory alternative to the radical mastectomy by 1980.[305] A randomized, prospective clinical study by W.A. Maddox in 1983 showed no significant differences in disease-free survival, overall survival, or local recurrence rates at 5 years for modified radical versus radical mastectomy. These differences are likely secondary to the routine use of chemotherapy for patients with involved axillary lymph nodes by this time period.[306] When patients are not candidates for breast conservation and SLNB, a modified radical mastectomy is indicated. Please see the section on ***Axillary Lymph Node Dissection*** above.

Radiation Therapy

The primary indication for the use of radiation therapy in breast cancer is to reduce the risk of a locoregional recurrence following surgery, and potentially improve survival by eradicating persistent locoregional disease that may be resistant to systemic therapy.

The standard approach for patients who undergo breast-conserving surgery is to deliver whole breast radiation therapy with a dose of 50 to 60 Gy. The regimen is often given in 2 Gy fractions 5 days a week for a total of 5 weeks. A 60 Gy regimen, which also includes a 10 Gy boost to the tumor bed, was found to be more effective for patients 45 years of age or younger, with a local relapse rate of 14% (60 Gy) compared to 28% (50 Gy) ($p < 0.0001$).[307] Alternative radiation therapy strategies are currently under investigation including the use of rapid fractionation schedules, such as the delivery of 41 to 42 Gy over 15 fractions, and accelerated partial breast radiation. Early results show excellent clinical outcomes.[308–310]

Although most women do not require radiation therapy following mastectomy, postmastectomy radiation therapy is often recommended for women at high risk for locoregional recurrence, including women with four or more positive lymph nodes, tumor size greater than 5 cm, or with positive surgical margins. In these instances, postmastectomy radiation can reduce the rate of chest wall recurrence by 65% to 75%.[311–315]

Of note, optimal locoregional management of the axilla remains to be defined. Both surgery and radiation therapy can be used to treat disease in the axilla. Previously, ALND was the preferred treatment modality for

prevention or treatment of axillary disease. More recent studies suggest that radiation therapy may be equally effective with less morbidity. The EORTC 11 AMAROS trial randomized patients with clinical T1–T2 N0 breast cancer to ALND or radiation therapy to the axilla after a positive SLNB.[316] The two arms had comparable axillary control, but patients in the radiation therapy arm had significantly less morbidity. At 5 years 23% of patients in the ALND arm had lymphedema compared to 11% in the radiation therapy arm. Currently, in patients with clinical T1–T2 N0 disease who undergo mastectomy with a positive SLNB, ALND is the standard approach as these patients were not included in the Z0011 study. However, findings from the AMAROS trial suggest that in this group of patients, radiation therapy may provide similar locoregional control with less morbidity.

Chemotherapy

The role of medical therapy is to eradicate breast cancer cells at the primary tumor site, or at any other site in the body. Systemic therapies include but are not limited to chemotherapy, endocrine therapy, and targeted therapy.

The decision as to whether or not to treat breast cancer patients with chemotherapy is complex. Considerations include patient age, menopausal status, AJCC TNM stage, histologic grade, biomarker profile, proliferation index, and medical comorbidities. Fortunately, online calculators exist to estimate the risks and benefits of chemotherapy and other adjuvant therapies. Adjuvant! Online is a popular risk–benefit calculator that is based on population-wide data that focuses on recurrence risk and probability of survival. This is a web-based program that is generated from collective data from the Surveillance, Epidemiology, and End Results (SEER) database, the Early Breast Cancer Trialists Collaborative Group (EBCTCG), individual clinical trial results, and published literature.[317] Other calculators include Cancermath.net[318] and FinProg project.[319] Molecular profiling using Oncotype DX or similar molecular assay can be used for patients with node-negative $ER^+/HER2^-$ breast cancers. For Oncotype DX a score of ≥31 is associated increased risk of recurrence with a recommendation for administration of chemotherapy.

Adjuvant chemotherapy is often initiated 4 to 6 weeks after surgery. Although treatment earlier is not beneficial, a delay of greater than 12 weeks

may be detrimental. If adjuvant radiation therapy is indicated, it is administered starting 3 to 4 weeks after completion of chemotherapy.

Anthracyclines (doxorubicin, daunorubicin, epirubicin)

These compounds are derived from *Streptomyces* bacteria and function by inhibiting DNA and RNA synthesis by intercalating between base pairs of the DNA/RNA strand, blocking DNA transcription and replication by inhibiting topoisomerase II enzyme, generating free oxygen radicals, and by inducing histone eviction form chromatin. The main adverse effect is cardiotoxicity.

Taxanes (paclitaxel, docetaxel)

These compounds are derived from plants of the genus *Taxus* (yews) and function by disrupting microtubule formation and inhibiting mitosis. The main adverse effect is peripheral neuropathy. Given that these compounds are not water soluble, allergic reactions to the diluent may result.

Cyclophosphamide

This compound is a nitrogen mustard alkylating agent that functions by adding an alkyl group to the guanine base of DNA, resulting in intrastrand and interstrand DNA crosslinks and therefore interferes with DNA replication. The main adverse effects include acute myeloid leukemia, bladder cancer, hemorrhagic cystitis, and infertility.

5-Fluorouracil

This compound is an antimetabolite that works as an irreversible inhibitor of thymidylate synthase and therefore interferes with DNA synthesis. The main adverse effect is mucositis.

Methotrexate

This compound is both an antimetabolite and an antifolate that blocks dihydrofolate reductase and therefore inhibits the synthesis of folic acid, which is essential for DNA, RNA, thymidylate, and protein synthesis. The main adverse effect is ulcerative stomatitis.

Platinum Agents (carboplatin or cisplatin)

These compounds bind to and cause crosslinks in DNA, triggering apoptosis. The main adverse effect is nephrotoxicity, neurotoxity, and ototoxicity.

Endocrine Therapy

Patients with all stages of breast cancer that express the estrogen receptor or progesterone receptor are candidates for endocrine therapy. In the premenopausal setting, the focus is on blocking ovarian function and the effects of estrogen. In postmenopausal women, the ovaries are no longer the predominant source of estrogen, but instead estrogen is synthesized mainly from nonglandular sources such as subcutaneous fat. As such, blocking estrogen production is very effective in the postmenopausal population.

Blocking Ovarian Function (leuprolide, goserelin, buserelin)

As the ovaries are the main source of estrogens in premenopausal women, ovarian ablation can be achieved either surgically by removal of the ovaries or through medical therapy with luteinizing hormone–releasing hormone (LHRH) agonists such as goserelin or leuprolide. These compounds function by binding to the gonadotropin-releasing hormone (GnRH) receptor, resulting in initial FSH and LH release. However, with prolonged drug exposure, desensitization of the pituitary occurs whereby the levels of LH and FSH become profoundly suppressed. This results in inhibition of the growth of ovarian follicles and steroidogenesis.

Blocking Estrogen at the Receptor (tamoxifen, raloxifene, fulvestrant)

As SERMs, tamoxifen and raloxifene competitively bind to the estrogen receptor and prevent estrogen from binding. As a selective estrogen receptor down-regulator (SERD), fulvestrant binds to the estrogen receptor and targets it for destruction. Fulvestrant is used only in postmenopausal women who have hormone receptor-positive metastatic disease who experience progression following endocrine therapy.

Blocking Estrogen Production (anastrozole, letrozole, exemestane)

The enzyme aromatase converts androgenic substrates to estrogen, and therefore its inhibition can effectively decrease plasma levels of estrogen. Nonsteroidal aromatase inhibitors include anastrozole and letrozole, whose binding activity can be reversed. Exemestane is a steroidal aromatase inhibitor that irreversibly binds aromatase and permanently inactivates it.

Targeted Therapy

Targeted Therapy for HER2+ Breast Cancers

Amplification or overexpression of the human epidermal growth factor receptor 2 (HER2) is present in approximately 20% of primary breast cancers. Given that effective targeted therapies exist for these patients, all newly diagnosed breast cancers are routinely tested for HER2 expression/amplification.

Trastuzumab is a monoclonal antibody that targets $HER2^+$ breast cancers by multiple mechanisms including (1) interfering with the homo- and heterodimerization of HER2 and inhibiting mitogen-activated protein kinase (MAPK) and phosphoinositide 3-kinase (PI3K/Akt) signaling pathways, (2) immune-mediated killing of tumors that overexpress HER2 by a mechanism referred to as antibody-dependent cellular cytotoxity (ADCC), and (3) triggering HER2 internalization and degradation through promoting the activity of tyrosine kinase-ubiquitin ligase c-Cbl.

Pertuzumab is a monoclonal antibody that interferes with the dimerization of HER2 to HER3, therefore interfering with MAPK and PI3K pathway activation. It also induces ADCC.

Trastuzumab emtansine (T-DM1) is an antibody-drug conjugate that consists of trastuzumab linked with the cytotoxic agent mertansine (DM1). While trastuzumab binds to the HER2 receptor, mertansine enters the cell and destroys it by binding to tubulin. This allows toxin to be targeted specifically to the cancer cell.

Targeted Therapy for Triple Negative Breast Cancers (experimental options)

Although patients with TNBC often have an excellent response to chemotherapy, overall outcomes are worse compared to patients with ER^+ and/or $HER2^+$ disease.[231,320,321] The lack of effective targeted therapies for TNBC likely contributes to this disparity in outcome. Drugs targeting TNBCs are in clinical trials and include inhibitors targeted to the epidermal growth factor receptor (cetuximab), angiogenisis (bevacizumab), DNA damage or poly adenosine diphosphate-ribose polymerase (olaparib, veliparib, iniparib), the proto-oncogene Src (dasatinib), and histone deacetylase (vorinostat). Given the heterogeneity of TNBC, multi-targeted therapy will likely be needed to eradicate this disease.

Special Issues in Breast Cancer Treatment

Inflammatory Breast Cancer

A common clinical presentation for IBC is *peau d'orange*, characterized by edema, warmth, and erythema. Unlike other types of breast cancer, patients with IBC often have associated pain and tenderness with an enlarged and firm breast. The nipple can also be involved with flattening, erythema, crusting, blistering, and retraction. Despite the reference to inflammation, the skin changes are not secondary to an inflammatory process but rather secondary to tumor emboli within the dermal lymphatics.[322] As noted by Sir Charles Bell in 1812, these cancers tend to be much more aggressive —"when a purple color is on the skin over the tumor accompanied by shooting pains, it is a very unpropitious beginning."[323] By 1924, Lee and Tannenbaum described 28 cases of women presenting with a rare, rapidly progressive breast cancer with inflammatory features and introduced the term "inflammatory breast cancer."[324]

IBC is an aggressive form of LABC that affects approximately 1% to 5% of women with breast cancer.[325] It is designated as primary tumor stage T4d. The consensus-based criteria for the diagnosis of IBC was determined by an international expert panel who proposed the following features: (1) rapid onset of breast erythema, edema, and/or *peau d'orange*, and/or warm breast,

with or without an underlying palpable mass, (2) duration of history no more than 6 months, (3) erythema occupying at least one-third of the breast, and (4) pathologic confirmation of invasive carcinoma.[326] Furthermore, although dermal lymphatic involvement supports the diagnosis of IBC, which can be obtained with a full-thickness skin punch biopsy, it is neither necessary nor sufficient in the absence of the classical clinical findings. The diagnosis of IBC is made with clinical exam findings, followed by breast imaging, which includes mammography and ultrasound to help detect sites within the breast that can be biopsied to confirm the breast cancer. To determine extent of disease, we routinely obtain a breast MRI. A skin punch biopsy can then be performed but is not required for diagnosis. As IBC is a clinically and pathologically distinct form of LABC that is particularly fast growing, invasive, and angiogenic, nearly all women have lymph node involvement at the time of presentation and approximately a third of patients will have distant metastases.[327,328] As such, all women with IBC need to undergo complete staging including a chest/abdomen/pelvic CT scan and bone scan. Head CT should be considered if symptoms are present.

The treatment for IBC is based on multimodality treatments, similar to those described for women with LABC. However, BCT, SLN biopsy, and immediate breast reconstruction are generally considered inappropriate for patients with IBC. Treatment often consists of neoadjuvant chemotherapy that is anthracycline- and taxane-based until all signs of skin inflammation have resolved and the breast and axillary masses are deemed operable. Surgical management with a modified radical mastectomy is then performed with delayed breast reconstruction, if appropriate. Adjuvant radiation therapy follows using standard fields determined by CT planning, ensuring that the chest wall, supraclavicular, infraclavicular, and the internal mammary lymph nodes are radiated.[326] Radiation therapy to the axillary bed after axillary dissection is often individualized. However, if the patient still remains inoperable after neoadjuvant chemotherapy, then radiation therapy ensues, with the goal that the patient will thereafter become operable. For ER^+ IBC, adjuvant endocrine therapy is given. For $HER2^+$ IBC, trastuzumab (+/– pertuzumab) is added to the neoadjuvant regimen and adjuvant trastuzumab is given to complete 1 year of treatment.

Currently there is no optimal systemic regimen (chemotherapy or targeted therapy) identified for IBC. However, patients who obtain a complete

pathologic response from chemotherapy have a significantly higher disease-free survival and overall survival.[329,330] Despite the combination of surgery and radiation therapy improving locoregional control, there is no impact on overall survival.[331] Even with multimodality treatments, the prognosis for patients with IBC remains poor with 5-year disease-free survival rates of 20% to 45% and an overall survival of 30% to 70%.[329,331–334]

Breast Cancer in the Elderly

In the United States, approximately half of newly diagnosed breast cancers are in older women, typically defined as age ≥65 years. Older patients tend to receive less than standard therapy worldwide,[335–338] with decreased rates of surgery and use of adjuvant radiation therapy, but with increased use of primary endocrine therapy.[339] This may be secondary to more indolent tumors present in elderly women versus younger women.[340] However after controlling for confounding factors such as comorbidity, social support, and functional status, older women are still treated less aggressively than their younger counterparts. In general, treatment approaches should not be altered for medically fit older women, except for the use of SLNB and/or radiation therapy in early ER^+ disease.

The ability to omit axillary surgery without an adverse effect on outcome in older women (age ≥70 years) with favorable breast cancers has been well studied and supported by multiple randomized trials. These women had clinically negative axillary examinations, small (<2 cm) ER^+ breast cancers, and were all treated with adjuvant endocrine therapy.[341–343]

The ability to omit adjuvant radiation therapy in older women who have undergone partial mastectomy for early ER^+ breast cancer is supported by CALGB 9343. This phase III study involved 636 women (age ≥70 years) who had T1N0M0 ER^+ breast cancer who were treated with partial mastectomy and then randomly assigned to either receive radiation therapy plus tamoxifen (317 women) or tamoxifen alone (319 women). The primary end points studied included time to local or regional recurrence, frequency of mastectomy, breast cancer-specific survival, time to distant metastasis, and overall survival (OS). At 10 years, 98% of patients receiving radiation therapy plus tamoxifen compared with 90% of those receiving tamoxifen alone were free from local and regional recurrences. However, there were

no significant differences in time to mastectomy, time to distant metastasis, breast cancer-specific survival, or OS between the two groups. Ten-year OS was 67% (95% CI, 62% to 72%) and 66% (95% CI, 61% to 71%), respectively.[344] This led to breast-conserving surgery and endocrine therapy alone being incorporated as a category I recommendation in the current consensus guidelines for older women.

For older women with comorbidities, functional status limitation, or frailty, the Comprehensive Geriatric Assessment (CGA) can serve as an objective measure to aid in treatment decisions. The CGA has been used in elderly cancer patients including those with breast cancer and range from 44 to 84 questions. The ELCAPA study looked at how the CGA could alter an initial treatment plan in 375 patients aged 70 years and older. Treatment plans were modified in 20.8% of cases, with most plans changed to decrease treatment intensity, although there were some regimens (10.8%) that were intensified.[345] Given how extensive the full CGA can be, other screening tools that have been developed include the Vulnerable Elders Survey-13, Barber Questionnaire, Geriatric 8, Cardiovascular Health Study, and the abbreviated CGA.

For medically frail patients, surgical management followed by observation is commonly offered, especially if a patient's life expectancy is limited. If surgical intervention is not an option, endocrine therapy can be offered to patients with ER^+ disease and single agent chemotherapy for those with ER^- disease. In the presence of $HER2^+$ disease, single agent HER2-directed therapy or its addition to systemic therapy can be prescribed, understanding that the latter approach carries additive risks of toxicity. Radiation therapy is not recommended unless local control of disease is needed for symptom management. Lastly, palliative and supportive care services need to be offered to patients who wish to avoid both surgical and systemic therapies.

Breast Cancer during Pregnancy

Gestational breast cancer is a rare disease affecting approximately 1 in 1,000 pregnancies, but may become more common as women delay childbearing.[346–349] It is defined as breast cancer that is diagnosed during pregnancy, within the first postpartum year, or anytime during lactation. Similar to nonpregnant women, women with gestational breast cancer present

most often with a breast mass or skin thickening. Any mass that persists for greater than 2 weeks needs diagnostic imaging and possible biopsy.

The breast becomes engorged and hypertrophied during pregnancy making imaging more difficult. When women present with a mass in pregnancy, ultrasound is first obtained, which can differentiate between a simple cyst, a complex cyst, or a solid tumor. The majority of gestational breast cancers present as a focal solid mass.[350,351] In the presence of an abnormal ultrasound, a diagnostic mammogram can then be obtained to further determine the extent of disease and has been shown to be safe in pregnancy as long as abdominal shielding is used.[352] Although MRI with gadolinium has been shown to be more sensitive than mammography for detecting invasive breast cancer, gadolinium is contraindicated in pregnancy. MRI has also not been systemically studied for the evaluation of breast masses in pregnancy or lactation. All suspicious masses must be biopsied, even in the presence of normal imaging studies, through core needle biopsy, incisional biopsy, or excisional biopsy. In a patient who has a concerning axillary exam, FNA biopsy is indicated.

The most common histologic type of gestational breast cancer is IDCs that are poorly differentiated and diagnosed at an advanced stage. Compared to nonpregnant women, women with gestational breast cancers have less hormone receptor-positive breast cancers (approximately 25% vs. 55% to 60%).[353,354] The association between HER2 disease and gestational breast cancer is not currently known. For pregnant or lactating women with locally advanced disease, staging evaluation is necessary. Given the large cumulative radiation dose that can be associated with CT scans and the contraindication for gadolinium use (therefore limiting the utility of MRI) in pregnancy, staging imaging for pregnant women commonly include a chest x-ray, an abdominal ultrasound of the liver, and a “low-dose” bone scan or a skeletal MRI.

For women diagnosed with breast cancer at an early gestational age, pregnancy termination is an option. However, studies have not shown better outcomes with early termination. In a study involving 176 patients, pregnancy did not directly affect the prognosis of breast cancer, instead poor survival was related to younger age (less than 40 years old) and to the large number of estrogen receptor-negative tumors (71%).[355] Multiple subsequent studies have shown that pregnancy does not have a negative impact on overall

survival.[356–358] In 2012, a meta-analysis involving 3,000 patients with gestational breast cancer who were compared to 37,100 controls, found that gestational breast cancer was associated with a higher risk of death. However, this was limited to women diagnosed in the postpartum period.[359]

The treatment for breast cancer for women diagnosed in the postpartum or lactational period does not differ from that recommended for nonpregnant patients. However, for patients receiving chemotherapy, trastuzumab, or endocrine therapy, breastfeeding is not recommended given the potential toxicity to the infant. The treatment for pregnant women does not differ significantly from established guidelines, but includes modifications to ensure the safety of the developing fetus. During any trimester of pregnancy, surgical and anesthetic risks to the fetus have been shown to be minimal.[360–363] Mastectomy can be performed and for early breast cancers, this can eliminate the need for radiation therapy as it is contraindicated in pregnancy. Typical radiation doses used for breast cancer range from 46 to 60 Gy, which has been shown to convey a first trimester fetal dose of 0.04 to 0.15 Gy or a third trimester dose as high as 2 Gy.[357,364] The threshold determined for prenatal radiation exposure for fetuses under 16 weeks of gestation is 0.10 to 0.20 Gy and after 16 weeks 0.50 to 0.70 Gy to avoid risk of congenital malformations.[365] As such breast conserving treatment (which necessitates radiation therapy) remote from delivery is not a feasible option. Otherwise the choice between breast-conserving surgery versus mastectomy can be guided by a patient's preference and the biology of the tumor.

Isosulfan blue dye is contraindicated in pregnant women, and methylene blue when used in amniocentesis has been associated with fetal complications. However, a small series of studies using methylene blue or double filtered technetium sulfur for SLNB have suggested its safety and success in pregnant women.[366–369] Given the small number of pregnant patients included in these studies, the potential risks of methylene blue and technetium sulfur to the fetus along with the potential inaccuracy of SLNB in pregnancy need to be discussed with the patient preoperatively.

The most common regimens used in gestational breast cancers are anthracycline-based, AC (doxorubicin plus cyclophosphamide) or FAC (fluorouracil plus AC). The exposure of the fetus during organogenesis or the first trimester to chemotherapy can be detrimental and conveys risks including congenital abnormalities, chromosomal abnormalities, and

miscarriage. Although chemotherapy exposure in the second and third trimesters is not associated with organogenesis, risks of intrauterine growth restriction, lower gestational age at birth, and low birth weight occurs in about half of exposed infants.[370–373] As such, chemotherapy is often initiated after the first trimester and given its association with transient neonatal myelosuppression, it should be avoided three to four weeks prior to delivery. When possible, timing of delivery is restricted to 34 or more weeks of gestation and requires confirmation of fetal lung maturity to minimize complications associated with prematurity. Given that gestational breast cancer can present as locally advanced disease, neoadjuvant chemotherapy can be first given, followed by surgery in the postpartum period, and if indicated adjuvant radiation therapy and endocrine therapy can then be initiated. For women who are diagnosed late in pregnancy or the postpartum/lactational period, prior to commencement of chemotherapy, which may impair infertility, these women should be offered consultation with a reproductive endocrinologist to discuss fertility-preserving options.

Trastuzumab is contraindicated in pregnancy given its association with oligohydramnios, which can result in fetal death, pulmonary hypoplasia, and fetal developmental abnormalities.[374,375] The use of methotrexate and endocrine therapy are also contraindicated during pregnancy. These therapies can be initiated in the postpartum period.

Given that the majority of women diagnosed with gestational breast cancers are of reproductive age, many desire additional pregnancies. In a meta-analysis of fourteen studies, 1,244 women who became pregnant following breast cancer were compared to 18,145 control patients. Pregnancy in breast cancer survivors did not convey a worse survival but suggested a protective effect. Some suggest that pregnancy may have an unknown biologic antitumor effect, although more likely this is secondary to healthier women with better prognosis choosing to reproduce over their sicker peers and therefore resulting in a bias toward improved survival. As most recurrences happen within the first two years after diagnosis and treatment, it is generally recommended that pregnant women wait 2 years before contemplating another pregnancy.

Breast Cancer in Men

Male breast cancer in the United States accounts for 0.5% to 1% of all breast cancers diagnosed annually.[376] Risk factors for male breast cancer include family history of breast cancer and genetic mutations including *BRCA1* and *BRCA2*. *BRCA2* is more commonly associated with male breast cancer and conveys a 6% lifetime absolute risk, which is an approximately 100-fold higher risk than in the general male population.[377] As such, all men diagnosed with breast cancer need genetic counseling and BRCA testing. Other genetic mutations include *PTEN* which is linked to Cowden syndrome, *TP53* which is associated with Li-Fraumeni syndrome, mismatch repair genes that are linked to hereditary nonpolyposis colorectal cancer (Lynch syndrome), and *PALB2* mutations.[378,379] Other risk factors include those that increase circulating estrogens such as hormonal therapies, hepatic dysfunction, obesity, marijuana use, and thyroid disease. It is also associated with Klinefelter syndrome, which is characterized by 47XXY genotype. These male patients have atrophic testes and gynecomastia. In addition, they have high serum concentrations of gonadotropins (follicular stimulating hormone, luteinizing hormone) and a low serum testosterone level, resulting in a high ratio of estrogen to testosterone. Those with Klinefelter syndrome have a 19.2- and 57.8-fold increase in the incidence of and mortality from breast cancer.[380] Primary testicular conditions (orchitis, undescended testes, testicular injury) are associated with an increased risk of male breast cancer as it can result in lower androgen production and therefore result in a higher than normal estrogen to androgen ratio.[381,382]

Unfortunately, men are often diagnosed with breast cancer at an advanced stage. They commonly present with a firm retroareolar mass that is painless. Workup for a suspicious breast mass in men is similar to that for a woman and includes a mammogram and biopsy. Ultrasound is typically less informative. The most common histologic subtype is invasive ductal carcinoma (90%). Lobular carcinoma is rarely diagnosed in men. DCIS is also less frequent in men versus women. Most male breast cancers are ER^+ (81.5%).[383] The staging system for male breast cancers is similar to that for women and is classified according to the TNM AJCC staging system.

The treatment for early-stage male breast cancer has generally been a modified radical mastectomy. However for a man with a clinically negative axillary exam, an expert panel from the American Society of Clinical Oncology (ASCO) considers SLN biopsy to be an “acceptable” method.[236] It

is generally accepted that in men who have no evidence of disease in the SLN biopsy, no further axillary surgery is needed. For men who have a positive SLN, given there is lack of data for men in regards to this issue, they should be treated similarly to women with positive SLN biopsies. There is limited data regarding the use of breast-conserving surgery in men. A retrospective study of seven men treated with breast conserving therapy followed for a median of 67 months reported that there was no recurrence of disease. If men do elect for a partial mastectomy, adjuvant radiation therapy is essential and is based on results showing that adjuvant RT after breast-conserving surgery for women conveys a survival advantage.[384] For men with LABC (T3N0, N1-2, or T2N2) or IBC, treatment plans are similar to that for women. Consideration for neoadjuvant chemotherapy prior to surgery should be made. The treatment of metastatic breast cancer in males should parallel that for women.

Adjuvant chemotherapy, radiation therapy, anti-HER2 therapy, and endocrine therapy should mirror those for women. As the majority of male breast cancers are estrogen receptor-positive, endocrine therapy with tamoxifen should be given. In a limited study involving 39 men, those treated with tamoxifen had better 5-year actuarial survival (61% vs. 44%) and disease-free survival (56% vs. 28 %).[385] Although there is limited data, tamoxifen appears to be superior to aromatase inhibitors in the adjuvant setting for male breast cancer.[386] Extrapolating from the ATLAS trial for women,[387] for men with higher risk breast cancers, consideration toward extending tamoxifen to 10 years should be considered.

Male breast cancer patients should undergo similar posttreatment surveillance as that recommended for women. However, the role of screening mammography for the contralateral breast in these men has not been explored. It is important to recognize that male breast cancer patients are at risk for developing secondary cancers such as those of the small intestine, rectum, skin (nonmelanoma), pancreas, and prostate.[388]

Locoregional Breast Cancer Recurrence

Breast cancer recurrence can occur after both mastectomy and BCT (partial mastectomy and radiation therapy), with the median time to recurrence after mastectomy of 2 to 3 years versus 3 to 4 years after BCT.[389–391] When breast

cancer reappears on the chest wall it is defined as a local recurrence. However, breast cancer that involves the lymph nodes such as the ipsilateral axillary, supraclavicular, infraclavicular or internal mammary nodes is referred to as a regional recurrence. Among patients who undergo mastectomy for an operable breast cancer, 5% to 10% of patients will have a local or regional recurrence within 10 years whereas patients who undergo BCT have a risk of 10% to 15%, and in patients who forego radiation therapy after a partial mastectomy, the risk of recurrence is as high as 35%.[392] Although BCT is associated with an increased risk of locoregional recurrence, there are no differences in overall survival as supported by a single institutional NIH randomized study (n = 237)[262] and two European randomized trails (EORTC trial 10801 and DBCG trial 82-TM). The latter involved approximately 1,800 patients with stage I and II breast cancer who were randomized to undergo a modified radical mastectomy or BCT. Patients who developed a local recurrence in these trials were then analyzed for survival and time to subsequent local recurrence after salvage treatment. There were no differences between the two groups in regards to survival and time to subsequent local recurrence after treatment for an early locoregional recurrence.[389]

The primary risk factors for postmastectomy recurrence include the size of the primary cancer and the number of positive axillary lymph nodes, where ≥4 involved nodes have been consistently shown to increase axillary recurrence rate to over 20%.[393] In women with four or more positive lymph nodes, tumor size greater than 5 cm, or those with positive surgical margins, postmastectomy radiation therapy is often recommended as it can reduce the rate of chest wall recurrence by 65% to 75%.[311–313] The most common presenting sign of a postmastectomy recurrence is a clinical mass or multiple small nodules on the chest wall or overlying skin in or near the mastectomy scar/skin flaps. Other signs of a recurrence can include inflammatory changes without an associated mass and painless masses found in the axilla or the supraclavicular fossa. Workup for a recurrence should also be undertaken for patients who present with lymphedema or a brachial plexopathy. When a recurrence is suspected, a core biopsy should be obtained to confirm the diagnosis and to evaluate hormone and HER2 receptor status. In addition, a metastatic workup should be performed. The 5-year survival rate for patients based on site of recurrence is 52% for chest wall alone, 50% for axilla

alone, 28% for supraclavicular nodes alone, 28% for chest wall plus axilla, and 7% when both the supraclavicular nodes and chest wall/axilla are involved.[394] The subsequent treatment plan for patients with recurrent breast cancer is complex and requires a multidisciplinary team.

After BCT, the primary risk factors for recurrence are the use of radiation therapy and pathologic margin status. When an ipsilateral breast cancer is identified it is important to determine whether this is indeed a true recurrence versus a second primary cancer; a true recurrence is often found within the primary tumor site or the boost volume of the treated breast. Unlike postmastectomy recurrences, which are commonly detected on physical examination, post-BCT recurrences are often identified by surveillance mammography. However, it is important to note that any physical examination changes that occur more than one year after completion of radiation therapy warrant further workup, even in the presence of a normal mammogram. In this setting, consideration should be made for MRI and biopsy. For any recurrent disease, biopsy is obtained to confirm diagnosis and tumor receptor status, followed by a complete metastatic staging workup. In the absence of metastatic disease, the standard approach to a local recurrence after BCT is a mastectomy, with most patients surviving at least 10 years.[395] In the setting of more advanced recurrent disease, such as that associated with skin involvement or inflammatory changes of the skin, systemic therapy may need to be considered prior to mastectomy. The decision to proceed with axillary restaging should be considered by a multidisciplinary team. Furthermore, the management of regional recurrence after BCT is complex and should be planned with a multidisciplinary approach.

Figure 74.26 Paget disease of the nipple. Depigmentation and desquamation of the nipple and areola are evident.

Paget Disease of the Breast

Although the presentation of breast cancer is commonly associated with a mass or a mammographic abnormality, it must be considered in the setting of chronic nipple ulceration. PDB was first noted by Sir James Paget in 1874 when he described 15 women with chronic nipple ulcerations who then developed cancer of the involved breast within 2 years.[396] The hallmark of Paget disease is a scaly, raw, vesicular, or ulcerated lesion that begins on the nipple and then spreads to the areola (Fig. 74.26). This is often a unilateral process and can be associated with bloody nipple discharge. Symptoms which can occur prior to the development of clinically apparent disease include pain, burning, and pruritus. PDB is a rare disease accounting for only 1% to 3% of new cases of breast cancer in females in the United States.

The diagnostic workup of PDB is to first establish the diagnosis and then to identify the underlying breast cancer which is present in 85% to 88% of cases, despite often not being associated with a breast mass or a mammographic abnormality.[397] Full-thickness wedge or punch biopsy of the nipple should be performed. PBD is characterized histologically by the presence of large cells with prominent nucleoli and a pale cytoplasm (Paget

cells) occurring singly or in small groups within the epidermis of the nipple. Other characteristics of Paget cells include the presence of low–molecular-weight cytokeratins such as CK7. Approximately 50% of PDB cases express hormone receptors and between 70% and 90% of cases overexpress HER2.

For patients with PDB, a physical examination including bilateral breast examination and mammography should be performed to help identify the underlying breast cancer. Approximately one-half of patients with PDB will have an associated mammographic abnormality. Interestingly, these abnormalities can occur distant from the nipple–areolar complex. If no palpable masses are found and mammography is normal, there is a greater likelihood of DCIS than an invasive cancer.[398] If mammography and breast imaging fail to locate disease, then a MRI can be obtained, recognizing that although it is highly sensitive it is not highly specific. As such, MRI detected lesions should be biopsied to confirm the diagnosis of a breast cancer.

The treatment for PDB is either a mastectomy or breast-conserving therapy, which includes a partial mastectomy and whole breast radiation therapy. Breast-conserving surgery includes resection of the nipple–areola complex and the underlying cancer with negative margins obtained (central lumpectomy). Given that the nipple–areola complex is removed, some women may consider this cosmetically unacceptable. Evaluation and treatment of the axilla is dependent on the underlying cancer identified. Adjuvant systemic therapy is also determined by the involved breast cancer.

Figure 74.27 Breast asymmetry resulting from a benign phyllodes tumor. Skin changes are caused by pressure necrosis.

Phyllodes Tumor

Phyllodes tumors are uncommon (<0.5% of all breast malignancies) fibroepithelial breast tumors first described by Johannes Muller in 1838 as *cystosarcoma phyllodes*.[399] Given that these tumors often do not have cystic components and are not true sarcomas, they are now referred to simply as phyllodes tumors (Fig. 74.27). The malignant potential of phyllodes tumors differ widely, with some behaving like fibroadenomas and others that can degenerate histologically into sarcomatous lesions and metastasize distantly. As such, they are histologically classified as benign (50%), borderline (25%), or malignant (25%) based upon the degree of stromal cellularity and atypia, mitotic rate, and the presence or absence of stromal overgrowth and infiltrative margins. Risk factors for phyllodes tumors are not known, aside from their association with Li-Fraumeni syndrome.[400]

Patients with phyllodes tumors present with a smooth, multinodular, well-demarcated, firm mass that is both mobile and painless. The average tumor size is 4 to 7 cm. Although palpable axillary lymphadenopathy can be found in up to 20% of patients, lymph node involvement is rare.[401] Imaging is

notable for a smooth multi-lobulated mass that resembles a fibroadenoma. Core needle biopsy is recommended for diagnosis. However, it has a false-negative rate of 25% to 30%.[402,403] As such, in the presence of a rapidly enlarging mass, excisional biopsy should be performed.

The treatment for all phyllodes tumors is surgical excision to negative histologic margins; however, the definition of negative margins does differ between institutions ranging from no tumor at ink to 1 cm margins. As such, these cases are best addressed in multidisciplinary fashion with pathology. Even large tumors can be treated with breast-conserving surgery without compromising cancer-specific survival. Lymph node involvement is also very rare, in the SEER database, only 8 of 498 women had involved nodes.[404] As such, most surgeons do not routinely perform SLNB for phyllodes tumors. The use of adjuvant radiation therapy and chemotherapy is controversial, however in the setting of a large borderline or malignant phyllodes tumor these treatments should be considered. If systemic therapy for malignant phyllodes tumor is undertaken, it is based on guidelines for treating sarcomas. Similar to breast sarcomas, malignant phyllodes tumors can metastasize to the lungs and as such patients should undergo chest x-ray every 6 months for 2 years and then annually. Unfortunately once metastasis develops, the mean overall survival is 30 months.[405]

Thyroid Gland

Sarah B. Fisher and Elizabeth G. Grubbs

Key Points

1. A thorough understanding of the anatomy and embryology of the thyroid gland will facilitate identification of the recurrent laryngeal nerves (RLNs) and parathyroid glands, avoiding damage to these key structures.
2. A non-recurrent recurrent laryngeal nerve is most commonly seen on the right and associated with vascular developmental abnormalities (arteria lusoria) whereas a left nonrecurrent nerve (rare) may be observed with situs inversus.
3. A thorough ultrasound (US) that includes the thyroid and the central and lateral neck compartments is vital to assessing thyroid pathology, with fine-needle aspiration (FNA) biopsy of appropriate nodules serving as the gold standard for initial diagnosis.
4. The Bethesda system uses cytopathology to risk stratify FNA biopsy results; molecular testing is a diagnostic adjunct for indeterminate nodules but requires an understanding of the strengths and limitations of the specific test.
5. A diagnosis of medullary thyroid cancer (MTC) should prompt a genetic evaluation, with the genotype/phenotype correlation guiding timing of care for those with hereditary syndromes (MEN2A, MEN2B, and familial MTC).
6. Anaplastic thyroid cancer (ATC) should be suspected in the patient with rapid growth and sudden onset of compressive symptoms, hoarseness, and/or dysphagia; imaging will often demonstrate invasion into local structures. These patients should be rapidly triaged to a multidisciplinary team experienced in treating ATC.
7. When deciding between lobectomy and total thyroidectomy for small well-differentiated thyroid cancers, surgical decision making should take into account the underlying disease process, the necessity of adjuvant radioactive iodine (RAI), and patient preferences.
8. Compartment-based lymph node dissection is therapeutic for patients with histopathologic evidence of lymph node metastases.

DISCLOSURES: This work was not supported by a specific funding source. The authors have no financial disclosures.

INTRODUCTION

Thyroid lobectomy or total thyroidectomy is appropriate for patients with thyroid cancer or as prophylaxis in the setting of multiple endocrine neoplasia, those with symptomatic nodular disease, selected patients with hyperthyroidism, or as a diagnostic modality for select patients with indeterminate nodules. A concomitant compartmental anatomically based lymph node dissection is appropriate for some thyroid malignancies. An understanding of the

embryology, anatomy, and physiology of thyroid disease and the technical aspects of the operation is essential to avoid complications of thyroid surgery.

EMBRYOLOGY

Primarily composed of foregut endoderm, the thyroid is the first endocrine gland in the body to form during development. The median thyroid component descends from the foramen cecum at the base of the tongue at around 4 weeks of gestation. The lateral portion of the thyroid develops later from the caudal pharyngeal endoderm and 4th and 5th branchial pouches; fusion with the median portion forms the tubercle of Zuckerkandl. By 6 weeks of gestation, the foramen cecum resorbs, leaving a fibrous thyroglossal duct attached to the central hyoid bone; incomplete resorption of the tract may result in a thyroglossal duct cyst, whereas the more common persistence of the distal portion of the tract results in a pyramidal lobe.[1,2] Developmental abnormalities of the aortic arch may lead to altered position of the recurrent laryngeal nerves (RLNs).[2,3] Embryologic anomalies and their surgical implications are summarized in Table 75.1.

ANATOMY OF THE THYROID

The thyroid is a bilobed gland that weighs between 15 and 30 gm and sits anterior to the trachea, just inferior to the cricoid cartilage within the central compartment of the neck. Each lobe is approximately 5 cm in craniocaudal dimension, 2 to 3 cm anteroposterior, and 3 cm in width, although substantial physiologic and pathologic variations exist. Laterally, the thyroid is bordered by the medial aspects of the carotid sheath. Anteriorly, the sternothyroid and sternohyoid muscles cover the gland. The trachea and the esophagus (particularly on the left side) comprise the posterior borders. The pretracheal fascia extends to form a thin layer of connective tissue that invests the thyroid; in the absence of thyroiditis or invasive malignancy, this layer represents an easily mobilized plane of dissection. The sheath condenses as the anterior suspensory ligament of the thyroid above the isthmus; posteromedially to the thyroid gland it condenses to form the firm attachment to 1 the trachea called the ligament of Berry. The RLN and its insertion into the cricopharyngeus muscle are often intimately associated with the ligament of Berry and the RLN is most vulnerable to iatrogenic injury at this relatively fixed point.

Table 75.1 Medical and Surgical Implications of Embryologic Thyroid Anomalies

Condition	Mechanism	Presentation	Treatment
Thyroid agenesis	Failure of the thyroid anlage to form	Congenital hypothyroidism (dwarfism and irreversible brain dysfunction, or cretinism)	Early recognition allows for thyroid hormone replacement
Thyroglossal duct cyst	Failure of the thyroglossal duct to completely resorb	Midline neck mass that elevates with tongue protrusion	Sistrunk procedure: resection of the entire thyroglossal duct including the midportion of the hyoid bone
Lingual thyroid	Failure of the median portion of the thyroid to descend	Mass at the base of the tongue, often combined with absence of thyroid tissue elsewhere	Surgical excision or radioactive iodine ablation, with awareness of the need for thyroid hormone replacement
Ectopic thyroid tissue	Embryologic rests of thyroid tissue in the *central* compartment of the neck	Ectopic thyroid mass (thyroid cancer may also develop in these rests)	Surgical excision; not to be confused with thyroid tissue in the lateral compartment, which is not an embryologic abnormality and instead represents a regional nodal metastasis of differentiated thyroid cancer
Nonrecurrent laryngeal nerve	Abnormal development of the aortic arch; most often right sided (0.3 to	Typically silent; may be associated with dysphagia lusoria (compression of	Preoperative imaging that suggests aberrant arterial anatomy should heighten

	1.6% of patients undergoing thyroid surgery) and associated with an aberrant right subclavian artery that arises directly from the aorta and courses posterior to the esophagus. May occur on the left (0.04%) but requires a right sided aortic arch (as in situs inversus)	the esophagus between the trachea and a retroesophageal right subclavian artery)	awareness of the possibility of a nonrecurrent nerve

Vasculature

The thyroid has a rich blood supply, which is increased in certain pathologic conditions such as toxic goiter. The superior thyroid artery arises off the external carotid artery and courses inferiorly along the inferior pharyngeal constrictor muscles to the thyroid, branching into at least an anterior and posterior branch close to the superior pole of the thyroid gland. The inferior thyroid artery arises from the thyrocervical trunk, courses medially deep to the carotid artery, and branches into several smaller vessels that join the thyroid directly just inferior to the ligament of Berry near the tracheoesophageal groove. These vessels are intimately and variably associated with the RLN, and care must be taken during ligation to avoid iatrogenic nerve injury. Careful ligation of both the superior and inferior thyroid arteries close to the thyroid capsule will allow preservation of branches that supply the parathyroid glands. The thyroid ima artery arises directly from the great vessels and courses anterior to the trachea to the inferior portion of the thyroid gland. It is variable in presence (approximately 10% of patients) and size, but can represent a significant source of blood loss when unrecognized.

The venous drainage of the thyroid is comprised of a plexus of anastomosing vessels that condense into three named veins: the superior and middle thyroid veins drain to the ipsilateral internal jugular vein, and the inferior thyroid vein drains into the ipsilateral brachiocephalic vein. The middle thyroid vein may be absent or duplicated; when present medialization of the thyroid may stretch and tear this vein if unrecognized.

Lymphatics

The lymphatic plexus surrounding the thyroid gland is rich and variable. Intracapsular lymph channels in the thyroid gland provide communication across the isthmus and between lobes. The central lymph node compartment includes levels VI and VII and encompasses the prelaryngeal, pretracheal, and paratracheal lymph nodes. It extends superiorly from the hyoid bone inferiorly to the innominate artery and is bounded laterally by the carotid sheath; level VI is distinguished from level VII at the level of the sternal notch (Fig. 75.1).[4] The prelaryngeal lymph nodes reside in the midline just above the anterior suspensory ligament and the isthmus of the thyroid. Also called Delphian lymph nodes after the Greek Mythology "Oracle of Delphi" for their role as a harbinger of outcome, these are frequently the first nodes encountered upon opening the midline raphe. When associated with metastasis from malignancy, these nodes are associated with adverse pathologic characteristics of the primary tumor and involvement of other central or lateral compartment lymph nodes.[5] Although most lymph node metastases from thyroid cancer occur in the central compartment before spread to the lateral compartment, "skip" metastases to the lateral compartments only have been reported, particularly in tumors located in the superior poles.[6]

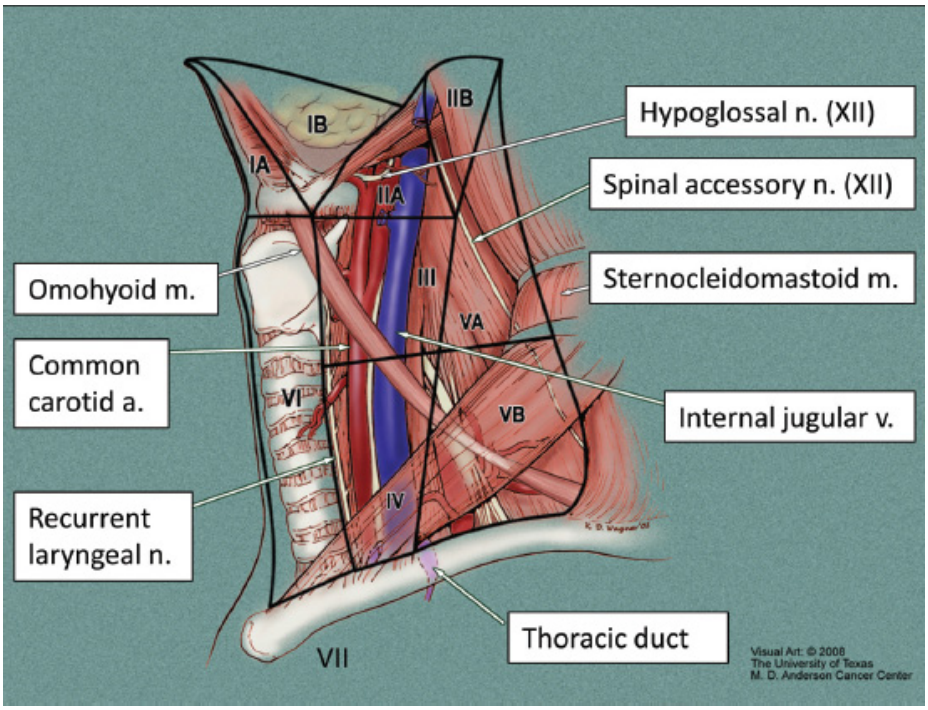

Figure 75.1 The central (VI and VII) and lateral (I–V) compartments of the neck. (Adapted from Fisher and Perrier[4] with permission from Libromed Panama, Republic of Panama. Comprehensive Clinical Oncology, Current Practices, English Edition, 2020.)

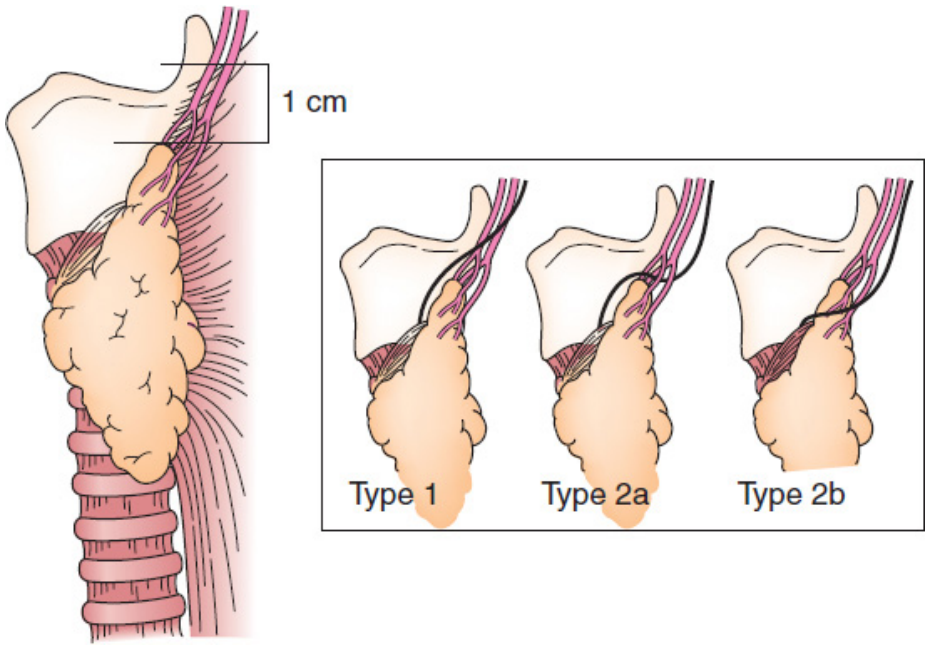

Figure 75.2 The Cernea classification of the external branch of the superior laryngeal nerve highlights the anatomic variability with progressively increasing risk of iatrogenic injury during thyroidectomy. Type I crosses the superior thyroid vessels ≥1 cm above the superior thyroid pole, type II crosses within 1 cm above the pole, and type III crosses below the superior pole.

The lateral compartment includes the submental nodes (level I), upper jugular (level II), midjugular (level III), lower jugular (level IV), and posterior triangle (level V) (Fig. 75.1).[4] The role and extent of prophylactic and therapeutic node dissection for thyroid cancer is discussed later (see Thyroid Surgery: Lymph Node Dissection).

Nerves

The thyroid gland itself is innervated by the cervical sympathetic chain, with two nerves in close vicinity that do not directly innervate the thyroid but are of critical importance: the external branch of the superior laryngeal nerve and the RLN.

The superior laryngeal nerve arises from the vagus and bifurcates into the internal branch (which enters the larynx at the thyrohyoid membrane to provide sensory information to the superior larynx) and the external branch, which contributes to voice pitch and projection by innervating the cricothyroid muscle. The course of the external branch is variable and meticulous dissection close to the superior pole is necessary to prevent iatrogenic injury during thyroidectomy (Fig. 75.2).

An understanding of the course of the RLN is critical for all surgeons who operate in the neck or chest (Fig. 75.3).[4] Inadvertent unilateral injury results in ipsilateral vocal cord paralysis and hoarseness; bilateral injury results in stridor and often requires an emergent surgical airway due to paralysis of the vocal cords in a closed position. On the right, the RLN arises from the vagus at the level of the subclavian artery, passing around it before ascending into the central neck at an oblique angle. The left RLN has a more vertical

trajectory, arising from the vagus nerve at the level of the aortic arch posterior to the ligamentum arteriosum and ascending in the tracheoesophageal groove. Up to 34% of RLNs will branch prior to insertion, with motor fibers carried anteriorly and sensory branches posteriorly.[7] In addition to hoarseness due to motor dysfunction, inadvertent injury to the posterior sensory fibers can result in aspiration.

A nonrecurrent, or direct, laryngeal nerve is most common on the right side (up to 1.6% of patients) and is typically associated with a retroesophageal right subclavian artery (Table 75.1). Left-sided nonrecurrent laryngeal nerves require a right-sided aortic arch (situs inversus) with an aberrant left 2 subclavian and are less common (Table 75.1). When available, preoperative recognition of aberrant vasculature on cross-sectional imaging (i.e., CT of the chest or upper mediastinum) should alert the surgeon to the possibility of a nonrecurrent nerve. As CT of the chest is not routinely performed for most patients undergoing thyroidectomy, thoughtful ultrasound (US) may offer a more accessible alternative. Although operator dependent, in experienced hands, US can correctly identify aberrant neck vasculature (specifically the lack of a brachiocephalic trunk) and preoperatively predict patients with nonrecurrent right-sided laryngeal nerves with minimal examination time (median 5 minutes in one study) and few false positives (associated with obesity, large goiter, or tortuous arteries).[8] Although nonrecurrent laryngeal nerves are rare, their presence is associated with increased risk of iatrogenic nerve injury (12.9%) and it is possible that surgeon-performed US may offer a cost-effective and easily implemented mechanism to augment recognition; this requires further evaluation.

Parathyroid Glands

The location of the parathyroid glands is variable but is often in close proximity to the thyroid, and care should be taken during thyroidectomy to preserve the parathyroid gland and its blood supply. Superior parathyroid glands are typically located superior to the tubercle of Zuckerkandl and posterior to the course of the RLN; they may be encountered adherent to the posterior thyroid capsule, within the tracheoesophageal groove, or directly adjacent to the RLN.[9] Inferior parathyroids are more variable and may be similarly adjacent to the RLN, associated with the inferolateral aspect of the thyroid, or within the thyrothymic ligament. True intrathyroidal parathyroids are rare. Normal parathyroids are often symmetric (80% for superior glands and 70% for inferior glands) and correct identification of their location and preservation of their blood supply is important to prevent postoperative hypocalcemia after thyroidectomy.

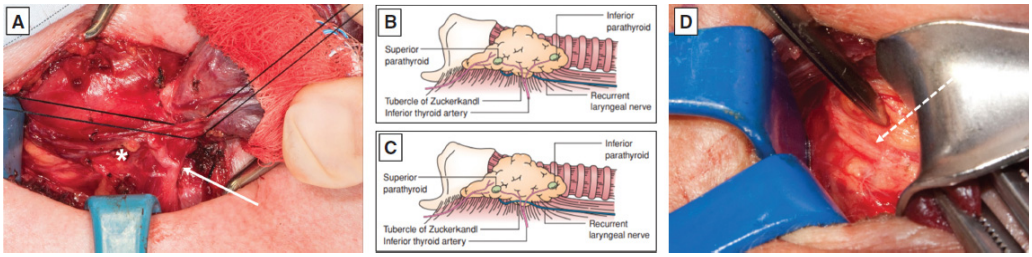

Figure 75.3 **A**: The most commonly encountered course of the right recurrent laryngeal nerve (RLN, *arrow*) with the thyroid rotated medially into the field, and the superior parathyroid preserved (*star*). The course of the nerve may vary with relation to the tracheoesophageal groove as well as the tubercle of Zuckerkandl, in which the nerve passes medial and posterior **(B)** versus **(C),** in which the RLN passes lateral to an enlarged tubercle. In the event of anomalous vasculature, the nerve will be nonrecurrent, as shown in **(D)** by the *arrow*, with the thyroid again retracted medially. (Pictures in **A** and **D** are adapted from Fisher and Perrier[4] with permission from Libromed Panama, Republic of Panama. Comprehensive Clinical Oncology, Current Practices, English Edition, 2020.)

THYROID PHYSIOLOGY

The follicular cells of the thyroid produce thyroxine (T4) and triiodothyronine (T3) under the stimulus of thyrotropin (or thyroid-stimulating hormone, TSH), which is secreted by the anterior pituitary. The process is dependent on dietary iodide, which in most developed regions typically far exceeds the daily requirement of 100 to 150 µg, with excess excreted by the kidneys. On a cellular level, thyroid follicles are comprised of epithelial cells (thyrocytes), which are organized in an ovoid structure with the interior containing iodinated thyroglobulin (colloid). The active uptake of iodide in cells occurs via a Na^+/I- symporter mediated by a Na^+/K^+-adenosine triphosphatase pump on the basolateral plasma membrane. After entry into the cell, thyroid peroxidase (TPO) catalyzes an oxidative reaction to couple iodide with tyrosine, leading to the production of T4 and T3, which are then coupled to thyroglobulin for storage (Fig. 75.4). The release of thyroid hormone into the circulation is mediated through micropinocytosis stimulated by TSH.

In humans, T4 is produced in excess of T3 by a ratio of 13:1 under normal physiologic conditions. A less active but more stable hormone, T4 is converted to T3 in the periphery (primarily liver and plasma) by type 1 deiodinase enzymes. The half-life of T3 is between 8 to 12 hours, whereas the half-life of T4 is approximately 7 days. The majority of circulating T4 and T3 (>99%) is bound to plasma proteins (thyroglobulin, albumin, thyroxine-binding prealbumin).

CLINICAL EVALUATION OF THE PATIENT WITH A THYROID DISORDER

A thorough history should include questions about prior thyroid-related concerns, medication use, previous thyroid biopsies, and history of head and neck or upper esophageal/thoracic surgery or radiation. Medications such as amiodarone or lithium can induce hyperthyroidism.

A history of transient hypothyroidism requiring exogenous thyroid hormone should alert the clinician to the possibility of thyroiditis. Previous thyroid biopsies or the presence of known nodules on previous imaging studies provide information regarding patterns of growth and natural history that can be used to assess the risk of malignancy. Previous surgical procedures in the region should prompt evaluation of RLN function with laryngoscopy or videostroboscopy. Radiation exposure history (therapeutic or environmental), in addition to potentially creating fibrosis within the surgical field, is an important risk factor for later development of papillary thyroid cancer (PTC).[10,11] Family history of thyroid disorders or syndromic patterns that suggest an increased risk of thyroid cancer should be evaluated (e.g., multiple endocrine neoplasia type II, Cowden syndrome, Carney complex, familial adenomatous polyposis and/or Gardner syndrome, Werner syndrome, *DICER1* syndrome) and referral to genetic counseling considered.

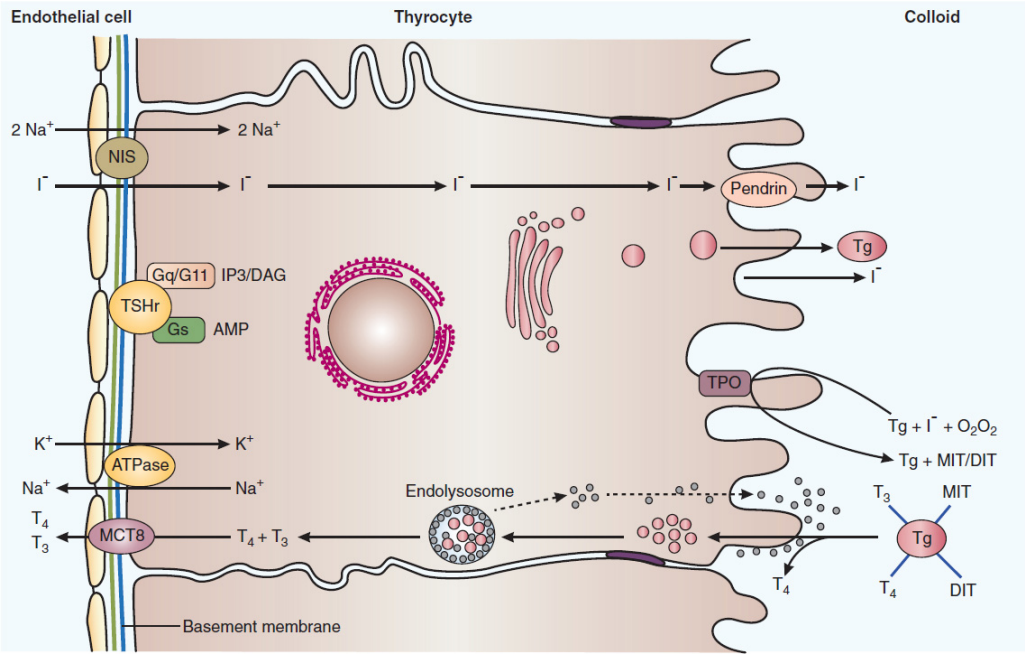

Figure 75.4 Thyroid hormone metabolism. Thyroxine (T_4) and Triiodothyronine (T_3) are produced by the thyroid follicular cell in a complex biochemical pathway. It is dependent on the movement of circulating iodide through the follicular cell and into the intracellular colloid space. T_3 and T_4 are then bound to Thyroglobulin (Tg) for eventual transport back through the follicular cell to be released into the intravascular space.

Table 75.2 Symptoms of Hypo- or Hyperthyroidism

	Hypothyroidism	Hyperthyroidism
Symptoms	Fatigue Sensitivity to cold Weight gain Dry skin/hair/nails Constipation Muscle weakness Depression	Nervousness or irritability Heat intolerance Palpitations Hyperphagia Weight loss Thin skin Diarrhea Weakness Insomnia
Signs	Puffy facies Macroglossia Bradycardia Hypermenorrhea or menorrhagia Delayed relaxation of deep tendon reflexes Hypercholesterolemia Generalized nonpitting edema	Thyromegaly +/− thyroid bruit Tachycardia Sweating Oligo- or amenorrhea Hyperactive deep tendon reflexes Tremor Pretibial myxedema[a] Exophthalmos[a]
Laboratory Findings	Low fT4 Elevated TSH	Elevated fT4 and/or T3 Low/suppressed TSH

[a]In patients with hyperthyroidism related to Graves disease.

fT4, serum free thyroxine; TSH, thyroid-stimulating hormone; T3, serum triiodothyronine.

Symptoms of hypo or hyperthyroidism (Table 75.2) should be assessed and confirmed with laboratory testing. Mechanical symptoms such as dysphagia, dysphonia, dyspnea, compressive symptoms, and neck pain should be clarified with attention to duration, severity, and exacerbating factors. The timeline of symptom presentation provides clues to the etiology. A rapidly growing mass is concerning for either thyroid lymphoma or anaplastic thyroid cancer (ATC), whereas a stable nodule over many years is less suspicious for malignancy.

The physical examination should include a thorough neck examination focusing on the thyroid (size, texture, nodularity, mobility) and evaluation for central and lateral adenopathy. Physical signs of hyper- or hypothyroidism should be noted (Table 75.2). Laboratory workup should include serum TSH and free thyroxine (fT4) levels to screen for hypothyroidism or hyperthyroidism, with additional laboratory testing tailored to the specific diagnosis (see Laboratory Assessment of Thyroid Abnormalities). Previous neck surgery, dysphonia, or perceived voice changes should prompt either laryngoscopy or videostroboscopy to evaluate

the vocal cords and the corresponding function of the RLNs. RLN injury and vocal cord dysfunction can be clinically occult but have significant consequences for future contralateral surgery. Vocal cord dysfunction in the absence of previous surgery should heighten the clinician's suspicion for malignancy.

Imaging of the thyroid should begin with an US that assesses the thyroid as well as the central and lateral compartments of the neck. The accuracy of fine-needle aspiration biopsy (FNA biopsy), if indicated, is usually increased by 3 US guidance (see Radiographic Assessment of Thyroid Abnormalities, below).

LABORATORY ASSESSMENT OF THYROID ABNORMALITIES

Basic thyroid function tests for the patient with any thyroid complaint should include measurement of TSH and free T4 (fT4). Under normal circumstances an inverse relationship between TSH and fT4 is observed, with small variations in fT4 leading to more substantial changes in TSH. Assuming a functional hypothalamic–pituitary axis, an elevated TSH in the setting of low fT4 suggests hypothyroidism (note that TSH measurement will be inaccurate in the patient with panhypopituitarism), whereas a suppressed TSH with high fT4 levels suggests hyperthyroidism.

Thyroid-Stimulating Hormone (Thyrotropin, TSH)

Immunometric assays to measure TSH are highly sensitive and specific, making it the ideal method for detecting thyroid dysfunction in the patient with a functioning hypothalamic–pituitary axis. The range of normal is a spectrum and is usually between 0.27 and 4.20 mIU/mL, although target ranges for treatment during specific conditions (such as pregnancy or as suppressive therapy for differentiated thyroid cancer) are typically lower. Interpretation of TSH, particularly within the spectrum of normal ranges, must be considered with regard to concomitant symptoms of hypo- or hyperthyroidism (Table 75.2).

Free versus Total Thyroxine (T4) and Triiodothyronine (T3)

Levels of total T3 and T4 (defined as both free and protein bound) can vary based on variation in levels of plasma proteins. Multiple medications, including nonsteroidal anti-inflammatories, birth control pills, phenytoin, carbamazepine, furosemide, and aspirin can either alter levels of transport proteins directly or compete with T4 and T3 for binding. These alterations do not typically impact true thyroid function, leading to variability in total T3 or T4. Measuring free T4 improves the ability to detect true physiologic thyroid dysfunction, independent of alterations in transport proteins. Measurement of free T3, while possible, is often unreliable due to the extremely low level of circulating T3 not bound to

plasma proteins. Instead, total T3 is often used as a surrogate, and is most useful when assessing hyperthyroid states—it may be elevated even then TSH and fT4 are normal. Conversely, it is also the last test to become abnormal in the hypothyroid state and thereby less useful in this condition.

Thyroglobulin and Thyroglobulin Antibodies

Thyroglobulin is a protein produced by normal thyroid tissue and differentiated thyroid cancer cells that clinically primarily serves as a tumor marker. After complete removal of native thyroid tissue (i.e., thyroidectomy), thyroglobulin should be undetectable, and, in the absence of thyroglobulin autoantibodies, a rise in thyroglobulin suggests microscopic disease recurrence. Thyroglobulin autoantibodies interfere with the radioimmunoassay commonly used to measure thyroglobulin and may artificially increase or decrease thyroglobulin. Thyroglobulin autoantibodies are present in up to 10% of the general population and up to 20% of patients with differentiated thyroid cancer. Knowledge of their presence is essential when interpreting thyroglobulin; in a patient with autoantibodies the antibody titer may gradually decrease (over years) after complete thyroidectomy. Elevated TSH also tends to stimulate higher levels of thyroglobulin, so interpretation of thyroglobulin must occur simultaneously with measurement of TSH. Measurement of thyroglobulin in the setting of an intact thyroid or after thyroid lobectomy is not informative.[12]

Thyroid Autoantibodies

Both thyroid peroxidase autoantibodies (TPO-Ab) and thyroglobulin autoantibodies are elevated in patients with Hashimoto thyroiditis (HT), whereas thyroid-stimulating immunoglobulins (TSI) and/or TSH receptor autoantibodies (TrAb) are elevated in Graves disease. Conversely, TrAb may also have a blocking effect on the TSH receptor and result in hypothyroidism in other conditions. Thyroid autoantibodies may also be present in the individual without thyroid dysfunction.

Calcitonin

Calcitonin, secreted by the parafollicular cells of the thyroid gland, may help modulate calcium and phosphorus homeostasis but is not the primary driver (parathyroid hormone is) in humans. It is useful as a tumor marker for medullary thyroid cancer (MTC). Given the rarity of MTC, calcitonin should not be used as a screening test for the general population, but tested only when suspicion for MTC exists.[12,13]

RADIOGRAPHIC ASSESSMENT OF THYROID ABNORMALITIES

US is the gold standard imaging modality for the thyroid and is particularly advantageous in that it does not expose the patient to ionizing radiation. Other imaging modalities, including radionuclide imaging, computed tomography (CT), magnetic resonance imaging (MRI), and/or fluorodeoxyglucose positron emission tomography (FDG-PET) have specific roles in the evaluation of the patient with a thyroid complaint.

Ultrasound

Although user dependent, US provides information on the size, location, and radiographic characteristics of thyroid nodules, assessment of thyroid parenchyma, and evaluation of cervical lymph nodes. Regardless of the presence of other imaging, all patients with suspected structural abnormalities (thyroid nodules, thyroid cancer) should undergo a dedicated US that examines the thyroid and the central and lateral compartments of the neck. This is best performed with a high-frequency probe (7.5 to 15 MHz). Assessment of constitution (solid, cystic, spongiform, or mixed), presence of microcalcifications, and evaluation of echogenicity, shape, and borders (smooth vs. irregular) are important when assessing risk for malignancy (Fig. 75.5).[12] Hypoechogenicity, irregular borders, and subtle microcalcifications are concerning for malignancy, whereas hyperechogenicity, smooth borders, or a "halo sign" (an anechoic rim) are more often benign. Large macrocalcifications, associated with posterior acoustic shadowing are often benign. Combined with size, US characteristics inform the decision to perform FNA (Table 75.3).[14] Routinely performing FNA biopsy on all nodules results in unnecessary procedures, whereas overly stringent criteria for biopsy may miss a clinically relevant cancer. In general nodules above 1 cm, those with particularly concerning US characteristics, or those that are increasing in size over time merit FNA biopsy. US should also be used to evaluate and/or FNA-biopsy lymph nodes (suspicious findings include loss of fatty hilum, microcalcifications, hyperechoic change, rounded shape, or necrosis),[15] which alters the planned operation in up to one-third of patients with thyroid nodules.[13]

Radionuclide Imaging

Radionuclide uptake scans provide information regarding thyroid function but do little to delineate anatomy. The most commonly performed examination, technetium (Tc) pertechnetate scintigraphy, uses ^{99m}Tc pertechnetate, an isotope that emits primarily gamma (γ) radiation and is rapidly absorbed by the thyroid. In contrast to iodine, ^{99m}Tc is not incorporated into thyroglobulin and therefore scintigraphy must be performed within 20 to 30

minutes after injection. Normal uptake scans demonstrate uptake of the radiotracer symmetrically across the thyroid. In patients with toxic adenoma the uptake will concentrate at the area with the nodule (a hyperfunctioning or "hot" nodule), whereas patients with hypofunctioning nodule(s) ("cold" nodule) will demonstrate relative photopenia.[16,17] While a hot nodule is rarely malignant, a "cold" nodule was historically considered suspicious for malignancy. Today with the sensitivity and specificity of FNA biopsy the use of scintigraphy in the evaluation for malignancy is outmoded.

The oral administration of ^{123}Iodine (^{123}I) allows for measurement of iodine uptake over time using the x-rays, β particles, and γ rays transmitted by this radiotracer, with images obtained at 4 and 24 hours. In patients with hyperthyroidism from Graves disease the thyroid will demonstrate increased symmetric uptake throughout the gland, which most often remains elevated 24 hours later.[16] The fraction of dose retained by the thyroid is calculated as the 24-hour radioactive iodine (RAI) uptake.

In contrast to ^{123}I, ^{131}I has a longer half-life (~8 days) and emits more β and γ radiation. It is thoroughly cleared from background tissues and is the isotope of choice when performing nuclear imaging for differentiated thyroid cancers. A diagnostic dose (1 to 5 mCi) allows for evaluation of iodine uptake, whereas therapeutic doses (30 to 150 mCi) ablate residual thyroid cells. Ablative ^{131}I scintigraphy may also be used for selected patients with Graves disease, often with resulting hypothyroidism.[18]

In summary, thyroid scintigraphy is most useful in patients with hyperthyroidism to distinguish the source of overproduction (i.e., a toxic adenoma vs. toxic multinodular goiter [MNG] vs. Graves disease).

Positron Emission Tomography

Although FDG-PET is routinely employed for staging and surveillance of many cancers, it is not a first-line imaging modality for well-differentiated thyroid cancers.[12] In contrast, for poorly differentiated thyroid cancers with loss of iodine uptake, in which ^{131}I scintigraphy will be falsely negative, FDG-PET has a sensitivity of up to 84%, which increases to 93% when combined with CT.[19] Another unique instance in which FDG-PET or other PET modalities such as ^{68}Ga-labeled somatostatin analogs (^{68}GA-DOTATATE or -DOTATOC) may be useful is in the case of locally advanced, recurrent, or metastatic MTC, particularly in patients with elevated or rising tumor markers without radiographic evidence of disease using conventional imaging.[20,21]

When an FDG-PET performed for other reasons identifies a thyroid nodule, the concern for malignancy is greater than for incidentally found nodules identified by other radiographic modalities. One systematic review of 55,000 patients identified PET-avid thyroid nodules in 1%, with 33% of those representing malignancy (most commonly PTC).[22] It is important to note that the pattern of uptake also provides information—diffuse tracer avidity within the thyroid gland in general represents benign disease, whereas uptake in a specific nodule is concerning for malignancy. Further evaluation of PET-avid thyroid nodules with US and FNA biopsy is necessary.[12]

Computed Tomography and/or Magnetic Resonance Imaging

Cross-sectional imaging with CT (most commonly) or MRI (in select instances) is indicated for patients with findings concerning for locoregionally advanced disease (bulky primary tumor, extensive nodal metastases, concern for RLN palsy or tracheal invasion) or for evaluation of substernal pathology (i.e., MNG) not well visualized on US (Fig. 75.6).

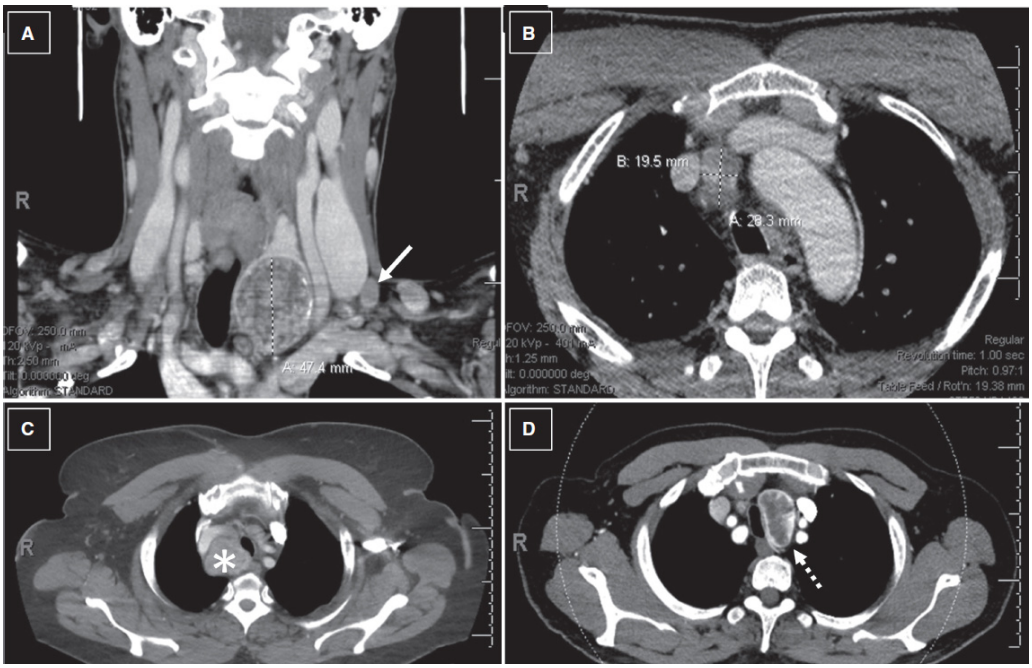

Figure 75.6 Utility of computed tomography in evaluating thyroid disease. **A**: Coronal view of a large left sided tumor (4.7 cm) causing mild tracheal deviation and a pathologic left level IV lateral neck lymph node (*arrow*). **B**: Identification of a pathologic mediastinal/level VII lymph node (1.9 × 2.8 cm). **C**: A substernal goiter (*star*) causing tracheal compression, and (**D**) a left-sided substernal thyroid nodule (*dashed arrow*) not palpable on physical examination.

THYROID DISORDERS CHARACTERIZED BY HYPERTHYROIDISM

Common causes of hyperthyroidism include toxic adenoma (a single hyperfunctioning nodule), toxic MNG, or diffuse toxic goiter (Graves disease). Less common causes include amiodarone-induced thyrotoxicosis (AIT), TSH secretion by a pituitary adenoma, or exogenous thyroid hormone supplementation. Presentation is variable and may range in severity from incidental detection on laboratory studies to thyroid storm. Elderly patients in particular may present with atrial fibrillation, angina, or congestive heart failure, and thyroid function should always be evaluated during initial presentation of these illnesses.

Initial treatment focuses on restoring normal physiology. Antithyroid drugs (ATDs) such as methimazole and propylthiouracil inhibit thyroid hormone synthesis with an onset of action

over a 2- to 6-week period. Patients should be monitored carefully for adverse effects including agranulocytosis (1 in 500 patients), which presents with fever and pharyngitis, and hepatotoxicity (0.3 to 0.7 per 1,000 patients). Hepatotoxicity is typically cholestatic when associated with methimazole, whereas propylthiouracyl may cause hepatocellular injury and/or fulminant liver failure. Both agranulocytosis and hepatotoxicity are most common within the first 90 days of use.[18] Rash, pruritus, and arthralgias are less severe but more commonly encountered with ATDs. Beta blockade is useful in controlling tachycardia, tremors, heat sensitivity, and anxiety, and may inhibit peripheral conversion of T4 to T3 at high doses.[23] Titration of therapy should be based on T3 and T4 levels, as TSH may remain suppressed for several months after normalization.

After stabilization, continuation of ATDs, ablation with RAI, or surgical resection offer potential definitive treatment for the patient with hyperthyroidism. The underlying etiology, patient-specific factors and preferences, and available healthcare infrastructure influence the optimal therapy for hyperthyroidism (Table 75.4).[24]

Toxic Adenoma

Typically toxic adenomas grow to at least 2 cm in size before becoming biochemically apparent. Although RAI is a potential therapeutic option, it has several disadvantages as compared to thyroid lobectomy, including the possibility of leaving behind a palpable nodule and the probability of inducing hypothyroidism (see Table 75.4).[24] Thyroid lobectomy for patients with toxic adenoma has a much lower rate of postoperative hypothyroidism (2% to 3%) as compared to when performed for other indications (20%). Thyroid lobectomy also has a faster return to the euthyroid state (2 to 3 days postoperatively, vs. 75% response rate at 3 months for RAI) and a lower risk of disease recurrence (<1% vs. 3% to 5.5% for RAI).[18]

Toxic Multinodular Goiter

Toxic MNG, in which hyperthyroidism results from more than one autonomously functioning nodules, may develop in a patient who was previously euthyroid either spontaneously or after exposure to an iodine load (Jod-Basedow phenomenon). Historically, efforts to iodinate salt or flour in iodine-deficient populations were followed by the development of toxic MNG over a time course of several years. Clinically, toxic MNG may be difficult to discern from Graves disease with nodular degeneration, however patients with toxic MNG are more often female and older than 50 years of age, with a history of MNG. Laboratory testing demonstrates the absence of TSI and/or TrAb. Patients with toxic MNG often have concomitant indications for thyroidectomy, including compressive symptoms and/or substernal extension. While RAI remains a possible treatment option, requirement of repeated doses because of goiter size and poor iodine uptake is more common. ATDs are less likely to achieve remission in patients with toxic MNG than in Graves disease.

Table 75.4 Comparison of Thyroidectomy, Radioactive Iodine Ablation, and Medical Therapy for Thyrotoxicosis

	Thyroidectomy	Radioactive Iodine Ablation (RAI)	Medical Therapy
Time of Onset	▪ Immediate	▪ 4–6 mo	▪ 4–6 wks
Advantages	▪ Immediately curative with quick onset ▪ May be beneficial for patients with limited access to care ▪ Lobectomy is appropriate for toxic adenoma, and may avoid iatrogenic hypothyroidism	▪ Less invasive than surgery ▪ May be more cost effective (dependent on geographic area)	▪ Noninvasive ▪ Nonablative (potential to retain native thyroid function) ▪ Achieves remission in 40–50% of patients with Graves after 12–18 mo; less likely in patients with toxic multinodular goiter
Disadvantages	▪ Typically requires medical therapy preoperatively ▪ Invasive—risk of surgical injury ▪ Results in iatrogenic hypothyroidism	▪ Requires medical therapy preprocedure in selected patients due to the risk of transient worsening of thyrotoxicosis ▪ May result in hypothyroidism (80% by 16 wks, up to 90% by 10 yrs) ▪ 5–15% require repeat treatment ▪ Requires isolation ▪ Avoid radioactivity in women who are pregnant or lactating ▪ 15–20% risk of inducing/aggravating Graves orbitopathy[a]	▪ Medication nonadherence ▪ Side effects Rare but serious: ▪ Agranulocytosis ▪ Hepatotoxicity ▪ Birth defects (methimazole) ▪ Vasculitis More common but less serious: ▪ Rash ▪ Arthralgias
Patient Preferences	Patients choosing surgery likely place a higher relative value on prompt and	Patients choosing RAI likely place a higher relative value on definitive control of symptoms with	Patients choosing medication likely place a higher relative value on the possibility of

	definitive control of symptoms and avoidance of radioactivity and/or side effects from medications, with less relative concern for potential surgical risks and need for lifelong hormone replacement	avoidance of surgery and/or side effects from medications, with less relative concern for the rapid resolution of symptoms, need for lifelong hormone replacement, and worsening of Graves orbitopathy	remission and avoidance of lifelong hormone replacement, and avoidance of surgery or radioactive exposure, with less relative concern for medication side effects and/or disease recurrence

[a]Exacerbation of orbitopathy may be ameliorated by concomitant steroid use.

RAI, radioactive iodine.

Graves Disease

Initially described by Robert Graves in the 1830s as an enlarged thyroid gland, accelerated heart rate, and ocular changes, Graves disease is an autoimmune disorder characterized by thyroid-stimulating antibodies. These antibodies bind to the TSH receptor to stimulate thyroid hormone release and cause hypertrophy of the thyroid. Graves disease occurs in 20 to 50 individuals per 100,000, affecting women more frequently than men (lifetime risk 3% vs. 0.5%).[25] In addition to hyperthyroidism, Graves disease has several distinct manifestations, including eye disease and localized dermopathy. Thyroid-associated eye disease (TED) is thought to be mediated by the accumulation of immune cells and fibroblasts within the orbit, and presentations include eyelid retraction (92%), exophthalmos (62%), extraocular muscle dysfunction (43%), ocular pain (30%), increased lacrimation (23%), and optic neuropathy (6%).[25] Thyroid dermopathy, or thickening of the skin (which is most commonly observed on the shins—pretibial myxedema—but may develop elsewhere) occurs less commonly (1% to 4%) and typically in conjunction with severe TED.

Therapeutic options for patients with Graves disease include ATDs, RAI, and total thyroidectomy; lobectomy is not appropriate. Practice patterns vary geographically and by access to specialists, and should take patient preferences into account. Patients with a high likelihood of remission (women with mild disease, small goiters, and negative or low-titer antibodies) may benefit most from ATDs, whereas those with severe adverse reactions to ATDs, known liver disease, or medication noncompliance may favor RAI or thyroidectomy.

Patients with life-limiting comorbidities, previous neck surgery or irradiation, or those without access to a high-volume thyroid surgeon may favor either RAI or ATDs. The presence of TED may be worsened by RAI, and although this effect may be ameliorated by corticosteroids,[23] thyroidectomy is often preferred in these patients. The presence of larger thyroid nodules, compressive symptoms, known or suspected malignancy, or concomitant hyperparathyroidism is an indication for thyroidectomy. Thyroidectomy is also favored for women who are pregnant, planning a pregnancy, or lactating, as RAI is contraindicated during pregnancy or lactation, and most experts recommend avoiding it within 6 months of a pregnancy. When surgery is pursued thyroidectomy should be delayed until second trimester (if disease severity allows) when the risk of preterm labor or pregnancy loss is lowest. Pediatric patients are often treated initially with ATDs but the rate of remission is lower than that observed in adults.[26] Hesitation to treat with RAI, which unlike external radiation has not been definitively associated with an increased risk of later development of thyroid cancer, exists, and thyroidectomy is often favored in the pediatric patient in whom ATDs are insufficient. Finally, thyroidectomy is appropriate in situations in which immediate control of symptoms is necessary (i.e., thyroid storm or cardiovascular exacerbation refractory to medical management) as ATDs require 2 to 6 weeks and RAI may take 4 to 8 weeks to normalize thyroid function.[18]

In an elective situation a patient with Graves disease should be rendered euthyroid prior to thyroidectomy with ATDs. Adjunct measures, which may be particularly useful for the management of the patient with severe Graves disease refractory to ATDs, include beta blockade, iodine, cholestyramine, and hydrocortisone. With the exception of iodine, the specific pros and cons of each of these are outside of the scope of this chapter. Most commonly given as Lugol solution (LS, a combination of elemental iodine and potassium iodide) or saturated solution of potassium iodide (SSKI), an iodine load preoperatively suppresses thyroid hormone synthesis and release (Wolff–Chaikoff effect). The American Thyroid Association (ATA) supports preoperative treatment with LS or SSKI in most patients with Graves disease to reduce thyroid blood flow and vascularity,[27] although the benefits of it in the setting of modern surgical technique have been contested.[28] While two early randomized studies demonstrated decreased blood flow on Doppler US and less operative blood loss in patients treated with LS[29–31] later retrospective studies failed to identify differences in blood loss or postoperative complications.[32,33] It is plausible that excellent surgical technique minimizes clinically relevant blood loss and iodine supplementation is unnecessary, however there are minimal side effects from a short course of LS or SSKI. When utilized, either may be administered as three to five drops every 8 hours for 7 to 10 days preoperatively, and are most palatable dissolved in juice.

Hypoparathyroidism, either transient or permanent, is a risk after total thyroidectomy (discussed in detail below in Complications) and merits specific mention with regard to Graves disease. Retrospective studies demonstrate a higher incidence of transient hypocalcemia in patients with Graves disease as compared to euthyroid patients undergoing thyroidectomy for other reasons,[34] with rates as high as 28% in one experienced tertiary care center.[35] The specific reasons for the increased risk are not clearly defined but are thought to be related to increased complexity of the operation due to increased thyroid gland size and

vascularity, and increased calcium metabolism and bone turnover due to hyperthyroidism.[36] Concomitant vitamin D deficiency, which may be observed at higher frequencies in patients with autoimmune thyroid disease including Graves disease,[37] likely also contributes to higher rates of postoperative hypoparathyroidism. Although not specific to patients with Graves disease, one randomized trial demonstrated reduction in transient hypocalcemia and related symptoms after thyroidectomy with the use of perioperative alfacalcidol (1α-hydroxy-vitamin D3).[38] Another prospective study treated patients with Graves disease with calcium carbonate for 2 weeks before thyroidectomy and demonstrated less symptomatic hypocalcemia than historic counterparts treated at the same institution.[39] When planning elective thyroidectomy vitamin D deficiency should be corrected and selective preoperative calcium supplementation may be considered, particularly in patients with Graves disease at higher risk for postoperative hypoparathyroidism.

Thyroid Storm

Thyroid storm is most often associated with uncontrolled Graves disease or AIT, and may be triggered by cessation of ATDs and/or physiologic stressors (illness or surgery), or RAI therapy (rare). The diagnosis is clinical and requires a high index of suspicion as many other critical illnesses have overlapping characteristics, including thermoregulatory dysfunction (hyperpyrexia), cardiovascular instability (tachycardia, arrhythmias, congestive heart failure), central nervous system disturbance (agitation, delirium, psychosis, stupor, coma), and/or gastrointestinal dysfunction (nausea, vomiting, diarrhea, hepatic failure). Associated with a mortality of 8% to 25%, thyroid storm requires both supportive intensive care and therapy aimed at inhibiting thyroid hormone secretion and synthesis.[18] Propylthiouracil, which is typically considered second line to methimazole in treatment of *stable* patients with thyrotoxicosis, is favored in treatment of thyroid storm due to the additional inhibition of peripheral conversion of T4 to T3. Beta blockade, with its antiarrhythmic properties and inhibition of peripheral conversion is also useful. Other adjuncts include steroids which may also block peripheral conversion; cholestyramine, which enhances enterohepatic clearance of thyroid hormone; and/or iodine, which should be started after initiation of ATDs and temporarily blocks new hormone synthesis and thyroid hormone release. Supportive therapy includes cooling blankets, volume resuscitation, cardiovascular and respiratory monitoring and invasive support as indicated, and nutritional support.

THYROID DISORDERS ASSOCIATED WITH HYPOTHYROIDISM

Hypothyroidism may be primary, arising from intrinsic thyroid disease, iatrogenic destruction or removal of the thyroid, or administration of ATDs; or secondary due to pituitary dysfunction. Tertiary hypothyroidism, in which the hypothalamus does not produce sufficient thyrotropin-releasing hormone, is a rare cause of hypothyroidism. Treatment is largely medical with replacement of T4.

THYROIDITIS

Inflammation of the thyroid, or thyroiditis, is frequently encountered and rarely an indication by itself for surgery. Although most often associated with hypothyroidism, thyroiditis may also present with transient hyperthyroidism due to the destruction of thyroid follicles and release of preformed thyroid hormone. Multiple factors contribute to the development of thyroiditis, which can be nonspecific or follow several distinct variations with specific clinical, laboratory, and imaging characteristics.

Hashimoto Thyroiditis

As the most common cause of hypothyroidism in adults, HT affects up to 10% of the population and may also be called autoimmune or lymphocytic thyroiditis. It is more common in women than men (9:1) and most commonly presents between 30 and 50 years of age but may occur across all age ranges. A typical presentation includes painless symmetric enlargement of the thyroid that is often characterized as rubbery and is sometimes accompanied by fullness or compressive symptoms. Laboratory studies may demonstrate a transient hyperthyroidism at the initial presentation (5% of patients), often followed by subclinical or clinical hypothyroidism; anti-TPO antibodies are typically elevated. US demonstrates a heterogeneous echotexture, and benign pseudonodules due to the autoimmune destruction of thyroid follicles and resulting architectural fibrosis and distortion may be observed. Nodular disease in a patient with HT should be evaluated with FNA biopsy to rule out malignancy. It is not clear whether patients with HT have an increased risk of well-differentiated thyroid cancer—surgical studies influenced by selection bias show a link between HT and malignancy, but population-based studies do not support a relationship.[40] Patients with HT are at a higher risk for the rare thyroid lymphoma, although the overall incidence (0.37% of patients with HT) remains low.[41]

Postpartum Thyroiditis and Painless Sporadic Thyroiditis

Postpartum thyroiditis affects up to 8% of pregnant women and is distinguished by presentation with pregnancy or during the year following pregnancy. The degree of cellular destruction (fibrosis, follicular atrophy) in postpartum thyroiditis is typically less than is observed in HT. Women with postpartum thyroiditis may demonstrate a relapsing clinical course, with periods of mild hyperthyroidism, euthyroidism, and/or hypothyroidism. Care is supportive, with thyroid hormone replacement as indicated by symptoms and laboratory assessment. One-third of women will remain hypothyroid 1 year after delivery; for those with spontaneous resolution relapse is often triggered by future pregnancies. Painless sporadic thyroiditis represents the same autoimmune process observed in postpartum thyroiditis, except it occurs independent of pregnancy or the postpartum period. Women

remain more frequently affected than men (2:1) and it is most common between the ages of 30 and 40. As with postpartum thyroiditis, treatment is supportive.

Subacute Thyroiditis

Also called de Quervain thyroiditis, giant cell thyroiditis, pseudogranulomatous thyroiditis, or subacute painful thyroiditis, subacute thyroiditis may be triggered by a virus (often coxsackievirus or echovirus). Women are more commonly affected than men (5:1) and the age of onset is typically 20 to 60 years. Following a prodromal upper respiratory illness, the patient often presents with fever, malaise, and painful and firm goiter that is ultimately transient over a period of weeks to months. Pain radiating to the jaw or ears and/or associated with specific movement may be observed. Laboratory studies may demonstrate transient hyperthyroidism followed by hypothyroidism; while antithyroid antibodies may be present they are often normal. Inflammatory markers such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often elevated in subacute thyroiditis. Treatment involves salicylates or nonsteroidal anti-inflammatory medications, with steroids reserved for more severe symptoms. Recurrence is rare.

Amiodarone-Induced Thyrotoxicosis or Thyroiditis

Amiodarone causes thyroid dysfunction in 15% to 20% of patients and may present as hypothyroidism or hyperthyroidism. Management of amiodarone-induced hypothyroidism is supportive; management of AIT may be more challenging. In contrast to many forms of thyroiditis, AIT is more common in men than women. Two forms of AIT exist with distinct mechanisms. In type I AIT, the iodine load from the drug itself exacerbates thyroid autonomous function, typically in the setting of a pre-existing MNG. Type I AIT is more common in iodine-deficient areas and can be treated by cessation of amiodarone (when feasible), ATDs, and/or LS or SSKI. Type II AIT is more common and develops independent of structural thyroid disease. Because type II AIT is a destructive process, ATDs are ineffective at controlling the hyperthyroidism and treatment consists of cessation of amiodarone (when feasible) and/or corticosteroids. Mixed or indefinite AIT may also occur with features of both type I and type II.[42] Thyroidectomy is appropriate for patients with medically refractory disease, but is associated with a higher complication rate.[43]

Acute Thyroiditis

Also called suppurative, pyogenic, bacterial, or infectious thyroiditis, acute thyroiditis is a rare condition caused by bacterial, fungal, mycobacterial, or parasitic infection. It is common in children and young adults aged 20 to 40 years. Patients may experience fever, malaise, and/or pain radiating to the ear, with enlargement of the thyroid related to abscess formation. Given the rich vasculature and lymphatic drainage of the thyroid, infection is rare and is most often seen in patients who are immunosuppressed, or those with congenital abnormalities predisposing to infection such as a pyriform sinus fistula. Thyroid function is

typically within normal limits, and antithyroid antibodies are rarely present. FNA biopsy with Gram stain and culture confirms the diagnosis and guides antibiotic therapy. Thyroidectomy, particularly in resistant cases or those in which a structural abnormality predisposes, may be appropriate.[44,45]

Riedel Thyroiditis

Also known as fibrosing thyroiditis, this form of thyroiditis presents with a painless progressive goiter. Women are more commonly affected than men (3 to 4:1) and the peak age of onset is between 30 and 60 years of age. The cause is unknown. Patients are typically euthyroid but may progress to hypothyroidism over the course of the disease. Physical examination reveals a firm, fixed goiter that is best described as "woody." The fibrous process may extend to surrounding tissues and cause tracheal or esophageal compression or hypoparathyroidism. Other focally sclerotic conditions (retroperitoneal fibrosis, mediastinal fibrosis, or sclerosing cholangitis) may also occur. Surgical resection may be necessary to rule out malignancy or alleviate symptoms, but total thyroidectomy may not be feasible due to infiltration with other structures. Medical adjuncts to therapy include corticosteroids, methotrexate, and/or tamoxifen.[45]

NODULAR THYROID DISEASE

Thyroid nodules, whether clinically evident or incidentally discovered, are commonly encountered by medical providers across multiple specialties. The prevalence of thyroid nodules identified by palpation is estimated to be between 4% and 7%,[46,47] with up to 10 times more identified by imaging studies. Autopsy studies estimate that thyroid nodules may be present in up to 50% to 60% of all adults.[48] Women are more frequently affected than men (4:1), with the prevalence of thyroid nodules increasing with age to 50% in women over 70 years.[46] Although most thyroid nodules are benign, appropriate risk stratification and identification of patients who need further evaluation, biopsy, and/or surgical intervention is essential. In addition to assessing the risk of malignancy, evaluation should include attention to the presence or absence of related symptoms, which may be mechanical (such as dysphagia, dysphonia, or compressive symptoms) or related to autonomous production of excess thyroid hormone (see *Hyperthyroidism*).

Multinodular Goiter

Endemic goiter, or goiter due to iodine deficiency, remains a world health problem, although it is less likely in developed areas with dietary fortifications (iodination of salt, bread, flour, or vegetable oil). Thyromegaly from TSH stimulation occurs along with an adaptive response in which the thyroid shifts production of thyroid hormone from T4 to the more biologically potent T3. Therapy involves support with exogenous thyroid hormone therapy and/or iodine supplementation, which may not be practical in populations with limited

access to care. Access to surgeons is similarly limited, and thyroidectomy in these areas is typically reserved for patients with very large goiters in whom symptoms have developed (compression, dyspnea, stridor, hoarseness, or dysphagia). In an iodine-deficient setting recurrence rates are high (25% to 30%) and reoperative thyroid surgery accounts for 16% of all thyroidectomies.[49]

In iodine-replete areas of the world goiter may occur independent of TSH stimulation, and it is unlikely to shrink with exogenous thyroid hormone or iodine. Management depends on assessment of risk of malignancy and presence of symptoms. When more than one nodule is present each must be assessed for risk of malignancy based on physical examination, patient risk factors, US characteristics, and/or FNA biopsy. Both benign and malignant lesions can grow over time, so change in size alone is not necessarily an indication for resection. Symptoms including a feeling of neck pressure or compression, dyspnea on exertion or at baseline or stridor thought to be related to tracheal compression, and/or dysphagia merit discussion of total thyroidectomy. In the patient with an asymmetric goiter in which the contralateral lobe is homogenous or characterized only by small, benign-appearing nodules who wishes to preserve thyroid function, thyroid lobectomy may be appropriate.

Uninodular Disease

The management of a single dominant thyroid nodule is similar to that of an MNG, in that risk assessment for malignancy and evaluation of symptoms should guide therapy in the euthyroid patient. In contrast to MNG, diagnostic lobectomy (in the case of indeterminate risk of malignancy) or therapeutic lobectomy (in the case of compressive symptoms) is the first choice of surgical management.

Substernal or Intrathoracic Thyroid Nodular Disease

Accurate preoperative assessment of the inferior extent of a multi- or uninodular goiter is imperative to avoid unwanted surprises in the operating room. Physical examination should include palpation of the inferior-most extent of the thyroid (or observation that it is not clearly assessable), which can be aided by neck extension and/or deglutition. Definite palpation and/or clear delineation of the inferior border on US suggests lack of a clinically meaningful intrathoracic component. In situations of uncertainty, CT of the neck and chest will clearly delineate the inferior-most extent of disease. The prevalence of substernal goiter ranges widely in the literature (2% to 19%), and sternotomy (partial or full) may be required in 5% (range 1% to 11%).[50]

Thyroid Cytopathology

FNA biopsy is the cornerstone of cytopathologic evaluation of structural thyroid abnormalities and is indicated for most solid or hypoechoic nodules greater than 1 cm in diameter, or for smaller nodules with radiographically suspicious features (Table 75.3,[14] Fig. 75.5).[12] The accuracy of FNA biopsy can be improved with image-guided techniques

(most commonly using US), which decrease the nondiagnostic rate from 15% to 20% to approximately 7%.[46,51,52] Onsite cytopathology can further improve diagnostic yield of FNA biopsy by evaluating adequacy of the obtained tissue and, if needed, prompting repeat passes in a single setting.[53] In the event of a nondiagnostic result, one repeat FNA biopsy is reasonable and may yield diagnostic material in more than half of the patients[54]; this is often best performed after a short surveillance interval to allow resolution of any associated hemorrhage from the initial biopsy. In addition to increasing diagnostic accuracy, US guidance during FNA biopsy also allows the clinician to select the most suspicious nodule, or area of the nodule, for biopsy, and to discern (and biopsy) multiple sites. With the exception of lymphoma, in which a core needle biopsy is often more appropriate, FNA biopsy is generally sufficient to yield diagnosis within the limits of cytopathology. Specific indeterminate lesions (see Bethesda Classification) require evaluation of the architecture of surrounding cells, and therefore are unlikely to be definitively diagnosed on FNA biopsy, which relies on aspiration of single cells. The false-negative rate for FNA biopsy ranges between 1% and 6% at high-volume centers, and the false-positive rate should be between 0% and 0.5%.

Bethesda Classification

The ATA recommends that thyroid FNA-biopsy cytology should be reported using the Bethesda system for reporting thyroid cytopathology.[12,55] The Bethesda system includes six categories with an associated range of risk of malignancy for each 4 (Table 75.5).[14] Bethesda V and VI represent clinically suspicious (V) or overt malignancy (VI) and should be addressed surgically in most situations. Bethesda I represents a nondiagnostic result and may be managed by repeat FNA biopsy (with management guided by specific results), or diagnostic lobectomy in the event of persistent nondiagnostic findings. Benign findings such as adenomas, colloid nodules, complex cysts, hyperplastic nodules, and thyroiditis, which are unlikely to be malignant (<3%), are categorized as Bethesda II. The majority of Bethesda II nodules may be safely observed with serial physical examination and US, although resection (thyroid lobectomy) remains an appropriate therapy for patients who are symptomatic. Repeat FNA biopsy during surveillance of Bethesda II nodules is not routinely indicated and should be reserved only for significant changes in nodule characteristics (with or without accompanying change in size) that may suggest original sampling error. A higher index of suspicion may be necessary for patients with nodules greater than 3 to 4 cm in size as the risk of sampling error and false-negative results increases with nodule size (>3 to 4 cm). Retrospective surgical series of patients with initially benign cytology identified malignancy in 11% to 13% of patients with tumors greater than 3 to 4 cm, although this is influenced by selection bias and likely overestimates the rate of false-negative findings.[56,57]

Table 75.5 The Bethesda System for Reporting Thyroid Cytopathology with Suggested Management and Corresponding Risk of Malignancy

Diagnostic Category	Usual Management	Predicted Risk of Malignancy (%)[b]	Actual Risk of Malignancy in Surgically Excised Nodules, % Median (Range)[°]
Nondiagnostic/unsatisfactory	Repeat FNA with US guidance	1–4	20 (9–32)
Benign	Clinical follow-up	0–3	2.5 (1–10)
Atypia or follicular lesion of undetermined significance	Observation, with or without molecular studies, and/or lobectomy	5–15	14 (6–48)
Follicular neoplasm or suspicious for follicular neoplasm	Lobectomy, with molecular diagnostics and or observation employed in select situations	15–30	25 (14–34)
Suspicious for malignancy	Lobectomy or thyroidectomy[a]	60–75	70 (53–97)
Malignancy	Lobectomy or thyroidectomy[a]	97–99	99 (94–100)

FNA, fine-needle aspiration; US, ultrasound.

[a]Based on tumor size, histopathologic characteristics, and anticipated need for postoperative radioablative iodine therapy.

[b]As predicted by the Bethesda system.[55]

[°]As summarized in Haugen et al.[12]

Adapted with permission from Fisher and Perrier.[14]

Patients with Bethesda III nodules comprise an indeterminate category in which the findings do not clearly meet criteria for benign or malignant lesions. Interpathologist variability is most pronounced in this category, with preparation quality and cellular adequacy heavily influencing interpretation.[58] Repeat FNA biopsy may yield a specific diagnosis in more than half of Bethesda III cases. Molecular diagnostics, discussed below,

may add additional risk stratification to persistently indeterminate findings. With appropriate patient counseling either diagnostic lobectomy or observation are reasonable therapeutic approaches.

Bethesda IV nodules represent follicular neoplasm or findings suspicious for follicular neoplasm. Although this category was created to signify the possibility of follicular thyroid cancer (FTC) and prompt diagnostic lobectomy, which remains standard of care, a majority will be benign on final pathologic evaluation. With appropriate patient selection and counseling, molecular diagnostics and/or close observation may be appropriate management strategies.

Molecular Evaluation

Up to 70% of PTCs display point mutations of the B-Raf proto-oncogene (*BRAF*, 45%) or RAS proto-oncogene family (*RAS*, 10%) or *RET/PTC* rearrangements (20%), with a smaller proportion demonstrating mutations in the promoter region of the telomerase reverse transcriptase (*TERT)* gene (10% to 12%).[59] FTC is more likely to demonstrate *RAS* mutations (45%) or paired box 8-peroxisome proliferator–activated receptor gamma (*PAX8-PPARγ*, 35%) rearrangements, with a higher prevalence of *TERT* promoter mutations (17%) than PTC.[59] Debate exists regarding the specific clinical implication of each mutation, and the prognostic significance of each is likely confounded by the presence of other adverse clinicopathologic factors. Mutations in *BRAF*, for example, are more frequently identified in patients with lymph node metastases and/or those with recurrence than in patients without metastases and/or recurrence, and *BRAF*-mutated patients are also more likely to have concomitant extrathyroidal extension and higher stage than non-*BRAF* mutated patients. Yet *BRAF* mutations may also be identified in a patient with an indolent microcancer, leading some to propose that specific combinations of mutations (i.e., the combination of *BRAF* and *TERT*) may be more prognostic.[12] It is likely that improved understanding of the molecular profile of the tumor rather than a single oncogene will provide better prognostic information, but further studies are necessary.

As to the indeterminate nodule, molecular diagnostics may aid in diagnosis. Currently multiple molecular panels, the majority of which use gene expression classification with or without additional evaluation for specific mutations or fusions which may be associated with thyroid cancer, are commercially available as a tool to augment decision making regarding indeterminate thyroid nodules. The two most commonly used tests in the United States currently are Thyroseq™ and Afirma™. When interpreting test results, it is essential to understand that positive and negative predictive values of tests depend on the underlying prevalence of disease, that is, the underlying prevalence of thyroid cancer, which may differ between institutions.

Thyroseq v3 (CBLPath, Rye Brook, NY, USA), tests for point mutations, insertions/deletions, copy number variations, gene fusions, and gene expression variations across 112 proprietary genes and is built upon a series of previous versions.[60] Internal validation studies suggested high sensitivity (92.9%) and adequate negative and positive predictive values (85.5% and 83.0%, respectively), with a relatively high prevalence of

malignancy (49.6% to 61.7%).[60,61] Multi-institution validation supported these results with a 94% specificity in Bethesda III/IV nodules and negative and positive predictive values of 97% and 66%, respectively, with an overall cancer prevalence of 28%, leading the authors to conclude that benign results on the classifier may obviate diagnostic surgery in up to 61% of all patients with Bethesda III/IV nodules.[62]

The Afirma Gene Expression Classifier™ (GEC, Veracyte, South San Francisco, CA) assesses expression of 167 genes (proprietary panel) with a high negative predictive value (95% and 94% for Bethesda III and IV, respectively), making it most useful in ruling out malignancy in cytologically indeterminate nodules.[63] Initial concern regarding performance for Hurthle cell tumors in particular was addressed with The Afirma Gene Sequencing Classifier™, which built on the original assay and added cassettes to aid in the detection of MTC, follicular and Hurthle cell neoplasms, RET fusion transcripts and BRAFV600E mRNA, and parathyroid tissue.[64] The initial reports cite improved specificity and an increased overall *benign* call rate particularly in Hurthle cell tumors (from 12% to 59%), while maintaining negative predictive value (96.1%).[64,65] If the greatest utility of this test is to identify benign lesions, the inherent drawback of it is the inability to definitively prove the diagnosis with resection and formal histopathologic evaluation. Currently only a small percentage of patients with Afirma GEC or GSC benign determinations undergo resection (6% to 13%), leading to the possibility that some of these patients may have an indolent malignancy that has not yet declared.[66] Patients electing for observation of a cytologically indeterminate nodule, with or without reassuring molecular testing, should undergo regular follow-up.

DIFFERENTIATED THYROID CANCER

The incidence of thyroid cancer in the United States has tripled over the past three decades[67] with a recent stabilization, possibly related to incorporation of more conservative diagnostic practices.[68] PTC is the most common form of thyroid cancer, accounting for 85% of the estimated 52,890 new cases per year in the United States, followed by FTC (12%), poorly differentiated or insular thyroid cancer (3%), MTC (1% to 2%), and ATC (<1%).[68,69] Thyroid cancer exhibits a wide range of behavior, from the very indolent papillary thyroid microcarcinoma to the extremely aggressive ATC. Fortunately, well-differentiated thyroid cancers form the bulk of the cancer burden with excellent long-term survival, and thyroid cancer accounts for only 0.4% of cancer deaths worldwide.[70]

Papillary Thyroid Cancer

PTC affects people of all ages with a peak incidence in the third and fourth decades and a female predominance (3:1). Microscopically, PTC is characterized by papillary architecture, calcifications, psammoma bodies, squamous metaplasia, and fibrosis. Large overlapping nuclei that are optically clear (Orphan Annie nuclei) and intranuclear grooves are common findings on cytology. Histopathologic variants include the follicular variant of

PTC, which is notable for its diagnostic ambiguity on FNA biopsy. This particular form of PTC combines architectural feature of a follicular tumor and is often characterized as a follicular lesion. Clinically it behaves in the same manner as classic PTC (not to be confused with the noninvasive, or encapsulated form, which is discussed below). Other histopathologic variants are associated with more aggressive clinical behavior, including the hobnail, tall cell, columnar, and solid variants. Often these histopathologic features are identified in the setting of other adverse factors, including larger tumor size, extrathyroidal extension, angiolymphatic invasion, lymph node metastases, and distant metastases.[71] The presence of these variants, in addition to other clinical factors, should be taken into consideration when planning extent of surgery (i.e., lobectomy vs. total thyroidectomy, discussed later).

Treatment for PTC localized to the thyroid and/or the cervical lymph nodes is surgical (thyroid lobectomy or thyroidectomy, with compartment base lymph node dissection as appropriate), with selective use of adjuvant RAI to minimize risk of recurrence. Excellent long-term oncologic outcomes for most patients with PTC have allowed discussion of quality of life to factor into surgical planning. For example, the extent of thyroidectomy must be balanced between the concern for recurrence and need for RAI versus the desire to maintain native thyroid function and/or minimize extent of surgery and surgical risks. Unlike many other cancers, multifocality (within the thyroid) and/or lymph node involvement does not necessarily convey a poorer prognosis. Interestingly, the size of the tumor also does not correlate with the risk of lymph node metastases, and the incidence of metastases varies depending on the extent of lymph node dissection performed. While therapeutic lymph node dissection for clinically evident disease is standard of care,[72] the value of prophylactic central neck dissection, which may identify micrometastases in as many as 30% to 80% is debated[73] (see Lymph Node Dissection).

In a small subset of patients (1% to 8%) PTC may present with metastatic disease, most commonly with lung metastases.[74] Thyroidectomy may be appropriate even for patients with distant metastases, as removal of native thyroid tissue will facilitate treatment with RAI therapy.

Papillary Thyroid Cancer: Nonoperative Management

In contrast to the more aggressive histologies, papillary thyroid microcancer is defined as a PTC that is ≤1 cm in diameter. Often found incidentally during thyroidectomy for other reasons, these are generally not life-limiting. Ten-year disease-specific survival for patients with surgically treated papillary thyroid microcancer is >99%,[75] and some have questioned the clinical impact of these cancers if left in situ. Active surveillance, which involves serial physical examination, US, and laboratory assessment, was first proposed in Japan for patients with small tumors (≤ 1 cm on US) located away from vital structures (RLNs, trachea, esophagus) without evidence of extrathyroidal extension or lymph node involvement, who wished to avoid surgery and its potential complications. In this highly monitored population of 1,235 patients, only 4.6% demonstrated tumor growth and 1.5% developed lymph node metastases with over 10 years of follow-up.[76] Importantly, no patient

developed distant metastases or died of thyroid cancer.[77] The first North American group to examine active surveillance showed similarly promising results with tumor growth observed in 3.8% of 291 patients over 25 months, and no regional or distant metastases.[78,79] Although promising, the oncologic safety of active surveillance and the efficacy of salvage surgery for tumor progression require further evaluation, and this method should be used with caution outside of a well-designed multidisciplinary trial.

Follicular Thyroid Cancer

FTCs comprise 10% to 15% of all thyroid cancers, present with a female predominance, and are most common in the fifth decade of life. The histologic diagnosis hinges on the identification of vascular and capsular invasion, which is not readily identified on FNA biopsy or frozen section determination. FTC tends to demonstrate hematogenous spread and these patients have a higher lifetime risk of distant metastases (10% to 15%) and are less likely to manifest regional nodal disease (10%) than patients with PTC. Surgical planning, staging, and adjuvant therapy (RAI, to which up to 80% are sensitive) decisions should take this propensity for distant metastasis into consideration and most patients with FTC are treated with total thyroidectomy, with therapeutic lymph node dissection as indicated by preoperative imaging.

Noninvasive Follicular Thyroid Neoplasm with Papillary-Like Nuclear Features

In 2012, the National Cancer Institute recognized the public health burden of the overdiagnosis of cancer and encouraged efforts to revise terminology when data supported a more indolent classification. In 2016, Nikiforov et al.[80] proposed that the *encapsulated* follicular variant of PTC, which comprises 10% to 20% of all thyroid cancers in North America and is characterized by lack of capsular or vascular invasion, be reclassified as a nonmalignant entity, and introduced the term “noninvasive follicular thyroid neoplasm with papillary-like nuclear features,” or NIFTP. That study, and others since, have demonstrated that for patients who meet the strict histologic criteria of NIFTP and were treated with surgery alone, long-term retrospective follow-up failed to show recurrence or distant metastasis.[81] Although the goal of the noncancer nomenclature is to reduce the number of unnecessary operations, diagnosis of NIFTP currently still requires complete histologic assessment, and therefore lobectomy. Improved understanding of the molecular profile of these tumors in the future may allow a less-invasive diagnostic option.

Hurthle Cell Cancer

Hurthle cell cancers are characterized by the presence of oncocytic cells (abundant eosinophilic granular cytoplasm and hyperchromatic nuclei) and evidence of capsular and vascular invasion, whereas Hurthle cell adenomas lack invasion. By definition, FNA biopsy

cannot evaluate the entire periphery of the lesion and therefore cannot distinguish benign from malignant for Hurthle cell neoplasms. It is also important to note that the specificity of available molecular diagnostics is the lowest for Hurthle cell neoplasms as compared to other indeterminate nodules (specificity for Afirma GSC 59%; Thyroseq v3 internal validation specificity 69.3%),[61,65] and as such diagnostic lobectomy is most commonly utilized for a "Hurthle cell neoplasm." Frozen section analysis has similar limitations to FNA biopsy, and final histopathology must make the diagnosis of Hurthle cell cancer. Once invasion is evident and the diagnosis of Hurthle cell cancer is made, the extent of invasion observed in the tumor can be used to further subdivide Hurthle cell cancer into two types: minimally invasive (<4 foci of angioinvasion) and widely invasive (>4 foci). Often the distinction between the two is subject to interobserver variability, but is no less important given the relatively indolent behavior of the former and the more aggressive behavior of the latter. Hurthle cell cancers are more likely than PTC or FTC to demonstrate lymph node metastases and less likely to take up radioiodine (10% radioiodine avid), making surgery the mainstay of treatment.

MEDULLARY THYROID CANCER

MTC is rare (~1% to 3% of all thyroid cancers) and derives from the calcitonin-producing parafollicular C cells of the thyroid. In contrast to PTC, the development of nodal metastases correlates with tumor size (central and lateral compartment nodal disease are present in 14% and 11% of patients with T1 tumors, and 86% and 93% of patients with T4 tumors, respectively) and nodal and distant disease is more common. When presentation is associated with a palpable nodule up to 70% of patients will have cervical metastases and 10% will have distant disease.[21]

Table 75.6 Disease Phenotypes Associated with Medullary Thyroid Cancer

Syndrome	Clinical Features (% Penetrance)
MEN2A	MTC (>90%), pheochromocytoma (40–60%), parathyroid hyperplasia (20–30%), cutaneous lichen amyloidosis, Hirschsprung disease
MEN2B	MTC (>98%), pheochromocytoma (40–60%), intestinal and mucosal neuromas (98%), marfanoid habitus, inability to produce tears, everted eyelids and/or ptosis, prominent corneal nerves
Familial MTC	Isolated MTC with typically later age of onset and less aggressive clinical course

MEN, multiple endocrine neoplasia; MTC, medullary thyroid cancer.

Adapted with permission from Kiernan and Grubbs.[82]

Of the 25% of patients in whom MTC is hereditary (multiple endocrine neoplasia [MEN] 2A and 2B or familial MTC) germline-activating point mutations of the *RET* proto-oncogene can be identified in the majority (95%). The specific mutation associated with hereditary MTC has a strong genotype–phenotype correlation and, when known, will guide timing of therapeutic interventions (Table 75.6).[82] Similar *RET* mutations may be identified in the remaining 75% of patients with sporadic disease, but at a lower frequency (40% to 50%), with *RAS* mutations accounting for an additional 10% to 15% and unknown or unidentified driver mutations in the remainder. Because a diagnosis of MTC may present as the initial proband in a family, any adult patient with MTC should undergo genetic counseling as well as screening for pheochromocytoma and hyperparathyroidism regardless of family history. In 5 children, in whom genetic counseling and testing of a family member often leads to subsequent presentation and diagnosis at a young age, prophylactic thyroidectomy should be performed within the first year of life for those with RET codon *M918T* mutations (ATA highest risk) and prior to age 5 for those with RET codon *C634* or *A883F* mutations (ATA high risk). For the remaining patients with moderate risk (mutations other than those mentioned above), the timing of thyroidectomy may be influenced by patient and family preferences, the natural history of other affected family members, and serial observation may be appropriate for those with normal US findings and a normal serum calcitonin.[21] In addition, screening for pheochromocytoma and hyperparathyroidism should be considered in children above the age of 10 depending on mutation profile, whereas it is not indicated in children under the age of 5 given the sequence of presentation.[82] Such care should occur in the context of a multidisciplinary center with providers who are familiar with the disease and its associated physiologic and psychosocial impacts.

As with other thyroid pathology, all patients with suspected MTC should undergo a thorough neck US that includes the draining central and (bilateral) lateral nodal basins. In addition to routine thyroid function tests, both calcitonin and carcinoembryonic antigen (CEA) should be evaluated. The baseline levels of these two tumor markers are valuable for assessing disease burden (calcitonin levels >400 pg/mL should prompt a metastatic workup with cross-sectional imaging, with particular attention to the liver as the most common site of metastasis) and over time yield insight into the rate of disease progression by allowing the calculation of doubling time. The ATA provides a calculator to assess the rate at which each biomarker doubles (https://www.thyroid.org/professionals/calculators/thyroid-cancer-carcinoma/). In general, doubling time is best calculated with at least four data points over a minimum of 2 years, and calcitonin is better correlated with outcome than CEA. Patients with a doubling time of less than 6 to 12 months most often demonstrate structural disease progression and decreased progression-free and overall survival, whereas those a doubling time greater than 2 years is associated with disease stability and improved survival.

Surgical resection is the mainstay of therapy for MTC, with prophylactic thyroidectomy for patients with known hereditary syndromes, ideally timed to be performed prior to detection of disease, and total thyroidectomy with bilateral central neck dissections performed for known disease, with lateral neck dissection guided based on the presence of biopsy-proven disease in the associated compartment. Postoperative radioiodine ablation is not indicated, except in the case of combination histology in which locoregional or distant metastases include a proportion of PTC or FTC. Adjuvant external-beam radiation is reserved for the patient judged to be at high risk of recurrence who has exhausted all surgical options, and is typically administered only after multiple operations. For those with distant metastatic disease and evidence of progression, two multitargeted tyrosine kinase inhibitors, vandetinib (a RET, epidermal growth factor [EGFR], and vascular endothelial growth factor receptor [VEGFR] inhibitor) and cabozantinib (a RET, MET proto-oncogene, and VEGFR2 inhibitor) are approved as single-agent therapy by the United States Food & Drug Administration, with ongoing promising phase I/II clinical trials for others (selpercatinib and pralsetinib).[83–85] Antimotility drugs and somatostatin analogs may be helpful for symptom relief of the hypersecretory diarrhea and flushing that may be seen with advanced MTC. Localized therapies (hepatic embolization strategies, surgical metastasectomy) may be employed in well-selected patients to palliate symptoms or delay disease progression. Although still in its therapeutic infancy, peptide receptor radionuclide therapy has shown promising results with improved survival in highly selected patients.[86]

ANAPLASTIC THYROID CANCER

ATC is a rare and aggressive malignancy which has traditionally been treated with palliative measures. Approximately 46% of patients present with known distant metastases, and often those without definite distant metastases have radiographically occult disease. The median overall survival for all patients is 3 to 5 months, with 1-year survival of 20%.

Traditionally surgical therapy for ATC has been limited to the palliation of acute airway compromise, although occasionally a small ATC limited to the thyroid or with limited extension to immediate surrounding tissues may be identified and 6 treated aggressively with curative intent. For those with disease amenable to resection, multimodal adjuvant therapy with taxane or platinum-based chemotherapy and radiation has been associated with improved overall survival as compared to palliative care, although often with limited overall impact (1-year OS 42%).[87]

Recently novel multidisciplinary efforts are extending survival and the discovery of the targetable BRAFV600E mutation in 25% to 45% of ATCs has provided at least some hope for life-prolonging therapy. In 2018, the dual-agent BRAF/MEK inhibitors dabrafenib and trametinib became the first FDA-approved targeted agents for ATC based on the results of a phase II open label trial in 16 patients that showed an overall response rate of 69% (1-year estimate of OS 80%, median not reached).[88] Since then, investigators at the same institution have utilized this regimen in a neoadjuvant fashion to downstage patients with initially unresectable disease, with six of six patients responding sufficiently to allow complete surgical resection. Overall survival was 100% at 6 months, and 83% at 1 year, with two patients dying of complications from distant metastases without evidence of locoregional recurrence.[89] The addition of checkpoint inhibitors such as pembrolizumab at the time of progression has been used to further extend survival.[90] Future investigations of the combination of immunotherapy and targeted agents are needed, and care of the patient with ATC should take place in a multidisciplinary setting with experience in management of this rare and aggressive disease.

OTHER THYROID MALIGNANCIES

Primary thyroid lymphoma, most commonly non-Hodgkin lymphomas of B-cell origin, comprise <5% of thyroid cancers. Patients often describe a rapidly enlarging mass with compressive symptoms and commonly have a history of hypothyroidism with evidence of HT. Distinguishing a thyroid lymphoma may be accomplished with FNA biopsy and/or core needle biopsy, with surgical resection reserved for diagnostically ambiguous cases. Definitive therapy mirrors the treatment of the lymphoma with chemotherapy and radiation.

Metastases to the thyroid from renal cell carcinoma, breast, lung, gastrointestinal cancers, melanoma, and sarcoma have been reported. Definitive treatment is based in the appropriate therapy for the primary disease process, with resection reserved for palliation of compressive symptoms.

STAGING OF DIFFERENTIATED, MEDULLARY, AND ANAPLASTIC THYROID CANCER

In 2018 the American Joint Committee on Cancer (AJCC) released the 8th edition[91] update for the staging of thyroid cancer, with several key changes. For differentiated thyroid cancers

(papillary, follicular, and Hurthle): (1) the age stratification between prognostic groups was dichotomized at 55 years (previously 45); (2) microscopic perithyroidal soft tissue invasion (extrathyroidal invasion) was removed from the tumor (T) classification, reserving the T3b status to tumors with gross extrathyroidal extension visualized at the time of surgery only; (3) superior mediastinal nodal disease (level VII) was combined with level VI as N1a disease (previously N1b); and (4) N1 disease no longer upstages patients to stage III: patients with N1 disease are stage I if they are <55 years of age, and stage II if they are ≥55 years of age, as summarized in **Table 75.7A–C**.[91,92] Recently a large retrospective single-institution analysis corroborated the anticipated 10-year disease-specific survival estimated by the AJCC, however further evaluations and refinements will continue to be necessary.[92,93]

For patients with MTC, the same tumor-node-metastasis (TNM) staging system is currently in use, without the stratification by age (**Table 75.7D**).[94] The limitations of applying a system designed primarily for PTC to a different disease process are inherently evident. Recently a large analysis using the National Cancer Database (NCDB) and the United States Surveillance, Epidemiology, and End Results program (SEER) showed that the current staging system upstages a large proportion of patients with MTC to stage IV and does not accurately stratify groups based on survival. The authors used recursive partitioning to propose new staging groups and demonstrated improved separation of survival curves by grouping patients with T1 and T2 tumors without nodal disease into stage I, expanding stage II to include patients with nodal disease or larger tumors without nodal disease, and limiting stage IV to only patients with distant metastases.[94] As with other rare cancers, continued refinements to a universal staging system will require assumptions based on large databases.

The ATC staging system follows the same definitions for TNM categories as PTC and MTC, however, all patients with ATC are considered to have stage IV disease (Table 75.7E).[91]

NONSURGICAL THERAPEUTIC ADJUNCTS FOR THYROID CANCER

TSH Suppression

Considered a trophic factor, TSH may be suppressed below physiologic levels by exogenous administration of thyroid hormone (levothyroxine) in patients with moderate- to high-risk differentiated thyroid cancer (papillary, follicular, and Hurthle cell cancers). The goal TSH range for patients with high-, moderate-, and low-risk disease are <0.1 mU/L, 0.1 to 0.5 mU/L, and 0.5 to 2 mU/L, respectively.[12] The suppressive effects of TSH therapy must be balanced against the long-term health effects of occult hyperthyroidism, including the risks of arrhythmias and osteoporosis, and the degree of suppression is typically reduced in patients without evidence of disease over time. Historically TSH suppression was thought to reduce the size of benign thyroid nodules, but the effect on nodule size is modest and potential side effects from suppression outweigh the benefit. Suppression for patients with benign nodules is not recommended.

Radioiodine Therapy

Radioiodine may be used in a dose-dependent manner to diagnose residual thyroid tissue, ablate remnant thyroid tissue, or treat residual or recurrent disease in patients with follicular-derived thyroid cancers. As thyroid cells should be adequately stimulated by TSH and deprived of iodine, the timing of postoperative RAI uptake scans and/or therapeutic administrations depends on the patient and specific sequence of therapy. Evaluation should be delayed at least 4 to 8 weeks after an iodine-rich contrasted CT scan is performed. Withdrawal of thyroid hormone replacement will allow the TSH to rise to stimulatory levels, but requires a 4- to 5-week period given the long half-life of levothyroxine and may result in significant hypothyroid symptoms. Replacement with T3 (liothyronine) during this time period allows a shorter withdrawal period of 2 weeks, or alternatively recombinant human TSH can be administered to avoid the withdrawal period entirely.

Selection for administration of adjuvant RAI is a careful risk assessment that requires close communication between surgeon and endocrinologist and an understanding of interobserver variability. Extent of disease at presentation, histopathologic factors, and postoperative structural or biochemical evidence of disease, influence the decision to administer RAI (Fig. 75.7).[12] In general, RAI is encouraged for patients with distant metastases, primary tumors >4 cm or with gross extrathyroidal extension, and lymph node involvement.

External-Beam Radiation Therapy

External-beam radiation therapy (EBRT) is rarely indicated for the treatment of locoregional differentiated thyroid cancer, and should only be used in the neck after all surgical options are exhausted. For poorly differentiated tumors that are anticipated to be RAI resistant and that have invaded the trachea or esophagus, surgical awareness of the possible need for EBRT and subsequent planning with flap placement is beneficial to prevent fistula. In contrast, EBRT is employed more often for the palliation of distant bony metastases, which are less likely to be fully treated by RAI. Bone-directed therapeutics (i.e., zoledronic acid or denosumab) may be combined with EBRT in the treatment of bony metastases with synergistic effect.

Metastatic Disease and Systemic Therapy

RAI therapy is a cornerstone of therapy for patients with locally advanced/unresectable or distant metastatic disease. Unfortunately, while 5% to 15% of patients with differentiated thyroid cancer display loss of differentiation and subsequent inability to uptake iodide (RAI-refractory disease), up to 50% of patients with metastatic disease will be RAI refractory. Patients with RAI-refractory disease have poorer prognosis, with 5-year disease-specific survival rates between 60% and 70%.[95]

Table 75.7 The American Joint Committee on Cancer Tumor-Node-Metastasis 8th Edition Staging System for Papillary Thyroid Cancer, (A) Tumor Staging, (B) Nodal Staging, and (C) Stage Grouping and Anticipated 10-yr Disease-Specific Survival, with modifications for Medullary Thyroid Cancer (D), and Anaplastic Thyroid Cancer (E)

Table 75.7A Tumor Staging

T Stage	Description
T0	No evidence of tumor
T1	<2 cm, confined to the thyroid
1a	<1 cm
1b	≥1 cm but <2 cm
T2	>2 cm but ≤4 cm
T3	>4 cm, confined to the thyroid or with gross extrathyroidal extension to the strap muscles only
3a	>4 cm without extrathyroidal extension
3b	Presence of gross extrathyroidal extension
T4	Gross extrathyroidal extension beyond the strap muscles
4a	Invasion into the soft tissues, larynx, trachea, esophagus, or recurrent laryngeal nerve
4b	Invasion into the prevertebral fascia or encasement of the carotid artery or mediastinal vessels

Table 75.7B Nodal Staging

N Stage	Description
N0	No evidence of nodal metastases
N0a	Histologic evidence of benign lymph nodes
N1	Presence of nodal metastases
1a	Metastases in levels VI or VII
1b	Metastases in levels I–V or retropharyngeal nodes

Table 75.7C Stage Grouping and Anticipated 10-Yr Disease-Specific Survival

Age (Yrs)	Stage	Tumor-Node-Metastasis Description	Anticipated 10-Yr Disease-Specific Survival (%)[91]	10-Yr Disease-Specific Survival (Tam et al.)[92]
<55	I	$T_{any}N_{any}M_0$	98–100	99.8%
	II	$T_{any}N_{any}M_1$	85–95	88.3%
≥55	I	$T_{1-2}N_0M_0$	98–100	99.8%
	II	$T_{1-2}N_{1a/b}M_0$ $T_{3a/b}N_0M_0$	85–95	88.3%
	III	$T_{4a}N_{any}M_0$	<50	72.4%
	IVa	$T_{4b}N_{any}M_0$	<50	71.9%[a]
	IVb	$T_{any}M_{any}M_1$	<50	–[a]

[a]Analyzed as stage IV inclusively.

Table 75.7D Staging Groups for Medullary Thyroid Cancer

Stage	TNM	Overall Survival (Adam et al.) (%)[94]
I	$T_1N_0M_0$	95
II	$T_{2-3}N_0M_0$	91
III	$T_{1-3}N_{1a}M_0$	89
IVa	$T_4N_{any}M_0$ $T_{1-3}N_{1b}M_0$	68[a]
IVb	$T_{4b}N_{any}M_0$	–[a]
IVc	$T_{any}N_{any}M_1$	–[a]

[a]Analyzed as stage IV inclusively in this retrospective analysis of 1,252 patients from the National Cancer Database.

Table 75.7E Staging Groups for Anaplastic Thyroid Cancer		
Stage	**TNM**	**Clinical Description**
IVA	$T_{1\text{-}3a}N_0M_0$	Intrathyroidal, surgical resectable
IVB	$T_{1\text{-}3a}N_1M_0$ $T_{3b}N_{any}M_0$ $T_4N_{any}M_0$	Extrathyroidal (due to locoregional nodal disease or direct extension) but without distant metastases
IVC	$T_{any}N_{any}M_1$	Distant metastases

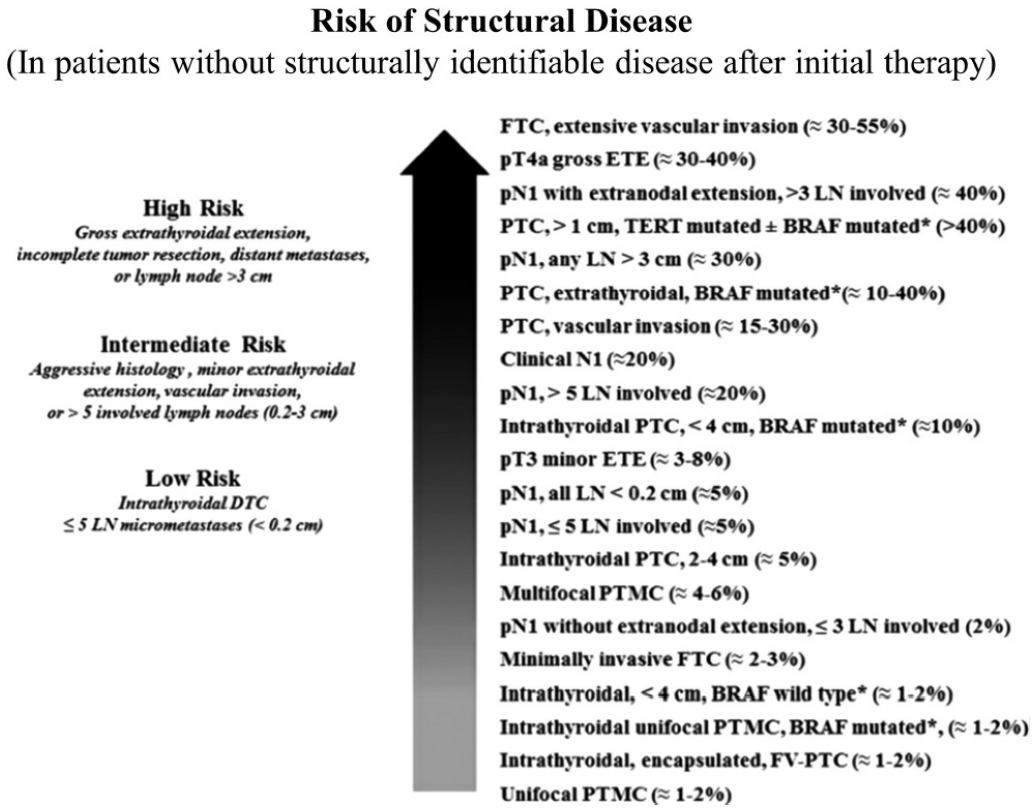

Figure 75.7 The American Thyroid Association risk stratification. In general, radioactive iodine (RAI) is encouraged for high-risk patients, considered for intermediate-risk patients, and avoided for low-risk patients. (Reprinted with permission from Haugen et al.[12])

The cornerstone of systemic therapy for thyroid cancer is based on an understanding of the altered signaling pathways, including point mutations in *BRAF* (40%) and the *RAS* family of proto-oncogenes (38%), rearrangement of *RET/PTC* (10% to 20%), rearrangements and mutations in anaplastic lymphoma kinase (*ALK*) and neurotrophic tropomyosin receptor kinase (*NTRK*)*1-3*.[85] Oral multitargeted tyrosine kinase inhibitors such as sorafenib (VEGFR, platelet-derived growth factor receptor [PDGFR], and RAF kinase inhibitor) and lenvatinib (VEGFR1-3, fibroblast growth factor receptors 1–4, PDGFRα, RET, and c-kit

signaling pathway inhibitor) are FDA approved for RAI-refractory differentiated thyroid cancer and poorly differentiated thyroid cancer. Both drugs were approved on the basis of phase 3 randomized placebo-controlled trial that demonstrated longer progression-free survival; Lenvatinib was also associated with improved overall survival in select subsets of patients (age >65 and follicular histotype).[85]

For patients with *BRAFV600E* mutated thyroid cancer either single-agent vemurafenib or dabrafenib (BRAF inhibitors) or combination therapy with trametinib or cobimetinib (MEK inhibitors, typically combined with dabrafenib) have demonstrated partial responses and promising progression-free survival (as opposed to placebo). The addition of the MEK inhibitor blocks the paradoxical activation of MAPK signaling and the increase in cutaneous malignancies observed with single-agent BRAF inhibitors. Additionally, the combination of BRAF and MEK inhibitors is thought to promote redifferentiation—or restoration of the ability of thyroid cancer cells to uptake RAI—and has great interest as adjuvant therapy for RAI-resistant disease.[85]

Other potential avenues of systemic therapy that are undergoing promising exploration currently include the mammalian target of rapamycin (mTOR) inhibitors (everolimus and temsirolimus), NTRK inhibitors (larotrectinib or entrectinib, relevant for the patient with gene fusions in NTRK, ALK, and ROS1), and selective RET inhibitors (selpercatinib and pralsetinib, as discussed in the MTC section). Immunotherapy and specifically anti-programmed cell death protein 1 (PD-1) inhibitors are also under investigation in combination with other targeted therapy.[85]

THYROID SURGERY

Shaped by contributions from Theodor Billroth, Theodor Kocher, and William Halsted, modern thyroid surgery is safe and effective. Thyroid lobectomy, total thyroidectomy, and occasionally isolated thyroid isthmusectomy may be performed. Historically, subtotal thyroidectomy (the Hartley-Dunhill procedure, in which approximately 2.5 gm of tissue is left on one side to avoid postoperative hypothyroidism) was performed for thyrotoxicosis, with the end objective to preserve native thyroid function. While this approach may still be useful in geographic areas in which thyroid hormone replacement is not readily available, subtotal thyroidectomy is rarely performed today. Near-total thyroidectomy, in which a conscious decision is made to leave a minor amount of thyroid tissue at the insertion of the RLN, is appropriate for patients with benign disease and anatomy such that further dissection may compromise the nerve.

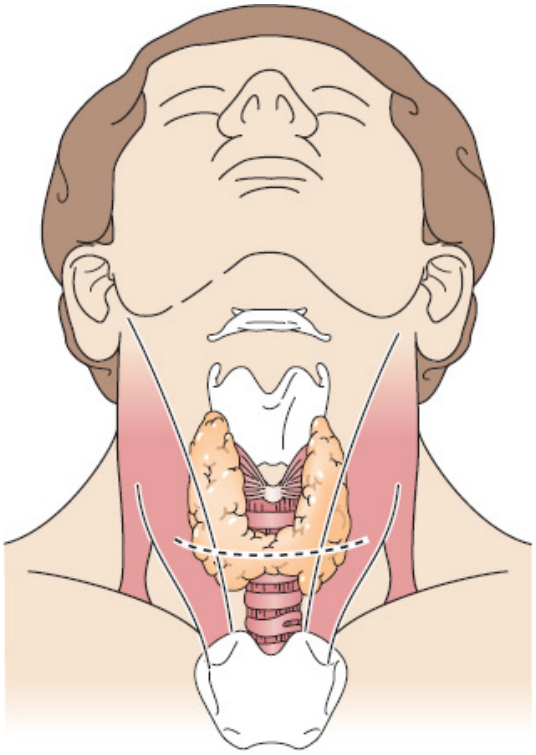

Figure 75.8 With the patient's neck extended, the *dashed line* indicates the appropriate site of incision for thyroid resection. Camouflage within an existing skin crease is often possible.

Technique

The patient is placed in the semi-Fowler position with the neck gently hyperextended and a horizontal shoulder roll placed to open the surgical field. A natural skin crease one- to two-finger breadth above the clavicles and approximately 1 cm below the cricoid cartilage is made (Fig. 75.8) and the subcutaneous tissue and platysma are divided. Subplatysmal skin flaps may be developed, extending to the thyroid cartilage, sternal notch, and laterally to the sternocleidomastoid muscles, prior to dividing the midline raphe. As an alternative to subplatysmal skin flaps, the avascular space between the sternohyoid and sternothyroid muscles may be gently dissected after the midline raphe is divided. Attention should be paid to the presence of a pyramidal lobe (which should not be inadvertently left during a total thyroidectomy) and/or midline prelaryngeal (Delphian) lymph nodes (which should be assessed early during an operation for malignancy). The middle thyroid vein is divided and the thyroid is rotated medially into the field, taking care to identify and dissect parathyroid glands laterally.

Normal parathyroid tissue is subtle and may be difficult to identify; it is characterized by a slight brownish color with a fine capillary vascular pattern not typically seen in adjacent lymph nodes, fat, or thymus. Knowledge of their common locations and careful dissection along the capsule of the thyroid will prevent inadvertent injury to the parathyroids or their blood supply. In the event of inadvertent resection or devascularization, the parathyroid should be confirmed with frozen section, morselized, and reimplanted—most commonly into

the sternocleidomastoid muscle. Deliberate marking of the reimplantation site with a Prolene suture facilitates future exploration in the event of hyperparathyroidism and marking the pocket with a radiopaque clip allows radiographic identification.

The superior pole is approached with close dissection along the capsule of the gland to avoid injury to the external branch of the superior laryngeal nerve. Although the external branch of the superior laryngeal nerve is not always directly visualized, in cases where it is observed, a nerve stimulator can be used to elicit contraction of the cricothyroideus muscle. The RLN should be directly visualized consistently and is often identified approximately 1.5 cm away from its insertion, facilitated by gentle traction of the surrounding tissues. Careful dissection along the anterior surface of the nerve and meticulous attention to early branches will preserve function (including attention early branching which may separate sensory fibers posteriorly toward the esophagus; injury of this posterior branch is associated with aspiration due to sensory dysfunction). Awareness of the possibility of a nonrecurrent laryngeal nerve, although rare (<1%), is important. More commonly found on the right side, a nonrecurrent laryngeal nerve is associated with an aberrant subclavian artery (most commonly retroesophageal).[2,3,96] Following identification of the course of the RLN, the inferior thyroid pole vessels can be divided near the thyroid capsule. Careful mobilization of the thyroid to the midline continues and Berry ligament is encountered along the anterior surface of the trachea just medial to the insertion of the RLN. Attention to hemostasis is important, as small vessels in this area in particular may bleed and obscure visualization of the RLN. The operation, as appropriate, proceeds in similar fashion on the contralateral side.

Surgical Energy Devices

There is variation in the use of specific energy devices during thyroidectomy, without a standard consensus regarding an optimal energy technique. In general, literature supports the use of energy devices with decreased operative time and similar complication rates.[97–99] The surgeon should be familiar with the use of electrocautery, bipolar electrocautery, and/or surgical energy devices such as the Harmonic Scalpel or Ligasure and the heat generation and lateral thermal spread of each. Successful thyroidectomy requires knowledge of the operation and relevant anatomy and facile use of more than one technique with the ability to adapt according to need.

Intraoperative Nerve Monitoring

Intraoperative nerve monitoring (IONM) has been proposed as an adjunct measure to provide dynamic functional feedback to enhance surgical decision making. It is not designed or proposed to replace surgeon familiarity with anatomy, gentle tissue handling, and meticulous dissection of the RLN. In the most commonly used form, intermittent IONM involves a hand-held probe that can be used to stimulate the RLN (or the vagus nerve). The transmitted signal is detected via an electrode attached to the endotracheal tube that is in contact with the vocal cords. Successful use of this system requires both the surgeon and

anesthesiologist understanding of the anatomy and positioning, as well as the ability to evaluate and troubleshoot the circuit and correctly interpret the signals. When used appropriately, feedback from the system may alert the surgeon to neuropraxia not readily recognized visually, although it is important to note that IONM has not been shown to consistently reduce the rate of nerve injury.[100–103] Information from IONM may be particularly useful in high-risk patients, including patients with bulky thyroid disease, thyrotoxicosis, or extensive malignancy, patients with known unilateral vocal cord palsy, and in reoperative settings. Both the American Academy of Otolaryngology Head and Neck Surgery[96] and the ATA[12] support the consideration of IONM during thyroidectomy.

Extent of Operation

Historically total thyroidectomy was the procedure of choice for most patients with thyroid cancer, with lobectomy reserved for very small unifocal tumors in low-risk patients. With improved understanding of the often indolent disease course of well-differentiated PTC, examination of large-scale datasets supports performing thyroid lobectomy for broader indications, with minimal impact on long-term survial.[104–107] The ATA encourages the consideration of lobectomy for well-selected younger patients (age ≤45 years) without family history or excess radiation exposure who have solitary tumors smaller than 4 cm, without evidence of extrathyroidal extension, lymphadenopathy, high-risk histopathology (i.e., tall cell variant, poor differentiation), or distant metastases, as RAI is unlikely to be required in these patients, and salvage completion thyroidectomy is a tenable option in the event of locoregional 7 recurrence.[12] The possibility of immediate or delayed completion thyroidectomy should be discussed in any cancer patient considering lobectomy. In addition to disease-related factors, discussion should also consider patient values regarding the possibility of postoperative hormone supplementation (which is required in about 20% of patients undergoing lobectomy, and is utilized more frequently in those who require TSH suppression as part of their oncologic therapy). The decision to proceed with lobectomy also mitigates the value of thyroglobulin as a postoperative tumor marker, as native thyroid tissue will also produce the protein. Finally, healthcare accessibility and compliance with follow-up should also be factored into the decision of lobectomy versus total thyroidectomy.

Lymph Node Dissection

Clinically and radiographically occult cervical lymph node metastases may be present in 24% to 82%[73] of patients with differentiated thyroid cancer selected for lymph node dissection, yet the prognostic value of prophylactic nodal dissection in these patients is controversial. Proponents cite the eradication of any microscopic disease (that would otherwise present as persistent or potentially recurrent) at the initial operative setting, thereby avoiding a reoperative field. Likely due to selection bias, retrospective analyses of prophylactic central node dissection have conflicting results, with some showing improved locoregional control,[108,109] and others showing minimal if any difference.[73,110] The information gained from additional dissection increases the likelihood of receiving adjuvant

RAI,[111] but also increases the risk of postoperative hypoparathyroidism[112–114] (3.45% vs. 1.55% in one meta-analysis).[73] The ATA recommends consideration of prophylactic central node dissection for patients with differentiated thyroid cancer who are most likely to demonstrate clinically relevant nodal metastases (T3/T4 tumors, extrathyroidal extension).[12] In contrast, prophylactic central node dissection should be performed for patients with known MTC.[21]

Therapeutic nodal dissection should be compartment based and performed when there is presence of radiographic biopsy-proven 8 disease. The anatomic boundaries of the central compartment begin superiorly at the hyoid bone, extend inferiorly to the innominate vein, and are bounded medially by the corresponding carotid artery to the midline of the trachea. The RLN should be identified and skeletonized, and care should be taken when sweeping the fibrofatty tissue to preserve the parathyroids and their blood supply.

Lateral neck dissection is most commonly performed for levels II–IV, with the decision to include levels I or V based on the presence of disease. The relevant anatomic boundaries include the belly of the digastric muscle superiorly, the sternocleidomastoid laterally, the clavicle inferiorly, the sternohyoid muscle medially, and the precervical fascia investing the scalene posteriorly. Identification and preservation of the spinal accessory, vagus, and phrenic nerves is essential. Awareness of the marginal mandibular nerve at the angle of the jaw will prevent injury (often related to pressure from a retractor). The hypoglossal nerve is not commonly seen but the surgeon should be cognizant of it. Lymphatic channels and the thoracic duct, (in the left neck) when visualized, should be carefully ligated.

COMPLICATIONS

Thyroid surgery is associated with low rates of overall morbidity (6% to 12%) and mortality (<1 in 10,000).[115,116] The most common serious complications after thyroidectomy include hypoparathyroidism, RLN injury, and/or postoperative hematoma.

Hypoparathyroidism

Hypoparathyroidism, or impaired/inadequate PTH secretion leading to hypocalcemia and hyperphosphatemia, is the most common thyroid-specific complication after thyroid surgery and may be transient or permanent. Estimates in the literature describe hypoparathyroidism in 0.33% to 68% of patients undergoing thyroid surgery.[36] This wide variability is multifactorial, influenced by differences in patient disease and risk factors, extent of the operation and surgeon experience, and a lack of consensus regarding a uniform definition of either transient or permanent hypoparathyroidism. Patients with hypoparathyroidism experience paresthesias of the hands, feet, or lips and may progress to tetany; laboratory evaluation confirms hypocalcemia. Treatment involves supplementation with oral calcium and/or calcitriol, with intravenous calcium infusion reserved for severe cases. Perioperative assessment of parathyroid hormone levels assists in identification of patients at risk for postthyroidectomy hypoparathyroidism.

Recurrent Laryngeal Nerve Injury

Loss of function of a unilateral RLN can result in voice changes, aspiration, dysphagia, and difficulty breathing. While some patients compensate well and the injury may be silent, many experience symptoms that impair their quality of life with far-reaching impacts on emotional and socioeconomic well-being. Bilateral loss of function of the RLNs results in a substantially morbid outcome, as paralysis of the cords in a paramedian position causes glottic obstruction and requires tracheotomy. Rates of VCP in the literature are highly variable due to differences in symptom severity, divergent practice patterns (i.e., routine postoperative laryngoscopy vs. symptom elicited), and lack of consensus in definition (transient vs. permanent). In general, in experienced hands the rate of permanent unilateral VCP should be <1%.

Hematoma

Postoperative hematoma can create a life-threatening airway emergency through both direct compression of the cartilaginous trachea and impaired venous and lymphatic drainage with resulting laryngopharyngeal edema. Hematoma after thyroid surgery fortunately occurs only rarely in experienced hands (0.7% in one national series of >19,000 patients,[117] range 0.49% to 4.3%).[118] Meticulous attention to hemostasis is essential.

In general, thyroid surgery is an elective and well-tolerated procedure. Surgeon experience with thyroid surgery correlates with outcomes,[115,119] with patients undergoing surgery by low-volume surgeons (≤25 cases per year) more likely to experience any complication (odds ratio 1.51, $p = 0.002$). In addition to surgeon experience, operative risk is dependent on multiple factors, including the underlying diagnosis, the impetus for and extent of surgery, and patient age and comorbidity. A thorough understanding of anatomy and careful attention to surgical technique is essential to ensuring optimal outcomes for patients undergoing thyroid surgery.

Parathyroid Glands

Gerard M. Doherty

Key Points

1 The normal parathyroid glands are flat, ovoid, and red-brown to yellow. Their dimensions are 5 to 7 mm × 3 to 4 mm × 0.5 to 2 mm, and they weigh between 30 and 50 mg each.

2 Parathyroid hormone (PTH) is the single most important hormonal regulator of calcium and phosphate metabolism in humans with direct effects on the skeleton and kidney and indirect effects on the intestine, mediated through vitamin D.

3 The demonstration of an elevated plasma PTH concentration alone does not establish the diagnosis of hyperparathyroidism; with a simultaneous elevated serum calcium level, this finding is virtually diagnostic.

4 A large proportion of patients with the diagnosis of hyperparathyroidism is minimally or asymptomatic and the appropriate treatment for these patients remains controversial.

5 It is routinely possible to identify abnormal parathyroid glands prior to operation for most patients, allowing the surgeon to know where to start the exploration; intraoperative PTH measurement can be used to confirm removal of all hyperfunctioning parathyroid tissue, that is, when to stop the operation.

ANATOMY

Typically, each person has four parathyroid glands—two superior and two inferior (**Fig. 76.1**).[1] The normal parathyroid glands are flat, ovoid, and red-brown to yellow. They measure 5 to 7 mm × 3 to 4 mm × 0.5 to 2 mm and weigh between 30 and 50 mg each. 1 The lower glands are usually larger than the upper glands. The superior glands are most often embedded in the fat on the upper posterior surface of the thyroid lobe near the site where the recurrent laryngeal nerve enters the larynx. The inferior glands are usually more ventral and lie close to or within the portion of the thymus gland that extends from the inferior pole of the thyroid gland into the chest. Although

this anatomy is fairly consistent, substantial variations from the usual can occur, and it is essential that the surgeon have a thorough understanding of these anatomic variations.

Variations in parathyroid gland anatomy are primarily caused by differences in patterns of embryogenesis. During the fourth and fifth weeks of fetal development, a series of four pharyngeal pouches develop (**Fig. 76.2**). The superior parathyroid gland arises from the fourth pharyngeal pouch in conjunction with the lateral thyroid, and the inferior gland arises from the third pouch along with the thymus. The derivatives of each pouch then migrate together so that the superior parathyroid gland usually remains in close association with the upper pole of the thyroid, although it may occasionally be loosely attached by a long vascular pedicle, migrating caudad along the esophagus into the posterior mediastinum. Occasionally, a gland may be totally embedded in the thyroid parenchyma. The inferior parathyroid gland descends with the thymus, but this migration is extremely variable. Inferior glands can be found anywhere from the pharynx to the mediastinum. Regardless of their location, they usually adhere to the thymus or are within the thyrothymic ligament. Supernumerary glands can be identified in up to 15% of patients, most often in association with the thymus. Autopsy studies suggest that four parathyroid glands are virtually always present.

The arterial supply to both the superior and inferior parathyroid glands is usually from the inferior thyroid artery, although it may arise from the superior thyroid or thyroidea ima arteries or from the rich anastomosis of vessels supplying the larynx, trachea, and esophagus. A mediastinal parathyroid gland that descended during embryonic development usually receives its blood supply from either the internal mammary artery or small arteries within the thymus; however, an enlarged parathyroid gland that grows into the mediastinum usually carries with it the corresponding branch of the inferior thyroid artery. The inferior, middle, and superior thyroid veins, which drain the parathyroid glands, empty into the internal jugular vein or the innominate vein.

Histologically, the normal adult parathyroid gland is about half parenchyma and half stroma, including fat cells (**Fig. 76.3**). In children, the gland is almost entirely composed of parenchymal chief cells. Beginning at puberty, adipocytes appear and, with age, occupy an increasing proportion of

the gland. Also with increasing age, acidophilic, mitochondria-rich oxyphil cells are present in increasing numbers and are intermixed with the glycogen-laden, polygonal, water-clear cells. The functional significance of the various cell types remains unclear, although the water-clear cells and oxyphil cells are probably derived from the chief cells and secrete parathyroid hormone (PTH).

PHYSIOLOGY

The primary physiologic role of the parathyroid gland is the endocrine regulation of calcium and phosphate metabolism. Average daily exchanges of these ions from the gastrointestinal tract, bone, and kidney are shown in **Figure 76.4**.

Calcium

Calcium ion plays a critical role in all biologic systems. It participates in enzymatic reactions and is a mediator in hormone metabolism. Calcium is intimately involved in the physiology of neurotransmission, muscle contraction, and blood coagulation. It is the major cation in bone and teeth. It represents about 2% of the average body weight, and almost all calcium is contained in the skeleton. The normal range of serum calcium is 9 to 10.5 mg/dL (4.5 to 5.2 mEq/L), and the daily variation in a normal person is generally less than 10%. About half of the total serum calcium is in an ionized, biologically active form; 40% is bound to serum protein, mainly albumin, and 10% forms compounds with organic ions, such as citrate. The total serum calcium concentration is a function of the serum protein content, and because hydrogen ion competes with calcium for the same binding sites on albumin, the body fluid pH is important. In general, for every change of 1 g/dL in the serum albumin level, a direct alteration of 0.8 mg/dL occurs in the serum calcium concentration. Almost all the physiologically important activity of calcium is represented by the unbound, or free, fraction.

Figure 76.1 Schematic illustration of the location of the superior (**A**) and inferior (**B**) parathyroid glands from 503 autopsy studies. The more common locations are indicated by the shaded areas. The numbers represent the percentage of glands found at each location. Typically, the glands were posterolateral to the thyroid and above or below the junction of the inferior thyroid artery with the recurrent laryngeal nerve.

Calcium is absorbed in its inorganic form from the duodenum and proximal jejunum. The rate of absorption is precisely regulated according to body calcium status. The calcium in the extracellular fluid is constantly being exchanged with that in the intracellular fluid, the exchangeable bone, and the glomerular filtrate. Calcium reabsorption by the kidney is closely related to that of sodium, and about 99% of the filtered load is reabsorbed under normal conditions.

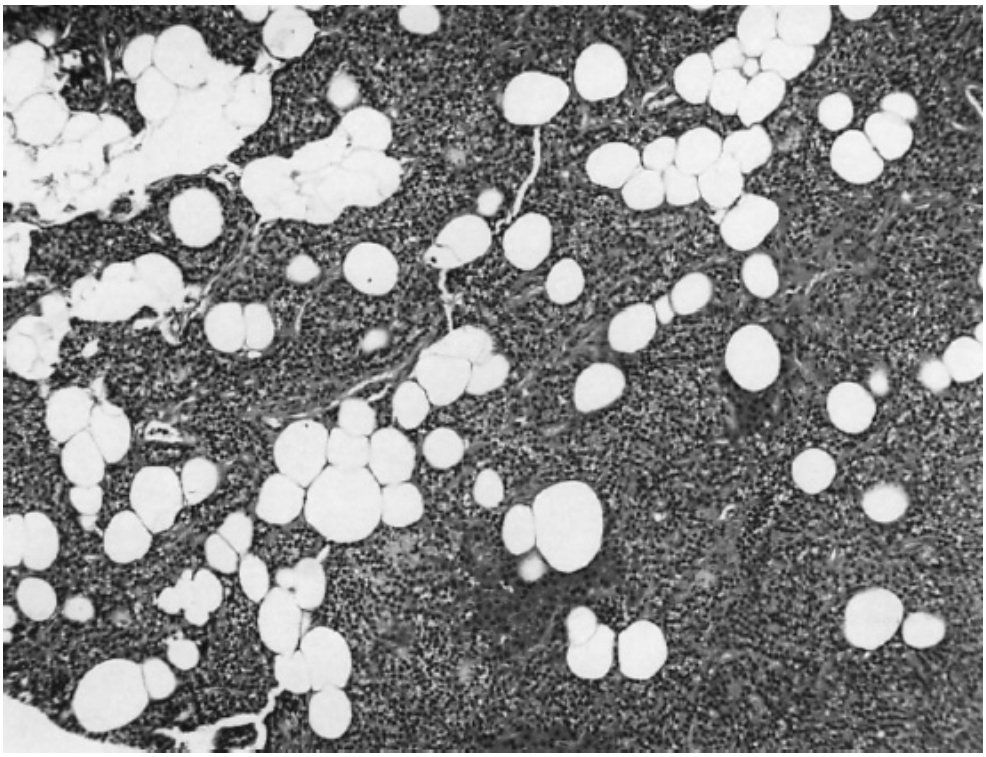

Figure 76.3 A normal adult parathyroid is composed of about half parenchyma and half fat (×150).

Phosphate

Phosphate anion is also an integral component of most biologic systems. It is critical to the pathways of glycolysis and is the functional group for a number of high-energy transfer compounds, including adenosine triphosphate. It is also the major anion in crystalline bone. Normal levels of plasma phosphate range from 2.5 to 4.3 mg/dL, and the level varies inversely with the serum level of calcium. The relation is such that the product of plasma calcium and phosphate is relatively constant ranging between 30 and 40 (with calcium and phosphate both expressed in mg/dL). When the product is above this level, the potential for the precipitation of calcium phosphate in body tissues increases.

In contrast to the percentage of calcium absorbed, the percentage of phosphate absorbed from the diet is relatively constant, and excretion usually provides the major mechanisms for regulating phosphate balance (**Fig. 76.4**). Unlike stores of calcium, the readily exchangeable soft tissue stores of phosphate, such as those in muscle, are large.

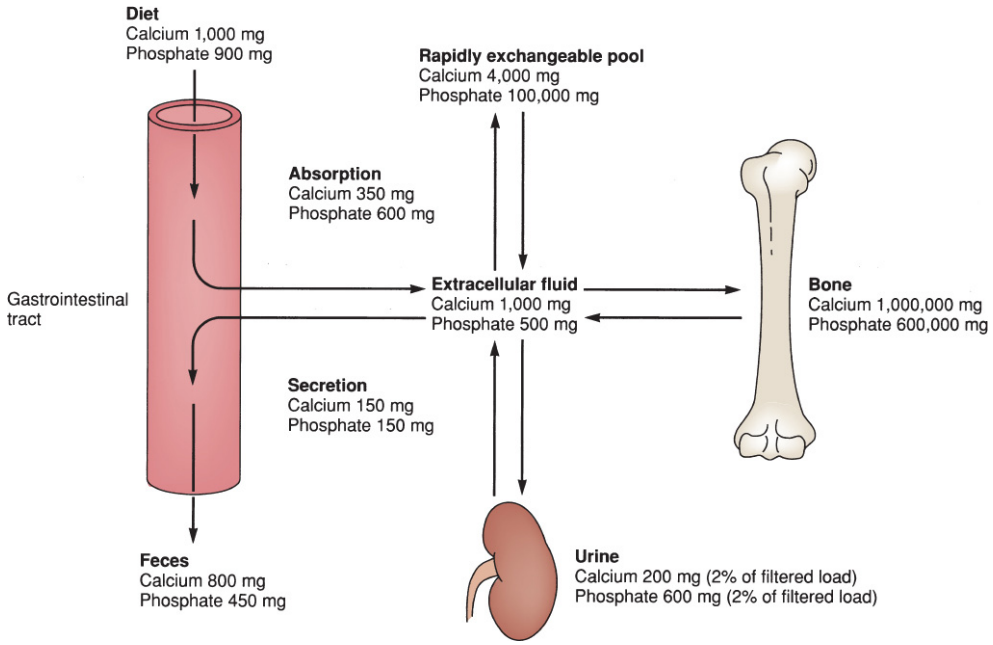

Figure 76.4 Average daily calcium and phosphate turnover in humans.

Regulation of Calcium and Phosphate Metabolism

The maintenance of calcium and phosphate homeostasis depends on major contributions from three organ systems—the gastrointestinal tract, the skeleton, and the kidneys—with minor contributions from the skin and liver.[2] The primary hormonal regulators of this metabolism are PTH, vitamin D, and calcitonin. The actions of each of these hormones in the organs are summarized in **Table 76.1**.

Parathyroid Hormone

PTH is the single most important hormonal regulator of calcium and phosphate metabolism in humans 2 . It has direct effects on the skeleton and kidney and indirect effects on the intestine, mediated through vitamin D. In target tissues, PTH binds first to membrane receptors, activating adenyl cyclase to generate cyclic adenosine monophosphate (cAMP), which regulates other intracellular enzymes.

In bone, the effects of PTH are complex, stimulating both resorption and the formation of new bone. However, sustained elevations of PTH stimulate

osteoclasts and inhibit osteoblasts. Osteocytes, in the matrix of cortical bone, may also act to reabsorb matrix in response to PTH, a process referred to as *osteocytic osteolysis*. Calcium and phosphate mobilization in response to PTH occurs in two phases. Initially, mineral is mobilized from areas of rapid equilibrium. This phase is followed by a more sustained release mediated by newly synthesized lysosomal and hydrolytic enzymes. In the kidney, PTH increases the reabsorption of extracellular fluid calcium at any given concentration, although excess secretion, because of hypercalcemia, increases the net daily amount of urinary calcium excretion. Reabsorption in the proximal tubule and loop of Henle is linked with sodium transport such that factors that alter sodium transport concomitantly alter calcium reabsorption. In contrast, reabsorption in the distal nephron is independent of sodium and directly influenced by PTH. PTH also increases phosphate excretion. This action is accompanied by enhanced bicarbonate secretion. PTH probably has only indirect effects on the gastrointestinal tract, by stimulating the hydroxylation of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D in the kidney.

PTH is synthesized initially as a precursor, prepro-PTH, which is sequentially cleaved in the parathyroid gland to pro-PTH and then to PTH (**Fig. 76.5**). Secretion of this 84-amino-acid molecule is controlled by a negative feedback loop with extracellular fluid calcium. Most PTH is secreted in this form and then cleaved in the liver into N- and C-terminal fragments. The N-terminus contains most of the biologic activity and is rapidly degraded by the liver, whereas the inactive C-terminus is slowly metabolized by the kidney.

Table 76.1 Hormonal Regulation of Calcium and Phosphate Metabolism

Location	Parathyroid Hormone	Vitamin D	Calcitonin
Gastrointestinal tract	No direct effect	Stimulates calcium and phosphate absorption	No direct effect
Skeleton	Stimulates calcium and phosphate resorption	Stimulates calcium and phosphate resorption	Inhibits calcium and phosphate resorption
Kidneys	Stimulates calcium resorption	No direct effect	Inhibits calcium and phosphate resorption

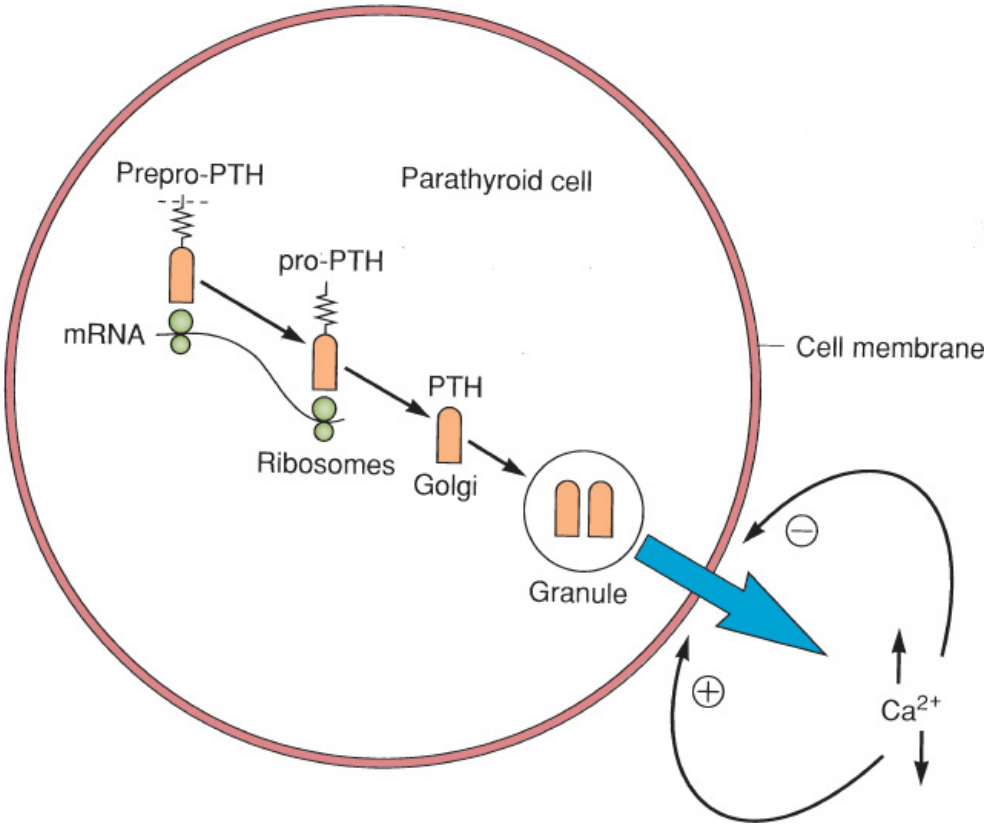

Figure 76.5 The parathyroid gland produces a precursor of PTH, prepro-PTH, that is sequentially cleaved to pro-PTH and PTH. PTH secretion is controlled by the extracellular fluid calcium concentration.

Vitamin D

Vitamin D acts at two major sites. It increases intestinal absorption of calcium and phosphate. In addition, in the skeleton, it promotes mineralization and enhances PTH-mediated mobilization of calcium and phosphate. It has no known direct effect on the kidney.

Vitamin D_3, or cholecalciferol, is produced normally by the action of sunlight on 7-dehydrocholesterol in the skin (**Fig. 76.6**). It is then hydroxylated in the liver (25 position) and kidney (1 position) to form the active 1,25-dihydroxyvitamin D_3 (calcitriol). Vitamin D_2 is normally present in yeast and fungi but not in humans. It is the major pharmacologic source of vitamin D. Pharmaceutical preparations include vitamin D_2 (ergocalciferol), 25-hydroxycholecalciferol (calcifediol), and 1,25-dihydroxycholecalciferol (calcitriol). 1-Hydroxycholecalciferol and dihydrotachysterol are synthetic preparations that require only 25-hydroxylation for activity and so are useful

for supplementation in patients with renal failure, who lack the 1-hydroxylase.

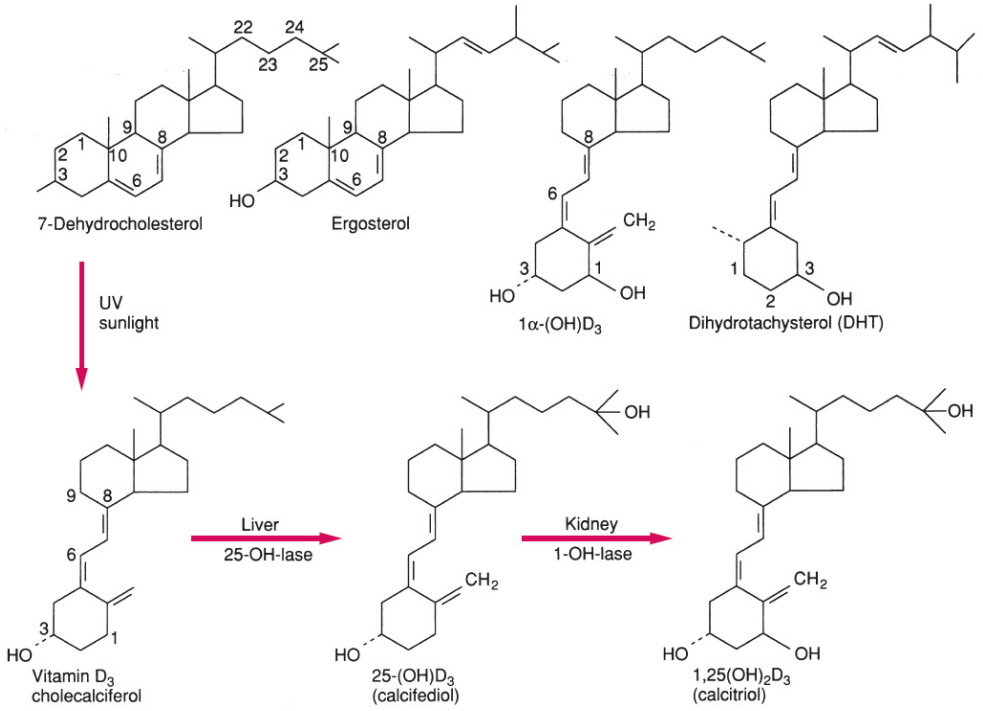

Figure 76.6 Schematic illustration of the synthesis of vitamin D_3. Ergosterol, 1-α-hydroxyvitamin D_3, and dihydrotachysterol are synthetic preparations of vitamin D.

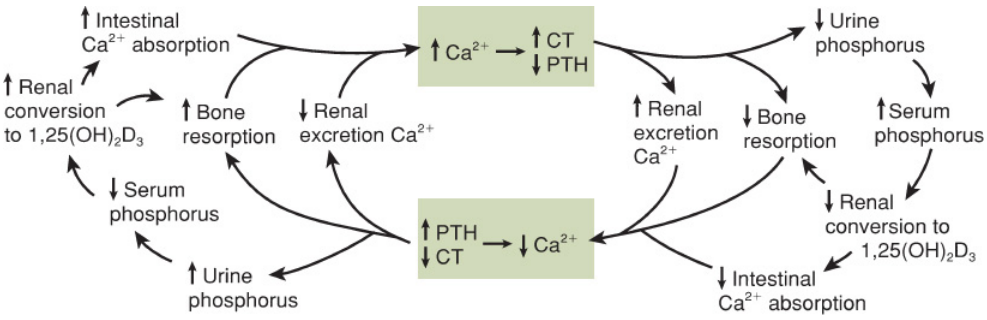

Figure 76.7 Feedback loops involved in the regulation of serum calcium and phosphorus. PTH, parathyroid hormone; CT, calcitonin.

Calcitonin

Calcitonin is a 32-amino-acid protein produced by the parafollicular C (calcitonin) cells of the thyroid. The C cells are embryologically derived from the neural crest and, in lower animals, are found in the ultimobranchial bodies, which are glandular structures derived from the lowest branchial

pouch. In humans, these structures are incorporated into the superior and lateral aspects of the thyroid lobes.

Total thyroidectomy, with removal of all the C cells, is well tolerated. Calcitonin is not essential for the normal control of calcium metabolism in adult humans. It does inhibit bone resorption and can produce hypocalcemia in experimental animals. It also increases urinary calcium and phosphate excretion. These effects are mediated primarily through cAMP. Several secretagogues for calcitonin have been identified, including catecholamines, gastrin, and cholecystokinin, but the most potent appear to be calcium and pentagastrin. Exogenously administered calcitonin can be useful pharmacologically to reduce serum calcium levels.

Mineral Homeostasis

Under normal conditions, serum calcium and phosphate levels vary minimally during the course of the day. Regulation occurs primarily through PTH but also through a series of feedback loops involving vitamin D and calcitonin (**Fig. 76.7**). A fall in serum-ionized calcium increases PTH secretion and stimulates the production of 1,25-dihydroxyvitamin D_3. Conversely, increases in serum calcium inhibit PTH secretion and the formation of active calciferol.

Pathophysiology

Diseases of the parathyroid glands present almost exclusively as disorders of calcium metabolism. Hypercalcemia is the most common manifestation, and in the patient who presents with an elevated serum calcium level, the differential diagnosis can be complex. A thorough understanding of both hypercalcemia and hypocalcemia is essential for the successful treatment of patients undergoing parathyroid surgery. Primary disorders of plasma phosphate are not usually related to surgical disease and are not discussed in detail here.

HYPERCALCEMIA

Hypercalcemia is a relatively common clinical problem.[3,4] In the general population and in hospital outpatients, the incidence is between 0.1% and 0.5%. Most patients in this group have primary hyperparathyroidism. In contrast, hypercalcemia is identified in almost 5% of hospitalized patients, and nearly two-thirds of them have a malignancy.

Clinical Manifestations

The symptoms of hypercalcemia are varied and nonspecific (**Table 76.2**). Severity is a function of both the magnitude and rapidity of onset of the hypercalcemia. Many of the manifestations are subtle and are evident only in retrospect, after the patient has been successfully treated for the cause of the elevated calcium. Specific symptoms and diagnostic tests are addressed in more detail in the section on hyperparathyroidism.

Differential Diagnosis

Although the diagnosis of primary hyperparathyroidism can, after appropriate investigation, be established with confidence in most patients, all causes of hypercalcemia must be considered and excluded. The multiple causes of hypercalcemia are listed in **Table 76.3**.

Etiology

Hyperparathyroidism

The diagnosis of hyperparathyroidism is discussed in detail later. Patients typically have elevated plasma concentrations of calcium and PTH, increased urinary excretion of calcium, and a low plasma concentration of phosphate.

Malignancy

Generally, patients with hypercalcemia and malignancy (humoral hypercalcemia of malignancy) can be classified into two groups.[5–7] Patients with solid tumors, such as lung carcinoma (25% of all cases of humoral hypercalcemia of malignancy); breast carcinoma (20%); squamous cell

carcinoma of the head, neck, esophagus, or female genital tract (19%); or renal cell cancer (8%), account for three-fourths of all cases. Humoral hypercalcemia of malignancy in this setting generally appears late in the disease, with nearly all patients having known, or readily evident, malignancy. These patients have elevated levels of serum calcium, low levels of serum phosphorus, and elevated levels of urinary cAMP, consistent with increased PTH activity but normal or low-serum PTH levels. The hypercalcemia is now known to be caused by PTH-related protein secreted by the tumor, rather than by the bony metastases that many of these patients have because of the advanced nature of their cancers. In the second group, accounting for one-fourth of cases, are patients with hematologic malignancies, such as multiple myeloma, certain lymphomas and leukemias, and a subset of the patients with breast cancer. These patients have elevated levels of serum calcium, but in contrast to most patients with solid tumors and humoral hypercalcemia of malignancy, they have elevated levels of serum phosphate and low levels of urinary cAMP. These patients always have lytic bony lesions and histologically demonstrate increased osteoclast bone resorption adjacent to tumor cells. This osteoclast-activating activity is an effect of cytokines, mainly interleukin-1 β and tumor necrosis factor-β (lymphotoxin). These cytokines promote local net bone resorption and thus produce hypercalcemia and hyperphosphatemia.

- Lithium therapy
- Addisonian crisis
- Idiopathic hypercalcemia of infancy

Vitamin D and Vitamin A Intoxication

When administered in excess, vitamins A and D can produce hypercalcemia. Affected patients tend to have normal or elevated serum phosphate levels associated with a low PTH level. Metastatic calcification may occur.

Thiazide Diuretics

Thiazides may increase serum calcium levels to a mild degree, primarily through hemoconcentration and decreased renal excretion. Serum phosphate may also be depressed. It often takes several weeks for the hypercalcemia to resolve after the medication is discontinued.

Hyperthyroidism

Hyperthyroidism is associated with increased bone resorption. Often, the plasma PTH is low, and a history of other thyrotoxic symptoms can be elicited. The hypercalcemia usually resolves as the patient becomes euthyroid.

Milk–Alkali Syndrome

Typically, the milk–alkali syndrome occurs in patients with peptic ulcers who consume large quantities of milk and absorbable antacids. Usually, some degree of renal failure is present. PTH levels are low. This syndrome has become much less common with the increased use of nonabsorbable antacids, histamine 2-receptor antagonists, and proton pump inhibitors as therapy for peptic ulcer disease.

Sarcoidosis and Other Granulomatous Diseases

These syndromes are associated with hypersensitivity to vitamin D. The granulomas can convert inactive vitamin D to its active form. Patients have elevated plasma globulins and low PTH levels. The administration of large doses of corticosteroids for 10 days usually reduces the hypercalcemia. Biopsy of lymph nodes or the liver may confirm the diagnosis.

Familial Hypocalciuric Hypercalcemia

This disease is an asymptomatic, autosomal dominant condition characterized by mild to moderate hypercalcemia, hypocalciuria, and normal or only slightly elevated PTH levels. It develops in people heterozygous for a mutation in the calcium-sensing receptor.[8–10] The mutation causes an increase in the set point for extracellular calcium concentration, so that the "normal" calcium level is higher in these people than in the normal population. No treatment is necessary, although people with this disease should receive genetic counseling. Neonatal severe hyperparathyroidism, which can be fatal, develops in children homozygous for mutations in this receptor. Treatment for neonates with this disease is controversial, but they appear to benefit from early surgical management.

Immobilization

Immobilization produces hypercalcemia by increasing the ratio of bone resorption to bone formation. These patients can usually be distinguished by history, although on laboratory evaluation they have elevated serum levels of calcium and phosphate and a decreased serum concentration of PTH. Often, hypercalciuria is present, which may lead to the development of renal stones. Treatment is early mobilization and forced diuresis.

Other Causes

A variety of other diseases may produce hypercalcemia. For example, Paget disease (osteitis deformans) typically causes mild elevations in serum calcium. Paget disease can be diagnosed on the basis of the characteristic radiographic lesion. Adrenal insufficiency may be associated with hypercalcemia, although the symptoms are typically those of the primary abnormality. Lithium therapy appears to produce hypercalcemia by altering the parathyroid set point for inhibition by calcium, and, over long courses of therapy, may also be associated with hyperparathyroidism. Idiopathic hypercalcemia of infancy is a rare disorder that is probably the result of hypersensitivity to vitamin D. It occurs in infants with mental retardation and is satisfactorily treated with glucocorticoids. Other causes include aluminum-induced renal osteomalacia and a host of analytic errors related to improper specimen collection with prolonged tourniquet times, tube contamination, and instrument drift.

Medical Treatment

Although the choice of therapy is tailored to the cause of the hypercalcemia, several general measures can prove effective.[11,12]

For the patient with mild hypercalcemia, a trial of a decrease in dietary calcium is indicated. A reduction in intake of milk and other dairy products is suggested, along with discontinuation of thiazide diuretics and vitamin D preparations. Mobilization prevents bone demineralization.

Patients with more marked hypercalcemia or severe symptoms should be admitted to the hospital for treatment, with careful observation and monitoring. In the patient with severe hyperparathyroidism, although the definitive therapy is surgical, it is unwise to proceed with neck exploration

until the calcium has been reduced to near-normal levels. The mainstay of therapy is intravenous hydration, preferably with normal saline solution in sufficient quantities to maintain the urine output above 100 mL/hr. These patients are often dehydrated before therapy, and fluid can be administered intravenously at a rate of 200 mL/hr. Caution must be exercised in older patients, whose cardiac reserve may be marginal. This therapy exploits the parallel handling of calcium and sodium by the kidneys. The diuretic furosemide also increases sodium and calcium excretion but should not be used until the patient is well hydrated.

The end points of therapy are a decrease in the serum calcium level and a reduction of symptoms. Diuresis with saline solution is usually effective when the hypercalcemia results from hyperparathyroidism or a benign cause. In contrast, the hypercalcemia of malignancy may produce severe symptoms associated with extremely high-serum calcium levels that are difficult to control. In this setting, a variety of other measures may be considered (**Table 76.4**). Some of the agents used to treat hypercalcemia cause significant toxicity, and close patient monitoring is required during treatment. Calcitonin is a fairly weak hypocalcemic agent, but it acts rapidly and is associated with less toxicity than many of the other drugs.[12] Salmon calcitonin is the most potent preparation. Treatment with glucocorticoids is particularly efficacious in patients with sarcoidosis and other granulomatous diseases. Plicamycin has proved useful in patients with hypercalcemia of malignancy, but it causes a cumulative toxicity (thrombocytopenia, hepatotoxicity, and nephrotoxicity). Bisphosphonates inhibit osteoclast activity directly. These agents are administered orally or parenterally and are particularly efficacious, although long-term use may be associated with significant osteomalacia.[7] Prostaglandin synthetase inhibitors were initially considered useful, but their efficacy has proved to be limited. Intravenous phosphates and chelating agents have largely been abandoned because of their severe toxicity; however, oral phosphates may be beneficial in patients requiring prolonged therapy.

HYPOCALCEMIA

Hypocalcemia can occur as a consequence of various acquired and hereditary diseases.[13,14] Generally, these disorders produce a deficiency or defect in the action of either PTH or vitamin D. It is most commonly a significant clinical problem after neck operation for thyroid disease. Chronic vitamin D deficiency is associated with compensatory PTH excess. The end result is rickets in children or osteomalacia in adults.

Clinical Features

The major signs and symptoms of hypocalcemia are a direct consequence of the reduction in plasma levels of ionized calcium, which increases neuromuscular excitability (**Table 76.5**). The earliest clinical manifestations are numbness and tingling in the circumoral area, fingers, and toes. Mental symptoms are also common. Patients become anxious, depressed, and occasionally confused. Tetany may develop, characterized by carpopedal spasm, tonic–clonic convulsions, and laryngeal stridor. The magnitude of symptoms at any given plasma concentration of ionized calcium varies from patient to patient. On physical examination, contraction of the facial muscles is elicited by tapping anterior to the ear, over the facial nerve (Chvostek sign), although this sign may be present in 10% of normocalcemic patients. Trousseau sign is elicited by occluding blood flow to the forearm for 3 minutes. The development of carpal spasm indicates hypocalcemia, although the test is unpleasant and clinically impractical.

Table 76.4 Treatment of Hypercalcemia

Therapy of Primary Disease
- Tumor resection (hypercalcemia of malignancy)
- Parathyroidectomy (primary hyperparathyroidism)

Expansion of Extracellular Volume
- Infusion of saline solution
- Enhancement of urinary calcium excretion
- Extracellular volume expansion
- Loop diuretics (furosemide and ethacrynic acid)

Inhibition of Bone Resorption
- Calcitonin
- Glucocorticoids
- Plicamycin (mithramycin)
- Bisphosphonates
- Gallium nitrate

Reduction of Intestinal Calcium Absorption
- Low-calcium diet
- Glucocorticoids

Other Treatments
- Dialysis
- Mobilization
- Oral phosphate
- Estrogens or progestogens (postmenopausal women with primary hyperparathyroidism)
- Chloroquine (sarcoidosis)

Modified from Attie MF. Treatment of hypercalcemia. *Endocrinol Metab Clin North Am* 1989;18(3):807–828.

Etiology

Some of the causes of hypocalcemia are listed in **Table 76.6**. The most common cause of hypocalcemia by far is excision of or damage to the

parathyroid glands during thyroid surgery.

Postoperative Hypoparathyroidism

Postoperative hypoparathyroidism commonly develops after total thyroidectomy.[15,16] Most patients undergoing operation on the thyroid experience some alteration in serum calcium, although they often are asymptomatic; the low calcium probably represents contusion or temporary alteration of the blood supply to the parathyroid glands. The hypocalcemia is usually transient and is not treated unless significant symptoms develop. Occasionally, in hyperparathyroid patients who have parathyroidectomy and significant bone disease, a marked skeletal deposition of calcium and symptomatic hypocalcemia occurs, the so-called *bone hunger*. The plasma calcium usually reaches its nadir at 48 to 72 hours after surgery and then slowly returns to normal within several days. These patients may require calcium and vitamin D therapy for weeks or months after parathyroidectomy.

Table 76.5 Clinical Features of Hypocalcemia

Neurologic

- Circumoral paresthesia
- Light-headedness

Table 76.6 Causes of Hypocalcemia

- Hypoparathyroidism
- Vitamin D deficiency
- Pseudohypoparathyroidism
- Hypomagnesemia
- Malabsorption
- Pancreatitis
- Hypoalbuminemia
- Chelation of calcium
- Osteoblastic metastases
- Toxic shock syndrome
- Hyperphosphatemia

Idiopathic Hypoparathyroidism

A less common form of hypoparathyroidism is idiopathic lack of function. It occurs both sporadically and in families. In some cases, it develops as part of a polyglandular disorder and is thought to have an autoimmune basis. DiGeorge syndrome is a group of congenital disorders involving the branchial pouches that produce partial or complete agenesis of the thymus and parathyroid glands. Hypoparathyroidism can also develop in newborns as a result of prenatal suppression of the fetal parathyroid glands as a consequence of maternal hypercalcemia.[17] It is also common in otherwise normal but premature infants.

Vitamin D Deficiency

Vitamin D deficiency can occur as a result of dietary deficiency or lack of sun exposure. Likewise, renal disease produces a decrease in the 1-hydroxylase activity necessary for the formation of active vitamin D. The result is a decrease in calcium absorption and an increased secretion of PTH by the stimulated parathyroid glands. Osteomalacia, abnormal fractures, and the deformities of rickets may result.

Pseudohypoparathyroidism

Pseudohypoparathyroidism is a familial disease characterized by a rotund appearance, shortening of the extremities, and sometimes mental deficiency. The defect is not in PTH secretion; in fact, most patients have elevated plasma levels of PTH with evidence of increased bone resorption. Rather, the kidney is unresponsive to the hormone, and as a consequence, hypocalcemia and hyperphosphatemia develop. The deficit appears to be in the renal adenyl cyclase system.

Hypomagnesemia

This unusual deficit may result from chronic alcoholism, malabsorption, parenteral nutrition, or increased renal clearance during therapy with aminoglycosides. The deficit appears to block the physical response to PTH in addition to its release from the parathyroid gland.

Other Causes

In short-gut syndrome, after extensive small-bowel resection or bypass, or after some forms of bariatric surgery, vitamin D and calcium may be absorbed in insufficient quantities. In pancreatitis, the massive soft tissue destruction and saponification that occur with hemorrhagic disease may sequester significant amounts of calcium in the retroperitoneum. Some undefined systemic factor also appears to contribute to hypocalcemia in these patients. Hypoalbuminemia causes a reduction in the total plasma calcium level, although the level of ionized calcium remains within the normal range and patients are asymptomatic. Circulatory substances, such as the citrate used to anticoagulate banked blood and radiographic contrast media, may bind to calcium. In patients with osteoblastic metastases, particularly associated with prostate carcinoma, hypocalcemia has been attributed to increased calcium flux into the lesions. Toxic shock syndrome is sometimes associated with hypocalcemia, but the mechanism has not been defined. Acute hyperphosphatemia, as a consequence of exogenous administration of phosphate or during the cytolytic chemotherapy of highly responsive tumors (e.g., Burkitt lymphoma and acute lymphoblastic leukemia), may produce symptomatic hypocalcemia associated with soft tissue calcification.

Treatment

The treatment of hypocalcemia is summarized in **Table 76.7**. For acute symptomatic hypocalcemia, calcium should be administered intravenously. Calcium gluconate is less irritating to the veins than calcium chloride, and the calcium release is slower, without a risk for overcorrection. Usually, 20 to 30 mL of 10% solution is infused over a 15- to 20-minute period, and then 50 to 100 mL is administered over the next 12 hours in adults. A practical guide after an initial bolus dose includes 60 mL of 10% calcium gluconate in a 500-mL bag of dextrose 5% in water, infused at 1 mL/kg/hr, and adjusted every 4 hours based on the serum level of calcium and patient symptoms. Bicarbonate precipitates any calcium infused through the same intravenous line. Serum magnesium should always be measured, and hypomagnesemia should be corrected if present. In patients with convulsions from advanced tetany, diphenylhydantoin therapy is useful, but symptoms should never be allowed to progress to this point.

Long-term therapy is gauged on the basis of symptoms. In the postoperative patient, the continued stimulus of mild hypocalcemia to any remaining parathyroid gland tissue may prove useful. Concomitant therapy with calcium and vitamin D is effective in a timely fashion. A starting dose of 2 g of oral calcium carbonate per day in divided doses is usually well tolerated. Vitamin D can be administered as calcitriol, an active synthetic vitamin D analog. Most adults respond to a dose of 0.5 to 1.0 mcg/day; reduced doses may be necessary for patients with renal dysfunction.

Table 76.7 Treatment of Hypocalcemia

Symptom or Goal	Treatment
Symptomatic hypocalcemia	Oral calcium carbonate or intravenous calcium gluconate, and possibly vitamin D supplements to increase the efficiency of absorption of oral supplements
Symptomatic tetany	Intravenous calcium gluconate
Correction of hypomagnesemia	Intravenous magnesium chloride
Vitamin D supplementation	Ergocalciferol, calcifediol (liver disease), calcitriol (renal disease)
Long-term therapy	Calcium carbonate; low-phosphate, low-oxalate diet; parathyroid grafting (immunosuppressed or cryopreserved autograft)

HYPERPARATHYROIDISM

Definitions

Parathyroid neoplasms are rarely identified by physical enlargement but rather are sought because of the peripheral effects of excess hormone. Primary hyperparathyroidism develops spontaneously, without apparent cause but possibly in response to exogenous stimuli. When the normal control of serum calcium is disturbed and the autonomous production of PTH is increased, the state is referred to as *primary hyperparathyroidism.* This category includes both benign single- and multiple-gland enlargements and the much rarer parathyroid carcinoma. In some cases, the disease is familial. In contrast, *secondary hyperparathyroidism* occurs when a defect in mineral

homeostasis leads to a compensatory increase in parathyroid function. This occurs most commonly in response to renal disease but may also develop as a consequence of the hypocalcemia associated with some diseases of the gastrointestinal tract, bones, or other endocrine organs. Occasionally, with prolonged secondary stimulation, the hyperfunctioning glands are no longer physiologically responsive to an increase in ionized calcium. This uncommon (affecting about 2% of patients after renal transplantation), relatively autonomous state referred to as *tertiary hyperparathyroidism,* develops most commonly after renal transplantation when the renal defect in calcium homeostasis is corrected.

Incidence

The advent in the 1970s of the widespread assessment of serum calcium as part of automated multichannel analysis has considerably altered our understanding of hyperparathyroidism. Before that time, primary hyperparathyroidism was thought to be a relatively rare condition. Most patients presented with symptoms of disease, usually renal stones or bony manifestations. Currently, most patients are asymptomatic or have only vague symptoms or signs that can be related to hyperparathyroidism.[18,19] Occasionally, patients recognize that they had symptoms only after their well-being improves following parathyroidectomy. Incidence varies with both age and gender, but hyperparathyroidism is believed to develop in about 50 to 100 people per 100,000 in the general population, with approximately 50,000 new cases occurring annually in the United States.[20] Marked variations have been noted worldwide; the reasons for these differences remain unclear.

Etiology

The cause of primary hyperparathyroidism is not known. Although the sequence of progression from secondary to tertiary disease in response to chronic stimulation has a logical appeal, it is difficult to draw parallels with primary disease. Most patients with primary hyperparathyroidism have disease of a single rather than of multiple glands, which is not what might be predicted if an external stimulus were part of the pathophysiology.

Hyperparathyroidism is most common in postmenopausal women, the population group with the highest incidence of osteoporosis and the most significant alterations in calcium and phosphate metabolism. Loss of renal function with aging is associated with elevations in PTH and decreases in phosphate clearance. It has been suggested but not demonstrated that a renal calcium leak, if sufficient, might result in a chronic calcium deficit stimulating the parathyroid glands.

Genetic studies of parathyroid adenomas have described an oncogene (*PRAD1*) that may be one step in the path to neoplasia in these tumors. Overexpression of the normal *PRAD1* gene, also known as *cyclin D1,* allows progression of the cell cycle from the G1 phase to the S phase, thus promoting cellular growth and division. *PRAD1* is overexpressed in 20% to 40% of parathyroid adenomas; further research may reveal other genetic alterations that contribute to the neoplastic growth. The *MEN1* tumor-suppressor gene has also been implicated in the molecular pathogenesis of sporadic hyperparathyroidism. About 15% to 20% of sporadic parathyroid adenomas have either somatic mutation or biallelic deletion of the *MEN1* gene.[21,22]

Hyperparathyroidism occurs in several familial forms. It is a major component of the multiple endocrine neoplasia (MEN) syndromes types 1 and 2A. The parathyroid disease of MEN-1 syndrome is multiple parathyroid adenomas that appear with increasing frequency over the patient's lifetime.[23] In other families, hyperparathyroidism is inherited in an autosomal dominant fashion without other manifestations of MEN-1 or MEN-2; some have osseous abnormalities (tumor–jaw syndrome) and some apparently have isolated disease.

Pathology

Single-Gland versus Multiple-Gland Disease

Microscopically, the cell most commonly involved in primary hyperparathyroidism is the chief cell. Less frequently, the oxyphil cell is the predominant cell type. Diseased glands typically have an increase in the proportion of stromal cells and a reduction in the proportion of stromal fat. Single diseased glands, or adenomas, have been classically described with a

predominance of chief cells centering in a single focus, with a compressed rim of surrounding normal tissue (**Fig. 76.8**). In contrast, parathyroid hyperplasia has been characterized as a diffuse proliferation of clear cells in multiple glands, with little remaining normal tissue (**Fig. 76.9**). These criteria have proved totally unreliable. Although pathologic studies can usually distinguish parathyroid glands from other tissue, they may not prove useful beyond this capacity. Intraoperative decisions frequently depend on recognizing disease of one or more parathyroid glands, and in this regard, the histologic description of adenoma or hyperplasia is generally unreliable in primary hyperparathyroidism.[24]

Patients with multiple-gland disease may have one gland that appears to be an adenoma and another that appears diffusely involved or even histologically normal with gross enlargement. The most reliable index of abnormality is the determination of glandular enlargement by visual inspection. The incidence of single- and multiple-gland enlargement as judged by visual inspection in 66 consecutive patients with hyperparathyroidism is shown in **Table 76.8**. The visual assessment and judgment of the experienced surgeon have proved to be an effective basis for intraoperative decisions. This approach requires that all four parathyroid glands be evaluated at the time of operation. However, the recent ability to rapidly measure PTH during operation has provided a method to assess gland function rather than size. This experience indicates that there may be more enlarged glands than there are hyperfunctioning glands.[25]

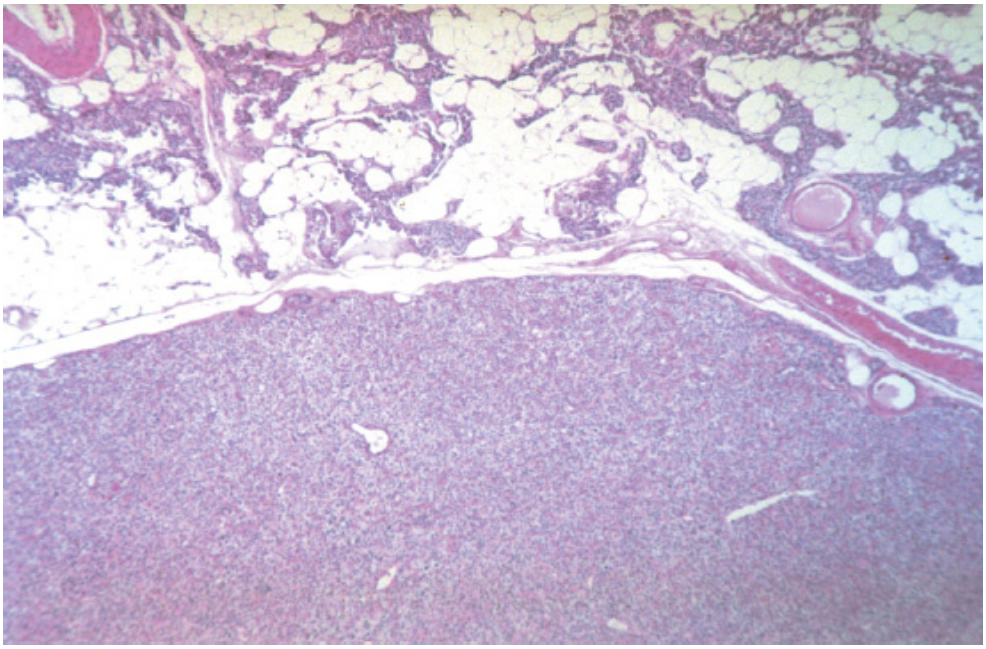

Figure 76.8 Parathyroid adenoma. The tumor consists of sheets of neoplastic chief cells and is separated from normal parenchyma by a thin capsule.

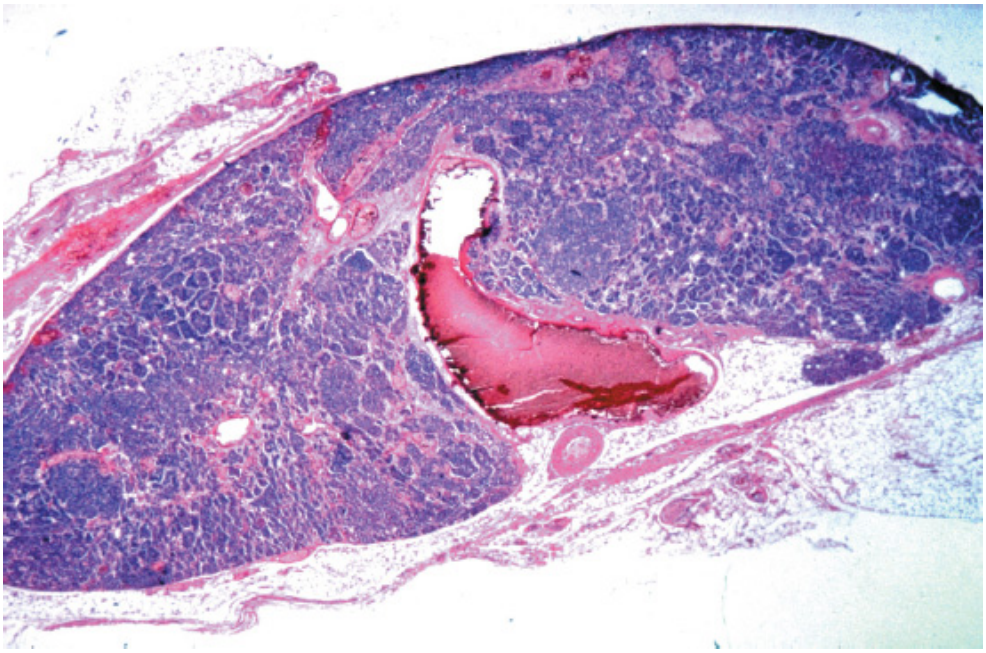

Figure 76.9 Primary parathyroid hyperplasia. The normal adipose tissue of the gland has been replaced by sheets and trabeculae of hyperplastic chief cells.

Carcinoma

Parathyroid carcinoma is a rare entity, and the histologic diagnosis can be exceedingly difficult. The surgeon may suspect the diagnosis when dense

invasion and scarring are encountered, although this may also be secondary to some other inflammatory disease in the neck. Pathologic criteria include marked mitotic activity, dense fibrous stroma, and evidence of local invasion into the capsule or surrounding vessels.[26] Malignant-appearing tumors, however, may pursue an apparently benign clinical course; the converse is less frequently true. The only reliable criteria of malignancy are metastases, most commonly to the lymph nodes, lung, or liver, and true local invasion.

Systemic Effects

The use of automated technology for determining serum calcium has changed not only the estimated incidence of hyperparathyroidism but also the usual mode of presentation. Before screening, three-fourths of patients presented with renal disease, particularly nephrolithiasis; one-third to one-half had skeletal manifestations, and rare patients had both. Most recent series suggest that at least half of the patients in whom hyperparathyroidism is diagnosed do not have renal or osseous disease and many are minimally symptomatic or asymptomatic. Manifestations of the disease are protean but generally nonspecific, and they may be difficult to elicit in the history. A significant proportion of patients present without a readily quantifiable index of disease severity. This finding has created some controversy about the need for surgery in the asymptomatic patient and particularly for the elderly or high-risk patient.[20,27]

Table 76.8 Gland Enlargement in 1,002 Consecutive Patients with Primary Hyperparathyroidism

Pathology	Patient, *n*	Percentage (%)
Adenoma	788	78
Double adenoma	98	9.8
Hyperplasia	116	11.6

From Hughes DT, Miller BS, Park PB, et al. Factors in conversion from minimally invasive parathyroidectomy to bilateral parathyroid exploration for primary hyperparathyroidism. *Surgery* 2013;154(6):1428–1434.

The earliest complaints are often the vague symptoms of hypercalcemia. These vary with the magnitude of plasma calcium elevation and can include muscle weakness, anorexia, nausea, constipation, polyuria, and polydipsia. These nonspecific symptoms may or may not cause the patient to seek medical attention. Some symptomatic patients have evidence of chronic disease involving the kidney or skeleton. Usually, only one of these systems is significantly involved in any individual patient. The treatment of hyperparathyroidism is designed to eliminate or halt the progression of the complications of the disease. Symptomatic patients can be divided into two groups. Members of the first group have renal manifestations, a slower onset of symptoms, and generally lower serum calcium concentrations. Patients in the second group have a more rapid onset of symptoms, higher-serum calcium levels, and significant bone disease. No recognizable histologic or physiologic characteristics distinguish patients with renal disease from those with bone disease.

Renal Manifestations

Renal complications develop because the hypercalcemia leads to an increase in urinary calcium excretion and because PTH increases the excretion of phosphate and produces urinary alkalosis. Both these events predispose to stone formation. Urinary stones can be treated surgically or with lithotripsy, and subsequent definitive treatment of the hyperparathyroidism reduces the rate of reformation. Of patients who present for the first time with renal colic, 5% to 10% are found to have primary hyperparathyroidism. Nephrocalcinosis (**Fig. 76.10**) is calcification of the renal parenchyma and occurs in 5% to 10% of patients with hyperparathyroidism. It causes more significant renal damage than nephrolithiasis does. In general, the more severe the renal damage, the less likely it is that nephrocalcinosis will regress after parathyroidectomy.

The incidence of hypertension in hyperparathyroidism increases with the degree of renal impairment. Hypertension may be a significant cause of the morbidity associated with hyperparathyroidism, but although a decrease in blood pressure has been demonstrated in some patients after parathyroidectomy, the correlation between the two conditions is not clear.

Figure 76.10 Abdominal film demonstrating nephrocalcinosis, or diffuse calcification of the renal parenchyma (*arrows*).

Figure 76.11 Magnification radiograph of the fingers in hyperparathyroidism. Subperiosteal cortical resorption (*arrows*) typically is most visible on the radial aspect of the middle phalanges.

Skeletal Manifestations

Parathyroid bone disease in its most classic and severe form, osteitis fibrosa cystica, is seldom encountered; however, 5% to 15% of patients with parathyroid bone disease present with significant symptoms of skeletal disease. Most commonly, these symptoms include bone pain and pathologic fractures.

Bone changes are often demonstrable on detailed plain radiographs of the hands (**Fig. 76.11**). Characteristically, subperiosteal resorption is evident on the radial aspect of the middle phalanx of the second or third finger. Because of tufting of the distal phalanges, clubbing may be evident on physical examination. Other findings that typically involve the skull and long bones include bone cysts, "brown" tumors (i.e., localized proliferations of osteoclasts), and diffuse demineralization or granularity. More subtle bone loss can be detected by iliac crest bone biopsy or dual-energy x-ray absorptiometry scan. The risk of bone fracture increases with increasing severity of bone loss.

Gastrointestinal Manifestations

Hypercalcemia is clearly associated with nonspecific gastrointestinal complaints, including nausea, vomiting, constipation, and anorexia, but attempts to demonstrate a definite relation between hyperparathyroidism and either peptic ulcer disease or pancreatitis remain unconvincing. Hypercalcemia stimulates gastric acid secretion experimentally and clinically, and has been associated with pancreatitis. Therefore, a theoretic rationale for the complex of hyperparathyroidism and gastrointestinal symptoms does exist.

Neuromuscular Manifestations

Neurologic and muscular complaints are those of hypercalcemia in general. Fatigability and proximal muscle weakness are among the most debilitating manifestations. Atrophy of type II muscle fibers, consistent with a neuropathic and not a myopathic cause, has been demonstrated. Sensory complaints include dysesthesia, a reduced vibratory sense, and stocking–glove sensory deficits.

Psychological Manifestations

The emotional disturbances of hyperparathyroidism are often subtle and difficult to quantify. As with other forms of hypercalcemia, they range from depression or anxiety to psychosis and coma. Patients undergoing parathyroidectomy frequently experience a sense of well-being and relief

from fatigue and dullness postoperatively, even if they may have had no noticeable complaints preoperatively.

Other Manifestations

A variety of signs and symptoms of soft tissue calcification have been described. Nonspecific arthralgia, particularly involving the proximal interphalangeal joints of the hands, is characteristic. The incidence of chondrocalcinosis is increased. Pruritus, vascular and cardiac calcification, and band keratopathy of the cornea have all been noted. Some reports have suggested an increased risk of malignancy and coronary artery disease, but the effects remain unsubstantiated, and it is not clear if the mortality risk is modifiable by correction of hyperparathyroidism.[28–31]

Physical Findings

Except in patients with the classic deformities of advanced bone disease, the physical examination is seldom helpful. Diseased parathyroid glands are infrequently palpable, except in patients with parathyroid carcinoma. A mass in the anterior neck in a patient with primary hyperparathyroidism is most commonly a thyroid nodule.

Laboratory Findings

Tests for calcium, PTH, phosphate, bicarbonate, and magnesium, in addition to other laboratory tests, are useful to establish the diagnosis of hyperparathyroidism.

Calcium

Hypercalcemia is the single most important diagnostic finding; however, particularly in early or mild cases, serial analysis may show fluctuations in and out of the normal range. Coexistent hypoalbuminemia and acidosis may produce an apparently normal total serum level of calcium, even though the ionized fraction is actually elevated. Serum concentrations of ionized calcium may be helpful in the patient with intermittent or mild hypercalcemia.

Parathyroid Hormone

PTH measurement is an important method for establishing the diagnosis of hyperparathyroidism. Because of the heterogeneity of the various circulating forms of PTH, measurement of C-terminal or N-terminal fragments give conflicting and confusing results. Intact hormone assays and whole molecule assays are the most dependable. The demonstration of an elevated plasma PTH concentration alone does not establish the diagnosis of hyperparathyroidism. 3 With a simultaneous elevated serum calcium level, this finding is virtually diagnostic (**Fig. 76.12**).

Phosphate

PTH increases renal phosphate excretion and, in about half of patients, produces hypophosphatemia. In the presence of renal disease, however, the serum phosphate levels may be normal or significantly elevated.

Bicarbonate

PTH also increases bicarbonate excretion, so that a hyperchloremic metabolic acidosis may develop. It has been suggested that the finding of an elevated serum chloride-to-phosphate ratio may be helpful in the differential diagnosis of hypercalcemia. A ratio greater than 30 is considered highly suggestive of hyperparathyroidism.

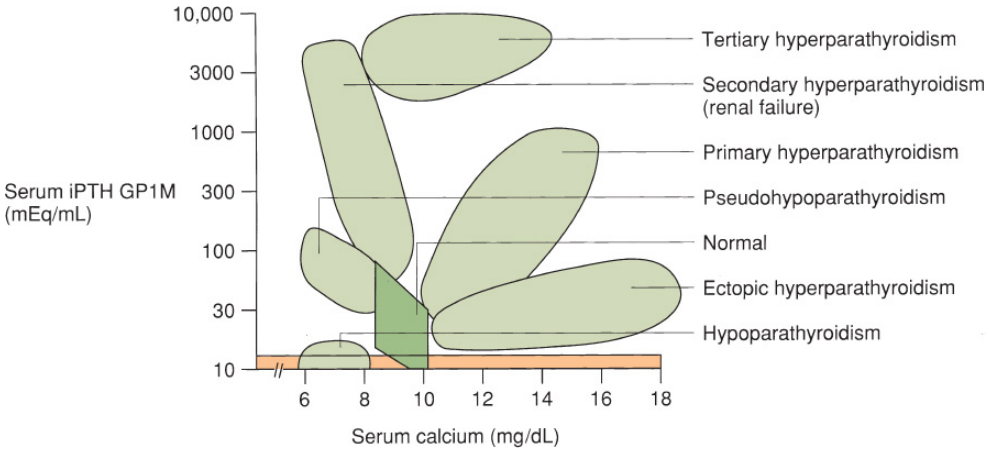

Figure 76.12 Relation between serum immunoreactive parathyroid hormone and serum calcium in patients with hypoparathyroidism, pseudohypoparathyroidism, ectopic hyperparathyroidism, and primary, secondary, and tertiary hyperparathyroidism. GP1M, guinea pig antiserum 1M.

Magnesium

Hypomagnesemia develops in 5% to 10% of patients with hyperparathyroidism. After parathyroidectomy, if both hypocalcemia and hypomagnesemia are present, it may be difficult to correct the calcium until the serum magnesium has been corrected.

Other Diagnostic Tests

A variety of special diagnostic tests for hyperparathyroidism are available. None is more specific than the measurement of serum concentrations of calcium and PTH, although they may be useful in equivocal cases. For example, the 24-hour urinary calcium excretion is usually elevated, but may be normal, in patients with hyperparathyroidism, although the finding is not specific for this disease. This test is helpful in identifying patients with familial hypercalcemic hypocalciuria, in whom the rate of urinary calcium excretion is low. Measurements of tubular reabsorption of phosphate below 30% suggest primary hyperparathyroidism. Urinary cAMP is generated specifically as a consequence of PTH activation of renal tubular adenyl cyclase. Increased urinary concentrations are identified in most patients with primary hyperparathyroidism. These measurements are rarely necessary because of the reliability of the intact PTH measurement.

Localization with Imaging Techniques

In order to try to simplify the operative approach to hyperparathyroidism, an attempt is usually made to localize enlarged glands preoperatively. In the hands of an experienced surgeon, the cure rate for hyperparathyroidism at the initial operation without preoperative localization exceeds 95% with the conventional full-neck exploration. However, technologic developments have led surgeons to pursue alternatives to the full-neck exploration. These innovations are increasingly accurate preoperative localization with ^{99m}technetium sestamibi scintigraphy, computed tomography scans with carefully timed intravenous contrast administration, or high-resolution ultrasound, combined with intraoperative intact PTH measurement that allows termination of the operation without visualization of all four parathyroid glands. Surgeons have used these technologies in various combinations to limit the extent of the neck exploration. All of the current alternative strategies, however, depend on a preoperative parathyroid localization study to direct the exploration.

The study most frequently used for imaging previously unoperated patients is ^{99m}technetium sestamibi scintigraphy (**Fig. 76.13**). Sestamibi scanning can identify the site of abnormal tissue in 75% to 80% of patients but has limitations in patients with small adenomas or multiple-gland disease. Sestamibi was originally developed for cardiac imaging. The use of a single nuclide with a short half-life and a high-energy profile has advantages in lateral, oblique, and three-dimensional imaging that technetium–thallium scanning, which was formerly used, does not provide. However, the availability of a CT scan with carefully timed contrast injection ("4D-CT") has replaced sestamibi scan in many centers.[27]

High-resolution ultrasound examination of the neck is also used for localization of abnormal parathyroid tissue, particularly when it is available for use by the clinician. The current machines scan at high frequencies (10 to 13 MHz) that allow demonstration of small abnormalities in the neck (**Fig. 76.14**). The examination is best done by a clinician in real time, as that allows the most complete assessment of the neck, rather than scans performed by a technician for later review of still pictures by the physician. The sensitivity of cervical ultrasound for abnormal parathyroid glands is about the same as for sestamibi scanning. Ultrasonography is an operator-dependent technique. It is rapid and relatively inexpensive and can direct fine-needle aspiration for cytologic confirmation and immunoassay for PTH.

In patients with persistent or recurrent hyperparathyroidism, preoperative imaging is important to guide the exploration. High-resolution real-time ultrasonography, computed tomography (CT), magnetic resonance imaging (MRI), and sestamibi scanning all appear to have comparable sensitivities of 50% to 60%. The results of these examinations may be less successful at centers without significant experience in their use.

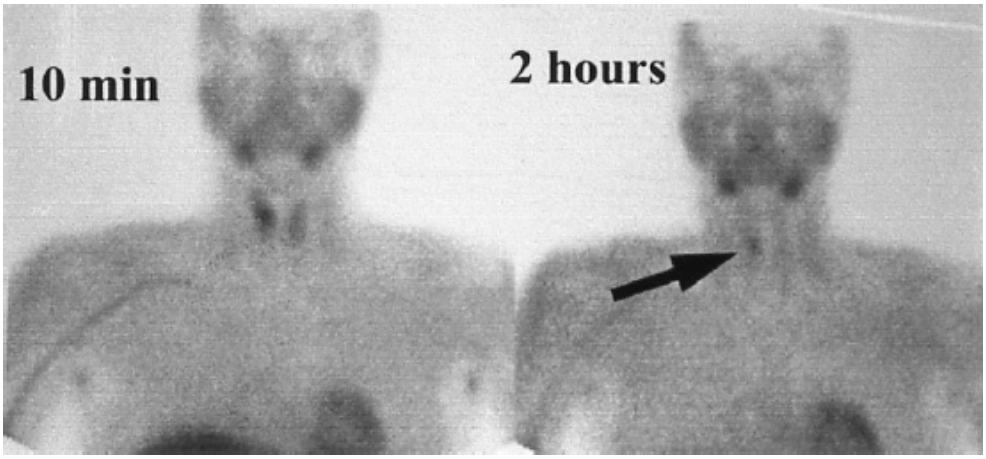

Figure 76.13 99mTechnetium sestamibi scan of a patient with a parathyroid adenoma. The radionuclide is present in both thyroid and parathyroid tissues on the 10-minute film; however, by 2 hours, the radionuclide has washed out of the thyroid and remains only in the right-sided parathyroid gland. This scan shows a 794-mg right upper parathyroid adenoma (*arrow*).

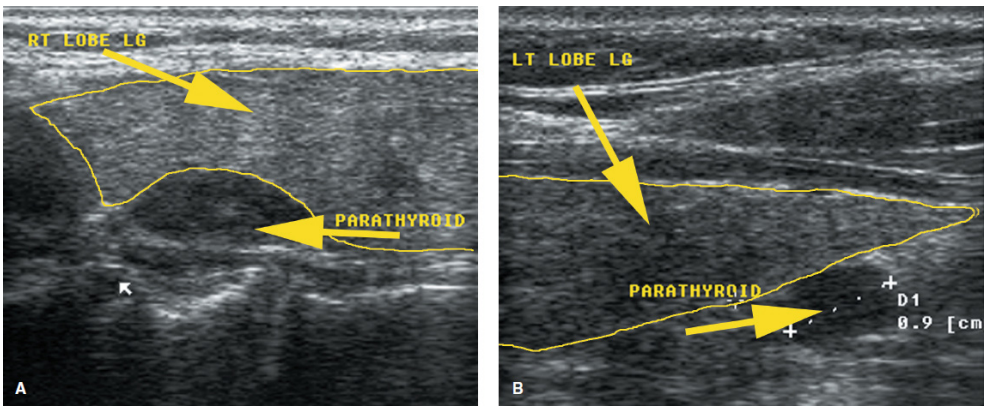

Figure 76.14 Ultrasound views of parathyroid adenomas. **A:** Sagittal image of the upper pole of the right lobe of the thyroid gland, demonstrating a hypoechoic parathyroid adenoma posterior to the thyroid parenchyma. **B:** Sagittal image of the lower pole of the left lobe of the thyroid gland with an adjacent hypoechoic parathyroid adenoma measuring 9 mm in greatest dimension.

Computed tomography is more expensive but less operator dependent than ultrasonography. It clearly is superior in identifying deeper structures and for examining the retrosternal mediastinum. MRI is considerably more expensive than CT and has not been shown to be superior. Most surgeons prefer to have results of two or more imaging tests that confirm an abnormality before exploration in the reoperative setting.[27]

Treatment

Indications for Surgery

Generally, the only practical therapeutic option is surgery. Nephrolithiasis, bone disease, and neuromuscular symptoms all respond well to surgical intervention.[32] In contrast, surgery in patients with renal failure, hypertension, and psychiatric symptoms is not so uniformly successful, although it benefits some patients and is usually indicated in all except those at highest risk. The question of how to manage the large group of patients with apparently asymptomatic disease requires particularly careful consideration.

Management of Asymptomatic Hyperparathyroidism

A large proportion of patients with the diagnosis of hyperparathyroidism are minimally symptomatic or asymptomatic. 4 The appropriate treatment for these patients remains controversial. Although little evidence indicates that irreversible complications, such as renal failure, eventually develop in patients with asymptomatic mild disease, the natural history of the disease remains incompletely defined. Many of the manifestations of this disease may go unrecognized until they are corrected surgically. Still unanswered is the question of how much asymptomatic disease may contribute to generalized osteopenia in this predominantly postmenopausal female population.

A report detailing the 15-year natural history of 116 patients with asymptomatic hyperparathyroidism was published in 2008. Operation was recommended for those in whom symptoms or findings developed, according to the prevailing guidelines. During the monitoring period, 51% of the patients had operation, and biochemical normalization and increased bone mass were observed in those who underwent surgery. However, the patients who did not undergo operative correction continued to have biochemical abnormalities and the cortical bone mass fell significantly. These data confirm the impression of most clinicians that mild hyperparathyroidism rarely takes a precipitously worsening clinical course; however, the differential bone effects that are evident by 15 years call into question how long such patients can be monitored without correction.

In October 1990, a National Institutes of Health Consensus Development Conference reviewed the available evidence regarding the management of asymptomatic primary hyperparathyroidism.[33] After interval developments, a panel of experts reconvened in 2002, and revisited this issue.[34] The panel agreed that operation is the indicated treatment for all patients with symptoms; however, they recognized a subgroup of patients who have no symptoms attributable to hyperparathyroidism, and their conclusions included several indications for surgical intervention in these asymptomatic patients (**Table 76.9**).

The panel mandated close (every 6 months) follow-up for those patients not treated by operation. In addition, they recommended surgery for cases in which medical surveillance is neither desirable nor suitable, such as when a patient requests surgery, consistent follow-up is unlikely, coexistent illness complicates management, or a patient is younger than age 50 years.

This remains an area of considerable controversy, and subsequent reviews have supported similar plans with only minor revisions.[27,35] The complication rate of operation by an experienced surgeon is very low. Within a short period, the financial cost of medical follow-up exceeds that of treatment by operation. Based on these considerations, most patients should undergo operation, and those who do not must be closely followed.

Table 76.9 National Institutes of Health Consensus Development Conference Indications for Surgical Intervention in Patients with Asymptomatic Primary Hyperparathyroidism

- Markedly elevated serum calcium (>1.0 mg/dL above normal)
- History of an episode of life-threatening hypercalcemia
- Reduced creatinine clearance
- Presence of one or more kidney stones detected by abdominal radiography
- Markedly elevated 24-hr urinary calcium excretion
- Substantially reduced bone mass as determined by direct measurement (dual-energy x-ray absorptiometry T-score ≤2.5)

Principles of Surgical Correction

Although neck exploration for hyperparathyroidism may be straightforward, it sometimes becomes an arduous procedure requiring considerable patience because of the variability in both the location and the number of diseased glands. Persistent hyperparathyroidism and the necessity for reexploration can usually be avoided by a meticulous initial procedure. Reoperation is predictably more difficult than the initial operation, and the risks for damage to the recurrent laryngeal nerves and hypoparathyroidism are greater during reoperation.

It is essential that the surgeon be confident of the preoperative diagnosis and prospectively discuss the procedure with the patient. The potential complications of damage to either the recurrent laryngeal nerve or the superior laryngeal nerve and the development of hypocalcemia require discussion. Likewise, the possibility of an unsuccessful initial operation must be explained, and the patient should recognize that reexploration, including median sternotomy, may be required. Although alternatives to full-neck exploration are often now applied, no patient should be explored by a surgeon who is unfamiliar with the principles and techniques of the conventional full-neck exploration.

For a full-neck exploration, the patient is placed under general anesthesia with a roll beneath the shoulders and the neck extended. The neck is opened through a transverse incision overlying the thyroid isthmus, and the platysma is similarly divided. Superior and inferior flaps are developed. The strap muscles are separated in the midline and retracted laterally; division is unnecessary. One lobe of the thyroid is chosen and rotated medially. Important landmarks include the tracheoesophageal groove, the recurrent laryngeal nerve, the inferior and superior thyroid arteries, and the middle thyroid vein (**Fig. 76.15**). In most patients, the nerve lies in the tracheoesophageal groove or just laterally. Occasionally, it may be situated more anteriorly. Uncommonly, it may originate directly from the vagus without passing around the right subclavian artery. Both of these latter variations make the recurrent nerve more susceptible to injury. The external branch of the superior laryngeal nerve, which innervates the cricothyroid muscle, usually lies medial to the superior thyroid vessels and should be carefully preserved.

For a full-neck exploration, all four glands should be identified at the initial exploration because of the possibility of multiple-gland disease.

Supernumerary glands may be present and should be sought at the initial procedure. Although a frozen section has not been helpful in differentiating diseased from normal glands, it is generally reliable for confirming the presence or absence of parathyroid tissue. Small, thin biopsy specimens are sharply incised from the gland, with extreme care taken to avoid damaging its delicate blood supply. Most surgeons use a frozen section selectively to confirm suspected abnormal parathyroid tissue or to document difficult or confusing situations.[27]

The upper glands are usually located far dorsally on the surface of the thyroid lobe at the level of the upper two-thirds of the gland. The lower glands are less constant and may be located anywhere from well above the thyroid to the anterior mediastinum. The lower glands are most typically in the region where the thyrothymic ligament attaches to the lower pole of the thyroid lobe. If the inferior glands cannot be localized, the thymic pedicle should be carefully examined and mobilized. Because of their common embryologic origin, the inferior gland is frequently associated with the thymic remnant. Parathyroid glands within the mediastinum sometimes can be removed by mobilizing the thymus through the cervical incision. If this technique is unsuccessful in identifying the parathyroid gland, the thyroid lobe on the side of the missing gland is mobilized and palpated. Intraoperative ultrasonographic examination may identify an intrathyroidal parathyroid gland. As a last resort, excision of the thyroid lobe may be indicated.

If after meticulous exploration of all these areas three or four parathyroid glands have been identified, none of which is enlarged, most surgeons favor terminating the operation.

Limited Surgical Exploration

With the availability of accurate preoperative localization methods, it has become routinely possible to identify abnormal parathyroid glands prior to operation for most patients. 5 This allows the surgeon to know where to start the exploration. Then, intraoperative PTH measurement can be used to confirm removal of all hyperfunctioning parathyroid tissue, that is, when to stop the operation. This strategy of directed, limited neck exploration is applicable to about 75% of initial parathyroid explorations, and has about

the same success rate as full-neck exploration. The preoperative localization can be done by either ^{99m}technetium sestamibi nuclear medicine scan or by high-resolution ultrasound. The intraoperative PTH measurement is first assessed at the outset of the procedure, and/or immediately preceding parathyroid gland excision (the pre-excision baseline). Blood samples are obtained at time intervals after parathyroid gland resection. A decrease of the PTH level by 50% from the higher of the incision or pre-excision baseline predicts long-term normocalcemia.[36] Other investigators use more sensitive criteria for the detection of multigland disease, including reduction of the PTH level into the normal range and kinetic assessments of the rate of PTH decrease.[37] This increase in sensitivity comes with the cost of decreased specificity, however. Blood samples can be obtained either centrally or peripherally.[38]

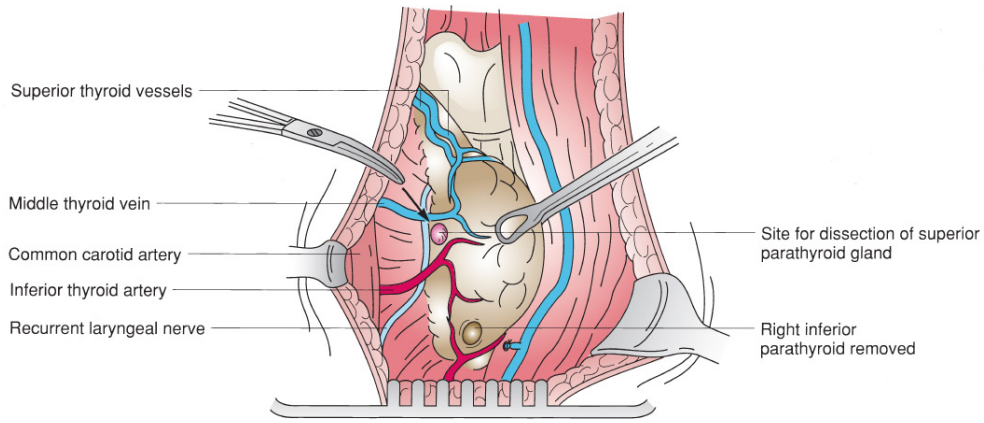

Figure 76.15 Lateral view of the right side of the neck after rotation of the thyroid lobe. The important anatomic landmarks are emphasized.

The limited nature of this operative approach also makes it easier to perform this operation under regional or local anesthetic in an ambulatory setting. However, because of the possibility of multiple-gland disease or inaccurate preoperative localization, all surgeons undertaking this approach should also be skilled in the full-neck exploration for hyperparathyroidism.[39]

Extent of Resection

The operative procedure performed has been based on the number of enlarged glands identified at full-neck exploration; however, with the use of intraoperative PTH monitoring, it has become clear that not all enlarged

parathyroid glands are hyperfunctioning.[40] In contrast, nearly all hyperfunctioning glands are enlarged and hypercellular. The full-neck exploration experience has demonstrated that removing all enlarged glands is a highly successful approach to curing hyperparathyroidism. In the absence of PTH monitoring, this remains an accepted approach. Typically, single-gland disease has been treated by simple excision, whereas any combination of two- or three-gland enlargement is treated by resecting the diseased tissue and leaving the normal glands in place. The question of whether two- or three-gland enlargement implies the presence of disease in all glands (hyperplasia) has not been resolved. If one gland is large and the remaining three are normal in size, resection of the single parathyroid cures virtually all patients. Of XX patients with two- or three-gland disease treated by excising the large glands and leaving the normal glands, only eight (10.5%) had recurrent hypercalcemia, which tended to be mild (follow-up of 12 to 140 months postoperatively). This approach seems satisfactory in most patients.[41]

Treating patients with four-gland disease has been more difficult. In many of these patients, the disease occurs as a component of one of the familial syndromes, particularly MEN-1. Patients with four-gland parathyroid disease can be treated by subtotal parathyroidectomy (removing three and a half glands) or by total parathyroidectomy with autotransplantation of some parathyroid tissue into the nondominant forearm. Both operations depend on meticulous identification of all parathyroid tissue for adequate results. The putative advantage of the subtotal parathyroidectomy is that it leaves the remaining parathyroid tissue with its native blood supply. Total parathyroidectomy with autograft has the advantage of removing all the abnormal parathyroid tissue from the neck and placing it in a site where reoperation for recurrent hyperparathyroidism is simpler. Over time, subtotal parathyroidectomy has become the more common approach.

The reported incidence of recurrent hypercalcemia after subtotal parathyroidectomy for nonfamilial parathyroid hyperplasia is 0% to 16%; the incidence of permanent hypoparathyroidism is 4% to 5%. Total parathyroidectomy with autograft is associated with a similar risk for permanent hypoparathyroidism in the sporadic setting (5%) and a higher reported risk for recurrent hypercalcemia (20%). Reoperation for recurrent hypercalcemia is simplified by the approach of total parathyroidectomy with autotransplantation. Thus, given the current data, sporadic parathyroid

hyperplasia can be acceptably treated by either operation. In patients with MEN-1, the disease is not the same as sporadic hyperplasia. Rather, defects in the MEN-1 gene cause multiple parathyroid adenomas that arise independently over the life of the patient.[23] The operative results reflect this independent capability of all parathyroid tissue in these patients to become neoplastic. The hypercalcemia recurrence rate is 26% to 36% with long-term follow-up after subtotal parathyroidectomy, and similar after total parathyroidectomy with autograft. However, the incidence of permanent hypoparathyroidism after autograft in MEN-1 is also significant (reported as high as 46%). While both approaches are currently accepted, most experienced centers now advocate subtotal parathyroidectomy as the initial operation in MEN-1 hyperparathyroidism, and anticipate that recurrent disease is likely, manageable, and less problematic than permanent hypocalcemia.[42]

Technique of Parathyroid Autotransplantation

The parathyroid gland is sliced into 15 to 20 pieces and autografted into a forearm muscle bed. This location permits easy subsequent access under local anesthesia if recurrent hypercalcemia develops; the grafts are easily identified by ultrasound. Function of the autograft is documented by (a) normocalcemia, with the autograft as the only source of PTH, (b) by measuring higher concentrations of hormone in the antecubital vein draining the graft bed than in the corresponding vein in the opposite arm, or (c) “transient parathyroidectomy,” by placing a venous occlusive tourniquet on the arm above the graft, and measuring changes over several minutes in the PTH levels drawn from the contralateral arm.[43] Lack of function is unusual outside of the MEN-1 patients; hypoparathyroidism develops in about 5% of patients. Glands can also be cryopreserved in dimethyl sulfoxide and serum. If in the postoperative period it becomes clear that the patient is aparathyroid, the cryopreserved tissue can be reimplanted under local anesthesia, though this technique is rarely used now in the era of available intraoperative PTH measurement.

Special Situations

Persistent or Recurrent Hyperparathyroidism

Persistent hyperparathyroidism occurs in fewer than 5% of patients after exploration by an experienced surgeon. Most commonly, it is the result of a single diseased gland remaining in the neck or the mediastinum. Recurrent disease develops after an interval of normocalcemia and may be the result of regrowth of diseased tissue, implantation from a tumor broken at the initial procedure, or recurrent parathyroid carcinoma.

In the evaluation of these patients, it is essential to document that the initial diagnosis was correct. Familial hypocalciuric hypercalcemia should be excluded by measuring urinary calcium excretion.

Reviewing the original operative notes and pathology reports may provide clues to the position of missed glands. The locations of parathyroid tumors not found at the initial operation but identified on subsequent exploration in one large series are shown in **Figure 76.16**.

It is generally agreed that localization studies have an important role in the management of recurrent disease. Noninvasive methods are used first, and if these are unsuccessful in identifying the diseased gland, selective angiography and venous sampling for PTH are used. The utility of the techniques vary across institutions, dependent on local experience, expertise, and preference. Selective angiography localizes 50% to 80% of parathyroid glands that cannot be detected by any other modality. Venous sampling may also be helpful in some patients, although interpretation can be complicated by the alteration in venous drainage that occurs postoperatively. Because it provides no direct image but indicates the side and level of the neck where the hyperfunctioning tissue is located, it may help to direct the interpretation of other imaging studies, and the exploration to one or the other side of the neck. Both of these invasive radiographic techniques require considerable expertise. Transient cortical blindness, transverse myelitis, and cerebrovascular accidents have all been reported as complications of arteriography. Angiographic ablation of mediastinal parathyroid tissue with large doses of ionic contrast has been successful in selected patients. This technique may be used in some patients with mediastinal parathyroid adenomas who are at increased surgical risk and who have other functional parathyroid tissue remaining.[44]

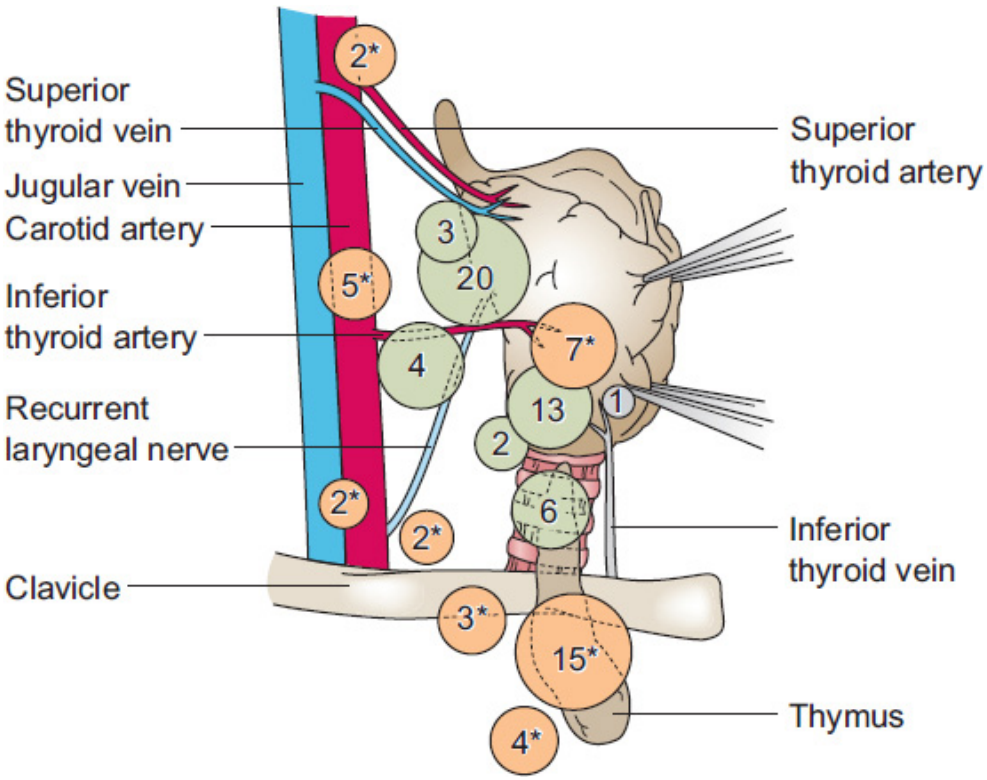

Figure 76.16 Location of parathyroid tumors missed on initial exploration but identified on subsequent operation.

Surgical reexploration can be a difficult procedure. The neck should almost always be reexplored first. If the thymic remnant has not already been removed, it should be excised at this time. Two adjunctive techniques, intraoperative ultrasonography to locate glands and intraoperative measurement of PTH to document the adequacy of resection, may be useful in patients undergoing operation for persistent disease.[27]

If the gland is not identified in the neck by means of the maneuvers described, the mediastinum is examined; most surgeons do this only if there is imaging evidence of disease in the mediastinum, rather than unguided exploration. Median sternotomy and exploration are necessary in very few patients with hyperparathyroidism. Successful transcervical mediastinal exploration is sometimes possible with use of the Cooper thymectomy retractor, a substernal retractor that permits more extensive mediastinal exploration and thymectomy through a cervical incision or using videoscopic techniques. Any remaining thymic tissue is first isolated and examined. Inferior parathyroid glands most commonly migrate into the anterior mediastinum. If the results of this exploration are negative, the area posterior

and lateral to the trachea is then explored. The location of superior parathyroid glands may be as far posterior as the esophagus and as far superior as the pharynx.

Surgical reexploration is successful in experienced hands in about 80% of cases. The incidence of complications is increased. Unilateral recurrent nerve injury occurs in 5% to 10% of patients postoperatively, and permanent hypoparathyroidism in 10% to 20% of patients. Cryopreservation of excised tissue may be included as a component of the management of these patients because it allows later autotransplantation if the patient becomes hypoparathyroid postoperatively. However, the demonstration of continued PTH production by intraoperative PTH measurement makes cryopreservation unnecessary. The risks of these complications must be clearly outweighed by the clinical improvement in patients with advanced disease. Reoperation in asymptomatic patients with mild disease is controversial.

Hypercalcemic Crisis

Occasionally, patients with hyperparathyroidism become acutely hypercalcemic with severe symptoms. The pathogenesis appears to involve a cycle of uncontrolled PTH secretion followed by hypercalcemia and secondary polyuria, dehydration, and reduced renal function, which exacerbate the hypercalcemia. Serum calcium concentrations may reach 16 to 20 mg/dL, and the syndrome is manifested by rapidly developing muscle weakness, nausea and vomiting, lethargy, fatigue, and even coma. Ultrasonography, sestamibi scan, or CT scan may help to identify the enlarged gland to allow expedient correction.

Definitive treatment involves resecting the diseased parathyroid tissue, which is almost always curative. Generally, however, it is safer to lower the serum calcium level before operation.

Hyperparathyroidism in Pregnancy

Hyperparathyroidism in pregnancy is a rare disorder that not only causes hypercalcemia in the mother but also is associated with increased morbidity and mortality rates in the fetus. Even the newborn is at risk for the development of tetany. The risk for fetal complications is higher if the hyperparathyroidism is left untreated. The mother should undergo operation

in the second trimester, though the outcome for the pregnancy with modern management is good overall.[45]

Neonatal Hyperparathyroidism

Neonatal hyperparathyroidism occurs in infants who are homozygous for a mutation of the calcium-sensing receptor and is characterized by hypotonia, poor feeding, constipation, and respiratory distress. Each parent of these children is affected by familial hypocalciuric hypercalcemia. The 1-year survival rate in children with symptoms is less than 50%, and patients without symptoms appear to have significant bone disease. Total parathyroidectomy appears to be the treatment of choice, although experience is very limited.[46]

Secondary Hyperparathyroidism

Secondary hyperparathyroidism develops as a consequence of chronic renal failure. Phosphate retention and hyperphosphatemia reduce the serum calcium levels. This effect is aggravated by the reduction in 1-hydroxylase activity in the kidney, necessary for the activation of vitamin D_3. The secondary increase in PTH levels to compensate for the hypocalcemic effects is exacerbated by aluminum accumulation in bone. Aluminum, present both in the dialysate fluid and in phosphate-binding medications, contributes to the osteomalacia (renal osteodystrophy) that develops in all these patients after several years of dialysis. Therapy includes controlling the hyperphosphatemia with dietary restriction and phosphate-binding gels, calcium supplementation orally and in the dialysate bath, correction of acidosis, administration of vitamin D sterol, and reduction in aluminum intake in both the dialysate and the diet. Therapy should be initiated carefully because metastatic soft tissue calcification can occur. Indications for surgical therapy include persistent, symptomatic hypercalcemia that cannot be controlled medically, particularly in prospective renal transplant patients; bone pain and abnormal fractures; ectopic calcification; and intractable pruritus. Subtotal parathyroidectomy and total parathyroidectomy with heterotopic autotransplantation both appear to be acceptable options, although reexploration for recurrent disease is less complicated after total parathyroidectomy with autotransplantation. Parathyroidectomy can enhance

aluminum deposition, so any excess should be corrected preoperatively through chelation.

Parathyroid Carcinoma

Parathyroid carcinoma is a rare condition, accounting for less than 1% of all cases of hyperparathyroidism. Histologic criteria remain controversial, and the diagnosis is securely made only on the basis of local invasion or distant metastases. In comparison to patients with benign disease, these patients tend to be somewhat younger and more symptomatic. In contrast to the marked female predominance in benign disease, the male-to-female ratio in carcinoma is equal. Serum calcium, PTH, and alkaline phosphatase levels are relatively more elevated, and patients often have an elevated level of human chorionic gonadotropin. Patients may have manifestations of both renal and bone diseases. The affected gland is palpable in almost half of patients.

Initial treatment should include radical resection of the involved gland, ipsilateral thyroid lobe, and regional lymph nodes. Neither chemotherapy nor radiation therapy has shown any benefit. If the disease recurs, resection should be attempted because without treatment these patients usually succumb to uncontrolled hypercalcemia. The long-term prognosis is poor, and the opportunity for survival depends on complete initial resection.[47,48]

MULTIPLE ENDOCRINE NEOPLASIA

Although these familial disorders are typically characterized by a predisposition to the development of tumors of multiple endocrine organs, the parathyroid is characteristically involved in two of them. The disorders are all inherited in an autosomal dominant fashion, and the tumors tend to be multicentric. The tumors can be benign or malignant and can occur metachronously or synchronously. MEN-1 is characterized by the concurrence of parathyroid hyperplasia, pancreatic islet cell tumors, and pituitary adenomas. MEN-2A consists of medullary thyroid carcinoma (MTC), pheochromocytoma, and parathyroid hyperplasia. MEN-2B includes MTC, pheochromocytoma, mucosal neuromas, and a distinctive marfanoid

habitus. Together these syndromes encompass much of the spectrum of endocrine neoplasia.

Pathogenesis

The genetic abnormality in MEN-1 has been identified and described in detail.[49,50] As a tumor-suppressor gene, the first mutation is inherited and becomes unmasked only when a second mutation, in some cases a deletion, develops in susceptible tissues. The resulting complete loss of the tumor suppressor allows neoplasia to develop. The occurrence of multiple second mutations explains the characteristic multicentric involvement of these diseases. Direct genetic testing is now available for some families with known mutations.

Mutations of the *RET* protooncogene are the cause of MEN-2A.[51] Genetic testing is now available to identify affected family members and provide the opportunity for early treatment of MTC in affected persons.

Clinical Features and Management of Multiple Endocrine Neoplasia Type 1

Characteristically, MEN-1 presents in the third and fourth decades, without any gender predilection. The syndrome is expressed with nearly complete penetrance, and autopsy studies suggest that all three organs are affected in more than 90% of patients. The phenotype varies, however; more than 90% of patients have hyperparathyroidism, but evidence of islet cell neoplasms (30% to 80%) and pituitary tumors (15% to 50%) is less common. The cause of death in carriers of the MEN-1 mutation is related to MEN-1 in about 45% of patients and often caused by malignant islet cell or carcinoid tumors.[52]

Parathyroid Disease

Hypercalcemia secondary to hyperparathyroidism is usually the first biochemical abnormality detected in MEN-1 and represents the best screening opportunity for members of affected kindreds until direct genetic screening is available in a specific family. Many of these patients are

asymptomatic and have relatively mild hypercalcemia. When symptoms do develop, they typically involve the urinary tract rather than the skeleton.

Typically, the patients have four-gland disease, which may be particularly difficult to manage. The disease is characterized by metachronous development of multiple parathyroid adenomas. There is no curative operation; the two accepted approaches (subtotal parathyroidectomy and total parathyroidectomy with autograft) each have faults (see earlier). Over time, the subtotal parathyroidectomy approach is becoming the preferred choice by most surgeons.

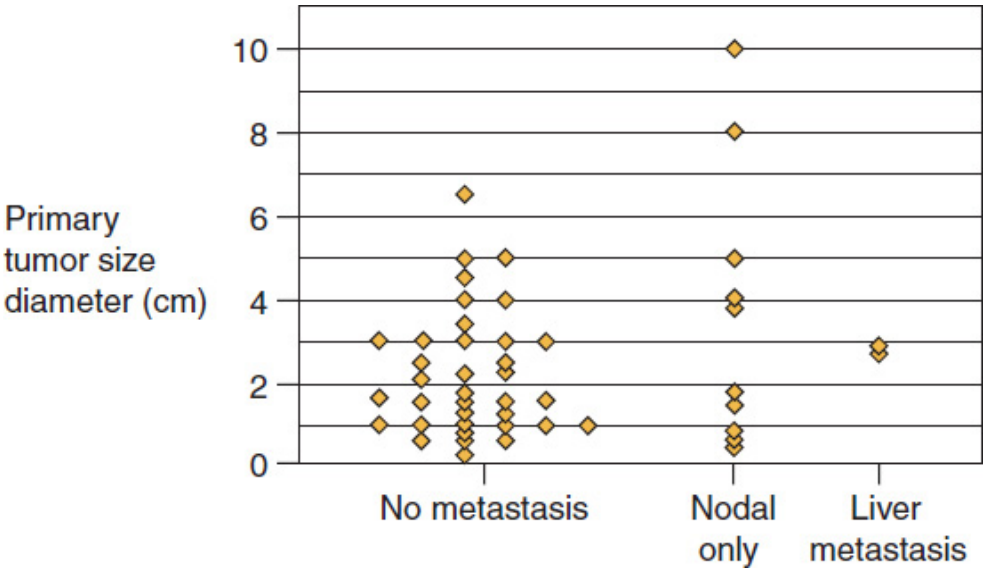

Figure 76.17 Scatter plot of largest primary tumor size versus metastatic status in 43 patients with pancreatic islet cell tumors associated with multiple endocrine neoplasia type I. Each point represents a single patient. Tumor size is not correlated with the presence of liver or lymph node metastases. (From Lowney JK, Frisella MM, Lairmore TC, et al. Pancreatic islet cell tumor metastasis in multiple endocrine neoplasia type I: correlation with primary tumor size. *Surgery* 1998;124:1043–1049.)

Pancreatic Tumors

In patients with pancreatic tumors, multicentric and diffuse hyperplasia of the pancreatic islets may occur in areas distant from any grossly evident tumor. The management of these tumors is controversial because although some patients have aggressive, malignant tumors, many patients have a fairly benign course. No reliable criteria are available to detect malignant tumors. Tumor size is often cited as a useful marker of prognosis, but substantial

overlap has been noted between the sizes of primary benign and malignant tumors (**Fig. 76.17**). Because of the difficulty in identifying the more aggressive subset, some authors have chosen a liberal policy of early operation to try to prevent metastasis and death. Pancreatic tumors are typically multicentric and frequently malignant. Somatostatin receptor scintigraphy can be a useful imaging technique to demonstrate the extent of tumor (**Fig. 76.18**).

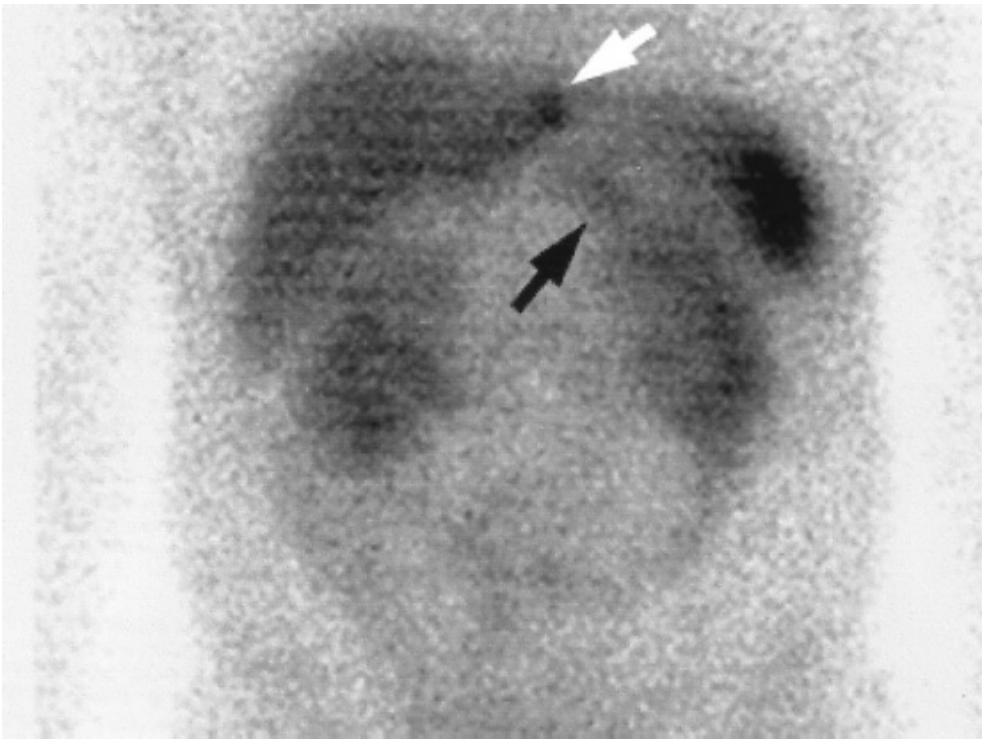

Figure 76.18 Somatostatin receptor scintigraphy in a patient with multiple endocrine neoplasia type I. This scintiscan detected an otherwise unrecognized metastasis to the left lateral segment of the liver (*white arrow*), which was resected along with the small primary tumor (*black arrow*).

Gastrinoma is the most common functional tumor in MEN-1; typically, a severe ulcer diathesis (Zollinger–Ellison syndrome) develops that is associated with secretory diarrhea. Serum gastrin levels are usually markedly elevated (>1,000 pg/mL); when levels are equivocal (250 to 1,000 pg/mL), provocative testing with secretin (2 m/kg) may be useful. An absolute serum gastrin increase of 200 pg/mL is diagnostic. The primary tumors are often in the submucosa of the duodenal wall.

Biochemical cure of these gastrinomas is almost never possible, which is different than patients with sporadic gastrinomas, although exploration can reduce the need for antisecretory medications and may reduce the risk for liver metastasis. Histamine 2-receptor antagonists or proton pump inhibitors are effective in controlling acid secretion, although very high doses may be necessary; the malignant disease is often indolent. Total gastrectomy is no longer ever necessary to eliminate acid secretion.

Insulinoma is the next most common functional pancreatic neoplasm in MEN-1. Patients present with a history of sweating, dizziness, confusion, and syncope, consistent with neuroglycopenia; these symptoms are relieved by consuming carbohydrates. The diagnosis is verified by documenting fasting hypoglycemia associated with inappropriately elevated plasma insulin levels. Preoperative tumor localization is usually achieved by a combination of CT and arteriography. Calcium is injected into various pancreatic arteries and plasma insulin levels in the hepatic vein plasma are measured to detect a gradient after the injection of specific pancreatic arteries localizing the area of the pancreas containing the functional tumor.

Because the available medical therapy for insulinoma is limited, patients are treated operatively. Lesions in the tail of the gland can be enucleated if they are small; however, distal pancreatectomy carries little morbidity. Tumors of the head can usually be enucleated, so that pancreaticoduodenectomy can be avoided. In patients with malignant disease, metastases may respond to streptozocin, diazoxide, verapamil, or octreotide may successfully reduce insulin secretion and control symptoms. A diet of complex carbohydrates can also help stabilize serum glucose levels in the hyperinsulinemic patient.

Nonfunctional tumors are the most common pancreas lesions in MEN-1. Their management is specific to their size and risk of malignancy.

Pituitary Adenomas

Prolactin-secreting tumors occur most commonly in this setting, although Cushing disease or acromegaly develops in an occasional patient. Symptoms may result from compression of the optic chiasm, which produces bitemporal hemianopsia, or from prolactin excess, which produces amenorrhea and galactorrhea in female patients and hypogonadism in male patients.

Bromocriptine inhibits prolactin secretion and shrinks many prolactinomas. Refractory tumors and those producing other hormones can be managed by pituitary ablation or radiation.

Other Tumors

MEN-1 is associated much less frequently with adrenocortical tumors and benign thyroid adenomas. Lipomas and carcinoid tumors may also occur.

Clinical Features and Management of Multiple Endocrine Neoplasia Type 2

Like MEN-1, the MEN-2 syndromes are inherited in an autosomal dominant fashion with complete penetrance but variable phenotype. Bilateral MTC occurs in every affected patient. More frequently than the other syndromes, MEN-2B can arise as a new mutation that can be transmitted to subsequent generations.

Figure 76.19 Medullary thyroid carcinoma. Coronal section of a total thyroid resection shows bilateral involvement by a firm, pale tumor.

Medullary Thyroid Carcinoma

MTC accounts for about 10% of all thyroid malignancies, and 20% of cases occur in the familial setting of MEN-2A, MEN-2B, or familial non-MEN MTC. It is usually the first tumor that develops in these patients and typically appears in the second or third decade. Tumors are virtually always bilateral and develop in multiple areas of the middle and upper portions of the thyroid lobe (**Fig. 76.19**). Occasionally, in young people, a diffuse proliferation of parafollicular C cells, termed *C-cell hyperplasia,* is present without frankly invasive carcinoma. This finding is highly suggestive of one of the familial MTC syndromes. Patients typically present with a neck mass and may have hoarseness, dysphagia, or palpable cervical adenopathy. MTC may produce a variety of hormones, including calcitonin, adrenocorticotropic hormone, prostaglandin, and serotonin. The hypercalcitoninemia is often asymptomatic, although severe diarrhea can develop.

By detecting minimal elevations of plasma calcitonin, it is possible to diagnose MTC at a clinically occult stage. Basal plasma calcitonin levels in normal subjects are in the range of 30 to 100 pg/mL. An increase to levels of 150 to 200 pg/mL occurs, however, after the administration of the potent secretagogues, calcium and pentagastrin. The plasma calcitonin levels of patients with MTC show striking increases (>1,000 pg/mL) after provocative testing, so that they can be identified readily. Patients with occult disease may have only minimally elevated basal calcitonin levels that increase in response to secretagogues. The combined infusion of calcium and pentagastrin was the most effective screening test for familial MTC before genetic testing became available. By means of provocative testing in kindred members at risk for disease, MTC was diagnosed at a preclinical stage, and a greater percentage of these patients were cured by surgical therapy. With genetic testing now available, prophylactic thyroidectomy to prevent the development of MTC is possible for all affected people.

Postoperatively, the presence of residual MTC can be readily detected by provocative testing. Meticulous reoperation in patients with recurrent or persistently elevated plasma calcitonin levels postoperatively, including mediastinal dissection on occasion, can normalize elevated plasma calcitonin levels and apparently cure many of them. For the patient with unresectable metastases, few therapeutic options are available. Neither radiation nor chemotherapy is of significant benefit.[53]

The clinical course of patients with the MEN-2 syndromes is determined primarily by the status of their MTC. In the setting of MEN-2A, the tumors are often indolent and survival prolonged, even in the presence of metastatic disease. By contrast, the tumors in patients with MEN-2B occur at an earlier age and are generally more aggressive neoplasms. Patients may succumb to the disease at a young age. As a consequence of this aggressiveness, the size of kindreds with the disease is typically small, and usually only a few generations are affected.

Figure 76.20 **A,B:** Characteristic appearance of patients with multiple endocrine neoplasia type IIB, including thick lips. **C:** Multiple mucosal neuromas on the tongue of a patient with MEN-2B. (From Norton JA, Froome LC, Farrell FE, et al. Multiple endocrine neoplasia type 2b: the most aggressive form of medullary thyroid carcinoma. *Surg Clin North Am* 1979;59:109–118.)

Pheochromocytoma

Pheochromocytomas are usually detected during the initial screening or follow-up of patients in whom MTC has already been diagnosed. They typically appear in the second or third decade of life, and about 80% are bilateral. Usually, pheochromocytomas are benign but multicentric, and they

almost always arise in the adrenal medulla. In patients with MEN-2A or MEN-2B, hyperplasia of the adrenal medulla may develop first, grossly characterized by thickening of the medullary tissue in both adrenal glands.

Pheochromocytomas can be asymptomatic, but most commonly, patients have pounding frontal headaches, episodic diaphoresis, palpitations, or anxiety. Hypertension also occurs and is often episodic.

The diagnosis is made by measuring the plasma concentration of metanephrines. Patients with MEN-2A or MEN-2B and MTC should be evaluated for pheochromocytoma before they undergo thyroidectomy. If a patient is found to have both lesions, adrenalectomy should be performed first, followed by neck exploration. The abdomen is explored through a bilateral subcostal incision or, more typically, with a laparoscope. Bilateral pheochromocytomas are treated by bilateral adrenalectomy. In patients with MEN-2A or MEN-2B and a unilateral pheochromocytoma, only the diseased adrenal gland is removed. In about 30% of patients treated in this manner, a tumor eventually develops in the opposite gland. In the remaining patients, this approach avoids the need for glucocorticoid and mineralocorticoid replacement and the risk for addisonian crisis. After unilateral adrenalectomy, patients are carefully screened at 6-month or 1-year intervals with plasma metanephrine measurements.

Parathyroid Disease

Hyperparathyroidism develops in about one-third of patients with MEN-2A, although it is usually asymptomatic. Occasionally, nephrolithiasis develops. Bone disease is unusual. Frequently, enlarged parathyroid glands are found at operation for MTC, although the patient is still normocalcemic. Multiglandular chief cell hyperplasia is the predominant histologic finding in MEN-2A. Significant parathyroid disease rarely develops in MEN-2B.

Total parathyroidectomy and heterotopic autotransplantation are performed in hypercalcemic patients with MEN-2A. In normocalcemic patients with MEN-2A undergoing thyroidectomy for MTC, total parathyroidectomy and heterotopic autotransplantation are performed in one session to ensure that the complete thyroidectomy does not compromise the parathyroid blood supply and to avoid reoperation in the neck for subsequent hyperparathyroidism. Evidence suggests that these patients are more easily

treated, with a lower incidence of recurrent hyperparathyroidism, than patients with MEN-1.

Nonendocrine Manifestations of Multiple Endocrine Neoplasia Type 2B

In addition to MTC and pheochromocytoma, marked abnormalities of the nervous and musculoskeletal systems develop in patients with MEN-2B. The classic phenotype is characterized by thick lips and a thin, marfanoid habitus (**Fig. 76.20A,B**). The incidence of associated skeletal abnormalities is high; these include kyphosis, pectus excavatum, pes planus or cavus, and congenital dislocation of the hip. Diffuse autonomic nervous hypertrophy is another feature. Mucosal neuromas appear on the tongue (**Fig. 76.20C**), eyelids, lips, and pharynx. Slit-lamp examination may reveal hypertrophied corneal nerves. Ganglioneuromatosis develops in the submucosal and myenteric plexuses of the gastrointestinal tract. Constipation is common, and radiographic findings may suggest megacolon or Hirschsprung disease.

Adrenal Gland

Hadiza S. Kazaure and Sanziana A. Roman

Key Points

1. Adrenocortical steroid hormones, glucocorticoids, mineralocorticoids, and androgenic steroids are all synthetic derivatives of cholesterol that are either extracted from plasma or synthesized intracellularly.
2. Catecholamines of the adrenal medulla include epinephrine, norepinephrine, and dopamine, the vasoactive synthetic derivatives of the amino acid tyrosine.
3. Unsuspected adrenal masses (incidentalomas) are detected by computed tomography (CT) in up to 1.9% of healthy patients; the goal of evaluation is to determine hyper-functionality and/or malignancy, and determine which need surgical intervention and which can be observed.
4. Hypercortisolism is due to Cushing disease, in 80% to 90% of cases. This is an adrenocorticotropic hormone (ACTH) dependent disorder. Cushing syndrome occurs in 10% to 20% of cases; it is not usually ACTH dependent and primarily due to an adrenal cause.
5. Primary hyperaldosteronism occurs in the setting of either a unilateral aldosterone-producing adrenal adenoma (Conn syndrome) in 60% to 70% of cases, or bilateral idiopathic adrenal hyperplasia.
6. Surgical removal by minimally invasive adrenalectomy of an aldosterone-secreting adenoma results in durable improvement of hypertension and hypokalemia in 70% to 90% of patients; management of idiopathic adrenal hyperplasia is usually medical, because fewer than 20% to 30% of patients with this disease are cured by adrenalectomy.
7. Adrenocortical carcinoma has an estimated incidence of 0.5 to 2 cases per million per year, is very aggressive, and hormone overproduction syndromes are frequent, including virilizing hormones, hypercortisolism, hyperaldosteronism, and can be multihormonal.
8. Recent advances in genetics and oncology have revealed that up to 40% of pheochromocytomas/paragangliomas are hereditary. The *rule of tens* is no longer a useful way to characterize pheochromocytoma. Determination of plasma-fractionated metanephrines is the best test for screening of pheochromocytoma.

ANATOMY

The adrenal glands are bilateral, retroperitoneal, endocrine organs located adjacent to the superior pole of each kidney. These glands appear grossly as flat, triangular structures each weighing approximately 4 g. Each adrenal gland is composed of two distinct endocrine organs, the cortex and medulla. The outer adrenal cortex is bright yellow and nodular, whereas the adrenal medulla is red brown in color and is sandwiched between the thin layers of the cortex. The adrenals are embedded in retroperitoneal perinephric fat but can be identified as distinct structures by their golden brown, nodular appearance. The right adrenal gland abuts the inferior vena cava medially and lies in close proximity to the diaphragmatic crus posteriorly and the liver anteriorly. The left adrenal gland resides between the kidney and aorta, immediately deep to the tail of the pancreas and spleen.

Embryologically, fetal and definitive adrenal cortices arise from coelomic mesoderm near the urogenital ridge during the fourth to sixth weeks of gestation. Postnatally, the fetal cortex involutes, leaving only the definitive cortex to differentiate into the three adult zonae, the glomerulosa, fasciculata, and reticularis. The adrenal medulla develops from the neural crest during the fifth gestational week and migrates along paraaortic and paravertebral routes to join the developing cortex. Ectopic adrenal cortex and medulla may be found anywhere along their respective paths of embryologic migration. Most neural crest tissue regresses, however, extraadrenal neural crest derivatives may be found along the retroperitoneum and at the aortic bifurcation (organ of Zuckerkandl).

The adrenal cortex is composed of three distinct zones. The outer zona glomerulosa, located just beneath the fibrous gland capsule, is the site of mineralocorticoid production. The middle zona fasciculata, composed of linear arrays of large, foamy cells with lipid inclusions, is the predominant site of glucocorticoid and adrenal sex steroid biosynthesis. The inner zona reticularis is the primary location of synthesis of adrenal androgens. Both the zona fasciculata and zona reticularis respond to stimulation by adrenocorticotropic hormone (ACTH). Throughout life, adrenocortical cells proliferate under the adrenal capsule as steroidogenic cells, and are then slowly displaced centripetally, until they undergo apoptosis at the adrenocortical–medullary

boundary. In the past decade, much has been learned about adrenocortical stem and progenitor cells and their roles in normal development, adrenal homeostasis, and in adrenal diseases, however, more research is needed to translate these major scientific advances to the clinical setting.

The adrenal medulla is smaller than the cortex. Cells of the adrenal medulla appear as homogeneous sheets, with large, irregular, atypical-looking nuclei. The cytoplasm of these cells has numerous secretory granules containing catecholamines, neuron-specific enolase, and chromogranin. Catecholamines in these granules precipitate chromium salts, which is the basis for the term *chromaffin cells*.

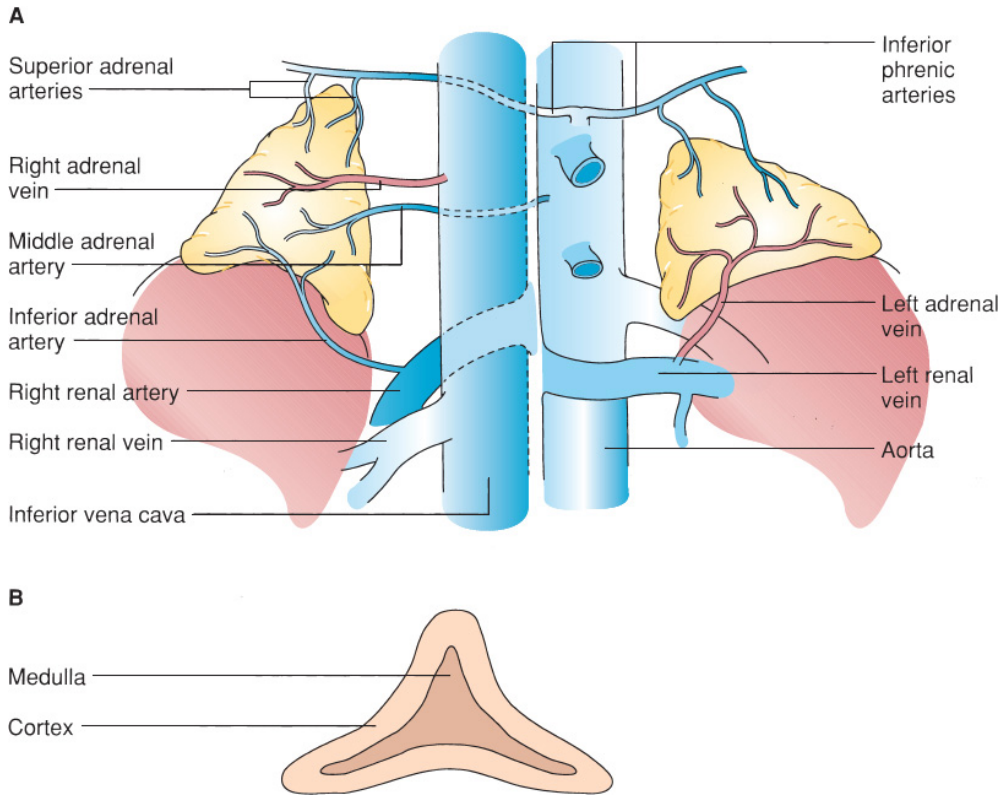

Figure 77.1 **A:** Arterial (*dark shaded*) and venous (*light shaded*) anatomy of the adrenal glands. **B:** Schematic showing outer adrenal cortex (*light shaded*) and inner adrenal medulla (*dark shaded*).

The adrenal glands have an extensive vascular supply derived from branches of the inferior phrenic artery superiorly, the aorta medially, and the renal artery inferiorly. Venous return from the right adrenal gland empties directly into the inferior vena cava through a wide but short central vein. Venous drainage from

the left adrenal gland empties into a smaller vein that shares a common trunk with the left phrenic vein. Together they join the left renal vein (**Fig. 77.1**).

BIOCHEMISTRY AND PHYSIOLOGY

Adrenal Cortex

1 Adrenocortical steroid hormones, glucocorticoids, mineralocorticoids, and androgenic steroids are all synthetic derivatives of cholesterol that are either extracted from plasma or synthesized intracellularly (**Fig. 77.2**). In mitochondrial cells of the adrenal cortex, cholesterol is converted by desmolase (CYP11A1) to delta-5-pregnenolone, the common parent compound for all adrenal cortex steroids. Pregnenolone is then shunted to the three biosynthetic pathways, each compartmentalized within the adrenal according to synthetic capabilities within each zone. In the zonae fasciculata and reticularis, pregnenolone is either converted to progesterone by 3-beta-hydroxysteroid dehydrogenase or is oxidized at position 17 by 17-alpha hydroxylase (CYP17) to form 17-hydroxypregnenolone. In the zona fasciculata, progesterone is hydroxylated by CYP17 at position 17 to form 17-hydroxyprogesterone. Subsequently, 17-hydroxyprogesterone is sequentially hydroxylated at the 21 position by 21-beta hydroxylase (CYP21A2) and at position 11 by 11-beta hydroxylase (CYP11B1) to form cortisol. In the zona reticularis, the androgenic steroids dehydroepiandrostenedione (DHEA) and androstenedione are made from 17-hydroxypregnenolone and 17-hydroxyprogesterone, respectively. Collectively, the glucocorticoid and androgenic steroids are known as *17-hydroxy corticosteroids and 17-hydroxy ketosteroids*. In the zona glomerulosa, progesterone is not hydroxylated at the 17 position owing to the lack of enzyme at this location. Instead aldosterone is made from progesterone by a sequential series of hydroxylation steps at position 21 by CYP21A2, position 11 by CYP11B1, and position 18 by aldosterone synthase (CYP11B2 and P450c11as). The zona glomerulosa is well suited to aldosterone biosynthesis because of the relative lack of 17-hydroxylase and the exclusive expression of aldosterone synthase, required for the conversion of corticosterone to aldosterone.

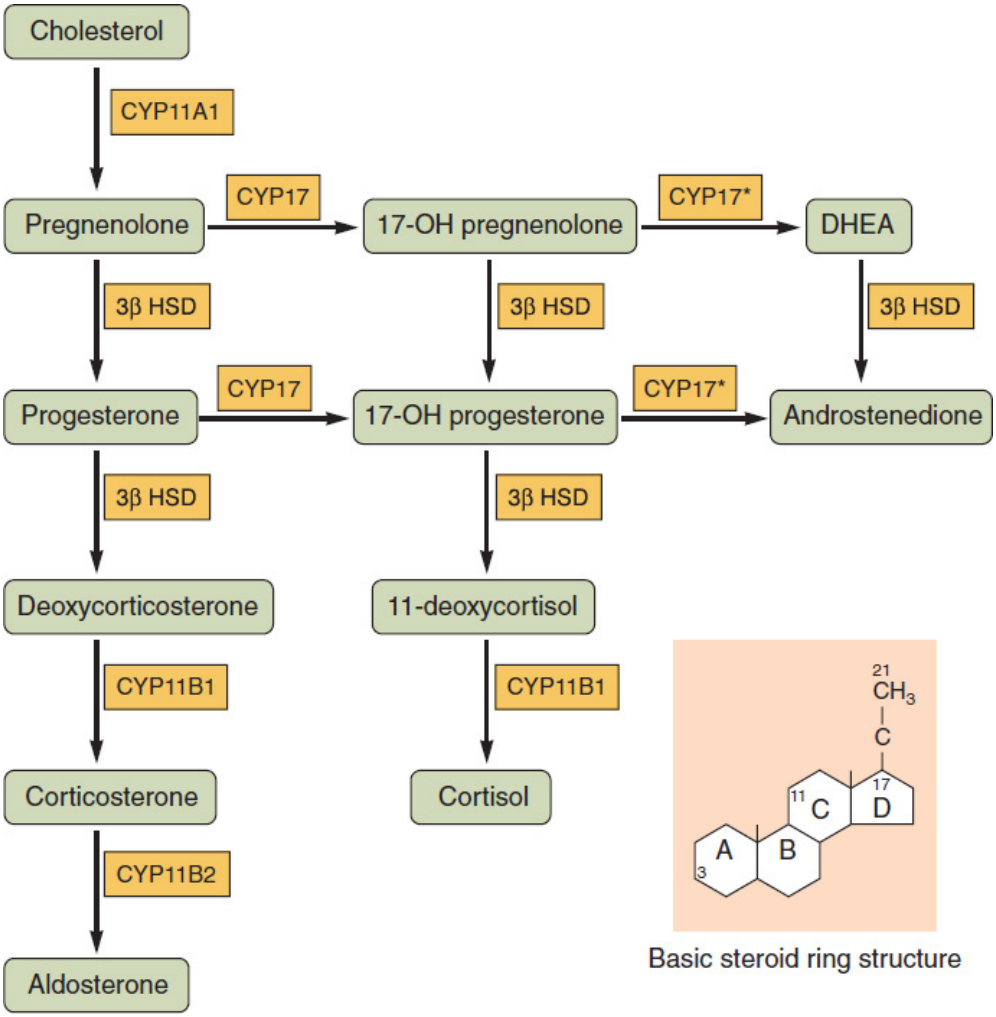

Figure 77.2 Steroid biosynthetic pathways in the adrenal cortex. Steroids and precursors are shown in *square boxes*. Enzymes are shown in *stippled boxes*. Enzyme gene symbol designations are: CYP11A1, desmolase; CYP17, 17α-hydroxylase (±17,20 lyase*); 3β-HSD, 3β-hydroxysteroid dehydrogenase; CYP21A2, 21-hydroxylase; CYP11B1, 11β-hydroxylase; CYP11B2, Aldosterone synthase. *Inset:* Basic steroid ring structure. The four basic carbon rings are designated A, B, C, and D. Individual carbons at sites of steroidegenic enzyme activity are designated numerically.

Cortisol

Cortisol is the predominant glucocorticoid in humans. Production and release of cortisol is tightly regulated by a complex feedback relationship between the hypothalamus, corticotrophs of the anterior pituitary, and cells of the adrenal cortex zonae fasciculata and reticularis. This endocrine system is called the *hypothalamic–pituitary–adrenal (HPA) axis*. Communication within the HPA axis is mediated by synthesis and secretion of corticotrophin-releasing hormone (CRH) by the hypothalamus and ACTH production by corticotrophs of the

anterior pituitary (**Fig. 77.3**). ACTH is a cleavage product of a precursor polypeptide, proopiomelanocortin (POMC) that is built of 241-amino-acid residues within corticotroph cells of the anterior and intermediate lobes of the pituitary. Several derivatives of POMC are important biologically active substances, including ACTH. Under stimulation of hypothalamic CRH stimulus, POMC can be cleaved into ACTH and β-lipotropic hormone in the anterior lobe. ACTH acts directly on the adrenal to regulate cortisol production by cells within the zonae fasciculata and reticularis. Feedback loops involving cortisol, hypothalamic CRH, and pituitary ACTH keep the concentration of cortisol in plasma within a narrow range of 10 to 15 μg/dL. Typical daily production of cortisol in humans ranges from 10 to 30 mg and can increase to as high as 300 mg/day under conditions of maximal stress.

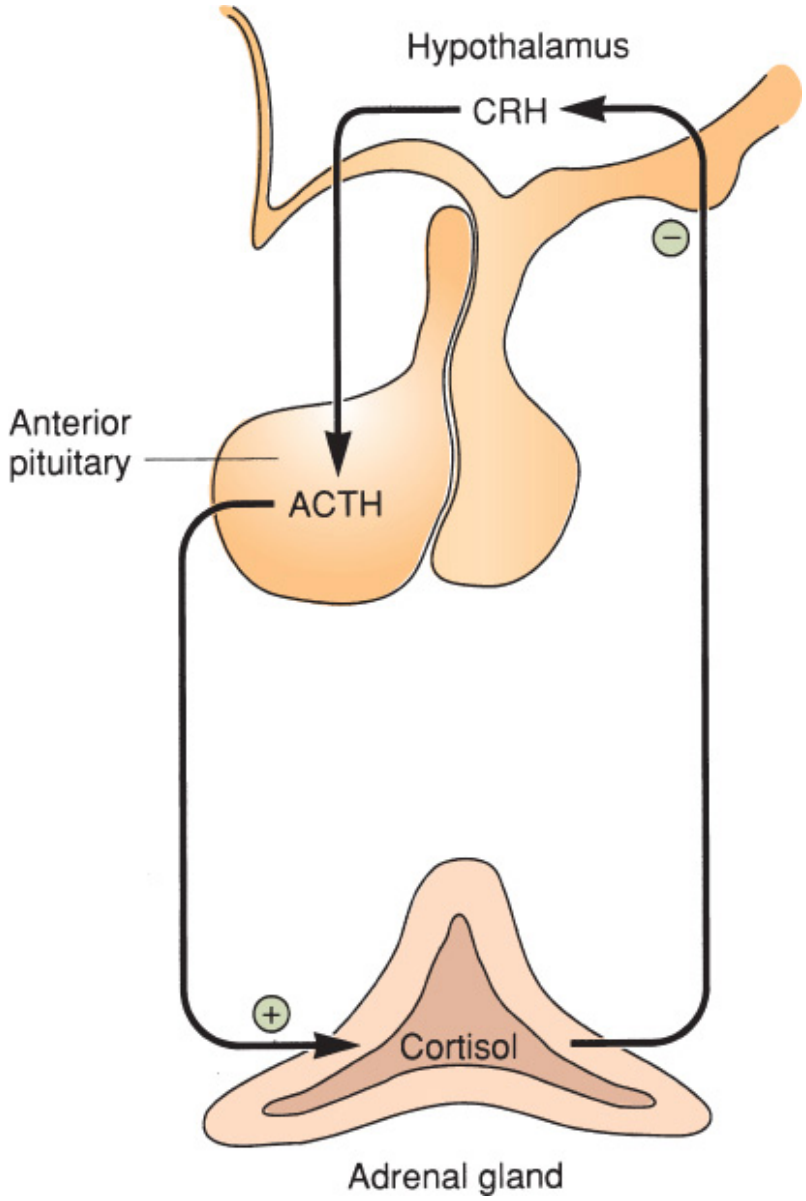

Figure 77.3 Schematic of hypothalamic–pituitary–adrenal axis for cortisol. Regulatory feedback relationships are designated with *arrows*.

In circulation, cortisol is protein bound to transcortin and albumin with a small percentage of free cortisol available to target tissues. The half-life of cortisol in circulation is 90 minutes. Cortisol is metabolized in the liver to the inactive metabolites dihydrocortisol and tetrahydrocortisol, which become conjugated to glucuronidate and excreted in the urine. These urinary metabolites, collectively known as *17-hydroxycorticosteroids,* as well as free cortisol, can be measured in the urine.

Cortisol binds to specific intracellular cytoplasmic receptors, causing translocation of activated receptor–ligand complexes to the nucleus. Biologic effects result from transcriptional activation of genes and may be grouped into intermediary metabolism, immunomodulation, and regulation of intravascular volume (**Table 77.1**). Important effects of cortisol on intermediary metabolism center on raising blood glucose directly and indirectly by providing substrate for gluconeogenesis by the liver. These effects include (a) stimulation of glucagon and inhibition of insulin-stimulated glucose uptake by cells; (b) decrease in peripheral protein synthesis and increase in proteolysis, thus delivering gluconeogenic amino acids to the liver; and (c) stimulation of peripheral lipolysis. In effect, cortisol acts anabolically in vital organs to preserve glucose supply and catabolically in peripheral tissues to mobilize gluconeogenic substrates. Cortisol also possesses profound anti-inflammatory and immunosuppressive activities. Impairment of cellular immunity is due to inhibition of interleukin production, impairment of monocyte and neutrophil chemotaxis despite raised leukocyte counts, and reduction of T-cell activation. Humoral immunity is inhibited by inhibition of T-cell stimulation of B cells and by direct inhibition of B-cell proliferation and activation. These immunomodulatory effects may also underlie the impairment of normal wound healing seen in states of cortisol excess. Cortisol also regulates intravascular volume through renal retention of sodium and maintains blood pressure through inotropic and chronotropic effects on the heart as well as by increasing peripheral vascular resistance. In bone, glucocorticoids promote osteopenia by inhibition of bone formation by osteoblasts.

Table 77.1 Systemic Effects of Cortisol

Function	Normal Amounts	Excessive Amounts
Metabolic Protein Glucose Fat	Proteolysis Gluconeogenesis Low-use peripheral lipolysis Central lipogenesis	Muscle wasting Hyperglycemia Limb thinness Truncal obesity
Gastrointestinal	Mucosal cells Prostaglandin	Ulceration Pancreatitis
Cardiovascular	Chronotropic, inotropic Vascular resistance	Hypertension
Renal	Sodium resorption	Hypertension
Bone	Osteoblastic development	Osteoporosis
Inflammatory and immune	Circulating cells Soluble mediators Antigen processing	Infection
Wound healing	Fibroblasts Epithelial cell	Striae Dehiscence

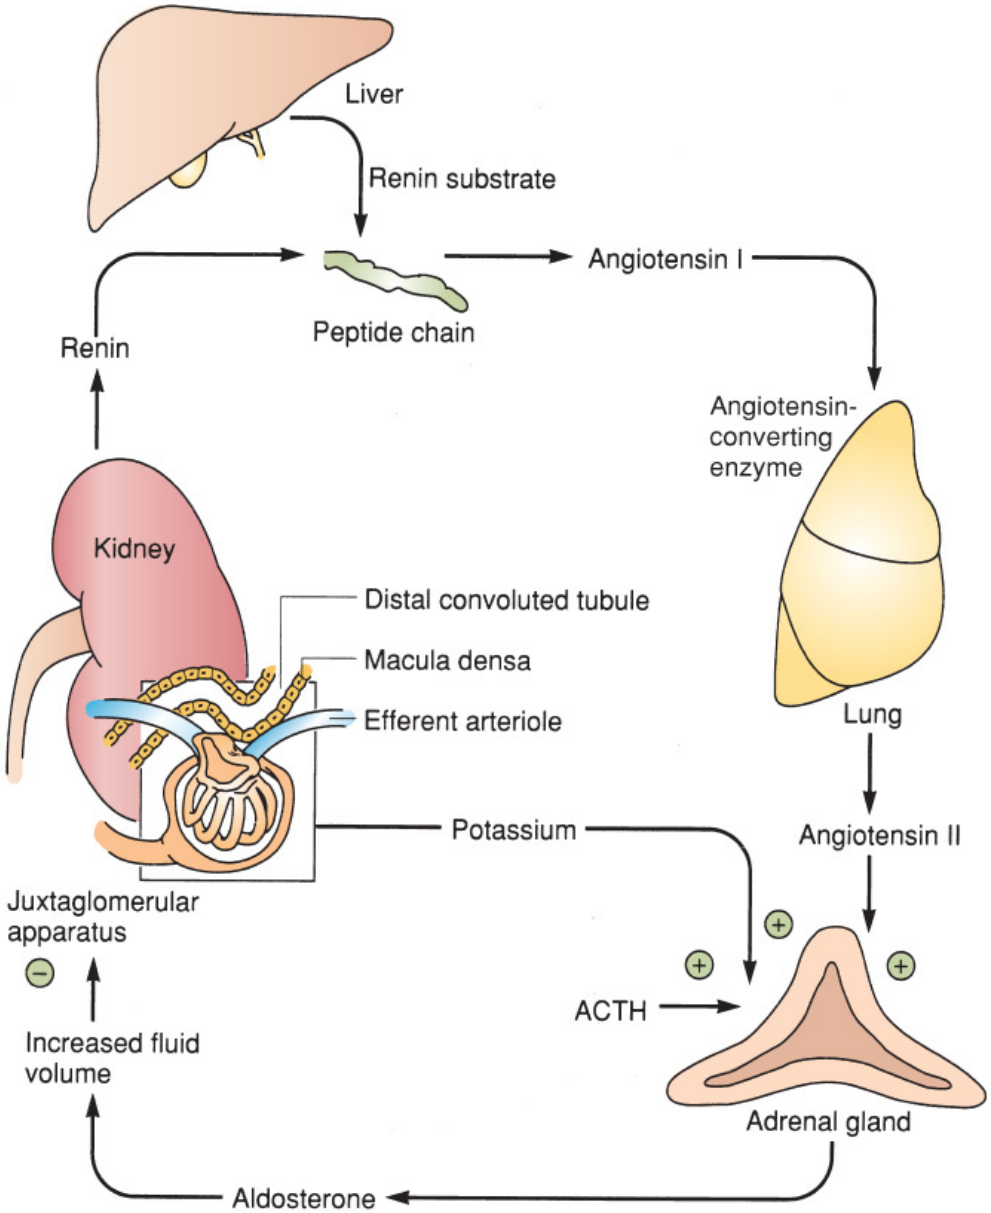

Figure 77.4 Regulatory relationships of renin, the angiotensins, and their sites of production and enzymatic conversion.

Aldosterone

Aldosterone is the principal mineralocorticoid in humans. Aldosterone secretion by the cells of the adrenal zona glomerulosa is regulated by the renin–angiotensin system and by plasma potassium (**Fig. 77.4**). Aldosterone is also regulated to a lesser degree by ACTH and plasma sodium concentration. Juxtaglomerular myoepithelial cells lining afferent arterioles of the kidney sense renal blood flow and pressure, and they secrete renin in response to decreased

perfusion. Renin enzymatically activates angiotensinogen to the inactive decapeptide precursor, angiotensin I. Angiotensin I is converted to angiotensin II by angiotensin-converting enzyme in the lung. Angiotensin II has three major effects: (a) arteriolar vasoconstriction; (b) renal sodium retention; and (c) increased aldosterone biosynthesis, each of which results in sodium retention and potassium excretion by the kidney. These effects work together to maintain arterial blood pressure as well as blood volume. Physiologic conditions that stimulate the renin–angiotensin cascade and aldosterone release include dehydration, upright posture, and hemorrhage. Inhibitory factors include volume repletion. Postural changes in renin–angiotensin and aldosterone are mediated by the sympathetic nervous system.

Under normal circumstances, aldosterone secretion is controlled by total body sodium and potassium levels. Excess sodium intake suppresses renin activity and leading to decreased aldosterone levels and increased renal excretion of sodium. Conversely, sodium depletion stimulates the renin–angiotensin system and aldosterone production, which promotes sodium retention by the kidney. Increased potassium intake directly decreases renin release and aldosterone production; decreasing potassium intake increases renin release. Humans with normal sodium intake typically produce 100 to 150 mg of aldosterone per day.

In circulation, aldosterone is bound to albumin and transcortin with a small percentage of free aldosterone available to target tissues. The half-life of aldosterone in plasma is 15 minutes. Aldosterone is metabolized rapidly in the liver and conjugated to glucuronidate, which is excreted in the urine. In liver failure, metabolism of aldosterone is impaired leading to elevated levels and fluid retention.

Aldosterone is the major regulator of extracellular fluid volume and potassium homeostasis (**Table 77.2**). Aldosterone binds to high-affinity aldosterone receptors in target tissues, including cells of the distal convoluted tubule in the kidney (the major site of action), the salivary glands, and colonic mucosa (minor sites). Stimulation of these cells results in retention of sodium and excretion of potassium. Retention of sodium in the kidney leads to passive reabsorption of water and an increase in extracellular fluid volume. To balance aldosterone-mediated retention of positively charged sodium ions, the kidney epithelium releases intracellular potassium into the distal convoluted tubule for excretion in the urine. Hydrogen ion is also released causing acidification of the urine.

Table 77.2 Effects of Aldosterone Secretion

Tubular Action	Normal Amounts	Excessive Amounts
Increased resorption of sodium	Protects against low-volume states	Hypertension Positive sodium balance Hyporeninemia
Decreased resorption of potassium	Protects against hyperkalemia	Hypokalemia Metabolic alkalosis Hyperglycemia Nocturia, polyuria Muscle weakness

Adrenal Androgens

Adrenal C-19 androgenic steroids, include DHEA and delta-4-androstenedione, are synthesized in cells of the zona reticularis. These steroids promote secondary sexual characteristics in men and virilization in women. DHEA is the major adrenal androgen, while androstenedione is relatively minor. Both are relatively weak androgens and exert their effects on target tissue after local tissue conversion to testosterone. Unlike gonadal androgens, adrenal androgens are regulated by ACTH, not gonadotropins, and can therefore be inhibited by glucocorticoid administration.

Adrenal Medulla

2 Catecholamines of the adrenal medulla include epinephrine, norepinephrine, and dopamine. These vasoactive hormones are synthetic derivatives of the amino acid tyrosine (**Fig. 77.5**). The biosynthetic pathway that converts tyrosine to active catecholamines involves four sequential enzymatic reactions: (a) tyrosine is converted to L-dihydroxyphenylalanine (dopa) by tyrosine hydroxylase; (b) dopa is converted to dopamine by aromatic-L-amino acid decarboxylase; (c) dopamine is converted to norepinephrine by dopamine beta hydroxylase; and (d) norepinephrine is converted to epinephrine by phenylethanolamine-N-methyltransferase (PNMT). Epinephrine is the major (80%) catecholamine stored in the adrenal medulla, followed by norepinephrine (20%) and dopamine (<1%). Tissue expression of the enzyme

PNMT is limited to cells of either the adrenal medulla or organ of Zuckerkandl, located near the aortic bifurcation, thus most extraadrenal pheochromocytomas produce norepinephrine, rather than epinephrine.

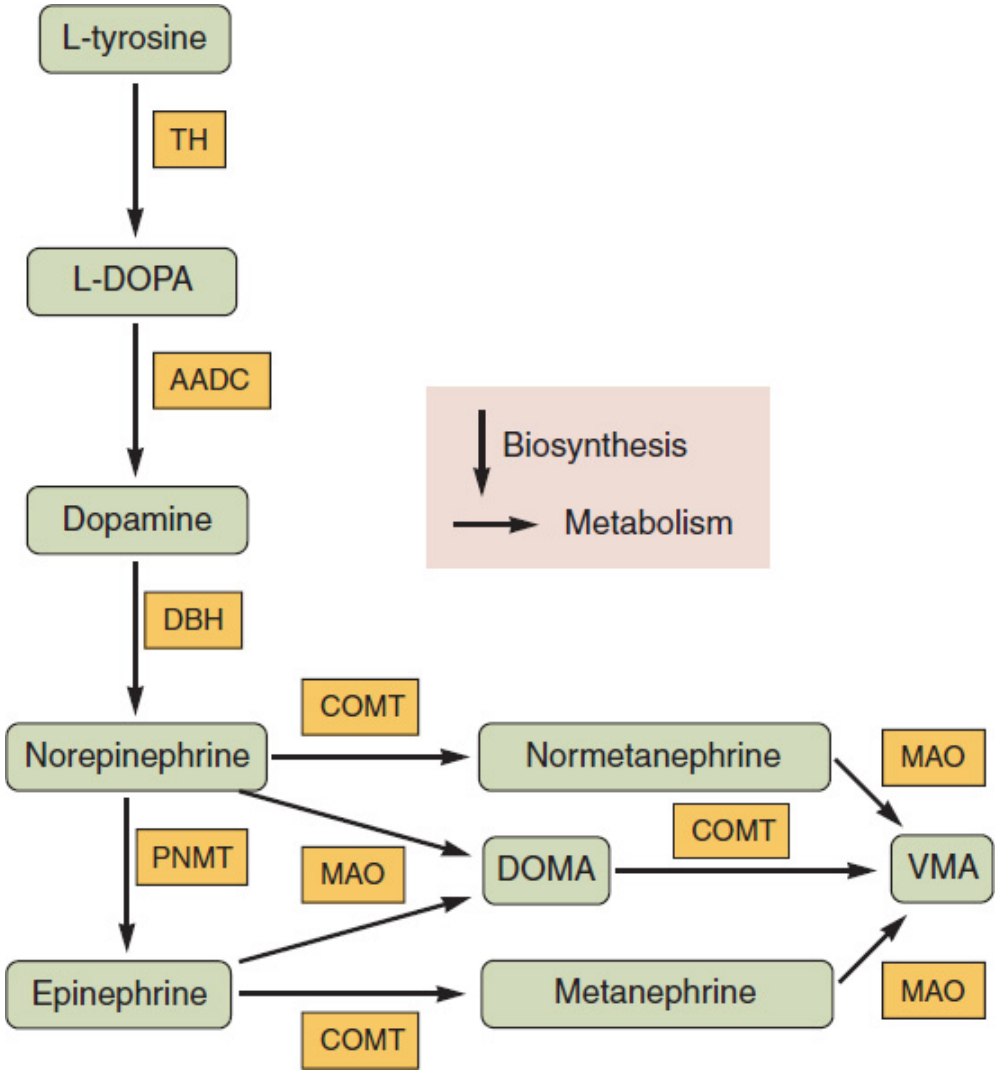

Figure 77.5 Catecholamine biosynthetic and metabolic pathways. Precursors, catecholamines, and metabolites are shown in *square boxes*. Enzymes are shown in *stippled boxes*. Enzyme gene symbol designations are: TH, tyrosine hydroxylase; AADC, aromatic-L-amino acid decarboxylase; DBH, dopamine-β-hydroxylase; PNMT, phenylethanolamine-N-methyltransferase; COMT, catechol-O-methyl-transferase; MAO, monoamine oxidase. VMA, 3-methoxy-4-hydroxy-mandelic acid.

A complex regulatory network governs synthesis and secretion of catecholamines. Factors that increase catecholamine release include splanchnic nerve stimulation, stress, and glucocorticoids. The metabolic milieu within the adrenal medulla also greatly influences catecholamine synthesis by regulating

enzymatic activity: glucocorticoids, phospholipids, cyclic adenosine monophosphate, adenosine triphosphate, protein kinase, and magnesium increase activity of PNMT and decrease catecholamine negative feedback. Catecholamines are stored and secreted from granules within cells of the medulla in association with the matrix protein chromogranin. Chromogranin A is measurable in the blood and their measurement may support the biochemical testing for pheochromocytoma, as well as other functional neuroendocrine tumors.

Catecholamines act on target tissues through membrane-bound receptors. Pharmacologic distinction of adrenergic receptors is made based on their relative responsiveness to natural and artificial bioamines. Alpha-adrenergic receptors show highest affinity for norepinephrine, less for epinephrine, and least for isoproterenol. Beta-adrenergic receptors are most responsive to isoproterenol and least to norepinephrine. In addition, specific antagonists recognize each receptor class: alpha receptors are antagonized by phentolamine and phenoxybenzamine, and beta receptors are blocked by propranolol and related compounds. Beta-adrenergic receptor subtypes include beta-1, which is present in cardiac muscle, adipose tissue, and small intestine, and beta-2 receptors, which are found in vascular, tracheal, and uterine smooth muscle, skeletal muscle, and liver. Alpha-adrenergic receptors are similarly subdivided: alpha-1 receptors mediate vasoconstriction whereas alpha-2 receptors modulate presynaptic norepinephrine release and platelet aggregation (**Table 77.3**).

Table 77.3 Catecholamine Effects

Receptor Class	Normal Amounts	Excessive Amounts
β_1	Chronotropic, inotropic Sweat glands Decreased glucose use	Tachycardia Sweating Hyperglycemia
β_2	Smooth muscle relaxation	Hypotension
α_1	Smooth muscle contraction Gluconeogenesis Glycogenolysis Suppressed insulin effects	Hypertension Hyperglycemia
α_2	Smooth muscle contraction[a]	Pallor

[a]Platelet aggregation.

Metabolism of catecholamines occurs through three mechanisms: by specific uptake by sympathetic neurons, by nonspecific uptake and degradation by peripheral tissues, and by excretion in the urine. Catecholamines are metabolized in liver and kidney by two enzymes, monoamine oxidase and catechol-O-methyltransferase (**Fig. 77.5**). In these tissues, monoamine oxidase and catechol-O-methyltransferase convert epinephrine or norepinephrine to normetanephrine, and metanephrine, 3,4-dihydroxy-mandelic acid, and 3-methoxy-4-hydroxy-mandelic acid. These inactive metabolites are excreted by the kidney and are measurable in the urine either as free compounds or as conjugates of glucuronide or sulfate.

ADRENAL NEOPLASMS AND DISEASES

Incidental Adrenal Mass

Clinically occult adrenal masses (also called *adrenal incidentalomas*) have become commonplace over the past 25 years with the increased use of abdominal imaging such as computed tomography (CT) and magnetic resonance imaging (MRI). The estimated prevalence of incidental adrenal neoplasms varies by population studied and method of detection. Unsuspected 3 adrenal masses are detected by CT in between 0.6% and 1.9% of healthy patients. Patients with a prior history of malignancy have a prevalence of adrenal masses of up to 4.4%. Adrenal masses increase in frequency with advancing age, ranging from 3% in midlife to 10% in the elderly. The combination of an aging population and increased application of abdominal imaging promises to create a significant public health challenge.

The goal of evaluation is to distinguish and remove those adrenal masses that are functioning or likely to be malignant versus those that are neither, and may be observed. Expectations of the yield for the workup of adrenal masses may be informed by epidemiologic reports and reports of pathologic findings in resected incidentalomas. A review of 44 reports describing over 3,000 such cases reported that 41% were cortical adenomas, 19% were metastases from other primary cancers, 10% were adrenocortical carcinomas, and 8% were pheochromocytomas, with the remainder including myelolipomas and cysts.

Diagnosis

In the evaluation of incidental adrenal masses, two simple questions must be answered: Is it functional? Is it malignant? The diagnostic approach should proceed to answer these questions sequentially (**Table 77.4**). Current opinion is that all asymptomatic patients with adrenal masses should be screened for pheochromocytoma, hypercortisolism, and hyperaldosteronism (**Algorithm 77.1**).

All patients require a complete personal and family history, physical examination, biochemical evaluation of pertinent hormones, and select imaging studies. Attention must be paid to episodes of hypertension, tachycardia, and anxiety that suggest pheochromocytoma. Physical findings such as muscle wasting, purple striae, hirsutism, and gynecomastia may suggest either Cushing syndrome or a virilizing tumor. Secondary metastases from underlying malignancy must be considered and evaluated with appropriate history, physical examination, and select tests including mammograms in women and chest radiography in all patients, especially smokers.

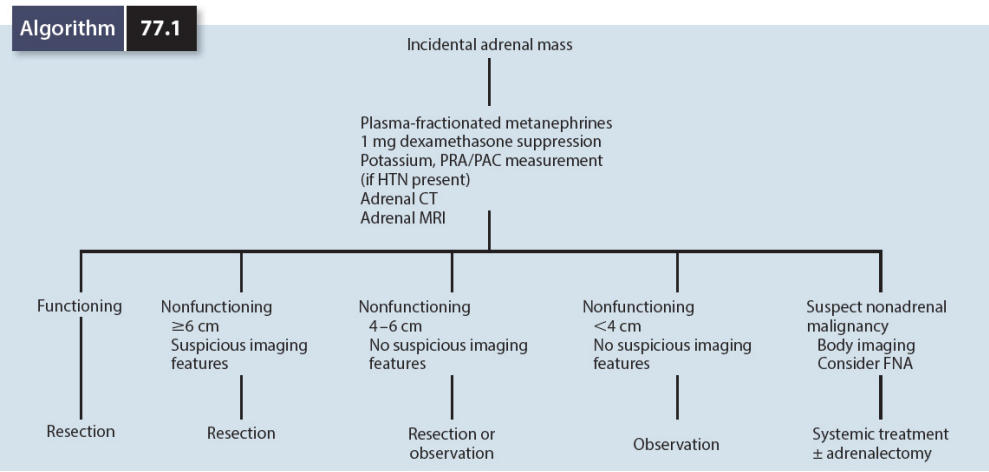
Biochemical testing should routinely exclude pheochromocytoma, hypercortisolism, and hyperaldosteronism. Pheochromocytoma is evaluated either by 24-hour urine collection for catecholamines, metanephrines, and 3-methoxy-4-hydroxy-mandelic acid, or by plasma fractionated metanephrines. Subclinical or clinically apparent Cushing syndrome is best evaluated with the overnight 1-mg dexamethasone suppression test. Hyperaldosteronism is best assessed by concurrent measurement of serum or plasma aldosterone and PRA while assuring that the serum potassium is normalized.

Imaging studies usually include cross-sectional imaging with either CT or MRI. Abdominal CT (noncontrast) is the best initial test for identifying and characterizing most adrenal masses. Using a fast scanner and 1-mm scanning intervals, both adrenal glands can be seen in 97% to 99% of patients and lesions as small as 5 mm can be readily identified. Currently, attenuation values expressed in Hounsfield Units (HU), along with mass size and margins have good performance to differentiate adenomas from adrenal malignancy or pheochromocytoma. Adenomas are usually lipid rich and have attenuation values less than 18 HU on unenhanced CT, a threshold with high sensitivity and specificity (85% to 95% and 93% to 100%, respectively). Generally, further workup is unnecessary when an adrenal lesion has an attenuation of less than 10 HU suggesting a lipid-rich adrenal adenoma. A notable exception is the lipid-poor or atypical adenoma, which has higher HU density. In these cases, rapid washout of intravenous contrast suggests a benign process. Using a 10- to 15-minute delayed enhanced CT, a washout value of 50% to 60% of the initial enhancement is used to distinguish adenoma from other mass etiologies.

MRI can differentiate adenomas, metastases and pheochromocytomas, although the best MRI technique for evaluating adrenal masses is complex and controversial. Adenomas usually show a loss in signal intensity on chemical shift MRI because of high lipid content. Malignant masses tend to be bright on T2-weighted images because of higher fluid content. Secondary metastases to the adrenal are hypointense to liver on T1-weighted images and are brighter than liver on T2-weighted images. Metastases also typically show strong contrast enhancement. Pheochromocytomas most often have low lipid content and high water content, giving low T1 signal intensities and very bright T2 signal intensities. Comparison of the adrenal mass to liver and spleen intensities on various sequences adds to specificity and sensitivity of the test.

Table 77.4 Diagnosis Summary of Tests for Evaluation of Incidental Adrenal Mass

Question	Best Test	Alternative Test	Diagnosis
Is it functioning?	Plasma-fractionated metanephrines 1-mg dexamethasone suppression test Serum potassium Plasma renin/plasma aldosterone ratio	24-hr urine for fractionated catecholamines, metanephrines, dopamine, VMA 24-hr urine for free cortisol 24-hr urine for potassium	Pheochromocytoma Hypercortisolism Hyperaldosteronism
Is it malignant?	Computed tomography	Magnetic resonance imaging Positron emission tomography	Cortical adenoma Adrenocortical Carcinoma Pheochromocytoma Myelolipoma Cyst
	Fine-needle aspiration		Metastasis



Algorithm 77.1 Diagnosis and management of the incidental adrenal mass. PRA, plasma renin activity; PAC, plasma aldosterone concentration; HTN, hypertension; CT, computed tomography; MRI, magnetic resonance imaging; FNA, fine-needle aspiration.

Fine-needle aspiration biopsy may be of value in patients with known extraadrenal malignancy; and with suspicion of harboring an adrenal metastasis; however, it is not indicated in the evaluation of primary adrenal neoplasms as it is not helpful, and is contraindicated if pheochromocytoma is suspected due to the possibility of inducing an adrenal crisis.

Treatment

Resection is indicated for all functioning adrenal incidentalomas and those suspected of harboring primary adrenal cancer. The prevalence of primary adrenal carcinoma in adrenal incidentalomas is related to mass size. The risk of primary adrenal carcinoma is <2% in lesions under 4 cm while the incidence rises to 25% for lesions larger than 6 cm. Lesions that are hormonally nonfunctional and <4 cm with benign imaging characteristics can be followed nonoperatively. For lesions between 4 and 6 cm, either resection or observation is acceptable. Decisions should not be based on size alone, but also on imaging characteristics including CT attenuation values, patient age (older patients with small benign nonfunctional lesions should be followed, but younger patients with relatively larger tumors may be considered for resection) and degree of hormonal activity. Resection of secondary adrenal metastases is recommended in selected patients for whom metastasectomy would confer significant benefit.

DISEASES OF THE ADRENAL CORTEX

Hypercortisolism

The term *hypercortisolism* refers to the physiologic state of glucocorticoid excess. The most common cause of hypercortisolism is the administration of exogenous steroids as immunosuppressive therapy for inflammatory disorders or after organ transplantation. Endogenous hypercortisolism in all cases is caused by increased adrenal production of cortisol, which may be ACTH dependent (ACTH-elevated Cushing *disease*) or independent (ACTH-suppressed Cushing *syndrome*). Some patients with major depression or chronic alcoholism have abnormally high cortisol secretion and may have clinical and biochemical features of Cushing syndrome.

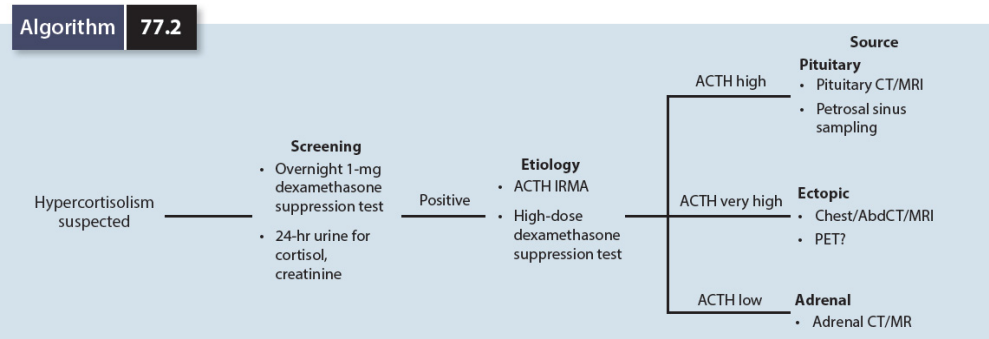
4 ACTH-dependent hypercortisolism is caused by an ACTH-secreting pituitary adenoma in 80–90% of cases. Ectopic ACTH-producing nonendocrine tumors (mostly non–small-cell lung cancer and bronchial carcinoids) represent 10% to 20% of cases of ACTH-dependent Cushing syndrome. All causes of ACTH-dependent Cushing syndrome involve bilateral adrenal hyperplasia in response to ACTH stimulation. Occasionally, a primary adrenal cancer may produce multiple hormones, including ACTH, which could lead to contralateral hyperplasia.

Among patients with endogenous Cushing syndrome, 10% to 25% have ACTH-independent disease caused by a primary adrenal cause. A solitary adrenal adenoma is present in the majority of these patients and is often associated with atrophy of both adjacent and contralateral adrenocortical tissue. Nodular cortical hyperplasia of both glands causes the remaining cases of primary adrenal Cushing syndrome. Although nodular hyperplasia represents a diffuse process, one or more distinct nodules may simulate adenomas. Rarely tumors secrete CRH ectopically, leading to ACTH-independent (though ACTH is elevated) Cushing syndrome with secondary adrenal hypertrophy.

Signs and Symptoms

Clinical features of cortisol excess are listed in **Table 77.1**. Truncal obesity with thinning of the limbs, accumulation of fat around the head and neck (*moon facies* and *buffalo hump*), and muscle wasting are present in most patients. Patients often have purple striae and purpura on the abdomen and extremities. Hirsutism may be present in women. High blood pressure is common and is

usually moderate, although malignant hypertension has been observed. Bone pain and muscle weakness (caused by proximal muscle wasting and hypokalemia) are also common. Osteoporosis is frequently diagnosed and pathologic fractures are observed in advanced cases. Neurologic symptoms, including headache, emotional lability, depression, and even psychosis may be observed. Glucose intolerance is common but can often be managed by alterations in diet alone. The serum potassium level may be low secondary to the weak mineralocorticoid properties of cortisol. Autonomous glucocorticoid production without specific signs and symptoms of Cushing syndrome is termed subclinical Cushing syndrome. This condition is being diagnosed with increased frequency because of the detection of adrenal incidentalomas by routine CT. A substantial percentage of incidentalomas are hormonally active, with 5% to 20% of the tumors producing glucocorticoids. The estimated prevalence of subclinical hypercortisolism is substantially higher than classic Cushing syndrome. Depending on the amounts of glucocorticoids secreted by the tumor, the clinical spectrum ranges from slightly attenuated diurnal cortisol rhythm to atrophy of the contralateral adrenal gland. Patients with subclinical Cushing syndrome lack the classical stigmata of hypercortisolism but have a high prevalence of obesity, hypertension, and type 2 diabetes.



Algorithm 77.2 Diagnosis of hypercortisolism. ACTH, adrenocorticotropic hormone; IRMA, immunoradiometric assay; CT, computed tomography; MRI, magnetic resonance imaging; PET, positron emission tomography.

Diagnosis

The investigation of suspected hypercortisolism should answer two questions: (a) Does the patient indeed have cortisol excess? (b) If the answer is yes, then what is the cause? The diagnosis of hypercortisolism is biochemical, however a careful history and physical examination form the basis for suspecting this condition. The laboratory approach to this diagnosis is summarized in

Algorithm 77.2. Radiologic investigations should not be undertaken until hypercortisolism has been confirmed and its likely etiology characterized biochemically.

Hypercortisolism insensitive to suppression by administration of exogenous glucocorticoid is the *sine qua non* of Cushing syndrome. Due to the circadian rhythm of the HPA axis, plasma cortisol levels can normally vary considerably during a 24-hour period, therefore a single random plasma cortisol level is not helpful in establishing a diagnosis of hypercortisolism. There are currently three screening tests for hypercortisolism: low-dose (1-mg) dexamethasone suppression test, 24-hr urinary free cortisol excretion, and late night/bedtime salivary cortisol levels. The low-dose dexamethasone suppression test is the best test in patients with suspected Cushing syndrome. For this test, 1 mg of dexamethasone is administered orally at 11 PM and plasma cortisol is obtained at 8 AM the following day. Normal individuals suppress cortisol to below 1.8 μg/dL. False-positive test results may occur if the patients metabolize the dexamethasone faster than normal, or if the timing of taking the pill is erroneous. A concomitant serum dexamethasone can be obtained in the morning to assure the serum dexamethasone level is in the adequate range. False-positive test results occur in 10% to 15% of cases with the overnight test and occur especially in patients with obesity or alcoholism or in those taking estrogens or phenytoin. Measurement of urinary-free cortisol (not metabolites) is an alternative screening test for Cushing syndrome. Collections should include concurrent creatinine measurement and urinary volume to evaluate the completeness of the collection. This test may be less sensitive than the low-dose dexamethasone suppression test in mild hypercortisolism. The salivary cortisol test quantifies the level of unbound, biologically active form of serum cortisol. The test should be done late at night when the HPA axis reaches a nadir. The salivary cortisol test relies on the fact that the circadian rhythm of the HPA axis is impaired in Cushing syndrome patients, who therefore feature higher cortisol values at night, which are easy to measure in saliva.

Once the presence of hypercortisolism is established, the next task is to determine whether this is ACTH-dependent (pituitary or ectopic source) or ACTH-independent (primary adrenal). Measurement of basal ACTH by radioimmunometric assay is the best test to make this distinction. Plasma ACTH levels are normally between 10 and 100 pg. Suppression of the absolute level of ACTH below 5 pg/mL is nearly diagnostic of adrenocortical neoplasms, which secrete high levels of cortisol and inhibit ACTH release by the pituitary.

Patients with pituitary neoplasms and secondary bilateral adrenocortical hyperplasia have ACTH levels that may range from the upper limits of normal (15 pg/mL) to 500 pg/mL. The highest plasma levels of ACTH (more than 1,000 pg/mL) are in patients with ACTH-producing nonendocrine tumors, such as non–small-cell lung cancer.

Although 80% to 90% of patients with ACTH-dependent Cushing syndrome have Cushing disease, a high-dose dexamethasone suppression test may be required to exclude ectopic ACTH syndrome. Hypercortisolism caused by ACTH-secreting pituitary adenomas is suppressed at least partially by high dexamethasone, whereas hypercortisolism caused by adrenal tumors and ectopic ACTH-producing tumors is not suppressed. For this test 2-mg dexamethasone is administered orally every 6 hours for 2 days, and a 24-hour urine collection for free cortisol is taken during the second day. About 90% of patients with pituitary source Cushing disease have a 50% reduction in urine-free cortisol. The specificity of the test can be improved to 100% for diagnosing pituitary disease if more than 90% suppression in urinary-free cortisol is used.

Biochemical testing of suspected Cushing syndrome is followed by radiologic studies. Pituitary adenomas are best imaged with gadolinium-enhanced MRI of the sella turcica, which has a sensitivity approaching 100%, although small pituitary microadenomas may be missed. Patients with ACTH-independent Cushing syndrome require thin-section CT or MRI of the adrenal, which identifies adrenal abnormalities with more than 95% sensitivity. CT or MRI of the chest may identify a source of ectopic ACTH and should be undertaken in patients with elevated ACTH and hypercortisolism that cannot be suppressed by high-dose dexamethasone.

Despite the accuracy of biochemical testing and radiographic localization, a pituitary versus ectopic source of ACTH sometimes cannot be determined. Bilateral inferior petrosal sinus sampling would need to be done by experienced physicians. An inferior petrosal sinus to peripheral plasma ACTH ratio of 2.0 at basal stimulated or of 3.0 after CRH administration is 100% sensitive and specific for pituitary adenoma. Comparison of right and left inferior petrosal sinus ratios may also lateralize the adenoma.

Treatment

ACTH-dependent Cushing syndrome is best treated by removing the source of ACTH excess. In the case of Cushing disease, transsphenoidal resection of the

pituitary microadenoma is successful in 80% or more of cases. If a microadenoma is not found, then hemihypophysectomy may be performed with the understanding that fertility may be impaired. Pituitary irradiation is a good treatment option when fertility is desired, when a tumor is not found or is unresectable, or cure is not achieved by transsphenoidal resection of a tumor. Debulking of unresectable primary lesions or recurrences with or without bilateral adrenalectomy may provide palliation in some patients. Treatment of ectopic ACTH syndrome involves removal of the primary lesion. Medical adrenalectomy with metyrapone, aminoglutethimide, and mitotane has been used to suppress production of corticosteroid in inoperable cases for both pituitary and ectopic sources of ACTH. Bilateral adrenalectomy could be considered for patients intolerant of mitotane.

ACTH-independent Cushing syndrome is best treated by removal of the adrenal tumor and affected gland, which can be done minimally invasively for most benign-appearing. Resection of cortisol-producing benign adrenal adenomas is curative and prognosis is good following resection. Cortisol-producing adrenocortical carcinomas recur frequently following adrenalectomy, heralded by the reemergence of hypercortisolism. Micronodular-pigmented hyperplasia and macronodular adrenal hyperplasia may involve both adrenal glands. If medical treatment cannot control the hypercortisolism, occasionally adrenal venous sampling may detect a unilateral adrenal gland that is the dominant secretor, and therefore a unilateral adrenalectomy may ameliorate the hypercortisolism for some time. If patients have symmetrical hyperfunction and medical treatment is not satisfactory, bilateral adrenalectomy can be performed. This procedure has the clear consequence of lifetime dependence on exogenous steroid replacement. All patients who undergo bilateral adrenalectomy should wear a medical alert bracelet warning of their adrenal status.

Whether patients with subclinical Cushing syndrome should undergo adrenalectomy is not always clear. Several small series have demonstrated weight loss, an improvement in hypertension and glucose control following adrenalectomy for subclinical Cushing syndrome. Patients with subclinical Cushing syndrome may progress to overt Cushing syndrome as frequently as 12.5% at 1 year. Accordingly, adrenalectomy for subclinical Cushing syndrome may be beneficial and is reasonable in young patients, patients with suppressed plasma ACTH, and patients with recent weight gain, substantial obesity, arterial hypertension, diabetes mellitus, and osteopenia. Truly asymptomatic patients

with normal plasma ACTH concentrations, the elderly, or those who are unfit for surgical intervention may be observed.

All patients who undergo adrenalectomy for Cushing syndrome require postoperative glucocorticoid replacement, since the contralateral gland is suppressed. A cortisol suppression test could be used to establish the need for glucocorticoid replacement. Replacement therapy with hydrocortisone, 12 mg/m^2 per day, may be required as long as 2 years postoperatively. Adequacy of replacement is monitored clinically. The duration of replacement therapy is guided by normalization of the ACTH stimulation test and patient symptoms.

Hyperaldosteronism

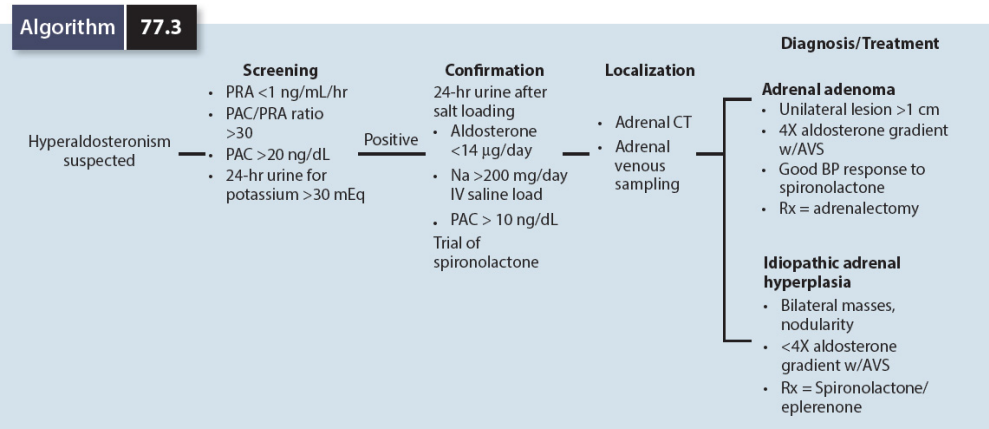
Hyperaldosteronism is a syndrome of hypertension and hypokalemia caused by autonomous adrenal secretion of the mineralocorticoid aldosterone. Hyperaldosteronism may be primary, as a result of an adrenal neoplasm with suppressed plasma renin, or may be secondary, as a result of elevated plasma renin. Primary hyperaldosteronism usually occurs between the ages of 30 and 50 years and is an important and increasingly prevalent cause of hypertension. Screening of hypertensive patients with plasma aldosterone and plasma renin activity (PRA) has suggested that primary hyperaldosteronism may be the underlying cause of up to 20% of cases of essential hypertension.

5 Primary hyperaldosteronism cases are attributable to either idiopathic adrenal hyperplasia or, more commonly, aldosterone-producing adenomas (Conn syndrome, 60% to 70% of all cases). Primary hyperaldosteronism affects both men and women with equal prevalence, although aldosterone-producing adenoma specifically has been shown to have a higher prevalence in women. Although the cause of either adenoma or idiopathic hyperplasia is not entirely understood, basic science research has elucidated various somatic mutations in aldosterone-regulating genes (i.e., *KCNJ5*, *CACNA1D*, *ATP1A1*, *ATP2B3*, *CTNNB1*) that can be present in either subtype of primary hyperaldosteronism. Familial hyperaldosteronism (types I to III) has been described but is rare. Other rare causes of primary hyperaldosteronism include adrenocortical carcinoma and ectopic aldosterone-secreting tumors. Autosomal dominant glucocorticoid-suppressible hyperaldosteronism is another rare cause of hyperaldosteronism resulting from the fusion of the ACTH-responsive 11-beta hydroxylase gene promoter to the aldosterone synthase gene in cells of the adrenal cortex.

Secondary hyperaldosteronism is a physiologic response of the renin–angiotensin system to decreased renal perfusion due to renal artery stenosis, cirrhosis, congestive heart failure, and normal pregnancy. The adrenal cortex functions normally and secretes aldosterone in response to the elevated plasma renin and angiotensin caused by these conditions. Secondary hyperaldosteronism responds to treatment of the underlying cause.

Signs and Symptoms

Clinical manifestations of primary hyperaldosteronism are attributable to hypersecretion of aldosterone by the adrenal gland (**Table 77.2**). Aldosterone-mediated retention of sodium and excretion of potassium and hydrogen ion by the kidney causes moderate diastolic hypertension. Edema is absent. Significant hypokalemia occurs in less than 40% of patients with primary hyperaldosteronism and is even less frequent in cases caused by adrenal hyperplasia, therefore hypokalemia is neither a sensitive nor specific marker of primary hyperaldosteronism. Potassium depletion causes symptoms of muscle weakness and fatigue, polyuria and polydipsia, as well as impaired insulin secretion and fasting hyperglycemia. Primary hyperaldosteronism should be suspected in hypertensive patients with spontaneous hypokalemia (serum concentration <3.5 mEq/L), moderate hypokalemia (serum potassium concentration <3.0) during diuretic therapy despite concomitant use of oral potassium or potassium-sparing diuretics, or refractory hypertension without explanation.



Algorithm 77.3 Diagnosis and management of hyperaldosteronism. PRA, plasma renin activity; PAC, plasma aldosterone concentration; CT, computed tomography; AVS, bilateral adrenal venous sampling.

Diagnosis

The clinical hallmarks of primary hyperaldosteronism are (a) medically refractory hypertension without edema; (b) suppression of plasma renin in the face of volume depletion; and (c) hypersecretion of aldosterone that fails to suppress with intravascular volume expansion. To establish a diagnosis of primary hyperaldosteronism, it is important to discern surgically correctable adrenal adenoma from medically treatable idiopathic hyperplasia, and localize an adrenal tumor (**Algorithm 77.3**).

Demonstration of an elevated plasma aldosterone concentration (PAC) in the setting of suppressed PRA is the best test to establish primary hyperaldosteronism. The ratio in normal subjects and patients with essential hypertension is 4:10 compared with more than 30 in most patients with primary hyperaldosteronism. A PAC of greater than 20 ng/dL and a PAC/PRA ratio of greater than 30 are diagnostic for aldosteronoma with almost 90% sensitivity. A serum potassium value less than 3.5 mEq/L and urinary potassium excretion greater than 30 mEq/day also support a diagnosis of primary hyperaldosteronism. Before biochemical evaluation, patients need to be potassium repleted and have an adequate sodium intake. Medications including ACE inhibitors and spironolactone should be withheld for at least 4 weeks before study.

An elevated PAC/PRA ratio alone does not establish the diagnosis of primary hyperaldosteronism. Although there is no optimal confirmatory test or gold standard, there are four confirmatory tests approved for the diagnosis of primary hyperaldosteronism: oral sodium loading, saline infusion test, fludrocortisone suppression test, and captopril challenge. The oral salt loading test involves a 24-hour urine collection for sodium and aldosterone after 3 days of a high-sodium diet. The 24-hour urinary excretion of aldosterone should be greater than 14 μg per 24 hours after a high-salt diet for patients with primary hyperaldosteronism.

After the diagnosis of primary hyperaldosteronism is made, imaging of the adrenal gland is indicated. High-resolution adrenal CT is a key noninvasive method used to localize an adrenal tumor (**Fig. 77.6**). An adrenal-based CT will detect an aldosterone-producing adenoma in 90% of cases overall, however CT has lower sensitivity for microadenomas (tumors <1 cm). MRI may be useful during pregnancy or in situations in which intravenous contrast medium injection is undesirable. Although idiopathic adrenal hyperplasia is bilateral

and often appears multinodular on CT, distinguishing an aldosteronoma from idiopathic adrenal hyperplasia can be difficult by imaging alone due to the possibility of asymmetric nodularity.

Adrenal vein sampling is an invasive procedure used to lateralize the source of aldosterone production. It is recommended for all patients with a working diagnosis of primary hyperaldosteronism but may be deferred in young patients (<40 years old) who have a unilateral adenoma (>1.0 cm) on CT with a normal contralateral adrenal gland in the setting of biochemical evidence primary hyperaldosteronism. Adrenal vein sampling is particularly crucial in patients with hyperaldosteronism when there is no adrenal abnormality on CT or MRI or when both adrenal glands are abnormal but asymmetric. Percutaneous transfemoral cannulation of both adrenal veins is performed and intravenous ACTH (50 μg/hr) may be administered. Cannulation of the right adrenal vein can be challenging due to the shorter, more posterior superior course. Simultaneous adrenal vein blood samples for aldosterone and cortisol are taken before and after ACTH injection, and their ratios are determined. The PAC is markedly higher (at least fourfold) on the side of an adenoma, whereas there is little or no left–right gradient present in cases of bilateral adrenal hyperplasia. A 10-fold gradient of cortisol in adrenal veins to a peripheral sample ensures adequacy adrenal vein cannulation. This study is greater than 90% accurate and has been shown to alter management in 30% to 50% of patients, even in those with an apparent unilateral adenoma. However, adrenal vein sampling is technically difficult and may be unsuccessful in 25% of patients. In addition, adrenal vein sampling may have some complications such as superficial skin burns from prolonged fluoroscopy, adrenal hemorrhage from cannulating too deeply into segmental adrenal veins, among others.

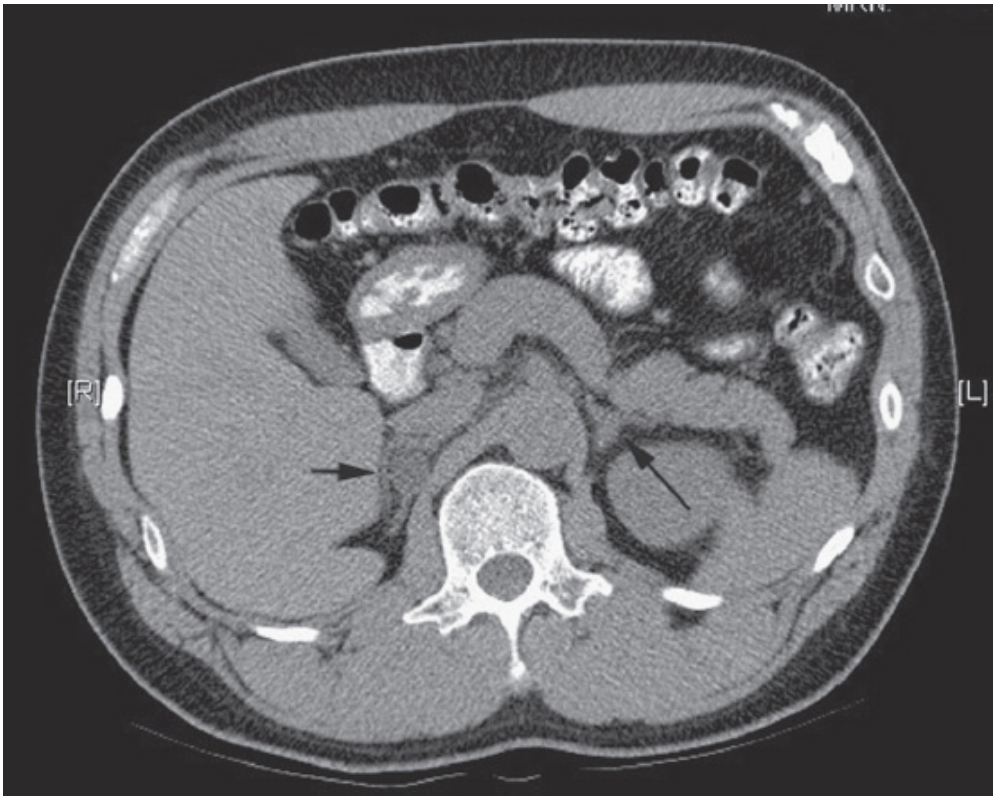


Figure 77.6 Computed tomography scan of right adrenal aldosteronoma. *Short arrow* shows aldosteronoma. *Long arrow* shows normal contralateral adrenal gland.

Figure 77.7 Aldosteronoma within right adrenal gland shown in **Figure 77.6**.

Treatment

6 Surgical removal of an aldosterone-secreting adenoma (**Fig. 77.7**) results in durable improvement of hypertension and hypokalemia in 70% to 90% of patients. Minimally invasive adrenalectomy is the preferred approach to

remove these tumors. Morbidity and mortality following these procedures are almost negligible. Preoperative spironolactone or eplerenone and potassium may be given to replenish potassium stores and correct alkalosis before anesthesia. Preoperatively, a significant fall in blood pressure with aldosterone receptor antagonists predicts a successful outcome after adrenalectomy. Response to adrenalectomy is also influenced by the duration and severity of hypertension and by the presence of histologic changes in the kidney. Factors associated with poor response to surgery include age greater than 50 years, male sex, the necessity for more than two antihypertensive medications prior to surgery, and the presence of multiple nodules within the adrenal gland.

Management of idiopathic adrenal hyperplasia is medical because fewer than 20% to 30% of patients with this disease are cured by adrenalectomy. Idiopathic adrenal hyperplasia is treated with spironolactone or with newer aldosterone antagonist eplerenone. Other potassium-sparing diuretics may be used including triamterene and amiloride. Exogenous administration of physiologic doses of glucocorticoids is the first-line therapy for glucocorticoid-suppressible hyperaldosteronism.

Adrenocortical Carcinoma

7 Adrenocortical carcinoma is a rare malignancy with an estimated incidence of 0.5 to 2 cases per million per year. Presentation peaks in the first and fifth decades of life and is more common in women. The cause of adrenocortical carcinoma is unknown, however somatic mutations in *P53*, *ERCC1*, and *IGF2* have been reported in the pathogenesis of the tumor.

Signs and Symptoms

Adrenocortical carcinoma is a very aggressive malignancy, and up to 75% of patients present with locoregionally advanced or distant disease. Syndromes of adrenal hormone overproduction are frequent (up to 60%) and may include hypercortisolism, hyperaldosteronism, or virilization. Patients with rapidly progressive Cushing syndrome or mixed presentations with signs of both Cushing syndrome and virilization should be suspected of having adrenocortical carcinoma. Nonfunctioning adrenocortical carcinomas present most commonly as abdominal pain or mass with vague symptoms of nausea, weight loss, and fatigue.

Diagnosis

Patients with suspected adrenocortical carcinoma should have biochemical testing to identify hormone overproduction followed by staging investigations including cross-sectional imaging and bone scans. Contrast-enhanced CT of the abdomen and chest is important to preoperatively diagnose local tumor invasion and metastatic lesions as well as to confirm a functioning contralateral kidney (**Fig. 77.8**). In the absence of distant metastases or local invasion, preoperative distinction between large adenomas and carcinomas can be difficult, although large (>6 cm) adrenal masses that have irregular shape and extend to nearby structures on CT scanning should be approached as carcinomas. Biopsy of adrenal lesions suspected of being adrenocortical carcinoma should be avoided as this is not helpful in distinguishing adenoma from carcinoma, and carries a high risk of tumor seeding. Biopsy of extraadrenal lesions may be performed to confirm metastatic disease. Positron emission tomography (PET) scans are often helpful in demonstrating distant disease in cases that are highly suspicious for adrenocortical carcinoma.

Figure 77.8 Computed tomography scan of right adrenocortical carcinoma showing invasion of liver and inferior vena cava. Note that a contralateral kidney is present and functioning.

A definitive diagnosis of adrenocortical carcinoma requires pathologic demonstration of tumor invasion to adjacent organs or spread to lymph nodes or distant sites. Practically, any adrenal neoplasm larger than 6 cm or weighing more than 100 g may be considered malignant. Histologic features of tumor necrosis, hemorrhage, and local invasion are gross pathologic evidence of carcinoma, while cells with large, hyperchromatic nuclei and more than 20 mitoses per high-power field suggest malignancy.

Treatment

Surgical resection is the mainstay of treatment for most stages of adrenocortical carcinoma. Open resection is preferred to minimize tumor spillage and seeding. Complete resection of locally confined tumor is the only chance for cure from adrenocortical carcinoma. However, distant or local spread is evident in 65% of cases at presentation and a minority of patients is resectable with curative intent. Recurrence rates after surgery range from 38% to 85%, depending on stage at presentation (**Table 77.5**).

Many patients with adrenocortical carcinoma present with metastatic disease, involving the lung, lymph nodes, liver, or bone. Resection or surgical debulking of locally advanced or oligometastatic lesions may provide symptomatic relief for selected patients, especially those with low-grade, slow-growing, hormonally productive cancers. Symptomatic locally recurrent or oligometastatic disease is best treated by resection when feasible. Overall median survival following diagnosis is approximately 18 months.

Mitotane is an adrenolytic drug that has high efficacy for adjuvant therapy in patients with adrenocortical carcinoma. Patients at high risk of recurrence include those with vascular or capsular invasion, histologically high-grade disease (high Ki-67, de-differentiation, or high mitotic figure rate), and those whose operation was complicated by intraoperative tumor spillage. These patients may additionally benefit from chemotherapy. Cisplatin, etoposide, and streptozosin have been trialed for the management of adrenocortical carcinoma, with varying success. Adjuvant radiation therapy may be considered in patients with advanced disease stage.

Table 77.5 American Joint Committee on Cancer Staging of Adrenocortical Carcinoma

TNM	Criteria
Tumor	
T1	Tumor <5 cm, no invasion
T2	Tumor >5 cm, no invasion
T3	Tumor with invasion to fat
T4	Tumor with organ invasion
Lymph nodes	
N0	No lymph node metastasis
N1	Lymph node metastasis present
Metastasis	
M0	No distant metastasis
M1	Distant metastasis present

DISEASES OF THE ADRENAL MEDULLA

Pheochromocytoma/Paraganglioma

Pheochromocytomas are functional adrenal tumors that arise from neuroectodermal cells of the adrenal medulla (80% to 85%) or in certain extraadrenal sites (paraganglioma, 15% to 20%). These tumors are uncommon, occurring in 0.005% to 0.1% of persons, but occur with increased frequency in hypertensive populations (0.2% incidence) and in heritable endocrine tumor syndromes. The peak incidence of pheochromocytoma/paraganglioma occurs during the fourth and fifth decades of life, and men and women are affected about equally.

Historically, the *rule of tens* was a useful way to characterize pheochromocytoma tumors (bilateral in 10% of cases, extraadrenal in 10%, familial in 10%, multicentric in 10%, and malignant in 10% and occur in children in 10% of cases). However, recent advances in genetics and oncology have revealed that 8 up to 40% of pheochromocytomas/paragangliomas are hereditary, and at least 19 susceptibility genes have been identified. These susceptibility genes include *RET* proto-oncogene, *VHL* tumor suppressor gene, neurofibromatosis type 1 (*NF-1*) tumor suppressor gene, and succinate dehydrogenase genes (*SDH*).

Approximately 10% of pheochromocytomas are extraadrenal and are called paraganglioma. However, most (98%) are still located within the abdomen. Paraganglioma can occur at any site in the abdomen where chromaffin tissue is located and have been found in the paravertebral ganglia, the organ of Zuckerkandl, and the urinary bladder. Clues to the presence of paraganglioma are predominance of norepinephrine secretion because extraadrenal sites lack the phenylethanolamine-N-methyltransferase (PNMT) enzyme necessary to convert norepinephrine to epinephrine.

Hereditary pheochromocytoma and paraganglioma tend to occur bilaterally, in synchrony or metachrony, have an early onset, may involve multiple disseminated primary tumors or manifest as part of a syndrome involving extraadrenal tumors. Familial transmission is generally autosomal dominant. Patients with von Hippel–Lindau syndrome have pheochromocytoma (usually bilateral), retinal angiomas, cerebellar hemangioblastoma, epididymal cystadenoma, renal and pancreatic cysts, and renal cell carcinoma. Patients with MEN 2A develop pheochromocytoma (usually bilateral), medullary carcinoma of the thyroid (MTC), and primary parathyroid hyperplasia. Patients with MEN 2B develop pheochromocytoma (usually bilateral), MTC, mucosal neuromas, intestinal ganglioneuromatosis, and have a characteristic Marfanoid body habitus. Pheochromocytoma also occurs in neurofibromatosis type 1 and

familial paraganglioma. The frequency of pheochromocytoma in these disorders is 10% to 20% in von Hippel–Lindau syndrome, 50% in MEN 2, and 1% to 3% with neurofibromatosis type 1. Patients with mutations of *SDHx (SDHA, SDHB, SDHC, SDHD, SDHAF2*), transmembrane protein 127 (*TMEM127*), or MYC-associated factor X (*MAX*) generally have only pheochromocytomas and paragangliomas. A minority of *SDHx* mutation carriers have been reported to have gastrointestinal stromal tumors (GISTs), renal cell carcinomas, or pituitary adenomas.

The diagnosis of malignant pheochromocytoma remains a challenge. Histologic features such as growth patterns, mitoses, and atypia of cells and nuclei correlate with malignant biologic features in pheochromocytomas and paragangliomas. However, it is difficult to predict the clinical behavior of individual tumors, and no single risk-stratification scheme is endorsed or in widespread use. The development or presence of metastasis is the proof for a malignant pheochromocytoma or paraganglioma. Metastases are located where chromaffin tissue is normally not found (e.g., lymph nodes, lung, liver, and bones), and frequently are not confirmed histologically but are instead documented on nuclear imaging. The typical metastatic sites for pheochromocytoma are bones and lymph nodes, whereas when paraganglioma is the primary tumor, hepatic metastases are more common.

Signs and Symptoms

Symptoms of pheochromocytoma are attributable to the effects of excessive circulating catecholamines on target tissues (**Table 77.3**), however the clinical occurrence of symptoms may not always correlate with the active release of catecholamines from the tumor. The classic triad of symptoms in patients with a pheochromocytoma is episodic headache, sweating, and tachycardia. Hypertension is common with pheochromocytoma and is sustained in roughly half of patients, is paroxysmal in one-third, and is absent in one-fifth. Orthostatic hypotension results from diminished plasma volume and blunted autonomic reflexes. Other symptoms include palpitations, anxiety, irritability, and tremulousness. Cardiovascular sequelae include myocardial infarction, cardiac dysrhythmias, and stroke. Gastrointestinal motility is also impaired, as is glucose tolerance. Asymptomatic patients with functioning tumors are rare, and nonfunctioning tumors are distinctly uncommon, however very small tumors may be very mildly functioning, and therefore may not become symptomatic until the tumors are larger. Sudden death has been reported in patients with

pheochromocytoma who have undergone surgical procedures or childbirth. Undiagnosed pheochromocytoma may also lead to spontaneous abortion in pregnant women.

Diagnosis

Elevation of catecholamines and their metabolites in either urine or blood is essential for the diagnosis of pheochromocytoma. Either a 24-hour urine collection for fractionated catecholamines and their metabolites (metanephrines) or plasma-fractionated metanephrines can be used to make the diagnosis. Urine catecholamines/metanephrines are the most reliable tests with a sensitivity and specificity of 98%. Plasma-fractionated metanephrines is similarly sensitive (99%), but lacks specificity (85%). Measurement of plasma catecholamines is not as useful in distinguishing patients with pheochromocytoma from those with essential hypertension. Measurement of plasma chromogranin A is nonspecific and a poor diagnostic but potentially helpful confirmatory test.

Many medications alter or interfere with measurement or either plasma or urine catecholamines. Such medications should be discontinued to ensure accurate testing. These drugs include acetaminophen, labetolol, clonidine withdrawal, tricyclic antidepressants, antipsychotics, and ethanol. To control blood pressure, other antihypertensives such as calcium channel blockers or alpha blockers may be substituted.

In normotensive or mildly hypertensive patients with elevated plasma catecholamine levels (1,000 to 2,000 pg/mL), a clonidine suppression test may be used to distinguish from pheochromocytoma. An oral 0.3-mg dose of clonidine suppresses centrally mediated release of catecholamines to less than 500 pg/mL within 2 to 3 hours but does not affect release of catecholamines by a pheochromocytoma.

Biochemical confirmation of the diagnosis should be followed by radiologic evaluation to locate the tumor. Tumor localization can be done using functional or nonfunctional imaging techniques such as CT or MRI. CT or MRI is often the first line of imaging. Contrast-enhanced CT readily detects tumors 1 cm and larger and has sensitivity of 87% to 100% for pheochromocytoma (**Fig. 77.9A**). On adrenal protocol CT, a pheochromocytoma often has attenuation values of >20 HU, however cases of pheochromocytoma with low HU (<10) have been reported. MRI is similarly sensitive, and a T2-weighted image brightness three times greater than liver is highly specific for pheochromocytoma

(**Fig. 77.9B,C**). MRI is useful in suspected malignant pheochromocytoma to evaluate for inferior vena cava thrombus or liver invasion.

Functional nuclear imaging with iodine-131-metaiodobenzylguanidine (131-I MIBG) is a useful adjunct to cross-sectional imaging for pheochromocytoma (**Fig. 77.9D**). MIBG resembles norepinephrine and is taken up by adrenergic tissues including pheochromocytoma. An MIBG scan can detect tumors not detected by CT or MRI or multiple tumors when CT or MRI is positive. Multi-institutional experience with this technique has demonstrated an overall sensitivity of 77% to 87% and a specificity of 96% to 100%. This test is usually not necessary for sporadic pheochromocytoma unless urinary or plasma catecholamines and metabolites are marginally elevated, or if malignant or extraadrenal pheochromocytoma is suspected. 131-I MIBG scanning is also useful to screen patients with metastatic pheochromocytoma for high-dose 131-I MIBG therapy. 111-In-pentetreotide scintigraphy (Octreoscan) may also identify pheochromocytoma and can be used therapeutically as with 131-I MIBG. Because pheochromocytomas and paragangliomas express somatostatin receptors, in recent years, PET-CT imaging tagged with ^{18}F-DOPA, ^{18}F-FDG, and ^{68}Ga-labeled somatostatin analogs (such as ^{68}Ga-DOTATATE) has been used, with better sensitivity and resolution than SPECT scintigraphy.

Treatment

Surgical resection is the only cure for pheochromocytoma. When the diagnosis of pheochromocytoma has been established and localization studies are completed, preoperative preparation of the patient centers on blood pressure control. Alpha-adrenergic blockade is initiated 1–3 weeks before the operation. Phenoxybenzamine, a nonspecific alpha-adrenergic blocking agent, has been a stalwart for decades in the medical treatment of pheochromocytoma, starting at 10 mg twice a day, and increasing by 10 to 20 mg per day until blood pressure normalizes and the patient becomes orthostatic. Alternatives to phenoxybenzamine include selective alpha blockers such as doxazosin and terazosin, which work very well, are cheaper, and better tolerated than phenoxybenzamine; calcium channel blockers (nifedipine and nicardipine) may be used, but are less effective. Side effects of nonselective alpha blockade include postural hypotension, reflex tachycardia, prostration, nasal congestion, and an inability to ejaculate. Preoperative alpha blockade also reverses the relative hypovolemia that is usually present in patients with pheochromocytoma and prevents severe blood pressure swings during intraoperative manipulation

of the tumor. Metyrosine inhibits the enzyme tyrosine hydroxylase and, therefore, catecholamine synthesis, consequently depleting the levels of the catecholamines dopamine, epinephrine, and norepinephrine in the tumor. This can be added preoperatively to alpha blockade to potentiate the control of catecholamine excess. Metyrosine is very expensive as it is produced by a single pharmaceutical company, but is very effective in patients who have very significant levels of catecholamine excess, and should be reserved for the week before surgery.

Beta-adrenergic blockade with propranolol added after alpha blockade can manage patients who develop tachycardia or who have inducible cardiac arrhythmias or ischemia. Propranolol may enhance pressor response to endogenous norepinephrine and thus should not be given until adequate alpha blockade has been established. Propranolol can also produce profound bradycardia, myocardial depression, and congestive heart failure.

Patients with pheochromocytoma can be expected to have blood pressure volatility and high intravascular volume requirements during and immediately after surgery. To avoid some of these fluid shifts, given patients with pheochromocytoma oral salt tablets several days before surgery helps restore intravascular volume and avoid very significant intraoperative hemodynamic shifts due to volume contraction.

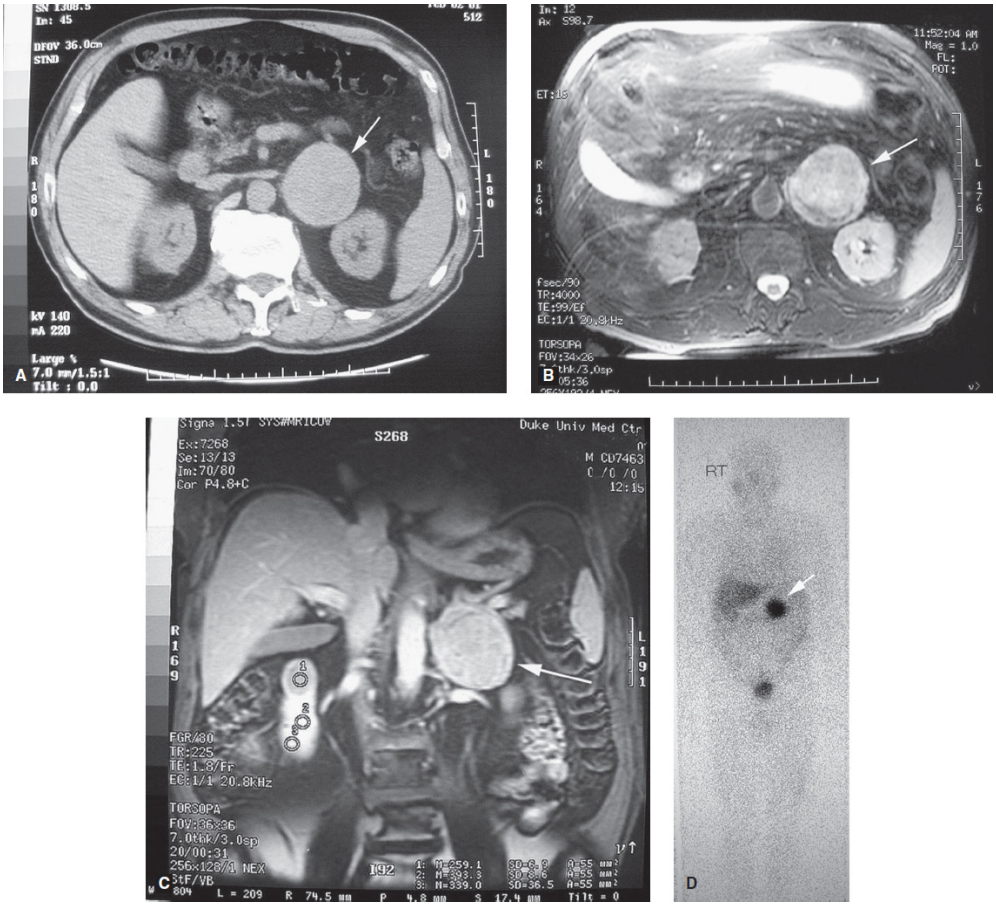

Figure 77.9 Imaging of pheochromocytoma (*arrows*). **A:** Computed tomography scan shows well-circumscribed left adrenal mass. **B:** T2-weighted magnetic resonance imaging shows the mass to be heterogeneously bright, consistent with pheochromocytoma. **C, D:** Coronal contrast-enhanced MRI and near-simultaneous 131I-metaiodobenzylguanine (131I-MIBG) scanning show location of the pheochromocytoma and relationship to surrounding structures.

Patients who have very high levels of circulating catecholamines or have had a longstanding history of undiagnosed pheochromocytoma should undergo a cardiac echocardiogram to evaluate for the potential of catecholamine-excess cardiomyopathy. Whenever available, anesthesiologists with experience in the perioperative management of pheochromocytomas should be selected for these cases. Patients require active hemodynamic monitoring with arterial line placement for careful monitoring of blood pressure and arterial pH, as well as possibly a central line for monitoring of central venous pressures. Anesthetic agents may trigger the release of catecholamines from pheochromocytomas. Intraoperative hypertension is best treated with a sodium nitroprusside drip, and

cardiac arrhythmias are best managed with short-acting beta blockers (esmolol) or lidocaine.

Recurrent, malignant pheochromocytoma can include locally advanced disease or metastasis to bone, liver, lymph nodes, lungs, and the central nervous system. Treatment of malignant pheochromocytoma involves resection of metastases when feasible and medical control of hypertension. Radiation therapy may be helpful to ameliorate pain from bony metastases. Ablative therapy with 131-I MIBG may also produce partial responses and palliation of hormonal symptoms. Radiofrequency ablation of hepatic and bone metastases can be effective in selected patients. Combination chemotherapy with cyclophosphamide, vincristine, and dacarbazine can also be effective. Overall 5-year survival for patients with malignant pheochromocytoma ranges from 36% to 60%.

Metastasis to the Adrenal Glands

The adrenal glands are frequent sites for metastases from many cancers. Carcinoma of the lung and breast account for most adrenal metastases; however, virtually any cancer including melanoma, lymphoma, renal, and ovarian carcinoma can spread to the adrenals. Autopsy series of patients with carcinoma show that the adrenal glands are involved in more than 25% of cases. Among cancer patients, 50% to 75% of newly discovered adrenal masses represent metastases. Usually, either a primary site is obvious, or widespread disease is apparent. Biopsy of adrenal masses in patients with a history of carcinoma may be performed after pheochromocytoma is excluded. Resection of isolated adrenal metastases in selected patients with long disease-free intervals from lung cancer, renal cell carcinoma, and melanoma can be considered, although subsequent extraadrenal disease usually develops. Median survival after complete resection of isolated adrenal metastases from a variety of tumors ranges from 13 to 60 months with actuarial 2- and 5-year survival of 40% and 20%, respectively.

ADRENALECTOMY

Surgical indications for adrenalectomy include adrenal tumors that are large or enlarging, worrisome for a malignancy, and those that exhibit evidence of

autonomous hormonal secretion. Surgical approaches to the adrenal glands include the laparoscopic approach, open anterior transabdominal approach, and less commonly, the combined open thoracoabdominal approach. Regardless of approach, important surgical principles include confirmation of the correct site of surgery during the preoperative and intraoperative timeouts, minimal handling of the tumor, early isolation and ligation of the adrenal vein, and avoidance of capsular rupture. Capsular rupture can lead to incurable tumor spread even for benign tumors. Surgeon volume is an important consideration in adrenalectomy: surgeons who perform at least six adrenalectomies per year have better outcomes as compared to lower-volume surgeons.

Minimally invasive adrenalectomy is the gold standard of surgical management of most adrenal tumors, and has advantages including reduced postoperative pain, earlier resumption of oral intake, shorter hospital stay, earlier resumption of baseline activity, and superior cosmesis. Minimally invasive adrenalectomy may be performed via a transabdominal (with or without robot-assistance or hand-assistance) or posterior retroperitoneoscopic approach. At all times, the surgeon must be prepared to convert from a laparoscopic to an open procedure, if necessary. An open approach is recommended in large tumors or in suspected cases of adrenocortical carcinoma.

Laparoscopic Transabdominal Adrenalectomy

Laparoscopic transabdominal adrenalectomy begins with induction of general anesthesia, placement of a urinary catheter and orogastric tube, and positioning of the patient in the lateral decubitus position with the affected side up. Exposure is facilitated by flexion of the operating table at the patient's waist to enhance the space between the rib cage and the iliac crest. A total of three or four intraperitoneal ports (one camera, two working ports, and one liver retractor particular for the right side) are placed at least 5 cm apart in a transverse line from the lateral edge of the rectus sheath to the midaxillary line between the costal margin and iliac crest (**Fig. 77.10A**). Visual four-quadrant exploration of the peritoneal cavity is first performed with the videoscope through the medialmost port, and the videoscope is then transferred to the middle port. If robot assistance is being used, the robot is docked at this time. A retractor is placed through the medial most port to retract the viscera medially. Operating instruments are alternately placed within the abdomen through the

lateral ports. Right adrenalectomy begins with mobilization of the liver to open the retroperitoneum and allow retraction of the right lobe of anteriorly and medially using the most medial port. Left adrenalectomy is performed with mirror-image patient and port-site orientation as right adrenalectomy. Dissection begins with mobilization of the splenic flexure of the colon and spleen from the left retroperitoneum. Subsequent medial retraction of the spleen, tail of the pancreas, and stomach is accomplished with the fan or similar retractor if necessary. In both cases, the adrenal vein should be clearly identified and then doubly clipped and divided. The transabdominal laparoscopic approach has the benefit of being able to have a hand port modification for patients who may have very friable tumors and/or large tumors. The hand port can replace one of the existing outer trocars. This can be considered a technique that preserves a minimally invasive approach with the benefits of manual manipulation (**Table 77.6**).

Table 77.6 Critical Steps in Laparoscopic Transabdominal Adrenalectomy

Left Adrenalectomy	Right Adrenalectomy
▪ After general anesthesia induction, place patient in lateral decubitus position. ▪ Obtain laparoscopic access, confirm no injuries upon entry and place other ports. ▪ Mobilize and retract the spleen medially. ▪ Mobilize the splenic flexure and distal transverse colon inferiorly. ▪ Identify and mobilize the tail of the pancreas off the retroperitoneum. ▪ Create plane medial to the adrenal and lateral to the aorta. ▪ Identify the left renal vein inferiorly. ▪ Continue dissection medially until left adrenal vein is identified. ▪ Clip and divide the adrenal vein. ▪ Mobilize the rest of the adrenal gland from surrounding attachments, carefully assessing for any potential renal polar arterioles, which should be avoided. ▪ Remove adrenal gland from abdomen. ▪ Confirm hemostasis and close. ▪ Use back table to confirm that adrenal gland is in specimen.	▪ After general anesthesia induction, place patient in lateral decubitus position. ▪ Obtain laparoscopic access, confirm no injuries upon entry and place other ports. ▪ Mobilize and retract right lobe of liver. ▪ Create plane medial to the adrenal and lateral to the vena cava. ▪ Identify the right renal vein inferiorly. ▪ Continue dissection medially until right adrenal vein is identified. ▪ Clip and divide the adrenal vein. ▪ Mobilize the rest of the adrenal gland from surrounding attachments, carefully assessing for any potential renal polar arterioles, which should be avoided. ▪ Remove adrenal gland from abdomen. ▪ Confirm hemostasis and close. ▪ Use back table to confirm that adrenal gland is in specimen.

Potential intraoperative complications of laparoscopic transabdominal adrenalectomy:

- Entry site injury from placement of ports
- Injury to surrounding viscera (on left: spleen, kidney, tail of pancreas, colon; on the right: liver, colon, duodenum, kidney)
- Injury or wrongfully clipping/dividing major vessels (renal vessels, vena cava, and aorta)

- Excessive handling of adrenal gland resulting in capsular rupture and tumor spillage
- Hemodynamic instability during adrenalectomy for pheochromocytoma

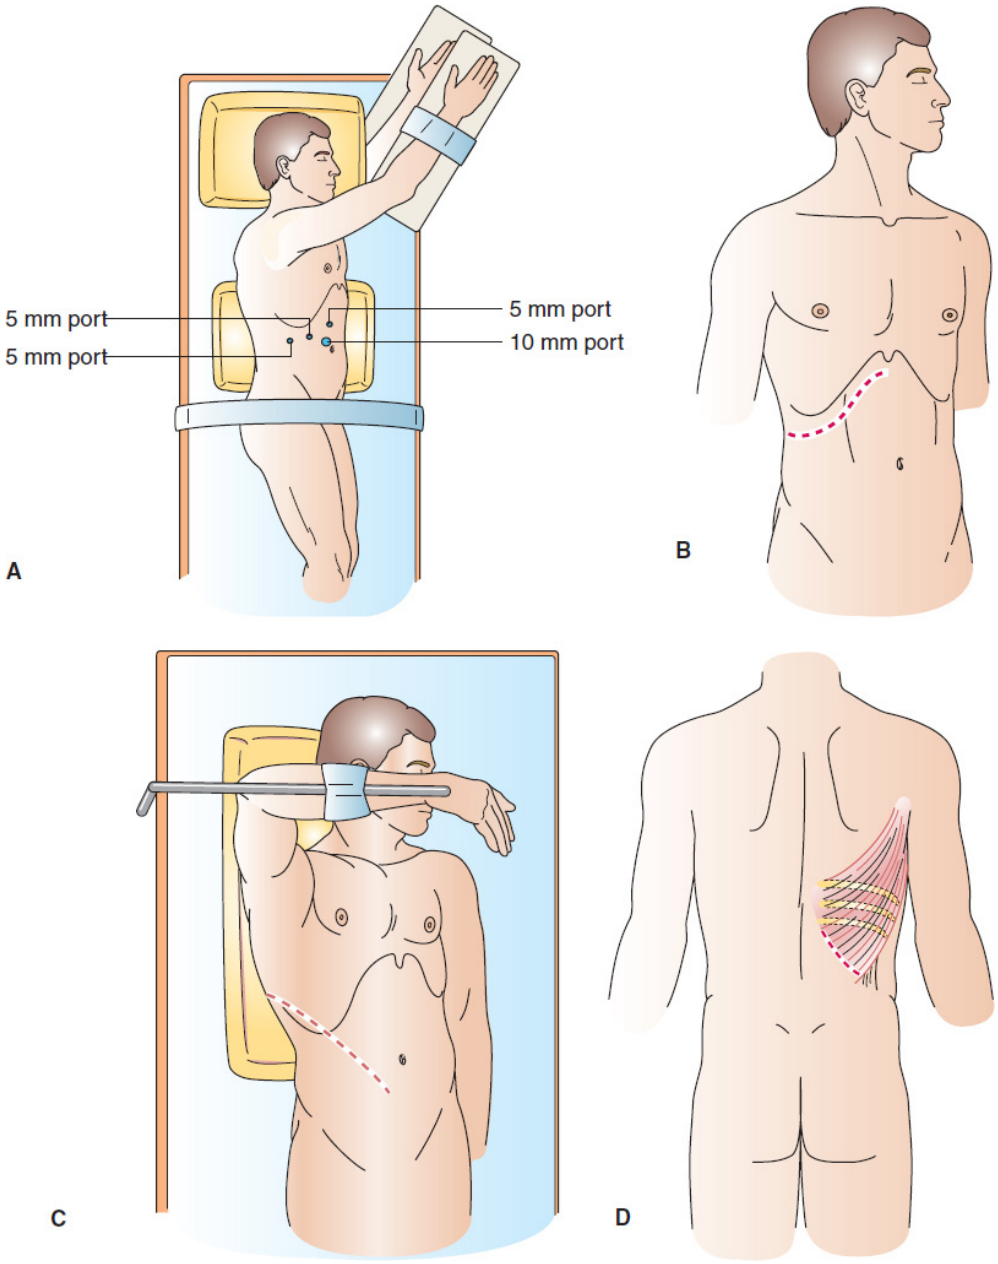

Figure 77.10 Incisions for right adrenalectomy. Shown are typical incisions for (**A**) laparoscopic approach, (**B**) open, anterior approach, (**C**) thoracoabdominal approach, and (**D**) posterior, open approach. Incisions for left adrenalectomy are positioned opposite.

Posterior Retroperitoneoscopic Adrenalectomy

Posterior retroperitoneoscopic adrenalectomy has the advantages of a minimally invasive approach while avoiding the abdominal cavity. This approach is ideal for patients with prior abdominal surgery or for bilateral adrenalectomy as both adrenal glands can be removed without repositioning the patient. It is more difficult in patients who have tumors larger than 6 cm, and should not be attempted if there is any suspicion for malignancy.

Posterior retroperitoneoscopic adrenalectomy begins with placing the patient in the prone jackknife position on a spinal table allowing the abdominal contents to fall by gravity forward. The hips and knees are positioned at 90-degree angles to the spine and femur and carefully padded. The first port is placed just below the tip of the 12th rib; after the incision is made the retroperitoneal space is entered sharply, a space is created bluntly with the index finger. This will become the middle trocar. A blunt 5- or 10-mm trocar is placed under digital guidance just medial to the paraspinous muscle and medial to the psoas internally at a 45-degree angle anteriorly toward the adrenal gland. A lateral 5-mm port is placed 5 cm lateral to the first port in a similar fashion. In the middle port, an 11-mm blunt balloon trocar is inserted. Pneumoretroperitoneum is achieved to 20 to 24 mm Hg to create an adequate working space. The videoscope is transferred from the initial middle port to the medial port to complete the dissection. The retroperitoneal space beneath the diaphragm is created bluntly and sharply. The superior border of the kidney is immediately identified and Gerota fascia is entered. The upper pole of the kidney is pushed caudally and the tissue superior to the kidney, which contains the adrenal gland is completely separated from the kidney. The medial dissection is then begun by carefully bluntly dissecting the adrenal gland and identifying the adrenal vein and dividing it between clips. Identification of the adrenal vein for both sides is easier in this approach than with the transabdominal laparoscopic approach. Dissection is completed circumferentially around the gland using electrosurgical or harmonic energy to coagulate any small vessels. Once the gland is completely free, it is placed in an endoscopic bag and removed through the middle port.

Anterior Open Approach

Anterior, open adrenalectomy begins with an ipsilateral or bilateral subcostal incision (**Fig. 77.10B**). The abdomen is opened and explored for evidence of metastatic disease, including biopsy or excision of suspicious lesions. Resection of the right adrenal gland proceeds with full mobilization and anteromedial retraction of the right hepatic lobe (**Fig. 77.11A**). In order to uncover the inferior vena cava, the right kidney and the right adrenal gland, the hepatic flexure and transverse colon and are retracted inferiorly, usually without need for extensive mobilization. The retroperitoneal space is entered behind the liver to expose the adrenal gland. Subsequent adrenalectomy is performed as in the laparoscopic approach.

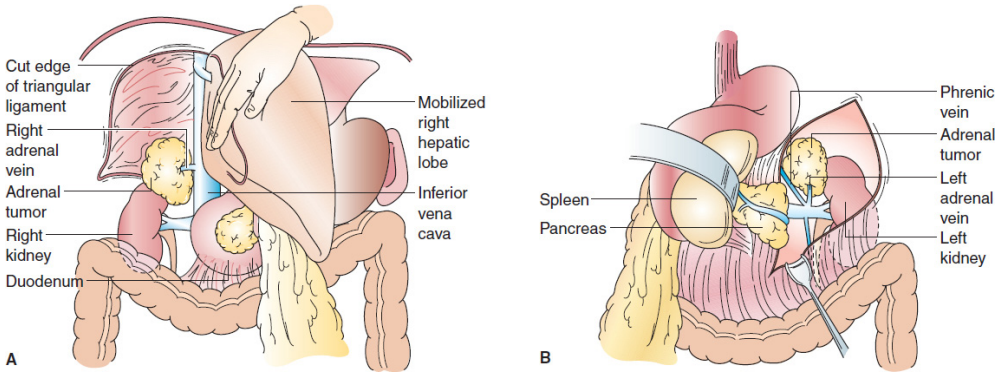

Figure 77.11 Anterior approach to right (**A**) and left (**B**) adrenalectomy. Note position of phrenic vein in relationship to the left adrenal vein and tumor.

Resection of the left adrenal gland requires mobilization of the spleen, tail of pancreas, and left colon. The left colon is freed from its peritoneal attachments and is reflected inferiorly. The spleen is then delivered from the left upper quadrant medially, and the splenocolic ligament is divided. The spleen, stomach, and pancreatic tail are retracted medially en bloc to expose the left kidney and adrenal (**Fig. 77.11B**). The left adrenal vein is ligated and divided at its junction with the left renal vein. The gland is dissected and the arterial vessels are ligated and divided sequentially, beginning at the superolateral aspect of the gland and continuing medially.

Thoracoabdominal Approach

The thoracoabdominal approach is used for large adrenal lesions with invasion of surrounding structures including the IVC, liver, and diaphragm on the right side, and the diaphragm or high gastric cardia on the left side, if control and

access to thoracic structures is necessary. The patient is positioned with the ipsilateral flank raised and arm-extended cephalad. Incision is made in the 10th or 11th intercostal space beginning at the posterior axillary line and is extended toward the midline of the abdomen (**Fig. 77.10C**). Retractors are placed and subsequent adrenalectomy is performed as for the anterior approach.

ADRENAL INSUFFICIENCY

Adrenal insufficiency reflects inadequate glucocorticoid and mineralocorticoid production by the adrenals, either secondary to suppression of the HPA axis or by destruction or surgical removal of the adrenal glands. The most common causes of primary adrenal insufficiency are autoimmune adrenalitis, infection, and, less commonly, gland replacement with metastatic disease. Chronic exogenous steroid use with HPA suppression and surgical resection of adrenal glands are important causes of secondary adrenal insufficiency.

Clinical signs and symptoms usually do not become manifest until at least 90% of the gland is destroyed. Adrenal insufficiency usually occurs gradually unless the patient experiences stress which may precipitate acute crisis.

Signs and Symptoms

Acute adrenal insufficiency usually manifests as shock in a patient with undiagnosed chronic adrenal insufficiency who has been subjected to physiologic stress. Similarly, patients with established adrenal insufficiency caused by exogenous steroid use may experience crisis if they do not increase glucocorticoid replacement during times of stress or illness. Symptoms of adrenal insufficiency reflect glucocorticoid and mineralocorticoid deficiencies. Signs and symptoms of acute insufficiency include fever, nausea, vomiting, refractory hypotension, and lethargy (**Table 77.7**). Acute adrenal insufficiency is a life-threatening emergency and should be suspected in stressed patients with a history of either adrenal insufficiency or exogenous steroid use. Chronic adrenal insufficiency presents more subtly, with fatigue, weight loss, anorexia, nausea and vomiting, abdominal pain, and diarrhea.

Diagnosis

Laboratory findings of adrenal insufficiency include hyponatremia, hyperkalemia, azotemia, and fasting or reactive hypoglycemia. Hypercalcemia may also be present. The rapid ACTH stimulation test is the best test for both acute and chronic adrenal insufficiency. Synthetic ACTH (250 μg) is administered intravenously, and plasma cortisol levels are measured 30 and 60 minutes later. Normal peak cortisol response should exceed 20 μg/dL. Measurement of ACTH by IRMA is then used to distinguish primary from secondary and tertiary adrenal insufficiency. High plasma concentration of ACTH (>200 pg/dL) and low plasma cortisol (<10 mg/dL) are diagnostic of primary adrenal insufficiency. Low levels of plasma ACTH indicate secondary (pituitary) or tertiary (hypothalamic) adrenal insufficiency.

Table 77.7 Symptoms and Signs of Acute Adrenal Insufficiency

Symptoms

- Extreme fatigue, lethargy
- Confusion or disorientation
- Nausea and vomiting
- Abdominal pain
- Coma, death

Signs

- Hypotension
- Hyponatremia, hyperkalemia, azotemia
- Hypoglycemia
- Fever
- Anemia

Treatment

Acute adrenal insufficiency is based on clinical suspicion before laboratory confirmation is available. Intravenous volume replacement with isotonic fluids and immediate intravenous steroid replacement therapy with 4-mg dexamethasone is essential. A rapid ACTH stimulation test is then performed to establish the diagnosis of adrenal insufficiency after resuscitation and corticosteroid replacement. Hydrocortisone acetate is detected in laboratory measurement for cortisol so dexamethasone should be used for replacement of

glucocorticoid function until ACTH testing is complete. Thereafter, 100 mg of hydrocortisone is administered intravenously every 6 to 8 hours and is tapered to standard replacement doses as the patient's condition stabilizes. Mineralocorticoid replacement is not required until oral intake resumes. Chronic adrenal insufficiency requires both corticosteroid and mineralocorticoid replacement. Usual daily dosing is 12 mg/m^2 of hydrocortisone and 0.05- to 0.10-mg fludrocortisone.

Patients who have known adrenal insufficiency or who have received supraphysiologic doses of corticosteroid recently in the period preceding surgery should receive perioperative stress-dose corticosteroids. Administration of 100-mg hydrocortisone the morning of major surgery followed by 100 mg of hydrocortisone every 8 hours during the perioperative 24 hours is usually more than sufficient. Steroids can be rapidly tapered to replacement levels as the patient's condition permits.

Pituitary Surgery

Benjamin I. Rapoport, Georgiana A. Dobri, and Theodore H. Schwartz

Key Points

1. Clinical manifestations of sellar masses may include local mass effect and pituitary hormone excess or deficiency.
2. Pituitary adenomas account for the vast majority (>90%) of sellar lesions in surgical series, although the differential diagnosis includes a variety of pathologies.
3. Incidental sellar lesions are common findings on cranial imaging.
4. Despite recent advances in genetics and molecular biology, the pathogenesis of most sellar masses remains incompletely understood.
5. Thorough clinical, radiologic, and endocrine testing can help significantly narrow the differential diagnosis before pituitary surgery.
6. There are a number of surgical techniques and approaches in current use with similar outcomes; the trend is toward increasing use of endoscopy.
7. Medical therapy is available for several types of hormone-secreting pituitary adenomas, and is generally considered first-line treatment in patients with prolactin-secreting tumors.
8. With the exception of many prolactin-secreting pituitary adenomas, transsphenoidal pituitary surgery remains first-line therapy for pituitary adenomas associated with mass effect or hormone excess.
9. Medical therapy has an adjuvant role in patients with conditions caused by other types of secretory adenomas (including acromegaly and Cushing disease) when pituitary surgery is not curative.
10. Management of pituitary adenomas is most effective in a multidisciplinary setting, in which the multiple treatment options available can be individualized to a given patient. Comprehensive care of these patients routinely involves collaboration among endocrinology, ophthalmology, rhinology, and neurosurgery.

Revised from a prior edition written by Brooke Swearingen and Nicholas A. Tritos.

INTRODUCTION

The pituitary, as the "master gland," is responsible for the control of much of the body's endocrine function. It affects the function of the thyroid, adrenals, and ovaries or testes, and regulates growth, lactation, and ovulation. Its posterior lobe helps to regulate water homeostasis and parturition. Surgical disorders of 1 the pituitary can manifest as either endocrinopathy, with syndromes of hormone hypo- or hypersecretion, or as abnormalities caused by mass effect, especially visual field deficits (classically, bitemporal hemianopsia due to compression of the optic chiasm). This chapter will review the anatomy and endocrine physiology of the pituitary gland, as well as the diagnosis, imaging, and pathology of pituitary disorders, and will describe the medical and surgical management of pituitary tumors.

ANATOMY

The pituitary gland lies within the sella turcica, a bony cavity in the posterior sphenoid bone. Anatomic boundaries are formed anteriorly and inferiorly by the sphenoid sinus, posteriorly by the dorsum sella and posterior clinoid processes, anterosuperiorly by the tuberculum sella, and superiorly by the diaphragm sella (a thin dural reflection over the superior margin of the gland) (**Fig. 78.1A,B**). The lateral boundaries are formed by the cavernous sinuses. The gland itself is composed of anterior, intermediate, and posterior lobes (the adenohypophysis, pars intermedia, and neurohypophysis or pars nervosa, respectively). The anterior lobe consists of the pars distalis, the bulbous portion of the gland located within the sella, and the pars tuberalis, the stalk-like segment along the anterior infundibulum, which penetrates the diaphragm sella and connects the gland to the hypothalamus. The vascular supply is formed by the inferior hypophyseal arteries, which arise bilaterally from the intracavernous segments of the carotid arteries and are classically described as supplying the neurohypophysis; and by the superior hypophyseal arteries, which supply the median eminence and infundibulum and also form the capillary network of the hypophyseal-portal system. This portal system carries hypothalamic-releasing hormones along the infundibulum to the anterior lobe. Venous drainage exits through the cavernous and superior and inferior petrosal sinuses bilaterally, and thence to the sigmoid sinuses and internal jugular veins.

There is often a variably developed dural venous sinus, the circular sinus, usually at the level of the tuberculum sella, connecting the two cavernous sinuses, and there may be dural venous plexi of variable size and location beneath and posterior to the sella.

Several anatomic relationships are particularly important with regard to pathologic effects and surgical approaches. These include the cavernous sinuses, located lateral to the pituitary and containing the cavernous segments of the carotid arteries; and the suprasellar cistern, located superior to the gland and containing the optic nerves and chiasm. The cavernous sinuses are venous plexi formed by venous drainage from the ophthalmic veins, middle and inferior cerebral veins, and sphenoparietal sinuses. Structures traversing the cavernous sinuses include the intracavernous segment of the carotid artery, as well as multiple cranial nerves, including cranial nerve III (oculomotor), cranial nerve IV (trochlear), the ophthalmic branch of the trigeminal (V1), and the maxillary branch of the trigeminal (V2). These nerves, from superior to inferior, respectively, travel in the dural reflection that forms the lateral wall of the cavernous sinus. The VIth cranial nerve (abducens) runs along the lateral aspect of the intracavernous carotid artery. Nerves III, IV, VI, and V1 exit into the superior orbital fissure, while V2 exits through the foramen rotundum. The relationship of the cavernous segment of the carotid artery to the cavernous sinus is important to understand; this segment of the artery is completely surrounded by the venous plexus. The optic nerves and chiasm are situated above the gland, within the suprasellar cistern. Superior extension of the sellar contents, for example, from a pituitary neoplasm, can compress the chiasm from below, leading to visual abnormalities. Axons from the nasal retinal ganglion cells (which receive input from the ipsilateral temporal visual fields) cross in the chiasm en route to the opposite occipital cortex. Compression of these crossing fibers at the level of the chiasm leads to bitemporal hemianopsia, the pathognomonic neurologic manifestation of a sellar mass.

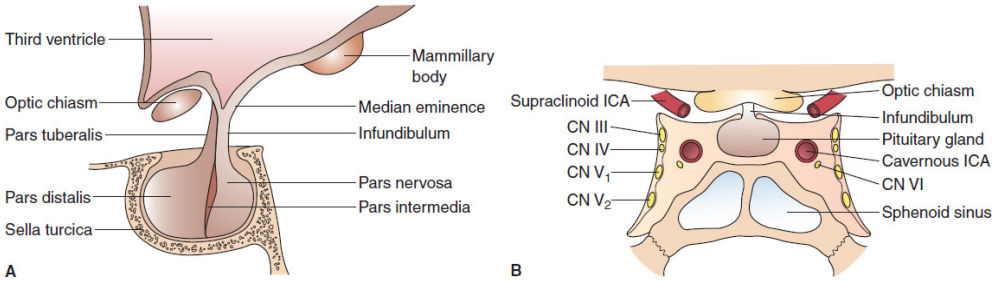

Figure 78.1 Sellar and parasellar anatomy. **A:** Sagittal view. **B:** Coronal view. ICA, internal carotid artery; CN, cranial nerve.

PATHOLOGY OF SELLAR LESIONS

Pituitary Adenomas

2 Pituitary adenomas are the most common tumors of the sella and most important surgical pathology of the sellar region, but the differential diagnosis of sellar lesions includes a variety of other pathologic entities (**Tables 78.1 and 78.2**). The true incidence of pituitary adenomas is difficult to determine as estimates differ depending on whether data are obtained from series of clinically significant tumors, autopsy findings, or imaging data. The prevalence of incidental sellar masses found in imaging 3 studies is about 10% to 22%, while it is about 14% in autopsy series.[1] The original pathologic classification was based upon staining affinity for histologic dyes, that is, acidophilic, basophilic, or chromophobe. A more recent and clinically useful pathologic classification from the WHO is based upon immunocytochemistry of various hormone subtypes.[2] The latest WHO classification of pituitary tumors (2017) includes the use of pituitary transcription factors to further characterize the adenomas.[3,4] Although not readily available in all centers, this new approach has led to diagnosis of more corticotroph, somatotroph, and gonadotroph adenomas and decreased the number of null cell adenomas, formerly called "null" because of weak immunocytochemistry staining.

Table 78.1 Tumors of the Pituitary Gland

Tumors of the Anterior Pituitary
Prolactin-producing adenoma
Growth hormone–producing adenoma
Adrenocorticotropin-producing adenoma
Gonadotropin-producing adenoma
TSH-producing adenoma
Null cell adenoma
Plurihormonal adenoma
Tumors of the Posterior Pituitary
Granular cell tumors
Pituicytoma
Spindle cell oncocytoma of the anterior pituitary
Sellar ependymoma

Prolactinomas (Lactotroph Adenomas)

Although less important in surgical series since the advent of dopamine agonist (DA) treatment, these are one of the most common pituitary adenomas with an incidence of 6 to 10 per million per year and a prevalence of 60 to 100 cases per million.[5] Also known as lactotroph adenomas, they arise from the prolactin-secreting cells of the adenohypophysis. They are commonly microadenomas in women, but especially in men may become large and invasive.

Table 78.2 Differential Diagnosis of Nonpituitary Sellar Lesions

Tumors
Craniopharyngioma
Meningioma
Neurohypophyseal gangliocytoma
Neurohypophyseal glioma
Granular cell tumor
Germ cell tumor
Chordomas and other soft tissue and bone tumors
Metastatic tumor
Cysts and malformations
Rathke's cleft cyst
Arachnoid cyst
Epidermoid cyst
Dermoid cyst
Vascular Lesions
Saccular aneurysm
Cavernous malformation
Inflammatory Conditions (lymphocytic hypophysitis, granulomatous hypophysitis)
Infiltrative Conditions (sarcoidosis, tuberculosis, Langerhans cell histiocytosis)

Modified from Gejman R, Hedley-Whyte T. Pathology of pituitary adenomas and other sellar masses. In: Swearingen B, Biller BMK, eds. *Diagnosis and Management of Pituitary Disorders*. Totowa, NJ: Humana Press; 2008.

Growth Hormone–Secreting Adenomas (Somatotroph Adenomas)

These tumors secrete excess levels of growth hormone (GH), leading to gigantism in children and acromegaly in adults. The incidence of acromegaly is about two to four cases per million per year.[6] These tumors may sometimes coexpress prolactin (mammosomatotroph adenomas) and rarely thyroid-stimulating hormone (TSH), as these cellular subtypes appear to arise from a common stem cell origin. They are typically invasive macroadenomas.

ACTH-Secreting Adenomas (Corticotroph Adenomas)

These tumors secrete excess levels of adrenocorticotropic hormone (ACTH), leading to excess production of cortisol by the adrenal glands (Cushing disease). They are uncommon, with an estimated incidence of 1.2 to 1.7 cases per million per year.[7] Pathologic diagnosis can be difficult, given that these tumors are often quite small and surgical specimens limited. Corticotroph adenomas typically exhibit loss of normal glandular architecture, with positive immunocytochemistry for ACTH.

TSH-Secreting Adenomas (Thyrotroph Adenomas)

These tumors are uncommon and typically comprise less than 1% of surgical series. Patients sometimes present with hyperthyroidism, but TSH staining without clinical hyperthyroidism is a more common scenario.[8]

Gonadotroph Adenomas

These tumors are common and comprise most of the "nonfunctioning" adenomas, as they express primarily hormone subunits, including beta-follicle stimulating hormone (FSH), luteinizing hormone (LH), or alpha subunits. They become symptomatic via mass effect, with compression of normal gland leading to pituitary hypofunction, or compression of the chiasm leading to visual field abnormalities. Very rarely, patients with these tumors may present with symptoms attributed to excess gonadal steroids, such as precocious puberty, irregular menses, or psychiatric manifestations.

Null Cell Adenomas

These tumors are uncommon; they manifest no clinical or immunocytochemical evidence of hormone secretion, but this may be a function of the sensitivity of the immunocytochemical technique.

"Atypical" Adenomas and Pituitary Carcinomas

Pituitary carcinoma is extraordinarily rare.[9] It is defined by the presence of distant metastases or cerebrospinal fluid (CSF) dissemination. While pituitary carcinomas may demonstrate extensive pleomorphism and/or necrosis, these pathologic findings are also seen in benign adenomas. The factors correlated with aggressive clinical behavior include an elevated Ki-67 labeling index

(MIB-1 fraction, proliferation index) and extensive p53 reactivity.[10] The previously used designation "atypical pituitary adenoma" has been abandoned by the current WHO classification system, in favor of "high-risk pituitary adenomas," describing their clinically aggressive behavior. This class includes the sparsely granulated somatotroph adenoma, the lactotroph adenoma in men, the Crooke cell adenoma, the silent corticotroph adenoma, and the newly introduced plurihormonal Pit-1-positive adenoma.[3]

Nonadenomatous Lesions of the Sella

Although pituitary adenomas are the most common neoplasms of the sella, a variety of other lesions can occur (**Table 78.2**).[11,12] We review them here briefly, maintaining our focus on lesions of the pituitary gland itself.

Neoplasms

Other neoplasms of the sella are uncommon but remain important in the differential diagnosis. *Craniopharyngiomas* are benign, solid, or partially cystic masses which presumably arise from remnants of Rathke's pouch.[13] They occur in a bimodal distribution with peaks in childhood and in older adults. The adamantinomatous type is typical in children, and is often cystic and partially calcified. The cysts contain a "motor oil"–appearing fluid, which can produce severe chemical meningitis when in contact with the CSF. The epithelium produces keratinaceous debris and cholesterol clefts. There is often a pronounced inflammatory reaction. The papillary type is seen almost exclusively in older adults, and is now known to be closely associated with the oncogenic BRAF V600E mutation, and to respond to treatment with BRAF and MEK inhibitors.[14] Papillary craniopharyngiomas may be cystic and/or solid, and can be adherent to surrounding neural structures, especially the optic nerves and hypothalamus. Surgical resection is challenging, recurrence is particularly common in children, and multidisciplinary treatment is essential. *Meningiomas* can arise anywhere along the intracranial dura, including within the sella. Meningiomas arising from the diaphragm sella or tuberculum sella can resemble pituitary adenomas and lead to endocrine dysfunction and chiasm compression. *Germ cell tumors* are most common in children and young adults and occur predominantly in males. The sella is the second most common location after the pineal region, and in many cases germ cell tumors arise

concurrently in both locations; the most common subtype is the germinoma followed by teratomas. *Metastases* to the sella are rare.[15]

Cysts

A variety of nonneoplastic cysts can arise within the sella. Although most are incidental findings seen on routine MRI imaging, large cysts can sometimes lead to endocrine dysfunction or chiasm compression. The most common cystic structure is *Rathke's cleft cyst,* arising from a remnant of Rathke's pouch within the pars intermedia. Rathke's cleft cysts can enlarge and may require drainage and/or resection. Most, however, are incidental findings, and require no treatment. *Epidermoid* or *dermoid cysts* arise from ectopic squamous or dermoid tissue and can fill with keratinaceous debris. *Arachnoid cysts* are CSF-containing structures which may also occur within the sella, presumably arising by means of a "one-way valve" mechanism allowing CSF to enter the cyst cavity but not exit; enlarging cysts may become clinically symptomatic. These must be distinguished from Rathke's cleft cysts and can be more challenging to treat. In contrast with Rathke's cleft cysts, which are self-contained and may be treated with fenestration, fenestration of arachnoid cysts results in a CSF leak that must be repaired at the time of surgery.

Inflammatory Lesions

Inflammatory lesions of the sella are rare. *Lymphocytic hypophysitis,* the most common, is thought to represent an immune-mediated phenomenon. It is sometimes seen in women during or after pregnancy, often in association with autoimmune disorders (Hashimoto's thyroiditis, atrophic gastritis). Lymphocytic hypophysitis has also been observed with increasing frequency in patients treated with immunotherapy.[16] The stalk and gland are enlarged and infiltrated with inflammatory cells, and pituitary dysfunction may occur. *Granulomatous hypophysitis* can arise from infections, tuberculosis or fungal, or as idiopathic granulomatous inflammation, either alone or in association with sarcoidosis. Other uncommon types of hypophysitis include xanthomatous, necrotizing, and IgG4 related.

MOLECULAR PATHOGENESIS

4 The molecular pathogenesis of pituitary adenomas remains incompletely understood.[17,18] The majority of pituitary adenomas are monoclonal in origin,[19,20] but the relative contributions of intrinsic genetic events and stimulation by hypothalamic hormones and local growth factors remain to be determined. Progression to malignancy with metastasis is rare, although local invasion is common. Genetic mutations predisposing to the development of pituitary adenomas include mutations in the *AIP* gene (aryl hydrocarbon receptor interacting protein) which has been found in some familial pituitary adenoma cohorts as well as some sporadic adenomas, especially in young acromegalic patients. The *MEN1* (multiple endocrine neoplasia) gene is also associated with familial adenomas, but is uncommon in sporadic disease, as is the *GNAS* mutation associated with McCune Albright syndrome. The *PRKAR1A* gene encodes a type 1A regulatory subunit of protein kinase A. Inactivating mutations of this gene are identified in 60% to 70% of patients with Carney complex, a condition of dominant inheritance, which may lead to acromegaly as a result of somatotroph hyperplasia or adenoma, as well as a variety of extrapituitary manifestations. Epigenetic modification has been suggested as a mechanism to influence gene expression without alteration in the underlying genome. Altered expression of genes encoding CDKN2A (cyclin-dependent kinase inhibitor), DAPK (death-associated protein kinase), FGFR2 (fibroblast growth factor receptor 2), among others, have been associated with sporadic pituitary adenomas. Loss of tumor suppressor genes may also be involved in adenoma pathogenesis. Loss of the *GADD45y* gene expression occurs in the majority of human pituitary adenomas, and products of the *AIP, PRKAR1A,* and *MEN1* genes may also act as tumor suppressors, with loss of these products in familial syndromes predisposing to the development of pituitary adenomas, in a "two-hit" model. Dysregulation of microRNAs, which can regulate translation of target mRNAs, has recently been found in pituitary adenomas, and differential expression can be associated with specific tumor subtypes. It is unclear which, if any, of these abnormalities are primary as opposed to epiphenomena in pituitary tumorigenesis.

ENDOCRINE EVALUATION

5 All patients with a sellar mass greater than 1 cm in diameter require endocrine evaluation for pituitary hypofunction, and patients with possible

pituitary adenomas of any size require evaluation for hypersecretory syndromes as well.[21] This is best done in conjunction with an endocrinologist experienced in the management of pituitary disease.

Pituitary Hypofunction (Hypopituitarism)

A complete history with questions targeted at change in energy, weight, appetite, thirst, urination as well as irregular menses or sexual dysfunction, along with physical examination and morning blood draw, are very important in diagnosing pituitary hypofunction. The key labs are sodium, free thyroxine (free T4) and 8 **AM** cortisol, especially in patients requiring surgical treatment, as unrecognized hypothyroidism or hypoadrenalism may have a profound effect on response to anesthesia and complicate recovery from surgery and can also cause hyponatremia. To avoid repeated blood draws one might add TSH, ACTH, estradiol/testosterone, LH, FSH, GH, and insulin-like growth factor 1 (IGF1) to fully characterize the pituitary axes.

Central (secondary) hypothyroidism is characterized by low free T4 levels in association with inappropriately low or normal TSH. Central hypogonadism is characterized by low morning testosterone levels in men, and low estradiol levels in women, associated with inappropriately low or normal FSH and LH. Central hypoadrenalism is characterized by low morning cortisol levels in association with inappropriately low or normal ACTH. Morning serum cortisol ≤3 mcg/dL is strongly suggestive of adrenal insufficiency (in the absence of corticosteroid or opioid medications), whereas morning serum cortisol ≥18 mcg/dL assures sufficient adrenal function. Intermediate cortisol levels are indeterminate with regard to adrenocortical function and require further evaluation, including stimulation, based on clinical suspicion. GH deficiency diagnosis requires a low IGF1 in the setting of other deficient pituitary axes, or a GH stimulation test, as GH is highly pulsatile and random levels are rarely useful.

Replacement therapy, especially levothyroxine and glucocorticoid (prednisone or hydrocortisone), should be considered as soon as the diagnosis of insufficiency is confirmed, especially in those patients who require surgery. Glucocorticoid replacement should precede thyroid hormone replacement in order to avoid precipitating adrenal crisis. Posterior pituitary dysfunction, typically diabetes insipidus (DI) is uncommon as a presenting symptom and points away from pituitary adenoma and toward alternative etiologies, such as

germ cell tumor, in the differential diagnosis of a sellar mass. DI is characterized by polyuria with polydipsia, dilute urine, and tendency to hyperosmolar dehydration if access to water is limited or thirst is deficient; confirmation may require a water deprivation test in uncertain cases.

Hypersecretory Syndromes

Pituitary adenomas may be associated with excess hormone secretion, giving rise to well-characterized clinical syndromes. It is important to recognize these preoperatively, especially since surgical treatment in some instances is not first-line therapy. In particular, patients with prolactin-secreting pituitary adenomas may be offered a trial of medical therapy, as DAs are effective in controlling tumor size and relieving mass effect.

Excess Prolactin (Prolactinomas)

Excess prolactin leads to the syndrome of amenorrhea and galactorrhea in women, and the syndrome of hypogonadism with sexual dysfunction in men. Mildly elevated prolactin levels may be related to medication effects (e.g., dopamine antagonists, psychotropic medications), macroprolactin (an inactive macromolecule, prolactin bound to IgG, with no physiologic effect and requiring no intervention), a microprolactinoma (<1 cm), or "stalk effect" (**Table 78.3**). Prolactin release from the anterior pituitary is, under normal circumstances, regulated by continuous inhibition; dopamine is continuously needed to inhibit the secretion of prolactin from the lactotrophs. The "stalk effect" occurs when a non–prolactin-secreting mass exerts pressure on the infundibulum and thereby diminishes the amount of dopamine that reaches the anterior pituitary (diminished inhibition), resulting in increased prolactin release. Usually the serum prolactin level associated with "stalk effect" is less than 150 ng/mL, and this must be distinguished from a prolactinoma, as the treatments are potentially different.[22] A large tumor in the setting of a mildly elevated prolactin level likely represents "stalk effect" rather than a true prolactinoma; a mildly elevated prolactin level in the setting of a microadenoma likely represents a true microprolactinoma.

Giant macroprolactinomas may secrete prolactin exuberantly, giving rise to the "hook effect," an immunoassay artifact that occurs in the presence of very high serum concentrations of prolactin, leading to substantial underreporting of

prolactin levels and potentially erroneous diagnosis. To avoid this artifact, prolactin should be measured in serially diluted serum specimens.[23]

Table 78.3 Causes of Hyperprolactinemia

Physiologic	Pathologic (Pituitary)	Pathologic (Other)
Pregnancy	Prolactin-secreting adenoma	Medications (e.g., antipsychotics, antidepressants, metoclopramide, verapamil, opioids, oral contraceptives)
Lactation	Growth hormone and prolactin-cosecreting tumor	Polycystic ovary syndrome
Physical stress	Any sellar mass causing "stalk effect"	Primary hypothyroidism
Sexual intercourse	Empty sella	Renal insufficiency
Nipple or breast stimulation	Hypothalamopituitary irradiation or trauma	Hepatic insufficiency (as in chronic liver disease)
Macroprolactin	Hypothalamopituitary infiltrative conditions (e.g., hypophisitis, sarcoidosis or tuberculosis)	Chest wall lesions

Excess Cortisol (Cushing Syndrome)

Hypercortisolemia of any cause is known as "Cushing syndrome." Patients with this condition may present with manifestations of various kinds, including metabolic (central adiposity, glucose intolerance), catabolic (muscle wasting, bone loss, skin thinning, spontaneous ecchymoses), cardiovascular (hypertension, thromboembolism, coronary artery disease), mineralocorticoid

(edema, hypokalemia), hypogonadal, hyperandrogenic (hirsutism, acne), increased risk of infections, and psychiatric symptoms. Most commonly the cause is iatrogenic administration of corticosteroids; the second-most-common etiology is a functioning adenoma. Approximately 80% of patients with neoplastic causes of Cushing syndrome have a pituitary adenoma (Cushing disease). The remainder have adrenal tumors (adenoma, carcinoma) or ectopic tumors (nonpituitary ACTH production).[24]

The diagnosis of Cushing disease can be difficult and is best made by an endocrinologist experienced in neuroendocrine disorders. Hypercortisolemia is determined by measurement of 24-hour urine free cortisol levels, nonsuppressed serum cortisol level after low-dose dexamethasone, and elevated late-night salivary cortisol levels. These tests help establish the presence of cortisol excess and differentiate between Cushing syndrome and other states associated with high cortisol levels (**Table 78.4**). An ACTH level is the next step in investigating the source of Cushing syndrome: low ACTH levels (<5 pg/mL), implying ACTH-independent etiology, are seen with adrenal disease, as the autonomous production of excess cortisol results in normal feedback inhibition of pituitary ACTH. High or inappropriately normal ACTH levels (>15 pg/mL), implying ACTH-dependent etiology, are seen with pituitary or ectopic etiologies. ACTH levels between 5 and 15 pg/mL, although not very common, fall into a grey area and cannot clearly point toward a central or adrenal source, necessitating further dynamic testing.

If the ACTH level is elevated an MRI of the pituitary is the next step. If no pituitary lesion is found (up to 40% of cases), or if an adenoma <6 mm is identified, further testing to confirm a pituitary source of ACTH is warranted. Bilateral inferior petrosal sinus sampling (IPSS) is the gold standard in such cases.[25] This is a catheter-based endovascular procedure in which ACTH levels obtained from the inferior petrosal sinuses (both before and after the intravenous administration of a corticotropin-releasing hormone [CRH] analog) are compared to levels obtained in the vena cava. A central-to-peripheral ACTH ratio of greater than 3:1 after the administration of CRH is considered diagnostic of a central (pituitary) source, even in the absence of tumor visualization on MRI.[26] The value of this procedure in predicting the laterality of the microadenoma is debated, but newer protocols, incorporating prolactin gradients, have improved the accuracy of lateralization predictions into the 80% range.[27] If IPSS is not available a CRH stimulation test in

combination with a high-dose dexamethasone suppression test can help to confirm a pituitary source.

Excess Growth Hormone (Acromegaly)

Excess GH secretion by a pituitary adenoma prior to epiphyseal closure leads to gigantism, while GH excess in adulthood leads to acromegaly. Adult patients typically report increased ring and shoe size, dental and jaw abnormalities with malocclusion, coarsening of facial features, headache, hoarseness, skin tags, increased sweating, carpal tunnel syndrome, arthralgias, snoring, and sleep apnea. Higher rates of hypertension, diabetes, hyperlipidemia, kidney stones, cardiomyopathy, gallstones, colon polyps, and thyroid nodules are all related to the excess of GH. Because these changes occur slowly over time, diagnosis can be delayed, and these tumors are often large and invasive at the time of detection. Acromegalic patients have a mortality risk on the order of two to three times that of the general population if GH excess is not adequately controlled. Many of these changes are reversible with successful control of the disease, but skeletal abnormalities are not.

Table 78.4 Conditions Associated with Cortisol Excess

Cushing Syndrome	Cortisol Excess in Patients with Some Manifestations of Cushing Syndrome (but No Tumor): "Pseudo-Cushing"	Cortisol Excess in Patients without Manifestations of Cushing Syndrome
Pituitary adenoma (Cushing disease)	Depression, anxiety, obsessive–compulsive disorders	Acute illness, injury, or surgery
Ectopic ACTH secretion	Alcoholism	Hospitalization
Adrenal tumor (adenoma, carcinoma) or hyperplasia	Severe obesity	Anorexia nervosa
Iatrogenic	Poorly controlled diabetes mellitus	High corticosteroid–binding globulin (CBG) levels
Surreptitious	Polycystic ovary syndrome Familial glucocorticoid resistance	

Because GH secretion is pulsatile, random GH measurements are not useful. The diagnosis is made by an elevated serum IGF1, produced by the liver overstimulated by the excess of GH. IGF1 assays are technically challenging and require gender and age adjustment.

Inadequate suppression of GH after a glucose load (administered in an oral glucose tolerance test as a 75-g bolus) confirms the diagnosis when the IGF1 is less than two times upper level of normal. Whether a GH nadir cutoff of 1

mg/L, 0.4 mg/L, or even lower can be used in patients with diabetes or other comorbidities is still a matter of debate, and in these situations the patient should be referred to an endocrinologist with more in pituitary diseases.[28]

TSH Adenomas

While immunocytochemical staining for TSH is not uncommon, secretion of active thyrotropin leading to central hyperthyroidism is rare. The hyperthyroidism tends to be mild, with palpitations, tremor, heat intolerance, and a diffuse goiter being more frequently found at diagnosis. The majority of these tumors are macroadenomas and may therefore be associated with mass effect. Biochemically, they demonstrate a nonsuppressed (inappropriately normal or increased) TSH level. This syndrome needs to be distinguished from resistance to thyroid hormone which can lead to a similar hormone profile.

Endocrine Evaluation of a Pituitary "Incidentaloma"

With the widespread availability of MRI, it is not uncommon for the radiologist to report the incidental finding of a pituitary mass. The endocrine evaluation requires screening of pituitary hormone levels to determine possible hypo- or hyperfunction, which will help to guide further therapy. Pituitary hyperplasia (which occurs when the pituitary is stimulated to produce a pituitary hormone in much higher quantity than usually) can be difficult to distinguish from a true pituitary adenoma, but requires an appreciation of the clinical setting to guard against unnecessary surgical intervention. Typically it is found in women going through puberty into early adulthood, menopause (proliferation of gonadotroph cells), pregnancy and lactation (proliferation of lactotrophs), or severe primary hypothyroidism (thyrotroph hyperplasia). Rarely, ectopic secretion of GH-releasing hormone or CRH may lead to somatotroph or corticotroph hyperplasia, respectively. All these conditions need to be distinguished from true pituitary adenomas.

NEUROLOGIC EVALUATION IN PITUITARY ADENOMAS

The primary neurologic manifestation of a pituitary mass is ophthalmologic, from compression of the optic nerves or chiasm traveling through the suprasellar cistern. Because the ipsilateral retinal ganglion cell axons cross in the optic chiasm en route to the contralateral occipital cortex, the pathognomonic finding on visual field examination is bitemporal hemianopsia. The chiasm may sometimes be associated with a relatively short intracranial optic nerve segment ("prefixed") or a relatively long intracranial optic nerve segment ("post fixed"). Depending upon the relative position of the tumor and chiasm, compression may also lead to uni- or bilateral optic nerve dysfunction, or compression of an optic tract, with resulting homonymous hemianopsia. Patients may sometimes report decreased acuity, although central vision is usually preserved unless compression is severe. Painless, unilateral decrease in color vision is a sensitive sign of early optic neuropathy, as is an afferent pupillary defect (Marcus Gunn pupil). This can be demonstrated by the "swinging flashlight test," in which light shown into the affected eye leads to a paradoxical increase in pupillary size, as the ipsilateral pupilloconstrictor fibers have been damaged by ipsilateral optic nerve compression and transmit relatively decreased retinal activity. Although pituitary adenomas often invade the cavernous sinus and displace the cranial nerves within, dysfunction of cranial nerves other than the optic nerve is uncommon. When other cranial neuropathies, such as oculomotor dysfunction, are present, and especially if they are of sudden onset, one should suspect a rapidly expanding mass, that is, pituitary apoplexy, or a more aggressive tumor, for example, a malignancy. Similarly, pituitary adenomas often circumscribe but rarely constrict the cavernous carotid artery, and rarely cause neurovascular dysfunction; when neurovascular dysfunction is present an alternate pathologic diagnosis (especially meningioma) should be considered.

Headaches can be part of the presentation for pituitary tumors, possibly via stretching of the surrounding dura mater, dural inflammation in apoplexy, or a form of trigeminal neuralgia. The headaches tend to be daily, retro-orbital or frontal, and throbbing. Such headaches are more frequently associated with cystic lesions and functioning adenomas (especially acromegaly), and resolve with surgery in only slightly more than 50% of patients.[29]

IMAGING OF PITUITARY ADENOMAS

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) represents the standard of care in evaluating pituitary tumors. Useful sequences for imaging the sella include T1 coronal and sagittal imaging before and after gadolinium contrast administration. Other sequences (e.g., T2 coronal) may be useful, especially in the evaluation of cystic structures (fluid is generally hyperintense on T2) and previous hemorrhage (which may be dark on T2). Because of the relatively decreased vascularity of adenomas compared with the normal gland, timing of scanning relative to the administration of gadolinium is important; adenomas are generally focally hypointense to normal gland. Dynamic scanning using thin section gradient echo sequences may improve the sensitivity of visualization with small microadenomas (in Cushing disease, for example), but gland heterogeneity may lead to decreased specificity. When preparing for surgery, it is essential to establish the location of the tumor with respect to the carotid arteries. Contrast-enhanced MRI sequences assist in assessing the extent of tumor invasion of the cavernous sinuses, and, if present, the degree of circumferential contact between the tumor and the cavernous segment of one or both carotid arteries.

Computerized Tomography

Computerized tomography (CT) scanning has largely been supplanted by MRI, but remains useful in the delineation of bony anatomy relevant to surgical planning and intraoperative navigation. At many centers it is common for pituitary surgery to be performed by a team comprising an otorhinolaryngologist and a neurosurgeon, the former performing the approach and the latter performing the tumor resection. Particularly when endoscopic sinus surgical approaches are used, preoperative CT is useful in defining the bony septations of the nasal sinuses, which are often poorly defined on MRI. Additionally, in those few patients who cannot undergo MRI, thin section coronal CT after contrast administration can be used to demonstrate a pituitary lesion. The presence of calcification on CT scanning can assist in the differential diagnosis; for example, a calcified cystic lesion, especially in a child, is highly likely to represent a craniopharyngioma.

MRI Characteristics of Pituitary Tumors and Other Sellar Lesions

The normal gland enhances relatively homogenously. It should be no greater than about 8 mm in coronal height in males and 10 mm in females. The infundibulum should be midline. The posterior pituitary may be bright on T1 without contrast (thought to represent secretory granules in axon terminals), although this is not a constant finding.

Pituitary adenomas should be focally hypointense relative to normal gland on T1 sequences after contrast. Microadenomas (<1 cm) may not significantly disrupt gland architecture. Macroadenomas (>1 cm) show upward bowing of the diaphragm sella associated with stalk deviation, and larger macroadenomas often demonstrate compression of the chiasm. The normal gland can be compressed, usually superiorly and posteriorly. The cavernous sinuses are variably involved; it can be difficult to distinguish invasion from compression. Lesions surrounding the cavernous carotid are obviously invasive; lesions which circumscribe less than 25% are usually compressive. It has been suggested than lesions which circumscribe less than 67% of the carotid diameter are not invasive, but this is very variable. Adenomas can also be cystic, and in such cases may show T1 bright signal before contrast consistent with high protein fluid or hemorrhage.

Craniopharyngiomas may be cystic or solid, and intra- or suprasellar. Characteristics of the cyst fluid can vary with the protein content, with greater T1 hyperintensity associated with higher protein. The cyst wall is commonly calcified (easily verifiable on CT), especially in children. Since the tumor is often suprasellar, involving the stalk and hypothalamus, the gland is typically compressed inferiorly from above.

Pituitary cysts can demonstrate variable imaging characteristics, also depending upon their protein content. Rathke's cleft cysts arise posteriorly in the sella, or sometimes along the stalk. They can be T1 hypo- or hyperintense depending on protein content, and can compress the gland anteriorly or from above. The cyst wall is usually thin, with minimal enhancement. If there is a solid component or calcification, the diagnosis is more likely to represent a craniopharyngioma. Arachnoid cysts of the sella contain fluid isointense to CSF. They exhibit minimal if any enhancement of the wall, as the cyst is lined

with a thin arachnoid layer. The gland is usually compressed inferiorly or anteriorly.

Germinomas usually involve the posterior gland, stalk, and/or hypothalamus. They are typically brightly enhancing, and the borders are relatively indistinct. An enhancing lesion of the posterior sella associated with a pineal mass is highly likely to represent a germinoma. Germ cell tumors may disseminate along CSF pathways, leading to enhancement around the fourth ventricle. *Meningiomas* are usually brightly enhancing, often more so than the gland itself. As they arise from the dura, they can be variably located in and around the sella. If they arise from the diaphragm, they can be difficult to distinguish from adenomas, but usually compress the gland from above. Meningiomas are often associated with a dural "tail," which spreads out from the central mass of the tumor, sometimes with focal hyperostosis. Meningiomas of the cavernous sinus can lead to carotid constriction, whereas adenomas rarely do. This phenomenon is best seen on coronal images when comparing the transverse diameter of the intracavernous carotid arteries. *Metastases* are typically locally invasive, brightly enhancing, rapidly growing, and associated with a clinical history of cancer. They can spread hematogenously to the gland, but more frequently represent focal metastases to parasellar bony structures. When invading the cavernous sinus they can lead to a cavernous sinus syndrome, whereas adenomas rarely do.

SURGICAL TECHNIQUE

6 Although the first reported pituitary operation was a craniotomy done in 1889 by Sir Vincent Horsley,[30] the first transsphenoidal approach was described in 1907 by Hermann Schloffer, a Viennese otolaryngologist, when he reached the sphenoid via a lateral rhinotomy incision.[31] Less disfiguring approaches were devised by the American neurosurgeon Harvey Cushing, who, with William Halsted, devised the sublabial approach in 1910, and another Viennese otolaryngologist, Oscar Hirsch, who described a fully endonasal procedure.[32] Variants of these approaches remain in use today. Cushing performed over 200 transsphenoidal operations with an overall mortality rate of 5%—amazingly low given the lack of imaging, antibiotics, hormone replacement, and modern visualization—but decided in 1927 that the craniotomy was the more preferred procedure. With his decision, the

transsphenoidal approach fell into relative disfavor, although kept alive by Dott in Edinburgh and Guiot in Paris, who introduced the use of intraoperative fluoroscopy as a navigation technique. Jules Hardy of Montreal described the use of the operating microscope and reported the first removal of a pituitary microadenoma in 1962, bringing pituitary surgery into the domain of microneurosurgery.[33] Since the 1990s, pituitary surgery has been reshaped by endoscopic techniques developed collaboratively by otorhinolaryngologists and neurosurgeons. With improvements in endoscope technology and compatible surgical instrumentation, purely endoscopic operations became commonplace in the field of sinus surgery, and these advances led to the use of endoscope-assisted and eventually purely endoscopic techniques for the management of pituitary adenomas and other lesions of the anterior skull base.[34]

The transsphenoidal approach is relatively noninvasive, as it employs the nasopharynx and sphenoid sinus to access the skull base, but the surgeon is constrained to operate through a narrow corridor, to a relatively deep target, surrounded by important structures (the carotid arteries and optic apparatus). The surgeon must (1) approach and navigate to the tumor, (2) visualize the pathology, and (3) maximally resect the tumor while minimizing damage to adjacent structures, including the normal gland and infundibulum.

Approach

There are two principal transsphenoidal approaches to the sella in use today, both of which are endonasal (**Fig. 78.2**). The sublabial approach, as well as the subfrontal craniotomy, deserve mention primarily for their historical significance. The pterional craniotomy remains useful for certain sellar lesions with significant suprasellar extension.

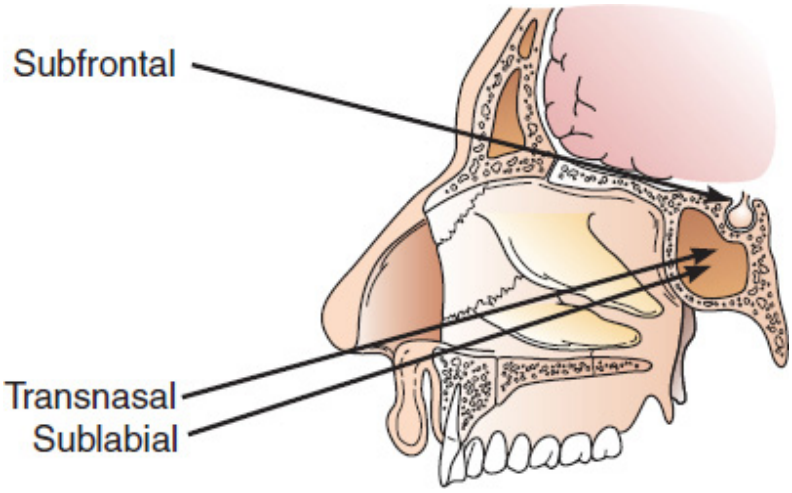

Figure 78.2 Surgical approaches to the sella.

The two endonasal approaches are limited to some degree by the width of the nasal apertures, but the advent of endoscopic systems allows contemporary surgeons access to adequate corridors for visualization and manipulation, through the nasal sinuses to the sella and anterior skull base. One endonasal approach, favored in some centers at which neurosurgeons perform both the approach and the tumor resection, uses a submucosal tunnel along the septum through an anterior mucosal incision immediately posterior to the columella. Postoperatively, nasal packing is used to reapproximate the mucosa to the septum. The direct endonasal approach, typically favored in centers at which endoscopic surgery is the norm, with the endonasal approach being performed by an otorhinolaryngologist, uses either an incision at the insertion of the septum into the face of the sphenoid, or an enlargement of the natural ostia, with a posterior septectomy. This approach facilitates bimanual surgery and operation through both nares.

Navigation

It is critical to maintain accurate orientation in the sellar approach, as the face of sella is bounded immediately laterally by the carotid protuberances, and superolaterally by the optic canals. The insertion of the nasal septum posteriorly is usually a midline structure and can be used for orientation, while the sphenoid septations are very variable, and can be used for orientation only when correlated with preoperative imaging. Lateral intraoperative fluoroscopy was used at some centers in the era before neuronavigation. In the last two

decades, neuronavigational devices have become a ubiquitous standard of care. These systems establish a three-dimensional (3D) reference frame by registering facial and bony anatomy with preoperative imaging, and they can be used to correlate intraoperative anatomy with preoperative imaging by means of a navigational "stylus" recognized by the device in real time. This gives 3D information to guide the approach, but is dependent on the accuracy of the registration, and is less valuable in determining the adequacy of resection and orientation within the tumor, as tumor anatomy can change during resection.

VISUALIZATION

Hardy introduced the use of the intraoperative microscope to pituitary surgery and it remains in widespread use today. After the introduction of the rigid endoscope to field of sinus surgery by otorhinolaryngologists, its use in transsphenoidal surgery was reported by Jankowski in 1992[35]; its utility and efficacy were confirmed in multiple studies and reviews in the ensuing two decades. In the present generation, endoscopy has replaced microscopy at many centers as the preferred mode of surgical visualization in transsphenoidal surgery. Advantages of the microscopic approach are the superb optics and binocular vision; a major disadvantage is the requirement for direct line-of-sight viewing, though for smaller tumors, including the microadenomas of Cushing disease, this disadvantage may not be significant. The endoscope affords a wider field of view and the ability to see at angles off the primary visual axis. Early endoscopes offered only monocular vision with no depth of field, though 3D endoscopes are under development. Although the endoscopic technique has the potential to be less invasive, the need to provide a surgical corridor sufficient for both the endoscope and working instruments may at times require greater dissection within the nasal sinuses. A number of meta-analyses have been published comparing endoscopic and microscopic techniques. The overall results for secretory tumors, where there are defined biochemical criteria for remission, appear similar, whereas endoscopy offers advantages in the setting of larger nonsecretory tumors and those invading the cavernous sinuses.

Determining the Adequacy of Resection

As most pituitary tumors are removed by internal decompression allowing collapse of the tumor capsule, there may be no direct visualization of the adequacy of resection. Endoscopic inspection of the tumor capsule can sometimes provide an indication, but prolapse of the diaphragm as the capsule collapses (itself an indication of adequacy of decompression) can make thorough internal visualization difficult. Intraoperative MRI (iMRI) has been used in the determination of resection adequacy, as the technique allows the surgeon to visualize areas of residual tumor not seen with direct inspection. A number of studies have reviewed the utility of intraoperative imaging. Most report that additional tumor resection can be achieved in about 20% of cases, but this is partly a function of when, during the course of the procedure, the surgeon chooses to image, as premature imaging may bias the results in favor of iMRI.[36] In addition, intraoperative imaging can show whether the chiasm has been adequately decompressed (which correlates with postoperative visual improvement) and may assist in the avoidance of postoperative complications. The iMRI equipment is costly, however, and requires significant alterations in surgical workflow and operative time, with the small but present risk of operating in close proximity to a high-strength magnetic field. It has been debated whether resection can be better optimized with the use of the iMRI versus the endoscope, although these technologies are not mutually exclusive and are used in combination at some centers. Each approach has its adherents. In those few studies combining the use of endoscopy with the iMRI, most suggest that some degree of additional resection can be achieved after imaging.[37–39]

A comparison of preoperative, immediate postoperative, and 1-year–postoperative MR images in a patient with a nonfunctioning macroadenoma causing elevation and compression of the optic chiasm is shown in **Figure 78.3**.

Surgical Technique

There are a number of variations in surgical technique, determined by the preference of the surgeons and the dictates of the anatomy. The patient is given antibiotics and stress-dose steroids preoperatively. Protocols for antibiotic use are not standardized, but a typical neurosurgical antibiotic regimen is almost universally extended to broad-spectrum coverage when a high-flow CSF leak is expected or encountered. A lumbar drain may be placed preoperatively if a

high-flow CSF leak is anticipated, and the abdomen may be prepared for harvest of a fat graft to be used in repairing the associated skull base defect. In selected cases, intrathecal fluorescein may be administered in order to assist in the detection of small CSF leaks. Almost all patients, except for patients with Cushing disease, are given stress-dose corticosteroids. After the induction of general endotracheal anesthesia, the patient is positioned supine. The head may be turned toward the surgeon or in a neutral position if two surgeons will together be performing an endoscopic approach while standing on opposite sides of the patient. At some centers, following the endonasal approach, the otorhinolaryngologist maneuvers the endoscope while the neurosurgeon performs the tumor resection; others prefer to place the endoscope on a fixed holder during the tumor resection. The head of the patient can be held in a gel headrest or pinned using the Mayfield clamp. If neuronavigation is used, the reference fiducials or surface anatomy is registered. The area of the proposed nasal mucosal incision is infiltrated with local anesthesia with epinephrine as a vasoconstrictor.

With a direct endonasal approach the incision is made along the posterior septum, and either the septum is fractured and deviated contralaterally, or a posterior septectomy is performed.[40,41] The microscopic approach employs either a sublabial incision or an endonasal transseptal approach. In both cases a nasal speculum is introduced, fracturing the septum and compressing the turbinates laterally. With the endoscopic approach, the middle turbinate may require removal to increase access. The face of the sphenoid is opened, and any septations impeding access are removed. Anatomy of the sphenoid septations gleaned from preoperative imaging can be useful in guiding the approach to the midline sella, which is drilled to dura. Diamond burr drill bits are used near the dura. The dura may be lightly cauterized prior to the dural incision.

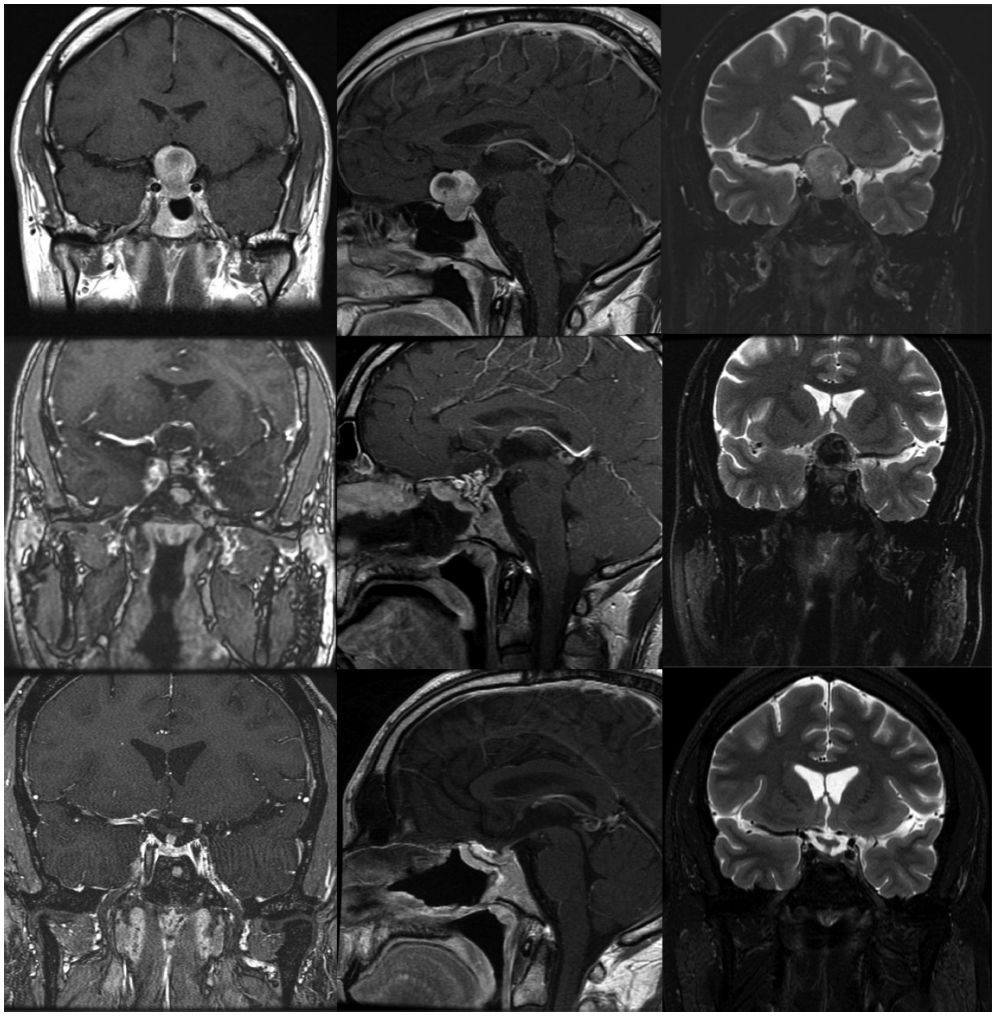

Figure 78.3 MR imaging of the sella before and after resection of a pituitary macroadenoma.

For macroadenomas, the tumor is usually immediately evident. The typical strategy involves dissecting the tumor from the dural leaflets, defining the interface between the tumor and normal gland, internally debulking the tumor with ring curettes, then completing the resection in a manner that preserves the normal gland. The normal gland can usually be distinguished by color and consistency, and in the case of macroadenomas is usually compressed posteriorly and superiorly. As the resection proceeds the diaphragm should prolapse into the operative field, particularly in cases in which the chiasm has been compressed. After tumor removal, the resection cavity is inspected for residual tumor; angled endoscopes can be useful in visualizing areas not in the direct line of sight.

When approaching microadenomas, especially those causing Cushing disease, detection can be difficult. If there is strong evidence from preoperative imaging, dissection in the indicated region may be attempted. Some surgeons approach microadenomas by dividing the gland into quadrants and taking biopsies from each quadrant. If no tumor is found on frozen section analysis, a hemihypophysectomy can be performed guided by IPSS.

Hemostasis is achieved by packing with any number of available hemostatic materials. After achieving hemostasis, many surgeons pack the tumor cavity with fat, muscle, or absorbable hemostatic material. A water-tight seal is essential if a CSF leak has been created. Many techniques have been described for achieving a water-tight reconstruction of the anterior skull base in this context.[42] When a microscopic approach is used, a fat graft is buttressed in place and the sellar floor reconstructed with septal cartilage or bone, titanium mesh, or proprietary, commercially available materials. Fibrin glue or other sellar sealant can be used if needed. When an endoscopic approach is used, such techniques are often supplemented by rotating a vascularized nasoseptal flap over the reconstructed skull base defect. Displaced turbinates and septum are then returned to their physiologic positions. With a direct endonasal approach, nasal packing is not always used. If a submucosal tunnel was created during the approach, nasal packing is placed. The use of iMRI can be timed at the discretion of the surgeon. Some surgeons maintain the sterile field and image before final closure; others complete the closure (since reopening is usually straightforward) and image prior to reversal of anesthesia.

Postoperative Management

Careful monitoring in the postoperative period is essential. Most patients require only one to two nights of hospitalization; an ICU stay is usually not necessary. Potential complications include postoperative hemorrhage, CSF leakage, meningitis, epistaxis, and endocrine dysfunction (including DI, the syndrome of inappropriate antidiuretic hormone secretion [SIADH], and hypopituitarism).

1. *Cavity Hemorrhage and Visual Compromise.* Postoperative hemorrhage can occur into the tumor resection cavity with resulting visual compromise. Thus, frequent testing of postoperative acuity and confrontational fields is necessary. Subjective reporting by the patient must also be taken seriously. Immediate

reexploration may be required, even in the absence of convincing findings on neuroimaging.

2. *Cerebrospinal Fluid Fistula.* CSF leakage can be sometimes difficult to differentiate from postoperative nasal drainage. Positional drainage (nose-down) and CT evidence of pneumocephalus are suggestive of persistent CSF leak. The classic confirmatory test to differentiate CSF from nasal drainage involves assaying collected fluid for tau protein (beta transferrin), which is found in CSF but not in nasal secretions or blood. Management options include the insertion of a lumbar drain to lower intracranial pressure and reduce flow through the fistula for several days, in order to allow for spontaneous closure of the leak, while maintaining antibiotic coverage. In the presence of a persistent, high-flow leak the optimal course is often reexploration and repacking of the tumor bed with closure of the fistula.
3. *Meningitis.* Infection in the immediate postoperative period is rare. Prophylactic antibiotic coverage is maintained for 24 hours, or until the nasal packing is removed. Delayed fever, especially with signs of meningitis, requires evaluation with a lumbar puncture; an occult CSF leak should be suspected. Patients may be at increased risk of sinus infection for many months.
4. *Epistaxis.* Bloody nasal secretions are common, and usually clear with nasal irrigation. Frank epistaxis is rare, usually occurs 2 or 3 weeks after surgery, and is most often caused by delayed hemorrhage from a septal branch of the sphenopalatine artery. It can sometimes be managed with nasal packing, but may require cauterization or clipping, or rarely embolization.
5. *Postoperative Endocrine Changes.* Postoperative endocrinologic changes are best managed in conjunction with an experienced endocrinologist.
   5.1. *Diabetes Insipidus.* Water/sodium imbalances occur in up to 75% of the patients who undergo transsphenoidal surgery in the first 14 days after surgery, with transient DI being the most common abnormality. Transient DI usually resolves spontaneously within days and permanent DI is unlikely (1% to 2% of patients). It is important to monitor liquid intake and urine output, urine specific gravity, and serum sodium levels in the immediate postoperative period, and to treat with hypotonic fluid and desmopressin if needed. Mild cases can be treated with ad lib fluid intake if the thirst mechanism is intact.

5.2. *Hyponatremia.* Immediate postoperative hyponatremia appearing on postoperative days (PODs) 1 to 3 tends to be mild and self-limited. Delayed hyponatremia is thought to be secondary to inappropriate release of the stored antidiuretic hormone (SIADH) following mechanical manipulation of the posterior pituitary. This syndrome typically starts between PODs 5 and 8 and can be severe (from nausea and headache to confusion and seizures). It is a significant cause of morbidity and is the leading cause of readmission after transsphenoidal surgery. More recently different regimens of fluid restriction have decreased the severity of hyponatremia and readmission (e.g., 1 L daily fluid restriction started POD 4 and maintained until sodium is checked and found normal POD 5–8).[43] Mild SIADH usually responds to fluid restriction and oral salt supplements. In more severe cases furosemide, urea, or hypertonic saline need to be used. It is important not to correct the hyponatremia too quickly in order to avoid central pontine myelinolysis. The hyponatremia usually resolves within 1 week with supportive care.[44]

5.3. *Hypopituitarism.* Immediate postoperative monitoring for pituitary insufficiency, especially hypoadrenalism and hypothyroidism, is necessary. Some centers prophylactically treat with replacement steroids until adequate cortisol levels can be proven. Another approach is to check an 8 AM cortisol POD 1–2, at least 24 hours after any steroids have been administered, and to discharge on physiologic corticosteroid replacement only patients with cortisol below a certain level (e.g., 13 to 15 mg/dL).[45] Central hypothyroidism might take longer to become evident on laboratory testing and it is recommended to check free T4 later (this test can be obtained concurrent with the sodium level required to monitor for delayed hyponatremia on POD 5–8). Complete postoperative hormone assessment is usually performed at 6 to 8 weeks postoperatively in order to establish remission of hormone excess and reassess pituitary function. New pituitary hormone deficiencies develop in in 5% to 10% of patients, while pre-existing pituitary hormone deficiencies may resolve in 30% to 40% of patients postoperatively.

5.4. *Biochemical Remission.* Patients treated for hyperfunctioning adenomas require special attention in the immediate postoperative period, especially patients with Cushing disease. Surgical remission leads to immediate lowering of ACTH and cortisol levels, and steroid replacement is required as the normal gland will remain suppressed for months. Patients can develop hypoglycemia, hypotension, tend to be hypercoagulable, and need higher doses of corticosteroid at the time of hospital discharge. Patients with acromegaly in remission postoperatively may have polyuria as GH levels fall, without developing DI.

RESULTS AND COMPLICATIONS

In considering the results of pituitary surgery, the most important outcome measures relate to resolution of presenting symptoms (visual, endocrine, or other), rates of gross total tumor removal and of biochemical remission in the case of functioning adenomas, and the durability of these results. The incidence, severity, and management of each of the principal complications are also important to understand, as are considerations of cost and postoperative quality of life. Additional questions relate to whether outcomes have changed over time, and whether contemporary evidence favors particular surgical techniques. Results from a number of meta-analyses addressing these outcome measures are summarized in **Table 78.5**.

E, endoscopic; M, microscopic.
Boldface E*/M* indicates statistically significant difference favoring endoscopic/microscopic approach.
NSD, no/not significant difference.
RR, risk ratio; OR, odds ratio; d, days.

Reviews of the literature on outcomes after transsphenoidal surgery require recognition of a number of factors potentially affecting the interpretation of the results. Endocrine diagnostic techniques, biochemical criteria for remission for secretory tumors, and surgical techniques have changed over time, which can make comparisons difficult. Publication and reporting biases typically favor newer over older techniques, and some series may selectively report certain classes of complications. Meta-analyses can be useful but need to be interpreted with an eye to the underlying data, and with an awareness that the overwhelming majority of these analyses review retrospective case series rather than prospective or randomized controlled studies.

Gross Total Resection. Pituitary surgery has been a mature field for decades, so an important question concerns the extent to which surgical outcomes have changed over time. A notable meta-analysis published in 2012 reviewed short-term remission and recurrence data over the preceding 25 years. No trend toward improvement in short-term remission was observed over time, but a reduced rate of tumor recurrence was noted.[46] Because of the historical time frame, the majority of series included in that analysis used a microscopic approach. In the last decade, however, a growing body of evidence has emerged suggesting that higher rates of gross total resection are being achieved with the use of endoscopy, particularly in the setting of larger tumors and those with suprasellar extension or cavernous sinus invasion.[47] In perhaps the largest meta-analysis to date comparing endoscopic and microscopic outcomes, published in 2018 and involving 70 studies and 8,257 patients, gross total removal was achieved at a rate of 74.0% for pituitary adenomas removed endoscopically as compared with 66.4% for those removed microscopically.[48]

Biochemical Remission. On the other hand, it is not clear that historical success rates for resection and biochemical remission in the management of hormone-secreting adenomas have improved over time or with the advent of endoscopic techniques.[49] The same 2018 meta-analysis found no difference in the rates of complete removal of functioning adenomas; both endoscopic and microscopic techniques achieved this endpoint at a rate of 75%. The risk of recurrence per patient year at risk has been reported to be 3.4% for prolactinomas, 0.7% in acromegaly, and 2.3% in Cushing disease, as compared with 2.2% for nonfunctioning adenomas.[46] A meta-analysis of 9 endoscopic series involving 821 patients indicated that biochemical (endocrinologic) remission was achieved in greater than 80% of cases.[50] However, it is notable

that the classic pseudocapsular resection technique pioneered by Oldfield was established using microscopic technique via a sublabial approach, and his results remain the gold standard: biochemical remission was achieved in all 261 cases of Cushing disease in which an encapsulated adenoma was identified at surgery.[51]

Visual Improvement. Visual improvement following decompression of the optic apparatus in patients with pituitary tumors causing visual field deficits is believed to depend more on the timing of the decompression than on the surgical technique. Multiple studies have suggested that microscopic and endoscopic approaches yield approximately equivalent visual outcomes.[47]

Recurrence versus Durability of Outcomes. With respect to the durability of surgical outcomes, several important findings are consistent across multiple series and meta-analyses. The most significant prognostic factors for long-term remission in functioning adenomas are low postoperative level of the relevant hormone and gross total resection.[46] Additionally, even accounting for observation bias, multiple studies have suggested that most adenomas that ever recur do so within the first 5 years after surgery.

Microscopic versus Endoscopic Techniques. Multiple meta-analyses have addressed the relative efficacy of endoscopic versus microscopic techniques.[52–64] The findings of these and others are summarized and cited in **Table 78.5**. Early analyses often compared results from newer endoscopic series to results from older or historical microscopic series. In recent years these studies have begun to favor endoscopic over microscopic approaches, but it is not entirely clear whether this trend reflects publication bias. Few controlled trials have been published, and a recent meta-analysis[65] identified only five: two randomized and three nonrandomized, involving a total of 328 patients. There was no evidence for superiority of either surgical technique with respect to gross total tumor removal or biochemical control, but endoscopic pituitary surgery was associated with a significantly reduced risk of complications (RR 0.37) relative to microscopic approaches. It is important to note that this finding is consistently, though not universally, supported by multiple large meta-analyses of retrospective case series, as we will presently discuss.

Cerebrospinal Fluid Leak. CSF leak, in the early years of endoscopic pituitary surgery, was considered a major potential liability of the newer technique. This concern drew extensive attention from the surgical community,

and a variety of techniques emerged and matured, including multilayer skull base reconstruction ("gasket" and "button" closures), use of vascularized nasoseptal flaps, and selective use of lumbar drainage and intrathecal fluorescein to identify small CSF leaks intraoperatively. Because many pituitary adenomas remain extra-arachnoid, pituitary adenoma surgery is typically associated with fewer CSF leaks than extended approaches to nonadenomatous lesions of the sellar and parasellar region. Recent series suggest that the risk of postoperative CSF leak in pituitary adenoma surgery is approximately 1%, as compared with 1% to 3% for microscopic approaches.[47]

Meningitis, Visual Loss, and Death. The rate of postoperative meningitis, which is often a sequela associated with CSF leak, is approximately 1% to 2% following pituitary surgery and has not been shown to differ as a function of technique. Similarly, the rates of permanent new visual loss, cranial nerve injury, and death are all less than 1%, with no significant difference in complication rates between microscopic and endoscopic approaches.

Diabetes Insipidus and Hypopituitarism. The rate of postoperative endocrine dysfunction has not consistently been shown to differ significantly as a function of surgical technique. Transient DI (posterior pituitary dysfunction) occurs in approximately 10% of cases. This condition resolves in most patients, with only approximately 2% to 4% developing permanent DI. The rate of anterior pituitary dysfunction (hypopituitarism) varies more substantially across meta-analyses, with estimates ranging from 3% to 11%.

Vascular Complications. One large meta-analysis has reported a significantly higher rate of vascular complications associated with endoscopic (1.58%) as compared with microscopic (0.5%) pituitary surgery. The study incorporated 38 studies involving a total of 5,643 patients.[64] The size of the reported effect may be called into question, however, given that at least one of the included microscopic series, accounting for 592 (19.6%) of the 3,023 microscopic cases pooled for analysis,[66] was credited with zero vascular complications even though the original series does not report on this outcome at all. This finding of a difference in rates of vascular complications has not been reproduced in other meta-analyses, and no meta-analysis has suggested a difference in the rates of visual loss or surgical mortality (feared consequences of carotid artery injury) between endoscopic and microscopic approaches.

Rhinologic Complications, Hospital Stay, Cost, and Quality of Life. Rhinologic complications, including septal perforations and impaired

olfaction, have consistently been shown to be less common following endoscopic pituitary surgery than following microscopic resection. This difference in the rate of common, non–life-threatening complications largely account for the observed difference in complication rates between endoscopic and microscopic approaches. Rhinologic quality of life outcomes favor endoscopic approaches. Hospital stay has consistently been shown to be shorter by 2 to 3 days following endoscopic surgery, though surgical and total hospitalization costs are not significantly different for endoscopic and microscopic pituitary surgery.

Prolactinomas

Given the efficacy of DA treatment, surgery for prolactinomas is rarely indicated. Nonetheless, it remains effective in selected cases, especially in smaller tumors. A large surgical series reported initial remission of 91.3% in microadenomas, with a recurrence rate of 7.1%. The overall remission rate was 53.2% including giant prolactinomas.[67]

Acromegaly

Surgery remains the most effective treatment for acromegaly, despite the availability of medical therapy. Multiple surgical series in the literature report remission rates of the order of 50% to 65% for macroadenomas, and 70% to 90% for microadenomas.[68–75] It is difficult to compare results as definitions of remission have changed over time from postoperative random GH levels, to GH nadir in the setting of oral glucose challenge, to yet lower GH cutoff levels, and the assays used to measure GH levels have also changed over time. Results from specialized centers are generally better than those results reported from tumor registries.

Cushing Disease

Surgical results for Cushing disease have been reported in multiple surgical series.[46,76–80] Remission rates for microadenomas from 70% to 90% are generally reported. Neither the definition of remission of Cushing disease nor the tests used for postoperative surveillance have been standardized. These remain variable from center to center, making it difficult to compare results. In

those patients not in remission after the initial procedure (reported rates range from approximately 2%[46] to 25% per year[81]), a second exploration is sometimes recommended, which can achieve remission in an additional 50% to 70% of patients.[82–85] While early as opposed to late reoperation is technically less challenging, delayed remissions have been reported, and it is important to determine that postoperative levels have plateaued at an elevated level before proceeding with reexploration.[86]

MANAGEMENT OF PITUITARY ADENOMAS BY SYNDROME

7 With the advent of medical therapy for some of the secretory tumors, surgical indications have changed, and surgical decision making needs to be considered in the context of the available treatment options.

Prolactinomas

Medical treatment with DAs is considered first-line therapy for most patients with prolactinomas, even those with large and invasive tumors.[87] Not all patients require treatment: patients with asymptomatic, stable microadenomas, who are not pursuing fertility (e.g., postmenopausal women), can often be followed expectantly. The commonly used agents, bromocriptine and cabergoline, are both oral agents with excellent efficacy, are relatively inexpensive, and have minimal side effects (gastrointestinal disturbances and dizziness, although depression, anxiety, and impulsivity have been reported). Cabergoline is more effective and generally better tolerated than bromocriptine. Quinagolide is another agent similar in efficacy to cabergoline. High doses of cabergoline (>3 mg/d) have been associated with cardiac valvular dysfunction, but this does not appear to be a significant risk in the dose range usually prescribed for prolactinomas (typically 0.5 to 2.0 mg/wk, **Table 78.6**). The duration of the treatment is at least 2 years with 50% to 70% remission rate at 5 years after discontinuation; for many patients lifelong therapy is required.[88] Tumor regression in response to these agents is often dramatic. Long-standing visual dysfunction will often improve after tumor regression from medical treatment.

Surgical treatment is indicated if there is an insufficient response to medical therapy (persistent neurologic deficit in the setting of inadequate tumor shrinkage, persistently elevated prolactin even on high-dose medication, or intolerance to the medications), and in selected cases with high surgical cure rate when the patient prefers surgery over long-term or potentially lifelong medical treatment. Other indications for surgery include CSF leak and pituitary apoplexy, which may rarely complicate the treatment of large prolactinomas with DAs. Relative indications include cystic tumors, which may not shrink with medical treatment, and infertility in women who wish to become pregnant without medication. Surgical remission rate is >80% for intrasellar tumors but falls to <20% for tumors with an extrasellar component or with abnormal visual fields.[67] Radiation therapy can be recommended for tumors unresponsive to medical and surgical treatment.

Acromegaly

8 Surgery remains first-line treatment in patients who are good surgical candidates, likely to be cured by surgery, or have large macroadenomas, as debulking has been shown to improve subsequent biochemical control with medical therapy.[56,89–92] Surgery is rapidly effective in reducing GH levels, leads to immediate relief of symptoms from mass effect (visual loss), and has the potential to be curative, depending upon the size and degree of tumor invasiveness.

Table 78.6 Medications Used to Treat Prolactin-Secreting Pituitary Adenomas

Name	Mechanism of Action	Usual Dose Range	Adverse Effects
Bromocriptine	Dopamine receptor agonist	1.25–10 mg/d (given orally, once–twice daily)	Nausea, vomiting, dizziness, headache, nasal congestion, constipation, digital vasospasm, vivid dreams, anxiety, depression, impulsivity
Cabergoline	Dopamine receptor (D2 selective) agonist	0.5–>2.0 mg per wk (given orally several times per wk or daily)	Similar to bromocriptine (often better tolerated); high doses (>3 mg/d) have been associated with cardiac valvulopathy
Quinagolide (not available in United States)	Dopamine receptor agonist	0.075–0.9 mg/d (oral, once–twice daily)	Similar to bromocriptine. No risk of valvulopathy
Pergolide (not available in United States)	Dopamine receptor agonist	0.05–0.1 mg/d (oral, once daily)	Similar to bromocriptine. Withdrawn in United States in 2007

	because of higher risk of valvulopathy

Table 78.7 Medications Used to Treat Acromegaly

Name	Mechanism of Action	Usual Dose Range	Adverse Effects
Octreotide acetate	Somatostatin receptor agonist (sstr2 and sstr5)	100–500 µg subcutaneously every 8 hrs	Gastrointestinal side effects, cholelithiasis, hyperglycemia, hypoglycemia, vitamin B12 deficiency, hypothyroidism, bradycardia, hair loss
Octreotide LAR	Somatostatin receptor agonist (sstr2 and sstr5)	10–40 mg intramuscularly every 4 wks	Similar to octreotide acetate
Lanreotide depot	Somatostatin receptor agonist (sstr2 and sstr5)	60–120 mg deep subcutaneously every 4 wks	Similar to octreotide acetate
Pasireotide LAR	Somatostatin receptor agonist (sstr2 and high sstr5)	20–60 mg intramuscularly every 4 wks	Same as octreotide acetate. Higher risk of hyperglycemia (50%)
Octreotide capsule	Somatostatin receptor agonist (sstr2 and sstr5)	40–80 mg orally, twice daily	Same as octreotide acetate. Needs to be taken on empty stomach
Cabergoline[a]	Dopamine receptor (D2 selective) agonist	0.5–7.0 mg by mouth weekly	Nausea, vomiting, dizziness, headache, nasal congestion,

			constipation, digital vasospasm, vivid dreams, anxiety, depression, impulsivity; high doses (>3 mg/d) have been associated with cardiac valvulopathy
Pegvisomant	Growth hormone receptor antagonist	5–40 mg subcutaneously daily	Lipohypertrophy, skin rash, hepatotoxicity

[a]Cabergoline is not approved by the FDA for use in acromegaly.

Pretreatment of surgical cases with somatostatin analogs (SSAs) both for improving postoperative remission rates and anesthetic risk have been debated without consensus. A meta-analysis, including 10 studies, both randomized and retrospective, showed a borderline positive effect with pretreatment that did not reach statistical significance, while analysis of the prospective controlled trials (with historically low pretreatment remission rates) demonstrated a statistically significant benefit.[93] Pretreatment in symptomatic acromegalic patients, especially those with cardiomyopathy and potential difficult airway management due to an enlarged tongue, is sometimes worthy of consideration as it may improve anesthetic risk.[94]

9 The available medical treatments include SSAs, DAs, and GH receptor antagonists.

The SSAs are usually the first line of medical treatment and are comprised of first-generation injectable agents (short-acting octreotide acetate, long-acting octreotide LAR, and lanreotide depot), second-generation injectable agents (pasireotide LAR) as well as oral agents (octreotide capsule). First generation agents normalize IGF1 levels in 20% to 50% of cases and reduce tumor size in 50% of cases. The long-acting forms are given every 4 weeks and

usually are well tolerated; the most common side effects are gastrointestinal disturbances and occasionally cholelithiasis and hyperglycemia.[90] The second-generation injectable agent pasireotide achieves better biochemical and tumor control but a majority of the patients develop hyperglycemia as a complication so it is usually used when first-generation agents fail.[95] Oral octreotide is the newest approved SSAs and is less efficacious than the injectable agents, though useful in milder acromegaly.[96]

Cabergoline, the most potent DA, is sometimes effective in acromegaly (leading to endocrine remission in up to 30% of cases), usually when the IGF1 level is not very elevated (<2.5 times the upper level of normal). It is an oral agent, well tolerated and relatively inexpensive. Its use in acromegaly is not FDA approved.[97]

The GH receptor pegvisomant blocks the peripheral action of GH and leads to dramatic lowering of the IGF1 level in 75% to 95% of patients, but has no direct antitumoral effect. It is administered daily, subcutaneously, and can cause rash, insomnia, or hepatotoxicity. It can be used as monotherapy or as adjunctive to SSAs or cabergoline (**Table 78.7**).[98]

Radiation therapy is usually a third-line option for patients who are not in remission after surgery and do not respond to or tolerate medical therapy. A flowchart for the management of acromegaly is shown in **Algorithm 78.1**.

Cushing Disease

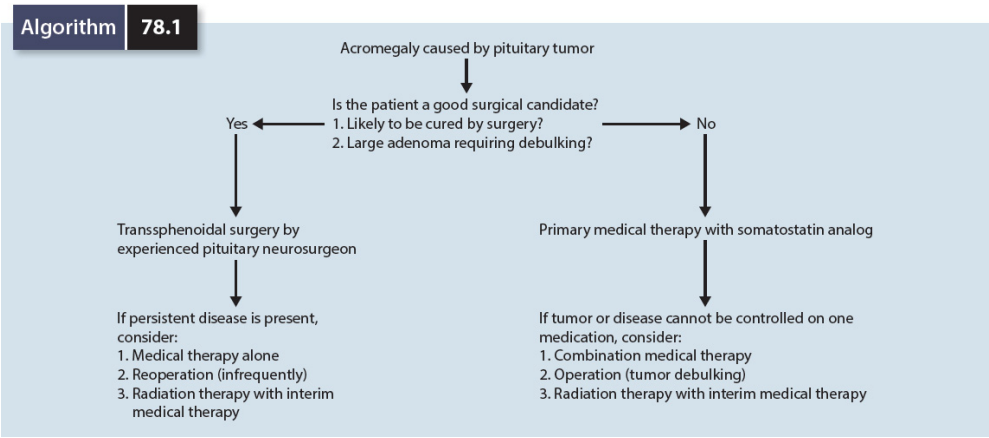
Surgical excision is generally considered to be first-line treatment for Cushing disease. Recurrent Cushing disease after initially successful surgery remains a significant problem and reexploration for recurrence is a reasonable option.

If transsphenoidal surgery is unsuccessful, a number of medications are available by acting at the level of the tumor (decreasing ACTH) and adrenals (inhibiting production of cortisol) or by blocking the cortisol receptors. Each medication has an associated set of side effects and none represents optimal therapy, but each may offer advantages in the individual patient. Combination therapy is at times used when hypercortisolemia cannot be controlled (**Table 78.8**).

Pasireotide and pasireotide LAR work at the level of the tumor as somatostatin receptor agonists, providing a modest degree of cortisol control and good tumor control, but 73% of patients develop hyperglycemia (severe in

some cases). It is not usually used as first-line therapy but it is a good option for locally aggressive tumors.[99]

Cabergoline works at the level of the tumor as a dopamine receptor agonist and controls hypercortisolemia in about 30% of patients, but higher doses are needed (2 mg/wk) that increase the side effect frequency. Control may escape after 2 years of treatment.[100] It is not FDA approved for treatment of Cushing disease.



Algorithm 78.1 Treatment algorithm for acromegaly.

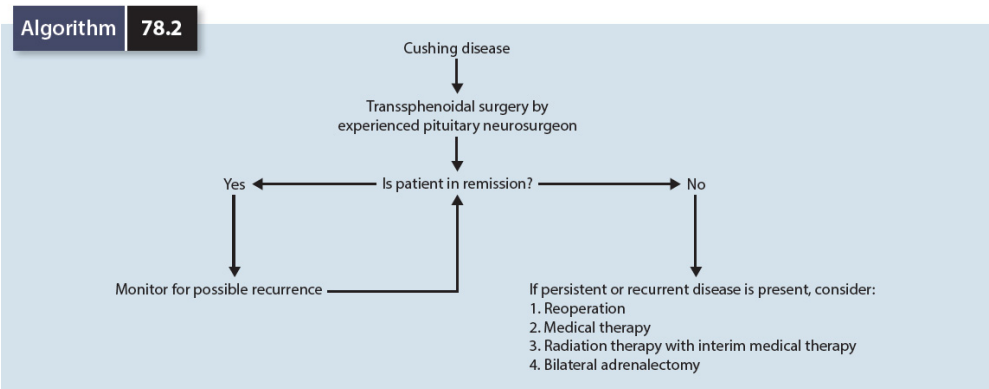
Table 78.8 Medications Used to Treat Cushing Disease

Name	Mechanism of Action	Usual Dose Range	Adverse Effects
Pasireotide	Somatostatin receptor agonist (sstr1, 2, 3, and 5)	0.3–0.9 mg subcutaneously twice daily	Gastrointestinal side effects, cholelithiasis, hyperglycemia (70%), vitamin B12 deficiency, hypothyroidism, bradycardia, hair loss
Pasireotide LAR	Somatostatin receptor agonist (sstr1, 2, 3, and 5)	10–40 mg intramuscularly every 4 wks	Similar to pasireotide
Cabergoline[a]	Dopamine receptor (D2 selective) agonist	0.5–7.0 mg/wk (oral, several times weekly or once per d)	Nausea, vomiting, dizziness, headache, nasal congestion, constipation, digital vasospasm, vivid dreams, anxiety, depression, impulsivity; high doses (>3 mg/d) have been associated with cardiac valvulopathy
Ketoconazole*	Adrenal steroidogenesis inhibitor	200–600 mg by mouth two to	Nausea, dyspepsia, skin rash,

		three times daily	hepatotoxicity, hypogonadism, gynecomastia
Metyrapone*	Adrenal steroidogenesis inhibitor	250–1,000 mg by mouth three to four times daily	Nausea, dizziness, hirsutism, hypertension, edema, hypokalemia
Mitotane*	Adrenal steroidogenesis inhibitor	0.5–3.0 g by mouth three times daily	Nausea, diarrhea, dizziness, ataxia, confusion, hepatotoxicity, rash, gynecomastia, dyslipidemia, teratogenicity
Osilodrostat	Adrenal steroidogenesis inhibitor	4–60 mg orally twice daily	Similar to metyrapone
Etomidate*	Adrenal steroidogenesis inhibitor	0.03 mg/kg intravenously as a bolus, followed by infusion: 0.1–0.3 mg/kg/hr	Sedation
Mifepristone[a]	Glucocorticoid receptor antagonist	300–1,200 mg by mouth daily	Fatigue, headache, nausea, hypokalemia, vaginal bleeding, endometrial thickening, pregnancy

	termination, abnormal thyroid function tests, dyslipidemia

[a]Only pasireotide and mifepristone are approved by the FDA for use in Cushing disease.



Algorithm 78.2 Treatment algorithm for Cushing disease.

Several medications that inhibit different steps in cortisol synthesis in the adrenal are available, some FDA approved, some not. Ketoconazole normalizes cortisol levels in about 50% of patients but has a black box warning for liver failure,[101] and a purified compound levoketoconazole is now in clinical trials. Metyrapone is used off-label, and an updated compound, osilodrostat, was recently FDA approved. It achieves eucortisolemia in close to 80% of patients, with hypertension and hypokalemia as side effects to monitor.[102] Etomidate is a parenteral compound used for severe hypercortisolemia in critically ill patients with Cushing syndrome, and mitotane is very rarely used outside of adrenal cancer due to the severe side effects and adrenolytic effects.

Mifepristone is a cortisol and progesterone receptor blocker FDA approved for treatment of patients with Cushing syndrome and hyperglycemia.[65,103,104] Hypertension, hypokalemia, and uterine hyperplasia are side effects to monitor. A purified cortisol receptor blocker is now in clinical trials.

Bilateral adrenalectomy remains a viable option, with immediate resolution of hypercortisolemia, but requires lifelong mineralocorticoid and glucocorticoid replacement. It is associated with radiographic progression of

the pituitary adenoma in about half of cases, and a smaller number of patients may develop Nelson syndrome.[105]

Radiosurgery with interim medical control is often a reasonable option after unsuccessful transsphenoidal surgery; normalization of cortisol levels occurs in about 50% to 70% of patients within 2 years of treatment, but with a significant risk of anterior hypopituitarism.[106,107]

A flowchart for the management of Cushing disease is shown in **Algorithm 78.2**.

Nonfunctioning Tumors

Surgical removal remains first-line treatment; there are no good medical options (as the response to DAs or SSAs has been poor). Small nonfunctioning tumors (<1 cm) can be followed with serial imaging, but macroadenomas should usually be resected, especially those which are close to the chiasm or enlarging on serial scans, even without visual abnormalities. After subtotal resection it is in many cases reasonable to follow the residual tumor, with reoperation or radiation therapy reserved for those which later enlarge.[108]

Thyrotropin-Secreting Pituitary Adenomas

Pituitary surgery is first-line therapy in most cases. Patients with hyperthyroidism can be pretreated with SSAs or methimazole in order to control hyperthyroidism preoperatively, if present. After surgery, patients with residual tumors or persistent hyperthyroidism may benefit from SSA therapy, which is very effective in controlling hyperthyroidism and also affords some degree of tumor control.[109] Cabergoline can be tried if SSAs are not tolerated but efficacy seems to be low. Radiation therapy and thyroidectomy are alternative options in patients who fail to enter remission after pituitary surgery and medical therapy.

SOCIOECONOMIC CONSIDERATIONS

A number of socioeconomic considerations now affect the practice of pituitary surgery. The volume–outcome relationship, which has been shown to be manifest in a number of surgical subspecialties, holds true in pituitary surgery

as well. This was originally suggested by a study showing improved outcomes for acromegaly with a dedicated pituitary surgeon.[110] Further studies have demonstrated a decrease in complication rate with increased experience,[111] and a significant decrease in operative mortality after pituitary surgery in high-volume as opposed to low-volume centers.[112] A recent study has demonstrated that surgeon and institutional performance continue to demonstrate improvements with respect to gross total removal, biochemical remission, and complication rates, even after many hundreds of operations over more than a decade.[113] With the multiplicity of available treatment modalities, comparative cost–benefit analyses are now being performed. Treatment algorithms in acromegaly which incorporated transsphenoidal surgery were shown to be less expensive than those using medical therapy alone, and algorithms using primary surgery followed by adjunctive medical treatment as opposed to the converse approach were shown to be 30% less costly overall.[114] In Cushing disease, the economic burden of managing patient comorbidities was shown to significantly decrease after successful surgery.[115] Despite the introduction of new pharmacologic agents, it is likely that surgery will continue to play a major role in the treatment of pituitary disorders; given the multiplicity of options, however, care is 10 best individualized for a given patient in a multidisciplinary setting.

Lung Neoplasms

Robert E. Merritt

Key Points

1. Lung cancer remains the leading cause of cancer-related death in the United States.
2. Advances in detection of somatic mutations in NSCLC have yielded targeted therapeutic molecular treatments for patients with metastatic lung carcinoma.
3. Non-small lung cancer is the most common lung neoplasm followed by small cell lung carcinoma (SCLC).
4. The common sites of metastatic spread include the brain, bone, adrenal glands, and liver. A metastatic evaluation includes positron emission tomography and computed tomography (PET-CT) scan, CT scan of the chest and abdomen, and a brain magnetic resonance imaging (MRI).
5. Anatomical lung resection remains the gold standard treatment for early-stage non–small cell lung carcinoma (NSCLC). Thoracoscopic and robotic assisted approaches are increasing in utilization with similar results to thoracotomy.
6. Pulmonary carcinoid tumors are relatively indolent neoplasms of the lung that are effectively treated with surgical resection.
7. Benign neoplasms of the lung, such as hamartomas, are very slow growing and can be managed with observation or surgical resection.

INTRODUCTION

Lung neoplasms can be classified histologically as malignant or benign.[1] NSCLC is the most common malignant lung neoplasm 1 encountered in clinical practice. The histologic classifications of lung neoplasms are further classified as SCLC and large cell lung carcinoma (**Table 79.1**). Carcinoid and carcinoma of the salivary glands are also classified as malignant lung neoplasms. Benign lung neoplasms that are commonly encountered in clinical practice include hamartoma, adenoma, and myelolipoma (**Table 79.2**).

Although population estimates of both the incidence and mortality of lung cancer have begun to decline, lung cancer remains second only to heart disease among all causes of mortality. With 228,150 new cases and 142,670 deaths projected for 2019, lung cancer remains the leading cause of cancer-related death in the United States. Lung cancer is second in cancer prevalence only to prostate cancer among men and breast cancer among women, and remains the leading cause of cancer-related death for both sexes. Since 2005, both the annual incidence and mortality rates due to lung cancer have started to decrease in the United States, reflecting improvements in cancer control and prevention, particularly efforts to reduce the prevalence of smoking.[2] There is also significant regional variation in both lung cancer incidence and mortality. Among men, lung cancer mortality has decreased from 1996 through 2005 in over 80% of the 50 states and the District of Columbia, whereas among women over the same period, mortality decreased in only three states (California, New Jersey, and Texas) and has increased in 13 other states, primarily in the Midwest and South, although more recently consistent rates of decline have been noted for both men and women.[3]

The best predictor of survival for patients with lung cancer is based on staging and effective treatment strategies. Anatomical pulmonary resection remains the gold standard treatment for lung cancer, yet only approximately 37% of all patients diagnosed with lung cancer are considered surgically resectable at the time of presentation. Even among patients who have undergone complete surgical resection with curative intent for early-stage lung cancer, as determined using pathologic *T*umor–*N*ode–*M*etastasis (TNM) criteria, a substantial number will have recurrence of their cancer (**Table 79.3**).[4]

Multiple randomized clinical trials have demonstrated that adjuvant chemotherapy has improved overall survival over surgery alone for early-stage lung cancer in patients with positive lymph nodes.[5,6] In addition, lung cancer screening low-dose chest computed tomography (CT) appears to improve early detection of resectable lung cancer with an improvement in overall survival in a high-risk population.[7–9] As understanding of molecular changes occurring in lung cancer evolves, new strategies that allow for early detection and classification of lung cancer will provide valuable information for the treatment of patients.

EPIDEMIOLOGY

Lung carcinoma is the leading cause of cancer-related death in the United States. The Surveillance, Epidemiology, and End Results (SEER) program estimated that 222,500 people were diagnosed with lung cancer in 2017, and lung cancer comprised 13.2% of all new cancer cases.[10] The prevalence of lung cancer is the Unites States is estimated to be at 408,800 people and accounted for 25.9% of cancer deaths, which is estimated to reach 155,870 cases in 2015. From 2005 to 2015, the number of lung cancer cases per 100,000 individuals has decreased from 63.0 to 54.5, and the number of lung cancer deaths has decreased from 52.9 to 45.0. Despite the improvements in the incidence and death rate for lung cancer, the lung cancer still accounts for more cancer-related deaths than the combined cancer-related deaths for breast cancer, prostate cancer, colon cancer, bladder cancer, and melanoma combined. The current median age for the diagnosis of lung cancer in the United States is 70 and 30% of cases occur in patients between the ages of 65 to 74. The current survival rate for lung carcinoma is 18.1% for patients in the United States. The highest incidence of lung cancer occurs in African-American males with 83.7 cases/100,000 persons. The incidence of lung cancer in Caucasian males is 65.9 cases/100,000 persons.

MOLECULAR TUMOR GENOMICS

2 The origin of carcinogenesis caused by a series of genetic alterations in metabolic pathways in individual cells resulting in defective cell growth and differentiation served as the basis for modern molecular therapy for lung cancer.[11] The epidermal growth factor receptor (EGFR) consists of four different transmembrane kinases that regulate the cell cycle and overexpression of the EGFR receptor has been detected in NSCLC.[12] Targeted molecular therapy has been shown to have clinical benefit notably for patients with advanced NSCLC. For example, among patients whose tumors are shown to carry specific somatic mutations in the EGFR gene, treatment with small molecule tyrosine–kinase inhibitors targeting EGFR has

been associated with improved progression-free survival as demonstrated by several randomized trials.[13] Whether such treatment regimens might be effective in the adjuvant setting for patients with early-stage NSCLC who have undergone curative-intent lung resection has yet to be established, but is the focus of a recently initiated cooperative group trial. The Adjuvant Lung Cancer Enrichment Marker Identification and Sequencing Trials (ALCHEMIST) will evaluate patients with resected lung adenocarcinomas (stage IB to stage IIIA). Those subjects found to have tumors carrying activating EGFR mutations or the echinoderm microtubule-associated protein-like 4 (EML4-ALK) fusion gene will be randomized to maintenance therapy with either erlotinib (EGFR) or crizotinib (ALK fusion), respectively, following completion of standard-of-care adjuvant chemotherapy with or without radiation therapy. Enrolled patients found to have neither of the targeted mutations will be followed in an observational study until tumor recurrence. These studies represent an exciting potential application of gene expression studies for use in determining patient prognosis, as well as guiding the clinical management of lung cancer and preventing the under treatment of patients with NSCLC.

3 NON–S MALL CELL LUNG CARCINOMA

Overview

Patients with suspected lung carcinoma typically present with a constellation of clinical findings.[14] In some cases, symptoms may not be present. The clinical evaluation for lung cancer includes history, physical examination, radiographic imaging studies, and risk factor assessment. The history should focus on symptoms such as cough, hemoptysis, weight loss, and cigarette smoking status. In addition, neurologic symptoms such as headache, gait imbalance, and motor weakness could indicate central nervous system involvement. The physical examination should focus on the cardiopulmonary system and the supraclavicular and cervical lymph nodes. Diagnosis and staging of lung carcinoma is typically achieved with a combination of diagnostic imaging studies, such as CT and PET. Histologic confirmation of the primary lung carcinoma may require fine-needle aspiration (FNA) with

CT guidance, bronchoscopy with biopsy, or video-assisted thoracoscopic surgery (VATS). In order to determine staging and extent of tumor involvement, the elements of the tumor (T), the regional and distal lymph nodes (N), and distant metastatic disease need to be elucidated. The determination of effective treatment depends on a careful evaluation of clinical staging for optimal results. Various professional medical organizations have created evidence-based clinical guidelines for the diagnosis, staging, and management of lung carcinoma.[15–17]

Diagnosis for Non–Small Cell Lung Carcinoma

The diagnosis of lung carcinoma is accomplished with a combination of diagnostic tools that can determine the histologic diagnosis. Sputum cytology is a rarely used diagnostic test, but is safe and noninvasive. The diagnostic specificity of sputum cytology is 99% but the specificity is relatively low in most cases; therefore, the test is not widely utilized in the diagnostic workup for lung carcinoma.[19] Flexible fiberoptic bronchoscopy is a commonly utilized safe and effective diagnostic technique for the diagnosis of lung carcinoma. The overall complication rate for flexible bronchoscopy is relatively low and many diagnostic procedures can be performed. Endobronchial biopsy, brushings, bronchoalveolar lavage, and transbronchial needle aspiration can be performed with fiberoptic bronchoscopy. For central lung tumors, flexible bronchoscopy is very effective for diagnosis, and the overall sensitivity is high as 88%.[14] Flexible bronchoscopy is most effective for lung carcinoma located in the central airways; however, peripheral lung tumors are difficult to access with standard flexible bronchoscopy. Image-guided biopsy technology such as electromagnetic navigational bronchoscopy (ENB) allows surgeons and pulmonologist to navigate to peripheral lung tumors and perform FNA biopsy. The reported sensitivity for ENB is 77% due to the limitation of not having real-time imaging available during the performance of the FNA biopsy.[20]

Table 79.3 Comparison of 8th and 7th Editions of TNM Classification for Lung Cancer

Descriptor	7th Edition TNM	8th Edition TNM
T Component		
0 cm (pure lepidic adenocarcinoma ≤3 cm in size)	T1a if <2 cm; T1b if >2–3 cm	Tis (adenocarcinoma in situ)
≤0.5 cm invasive size (lepidic predominant adenocarcinoma <3 cm total size)	T1a if <2 cm; T1b if >2–3 cm	T1 mi (minimally invasive)
≤1 cm	T1a	T1a
>1–2 cm	T1a	T1b
>2–4 cm	T1b	T1c
>3–4 cm	T2a	T2a
>4–5 cm	T2a	T2b
>5–7 cm	T2b	T3
>7 cm	T3	T4
Bronchus <2 cm from carina	T3	T2
Total atelectasis/pneumonitis	T3	T2
Invasion of diaphragm	T3	T4
Invasion of mediastinal pleura	T3	—
N Component		
No assessment, no involvement, or involvement of regional lymph nodes	NX, N0, N1, N2, N3	NX, N0, N1, N2, N3

M Component		
Metastasis within the thoracic cavity	M1a	M1a
Single extra thoracic metastasis	M1b	M1b
Multiple extra thoracic metastasis	M1b	M1b

For the diagnosis of peripheral lung nodules, transthoracic needle aspiration (TTNA) is utilized in conjunction with CT to enhance diagnostic yield. The technique is very safe and effective; however, there is a 15% risk of postprocedure pneumothorax and 7% risk of developing a pneumothorax that requires chest tube thoracostomy.[21] The diagnostic sensitivity of TTNA is greater than 90% and the false-negative rate can be as high a 20% to 30%.[22] TTNA is very effective in obtaining a diagnosis of primary lung carcinomas, particularly for peripheral lung nodules. For patients with lung nodules that are located in areas of the lung that are not accessible with TTNA, VATS offers a minimally invasive approach to perform a wedge resection. Lung nodules that are located on the outer third of the lung parenchyma are easily accessible for a diagnostic wedge excision; however, lung nodules that are located deeper in the lung parenchyma are more challenging to access with the VATS approach. Smaller lung nodules that are less than 1 cm in diameter pose a challenge to localize and perform a wedge excision for diagnostic biopsy. Needle localization, methylene blue injection, and radio-opaque fiducial marker placement can greatly enhance the ability to localize small lung nodules with the VATS technique.[23,24]

Staging of Non–Small Cell Lung Carcinoma

4 The clinical staging of lung carcinoma is paramount to determining the extent of tumor dissemination which has implications on treatment decisions and overall prognosis. Optimal clinical staging can be determined with a careful assessment of tumor (T), node (N), and metastasis (M) utilizing invasive and noninvasive diagnostic methods. The lung cancer staging system

has changed and undergone many revisions over the past several years. The original survival analysis was led by Mountain and colleagues.[25] The definitions for TNM staging system were further refined by Goldstraw and colleagues through the International Association for the Study of Lung Cancer (IASLC) staging project to develop a statistically valid foundation for the 8th edition of the TNM staging system.[26,27] The American Joint Committee on Cancer (AJCC) and the Union for International Cancer Control (UICC) utilizes the IASLC-TNM staging system recommendations into an international staging system for lung carcinoma. For the current AJCC 8th edition staging system of lung carcinoma, the IASLC collected over 94,708 NSCLC cases from multiple institutions from multiple countries between 1990 and 2010.

The aims of the initial evaluation of a patient with NSCLC are to determine whether distant metastatic disease is present and to assess the extent of intrathoracic disease. A multidisciplinary approach, involving input from pulmonary medicine, chest radiology, medical and radiation oncology, and thoracic surgery, should be undertaken in the selection of the most appropriate diagnostic testing for any individual patient. A thorough history and physical examination, combined with a plain chest radiograph and baseline laboratory data (complete blood cell count and measurement of serum sodium, calcium, alkaline phosphatase, and lactate dehydrogenase levels), can suggest the presence of distant metastatic disease. The most common sites for metastatic for NSCLC include the brain, supraclavicular lymph nodes, bones, liver, adrenal glands, and contralateral lungs. An extensive metastatic workup is recommended and should include a CT scan of the chest and abdomen, a magnetic resonance imaging (MRI) of the brain, and a whole-body fluorodeoxyglucose (FDG)-PET Scan. In order to confirm the histologic diagnosis, a biopsy by FNA or bronchoscopy can be performed to obtain confirmation of malignancy and to determine the extent of disease.

If the initial clinical evaluation does not demonstrate evidence of distant disease, the extent of further evaluation by additional imaging studies is controversial. Some clinicians routinely perform a complete metastatic workup with a CT scan of the chest and abdomen, CT or MRI of the brain, and FDG-PET scan. A CT scan of the chest and upper abdomen as well as FDG-PET scan have become standard to evaluate the extent of the primary

tumor and the status of the mediastinal lymph nodes and to detect metastases in the contralateral lung, liver, bones, or the adrenal glands. Additional imaging studies in asymptomatic patients may detect the 5% to 10% of metastases that are occult, but these imaging studies are not clearly cost effective in patients with clinical stage I tumors. In patients who are acceptable candidates for pulmonary resection and have a suspicious solitary pulmonary nodule that is indeterminate despite appropriate evaluation, an excisional biopsy with a wedge resection and subsequent lobectomy for surgically resectable lung cancer should be pursued.[28]

The evaluation of the mediastinal lymph nodes for NSCLC is very critical for accurate staging and multimodality treatment which consists of neoadjuvant chemoradiation.[29] Chest CT scans provide only anatomic confirmation for tumor involvement of mediastinal lymph nodes based on enlarged size greater than 10 mm. A meta-analysis of over 3,400 evaluable patients demonstrated a pooled sensitivity of 57% and specificity of only 82% for CT scans. This meta-analysis also demonstrated that FDG-PET scanning appears to provide increased sensitivity of 84% and specificity of 89% in over 1,100 patients studied for the detection of mediastinal malignancy.[30] Several prospective studies have also demonstrated a superior diagnostic accuracy of FDG-PET imaging.[31–33] Although the overall sensitivity and specificity of FDG-PET mediastinal lymph node staging was 61% and 84%, respectively, there was a significant improvement with FDG-PET over chest CT scans in the detection of both hilar (N1) lymph node (42% vs. 13%, $p = 0.0177$) and mediastinal (N2 and N3) tumor involvement (58% vs. 32%, $p = 0.004$). Whereas FDG-PET scanning can increase the suspicion of malignancy, the negative predictive value for mediastinal lymph node metastasis does not appear to be sufficient with a false-negative rate reported as high as 13%.[34] FDG-PET evaluation of the solitary pulmonary nodule also appears to be somewhat insensitive, with a negative predictive value for benign lesions of only 57%, indicating a false-negative rate of 47%. Reliance on this modality could lead to delayed treatment for resectable early-stage NSCLC.[35]

Clinical staging for NSCLC can be accomplished by needle aspiration utilizing several approaches, including endobronchial ultrasound (EBUS) and endoscopic ultrasound (EUS). EBUS-guided transbronchial biopsy has been shown to be safe, effective, and similar in accuracy to cervical

mediastinoscopy.[36] EUS with FNA (EUS-FNA) can be utilized to biopsy the mediastinal lymph nodes in the subcarinal, paratracheal, and aortopulmonary window. Cervical mediastinoscopy remains an important diagnostic modality for sampling mediastinal lymph nodes. This modality has a procedural sensitivity greater than 90%, and specificity of 100%.[37]

Treatment

5 Pulmonary resection remains the gold standard treatment for stage I, II, and selected stage III NSCLC. The extent of resection, segmentectomy, lobectomy, bilobectomy, or pneumonectomy, is determined by the location and size of the primary tumor and also whether adjacent bronchopulmonary nodes are involved. At operation, tumor extent is evaluated by examination of the parietal pleura, pericardium, and mediastinal structures. Complete resection must achieve microscopically negative bronchial and vascular margins. If a tumor extends directly into the chest wall, diaphragm, or pericardium, an en bloc resection of the adjacent involved structures should be performed with the pulmonary resection. If there is endobronchial involvement present, the tumor can be surgically resected by lobectomy with segmental resection of the bronchus and/or pulmonary artery (bronchovascular sleeve resection), thus preserving lung function.

Patients with centrally located tumors should undergo sleeve lobectomy rather than pneumonectomy if complete resection can be achieved and such an approach is technically feasible. Several retrospective studies have demonstrated that operative mortality is reduced among patients undergoing sleeve lobectomy (0% to 5.2%) when compared with patients undergoing pneumonectomy (1.7% to 8.9%).[38–41] Moreover, overall 5-year survival is improved among patients undergoing sleeve resection, particularly among those with N0 or N1 nodal status. For peripherally located clinical stage I tumors, particularly among patients with limited pulmonary reserve or those at high risk from other comorbidities, segmental or nonanatomic wedge resection can be performed. Whether such patients are at greater risk for locoregional recurrence as suggested in earlier series, sublobar lung resection is under investigation in an ongoing multi-institutional prospective and randomized cooperative group clinical trial (CALGB 140503).[42–45]

Long-term survival after resection for NSCLC is linked to the pathologic stage of disease. The overall 5-year survival rates range from 60% to 70% for stage I tumors, from 40% to 50% for stage II tumors, and from 15% to 30% for stage IIIA tumors. Nodal involvement has the strongest adverse influence on survival. Large peripheral tumors that extend directly into the chest wall without nodal involvement (T3N0) are associated with a 5-year survival rate of 40% after complete resection, whereas involvement of mediastinal nodes is associated with only a 20% survival rate.

Some series suggest that histology also affects survival. In node-negative NSCLC, large cell neuroendocrine differentiation conferred worse survival than other types of NSCLC.[46] Different adenocarcinoma subtypes, particularly in more advanced tumors, also appear to confer worse prognosis, but the influence of histology has not been described uniformly in series to date.[47] Delineation of tumor biology by more refined histologic and molecular analyses will be needed to define which patients might be at increased risk for recurrence or treatment resistance.

The predominant sites of relapse for all stages of NSCLC after resection are distant metastases. Approximately 30% of recurrences are locoregional with tumors of both squamous and nonsquamous histology.[48] For all stages of disease, the brain is the single most common site of relapse, and brain metastases occur more frequently with nonsquamous tumors. Other common metastatic sites include bone, ipsilateral or contralateral lung, liver, and the adrenal glands.[49] At least 60% of recurrences develop in the first 2 years after operation, and virtually all recurrences related to the original primary tumor occur within 5 years after surgical resection. Even the small proportion of patients with stage II or III disease who survive 5 years are likely to survive 10 years or more postoperatively. Recurrences of the original primary tumor are uncommon after 5 years, and after that time the occurrence of new pulmonary cancers becomes the dominant problem. The risk for development of a second lung cancer in patients with a prior history of cancer resection for NSCLC is estimated to be 2% to 3% per patient per year, with a second lung cancer developing rarely in never-smokers at the time of initial resection, and at rates of 1.8% per patient-year in former smokers and 2.7% per patient-year in current smokers.[50,51] Patients also face a consistent risk for the development of new, nonpulmonary primary cancers during the first 5 years after operation.

PULMONARY CARCINOID TUMORS

6 Carcinoid tumors, which are neoplasms with a low-grade malignant potential, account for about 2% of lung tumors in the United States. They arise from neuroendocrine stem cells of the bronchial epithelium and are classified as either typical or atypical. Histologically, typical carcinoids consist of uniform polygonal cells with round nuclei and fine granular chromatin (**Fig. 79.1**). Mitotic figures are rarely seen. Atypical carcinoids show increased mitotic activity, nuclear pleomorphism, and areas of disorganized architecture and tumor necrosis (**Fig. 79.2**).[52]

Carcinoid tumors occur equally in both sexes and at a median age of 55 years. Half of patients present with pulmonary symptoms, including hemoptysis, dyspnea, and recurrent or persistent pneumonitis because 40% of lesions are centrally located in the main or lobar bronchi. The lesions may be diagnosed by bronchoscopy, appearing as pink or purple friable endobronchial masses covered by intact epithelium. In the other half of patients, carcinoid tumors are diagnosed when radiologic abnormalities are detected on a chest roentgenogram as part of a routine examination.[53] Lymph node metastases occur in approximately 10% to 15% of patients at diagnosis but are more frequent in atypical carcinoids. Carcinoid syndrome is associated with bronchial carcinoids in only 2% of cases, usually in patients with metastatic disease, particularly to the liver. The most common sites of metastases are lung, bone, liver, adrenals, and brain.[53]

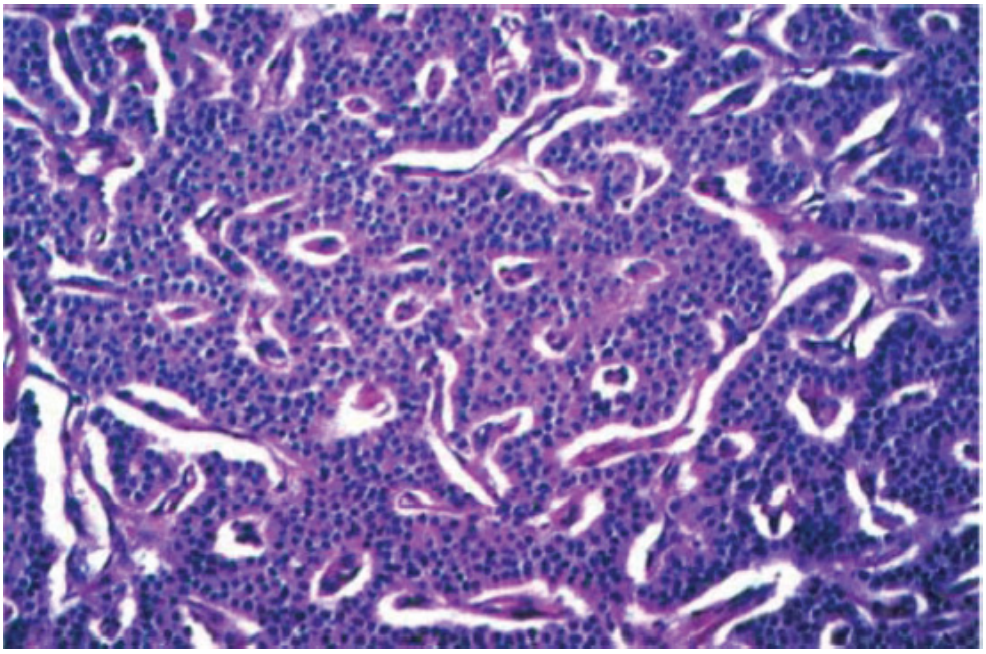

Figure 79.1 Typical carcinoid tumor of the lung. A microscopic view shows ribbons of tumor cells embedded in vascular stroma. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

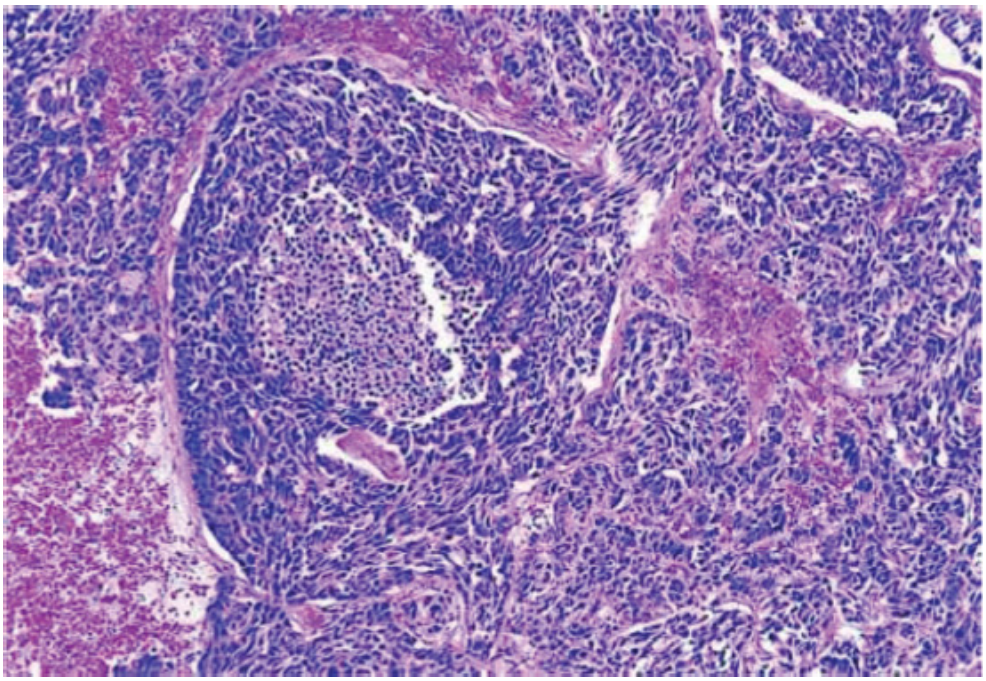

Figure 79.2 Atypical carcinoid tumor of the lung. A cellular tumor shows central necrosis and disorganized architecture. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

The standard treatment for bronchial carcinoids is complete resection, regardless of the presence of nodal involvement, with mediastinal lymph node sampling or dissection. Lobectomy can be accomplished in the majority of patients with resectable disease, although parenchymal-sparing segmentectomy or nonanatomic wedge resection can be considered particularly for patients with a typical carcinoid tumor.[54] For patients who have centrally located tumors and for which pneumonectomy might be performed, bronchoplastic techniques should be considered instead.[55] Endoscopic resection is invariably associated with local recurrence and should be used only as a palliative maneuver in patients whose general medical condition precludes thoracotomy and pulmonary resection.

The long-term survival rate after resection exceeds 90% in patients with typical carcinoids, even when hilar or mediastinal nodal metastases are present. In contrast, patients with atypical carcinoids have a 5-year survival rate of 60% after complete resection. The outcome is more closely linked to histology than to tumor size, location, or nodal involvement. Recurrence is more frequent with tumors larger than 3 cm and in patients who present with lymph node metastases.[55,56]

LARGE CELL NEUROENDOCROINE CARCINOMA

Large cell neuroendocrine carcinoma is characterized by the microscopic features of neuroendocrine tumors, but the tumor cells are large, have a high mitotic rate, and frequently show necrosis (**Fig. 79.3**).[52,57] According to Travis and colleagues, large cell neuroendocrine carcinomas are related to smoking, as is SCLC, and are high-grade tumors with 5- and 10-year survival rates of 27% and 9%, respectively, despite complete resection.[58,59] There is very minimal data available concerning adjuvant therapy. For the time being, the management of large cell neuroendocrine carcinoma is identical to that of NSCLC.[60]

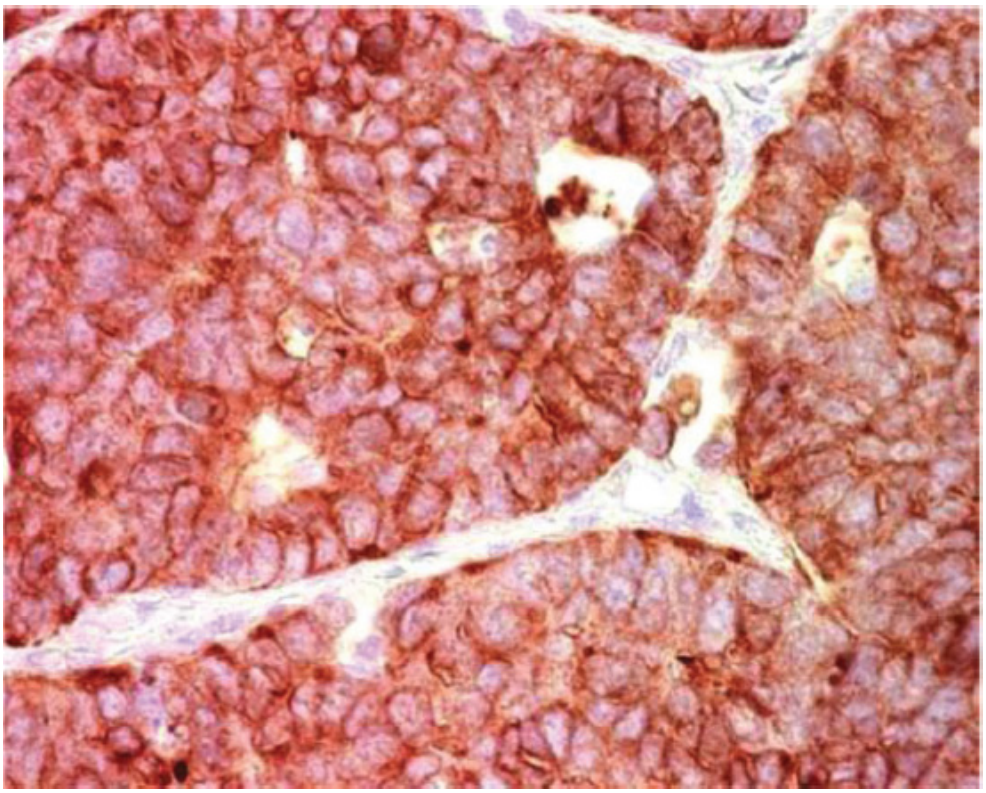

Figure 79.3 Large cell neuroendocrine carcinoma of the lung demonstrates positive immunostaining with synaptophysin antibody. (From Cagle PT. *Color Atlas and Text of Pulmonary Pathology*. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

SMALL CELL LUNG CARCINOMA

SCLC has the most aggressive clinical course of any type of pulmonary tumor and is often widely disseminated by the time of diagnosis. The proportion of patients with SCLC has been decreasing from 17% in the 1980s to 13% of lung cancer cases in 2002.[61] In contrast to non–small cell lung tumors, these lesions are notably responsive to chemotherapy and radiotherapy. Surgical resection is rarely indicated for SCLC since the tumor typically presents with advanced disease. The staging system for SCLC was developed by the Veterans Administration Lung Cancer Staging Group and divides patients into those with limited-stage (LS) and those with extensive-stage (ES) disease. This distinction was first based on what could be encompassed by a tolerable radiation portal. After clarification by the IASLC, LS disease includes patients with tumors confined to one hemithorax and regional lymph

nodes (hilar, ipsilateral, and contralateral mediastinal nodes, and ipsilateral and contralateral supraclavicular nodes) as well as patients with ipsilateral pleural effusion, regardless of whether the cytology is positive or negative.[62] On the other hand, both pericardial and bilateral pulmonary involvement are considered ES disease.[63]

Common sites of distant metastases are bone, liver, bone marrow, and the central nervous system, and therefore the metastatic evaluation includes a bone scan, CT of the chest and abdomen, and brain MRI. Some oncologists also perform bone marrow biopsies, but because the marrow is the sole site of extensive disease in fewer than 5% of patients, biopsies are usually judged unnecessary. After the staging process, approximately 30% to 40% of patients are found to have LS disease. For patients with LS SCLC, response rates of 85% to 90% and complete response rates of 50% to 60% can be expected with the combination of etoposide and cisplatin and radiation therapy.[64] The median survival is 18 to 24 months, and the 2-year survival rates are 40% to 50%. The addition of definitive-dose thoracic radiation therapy, particularly when administered concurrently or within several weeks of completing chemotherapy confers a 5% 2- to 3-year overall survival benefit.[65–67] In ES SCLC treated with chemotherapy, response rates reach 75% to 85%, although complete response is seen in only 15% to 25% of patients. The median survival is between 7 and 11 months, with a 2-year survival less than 5%.[61] Although the prognosis in SCLC depends primarily on the anatomic extent of disease, after a review of prognostic variables in its 2,580-patient SCLC database, the Southwest Oncology Group (SWOG) determined that the two-stage system should be extended into a four-stage system, with serum lactate dehydrogenase level, age, and pleural effusion used as additional staging criteria.[68]

The small numbers of patients with SCLC evaluated by surgeons represent fewer than 10% of all patients with SCLC. These patients have peripheral tumors with no nodal involvement or only hilar nodal involvement, which would be classified as Tl–2 N0–l (stage I or II) tumors in the TNM staging system. In the past, such tumors were often diagnosed at exploratory thoracotomy for an asymptomatic coin lesion, but with the increasing use of diagnostic percutaneous needle aspiration, more patients with early-stage SCLC are now identified preoperatively. Patients with SCLC should be evaluated by a multidisciplinary team consisting of medical and radiation

oncology, and surgical resection should be considered after distant disease has been excluded. For such potentially operable patients, it has been suggested that the TNM classification be used in future trials and studies.[69,70]

Retrospective series have demonstrated a 5-year survival rate of 30% to 50% after resection of T1N0 or T2N0 SCLC.[69,71,72] Because of the propensity for small cell cancers to disseminate, adjuvant chemotherapy has traditionally been given to patients although no prospective, randomized trials have demonstrated whether this is of any benefit, due to the small numbers of patients available.[72] Relapse at the primary site, which is a problem for most patients with LS SCLC, is distinctly uncommon after complete resection of these early tumors.[73] Radiation therapy to the chest has been suggested after complete resection, but because insufficient information is available in the literature, and local relapse is uncommon, this is not considered standard treatment.[71,72] Given the propensity for patients to develop brain metastases, prophylactic cranial irradiation is recommended for patients with either LS or ES SCLC with good performance status and who have completed initial therapy with either complete or partial response.[74]

As the role of resection in patients with mediastinal nodal involvement (N2 disease) is questionable, mediastinoscopy or EBUS should be considered mandatory to exclude mediastinal nodal disease.[75] This should be performed separately from thoracotomy since it can be difficult for the pathologist to diagnose small cell cancer on a frozen section. The intraoperative management of SCLC is not significantly different from that of NSCLC, and an incomplete resection does not benefit the patient.

The addition of resection after response to induction chemotherapy has been proposed by some surgeons to cure a small number of patients with LS SCLC without mediastinal involvement.[76] Currently, the Lung Cancer Study Group (LCSG) has performed the only prospective, randomized trial evaluating the role of surgery in LS SCLC.[77] All patients enrolled in this study received induction chemotherapy followed by surgical resection. Objective responders were randomized either to lung resection followed by thoracic and cranial radiation or to radiation therapy alone. Because the survival rate was the same in both groups, with 2-year overall survival of 20%, this trial did not support the addition of pulmonary resection to the multimodality treatment of SCLC. More recently, retrospective studies

suggest better long-term survival, in selected patients with stage I SCLC, of over 50% at 5 years.[70]

Finally, the occurrence of a second primary lung carcinoma after treatment for SCLC has been reported in the few patients with prolonged survival. It should not be assumed that the new tumor is of small cell histology, and these patients should be evaluated for the possibility of resection.[78] The average risk for the development of a second lung cancer in patients who survive SCLC is approximately 6% per patient per year.[79]

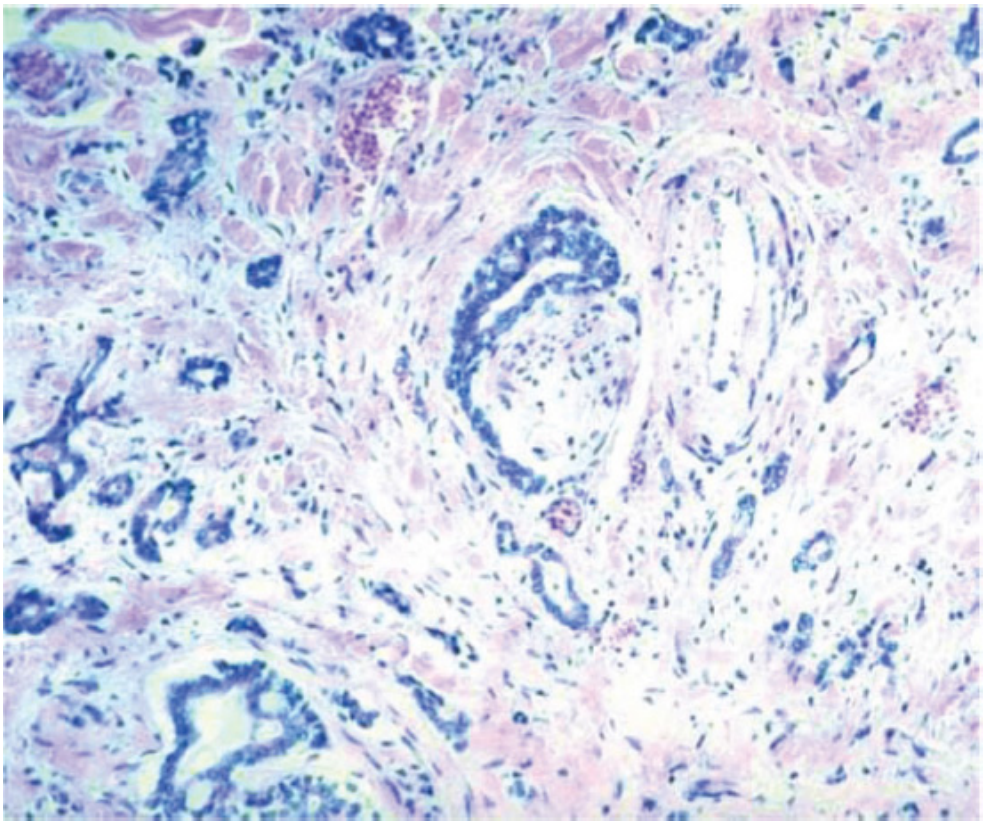

Figure 79.4 Adenoid cystic carcinoma. A photomicrograph demonstrates perineural infiltration of the tumor. (From Rubin E, Farber JL. *Pathology*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.)

ADENOID CYSTIC CARCINOMA

Adenoid cystic carcinomas are slowly growing malignant tumors that arise from the submucosal glands of the trachea and main bronchi (**Fig. 79.4**). They have also been called cylindromas, adenoid cystic basal cell carcinomas,

adenomyoepitheliomas, and pseudoadenomatous basal cell carcinomas. Adenoid cystic carcinomas behave much like the major and minor salivary gland tumors, to which they are microscopically identical. An important aspect of their clinical behavior is that they tend to spread in the submucosal plane along the perineural lymphatics, well beyond the obvious endoluminal component of the tumor. In a small biopsy specimen, it can be difficult to distinguish adenoid cystic carcinoma from a conventional adenocarcinoma.

Immunohistochemical stains may assist the pathologist to differentiate the two by showing the presence of the myoepithelial cell immunophenotype in adenoid cystic carcinoma.[79] Whenever possible, total excision by tracheal resection or tracheobronchial resection is the treatment of choice.[80–83] This is not always possible because of the extensive submucosal spread of tumor. In such cases, the tumor should be resected with grossly negative margins along with adjuvant radiation since these tumors are radiation sensitive.

When resection is not feasible because of the extent of the lesion or the functional status of the patient, a palliative treatment option is endoscopic laser removal followed by radiation (brachytherapy, external beam irradiation, or both). When complete resection is possible, the prognosis is excellent. However, because of the indolent nature of adenoid cystic tumors and its responsiveness to radiation, prolonged survival is possible even with incomplete resection or palliative measures. Patients frequently live 10 years or more with persistent disease, including pulmonary metastases. In such cases, repeated efforts at palliation are indicated.

MUCOEPIDERMOID CARCINOMA

Mucoepidermoid carcinomas may be low-grade or high-grade malignancies and have the same microscopic appearance as mucoepidermoid tumors of salivary gland origin. These tumors also arise in the glandular submucosa, presenting as submucosal lesions. The distinction between a low-grade and a high-grade tumor is based on mitotic activity, cellular necrosis, and nuclear pleomorphism.[84] The principles of treatment of mucoepidermoid tumors are similar to those of carcinoid tumors. The more malignant variety must be treated as a bronchogenic carcinoma. Some authors even think that adenosquamous carcinoma is the same entity as mucoepidermoid carcinoma,

but arising in the periphery of the lung.[84] The prognosis for these tumors depends on the grade of malignancy and the stage of the disease. High-grade mucoepidermoid tumors have the same prognosis as bronchogenic carcinoma. Complete surgical resection with negative margins is the mainstay of treatment. Mucoepidermoid tumors are too rare to permit an evaluation of combined modality therapy for more aggressive, high-grade tumors.

Hamartoma

7 Pulmonary hamartomas are benign neoplasms composed of predominantly of chondroid and mesenchymal components and are classified as true pulmonary neoplasms.[1] Pulmonary hamartomas are the most common benign lung tumor and account for up to 7% of solitary lung nodules. They occur more commonly in male patients and have a peak incidence in the fifth to seventh decades of life.[85] The clinical presentation of pulmonary hamartomas is typically asymptomatic and they are usually detected incidentally. Larger tumors can present with cough, hemoptysis, chest pain, and postobstructive pneumonia. Hamartomas in the lung are typically located in the periphery of the lung and are well-circumscribed with smooth borders.[86] Approximately 8% of pulmonary hamartomas can be located in the central airways within the bronchus. In general, hamartomas in the lung are indolent and slow-growing neoplasms. The average growth rate of these benign lung neoplasms has been shown to be 3.2 mm, 0.8 mm, to 5.8 mm per year.[87]

Pulmonary hamartomas typically appear as solitary, peripheral, well-circumscribed lung nodules with characteristic smooth borders. Calcification is present in 10% to 30% of hamartomas of the lung although fat can be present in up to 50% of lesions.[88] CT scan can be an effective diagnostic tool for hamartomas of the lung. Small peripheral and well-circumscribed lung nodules with calcification are pathognomonic for pulmonary hamartomas.[89] MRI can identify a common cleft-like architecture of a pulmonary hamartoma which can increase the confidence of the diagnosis.[90] Endobronchial hamartomas are easily identified with flexible fiberopetic bronchoscopy. CT-guided FNA is the most effective modality for obtaining a histologic diagnosis of pulmonary hamartoma. The diagnostic yield is as high as 85%.[91]

The presence of fibromyxomatous tissue and fragments of cartilage are diagnostic of hamartoma.

The management of pulmonary hamartomas depends on the clinical presentation. The benign tumor typically has slow growth and is asymptomatic. Follow-up with a CT scan of the chest annually is recommended. Patients with a diagnosis of a pulmonary hamartoma are very unlikely to develop symptoms or malignant transformation during their lifetime even without surgical resection.[92] When patients present with pulmonary hamartomas with associated symptoms or lesions with concerning growth rates, surgical resection may be indicated. Limited resections with a wedge resection with negative margins can be achieved for small peripheral pulmonary hamartomas with thoracoscopic or robotic approaches.[93–96] Pulmonary lobectomy is reserved for surgical resection of large, centrally located pulmonary hamartomas.

Nonneoplastic Thoracic Disease

Rishindra M. Reddy

Key Points

1. Surgical intervention for chest wall tumors depends on the type of lesion and goals of surgery (resection vs. diagnosis). Reconstruction varies depending on the size of the defect and location on the chest wall.
2. Thoracic outlet syndrome (TOS) may be arterial, venous, or neurogenic. Neurogenic TOS is the most difficult to diagnose and surgery for this should be performed in high-volume centers.
3. The primary treatment for a lung abscess is antibiotic therapy.
4. Hemoptysis can be life threatening from suffocation due to a low volume of blood in the lungs, not from blood volume loss requiring transfusion.
5. Primary spontaneous pneumothoraces will recur in only 30% of patients after initial treatment. When they recur, the treatment should include a thoracoscopic evaluation and possible pleurodesis.
6. Transudative pleural effusions should be treated medically, while exudative effusions may need more intervention. One-quarter of pleural effusions in a community hospital are due to malignancy.
7. Empyema is a part of a spectrum of disease that may be treated early on with drainage alone, but may require debridement and decortication in more advanced cases.
8. Complications of tracheostomies are usually due to improper placement of the tracheostomy on the trachea (below the 3rd ring, risking a tracheoinnominate fistula) or to the use of high pressures in the cuff of the tracheostomy (causing ischemia and long-term stenosis).
9. Mediastinitis is life threatening and warrants immediate evaluation, antibiotic therapy, and surgical drainage.

INTRODUCTION

This chapter is meant as resource for the general surgery community and surgery residents with regard to pathology in the chest. We will cover a wide variety of topics including most noncardiac congenital disease processes in the thorax.

CHEST WALL ANATOMY

The chest wall is the musculoskeletal structure that contains and protects the structures of the upper trunk or thorax. There are two openings to the thorax, the superior aperture, or the thoracic inlet, and the inferior aperture, which leads to the abdominal cavity. The head and arms connect to the intrathoracic structures via the inlet, whereas the diaphragm separates the thoracic and abdominal cavities at the inferior aperture. The inferior vena cava, esophagus, and aorta travel to the abdomen through the diaphragm at levels T8, T10, and T12, respectively.

The sternum, commonly known as the breast bone, is comprised of three parts, the manubrium, the body, and the xiphoid. The manubrium attaches to the clavicles and the first costal cartilages. The sternal angle, also called the angle of Louis, refers to connection between the manubrium and the sternal body and is an important landmark. The second ribs attach to the sternum at this angle and they allow one to count the ribs from this point down, as the first ribs are not palpable. The body of the sternum contains articular facets for ribs 2 to 7 and connects to the cartilaginous xiphoid inferiorly. The xiphoid may be bifid and will eventually ossify in older adults (**Fig. 80.1**).

The ribs are split into two groups; the upper 7 pairs are the true ribs, with articulations to the sternum, while the lower 5 pairs are the false ribs. Ribs 8, 9, and 10 connect to each other and the upper ribs via their costal cartilage. Ribs 11 and 12 are called floating ribs as they have no anterior connection. Rib 1 is uniquely shaped as it is flat, short, and extremely curved. Ribs 2 through 10 have a more standard configuration with the head containing articular facets for the vertebrae. After the neck, the tubercle contains the facet for the vertebral transverse process. The costal groove along the inferior portion of the shaft houses the intercostal bundle, consisting of the nerve, artery, and vein (**Fig. 80.2**). Because of this inferior placement, most chest wall procedures such as thoracostomy tube placement or

thoracentesis should be aimed at the superior aspect of the rib to avoid injury to this bundle.

There are three intercostal muscles, the external intercostal, the internal intercostal, and the innermost intercostal muscle. The intercostal bundle lays just external to the innermost intercostal layer (**Fig. 80.3**). On the inner aspect of the chest wall, the internal thoracic (mammary) artery and vein run between the innermost intercostal muscle and the transversus thoracic muscles which connect the ribs to the lower half of the sternal body. The intercostal arteries have two sources, posteriorly from the descending thoracic aorta and anteriorly from the internal thoracic arteries. The intercostal nerve is a branch off the ventral ramus after it joins the sympathetic trunk. The intercostal veins follow the arteries and posteriorly drain into the azygos and hemiazygos veins. Lymphatic drainage from the posterior chest wall drains into the thoracic duct on the left and into the right lymphatic duct on the right.

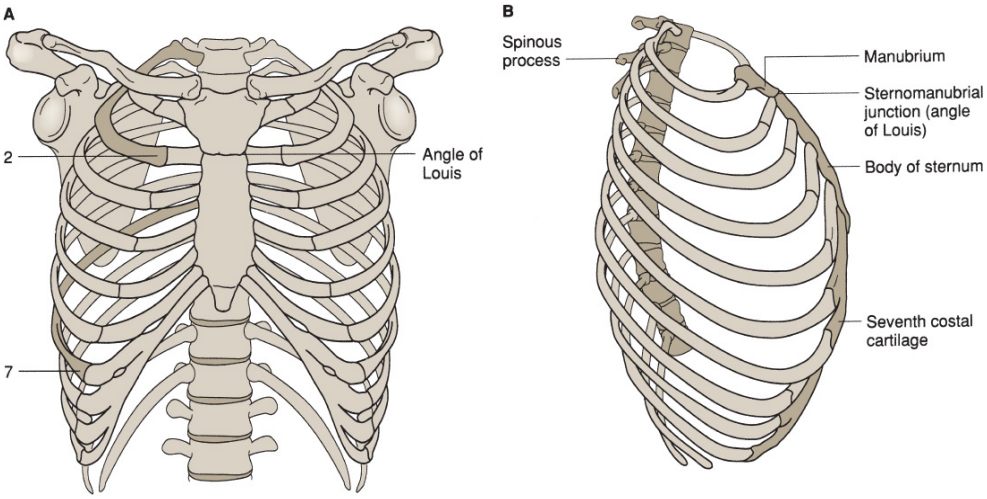

Figure 80.1 Skeletal support of the thorax. Anterior (**A**), and lateral (**B**), views. Note the anterior cartilaginous component of the upper 10 ribs, the fused costal cartilages of ribs 7 through 10, the location of the sternomanubrial junction (angle of Louis) at the level of the second rib, and the oblique course of the ribs laterally from posterior to anterior.

The muscles of the chest wall can be divided embryologically into those from the epimeres, such as the deep back muscles, innervated by the dorsal rami, and those from the hypomeres, such as the intercostals and rectus, innervated by the ventral rami. The musculature can also be classified based

on respiratory function, where the primary muscles of respiration are the intercostals and the diaphragm, and the secondary, or accessory muscles are the sternocleidomastoid, scalenes, pectoralis, serratus, and abdominal wall musculature. The major back muscles include the trapezius and latissimus dorsi (**Fig. 80.4**). In normal breathing, the diaphragm performs a majority of the work with the intercostals supplying about a quarter of the workload. In full inspiration, the pleura extends bilaterally down to the level of the 11th and 12th ribs (**Fig. 80.5**).

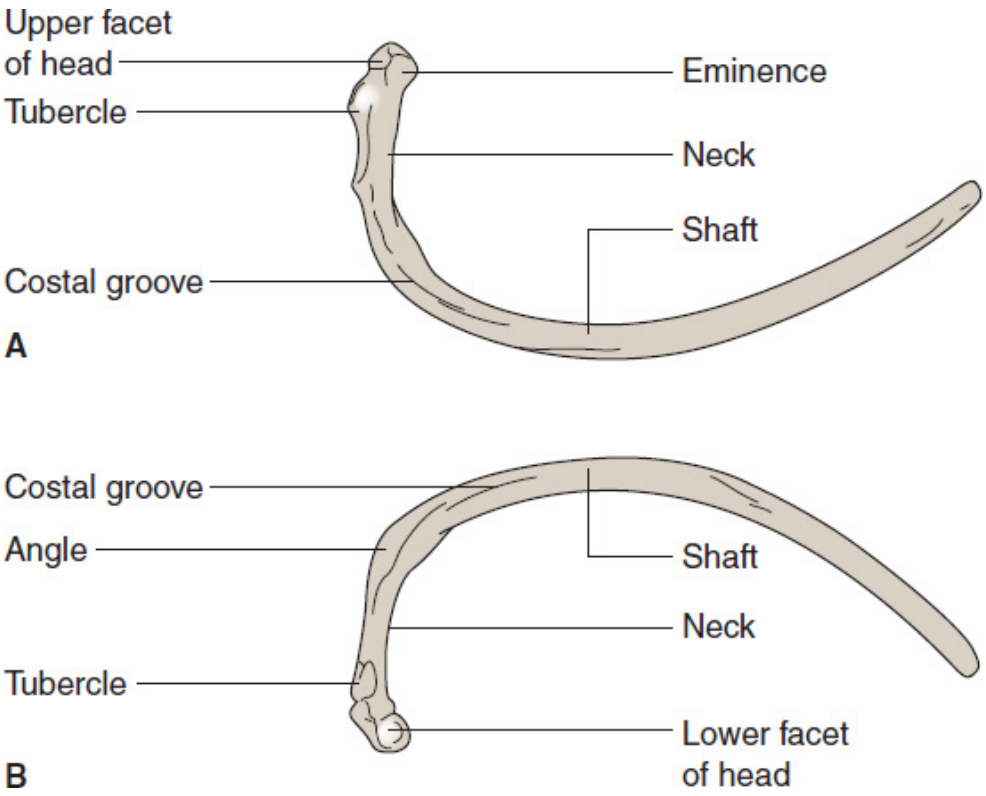

Figure 80.2 Anatomy of ribs 2 to 10 as viewed from above (**A**), and below (**B**).

CHEST WALL NEOPLASMS

Chest wall tumors are very rare. Lesions may be divided into benign and malignant, and then further subdivided into soft tissue versus bony/cartilaginous tumors (**Table 80.1**). Most malignant tumors of the chest wall are either metastatic from carcinomas or sarcomas arising in other sites of the body, or from local extension of lung cancers or breast cancers.[1]

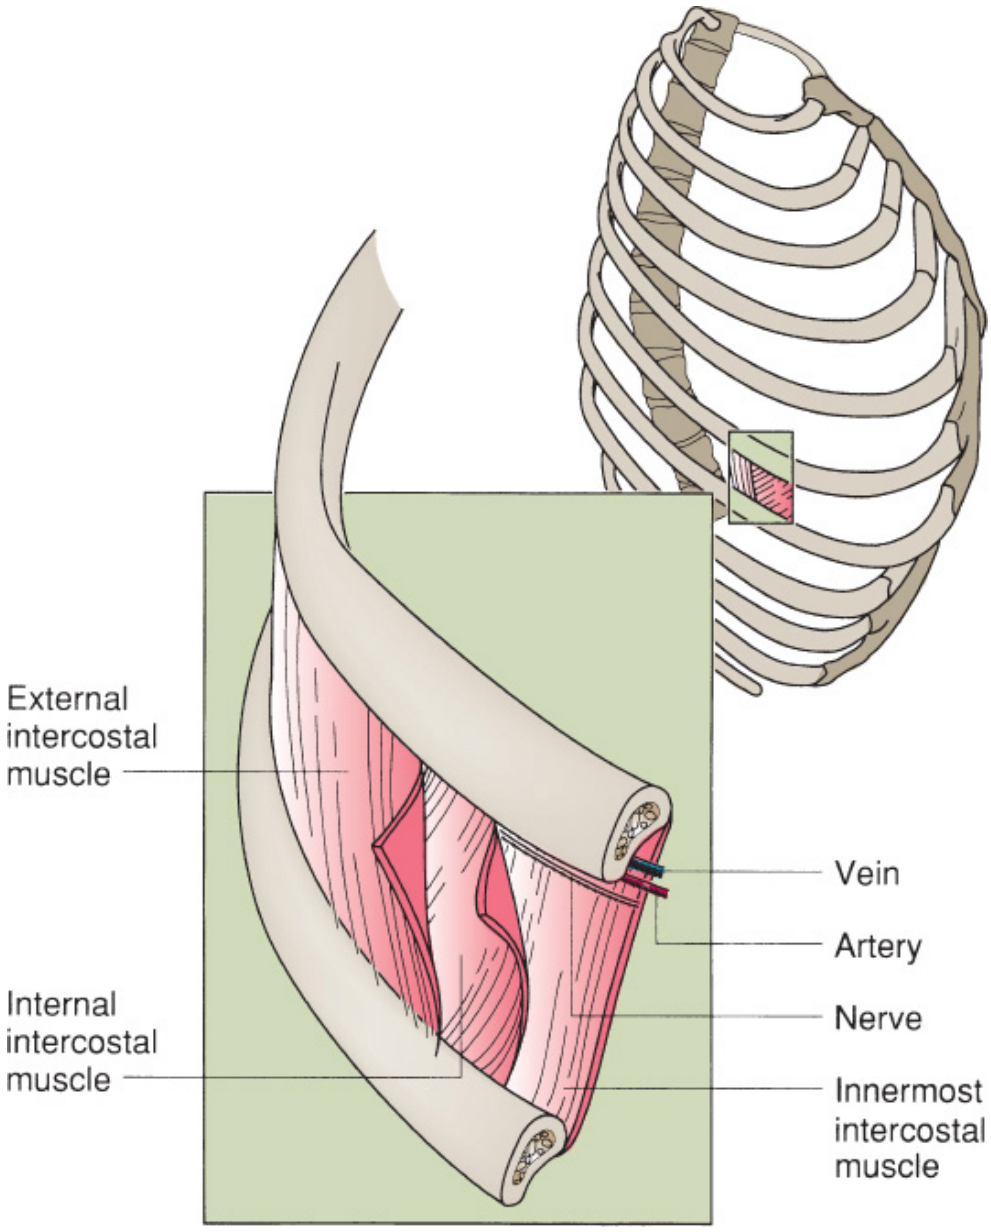

Figure 80.3 Anatomy of the intercostal space. The major intercostal muscles are the external and internal. The neurovascular bundle courses in the costal groove along the inferior aspect of the rib.

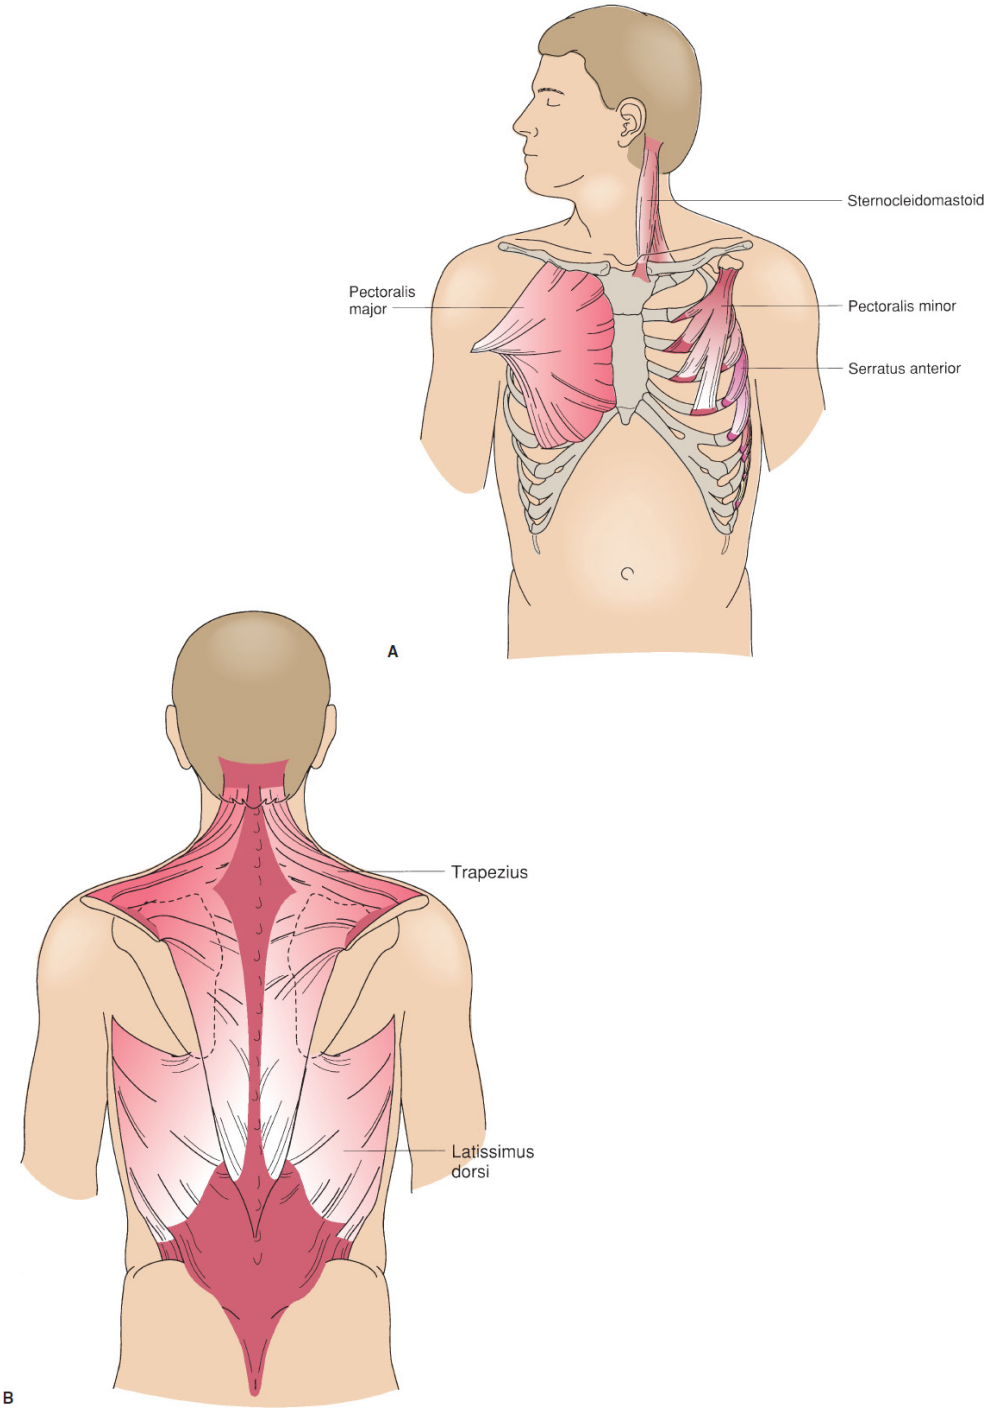

Figure 80.4 Thoracic musculature. Anterior (**A**), and posterior (**B**), views.

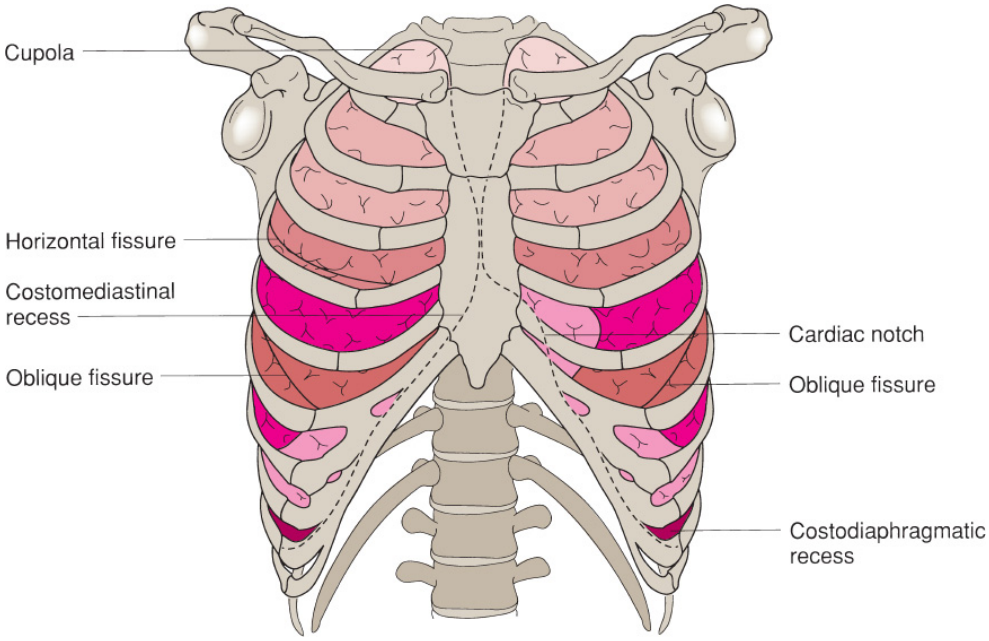

Figure 80.5 Topographic relations of the pleura to the chest wall. Laterally, the pleura extends to the level of the 11th to 12th ribs. The anterior reflection of the mediastinal and costal pleurae forms the costomediastinal recess, whereas the reflections of the costal and diaphragmatic pleurae form the costodiaphragmatic recess.

Table 80.1 Chest Wall Tumor Classification

  - Breast cancer
  - Lung cancer
  - Mediastinal tumors

Mesothelioma
Other sarcomas or carcinomas

Almost all lesions will present as a mass, as pain, or as a combination of both. Occasionally, they will be asymptomatic and be identified on imaging for cancer surveillance or other reasons.[2] Evaluation of these lesions includes a thorough history and physical and appropriate imaging, which may begin with plain radiographs, but should include three-dimensional imaging such as a CT scan and/or MRI as well as PET scan for staging if clinically indicated.[1]

Surgical intervention depends on the type of lesion and the goal of surgery. Tumors that are suspected metastases may require only a needle or an incisional biopsy to confirm the diagnosis. Lesions that are possible primary tumors, whether benign or malignant, require excisional biopsies. Some low-grade malignant tumors may be underdiagnosed and considered benign if the entire specimen is not removed and examined. If a tumor is proven to be a primary malignant lesion, wide excision is required, with margins up to 4 cm.[3]

BENIGN SOFT TISSUE TUMORS

These tumors include lipomas, fibromas, hemangiomas, and neurofibromas among others. These can be removed by excisional biopsy and require no further treatment unless they recur. Inflammatory osteomyelitis can mimic tumors by causing pain.

BENIGN BONY/CARTILAGINOUS TUMORS

About two-thirds of benign chest wall tumors are either osteochondromas, chondromas, or fibrous dysplasia, with osteochondromas comprising almost 50% of all nonmalignant rib tumors. Osteochondromas usually present as painless masses with a male-to-female predominance of 3:1. If the lesion becomes painful it may indicate malignant degeneration.[3] They are often

found on routine radiographic examinations for other reasons and have a characteristic appearance of a pedunculated bony prominence (**Fig. 80.6**).

Figure 80.6 Osteochondroma of left second rib. The stippled calcification within the tumor and the intact cortex of the rib are characteristic.

Chondromas account for 15% of benign rib lesions and grow from the cartilage at the sternocostal junction.[1] They have an equal male-to-female incidence. Clinically and radiographically, it is impossible to distinguish chondromas from chondrosarcomas. It can be difficult microscopically to distinguish chondromas from low-grade chondrosarcomas as well. As a

result, all chondromas must be treated as if they are potentially malignant and require complete excision.[3]

Fibrous dysplasia arises in the lateral portion or shaft of the rib and can have a "soap bubble" or "ground-glass" appearance on radiographs (**Fig. 80.7**). These lesions may become painful if they enlarge and can result in rib fractures. Surgical excision is needed for diagnosis and symptom relief.[4] Eosinophilic granulomas and osteoid osteomas are rare conditions that affect men more often. Patients may have multiple granulomas, including the skull and may benefit from radiotherapy as opposed to surgical resection. Osteomas may be symptomatic and if so, should be resected.

MALIGNANT SOFT TISSUE TUMORS

These lesions can range from melanomas to desmoid tumors to malignant fibrous histiocytomas (MFHs). Sarcomas also arise in the soft tissue of the chest wall, but they comprise less than 10% of all sarcomas.[2] Desmoid tumors are borderline lesions between a benign and malignant classification, and are sometimes considered low-grade fibrosarcomas.[1] Almost half of all desmoids occur in the chest wall and shoulder where they can encapsulate the brachial plexus. They require wide local excision and have a high rate of recurrence. If they encircle vital structures, they can be treated with radiotherapy after surgical excision.[3]

MFHs are the most common primary chest wall tumors. They are more frequent in men (2:1 ratio) and generally occur after the age of 50. They are slow growing, painless, and spread along the facial planes or between muscle fibers. MFHs are unresponsive to other forms of therapy and require wide local excision. Because of the lesion's propensity for fascial plane infiltration, there is a high rate of recurrence following resection and patients who have undergone resection have a 5-year survival of under 40%.[3] Rhabdomyosarcoma is the second most common soft tissue lesion of the chest wall and usually occurs in children and younger adults. It grows rapidly from the striated muscle, but is usually painless. It is treated with wide excision followed by radiation and chemotherapy with a reported 70% survival at 5 years.[3]

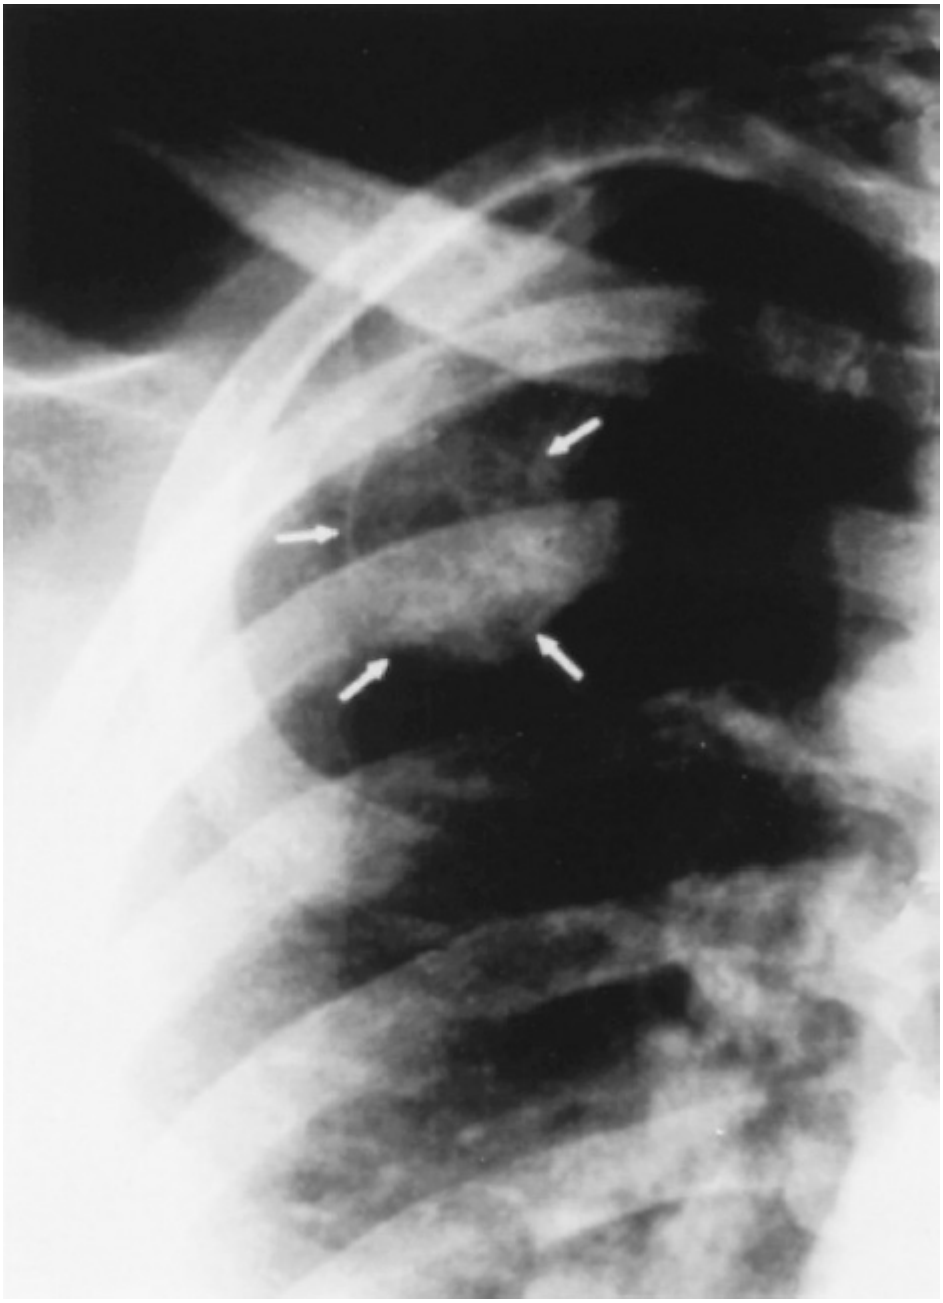

Figure 80.7 Fibrous dysplasia of the rib. Note the characteristic expansion and thinning of the cortex (*arrows*) and the central ground-glass appearance.

MALIGNANT BONY/CARTILAGINOUS TUMORS

Chondrosarcomas are the most common primary malignant bony tumors, accounting for 20% to 30% of lesions. These are well-differentiated tumors and on microscopic examination may be difficult to distinguish from their benign counterparts. Local recurrence can occur after excision and if untreated, distant metastases can develop.[3] Osteogenic sarcomas are more common in the limbs, but also occur in the ribs. Radiographs depict a characteristic "sunburst" pattern. These tend to grow quickly and often have metastases at the time of initial presentation. Patient evaluation should include a CT scan and bone scan to check for the presence of metastatic disease. Surgery with adjuvant chemotherapy is the treatment of choice for local disease.[5] Ewing sarcomas constitute 5% to 10% of chest wall tumors. They occur in children and younger adults with a male-to-female ratio of 1.6:1. Symptoms include pain, fever, and fatigue. Radiographs show a large soft tissue mass with bony destruction. Patients often present with metastatic disease, and ultimately three-quarters of patients will develop metastases. Multimodality treatment is the key to treatment. Survival may be less than 30% at 5 years in patients with metastatic disease.[6]

Solitary plasmocytoma is a rare tumor of the plasma cells and can be part of a systemic disease in multiple myeloma. Lesions can be painful and usually occur in men over the age of 50. X-ray findings show cortical destruction of the rib (**Fig. 80.8**). In the setting of systemic disease, only a needle biopsy may be needed, but if the lesion is small and symptomatic, resection can be offered. For larger lesions, radiotherapy is the primary treatment.[1]

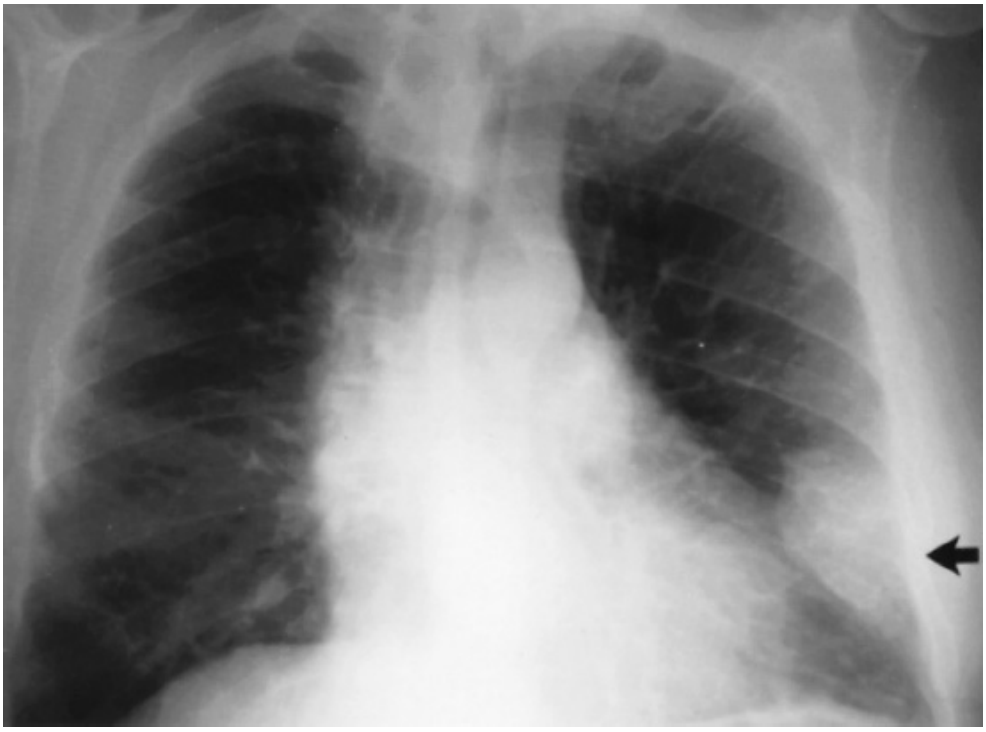

Figure 80.8 Plasmacytoma of the left seventh rib, showing characteristic cortical destruction and relatively large soft tissue component projecting into the chest.

METASTATIC TUMORS

As discussed before, metastatic lesions can arise from a variety of other cancers, and treatment depends on the primary histology, time to recurrence, and goals of intervention. For isolated metastases with a long interval before recurrence, surgical resection may be warranted. Each case should be individualized and discussed within a multidisciplinary team.

CHEST WALL RECONSTRUCTION

Chest wall defects can result from cancer, radiation, trauma, or infection.[7] The goals of repair are to provide stabilization and protection to the thoracic cavity, to minimize complications of respiration due to a flail 1 chest, and to provide cosmetic coverage as needed. Size and location generally determine the need for chest wall stabilization. Defects less than 5 cm anywhere in the chest wall, or defects less than 10 cm in the posterior chest wall that are

anterior to the scapula do not usually need stabilization.[7,8] An alternative criterion is to use the number of ribs resected, and to avoid stabilization when a portion of three ribs or less has been removed.[9] Techniques for closure of the defect include utilizing absorbable Vicryl mesh, used in the setting of infection or if small defects are present. This approach does not provide any stabilization. More definitive repairs utilize polytetrafluoroethylene (PTFE), polypropylene methylmethacrylate (PPM) sandwich mesh, or titanium-plating systems.[10] PTFE is a flexible, soft material, while the PPM sandwich mesh resembles a hardened piece of plaster between two portions of woven mesh. Different surgeons prefer different approaches, but some of the benefits cited for the PTFE repair include greater stretch and the ability to create a water tight seal.[7] The PPM sandwich repair on the other hand allows the ability to mold the prosthetic and provides a firmer stabilization (**Fig. 80.9**).[10] Mortality rates from chest wall reconstruction in the setting of cancer resections have been reported at 4% in multiple series.[7,9]

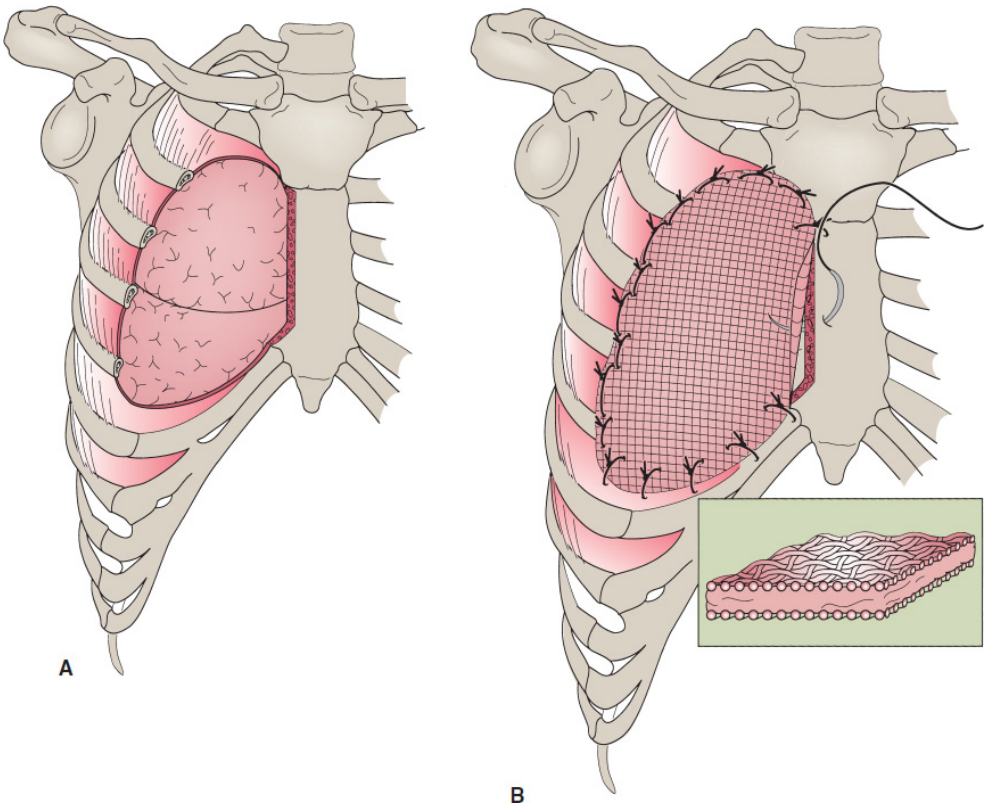

Figure 80.9 Marlex methylmethacrylate sandwich technique for chest wall reconstruction. **A:** Upper anterior chest wall defect resulting from resection of ribs two to five and a portion of sternum. **B:** Marlex methylmethacrylate prosthesis being sutured in place. Heavy, nonabsorbable sutures either encircling the ribs or passed through the sternum are used to anchor the prosthesis in place. *Inset:* Detail of prosthesis showing sandwich of hardened methylmethacrylate between two sheets of Marlex.

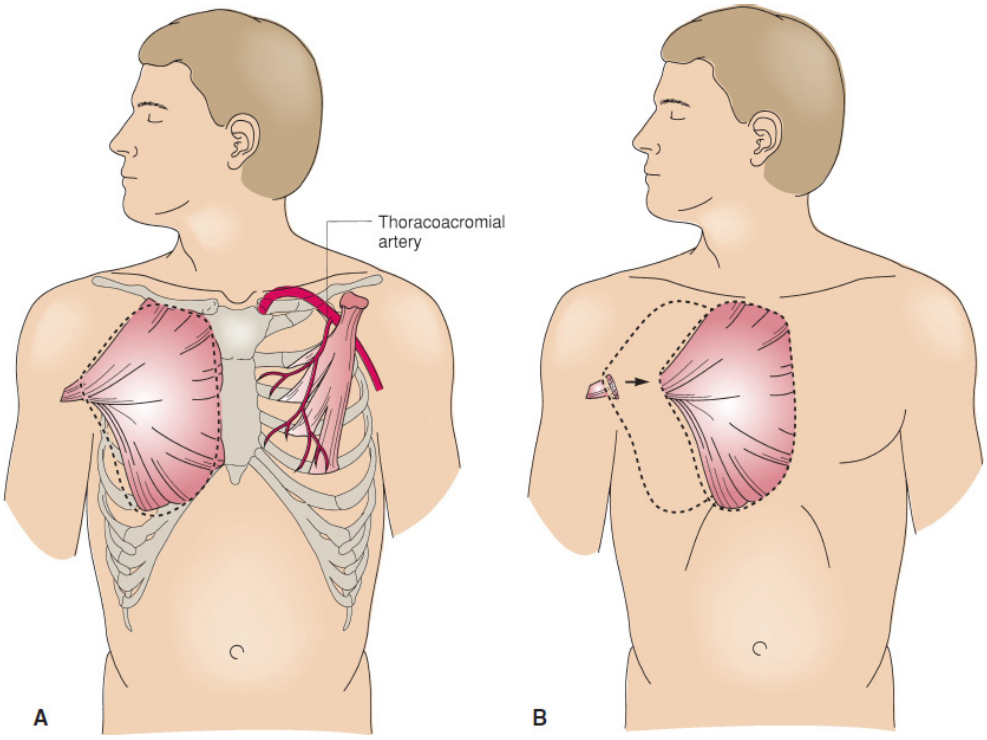

Figure 80.10 Pectoralis major muscle rotation flap. **A:** Mobilization of the flap by detaching the clavicular, sternal, and chest wall origins as well as the insertion of the muscle on the greater tubercle of the humerus. The dominant blood supply, the thoracoacromial artery, which arises from the axillary artery medial to the proximal border of the pectoralis minor muscle, is shown on the left side where the pectoralis major muscle has been removed. **B:** Medial transposition of the muscle flap, preserving the thoracoacromial neurovascular bundle.

Flap coverage of the soft tissue defect will almost always require the assistance of a plastic surgeon, and they should be involved preoperatively in the planning of a chest wall resection and reconstruction. The decision-making process for which flap to use depends on the location of the defect, the size of the defect, the corresponding size of the flap, and its vascular source. Pectoralis major flaps are the most common in the upper chest/neck region. Its blood source can be from the thoracoacromial artery or from intercostal perforators from the internal thoracic arteries (**Fig. 80.10**). The latissimus dorsi flap is also commonly used for large, ipsilateral defects. Its blood source is from the thoracodorsal artery or from perforators from the posterior intercostal vessels. It has a large arc of rotation from the thoracodorsal pedicle and can cover a wide area of the chest wall (**Fig. 80.11**). Also commonly used are rectus abdominal muscle flaps in either a vertical (VRAM) or transverse (TRAM) orientation (**Fig. 80.12**).

External obliques can be used on the lower anterior chest wall, and the trapezius can be used in the mid back.[11] Omental flaps are extremely useful and versatile. They can be used to cover large defects or to fill cavities, such as the pleural space in the setting of a bronchopleural fistula and empyema. The omentum can be taken off of the right or left gastroepiploic artery, but using the right arterial source allows a greater arc of rotation than from the left. The limitations of this flap are that it requires a laparotomy, although laparoscopic techniques have been described,[12] and that the size of the omentum can be variable, and difficult to assess preoperatively (**Fig. 80.13**).[11]

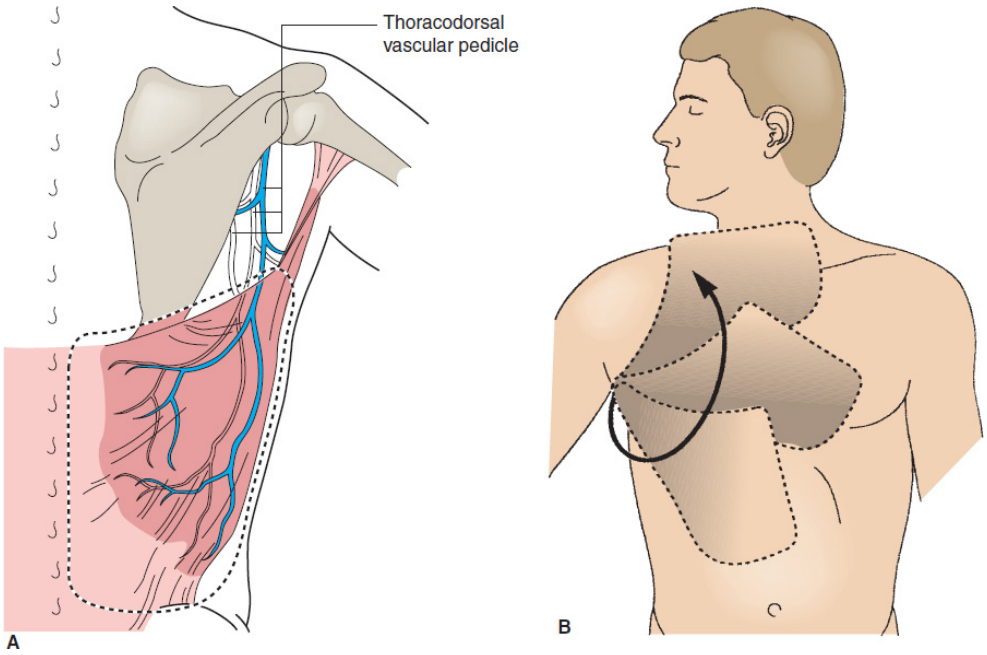

Figure 80.11 Latissimus dorsi muscle rotation flap for chest wall reconstruction. **A:** Posterior view showing detachment of the origins of the muscle. The dominant blood supply, the thoracodorsal artery, is preserved. **B:** Anterior view showing the extent to which the mobilized muscle reaches.

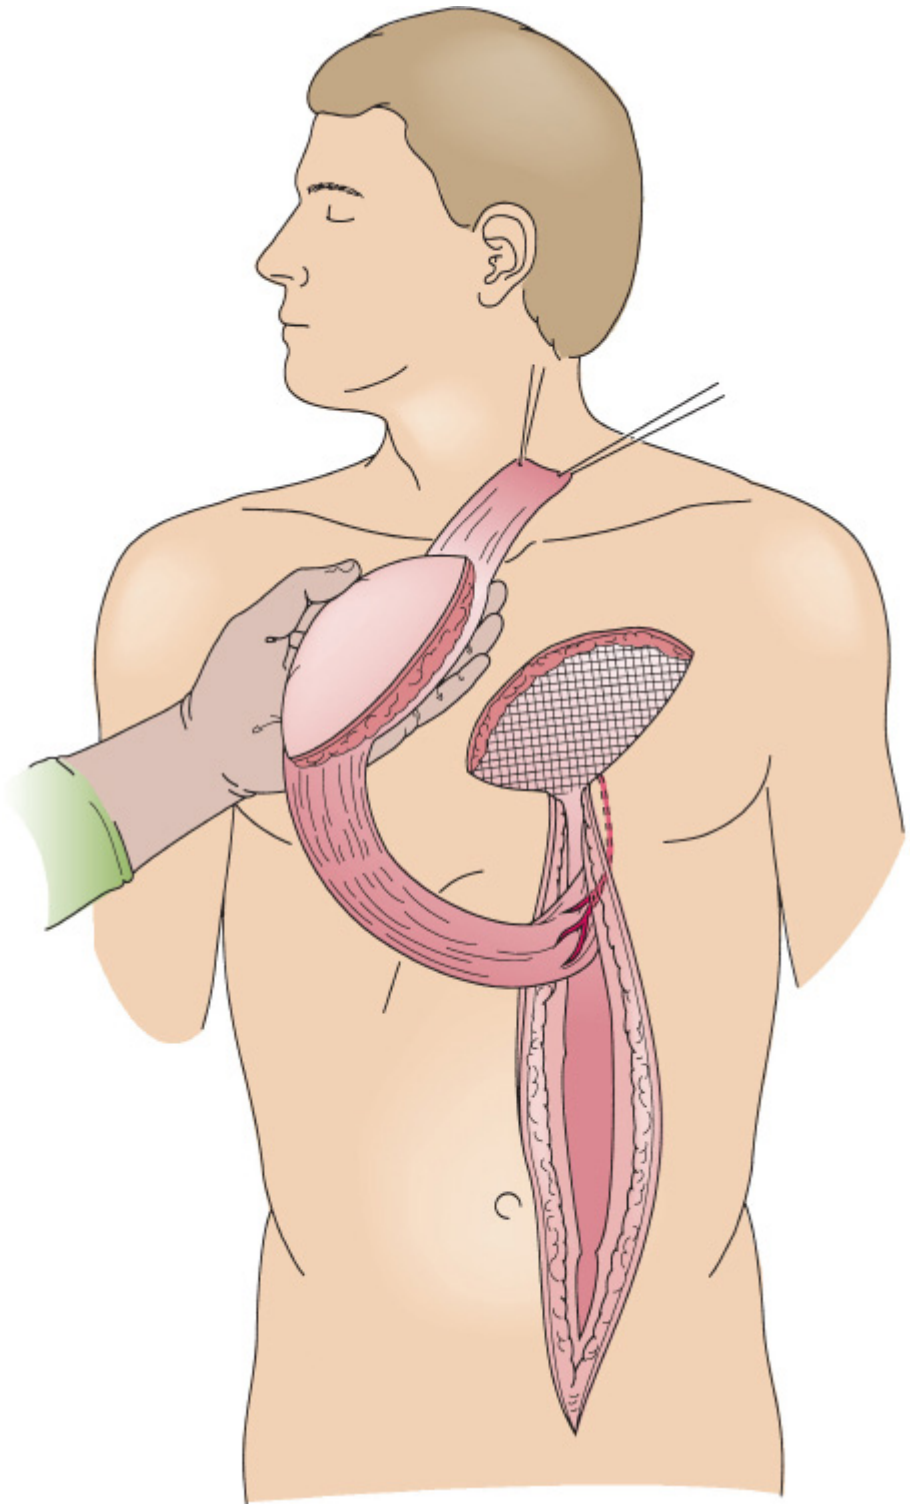

Figure 80.12 Rectus abdominis muscle rotation flap. Shown is the mobilization of the rectus abdominis muscle, which is based on the superior epigastric artery (the continuation of the internal thoracic artery), and rotation of the muscle and overlying skin to fill an anterior chest wall defect.

CHEST WALL CONGENITAL ABNORMALITIES AND THORACIC OUTLET SYNDROME

Pectus Excavatum and Pectus Carinatum

Chest wall deformities occur in 1/1,000 live births. They are five times more common in men than women, and up to 6% of people with these deformities will also have a connective tissue disorder. Pectus excavatum is the most common deformity and appears as a sternal depression that can be off midline approximately 50% of the time. Pectus carinatum is the opposite, with a sternal protrusion, often described as a "pigeon chest" deformity. Pectus excavatum is five times more common than pectus carinatum. Scoliosis is frequently seen in this population.[13] Less common deformities include sternal clefts, which are incomplete fusions of the sternum, and Poland syndrome, where there is an absence of a pectoralis muscle and underlying bony support in the chest wall.

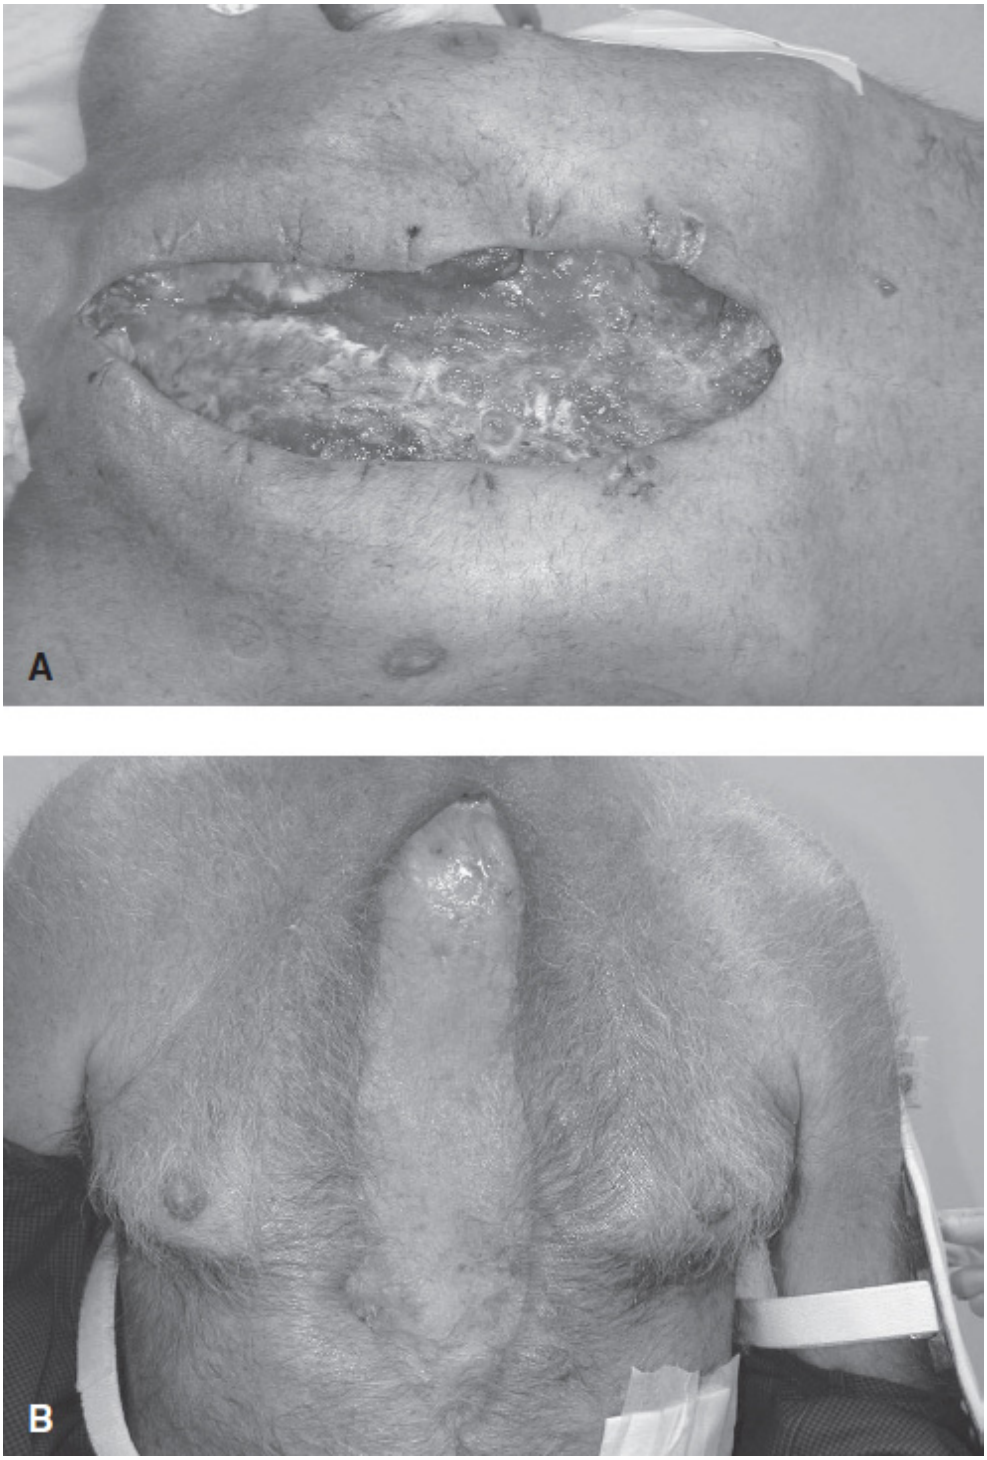

Figure 80.13 The omentum can be used to cover large defects. Shown is an open sternal wound after debridement with failed prior muscle flap (**A**), and wound 6 months after omental flap placement (**B**). (Reproduced with permission from Ghazi B, Carlson G, Losken A. Use of the greater omentum for reconstruction of infected sternotomy wounds: a prognostic indicator. *Ann Plast Surg* 2008;60(2):169–173.)

The techniques for surgical correction of pectus excavatum have been evolving, including the Ravitch and Nuss procedures. Despite this, less than 15% of patients undergo surgery.[14] Most patients present as children with notable deformities. People can be physiologically asymptomatic, but can also present with fatigue, limited stamina, and cardiopulmonary limitations. The workup includes pulmonary function testing, echocardiography, and CT scans. The pectus severity index (Haller index) can be calculated by dividing the inner thorax width by the depth measured from the posterior aspect of the sternum to the anterior aspect of the spine (**Fig. 80.14**). Normal values are 2 to 2.2, and repair is only recommended when the index is at least greater than 3.1.[13,15] The age of the patient at which repair should be performed is also somewhat controversial, as some surgeons advocate waiting until after the age of 10, but many series have reported on a large number of patients treated at a much younger age with good outcomes.[14,16] There is a growing experience with treating adults also, as some patients seek repair at a later age (**Fig. 80.15**).[17,18]

The most commonly used open repair was first described by Dr. Ravitch and is based on removing sections of the deformed cartilage from around the sternum laterally at the ribs, while preserving the perichondrium. Many advocate using a stabilizing bar for a minimum of 6 months, usually placed in an intrathoracic position, to minimize the occurrence of flail chest and to allow the sternum to heal in an anterior position. An essential part of the procedure is a transverse sternal wedge resection through the anterior table to allow the inferior aspect of sternum to bend forward.[13,18] Incisions may be in a vertical midline over the lower half of the sternum or in an inframammary position (**Fig. 80.16**). Recurrences occur in 5% to 10% of patients, with recurrence more common in patients with connective tissue disorders.

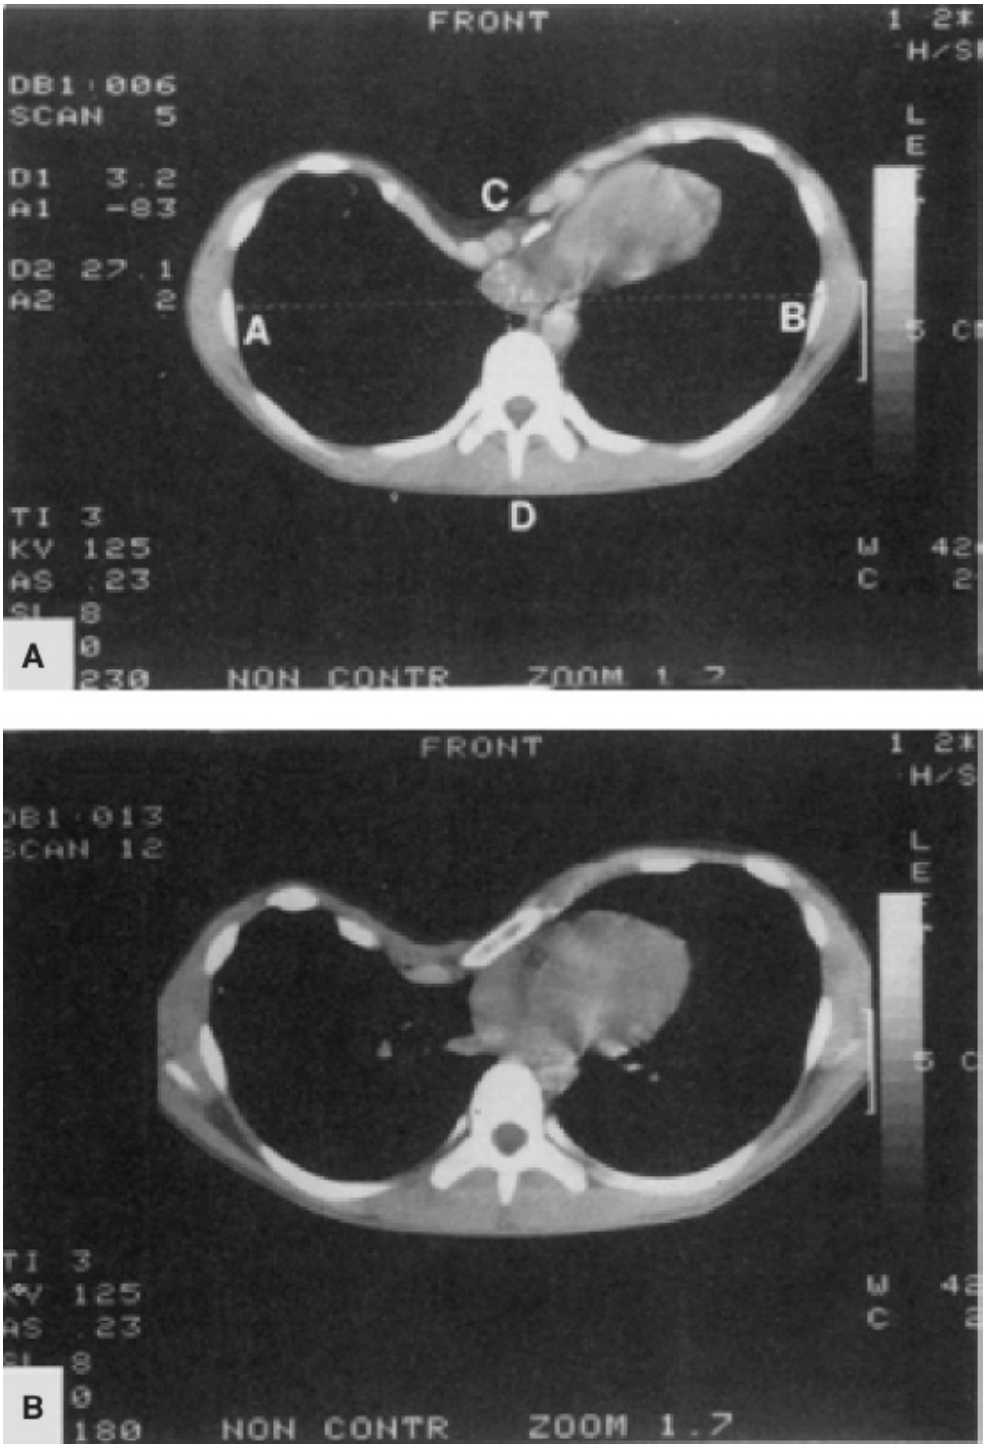

Figure 80.14 Chest CT of pectus excavatum. CT image at xiphoid with A–B (transverse diameter) and C–D (anterior–posterior diameter) indicated for the calculation of the pectus severity index A–B/C–D (**A**). CT image demonstrating angulation of the sternum to the right in the severe defect (**B**). (Reproduced with permission from Haller JA Jr, Scherer LR, Turner CS, et al. Evolving management of pectus excavatum based on a single institutional experience of 664 patients. *Ann Surg* 1989;209(5):578–582.)

Since the 1990s, the Nuss procedure, which utilizes a minimally invasive approach, has been described and performed. The Nuss procedure utilizes one or two stabilization bars, secured to the ribs laterally in multiple points of fixation. It routinely employs thoracoscopy, either unilateral or bilateral. Skin incisions are limited to small lateral locations at the site of the bar insertion and thoracoscopic port sites. In both the Ravitch and Nuss procedures, the stabilization bars stay in for at least 6 months.[19] As the Nuss procedure has grown in popularity, many modifications have been made, including precise shaping of the bars and increased bar stabilization with wire fixation around the ribs to minimize bar displacement.[20]

Pectus carinatum does not have the same cardiac compression concerns as pectus excavatum, but the chest is held in an enlarged position, limiting normal respiration mechanics. Patients can have increased residual lung volumes and their respiratory physiology can mimic emphysema physiology. This can result in breathing difficulties and limited stamina.[18] The Ravitch procedure is most commonly performed to remove the deformed cartilage. Special attention is placed on the transverse sternal osteotomy, to depress the sternum and align it with the anterior ribs (**Fig. 80.17**).[13]

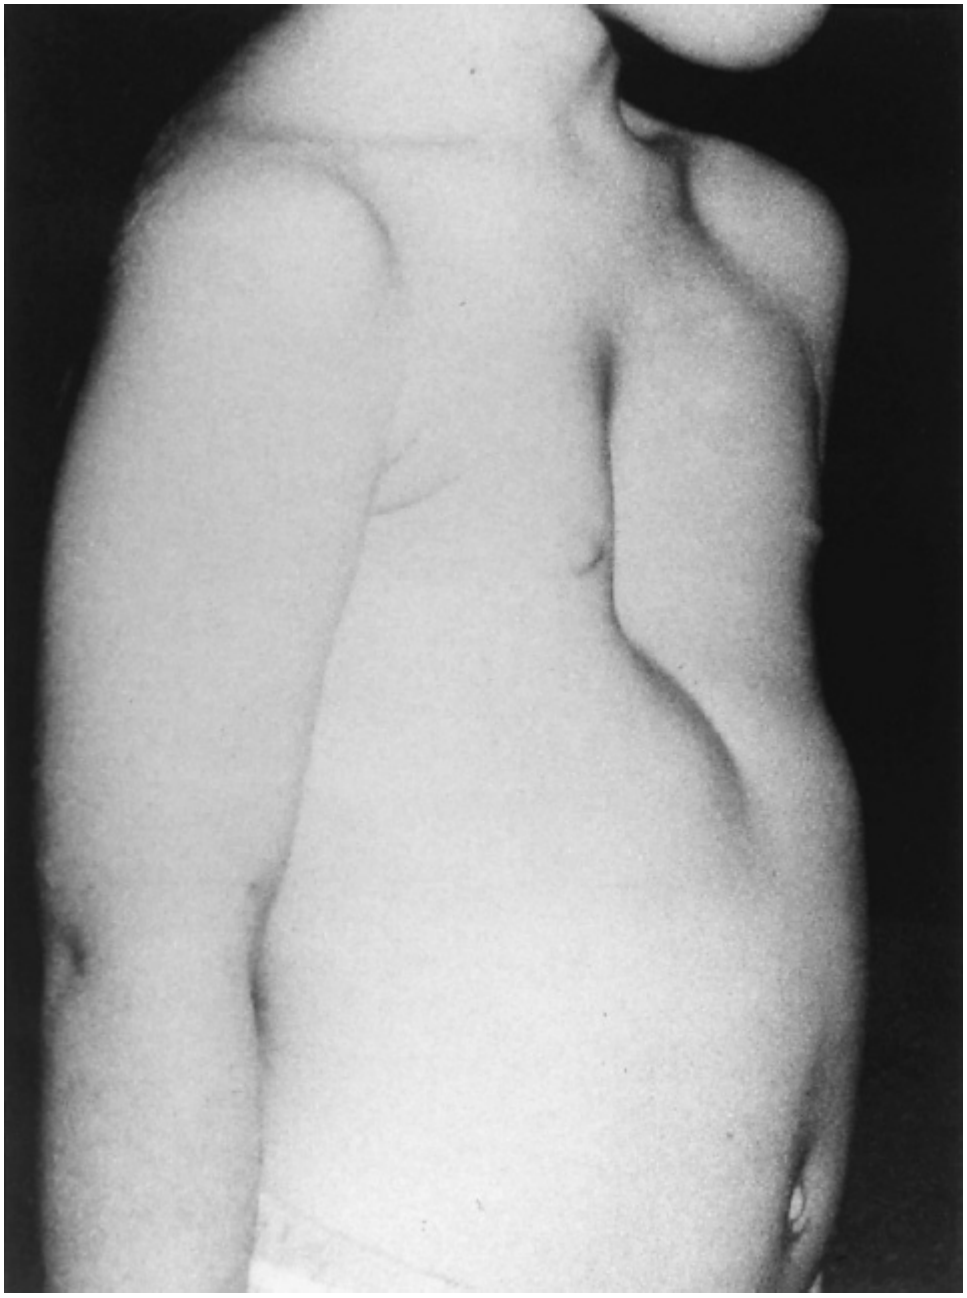

Figure 80.15 Photograph of a 4.5-year-old girl with a symmetric pectus excavatum deformity. Note that the depression extends to the sternal notch. (Adapted with permission from Shamberger RC. Chest wall deformities. In: Shields TW, ed. *General Thoracic Surgery*. 4th ed. Baltimore, MD: Williams & Wilkins; 1994:529–557.)

Sternal Clefts

Sternal clefts are much rarer than either pectus deformity. They result from the failure of the sternum to fuse in the midline. They can vary from minor defects with the upper half of the sternum separated, to complete dissociation and thoracic ectopia cordis (the heart being outside the chest wall). Upper sternal defects have a U- or V-shaped appearance and usually extend to the fourth intercostal space (**Fig. 80.18**). Repair of these defects can be easily performed by incision, complete sternotomy, oblique chondrotomies of the sternal halves, and closure. Complete sternal clefts are associated with diastasis recti and an opening between the peritoneal and pericardial cavities. Inferior clefts are associated with the pentalogy of Cantrell, a constellation of defects which include supraumbilical abdominal wall defect, lower sternal cleft, defect in the anterior diaphragm, defect in the associated pericardium, and congenital cardiac defects, often tetralogy of Fallot.[21]

Poland Syndrome

Poland syndrome is the clinical absence of a pectoralis muscle and underlying bony support in the chest wall, and it occurs in 1/30,000 live births. It is usually a right-sided, unilateral defect. Patients commonly have associated limb abnormalities, and may also present with renal and spinal lesions (**Fig. 80.19**). Clinical symptoms may be absent, though lung herniation can occur, requiring a more urgent repair. The surgical approach is usually multidisciplinary and ideally is deferred until after the patient has stopped growing. Repairs typically utilize mesh placement over the defect, and/or muscle flap placement.[22]

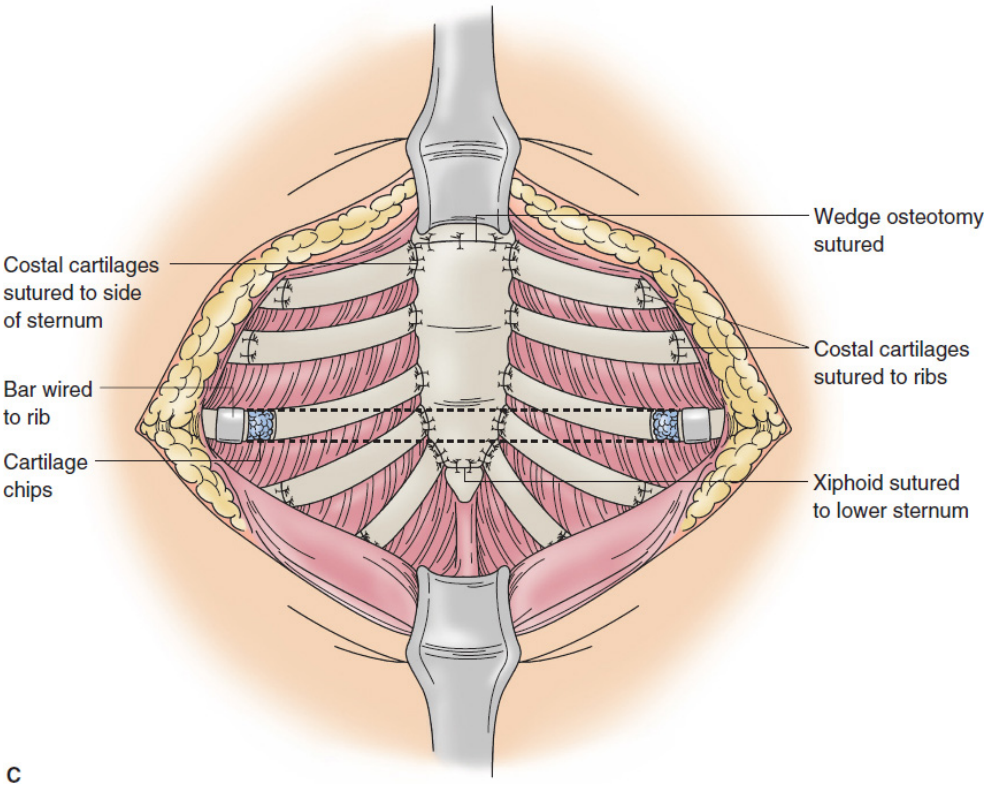

Figure 80.16 A chevron incision is made with flaps elevated. The perichondrium on the deformed cartilage is removed (**A**). A transverse wedge osteotomy is made across the anterior table of the sternum. The lower sternum is elevated to the desired level (**B**). A metal strut is placed posterior to the sternum and attached to the ribs with fine wire (**C**).

Thoracic Outlet Syndrome

The thoracic outlet in thoracic outlet syndrome (TOS) refers to the area described at the beginning of this chapter as the thoracic inlet, the correct anatomic term for the region of the first rib and the middle and anterior scalene muscles. Through these structures, the brachial plexus, subclavian artery, and subclavian vein travel to the upper limbs (**Fig. 80.20**). Because of the close proximity in this area, these conduits may be subjected to abnormal compression by inflammation around the muscles or abnormal bony structures such as cervical ribs, causing pain, thrombosis, and other 2 symptoms that are described as TOS. TOS can be divided into arterial, venous, or neurogenic diseases, or a combination, depending on the symptoms and clinical findings. Vascular TOS is easier to document with vascular imaging. Neurogenic TOS is more difficult to diagnose.

Unfortunately for neurogenic TOS, there is no gold standard diagnostic test to confirm the syndrome. As a result, there has been significant controversy over the diagnosis and the indications for surgical treatment, especially in light of the potential for significant postoperative complications.[23,24]

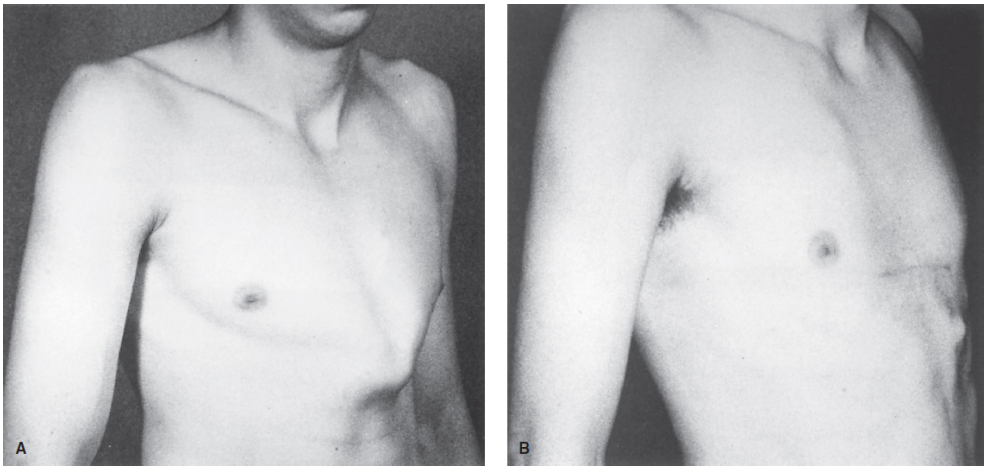

Figure 80.17 Photograph of (**A**) symmetric chondrogladiolar pectus carinatum in a 19-year-old man. Postoperative photograph (**B**) shows correction of the protruding sternum and costal cartilages. (Adapted with permission from Shamberger RC. Chest wall deformities. In: Shields TW, ed. *General Thoracic Surgery*. 4th ed. Baltimore, MD: Williams & Wilkins; 1994:529–557.)

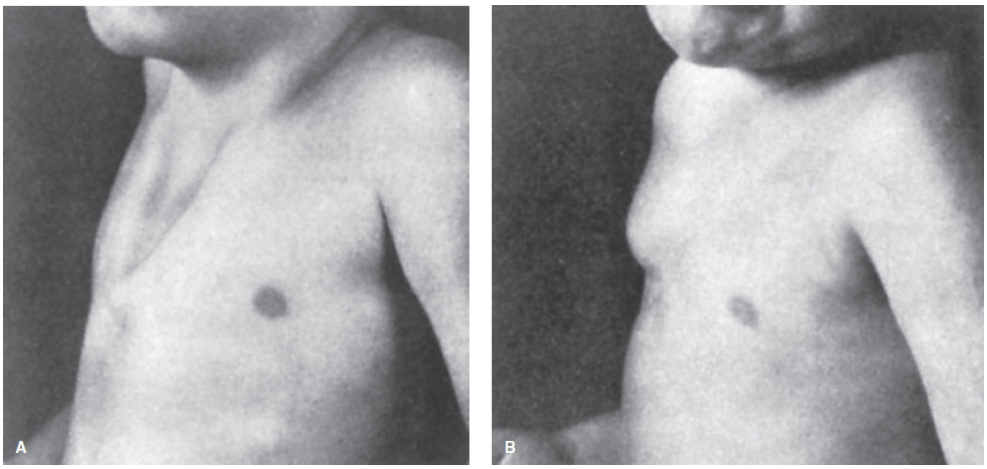

Figure 80.18 Cleft sternum at rest (**A**) and during forced expiration (**B**). Superior clefts of the sternum are variously V- or U-shaped. The appearance of the child as he cries explains the term ectopia cordis, although the heart is actually not misplaced. In the newborn, defects of this kind can be corrected by direct apposition of the sternal halves. In this child, closure of the defect was made possible by sliding chondrotomies on either side. (Reproduced with permission from Sabiston DC Jr. The surgical management of congenital bifid sternum with a partial ectopia cordis. *J Thorac Surg* 1958;35:118–122.)

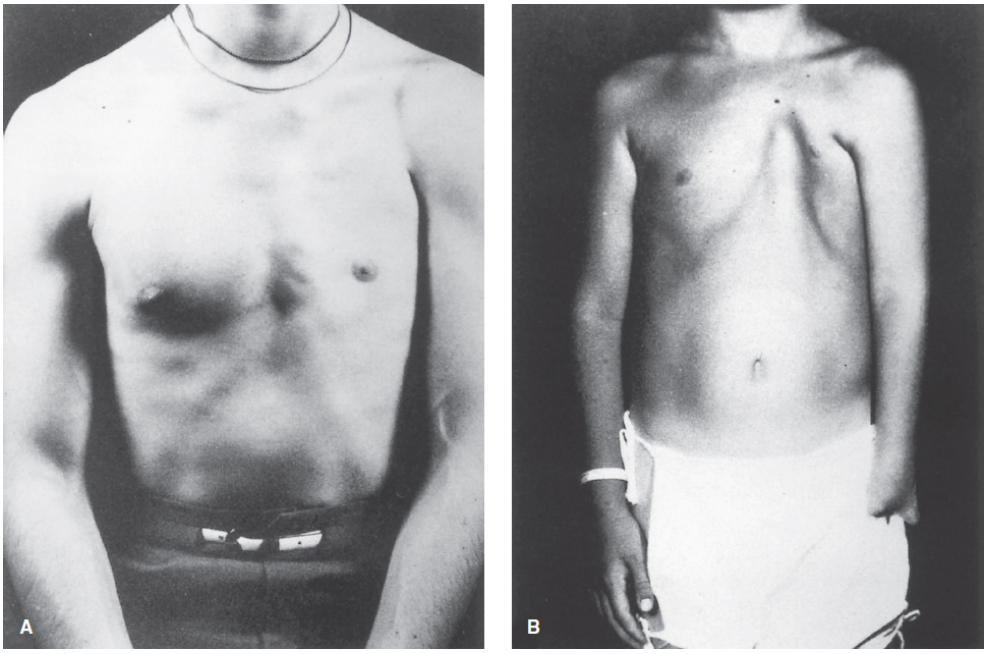
Vascular TOS can be divided into venous disease and arterial disease. Venous disease results in thrombosis of the subclavian vein and is also called Paget–Schroetter syndrome. This syndrome usually presents in men who use their upper bodies and dominant arm for work. Symptoms may present as pain, swelling, and cyanotic discoloration from venous congestion.[23] Contrast venography is the best test to make the diagnosis, and the radiologist should be instructed to perform positional maneuvers with the patient's arm to replicate narrowing that occurs with arm movement.[24] Arterial TOS accounts for about 5% of all cases of TOS[25] and also may result from repetitive and strenuous use. Patients will present with arm fatigue and may even have evidence of ischemia in their distal digits. Patient evaluation includes pulse examination with the arm relaxed and elevated, bruit examination for poststenotic dilatation, and blood pressure readings in both arms. Duplex scanning and angiography will often confirm the diagnosis. Decompression of the scalene muscles and any abnormal bony structures will alleviate these symptoms.[23]



A
B

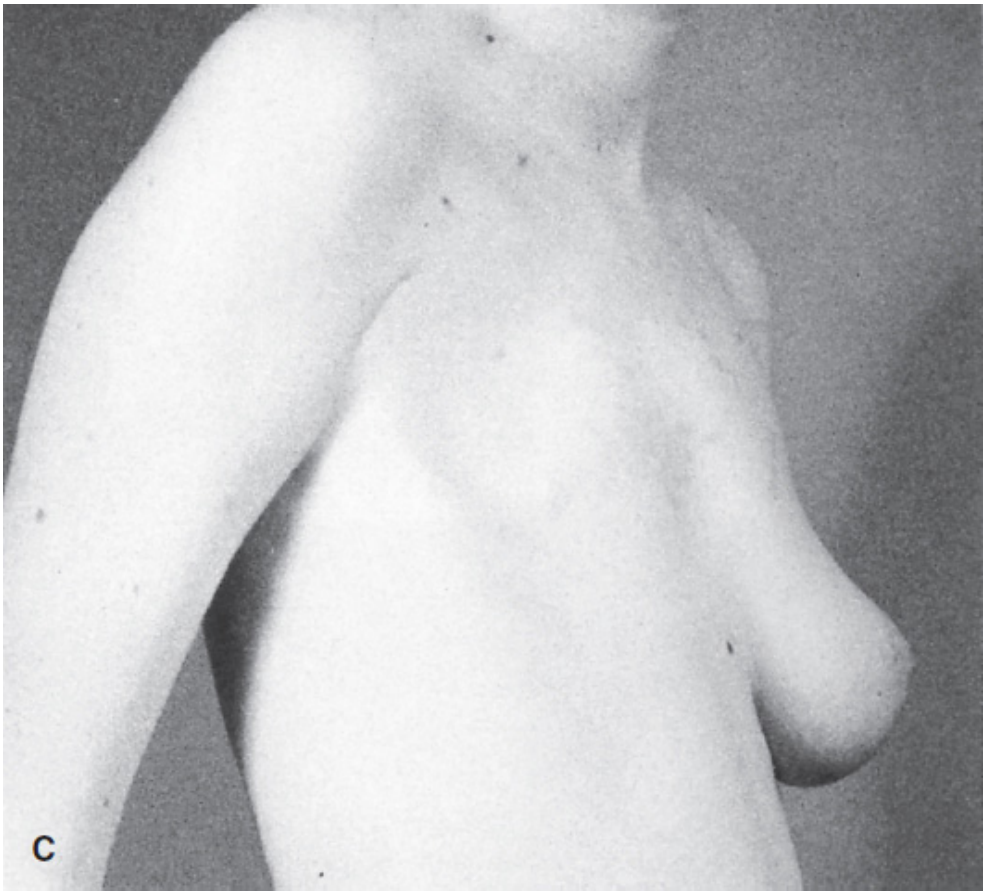


Figure 80.19 **A:** Muscular 15-year-old boy with loss of the left axillary fold, orthotopic sternum, and normal cartilages. He compensates adequately for loss of the pectoralis major and minor muscles. Surgery is not indicated in males with these findings. **B:** An 8-year-old boy with Poland syndrome. The pectoralis major and minor muscles and the serratus to the level of the fifth rib are absent. The boy has sternal obliquity, and the third to fifth ribs are short, ending in points. The corresponding cartilages are absent. The endothoracic fascia lies beneath a thin layer of subcutaneous tissue. Note the hypoplastic nipple and ectromelia of the ipsilateral hand. **C:** A 14-year-old girl with Poland syndrome. Note the high position of the right nipple, amastia, sternal rotation, and depressed right anterior chest. The second to fourth ribs and cartilages were missing, reconstructed with rib grafts. Breast augmentation will be required at full growth. (Reproduced with permission from Shamberger RC. Chest wall deformities. In: Shields TW, ed. *General Thoracic Surgery*. 4th ed. Baltimore, MD: Williams & Wilkins; 1994:529–557.)

ORIENTATION

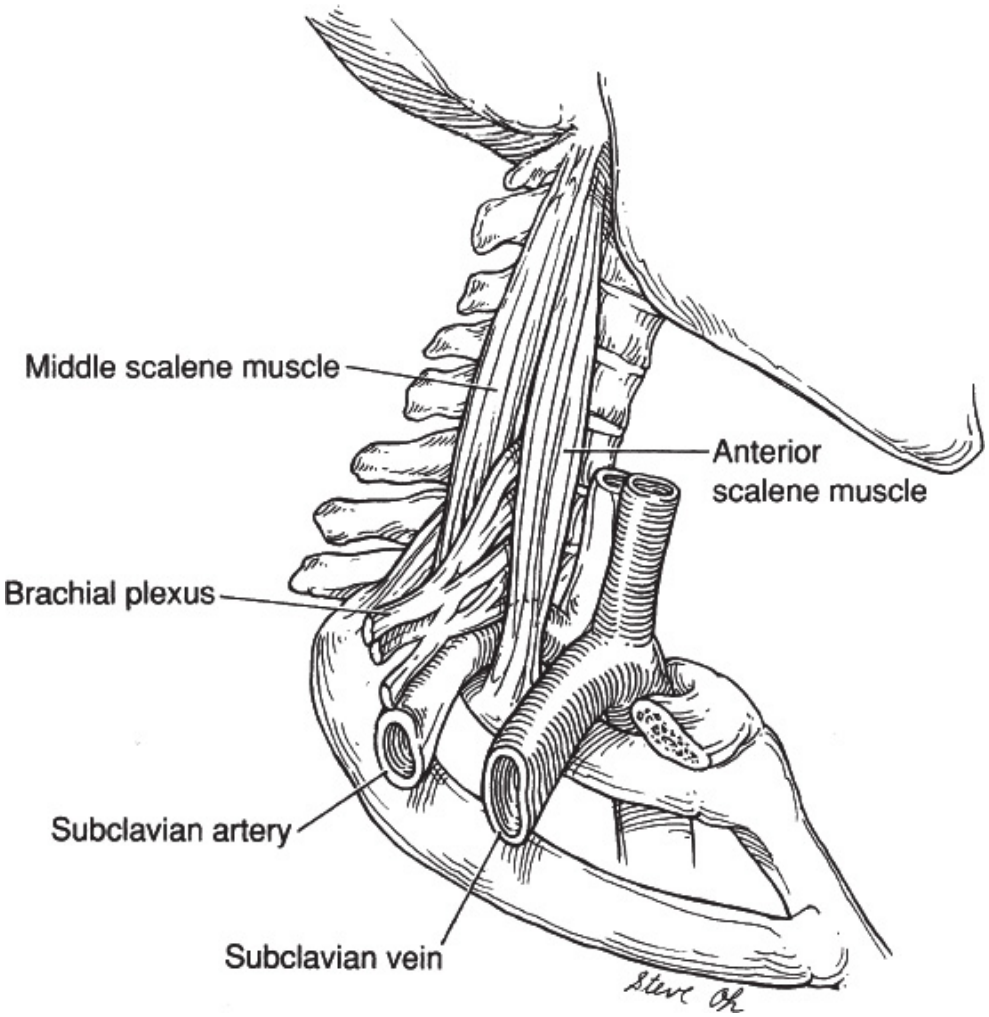

Figure 80.20 Important structures in the thoracic outlet. (Reproduced with permission from Scott-Conner CE, Dawson DL, Shirazi MK, et al. *Operative Anatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

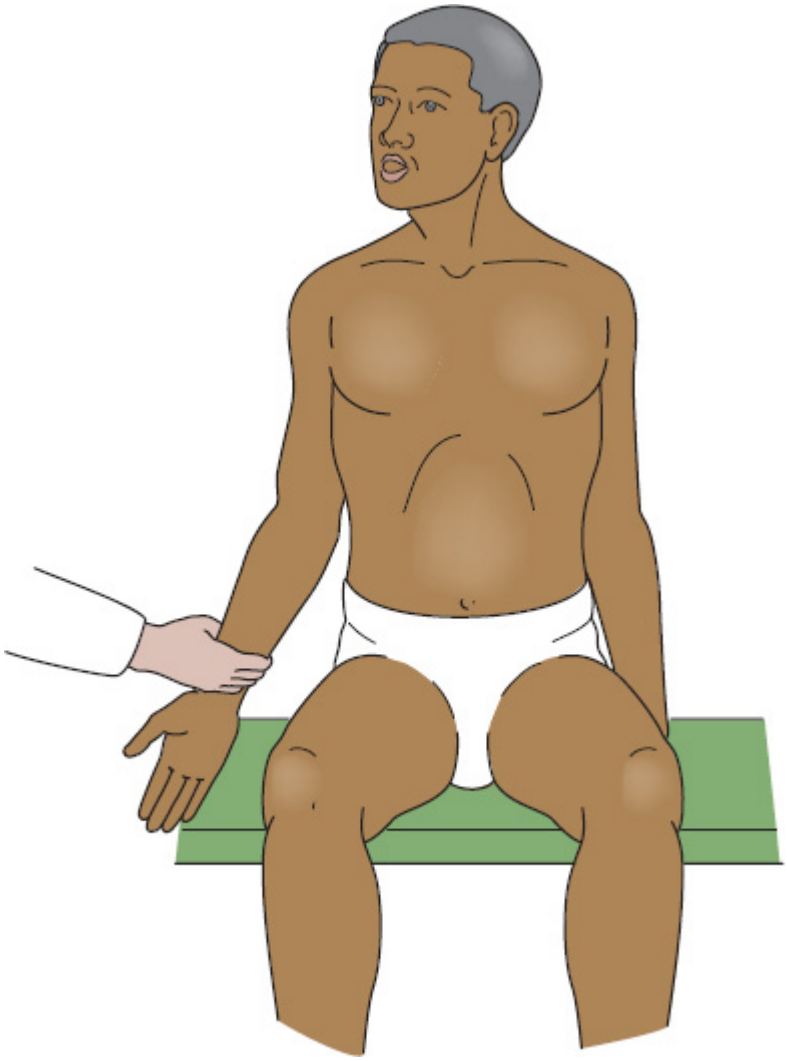

Figure 80.21 The Adson maneuver. Patient inspires and turns head away from the affected arm. The test is positive if the pulse disappears.

Neurogenic TOS presents with limb pain, numbness, or weakness. Symptoms may be bilateral, but are usually worse in the dominant arm. The distribution may not follow a peripheral nerve pattern, thus making the diagnosis confusing, but also ruling out more distal compression syndromes such as carpal tunnel in the wrist or cubital compression at the elbow. The physical examination should be focused on duplicating the patient's symptoms. The Adson maneuver may detect artery compression and is performed by palpating the affected radial pulse, and having the patient take a deep inspiration while turning their head away from the affected arm (**Fig. 80.21**). The test is positive if the pulse disappears, but a positive result can also be seen in asymptomatic people without TOS. Another test requires

the patient to elevate their arms in a "surrender" position and open and close their hands repeatedly. Most people with neurogenic TOS will be fatigued within a minute and be unable to continue (**Fig. 80.22**). Plain radiographs may show bony abnormalities, but no other imaging will help diagnose neurogenic TOS. Physical rehabilitation is the first step to treat patients with neurogenic TOS, and over a third of patients may get a significant improvement in their symptoms. If there is no significant improvement in symptoms, then surgical intervention is suggested.[24]

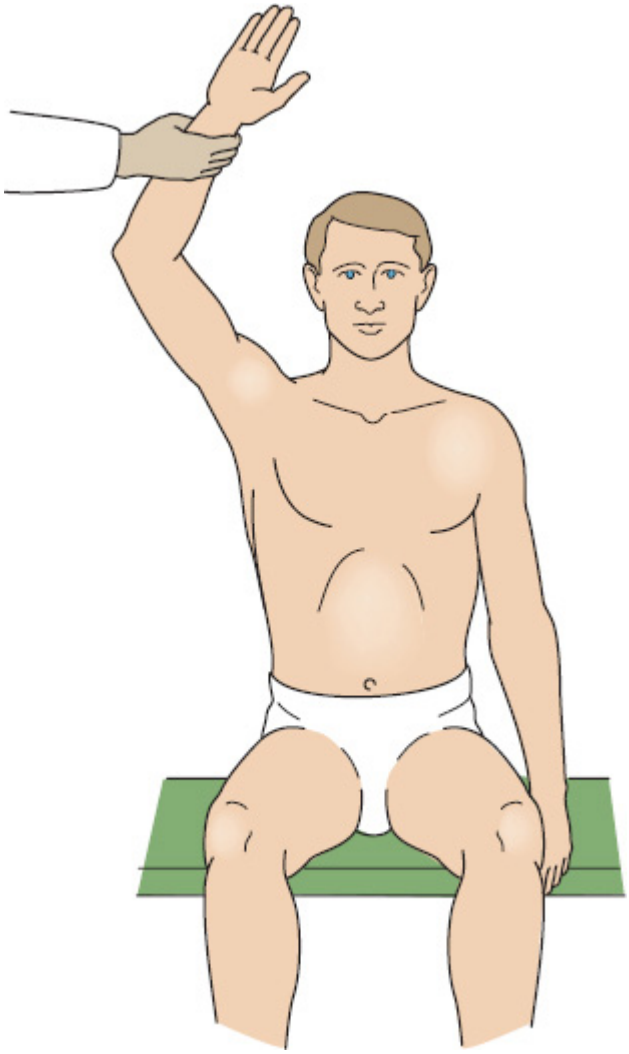

Figure 80.22 Surrender position with opening and closing of hand. Early fatigue is seen in neurogenic TOS.

The surgical approach for TOS was traditionally a transaxillary first rib resection (**Fig. 80.23**). In recent years, a supraclavicular approach has

become increasingly popular as it gives better exposure to the scalene muscles and any cervical ribs. In either approach, the first rib is exposed, attachments to the anterior and middle scalenes are divided, and the rib is removed (**Fig. 80.24**). Special attention must be paid to the phrenic nerve lying along the anterior scalene and the axillary branches off of the brachial plexus. Small drains may be placed in the apex of the thorax if the pleural space is entered.[24,26] The supraclavicular approach also gives access to perform a cervical sympathectomy if indicated for symptoms consistent with sympathetic overactivity. In patients with arterial aneurysms, reconstruction with synthetic grafts or autologous conduits such as an external iliac artery can be performed. For patients with venous TOS, care should be taken to perform a circumferential venolysis and to remove the medial aspect of the first rib.[26]

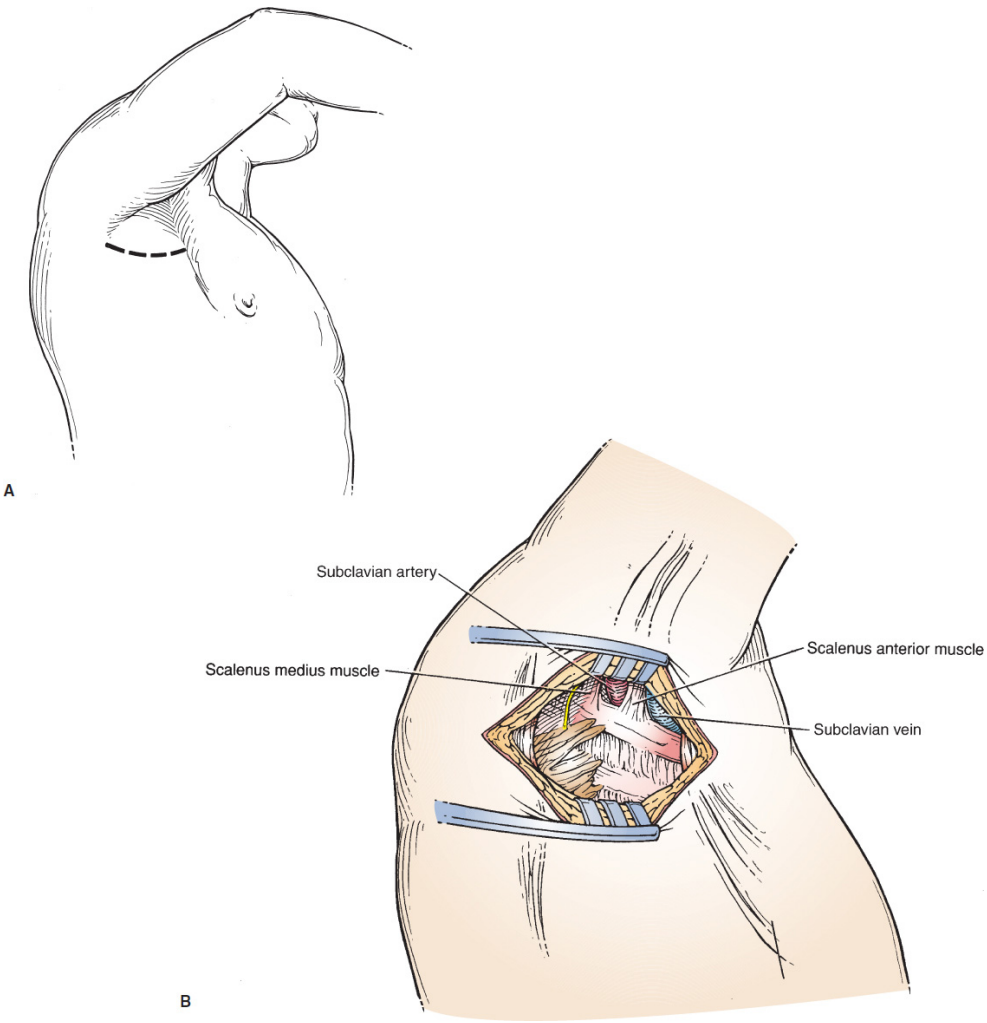

Figure 80.23 Position of the patient (**A**) and skin incision (**B**) for transaxillary approach. (Reproduced with permission from Scott-Conner CE, Dawson DL, Shirazi MK, et al. *Operative Anatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

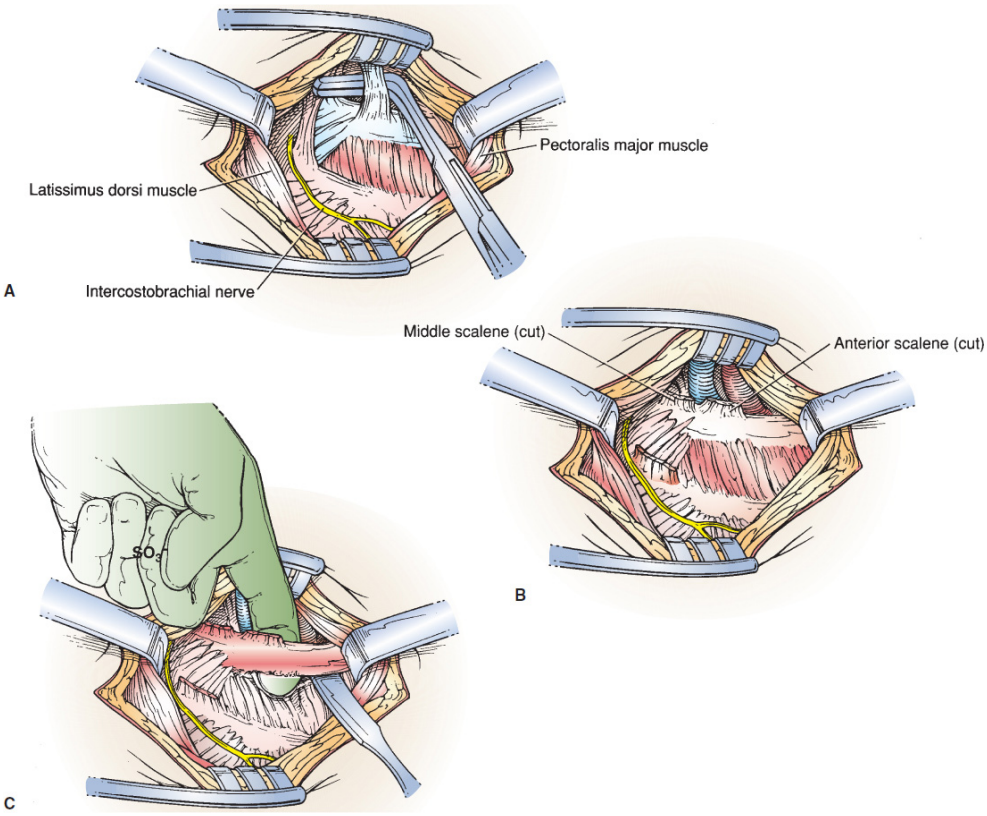

Figure 80.24 Division of the scalene muscles and the first rib. **A:** Mobilization of the scalene muscles off of the first rib. **B:** Exposure of the subclavian vessels. **C:** Mobilization of the first rib, protecting the vessels. (Reproduced with permission from Scott-Conner CE, Dawson DL, Shirazi MK, et al. *Operative Anatomy*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2008.)

Postoperative complications include pneumothorax, lymphatic leaks, especially on the left side where the thoracic duct enters the operative field, phrenic nerve palsy, and traction injury to the brachial plexus.[25] Rehabilitation and range of motion exercises should begin as soon as possible to reduce the risk of frozen shoulder.[24,26] Up to 12.5% of patients may not get any symptom relief after the surgery, and long-term physical rehabilitation is recommended.[25] Patients with combined symptoms of venous and neurogenic TOS have worse outcomes when compared to patients with only venous disease. A higher percentage of patients had persistent pain in the neurogenic group as might be expected.[27] The treatment of this disease process requires a significant investment into the pre- and postoperative care of these patients and should only be done in centers with a high volume and expertise in this syndrome.

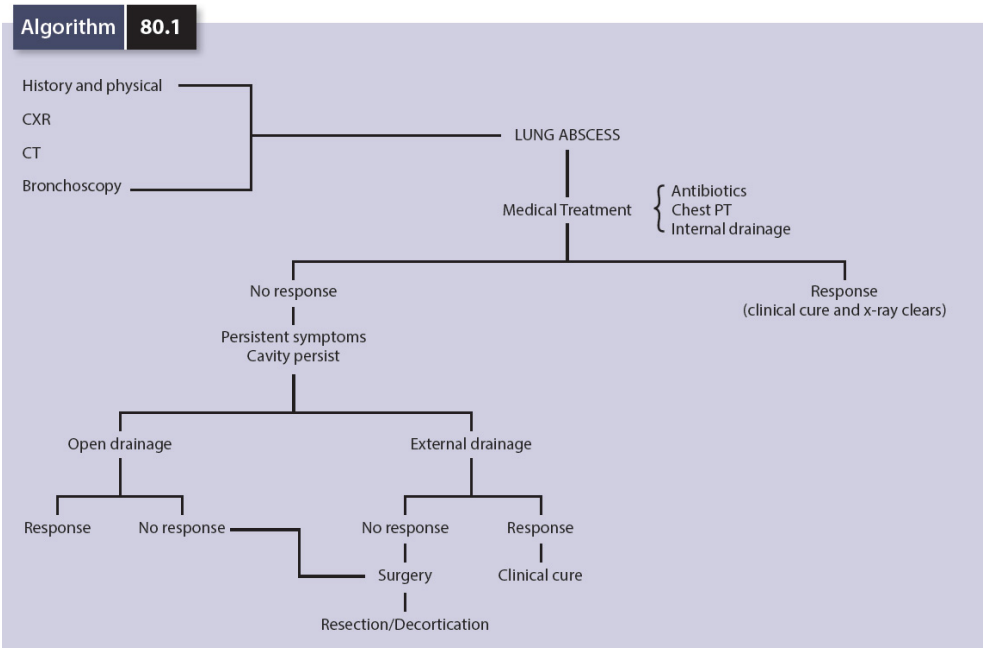
NONNEOPLASTIC LUNG DISEASE

Lung Abscess and Bronchiectasis

Lung abscesses can result from aspiration or occur after necrotizing pneumonia. Patients may present with chest pain and fever. Routine use of antibiotics for pneumonias has dramatically reduced the rate of lung abscess sequelae. In over 80% of cases, a pathogen can be found, and in immunocompromised patients, there are usually multiple organisms involved including *Pseudomonas aeruginosa* 3 and *Haemophilus* species. The primary treatment for lung abscesses is medical therapy with antibiotics. If a patient is clinically not improving with medical therapy alone, a guided drainage tube may be placed. A complication of this approach is the risk of a chronic air leak from a percutaneous tube placed into the lung parenchyma. Surgery may be indicated in the setting of large abscesses causing hemoptysis or other symptoms (**Algorithm 80.1**). Complications from pulmonary infections that require surgery are not common relative to the frequency of pneumonias in both the inpatient and outpatient community. However, some patients may benefit from surgical intervention to treat lung abscesses.[28]

Bronchiectasis is the abnormal dilation of bronchi/bronchioles as the result of multiple episodes of infection and inflammation. Patients can present with respiratory symptoms like dyspnea, hemoptysis, or pleuritic pain, or alternatively may present only with systemic changes such as fatigue and weight loss.[29] Almost all patients will have a chronic cough with or without sputum production.[30] Factors contributing to the development of this disease may be genetic, anatomic, or even systemic. Genetic causes of bronchiectatasis include cystic fibrosis and primary ciliary dyskinesia, which results in reduced mucus clearance, and alpha-1-antitrypsin deficiency which results in destruction of lung parenchyma.[29] Anatomic causes include postsurgical changes or acquired diseases such as chronic obstructive pulmonary disease (COPD) that lead to an increased risk of infection, again by the inability to clear secretions. Autoimmune diseases such as rheumatoid arthritis and inflammatory bowel disease have been associated with increased rates of bronchiectasis.[29,30] Infectious causes include allergic bronchopulmonary aspergillosis and nontuberculous mycobacterium

infections. Reflux disease is also being studied as a potential contributor. Most often the etiology of the disease is idiopathic.[29]



Algorithm 80.1 Algorithm for management of lung abscess. (Adapted from Shields TW, ed. *General Thoracic Surgery*. 6th ed. 2005.)

There are estimated to be 110,000 patients in the United States being treated for noncystic fibrosis bronchiectasis each year. Pulmonary function tests may demonstrate moderate to severe airflow obstruction.[29] A chest CT scan is the optimal test to diagnose bronchiectasis (**Fig. 80.25**), and once the diagnosis is made, the search for an etiology should begin, including obtaining sputum cultures and blood tests for autoimmune markers such as rheumatoid factor.[30]

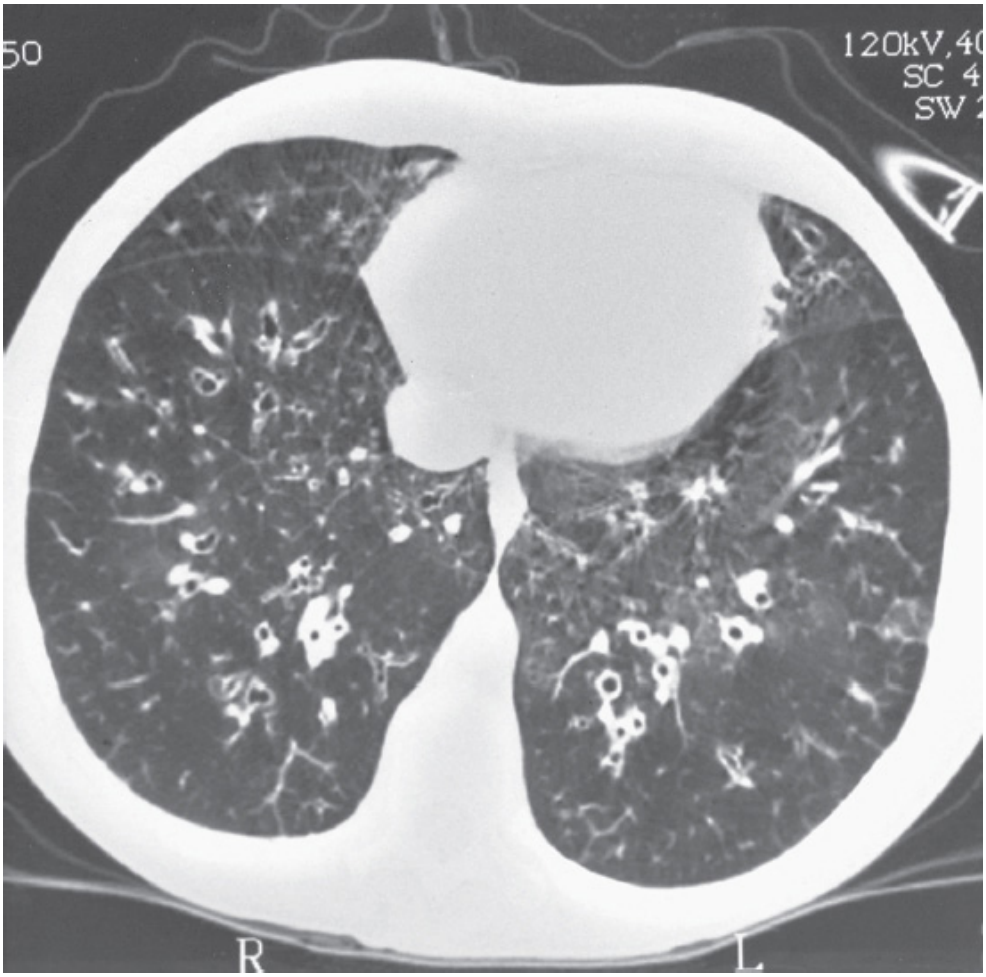


Figure 80.25 CT scan of bronchiectatic lungs. (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*. 6th ed.)

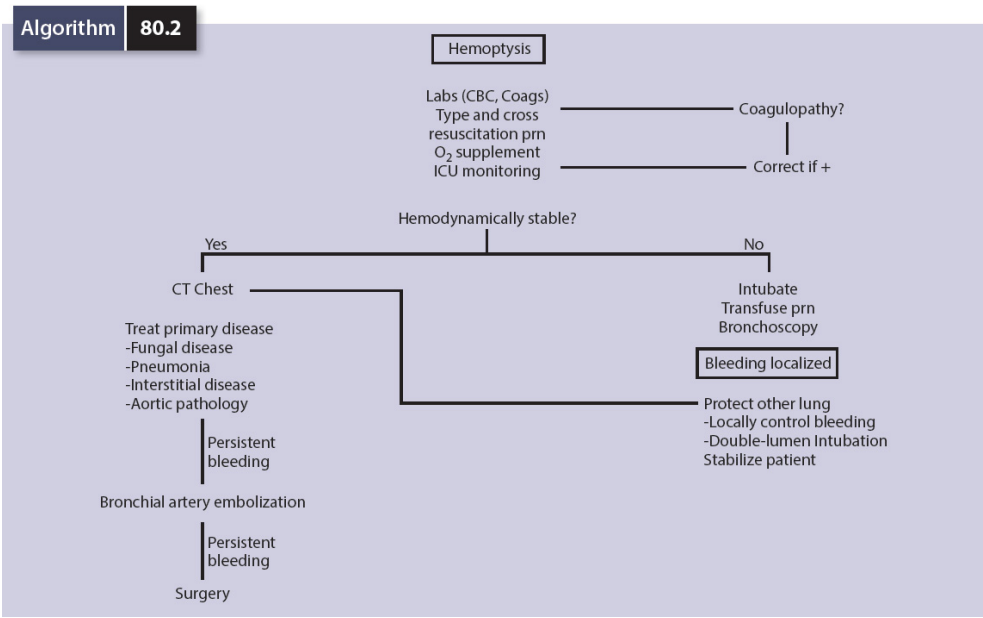
The treatment of the disease includes antibiotic therapy to control infection, the treatment of underlying diseases if they exist, reducing inflammation, improving secretion clearance, and surgery to remove focally damaged areas or transplantation if needed for more diffuse, severe disease. Antibiotic therapy includes inhaled tobramycin and gentamicin.[30] Macrolide antibiotics, like erythromycin and clarithromycin, have been increasingly studied for anti-inflammatory benefits outside for their antibiotic effects. They disrupt the biofilm produced in *Pseudomonas* infections resulting in decreased sputum volume and improved symptoms.[31] Secretion removal is also essential to improving symptoms. Besides the standard treatments of percussive therapy and postural drainage, the use of nebulized

acetylcysteine[30] or hypertonic saline[31] has been shown to improve mucus clearance.

Surgical intervention may occur at many stages of the disease process. Bronchoscopy can be useful to clear secretions or to manage hemoptysis. If the bronchiectasis is localized to a single lobe, resection can eliminate the disease and the source of chronic infection. If a patient has a genetic disease such as cystic fibrosis, a double-lung transplant may be the best treatment if the patient's symptoms are severe enough.[30] Pulmonary tuberculosis can have similar indications for surgical intervention when it results in bronchiectasis or hemoptysis.[32] The rise of more multidrug-resistant tuberculosis strains has led to the increasing need for surgical intervention.[33]

Hemoptysis

Hemoptysis is often used to describe any blood streaking associated with cough. True hemoptysis may only be a few drops of 4 blood, and it requires investigation. Massive hemoptysis is acutely life threatening, not from blood or volume loss, but rather from suffocation secondary to blood in the airway. The causes of hemoptysis include cancer, infections/bronchiectasis, vascular injuries, vasculitides, and coagulopathies.[34] The immediate goals when this is encountered are airway control, improved oxygenation, and resuscitation if needed. Intubation may or may not be necessary, depending on the volume of blood in the airway and the patient's ability to cough.[35] If the bleeding is able to be lateralized, the patient should be placed in a lateral decubitus position with the bleeding site in the dependent position.



Algorithm 80.2 Hemoptysis management. (Adapted from Jean-Baptiste E. Clinical assessment and management of massive hemoptysis. *Crit Care Med* 2000;28(5):1642–1647.)

In patients with hemoptysis, any coagulopathy should be corrected. Early bronchoscopy is essential and the goals are to lateralize the site of bleeding and identify the site and cause of the bleeding. Flexible bronchoscopy may be done, but rigid bronchoscopy is the best approach to maintain airway control, in particular in the setting of large volume hemoptysis.[35] Initial treatment may include topical therapy such as cold saline lavage, bronchial tamponade, and intubation of the contralateral good lung. Double-lumen endotracheal tubes may also be useful to isolate and protect the uninvolved lung from blood from the contralateral side obstructing its lumen. If a patient is stable, a chest CT scan is useful to identify tumors or other potential sources of bleeding.[34]

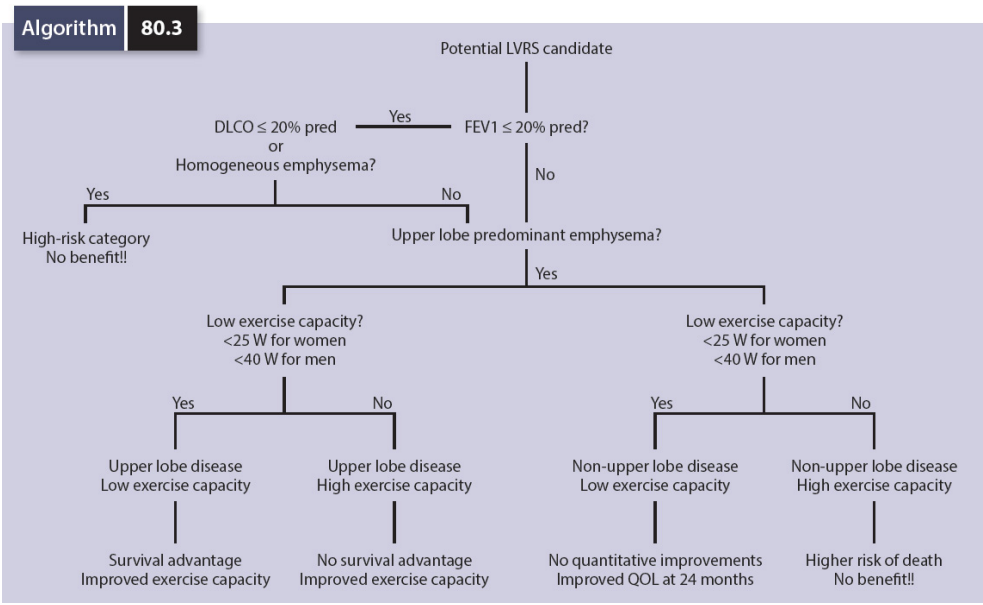
Once a patient is stabilized and appropriate diagnostic tests performed, the treatment of continued bleeding includes the use of interventional radiology and bronchial artery embolization (BAE).[35] First introduced in 1973, BAE is the best nonsurgical treatment of massive hemoptysis, with a success rate of up to 98% within 24 hours, however there is a recurrence rate up to 58% at 30 days.[34,35] Surgery is reserved to treat the underlying condition once the patient has been stabilized and bleeding controlled by other methods. Emergent surgery to treat bleeding may have a mortality rate as high as 38%,[36] and increase to 59% in the setting of malignancy.[34] However, if a

patient undergoes surgery after initial control of hemorrhage by other means the mortality rate decreases to 4%.[35] Depending on the patient's baseline lung function, a lobectomy, let alone a pneumonectomy, may not be tolerated. A risk assessment of the benefits of surgery must be performed. In the setting of a vascular etiology of the hemoptysis such as a ruptured aortic aneurysm, surgical repair is essential and should not be delayed once the patient is hemodynamically stable and the airway is controlled.[34] A detailed algorithm in the assessment and treatment of hemoptysis is shown in **Algorithm 80.2**.

COPD and Lung Volume Reduction

COPD includes a broad group of diseases that result in airflow obstruction and hyperinflation. Medical therapy involves smoking cessation, bronchodilator treatment, steroids, home oxygen, and antibiotics as needed. Despite improvements in the medical management of this condition, patients continue to suffer severe limitations due to their breathing and exercise capacity. As a result, surgical interventions have continued to play a role in trying to ameliorate symptoms and improving survival in these patients.[37,38]

There is a more than 50-year history in the literature recording a variety of surgical approaches to help treat COPD. Interest was diminished, however, because of the high mortality associated with surgical intervention in this patient population. In the 1990s, a renewed interest in lung volume reduction surgery (LVRS) was observed following reports that this procedure was associated with a low published mortality rate and a significant improvement in FEV_1 seen on pulmonary function testing. There was a national increase in interest in the procedure, as many centers began offering it. Despite continued publication of low mortality rates, evaluation of Medicare data in 1996 showed a mortality of 23% in surgically treated patients at 12 months, and Medicare reimbursement for the procedure stopped. This led to the development of the National Emphysema Treatment Trial (NETT), a prospective randomized trial to evaluate the outcomes of LVRS compared to optimal medical treatment (**Algorithm 80.3**).[37]



Algorithm 80.3 LVRS candidate workup. (Adapted from Martinez FJ, Chang A. Surgical therapy for chronic obstructive pulmonary disease. *Semin Respir Crit Care Med* 2005;26(2):167–191.)

The goal of the NETT study was to evaluate short- and long-term survival, lung function, exercise capacity, and quality of life. Patients with upper lobe disease and a low exercise capacity, defined as achieving less than the 40th percentile on exercise testing, 25 W for women and 40 W for men, showed a survival advantage and improved exercise capacity after surgery.

A new technique aimed to provide the same benefit of LVRS but without the surgical risk is the placement of one-way endobronchial valves. These are designed to allow air to escape the hyperinflated apical regions and not allow air to reenter. Endobronchial valves significantly improved pulmonary function and exercise capacity but serious adverse events occur in 21% of patients.[39] Endobronchial stents have been designed to cross bronchioles into hyperinflated regions of the lung and allow decompression. Other approaches being tested include the bronchoscopic introduction of biologic substances such as trypsin or thrombin into hyperinflated regions of the lung with the goal of causing local scarring and reduce the hyperinflation.[40] Other surgical procedures in the treatment of COPD include bullectomy in selected patients and lung transplants in patients with end-stage disease.[38]

Tracheobronchial Foreign-Body Aspiration

Tracheobronchial foreign-body (TFB) aspiration occurs most often in children, but up to 20% of cases have been reported in adults. Risk factors in adults include older age, as elderly patients have a higher incidence of neurologic disease and an impaired cough reflex. Symptoms usually involve an episode of choking, followed by a protracted cough. Fever, dyspnea, hemoptysis, and wheezing can also be present.[41] Chest x-ray may aid in the diagnosis if the aspirated TFB is radio-opaque or if there is associated air trapping, atelectasis, or pneumonia, however, the TFB is visible less than a quarter of the time as most foods are not radio-opaque.[42] Chest CT scans are a more sensitive imaging modality, but not necessarily more specific. Bronchoscopy should be performed if TFB aspiration is suspected. Removal of the TFB can usually be accomplished by flexible bronchoscopy but may require rigid bronchoscopy in difficult cases.[41,42] A recent review found flexible bronchoscopy was successful for removal of TFB in 79% of cases.[43]

Pneumothorax

Pneumothoraces are classified as spontaneous, primary or secondary, traumatic, or iatrogenic. Primary spontaneous pneumothoraces occur in patients with no known lung disease, whereas secondary spontaneous ones occur in patients with underlying lung pathology thought to predispose those patients to a pneumothorax. Iatrogenic pneumothoraces may occur in either the postsurgical or postprocedural setting, typically following central line placement or thoracentesis.[44] Traumatic pneumothoraces are covered elsewhere in this text.

Primary spontaneous pneumothoraces occur more frequently in men than women, with an incidence of 7 to 18 cases per 100,000 people for men, compared to an incidence rate of 1 to 6 cases per 100,000 people in women. Most cases occur in males younger than 30 years of age, and they rarely occur in people over the age of 40. Even though many patients with primary pneumothoraces do not have apparent lung disease, almost all are found to have subpleural bullae, the pathophysiology of which is unknown.[44] Most bullae are apical in location.[45] Patient symptoms can range from minimal to severe, and usually include pleuritic pain, dyspnea, or both. Tachycardia may also be present, and if a person is tachycardic and hypotensive, a tension pneumothorax must be high on the differential and appropriate needle

decompression considered. A tension pneumothorax occurs when air entering the pleural cavity cannot escape and the air compresses the vena cava and even the heart, resulting in hemodynamic instability (**Fig. 80.26**). Urgent needle decompression followed by chest tube placement is the preferred treatment. Most spontaneous pneumothoraces occur while patients are at rest.[44,46]

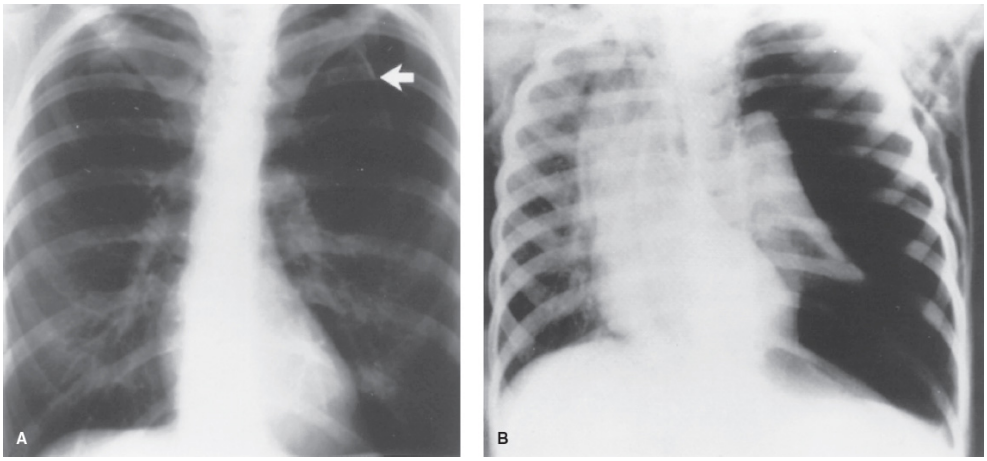


Figure 80.26 **A:** A 40% left-sided spontaneous pneumothorax (*arrow*). **B:** Progression of simple pneumothorax to a tension pneumothorax, showing the characteristic radiographic findings—virtual collapse of the entire involved lung, shift of the mediastinum to the contralateral side, and compression of the contralateral lung. Subcutaneous air dissecting along the left chest wall is also evident.

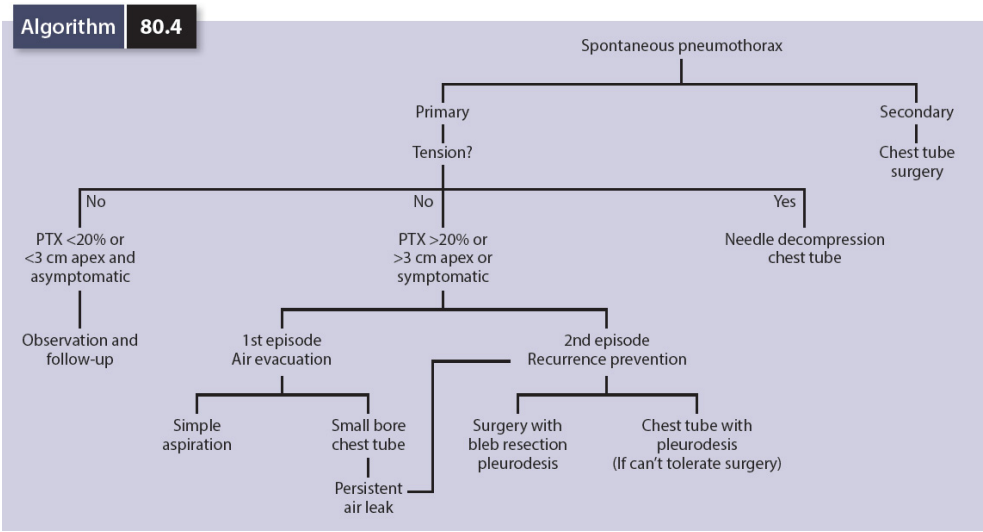
Observation is often the treatment of a stable, small pneumothorax, defined as being less than 3 cm from the apex. For a larger pneumothorax, chest tube placement is the standard treatment, though some advocate a trial of aspiration. Most patients will have a complete resolution of their pneumothorax 5 and not need further treatment. In the group of patients who have a persistent air leak from the initial pneumothorax, or the 30% who have a recurrent pneumothorax, usually within 2 years, further treatment is warranted. This involves some form of pleurodesis, chemical or mechanical, either via a chest tube (talc infusion), or during a thoracoscopic evaluation where apparent blebs can also be resected (**Algorithm 80.4**).[45,46]

Secondary spontaneous pneumothoraces can occur due to a variety of lung diseases, but COPD is the most common.[47] While primary pneumothoraces can be mild clinical events, secondary ones are much more concerning

because of the baseline lung disease and poor pulmonary reserve. Observation has no role in this patient population who should undergo definitive treatment to prevent a recurrence during the first event. Here a thoracoscopic approach may be more effective in establishing an adequate pleurodesis and allow the evaluation for sources of air leaks.[46] Iatrogenic pneumothoraces can result from transthoracic needle lung biopsies, central line placement, thoracentesis, transbronchial lung biopsies, pleural biopsies, and positive pressure ventilation. Patients with underlying lung disease are at a higher risk of developing a pneumothorax after these procedures. Treatment should follow the same paradigm as for spontaneous pneumothoraces. Patients with a small, asymptomatic, stable pneumothorax and no underlying lung disease may be safely observed, while all others should undergo placement of a chest tube.[46] Some studies have suggested immediate aspiration of air after a CT-guided lung biopsy resulting in a pneumothorax, with an 85% success rate in avoiding the need for chest tube placement.[45]



Algorithm 80.4 Algorithm to treat pneumothorax. (Adapted from Baumann MH, Noppen M. Pneumothorax. *Respirology* 2004;9(2):157–164.)

Table 80.2 Phases of Lung Development Classification

Phase	Gestation Period	Major Developments
Embryonic	26 days to 6 wks	5 lobar bronchi
Pseudoglandular	6–16 wks	Cartilage rings, cilia form
Acinar/canalicular	16–28 wks	Type I and II pneumocytes
Saccular	28–34 wks	Distal airspace development
Alveolar	34 wks to 2 years	Alveoli proliferate from 20 to 600 million

Congenital Lung Disease

Congenital malformations of the lung develop during fetal lung growth. They may be identified during an in-utero evaluation, present as respiratory distress in the newborn, or be completely asymptomatic and found in patients as adults. They can frequently occur with other congenital malformations and may be life threatening. Lung development begins during week 3 from the foregut. It progresses through birth to approximately 2 years of age when alveolar development is complete. The five stages of lung development have been divided into the embryonic, pseuodglandular, acinar, saccular, and alveolar stages (**Table 80.2**). Malformations may occur at each step and lead to different pathologic conditions.[48] Four separate conditions will be discussed here; pulmonary sequestration, lobar emphysema, congenital cystic adenomatoid malformation (CCAM), and bronchogenic cysts.[49]

Pulmonary Sequestrations

Pulmonary sequestrations are defined as pieces of parenchymal lung separated from the respiratory tree, with the sequestration receiving its blood

supply from an anomalous artery arising from the aorta, rather than having the blood supply arising from the pulmonary artery. Sequestrations have been further subdivided into extra- and intralobar lesions, with very distinct anatomic alterations and clinical presentations. Extralobar sequestrations reside outside of the true pleural space. Venous drainage is usually into the azygos or hemiazygos veins. They are most often on the left side between the left lower lobe and diaphragm (**Fig. 80.27**). Up to 80% of extralobar sequestrations occur in males. Most patients present with dyspnea in the first 6 months of life. They may be diagnosed by fetal ultrasound or after birth by chest x-ray. Other congenital abnormalities are found in up to two-thirds of patients, with congenital diaphragmatic hernias present in a quarter of patients.[48] Intralobar lesions reside within the normal lung and within the normal pleura. They are almost always in the lower lobes and occur in the left side just over 50% of the time. Venous drainage is usually through the pulmonary vein. It is suggested that intralobar sequestration may be an acquired disease, caused by repeated episodes of inflammation that lead to bronchiole narrowing and scarring. Ultimately the "lobe" becomes isolated and may develop new feeding blood vessels from collateral arteries in the inferior pulmonary ligament. A complete assessment of a sequestered lesion must be performed prior to resection, and should include assessment of any potential airway or gut connection, determining the vascular supply of the sequestration, and determining if there are any other congenital malformations.[48]

Congenital Lobar Emphysema

Lobar emphysema is the cause of half of the episodes of newborn respiratory distress that are due to structural anomalies. Two-thirds of the cases occur in males. Distension of the distal lung occurs from obstruction of the airway, either from an intrinsic cause, such as meconium or torsion, or an extrinsic cause, such as obstructing lymph nodes. In up to half of the cases, no cause can be found. Almost all cases occur in the upper lobes, with almost equal distribution between sides. Half of the lesions will present in newborns, and the remaining 50% will reveal themselves by 6 months. Chest x-rays are diagnostic (**Fig. 80.28**).[48] Surgical resection may not be immediately necessary, and may be delayed until the child has grown, or until they

develop a failure to thrive. Even after surgical resection, patients may have bronchomalacia and a tendency toward bronchospasm.[50]

Congenital Cystic Adenomatoid Malformation

CCAM lesions are the second most common cause (25%) of newborn respiratory distress, secondary to structural problems. Children will present either at birth or in early childhood with recurrent respiratory infections. The anomalies are due to an overgrowth of bronchioles, likely during the acinar phase of fetal lung development. Lesions can occur on either side and are usually isolated to one lower lobe. The classification system by Stocker (**Table 80.3**) organizes these lesions based on pathologic appearance and clinical outcome. Prenatal MRI best serves to evaluate these lesions, while postnatal chest x-ray and/or chest CT scan can be used to differentiate CCAMs from other lesions.[48] Even though lesions may be small and asymptomatic, these lesions possess the potential for malignant transformation and should be resected (**Fig. 80.29**).[50]

Bronchogenic Cysts

Bronchogenic cysts are formed from primitive foregut tissue present in the airway. They can present as single or multiple cysts in a wide variety of locations in the thorax. They usually present in young children who develop symptoms such as stridor due to airway obstruction or compression caused by the cysts.[49] Alternatively, cysts located within the lung parenchyma can become infected and present as an abscess. Therapeutic aspiration may be temporizing, but ultimately surgery is needed.[51] Resection may have a mortality of up to 14%, but untreated lesions have a 100% mortality.[49] Most cases of congenital lung disease will present in the first 6 months of life. The main symptom is usually respiratory distress, but once children reach 1 year in age, chronic infections become the most common symptom. Diagnostic tests begin with chest x-rays, but can include ultrasound, MRI, CT scans, angiography, and bronchoscopy, depending on the lesion and location.[52] Decision making regarding the timing of surgical resection should

incorporate the patient's acuity due to symptoms and their overall ability to tolerate surgery based on size.

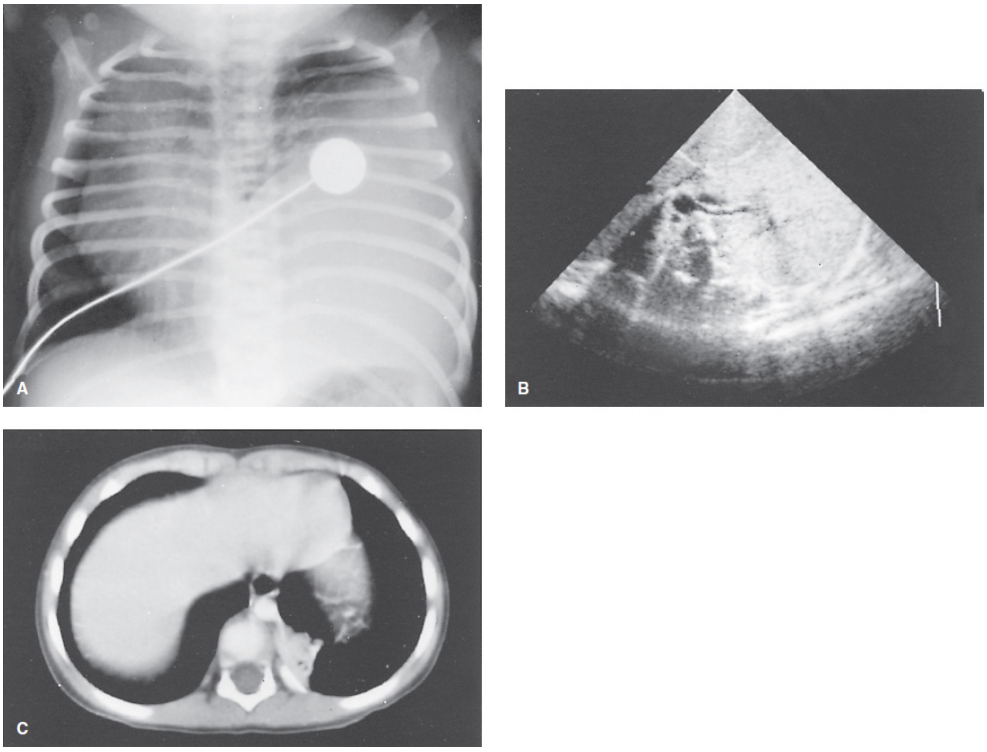


Figure 80.27 Abnormal radiograph of the chest of a newborn with respiratory distress (**A**). Ultrasound identified the anomalous vessel coursing through the diaphragm and entering the sequestration (**B**). This computed tomographic scan clearly demonstrates the anomalous artery arising from the thoracic aorta and entering the sequestered lung (**C**). Pleural Disease

Pleural diseases include benign complications from systemic disease, postoperative infections, local infections, and cancers from primary and metastatic sites. Diseases involving the pleura can lead to limitations to respiration and symptoms of dyspnea. Surgical intervention may be indicated, and it is imperative for the surgeon to be able to recognize which disease processes require a surgical procedure. Pneumothoraces are discussed earlier in this chapter, and here we will cover pleural effusions, including empyemas, and malignant pleural mesotheliomas (MPMs).

Table 80.3 The Stocker Classification of CCAM

▪ Type I 75% of lesions Few large cysts Parenchymal compression
▪ Type II Numerous, <1 cm cysts Associated with other congenital anomalies Worse prognosis
▪ Type III Rarest type Cysts are solid and smaller (few mm in diameter)

Figure 80.29 Specimen removed from an infant with a cystic adenomatoid malformation. Microscopically, there was marked proliferation of terminal bronchioles, and cartilage was lacking. (Reproduced with permission from Shields TW, ed. *General Thoracic Surgery*. 6th ed. 2005.)

PLEURAL EFFUSIONS

Pleural effusions are a common condition that elicits a surgical consult for potential drainage and even thoracoscopic intervention to assist in the

diagnosis and treatment of the condition. The essential first step in the evaluation of a new effusion is to determine if it is a transudative or exudative process. A transudative fluid collection is the result of a poorly balanced hydrostatic and/or osmotic pressure across the pleural membrane resulting in increased serum leak across the pleural barrier. Exudative processes result from inflammation or neoplastic processes that cause increased capillary leak at the pleural membrane, which results in higher protein and lactate dehydrogenase (LDH) levels in the exudative fluid compared to the transudative fluid (**Table 80.4**).[53] The Light's criteria are commonly used to distinguish transudative and exudative effusions (**Table 80.5**). If one or more of the criteria are met, then the fluid is considered exudative.[54] Other tests have been evaluated, including measuring cholesterol ratios, albumin gradient, but Light's criteria are still the best overall test.[53]

Transudative effusions are most often caused by congestive heart failure. Even if a patient does not have other symptoms of heart failure, in the setting of a transudative effusion, a complete cardiac workup should be considered. The pleural fluid concentration of N-terminal pro–B-type natriuretic peptide can accurately identify effusions due to heart failure.[55] Other causes include cirrhosis which may or may not be associated with ascites. Isolated right- and left-sided effusions due to liver disease have been described. Effusions can be seen in more than 20% of patients with nephrotic syndrome, and so all patients with new effusions should be evaluated for the presence of proteinuria. Rarer causes include retroperitoneal urine leaks or cerebrospinal 6 fluid leaks.[56] Surgical interventions, such as chest tube placement, should be avoided in transudative disease settings, as patients will continue to drain fluid from their chest until the primary cause is treated. Aspiration of fluid may help temporarily while systemic treatment is instituted, but should only be done as part of a larger treatment plan.

Table 80.4 Differential Diagnosis of Pleural Effusions

Transudative Pleural Effusions

Congestive heart failure
Pericardial disease
Cirrhosis
Nephrotic syndrome
Peritoneal dialysis
Superior vena cava obstruction
Myxedema
Pulmonary emboli
Sarcoidosis
Urinothorax

Exudative Pleural Effusions

Neoplastic diseases
- Metastatic disease
- Mesothelioma

Infectious diseases
- Bacterial infections
- Tuberculosis
- Fungal infections
- Viral infections
- Parasitic infections
- Pulmonary embolization

Gastrointestinal disease
- Esophageal perforation
- Pancreatic disease
- Intra-abdominal abscess
- Diaphragmatic hernia
- Postabdominal surgery
- Endoscopic variceal sclerotherapy

Collagen vascular diseases
- Rheumatoid pleuritis
- Systemic lupus erythematosus
- Drug-induced lupus erythematosus
- Immunoblastic lymphadenopathy
- Sjögren syndrome

Wegener granulomatosis
Churg–Strauss syndrome
Postcardiac injury syndrome
Asbestos exposure
Sarcoidosis
Uremia
Meigs syndrome
Yellow nail syndrome
Drug-induced pleural disease
Nitrofurantoin
Dantrolene
Methysergide
Bromocriptine
Procarbazine
Amiodarone
Trapped lung
Radiotherapy
Electric burns
Urinary tract obstruction
Iatrogenic injury
Ovarian hyperstimulation syndrome
Chylothorax
Hemothorax

Table 80.5 Criteria for Exudative Effusions Based on Ratio of Pleural Fluid Protein and LDH Concentrations to Serum Concentration

Protein/serum protein >0.5
LDH/serum LDH >0.6
Pleural LDH 1.67 times normal serum LDH

LDH, lactate dehydrogenase.

Exudative effusions have a number of etiologies, but infections, typically pneumonia, are the most common cause.[54] Tuberculosis (TB) and fungal infections can also cause exudative effusions. Although rarer in the United States, TB is still a common etiology worldwide. If someone is suspected of having pleural TB, the pleural fluid should be evaluated for adenosine deaminase (ADA) and gamma-interferon levels, which if low will rule out the diagnosis of TB. If other infections are suspected, the pleural fluid should be cultured.

Malignancy is the next most common cause of exudative effusions.[54] Approximately a quarter of pleural effusions in a community hospital setting have been attributed to cancer. The malignancies that cause the effusions are, in order of decreasing frequency: lung cancer, breast cancer, and hematologic cancers such as lymphoma. Other malignancies can also cause effusions, such as ovarian cancer.[57] Pancreatitis may also cause an exudate, and elevated serum amylase levels will support the diagnosis. Autoimmune processes, such as rheumatoid disease and lupus, can also cause effusions. A chylothorax may present after problems with thoracic duct lymphatic drainage leading to an accumulation of lymphatic fluid, "chyle," in one or both thoraces. The thoracic duct collects lymph from the cysterna chyli, the plexus of lymphatics in the upper abdomen, and travels anterior to the spine and just posterolateral to the aorta. It follows behind the aorta and enters the left neck where it empties into the confluence of the left internal jugular and subclavian veins (**Fig. 80.30**). Chylous leaks are due primarily to thoracic duct injury from trauma or surgery or lymphomas resulting in obstructed lymphatics. Pleural triglyceride and cholesterol levels will be elevated and the fluid will have a milky color. Treatment for persistent chylothoraces includes thoracic duct ligation by surgery or by embolization of the site of leak in the interventional suite.[58]

The management of malignant pleural effusions includes a variety of options, but critical to the decision-making process is the knowledge of the median life expectancy in that patient due to the underlying malignancy. Chest tube drainage may be therapeutic and diagnostic, allowing fluid drainage and alleviation of symptoms of dyspnea. It will also allow determination of whether the underlying lung is able to expand. If not, it is described as a "trapped lung" and although the fluid may be gone, a persistent pneumothorax appears on chest x-rays as the lung cannot expand and fill the thorax. In these

settings, an indwelling pleural drainage catheter may be the best option to intermittently drain accumulating fluid. Decortication is not recommended, as most patients with malignancy in this setting have a limited life expectancy and the success rate is low compared to decortication in the setting of an empyema. VATS exploration may also be used to remove loculated fluid collections and to evaluate for lung reexpansion after the procedure. If the lung reexpands, further treatment includes pleurodesis, utilizing talc, doxycycline, or bleomycin. These medications will cause an inflammatory reaction between the parietal and visceral pleura resulting in the lung being "stuck" in an expanded state. Mechanical pleurodesis can also be performed by mechanical debridement of the pleura via VATS. Chemical pleurodesis may be performed via VATS or through an existing thoracostomy tube. The goal of treatment in the setting of a malignant pleural effusion is palliation.[57] Patients treated with indwelling pleural catheters may spend fewer days in the hospital at the end of life than patients treated with pleurodesis.[59]

THORACIC DUCT

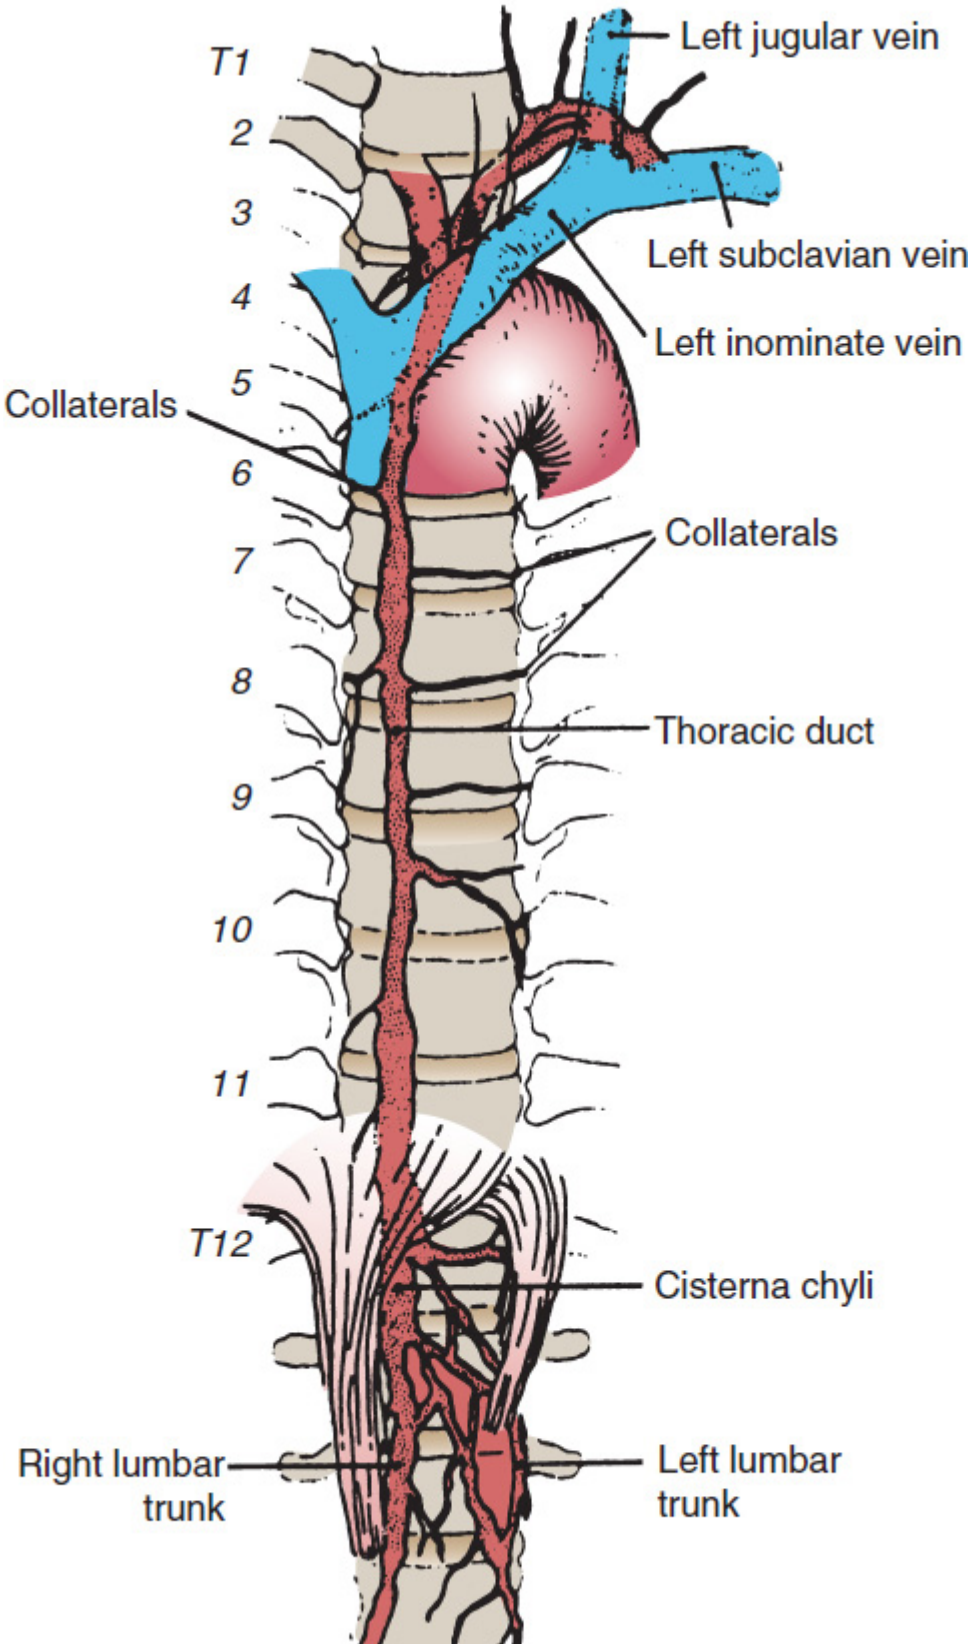

Figure 80.30 Schematic drawing of the most usual pattern and course of the thoracic duct. The single duct that enters the chest through the aortic hiatus between T12 and T10 is a relatively consistent finding and the usual site for surgical ligation.

Empyema

7 Empyemas are defined as frank pus in the thoracic cavity. This represents part of the continuum of disease that begins with simple parapneumonic effusion, where exudative fluid is not infected and not loculated. As the disease progresses, fluid becomes loculated with fibrinous septations and becomes infected, leading to pus and ultimately the development of a fibrinous peel. Up to half of pneumonias have an associated effusion, but less than 5% of cases lead to an empyema.[60] Other causes include surgical thoracotomies and/or other infections from nearby organs, such as esophageal injuries. Pleural infections have been categorized into three overlapping stages. The first is the exudative stage, where the fluid is thin, sterile, has a lower white blood cell (WBC) count and LDH levels, and the glucose level is still above 40 mg/dL (**Table 80.6**). Treatment usually involves addressing the underlying etiology, such as pneumonia. The second stage is the fibrinopurulent stage, where the fluid becomes infected and fibrin deposits accumulate on the pleura. The LDH and WBC count increases, the glucose and pH levels drop. The fluid becomes thick and purulent and the lung is often unable to expand. Chest tube drainage alone at this stage may not be effective to remove the fluid. The third stage is the organizing stage, and a thick pleural peel is created by migrating fibroblasts. At this point, a formal debridement and decortication are required to allow the lung to return to full function.[60]

Table 80.6 Diagnostic Criteria for Pleural Fluid in Empyema

Stage	Fluid/Peel	WBC	LDH (cells/mm^3)	pH (IU)	Bacteria
Exudative	Thin/elastic	<1,000	<500	>7.3	Absent
Fibrinopurulent	Purulent/ inelastic	>5,000	>1,000	<7.1	Present
Organizing	Thick/rigid peel	Varies	Varies	<7.1	Varies

Organisms causing empyemas have shifted from predominately *Streptococcus pneumoniae* in the preantibiotic era, to anaerobic organisms in up to three-quarters of empyemas in the current era. There is also a notable difference between community-acquired and hospital-acquired empyema, with a higher prevalence of *S. aureus* and *Klebsiella pneumoniae* in hospital-acquired empyemas.[61] Imaging to evaluate the presence of an empyema begins with a simple chest x-ray, but requires a chest CT to show potential loculations. After the institution of antibiotic therapy, surgical intervention depends on the stage of the disease, but may require a VATS exploration or even a thoracotomy to debride the thorax effectively and to decorticate the pleural peel off of the lung to allow reexpansion.[60] Postpneumonectomy empyemas are an especially difficult problem as there is no lung tissue to occupy the empty thorax. Risk factors in this setting include right pneumonectomies (vs. left), the need for postoperative ventilation, lower starting hematocrit levels, and poor preoperative pulmonary function test results.[62,63] Treatments of these empyemas are particularly difficult and may include an Eloessor flap or the Clagget procedure which allows for the creation of an open wound that allows for packing and granulation tissue to form in the empyema cavity.[64]

Mesothelioma

MPM is a cancer of the serosal pleura, related to the exposure to asbestos. Multiple hypotheses have been formed regarding how asbestos causes mesothelioma, and include the idea that asbestos fibers are inhaled deeply into the lung and penetrate the parenchymal surface, causing irritation of the pleura and repeated episodes of inflammation, ultimately leading to cancer. Other potential mechanisms include asbestos interfering with mitosis,

inducing free-radical production, and induction of proto-oncogene kinases by asbestos fibers.[65] Exposure to asbestos usually occurs decades prior to presentation with mesothelioma, and has been seen in miners exposed to asbestos dust, industrial workers such as plumbers and carpenters who used asbestos products, and even in 20% of patients with no known exposure but living in industrial countries. Mesothelioma is a relatively rare malignancy, with less than 5,000 cases in the United States per year.[66]

Patients with mesothelioma may present with dyspnea or chest pain. Often, patients are asymptomatic and the diagnosis is made after abnormalities are seen on a chest x-ray performed for another reason. Radiographs may show unilateral effusions and a loss of volume on the affected side, as the lung capacity is diminished due to disease. As the disease progresses, patients may have weight loss, worsening pain, and night sweats. Median survival may be as little as 1 year from the time of diagnosis.[67] Diagnostic studies include a chest CT scan or MRI to show the extent of pleural thickening as well as signs of local spread or metastasis (**Fig. 80.31**). The pathologic diagnosis almost always requires a tissue biopsy with a CT-guided biopsy, VATS, or thoracotomy approach. Cytologic examination of pleural fluid from a thoracentesis cannot differentiate between mesothelioma cells and other potential lung cancers. If the patient is being considered for surgical resection, a limited thoracotomy in the site of a potential later incision is optimal to limit seeding of the tumor.[67]

Mesotheliomas can be categorized into epithelial, sarcomatoid, and mixed histologies. Patients with epithelial histology have longer median survival than those with a sarcomatoid histology.[68] There are a variety of staging systems for mesothelioma, including the Butchart system, the revised Brigham and Women's Hospital system, and the TNM-based system by the International Mesothelioma Interest Group (IMIG) and International Association for the Study of Lung Cancer (IASLC) (**Table 80.7**).[69] The IMIG system allows for better reproducibility of the interpretation of local and regional lymph node spread. Laparoscopy may be useful to evaluate the patient for transdiaphragmatic spread of the tumor, differentiating between T3 and T4 tumors.[70]

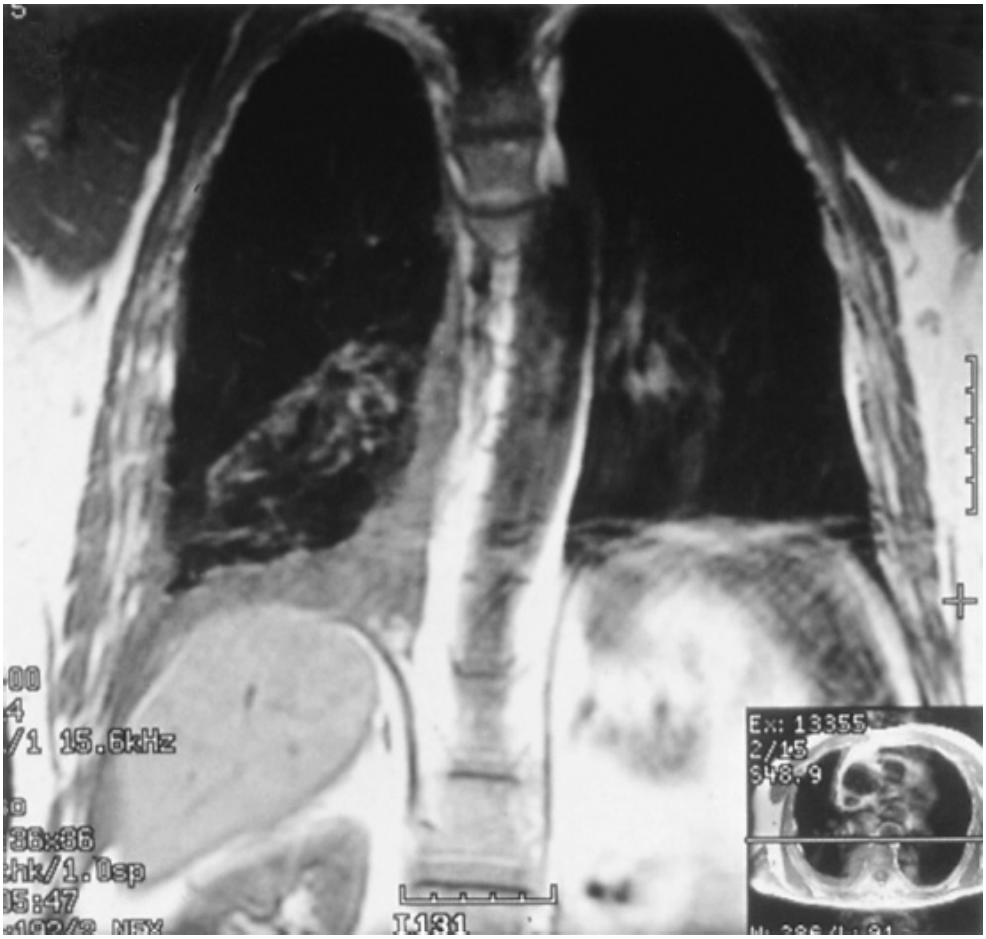

Figure 80.31 Magnetic resonance imaging of the patient in **Figure 80.25** shows a large amount of tumor within the pleural space and into the diaphragmatic sulcus with no evidence of extension outside the hemithorax. (Reproduced with permission from Flores RM, Sugarbaker DJ. Malignant mesothelioma of the pleural space. *Ann Thorac Surg* 2000;70:306.)

Table 80.7 The International Mesothelioma Interest Group (IMIG) and IASLC Staging System

T–Tumor	
T1	Tumor involving the ipsilateral parietal pleura (including mediastinal and diaphragmatic pleura) with or without involvement of visceral pleura
T2	Tumor involving each of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: Confluent visceral pleural tumor (including the fissures), involvement of diaphragmatic muscle, invasion of the lung parenchyma
T3	Locally advanced but potentially resectable tumor; tumor involving all of the ipsilateral pleural surfaces (parietal, mediastinal, diaphragmatic, and visceral pleura) with at least one of the following features: Involvement of the endothoracic fascia, extension into the mediastinal fat, solitary, completely resectable focus of tumor extending into the soft tissues of the chest wall, nontransmural involvement of the pericardium
T4	Tumor involving all of the ipsilateral pleural surfaces with at least one of the following features: Diffuse multifocal invasion of soft tissues of the chest wall, any rib involvement, invasion of the peritoneum through the diaphragm, invasion of any mediastinal organ, direct extension to the contralateral pleura, invasion of the spine or brachial plexus, transmural invasion of the pericardium (with or without pericardial effusion) or myocardium invasion
N–Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases

N1	Metastases in the ipsilateral bronchopulmonary, hilar, or mediastinal lymph nodes (including the internal mammary, peridiaphragmatic, pericardial fat pad, or intercostal lymph nodes)
N2	Metastases in the contralateral bronchopulmonary, hilar, or mediastinal lymph nodes or ipsilateral or contralateral supraclavicular lymph nodes
M– Metastases	
MX	Presence of distant metastases cannot be assessed
M0	No evidence of distant metastases
M1	Evidence of distant metastases
Stage	**Description**
I	
Ia	T1N0M0
Ib	T2N0M0, T3N0M0
II	T1N1M0, T2N1M0
IIIa	T3N1M0
IIIb	T1N2M0, T2N2M0, T3NM0
IV	Any T4 Any M1

Adapted from Berzenji L, Van Schil P, Carp L. The eighth TNM classification for malignant pleural mesothelioma. *Transl Lung Cancer Res* 2018;7(5):543–549.

Treatment for mesothelioma may include chemotherapy, radiation therapy, and surgery. Surgical treatment ranges from a pleurodesis for palliation in the setting of effusions and unresectable disease, to pleurectomy/decortication for limited disease, and to the most aggressive treatment of an extrapleural pneumonectomy (EPP), with the goal of complete tumor resection. Less than a third of patients are candidates for any surgical intervention. Preoperative

workup for an EPP should include a cardiac evaluation, and optimal surgical candidates have pulmonary function tests with an FEV_1 of greater than 2 L/sec and an age under 70.[70] Surgery involves an en bloc removal of the lung, pleura, pericardium, and diaphragm with reconstruction of the pericardium and diaphragm. Pleurectomy and decortication are reserved for very early-stage disease and involves removal of the pleura only with preservation of the lung parenchyma. Multimodality approaches have shown better results, with neoadjuvant chemotherapy and adjuvant radiation therapy.[71] Chemotherapy for advanced disease includes pemetrexed and cisplatin or the combination of gemcitabine and cisplatin.[72] Both have shown similar levels of palliation. Radiotherapy may also be used, but is limited by the large field requiring treatment and the risks of pneumonitis and esophagitis.[65] It is best used in combination with EPP for local control after surgery, or to treat local painful areas.[70] Because of the rarity of surgical cases, most patients who are considered for surgery should be referred to high-volume centers where surgeons and other clinicians are comfortable treating this disease.

Trachea

The trachea is a well-known structure to the general surgeon who may perform tracheostomies and bronchoscopies as part of their clinical practice. A thorough knowledge of the anatomy and vascular supply is essential to minimize complications such as postintubation tracheal stenosis and tracheoinnominate fistulas after tracheostomies.

Anatomy

The trachea is the connection from the cricoid cartilage to the carina that allows ventilation and mucous clearance from the lungs. It is oval shaped, with C-shaped cartilaginous rings creating the anterior and lateral borders. A soft tissue membrane forms the posterior wall to complete the oval shape. In the average male, the anterior–posterior dimension is 1.8 cm, while the lateral aspect is 2.3 cm. Tracheal length reaches almost 12 cm with about 2 rings/cm. Tracheae in women are 10% to 20% smaller in size. In children, the shape is more circular, but becomes gradually more ovoid as people age.

There is a significant amount of flexibility in the normal trachea, and remodeling can occur in chronic disease states such as emphysema. The inner lining consists of ciliated pseudostratified columnar epithelium with goblet and mucous cells interspersed. At the carina, the right and left mainstem bronchi split off. The right side is characterized by the quick takeoff of the right upper lobe bronchus, with the bronchus intermedius continuing into the middle and lower lobe bronchi. The left side has a longer mainstem bronchus with a split into the upper and lower lobes.[73] The blood supply begins with the inferior thyroid artery supplying the cervical trachea through three tracheoesophageal branches. The lower trachea is supplied by bronchial arteries arising off the aorta. As the arteries approach the trachea, they further split to supply separate segments. Even within segments, it will branch into anterior and posterior transverse intercartilaginous arteries (**Fig. 80.32**). Because of this segmental blood supply, there should be minimal circumferential dissection around the trachea to limit impairment of the blood supply and healing in tracheal/bronchial surgery.

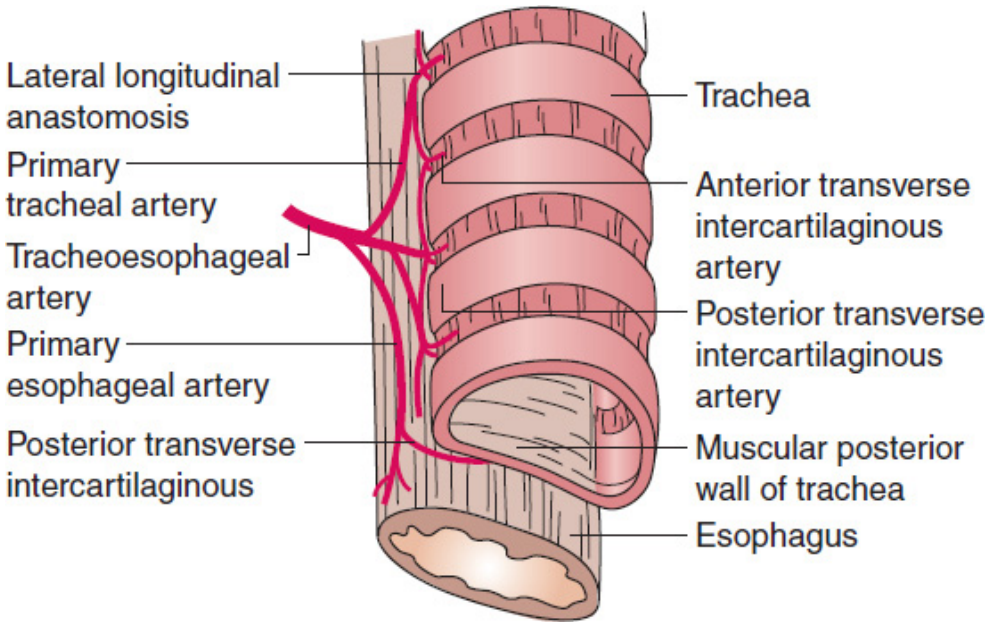

Figure 80.32 Semischematic view of the tracheal microscopical blood supply. Transverse intercartilaginous arteries derived from the lateral longitudinal anastomosis penetrate the soft tissues between each cartilage to supply a rich vascular network beneath the endotracheal mucosa.

Surgical Airways

The most common tracheal procedure is a tracheostomy. Over the last 20 years, there has been an increasing utilization of percutaneous tracheostomy. For patients who are intubated, the indication for and timing of tracheostomy depends on a multitude of factors, of which there is very little consensus in the medical literature. The goal of a tracheostomy is to limit the risk of laryngeal stenosis caused by prolonged endotracheal intubation, to improve pulmonary toilet, and to improve oral hygiene. Generally, tracheostomy should be considered after a patient has been intubated for more than 10 days, without clear expectation for immediate extubation.[74] Ideally, patients should be on minimal ventilator settings, but tracheostomy may be performed in patients with elevated oxygen (FiO_2 of up to 60%) and ventilatory (PEEP under 10) requirements. Patients requiring more support are at high risk of decompensating if they lose their airways, even if just for a moment, and the decision to perform a tracheostomy should be carefully considered in this setting (**Table 80.8**).[75]

Tracheostomies are performed with the neck extended. A 2- to 3-cm incision is made approximately 2 cm above the sternal notch. Dissection is carried down through the platysma, and the strap muscles are divided longitudinally. Exposure of the trachea and the 2nd and 3rd rings may require elevation of the thyroid. Lateral traction sutures may be placed around the 2nd or 3rd rings. A vertical incision is made between rings 2 and 4 and gradually dilated. A tracheostomy tube is placed under direct vision.[74,76] Percutaneous tracheostomy placement is based on the Seldinger technique. A needle is placed percutaneously into the trachea at the estimated level of the 2nd or 3rd rings with bronchoscopic visualization. A guidewire is placed into the airway, and serial dilations performed, until a tracheostomy tube is able to be advanced over the wire.[75] Cricothyroidotomy should only be performed in the emergent setting. The cricothyroid membrane is palpated below the superior thyroid notch. A transverse incision is made to the lateral borders of the thyroid cartilage. Rapid dilation is followed by tube insertion.

Complications can vary depending on the technique. Fistulas result from erosion of the tracheostomy tube into the innominate artery, with placement below the 3rd ring placing patients at higher 8 risk. A sentinel bleed may be the initial presentation. Pressure on the fistula with immediate repair or ligation of the vessel is required (**Fig. 80.33**).[77] Postintubation stenosis is

usually due to necrosis caused by high-pressure cuffs resulting in impaired blood flow to the segmental area of the trachea. This leads to the long-term loss of cartilage and narrowing of the airway. The use of low-pressure cuffs has reduced the incidence of this complication, but not eliminated it. Bronchoscopy and dilation may alleviate symptoms, but resection of the stenotic area may be needed (**Fig. 80.34**).[76]

Table 80.8 Tracheostomy Complications

Immediate Complications	Early Complications	Late Complications
Hemorrhage	Hemorrhage	Tracheal Stenosis
Structure damage to trachea	Tube displacement	Granulation tissue
Failure of procedure	Pneumothorax	Tracheomalacia
Aspiration event	Pneumomediastinum	Pneumonia
Air embolism	Subcutaneous emphysema	Aspiration event
Loss of airway	Stomal infection	Tracheoarterial fistula
Death	Stomal ulceration	Tracheoesophageal fistula
Hypoxemia, hypercarbia	Accidental decannulation Dysphagia	Accidental decannulation Dysphagia

Adapted from Cheung N, Napolitano LM. Tracheostomy: epidemiology, indications, timing, technique, and outcomes. *Respiratory Care* 2014;59(6):895–919.

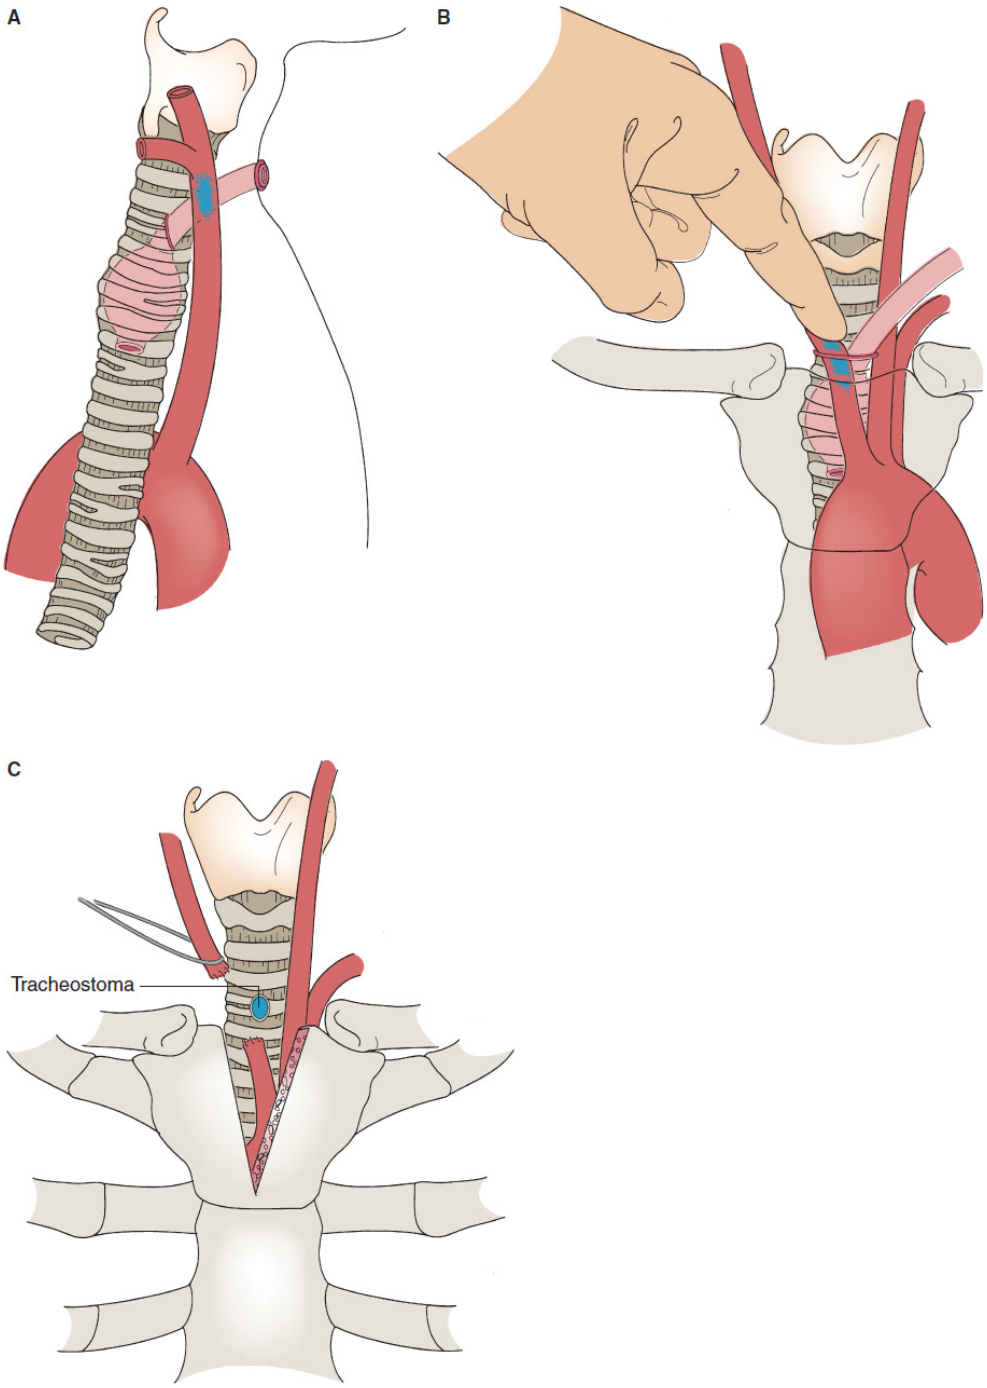

Figure 80.33 Management of tracheoinnominate artery fistula. **A:** Common mechanism of injury from erosion of innominate artery by adjacent tracheostomy tube. **B:** Emergency treatment of hemorrhage involves insertion of an endotracheal tube into the tracheostomy stoma, inflation of the cuff, and downward and outward pressure on the fistula by the finger inserted through the tracheostomy incision to further tamponade the bleeding. **C:** Through a partial upper sternal split, the segment of involved innominate artery is resected and the oversewn ends covered with adjacent mediastinal fat or muscle. Tracheal resection is usually not necessary. A new tracheostomy tube may have to be inserted higher in the trachea or, if

possible, the tracheostomy tube removed and the stoma covered with a sternohyoid muscle flap.

Tracheal Tumors

Benign lesions of the trachea are less common than malignant ones. They include papillomas, chondromas, hamartomas, fibromas, and hemangiomas. Papillomas are associated with the human papilloma virus and can degenerate into malignant lesions, thus requiring resection. Chondromas arise from the cartilage, and may recur after resection. Hamartomas are comprised of cartilage, epithelial, and lymphatic tissues. Recurrence is rare after resection. Fibromas can be resected via bronchoscopy. Hemangiomas are the most common pediatric tracheal mass. They may regress without treatment and can be observed if not causing obstructive symptoms. Biopsy is generally avoided due to bleeding risk. Surgery may be required if lesions persist.[78]

Although more common than benign lesions, malignant tracheal tumors are very rare with only 600 to 700 cases in the United States per year. Lesions may be primary tracheal lesions, tumors from adjacent organs growing into the trachea, or metastatic lesions.[79] Primary tumors are most commonly squamous cell carcinomas or adenoid cystic carcinomas in the trachea, followed by carcinoids in the bronchi.[79,80] Adjacent tumors may arise in the lung, esophagus, thyroid, or mediastinum. The most common cancers that cause tracheal metastases include renal cell cancers, sarcomas, breast cancers, and colon cancers.[79] Patients will present with stridor and wheezing, and have often been recently diagnosed with adult-onset asthma and treated with inhalers and even steroids without alleviation of symptoms. Hemoptysis may also occur, though it is more common in lung cancer than in tracheal disease.[80] Patients should undergo imaging such as a neck and chest CT scan to assist in making the proper diagnosis. Bronchoscopy with a flexible or rigid endoscope is essential to aid in the evaluation of the extent of disease and to control the airway if necessary. Treatment includes tracheal resection for primary tumors if possible. For metastatic disease, palliative treatment includes endoluminal resection and/or radiotherapy.[80] Endoluminal treatments include mechanical core-out, YAG-laser treatment, photodynamic therapy (PDT), cryotherapy, or brachytherapy. Stenting also may play a role

to maintain airway patency, either for a temporary period during radiation treatment, or in the setting of end-stage disease (**Algorithm 80.5**).[79]

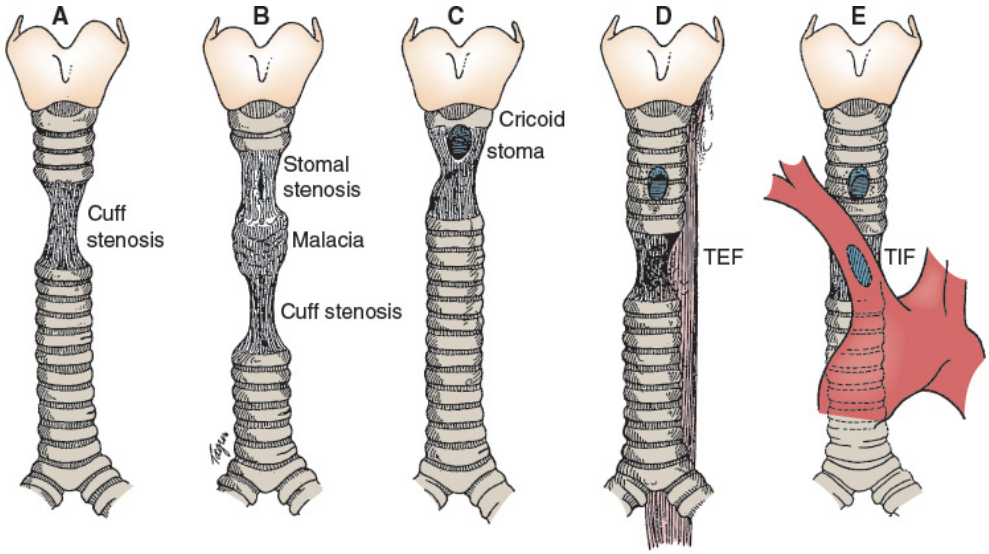

Figure 80.34 Diagrams of principal postintubation tracheal lesions. **A:** Cuff stenosis from the cuff of an endotracheal tube. **B:** Cuff stenosis from the cuff of a tracheostomy tube, usually lower in the trachea than that from an endotracheal tube. Stomal stenosis also occurs at the site of the tracheostomy itself. Malacia may occur either at the level of the cuff or in the segment between the stoma and the cuff stenosis. **C:** Cuff stenosis at the site of a high tracheostomy stoma, which has eroded into the lower margin of the cricoid cartilage. In older patients, this may erode back farther into the subglottic larynx, producing a laryngotracheal stenosis. A stoma placed in the cricothyroid membrane will, by definition, produce an intralaryngeal stenosis. **D:** Tracheoesophageal fistula (TEF) produced by pressure of the cuff against the "party wall," often abetted by an indwelling firm nasogastric tube. **E:** One type of tracheoinnominate fistula (TIF) as the result of a high-pressure cuff erosion. The more common type, but also rare, is that seen with a low-placed tracheostomy stoma, which rests against the innominate artery itself. (Reproduced with permission from Grillo HC. Surgical treatment of postintubation tracheal injuries. *J Thorac Cardiovasc Surg* 1979;78:860–875.)

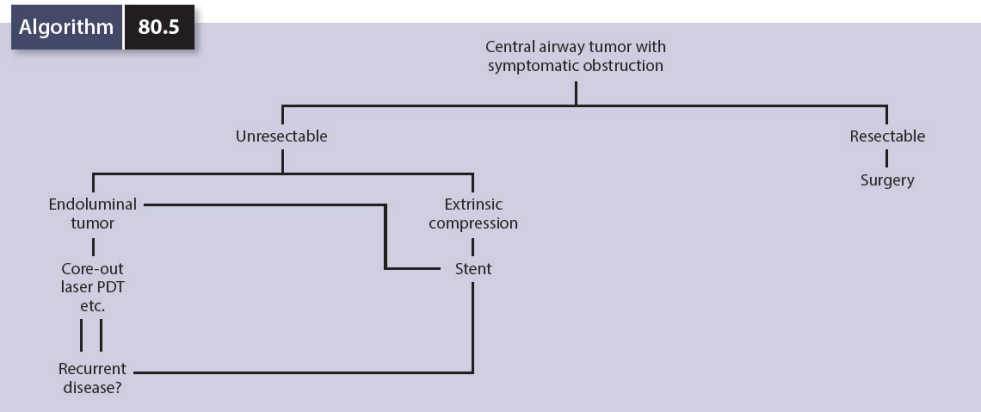
Tracheomalacia and Airway Stents

Tracheomalacia occurs when the trachea loses its rigid form and the posterior membranous wall approaches the anterior wall, causing luminal narrowing and obstruction leading to dyspnea. Patients have a characteristic seal-like cough. Chest CT scans may demonstrate this condition, and pulmonary function testing in these patients will show reduced FEV_1, FVC, and peak expiratory flow rates. Bronchoscopy is the best diagnostic test and

reveals real-time airway collapse with expiration. Etiologies include congenital tracheomalacia, extrinsic compression, postintubation stenosis and inflammation, relapsing polychondritis, and COPD.[81] Surgical intervention may include resection for localized involvement, tracheoplasty, or stenting.[81,82] Airway stents can be divided into two groups, silicone and metal, with each type having distinct advantages (**Table 80.9**). Newer stents being developed include covered metal stents that prevent tumor in growth along the stent, but unfortunately still allow granulation tissue to grow in at the ends.[83] In addition to being useful in the setting of tracheal stenosis, they can also play an essential role in palliating posttransplant bronchial stenosis.[84]



Algorithm 80.5 Algorithm for management of tracheal masses. (Adapted from Wood DE. Management of malignant tracheobronchial obstruction. *Surg Clin North Am* 2002;82(3):621–642.)

Table 80.9 Classification of Airway Stents

- Silicone stents
  - Advantages
    - Adjustable
    - Removable
    - Minimal granulation
  - Disadvantages
    - Gen. anesthesia/rigid bronch to place
    - Migrates
    - Secretions adhere to stent
    - Interferes with ciliary clearance
    - Smaller inner diameter
- Metal stents
  - Advantages
    - Less migration
    - Larger inner diameter
    - Less ciliary interference
    - Flexible bronch to place
  - Disadvantages
    - May need balloon dilation
    - Difficult to remove
    - Granulation and tumor ingrowth in the stent
    - Radial force may lead to necrosis/fistula

Mediastinum

The mediastinum contains a number of important structures and may be involved in different disease processes. The mediastinum is divided into several compartments, including the superior, anterior, middle, and posterior regions. Sometimes the lower three compartments are extended superiorly and only three are described (**Fig. 80.35**). The anterior mediastinum includes the fat and lymph nodes posterior to the sternum, but anterior to the pericardium. The middle compartment includes the pericardium, heart, aorta, and trachea. The posterior compartment includes the esophagus, sympathetic

chain, and vertebral column (**Fig. 80.36**). Most lesions are found in asymptomatic patients, but presenting symptoms include dyspnea and chest pain. Symptoms may be local, related to compression on mediastinal structures, or systemic, caused by the release of cytokines or inflammatory factors, such as in lymphomas or thymomas with myasthenia gravis (MG). Imaging begins with plain radiographs, but CT scans are essential. MRI scans may be helpful to evaluate vascular or spinal involvement. PET scans are increasingly utilized as they may further aid in staging. Biopsy and/or surgical resection is required to confirm the diagnosis in almost all patients.[85]

Anterior Mediastinum

The anterior mediastinum can contain a variety of tumors (**Table 80.10**). Most common are thymomas, lymphomas, and germ cell tumors, in that order. Thymomas account for one-fifth of all anterior mediastinal masses in the adult population. They arise from the thymus gland and can be seen with autoimmune diseases such as MG and pure red cell aplasia. Tumors were previously classified by the Masaoka classification system which has now been supplanted by the IASLC TNM system (**Table 80.11**).[86] The World Health Organization (WHO) histologic criteria, which is based upon the morphology of the epithelial cells as well as the lymphocyte to epithelial cell ratio. Diagnosis is usually made by chest CT scan. Needle biopsy of a potential thymoma is not routinely recommended for fear of seeding the needle track. When thymomas are suspected, resection is the best option, via a midline sternotomy or thoracoscopic approaches (**Fig. 80.37**). During resection, one must take care to remove all of the tissue in the anterior compartment, including all fat and tissue around the innominate vein. Pleural seeding via drop metastases is a theoretical downside of thoracoscopic approaches compared to sternotomy.

Neoadjuvant chemotherapy and radiation may be used to downstage locally invasive tumors and allow for subsequent resection. Postoperative radiation is recommended for tumors that demonstrate capsular invasion or if residual disease is present. Platinum-based chemotherapy is typically utilized in the unresectable setting.[87] MG presents with diplopia, ptosis, fatigue, and weakness. One-third to one-half of patients with thymomas have

MG, but only 10% of patients with MG have thymomas. Antiacetylcholine receptor antibody levels may be measured to evaluate for MG in patients with suspected thymomas.[88] Thymic carcinomas and thymic carcinoids are other tumor types that can also arise from the thymus.

Germ cell tumors can present as benign teratomas, seminomas, and embryonal tumors, which include nonseminomatous germ cell tumors and malignant teratomas. Benign teratomas have a good prognosis and resection is the best treatment. Seminomas comprise up to half of mediastinal germ cell malignant tumors. Patients may have symptoms from local compression or systemic symptoms such as fever, weight loss, and even gynecomastia. These tumors are radiosensitive, but in locally advanced disease, chemotherapy with later surgical resection is the favored treatment. Nonseminomatous tumors include a wide variety of histologic malignancies. They usually occur in young men and are often symptomatic (**Fig. 80.38**). Elevated alpha-fetal protein (AFP) and beta-human chorionic gonadotropin (β-hCG) levels are seen with these tumors and should be measured. Chemotherapy is the best treatment, but patients have a poorer prognosis when compared to those with seminomas. Lymphomas in the mediastinum are usually part of a wider spectrum of disease. Two-thirds of cases are Hodgkin disease. Most patients present with symptoms of fevers, night sweats, and even weight loss. Treatment is always chemotherapy based, and surgery in the form of a biopsy is utilized only to help make the diagnosis.[88]

Middle and Posterior Mediastinum

Middle mediastinal masses include esophageal and bronchogenic cysts, pericardial cysts, lymphangiomas, and lymphomas (**Fig. 80.39**). For cystic lesions, surgical resection is the best treatment option. Posterior lesions include neurogenic tumors which may be benign or malignant. Almost 95% of tumors come from the sympathetic chain or intercostal nerve rami. Up to two-thirds of these tumors are benign nerve sheath tumors and are usually discovered incidentally. An MRI scan may be used to evaluate intraspinal extension.[88]

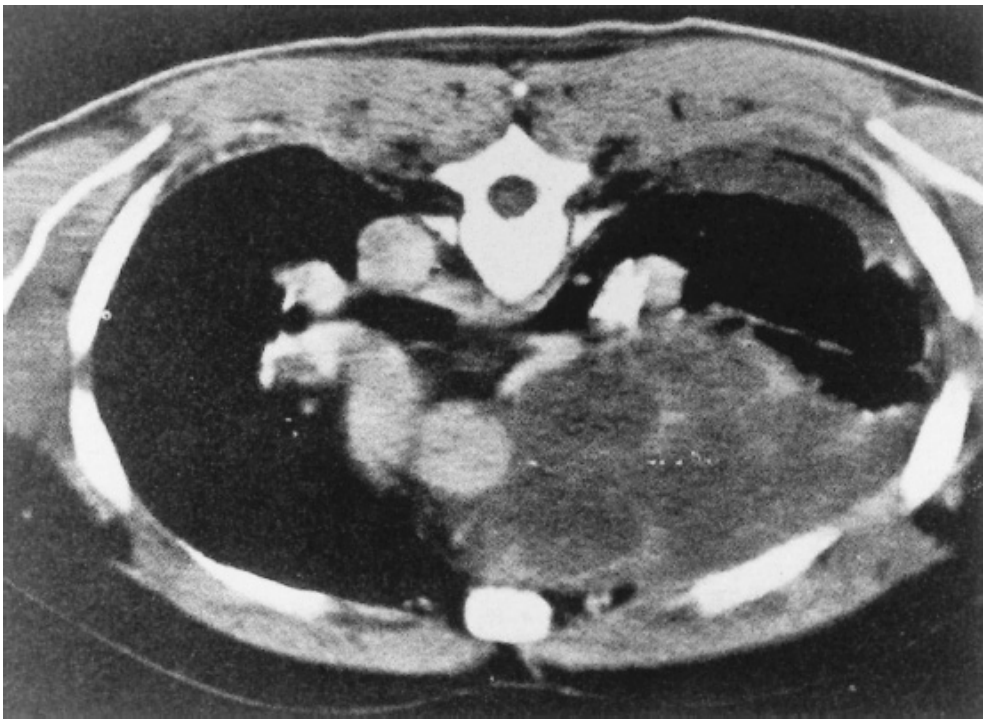

Figure 80.38 Computed tomography scan of a malignant nonseminomatous germ cell tumor of the anterior mediastinum reveals the inhomogeneous anterior mediastinal mass in contrast to the homogeneous density of a seminoma. Pleural effusion is also demonstrated in the right hemithorax. (Reproduced with permission from Shields TW. Primary lesions of the mediastinum and their investigation and treatment. In: Shields TW, ed. *General Thoracic Surgery*. Baltimore, MD: Williams & Wilkins; 1994:1724–1769.)

Pediatric Mediastinum

The presentation of mediastinal masses in the pediatric population varies from what is observed in adults. The rate of malignancy is slightly lower in children, and while thymomas are the most common adult masses seen, neurogenic tumors are more common in children (**Table 80.12**). Just over half of all mediastinal tumors arise in the posterior compartment.[89] Anterior masses may include the normal thymus in a young child. Teratomas are the most common germ cell tumor seen.[89] Vascular anomalies may be seen in children and include hemangiomas and cystic hygromas.[90] Middle compartment tumors are usually foregut cysts, as in the adult population. Posterior tumors are most often malignant neurogenic tumors, compared to more benign pathology in adults.[89]

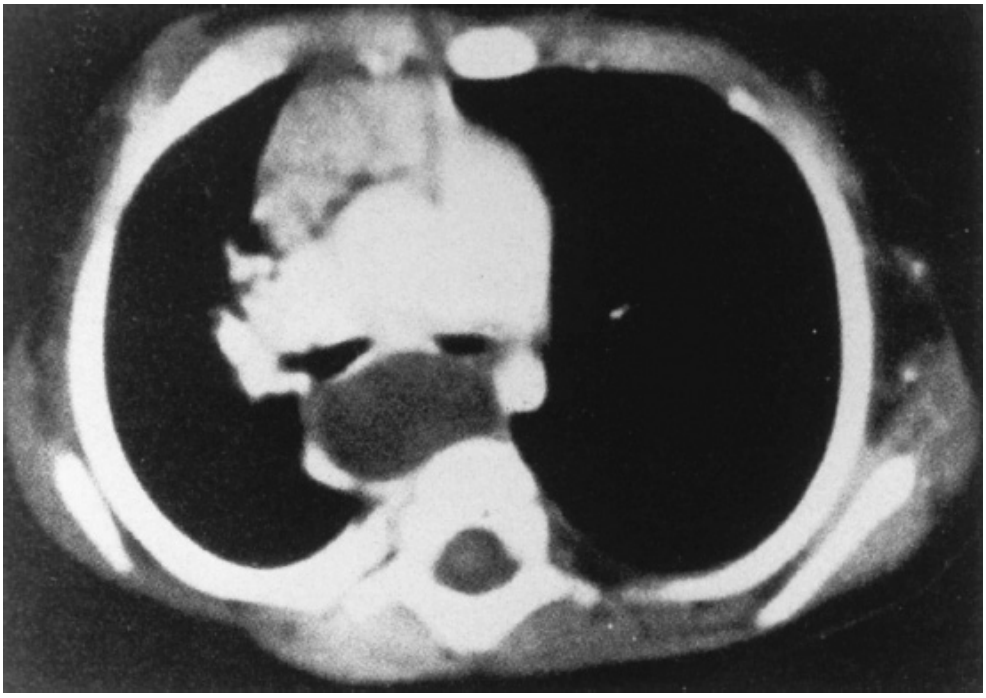

Figure 80.39 Computed tomography scan reveals a bronchogenic cyst located in the subcranial area with compression of the left mainstem bronchus with hyperinflation of the left lung and a mediastinal shift to the right. (Reproduced with permission from Shields TW. Primary lesions of the mediastinum and their investigation and treatment. In: Shields TW, ed. *General Thoracic Surgery*. Baltimore, MD: Williams & Wilkins; 1994:1764–1769.)

Mediastinitis

Mediastinal inflammation can arise from different sources, but it is most often infectious in nature. Acute mediastinitis is life threatening and usually results from a perforated esophagus, postcardiac procedure, or trauma. Oral infections can also result in organisms traveling through the neck into the mediastinum along fascial planes. These infections can travel as quickly as necrotizing fasciitis does in other parts of the body and should be addressed immediately. A wide variety of organisms can cause mediastinitis. Patients will have chest pain, dyspnea, and fevers. Radiographic films may show pneumomediastinum or pneumothoraces. If an esophageal perforation is suspected, an esophagogram should be performed.[9] Treatment is broad-spectrum antibiotics and surgical drainage via a cervical incision and/or thoracotomy. Quick debridement and drainage are keys to patient survival. Minimally invasive approaches to the chest may be adequate, but surgeons should have a low threshold to perform a posterolateral thoracotomy, which may give the best exposure and opportunity to debride the chest. Sternal infections after cardiac surgery can also be a serious problem requiring drainage and debridement. Ultimate repair of the defect following debridement may involve muscle or omental flaps for sternal reconstruction.

Chronic mediastinitis is a separate entity from acute mediastinitis and may arise from infectious sources or autoimmune disorders. Patients may be asymptomatic until a mass effect is seen on their mediastinal organs. CT scans are the best imaging modality to diagnose this condition, and surgery is reserved only for diagnosis or in the end stages of the disease to relieve compression on other organs. Sclerosing mediastinitis may be seen in patients with retroperitoneal fibrosis.[91]

Superior Vena Cava Syndrome

Superior vena cava (SVC) syndrome is a rare condition seen when a mediastinal mass compresses the SVC resulting in facial and upper body edema. Only 15,000 cases per year are seen in the United States. Patients may present with cough, dyspnea, or even stridor from upper airway edema. When patients start to have symptoms, collateral venous drainage develops to drain into the azygos vein or inferior vena cava. This process usually takes

weeks. Malignant tumors are the most common cause, but venous thrombosis and nonmalignant lesions cause up to one-third of cases. CT scans are the best diagnostic test. Treatment is based on supportive care and addressing the underlying condition causing the obstruction. If a malignant tumor is causing the obstruction, chemotherapy or radiotherapy may shrink the tumor and lessen symptoms. Surgical resection with SVC reconstruction may be used in specific tumors such as locally advanced thymomas. Angioplasty and stenting may be of benefit but is usually palliative.[92] Although it is often felt to be an emergency, most cases of SVC syndrome have a slowly progressive course. When a patient develops symptoms, supportive care, including possible intubation, will allow time for collateral venous drainage to develop and symptoms to improve without other interventions. Although the median survival is typically 6 months or less in patients with SVC syndrome from malignant obstruction, some have seen long-term survivors when the primary tumors have responded to appropriate treatment.[93] When patients present with severe symptoms, it is a mistake to rush to surgical intervention without a long-term plan. Symptoms should be managed and the etiology discovered and treated appropriately.

Section M: VASCULAR DISEASE

81

Congenital Heart Disease

Vikram Sood and Jennifer C. Romano

Key Points

1 An atrial septal defect (ASD) is a hole in the atrial septum. ASDs are the third most common congenital heart defect (CHD), occurring in 1–2 out of 1,000 live births and representing 1% of CHDs. ASDs cause right heart volume overload and can lead to pulmonary vascular obstructive disease (PVOD) later in life. The majority of ASDs are now closed with a device in the catheterization laboratory.

2 Ventricular septal defects (VSDs) are the most common CHD (with the exception of bicuspid aortic valve [BAV], which occurs in about 1.3% of the population). VSDs cause left heart volume overload.

3 Over 50% of children with trisomy 21 have a CHD. The most common heart defect in this population is an atrioventricular septal defect (AVSD). All infants with trisomy 21 should have an echocardiogram to rule out CHD.

4 Tetralogy of Fallot (TOF) is the most common cyanotic CHD. It occurs in 0.4 per 1,000 live births and has a prevalence of about 5% among all patients with congenital heart disease. The pathologic anatomy is frequently described as having four components: ventricular septal defect, overriding aorta, right ventricular outflow tract obstruction (RVOTO), and right ventricular hypertrophy.

5 Transposition of the great arteries (TGA) is the most common congenital heart defect presenting with cyanosis in the first week of life. In this lesion, the aorta arises from the right ventricle and the pulmonary artery originates from the left ventricle (ventriculoarterial discordance). This malformation accounts for approximately 10% of all congenital cardiovascular malformations in infants.

6 Upper extremity hypertension with diminished femoral pulses are hallmark clinical findings in patients with aortic coarctation.

7 The first successful treatment of a congenital lesion was the closure of a patent ductus arteriosus (PDA) by Gross and Hubbard in 1938. Prostaglandin inhibitors, such as ibuprofen, can be used to induce

closure of a PDA in the premature newborn with a success rate of 65%. When this is not successful, surgical closure or coil occlusion may be necessary.

INTRODUCTION

This chapter focuses on the major congenital cardiac lesions and their etiology, workup, indications for intervention, and treatment options. The aim is to provide the noncongenital heart surgeon with a basic survey of congenital heart disease and its surgical treatment.

HISTORY

Congenital cardiac surgery, as a specialty, is notable for rapid technical advances with marked improvement in survival and reduction in morbidity. Much of the original interest in cardiac surgery was focused on attempts to treat congenital heart defects associated with cyanosis and early mortality. The first successful treatment of a congenital lesion was the closure of a patent ductus arteriosus (PDA) by Gross and Hubbard in 1938.[1] The description of the subclavian artery-to-pulmonary artery (PA) shunt by Blalock, Taussig, and Thomas in 1945[2] introduced the palliation of many complex cyanotic lesions—most notably, tetralogy of Fallot (TOF). The 1950s represented the decade of greatest advances, which laid the foundation for the field of cardiac surgery. In 1952, Lewis and Taufic[3] performed the first open closure of an atrial septal defect (ASD) by using surface hypothermia and inflow occlusion. In 1953, Gibbon[4] performed the first ASD repair with the use of a pump oxygenator that became the model for modern cardiopulmonary bypass. Next, Warden et al.[5] used controlled cross-circulation with an adult as the oxygenator during intracardiac repairs. Building on the work of Gibbon, Kirklin et al.[6] published the first series of eight intracardiac operations performed at the Mayo Clinic with the use of cardiopulmonary bypass. With these landmark efforts focused on congenital heart disease, the field of cardiac surgery was established.

ATRIAL SEPTAL DEFECT

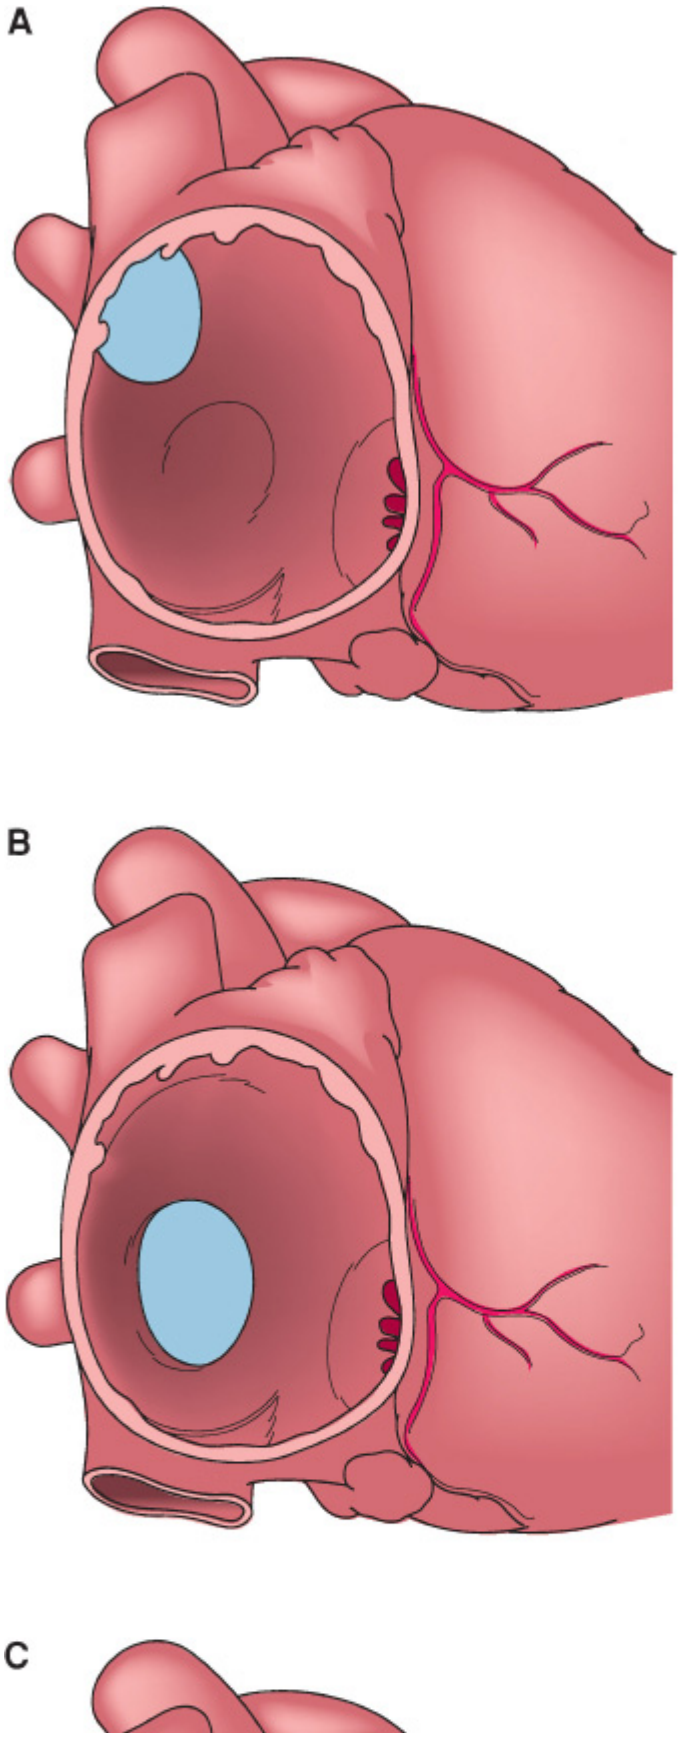
Embryology

Cardiac septation occurs between the third and sixth weeks of fetal development. The septum primum, which arises from the roof of the common atrium and descends inferiorly, initially divides the common atrium. The ostium primum is the opening below the inferior edge of the septum primum, which is obliterated as the septum primum fuses with the endocardial cushions. The ostium secundum forms in the midportion of the septum primum prior to closure of the ostium primum. The septum secundum arises from the roof of the atrium and descends along the right side of the septum primum and covers the ostium secundum. This creates a flap valve whereby blood from the inferior vena cava may preferentially stream beneath the edge of the septum secundum and through the ostium secundum into the left atrium. After birth, with increased pulmonary blood flow, the left atrial pressure increases and closes this pathway.

Anatomy and Pathophysiology

An ASD is a hole in the atrial septum (Fig. 81.1). ASDs are the third most common congenital heart defect, occurring in 1–2 out of 1,000 live births and representing 15% of congenital heart defects.[7] The most common ASD is the secundum defect, which occurs when there is excessive resorption of the septum primum or incomplete coverage of the ostium secundum by the septum secundum. Ostium secundum defects account for about 80% of ASDs. An ostium primum ASD, representing 10% of ASDs, occurs from failure of fusion of the septum primum with the endocardial cushions. Ostium primum defects are discussed later, in the section on atrioventricular septal defects (AVSDs). A third type of ASD is the sinus venosus defect, seen in about 10% of cases. Sinus venosus ASDs are caused by abnormal fusion of the venous pathways with the atrium and are characterized by defects high in the atrial septum near the orifice of the superior vena cava or, less commonly, low in the atrial septum near the inferior vena cava. Sinus venosus defects are frequently associated with partial anomalous pulmonary venous connection, usually with the right upper pulmonary vein draining into the superior vena

cava near the cavo–atrial junction. Finally, the rarest type of ASD is the unroofed coronary sinus septal defect. This occurs when there is loss of the common wall between the coronary sinus and the left atrium adjacent to the atrial septum. This unroofing of the coronary sinus leads to a communication between the right and left atria at the site of the coronary sinus.



A
B
C

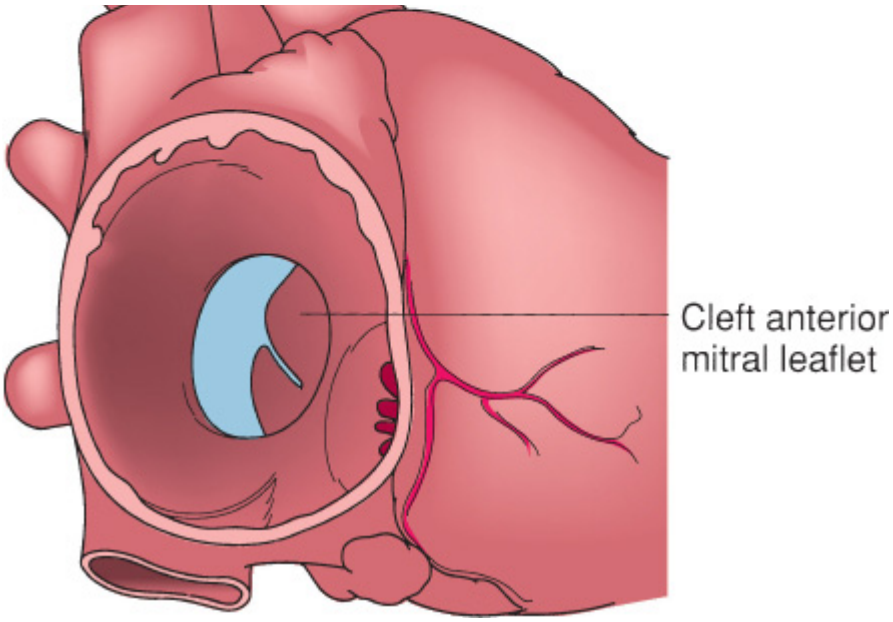


Figure 81.1 The anatomy of atrial septal defects. In the sinus venosus type (**A**), the right upper and middle pulmonary veins frequently drain to the superior vena cava or right atrium. **B:** Secundum defects generally occur as isolated lesions. **C:** Primum defects are part of a more complex lesion and are best considered as incomplete atrioventricular septal defects.

Patent foramen ovale (PFO) is extremely common in the general population, and autopsy studies have demonstrated a prevalence of 27%.[8] A PFO is generally considered distinct from other ASDs due to the absence of significant shunting. Failure of postnatal fusion of the septum secundum to the septum primum results in a persistent slit-like communication known as a PFO. Nevertheless, PFOs remain important clinically due to the potential for paradoxical embolization. A paradoxical embolus is a blood clot arising from a systemic vein that would normally pass to the lungs, but in the presence of a septal defect, may cross into the systemic circulation.

Increased pulmonary blood flow (PBF) results from ASDs secondary to left-to-right shunting. Shunting at the atrial level is determined by the size of the defect and by the relative ventricular compliance (i.e., blood preferentially fills the more compliant ventricle). At birth, both ventricles are equally compliant, but as pulmonary vascular resistance (PVR) falls, the right ventricle remodels and becomes more compliant. Shunting across the atrial septum causes a volume load on the right heart.

The volume overload from an ASD is usually well tolerated, and patients are frequently asymptomatic. Symptoms tend to develop when the ratio of

pulmonary to systemic blood flow (Q_p/Q_s) exceeds 2:1. The most common symptoms are fatigue, shortness of breath, exercise intolerance, and recurrent respiratory infections. Adults with untreated ASDs tend to develop atrial dysrhythmias (secondary to long-standing right atrial enlargement) and may develop congestive heart failure (CHF) and right ventricular dysfunction. Pulmonary vascular obstructive disease rarely occurs as a late complication of an untreated ASD. Paradoxical embolization, as described above, is also an important potential complication of an ASD.

Diagnostic Findings

The classic physical examination findings in patients with ASDs include fixed splitting of the second heart sound and a systolic ejection murmur at the left upper sternal border due to increased flow across a normal pulmonary valve. A diastolic flow murmur across the tricuspid valve is occasionally audible. A prominent right ventricular lift and increased intensity of the pulmonary component of the second heart sound may occur with pulmonary hypertension. Chest radiography shows cardiomegaly, with enlargement of the right atrium, right ventricle, and pulmonary artery. Electrocardiography (ECG) frequently demonstrates right axis deviation. Cardiac catheterization is important in selected cases to assess PVR in older patients, but it is used more frequently with therapeutic intent for device closure of ASDs.

Indications for Intervention and Treatment Options

Due to the long-term complications associated with ASDs, repair is recommended for all patients with symptomatic defects and in asymptomatic patients with a Q_p/Q_s is greater than 1.5 or signs of right heart enlargement. Repair is usually performed in children prior to school age (3 to 5 years), as it is anticipated that spontaneous closure is unlikely after this age. Closure of ASDs may be performed surgically or using a device deployed in the cardiac catheterization laboratory.

OPERATIVE STEPS

Table 81.1 Secundum ASD via Limited Sternotomy

CPB configuration	Bicaval cannulation, normothermia, and antegrade cardioplegic arrest
Exposure and intracardiac steps	Oblique right atriotomy, inspection of atrial septum/systemic venous return/pulmonary venous return, patch closure of ASD
Completion	De-airing of left heart, removal of cross clamp, primary closure of right atriotomy
Final steps	Wean off bypass, TEE, standard closure

CPB, cardiopulmonary bypass; ASD, atrial septal defect; TEE, transesophageal echocardiogram.

The operative steps are detailed in Table 81.1. Surgical repair is usually recommended for large, secundum defects that are not amenable to device closure and for all other types of ASDs. Small secundum defects or PFOs may sometimes be closed primarily by suturing the edge of the septum primum to the edge of the septum secundum. More commonly, larger defects are closed using a patch (polytetrafluoroethylene or autologous pericardium) and a running polypropylene suture. In sinus venosus defects, when anomalous pulmonary venous drainage is present, a baffle is created to redirect pulmonary venous return across the ASD. Surgical closure of an ASD can be accomplished with a mortality approaching zero and minimal morbidity.[9] Common postoperative complications include atrial arrhythmias and postpericardiotomy syndrome.

A number of devices are currently available for percutaneous closure of secundum ASDs with excellent efficacy.[10,11] The presence of a deficient rim is the most common reason for failed implantation.[11] Device closure has the advantages of fewer complications and a shorter hospitalization and recovery time.[12] 1 Device closure of small to moderate secundum ASDs and PFOs has now become the standard of care.

The long-term survival for patients undergoing ASD repair in childhood is equivalent to nonaffected patients.[13] The major long-term complication following closure of an ASD is the development of supraventricular arrhythmias, although the risk is lowered when it is closed in childhood.[13,14] Long-term follow-up of percutaneous device closure of secundum ASDs reveals excellent durability and safety.[15]

Occasionally, adults will present with a newly diagnosed ASD. Many studies have confirmed that ASD closure in adults over the age of 40 increases survival and limits the development of heart failure.[16] Nevertheless, when the Q_p/Q_s is less than 1.5, and the ratio of pulmonary to systemic vascular resistance (R_p/R_s) is greater than 0.7, significant PVOD is usually present. A PVR in excess of 10 to 12 Wood units/m^2 represents a contraindication to ASD closure.

VENTRICULAR SEPTAL DEFECT

Embryology

Ventricular septation is a complex process that requires accurate development and alignment of a number of structures including the muscular interventricular septum, the atrioventricular (AV) septum (arising from the endocardial cushions), and the infundibular septum (which divides the outflow tracts of the right and left ventricles). The membranous septum is a fibrous portion of the ventricular septum that is adjacent to the central fibrous body (where the mitral, tricuspid, and aortic valve annuli make contact). Septation is usually complete by the seventh week of gestation.

Anatomy and Pathophysiology

2 Ventricular septal defects (VSDs) are the most common congenital heart anomalies (with the exception of bicuspid aortic valve [BAV], which occurs in about 1.3% of the population). VSDs are present in about 2–3 of 1,000 live births and represent about 35% of congenital heart defects.[7] VSDs are classified based on their location in the ventricular septum (Fig. 81.2). The most common defects are perimembranous (80%), which are located in the

area of the membranous septum. Defects located high in the ventricular septum are termed outlet defects (10%) and are typically adjacent to the pulmonary and aortic valves. Outlet defects are more common in the Asian population. Inlet defects (5%) are located beneath the septal leaflet of the tricuspid valve and are sometimes called AV canal-type defects. Finally, muscular VSDs (5%) are completely bordered by muscle and often exist alongside perimembranous or outlet defects. The size of VSDs varies. By definition, a VSD is nonrestrictive when its size (or the cumulative size of multiple defects) is greater than or equal to the size of the aortic annulus.

A VSD causes increased PBF due to left-to-right shunting primarily during systole. This creates a volume load on the *left heart* (the left atrium and ventricle receive the increased venous return during diastole). The right ventricle is not volume loaded (blood is ejected from the left ventricle [LV], through the VSD, and directly into the pulmonary circulation during systole); however, the RV does experience a pressure load. The volume of shunt flow is determined by the size of the defect and by the ratio of pulmonary to systemic resistance.

Immediately after birth, the PVR is still high and shunting across a VSD may be minimal. Over the first several weeks of life, shunting tends to increase as the PVR falls. Therefore, a patient with a large VSD may be asymptomatic at birth and develop severe CHF symptoms over the first 6 weeks of life.

The natural history for patients with isolated VSDs is highly variable. Most VSDs are restrictive and tend to close spontaneously during the first year of life. Large VSDs are nonrestrictive, resulting in right ventricular and pulmonary pressures equal to systemic pressures, and high PBF with Q_p/Q_s ratios greater than 2.5 to 3. Moderate VSDs are restrictive, with pulmonary pressures that are one-half systemic (or less) and Q_p/Q_s ratios of 1.5 to 2.5. Small VSDs are highly restrictive, right ventricular pressures remain normal, and the Q_p/Q_s is less than 1.5.

Patients with large VSDs tend to develop symptoms of CHF by 2 months of age. Patients with smaller VSDs may remain asymptomatic. In patients with outlet VSDs, prolapse of the aortic valve into the defect with partial or complete closure of the defect may occur, producing aortic insufficiency. If left untreated, excessive PBF leads to PVOD by the second year of life.

Diagnostic Findings

Infants with large VSDs will have signs of CHF: tachypnea, hepatomegaly, poor feeding, and failure to thrive. On physical examination, there is a holosystolic murmur at the left sternal border. Usually, the murmur is louder with smaller defects. The precordium is active. The pulmonary component of the second heart sound is accentuated in the presence of pulmonary hypertension. Chest radiography shows increased pulmonary vascular markings and cardiomegaly. The ECG demonstrates right ventricular hypertrophy. Patients with small VSDs have little shunting and are usually asymptomatic, having only a pansystolic murmur. Patients with moderate VSDs manifest symptoms and signs that are proportional to the degree of shunting. In patients who have developed significant PVOD, the volume of left-to-right shunting is decreased, and the murmur may disappear. Eisenmenger physiology results when the shunt flow reverses to right to left (as a result of long-standing excessive PBF and resultant pulmonary HTN), creating cyanosis.

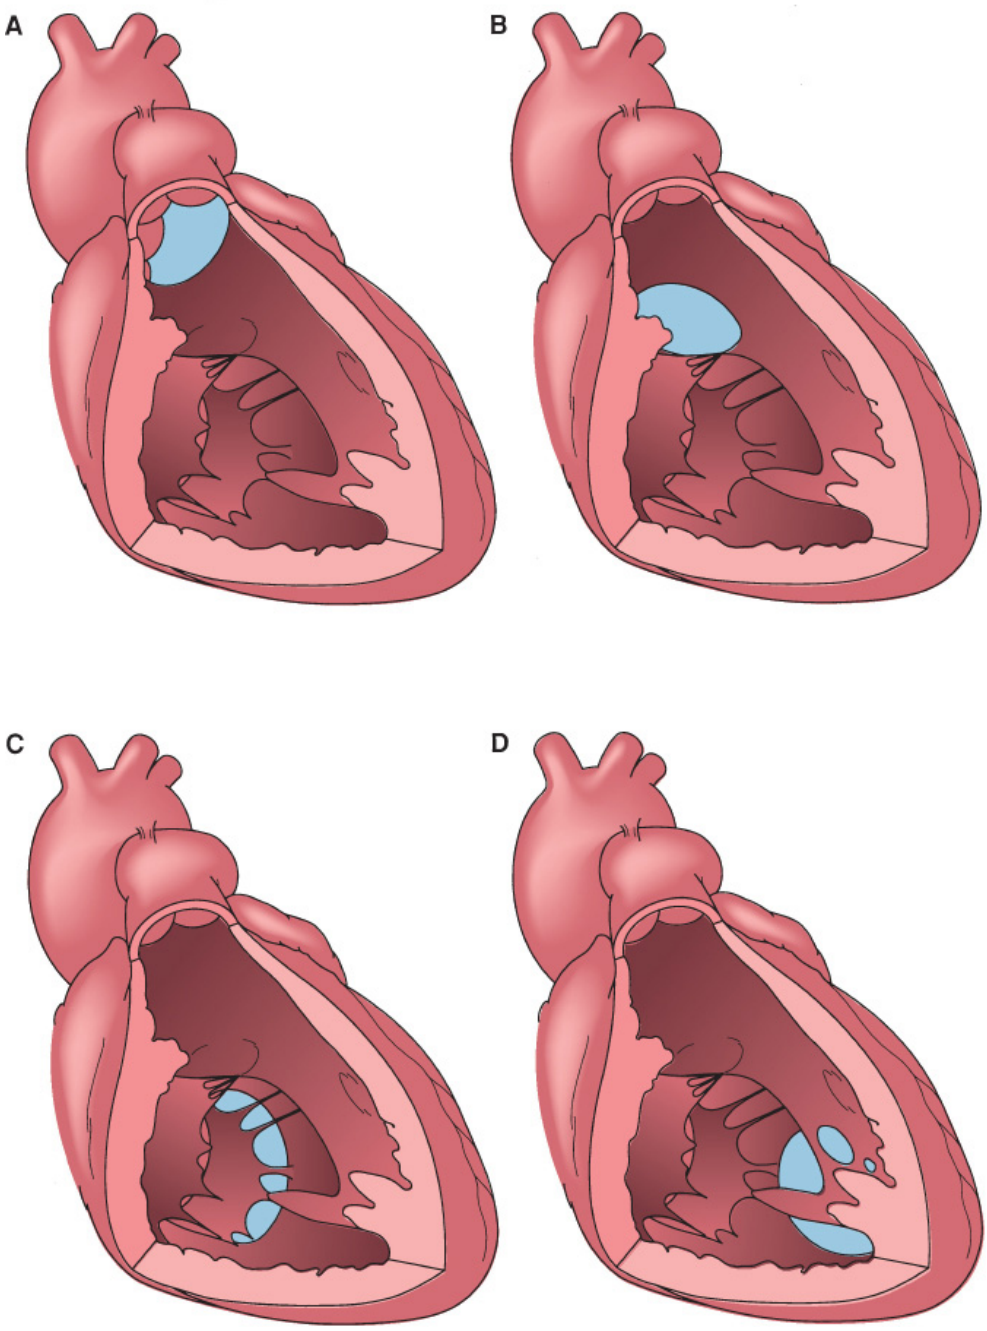

Figure 81.2 The anatomy of ventricular septal defects (VSDs) as seen through the right ventricle. **A:** Outlet, or subarterial, VSDs are generally bordered superiorly by the pulmonary valve annulus. **B:** Perimembranous VSDs are most common, extending from the membranous septum into the infundibular septum. **C:** Inlet defects are located predominantly beneath the septal leaflet of the tricuspid valve. **D:** Muscular VSDs are situated away from the valves, toward the cardiac apex.

The diagnosis of VSD is confirmed by echocardiography, which accurately defines the anatomy and excludes the presence of associated

defects. Cardiac catheterization is used selectively in older children and adults in whom elevated PVR is suspected. The PVR may be fixed or reactive, and, at the time of cardiac catheterization, response to nitric oxide or 100% fraction of inspired oxygen (FiO_2) may be assessed.

Indications for Intervention and Treatment Options

The management of a patient with a VSD depends on the size of the defect, the type of defect, the shunt volume, and the PVR. In general, patients with large defects who have intractable CHF or failure to thrive should undergo early surgical repair. If the CHF symptoms can be mitigated by medical therapy, then surgery may be deferred until 6 months of age.

Patients with small and moderate-sized VSDs may be safely followed out of infancy. If closure has not occurred by 2 years of age, then surgical closure is indicated if $Q_p/Q_s > 2:1$ or there is left-sided chamber enlargement. The majority of muscular defects close spontaneously and will not require intervention. There is a small long-term risk of endocarditis for these patients, though American Heart Association guidelines do not recommend the use of prophylactic antibiotics.[17] Patients with outlet VSDs have a risk of developing aortic insufficiency due to leaflet prolapse, and, therefore, all should undergo surgical closure if there is evidence of leaflet prolapse or aortic insufficiency.[18] Older children and adults must undergo cardiac catheterization to assess the pulmonary circulation. When there is a fixed PVR greater than 8 to 10 Wood units/m^2, surgery is contraindicated.

The operative steps are detailed in Table 81.2. Most perimembranous, inlet, and trabecular VSDs are exposed through the tricuspid valve via a right atriotomy, while outlet VSDs are frequently best exposed via a pulmonary arteriotomy. Trabecular VSDs located near the ventricular apex can be very difficult to expose, and an apical ventriculotomy may be necessary.

It is important to understand the anatomy of the conduction tissue when closing VSDs. The AV node is an atrial structure that lies at the apex of an anatomic triangle (known as the triangle of Koch) formed by the coronary sinus, the tendon of Todaro (a prominent band leading from the inferior vena cava and inserting in the atrial septum), and the septal attachment of the

tricuspid valve. The node gives rise to the bundle of His, which penetrates the AV junction beneath the membranous septum. The bundle of His then bifurcates into right and left bundle branches, which pass along either side of the muscular ventricular septum. In the presence of a perimembranous VSD, the bundle of His passes along the posterior and inferior rim of the defect, generally on the left ventricular side. In this critical area, sutures must be placed superficially on the right ventricular side a few millimeters from the edge of the defect. The bundle of His also tends to run along the posterior and inferior margin of inlet VSDs. The conduction tissue is usually remote from outlet and trabecular VSDs.

OPERATIVE STEPS

Table 81.2 VSD via Sternotomy

CPB configuration	Bicaval cannulation, mild hypothermia, antegrade cardioplegic arrest
Exposure and intracardiac steps	Oblique right atriotomy, retraction of anterior and septal leaflets of tricuspid valve, inspection of ventricular septal defect and nearby aortic valve, patch closure of VSD with running suture technique
Completion	De-airing of left heart, removal of cross clamp, primary closure of right atriotomy
Final steps	Wean off bypass, place temporary pacing wires, TEE, standard closure

CPB, cardiopulmonary bypass; VSD, ventricular septal defect; TEE, transesophageal echocardiogram.

Pulmonary artery banding is an alternative to primary surgical closure of a VSD. Pulmonary artery banding is a palliative maneuver that is used to protect the pulmonary circulation from excessive PBF while awaiting more optimal circumstances for VSD closure. A PA band increases the effective PVR, thereby reducing the shunt volume. This palliative procedure is

currently performed only in patients who are felt to be poor candidates for VSD closure, either due to associated illness or due to anatomic complexity, such as multiple trabecular VSDs ("Swiss cheese" septum).

Pulmonary artery banding is performed without the need for cardiopulmonary bypass. A band is placed around the main PA and tightened to achieve a distal PA pressure of about one-half systemic. The band is secured to the adventitia of the PA to prevent its migration. Later, when the patient is a candidate for VSD closure or when the muscular defects have spontaneously closed, the band must be removed. Repair of the main PA at the band site is usually necessary and can typically be accomplished by scar resection and patch repair.

Surgical closure of a VSD is associated with mortality less than 1%.[19] Potential complications include injury to the conduction tissue and injury to the tricuspid or aortic valves. Closure of perimembranous and inlet VSDs may result in distortion of the tricuspid valve and resultant regurgitation. Aortic valve injury may occur as a result of inaccurate suturing, especially in perimembranous and outlet defects. Transient heart block may result from tissue swelling or injury from retraction, but permanent heart block occurs in less than 1% of cases. When heart block develops after surgery, patients are usually observed for a period of 7 to 10 days prior to permanent pacemaker implantation. A residual VSD is seen in about 5% of cases, and reoperation is indicated when significant shunting persists (Q_p/Q_s ratio >1.5).

Transcatheter devices have been developed to allow closure of some VSDs in the cardiac catheterization laboratory or by periventricular deployment without the use of cardiopulmonary bypass. Device closure is optimal for large muscular defects with sufficient rims for securing the device. These defects are often difficult to visualize and close surgically. Periventricular closure allows the use of VSD device closure in smaller infants with symptomatic muscular VSDs with excellent results without the challenges of transvenous access.[20] The use of devices for perimembranous VSDs remains limited by the risk of damage to the conduction system or impingement on the function of the tricuspid or aortic valves.[21,22]

ATRIOVENTRICULAR SEPTAL DEFECT

Embryology

Defects in the embryologic development of the endocardial cushions may result in a variety of morphologic abnormalities in the AV valves and the atrial and ventricular septa. These anomalies range from ostium primum ASD to complete AVSD with a spectrum of intermediate forms.

Anatomy and Pathophysiology

Atrioventricular septal defects (AVSDs) are relatively uncommon forms of congenital heart disease, occurring in 0.3 per 1,000 live births, and making up approximately 4% of all CHDs.[7 3] There is a strong association between AVSDs and Down syndrome (trisomy 21); approximately 50% of patients with an AVSD have Down syndrome. Complete AVSD is an anomaly characterized by a common AV orifice rather than separate mitral and tricuspid orifices. There is a deficiency of endocardial cushion tissue, which results in a primum ASD and an inlet type of VSD. Complete AVSDs were subclassified by Rastelli et al.[23] into three types according to the morphology of the anterior leaflet of the common AV valve. Incomplete AVSDs are variants in which there is partial fusion of the AV valves, resulting in separate right and left AV valve orifices. The ostium primum ASD is a type of incomplete AVSD in which the VSD component is absent.

When both left and right AV valves equally share the common AV valve orifice, the AVSD is termed *balanced.* Occasionally, the orifice may favor the right AV valve (right dominance) or the left AV valve (left dominance). In marked right dominance, the left AV valve and LV are hypoplastic, and frequently coexist with other left-sided abnormalities, including aortic stenosis (AS), hypoplasia of the aorta, and coarctation. Conversely, marked left dominance results in a deficient right AV valve with associated hypoplasia of the right ventricle, PS or atresia, and TOF. Patients with severe imbalance require staged, single-ventricle palliation.

The conduction tissue is displaced in an AVSD and is at risk during surgical repair. The AV node is located posteriorly and inferiorly of its normal position toward the coronary sinus in what has been termed the *nodal triangle.* This triangle is bounded by the coronary sinus, the posterior attachment of the inferior bridging leaflet, and the rim of the ASD. The

bundle of His courses anteriorly and superiorly to run along the leftward aspect of the crest of the VSD, giving off the left bundle branch and continuing as the right bundle branch.

A number of other cardiac anomalies are associated with AVSDs including a PDA (10%) and TOF (10%).[24] Important, albeit rare, abnormalities of the left AV valve include single papillary muscle (parachute mitral valve) (2% to 6%) and double orifice mitral valve (8% to 14%).[24] A persistent left superior vena cava with or without an unroofed coronary sinus is encountered in 3% of patients with an AVSD. Left ventricular outflow tract obstruction (LVOTO) from subaortic stenosis or redundant AV valve tissue occurs in 3%.[24]

The pathophysiology of an AVSD is dependent on the sub-type. Complete AVSDs have excessive PBF due to shunting at the atrial and ventricular septal defects. As described in the section on ASDs and VSDs: an ASD leads to left-to-right shunting during diastole and a VSD leads to left-to-right shunting during systole. When left-sided AV valve regurgitation is present (10%) there is even more left-to-right shunting at the atrial septum. This exacerbates excessive PBF and places an additional volume load on the right ventricle.

Infants with complete AVSDs will develop heart failure symptoms within the first 2 months of life. Excessive PBF leads to PVOD and resultant pulmonary hypertension; this process is accelerated in patients with trisomy 21 for unknown reasons.

Incomplete AVSDs, which are associated with a cleft mitral valve and no VSD component, generally present in a similar fashion as a patient with a large secundum ASD. While there is a left-to-right shunt at the atrial septum, causing a volume load on the right ventricle, the degree of excessive PBF is far lower than in a complete AVSD. When there is a cleft mitral valve and resultant mitral regurgitation, there is increased left-to-right shunting at the ASD. Nevertheless, patients with incomplete AVSDs do not develop typically heart failure in infancy.

Diagnostic Findings

In patients with complete AVSD, on physical examination, the precordium is hyperactive, often with a prominent thrill. Auscultatory findings include a

systolic murmur along the left sternal border (VSD), a high-pitched murmur at the apex (left AV valve regurgitation), and a mid-diastolic flow murmur across the common AV valve. In the presence of elevated PVR, there may be a split first heart sound. Significant cardiomegaly and pulmonary over-circulation are found on the chest radiograph. The ECG reveals biventricular hypertrophy, atrial enlargement, prolonged PR interval, leftward axis, and counterclockwise frontal plane loop. Transthoracic echocardiography is diagnostic, defining the atrial and ventricular level shunting, valvular anatomy, and any associated anomalies.

Cardiac catheterization should be performed for patients older than 1 year of age, for patients with signs or symptoms of increased PVR. If the PVR is high, it is important to determine pulmonary vascular reactivity on 100% oxygen, with and without nitric oxide. If the pulmonary resistance falls, it implies that much of the elevated resistance is dynamic and can be managed in the perioperative period by ventilatory manipulation, supplemental oxygen, and nitric oxide. Later, these children can be transitioned to Sildenafil.[25] Markedly elevated pulmonary resistance (>10 Wood units/m^2) that does not respond to oxygen administration is generally considered a contraindication to repair of a complete AVSD.

Indications for Intervention and Treatment Options

In patients with complete AVSD, operative treatment should be performed prior to 6 months of age to prevent progressive PVOD. The majority of infants with symptoms can be medically managed to allow for repair between 3 and 6 months of age. Rarely, in patients refractory to medical management—often due to associated significant left AV valve insufficiency—surgical repair is needed earlier. Pulmonary artery banding, as described in the section on VSDs, permits delayed repair. This strategy is reserved for select cases such as extremely low–birth-weight infants, complex valvular anatomy, and infants in otherwise poor clinical condition.

The operative steps for repair of complete AVSD are listed in Table 81.3. Correcting AVSDs requires patch closure of both septal defects, with any necessary valve reconstruction. Separate atrial and ventricular patches or a

single patch for both chambers can be used.[26] During closure of the ventricular defect, the surgeon must be careful to avoid injury to the conduction system, which passes along the posterior and inferior rim of the ventricular septum.

Operative mortality for AVSDs varies with the sub-type, associated cardiac anomalies, and left AV valve regurgitation. Hospital mortality for repair of complete AVSD is 3%; weight (<3.5 kg) and age (<2.5 months) are associated with higher mortality.[27] Long-term survival is good after complete AVSD repair, though late reoperation occurs in approximately 20% of patients. The majority of reoperations are due to left AV valve regurgitation or subaortic stenosis.[28]

OPERATIVE STEPS

Table 81.3 Complete AVSD via Sternotomy

CPB configuration	Bicaval cannulation, mild hypothermia, antegrade cardioplegic arrest
Exposure and intracardiac steps	Oblique right atriotomy, patch closure of VSD, attachment of inferior aspect of ASD patch to superior aspect of VSD to partition the common AV valve in to right and left side components, closure of left AV valve cleft, and completion of patch closure of ostium primum ASD
Completion	De-airing of left heart, removal of cross clamp, primary closure of right atriotomy
Final steps	Wean off bypass, place temporary pacing wires, TEE, standard closure

CPB, cardiopulmonary bypass; AV, atrioventricular; VSD, ventricular septal defect; ASD, atrial septal defect; TEE, transesophageal echocardiogram.

Hospital mortality for repair of incomplete AVSDs is approximately 1%.[29,30] Long-term survival is excellent. As with complete AVSDs,

reoperation for left AV valve regurgitation or subaortic stenosis is the most common reason for late reintervention.[30]

TETRALOGY OF FALLOT

Embryology

The conotruncus usually divides into two equal-sized great vessels (aorta and pulmonary artery) during the fifth week of gestation. During normal development, the infundibular septum separates the primitive outflow tracts and fuses with the ventricular septum. In TOF, there is unequal division of the conotruncus which leads to narrowing of the pulmonary artery and anterior deviation of the infundibular septum. This results in an anterior, malaligned VSD with an overriding aorta and resultant variable RVOTO.[31] Neural crest-derived tissue is thought to play a central role in the development of TOF.

Anatomy and Pathophysiology

4 TOF is the most common cyanotic congenital heart defect. It occurs in 0.4 per 1,000 live births and has a prevalence of 5% among all patients with congenital heart disease.[7] The pathologic anatomy is frequently described as having four components: anterior malaligned VSD, overriding aorta, pulmonary stenosis (PS), and right ventricular (RV) hypertrophy (Fig. 81.3).

Infundibular malalignment crowds the right ventricular outflow tract, causing PS. Prominent muscle bands also extend from the septal insertion of the infundibular septum to the right ventricular free wall and contribute to RVOTO. The pulmonary valve is usually stenotic and is bicuspid in approximately 60% of cases. Right ventricular hypertrophy is thought to be a down-stream sequela of PS and RVOTO.

There are many associated cardiac lesions with TOF.[32] Pulmonary atresia —no communication between the right ventricle and main PA—is an uncommon variant of TOF (7%). The branch pulmonary arteries in TOF may exhibit mild, diffuse hypoplasia or discrete stenosis (most frequently of the left PA at the site of ductal insertion). Coronary artery anomalies are frequently present. The origin of the left anterior descending from the right

coronary artery, which occurs in 10% of cases, is clinically important because the vessel crosses the right ventricular infundibulum and is vulnerable to injury at the time of surgery. A right aortic arch is present in 25% of patients with TOF. Additional associated defects include ASD, complete AVSD, PDA, or multiple VSDs.

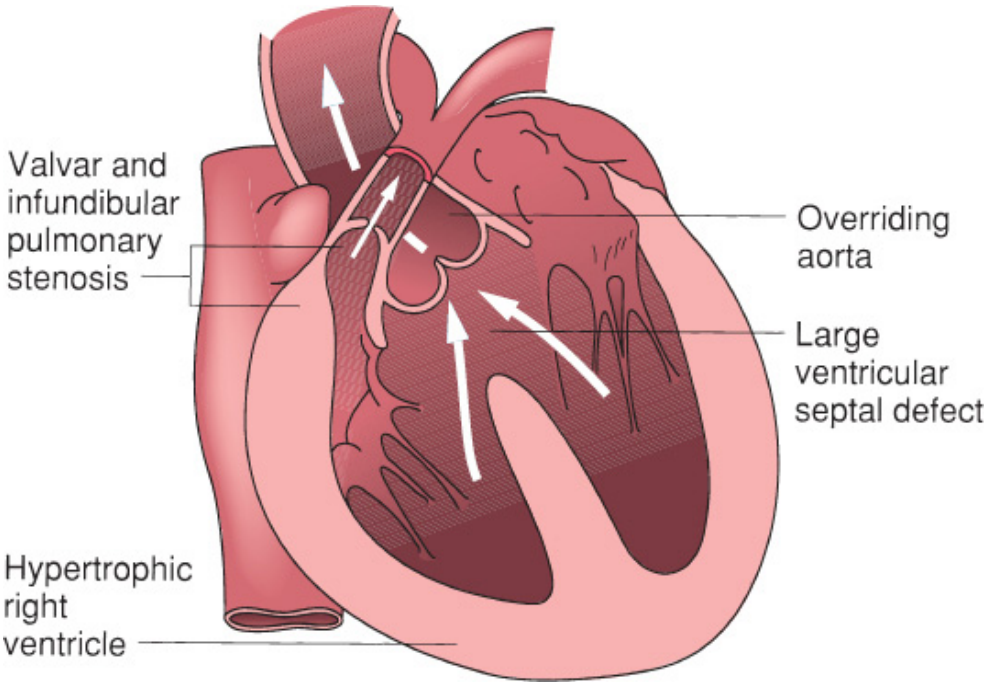

Figure 81.3 The four anatomic features of tetralogy of Fallot. The primary morphologic abnormality, anterior and superior displacement of the infundibular septum, results in a malalignment ventricular septal defect, overriding of the aortic valve, and obstruction of the right ventricular outflow. Right ventricular hypertrophy is a secondary occurrence.

Patients with TOF develop cyanosis due to *right-to-left* shunting across the VSD. The shunt is right to left because the effective PVR (obstructing muscle bundles, valvar PS, and hypoplastic MPA) is greater than the SVR. The degree of cyanosis depends on the severity of RVOTO. Neonates with severe infundibular obstruction or pulmonary atresia will require a prostaglandin infusion to maintain ductal patency to ensure adequate PBF and will ultimately require either a systemic to pulmonary artery shunt or ductal stent. In most infants though, there is adequate antegrade PBF in the neonatal period, and infants may be discharged with instructions of how parents may determine worrisome cyanosis. Of note, there are some patients with TOF

who have very mild RVOTO. In these patients, the predominant physiology is that of a large VSD with left-to-right shunting and CHF. These patients present similarly to patients with isolated VSDs (and are not cyanotic).

The occurrence of intermittent hypercyanotic spells is a well-known feature of TOF. The etiology of spelling is related to a transient imbalance between pulmonary and systemic blood flow. A spell may be triggered by hypovolemia or peripheral vasodilation (e.g., after a bath or vigorous physical exertion). Spells may occur in neonates but are most frequently reported in infants between the ages of 3 and 18 months. Most spells resolve spontaneously within a few minutes, but spells can be fatal. Older children have been observed to spontaneously squat to terminate spells. The squatting position increases SVR, which thereby favors PBF.

Diagnostic Findings

Cyanosis is the most frequent physical finding in TOF. Auscultation reveals a normal first heart sound and a single second heart sound. A systolic ejection murmur is present at the left upper sternal border. Older children may develop clubbing of the fingers and toes from long-standing cyanosis, but this is rare in the current era. Chest radiography typically demonstrates a boot-shaped heart due to elevation of the cardiac apex from right ventricular hypertrophy. Pulmonary vascular markings are usually reduced. A right aortic arch may be present. An ECG shows right ventricular hypertrophy. Echocardiography is definitive, and catheterization is not necessary in most cases.

Indications for Intervention and Treatment Options

While all patients with TOF should undergo surgical repair, most will not require palliation or complete repair at birth. Early repair is indicated for neonates with severe cyanosis and for infants who have had a documented spell or worsening cyanosis.

Medical management of TOF is directed toward the treatment and prevention of cyanotic spells. Transfusion is indicated for anemic infants.

Some centers have used beta-blockers as a form of long-term therapy to suppress the incidence of spells. In the appropriate setting, the immediate treatment of the spelling patient includes administration of oxygen, narcotics for sedation, and correction of acidosis. Alpha-agonists are useful for increasing systemic vascular resistance (which favors PBF) during a refractory spell.

In the current era, single-stage repair of TOF is preferred by most centers between 4 and 6 months of age. Initial palliation with a systemic to pulmonary artery shunt, usually modified Blalock–Taussig–Thompson, which is a polytetrafluoroethylene graft from the innominate artery to the ipsilateral PA, is still indicated for some patients who are at high risk for early complete repair. For example, patients with multiple congenital anomalies, severe concurrent illness, intracranial hemorrhage, an anomalous coronary artery crossing a hypoplastic infundibulum, or those presenting with prohibitive cyanosis as a newborn may benefit from shunt palliation prior to complete repair. In the absence of these risk factors, complete repair in the symptomatic neonate can be performed with lower mortality and reoperation rate compared to staged palliation.[33,34] Complete repair of TOF is described in Table 81.4.

When the pulmonary valve annulus or infundibulum is severely hypoplastic, a transannular outflow tract patch may be necessary to relieve the obstruction. In this setting, the pulmonary valve is typically excised. When an anomalous coronary artery crosses the infundibulum, a transannular incision may be contraindicated. In these cases, and in patients with pulmonary atresia, placement of a conduit (cryopreserved homograft, valved xenograft, or bioprosthetic heterograft) between the right ventricle (via a separate ventriculotomy) and main PA will be necessary.

OPERATIVE STEPS

Table 81.4 Complete Repair of TOF via Sternotomy

CPB configuration	Bicaval cannulation, mild hypothermia, antegrade cardioplegic arrest
Exposure and intracardiac steps	Oblique right atriotomy, retraction of septal and anterior leaflets of tricuspid valve, division of obstructing RV muscle bundles, patch closure of VSD, closure of ASD, pulmonary valvotomy or transannular patch placement as needed
Completion	De-airing of left heart, removal of cross clamp, primary closure of right atriotomy
Final steps	Wean off bypass, place temporary pacing wires, TEE, standard closure

CPB, cardiopulmonary bypass; RV, right ventricle; VSD, ventricular septal defect; ASD, atrial septal defect; TEE, transesophageal echocardiogram.

Patients who have a transannular patch develop pulmonary insufficiency as a consequence. This is well tolerated in most infants and children, as long as the tricuspid valve is competent. As these patients grow older, all will develop progressive dilation of their RV due to chronic pulmonary insufficiency, with the risk of progressing to ventricular failure over the long term. Pulmonary valve implantation is ultimately required to prevent this chronic volume overload, but this can usually be deferred until somatic growth is complete, often into the second or third decade of life.[35]

The early mortality following complete repair of TOF is approximately 1%.[36] Notable long-term complications include recurrent obstruction of the right ventricular outflow tract, development of right ventricular dysfunction due to chronic pulmonary insufficiency, aortic root dilation, and atrial arrhythmias. Actuarial survival at 20 years is 86% with excellent functional status.[37]

TRANSPOSITION OF THE GREAT ARTERIES

Embryology

There is not a unified theory defining the morphogenesis of transposition of the great arteries (TGA). In normal development, the subaortic conus is resorbed by the fifth week of gestation and allows for the usual mitral and aortic valve fibrous continuity. In dextro-TGA (d-TGA), Van Praagh postulates that the sub-pulmonary conus is resorbed, leading to fibrous continuity between the pulmonary and mitral valve.[38] As a result, the pulmonary valve (and PA) becomes continuous with the LV, and the aortic valve (and aorta) becomes continuous with the RV (ventriculoarterial discordance).

Looping refers to the right or left looping of the primitive heart tube during fetal development, which determines whether the atria and ventricles are concordant (right atrium attaches to RV and left atrium attaches to LV) or discordant. Levo-TGA (l-TGA) is associated with AV discordance (right atrium attaches to LV and left atrium attaches to right ventricle) along with ventriculoarterial discordance. This is also referred to as *congenitally corrected* TGA. Levo-TGA is a rare variant of TGA and is beyond the scope of this chapter, which will focus on d-TGA.

Anatomy and Pathophysiology

5 TGA is the most common form of congenital heart disease presenting as cyanosis in the first week of life. The malformation occurs in 0.3 of every 1,000 live births and accounts for approximately 4% of all CHDs.[7] TGA can be subdivided into d-TGA with intact ventricular septum (IVS) (55% to 60%) and d-TGA with VSD (40% to 45%), with one-third of the VSDs being hemodynamically insignificant. Pulmonary stenosis, causing significant LVOTO, occurs rarely with d-TGA/IVS and in approximately 10% of d-TGA/VSD.

The degree of cyanosis depends on the amount of mixing between the pulmonary and systemic circulations. 5 In d-TGA, oxygenated pulmonary venous blood is delivered to the lungs, while desaturated systemic blood is delivered to the body (Fig. 81.4). Because the two circulations exist in

parallel, some mixing between them must occur to allow oxygenated blood to reach the systemic circulation and the desaturated blood to reach the lungs. Mixing may occur at a number of levels, most commonly at the atrial level through an ASD or a PFO. Generally, two levels of mixing are necessary to maintain adequate systemic oxygen delivery, with a VSD or PDA serving as an additional site for cardiac mixing. Atrial level mixing is almost always required for adequate systemic oxygen delivery.

Clinical characteristics are dependent on the degree of mixing and the amount of PBF. These factors relate to the specific anatomic subtype of d-TGA. Neonates with d-TGA with IVS (or small VSD) have mixing limited to the atrial level and PDA. The ASD may be restrictive and the PDA generally will close over the first days to week of life (in the absence of PGE). As the degree of mixing decreases, the patient becomes increasingly cyanotic and will eventually suffer cardiovascular collapse within the first weeks of life. In d-TGA with a large VSD, there is additional opportunity for mixing and increased PBF. The neonate with d-TGA/VSD may only manifest mild cyanosis, which may be initially overlooked. Generally, within 2 to 6 weeks, tachypnea and tachycardia become prominent, whereas cyanosis may remain mild.

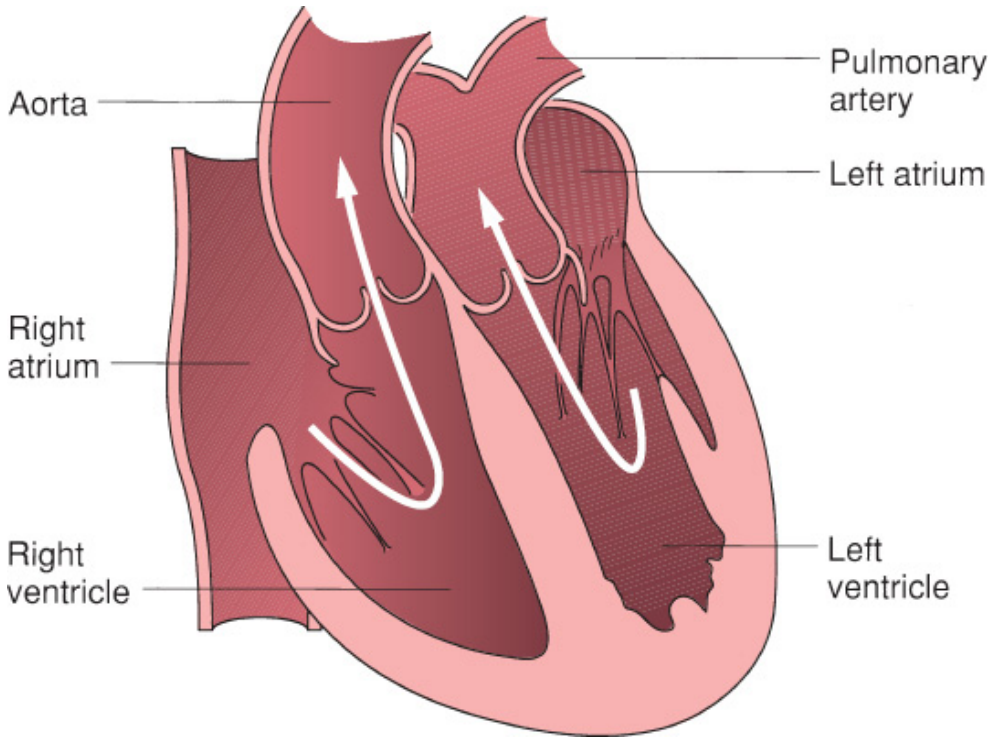

Figure 81.4 Anatomy of the most common type of transposition of the great arteries. The location of the ascending aorta is usually anterior and to the right of the pulmonary artery.

Auscultatory findings are consistent with CHF with increased PBF, including a pansystolic murmur, third heart sound, mid-diastolic rumble, gallop, and narrowly split second heart sound with increased pulmonary component. Neonates with d-TGA and significant PS present with severe cyanosis at birth. Lesser degrees of PS will result in varying levels of cyanosis. The ECG is normal at birth, demonstrating the typical pattern of right ventricular dominance. Although the classic chest radiographic appearance of an egg-shaped heart with a narrow superior mediastinum may be seen, this finding is often obscured by an enlarged thymic shadow. Echocardiography is diagnostic, demonstrating that the posterior great vessel arising from the LV is a PA that bifurcates soon after its origin. The anterior great vessel is the aorta and arises from the right ventricle. Associated lesions, including VSD, LVOTO, and coarctation, may also be diagnosed.

While diagnostic catheterization is not required, interventional catheterization to improve cardiac mixing by means of balloon atrial septostomy is frequently employed. The infant with d-TGA and severe cyanosis requires prompt diagnosis and treatment to improve mixing and

increase the arterial oxygen saturation. The first intervention to improve mixing in a cyanotic newborn suspected of having d-TGA is to ensure ductal patency by beginning an infusion of prostaglandin E_1 (PGE_1). In the presence of a restrictive ASD, a balloon atrial septostomy, a technique developed by William Rashkind in 1966, is performed. The procedure involves inserting a balloon-tipped catheter across the foramen ovale into the left atrium. Inflation and forcible withdrawal of the catheter tears the septum primum and enlarges the ASD. Mixing generally increases immediately, with a substantial improvement in arterial oxygen saturation.

Indications for Intervention and Treatment Options

Without intervention, d-TGA is universally fatal. Historically, definitive repair was achieved by redirecting venous inflow at the atrial level and allowing for persistent ventriculoarterial discordance thereby leaving the RV as the systemic ventricle. First successfully performed by Senning in 1959; the operation was further modified by Mustard in 1964. Although physiologic repair at the atrial level is associated with a low operative mortality rate (<5%), a number of late problems have occurred. The most serious long-term complication of repair by either the Senning or Mustard technique has been right ventricular dysfunction.[39] Right ventricular failure with an enlarged, poorly contractile chamber and secondary tricuspid regurgitation has been found in a significant number of these patients in long-term follow-up studies.[40]

OPERATIVE STEPS

Table 81.5 Arterial Switch Operation via Sternotomy

CPB configuration	Bicaval cannulation, mild hypothermia, antegrade cardioplegic arrest
Exposure and intracardiac steps	Division of aorta and PA, harvesting of coronary buttons, LeCompte maneuver, reconstruction of neo-aorta and positioning of coronary buttons, oblique right-atriotomy and patch closure of ASD
Completion	De-airing of left heart, removal of cross clamp, primary closure of right atriotomy, completion of neo-pulmonary root reconstruction and reanastomosis with branch PAs
Final steps	Wean off bypass, place temporary pacing wires, TEE, standard closure

CPB, cardiopulmonary bypass; PA, pulmonary artery; ASD, atrial septal defect; TEE, transesophageal echocardiogram.

The long-term complications of atrial repair prompted a reexamination of direct arterial repair for d-TGA. The "arterial switch" operation (ASO), first successfully performed by Jatene in 1975, has become the standard surgical procedure for neonates with this condition.[41] The operative technique is described in Table 81.5. Chiefly, the procedure reestablishes ventriculoarterial concordance (Fig. 81.5). The extensive experience gained with this procedure has confirmed that any variant of coronary artery anatomy can be successfully repaired. Certain coronary anatomy variants were previously felt to be associated with higher risk; however, this concern has been neutralized in recent series.[42,43]

Many patients with d-TGA have an IVS, and left ventricular pressure falls early in life as PVR decreases. In this situation, it is essential that the arterial

repair be performed within the first week of life, while the LV is still able to meet systemic workloads. In patients presenting later, the LV can be retrained with a preliminary PA band and a systemic-PA shunt, if necessary, followed by the definitive arterial repair. Patients with large VSDs do not require early repair because they maintain systemic left ventricular pressures. Nevertheless, experience has indicated that even in this subgroup, the operation is best performed within the first 1 to 2 weeks of life, before secondary complications such as pulmonary hypertension, CHF, or infection develop.

Patients with fixed LVOTO are not candidates for the arterial switch operation because correction would result in systemic ventricular outflow tract obstruction. Most of these patients also have large VSDs. Palliation early in life with systemic-to-PA shunting is an option, with definitive repair postponed until somatic growth results in cyanosis as the shunt is outgrown. At that time, the Rastelli procedure is performed, in which left ventricular blood is redirected through the VSD and to the anterior aorta by placement of an intraventricular patch along with the placement of a conduit between the RV and the PA (Fig. 81.6). An increasing number of experienced centers currently recommend early complete repair in the neonatal period using a Rastelli procedure. Early repair eliminates the interim morbidity and mortality associated with a systemic-to-PA shunt and chronic cyanosis however at the expense of usually a more complex neonatal postoperative course and the placement of a smaller initial conduit.

Current hospital mortality for the arterial switch operation is 2.2% (d-TGA/IVS) and 4.6% (d-TGA/VSD).[36] Prematurity, low birth weight, and complex d-TGA including d-TGA/VSD/PS and d-TGA/VSD with aortic arch hypoplasia are independent predictors of increased operative complexity and mortality.[42,44] Coronary artery anatomy does not affect mortality.[42] The most common cause for reintervention is supravalvar PS (15% to 20%).[45] Long-term survival among perioperative survivors is excellent (approximately 97% at 25 years).[46] Nevertheless, late follow-up of arterial switch operation patients has led to increased concern regarding late coronary artery patency and neoaortic root dilation with subsequent aortic insufficiency.[47]

TRUNCUS ARTERIOSUS

Embryology

In normal development, the conotruncal septum divides the truncal root into the main PA and aorta by the fifth week of gestation. Abnormal development of the conotruncal septum results in truncus arteriosus (TA). The lack of a division between the aorta and PA results in a single truncal valve. Normal septation leads to the development of both pulmonary and systemic outflow tracts, division of the semilunar valves, and formation of the aorta and pulmonary arteries. Failure of septation results in a VSD (absence of the infundibular septum), a single semilunar valve, and a single arterial trunk. Neural crest cell–derived tissue is thought to play a critical role in the development of this lesion.

Anatomy and Pathophysiology

Truncus arteriosus is a rare anomaly. The lesion accounts for 1% of cyanotic congenital heart disease.[7] Truncus arteriosus is defined by a single arterial vessel arising from the heart, overriding the ventricular septum and giving rise to the systemic, coronary, and pulmonary circulations. Two classification schemes have been proposed: one by Collett and Edwards[48] in 1949 and the other by Van Praagh and Van Praagh[49] in 1965 (Fig. 81.7). The Collett and Edwards classification, the most widely used, focuses on the origin of the pulmonary arteries from the common arterial trunk (Table 81.6).

The truncal valve leaflets are generally dysmorphic, and their motion may be restricted. Leaflet number is highly variable, with 70% tricuspid, 20% quadricuspid, 10% bicuspid, and rarely unicuspid or pentacuspid. As a result of these abnormally developed valve leaflets, a moderate or greater degree of truncal insufficiency is present in approximately 25% of patients. Mild stenosis is common; however, significant stenosis is rare. Significant obstruction is predicted by gradients of more than 30 mm Hg in the presence of a normal cardiac output following complete repair. The PAs are of normal size and most often arise from the left posterolateral aspect of the truncal artery, often in close proximity to the truncal valve and ostium of the left coronary artery.

Other cardiac anomalies are common in TA, with a PFO usually present. An interrupted aortic arch is associated with TA in approximately 10% to 20%.[50] The arch is rightward in 25% to 35%. Coronary ostial abnormalities are of particular surgical significance and occur in approximately 35% to 50% of cases. The left coronary artery is frequently noted to have a high origin, not uncommonly near the takeoff of the pulmonary arteries. Rarely, the left coronary can originate from the main pulmonary trunk or a branch PA.

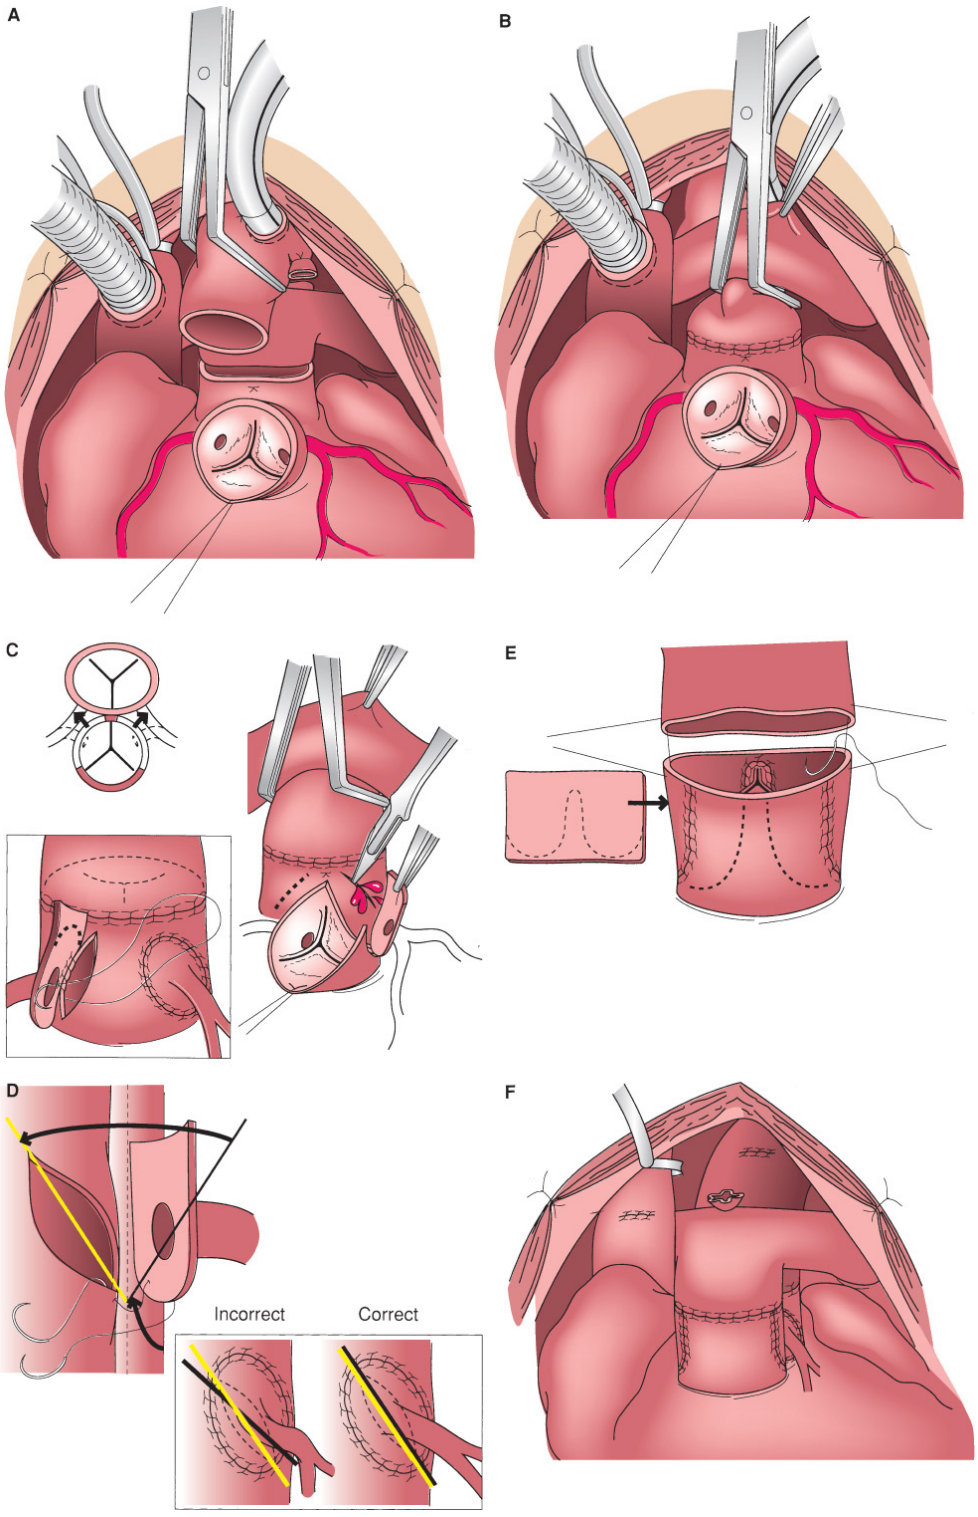

Figure 81.5 Arterial switch procedure for transposition of the great arteries. **A:** Division of aorta and pulmonary artery. **B:** LeCompte maneuver; anterior translocation of the pulmonary arteries. **C:** Mobilization of the coronary arteries. **D:** Correct orientation for coronary re-implantation. **E:** Placement of a pantaloon-

shaped pericardial patch to reconstruct the neo-pulmonary artery. **F:** Completed repair.

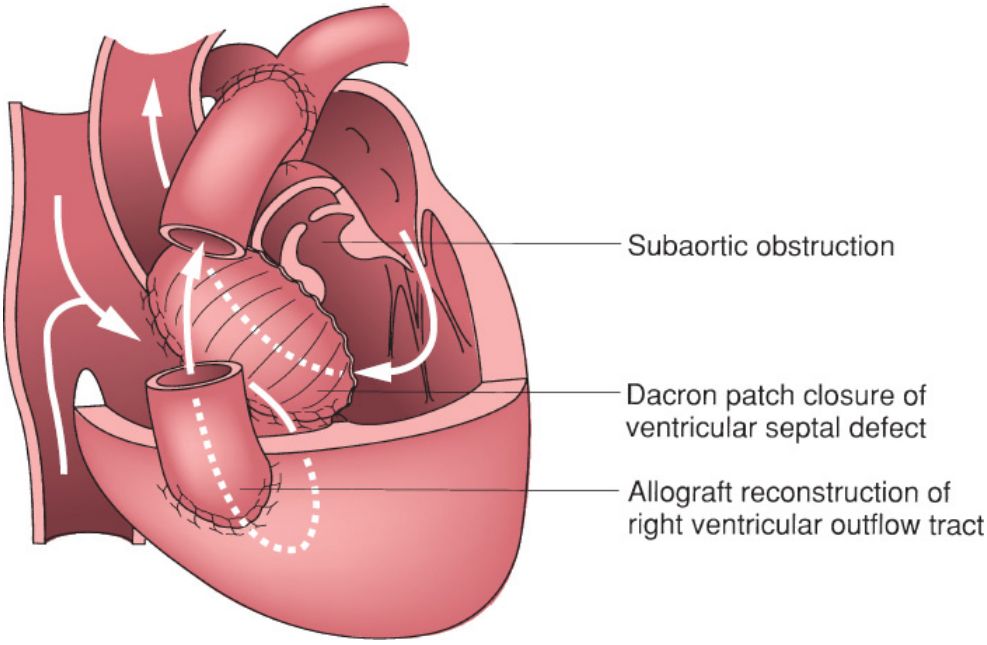

Figure 81.6 The Rastelli procedure for transposition of the great arteries with ventricular septal defect and pulmonary stenosis. A prosthetic patch placed within the right ventricle directs left ventricular blood through the defect to the aorta. The main pulmonary artery is ligated, and right ventricular blood then passes through a conduit to the distal pulmonary arteries.

Extracardiac anomalies are reported in approximately 40% of patients.[51] Described abnormalities include skeletal, genitourinary, and gastrointestinal deformities. Monoallelic microdeletion of chromosome 22q11 occurs in 40% of patients.[52]

The anatomy of TA results in the obligatory mixing of systemic and pulmonary venous blood at the level of the VSD and truncal valve, which produces arterial saturations of 85% to 90%. The systemic arterial saturation depends on the volume of PBF, which in turn is determined by the PVR. As the PVR begins to fall, excessive pulmonary circulation ensues and leads to pulmonary congestion and signs and symptoms of CHF. This nonrestrictive left-to-right shunt may cause early development of irreversible PVOD.

Truncal valve abnormalities add further hemodynamic burden. Truncal valve regurgitation leads to ventricular dilatation and low diastolic coronary perfusion pressures that can result in myocardial ischemia. Truncal valve

stenosis promotes ventricular hypertrophy, increases myocardial oxygen demand, and limits coronary and systemic perfusion.

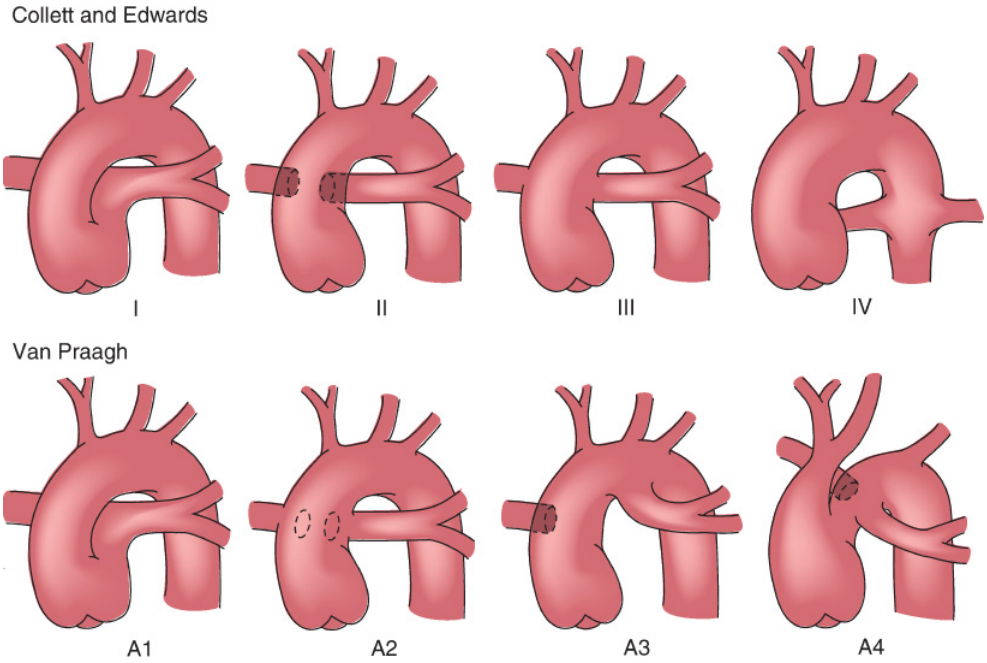

Figure 81.7 Truncus arteriosus: classification schemes as described by Collett and Edwards[48] and by Van Praagh and Van Praagh.[49] (Adapted from Hernanz-Schulman M, Fellows KE. Persistent truncus arteriosus: pathologic, diagnostic, and therapeutic considerations. *Semin Roentgenol* 1985;20:121.)

Table 81.6 Collett and Edwards Classification of Truncus Arteriosus

Type	Description
I	Common arterial trunk gives rise to a main pulmonary artery and the aorta.
II	Right and left pulmonary arteries arise directly and in close proximity from the posterior wall of the truncus.
III	Right and left pulmonary arteries arise from more widely separated orifices on the posterior truncal wall.
IV	Branch pulmonary arteries are absent. Pulmonary blood flow is derived from aorticopulmonary collaterals.

OPERATIVE STEPS

Table 81.7 Repair of Truncus Arteriosus via Sternotomy

CPB configuration	Bicaval cannulation, snare PAs immediately upon commencement of CPB, mild hypothermia, antegrade cardioplegic arrest
Exposure and intracardiac steps	Division of truncal vessel and removal of PAs, repair of defect within aorta, patch closure of VSD via ventriculotomy, oblique right atriotomy and closure of ASD, restoration of continuity between RV and branch PAs with extracardiac conduit
Completion	De-airing of left heart, removal of cross clamp, and primary closure of right atriotomy
Final steps	Wean off bypass, place temporary pacing wires, TEE, standard closure

CPB, cardiopulmonary bypass; PA, pulmonary artery; VSD, ventricular septal defect; ASD, atrial septal defect; RV, right ventricle; TEE, transesophageal echocardiogram.

Diagnostic Findings

Neonates with TA present with signs of CHF and diminished peripheral pulses. Chest radiography shows marked cardiomegaly; pulmonary plethora, often with minimal thymic shadow; and a right aortic arch (when present). The ECG most often depicts biventricular hypertrophy. Echocardiography is the diagnostic procedure of choice and can demonstrate the truncal vessel, the structure and function of the truncal valve, associated lesions such as interrupted aortic arch, and the PA anatomy. Cardiac catheterization is not performed unless the status of the pulmonary vasculature is unclear (i.e., infants older than 3 months at diagnosis).

Indications for Intervention and Treatment Options

The natural history of patients born with TA is early demise secondary to CHF. Survivors may do well for a period of time until the development of PVOD and Eisenmenger syndrome.

The standard treatment of TA is surgical correction in the neonatal period. Complete repair is detailed in Table 81.7. Severe truncal valve regurgitation requires truncal valve repair[53] or replacement, which is best done with a cryopreserved allograft. An associated interrupted aortic arch is repaired by constructing a primary end-to-end anastomosis with proximal augmentation if necessary.

The results of TA repair have improved greatly during the last two decades. Current hospital mortality for the neonatal repair of TA is 9.5%.[36] Severe truncal valve regurgitation increases the risk of perioperative mortality.[53] Risk factors for poor outcome identified in various studies include significant truncal regurgitation, need for truncal valve replacement, birth weight less than 2.5 kg, coronary artery anomalies, pulmonary reconstruction with a technique other than valved heterograft or allograft, and age older than 100 days.[53,54]

HYPOPLASTIC LEFT HEART SYNDROME

Embryology

Hypoplastic left heart syndrome (HLHS) refers to a constellation of congenital cardiac anomalies characterized by marked hypoplasia of left-sided heart structures. While there is growing evidence of genetics playing a role in the development of HLHS,[55] the most commonly cited theory centers upon altered blood flow through the left side of the heart in utero.[56] Advanced animal models have demonstrated the complex interaction between intracardiac hemodynamics and embryonic cardiogenesis.[57]

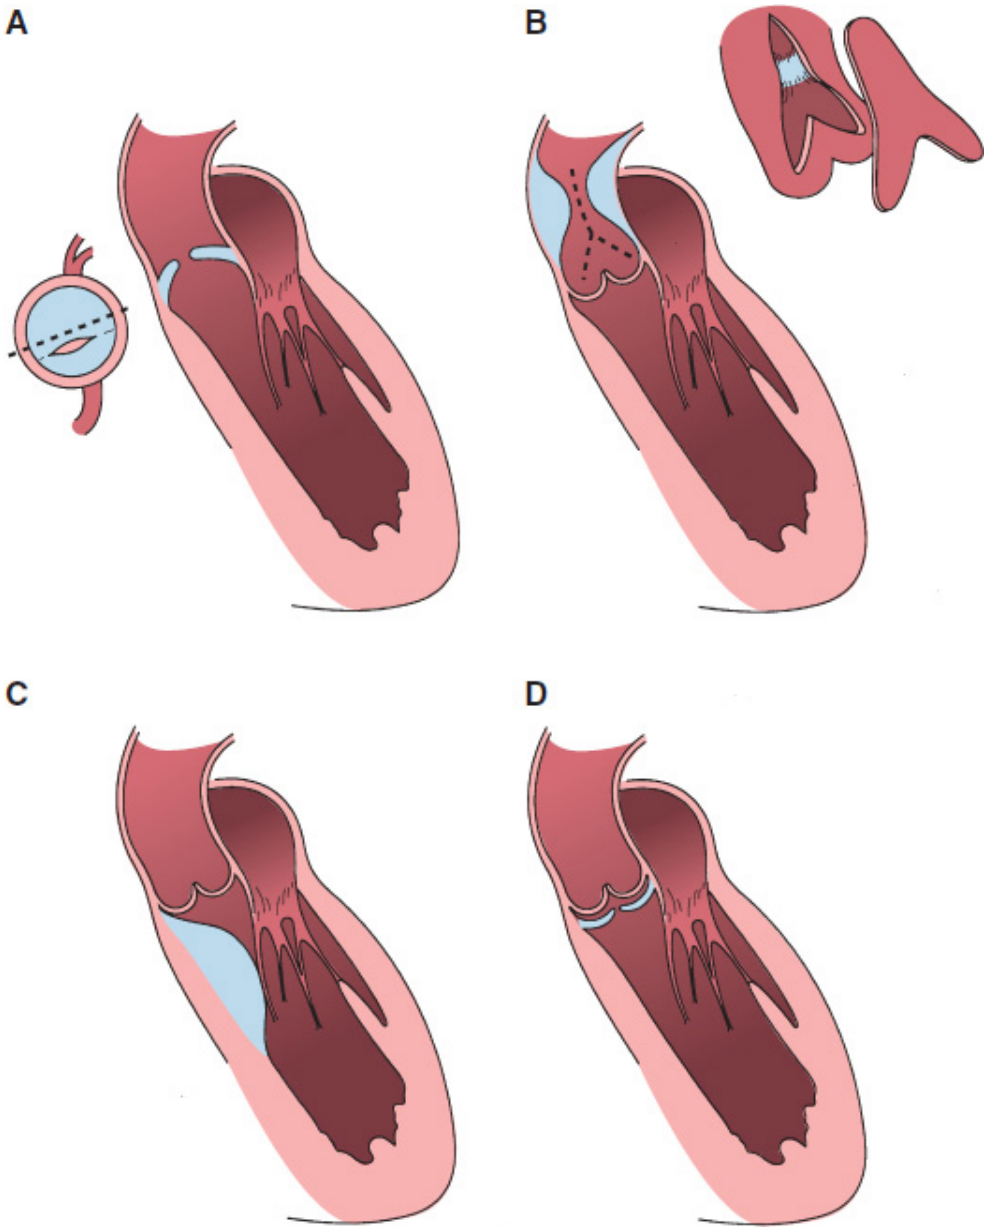

Figure 81.8 Anatomy of the types of congenital aortic stenosis. **A:** Valvar aortic stenosis. **B:** Supravalvar aortic stenosis and its repair (*inset*). **C:** Diffuse (tunnel) subvalvar aortic stenosis. **D:** Discrete subvalvar aortic stenosis.

Anatomy and Pathophysiology

HLHS accounts for 2% to 3% of CHD and is found in 0.2 per 1,000 live births.[7] While there is a spectrum of anatomic variants, HLHS is defined by underdevelopment of left-sided structures (mitral valve, aortic valve, left ventricle, ascending aorta, and aortic arch). Survival is dependent on a

nonrestrictive ASD with obligatory mixing of pulmonary and systemic venous blood in the right atrium and maintenance of ductal patency to maintain systemic output via the right ventricle.

Infants born with HLHS may initially have balanced circulation owing to relatively high PVR. However, in the absence of PGE to maintain ductal patency and with decreasing PVR, the infant will develop shock and intractable hemodynamic instability. If left untreated, HLHS is uniformly fatal within the first few days to weeks of life.

Diagnostic Findings

The diagnosis of HLHS is often made prenatally on ultrasound. In patients without a prenatal diagnosis, tachypnea and cyanosis with cardiovascular collapse within 24 to 48 hours of birth often lead to confirmatory studies. If the ductus is closing, diminished pulses within the lower extremities may be palpated. Auscultation will reveal a single second heart sound, and a nonspecific, soft, systolic murmur at the left sternal border. The ECG demonstrates right atrial enlargement and RV hypertrophy. Chest radiograph demonstrates cardiomegaly and increased pulmonary vascular markings. Transthoracic echocardiogram is diagnostic. Catheterization is rarely utilized for diagnostic benefit but may be employed to enlarge the ASD if it is restrictive.[58]

Indications for Intervention and Treatment Options

All patients with HLHS should be considered for staged palliation or evaluation for orthotopic heart transplant. In some variants of HLHS that portend a very poor prognosis, consultation with the family regarding palliative options is critically important. The initial management of HLHS includes a PGE_1 infusion to maintain ductal patency and correction of metabolic acidosis. The patient may require intubation and ventilator adjustment to reduce supplemental oxygen and maintain a partial pressure of carbon dioxide (PCO_2) of about 40 mm Hg to avoid excessive pulmonary flow.

Treatment options for this lesion include staged reconstructive surgery and cardiac transplantation. In the context of improving results for staged reconstruction, risks of immunosuppression, and limited donor availability, competing risk analysis favors staged repair, and most centers pursue this option as primary therapy for HLHS.[59,60] Transplantation is generally reserved for very high-risk patients, such as those with depressed right ventricular function or severe tricuspid regurgitation. Results of transplantation in neonates have been excellent in centers with extensive experience in this area, and a 2-year survival as high as 70% has been reported.[61]

The first successful palliation of HLHS was reported by Norwood et al. on a series of infants operated on between 1979 and 1981.[62] This procedure has been technically refined over the years, but three essential components remain: atrial septectomy, anastomosis of the proximal PA to the aorta with homograft augmentation of the aortic arch, and aortopulmonary shunt or RV–PA conduit. With the advance of transcatheter techniques, hybrid stage 1 palliation (HS1P) has developed into a viable and important technique. In the HS1P, bilateral pulmonary artery bands are placed to restrict pulmonary blood flow, and the ductus is stented to preserve unobstructed outflow to the systemic circulation. While HS1P has gained traction, it accounts for a minority of stage 1 palliation patients.[63]

At the second stage, a hemi-Fontan procedure or bidirectional Glenn anastomosis is performed. Stage 2 is usually performed at 4 to 6 months of age. The original shunt is removed, and superior vena cava blood flow is directed to the pulmonary artery. Principally, the hemi-Fontan and bidirectional Glenn procedures achieve the same goals, however there is evidence of improved fluid dynamics with the hemi-Fontan procedure.[64,65]

At the third stage, the Fontan procedure, is performed at about 18 to 24 months. The inferior vena caval flow is directed to the PA with an intra-atrial baffle (lateral tunnel technique, or an extracardiac conduit). All oxygenated pulmonary venous flow now empties into the ventricular chamber through the AV valves to be ejected to the systemic circulation, while superior and inferior vena caval blood flows passively to the lungs to acquire oxygen prior to returning to the heart. For the Fontan procedure to be performed with a low operative mortality and an acceptable functional result, certain criteria must be met. Normal PA pressure (<20 mm Hg) and PVR (<2 Wood units/m^2)

are the most important prerequisites. Additionally, it is essential that ventricular function and AV valve function be normal. Although the Fontan procedure cannot be considered a truly corrective operation, it offers benefits that cannot be equaled by any of the other palliative procedures. The major advantages include restoration of normal systemic oxygen saturation and reduction of ventricular volume overload.

Universally fatal only four decades ago, tremendous strides have been made in improving the outcomes for patients with HLHS. Of the three stages, the highest-risk stage of the repair remains the Norwood operation. Currently, select centers have reported hospital survivals of 90% or greater.[65,66] Reported survivals for the hemi-Fontan and Fontan procedures have also been excellent at 98% for both operations.[67–71]

While major advancements have been made in the outcomes of patients with HLHS, a vast spectrum of techniques and corresponding results exists. In 2005, a prospective, randomized clinical trial was initiated in order to determine the impact of shunt type at the Norwood procedure. This trial, termed the Single Ventricle Reconstruction trial, has had a significant impact on the treatment of HLHS. In addition to demonstrating early superiority of an RV to PA shunt, this study revealed sobering 1-year mortality of 30%.[72,73] The risk factors for mortality included low gestational age, weight <2.5 kg, and noncardiac abnormalities.[74,75]

AORTIC STENOSIS

Embryology

Left ventricular outflow tract development is related to appropriate development of the aorticopulmonary septum and conotruncal septum. The aortic valve leaflets develop as subendothelial swellings within the developing aorta. Inappropriate development of the aorticopulmonary septum, conotruncal septum, or of the endocardial cushions can be related to LVOTO.

AS broadly refers to a form of LVOTO that may occur at the valvar (71%), subvalvar (14%), or supravalvar (8%) level (Fig. 81.8). AS occurs in about 2.5% of patients with congenital heart disease.[7] BAV is the most common

congenital heart lesion—though many individuals with BAV without stenosis or insufficiency are never diagnosed and do not require any intervention.

Anatomy and Pathophysiology of Valvar Aortic Stenosis

Valvar AS occurs secondary to maldevelopment of the aortic valve. Most commonly, a bicuspid valve is present, although tricuspid and unicuspid valves may also produce AS. In valvar AS, the leaflets are thickened and frequently dysmorphic, and there is a variable degree of leaflet fusion along the commissures. The aortic annulus may be hypoplastic. In 20% of cases, valvar AS is associated with other cardiac defects, most commonly coarctation of the aorta, PDA, VSD, or mitral stenosis.

There is a wide spectrum of clinical presentation for valvar AS, but patients tend to present in one of two groups: younger patients (neonates and infants) with severe AS who develop symptoms of rapidly progressive CHF, whereas older patients, with less severe obstruction at birth, have a more indolent course. Older patients will be discussed later in this section.

Severe valvar AS is usually well tolerated during fetal development. While left ventricular output and antegrade flow across the aortic valve are decreased, the right ventricle compensates with increased output, and systemic perfusion is maintained by flow across the ductus. After birth, there is increased venous return to the left heart, and this exacerbates the pressure load created by the stenotic aortic valve, leading to left ventricular dysfunction. As the ductus closes during postnatal life, systemic malperfusion may develop with resulting hypotension, acidosis, and oliguria. Coronary perfusion is also impaired due to the combination of systemic hypotension and elevated left ventricular end-diastolic pressure.

Diagnostic Findings of Valvar AS in the Neonate or Infant

Infants with critical valvar AS typically exhibit severe left ventricular dysfunction. These patients show signs of distress soon after birth. On examination, there is impaired distal perfusion with poor capillary refill and

diminished pulses. A systolic ejection murmur may be absent if the cardiac output is severely diminished. Differential cyanosis may be observed due to perfusion of the lower body with desaturated blood shunting through the ductus. The ECG shows left ventricular hypertrophy, and the chest radiograph displays cardiomegaly and pulmonary congestion. Echocardiography establishes the diagnosis. The severity of valvar AS may be graded by echocardiography or catheterization. Classification by echocardiography peak instantaneous pressure gradient is mild (<40 mm Hg), moderate (40 to 70 mm Hg), and severe (>70 mm Hg). Classification by catheterization peak-to-peak pressure gradient is mild (<30 mm Hg), moderate (30 to 50 mm Hg), and severe (>50 mm Hg).

Fetal echocardiography has allowed for early diagnosis of critical valvar AS. For some, this may predict the progression to HLHS or irreversible left ventricular dysfunction.

Indications for Intervention and Treatment Options for Valvar AS in the Neonate or Infant

The neonate or infant with severe or critical valvar AS represents a true emergency. Endotracheal intubation and inotropic support are routine. Ductal patency is maintained with prostaglandins, and acidosis is corrected. All patients with critical valvar AS require some form of urgent intervention. The approach is determined by the valve morphology and by the presence of associated defects.

In its most extreme form, critical AS may be associated with underdeveloped left-sided cardiac chambers and therefore may represent a form of HLHS. In these cases, single-ventricle palliation must be undertaken.

For patients with adequate left-sided chambers, relief of valvar AS may be achieved by one of the following three approaches: percutaneous balloon valvuloplasty, surgical valvotomy, or aortic valve replacement. Balloon valvuloplasty is generally considered the procedure of choice when the aortic valve annulus is adequate and there are no associated cardiac defects. Alternatively, surgical valvotomy may be accomplished by closed or open techniques. The closed approach is performed using cardiopulmonary bypass, but without aortic cross-clamping. Dilators of increasing size are

passed through a ventriculotomy in the left ventricular apex and advanced across the aortic valve. Alternatively, some centers prefer open surgical valvotomy, which allows a precise valvotomy under direct vision. Surgical valvotomy has been demonstrated to have improved reduction in aortic valve gradient, less postprocedural aortic insufficiency, and excellent freedom from reintervention (72% at 10 years).[75] In all cases, the goal of therapy is to relieve stenosis without creating excessive aortic insufficiency. Dramatic clinical improvement is expected following balloon or surgical valvotomy, and early survivals of greater than 80% have been reported regardless of approach.[76] The incidence of aortic insufficiency is slightly higher following balloon valvotomy.[75,76] In most cases stenosis will recur and repeat valvotomy or aortic valve replacement will eventually be required.

Aortic valve replacement is problematic in the neonate due to small patient size. In these cases, many consider the best valve replacement to be a pulmonary autograft (Ross procedure)[77] with enlargement of the aortic annulus (Konno aortoventriculoplasty).[78] The Ross–Konno procedure has been used successfully for neonates with critical AS in whom the aortic annulus is hypoplastic and for selected patients in whom valvuloplasty was unsuccessful. Survival following the Ross–Konno procedure in infants has been shown to be excellent.[79] Growth of the pulmonary autograft has been documented, thereby making it an ideal valve replacement for children. Unfortunately, as part of the Ross procedure, the pulmonary valve must be replaced using a cryopreserved homograft that does not grow, and homograft replacement must be anticipated at intervals as the patient grows.

Notably, select centers have been able to successfully balloon dilate the aortic valve in utero to promote left ventricular growth and preserve function in select cases.[80–82] This therapy is more often utilized as a measure to prevent the development of HLHS rather than treatment of simple, valvar AS.

Diagnostic Findings of Valvar AS in the Older Child

In contrast to infants with critical AS, older children with valvar AS usually present with less severe stenosis (mild or moderate) and most are asymptomatic. Symptoms of angina, syncope, and CHF are not commonly

reported. Congenital valvar AS is a progressive lesion, however, and survival is dependent on the severity of stenosis and the rate of its progression. Sudden cardiac death is the most common cause of mortality. Endocarditis occurs in less than 1% of patients.

The diagnosis of valvar AS in older children is usually made on physical examination. There is a classic systolic crescendo–decrescendo murmur at the upper sternal border, which radiates to the neck. An ejection click is often present. A visible apical impulse is suggestive of significant left ventricular hypertrophy. In severe cases, the pulse may be weak and delayed (*pulsus tardus et parvus*). The ECG shows left ventricular hypertrophy. The chest radiograph is usually normal. Echocardiography accurately defines the level of stenosis and its severity. Using Doppler techniques, the pressure gradient across the stenotic valve may be estimated using a simplified form of Bernoulli's equation, $P = 4V^2$, where P is the pressure gradient and V is the peak flow velocity. Cardiac catheterization is generally reserved for therapeutic intervention.

Indications for Intervention and Treatment Options for Valvar AS in the Older Patient

All patients with severe valvar AS should undergo intervention, as should all symptomatic patients with moderate stenosis. Asymptomatic patients with mild or moderate stenosis are generally observed. As described previously for critical valvar AS in the neonate, the techniques used to relieve AS in older patients include percutaneous balloon valvuloplasty, surgical valvulotomy, and valve replacement. In older patients, balloon valvuloplasty is usually performed as the primary intervention, with comparable rates of efficacy, safety, and reintervention as surgical valvotomy.[83]

For valves that are severely dysplastic, develop restenosis after intervention, or become insufficient as a result of prior intervention, valve replacement may be necessary. For older children, there are more options for valve replacement. The choices include mechanical prostheses, bioprosthetic valves, cryopreserved human allografts, and pulmonary autografts (Ross procedure). Mechanical valves are the most durable but require chronic anticoagulation. Bioprosthetic valves do not require long-term

anticoagulation but tend to deteriorate over time (with the exception of the pulmonary autograft). The pulmonary autograft has the potential advantage of growth, but the homograft used to replace the pulmonary valve will require replacement. Selection of the appropriate replacement valve is a complex decision that requires input from all involved parties.

Anatomy and Pathophysiology of Subvalvar Aortic Stenosis

Subvalvar AS occurs below the level of the aortic valve and may be discrete (80%) or diffuse (20%). Discrete (or membranous) subaortic stenosis is rarely seen in infants and tends to progress over time. This lesion consists of a crescentic or circumferential fibrous or fibromuscular membrane that protrudes into the left ventricular outflow tract. The pathogenesis of discrete subaortic stenosis is unknown, but it is thought to be an acquired lesion that develops secondary to a congenital abnormality of the left ventricular outflow tract in which abnormal flow patterns lead to endocardial injury with resultant fibrosis. Although the aortic valve leaflets are usually normal in discrete subaortic stenosis, the turbulent flow created by the obstruction can cause leaflet thickening and progressive aortic insufficiency. Diffuse subaortic stenosis is a more severe form that creates a long, tunnel-like obstruction. Diffuse subaortic stenosis should be distinguished from hypertrophic cardiomyopathy. Both forms of subaortic stenosis (discrete and diffuse) are associated with a higher risk of endocarditis.

Diagnostic Findings of Subvalvar AS

The clinical findings in subvalvar AS are similar to those for valvar stenosis. With a Valsalva maneuver, the intensity of the systolic murmur typically decreases in subvalvar AS. Echocardiogram remains the gold standard for evaluating the LVOT and any associated lesions.

Indications for Intervention and Treatment Options for Subvalvar AS

Intervention for *discrete* subvalvar stenosis is usually undertaken when the gradient exceeds 30 to 50 mm Hg or when aortic insufficiency is present. In these patients, resection of the membrane is easily performed by a transaortic approach and is durable. To reduce the incidence of restenosis, we advocate concurrent performance of a septal myomectomy to alter the geometry of the left ventricular outflow tract. Operative mortality ranges from 0% to 3%.[84] The reoperation rate for discrete stenosis following membrane resection and myomectomy has been reported to be 2% per year.[84] Complications associated with membrane resection can include heart block, iatrogenic VSD, or damage to the aortic or mitral valve leaflets.

The indications for operative intervention in *diffuse* subaortic stenosis are similar to those for valvar stenosis. When diffuse subaortic stenosis is associated with hypoplasia of the aortic annulus, repair is best achieved with a Konno aortoventriculoplasty, whereby an incision is carried across the aortic annulus and subjacent ventricular septum, the opening patched, and an aortic valve implanted. Patients with an adequate aortic annulus may undergo a septoplasty (modified Konno),[85] in which the septal incision is confined to the immediate subvalvar area and a patch is used to widen the left ventricular outflow tract without replacing the aortic valve. Despite the technical complexity of repair for diffuse subaortic stenosis, excellent results have been reported with high survival and freedom from reoperation.[85]

Anatomy and Pathophysiology of Supravalvar Aortic Stenosis

Supravalvar AS is characterized by thickening of the wall of the ascending aorta. The lesion may be localized (80%) to the region of the sinotubular ridge (at the level of the valve commissures), creating an hourglass deformity, or it may be more diffuse (20%), extending into the aortic arch and its branches.[86] In both varieties, the aortic valve leaflets may be abnormal. The free edges of the aortic valve leaflets may adhere to the aortic wall in the region of intraluminal thickening, and this may lead to reduced coronary blood flow during diastole. Aortic wall thickening may also extend into the coronary ostia and further impair coronary blood flow.

Associated cardiac lesions are common, particularly branch PA stenoses. A genetic basis for supravalvar AS has been established. Supravalvar AS is associated with Williams syndrome, in which a partial deletion of chromosome 7 (including the elastin gene) leads to the triad of supravalvar stenosis, mental retardation, and characteristic "elfin" facies.[87] Isolated mutations in the elastin gene have also been shown to produce familial supravalvar AS with an autosomal dominant pattern of transmission. There is a significant incidence of endocarditis in patients with supravalvar AS. Sudden death is frequently reported and is probably related to coronary obstruction.

Diagnostic Findings of Supravalvar AS

The signs and symptoms of supravalvar AS are similar to those in other forms of LVOTO. The diagnosis is made by echocardiography. Cross-sectional imaging with MRI or computed tomography (CT) scan has become essential to define the aortic, coronary, and pulmonary arterial anatomy prior to surgical intervention.

Indications for Intervention and Treatment Options for Supravalvar AS

Operative intervention is indicated for patients with supravalvar AS in whom the gradient exceeds 50 mm Hg. A number of operations have been proposed for the treatment of localized supravalvar stenosis. The classic repair involves a longitudinal incision across the obstruction in the ascending aorta, which is extended into the noncoronary sinus. The thickened, hypertrophic ridge is resected by endarterectomy and the aortotomy is augmented with an elliptical patch. A variation of this repair involves creation of an inverted-Y aortotomy with one limb of the Y extended into the noncoronary sinus and the other into the right coronary sinus. A Y-shaped patch is then used to augment the aortotomy. Finally, the Brom repair is performed by transection of the ascending aorta beyond the supravalvar ridge. Separate incisions are then made through the supravalvar ridge into each sinus of Valsalva. Triangular patches are placed to augment each of

these incisions, thereby relieving the supravalvar obstruction. Reconnection of the aortic root to the ascending aorta completes the repair.

The repair of the diffuse type of supravalvar stenosis is performed under circulatory arrest with extensive patching of the ascending aorta, transverse arch, and involved arch arteries.

The results of surgery for localized supravalvar AS are generally good with low operative mortality and excellent long-term survival.[88–90] The diffuse form is more difficult to treat, and recurrence is more likely.[90]

COARCTATION OF THE AORTA

Embryology

Coarctation of the aorta is thought to occur as a result of ectopic tissue from the ductus arteriosus which migrates into the wall of the adjacent aorta. After birth, as the ductus closes, the ectopic tissue in the aorta also constricts. Frequently, a posterior shelf of tissue is present within the aorta at the point of most severe obstruction.

Anatomy and Pathophysiology

Coarctation of the aorta is a narrowing of the proximal descending thoracic aorta distal to the origin of the left subclavian artery, near the insertion of the ductus arteriosus (or ligamentum arteriosum). The severity of luminal narrowing and the length of the aorta affected are variable. The aortic obstruction caused by coarctation creates a pressure load on the LV.

The incidence of coarctation is about 0.3 per 1,000 live births, and it accounts for 3% to 4% of congenital heart defects.[7] Coarctation is commonly associated with other heart defects including BAV (in more than 50% of cases), PDA, and VSD. Other left-sided obstructive lesions may also be present, such as aortic arch hypoplasia, valvar AS, mitral stenosis, and left ventricular hypoplasia. Turner syndrome (XO) has been associated with a higher incidence of coarctation.[91]

Diagnostic Findings

6 Patients with severe coarctation present in the newborn period. Aortic obstruction is so significant that perfusion of the lower body is dependent on flow from the RV through the ductus arteriosus. Spontaneous ductal closure typically worsens the aortic obstruction and may lead to malperfusion distal to the coarctation. The pressure load on the LV may precipitate CHF. Infants may develop shock with severe acidosis, oliguria, and diminished distal pulses.

Unlike infants, older children with coarctation are usually asymptomatic. The diagnosis is commonly made on the basis of hypertension in the upper extremities with decreased pulses in the lower extremities. Noninvasive blood pressure measurements in all four extremities help to quantify the severity of aortic obstruction. Notably, older patients tend to develop extensive collateral arteries that bypass the obstruction.

The diagnosis of coarctation in the neonate can usually be made clinically. The infant with significant coarctation is frequently asymptomatic at birth. Following closure of the ductus, though, the infant will develop signs of heart failure, such as irritability, tachypnea, and poor feeding. Lower extremity pulses are absent, and upper extremity pulses may be weak. Chest radiography shows cardiomegaly and pulmonary venous congestion. There is a left ventricular strain pattern on the ECG. Echocardiography is usually diagnostic, demonstrating narrowing of the aorta at the coarctation site with loss of pulsatile blood flow in the descending aorta.

In older children and adults with coarctation, the diagnosis is usually made after workup of a pressure gradient between the arms and legs. On chest radiography, rib notching may be evident, secondary to erosion of the inferior rib borders from the development of large intercostal collateral vessels. Echocardiography usually confirms the diagnosis. Anatomic details may also be clarified with CT and MRI. Cardiac catheterization is usually not necessary unless balloon angioplasty or aortic stent placement is being considered.

Indications for Intervention and Treatment Options

Generally, all patients with a coarctation gradient >20 mm Hg should undergo surgical repair. For neonates, the acute medical management includes initiation of PGE_1 for the purpose of reopening the ductus; this maneuver partially relieves the aortic obstruction and augments perfusion of the lower body due to improved antegrade flow across the arch, as well as right-to-left flow across the ductus. Prostaglandins are usually effective for reopening the ductus when initiated within 7 to 10 days of life but are less successful thereafter. There is no role for PGE_1 in the older patient.

Surgical repair of coarctation is described in Table 81.8. Neonates with an associated hypoplastic aortic arch may require sternotomy for extended arch augmentation with either primary extended end-to-end repair or patch augmentation. The preferred surgical approach to isolated coarctation in infants and children is a resection with end-to-end anastomosis or extended end-to-end repair if there is associated mild distal arch hypoplasia.[92]

In older children and adults, it may not be possible to perform a resection with primary repair without creating excessive tension on the anastomosis, which may lead to hemorrhage or scarring with recurrent coarctation. An alternative strategy is necessary in these cases. Patch aortoplasty may be performed in children in whom further growth is anticipated. The subclavian flap repair augments the narrowed aorta using native arterial tissue. Blood flow to the left arm is maintained by collateral vessels, although long-term studies have demonstrated a slight discrepancy in limb length in some patients. Prosthetic patch material may also be used.

OPERATIVE STEPS

Table 81.8 Repair of Coarctation of the Aorta in the Infant

Incision and exposure	Right lateral decubitus position, left third intercostal space posterolateral thoracotomy, retraction of lung anteriorly, and opening of posterior pleura
Critical steps	Exposure of left subclavian artery, aortic arch, descending thoracic aorta, and ductus; division of ductus; placement of proximal and distal clamps, excision of coarctation segment, extended end-to-end anastomosis
Completion	De-airing of anastomosis, removal of vascular clamps, assessment of pressure gradient
Final steps	Intercostal nerve block, closure of overlying pleura, and standard closure

By avoiding circumferential prosthetic material, growth potential of the native aorta is preserved. The disadvantage of patch repair is a high risk of aneurysm formation. In adults in whom growth is no longer a concern, resection of the coarctation may be performed with subsequent placement of a prosthetic interposition graft (either Dacron or polytetrafluoroethylene).

One of the principal concerns during coarctation repair is interruption of distal aortic blood flow, especially to the spinal cord. The anterior spinal artery is fed by major radicular branches from intercostal arteries. In patients without well-formed collaterals, ischemia of the spinal cord may be precipitated by aortic cross-clamping, and paraplegia may result. Protective measures include induction of mild hypothermia, maintenance of a high proximal aortic pressure, and minimization of cross-clamp time. In older patients, distal aortic perfusion may be maintained by the technique of left heart bypass, in which oxygenated blood is taken from the left atrium and delivered to the femoral artery or distal aorta using a centrifugal pump.[93]

This is usually not necessary due to the presence of significant collaterals in older children. Overall, the incidence of paraplegia following coarctation repair is less than 1%.

Following repair, patients may develop severe hypertension. This can be managed using intravenous beta blockers (e.g., esmolol). Uncontrolled hypertension can lead to of mesenteric arteritis with resultant gut ischemia. Hypertension usually resolves within days to weeks after repair, although older children and adults may require lifelong antihypertensive therapy. Repair of coarctation during infancy is thought to minimize the risk of late hypertension.

Transcatheter interventions (balloon angioplasty [BA] or stenting) are not recommended for infants due to poor rates of success. Transcatheter intervention for primary therapy of discrete coarctation in young children and adolescents remains controversial. In older patients, BA is effective and safe, with similar short-term results to surgery.[94] Nevertheless, long-term follow-up after BA reveals increased incidence of short-term recoarctation[94] and higher incidence of aneurysm formation and iliofemoral artery injury.[95] Stent placement in older children and adolescents was studied by the Multicenter Coarctation of the Aorta Stent Trial (COAST). The COAST trial demonstrated excellent safety (no procedural deaths) and immediate and sustained reduction in pressure gradient.[96] Nevertheless, reintervention to re-expand the stent or to treat aortic wall injury was common.[96] Notably, balloon angioplasty is widely accepted for the treatment of recurrent coarctation following surgery, in which the success rate is on the order of 90% with low recurrence rates.[97–99]

Early mortality following surgical repair of coarctation in neonates and children approaches 0%.[92,100] The incidence of recurrent coarctation following resection and end-to-end repair is 2% to 5%.[92,100] Importantly, while long-term survival following repair of coarctation is excellent, many patients will require reintervention and survival is reduced compared to age- and sex-matched population which may be related to persistent hypertension.[101]

PATENT DUCTUS ARTERIOSUS

Embryology

The ductus arteriosus is a normal fetal vascular structure that allows blood from the right ventricle to bypass the high-resistance pulmonary vascular bed and pass directly to the systemic circulation. The ductus communicates between the main PA (or proximal left PA) and the proximal descending thoracic aorta. During fetal development, low oxygen tension and high levels of circulating prostaglandin maintain ductal patency. During the final trimester, the ductus becomes less sensitive to prostaglandins and more sensitive to the effects of oxygen tension. Following birth, the rise in oxygen tension and a fall in prostaglandins (which were previously supplied principally by the placenta) lead to ductal closure, which is usually complete by 12 to 24 hours. After closure, the ductus becomes a fibrous cord known as the ligamentum arteriosum. Failure of closure of the ductus leads to the condition called PDA.

Anatomy and Pathophysiology

Patent ductus arteriosus occurs in about 1 out of 10,000 live births and accounts for 10% of congenital heart defects.[7] The incidence is much higher in premature infants (>20%).[102] This elevated incidence is thought to be related to immaturity of the ductal wall, resulting in impaired sensitivity to oxygen tension.

Patent ductus arteriosus may occur as an isolated defect or in association with a number of other anomalies. Patency of the ductus arteriosus is desirable in a number of defects in which there is either inadequate PBF (such as pulmonary atresia) or inadequate systemic blood flow (as in severe coarctation of the aorta). The discovery that extrinsic delivery of prostaglandins can maintain ductal patency has played a critical role in improving the survival of these patients.[103]

The physiologic manifestation of PDA is shunting of blood across the ductus. The shunt volume is determined by the size of the ductus and by the ratio of pulmonary to systemic vascular resistance. At birth, the PVR drops dramatically and continues to decline over the first several weeks of life. As a result, shunting across a PDA is from left to right. Excessive PBF can lead to CHF. In extreme cases, hypotension and systemic malperfusion may result.

Patients with a large PDA who survive infancy tend to develop PVOD. Eisenmenger physiology results when the PVR exceeds the systemic vascular resistance, producing a reversal of shunting across the ductus to right to left. This leads to cyanosis and, eventually, right ventricular failure. Small PDAs may persist to adulthood without producing any symptoms or physiologic derangement. Endocarditis and endarteritis have been reported as long-term (but quite rare) complications of PDA.[104,105]

Diagnostic Findings

In patients with PDA, symptoms are proportional to the shunt volume and the presence of associated defects. Left-to-right shunting across the PDA produces volume overload of the left heart. Infants with CHF demonstrate symptoms of tachypnea, tachycardia, and poor feeding. Older children may present with recurrent respiratory infections, fatigue, and failure to thrive. Physical examination findings include a widened pulse pressure and a continuous "machinery" murmur heard best along the left upper sternal border. Chest radiography shows increased pulmonary vascular markings and left heart enlargement. Left ventricular hypertrophy and left atrial enlargement may be evident on the ECG. Echocardiography is the diagnostic method of choice. Cardiac catheterization is performed in older patients with suspected pulmonary hypertension to evaluate for PVOD or for transcatheter occlusion of the ductus.

Indications for Intervention and Treatment Options

Closure of PDA is performed for all symptomatic patients. Closure is also recommended for asymptomatic patients due to the risk of heart failure, pulmonary hypertension, and endocarditis. Closure of the ductus may be accomplished by one of three approaches: pharmacologic, surgical, and endovascular.

Pharmacologic closure of PDA in premature infants is accomplished by indomethacin and ibuprofen, which are cyclooxygenase inhibitors.[106,107] Due to improved side-effect profile of gastrointestinal bleeding and renal

dysfunction, ibuprofen is the current drug of choice.[108] 7 Pharmacologic closure is effective in about 65% of premature infants.[109] Due to their side effects, indomethacin and ibuprofen are contraindicated in patients with sepsis, renal insufficiency, intracranial hemorrhage, or bleeding disorders. Failure of ibuprofen after three complete courses results in referral for endovascular or surgical closure.

The surgical approach to PDA is accomplished via a left, third intercostal space, posterolateral thoracotomy, with exposure of the transverse aortic arch and descending thoracic aorta, along with circumferential control of the PDA. In many cases, the ductus is the largest vascular structure present, and it must not be confused with the aorta. Ductal tissue is extremely friable, so direct manipulation is minimized. In premature infants, the ductus is controlled with a single surgical clip; this procedure is commonly performed in the neonatal intensive care unit, thereby avoiding problems associated with patient transfer.[110,111] In older patients, occlusion of the ductus is achieved with simple silk ligature, or, preferably, by division between ligatures to minimize recurrence.

Thoracoscopic techniques can be employed to perform PDA ligation.[112,113] This approach has the potential benefits of decreased pain and quicker recovery. Disadvantages include a substantial learning curve and increased operating time.

A number of endovascular devices have been developed for the purpose of transcatheter occlusion of the PDA.[114] This approach is very successful in older infants, children, and adults with small and moderate-sized PDAs and has become the treatment of choice.[115,116] A new device, the Amplatzer Piccolo Occluder (Abbott Laboratories, Abbott Park, IL), was recently granted FDA approval for endovascular PDA occlusion in infants less than 2 kg. The device has demonstrated excellent safety (3% procedural mortality) and efficacy (>90% with complete ductal closure).[117] As a result of the major advancements in device technology, surgical closure is rarely needed and is reserved for PDAs having a large diameter or very short length.

Rarely, an adult will present with a significant PDA. These patients must be carefully evaluated for the presence of PVOD prior to ductal closure. If the patient is not a candidate for device closure, surgical closure can be problematic. Calcification of the ductal wall is common in adults, making

ligation hazardous. In some cases, cardiopulmonary bypass may be required with closure of the ductus from within the PA.[118,119]

Closure of the ductus by surgical or transcatheter techniques is achieved with a periprocedural mortality that approaches zero.[120] Potential complications of surgery include pneumothorax, recurrent laryngeal nerve injury, phrenic nerve injury, and chylothorax (from injury to the thoracic duct). Long-term survival should be normal following PDA ligation in most patients. Survival in premature infants depends primarily on the extent of prematurity with its attendant complications.

VASCULAR RINGS

Embryology

By the end of the fourth week of embryonic development, the six aortic or branchial arches have formed between the dorsal aortae and ventral roots. Subsequent involution and migration of the arches result in the anatomically normal or abnormal development of the aorta and its branches. The majority of the first, second, and fifth arches regress. The third arch forms the common carotid artery and proximal internal carotid artery. The right fourth arch forms the proximal right subclavian artery. The left fourth arch contributes to the portion of the aortic arch from the left carotid to left subclavian arteries. The proximal portion of the right sixth arch becomes the proximal portion of the right pulmonary artery, while the distal segment involutes. Similarly, the proximal left sixth arch contributes to the proximal left pulmonary artery (LPA), and the distal sixth arch becomes the ductus arteriosus.

Anatomy and Pathophysiology

Vascular rings comprise a spectrum of vascular anomalies of the aortic arch, pulmonary artery, and brachiocephalic vessels. The clinically significant manifestation of these lesions is a varying degree of tracheoesophageal compression. These vascular anomalies can be divided into *complete* vascular rings and *partial* vascular rings. Partial vascular rings include aberrant right subclavian artery, innominate artery compression, and

pulmonary artery sling. Complete rings include double aortic arch and right aortic arch with mirror image branching or retroesophageal left subclavian artery (and leftward ligamentum). The incidence of clinically significant vascular rings is 1% to 2% of all congenital heart defects.[121]

Vascular rings and pulmonary slings have been described in conjunction with other cardiac defects, including TOF, ASD, branch pulmonary artery stenosis, coarctation, AVSD, VSD, interrupted aortic arch, and aortopulmonary window. Significant associated cardiac anomalies occur in 12% to 30% of patients with a vascular ring.[122,23] A right aortic arch is generally associated with a greater incidence of coexisting anomalies.

Complete Rings

A double aortic arch occurs when the distal portion of the right dorsal aorta fails to regress. The two arches form a complete ring, encircling the trachea and esophagus. The right arch is dominant in the majority of the cases, followed by left dominance, with codominant arches being the least common. The left and right carotid and subclavian arteries generally arise from their respective arches. The ligamentum arteriosum and descending aorta usually remain on the left.

A right aortic arch occurs if the left fourth arch involutes; the apex of the arch is to the right of the trachea. The two most common variants of a right arch are: mirror image arch branching, and an aberrant, retroesophageal left subclavian artery.[121] When the ligamentum arises from the descending thoracic aorta, a complete ring is formed.

Partial Rings

In innominate artery compression syndrome, the aortic arch and ligamentum are in their normal, leftward position. However, the innominate artery arises partially or totally to the left of midline. As the artery courses from left to right, anterior to the trachea, it causes tracheal compression.

An aberrant right subclavian artery, arising from the descending thoracic aorta and coursing posteriorly across the mediastinum can compress the esophagus posteriorly. An indentation can be seen on the esophagus, though this is not a complete ring. Aberrant right subclavian artery is the most common arch anomaly, occurring in approximately 0.5% to 1% of the population.

Pulmonary artery sling is thought to develop when the left lung inappropriately captures its arterial supply from the right sixth arch *below* the tracheobronchial tree. The LPA branches from the RPA rather than the main PA, passes behind the right main bronchus, and travels between the trachea and esophagus (causing compression to the tracheobronchial tree).[121]

Diagnostic Findings

Children with a *complete* vascular ring generally present within the first weeks to months of life. Typically, children with a double aortic arch present earlier in life than those with a right arch and retroesophageal left ligamentum. In the younger age group, respiratory symptoms predominate, as liquids are generally well tolerated. Respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections. The cough is classically described as a "seal bark" or "brassy." These symptoms may mimic asthma, respiratory infection, or reflux, and children with vascular rings are often initially misdiagnosed. With the transition to solid food, dysphagia becomes more apparent.

The presentation of a patient with a *partial* vascular ring is variable. Children with innominate artery compression usually present within the first 1 to 2 years of life with respiratory symptoms. Aberrant right subclavian artery does not cause significant tracheoesophageal compression and is therefore usually asymptomatic. Classically, when symptoms do occur, they present in the seventh and eighth decades, as the aberrant vessel becomes ectatic and calcified, causing *dysphagia lusoria* due to impingement of the artery on the posterior esophagus.

Children with pulmonary artery slings generally present with respiratory symptoms within the first few weeks to months of life. As with complete vascular rings, respiratory symptoms may include stridor, nonproductive cough, apnea, or frequent respiratory infections and may mimic other conditions, leading to misdiagnosis. Pulmonary artery slings are associated with complete tracheal rings in 30% to 40% of patients, leading to focal or diffuse tracheal stenosis which is the primary cause of the respiratory symptoms.

The methods for diagnosing a vascular ring are nonuniform due to the variability in presentation and the spectrum of diagnostic tests available. A

child with a presumptive diagnosis of asthma or tracheomalacia may be referred to a pulmonologist and a diagnosis of vascular ring made or suspected initially by chest radiograph and bronchoscopy. In some situations, the diagnosis is made by echocardiography during evaluation for concurrent cardiac defects. Regardless, the diagnosis generally begins with a chest radiograph. Complementary studies may include barium esophagogram, CT, MRI, and bronchoscopy. CT, MRI, and bronchoscopy are important modalities to define the tracheal anatomy in a patient with a pulmonary artery sling. Echocardiography may be diagnostic and may be used to rule out other cardiac anomalies.

Indications for Intervention and Treatment Options

Complete Rings

Patients with symptoms secondary to complete vascular rings should undergo surgical correction. Repair of a double aortic arch is accomplished via a left, third intercostal space posterolateral thoracotomy; exposure of the left subclavian artery, left and right aortic arches, descending thoracic aorta; ligation and division of the ductus; and ligation and division of the atretic segment of the nondominant arch. If there is concern regarding the location for division, the arches can be temporarily occluded at various points while monitoring pulse and blood pressure in each limb. Dissection around the esophagus and trachea in the regions of the ligamentum/ductus and nondominant arch allows for retraction of the vascular structures and lysis of any residual obstructing adhesions.

The surgical approach for a right aortic arch with retroesophageal left ligamentum arteriosum is the same as for a double arch. The ligamentum is divided and any adhesions around the esophagus and trachea are lysed. Rarely, the Kommerell diverticulum has been reported to cause compression even after division of the ligamentum. As such, it may be prudent to resect or suspend the diverticulum posteriorly.

Partial Rings

Similar to patients with complete rings, individuals with partial rings and symptoms should undergo surgical correction. The symptoms of innominate artery compression may be mild to severe. With mild symptoms and minimal tracheal compression on bronchoscopy, children can be observed expectantly as the symptoms may resolve with growth. Indications for surgery include apnea, severe respiratory distress, significant stridor, and recurrent respiratory tract infection. Several approaches for the correction of innominate artery compression syndrome have been described. These include simple division, division with reimplantation into the right side of the ascending aorta, and suspension to the overlying sternum.

An aberrant right subclavian artery can compress the esophagus posteriorly, though it is rarely the cause of symptoms in children. Surgical treatment involves simple division via a left posterolateral thoracotomy. Rarely, reimplantation or grafting from the right carotid or aortic arch may be necessary.

Patients with PA sling, compression of the tracheobronchial tree, and associated respiratory symptoms should undergo surgical correction. Evaluation of the trachea must be undertaken in order to determine if complete tracheal rings are present (absence of the membranous portion of the trachea).

Initial attempts at the repair of a pulmonary artery sling involved reimplantation after division of the LPA and translocation of the trachea without cardiopulmonary bypass. These early reports had a high incidence of LPA thrombosis. This has led some authors to advocate for division of the trachea and translocation of the LPA. This approach would seem sensible if the trachea were being divided in the course of tracheal reconstruction. However, currently, most authors advocate the reimplantation of the LPA, which has resulted in excellent results. The procedure is done via a median sternotomy on cardiopulmonary bypass to ensure optimal visualization of the repair. Aortic cross-clamping is not necessary. The LPA is divided off of the right pulmonary artery, translocated anterior to the trachea, and reimplanted into the main pulmonary artery. Any necessary reconstruction of the trachea is done concurrently with bronchoscopic assistance if complete tracheal rings are present. Many techniques for tracheal reconstruction have been described, the most common of which are resection with primary reanastomosis and sliding tracheoplasty for long-segment stenosis.[124]

Outcomes

Over 95% of vascular rings without concurrent cardiac defects can be performed through a left thoracotomy. A right thoracotomy is indicated for the rare cases where there is a right ligamentum arteriosum. In addition, a double aortic arch with an atretic segment proximal to the right carotid artery is more easily divided through a right thoracotomy. The approach to these anomalies is the same as for a left-sided ring division, with the caveat that the right recurrent laryngeal nerve will loop around the right ligamentum.

Repair of vascular rings has been described using video-assisted thoracoscopic surgery (VATS) both with and without robotic assistance. Candidates for thoracoscopic division are limited to those patients requiring only the division of nonpatent vascular structures. In general, VATS is used for patients greater than 15 kg due to current size limitations of the instruments.[125]

Mortality for the repair of a vascular ring is 0% to 4%, with improved survival occurring in more recent series.[123,126,127] The majority of deaths are related to other cardiac defects or respiratory infection and failure. Backer et al. reported a series of 34 patients repaired utilizing LPA division and reimplantation for pulmonary artery sling, many whom also required tracheal reconstruction. There were no operative mortalities and four late deaths.[124] The major source of morbidity, as well as mortality, in this and other series is related to the tracheal reconstruction.

CORONARY ARTERY ANOMALIES

Embryology

The embryology of congenital coronary artery anomalies is not fully understood. Complex theories have been postulated that suggest the importance of in utero wall tension within the right and left coronary sinuses of the aorta to go on to have normal coronary development.[128] Controversy still exists, however, on whether the coronary arteries grow outward from the aortic root or originate on the epicardium and grow inward toward the aortic root.[129]

Of note, this section is structured differently: each lesion's anatomy, pathophysiology, diagnostic findings, and potential treatment are discussed independently of one another.

Background

Coronary artery anomalies occur in 0.3% to 1.3% of the population.[130,131] They can be classified as minor, secondary, or major based on their clinical significance.[132] Minor defects have no functional significance and are usually detected as incidental findings at cardiac catheterization. Secondary defects have no intrinsic significance but alter surgical management when they are present. An example of a secondary defect is an anomalous origin of the left anterior descending artery from the right coronary artery that crosses the hypoplastic infundibulum in a patient with TOF. The presence of this vessel may prevent the safe performance of a transannular incision and thereby mandate the use of a conduit. Major defects are the most important form of coronary anomaly, because they exert an intrinsically adverse effect on the myocardium. Major anomalies can be subdivided based on anatomy: coronary arteriovenous fistula, anomalous pulmonary origin of a coronary artery, anomalous aortic origin of a coronary artery, myocardial bridging, and coronary artery aneurysm.

Coronary Arteriovenous Fistula

Coronary arteriovenous fistula is the most common major coronary anomaly. An abnormal connection exists between a coronary artery (usually the right) and another vascular structure (usually one of the right heart chambers). Most fistulae are isolated and solitary. The fistula leads to left-to-right shunting, which can produce CHF. Other symptoms include angina, endocarditis, myocardial infarction, arrhythmia, and sudden death. The diagnosis is suggested by echocardiography and confirmed by catheterization. All symptomatic fistulas should be occluded, either surgically or by transcatheter techniques.[133] In some cases, coronary bypass grafting may be necessary when distal flow is compromised by fistula occlusion. Treatment of asymptomatic fistulae is controversial, but occlusion should probably be undertaken when significant left-to-right shunting is present.[133] Coronary

artery fistulae can be surgically corrected with minimal mortality and morbidity.[134] Alternatively, transcatheter closure, when technically feasible, can be utilized with similar results.[135]

Coronary Artery Origin from the Pulmonary Artery

The second most common major coronary anomaly is origin of a coronary artery from the PA. The most common manifestation is anomalous left coronary artery arising from the pulmonary artery (ALCAPA). The right coronary (or both coronaries) may also arise anomalously from the PA, but only in very rare cases. Anomalous left coronary artery arising from the pulmonary artery is usually well tolerated during fetal development, but after birth, the pulmonary systolic pressure usually drops (following ductal closure and decline in PVR) and the anomalous coronary is perfused with desaturated blood at low pressure. Collateral vessels develop between the normal right coronary artery and the abnormal left coronary, but the benefit is negated due to the development of coronary steal, whereby the collateral blood shunts left to right by retrograde flow in the anomalous coronary into the low-pressure PA.

Most patients will present between 6 weeks and 3 months of life. Typical symptoms include irritability, difficulty in feeding, and other signs of CHF. Untreated, ALCAPA is nearly always fatal. Rarely, patients will survive to adulthood and present with symptoms of angina or sudden death. On examination, patients with ALCAPA frequently have a holosystolic murmur of ischemic mitral regurgitation. The pulmonary component of the second heart sound may be pronounced due to pulmonary hypertension. Chest radiography is significant for cardiomegaly and pulmonary edema. Electrocardiographic evidence of ischemia and infarction is usually present. Echocardiography is usually diagnostic and is useful for assessing the severity of left ventricular dysfunction and ischemic mitral regurgitation, which are commonly present. Catheterization is occasionally necessary to clarify the anatomy, but this technique is used less frequently due to the risk of inducing life-threatening arrhythmias.

Surgical repair is indicated for all patients with ALCAPA. Historically, the initial surgical approach involved ligation of the proximal left coronary artery. This served to eliminate coronary steal and allow perfusion of the left coronary system by collaterals from the right. Despite the ease of simple ligation, most centers have abandoned this approach in favor of establishment of a two-coronary system, which offers better long-term freedom from ischemia. Most commonly, this can be achieved by removing the origin of the left coronary artery (along with a button of adjacent PA) and reimplanting the vessel directly into the side of the aorta. Another approach involves creation of a side-to-side connection between the aorta and PA with placement of an intrapulmonary baffle to direct flow from this connection to the anomalous left coronary ostium. With improved coronary transfer techniques learned from the arterial switch operation, direct reimplantation of the anomalous coronary artery is always feasible and preferred. Survival following surgical repair of ALCAPA has improved over the years.[136] Recent reports have suggested an operative mortality of 6% or less.[136] Ventricular function tends to normalize after surgery.[137] In most patients, mitral valve function also improves. Nevertheless, for patients with severe mitral regurgitation, concurrent mitral valve repair may rarely be indicated.[137] These patients should be followed for life with serial imaging due to rare but potentially lethal LV scarring and subsequent failure.[138]

Anomalous Aortic Origin of Coronary Artery

Most anomalous aortic origin of the coronary arteries (AAOCA) are usually minor defects, but AAOCA can be a major coronary anomaly when the left main coronary artery arises from the right coronary sinus and passes between the PA and aorta. This defect has been associated with cardiac symptoms and sudden death, as has the origin of the right coronary artery from the left coronary sinus (usually when the right coronary is dominant).[139,140] The etiology of ischemia in both defects is thought to be related to the acute angle of origin and slit-like orifice of the anomalous vessel often with an intramural course. These defects usually present in older patients. Symptomatic patients are treated surgically by unroofing the coronary ostia into the aorta or, rarely, by coronary artery bypass. Because of highly variable practice patterns, an expert consensus guideline was recently

published detailing the management of AAOCA.[141] Surgical correction of AAOCA has been demonstrated to be very safe and efficacious in select patients.[142]

Myocardial Bridging

Myocardial bridging occurs when a segment of an epicardial coronary artery (usually the left anterior descending) takes an intramyocardial course over a short segment. Although this is a common incidental finding at cardiac catheterization, this defect has been associated in some cases with myocardial ischemia.[143] Treatment involves dividing the muscle bridge to free the coronary, coronary bypass beyond the bridge, or transcatheter stenting.

Coronary Artery Aneurysms

Coronary aneurysms are rare and usually occur in conjunction with an inflammatory condition, such as Kawasaki syndrome, polyarteritis nodosa, Takayasu arteritis, or syphilis. Coronary aneurysms may thrombose or lead to distal coronary stenosis or embolization. Rupture occurs uncommonly. Treatment ranges from antiplatelet therapy to coronary bypass grafting.

Valvular Heart Disease

Daniel J. P. Burns, Per Wierup, and A. Marc Gillinov

Key Points

1. The most common cause of aortic stenosis (AS) is degenerative calcific disease, followed by congenital AS due to bicuspid valve anatomy.
2. Two-dimensional (2D) echocardiography with Doppler allows precise real-time analysis of valvular anatomy and function and is the study of choice for the diagnosis and management of valvular lesions.
3. The current indication for cardiac catheterization in patients with valvular heart disease is limited to preoperative evaluation of coronary artery disease.
4. There is no effective medical therapy for patients with severe AS. Mechanical relief of the obstruction to blood flow is the only effective treatment.
5. The most common causes of aortic regurgitation (AR) include bicuspid valve disease, rheumatic fever, and endocarditis.
6. Mitral stenosis (MS) is almost exclusively caused by rheumatic fever.
7. The most common cause of mitral regurgitation is degenerative mitral valve disease. Other causes include rheumatic valve disease, endocarditis, certain drugs, and collagen vascular diseases.

VALVULAR ANATOMY

The basic structural framework of all heart valves is provided by the fibrous cardiac skeleton (Fig. 82.1). The skeleton is a collection of dense connective tissue in the shape of four interconnected rings in the plane between the atria and the ventricles. The interconnecting areas include the right fibrous trigone, which is between the aortic and tricuspid rings and contiguous with the membranous septum, and the left trigone and intervalvular fibrosa, which are between the aortic and mitral rings and form the posterior wall of the left ventricular (LV) outflow tract. The cardiac skeleton maintains the integrity of

the valve orifices and provides points of attachment for the valve leaflets. It also serves as a partition by electrically isolating the atria and ventricles except at the atrioventricular bundle, which passes through the right fibrous trigone near the septal leaflet of the tricuspid valve (TV).

The normal aortic valve (AV) consists of three semilunar cusps projecting outward and upward into the lumen of the ascending aorta (Fig. 82.2). The space between the free edge of each cusp and the points of attachment to the aorta comprises the sinuses of Valsalva. Since the coronary arteries arise from two of the three sinuses, the sinuses and the respective cusps are named the right coronary, left coronary, and noncoronary (or posterior) sinuses and cusps.

The properties of the AV ensure minimal obstruction to flow when open and minimal flow reversal when closed. The valve function is passive, as it functions only in response to pressure differences between the left ventricle and aorta during the cardiac cycle. The pressure generated from ventricular contraction forces the valve open, and the subsequent recoil of blood from the aorta fills the sinuses of Valsalva and forces the leaflets closed.

There are two structures in close proximity to the AV susceptible to injury during AV surgery (Fig. 82.2). The anterior leaflet of the mitral valve (MV) is positioned under the commissure between the left and noncoronary cusps. The left bundle of His is positioned under the commissure between the right and noncoronary cusps, in the area of the membranous septum.

The anatomy and active valve mechanics of the MV are more complex. Indeed, proper functioning of the MV depends on the organized interaction of all components of the MV apparatus, which consists of the leaflets, annulus, LV papillary muscles, and chordae tendineae.

The normal MV consists of two leaflets: the anterior and posterior leaflets. The anterior leaflet is semicircular, extends from the anteromedial aspect of the mitral annulus, and encompasses approximately one-third of the annular circumference. The posterior leaflet is rectangular, extends from the posterolateral aspect of the mitral annulus, and encompasses approximately two-thirds of the annular circumference. The leaflets are separated from one another at the annulus by the posteromedial and anterolateral commissures. Indentations subdivide the posterior leaflet into three scallops, namely, laterally to medially, P1, P2, and P3. Corresponding regions of the anterior leaflet are analogously referred to as A1, A2, and A3. Together these

comprise an average cross-sectional area of 5 to 11 cm^2. The mitral annulus is formed anteriorly by the confluence of the right and left fibrous trigones and the intervalvular fibrosa and posteriorly by a less well-developed fibrous band. Due to the trigones and intervalvular fibrosa, the anterior mitral annulus has limited flexibility. Conversely, the posterior aspect of the annulus, which is not surrounded by any rigid structures, has more flexibility. In systole, the mitral annulus contracts (primarily the posterior aspect) and adopts an elliptical shape (shortening occurs perpendicular to the line of leaflet coaptation), and in diastole, it relaxes and adopts a circular shape.[1,2] This dynamic motion of the annulus provides increased leaflet coaptation during systole and increased orifice area during diastole.

Two papillary muscles arise directly from the ventricular wall: the anterolateral and posteromedial papillary muscles. Importantly, the anterolateral papillary muscle usually is supplied by two coronary arteries, the left anterior descending artery and branches of the circumflex artery. The posteromedial papillary muscle is usually supplied by a single coronary artery, either from the right coronary artery or from the circumflex artery, which makes it more susceptible to rupture as a complication of myocardial infarction. The papillary muscles play an important role in the proper function of the MV, as closure and appropriate leaflet coaptation are permitted by end-diastolic and early systolic lengthening of the papillary muscles.[3]

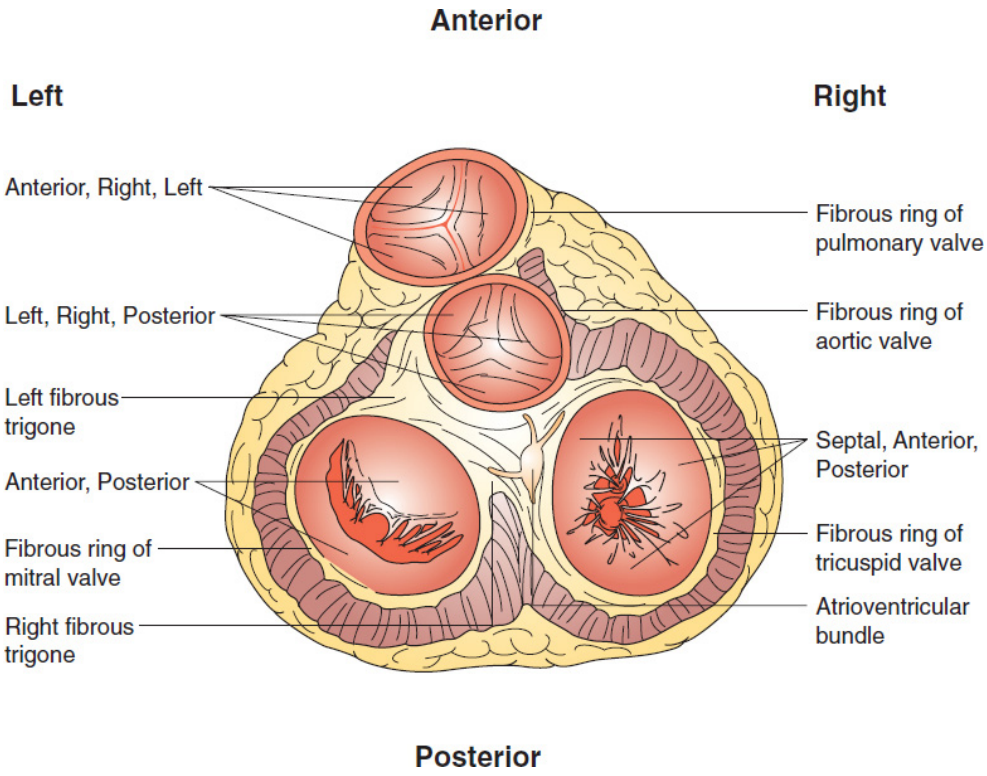

Figure 82.1 Schematic diagram of the fibrous cardiac skeleton.

Chordae tendineae attach the leaflets to either the papillary muscles or the ventricular wall and can be categorized by the attachments. Primary chordae extend from the papillary muscle and attach to the leaflets at the free edge, ensuring proper coaptation without prolapse or flail. Secondary chordae attach to the ventricular side of the leaflets, along the line of coaptation, and are more prominent on the anterior leaflet. Tertiary chordae can arise from the papillary muscle or directly from the ventricular wall and attach to the base of the posterior leaflet. Fan-like commissural chordae attach to both leaflets and arise from either papillary muscle.

The structures in close proximity to the MV susceptible to injury during MV surgery include the AV, the atrioventricular node, and the circumflex coronary artery (Fig. 82.3).

AORTIC STENOSIS

Prevalence and Etiology

Aortic stenosis (AS)[1] is the most prevalent valvular heart disease in developed countries. The most common cause of AS is degenerative calcific disease, followed by congenital AS due to bicuspid valve anatomy. Rheumatic AS is becoming exceedingly uncommon in developed countries due to efficient prevention of rheumatic heart disease.

Degenerative Calcific Aortic Stenosis

The most frequent cause of AS is degenerative calcification of the AV. The prevalence of degenerative AS in persons older than 65 years, which is the most commonly affected age group, is 2%.[4] The degenerative process that leads to stiffening of the aortic leaflets is the result of proliferative and inflammatory changes with lipid accumulation and infiltration of macrophages and T lymphocytes.[4–9] Fibrosis and calcification initially affect the base of the leaflets but ultimately progress to immobilization of the leaflets due to large calcific deposits that can extend deep into the annulus. These deposits may also extend onto the ventricular surface of the anterior leaflet of the MV, as well as into the wall of the ascending aorta. The risk factors for the development of calcific AS are similar to those for atherosclerosis and include elevated serum levels of low-density lipoprotein (LDL) cholesterol, diabetes, smoking, and hypertension.[10,11]

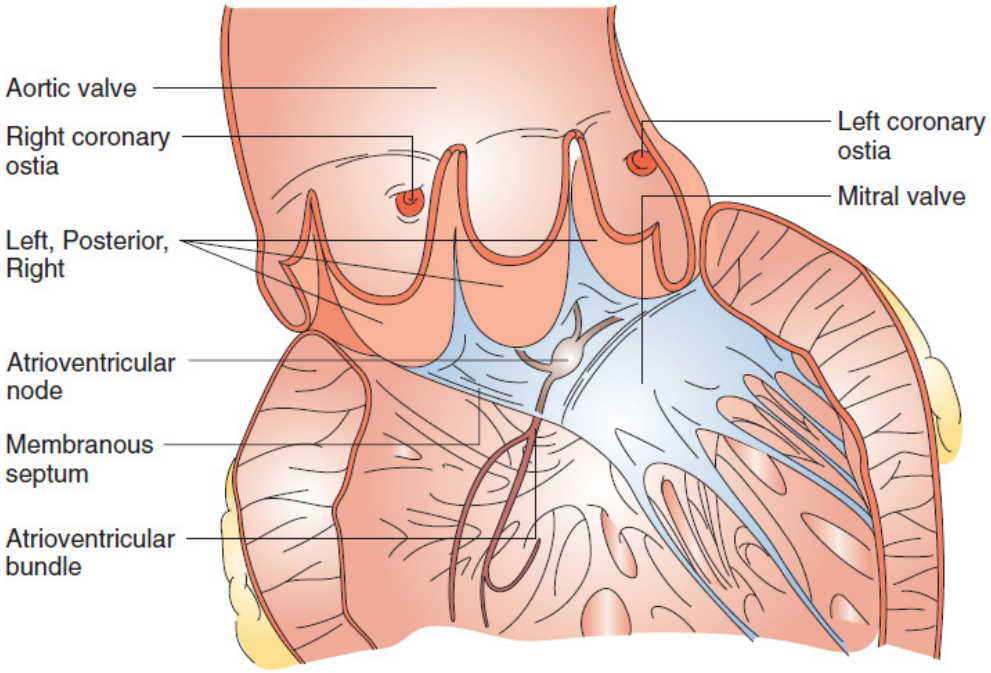

Figure 82.2 Schematic diagram of the relationship of the aortic valve to the underlying structures.

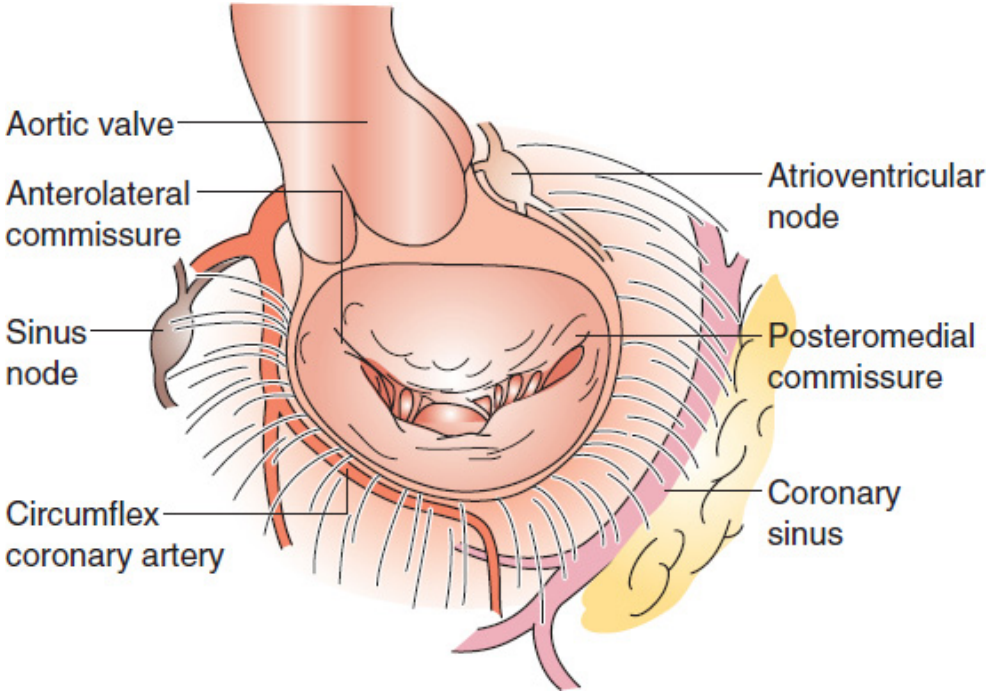

Figure 82.3 Schematic diagram of the relationship of the mitral valve to the underlying structures.

Bicuspid Aortic Stenosis

Bicuspid AVs are present in approximately 2% of the population. Degeneration of bicuspid AVs represents the most common form of congenital AS. Most commonly, the left and right coronary cusps are fused at a rudimentary commissure known as a raphe, while the noncoronary cusp is freestanding. Gradual calcification of the bicuspid valve results in AS, with typical onset of symptoms in the fifth or sixth decades of life, in contrast to degenerative AS, which causes symptoms in elderly individuals. Bicuspid AS is frequently associated with degenerative changes in the wall of the ascending aorta with resultant dilation or aneurysm formation.

Rheumatic Aortic Stenosis

Introduction of effective antibiotic therapy has resulted in a decline in the prevalence of rheumatic fever and rheumatic valve disease. Rheumatic AS is caused by inflammation and thickening of the AV leaflets, producing a mixture of AS and regurgitation. Rheumatic AS is rarely an isolated disease and usually occurs in conjunction with MV stenosis.[12]

Pathophysiology

Regardless of the etiology of AS, the pathophysiologic consequences are similar. Narrowing of the AV to a quarter of its normal area of 3 to 4 cm^2 produces a significant pressure gradient between the LV and the aorta. There is a resultant increase in LV workload and compensatory LV hypertrophy.

Even though this hypertrophy is an appropriate response to the increased afterload, there are numerous harmful effects. The increased wall thickness makes the ventricle stiff and less compliant. This leads to diastolic dysfunction and increased wall tension. Systolic dysfunction can develop from chronic ischemia. All of the following contribute to increased myocardial oxygen demand: increased LV muscle mass, increased wall tension, increased systolic ventricular pressure, and increased systolic ejection time. There is also decreased coronary artery perfusion, which occurs during diastole, due to increased wall tension, increased diastolic ventricular pressure, and decreased diastolic aortic pressure.[13,14] Subsequent ischemia of the subendocardium due to increased oxygen demand and decreased perfusion leads to cell death and fibrosis.

Diagnosis

Symptoms

The most common symptoms of AS are angina pectoris, syncope, and heart failure.[15] Angina pectoris occurs in 30% to 50% of patients with severe AS. It reflects myocardial ischemia caused by increased metabolic demands and decreased coronary perfusion. Coronary artery disease, which affects >70% of elderly patients with degenerative AV disease, further decreases myocardial perfusion, lowering the threshold for angina.

Syncope is most commonly due to reduced cerebral perfusion that occurs during exertion. Reduced cerebral perfusion is a result of decreased mean arterial pressure from peripheral vasodilation in the presence of a fixed cardiac output. Approximately 15% of patients present with syncope and only 50% of these survive for 3 years.

Congestive heart failure in patients with severe AS is typically a sign of advanced and long-standing disease. It is marked by dyspnea on exertion, fatigue, and/or peripheral edema resulting from ongoing LV outflow obstruction. Heart failure is a consequence of the aforementioned diastolic and systolic dysfunction from decreased compliance and ischemia, respectively. As the left ventricle becomes less compliant, atrial systole becomes more important for maintaining cardiac output, and the onset of atrial fibrillation may result in worsening congestive heart failure.

Some patients with severe AS may develop serious gastrointestinal bleeding secondary to angiodysplasia occurring predominantly not only in the right colon but also in the small bowel and stomach (Heyde syndrome). This is due to shear stress–induced platelet aggregation with reduction in high-molecular-weight multimers of von Willebrand factor.

Signs

Signs of AS include a loud systolic ejection murmur that radiates to the neck and may be accompanied by a thrill. “Pulsus parvus et tardus” describes a weak and prolonged arterial pulse characteristic of advanced AS. The weak pulse reflects a narrowed pulse pressure, while the slow rise in pulse reflects a prolonged ejection of blood volume through a stenotic valve.[16]

Electrocardiogram and Imaging

The electrocardiogram typically shows signs of LV hypertrophy, which is found in the majority of patients with AS. Echocardiography represents the gold standard modality for the diagnosis of AS.[2] Two-dimensional (2D) echocardiography with Doppler allows precise noninvasive real-time analysis of the anatomy and function of both the valve and the ventricle. The most important objective is the correct assessment of AS severity, calculating jet velocity, mean transvalvular pressure gradient, and valve orifice area (Table 82.1). It is also used to assess valve thickening and calcification, leaflet motion, and the presence of any concomitant aortic insufficiency. The echocardiogram is often able to distinguish between bicuspid and tricuspid AVs, particularly with less severe calcification.

2 2D echocardiography is also used to detect disease in additional valves, as well as assess LV hypertrophy and systolic/diastolic function. Ejection fraction is used to measure LV systolic function. However, a decreased ejection fraction can falsely lower estimates of AS severity due to the inability of the LV to generate the expected pressure gradients. This is known as low-flow low-gradient AS. Stress echocardiography with dobutamine administration may be required to properly assess the severity of valvular disease and to distinguish it from primary contractile dysfunction.[17]

Table 82.1 Classification of Aortic Stenosis Severity

Indicator	Mild	Moderate	Severe
Jet velocity (m/sec)	2.0–2.9	3.0–4.9	≥4.0
Mean gradient (mm Hg)	<20	20–39	≥40
Valve area (cm^2)	>1.5	1.0–1.5	<1.0
Valve area index (cm^2/m^2)			<0.6

Invasive cardiac catheterization with direct measurement of the pressure gradients across the AV has been replaced by echocardiography. 3 The current indication for cardiac catheterization is limited to preoperative evaluation of coronary artery disease.

Natural History

The natural history of AS is marked by a prolonged latent period with few symptoms and minimal morbidity. Even patients with moderately severe AS have a slow decrease in AV area, generally by approximately 0.1 cm^2 per year.[18,19] The natural history of severe AS correlates well with the onset and severity of symptoms. The average life expectancy of patients with symptomatic, severe, and untreated AS is 5, 3, and 2 years for patients with angina, syncope, and heart failure, respectively (Fig. 82.4).[20]

Treatment

There is no effective medical therapy 4 for patients with severe AS. Diuretics and digitalis may alleviate the symptoms of congestive heart failure. Mechanical relief of AS is accomplished by surgical AV replacement (SAVR), transcatheter AV replacement (TAVR), or percutaneous balloon aortic valvuloplasty (PBAV).

Surgical Aortic Valve Replacement

The primary indication for surgery is the presence of symptoms in patients with severe AS. AV replacement (AVR) is also indicated in patients with severe AS and reduced LV function and in patients with moderate AS requiring cardiac surgery for other indications.[17] AVR may also be beneficial in patients with asymptomatic severe AS and severe LV hypertrophy.[21]

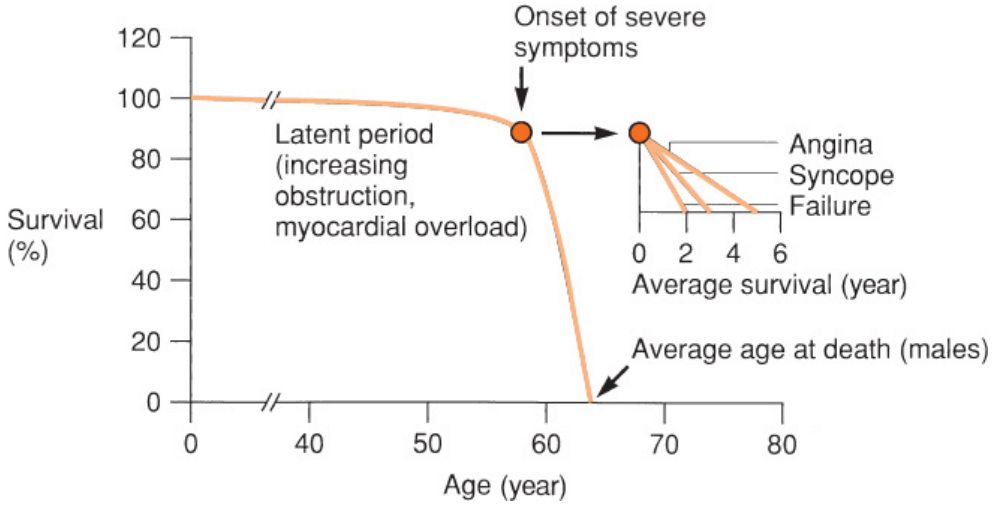

Figure 82.4 Natural history of aortic stenosis without operative treatment. Onset of symptoms identifies patients at high risk of death over the next 2 to 5 years.

Figure 82.5 St. Jude Medical Regent Valve.

Choice of valve prosthesis for AVR is primarily influenced by the patient's age.[22] Mechanical prostheses are made of carbon, require lifelong anticoagulation, and are very durable (Fig. 82.5). Mechanical prostheses are therefore indicated in patients younger than 50 years. Stented biologic prostheses are most commonly made of bovine pericardium or porcine valve leaflets, do not require anticoagulation, and have a limited durability of approximately 15 years (Fig. 82.6). Biologic prostheses are used in elderly patients (>70 years) and in younger patients in whom long-term anticoagulation is contraindicated (bleeding diathesis, peptic ulcer disease, etc.).

Transcatheter Aortic Valve Replacement

TAVR utilizes a bioprosthesis mounted on a balloon or self-expandable stainless steel or nitinol stent (Fig. 82.7). The prosthesis is introduced through the femoral artery retrogradely into the aorta and placed at the mid-part of the native stenotic AV. The radial forces of the stent push the native AV aside to increase the valve orifice area. In cases where the femoral artery is not usable due to artery size or vascular disease considerations,

alternative access may be utilized. These approaches include subclavian, carotid, direct aortic, caval, and apical. The transapical approach via the LV apex, accessed by a left anterior mini-thoracotomy, was the initial alternative access of choice. However, in recent years, this has fallen out of favor relative to the other access routes.

TAVR is an actively evolving therapy for patients with surgical AV disease. Previously, this therapy was limited to patients deemed at high or prohibitive risk for SAVR, though TAVR has now expanded into intermediate- and low-risk cohorts following encouraging results from recent randomized trials in these lower-risk populations, with TAVR being not worse than SAVR.[17,23–26] In low-risk patients at 1 year, TAVR has also been shown to be superior to SAVR when considering the composite outcome of death, stroke, or rehospitalization, with a demonstrated hazard ratio for TAVR of 0.54 (0.37 to 0.79) 95% CI.[27] Although recent results are encouraging, it must be remembered that data are limited to 1 to 5 years and in active evolution.

Figure 82.6 St. Jude Medical Epic Valve.

Percutaneous Balloon Aortic Valvuloplasty

PBAV is a procedure in which a balloon is placed across a stenotic AV and inflated in order to decrease the degree of valve narrowing. This procedure

is a valuable tool for treatment of AS in children and young adults. Rapid development of restenosis and clinical deterioration limits its application in the treatment of adults to those who require a bridge to definitive management or who are otherwise not SAVR or TAVR candidates.

AORTIC REGURGITATION

Prevalence and Etiology

AR results from the improper coaptation of the AV leaflets due to either intrinsic leaflet abnormalities or aortic root distortion. 5 The most common causes of aortic regurgitation (AR) include bicuspid valve disease, rheumatic fever, and endocarditis. Regurgitant bicuspid AVs are often partly calcified, which results in limited opening and closing of the valve and a mixture of AR and AS. Rheumatic fever causes inflammation and fibrosis of the leaflets, while endocarditis causes destruction of leaflets. In addition, AR can occur as a secondary phenomenon of aortic root enlargement due to connective tissue disorders, annuloaortic ectasia, or aortic dissection. Most of these causes produce chronic AR with a slow increase in LV size. Some lesions, in particular acute aortic dissection and endocarditis, cause acute AR with a sudden decrease in cardiac output.

Pathophysiology

In patients with AR, inappropriate coaptation of the aortic leaflets causes diastolic reflux of blood from the aorta into the LV with a consequent increase in LV end-diastolic volume and pressure. In chronic AR, compensatory mechanisms of the LV result in dilation and hypertrophy. Over time, these measures decompensate and ultimately result in decreased LV function and heart failure.

Diagnosis

Symptoms

Chronic AR is usually well-tolerated, and patients with even severe AR often remain asymptomatic for years. Initial symptoms of severe AR include fatigue, shortness of breath, and dyspnea on exertion. Advanced AR is marked by the onset of congestive heart failure, syncope, and angina. Acute onset of severe AR, such as in cases of aortic dissection or endocarditis-induced valve destruction, causes a sudden increase in LV end-diastolic volume and pressure with subsequent cardiogenic shock and pulmonary edema.

Signs

Lateral displacement of the point of maximum impulse is seen in chronic AR due to LV dilation and hypertrophy. The classic auscultatory findings of AR are best heard at the right sternal border of the second intercostal space and include a high-pitched, blowing holodiastolic decrescendo murmur, an S_3 heart sound, and a systolic ejection murmur.

The widened pulse pressure leads to a number of interesting findings, such as bounding pulses (water hammer pulse), Quincke pulse (pulse in fingernail bed), De Musset sign (rhythmic bobbing of the head), Duroziez sign (systolic and diastolic murmurs heard over the femoral artery when it is gradually compressed), and Müller sign (pulsations of the uvula).[16]

Imaging

Echocardiography represents the diagnostic gold standard for patients with AR. It allows assessment of the valvular and aortic anatomy, the severity of regurgitation, and ventricular size and function. Assessment of the severity of AR is determined by color Doppler jet width, regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 82.2). The role of coronary angiography is limited to the preoperative diagnosis of coronary artery disease.

Natural History

The natural history of AR is strongly dependent on the presence of symptoms and LV dysfunction at the time of presentation. Asymptomatic patients with

normal LV function develop symptoms and/or LV dysfunction at a rate of 6% per year. Asymptomatic patients with LV dysfunction at presentation develop cardiac symptoms at a rate of 25% per year. Finally, the mortality rate of symptomatic patients is 10% per year.[17]

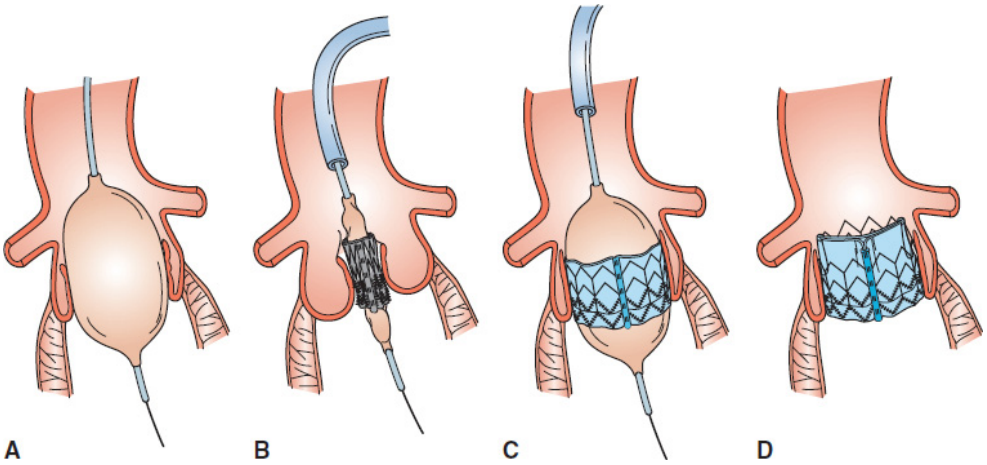

Figure 82.7 Schematic diagram of percutaneous aortic valve replacement. **A:** Balloon valvuloplasty. **B:** Balloon catheter with valve in the native diseased valve. **C:** Balloon inflation to secure the valve. **D:** Valve in place.

Table 82.2 Classification of Aortic Regurgitation Severity

Indicator	Mild	Moderate	Severe
Angiographic grade	1+	2+	3–4+
Doppler jet width	<25% LVOT	25–64% LVOT	≥65% LVOT
Regurgitant volume (mL/beat)	<30	30–59	≥60
Regurgitant fraction (%)	<30	30–49	≥50
Effective regurgitant orifice (cm^2)	<0.10	0.10–0.29	≥0.30
Vena contracta (cm)	<0.3	0.3–0.6	>0.6

Treatment

Management of patients with AR depends on the severity of symptoms and the size and function of the left ventricle. Asymptomatic patients with chronic severe AR and preserved LV size and function are treated with vasodilator medical therapy, which reduces afterload and improves forward flow.

Surgery is indicated in symptomatic patients with chronic severe AR and in asymptomatic patients with severe AR and evidence of LV dilation (end-

systolic LV diameter >55 mm) or dysfunction (ejection fraction <50%). Additionally, acute severe AR with consequent pulmonary edema and shock caused by endocarditis or aortic dissection is a surgical emergency.

AVR should be performed before irreversible changes in LV function occur. Considerations for prosthetic valve choice in replacement are identical to those discussed previously. AV repair can often be performed in patients with severe AR caused by bicuspid valve disease or connective tissue disorders. Traditionally, patients with proximal aortic root pathology, including dissection and aneurysms with secondary AR, underwent aortic root replacement with a mechanical valve. The valve-sparing root replacement (the David procedure) has been shown to have similar morbidity and mortality with minimal risk of thromboembolism or endocarditis. Additionally, it precludes the need for anticoagulation and has an acceptably low reoperation rate. This makes it ideal for young patients, especially those with connective tissue disorders.[28–31]

MITRAL STENOSIS

Prevalence and Etiology

6 Mitral stenosis (MS) is predominantly caused by rheumatic fever. The steady rate of decline of rheumatic fever in developed countries has resulted in a similar decline in the prevalence of MS. Less common causes of MS include severe annular and leaflet calcification, congenital malformations, malignant carcinoid, left atrial myxoma, left atrial thrombus, and endocarditis. A definitive history of rheumatic fever can only be obtained in 50% to 60% of cases, and women are affected more often than men by a 2:1 ratio.[32,33] Rheumatic fever commonly occurs in childhood or adolescence and can lead to a postinfective pancarditis, affecting to various degrees the valves, endocardium, myocardium, and pericardium. In MS due to rheumatic fever, there is leaflet thickening and calcification, chordal shortening and fusion, and commissural fusion, which all lead to a smaller, funnel-shaped mitral orifice. This deformation can also prevent complete closure of the valve, which is evidenced by concomitant regurgitation in about half of patients with MS.

Pathophysiology

The cross-sectional area of the normal MV is 4 to 6 cm^2. Normally, there is a trivial diastolic pressure gradient present to move blood across the MV from the left atrium into the left ventricle. An increasing gradient is required as the MV becomes more narrowed, and a significant transvalvular gradient first develops when there is reduction of the mitral orifice to <2.5 cm^2. Increasing atrial pressure leads to left atrial enlargement, and the pressure is subsequently transmitted retrograde into the pulmonary veins, capillaries, and arteries. The determinants of the transvalvular gradient and left atrial pressure are atrial contractility, cardiac output, and heart rate. Consequently, the gradient and atrial pressure are increased if atrial kick is lost (decreased atrial contractility), flow rate across the valve increases (increased cardiac output), or transit time across the valve is shortened (increased heart rate).

Diagnosis

Symptoms

Symptoms of left-sided heart failure, such as dyspnea, orthopnea, and paroxysmal nocturnal dyspnea, are the primary indicators of MS and are typically triggered by exertion, stress, infection, pregnancy, or the abrupt onset of atrial fibrillation. The increased heart rate and cardiac output that can occur under these circumstances, and the mechanical obstruction inherent to MS, lead to an increased transvalvular gradient and left atrial pressure. The ensuing pulmonary congestion results in dyspnea. Likewise, the loss of atrial kick with atrial fibrillation increases the gradient and atrial pressure and may be poorly tolerated. Patients with atrial fibrillation may also present with palpitations or systemic embolization.

Patients infrequently present with hoarseness, dysphagia, hemoptysis, and symptoms of right-sided heart failure. Hoarseness and dysphagia may result if left atrial enlargement is sufficient to compress surrounding structures. Hemoptysis may occur from significant pulmonary venous hypertension. Symptoms of right-sided heart failure arise when right ventricular function is impaired due to an increased afterload from the stenotic MV and secondary

pulmonary hypertension. Patients may present without symptoms but have an abnormal physical examination.

Signs

The left ventricle is typically not enlarged, and the point of maximum impulse is not displaced. The typical auscultatory findings of MS are best heard at the apex and include a low-pitched, rumbling mid-diastolic murmur; an accentuated first heart sound; and an opening snap. These findings may be absent with a heavily calcified immobile valve, severe pulmonary hypertension, or low cardiac output. Physical findings of pulmonary hypertension, such as a loud pulmonic component of the second heart sound (P_2), a right ventricular heave, distended neck veins, hepatomegaly, ascites, and peripheral edema, can also be observed with MS.[16]

DIAGNOSIS

Table 82.3 Classification of Mitral Stenosis Severity

Indicator	Progressive	Severe
Mean gradient (mm Hg)		>5–10
Diastolic pressure half-time (msec)	<150	≥150 ≥220 (very severe)
Valve area (cm^2)	>1.5	≤1.5 ≤1.0 (very severe)

Adapted from Nishimura RA, Otto CM, Bonow RO, et al. 2014 AHA/ACC Guideline for the management of patients with valvular heart disease: executive summary a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;129(23):2440–2492.

Imaging

Echocardiography is the principal tool used in the diagnosis of MS. It is used to assess the morphologic characteristics of the valve apparatus: leaflet mobility, leaflet flexibility, leaflet thickness, presence of calcifications, subvalvular fusion, and appearance of the commissures. Doppler echocardiography is utilized to determine the hemodynamic severity by measurement of the mean transvalvular pressure gradient, pulmonary artery systolic pressure, diastolic pressure halftime, and valve area (Table 82.3). This morphology and severity information is fundamental in determining the timing and type of intervention to be used.[17]

The enlarged left atrium gives rise to characteristic findings on the chest radiograph, which includes displacement of the left main-stem bronchus superiorly and displacement of the esophagus posteriorly. Additionally, calcification of the mitral leaflets and enlarged pulmonary arteries with cephalization of pulmonary blood flow can be seen.

Similar to the diagnosis of other valvular heart disease, cardiac catheterization with direct pressure measurement has largely been replaced by echocardiography.

Natural History

The natural history of MS is that of a continuous decline usually consisting of a slow, stable course, followed by a progressive acceleration. The latent period from rheumatic fever to the onset of symptoms is typically 20 to 40 years, with another decade before symptoms become disabling. Depending on the symptoms at presentation, the overall 10-year survival rate of untreated patients presenting with MS is 50% to 60%. Once disabling symptoms occur, the 10-year survival rate is a bleak 0% to 15%.[32–35] Mortality in untreated patients is due to pulmonary and systemic congestion, systemic embolism, pulmonary embolism, and infection.[34,36]

Treatment

For the asymptomatic patient with mild MS in sinus rhythm, prophylaxis against rheumatic fever is the only therapy indicated. A yearly history, physical examination, chest radiograph, and electrocardiogram should be

obtained; serial echocardiograms are only warranted in patients with severe MS or when there is a change in symptoms.[17]

Mechanical relief is considered in symptomatic patients with moderate to severe MS. In symptomatic patients with mild MS, further exercise testing or dobutamine stress testing is useful to determine whether or not mechanical relief is warranted. Patients with a significant elevation in mean transmitral gradient (>15 mm Hg), pulmonary artery systolic pressure (>60 mm Hg), or pulmonary artery wedge pressure (>25 mm Hg) during provocative testing have hemodynamically significant MS and should be considered for mechanical relief.[17] The options for mechanical relief of MS include percutaneous balloon mitral valvuloplasty (PBMV), open mitral commissurotomy (OMC), and MV replacement.

Percutaneous Balloon Mitral Valvuloplasty

PBMV requires a balloon-tipped catheter to be introduced into the right atrium via a transseptal approach and inflated across the diseased valve.[37] This has become the standard of care for select MS patients.[17] Scoring systems have been developed to aid in patient selection. Leaflet thickness, pliability, and degree of calcification of the valves and the subvalvular apparatus are central in these scoring systems. Lower scores (e.g., <8 in the Wilkins score) correlate with improved outcomes.[38] Contraindications include the presence of a left atrial thrombus, moderate to severe MR, heavy annular or leaflet calcification, and severe subvalvular distortion.

Procedural mortality of PBMV is 1% to 2% in large series. Rare risks of the procedure include MR, iatrogenic creation of an atrial septal defect, perforation of the left ventricle, embolic events, and myocardial infarction.[39–43]

Success of PBMV can be measured by the increase in mitral valve area (MVA), restenosis at long-term follow-up, and event-free survival (death, repeat procedure or surgery, NYHA III or IV). Overall, significant (MVA $\geq$1.5 cm^2) increases in MVA are obtained in over 80% of patients,[44] with a 10-year event-free survival rate of 80% and 10-year freedom from restenosis of 70%.[45,46]

Open Mitral Commissurotomy

OMC permits direct inspection of the MV apparatus and allows debridement of calcium deposits, division of the commissures, and splitting of fused chordae tendineae under direct vision. Additionally, the left atrial appendage can be surgically excluded, reducing the risk of postoperative embolization. The contraindications to OMC are similar to those of PBMV.

The operative mortality of OMC is <2%,[47,48] and complication rates are similar to those of PBMV.[49,50] Short- and long-term hemodynamic results and symptomatic results are similar between PBMV and OMC in younger patients with less severe valve pathology.[49] More favorable results are seen with OMC in older patients with subvalvular fusion, leaflet calcification, and less valve flexibility.[50]

Mitral Valve Replacement

MV replacement is necessary in symptomatic patients with moderate to severe MS when there is a significant amount of calcification or subvalvular fusion, since PBMV and OMC are less likely to be successful. MV replacement is also necessary in symptomatic patients with moderate to severe MS and concomitant moderate to severe MR.[17] The choice of valve prosthesis for MV replacement is determined similarly to choosing the prosthesis for AVR.[22] Regardless of the prosthesis used, it is well established that preservation of the papillary muscle attachments to the annulus plays an important role in the maintenance of LV function.[51–55] The operative mortality rate of MV replacement is 5% to 6% and freedom from reoperation at 15 years is 50% to 75%.[56]

MITRAL REGURGITATION

Prevalence and Etiology

Competency of the MV is dependent on the entire MV apparatus; dysfunction of any one of the components can 7 lead to mitral regurgitation (MR). The most common overall cause of MR is degenerative MV disease. Other causes of MR include rheumatic valve disease, endocarditis, certain drugs, and collagen vascular disease. In some cases, functional MR develops as a result of dilation of the LV from cardiomyopathy or severe ischemic heart disease.

Rupture of a papillary muscle from myocardial infarction or endocarditis, or rupture of a chord, can lead to the onset of acute, severe MR.

Pathophysiology

Myxomatous degeneration of the valve leaflets leads to leaflet thickening, leaflet redundancy, and chordal elongation. Annular dilation is also present to varying degrees. This ultimately leads to leaflet malcoaptation and/or chordal rupture, leading to regurgitation: blood flow from the left ventricle into the left atrium during systole. Regardless of etiology, the pathophysiology of chronic MR is similar. MR results in gradual enlargement of the left atrium as a result of volume overload. Decrease in the functional stroke volume causes an increase in LV size with a subsequent decrease in LV function.

The pathologic process that takes place in acute MR is quite different. Sudden volume overload results in an increase in LV preload and a decrease in forward stroke volume, since compensatory LV eccentric hypertrophy has not had time to develop. Similarly, acute volume overload of the left atrium results in an increase in left atrial pressure and pulmonary congestion.

Diagnosis

Symptoms

Symptoms of chronic MR include fatigue, dyspnea on exertion, and shortness of breath. More advanced stages of disease are characterized by the development of heart failure. Acute, severe MR is characterized by acute pulmonary edema and cardiogenic shock.

Signs

The point of maximum impulse is typically laterally displaced. The classic auscultatory findings of MR are best heard at the apex and include a high-pitched, blowing, holosystolic murmur radiating to the axilla; a diminished S_1; and an S_3.

Imaging

Echocardiography is used to assess the severity of MR, morphology of the MV, and size and function of the LV and atrium. Assessment of the severity of MR is determined by the jet area/left atrial area, regurgitant volume, regurgitant fraction, and regurgitant orifice area (Table 82.4). Additionally, magnetic resonance imaging (MRI) allows accurate measurements of the severity of regurgitation and quantification of regurgitant volumes, along with assessment of LV size and function.

Natural History

Patients with mild to moderate MR usually remain asymptomatic with little or no hemodynamic compromise for many years. In patients with severe MR caused by flail leaflets, the mortality rate is 6% to 7% per year, and 90% of patients die or require an MV operation within 10 years.[57]

Treatment

Surgery should be performed early, before the onset of LV dysfunction. Even asymptomatic patients with severe MR should be offered surgery if there is a high probability of successful repair and low mortality risk.[22,58] MV repair is the preferred surgical therapy for most patients, since it preserves the native valve and avoids the need for anticoagulation, which is required in many patients who undergo MV replacement.[59] Preservation of the MV and chordae preserves LV function and improves survival. Success rates of MV repair depend on the etiology of regurgitation. Durable MV repair can be accomplished in >90% of patients with degenerative MV disease. Techniques for MV repair include resection of the prolapsed portion of the MV leaflet with leaflet reconstruction or remodeling the zone of coaptation by creating artificial chordae (Fig. 82.8). Whichever repair technique is used, it must be supplemented by the placement of a prosthetic annuloplasty ring or band.

Table 82.4 Classification of Primary Mitral Regurgitation Severity

Indicator	Progressive	Severe
Angiographic grade	1–2+	3–4+
Jet size	Central jet 20–40% of LA or Late systolic eccentric jet	Central jet >40% of LA or Holosystolic eccentric jet
Vena contracta (cm)	<0.7	≥0.7
Regurgitant volume (mL/beat)	<60	≥60
Regurgitant fraction (%)	<50	≥50
Effective regurgitant orifice (cm^2)	<40	≥0.40

Mortality of isolated MV repair is <1%, with >90% freedom from reoperation at 10 years. Functional MR is usually repaired with the use of an undersized annuloplasty ring to reduce the diameter of the mitral annulus and restore valve competency. MV repair, if possible, is also the preferred surgical therapy in patients with MV endocarditis. Resection of all infected valve tissue is the mainstay of valvular reconstruction in patients with

endocarditis. This is followed by leaflet reconstruction, commonly with the use of an autologous pericardial patch and an annuloplasty (Fig. 82.9).

MV replacement is indicated when adequate MV repair cannot be accomplished. Mechanical valve replacements are indicated in patients younger than 50 years and stented bioprostheses are indicated in elderly patients (>70 years).[22]

Isolated MV surgery is traditionally performed through a full sternotomy. Minimally invasive approaches, which include partial upper and lower sternotomy and right mini anterolateral thoracotomy, decrease the degree of surgical trauma and blood loss and allow faster recovery with less postoperative pain and sternal wound complications and better cosmetic result.[60–62] Robotically assisted MV repair, which is performed through small port-like incisions, is the least invasive surgical approach that eliminates the need for sternotomy or thoracotomy and as such provides faster postoperative recovery in hospital as well as after discharge (Fig. 82.10).[63–66]

In patients with severe MR who are determined to be at prohibitive risk for surgery, given existing comorbidities, an alternative treatment option is percutaneous MV repair. The MitraClip system (Abbott, Abbott Park, Illinois, USA) is a percutaneously delivered device that offers similar mortality and symptomatic improvement. However, due to the higher rate of MR requiring repeat procedures, and less improvement in LV dimensions as compared to surgery, surgical repair remains the standard of care for treatment of MR among eligible patients.[67]

P2 triangular section. **B:** Suture reconstruction of P2 scallop. **C:** Posterior annular sutures placed through annuloplasty band. **D:** completed mitral valve repair.

TRICUSPID VALVE DISEASE

TV disease is less common than AV and MV disease. Tricuspid regurgitation (TR), the most common form of TV dysfunction, can occur with anatomically normal or abnormal valves. Functional TR is caused by right ventricular dilation and consequent leaflet malcoaptation in an otherwise anatomically normal valve. Right ventricular enlargement occurs in patients with pulmonary hypertension, most commonly caused by long-standing MV dysfunction. TV endocarditis most commonly occurs in intravenous drug users and causes TR by destruction of the leaflets.

Echocardiography is used to assess the degree of TR, anatomy of the TV, right ventricular function, and pulmonary pressures.

Mild to moderate degrees of TR often resolve due to remodeling after the correction of MV disease causing pulmonary hypertension. Severe functional

TR is corrected by reduction in the diameter of the tricuspid annulus using an annuloplasty band. Severe endocarditis requires complete resection of infected valve tissue, followed by TV reconstruction with pericardium or replacement with a bioprosthesis. In active drug users, insertion of a valve prosthesis may be delayed by several months to decrease the risk of recurrent endocarditis.

Valve Prostheses

Numerous types of valve prostheses are currently available for clinical use. All differ in design, biocompatibility, and hemodynamic characteristics. They are broadly classified into mechanical and bioprosthetic.

Contemporary mechanical valves are bileaflet valves composed of carbon material that is mounted on a sewing ring (Fig. 82.5). Mechanical valve prostheses are durable and have excellent hemodynamic performance. Patients with mechanical prostheses require lifelong anticoagulation with warfarin, which results in a 1% to 3% risk of bleeding per year. These

characteristics make mechanical valves the prosthesis of choice for younger patients with no contraindications to long-term anticoagulation.[22]

Biologic prostheses are composed of valve leaflets created from bovine pericardium, or a porcine heart valve xenograft, each mounted on a stented sewing ring (Fig. 82.6). Biologic prostheses have slightly inferior hemodynamic characteristics when compared with mechanical prostheses and a limited durability of 10 to 15 years. Bioprostheses are not thrombogenic and therefore do not require anticoagulation. Bioprostheses are generally indicated in older individuals and younger patients who have contraindications to long-term anticoagulation.

There has been an increased use of bioprostheses in younger individuals due to recent improvements in design of the prostheses, expected increases in valve durability, decreased risk of reoperations, and the ability to perform valve-in-valve TAVR.

Aortic homografts are cryopreserved cadaveric allografts. These consist of the entire aortic root (including the AV, surrounding ventricular myocardium, intervalvular fibrosa, and anterior MV leaflet) and the ascending aorta. Homografts are not thrombogenic, have excellent hemodynamic characteristics, and have high resistance to infection. Homografts are indicated in patients with AV endocarditis. Their use for primary AVR is limited due to the complexity of the operation and limited durability (10 years).

Mechanical Circulatory Support

Eric I. Jeng

Key Points

1. The term mechanical circulatory support (MCS) refers to a broad array of cardiac support devices distinguished by the following important features: location of the pumping chamber of the device, ventricle being supported, and pumping mechanism.
2. Indications for MCS include bridge to recovery, bridge to transplantation, and destination therapy.
3. Durable devices utilized for bridge to transplantation or destination therapy require major operative implantation that facilitates patient discharge from the hospital.
4. Delay in establishing any type of MCS results in a greater acuity and severity of illness delay in establishing any type of MCS results in a greater acuity and severity of illness, decreasing survival secondary to a greater degree of organ failure present at the time of implantation survival secondary to a greater degree of organ failure present at implant.
5. Patient selection is the most important factor in determining outcome of patients who receive MCS.
6. Major adverse events following initiation of MCS are those related to anticoagulation therapy necessary during MCS, infection, right-sided heart failure, and malfunction of the device.
7. The Interagency Registry of Mechanically Assisted Circulatory Support (INTERMACS) is a National Institutes of Health-funded data registry designed to study outcomes for patients with durable, long-term implantable MCS devices.
8. Major technologic advances in device designs for temporary and durable devices have incorporated continuous-flow rotary pumps.

INTRODUCTION

The term mechanical circulatory support (MCS) refers to a broad 1 array of cardiac support devices. These devices are distinguished by the following important features: (1) location of the pumping chamber of the device (extracorporeal vs. intracorporeal or "implantable"); (**Fig. 83.1**) (2) ventricle being supported (left ventricular assist device [LVAD] vs. right ventricular assist device [RVAD] vs. biventricular assist device [BiVAD] vs. total artificial heart [TAH]); (**Fig. 83.2**) and (3) pumping mechanism (pulsatile, volume displacement device vs. continuous-flow rotary device with axial or centrifugal design) (**Fig. 83.3**). Generally, the pumping chamber of short-term support devices is extracorporeal or paracorporeal in location, while durable systems are intracorporeal.

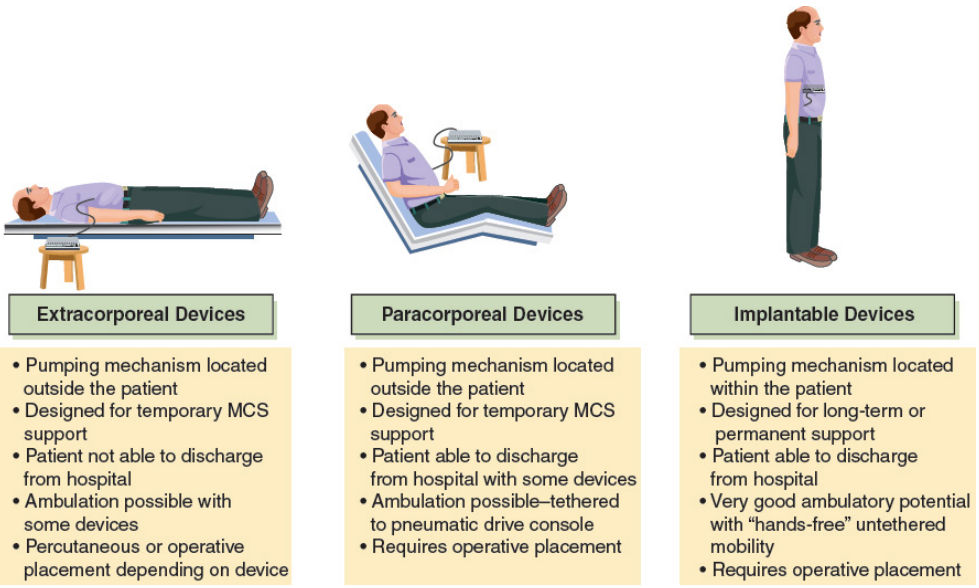

Figure 83.1 Classification of mechanical circulatory support devices by location of the pumping mechanism (extracorporeal, paracorporeal, and implantable).

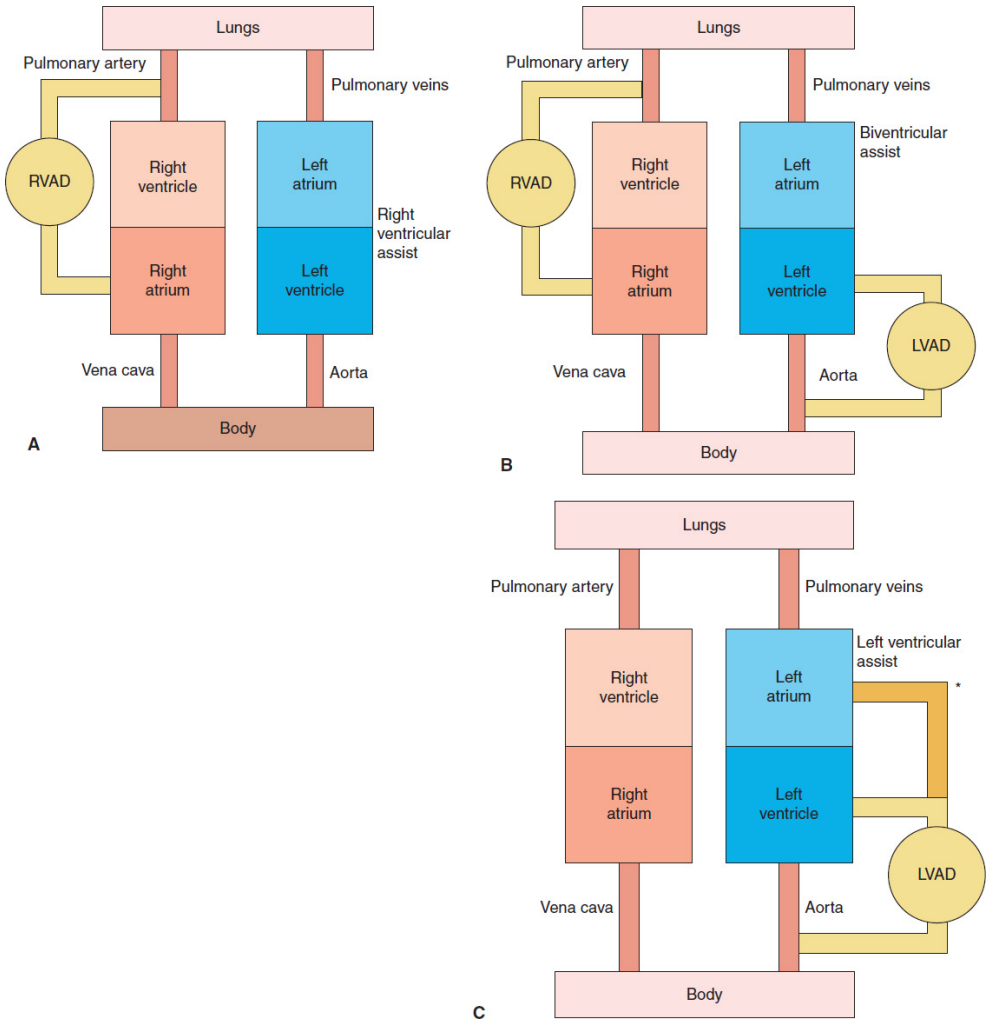

Figure 83.2 Classification of mechanical circulatory support devices by the ventricle being assisted. **A**: right ventricular assist. **B**: biventricular assist. **C**: left ventricular assist.

INDICATIONS FOR MCS

The spectrum of MCS therapy encompasses several indications for 2 use and a broad range of MCS device designs. Currently, there are three accepted indications for MCS based upon regulatory oversight by the U.S. Food and Drug Administration (FDA) and reimbursement criteria set by the Centers for Medicare & Medicaid Services, bridge to recovery (BTR), bridge to transplant (BTT), and destination therapy (DT).

BTR refers to the use of MCS in patients who are presenting with acute cardiogenic shock and/or decompensated heart failure, where the optimal

medical therapy (OMT), including intravenous inotropes and/or vasoconstrictors, has failed. These patients are thought to have an expectation of myocardial recovery following a short period (days to weeks) of temporary MCS. The short-term utilization of MCS for BTR is the most common application of MCS in the United States.[1] Examples of reversible forms of myocardial injury include acute myocardial infarction, viral myocarditis, or postcardiotomy cardiogenic shock with failure to separate from cardiopulmonary bypass (CPB) following various cardiac surgical procedures. Several types of devices can provide temporary MCS in these circumstances and include an intra-aortic balloon pump (IABP), extracorporeal ventricular assist device (VAD), or extracorporeal membrane oxygenation (ECMO)/extracorporeal life support (ECLS).[1] Typically, temporary MCS devices are implanted percutaneously allowing for rapid initiation of support and facilitating removal once cardiac function returns.[1] Certain types of extracorporeal VAD systems require major operative procedures via sternotomy and/or thoracotomy for insertion. These types of systems are utilized for postcardiotomy support where access to the mediastinum is facilitated by prior sternotomy and/or thoracotomy performed initially for the open-heart operation.

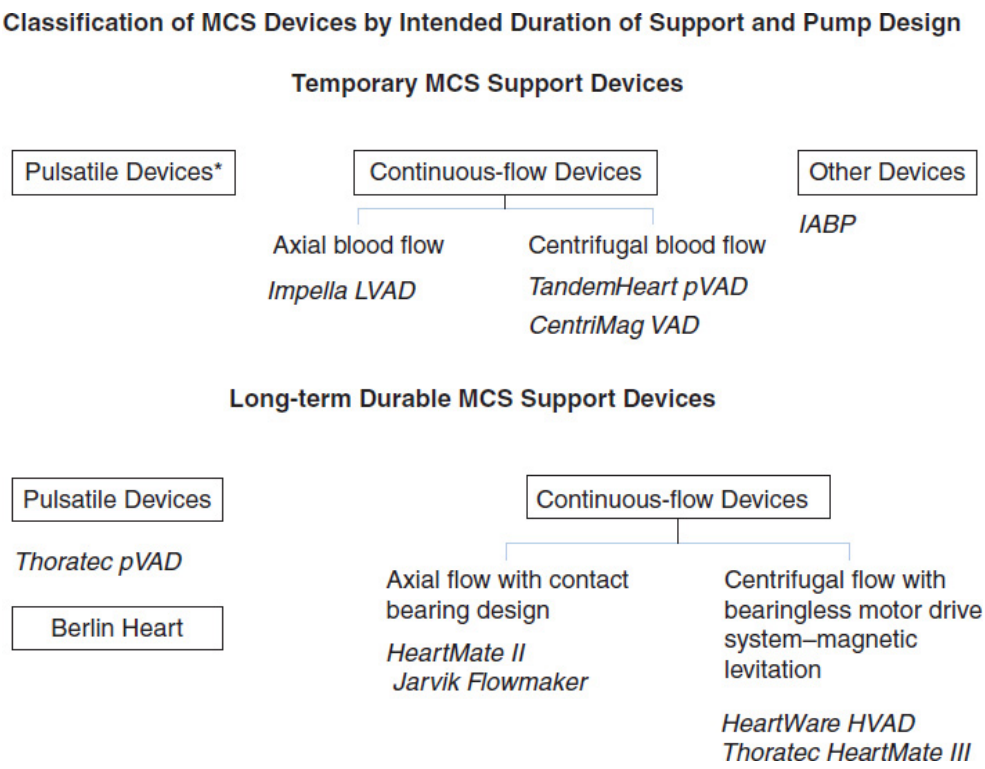

Figure 83.3 Classification of mechanical circulatory support devices by intended duration of support and pumping mechanism (pulsatile, volume displacement, or continuous-flow rotary pumps). (Impella, Abiomed Corporation, Danvers, MA; pVAD, HeartMate II, HeartMate III, Abbot Laboratories, Chicago, IL; CardioWest TAH, Syncardia Systems, Tucson, AZ; TandemHeart pVAD, CardiacAssist Corporation, Pittsburgh, PA; CentriMag VAD, Levitronix LLC, Waltham, MA; Jarvik LVAD, *Jarvik Heart Corporation*, New York, NY; HVAD, Berlin Heart, The Woodlands, Tx; LVAD, HeartWare Medtronic, Minneapolis, MN.)

BTT applies to patients presenting in cardiogenic shock and/or 3 decompensated heart failure refractory to OMT where myocardial function is unlikely to recover and the patient is considered a candidate for heart transplantation. Durable MCS devices designed for long-term support as a BTT and permit discharge from the hospital. Implantation of these types of MCS devices requires a major operative procedure usually including CPB and is ideal for patients who are hemodynamically stable with advanced symptoms and/or inotrope dependence in the absence of significant end-organ dysfunction or cardiogenic shock.

DT applies to hemodynamically stable patients with chronic refractory symptoms of advanced heart failure due to irreversible forms of cardiomyopathy, but who are not eligible for heart transplantation. These patients require long-term, durable, and reliable MCS devices permitting

patient mobility and discharge home.[2] Long-term, durable MCS devices are implantable and are ideally placed in patients with significant symptoms of advanced heart failure refractory to OMT but with stable hemodynamics. The survival, functional, and quality-of-life benefit of MCS for DT for the treatment of chronic advanced heart failure was established in a prospective, randomized trial known as the REMATCH Trial (Randomized Evaluation of Mechanical Assistance in the Treatment of Congestive Heart Failure).[2] This prospective, randomized trial evaluated the use of an implantable LVAD compared with OMT for refractory chronic advanced heart failure. LVAD therapy significantly reduced (relative risk, 0.52; 95% confidence limit, 0.34–0.78 at 1 year) the mortality seen in the control population treated with OMT at both 1-year and 2-year follow-up. Despite serious adverse events attributable to MCS from infection, bleeding, and device malfunction, LVAD recipients had an improved survival rate and experienced a superior quality of life compared to the medical therapy group. Currently, patients evaluated for DT must meet the following specific criteria: (1) New York Heart Association Class IV or American Heart Association Stage D heart failure symptoms; (2) a left ventricular ejection fraction of <25%; (3) a peak exercise oxygen consumption of <14 mL/kg/min (if unable to exercise be dependent on intravenous inotropes for 14 days or intra-aortic balloon pump therapy for 7 days); and (4) significant functional limitations despite the use of maximally tolerated doses of drugs outlined in the recent guidelines for heart failure treatment for at least 45 of the last 60 days.[3] The intended use and indication for MCS significantly influence MCS device selection and use and must be individualized.

TIMING OF MCS INTERVENTION

Cardiogenic Shock and Acute Heart Failure

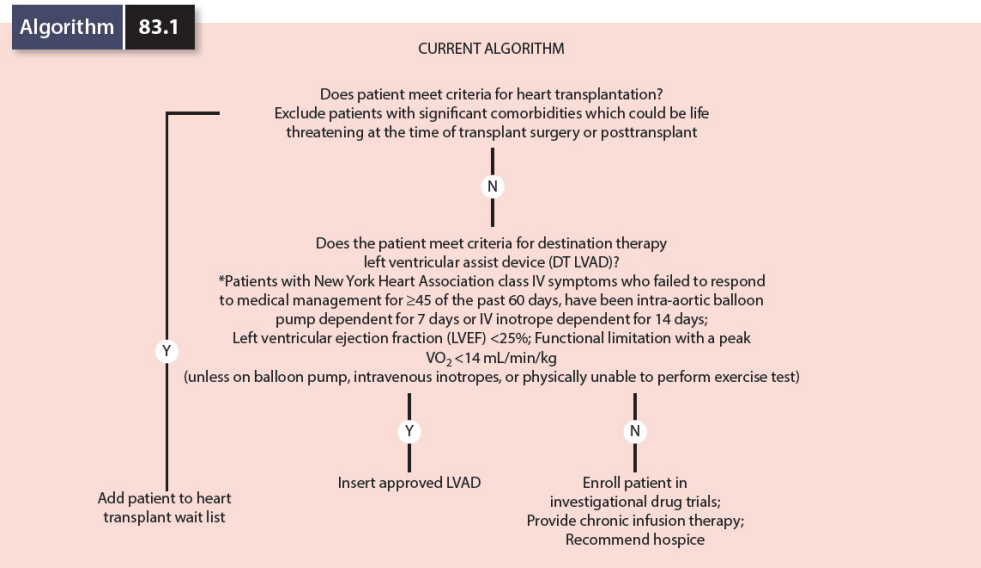
Criteria for initiation of MCS vary widely in clinical practice,[1] and the timing of implant is paramount and directly affects outcomes. Generally, patients presenting with acute forms of myocardial injury have recognizable hemodynamic changes—a cardiac index of less than 2.2 L/min/m^2, systolic blood pressure less than 90 mm Hg, pulmonary capillary wedge pressure

higher than 20 mm Hg, right atrial pressure higher than 18 mm Hg, and evidence of tissue malperfusion and multiorgan dysfunction, despite OMT. Patient history and overall clinical setting need to be considered in the decision to initiate MCS. When patients reach this degree of hemodynamic compromise, the mortality risk is substantial and frequently exceeds 50% at 30 days despite the availability of OMT, invasive circulatory monitoring, thrombolysis, and IABP support.[4,5] Data from the Abiomed BVS 5000 registry demonstrated that delay in initiating temporary MCS for more than 6 hours in the context of postcardiotomy shock or after failure to separate from CPB is associated with a significant decrease in survival rate; 44% versus 14%.[6] Delay in instituting any type of MCS with rapid progression of multiorgan failure increases the need for biventricular4 support as opposed to LVAD support alone.[7–11] Similarly, an episode of cardiac arrest prior to the initiation of MCS significantly impacts survival rate, decreasing it from 47% to only 7%.[6]

Chronic Heart Failure

Patients with chronic advanced heart failure are evaluated for BTT or DT MCS when they experience dyspnea at rest and/or with any effort and accompanied by resting tachycardia, progressive organ dysfunction (reflected in worsening renal or hepatic parameters), limited functional capacity, and poor quality of life despite OMT with or without inotrope therapy. Deterioration in end-organ function or progressive decline in functional performance may occur in the absence of a significant change in hemodynamic parameters due to chronic adaptation to low cardiac output. In addition, patients who experience renal insufficiency or hypotension in the setting of optimal doses of ACE inhibitors or beta blockers, as well as those who do not tolerate inotrope therapy due to refractory ventricular arrhythmias or have life-threatening coronary disease may benefit from MCS therapy (Algorithm 83.1). Dependence on intravenous inotropes has traditionally been considered the threshold that prompts consideration of MCS[12–14] (Fig. 83.4). However, patients with advanced systolic heart failure are currently eligible for DT therapy even if they are not dependent on inotropes, provided they meet indications for DT therapy. Only 18% of durable adult LVADs are currently implanted in patients not yet dependent on

intravenous inotropes.[12,13] Low implant rates in ambulatory advanced heart failure (noninotrope dependent) may reflect reluctance of both physicians and patients.[15] Ambulatory patients with advanced heart failure should have ongoing discussions about the trade-offs of living with heart failure in comparison with undergoing LVAD implantation to identify preferences and thresholds for considering elective LVAD therapy. Evidence to guide LVAD use before inotrope dependence is growing.[16]



Algorithm 83.1 Current algorithm for assessing patients with advanced heart failure for heart transplantation and mechanical circulatory support. Transplant status is initially assessed to determine appropriate indication for MCS use; BTT versus DT. (Adapted from Mancini D, Colombo PC. *J Am Coll Cardiol* 2015;65(23):2542–2555, with permission.)

PATIENT SELECTION AND INFLUENCE OF COMORBIDITIES ON OUTCOMES

Patient selection is paramount in determining outcome in patients requiring MCS. Relative contraindications to MCS include irreversible renal, hepatic or respiratory failure, sepsis, and/or a significant cognitive deficit.

Renal Function

MCS in the setting of renal dysfunction has consistently been associated with increased morbidity and mortality rates.[17,18] The patient's baseline renal function and the duration and chronicity of cardiogenic shock play an important role in predicting the probability of recovery of renal function. In some instances, reestablishing normal hemodynamics with short-term MCS facilitates resolution of the acute renal failure. Clinically, this may guide decisions for durable MCS options.

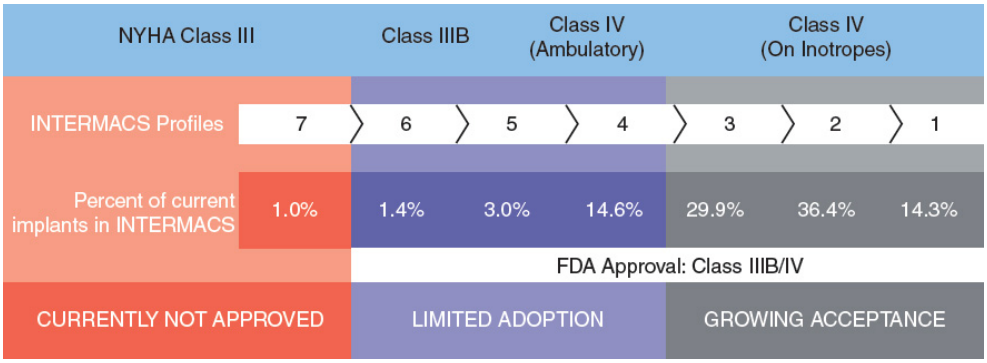


Figure 83.4 INTERMACS scale for classifying patients with advanced heart failure. Percent of implants by INTERMACS profile. Current U.S. Food and Drug Administration (FDA) approval status and acceptance in the medical community. (Adapted from Mancini D, Colombo PC. Left ventricular assist devices: a rapidly evolving alternative to transplant. *J Am Coll Cardiol* 2015;65(23):2542–2555, with permission.)

Pulmonary Function

Patients with a history of smoking and/or intrinsic lung disease identified by abnormalities on pulmonary function testing warrant high-resolution computed tomography (CT) to characterize the lung disease. Perioperative hypoxia related to lung disease may contribute to pulmonary vasoconstriction and worsening of right heart function. Moderate elevations of pulmonary vascular resistance encountered in patients with cardiogenic shock do not preclude the successful use of MCS if reversibility of the pulmonary vascular resistance can be achieved with inotropes or pulmonary vasodilators. Patients with severe pulmonary disease may have fixed high pulmonary vascular resistance (>8 Wood units), which represents an absolute contraindication to heart transplantation.

Liver Function

Total bilirubin and hepatic cellular enzyme levels more than three times normal are independent risk factors for adverse outcomes.[18,19] The etiology of the hyperbilirubinemia may be multifactorial, resulting from any combination of congestive hepatopathy, cholestasis, primary biliary, or infectious or parenchymal disease. Attempts should be made to normalize the liver function prior to initiation of durable MCS, as abnormal liver function often results in low serum albumin and abnormal coagulation. In our potential MCS patients we review for significant alcohol and drug use, and test for presence of hepatitis A, B, or C or other viruses. We obtain a CT of the chest, abdomen, and pelvis for surgical planning. If the liver is abnormal on CT, we utilize liver ultrasonography and/or magnetic resonance imaging to rule out infiltrative disease, mass or other pathology that may warrant biopsy. While permanent liver dysfunction may rule out durable MCS options, these same patients may in fact be candidates for multi-organ heart-liver transplantation.

Right Ventricular Heart Failure

Right ventricular (RV) heart failure presents as signs of renal, pulmonary, and hepatic dysfunction following LVAD implantation. It is a significant cause of mortality and morbidity, and often necessitates initiation of BiVAD support.[7–11,20–22] BiVAD support is associated with lower survival during both short- and long-term MCS. Thus, preoperative optimization of RV function with 5 a goal of lowering the right atrial pressure lower than 15 mm Hg is important in reducing the need for postoperative RVAD support. Patient selection is the most important factor in determining outcomes of those receiving MCS therapy.

Nutrition

Malnutrition is an important contributor to morbidity among patients on MCS. A serum albumin lower than 3.3 mg/dL appears to increase the mortality rate 6.6 times in the DT population of LVAD patients.[23,24] Significant nutritional deficiency is often associated with poor wound

healing, an increased risk of infection. Patients whose body mass index is either less than 22 or more than 36 are at risk for perioperative complications. In morbidly obese patients, some have described bariatric surgery as a means for weight reduction to bridge to transplantation.[25]

OTHER IMPORTANT MEDICAL CONSIDERATIONS WHEN INITIATING MCS

Valvular Heart Disease

Valvular heart disease can have important consequences in patients considered for MCS. In the aortic position, preexisting stenosis mild, moderate, and severe can left alone as it does not affect LVAD function. Severe aortic stenosis should be addressed if recovery is an option.[26] The presence of greater than mild aortic insufficiency can have a significant impact on the effectiveness of MCS therapy as it leads to recirculation, LV distention, decrease in subendocardial blood flow, and potentially decreased systemic forward flow and end-organ perfusion. The presence of aortic insufficiency can be confirmed by perioperative echocardiography and addressed by either AV replacement with a bioprosthesis, repair via a Park's Stitch, and/or complete closure.[27] Patients with a mechanical valve prosthesis in the aortic valve position should have the mechanical valve replaced with a bioprosthetic valve prior to institution of LV assistance. During unloading of the LV by an LVAD, the aortic valve may not open and a mechanical valve may be prone to thrombosis, potentially propagating clot in the aortic root, the coronaries, and potentially act as a nidus for stroke. Development of aortic insufficiency after LVAD implantation may be addressed at later date with aortic valve replacement, via either open surgical or transcatheter aortic valve replacement.[28,29]

Patients with significant mitral stenosis at the time of initiation of device support may require correction of the valvular problem before implantation, as LV filling is impaired which limits device filling. Mitral regurgitation likely does not have an impact on the filling of a VAD, and we do not routinely repair or replace the mitral valve in the setting of regurgitation. Multiples studies have shown that mitral valve intervention does not change

mortality, rates of right heart failure, and readmission rates.[30,31] Tricuspid regurgitation and RV dilatation contribute to elevated central venous pressure, hepatic congestion, and renal dysfunction.[20–22,32–34] Significant degrees of tricuspid regurgitation can impair the flow of blood from the RV through the pulmonary circuit. Studies that while CPB times were longer, there were no significant differences in early mortality and late mortality, early RV failure and late RV failure, acute kidney failure, early RV assist device implantation or length of hospital stay in patients undergoing LVAD + tricuspid valve surgery versus LVAD alone.[34] With that said, it is our practice to evaluate the tricuspid annular dimensions and perform an annuloplasty for moderate or more degrees of tricuspid regurgitation.

Coronary Artery Disease

The presence of coronary disease may contribute to ongoing myocardial ischemia and increase the risk of ventricular arrhythmias for patients supported with temporary or durable MCS. Perioperative ischemia of the RV may be of hemodynamic significance during initiation of LVAD support. In patients who have had coronary bypass surgery and are candidates for MCS, patent bypass grafts, particularly to the right coronary artery or left anterior descending coronary artery should be preserved to reduce the risk of perioperative RV failure and arrhythmias. In highly selected situations, it may be important to perform a coronary artery bypass to the right coronary artery or left anterior descending coronary artery systems to optimize RV or septal function in the perioperative period.

Arrhythmias

Atrial and ventricular arrhythmias are common in patients with cardiogenic shock and underlying cardiomyopathies. Early perioperative period, some patients with refractory ventricular arrhythmias may require biventricular support. In situations where weaning from MCS is feasible or planned, elimination of the ventricular arrhythmias with antiarrhythmic therapy is essential. The majority of patients undergoing implantation of a durable VAD have an implantable cardiac defibrillator (ICD) in place as part of their care for advanced heart failure. Currently, for those patients who do not have an

ICD at the time of VAD implant, the International Society for Heart and Lung Transplantation (ISHLT) guidelines recommend routine evaluation for ICD therapy.[35,36]

Intracardiac Shunts

Intracardiac shunts (atrial or ventricular septal defects) identified by transesophageal echocardiography prior to surgery should be closed at the time of implantation of a VAD to prevent right-to-left shunting.[37] As LV assistance is initiated, left atrial pressure can be reduced compared with right atrial pressures causing shunting of deoxygenated blood from the right atrium into the left resulting in systemic hypoxemia.

PATIENT OUTCOMES AND MAJOR ADVERSE EVENTS FOLLOWING INITIATION OF MCS

6 Bleeding, stroke and thromboembolism, infection, and RV failure are the most frequent complications that occur following initiation of MCS.

Bleeding

Bleeding is a frequent complication in patients supported by MCS. Risk factors for early bleeding include preoperative hepatic congestion and failure, poor preoperative nutritional status, prolonged CPB times, extensive surgical dissection, reoperative surgery, multiple cannulation sites, and decreased platelet function. Nonsurgical sources of bleeding are epistaxis, GI tract bleeding, bleeding of the mediastinum and thorax, and intracranial hemorrhage.[38–43] Some data demonstrate patients supported with long-term durable MCS have acquired von Willebrand disease caused by high shear stresses within continuous-flow rotary pumps.[41–42] These bleeding episodes manifest at mucosal sites including gastrointestinal bleeding and epistaxis and appears to accentuate previous subclinical arteriovenous malformations.[44,45]

RV Failure

RV failure occurs in approximately 3% to 30% of patients supported by LVAD support alone. The large variation in occurrence of RV failure is dependent on various patient factors including severity of illness and timing of intervention. The etiology of RV failure is multifactorial and includes pathologies within the pulmonary vascular bed and/or RV. Factors contributing to RV failure include impaired RV function as a result of intraoperative air embolism, myocardial stunning due to poor intraoperative myocardial protection, ischemia secondary to coronary artery disease, arrhythmias, volume loading, and alteration of RV septal geometry induced by LV unloading. Several studies have demonstrated that factors such as elevated central venous pressure, reduced RV stroke work index, low preoperative pulmonary artery pressures, increased transpulmonary gradient greater than 16 mm Hg, acute decrease in pulmonary artery pressures equal to or greater than 10 mm Hg at the onset of LVAD support, degree of preoperative pulmonary edema, increased need for perioperative transfusions, increasing degree of renal and hepatic dysfunction, female gender, nonischemic etiology, and preoperative temporary MCS support, all increase the need for RV MCS following LVAD implantation.[7–11,20–22] Data analysis revealed that a central venous pressure/pulmonary capillary wedge pressure ratio greater than 0.63, need for preoperative ventilator support, and blood urea nitrogen level higher than 39 mg/dL were independent predictors of right-sided heart failure after LVAD implantation.[20] Acute unloading of the LV by MCS may cause the septum to shift leftward, increasing RV volume loading and reducing its function.[21,22,46] The negative consequences of this phenomenon may be offset by the reduction in pulmonary artery pressures and RV afterload caused by device-mediated LV decompression.[21,22,46] Hemodynamic stability can be attained with isolated mechanical LV support in the overwhelming majority of patients, even in those patients with substantial RV dysfunction, if there is effective replacement of left-sided heart function and aggressive treatment of pulmonary hypertension. More recently, the improved perioperative management of elevated pulmonary vascular resistance including the use of inhaled nitric oxide and/or flolan, in combination with milrinone, isoproterenol, or dobutamine has significantly reduced the need for placement of an RVAD.[46] In patients with marked

elevation of central venous pressure, multiorgan failure, and severe RV dysfunction with low pulmonary artery pressures, early biventricular support may be indicated.[46]

Intracranial Bleeding and Thromboembolism

Cerebral vascular accidents are one of the most feared complications of MCS. The reported rates of hemorrhagic stroke range from 0.01 to 0.08 events per patient-year.[45] The occurrence of thromboembolic events following MCS is variable and depends on a number of factors including the type of device, duration of support, location and number of cannulation sites, and the presence of prosthetic valves within the heart. Approximately 10% of patients receiving MCS with implantable devices will experience a thromboembolic event or stroke.[23,45,47] This rate is in the range of 20% for patients on short-term extracorporeal MCS devices.[1] Hemorrhagic stroke rates have been improved with guided blood pressure control protocols[48] Improvement in the rate of thromboembolic events has come from more aggressive antiplatelet therapy in conjunction with warfarin, in addition to improved device design. In MOMENTUM 3, where patients with axial and centrifugal continuous-flow devices were prospectively compared, the numbers of events per patient-year for stroke of any severity, major bleeding, and gastrointestinal hemorrhage were lower in the centrifugal-flow pump group than in the axial-flow pump group.[49]

Infection

Infections can be device-related (i.e., device endocarditis, percutaneous lead or cannula site infection, pocket infection [infection external to an implanted device]) or non–device-related (i.e., pneumonia and urinary tract infection). The incidence of early nosocomial device-related infections in patients undergoing MCS is approximately 30% in many series and is related to the acuity of illness in this population of patients.[50–55] Patients with persistent or recurrent sepsis, and those patients with device-related infections, tend to have a higher mortality rate than patients without these complications.[55] In patients on long-term MCS, infection remains an important obstacle to successful outcome.[55] Most of these late infections begin in the percutaneous

driveline tract and pocket of the device. However, clinical experience has revealed that VAD infection rates can be minimized with attention to infection control guidelines, optimal implantation techniques, meticulous wound care, and the utilization of new continuous-flow rotary pump technology.[55] The risk factors for development of infection include preoperative infection at remote sites (not in the area of implantation), malnutrition, prolonged hospitalization, immobilization, broad-spectrum antibiotic therapy, immunosuppressive medications, mechanical ventilation, and the presence of central venous catheters. Device-related infections can sometimes be successfully treated with antibiotic suppression and device exchange or removal. Patients who are device-dependent and awaiting transplantation generally cannot tolerate device removal as a therapeutic option to eradicate the infection. Antibiotic suppression and transplantation remain the only chance for cure of device-related infections in these instances.

Device Malfunction and Thrombosis

The types and severity of device malfunctions vary with each MCS device. Many devices have built-in backup systems that, in the event of catastrophic device failure, provide some support to the patient. In some instances, patients supported by an LVAD have enough residual LV function remaining to help sustain them until corrective measures can be taken in the event of complete device failure. Fortunately, the reported frequency of this event is low.[23] Device malfunctions in TAHs are more problematic as there is no native heart to provide hemodynamic support in the event of a total device failure.

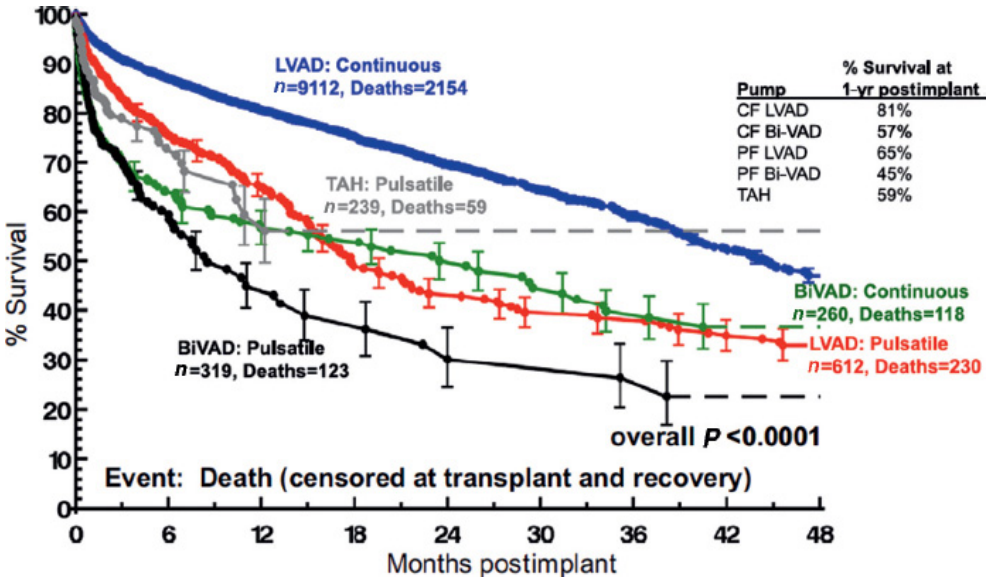

Figure 83.5 Actuarial survival for primary device implant, stratified by device type. Error bars indicate ± 1 SE. Patients are censored at transplant and recovery. CF, continuous flow; LVAD, left ventricular assist device; PF, pulsatile flow; TAH, total artificial heart. (From Kirklin JK, Naftel DC, Pagani FD, et al. Sixth INTERMACS annual report: a 10,000-patient database. *J Heart Lung Transplant* 2014;33:1304–1311, with permission.)

Pump thrombosis is potentially a catastrophic complication of VAD therapy. The variability in clinical presentation makes it a challenging diagnosis. It occurs both early and late after VAD implantation and may manifest itself with increased pump power, decreased device flow with heart failure, and hemolysis with hemoglobinuria or with embolic event. Serum lactate dehydrogenase level is as the primary biochemical marker of hemolysis in this clinical context. Clinically suspected thrombosis can be managed medically by intravenous anticoagulation, antiplatelet agents, or thrombolytics in some cases. Surgical treatment by pump explantation and pump replacement and/or urgent heart transplantation is generally indicated.

The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) Database

7 The INTERMACS registry represents one of the largest available data repositories for the study of durable MCS device outcomes. The most recent INTERMACS database annual report summarizes outcomes in patients (≥19 years of age) who underwent durable MCS implant between June 23, 2006, and December 31, 2017. There were 25,145 adult patients with MCS

reported, of whom 18,539 (74%) received CF LVADs, 667 (2.6%) had an RVAD with CF LVAD, 339 received a total artificial heart (1.3%), and 20 (0.07%) received an isolated RVAD. CF LVADs included 14,527 axial flow (78%) and 4,012 centrifugal flow (22%) devices. Mean CF LVAD support duration was 20 months (31,563 patient-years). One-year survival for isolated CF LVADs was 83% and 5-year survival was 46%. One-year survivals for centrifugal versus axial flow devices were 85% and 84%, respectively. Patients who required concomitant RVAD support had 1- and 5-year survivals of 58% and 28%, respectively.[12,13,56] The actuarial survival for primary device implant as stratified by device type is summarized in Figure 83.5. Figure 83.6 displays the actuarial survival for primary continuous-flow devices as stratified by strategy at implant. The survival analysis for patients on mechanical circulatory support stratified by INTERMACS profile is presented in Figure 83.7. On January 1, 2018, the INTERMACS Database became part of The Society of Thoracic Surgeons National Database.[13] Table 83.1 exhibits MCS device implants by implant era and indication for implantation.

WEANING PATIENTS FROM MCS

Weaning Short-Term MCS

A number of factors are considered when weaning patients from MCS. Optimization of volume status, afterload, cardiac rhythm, and degree of inotropic support as well as exclusion of obvious surgical pathology, such as tamponade, is paramount before attempting separation from MCS. In addition, extracardiac causes, such as pulmonary edema, elevated pulmonary vascular resistance, acute respiratory distress syndrome, and pneumonia, may worsen RV function and prevent successful weaning from MCS. Once a patient's status has been optimized, weaning from MCS aided with echocardiographic monitoring is preferred. As device flows are reduced, echocardiogram provides information on ventricular filling and performance and valve function. If patients maintain satisfactory hemodynamics with reduction of pump flow, they can be considered for weaning. In the setting of biventricular support, it is important that device flows on the right side be

reduced before lowering left-sided device flows. This prevents pulmonary edema in the event of inadequate LV function. As device flows are reduced, native heart function begins to support the circulation. When weaning from MCS is not possible, patients should be evaluated for heart transplantation and/or bridged to a durable MCS device.

Sixth INTERMACS annual report: a 10,000-patient database. *J Heart Lung Transplant* 2014;33:1304–1311, with permission.)

Weaning Long-Term MCS

Observations from the cumulative experience with long-term MCS for BTT and recent small clinical studies have demonstrated that long-term MCS, associated with sustained mechanical unloading of the LV, can improve myocardial function even in those patients initially thought to have irreversible, dilated cardiomyopathies.[57–59] Several studies have demonstrated that long-term MCS can restore ventricular geometry, improve myocyte function, orientation, and size, reduce myocyte apoptosis, reduce myocardial cytokine gene and protein expression, reverse abnormal neurohormonal patterns associated with advanced heart failure, and improve myocardial mitochondrial function.[57–59]

MCS DEVICES

The devices currently approved by the FDA are broadly grouped into two categories based on durability and the intended length of support and use.

Devices Intended for Short-Term MCS (Temporary Devices)

IABP

Since its first reported clinical use by Kantrowitz in 1968, the IABP has become the most frequently utilized MCS device (Fig. 83.8).[60] The IABP is positioned within the descending thoracic aorta, augmenting ventricular performance and cardiac output increasing diastolic coronary blood flow, decreasing myocardial oxygen consumption, and reducing left ventricular afterload. Inflation of the balloon during diastole increases diastolic pressure and coronary blood flow and deflation of the balloon during systole reduces arterial afterload facilitating LV ejection. Although the IABP has been the mainstay of circulatory support for decades, the utility of IABP in cardiogenic shock complicating acute myocardial infarction was recently challenged by the results of the SHOCK-IABP Trial, and SHOCK-IABP II Trial.[61–63] These prospective studies randomized patients to IABP counterpulsation or no IABP counterpulsation in addition to revascularization and OMT. Both studies revealed no difference in 30-day mortality, length of stay in the intensive care unit, serum lactate level, incidence of renal failure, or duration of catecholamine therapy.[61–63] In the long-term follow-up, IABP has no effect on all-cause mortality at 6-year long-term follow-up. Mortality is still very high, with two-thirds of patients with cardiogenic shock dying despite contemporary treatment with revascularization therapy.[63] Complications from the use of the IABP include leg ischemia, balloon rupture, infection, bleeding, false aneurysm formation, femoral neuropathy, vessel perforation with hemorrhage, and aortic dissection. Female gender, peripheral vascular disease, diabetes, smoking, advanced age, obesity, and cardiogenic shock are predisposing factors for tissue malperfusion and limb ischemia.

Table 83.1 MCS Device Implants by Implant Era and Indications for MCS Device Implantation in the INTERMACS Registry

Device Strategy at the Time of Implant	Implant Date Era							
	2006–2007		2008–2010		2011–2013		Total	
	n	%	*n*	%	*n*	%	*n*	%
BTT listed	185	42.4	1,335	39.2	1,453	21.7	2,973	28.2
BTT likely	85	19.5	884	26.0	1,474	22.0	2,443	23.2

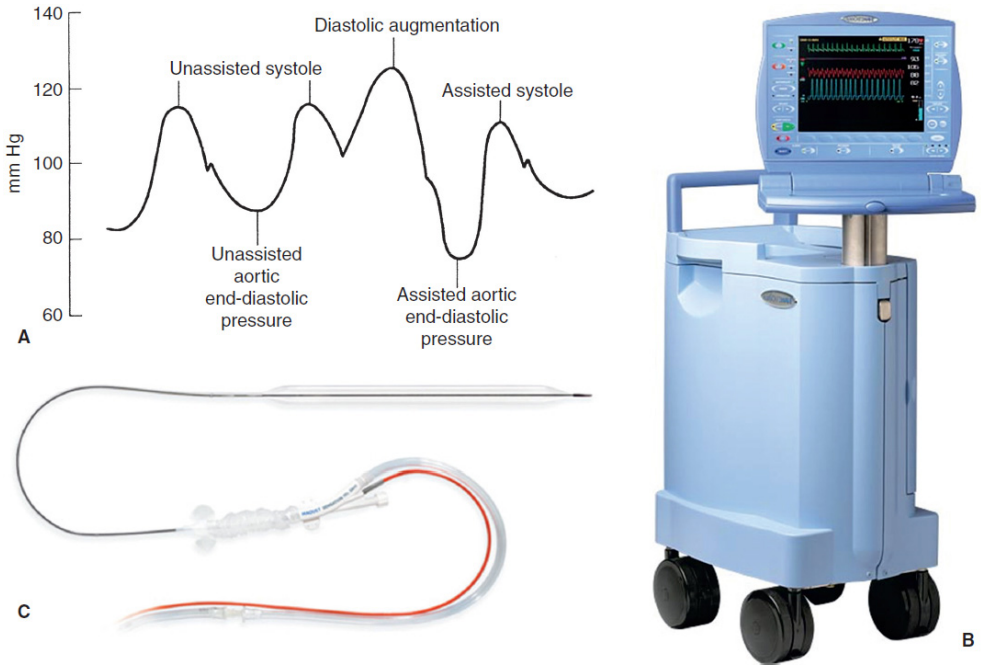

Figure 83.8 Intra-aortic balloon pump. **A:** Aortic pressure tracing during intra-aortic balloon pump support. Balloon counterpulsation is occurring after every other heartbeat (1:2 counterpulsation). With correct timing, balloon inflation (IP) begins immediately after aortic valve closure, signaled by the dicrotic notch of the arterial waveform. Compared with unassisted ejection, the pump augments diastolic blood flow by increasing peak aortic pressure during diastole. Balloon deflation before systole decreases ventricular afterload, with lower aortic end-diastolic pressure and lower peak systolic pressure. **B:** Console for the intra-aortic balloon pump. **C:** Catheter-mounted balloon is positioned within the thoracic aorta through a percutaneous or surgical approach via the femoral artery. Impella

Impella (Abiomed Corporation, Danvers, MA) is a continuous-flow rotary pump with axial design that propels blood from the LV across the aortic valve and into the ascending aorta[64,65] (Fig. 83.10). It is available in four delivery platforms for LV support including Impella LP 2.5, Impella CP, Impella LP 5.0, and Impella 5.5 with smart assist system and the Impella RP, a system uniquely designed for RV support. The LVAD is positioned across the aortic valve with the inlet port below and outlet above the aortic valve. The hemodynamic effects of Impella devices are based on LV unloading and augmentation of forward flow. This reduces myocardial oxygen consumption, improves mean arterial blood pressure, and reduces pulmonary capillary wedge pressure.[66] In a prospective, randomized clinical trial comparing the

Impella LP2.5 to IABP, cardiac index was significantly increased in patients with the LP2.5 compared with patients supported with an IABP. Overall mortality rate at 30 days 8 was similar in both groups.[64] The Impella RP (Fig. 83.9) is a novel RVAD designed using the Impella system but adapted for RV support. The major technologic advances in device designs for temporary and durable MCS devices have incorporated continuous-flow rotary pumps.

Tandem Heart

The Tandem Heart/Life Sparc (LivaNova, London, England) is a low-speed continuous-flow, centrifugal device MCS. With its most recent hardware upgrade in the LifeSparc design, the pump can now flow up to 8 L/min. The percutaneous cannulation strategy originated as a transseptal approach for left atrial-to-femoral artery VAD[67] (Fig. 83.10). Hemodynamic effects of this device are based on the parallel flow contribution to the aorta of both the device and the LV itself. This results in reduction of LV preload, myocardial oxygen consumption, filling pressures, and ventricular wall stress.[68] Protek Duo is a multilumen cannula that has been utilized as an RVAD. It is usually inserted through the right internal jugular vein or the left subclavian vein, with proximal ports in the right atrial and distal port in the distal main pulmonary artery. More recently, some groups[69] have described utilization of the Protek Duo Rapid Deployment in left apical cannulation to function as temporary LVAD.

The CentriMag can provide univentricular or biventricular support. **A:** The CentriMag console (background) and pump/motor (foreground). **B:** Schematic representation of the CentriMag pump. The rotor located within the upper pump housing is magnetically coupled to the lower motor housing to produce rotor levitation and spin. (Photograph courtesy of Levitronix LLC, Waltham, MA.)

CentriMag

The CentriMag (Abbot Laboratories, Chicago, IL) is an extracorporeal, continuous-flow centrifugal pump[70,71] (Fig. 83.11) based on a magnetically levitated "bearingless motor" design. This device can produce flows of up to 10 L/min under normal physiologic conditions, and can used as the pump with various cannulation strategies to support the left, or right ventricle.

Extracorporeal Life Support

Extracorporeal life support, or extracorporeal membrane oxygenation, is a temporary form of MCS similar to CPB that provides circulatory assistance while allowing for both oxygenation and carbon dioxide removal from blood.[72–79] ECLS has been used in a variety of both pediatric and adult clinical settings, including respiratory support, postcardiotomy support, and as a bridge to an LVAD or heart and/or lung transplantation.[76]

In venoarterial ECLS, the blood is drained from the venous circulation, oxygenated, and returned to the arterial circulation. Although it does reduce LV preload by decreasing the pulmonary venous return, ECLS does not directly unload the LV. In patients with severe LV dysfunction, the use of an

IABP and catecholamines helps reduce LV afterload and improves myocardial contractility, thus preventing blood stasis and thrombus formation within the LV. If LV function is so severely reduced that there is essentially no ejection, an atrial septostomy or insertion of a left ventricular vent can be inserted to relieve LV distention, a potential cause of pulmonary edema.

Venovenous ECLS, unlike venoarterial ECLS, maintains flow through the heart and is used solely for oxygenation and ventilation pulmonary support. Current ECLS circuits are typically composed of a centrifugal pump with membrane oxygenator, oxygen blender, pump console, heat exchanger, and pump cart. The CardioHelp (Maquet Cardiopulmonary GmbH, Rastatt, Germany) is a compact, portable unit useful due to the relative ease of transport and initiation. Gray and colleagues[76] at the University of Michigan reported on the outcome of 2,000 patients supported with ECLS from 1973 through 2010. Of the 2,000 patients, 74% were weaned from ECLS and 64% survived to hospital discharge. In patients with respiratory failure, survival to hospital discharge was 84% in 799 neonates, 76% in 239 children, and 50% in 353 adults. Survival in patients with cardiac failure was 45% in 361 children and 38% in 119 adults. ECLS during extracorporeal cardiopulmonary resuscitation was performed in 129 patients, with 41% surviving to discharge.

Implantable Devices Intended for Durable MCS

Historical Perspective

The majority of patients receiving long-term MCS in the 1990s and early 2000s were supported by devices engineered with pulsatile, volume displacement designs. A critical limitation of these devices were the large pump size restricting mobility, and the requirement for extensive surgical dissection for implant leading to bleeding and infection complications, both of which contributed to the high incidence of device malfunction.[80] These first-generation devices, now obsolete in clinical practice in favor of smaller, continuous-centrifugal-flow MCS device designs.

Implantable, Axial, Continuous-Flow MCS Devices

Implantable, continuous-flow, rotary pumps with axial or centrifugal blood flow design represent a new generation of implantable VAD technology that have now completely replaced pulsatile devices for long-term MCS indications.[23,47–49,81,82]

HeartMate II

The HeartMate II LVAD (Abbot Laboratories, Chicago, IL)[23,47–49,81] (Fig. 83.12) is a continuous-flow rotary pump with axial design and mechanical bearing support of the internal impeller. The sealed inflow conduit of the pump is attached to the apex of the LV and the pump-sealed outflow graft is connected to the ascending aorta, creating a circuit parallel to the native circulation. The percutaneous driveline transmits commands and power from the external System Controller and power source to the LVAD itself. The HeartMate II was approved for BTT therapy in 2008 and for DT in 2010. In a prospective, multicenter, controlled study of HeartMate II as BTT the overall survival rate for the patients who continued on LVAD support was 82% (95% confidence interval [CI]: 77% to 87%) at 6 months, 73% (95% CI: 66% to 80%) at 1 year, and 72% (95% CI: 65% to 79%) at 18 months. The most common adverse effects were bleeding, stroke, infection, and neurocognitive dysfunction, while sepsis and stroke were the primary causes of mortality. The randomized, prospective, multicenter HeartMate II Pivotal Trial for DT followed patients implanted with HeartMate II or HeartMate XVE. The primary composite end-point was reached in more patients in the study group than in the control group (46% vs. 11%; hazard ratio, 0.38; 95% CI, 0.27 to 0.54; p <0.001).[23,47,81] The HeartMate II population experienced higher actuarial survival rates and lower rates of pump replacement for malfunction and thrombosis, infection, renal failure, RV failure, respiratory failure, and arrhythmias. Both groups experienced significant improvement in functional capacity and overall quality of life.[83]

Implantable, Centrifugal, Continuous-Flow MCS Devices

Although significant improvements in pump design have occurred with continuous-flow rotary pumps, the use of a mechanical bearing support for the internal impeller, typical of most axial designs, has potential limitations. The presence of motor-suspending contact bearings in the blood path represents a potential point of frictional wear that can result in device failure and subsequent need for device exchange.[82,84,85] Rotary pumps with axial design with bearing support still demonstrate the potential for thrombus formation on the device rotor and bearing interface due to the presence of stasis and incomplete "wash" of the bearings and formation of heat from frictional at the bearing surfaces.[86,87] The major feature of current designs are the impeller rotation and levitation with magnetic and/or hydrodynamic forces, which eliminate the need for bearings and the subsequent bearing

associated problems, enabling the potential for very long term durability[81,83,84,88,90] (Fig. 83.13).

HVAD

The HVAD (Medtronic, Minneapolis, Minnesota) is a small continuous-flow rotary pump with centrifugal and noncontact bearing design. The unique feature of the HVAD is its small design size[81,90,91] (Fig. 83.14). It has a flow capacity of up to 10 L/min, and is designed for intrapericardial placement. The HVAD is approved for use in the United States for BTT and DT indications. The ADVANCE trial was a prospective, evaluation of the HVAD for BTT indication in the United States.[90] The success primary outcome, was defined as survival on the originally implanted device, transplantation, or explantation for ventricular recovery at 180 days. Secondary outcomes included a comparison of survival between groups and functional and quality-of-life outcomes and adverse events in the investigational device group. Success occurred in 90.7% of investigational pump patients and 90.1% of controls, establishing the noninferiority of the investigational pump ($p < 0.001$; 15% noninferiority margin). Kaplan–Meier survival estimates at 30, 60, 180, and 360 days were 99%, 96%, 94%, and 86%, respectively, for the investigational device group and 97%, 95%, 90%, and 85%, respectively, for the INTERMACS control group. Bleeding, infections, and perioperative right-sided heart failure were the most frequent complications. Inotropic support for greater than 14 days was required by 16.4% of patients. Driveline exit site infections and sepsis occurred in 12.1% and 11.4% of recipients, respectively. The ENDURANCE Trial prospectively compared DT LVAD patients and found centrifugal-flow LVAD was noninferior to an axial-flow LVAD with respect to survival free from disabling stroke or device removal for malfunction or failure.[91] Subsequently, the ENDURANCE Supplemental Trial followed to evaluate the primary end-point of 12-month incidence of transient ischemic attack or stroke with residual deficit 24 weeks post-event. While enhanced blood pressure protocol significantly reduced mean arterial blood pressure, the primary endpoint was not achieved (14.7% with HVAD vs. 12.1% with control, noninferiority [margin 6%], $p = 0.14$).[48]

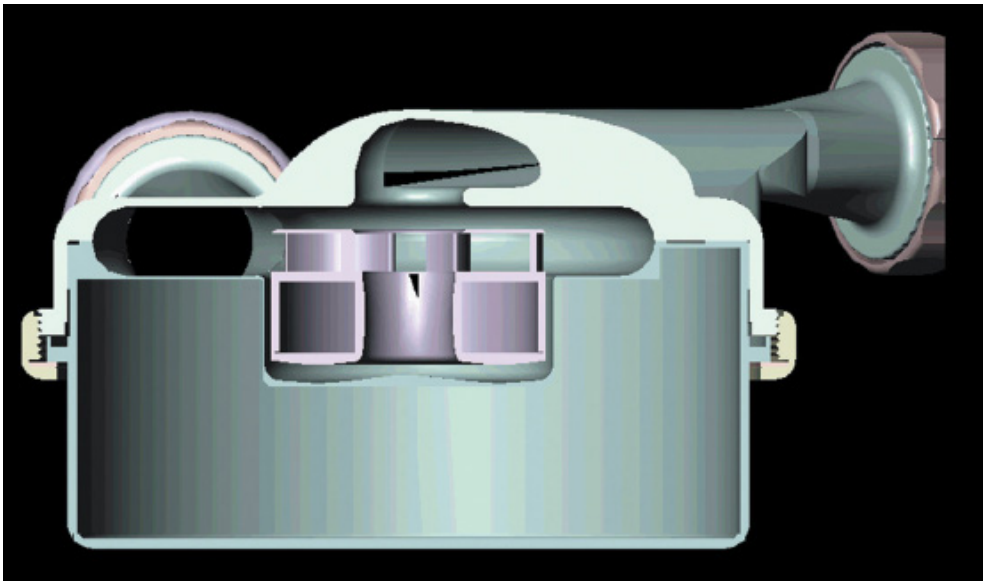

Figure 83.13 Schematic representation of a continuous-flow rotary pump utilizing magnetic coupling of the internal impeller for levitation and rotation that obviates the need for bearings in the blood flow path.

The device incorporates passive magnetic and hydrodynamic forces for impeller levitation and rotation. **B:** Schematic representation of the HVAD with the inlet cannula inserted into the apex of the left ventricle. The outflow cannulae and graft are anastomosed to the ascending aorta. (Photograph courtesy of Medtronic, Minneapolis, MN.)

HeartMate III

The HeartMate III LVAD (Abbot Laboratories, Chicago, IL) is intrapericardial-positioned continuous-flow rotary pump with centrifugal design[88] (Fig. 83.15). The unique feature of the HeartMate III is the full magnetic levitation of the internal rotor. The design differs from currently used devices due to active control of rotation and levitation of the rotor that permits impellor movement further away from the outer housing creating larger gaps for blood flow within the device. The larger gaps may reduce blood component trauma and improve biocompatibility. MOMENTUM 3 was a prospective randomized trial comparing axial continuous-flow LVAD to centrifugal-continuous-flow LVAD. The final analysis of 1,028 patients, the primary end-point (alive and free of disabling stroke or reoperation to replace or remove a malfunctioning device at 2 years) was 64.8% in the axial-flow pump group as compared to 76.9% in the centrifugal-flow pump group, demonstrating superiority ($p < 0.001$). Furthermore, the numbers of events per patient-year for stroke of any severity, major bleeding, and gastrointestinal hemorrhage were lower in the centrifugal-flow pump group than in the axial-flow pump group.[49]

MVAD

The MVAD (Medtronic, Minneapolis, MN) is a novel continuous-axial-flow pump, approximately one-third the size of the HVAD (Fig. 83.16).[92] The contactless impeller suspension technology has a single moving part—the rotor, secured in place by a combination of passive-magnetic and hydrodynamic forces. Urban and colleagues highlighted the first-in-man implantation of a HeartWare MVAD and reported excellent results after more than 2 years of support. The European MVAD clinical trial for MVAD enrolled 11 patients beginning in July 2015, but was stopped in August 2016 due to controller issues. During that stoppage there were 4 pump thrombus events, but no patient has had a neurologic event. Currently, 5 patients have undergone successful transplantation, 3 remain on MVAD support at 27 to 28 months, 2 underwent exchange to an HVAD system, and 1 died. Since cessation of the clinical trial, improvements to the original MVAD system have been identified and will be reintroduced in the future.[93]

Total Artificial Heart

Syncardia Total Artificial Heart

The Syncardia TAH-t (SynCardia Systems Corporation, Tucson, AZ) is a pulsatile, volume displacement, TAH[94–98] (Fig. 83.17). The rigid polyurethane pump contains a flexible polyurethane diaphragm that separates blood and air chambers. Two mechanical valves located at the inflow and outflow orifices ensure unidirectional blood flow. Compressed air from the external drive console moves the diaphragm upward, pressurizing the blood chamber and causing ejection of blood. The pump has a maximum stroke volume of 70 mL and a maximum flow rate of 15 L/min, although the average flow rate is <8 L/min. Pump rate, duration of systole, and driving pressure can be adjusted to achieve optimal flow conditions. The TAH is surgically implanted in the mediastinal space after the ventricles have been excised, while the atrial cuffs are retained. The pneumatic drivelines are externalized percutaneously and attached to the drive console. Ambulation is facilitated by small portable drive systems and consoles. The Syncardia TAH-t is approved by the FDA for bridge to heart transplant indication. Copeland and colleagues reported a survival rate of 79% to heart transplantation compared with 46% for the observational arm, with one-year posttransplant survival rate was 86%.[95] The SynCardia TAH-t has now been implanted in more than 1,100 patients in approximately 100 centers in North America, Western Europe, Russia, Turkey, Israel, and Australia. To date, the longest duration of support has been 3.75 years, in a man who has since survived after transplantation. More than 47 patients have survived for longer than 1 year of support, and 72% of those underwent transplantation.[98]

FUTURE DIRECTIONS

Recent rapid technologic advancements and successful clinical applications of MCS have made the future of this field optimistic, but uncertain. Areas of continued research include the use of wireless energy transfer to facilitate complete internalization of MCS devices, application of less invasive surgical techniques for device implantation, application of MCS devices for the pediatric population, partial support devices and device designs, and new materials to improve compatibility of the blood–device interface to reduce thromboembolic complications and need for anticoagulation. It is possible that long-term MCS will provide a viable alternative to heart transplantation and medical therapy for patients with advanced heart failure.

Pericardium

Jules Lin

Key Points

1. Prompt recognition and treatment of cardiac tamponade can be lifesaving.
2. The echocardiogram is the most useful noninvasive test in evaluating pericardial disease.
3. The electrocardiogram is important in the diagnosis of acute pericarditis and classically shows diffuse ST elevations.
4. The hemodynamic significance of a pericardial effusion depends on the volume and the rate of accumulation.
5. Postoperative tamponade should always be in the differential diagnosis with low cardiac output after cardiac surgery.
6. Distinguishing constrictive pericarditis from restrictive cardiomyopathy can be difficult but is important since the treatment is significantly different.
7. Metastatic disease is the most common cause of pericardial effusion.
