Gut peptides have diverse metabolic functions including regulating satiety and hunger within the hypothalamic feeding center, and include glucagon-like peptide 1 (GLP-1), cholecystokinin, ghrelin, oxyntomodulin, pancreatic polypeptide, and amylin. Drugs based on these mediators show promise. Many gut peptides have short biologic half-lives and research has focused on long-acting analogs or mediators that target degradation pathways. GLP-1, secreted by ileal L cells in response to a meal, induces satiety and potentiates insulin secretion and peripheral insulin sensitivity. Long-acting GLP-1 analogs, including liraglutide (Victoza) and exenatide (Byetta), are FDA approved for treatment of type 2 diabetes and are under investigation as primary weight loss agents.[18] Ghrelin is an orexigenic hormone secreted by gastric fundus mucosal cells, and ghrelin antagonists, agonists of ghrelin degradation pathways, and antighrelin vaccines are in development. Amylin, released by pancreatic beta cells, induces satiety via CNS-based mechanisms and also potentiates peripheral insulin resistance; pramlintide (Symlin), a human amylin agonist, is approved for treatment of diabetes and induces modest weight loss. Orlistat (Xenical), approved by FDA in 1999, is a pancreatic lipase inhibitor that blocks intestinal absorption of fat, and the only drug to date that functions by reducing absorption of ingested calories. Side effects of orlistat include diarrhea, steatorrhea, and increased risks of kidney stones and pancreatitis. Second-generation lipase inhibitors are in development.

Agents designed to manipulate neuropeptide signaling within the hypothalamus, while not yet approved for use in humans, are important targets, and include drugs directed toward leptin, melanocortin-4 receptor (MC4R), neuropeptide Y, and melanin-concentrating hormone. While leptin resistance has confounded development of leptin as a therapeutic agent, recent data from animal models suggest that concomitant treatment of endoplasmic reticulum stress may abrogate leptin resistance,[19] while separate research demonstrates that amylin agonists also restore leptin sensitivity.[20] These lines of research have reinvigorated interest in leptin therapy. Mutations in the MC4R gene, a central hypothalamic satiety mediator, are implicated in up to 5% of cases of common human obesity, and MC4R agonists are currently in development. Other central-acting agents are directed toward endocannabinoid signaling: rimonabant (Acomplia), a selective endocannabinoid antagonist, was denied FDA approval in 2008 despite promising weight loss results in clinical trials due to an association with depression and suicide, but interest in manipulation of endocannabinoid signaling persists.

Manipulation of thermogenesis and metabolic rate remains an active field of research. Thyroid hormone achieves weight loss by increasing metabolic rate, but is associated with cardiac toxicity and has detrimental effects on glucose homeostasis. Despite these failures, research persists. Many agents discussed above that regulate food intake, most notably the sympathomimetics, also increase metabolic rate, and it is unclear to what extent these effects contribute to weight loss. Agents that regulate steroid metabolism, fatty acid oxidation and other aspects of adipose tissue, and skeletal muscle metabolism are under study. Dietary constituents also regulate thermogenesis, including methylxanthines (e.g., caffeine), polyphenols (e.g., resveratrol, quercetin), capsaicinoids (found in chili peppers and mustards), and medium-chain fatty acids, all of which represent potential therapeutic agents.

Overall efficacy of current obesity pharmacotherapy is modest, achieving weight loss of 3% to 10% of total body weight. Most agents demonstrate synergy with lifestyle interventions. Current drugs approved by the FDA specifically for weight loss include orlistat, the only drug approved for long-term use; phentermine, approved for short-term use (<12 weeks) due to addiction potential and cardiovascular toxicity; phentermine/topiramate, and liraglutide, a GLP-1 agonist. The XENDOS study (XENical in the Prevention of Diabetes in Obese Subjects) randomized 3,305 patients to lifestyle intervention combined with either orlistat or placebo and at 4 years, and demonstrated a 5.8-kg weight loss in the orlistat arm compared with a 3.0-kg weight loss in the placebo arm, as well as a reduced incidence of diabetes with orlistat therapy.[21] Lorcaserin-induced 5% weight loss compared with 3% in placebo-treated patients at 1 year.[22] The phentermine/topiramate combination drug achieved 10.5% weight loss compared with 1.8% in placebo-treated patients at 2-year follow-up.[23]

A complete summary of obesity pharmacotherapy is beyond the scope of this chapter, which has by necessity omitted important areas of research, including drugs that target steroid metabolism, lipid metabolism, adipocyte differentiation and proliferation, and efforts to shift white adipose tissue toward a brown adipose tissue phenotype (the "browning" of adipose tissue). This discussion has focused on agents designed to treat obesity directly with the goal of weight loss, but an important parallel class of drugs target metabolic disease independent of or in conjunction with weight loss. The activities of weight loss drugs are complex and overlapping, with many agents regulating body weight and metabolism via multiple mechanisms. Multiple redundancies in the regulation of energy homeostasis suggest that drug combinations will enhance efficacy. As an understanding of these mechanisms increases, safe and effective pharmacotherapy for obesity and metabolic disease will emerge.

SURGICAL MANAGEMENT

Bariatric Surgery—Beginnings

5 In contrast to lifestyle interventions and pharmacotherapy, surgical management of obesity is highly efficacious. Modern bariatric surgery (Gr. *baros,* heavy, burden) is the result of over a half century of evolution in surgical technique that has its genesis in the 1940–50s with experiments in animals and isolated operations in humans that employed small intestinal resection and jejunocolic and ileocolic bypasses of various anatomic configurations. These operations involved substantial morbidity and did not achieve widespread acceptance, but set the stage for development of the *jejunoileal bypass,* the first bariatric operation to be widely applied in humans. Jejunoileal bypass involved division of the jejunum 14 in distal to the ligament of Treitz and creation of a jejunoileostomy 4 in proximal to the ileocecal valve, and was thus referred to as a "14–4 bypass." In 1969, Payne and DeWind[24] published the first report describing long-term clinical outcomes in a large group of patients who underwent jejunoileal bypass in the 1950–60s, describing dramatic weight loss ("A total of 10,373 pounds have been lost by the [80] patients") along with improvements in insulin resistance, hypercholesterolemia, and hepatic steatosis. Jejunoileal bypass was widely used throughout the 1960s and early 1970s.

Despite its efficacy, as experience accumulated, it became clear that jejunoileal bypass was associated with significant morbidity. Diarrhea, steatorrhea, dehydration, electrolyte imbalances, and micro- and macronutrient deficiencies resulted from the highly malabsorptive nature of the operation. Patients also suffered a host of complications not obviously linked to malabsorption, including liver disease, nephropathy, arthropathy, neuropathy, and myopathy. While the cause of these latter complications was not completely clear, an immune response directed toward bacterial overgrowth in the blind intestinal limb was implicated. Overall morbidity afflicted as many as 70% of patients and led to abandonment of jejunoileal bypass by the late 1970s. Nonetheless, up to 30% of patients achieved good results, and the clinician may still encounter rare remaining patients. Indications for reversal or conversion to modern bariatric operations are not well established and must be considered on an individual basis,

but include progressive liver or kidney disease not attributable to other causes. Some clinicians advocate reversal and conversion to a modern bariatric operation in all patients who are good operative candidates regardless of the presence or absence of complications.

Gastric Bypass

With the decline of jejunoileal bypass, surgeons began searching for alternatives. In the 1960s, Edward Mason at the University of Iowa experimented with operations based on observations that patients who underwent gastric resections for ulcer disease had difficulty maintaining their weight. Mason's efforts led to the development of the *gastric bypass,* for which he earned the title "father of bariatric surgery." Mason's original gastric bypass consisted of a pouch gastroplasty with a loop gastrojejunostomy reconstruction. Gastric bypass subsequently evolved through a number of iterations, all with important clinical implications. Large horizontal fundal-based pouches were replaced with smaller vertical lesser curve–based pouches, which improve gastric emptying. Undivided gastric pouches were associated with high rates of staple-line dehiscence and gastrogastric fistula, and were replaced with divided gastric bypass, expedited by the development of cutting staplers. Roux-en-Y reconstruction, compared to loop reconstruction, reduces tension on the gastrojejunal anastomosis and prevents bile reflux gastritis, but may be associated with higher rates of anastomotic ulcer disease. Retrocolic Roux limbs may improve pouch emptying and generate less tension on the gastrojejunostomy, but at the price of higher rates of mesocolic internal hernias. Banding of the gastrojejunal anastomosis may increase weight loss, but also increases risks of stenosis, obstruction, and erosion. Variations persist, including retrocolic Roux limbs, loop reconstructions ("minigastric bypass"), and prosthetic-banded gastric pouches. The modern gastric bypass practiced by the majority of surgeons today consists of a divided, unbanded, lesser curve-based pouch gastroplasty of 15 to 30 cc with an antecolic Roux-en-Y gastrojejunal reconstruction with a 100- to 150-cm Roux/alimentary limb and a 50- to 100-cm afferent/biliopancreatic limb (**Fig. 46.1**). The modern gastric bypass is a robust operation because within limits, subtle variations in technique, including pouch size and morphology and intestinal limb length and position, do not greatly affect efficacy or morbidity. Gastric bypass remains, as of this writing, the dominant bariatric operation worldwide and the gold standard against which all other operations are measured.

Malabsorption Revisited

Despite the failure of jejunoileal bypass, interest in operations that relied on small intestine bypass persisted. *Biliopancreatic diversion* consists of an antrectomy with a gastrojejunostomy and distal Roux-en-Y jejunoileostomy. The *duodenal switch modification of the biliopancreatic diversion* involves a sleeve gastrectomy, division of the duodenum distal to the pylorus, and a duodenojejunostomy and distal Roux-en-Y jejunoileostomy, thus maintaining the pylorus in the alimentary stream (**Fig. 46.2**). Biliopancreatic diversion/duodenal switch differs from jejunoileal bypass in two important regards. First, maintenance of forward flow of biliopancreatic effluent in the bypassed afferent limb prevents stasis and bacterial overgrowth. Second, common channel length was increased to 100 cm, reducing malabsorptive complications. Biliopancreatic diversion/duodenal switch provides weight loss and metabolic disease remission equivalent to, and in many series, greater than gastric bypass. Morbidity and mortality for biliopancreatic diversion/duodenal switch span a wide range, with centers with significant expertise reporting low rates similar to gastric bypass. Nonetheless, when the literature as a whole is considered, biliopancreatic diversion/duodenal switch is associated with higher morbidity and mortality than gastric bypass. Perioperative mortality reported by meta-analyses is at least twofold higher than gastric bypass, possibly due to a higher risk of anastomotic dehiscence, as laparoscopic creation of the duodenojejunal anastomosis associated with the duodenal switch modification is technically challenging.[25] Late malabsorptive complications which may require surgical revision, while much improved over jejunoileal bypass, range from 2% to 20%. Unlike gastric bypass, in which small changes in pouch size or limb length do not substantially alter clinical outcome, outcomes of biliopancreatic diversion/duodenal switch are relatively sensitive to differences in efferent limb length, small changes in which may make the difference between poor weight loss and malabsorptive complications. Predicting the correct efferent limb length for an individual patient is challenging. Most surgeons advocate a fixed length of 100 cm, while others advocate an ad hoc limb length proportional to total small intestine length. While advocated by select surgeons and associated with good outcomes in centers with significant experience, biliopancreatic diversion/duodenal switch is nonetheless waning in use, currently comprising less than 2% of bariatric operations. This is often reserved as a revisional option for those with insufficient weight loss following sleeve gastrectomy.

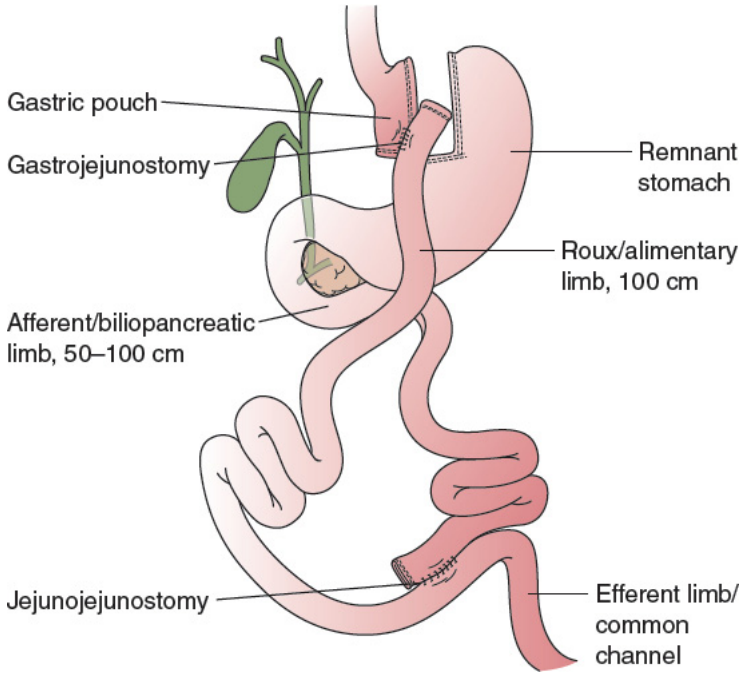

Figure 46.1 Anatomy of modern Roux-en-Y gastric bypass. Modern gastric bypass consists of a divided pouch gastroplasty with Roux-en-Y jejunojejunal reconstruction. The Roux limb is most commonly placed in the antecolic position. Intestinal limbs are termed with either standard Roux (Roux, afferent, efferent) or bariatric (alimentary, biliopancreatic, common channel) nomenclature as shown.

Pure Restriction

In Mason's era, morbidity from gastric bypass was not trivial. In an effort to design a simpler and safer operation, Mason experimented with gastroplasties that precluded the need for small intestinal reconstruction. Like gastric bypass, these operations evolved through a number of iterations, eventually leading to the modern *vertical banded gastroplasty,* which involves creation of a partitioned upper stomach pouch with a prosthetic band restricting pouch outlet diameter. Vertical banded gastroplasty achieved widespread acceptance and peaked in the 1970–80s. Vertical banded gastroplasty weight loss is substantially less and late weight regain substantially greater compared to gastric bypass, however, and vertical banded gastroplasty has therefore been relegated to a minority operation that is rapidly being eliminated from use.

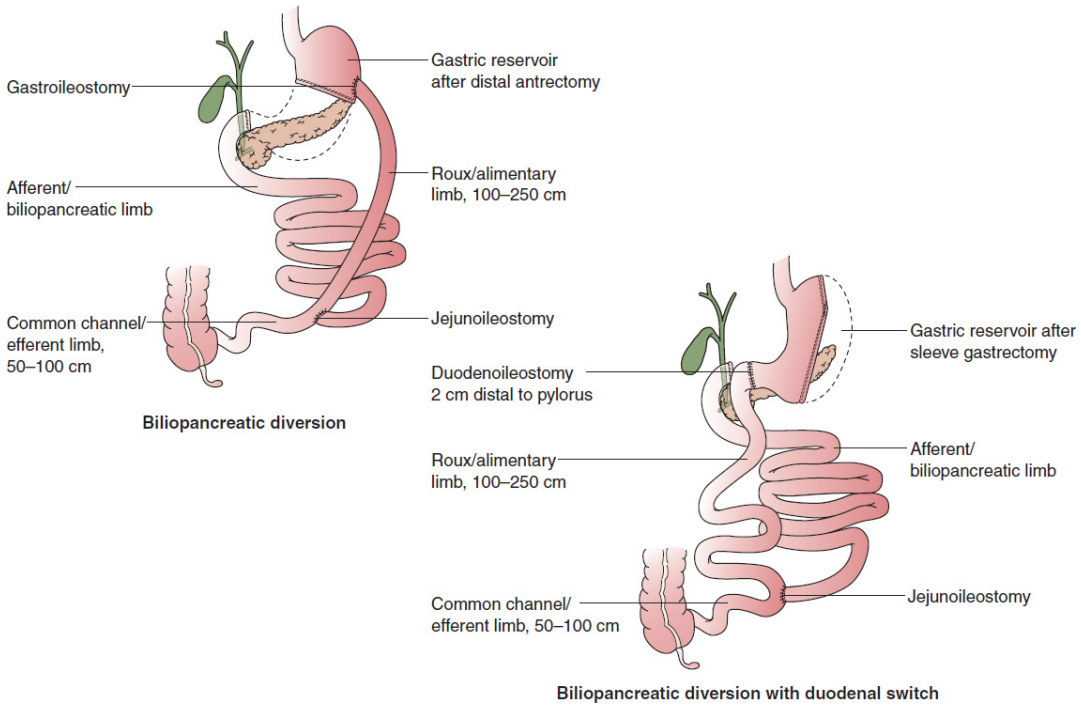

Figure 46.2 Biliopancreatic diversion (BPD). BPD involves a distal antrectomy with a Roux-en-Y jejunoileal reconstruction; BPD+DS involves a sleeve gastrectomy with a Roux-en-Y duodenoileal reconstruction, with the duodenoileostomy created 2 cm distal to the pylorus, thus preserving the pyloric emptying mechanism. Note that, unlike JIBP, the afferent/biliopancreatic jejunoileal limb is in continuity with biliopancreatic effluent, reducing limb stasis.

Study of prosthetic bands applied to the upper stomach to limit food intake began in the late 1970s using devices made from Prolene, Marlex, and other materials. These devices were nonadjustable and plagued with complications related to erosion, migration, stenosis, and obstruction. Efforts persisted, eventually culminating in the modern *adjustable gastric band,* a silicone device that was FDA approved in the United States in 2001 (**Fig. 46.3**). A primary advantage of gastric band is its technical simplicity and low rates of major morbidity and mortality. Unlike gastric bypass, which continues to be associated with low but finite rates of anastomotic dehiscence and mortality, gastric band is associated with 5 to 10 lower rates of life-threatening complications and mortality. Much enthusiasm accompanied the introduction of gastric band in the late 1990s, but over the past decade, enthusiasm has waned for two reasons. First, therapeutic efficacy of gastric band in the majority of patients is substantially less than gastric bypass. Second, as years passed, late complication rates have increased. These complications, including band slippage, erosion, and esophageal dilation and development of gastroesophageal reflux disease (GERD), are usually not life-threatening, but range between 10% and 50% and often lead to band removal.[26] Despite these problems, gastric band efficacy, while not as high as gastric bypass, is acceptable. Gastric band remains the bariatric operation with the lowest major morbidity and mortality rates, an appealing quality for risk-averse patients. Gastric band does not require Roux-en-Y reconstruction, an advantage in patients with complex abdominal surgical histories. However, given the known late term complications and availability of sleeve gastrectomy, gastric bands have fallen out of favor and as of 2018 comprise only 1.1% of bariatric operations.[27]

Sleeve gastrectomy was introduced initially as a component of the duodenal switch modification of biliopancreatic diversion, but did not gain significant attention as a stand-alone bariatric operation until the early 2000s. Sleeve gastrectomy involves a lateral gastrectomy, leaving a narrow "sleeve" of stomach 32 to 40 Fr in diameter (**Fig. 46.4**). Originally proposed as the first step in a staged approach for high BMI patients prior to definitive gastric bypass, early follow-up data demonstrated excellent results, and long-term efficacy appears similar to gastric bypass. Sleeve gastrectomy is associated with perioperative complication rates similar to gastric bypass, but late complications are rare, in part due to elimination of morbidity associated with alterations in small intestinal anatomy. For these reasons, sleeve gastrectomy has engendered significant enthusiasm and is now the most commonly performed primary bariatric procedure.[27]

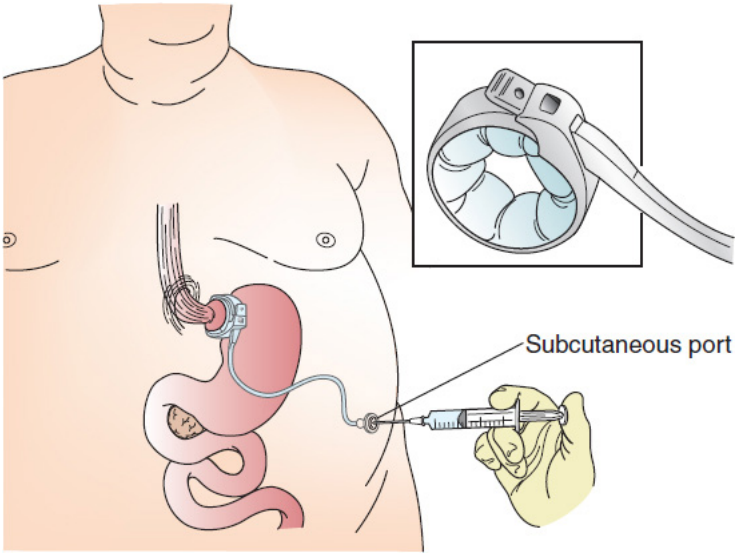

Figure 46.3 Gastric band. A silicone adjustable band is positioned around the upper stomach, creating a gastric pouch. A port attached to the band via silicone tubing is placed in the subcutaneous tissue in the abdominal wall, permitting percutaneous access and adjustment of band diameter.

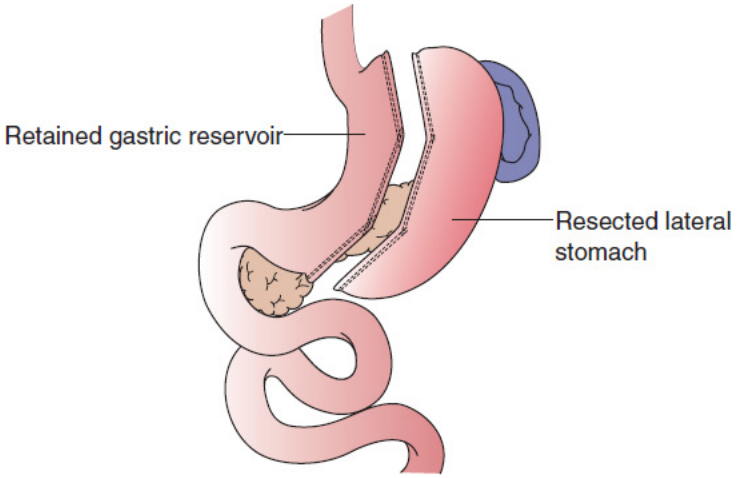

Figure 46.4 Sleeve gastrectomy. A lateral gastrectomy is performed with a linear cutting stapler, creating narrow gastric reservoir 32 to 40 Fr in diameter.

Endoscopic bariatric procedures have recently emerged as attractive interventions for weight management as they are low risk, reversible and potentially applicable to the population who are not candidates for bariatric surgery. In recent years, the Food and Drug Administration has approved several devices with gastric balloon systems the most widely adopted. Gastric balloon systems are intended as restrictive devices that take up space in the stomach. Results vary; however, randomized control trials demonstrate improved excess and total body weight loss (TWL) as compared to sham or diet and exercise alone. This weight loss, however, is much lower than with a bariatric operative procedure. Weight loss at 9 months is reported at up to 26% *excess weight lost* (EWL) and 8.8%TWL.[28] Enthusiasm for these devices has also been dampened due to questions on long-term sustainability of weight loss and emerging safety concerns. The endoscopic sleeve gastrectomy is another novel procedure where an endoscopic suturing device is used to place stitches on the inside of the stomach to reduce its size. Early data demonstrate this procedure as safe and effective, with weight loss outcomes up to 18% EWL. While promising, these procedures should be used in select patients and should not be used in lieu of bariatric surgical procedures where indicated.[29]

Epidemiology of Modern Bariatric Surgery

As of 2017, approximately 228,000 bariatric procedures were performed per year in the United States. Currently, sleeve gastrectomy accounts for the vast majority of primary bariatric procedures at 60%. Gastric bypass accounts for 18% of all procedures and the gastric band and duodenal switch each account for less than 3%. Revisions of bariatric procedures either for complication or weight recidivism have dramatically increased in recent time. In the last 3 years, approximately 14% all bariatric procedures were revisions.[27] The characteristics of the patient population undergoing bariatric surgery have also changed over the past two decades. Nationally representative data show that the mean age increased from 38.9 years in 1993 to 44.4 years in 2016 ($p < 0.001$).[3] Additionally, the proportion of male patients (15.3% to 20.4%), patients who self-identified as Black (11.6% to 17.7%) or Hispanic (1.4% to 13.7%), and those with Medicaid (8.1% to 17.2%) or Medicare insurance (5% to 14.2%) increased significantly. Low socioeconomic status is a documented risk factor for reduced access to bariatric surgery, although recent expansion of Medicaid has attenuated this problem in the United States. Rates of bariatric procedures are also increasing in adolescents, although the total number remains small at approximately 220 cases in 2016.[27,30–32]

While robust data support bariatric and metabolic surgery as the most-effective long-term treatment for severe obesity and associated metabolic conditions, fewer than 1% of eligible persons undergo surgery. Clinician and patient concerns persist about the safety and durability of these operations, and some continue to question whether the short- and long-term risks outweigh the benefits. Many of these concerns stem from a checkered history of poor patient outcomes, unacceptable mortality rates, and poor long-term outcomes when the procedure started gaining traction in the 1990s. With the introduction of laparoscopy, attention to technique and education, options for less morbid procedures such as the adjustable gastric band, and accreditation programs requiring outcome reporting to a national registry and multidisciplinary team review, bariatric surgery is now among the safest operations performed.

Eligibility

In 1991 National Institutes of Health (NIH) guidelines recommended that the surgical treatment for obesity should be reserved for persons with a BMI ≥ 40 kg/m^2 or ≥35 kg/m^2 with serious obesity-related co-morbid condition.[27] These guidelines are still widely used by insurers to determine eligibility for surgery; however, there is growing evidence that bariatric procedures should also be considered for patients with lower BMI (30.0 to 34.9 kg/m^2) and type II diabetes if hyperglycemia is inadequately controlled despite optimal medical treatment.[33] Recent guidelines also recommend the need for separate cut-off limits for Asian populations, and recommend consideration of surgery for BMI ≥35 kg/m^2 regardless of the existence of comorbidities and BMI ≥35 kg/m^2 with the existence of a comorbid condition.[34] All persons who meet the BMI threshold should be further evaluated with a thorough history and physical to mitigate and optimize comorbid conditions, nutritional and psychological evaluation. Patients may be contraindicated for bariatric surgery if they have severe heart failure, unstable coronary artery disease, end-stage lung disease, active or recent history of cancer, cirrhosis with portal hypertension, uncontrolled drug or alcohol dependency, unstable psychiatric disorders, Crohn disease, severely impaired intellectual capacity, or if they are pregnant or planning to become pregnant within the next 1 to 2 years.[35]

Efficacy

Bariatric surgery achieves dramatic results. Weight loss was commonly reported as a percentage of EWL, defined as the difference between presurgical weight and ideal weight, with ideal weight calculated for BMI = 25 for height. Of note, there has been a recent effort to standardize weight loss reporting as percent TWL, total pounds lost divided but initial weight, to align with the medical literature, as TWL is less dependent than EWL on initial BMI.[36] Weight loss typically peaks 1 to 2 years after surgery and may approach 70% to 90% EWL, followed by partial weight regain at 3 to 10 years after surgery, leading to a plateau at 50% to 70% EWL at long-term follow-up.[36–66] The mechanisms underlying this weight loss pattern are unknown but may involve development of adaptive eating patterns that increase caloric intake over time. For gastric band, weight loss is typically slower and more gradual, with a plateau after 2 to 3 years. These varying patterns of weight loss complicate comparison of results of different operations and analysis of published data due to variable length of follow-up among studies. Analysis is further complicated by significant attrition of patients over long-term follow-up in most studies. Despite these challenges, meta-analyses, controlled trials, and uncontrolled case series provide estimates of the efficacy of bariatric operations (**Table 46.1**). Weight loss is highest for biliopancreatic diversion/duodenal switch, ranging from 55% to 75% EWL, followed by gastric bypass and sleeve gastrectomy (50% to 70% EWL) and gastric band (40% to 60% EWL).[36–38]

Table 46.1 Bariatric Surgery Long-Term Weight Loss Responses. Short-Term Comparative Outcomes at 2 Years

	RYGB	SG	BPD/DS
Weight Loss			
% EBWL	61.4–79.8 (21,22,32, 34,115)	60.8–77.8 (32,34,115)	65.1–69.4 (21,25)
% EBMIL	74.7–84.8 (3,19–22,33)	72.1–74.7 (11,33)	76.1–85.0 (16,21,25)
% TBWL	21.0–37.4 (19–22)	23.4–34.1 (23,24)	33.8–36.7 (21,25)
Comorbidities			
Diabetes remission; %	66.7–75.0 (21,69,70)	35.0–41.0 (70,71)	95.0–100 (21,69)
Hypertension remission; %	53.0–65.4 (75)	54.0–72.0 (36,37)	49.3–76.0 (37,76)
Dyslipidemia remission; %	52.0–57.0 (75,77)	60.0–65.2 (36,82)	70.0–92.1 (76,77)
GERD remission; %	61.0 (77)	77.4 (36)	48.0 (77)
OSA remission; %	29.0–100.0 (19,28,33, 35–39)	56.2–100.0 (19,28,33, 35–39)	80.0–100.0 (19,28,33, 35–39)

RYGB indicates Roux-en-Y gastric bypass; SG, sleeve gastrectomy; BPD/DS, biliopancreatic diversion with/without duodenal switch; % EBWL, percent excess body weight loss; % EBMIL, percent excess body mass index loss; % TBWL, percent total body weight loss; GERD, gastroesophageal reflux disease; OSA, obstructive sleep apnea.

Rates of improvement and remission of metabolic diseases parallel weight loss, with gastric bypass, sleeve gastrectomy, and biliopancreatic diversion/duodenal switch associated with higher remission rates than gastric band. Diabetes, steatosis, sleep apnea, hypertension, and hyperlipidemia improvement/remission rates range from 60% to over 90% (**Table 46.1**). Weight loss is durable, lasting decades in most patients, and accompanied by marked reductions in long-term incident diabetes, cardiovascular disease, and cancer, increased quality of life, reduced long-term healthcare costs, and a 25% to 40% reduction in long-term mortality. Currently 12 randomized controlled trials have been published and demonstrate that bariatric surgery is substantially more efficacious than medical therapy for weight loss and diabetes, and multiple medical societies, including the American Diabetes Association, the International Diabetes Federation, and the American Heart Association, endorse bariatric surgery as treatment for metabolic disease.[36–66]

Despite its efficacy, results of bariatric surgery are variable, with a substantial minority of patients achieving significantly better than average weight loss and disease response rates, while a similar minority experience suboptimal results. Anywhere from 10% to 30% of patients achieve <50% EWL, which may be due to insufficient initial weight loss, or weight regain after a period of adequate weight loss. Mechanisms underlying insufficient weight loss are poorly defined, and identification of accurate predictors of response to surgery is an important area of research.[43] While suboptimal results are often attributed to lack of patient compliance with postoperative diet and exercise, these arguments ring false, echoing similar arguments that attribute obesity itself to a lack of "willpower." Instead, compeling evidence implicates genetic and epigenetic mechanisms. Like obesity itself, responses to bariatric surgery are highly hereditable. Ethnicity is a predictor of outcome, with Caucasians and Hispanics experiencing greater weight loss than Blacks and Asians. Multiple single-nucleotide polymorphisms have been

linked to surgical outcome. Future research will identify clinical and genetic predictors of response and permit optimization of allocation of surgical resources (**Table 46.2**).[36–66]

Perioperative Mortality and Morbidity

Morbidity and mortality associated with bariatric surgery have decreased over the past two decades as surgeon experience increased 6 and techniques evolved. Currently, gastric bypass and sleeve gastrectomy are associated with mortality risks similar to hip replacement, Perioperative mortality is high-est for biliopancreatic diversion/duodenal switch, followed by gastric bypass and sleeve gastrectomy, then gastric band (**Table 46.3**).[67–76] Life-threatening perioperative morbidity associated with gastric bypass and sleeve gastrectomy consists primarily of anastomotic dehiscence, staple-line leaks, hemorrhage, thromboembolic events, and cardiac events. Life-threatening perioperative morbidity associated with gastric band is rare and consists primarily of gastric perforation, thromboembolic events, and cardiac events.

The most dire perioperative complication of gastric bypass is anastomotic dehiscence of the gastrojejunostomy which usually occurs within 2 weeks of surgery. Incidences in most series range from 0.1% to 4%, although recent data suggest that anastomotic dehiscence rates are decreasing and high-volume centers report rates in the range of 0.1% to 0.2%. Signs and symptoms are similar to those of anastomotic dehiscence after any intestinal operation, but may be less apparent in the obese. Persistent tachycardia and abdominal pain are important but nonspecific sentinel signs. Upper GI radiographs may be of diagnostic utility but lack sensitivity. Abdominal CT scan, even within a few days of surgery, may be useful, as the lack of a fluid collection near the gastrojejunostomy has a high negative predictive value for leak, while contrast extravasation has a high positive predictive value. Nonetheless, data are conflicting regarding the sensitivity and specificity of radiologic studies for diagnosing anastomotic dehiscence, and laparoscopic reexploration should be employed aggressively in suspected cases. Operative management consists of washout, wide drainage, judicious attempt at repair, and consideration of distal enteral access, usually with a gastrostomy tube in the remnant stomach, although a jejunostomy tube in the distal Roux limb or biliary limb is an option if access to the remnant stomach is difficult. Anastomotic dehiscence can be managed laparoscopically in some cases, reducing the high risk of ventral hernia associated with laparotomy. Most will heal if sepsis is controlled. Endoscopic management of anastomotic dehiscence with suture, over-the-scope clipping systems, and endoscopic esophageal stent placement may also be employed for appropriate patients by advanced endoscopists with the appropriate skill set and training.

Staple-line leaks are an equally dire event after sleeve gastrectomy, occurring anywhere from 1 to 2 weeks to many months after surgery. Leaks may occur at any point along the staple line, but when involving the thicker tissue of the antrum may be less prone to heal, and interval conversion to gastric bypass with resection of the involved portion of gastric sleeve may be necessary. Depending on the acuity and location of the leak and the clinical status of the patient, a wide variety of options may be used to manage sleeve leaks. Options range from nasogastric tube feeding and antibiotics with or without external drainage, to endoscopic interventions such as those mentioned above as well as internal drainage with a pigtail catheter, to operative intervention with wide drainage and potential conversion to RYGB. For chronic leaks that have matured and contain a fibrous septum, endoscopic septotomy has demonstrated reasonable success for definitive treatment. Proper stapler selection and use during primary operation with avoidance of overly narrow sleeves (current consensus recommends 32- to 40-Fr diameter) may reduce the risk of sleeve gastrectomy staple-line leaks, which currently occur with an incidence of approximately 1% to 3%. Gastric band is only rarely associated with perioperative septic complications, most often in the form of gastric perforation, which occurs in 0% to 0.5% of cases. Perforation, if not recognized, may be life-threatening and is a primary cause of rare perioperative mortality and major morbidity after gastric band.

RYGB, Roux-en-Y gastric bypass; SG, sleeve gastrectomy; BPD/DS, biliopancreatic diversion with/without duodenal switch; VTE, venous thromboembolism; SBO, small bowel obstruction; PNA, pneumonia; SSI, surgical site infection.

Perioperative hemorrhage after gastric bypass occurs with an incidence of 1% to 4%, often originating from staple lines, and may be intraperitoneal or intraluminal. Intraluminal bleeding presents with melena and is often self-limited, requiring only transfusion and observation. Infrequently, endoscopic or operative intervention may be necessary. Hemorrhage after sleeve gastrectomy ranges from 1% to 4%, is usually intraperitoneal from the gastric staple line, and may require operative intervention, although observation in the hemodynamically stable patient is a reasonable initial course. Early small bowel obstruction, and thromboembolic, pulmonary, and cardiac events comprise the majority of the remainder of acute postoperative complications after bariatric surgery. Pathophysiology is not substantially different than after nonbariatric GI operations, although the obese may be at higher risk, reinforcing the importance of preoperative evaluation and preparation.

Late Morbidity

Late morbidity after bariatric surgery is similar to that associated with complex nonbariatric GI operations, may occur months or years later, and often presents with abdominal pain. Gallbladder disease and small bowel obstruction from adhesions and ventral/trocar hernias may occur after all bariatric operations. Other complications are operation specific. While definitions vary, overall late morbidity rates for gastric bypass range from 5% to 10%.

Many late complications of gastric bypass result from Roux-en-Y anatomy. Internal hernias occur in 0.5% to 9% of patients, and are categorized as mesenteric (common to all Roux-en-Y reconstructions, in which bowel passes through the mesenteric split in the Roux limb), mesocolic (specific to retrocolic reconstructions, in which bowel passes through the mesocolic defect created for the Roux limb), and Petersen (more often associated with antecolic than retrocolic reconstructions, in which bowel passes under the Roux limb and its mesentery) (**Fig. 46.5**).[67] Closure of internal hernia defects at primary operation is straightforward and recommended, and recent meta-analyses suggest that this practice likely reduces internal hernia rates, but does not obviate the future risk of hernia.[67] Patients often present years after surgery with a history of severe episodic abdominal pain. Diagnosis may be challenging, as obstipation may be absent and imaging normal even in the face of incarceration, especially if the biliopancreatic limb, which is out of continuity with the alimentary stream, is involved. A low threshold for operative exploration must be maintained in any patient with unrelenting abdominal pain after gastric bypass. Operative reduction and closure of internal hernia defects can usually be performed via a laparoscopic approach.

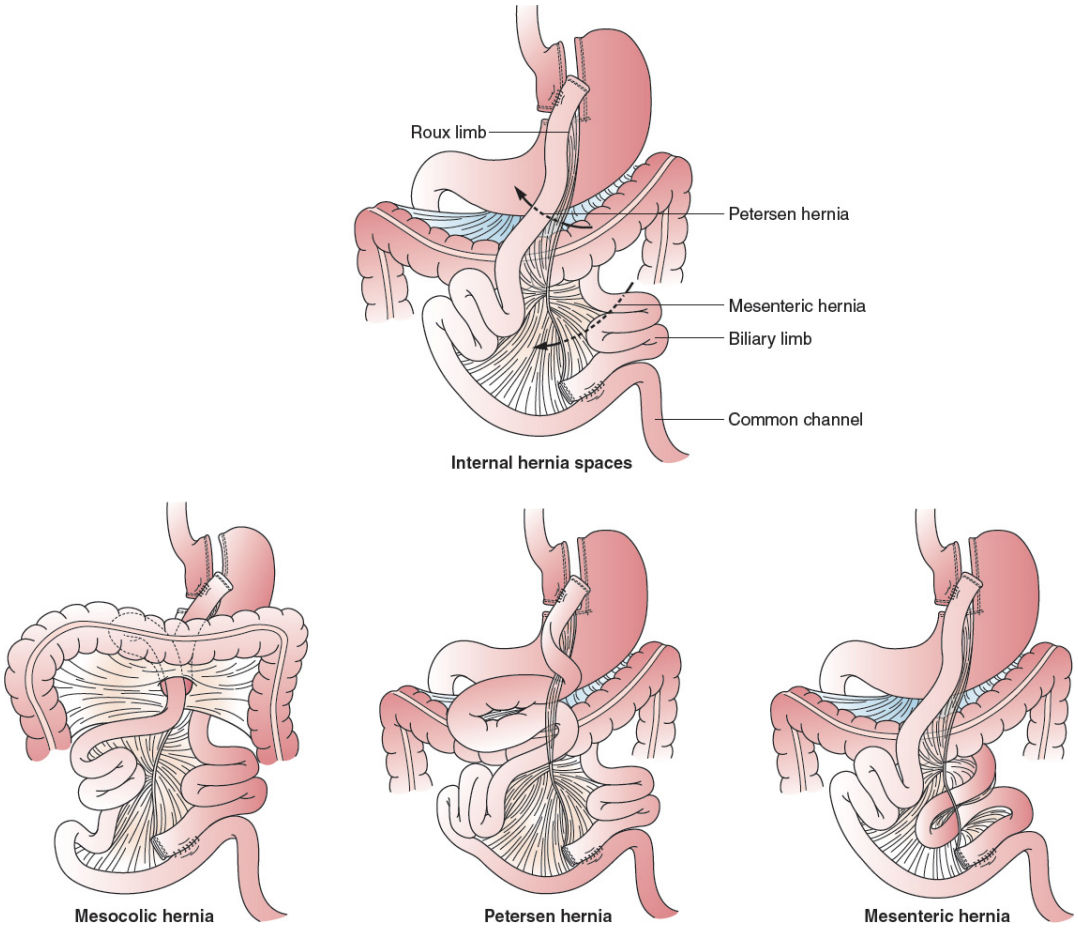

Figure 46.5 Internal hernias. Internal hernias may occur after any Roux-en-Y reconstruction, and include mesenteric, Petersen, and mesocolic hernias. Weight loss after gastric bypass and loss of adipose tissue in the intestinal mesentery may predispose to internal herniation.

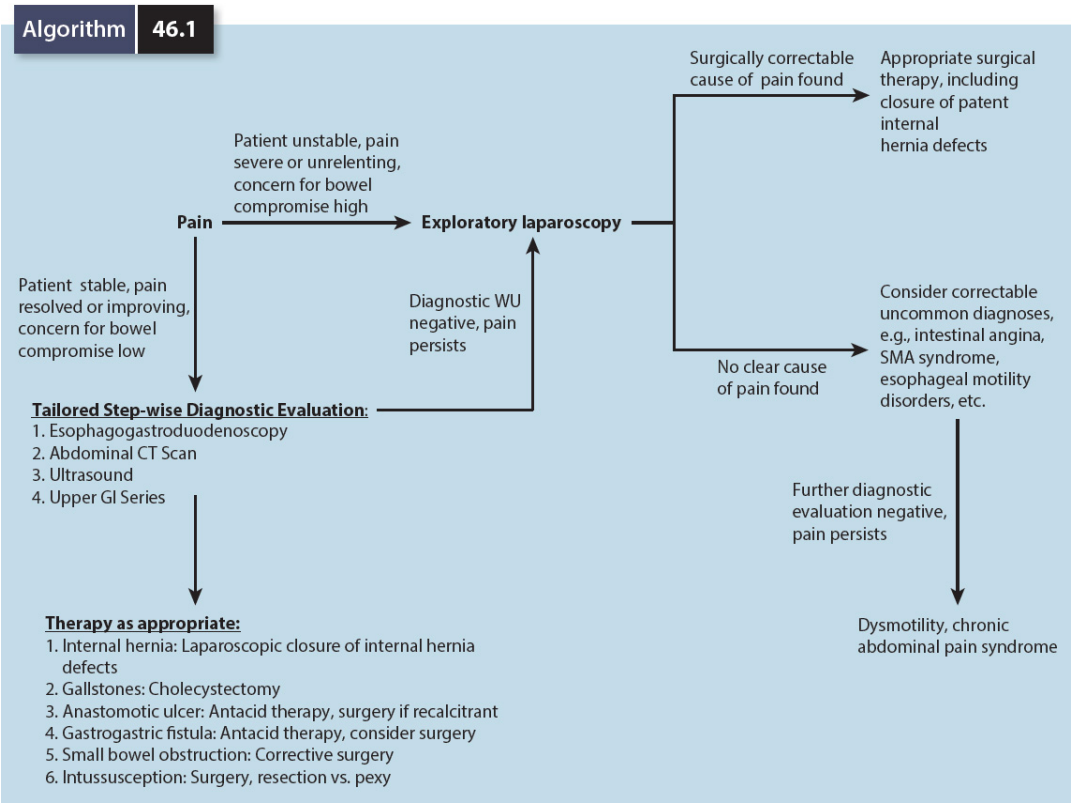
Gastrojejunal anastomotic ulcer occurs in 0.5% to 25% of patients after gastric bypass, with the majority of series reporting incidences between 2% and 8%. Tobacco or NSAID use increases risk, but ulcers may occur in the absence of these risk factors. Diagnosis by upper endoscopy is usually straightforward. Upper GI radiography is advisable to rule out an associated gastrogastric fistula, especially if an ulcer is recalcitrant to medical treatment or is associated with weight regain. Most ulcers heal with high-dose antacid therapy, and once healed, most surgeons recommend maintenance antacid therapy for life, although data supporting this practice are sparse. Rarely, ulcers recalcitrant to medical therapy require resection with anastomotic revision or reversal of the gastric bypass. Large pouches are a risk factor for ulcers due to retention of parietal cells in the distal gastric pouch that do not participate

in negative inhibition of gastrin secretion, thus rationalizing pouch resection and anastomosis revision as a treatment strategy. Gastrogastric fistula occurs with an incidence of 0% to 2% and may be associated with ulcers. Gastrogastric fistula incidence has decreased substantially since the advent of divided gastric bypass. Gastrogastric fistula often results from incomplete division of the gastric pouch from the gastric remnant at primary operation. Stenosis of the gastrojejunostomy typically presents with intolerance of solid foods and vomiting within 1 to 3 months of surgery with a wide range of reported incidences from <1% to >20%, but most commonly 3% to 7%. Stenosis is usually easily treated with endoscopic dilation, although rare cases may require anastomotic revision. Retrograde intussusception at the jejunojejunostomy is a rare cause of abdominal pain after gastric bypass with a reported incidence of 0.1%. Pathogenesis is likely related to motility disorders resulting from disruption of enteroenteric nerves and divorce of the small intestine from duodenal pacemaker plexi with subsequent development of aberrant ectopic pacemakers in the involved intestinal limbs. Diagnosis may be challenging and imaging unreliable. Treatment consists of either plication/pexy of involved limbs or resection and revision of the jejunojejunostomy, with the latter approach associated with lower rates of recurrence.



Algorithm 46.1 Algorithm for management of abdominal pain months or years after Roux-en-Y reconstruction.

The clinical presentation and differential diagnosis of abdominal pain after gastric bypass is diverse and diagnostic imaging may be unreliable. The clinician is not infrequently faced with a gastric bypass patient who presents with persistent pain in the absence of a clear cause after thorough diagnostic evaluation. Exploratory laparoscopy in such patients provides a diagnosis in up to 90% of cases. Even in the absence of intraoperative findings other than patent internal hernia defects without incarceration, closure of defects provides relief in the majority of patients. Less commonly, in the absence of a clear cause, pain is presumed to result from atypical motility disorders associated with Roux-en-Y anatomy and may be difficult to treat **(Treatment Algorithm 46.1)**.

Rates of reoperation following bariatric surgery range from 5% to 22.1%, with higher rates of reoperation for the gastric bypass as compared to sleeve gastrectomy. However, two small randomized control trials reported no significant difference in 5-year rates of reoperations between the two operations. Specifically, the SLEEVEPASS trial reported an 8.3% reoperation rate following sleeve gastrectomy and a 15.1% rate of reoperation for gastric bypass.[76] Data from the SM-BOSS trial mirrored these finding with rates of reoperation at 15.8% for sleeve gastrectomy versus 22.1% for gastric bypass.[84] Later complications of sleeve gastrectomy include stricture, stenosis,

or GERD. GERD is a more frequent complication for patients who undergo sleeve gastrectomy. While many patients respond to therapy with antacid medication, conversion to a gastric bypass may be required for those with refractory symptoms. As such, gastric bypass is often the procedure choice for patients with both severe obesity and GERD due to the reduction of acid in a small gastric pouch and a long Roux limb. There is increasing clinical concern that sleeve gastrectomy may worsen GERD or increase risk for development of Barrett esophagus. Studies are mixed in their findings of symptoms or complications of GERD after a sleeve gastrectomy.

Late complications after gastric band are common, afflicting 10% to 50% of patients, may occur years after primary operation, and include band slippage, band erosion, and development of GERD and esophageal motility disorders. Treatment often requires band explant, with late explant rates of 30% to 50% in some series.

Bariatric operations alter absorption of macro- and micronutrients. Protein and lipid malabsorption, steatorrhea, and protein wasting are rare after modern gastric bypass and virtually absent with gastric band and sleeve gastrectomy, but afflict anywhere from 2% to 20% of patients after biliopancreatic diversion/duodenal switch.[85,86] The elimination of the pyloric emptying mechanism in gastric bypass is associated with dumping and hypoglycemic syndromes, the underlying mechanisms of which are not well understood. Early dumping occurs within 10 to 30 minutes of a meal, and is thought to result from intraluminal fluid shifts and acute intravascular volume depletion secondary to rapid emptying of hyperosmolar gastric contents into the small intestine. Early dumping is associated with tachycardia and diaphoresis. Aberrations in gut hormone secretion, including elevated secretion of vasoactive intestinal polypeptide, enteroglucagon, pancreatic polypeptide, and GLP-1, have been associated with a predisposition to early dumping. Late dumping occurs hours after a meal and is thought to be due to hypersecretion of insulin with subsequent reactive hypoglycemia; excess secretion of GLP-1 and vasoactive intestinal peptide (VIP) have also been implicated. Dumping and hypoglycemia typically respond to a low-carbohydrate diet and preprandial therapy with acarbose, an intestinal alpha glucosidase inhibitor that decreases glucose release from ingested carbohydrates. In cases recalcitrant to these measures, pharmacotherapy with agents that reduce insulin secretion, including octreotide, diazoxide, and calcium channel blockers, may be of benefit. Surgical banding of the gastric pouch to delay emptying has been employed with variable efficacy.

Micronutrient deficiencies are underreported after bariatric surgery. The reported prevalence of deficiencies of virtually all micronutrients after surgery span a broad range from 10% to >80% for biliopancreatic diversion/duodenal switch and gastric bypass. Deficiencies are less common after sleeve gastrectomy and gastric band. An understanding of the anatomic sites and mechanisms of micronutrient absorption affected by gastric bypass foregut diversion guides diagnosis and management. Anemia, neurologic, dermatologic, and GI symptoms are common clinical manifestations of many micronutrient deficiencies (**Table 46.4**). Acute deficiencies may involve dramatic presentations (e.g., thiamine deficiency and Wernicke encephalopathy). Chronic occult micronutrient deficiencies are associated with increased risk of chronic disease. Chronic magnesium deficiency, for example, is associated with an increased risk of type II diabetes. Chronic selenium deficiency has been associated with an increased risk of cancer and cardiovascular disease. The most common deficiencies associated with gastric bypass involve calcium, vitamin D, folate, iron, and B12. Vomiting due to stenosis or gastroenteritis increases the risks of severe micronutrient deficiencies, and nutritional status should be monitored carefully in any bariatric surgery patient with significant vomiting. It is important to note that obesity is associated with multiple micronutrient deficiencies independent of bariatric surgery, which should be identified and corrected in the preoperative period, and which may resurface in the postoperative period.

Operative Considerations

A thorough discussion of the technical aspects of bariatric surgery is beyond the scope of this chapter, but a few important issues warrant mention. Obesity is a risk factor for DVT, and aggressive DVT prophylaxis should be employed. Optimal prophylaxis agents and regimens have not been determined, but unfractionated or low–molecular-weight heparin during operation and continued through the hospitalization period is typical. Subtherapeutic dosing of these agents is common in the obese, and the American College of Chest Physicians recommends weight-based dosing.

Hand-sewn, linear stapler, and circular stapler techniques are used to create the gastrojejunostomy in gastric bypass. No single technique demonstrates a clear advantage, although stenosis rates may be higher with the circular stapler technique. Absorbable suture should be used for all anastomoses, as nonabsorbable suture is a nidus for ulcer formation. Routine intraoperative testing of the gastrojejunal anastomosis with EGD-air insufflation or methylene blue instillation may be associated with reduced anastomotic dehiscence rates and is advisable. The use of drains at

the gastrojejunal anastomosis is practiced selectively, and no clear data demonstrate that routine drain placement aids in early detection or reduced morbidity of anastomotic dehiscence. Routine closure of internal hernia defects during gastric bypass is controversial, as data do not clearly demonstrate that this practice reduces late hernia incidence. Nonetheless, closure is straightforward, entails low morbidity, and is therefore recommended. Risk–benefit analyses do not support prophylactic cholecystectomy during laparoscopic bariatric surgery in the absence of cholelithiasis, or in the presence of asymptomatic cholelithiasis. It is therefore reasonable to manage cholelithiasis in bariatric surgery patients as in all patients, that is, perform cholecystectomy only if symptoms are present.

Perioperative and Postoperative Management

Perioperative care of the bariatric surgery patient is similar to that of any patient undergoing complex GI surgery but must be tailored to the obese. Inpatient, outpatient, and operating room facilities should be equipped with beds, chairs, lifting and transfer apparatuses, and other equipment capable of bearing the weight of obese patients. Anesthesia, nursing, dietician, physical therapy, and other subspecialty staff with experience in the management of obese patients are necessary. Hospital stays after laparoscopic gastric bypass and sleeve gastrectomy are typically 1 to 3 days, while gastric band is generally performed on an outpatient basis.

The dietary regimen in the first few weeks after surgery is designed to prevent food impaction at an edematous surgical site and maintain adequate hydration, and includes clear liquids progressing to soft foods. Caloric intake in the early postoperative period may be less than 500 cal/d, which is acceptable as long as hydration is maintained. Within 2 to 3 weeks of surgery, solid foods may be introduced and caloric intake will slowly rise, with a long-term maintenance target of 1,200 to 1,500 calories and 50 to 70 g of protein per day. Within a few months of surgery, most patients are able to eat any foods in small quantities with few exceptions. Deviation from this pattern should raise concerns for anastomotic stenosis, ulcer, or other complications. Persistent vomiting, unless clearly associated with a specific food that when eliminated ameliorates symptoms, is abnormal and should prompt a diagnostic workup, usually with UGI and/or EGD.

The incidence of cholelithiasis after bariatric surgery ranges from 15% to over 70%, but only approximately 7% of patients will require cholecystectomy. Prophylactic treatment with ursodeoxycholic acid reduces the risk of postoperative cholelithiasis, from 28% to 9% in one recent meta-analysis. Such therapy entails little morbidity and a 6-month postoperative treatment regimen is common practice. Data are equivocal, however, regarding whether this practice reduces cholecystectomy rates or is cost-effective.[87]

The variability in surveillance practices makes accurate estimation of the incidence of postoperative nutritional deficiencies challenging, and a wide range of supplementation practices exist. Interpretation of the data is made more difficult because obese patients are at high risk for pre-existing micronutrient deficiencies independent of surgery. Vitamin D and zinc deficiencies, for example, afflict over 50% and 30% of obese patients, respectively. Abnormal serum levels of micronutrients after surgery are common, ranging from 10% to >80% depending on the micronutrient, operation, and patient population studied; clinically symptomatic deficiencies are less common. Consensus guidelines from the American Association of Clinical Endocrinologists, the Obesity Society, and the ASMBS recommend that gastric bypass patients undergo annual surveillance of 25-hydroxyvitamin D, calcium, iron, and B12 levels, along with a complete blood count, electrolyte and lipid panels, and liver function tests and periodic bone scans, and receive lifelong daily multivitamin (including folate), calcium citrate, vitamin D, and vitamin B12 supplementation, with iron supplementation in menstruating women.[88] Sleeve gastrectomy patients likely have a lower risk of nutritional deficiencies, but similar regimens are recommended. Gastric band patients receive a daily multivitamin, calcium, and vitamin D supplementation.

Table 46.4 Select Micronutrient Deficiencies Associated with Bariatric Surgery

Micronutrient	Signs, Symptoms of Deficiency	Site of Absorption	Mechanism of Absorption, Other Issues
B9 (folate)	Macrocytic megaloblastic anemia, leukopenia, thrombocytopenia, glossitis, elevated homocysteine levels, neural tube defects in pregnancy	Duodenum, jejunum, ileum	Water soluble, conserved via enterohepatic circulation; B12 required for folate activation, B12 deficiency can cause folate deficiency; multivitamin generally sufficient for supplementation after surgery
B1 (thiamine)	Wernicke encephalopathy (ophthalmoplegia, nystagmus, ataxia, dementia), Korsakoff psychosis, beri-beri, peripheral neuropathy	Jejunum, ileum	Water soluble, depletion may occur with 2 to 3 weeks; rapid weight loss, vomiting increase risk of deficiency; symptoms of acute deficiency may mimic stroke
B6 (pyridoxine)	Seborrheic dermatitis, atrophic glossitis, conjunctivitis, neuropathy	Jejunum, ileum	Water soluble, passive absorption
B12 (cobalamin)	Macrocytic anemia, leukopenia, thrombocytopenia, glossitis, irreversible neuropathies	Ileum	Binds salivary R-proteins which prevent acid hydrolysis, then binds intrinsic factor secreted by parietal cells in gastric antrum; intrinsic factor-B12 complex absorbed in ileum; found in foods of animal origin—be alert for deficiency in vegetarians
C	Scurvy: malaise, myalgias, petechiae, mucosal bleeding, edema; iron deficiency	Jejunum	Symptomatic deficiency rare after bariatric surgery; potentiates iron absorption, should be used in iron deficient patients
D	Fatigue, myalgia, arthralgia, osteopenia	Jejunum, ileum	Fat soluble; deficiency common in obesity independent of surgery in up to 50% of patients
A	Xerophthalmia, night blindness, keratitis	Duodenum, jejunum, ileum	Fat soluble; deficiency associated with

			malabsorptive procedures
E	Ataxia, paresthesias, myopathy, arthropathy, anemia, retinopathy, immune dysfunction	Jejunum, ileum	Fat soluble; deficiency associated with malabsorptive procedures
K	Coagulopathy	Jejunum, ileum	Fat soluble; deficiency associated with malabsorptive procedures
Calcium	Tetany (Trousseau, Chvostek signs), paresthesias, QT prolongation, cardiac arrhythmias, petechiae, purpura, osteopenia	Duodenum, jejunum	Symptoms of acute deficiency rare; chronic deficiency common, manifests as osteopenia, related to vitamin D deficiency
Copper	Ataxia, anemia, demyelinating neuropathy, paresthesias; chronic deficiency associated with osteoporosis, cardiovascular disease, cancer	Stomach, duodenum	Involved in antioxidant metabolism
Iron	Microcytic anemia, fatigue, cold intolerance, atrophic glossitis, angular stomatitis	Duodenum	Conversion from ferric to ferrous form requires acid hydrolysis; supplements interfere with calcium absorption, should be taken at different times
Magnesium	Alopecia, muscle cramps, hypocalcemia, hypokalemia, hypoparathyroidism, chronic deficiency linked to increased risk of diabetes, cardiovascular disease	Duodenum	Deficiency common in obesity independent of surgery in up to 35% of patients
Selenium	Acute deficiency rare; chronic deficiency linked to increased risk of cancer, diabetes, long-term mortality	Duodenum	Involved in antioxidant metabolism; excess selenium is toxic
Zinc	Alopecia, dermatitis	Duodenum	Deficiency common in obesity independent of surgery in up to 50% of obese patients

Dominant anatomic sites of absorption are listed, but many micronutrients are absorbed throughout the GI tract. In cases of micronutrients absorbed via active transport mechanisms, passive absorption also occurs in lesser amounts, and supplementation with suprapharmacologic doses overcomes bypassed

active uptake mechanisms via passive absorption (e.g., B12).

Clinical follow-up after bariatric surgery should be lifelong. Primary care providers play a critical role in preoperative and postoperative care. Endocrinology expertise may be required, especially in the early postoperative period when diabetes may resolve rapidly. A medical bariatrician subspecialty is evolving to care for this expanding patient population.

Physiologic Mechanisms Underlying Bariatric Surgery Efficacy

7 Restriction of caloric intake and nutrient malabsorption are the classic presumed mechanisms of bariatric operations. These mechanisms are important, but their relationship to outcome is complex and nonlinear. For example, data are conflicting regarding the correlation between gastric bypass pouch size and weight loss. In general, pouch volumes <50 cc are associated with good results with little evidence that smaller pouches achieve greater weight loss, while efficacy may decrease substantially as pouch sizes increase beyond 50 cc. Similar observations apply to sleeve gastrectomy: a recent MBSAQIP study of 189,477 sleeve gastrectomies demonstrated that bougie size ≥40 Fr was associated with greater weight loss relative to smaller bougies.[89] Similarly, common channel length teeters on a less well-defined threshold, above which weight loss is poor and below which malnutrition results. Other features of restriction are counterintuitive: more rapid gastric pouch emptying on oral contrast studies is associated with greater weight loss after gastric bypass while sleeve gastrectomy is associated with increased gastric emptying rates compared to native anatomy. These observations suggest a complex relationship between weight regulation, metabolism, and gut anatomy and motility.

Complex mechanisms in addition to restriction and malabsorption contribute to weight loss and improved metabolism after surgery, with qualitatively different responses than those associated with diet-induced weight loss. Satiety is increased, hunger decreased, and metabolic rate increased after bariatric surgery, the opposite of responses observed with diet-induced weight loss. Bariatric surgery somehow "sidesteps" the normal compensatory responses that act to defend body weight with nonsurgical weight loss. The mechanisms underlying these counterintuitive responses are not well established. Among putative mechanisms are changes in gut hormone secretion secondary to altered intestinal anatomy. Decades ago, it was observed that an oral glucose load elicits a greater insulin response than an intravenous glucose load, leading to postulation of the existence of *incretins,* gut hormones secreted in response to a meal that regulate systemic glucose metabolism. Subsequent research led to the discovery of GIP and GLP-1, incretins secreted by duodenal K cells and ileal L cells, respectively, in response to nutrient delivery to the small intestine. Incretins have diverse effects on glucose homeostasis, potentiating central insulin secretion and peripheral insulin sensitivity. Alterations in incretin hormone secretion secondary to gut anatomic derangements were invoked to explain the observation that diabetes often improved within days of gastric bypass, well before substantial weight loss.

The *foregut and hindgut hypotheses* have been proposed to explain this phenomenon: bypass of the alimentary stream from the stomach, duodenum, and proximal jejunum (the foregut hypothesis), and increased caloric delivery to the distal jejunum and ileum (the hindgut hypothesis) alter secretion of gut hormones with improvement in glucose homeostasis. While data are less compelling for GIP and other putative foregut hormones, evidence supports the hindgut hypothesis, including data demonstrating increased serum GLP-1 levels after gastric bypass. While debate persists regarding the magnitude of these effects on diabetes remission after gastric bypass, an understanding of incretin physiology has led to the development of GLP-1 agonists as pharmacologic therapy for diabetes independent of bariatric surgery.

Gut anatomic derangements mediate additional metabolic changes. Gastric bypass and sleeve gastrectomy are associated with alterations in serum levels of the orexigenic hormone ghrelin, which is secreted by gastric fundus enteroendocrine cells, and peptide YY and oxyntomodulin, gut hormones secreted by L cells in parallel with GLP-1 in response to a meal that induce satiety and inhibit gut motility and are central mediators of the "ileal brake" mechanism. These changes may contribute to satiety and altered food responses after bariatric surgery. Gastric bypass and sleeve gastrectomy alter bile acid metabolism, increasing serum levels of conjugated bile acids with beneficial effects on glucose and lipid metabolism. Bariatric surgery disrupts vagal and enteroenteric innervations of the gut with downstream effects on CNS satiety responses. Finally, bariatric surgery is associated with alterations in gut microbiota that contribute to weight loss and resolution of metabolic disease, with data demonstrating that fecal transplant from mice that have undergone bariatric surgery transfers a lean, insulin sensitive phenotype to obese, nonoperated mice. The precise mechanisms by which these diverse effects contribute to weight loss and metabolic disease remission remain unclear but are areas of active research.

Mechanisms other than restriction and malabsorption underlie the systemic effects of bariatric surgery. An emerging field of *metabolic surgery* is exploring operations designed to mimic the metabolic effects of gastric bypass (e.g., ileal transposition, foregut exclusion, biliary diversion) in animals and lean diabetic humans with promising results. Also in development are endoscopic and laparoscopic gastric plications, intragastric balloon placement, vagal nerve blockade, gastric simulators, and impermeable intraluminal duodenal and jejunal stents designed to prevent caloric absorption. Bariatric surgery in the 21st century will evolve to include a broad array of procedures applied to a diverse patient population as these efforts mature.

Gastric Neoplasms

Andrew P. Loehrer and Sandra L. Wong

Key Points

1. While the incidence and mortality of gastric cancer have decreased substantially over the past several decades, it is still a leading cause of cancer-related mortality in many parts of the world.
2. *Helicobacter pylori* infection is the predominant risk factor for gastric carcinogenesis and *H. pylori* eradication is responsible for a marked decline in intestinal type gastric cancers.
3. The symptoms produced by gastric cancer are nonspecific and can mimic those associated with a number of nonneoplastic gastroduodenal diseases, especially benign gastric ulcer.
4. The extent of gastric resection is determined by the need to obtain a resection margin free of microscopic disease, and examination of a minimum of 16 nodes is suggested for adequate staging.
5. Multimodality treatment should be the standard of care for treating locally advanced resectable gastric cancer.

Gastric cancer remains a relatively common and frequently lethal malignancy, noting that it is the fifth most commonly diagnosed cancer in the

world.[1] The disease is often not recognized until it is at an advanced stage. Gastric cancer usually cannot be treated with resection alone, and surgical cure rates have remained disappointingly low. Multidisciplinary approaches must be considered the standard of care for these difficult neoplasms, noting some modest improvements in outcomes finally being observed. Technical innovations and basic/translational scientific investigations must continue to be applied to this disease.

ADENOCARCINOMA

Epidemiology

1 The incidence of gastric cancer has declined dramatically in the United States over the past century, noting that it still constitutes a major global health problem in low- and middle-income countries. There is truly wide geographic variation in incidence, with 15- to 20-fold difference between the high- and low-incidence regions. The rates are particularly high in Japan, Korea, and China, where gastric cancer is commonly diagnosed and a leading cause of cancer-related mortality. Globally, there will be an estimated 1,030,000 cases and over 782,000 deaths in 2018.[1] In comparison, gastric cancer is an uncommonly diagnosed cancer in the United States, with an estimated 27,600 cases and an estimated 11,010 deaths in 2020.[2] Of note, Asian Americans appear to have a much higher incidence (15 cases per 100,000) compared to non-Hispanic Whites (6 per 100,000), and Korean Americans and Japanese Americans (40 per 100,000 and 30 per 100,000, respectively) face a particularly high risk of disease.[3]

Worldwide geographic variability in the incidence of gastric cancer is shown in **Figure 47.1**. The highest incidence occurs in Eastern Asia, but Central and Eastern Europe and South America also have high incidence of gastric cancer. The lowest incidence of gastric cancer is seen in Africa and North America. It has long been thought that environmental exposures play a role in gastric carcinogenesis, a notion that is supported by the finding that groups who migrate from regions with high prevalence of gastric cancer to those with low prevalence experience a decreasing incidence of gastric cancer with time.[4,5] Factors including diet and associated issues of hygiene

and food conservation have been linked to incidence, and variation in the gut microbiome, which is closely linked with both diet and environment, is being increasingly explored as a causal determinant.

Specifically, the intestinal histologic subtype of gastric adenocarcinoma appears to account for most of the geographical variation seen with this disease and is strongly related to environmental exposures. The strongest known risk factor for intestinal type gastric cancer (with well-differentiated tumor cells) is infection with *Helicobacter pylori*. Approximately 75% of gastric cancer cases are, in fact, attributable to *H. pylori* infection, making this organism the dominant infectious cause of cancer in the world.[6] It is associated with a six-fold increased risk of (noncardia) gastric cancer[7,8] and eradication of *H. pylori* is a major factor in the marked declines of intestinal type cancers of the distal stomach in the United States and much of the developed world.[9]

The anatomic distribution of gastric cancers also varies widely. Unfortunately, the incidence of diffuse type gastric cancer, characterized by undifferentiated tumor cells arranged in scattered formation in fibrous stoma, of the proximal stomach is rising. While distal tumors still predominate in developing countries, proximal cancers appear to occur more commonly in relatively younger, white, and male patients.[10,11]

Premalignant Lesions

The risk for development of gastric cancer is greater in stomachs that harbor polyps. This risk is related most closely to polyp histologic type, size, and number. Variations in these three factors account for the wide range in reported risk associated with gastric polyps. In terms of malignant potential, gastric polyps can be divided into two broad categories— hyperplastic polyps and adenomatous polyps. Although not premalignant, hyperplastic polyps are discussed here because they are common, occurring in up to 1% of the general population and accounting for 75% of all gastric polyps. The hyperplastic polyp contains an overgrowth of histologically normal-appearing gastric epithelium. Atypia is rare, and hyperplastic gastric polyps have little to no neoplastic potential.

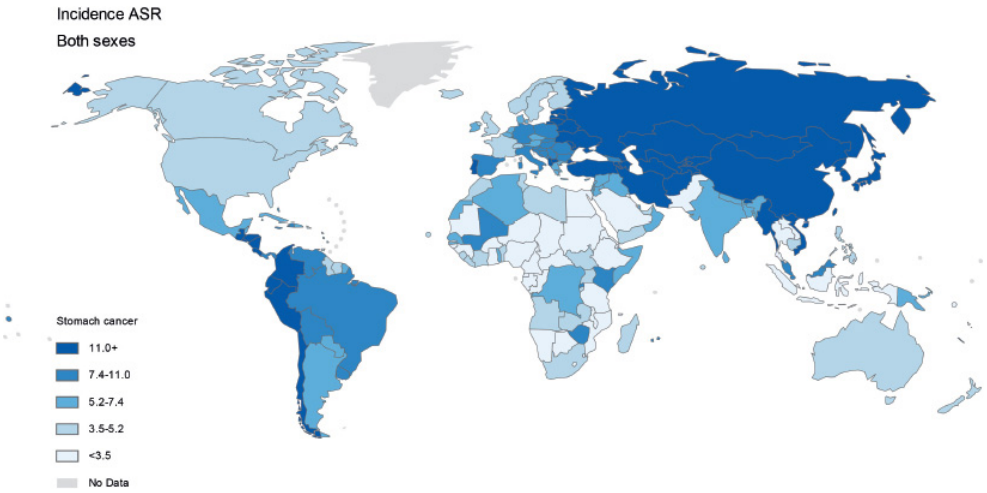

Figure 47.1 Worldwide geographic variability in gastric cancer incidence. (Reprinted from Ferlay J, Soerjomataram I, Ervik M, et al. GLOBOCAN 2012 v1.0 Cancer Incidence and Mortality Worldwide: IARC CancerBase No. 11 [Internet]. France: International Agency for Research on Cancer, 2013.)

Hyperplastic polyps are generally asymptomatic. When hyperplastic polyps are discovered, endoscopic removal for histologic examination is indicated and such removal results in sufficient treatment. Subsequent surveillance is not necessary, given the lack of neoplastic potential in these polyps. Adenomatous polyps also tend to be asymptomatic, but in contrast to hyperplastic polyps, adenomatous polyps carry a distinct risk for the development of malignancy.[12] Mucosal atypia is frequent, and mitotic figures are more commonly seen than in hyperplastic polyps. Dysplasia and carcinoma in situ have developed in adenomatous polyps observed over time. In fact, the risk for the development of carcinoma has been estimated at 10% to 20% and is greatest for polyps more than 2 cm in diameter. The presence of multiple adenomatous polyps increases the risk of cancer.

Endoscopic removal is indicated for pedunculated lesions and is sufficient if the polyp is completely removed and shows no evidence of invasive cancer on histologic examination. Operative excision is recommended for sessile lesions larger than 2 cm, for polyps with biopsy-proved invasive carcinoma, and for polyps complicated by pain or bleeding. Because the presence of gastric adenomatous polyp is a marker of increased risk for the development of cancer in the remaining gastric mucosa, repeat endoscopic surveillance is indicated. Enrollment in a surveillance program is indicated in order to rule out recurrence at the site of previous excision, evaluate for

new or missed polyps or an early carcinoma, and confirm eradication of *H. pylori,* if applicable.

Gastritis

The incidence of atrophic gastritis and gastric cancer increases with age. Chronic gastritis is frequently associated with intestinal metaplasia and mucosal dysplasia, and these histologic features are often observed in mucosa adjacent to gastric cancer. Gastritis is frequently progressive and quite severe in the gastric mucosa of patients with cancer. Gastric malignancy seems to be increased in patients with chronic gastritis associated with pernicious anemia, although the risk appears to have been overstated in the past. Nevertheless, this disease, which is characterized by fundic mucosal atrophy, loss of parietal and chief cells, hypochlorhydria, and hypergastrinemia, is present in 3% of people older than 60 years. For people in whom pernicious anemia has been active for more than 5 years, the risk of gastric cancer is twice that of age-matched control subjects and there is increased risk for gastric carcinoid tumors as well.

Helicobacter Pylori

2 As outlined above, infection with *H. pylori* has been unequivocally associated with chronic inflammatory conditions in the stomach, and this association has stimulated interest in the role of chronic infection by this organism in gastric carcinogenesis. Childhood acquisition of *H. pylori* infection is frequent in areas of high gastric cancer incidence, and high rates of infection have been identified in patients with premalignant lesions and invasive cancer. Infection with *H. pylori* is associated with an increased risk of adenocarcinoma of both the body and the antrum of the stomach.[13] In contrast, *H. pylori* infection is not a risk factor for proximal cancers of the cardia or gastroesophageal junction, which are associated with mucosal abnormalities of Barrett esophagus and which seem to follow the metaplasia to dysplasia to carcinoma pattern of development.

The mechanism of carcinogenesis related to *H. pylori* infection is incompletely understood but is thought to be related to the chronic inflammation caused by the organism.[14] Only ~1% of patients chronically

infected with *H. pylori* will develop the gastric cancer phenotype, which consists of corpus-predominant gastritis, multifocal atrophic gastritis, high gastrin levels, hypo/achlorhydria, and low pepsinogen I/II ratio. The majority of subjects infected with *H. pylori* will develop the simple gastritis phenotype which is not associated with any significant clinical outcome, or the duodenal ulcer phenotype (10% to 15% of infected subjects) which consists of antral-predominant gastritis and high gastrin and acid secretion and actually provides protection from developing gastric cancer.[15] Of note, there is variable distribution of these three phenotypes geographically, with particular prevalence of the gastric cancer phenotype in certain parts of Asia where gastric cancer is common.[16] While eradication of *H. pylori* is globally associated with decreased incidence of gastric cancer, it may not prevent the development of gastric cancer once premalignant lesions have already developed.[17]

Previous Gastric Surgery

A number of historical reports[18,19] have suggested that gastric cancer is more likely to develop in people who have undergone previous partial gastrectomy, with patients who have undergone a gastrojejunal (Billroth II) anastomosis at apparently higher risk for carcinogenesis than those reconstructed with a gastroduodenal anastomosis (Billroth I). The so-called *gastric remnant cancer* is a true clinical entity, although the risk for development of this gastric neoplasm appears to have been overestimated. Several large, prospective studies with long-term follow-up indicate that the relative risk is not increased for up to 15 years after gastric resection, likely due to surgical removal of mucosa at risk for development of gastric cancer, followed by modest increases in cancer risk (three times the control value) observed only after 25 years.[20–23] The cellular mechanisms that contribute to the development of neoplasia in the remnant stomach are unknown. Decreased luminal pH, bacterial overgrowth with increased production of *N*-nitroso carcinogens, and reflux of bile acids into the stomach have been postulated to promote cancer development but remains unproved. Vagotomy, when performed in conjunction with (legacy) gastric surgery for benign disease, does not appear to promote cancer development. A population-based study from Sweden of 7,198 patients who had previously undergone

vagotomy and then followed for up to 18 years did not seem to have increased risk of gastric cancer.[21]

A recent study explored genetic alterations in gastric remnant cancer and found that the microsatellite instability-high (MSI-H) phenotype was much more common (43%) in gastric remnant cancers than in sporadic gastric cancers (6%), and that this incidence was much higher in patients who had undergone a Billroth II anastomosis (67%) as compared to those who had undergone a Billroth I anastomosis (11%). The MSI-H phenotype in these tumors was associated with inactivation of the DNA mismatch repair genes hMLH1 and hMSH2 though the significance of this relationship is not yet clear.[24] Reported 5-year survival ranges from only 7% to 33% for gastric remnant cancers, but this poor prognosis is most likely due to the fact that these cancers are usually diagnosed at an advanced stage when treatment options are limited.

Hereditary Syndromes

Approximately 5% to 10% of gastric cancer may have a familial component, and 3% to 5% are associated with known inherited cancer syndromes. Hereditary diffuse gastric cancer (HDGC) is an autosomal dominant syndrome that confers a lifetime risk for the development of gastric cancer by age 80 years of 67% for men and 83% for women.[25] The average age at diagnosis is 37 years, and these cancers tend to be of the diffuse histologic type. Germline mutations in CDH1, a tumor suppressor gene that encodes the cell-to-cell adhesion protein E-cadherin, are found in at least 25% of patients with HDGC.[26] CDH1 carriers, with and without close family histories of diffuse gastric cancer, appear to have similar incidence of gastric cancer on endoscopic surveillance and gastrectomy.[27] Therefore, those patients with documented CDH1 mutations may be offered prophylactic total gastrectomy, with or without lymph node dissection at a young age (between 18 and 40 years of age).

Other familial cancer syndromes associated with an increased risk of gastric cancer include Lynch syndrome (hereditary nonpolyposis colorectal cancer), juvenile polyposis syndrome, familial adenomatous polyposis (FAP), and Peutz–Jeghers syndrome. Given the autosomal dominant nature of these syndromes, screening upper endoscopy may be considered in these

patients, often starting at a young age. Findings of polyps could lead to recommendations for surveillance upper endoscopy in patients with these syndromes though no formal guidelines exist. In FAP, with germline mutations in the adenomatous polyposis coli (APC) gene on chromosome 5q21, the majority of polyps are benign (nonadenomatous). In individuals with FAP, 10% of gastric polyps are adenomatous in nature and could lead to gastric cancer, noting a 1% to 2% lifetime risk.[28]

Clinical Features

3 The symptoms produced by gastric cancer are nonspecific and can closely mimic those associated with a number of nonneoplastic gastroduodenal diseases, especially dyspepsia or benign gastric ulceration (**Fig. 47.2**). In early gastric cancers, epigastric pain is present in over 70% of patients.[29] Pain may be relieved, at least temporarily, by antacids or gastric antisecretory drugs. Anorexia, nausea, and weight loss are present in less than 50% of patients with early gastric cancers but become increasingly common with disease progression. Dysphagia is present in 20% of patients with proximal gastric lesions. Overt gastrointestinal hemorrhage (5%) and perforation (1%) are uncommon.

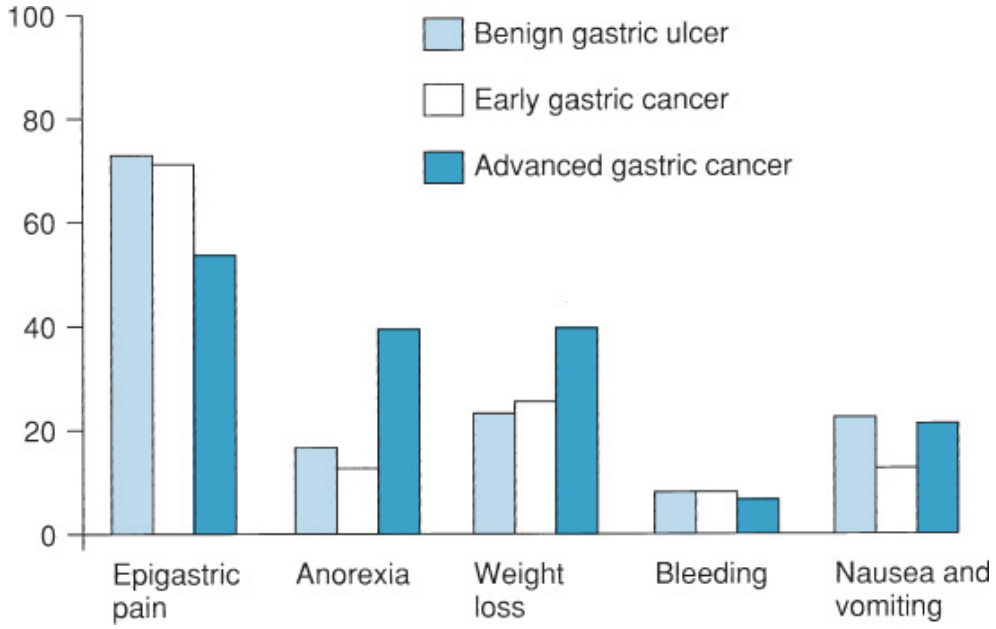

Figure 47.2 Clinical symptom frequency in benign gastric ulcer, early gastric cancer, and advanced gastric cancer. (From: Meyer WC, Damiano RJ Jr, Postlethwait RW, et al. Adenocarcinoma of the stomach. Changing patterns over the past four decades. *Ann Surg* 1987;205[1]:1–8.)

In most patients with early gastric cancers, physical examination is typically unremarkable. Stool tests positive for occult blood in one-third. There are no laboratory tests specific for gastric neoplasms. Abnormal physical findings usually reflect advanced disease (**Table 47.1**). Cachexia, abdominal mass, hepatomegaly, and supraclavicular adenopathy usually indicate advanced or metastatic disease.[30]

Diagnosis and Staging

Fiberoptic endoscopy is the most definitive diagnostic method when gastric neoplasm is suspected. In the initial stages, gastric cancers can appear polypoid, as flat, plaque-like lesions, or as shallow ulcers. Advanced lesions are typically ulcerated. The ulcer border can have an irregular, beaded appearance because of infiltrating cancer cells, and the base is frequently necrotic and shaggy. The ulcer can appear to arise from an underlying mass. Although each of these features suggests a malignant ulcer, differentiation of benign from malignant gastric ulcers can be made definitively only with gastric biopsy. Multiple biopsies of any gastric ulcer

should be performed, increasing sensitivity to 98% as compared to 70% for single biopsy.[31] False-negative results occur in approximately 10% of patients, usually as the result of inadequate sampling, sampling error, or due to the absence of a mucosal abnormality as can occur with linitis plastica; false-positive results in this setting are rare.

Table 47.1 Common Symptoms and Physical Findings in Gastric Cancer

Symptoms	Physical Findings
Weight loss	Guaiac-positive stool
Pain	Cachexia
Nausea and vomiting	Abdominal mass or fullness
Anorexia	Abdominal tenderness
Dysphagia	Hepatomegaly
Melena	

Diagnostic accuracy can be further enhanced by the addition of endoscopic ultrasound (EUS) with fine-needle aspiration biopsy for infiltrative tumors involving the wall of the stomach without obvious mucosal abnormalities. EUS has added benefit of being able to provide staging information on the depth of tumor invasion when done by experienced endoscopists.

Annual mass screening programs have been instituted in some countries (e.g., Japan, Venezuela, Chile) where there is a high incidence of gastric cancer. However, whether such programs significantly reduce gastric cancer mortality is unclear. In Japan, compliance with screening has been associated with a 50% decrease in gastric cancer mortality, but most of this benefit may actually be attributable to confounding factors such as good general health at baseline.[32] Cancers detected in screened patients do tend to be earlier cancers with fewer nodal metastases,[33] and patients with resected gastric cancer diagnosed by screening in Japan have better survival than those diagnosed after development of symptoms (**Fig. 47.3**). However, a survival difference between screened and unscreened gastric cancer patients persists

even after accounting for stage,[33] suggesting that patient selection confounds the effect of screening on mortality. The Japanese findings that early detection and identification of early gastric cancer can improve survival has been confirmed by European investigations, in which patients with early gastric cancers have been shown to have survival rates equivalent to those of patients with benign gastric ulcer (**Fig. 47.4**).[29] Mass screening programs have been found to be cost-effective in high-incidence countries such as Japan and China,[34] but they are unlikely to be cost-effective in lower-incidence countries such as the United States.

Barium-contrast radiographs have, in the past, been the standard method for diagnosing gastric neoplasm. Single-contrast examinations have a diagnostic accuracy of 80%. This diagnostic yield increases to approximately 90% when double-contrast (air and barium) techniques are used. Typical findings include ulceration, the presence of a gastric mass, loss of mucosal detail, and distortion of the gastric silhouette (**Fig. 47.5**). However, contrast radiography has been largely supplanted by endoscopy (with or without EUS) in contemporary practice because of the ability to obtain biopsy material concurrently by the latter technique.

Computed tomography (CT) can provide information both about the primary tumor and visceral metastatic disease. Because it is noninvasive and widely available, it is often the first staging modality that is employed in a patient diagnosed with gastric cancer. Patients who are found to have

metastatic disease can be spared further, potentially invasive staging studies. When performed with intraluminal and intravenous contrast, CT can demonstrate infiltration of the gastric wall by tumor, gastric ulceration, and the presence of hepatic metastases (**Figs. 47.6 and 47.7**). While depth of invasion and serosal involvement can be assessed, CT is generally not as accurate as EUS for assessment of depth of tumor (T category).

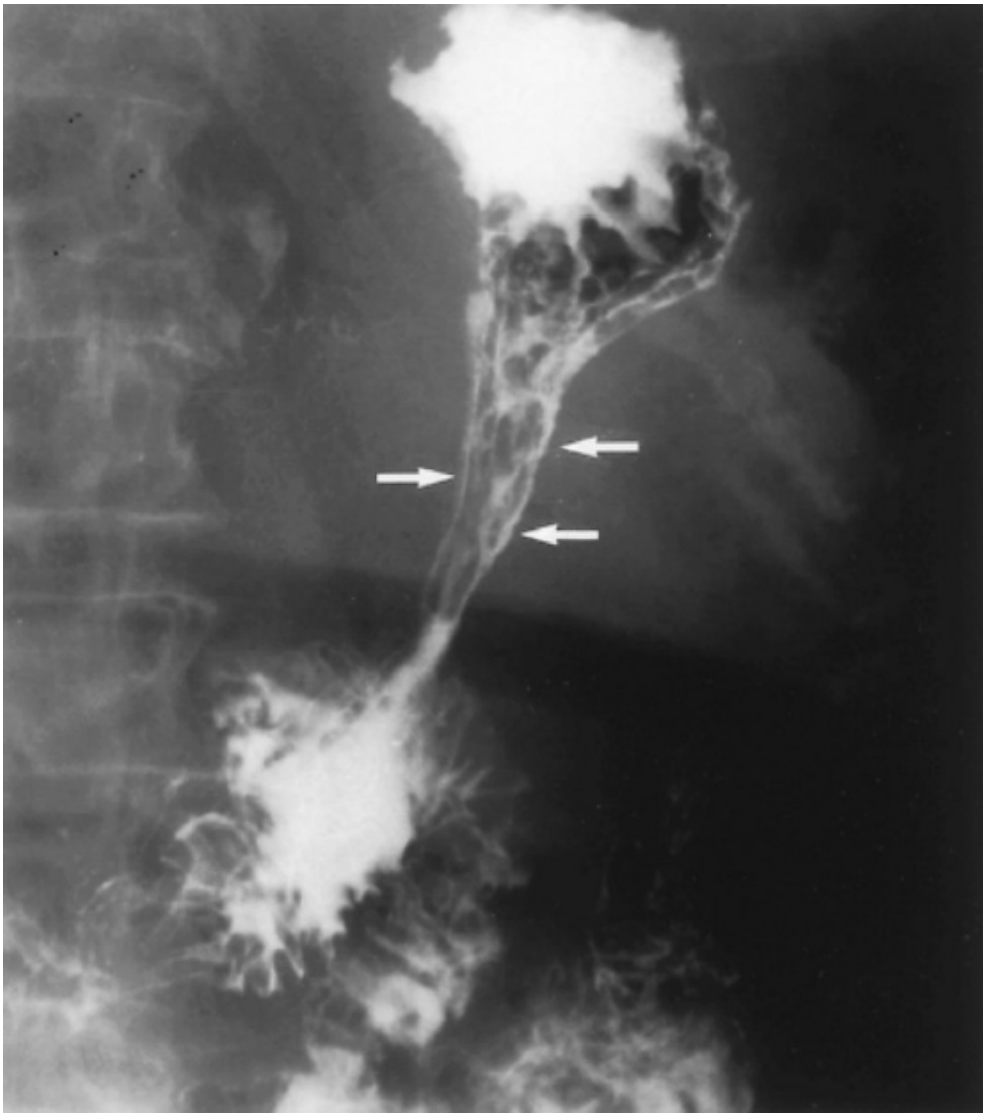

Figure 47.5 Barium-contrast radiograph demonstrating extensive involvement of the gastric body by infiltrating adenocarcinoma (linitis plastica). The gastric silhouette is narrowed (*arrows*), and the stomach is nondistensible.

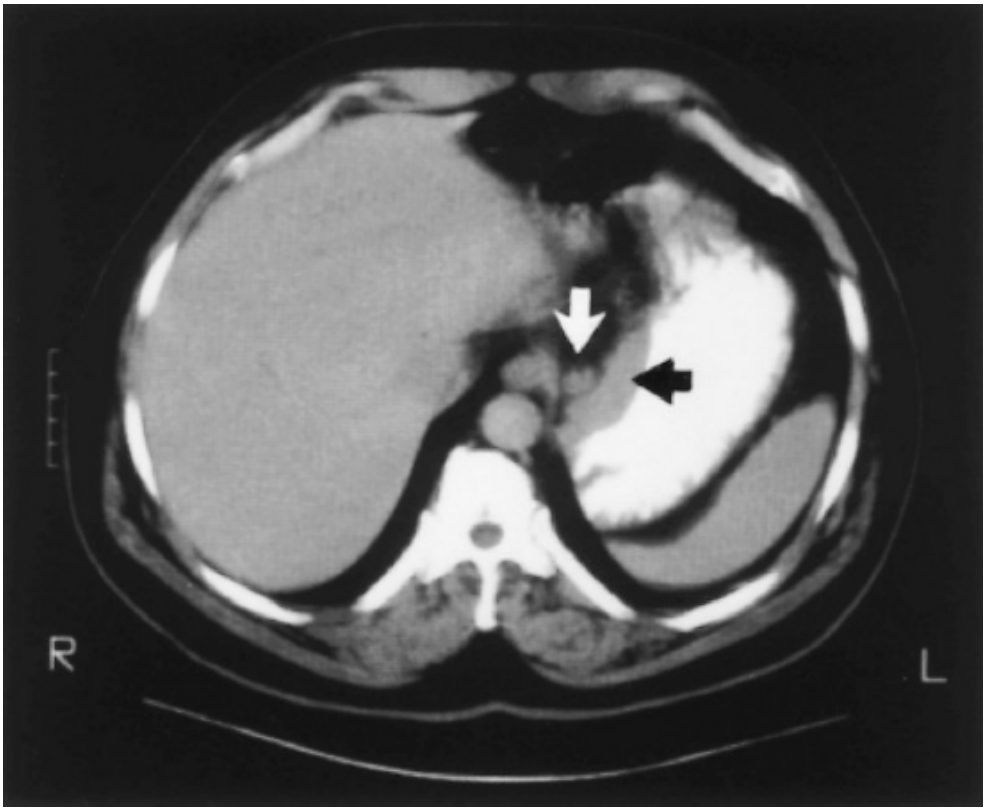

Figure 47.6 Computed tomography scan demonstrating mass along lesser curvature of the stomach (*black arrow*) and associated lymph node enlargement (*white arrow*).

EUS is a useful method of preoperative evaluation for local staging and diagnosis. As noted above, EUS can assess subepithelial lesions that may be confused with gastric cancer and guide biopsy of submucosal tumors within the wall of the stomach. Investigation of submucosal masses, infiltrative gastric disorders, and enlarged gastric epithelial folds, as well as differentiation of gastric lymphoma from gastric adenocarcinoma are all aided by EUS. This technique has the ability to assess the depth and pattern of gastric wall penetration by the tumor as well as relationship to adjacent structures and has good correlation with intraoperative assessment and histologic findings. Perigastric lymph nodes involved with tumor are also reliably identified by EUS, though limitations with the transducer makes visualization of more distant lymph nodes difficult. Nevertheless, EUS provides an accurate assessment of local stage of disease (TN status), with an accuracy of 46% to 88% for staging depth of tumor invasion and 30% to 90% for nodal involvement.[35,36]

EUS serves as a useful adjunct to cross-sectional imaging and can help guide selection of patients for further staging studies or multimodality therapy. Evaluation of nodal disease by CT is very limited and CT is not reliable for detection of small peritoneal metastases, which may be missed in 30% of cases.[37] Interestingly, the addition of 18-fluorodeoxyglucose (FDG) positive emission tomography (PET) has been found to be less accurate than cross-sectional imaging and EUS for assessing locoregional involvement, but more sensitive for detecting distant metastases in patients with gastric cancer.[38] A meta-analysis comparing PET, ultrasound, CT, and magnetic resonance imaging (MRI) found that PET scan was the most sensitive imaging modality for detecting hepatic metastases.[39] A separate study found that tumors which demonstrated metabolic response to neoadjuvant chemotherapy on PET correlated highly with histopathologic response and improved patient survival.[40] Therefore, current recommendations regarding the use of PET for staging gastric cancer are for selective use for patients with locally advanced tumors where the metastatic potential is high and for cases in which neoadjuvant therapy is being considered.[39]

EUS is generally not useful for detecting metastatic disease, but it may help identify patients at risk for radiographically occult metastatic disease (e.g., peritoneal metastases) for staging laparoscopy.[37] However, even with adequate endoscopic evaluation and cross-sectional imaging, occult metastases may be missed in 16% to 37% of patients.[41] As such, staging laparoscopy is recommended for patients with potentially resectable gastric cancer.[42]

Staging Laparoscopy

The peritoneal lining, omentum, and liver capsule are common sites for gastric cancer metastasis that are difficult to evaluate preoperatively by CT scanning. In prospective studies, diagnostic laparoscopy has been superior to preoperative CT or percutaneous ultrasound in detection of peritoneal, hepatic, or lymphatic metastasis.[43] Accurate identification of patients with metastatic disease is important in order to spare them futile, ultimately noncurative surgical procedures. Laparoscopy, that includes peritoneal lavage and acquisition of fluid for cytologic examination, will detect metastatic disease that precludes curative resection in up to 37% of patients.[41,42] The highest yield for detection of occult metastatic disease is in those with T3 or T4 disease, and nodal involvement, noting low yield in cases that are T1 or T2, and N0.

Even in cases with planned upfront resection, staging laparoscopy should be performed prior to gastrectomy. Most patients with systemic metastasis detected at time of laparoscopy can be treated without the need for palliative surgical resection. Laparoscopy affords excellent visualization of the peritoneum, especially if care is taken to examine parietal and visceral surfaces, including the diaphragm, liver, spleen, bowel, and omentum. In addition to detection of grossly evident intra-abdominal metastatic disease, patients with findings of microscopic metastatic disease are at high risk for early recurrence and death after attempted curative resection.[44–46] Based on

such a finding, patients with positive cytology in peritoneal washings are considered to have M1 disease. Approximately one-fourth of patients subjected to staging laparoscopy prior to planned curative resection of gastric cancer will have positive peritoneal cytology; one-third of these patients will not have had grossly apparent metastatic disease. The peritoneum also remains the most common organ of recurrence after R0 resection.[46] Patients who clear their initially positive peritoneal cytology after systemic chemotherapy have an improved prognosis.[45] These considerations have led to recent work examining the role of heated intraperitoneal chemotherapy (HIPEC) with or without cytoreductive surgery for patients with evidence of carcinomatosis.[47–49] Early results suggest that survival can be improved to comparable patients without peritoneal disease. However, long-term survival or cure remains highly unlikely in presence of peritoneal disease.

Patients with locally advanced (T3–T4 or node-positive) tumors who are being considered for neoadjuvant therapy should undergo diagnostic laparoscopy with peritoneal washings prior to initiation of chemotherapy. In this situation, the finding of positive peritoneal cytology should prompt adoption of a noncurative paradigm of treatment in most cases. If carcinomatosis is limited or cytology positive only, patients may be eligible for ongoing trials neoadjuvant HIPEC (with or without cytoreduction) with chance to treat the carcinomatosis and proceed with curative-intent gastrectomy.

Relative to laparotomy, the shorter hospitalization and reduced operative trauma following laparoscopy may both hasten recovery and facilitate earlier initiation of systemic chemotherapy. Despite strong evidence supporting benefits of accurate staging, laparoscopy is underused in the management of gastric cancer, noting that less than 10% of potentially eligible patients[50,51] undergo staging laparoscopy prior to planned gastrectomy or neoadjuvant treatment.

Pathology

Gastric adenocarcinoma occurs in two distinct histologic subtypes—intestinal and diffuse. These subtypes are characterized by differing

pathologic and clinical features and by differing patterns of metastatic spread.

In the intestinal form of gastric cancer, the malignant cells tend to form glands. The intestinal form of malignancy is more frequently associated with gastric mucosal atrophy, chronic atrophic gastritis, intestinal metaplasia, and dysplasia. Gastric cancer with the intestinal histologic subtype is more common in populations at high risk (e.g., Japan), and it occurs with increased frequency in men and older patients. Clinical studies suggest that this subtype more frequently demonstrates blood-borne metastases.

The diffuse form of gastric adenocarcinoma does not demonstrate gland formation and tends to infiltrate tissues as a sheet of loosely adherent cells. Lymphatic invasion is common. Intraperitoneal metastases are frequent. The diffuse form of gastric adenocarcinoma tends to occur in younger patients, in women, and in populations with a relatively low incidence of gastric cancer (e.g., the United States). The prognosis is poorer for patients with the diffuse histologic subtype.

Additionally, signet ring cell carcinoma (SRC) is being investigated as a unique form of adenocarcinoma. SRC tumors contain scattered malignant cells containing intracytoplasmic mucin and this prognostic importance in both Western and Eastern studies remains less than clear. A recent analysis that compared over 1,600 patients with SRC with well-to-moderately differentiated adenocarcinoma found that SRC has mixed prognosis, having better survival for early gastric cancer (i.e., T1) but worse prognosis in advanced disease compared to well-to-moderately differentiated adenocarcinoma.[52]

Sporadic gastric adenocarcinomas demonstrate a number of chromosomal and genetic abnormalities. Cytometric analysis reveals that gastric tumors with a large fraction of aneuploid cells (with a greater-than-normal amount of nuclear DNA) tend to be more highly infiltrative and have a poorer prognosis. Amplifications of both the HER-2/*neu* and K-*ras* proto-oncogenes have been consistently detected in gastric adenocarcinomas, and in a small percentage of tumors a lack of expression of the tumor suppressor gene *MKK4* is robustly associated with poor survival.[53]

In the United States, the incidence of proximal gastric cancers has been increasing markedly over past few decades while tumors of body and distal stomach are relatively stable.[54] Proximal cancers are more likely to occur in

young White men and distal cancers are more likely to occur in Asian, African American, and Hispanic patients within the United States. In 10% of cases, the stomach is diffusely involved at the time of diagnosis based on historical data.[30] Prognosis is poorer for tumors arising from the proximal stomach and for those with diffuse involvement of the organ relative to distal tumors. As such, these patients are much more likely to need neoadjuvant and adjuvant therapy.[10,55]

The 8th edition American Joint Committee on Cancer (AJCC) staging system[56] for gastric cancer is presented in **Table 47.2.** The staging system accurately discriminates prognosis based on pathologic factors for tumors located 5 cm distal to the esophagogastric junction (EGJ) and below or arising within 5 cm of, but not crossing, the EGJ (**Fig. 47.8**). The AJCC recommends that cancers arising within 5 cm of the EGJ that cross into the EGJ or esophagus be staged and treated as esophageal cancers. A consideration of staging data illustrates the high frequency with which lymph node metastases are present at the time of diagnosis in the United States, and the severe impact lymphatic involvement has on survival. Even early gastric cancers (tumors restricted to the mucosa and submucosa) have a 15% prevalence of nodal metastasis.

Curative-Intent Treatment

Surgical resection is the only potentially curative therapy for gastric cancer, but an advanced stage of disease at the time of diagnosis precludes curative resection for most patients. Since the mid-1990s, the surgical treatment of gastric cancer has continued to evolve, with minimally invasive approaches increasingly pursued for early cancers and increasingly radical operations advocated by some for advanced tumors. The Japanese Gastric Cancer Association defines early gastric cancer as tumor in which invasion is restricted to the mucosa or submucosa, noting that the presence or absence of lymph node metastasis is not considered in this classification.[57] While the presence of lymphatic metastasis cannot be correctly judged by endoscopic findings, it is critically important in prognosis. For tumors confined to the mucosa, lymphatic metastasis is present in 1% to 3% of cases; with submucosal involvement, the rate of nodal positivity increases to 14% to 20%.[58,59]

Endoscopic Resection

Endoscopic approaches to the treatment of gastric cancer continue to evolve and advance. Endoscopic mucosal resection (EMR) and endoscopic mucosal dissection (EMD) may be considered as alternatives to surgical resection for very early-stage gastric cancer, especially by those with extensive experience with the techniques. For intestinal-type mucosal tumors less than 2 cm in size without ulceration or evidence of lymphovascular invasion, EMR may be performed with achievement of an R0 resection. With this approach, postoperative bleeding or perforation has been reported in up to 5%, and in up to 17% histologic examination revealed submucosal invasion that required further operative treatment.[60] A Japanese series of 131 patients reported disease-free survival of 99% at 10 years[61] and others have demonstrated long term results comparable to gastrectomy in terms of recurrence and mortality.[62] ESD is an emerging technique that may allow larger tumors (>3 cm) to be endoscopically resected. Even in experienced hands at high volume centers, there are higher associated rates of bleeding and perforation and there may not be any benefit over EMR for lesions less than 5 cm in size.[63,64] Attention to surveillance endoscopy following EMR or ESD is mandatory.

Table 47.2 8th Edition AJCC Staging System for Carcinoma of the Stomach

Primary Tumor	
T0	No evidence of primary tumor
Tis	Carcinoma in situ; intraepithelial tumor without invasion of the lamina propria, high-grade dysplasia
T1a	Tumor invades lamina propria or muscularis mucosae
T1b	Tumor invades submucosa
T2	Tumor invades muscularis propria
T3	Tumor penetrates subserosal connective tissue without invasion of visceral peritoneum or adjacent structures
T4a	Tumor invades serosa (visceral peritoneum)
T4b	Tumor invades adjacent structures
Regional Lymph Node Involvement	
N0	No regional nodal metastasis
N1	Metastasis to 1–2 regional lymph nodes
N2	Metastasis to 3–6 regional lymph nodes
N3a	Metastasis in 7–15 regional lymph nodes
N3b	Metastasis in 16 or more regional lymph nodes
Distant Metastasis	

M0	No distant metastasis
M1	Distant metastasis

Validation of the 8th edition of the AJCC TNM staging system for gastric cancer using the National Cancer Database. *Ann Surg Oncol* 2017;24:3683–3691.)

Surgical Resection

4 The fundamental principle of surgical resection of gastric cancer is complete extirpation of the primary tumor. The extent of gastric resection is determined primarily by the need to obtain a resection margin free of microscopic disease (R0 resection) and requires formal, anatomic gastrectomy. Microscopic involvement of the resection margin by tumor cells (R1 resection) is associated with poor prognosis. Patients with positive surgical margins are at high risk for development of recurrent disease, and histologically positive margins are strongly correlated with the development of anastomotic recurrence. In the setting of ≥5 positive nodes, however, margin positivity itself does not impact survival,[65] because these patients are

at higher risk for systemic recurrence. In contrast to other gastrointestinal malignancies such as colon cancer, gastric cancer frequently demonstrates extensive intramural spread, especially the diffuse type. The propensity for intramural spread is related, in part, to the extensive anastomosing capillary and lymphatic network in the wall of the stomach. As such, wedge or segmental resections are inadequate and should not be performed. Based on retrospective studies as well as prospective data from the Italian Gastrointestinal Tumor Study Group, when performing a subtotal gastrectomy, a 3- to 6-cm (commonly cited as 5-cm) margin of resection is adequate and necessary to minimize anastomotic recurrence.[66,67]

For lesions in the distal two-thirds (middle or distal third) of the stomach, subtotal gastrectomy is usually sufficient for complete removal of the primary tumor.[42] In contrast, lesions in the upper third of the stomach generally require total gastrectomy (or esophagogastrectomy) to assure adequate resection (**Fig. 47.9**).[42] For tumors involving the cardia without involvement of the gastroesophageal junction, some have advocated proximal gastrectomy as an alternative to total gastrectomy with esophagojejunostomy with the goal of preserving a gastric reservoir. This procedure does not compromise oncologic outcomes,[68] but there is a significantly higher incidence of severe reflux esophagitis with proximal gastrectomy and is generally not recommended even with jejunal interposition or fundoplication. The distal stomach is typically divided at the level of the duodenal bulb, beyond the pylorus. Local invasion into the duodenum on the distal margin can occur though pancreaticoduodenectomy is rarely needed to assure clearance of disease. Frozen section evaluation of resection margins may be obtained prior to proceeding with reconstruction in order to improve the probability that radical (R0) resection is achieved, especially if gross margins are deemed closer than 3 cm. However, the decision to reresect in the setting of a positive frozen section margin is controversial and must take operative risk as well as tumor biology into account. Reexcision has only been associated with improved survival in early-stage gastric cancer.[69,70] It is plausible that positive frozen section margins may be a surrogate for aggressive disease.

During the course of a radical resection, ligation of the right gastric and right gastroepiploic artery is standard. Ligation of the left gastric artery is a required part of a total gastrectomy, and is done selectively for partial gastrectomy. While the omentum is commonly removed en bloc as part of a

radical gastrectomy, complete removal of the omental bursa (the peritoneum overlying the pancreas and anterior transverse mesocolon) is not indicated.[42] For some T4 tumors, a multivisceral resection is indicated if required to achieve complete removal of the tumor in the course of a curative intent resection. Data evaluating the additional morbidity and mortality associated with multivisceral resection is variable and may be dependent on the organs removed, with higher risks associated with pancreatectomy than with splenectomy or colectomy.

Radical gastric operations can be performed with acceptable morbidity and low mortality rates in the older age groups at greatest risk for gastric cancer. In modern series, mortality rates for total gastrectomy range from 3% to 6%.[71] There is some evidence that outcomes are superior at higher-volume centers.[72,73] In the postacute setting, nutritional support in the immediate postoperative period is an important adjunctive measure as patients resume oral intake, and many surgeons place a jejunal feeding tube at the time of total gastrectomy to ensure that optimal enteral nutrition can be delivered in the postoperative period. Surgical reconstructions that interpose a small intestinal reservoir between the esophagus and the jejunum have been advocated after total gastrectomy, but a clear nutritional benefit has not been demonstrated.[74–76] Postoperative complications, including malnutrition, adversely impacts long-term survival in patients with gastric cancer due to a generalized failure to thrive or perhaps due, at least in part, to lower rates of adjuvant therapy.

Because gastric cancer metastasizes so frequently to lymph nodes, radical extirpation of draining lymph nodes has both diagnostic/staging and therapeutic implications.[77] The value of routine-extended lymphadenectomy beyond the perigastric lymph nodes in the treatment of gastric adenocarcinoma, however, is controversial. The first favorable experience was reported from Japan[78,79] and extent of resection in the original Japanese system is shown in **Table 47.3**; the current nomenclature used to define extent of lymphadenectomy is shown in **Table 47.4** and **Figure 47.10**. Only retrospective studies of extended perigastric lymphadenectomy have been reported from Japan and those reports suggested an improvement of approximately 10%, stage for stage, for patients with advanced disease treated with D2 or D3 operations.[78–80] The benefits of extended lymphadenectomy have not been confirmed in non-Japanese centers, and

several randomized trials in Western centers have failed to show a survival benefit for extended lymphadenectomy when the entire patient population was analyzed.[81–84] Long-term follow-up results from the Dutch trial of D1 versus D2 lymphadenectomy have shown a lower gastric cancer–related death rate in the D2 group (37% vs. 48%) and lower rates of local and regional recurrence.[85] However, the significance of this finding and implications for extended lymphadenopathy is unclear given the absence of an overall survival benefit as well as intervening improvements in adjuvant therapy over the 15-year follow-up period.

Data from a national Japanese registry indicate a contemporary mortality of less than 1% associated with extended lymphadenectomy[86] and low mortality risks have been reported from multi-institutional trials conducted in Italy and Germany.[84,86,87] Investigations from the United States, Britain, and the Netherlands have been less optimistic, indicating increased short-term morbidity and in-hospital mortality.[81,82] Histologically positive lymph nodes are frequently present in the splenic hilum and along the splenic artery, and routine splenectomy has been practiced in some centers. Splenectomy in this setting has not been demonstrated to improve outcome for similarly staged patients.[88,89] Associated splenectomy or pancreatosplenectomy is only beneficial when there is direct extension or bulky adenopathy at the splenic hilum.

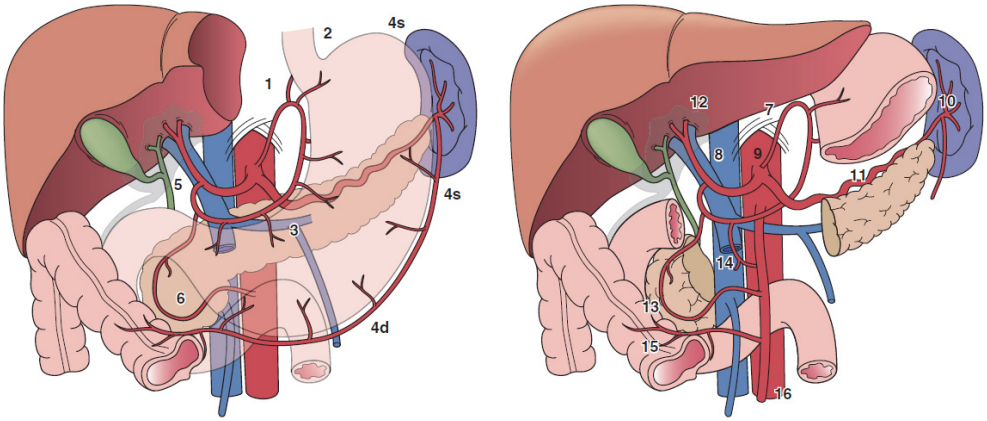
Table 47.3 Lymphadenectomy in the Original System of the Japanese Research Society for Gastric Cancer

Level	Description
R1	Resection of stomach, omentum, and perigastric lymph nodes
R2	Resection of stomach, omentum, and en bloc removal of the superior leaf of the transverse mesocolon, the pancreatic capsule and lymph nodes along the branches of the celiac artery and in the infraduodenal and supraduodenal areas
R3	Resection of the above structures plus lymph nodes along the aorta and esophagus, along with the spleen and the tail of the pancreas, and skeletonization of vessels in the porta hepatis

Recommendations for a minimum number of regional lymph nodes retrieved and examined with lymphadenectomy serve as a proxy for adequacy of resection. Emphasis on the total number of nodes removed rather than the location of the nodes (e.g., D1 lymphadenectomy) continues to be debated. While the AJCC staging system does not strictly specify a minimum number of nodes, N3b disease is defined by metastases in 16 nodes. As such, current recommendations for gastric cancer staging suggest that a minimum of 16 nodes need to be evaluated.[42,56,90]

Table 47.4 Current Nomenclature Used to Describe the Extent of Lymphadenectomy Performed in Conjunction with Gastrectomy

Level	Description
D0	Any lymph node removal that is less than D1
D1	Resection of greater and lesser omenta, including the perigastric nodes along the right and left cardia, nodes along the lesser and greater curvatures, suprapyloric nodes along the right gastric artery, and infrapyloric nodes
D2	D1 dissection plus nodes along the left gastric artery, common hepatic artery, celiac trunk, splenic hilum, and splenic artery
D3	D2 dissection plus nodes in the hepatoduodenal ligament, retropancreatic nodes, and nodes at the root of the mesentery the para-aortic lymph nodes
D4	D3 dissection plus paracolic and para-aortic nodes



N1 Lymph nodes (perigastric)
1 Right cardiac nodes
2 Left cardiac nodes
3 Nodes along the lesser curvature
4d Lymph nodes along the short gastric and the left gastroepiploic vessels
4s Lymph nodes along the right gastroepiploic vessels
5 Suprapyloric nodes
6 Infrapyloric nodes

N2 Lymph nodes (celiac axis branches)
7 Nodes along root left gastric artery
8 Nodes along common hepatic artery
9 Nodes around celiac axis
10 Nodes at splenic hilum
11 Nodes along splenic artery

N3 Lymph nodes
12 Nodes at the hepatoduodenal ligament
13 Retropancreatic (periduodenal) nodes
14 Nodes at the root of the mesentery

N4 Lymph nodes
15 Nodes along the middle colic vein
16 Para-aortic nodes

Figure 47.10 Lymph node locations and groupings. D1 dissection: removal of N1 nodes. D2 dissection: removal of N1 and N2 nodes. D3 dissection: removal of N1, N2, and N3 nodes. D4 dissection: removal of N1–N4 nodes.

A minimally invasive approach to gastrectomy, defined as laparoscopic or robotic, appears to be increasingly acceptable as an alternative to open surgery. The main use of minimally invasive gastrectomy includes, but is not necessarily limited to, early and distal tumors. Resection of more advanced cancers or total gastrectomy have been reported for treatment of known gastric malignancy, but must take surgeon experience into account. Multiple studies from Japan, Korea, and Italy have demonstrated that distal, subtotal, or total gastrectomy with lymphadenectomy is feasible with acceptable morbidity and mortality. A meta-analysis of four small single-institution randomized trials from Asia demonstrated lower nodal harvests with a laparoscopic approach for early gastric cancer. Complication rates were lower in the laparoscopic group but did not translate into differences in time to oral intake or length of stay.[91] However, a single-institution Western randomized trial of laparoscopic versus open subtotal gastrectomy for distal gastric cancer (both early and locally advanced) did report equivalent lymph node retrieval (33.4 ± 7.4 in the open group vs. 30 ± 14.9 in the laparoscopic group), as well as similar rates of perioperative morbidity and mortality. Their 5-year overall and disease-free survival were also similar for both groups: 55.7% and 54.8% for the laparoscopic group versus 58.9% and

57.3% for the open group, respectively.[92] More recently, results of the Korean Laparoendoscopy Gastrointestinal Surgery Study (KLASS), a multicenter randomized trial focused on distal gastrectomy for early gastric cancer demonstrated improved perioperative morbidity and no differences in oncologic outcomes have been shown with short follow-up.[93] Early results from the Chinese Laparoscopic Gastrointestinal Surgery Study (CLASS) Group randomized clinical trial comparing the safety of laparoscopic versus open total gastrectomy with lymphadenectomy for patients with clinical stage I gastric cancer showed that overall morbidity and mortality rates were not significantly different between the groups.[94]

Neoadjuvant and Adjuvant Therapies

5 Given the largely disappointing outcomes of locoregional or locally advanced gastric cancer in Western countries, significant interest has focused on the use of multimodality therapy. Several neoadjuvant and adjuvant approaches have been explored. Although there is no consensus on the optimal approach, it is clear that all patients with locally advanced disease should be considered for multimodality therapy. Several landmark trials highlight a primary role for both adjuvant and neoadjuvant chemotherapy. Despite the limitations of these studies, which are beyond the scope of the present discussion, improved survival observed across trials makes it clear that a multimodality approach is superior to surgery alone for those patients with locally advanced gastric cancer. The addition of radiation to surgery has also been associated with improved local control and survival.[95] A randomized phase III trial (CRITICS) comparing perioperative chemotherapy with preoperative chemotherapy followed by postoperative chemoradiation found no improvement in overall survival with the addition of postoperative radiation.[96] However, numerous ongoing studies are investigating the relative benefits of various chemotherapeutic regimens as well as the incremental benefit of chemoradiotherapy (with radiation in both the preoperative and postoperative settings) versus chemotherapy alone. This includes CRITICS II which compares three preoperative strategies: chemotherapy, chemoradiation (concurrent), and sequential chemotherapy and chemoradiation treatments.[97]

A neoadjuvant, or perioperative, approach is preferred for resectable disease. A randomized controlled phase II/III trial led to standard

recommendations for fluorouracil, leucovorin, oxaliplatin, and docetaxel (FLOT) for patients with T2 or greater disease and/or node-positive disease if performance status is good.[98] Other regimens may be considered if performance status is more concerning since a regimen of fluorouracil and oxaliplatin (FOLFOX) is better tolerated and has a lower chemotherapy-related toxicity profile. There are newer considerations for a total neoadjuvant therapy approach, meaning that all systemic therapy is administered in advance of the operation. In these cases, additional chemotherapy in the postoperative setting is only administered if microscopic disease or unexpectedly advanced nodal disease is found at time of gastrectomy. Some have advocated for the total neoadjuvant approach in order to mitigate against the adverse impact postoperative complications, and subsequent delays in adjuvant treatment, may have on long-term survival[99] as it appears that rates of completion of multimodality treatment are much higher when given in the preoperative setting.

Targeted therapies, which are currently approved for use for recurrent, advanced, or metastatic disease, are also being actively investigated for use in the neoadjuvant setting. Treatment with trastuzumab is based on HER-2 status, with phase III trial evidence supporting first-line use in metastatic gastric cancer.[100] Testing for HER-2 expression, microsatellite instability/DNA mismatch repair deficiency, and PD-L1 status are recommended in the setting of metastatic disease.

As preoperative strategies continue to evolve, patients with locally advanced resectable gastric cancer are optimally treated in a center where a collaborative multidisciplinary treatment approach can be devised and executed (**Algorithm 47.1**). Not only is discussion at a team meeting, or tumor board, important for decision making and treatment planning, but it also helps with careful coordination across the continuum of cancer care.

Palliative Surgical Treatment

When preoperative evaluation demonstrates disseminated disease, palliation of symptoms becomes a primary consideration. Palliation does not usually require surgical intervention. Obstruction and bleeding can be managed nonoperatively with endoscopic techniques, including intraluminal stents, or radiotherapy in selected patients. Dysphagia and bleeding caused by

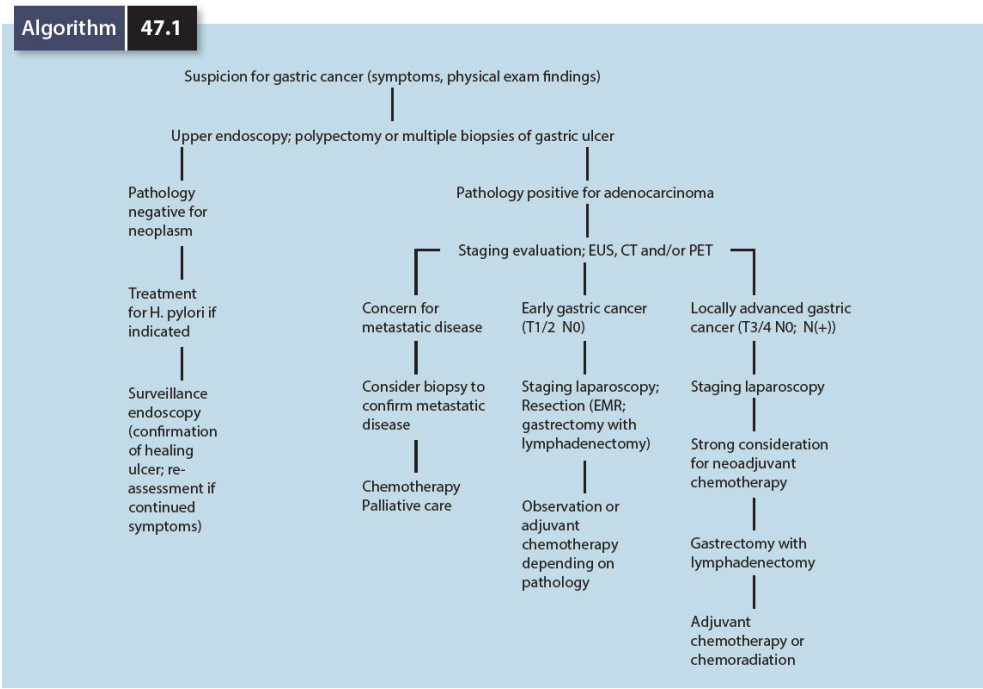
proximal lesions can also be alleviated endoscopically (laser therapy or stenting) in the majority of patients. Surgical palliation of obstructive symptoms (via formal resection or gastrojejunostomy) should generally be reserved for cases in which less invasive methods are contraindicated, technically infeasible, or unsuccessful. In addition to radiotherapy and endoscopic ablation or stenting, placement of a feeding jejunostomy tube with or without venting gastrostomy may be used to palliate gastric outlet obstruction, especially in patients with limited life expectancy. Many of these interventions area associated with high morbidity and are often ineffective at relieving symptoms; for example, gastrojejunostomy intended as a bypass procedure often does not afford gastric drainage and could delay onset of systemic treatments. Nonetheless, for a minority of patients, surgical palliation may be indicated; for example, noncurative resection may be necessary in the setting of intractable bleeding from the primary tumor. In the setting of metastatic gastric cancer, palliative resection does not improve survival, and systemic therapy is considered first-line treatment.

OTHER GASTRIC NEOPLASMS

Gastric Lymphoma

Clinical Features

The stomach is the site of more than half of gastrointestinal lymphomas and is the most common organ involved in extranodal lymphomas. Non-Hodgkin lymphomas account for approximately 5% of malignant gastric tumors. Patients are considered to have primary gastric lymphoma if initial symptoms are gastric in origin and the stomach is exclusively or predominantly involved with the tumor. Patients who do not fulfill these criteria are considered to have secondary gastric involvement from systemic lymphoma.



Algorithm 47.1 Diagnosis and management of gastric cancer.

Gastric lymphoma has peak incidence in the sixth and seventh decades. Symptoms are usually indistinguishable from those of peptic ulcer disease and gastric adenocarcinoma. Epigastric pain, weight loss, anorexia, nausea, and vomiting are common.[101] Systemic B symptoms such as fever and night sweats occur in a minority of patients but may be suggestive of the diagnosis. Although gross bleeding is uncommon, occult hemorrhage and anemia are observed in more than half of patients. Patients rarely have spontaneous perforation.

Diagnosis

Radiologic findings are similar to those for adenocarcinoma (gastric thickening and lymphadenopathy). Endoscopic examination is the diagnostic method of choice. The endoscopic appearance of lesions may be ulcerated, polypoid, or infiltrative, and this morphology may be further characterized by EUS. Gastric lymphoma is most commonly localized to the middle or distal stomach and unusually involves the proximal stomach, in contrast to gastric adenocarcinoma. Endoscopic biopsy, combined with endoscopic brush cytology and EUS, provides positive diagnosis in 90% of cases. Submucosal growth without ulceration of the overlying mucosa can occasionally render

endoscopic biopsy nondiagnostic. EUS-guided biopsy is useful in this circumstance.

Appropriate staging should search for evidence of systemic disease. CT of the chest and abdomen (to detect lymphadenopathy), bone marrow biopsy, and biopsy of enlarged peripheral lymph nodes are all appropriate.

Mucosa-Associated Lymphoid Tissue

The concept that low-grade gastric lymphomas have features resembling mucosa-associated lymphoid tissue (MALT) is a major advance in the understanding of gastric lymphomas. A number of observations support a causal relationship between chronic *H. pylori* infection and gastric lymphoma development. *H. pylori* is present in the stomachs of more than half of patients with gastric lymphoma[102] and 90% of those with gastric MALT lymphoma.[103] As with gastric adenocarcinoma, geographic regions with a high prevalence of *H. pylori* also have a high incidence of gastric lymphoma. Infection with *H. pylori* has been noted to precede development of gastric lymphoma.[104]

Gastric MALT lymphoma is postulated to begin with chronic inflammation due to infection with *H. pylori*. Chronic gastritis leads to the accumulation of CD4+ lymphocytes and B cells in the gastric lamina propria. *H. pylori*–derived antigens drive T-cell activation, interleukin-2 (IL-2) release, and B-cell proliferation.[105] Progressive genetic rearrangements lead to IL-2–independent B-cell proliferation. With cumulative genetic defects, low-grade MALT lymphoma progresses to high-grade disease.

Low-grade MALT lymphomas resemble Peyer patches. Lymphoma cells invade between follicles and into gastric epithelium; invasion of gastric glands forms characteristic lymphoepithelial lesions. Low-grade lesions are often multifocal. Low-grade MALT lesions are less likely than high-grade tumors to invade transmurally, involve perigastric lymph nodes, or invade adjacent organs.[104] Approximately 40% of gastric lymphomas are low-grade MALT lymphomas.

The concept that low-grade lymphoma depends on continued *H. pylori* antigenic stimulation supports eradication of *H. pylori* with antibiotics as first-line antineoplastic therapy. Complete regression of low-grade gastric MALT lymphomas with antibiotic treatment has been reported in 70% to

100% of cases. The median time to complete response is 5 months.[106–108] Most patients with partial responses were subsequently determined also to have foci of high-grade lymphoma. Radiation and chemotherapy have been proposed as salvage for antibiotic treatment failures or for the minority of patients with *H. pylori*–negative gastric MALT lymphoma.

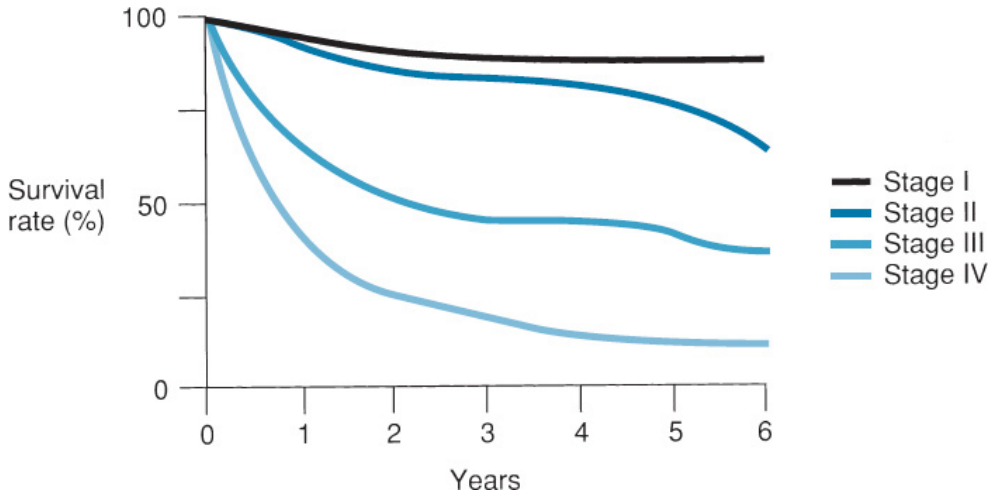


Figure 47.11 Survival with gastric lymphoma, by stage.

Non-MALT Lymphomas

Most non-MALT gastric lymphomas are diffuse large B-cell lymphomas (DLBCLs), including those that were previously called "high-grade MALT lymphomas." DLBCLs typically exhibit more aggressive behavior and worse prognosis than MALT lymphomas. Other histologies, such as mantle cell, follicular, and peripheral T-cell lymphomas can also be seen. Survival for gastric lymphoma is closely linked to stage at diagnosis (**Fig. 47.11**).

In the past, a multimodality treatment program was used in most centers for primary gastric lymphomas, with gastrectomy as the first step in the therapeutic strategy.[109] Even without prospective data to support gastrectomy, several advantages of this approach had been cited: (a) more accurate histologic evaluation was possible; (b) in cases with localized tumor, the procedure could be curative; and (c) gastrectomy eliminated the risk of life-threatening hemorrhage or perforation which may occur with the treatment of tumors involving the full thickness of the gastric wall.[110] However, the role of gastrectomy for both staging and treatment of gastric lymphoma has diminished significantly, based in part on results of a randomized trial

demonstrating superior outcomes with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone) chemotherapy compared with surgery, surgery plus radiotherapy, or surgery with CHOP (**Fig. 47.12**).[111] It has also been recognized that the incidence of perforation during chemotherapy is only 5%. Most patients are currently treated with chemotherapy (commonly CHOP with rituximab) with or without radiotherapy. Surgical intervention is generally reserved for complications such as obstruction, bleeding, or perforation.

Gastric Carcinoids

Neuroendocrine, or carcinoid, tumors of the stomach were previously considered to be very rare tumors, but more recent studies report that as many as 10% to 30% of all carcinoids occur in the stomach, and they account for at least 1% of all gastric neoplasms.[112] Most patients with small gastric carcinoids are asymptomatic, and these tumors are most commonly diagnosed incidentally. Occasionally, however, larger tumors can present with abdominal pain, bleeding, or symptoms related to the secretion of bioactive substances (serotonin, histamine, or tachykinins) which can be produced by the tumor. When viewed endoscopically at an early stage, carcinoids are reddish-pink to yellow submucosal nodules in the proximal stomach. Endoscopic biopsy is usually diagnostic if sampling can be directed deep enough to sample submucosal tumor cells.

Classically, three types of gastric carcinoids have been described. Type 1 is the most common (70% to 80%) and is associated with chronic atrophic gastritis and pernicious anemia. These tumors tend to be small (<1 cm) and multiple, and exhibit indolent behavior. When they are less than 2 cm in size, they metastasize less than 10% of the time.[113] They can typically be followed and removed endoscopically, but surgery may be necessary for larger or very numerous tumors. Type 2 tumors comprise approximately 5% of gastric carcinoids and occur in patients with Zollinger–Ellison syndrome (gastrinomas), often in the setting of multiple endocrine neoplasia type 1 (MEN-1). Like type 1 tumors, they are often small, multiple, and indolent, and they can be treated endoscopically for the most part. Both type 1 and type 2 gastric carcinoid tumors are associated with hypergastrinemia. Type 1 and 2 gastric carcinoids arise from enterochromaffin-like (ECL) cells, which

mediate the secretion of histamine and in turn stimulate parietal cells to secrete acid. Hypergastrinemia (due to chronic atrophic gastritis in type 1 and gastrinoma in type 2) is thought to cause ECL cell hyperplasia and lead to the development of gastric carcinoids over time.

Type 3 lesions account for 20% of gastric carcinoids. Type 3 gastric carcinoids tend to be larger, solitary lesions. They are associated with normal gastrin levels and behave much more aggressively than other gastric carcinoid tumors.[114] Metastases are common, and these tumors can cause an atypical carcinoid syndrome. Type 3 carcinoids are best dealt with by resection and lymphadenectomy, the extent of which depends on the size of the tumor.

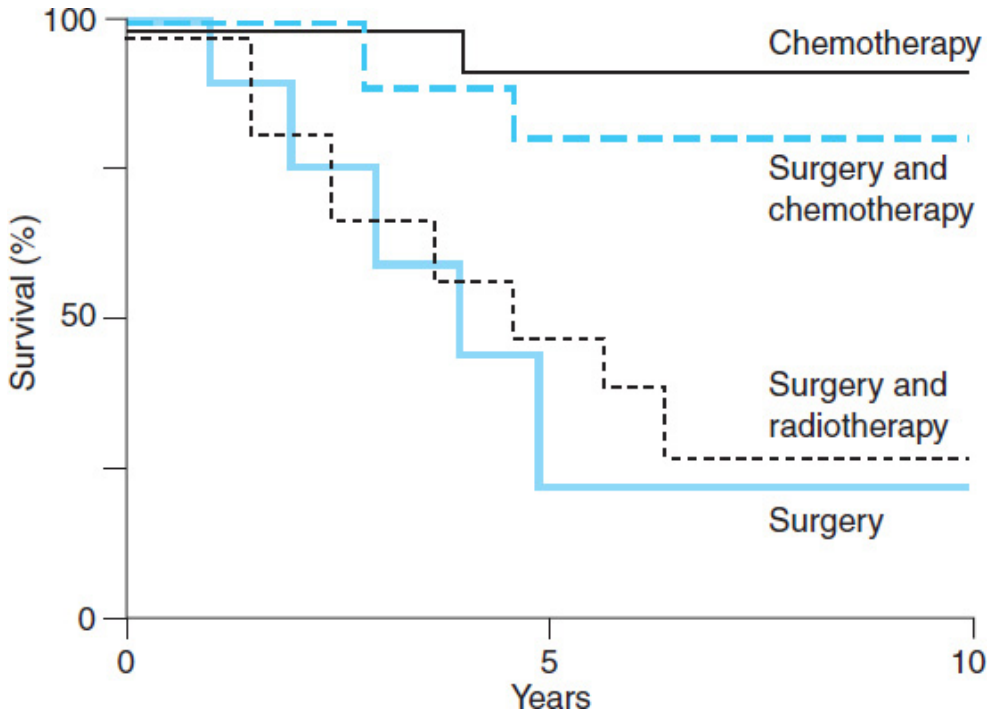

Figure 47.12 Relapse-free survival by treatment assignment for primary gastric diffuse large B-cell lymphoma.

Gastrointestinal Stromal Tumors of the Stomach

Gastrointestinal stromal tumors (GISTs) were historically misclassified as leiomyomas, leiomyosarcomas, and leiomyoblastomas due to a mistaken belief that they arose from the smooth muscle in the bowel wall. However, it

is now recognized that GISTs represent a distinct mesenchymal tumor type, and actually arise from the interstitial cells of Cajal, intestinal pacemaker cells located in and around the myenteric plexus in the bowel wall. While GISTs can arise anywhere within the gastrointestinal tract, approximately 50% of these tumors are found in the stomach. With a slight male predominance, GISTs are typically present in middle-aged and elderly individuals, with a median age at presentation of approximately 60 years. They are typically asymptomatic and are most commonly identified incidentally during endoscopy performed for other reasons. Their endoscopic appearance is that of a submucosal mass with normal overlying mucosa. If these tumors become large, however, they may present with symptoms of abdominal pain and bleeding. GISTs frequently have prominent extraluminal growth patterns, and central necrosis occurs as these tumors become very large and outgrow their blood supply (**Fig. 47.13**). If the majority of the growth is extraluminal, endoscopic examination may be unrevealing or only demonstrate umbilication of the mucosa suggestive of an underlying mass. EUS or CT imaging may be helpful for diagnosis in these cases. With large tumors, symptoms related to mass effect may occur. Ulceration of the overlying gastric mucosa may occur with tumor necrosis, and these patients may present with significant and intermittent gastrointestinal hemorrhage even at relatively small sizes.

The molecular hallmark of GISTs is overexpression of the CD117 antigen, which is part of the KIT transmembrane receptor tyrosine kinase. Mutations in *c-kit,* the proto-oncogene that encodes KIT, can lead to constitutive activation of the receptor and abnormal cell proliferation. Approximately 95% of GISTs overexpress KIT. Of those that do not, many have activating mutations in platelet-derived growth factor receptor alpha (PDGFRA), another receptor tyrosine kinase. However, some GISTs lack mutations in either of these genes, and many of these are characterized by inactivating mutations in the succinate dehydrogenase (SDH) complex. The molecular pathogenesis of GIST is important because of the availability of tyrosine kinase inhibitors (TKIs), such as imatinib and sunitinib. However, for GISTs that lack KIT or PDGFRA mutations, as well as those with certain types of KIT or PDGFRA mutations, there is resistance to TKI therapy.

Figure 47.13 CT scan of GIST of stomach arising from lesser curvature. The *arrow* indicates central tumor necrosis. The lesion caused mucosal erosion with gastrointestinal hemorrhage.

Table 47.5 Risk of Aggressive Behavior in Gastrointestinal Stromal Tumors

Risk	Size (cm)	Mitotic Count (per 50 HPF)	Primary Tumor Site
Very low	<2.0	≤5	Any
Low	2.1–5.0	≤5	Any
Intermediate	2.1–5.0	>5	Gastric
	<5.0	6–10	Any
	5.1–10	≤5	Gastric
High	>10	Any	Any
	Any	>10	Any
	>5.0	>5	Any
	2.1–5.0	>5	Nongastric
	5.1–10	≤5	Nongastric
	Any	Any	Tumor rupture

HPF, high-powered fields.

All GISTs should be considered potentially malignant, especially those >1 cm in size.[115] Tumor size and mitotic index are the most important prognostic variables (**Table 47.5**).[116] Site of origin is also prognostic, with gastric GISTs behaving generally less aggressively than intestinal GISTs.[117] For localized GISTs, surgical resection is the treatment of choice. When GISTs do metastasize, they do so by a hematogenous route (most commonly to peritoneal surfaces and the liver). Therefore, associated lymphadenectomy is typically not recommended or performed at the time of gastric resection for GIST. Additionally, unlike adenocarcinoma, GISTs do not present with an intramural growth pattern and thus gross margins of 1 to 2 cm are deemed adequate for resection of a GIST. Ultimately the goal of resection is a negative microscopic margin. If the tumor involves adjacent structures, then en bloc resection of nonvital structures should be performed whenever possible. Due to the less radical nature of surgery required for appropriate oncologic resection of these tumors as compared to adenocarcinoma of the stomach, minimally invasive surgical techniques have become widely

accepted as an appropriate and acceptable operative approach for these tumors.

For patients with metastatic or locally advanced, unresectable GISTs, imatinib is first-line therapy. Although most patients will respond to imatinib therapy, development of resistance is common, likely due to selection of clones with secondary KIT mutations.[118,119] These patients may be managed either with imatinib dose escalation or by using another TKI (e.g., sunitinib). Imatinib is also indicated in the adjuvant setting for tumors at high risk for recurrence. The ACOSOG Z9001 trial evaluated the efficacy of 1 year of adjuvant imatinib versus placebo in patients with resected GIST ≥3 cm in size and KIT positive.[120] Recurrence-free survival at 1 year was significantly higher in the imatinib arm (98% vs. 83%). No overall survival difference was shown, likely because patients were allowed to cross over to the imatinib arm after the study was unblinded. The Scandinavian Sarcoma Group evaluated the effect of 3 years versus 1 year of adjuvant imatinib after resection of high-risk GIST and found differences in 5-year recurrence-free survival (66% vs. 49%) and overall survival (92% vs. 82%), respectively.[121] Based on these data, 3 years of imatinib therapy are recommended after resection of high-risk GIST. Rates of recurrence after discontinuation of imatinib therapy are similar to those in untreated patients, suggesting that TKI therapy may simply be delaying recurrences rather than actually preventing them. Though no prospective randomized trial has determined a role for neoadjuvant imatinib, there are compelling data that in select populations (namely large and locally advanced tumors), neoadjuvant imatinib may help decrease size of tumor and morbidity of resection. If using neoadjuvant imatinib to help downsize borderline resectable GIST, early evaluation with PET CT can determine whether tumor is responding to therapy with decreasing FDG avidity within 1 to 2 weeks of onset of treatment, noting that changes in size are lagged and can take 6 to 9 months.

Section F: SMALL INTESTINE

48

Anatomy and Physiology of the Small Intestine

Joslin Cheverie, Jared S. Matson, and Sonia L. Ramamoorthy

Key Points

1 The normal adult anatomy of the small intestine is the result of a complex cascade of embryologic events which result in 270 degrees of counterclockwise rotation of the bowel around its axis. A failure of these precise steps produces a spectrum of congenital abnormalities.

2 There is no clear anatomic boundary between the jejunum and ileum. The proximal two-fifths of the small intestine distal to the ligament of Treitz have been defined as *jejunum* and the distal three-fifths as *ileum.*

3 The small intestine is the largest endocrine organ in the human body. The secretion of numerous hormones and neurotransmitters are specific to distinct anatomic zones within the small intestine.

4 The coordinated movement of the gastrointestinal (GI) tract is necessary for the proper digestion of food. Well-timed contraction and relaxation patterns are initiated in GI nervous system causing coordinated electrical activity and muscular movements.

5 The lumen of the GI tract is connected to the outside environment and comes in direct contact with many potentially pathogenic microorganisms. Consequently, the small intestine needs a complex defense mechanism to battle against these exposures in different ways.

6 While the exact mechanisms of many of the interactions between the gut microflora and the small intestinal microenvironment are still speculative, it has become evident that a symbiotic environment is present which, at least in part, is responsible for proper homeostasis of the small intestine.

7 The small intestine reabsorbs nearly 80% of the fluid that passes through it. This dynamic process is accomplished by a rapid bidirectional movement of fluid in the intestinal lumen.

8 The small intestine's intrinsic design provides a maximum amount of surface area to absorb nutrients, water, and electrolytes. Specialized areas provide neurohormonal stimulation to the digestive tract. Its

structure also provides an important physical barrier to potential pathogens and certain areas are critical in immune surveillance.

GROSS ANATOMY AND EMBRYOLOGY

The small intestine spans from the pylorus to the ileocecal valve, and includes three distinct regions: the duodenum, the jejunum, and the ileum. These areas combined measure approximately 200 to 300 cm in a newborn and 5 to 7 m (16 to 23 ft) in an adult, comprising greater than 60% of the total length of the alimentary tract. The gastrointestinal (GI) tract is formed from the endodermal layer of the developing embryo. The small intestine is derived from the distal foregut, midgut, and the adjacent splanchnic mesenchyme. Epithelium and glands develop from the embryonic endoderm, while connective tissue, muscle, and serosa develop from the mesoderm. During the fifth and sixth weeks of development, the duodenal lumen is temporarily obliterated due to proliferation of its mucosal lining. In subsequent weeks, luminal vacuolization and apoptosis result in recanalization of the duodenal lumen. From the 7th to 10th week of development, a large portion of the midgut is herniated through the umbilicus. At about 8 weeks of gestation, the midgut rotates counterclockwise 90 degrees around the axis of the mesenteric vasculature. The extra-abdominal portion of the gut returns to the abdominal cavity approximately 2 weeks later, rotating an additional 180 degrees. These two rotations provide 270 degrees of total rotation and result in the typical anatomy found in humans. Failure 1 of these precise steps produces a spectrum of anatomical variants which are grouped together as malrotation of the intestinal tract (**Table 48.1**).[1]

DUODENUM

The duodenum comprises the first portion of the small intestine and plays an important role in connecting the foregut organs to the midgut. It begins immediately distal to the pylorus and terminates at the ligament of Treitz,

where it joins the jejunum. The duodenum is divided into four distinct areas totaling approximately 20 to 30 cm in length.

The first portion (the bulb or cap) is approximately 5 cm in length. This area is directly attached to the pylorus and extends laterally and cephalad. It serves as an attachment for the hepatoduodenal ligament and traverses the common bile duct, portal vein, and pancreatic head. The mucosal surface of the duodenal bulb is smooth until its junction with the second portion of the duodenum. This area of the duodenum is prone to ulceration, accounting for approximately 90% of duodenal ulcers. These ulcers may erode into the gastroduodenal artery which lies directly posterior, causing potentially life-threatening bleeding (**Fig. 48.1**).

The second portion of the duodenum (descending duodenum) extends from the origin of the Kerckring folds to the beginning of the transverse duodenum and travels over the right renal vasculature and the inferior vena cava to the right of the L1 and L2 vertebrae. It is approximately 10 cm in length and 3 to 5 cm in diameter. The Kerckring folds (plicae circulares) are 1 to 2 mm thick and 2- to 4-mm high concentric mucosal folds separated by 2 to 4 mm of smooth, flat mucosa. The midportion of the descending duodenum serves as the entry point for pancreatic and biliary secretions into the GI tract, typically through the major papilla (ampulla of Vater), 7 to 10 cm from the pylorus. Through this point, the confluence of the common bile duct and the main pancreatic duct (duct of Wirsung) joins the duodenum. The valvular function of the papilla is regulated through the muscular sphincter of Oddi. The minor pancreatic duct (duct of Santorini) enters through the minor papilla proximal to the ampulla of Vater and endoscopically appears as a 1 to 3 mm polypoid structure.

Table 48.1 Small Intestine Development and Associated Pathology

Wk of Development	Key Steps in Small Bowel Formation	Associated Pathophysiology
3	Gut tube forms from endoderm lining the yolk sac	Duplication cysts
3–4	Regions of the gut become more defined as embryo grows and folds	
5–6	Obliteration of intestinal lumen due to endodermal proliferation	
7–8	Physiologic herniation of midgut into umbilical cord accompanies rapid increase in length	
7–9	Apoptosis of endoderm and growth of mesoderm recanalizes gut tube. Midgut rotates 90 degrees counterclockwise. Omphalomesenteric/vitelline duct closes	Duodenal atresia; malrotation; Meckel diverticulum, patent vitelline duct, umbilical hernia
8–12	Midgut rotates an additional 180 degrees counterclockwise (total rotation: 270 degrees) as it returns to the abdomen	Malrotation; omphalocele

The descending duodenum is important surgically as it represents the entry of the duodenum into the retroperitoneum. Surgical evaluation of the retroperitoneal duodenum, as well as the pancreatic head and bile duct,

requires mobilization from its posterior and lateral attachments (Kocher maneuver).

The third (transverse) and fourth (ascending) portions of the duodenum complete the duodenal sweep. The third portion is about 10 cm in length and courses from right to left; crossing the midline anterior to the spine, aorta, and inferior vena cava; and is closely attached to the uncinate process of the pancreas. The superior mesenteric artery (SMA) and vein (SMV) course anterior to the transverse duodenum to provide blood supply to the gut. The SMA forms an acute angle as it originates from the aorta and crosses over the duodenum, marking the transition to the fourth portion. An abnormally narrow angle can result in obstruction of the duodenum. The ascending duodenum is approximately 5 cm long and courses upward and obliquely to the ligament of Treitz, marking the end of the duodenum and the return of the small bowel to the peritoneal cavity.

VASCULAR AND LYMPHATIC SUPPLY

The vascular supply to the duodenum follows its embryologic origins, with branches of the celiac trunk supplying the foregut portion and branches of the SMA feeding the distal (midgut origin) duodenum. Venous drainage includes a series of pancreaticoduodenal veins which drain into the SMV–portal vein system. Lymphatic drainage follows the vascular supply with drainage to the pancreaticoduodenal nodes. From here, lymph drains superiorly to the hepatic nodes or inferiorly to the superior mesenteric nodes.

JEJUNUM AND ILEUM

2 Distal to the ligament of Treitz, the jejunum and ileum form the intraperitoneal small intestine. The boundary between them is determined such that 40% of the intraperitoneal small intestine comprises jejunum and 60% comprises ileum. This portion of the bowel is suspended within the peritoneal cavity by a thin, broad-based mesentery attached to the posterior abdominal wall. The jejunum and ileum move freely within the peritoneal cavity. The jejunum is the widest portion of the small intestine, whose

caliber progressively decreases until it terminates in the right lower quadrant at the ileocecal valve. The mucosa of the jejunum has a thick lining characterized by prominent plicae circulares that become shorter and less frequent in the ileum. The ileocecal valve exhibits motor characteristics separate from the terminal ileum and colon, postulated to prevent reflux of fecal material from the colon into the small intestine.[2] However, contrast studies have shown between 70% and 90% of patients have an incompetent ileocecal valve.[3,4]

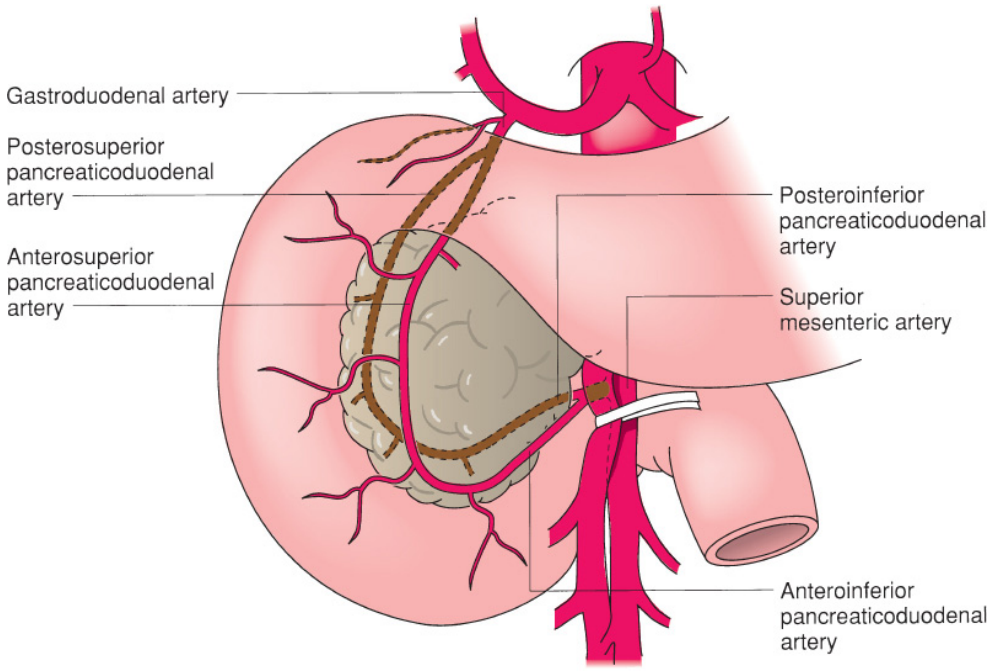

Figure 48.1 Arterial blood supply to the duodenum.

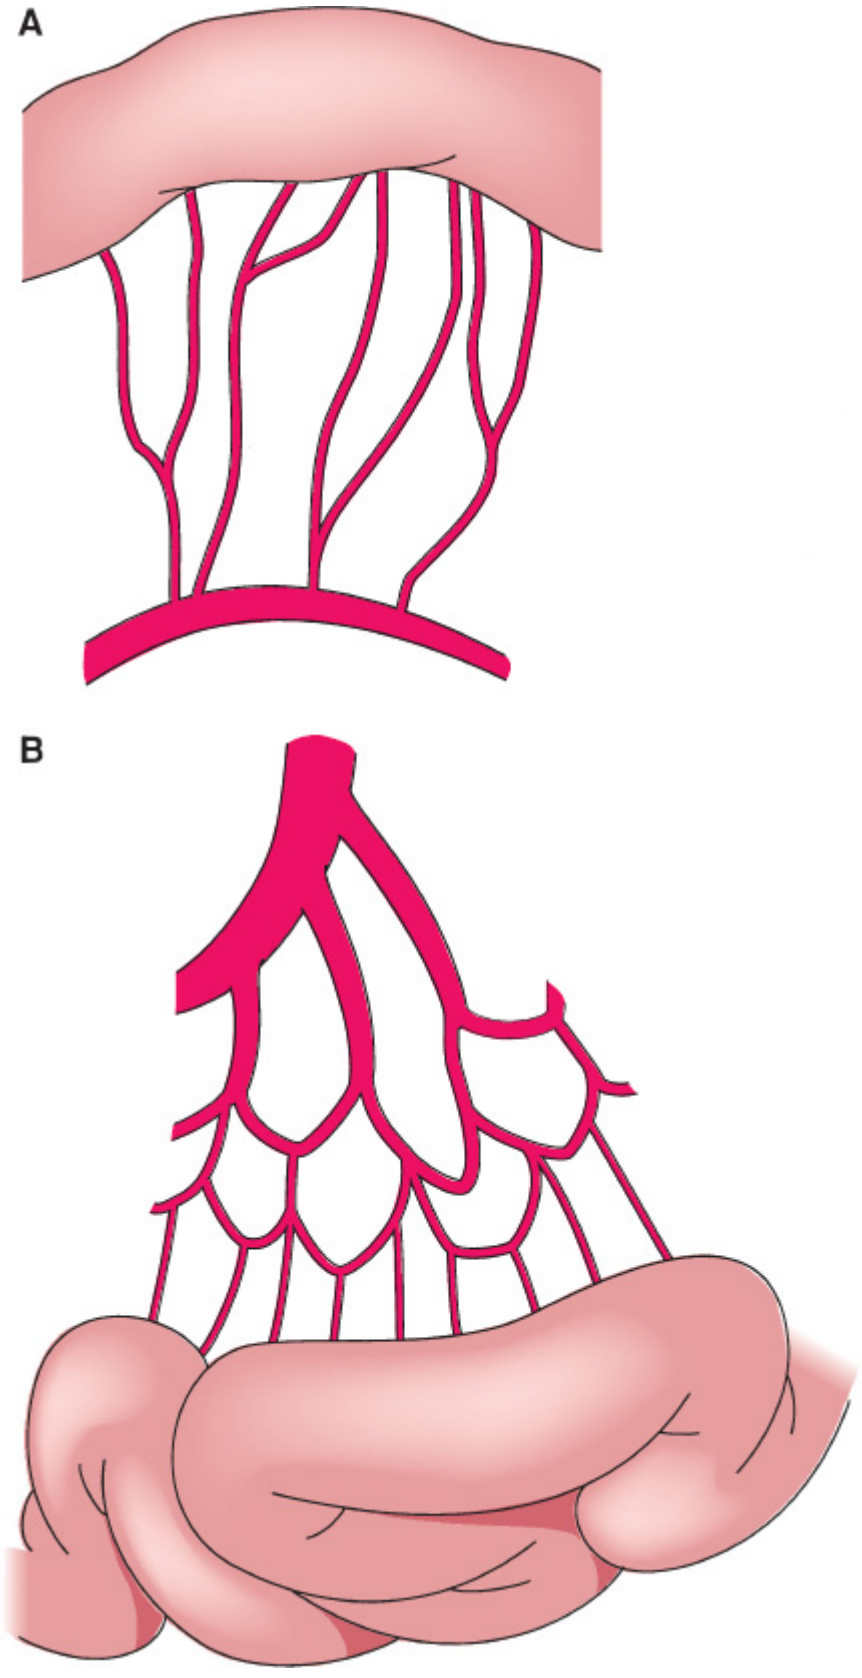
VASCULAR AND LYMPHATIC SUPPLY

The arterial blood supply of the jejunum and ileum arises from the SMA. The main vascular branches form arcades within the mesentery. The vasa recta, intestinal arterial branches, enter into the intestinal wall without anastomosing. The vasa recta of the jejunum are straight and long, in contrast to those of the ileum, which are shorter with greater arborization (**Fig. 48.2**). The venous and lymphatic drainage follow the arterial supply. The main venous outflow is through the SMV.



A
B

Figure 48.2 The superior mesenteric artery supplies blood flow into the small intestinal arteries (vasa recta) which branch within the mesentery. In the jejunum (**A**), the vasa recta are straight and long; this is in contrast to the vasa recta within the ileum (**B**), which are shorter with greater arborization.

MICROSCOPIC ANATOMY

General Considerations

The wall of the small intestine is composed of four distinct layers—mucosa, submucosa, muscle, and serosa. The role of the mucosa is absorption and secretion. The luminal mucosal surface forms circular folds known as plicae circulares or valvulae conniventes in all segments of the small intestine distal to the first portion of the duodenum. The submucosa contains an elaborate network of blood vessels, lymphatics, and nerves. The muscular portion of the wall includes outer longitudinal and inner circular muscle layers. Between the muscle layers lies the myenteric (Auerbach) plexus. The muscular layers are responsible for coordinating peristaltic movements. The outermost layer, the serosa, is composed of a thin layer of mesothelial cells overlying loose connective tissue. The serosa covers only the anterior surface of the retroperitoneal segments of small bowel, but it completely covers the portions of small bowel that are invested with mesentery.

Mucosa

The mucosa lines the luminal surface of the small intestine. It consists of three layers: epithelial cells, lamina propria, and a narrow layer of smooth muscle, the muscularis mucosae. Most of the intestinal lining is renewed over a period of approximately 5 days. The basic structural unit of the mucosa is the crypt and villus. Villi are finger-like projections of extending into the intestinal lumen that have a columnar epithelial surface and a cellular connective tissue core of lamina propria. Each villus contains a central lacteal (lymphatic), and a vascular network consisting of a small artery, vein, and capillaries. Ninety percent of the cells of the villi are columnar epithelial cells responsible for absorption and secretion. The apices of these cells have microvilli, produced by numerous folds in the apical membrane,

which account for the brush border appearance. Their surface is coated by glycoproteins rooted in the cell membrane. These glycoprotein filaments are referred to as the glycocalyx and are essential for digestion and absorption. The lateral membranes of neighboring enterocytes are connected by tight junctions, an apparent fusion of adjoining plasma membranes just below the level of the brush border. Movement of ions and water can occur by either a transmembrane or a paracellular route through tight junctions, which behave as selective pores.

Between the villi lie the crypts of Lieberkühn. Stem cells within the crypts of Lieberkühn are the source of the four major types of differentiated cells: the absorptive enterocyte, goblet cells, enteroendocrine cells, and Paneth cells. At the base of the crypt are Paneth cells that not only secrete antimicrobial peptides and play a key role in host microbiome interactions, but also help provide much of the environment for maintaining a stem cell niche.[5] As the stem cells divide, they move upward and out of the crypt, moving along signaling gradients triggering differentiation to the mature cell types populating the intestine. Mature cells include the enterocytes that make up the bulk of the cell type of the villus epithelium and are responsible for nutrient absorption. In addition, many epithelial cell genes are selectively expressed in the proximal small intestine, whereas other genes are specifically expressed only in the ileum.[6,7] Goblet cells secrete mucus into the intestinal lumen to help protect the epithelial lining of the intestine, and aid in the movement of luminal contents through the intestine. Enteroendocrine cells remarkably constitute the largest endocrine system in the body and secrete multiple regulatory hormones to regulate metabolism and postprandial secretion and motility.[8] As new cells arise in the crypt, all cells continue to migrate toward the tip of the villus, then undergo apoptosis and are shed into the intestinal lumen (**Fig. 48.3**).[7]

Enteroendocrine (also referred to as amine precursor uptake and decarboxylation, or APUD) cells may reside in either the crypts or the villi, depending on the particular neuroendocrine substance they produce. Specific areas of the small intestine have higher concentrations of specific neuroendocrine substances than other areas. These cells do not contact the intestinal lumen, unlike exocrine cells, and their secretory granules are located below the nucleus near the basement membrane. This suggests that

these cells secrete their contents into the circulation rather than into the intestinal lumen.

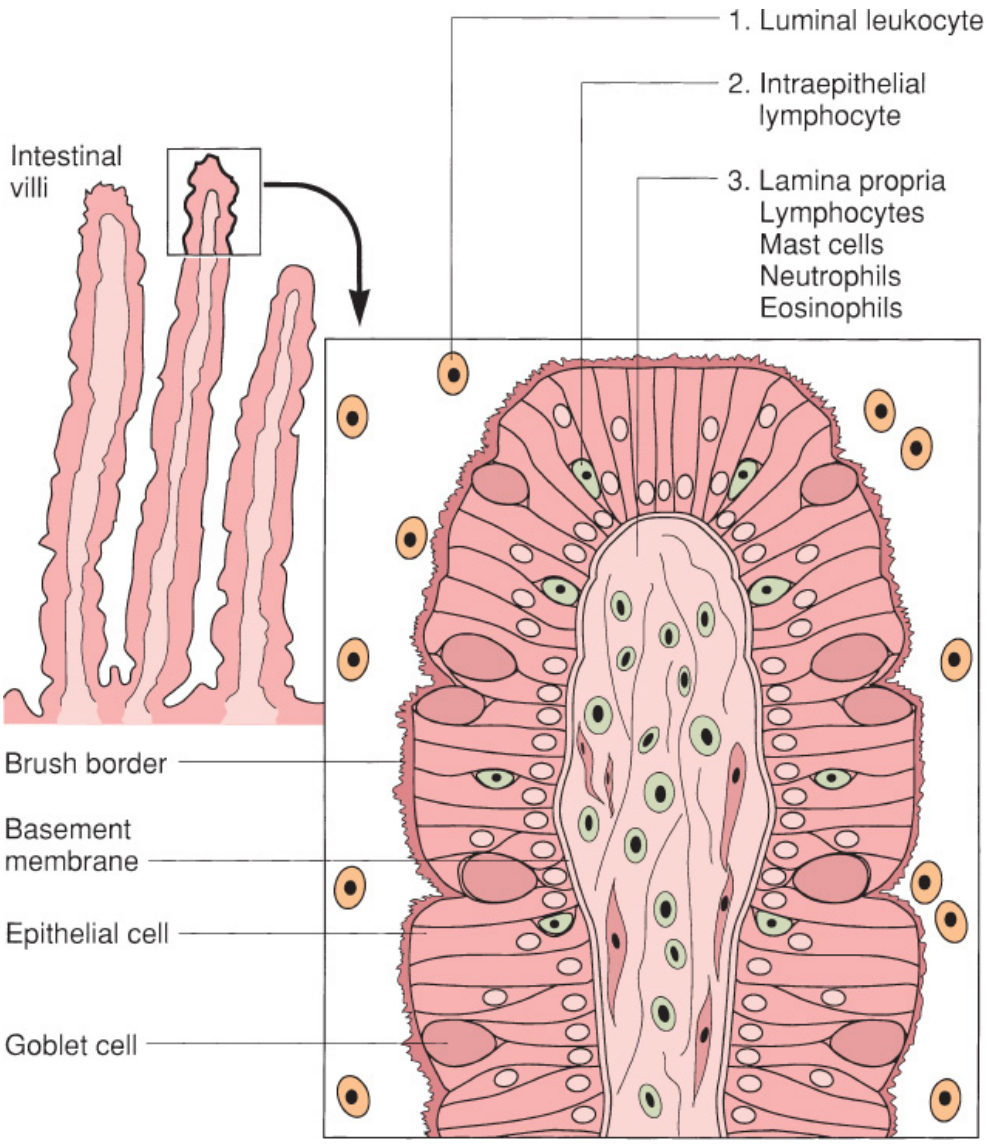


Figure 48.3 Small intestinal villus with associated immunologic cells.

Submucosa

The submucosa is a dense connective tissue layer with a rich network of blood vessels, nerves, and lymphatics. The submucosa contains Meissner plexus and is the strongest layer of the intestinal wall. Brunner glands are found in the submucosa of the duodenum and secrete mucus and bicarbonate into the intestinal lumen. These secretions aid in the neutralization of the

gastric acid load which enters the duodenum. Peyer patches are localized collections of lymphoid follicles that are most prominent in the submucosa of the ileum. These are most abundant early in life, gradually disappearing with age.

Physiology

The small intestine plays important physiologic roles in motility, blood flow, growth, digestion, absorption, immune function, and endocrine secretion. In fact, the small intestine is the largest 3 endocrine organ in the human body.[9] The secretion of numerous hormones and neurotransmitters are specific to distinct anatomic zones within the small intestine (**Table 48.2**). There is no specific cell mass which produces these hormones, but rather individual cells scattered along the GI tract.

Gastrin is a peptide produced in the gastric antrum and in the duodenum by the G cells and secreted into the circulation in response to gastric distension, vagal stimulation, amino acids, and hypercalcemia. Its release is inhibited by low intraluminal pH, somatostatin, secretin, gastric inhibitory peptide (GIP), vasoactive intestinal peptide (VIP), glucagon, and calcitonin. Gastrin binds to cholecystokinin 2 (CCK2)/gastrin receptors on enterochromaffin-like (ECL) cells causing a release of histamine which in turn stimulates the parietal cells in a paracrine fashion. Gastrin also causes an increase in gastric blood flow and the release of pepsinogen by the chief cells and pancreatic enzymes from the pancreatic centroacinar cells.

CCK is produced in the proximal two-thirds of the small intestine by the I cell and is released into the gut lumen. It shares the final five amino acids adjacent to the C-terminus with gastrin, and this accounts for its hormonal activity. Stimulation of I cells by amino or fatty acids causes release of CCK; this in turn stimulates contraction and emptying of the gallbladder, increases bile flow, causes relaxation of the sphincter of Oddi, and stimulates pancreatic enzyme secretion. CCK also has trophic effects on the small intestinal mucosa and pancreas.

Secretin is produced by the S cells of the duodenum and jejunum. Secretin is released into the circulation and intestinal lumen in response to low intraluminal pH, fatty acids, and bile salts. Water and bicarbonate are secreted by the pancreas in response to secretin. Bicarbonate is also released

from the biliary ductal epithelium and Brunner glands in response to secretin. In turn, pancreatic enzymes are released from the pancreas. The increased pH and the presence of pancreatic enzymes aid in the digestion of lipids. The increased pH also provides a negative feedback loop to inhibit further production of secretin. Secretin produces a paradoxical release of gastrin in patients with gastrinomas but does not produce this effect on normal individuals.

Somatostatin is a peptide hormone is produced by the D cells in the pancreatic islets, gastric antrum, and duodenum. Its primary role is inhibition of other GI hormones and inhibition of pancreatic, biliary, and gastric secretion. In addition, somatostatin decreases splanchnic and portal blood flow. Somatostatin is stimulated by the presence of fat, proteins, acid, glucose, amino acids, and CCK. Octreotide, a long-acting synthetic somatostatin analog, is used in the treatment of variceal bleeding, hormone secreting neuroendocrine tumors, carcinoid syndrome, and enterocutaneous and pancreatic fistulas.[10]

Table 48.2 Intestinal Hormones

Hormone	Location	Cell	Stimulated by	Function
Gastrin	Stomach, duodenum	G cells	Vagal stimulation, gastric distension, amino acids, and hypercalcemia	Stimulates secretion of gastric H^+ and intrinsic factor from parietal cells and pepsinogen from chief cells, promotes gastric and intestinal motility, mucosal growth
Cholecystokinin (CCK)	Duodenum, jejunum	I cells	Vagal stimulation, fatty acids	Gallbladder contraction, release of pancreatic enzymes, relaxes sphincter of Oddi to release bile, induces satiety
Secretin	Duodenum, jejunum	S cells	Low intraluminal pH, fatty acids, and bile salts	Secretion of HCO_3 from pancreas inhibits gastrin and gastric acid secretion
Somatostatin	Throughout small intestine	D cells	Fatty acids, proteins, low intraluminal pH, glucose, amino acids, and CCK	Inhibits secretion and function of gut hormones
Vasointestinal Peptide (VIP)	Enteric nerves	Fat	Vagal stimulation	Increases water and electrolyte secretion from gut and pancreas
Gastrin-Releasing Peptide	Duodenum, jejunum	K cells	Vagal stimulation	Reduces gastric acid secretion and motility
Motilin	Throughout small intestine	Mo and ECL cells	Released during interdigestive periods, high pH	Increases small bowel motility (MMC) and gastric emptying
Neurotensin	Ileum, proximal small intestine	N cells	Fatty acids	HCO_3, motility
Pancreatic glucagon	Proximal small intestine	L cells	Low serum glucose	Induces glycogenolysis, lipolysis, gluconeogenesis, and ketogenesis

Gastrin-releasing peptide, the mammalian homolog of bombesin, is a peptide which is produced by the small intestine and is released in response to vagal stimulation. It is a prostimulatory molecule which causes the release of most GI hormones, except for secretin. It also has a promotility effect and stimulates endothelial proliferation. GIP or glucose-dependent insulinotropic peptide (GIP) is a 42 amino acid peptide produced by the K cells of the duodenum and jejunum. It is released in response to glucose, fat, protein, and adrenergic stimulation. It stimulates secretion of insulin and inhibits gastric acid and pepsin production.

Motilin is a peptide produced by the enteroendocrine cells in the duodenum and jejunum. Release of motilin occurs during the interdigestive and fasting periods. Release may also be related to alkalinization of the duodenum. Motilin's main function is to stimulate the migrating myoelectric

complex. Motilin agonists such as erythromycin, are used clinically as stimulants of GI motility.

VIP is an amino acid peptide which is produced by GI tract neurons. It serves as a neurotransmitter stimulating pancreatic exocrine and intestinal secretion. Conversely, it has an inhibitory effect on gastric acid secretion. VIP is a potent vasodilator and relaxant of enteric smooth muscle and stimulates secretion of water into pancreatic juice and bile, and cause inhibition of gastric acid secretion and absorption from the intestinal lumen. These effects work together to increase motility.[11]

Neurotensin is a peptide that is produced by the N cells primarily in the ileum, but also in the proximal small intestine and colon in response to the presence of intraluminal fat. It stimulates pancreatic bicarbonate secretion and intestinal motility. Neurotensin also serves as a trophic factor on the small intestinal mucosa and inhibits gastric secretion.

Pancreatic glucagon and enteroglucagon are peptides produced by the α-islet cells of the pancreas and the L cells of the small intestine, respectively. Pancreatic glucagon is released in response to low serum glucose and subsequently induces glycogenolysis, lipolysis, gluconeogenesis, and ketogenesis. Enteroglucagon is released in response to the presence of a mixed meal and inhibits gastric emptying and small bowel motility.

Motility

The coordination of movements of the GI tract is necessary for 4 the proper digestion of food. Well-timed contraction and relaxation patterns are initiated in GI nervous system causing coordinated electrical activity and muscular movements. This may be influenced by both internal and external factors. During and immediately following times of feeding, the intestinal movements are not rhythmic, with complexes of peristaltic and antiperistaltic contractions. This is thought to be a disruption of the migrating motor complex (MMC) from bolus feeding. This seemingly random pattern of movements allows for effective mixing of chyme. Hormonal changes are thought to play a role in this process. Physiologic doses of neurotensin, insulin, gastrin, and CCK cause an alteration in the MMC similar to bolus feeding. The MMC is more significantly inhibited by fatty meals as opposed to protein or carbohydrate meals of similar caloric value. The intrinsic

nervous plexus or Meissner plexus innervating the submucosa helps to regulate mucosal absorption and secretion but has no control on motility.

The small intestine has motor functions which are distinct from the other parts of the GI tract. The intrinsic nerves (myenteric or Auerbach plexus) provide the basis for coordinating the circular and longitudinal smooth muscles of the small intestine. Extrinsic sympathetic (epinephrine) stimulation slows motility while parasympathetic (acetylcholine) stimulation increases motility. The intrinsic electrical activity of the small intestine is based on the intestinal smooth muscle normal resting potential. This normally is maintained by Na^+–K^+-ATPase activity.[12] The resting potential varies and results in a phasic depolarization which is referred to as slow waves, basic electrical rhythm, or pacemaker potential. These depolarizations occur at regular intervals of approximately 11 to 13 times per minute in the duodenum and decrease to 8 to 10 times in the ileum, but do not directly lead to muscular contractions. The electrical activity is coupled to muscular contraction at the level of gap junctions, which are low resistance cell-to-cell connections. These gap junctions become less regular in the midjejunum and in the distal small intestine. This causes slowing of the frequency of contractions distally, allowing for absorption of more slowly digested intestinal contents, including fats and bile salts.

Spike potentials represent a second mode of electrical stimulation of the small intestine. Spike potentials result in rapid depolarization of the membrane potential. Repeated bursts of spike potentials cause a short area of contraction. In contrast to the always present slow waves, spike potentials occur at discrete time intervals. The coordination of a slow wave and a spike potential leads to the initiation, duration, and frequency of rhythmic migratory small intestinal contractions.

During the interdigestive period between feeding, the small intestine follows a well-defined rhythmic pattern. This pattern consists of muscular contractions that migrate from the stomach or duodenum, continue to the terminal ileum, and are regulated by the MMC. This pattern can be broken down into four distinct phases. Phase I is a period of relative quiescence; phase II is a period of accelerated irregular electrical spiking and muscular activity; phase III is a series of high-amplitude rapid electrical spikes corresponding to rhythmic gut contractions; and phase IV is a period of subsiding activity. This process occurs over a period of 90 to120 minutes

and progresses from the proximal small bowel and terminates in the ileum. Once the MMC reaches the terminal ileum, the process starts over again in the proximal small bowel. The circular muscles provide segmental contraction over a 1-cm length of small intestine. These contractions occur approximately 11 to 13 times per minute in the duodenum and decrease to 8 to 10 times in the ileum. This creates functional compartments where prolonged exposure to the mucosa and mixing of the intestinal chyme occurs, aiding the process of digestion and absorption. The circular muscles are also responsible for the peristaltic waves which propagate regularly at a rate of 1 to 2 cm/sec. These regular waves may be interspersed with rushes of contractions followed by periods of no motor activity. This rate becomes progressively slower in the distal small intestine. These peristaltic movements serve as a method of propelling chyme through the length of the small intestine. The total transit time from the duodenum to the terminal ileum is approximately 220 minutes (+/−53 minutes).[13] Serum motilin levels have been found to mirror the activity of the MMC. Exogenous motilin administration has been found to increase MMC activity.

IMMUNOLOGY

Principles of Gut Immunology

The lumen of the GI tract is connected to the outside environment and comes in direct contact with many potentially pathogenic microorganisms. Lymphocytes, macrophages, polymorphic granulocytes, and other cells that take part in immune response are distributed throughout the whole gut. The commensal microflora has many benefits to the host by supporting digestion and keeping the appropriate balance among different microbial species.[14] The immune system is highly effective at responding selectively to invading pathogens, yet on the other hand tolerating a much larger number of harmless food antigens and commensal organisms. Many bacteria, viruses, and parasites are digested and enter the small intestine 5 every day.[15] Consequently, the small intestine needs a complex defense mechanism to battle against these exposures in different ways.[16]

While the immune system in the small intestine is important for host defense, other mechanisms within the small intestine also participate in host defense. Proteolytic and lipolytic enzymes are produced in high concentrations by extraintestinal cells in the pancreas and degrade different pathogenic agents at an early phase of digestion. In addition, mucin is produced by the enterocytes which is cytoprotective and inhibits bacterial growth. The small intestine can actively increase peristalsis functions to mechanically get rid of pathogenic agents, which may be potentially dangerous to the gut. In addition, tight junctions between epithelial cells prevent penetration of bacteria in between cells. Potential pathogens vary greatly in size, from very small viruses that are nanometer in size, to parasites such as helminths that are macroscopically visible and quite large. To put this into the broader picture of evolution, a large range of defense mechanisms is essential for survival of each individual.

The primary cellular barrier in the gut that prevents antigens from encountering the immune system is the single layer of gut epithelium. The total surface area of the small intestine is 400 m^2, due not only to intestinal length but also due to the formation of millions of villi in the small bowel which contribute significantly to the overall surface area.[17] In the upper small intestine, the bulk of antigen exposure comes from the diet, whereas in the ileum and colon, the additional antigenic load of an abundant and highly complex commensal microflora is prevalent. The epithelial cells of the gut mucosa have developed features that make the intestinal epithelium an active immunologic as well as anatomic barrier. For example, these nonclassical immune cells express major histocompatibility complex (MHC) class I and II molecules, consistent with their ability to participate in adaptive immune recognition of pathogenic bacteria. Small intestinal epithelial cells also express toll-like receptors on their apical surface that enables them to detect bacterial products and to initiate an innate immune response. Antigen-presenting dendritic cells (DCs) also send processes between gut epithelial cells without disturbing tight junction integrity and sample commensal and pathogenic gut bacteria.[18,19] The gut epithelial barrier therefore represents a highly flexible structure that limits antigens from entering the systemic body. The gut-associated immune system represents one of the largest immunologic compartments in the body. Lymphoid tissue in the GI tract is a major part of the whole-body immune system and consists of both aggregated (lymphoid

follicles, Peyer patches) and nonaggregated (luminal, intraepithelial and in lamina propria) immune cells. Under physiologic circumstances, oral administration of protein antigens induces systemic unresponsiveness when the same antigen is given parenterally (a phenomenon known as oral tolerance). In animal models, oral tolerance appears to be a specific consequence of the immune environment in the gut, which favors the generation of regulatory T cells.

Nonaggregated and Aggregated Lymphoid Tissue

The gut epithelium and its mucous layer form a major barrier to trap pathogens which are then eliminated when the gut epithelium is shed and replaced by new cells deriving from stem cells in the crypts. Several different cell types face antigenic exposure present in the intestinal lumen and include the epithelium, neutrophils, lymphocytes, and macrophages. These luminal cells represent an initial effector mechanism in the first front directed toward an antigenic exposure. In addition, there are also immigrated intraepithelial lymphocytes, which are found in between epithelial cells beneath the tight junctions. Local defense depends in part on these T lymphocytes that are nestled among gut epithelial cells. These T cells modulate homeostasis of the gut epithelium through local production of cytokines and have cytolytic effects. In fact, the number of intraepithelial lymphocytes can increase dramatically in response to inflammation or infection. After exposure to antigens, these cells reenter the circulation to initiate a systemic immune response. The lamina propria contains nonaggregated, diffusely distributed lymphoid tissue, including different types of immune cells. B cells in the lamina propria undergo cytokine-induced differentiation to become active producers of immunoglobulin A (IgA) that is secreted into the gut lumen. Mast cells and eosinophils are also present in the lamina propria in small numbers. They exhibit an important role in allergic and hypersensitivity reactions as well as defense against parasites. Parasites including worms are recognized and tagged using the monovalent immunoglobulin E (IgE) which is mostly bound to host cell

surfaces. Actual parasite killing is depending on toxic proteins secreted by eosinophils.

There are also large aggregates of lymphoid tissue found in the small intestine. These so-called Peyer patches are localized collections of lymphoid follicles that are most prominent and macroscopically visible in the submucosa of the ileum. Peyer patches are most prominent in children and gradually disappear with age. Along with the nonaggregated immune system, the enormous quantity and diversity of antigens present within the gut are also processed via Peyer patches in the lamina propria and the mucosa-associated lymphoid tissue (MALT), which in total contains about 70% of the body's lymphoid cells. Another often used term to describe the immune system within the small intestine is gut-associated lymphoid tissue (GALT). Peyer patches do not have any villi, and so-called microfold (M) cells concentrated within the epithelium allow the selective uptake of food antigens and microorganisms. M cells are specific cells in the intestinal epithelium over lymphoid follicles that endocytose antigens. M cells transport them into the underlying tissue, where they are taken up by local DCs and macrophages.[20] DCs and macrophages that receive antigens from M cells present them to T cells in the GALT, leading ultimately to appearance of IgA-secreting plasma cells in the mucosa. B-lymphocyte precursors proliferate in germinal centers within the Peyer patches. DCs below the epithelium can also take up luminal antigens by pushing pseudopods up between epithelial cells.

Immunoglobulin Secretion

At an early level of exposure at the gut epithelium, M cells take up antigen and transport it transcellularly using an endocytic mechanism into the underlying lymphoid tissues of Peyer patches. Lymphocyte activation ensues, and these activated lymphocytes migrate into afferent lymphatics, pass through mesenteric lymph nodes, and enter the circulation through the thoracic duct. During this process, the lymphocytes mature into B and T lymphoblasts with an enriched population of IgA-producing B cells.[21] Passage of viable bacteria from the intact GI tract to the mesenteric lymph node and beyond has been termed bacterial translocation, possibly explaining septic complications and multiple organ failure in peritonitis, burn, and trauma patients. The immunogenic integrity of the mucosa is

significantly damaged by systemic injury of different kinds. A major protective mechanism of the intestinal immune system is synthesis and secretion of IgA. In the intestine, IgA exists as a dimer that is linked with two additional molecules—the J chain—linking two IgA molecules, and the polymeric immunoglobulin receptor, which transports the IgA complex across the cell and allows release of the complex, termed secretory component, into the intestinal lumen. The transmembranous immunoglobulin receptor is produced by the intestinal epithelial cell. It is thought that the secretory component may prevent proteolytic degradation of the IgA molecule and may stabilize the structure of the polymeric IgA complex in an environment containing numerous proteolytic enzymes and bacteria that would otherwise rapidly degrade it. Unlike IgG and IgM, IgA does not activate complement and does not promote cell-mediated opsonization. The major function of secretory IgA in host defense is protection against bacteria, viruses, and luminal antigens. Secretory IgA inhibits the adherence of bacteria to epithelial cells. It is well known that a breast-feeding mother transfers secretory IgA to her nursing infant, protecting the infant from bacteria and viruses that were originally present in the mother's GI tract.

Small Intestine Microbiota

The importance of the microbiota of the small intestine on metabolism and its impact on health and disease processes are increasingly being realized. The communities of microorganisms in the human digestive tract are a complex ecosystem that is both essential for human life and a potential driver of a variety of human diseases. The small intestine is not highly populated by bacteria due to its relatively short transit time, intermittent substrate availability, and its inhospitable environment, which is comprised of a variety of antimicrobial proteins, immunoglobulins, bile and a low pH. A challenging feature of the small intestine when compared with the colon is its relative inaccessibility, which makes sampling for microbiome studies.[22] Bacterial populations of the small intestine have been estimated at 103/g in the duodenum to 108/g in the distal ileum, but despite these relatively low populations there is evidence that there is interplay between the microbes and the intestinal lining that may directly affect intestinal health (**Fig. 48.4**).[22,23] One of the key determinants of small intestine microbiota is

host diet. The proportion of gram-positive to gram-negative, as well as facultative anaerobic and strict anaerobic species increases from proximal to distal segments of the small intestine and colon based on oxygen use.[24,25]

Carbohydrate metabolism is a key function of the small intestine microbes by comparison to colonic microbes. The role of microbes and bile acid metabolism is relatively well understood, but new findings about the regulation of bile acid conjugation are cited as possible factors in irritable bowel disease and inflammatory bowel disease.[26] Metabolism of fatty acids, dietary fiber, and amino acids alter the production of microbial anti-inflammatory and proinflammatory factors and is thought to play an important role in mucosal integrity and translocation, as well as, hepatic function and may have a role in the pathogenesis of nonalcoholic 6 fatty liver disease.[27,28] While the exact mechanisms of many of the interactions between the gut microflora and the small intestinal microenvironment are still speculative, it has become evident that a symbiotic environment is present which, at least in part, is responsible for proper homeostasis of the small intestine.

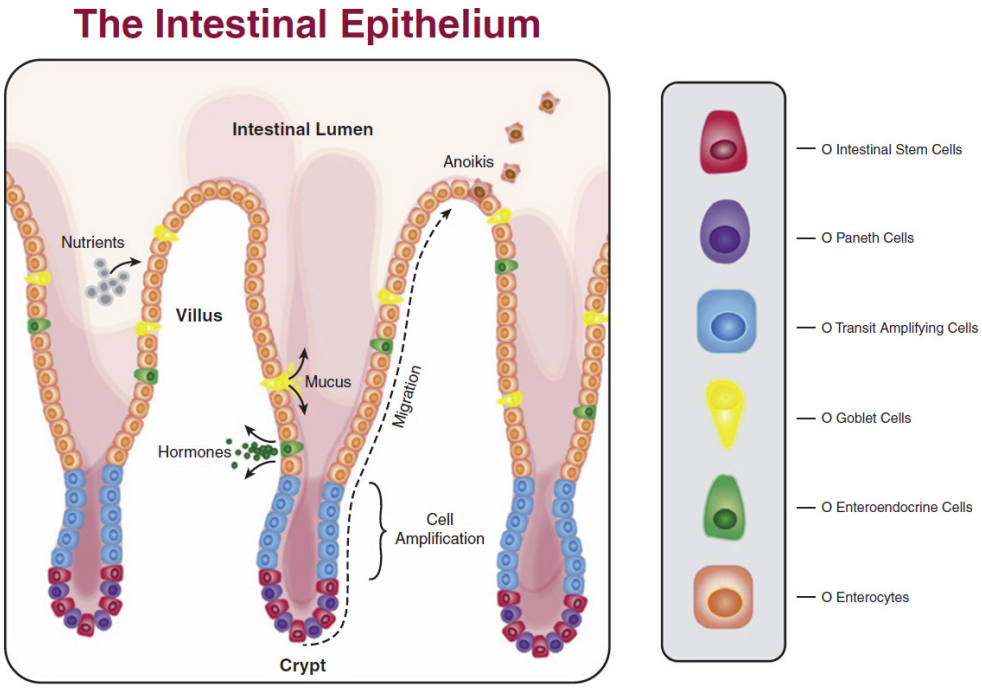

Figure 48.4 Intestinal epithelium. (Reprinted from Dey I and Bradbury NA. Physiology of the Gut: Experimental Models for Investigating Intestinal Fluid and Electrolyte Transport. Chapter 10.)

DIGESTION AND ABSORPTION

Absorption of Water

Recommended daily intake of water from all sources (water, other beverages, and food) is 3.7 L for men and 2.7 L for women. This varies depending on personal and environmental factors. Approximately 2 L (64 oz) per day is recommended from water alone. The GI tract adds notable fluid volume along its course (**Table 48.3**). The small intestine reabsorbs nearly 80% 7 of the fluid that passes through it. This dynamic process is accomplished by a rapid bidirectional movement of fluid in the intestinal lumen. This ebb and flow of fluid in the intestinal lumen is critical in maintaining normal homeostasis. Minor changes in intestinal permeability or rate of flow of the intestinal contents can result in net secretion and diarrheal states.

Table 48.3 Average Daily Intestinal Secretions

Anatomic Source	Intraluminal Secretion (mL)	Fluid Reabsorption (mL)
Oral Intake	**2,000**	—
Oropharyngeal	**1,500**	—
Stomach	**5,000**	—
Liver	**1,000**	—
Pancreas	**1,000**	—
Small Intestine	**2,000**	**8,000**
Large Intestine	**200**	**1,250**

The tonicity of the intraluminal contents determines the overall net movement of water. In general, after a meal is consumed, the addition of large amounts of saliva, gastric juice, and hypotonic chime enters the proximal small intestine. Acid gastric contents are neutralized by the secretion of bicarbonate, creating NaCl and water, and decreasing the

osmotic pressure. The jejunum is effective at passively reabsorbing water in a paracellular fashion due to its relatively large intercellular pores. As the chyme travels through the length of the small intestine, the intercellular channels become more tightly arranged and the movement of water becomes dependent on the active transport of solutes into the paracellular spaces. A total of 6 to 11 L of water enters the duodenum every day, of this, less than 1 L enters the colon.

Absorption of Electrolytes

The small intestine is responsible for the bulk of electrolyte transport via transport protein mechanisms located along the brush border driven primarily by active transport of sodium, chloride, and bicarbonate (**Table 48.4**). This results in a net fluid movement across the GI epithelium.

Sodium

Approximately 800 mmol of sodium passes through the intestinal lumen daily. Apical transport in the small intestine are reliant on the Na^+–K^+-ATPase pump on the basolateral membrane of the cell. This pump utilizes the hydrolysis of ATP providing energy to move three Na^+ ions out of the cell while transporting 2 K^+ ions into the cell; movement against an electrical gradient. This process maintains a negatively charged low Na^+ intracellular environment, allowing for several mechanisms of absorption:

Table 48.4 Small Intestine Absorption of Electrolytes

Major Mineral	Recommended Daily Intake	Route of Absorption	Function	Dietary Source
Sodium	less than 2.3 g	Small intestine, colon	Fluid balance, nerve	Foods, small amounts in milk, breads, unprocessed meat
Chloride	2.3 g	Ileum, colon	Gastric acid, fluid balance	Table salt, soy sauce, processed foods, small amounts in milk, breads, unprocessed meat
Potassium	5–6 g	Jejunum, ileum (passive)		Meats, milk, fresh fruits and vegetables, whole grains, legumes
Calcium	1 g	Duodenum (Ca-ATPase, vit D dependent), ileum	Bone and teeth health; muscle contractility	Milk and milk products, canned fish with bones, leafy green vegetables, fortified tofu and other soy products, baked goods made with fortified flour
Phosphorus	0.5–1 g	Jejunum	Bone and teeth health; acid–base balance	Meats, fish, poultry, eggs, milk, nuts, seeds, legumes, grains, processed foods (incl. sodas)
Magnesium	350–450 mg	Jejunum, ileum (both passive and active)	Bone composition; protein; muscle	Nuts and seeds, legumes, leafy green vegetables, seafood, whole grains, and some fortified cereals and other foods
Sulfur	2–3 g total in conjunction with sulfur amino acids	Jejunum	Protein molecules, complex biosynthesis	Meats, poultry, fish, eggs, milk, legumes, leafy green vegetables, nuts, beer, wine, coffee

Simple electrogenic absorption is the process of an influx of Na ions from the sodium-rich intestinal lumen into the negatively charged, low-sodium intracellular environment. This process is indirectly energy dependent, as it relies on the function of the Na^+–K^+-ATPase pump and resultant negative intracellular charge. The process can be inhibited by ouabain, a Na^+–K^+-ATPase inhibitor.[29]

Nonelectrolyte-stimulated sodium absorption occurs when sodium is coupled with an organic solute, such as glucose, amino acids, dipeptides, tripeptides, and bile acids. Sodium is preferentially transported down its electrochemical gradient which is created by the Na^+–K^+-ATPase pump.

Electroneutral absorption of sodium chloride is a process which couples two neutral ion counter transport mechanisms. Na^+ is exchanged for H^+ and Cl^- is exchanged for HCO_3^-, resulting in no net change in intracellular charge. This process provides an influx of NaCl in exchange for H^+ HCO_3^- efflux. This 8 electroneutral transfer of ions allows for intracellular pH regulation and for sodium and chloride transport.

Chloride

Efficient chloride absorption passing through the gut lumen daily allows for normal stool concentration of 10 to 15 mmoles/L. In states of malabsorption and diarrhea, the concentration can exceed 90 mmoles/L. Chloride is a major determinant of the regulation of fluid secretion into the small intestine and in intestinal hydration.[30] Three distinct mechanisms of physiologic absorption occur:

Electroneutral transfer is the main route of chloride absorption in the ileum and colon mediated by apical Na/H and Cl/HCO_3 exchangers.[31]

Paracellular passive diffusion is predominant in the small intestinal epithelium and depends on the positively charged interstitium compared to the gut lumen. This allows negatively charged chloride ions to be absorbed via transmural potential and the downhill Cl^- gradient.

HCO_3-dependent Cl absorption is the alkalinization of HCl in the duodenum and proximal small bowel and recycling of chloride back into cells in exchange for HCO_3.

Bicarbonate

Absorption of bicarbonate primarily takes place in the jejunum and requires the formation of carbon dioxide and water in the intestinal lumen from HCO_3^- and H^+, thereby increasing the intraluminal pressure of CO_2. Carbon dioxide diffuses back into the enterocyte and is enzymatically cleaved into H^+ and HCO_3^- by the action of carbonic anhydrase. HCO_3^- diffuses into the interstitium and H^+ is resecreted in exchange for other cations, predominantly Na^+. In the duodenum and ileum, HCO_3^- is secreted in exchange for Cl^-. This efflux of HCO_3^- provides a mechanism to neutralize gastric acid entering into the duodenum. HCO_3^- secretion in the ileum most likely helps maintain acid–base equilibrium, although this process is not well understood.[32]

Potassium

Approximately 90 mEq/d of potassium is ingested in a normal diet of which 90% is absorbed. An equal amount of potassium is excreted in the urine as is absorbed in the intestine, allowing maintenance of potassium homeostasis.

Most of the absorption occurs in the small intestine mainly through passive mechanisms.[33] This process is thought to occur through intercellular pores or through an H^+–K^+ exchange pathway facilitated by the intracellular electrochemical gradient which is created predominantly by the basolateral ATPase pump. Intracellular K^+ then diffuses across the basolateral membrane by a K^+ channel or carrier.

Carbohydrates

Comprised of sugars and starches, carbohydrates provide a major source of daily caloric intake in Western diets with each absorbed gram producing 4 kcal of energy. Carbohydrates are present in three main digestible forms with the enzymatic breakdown into simple sugars being required for transport across the apical cell membrane.

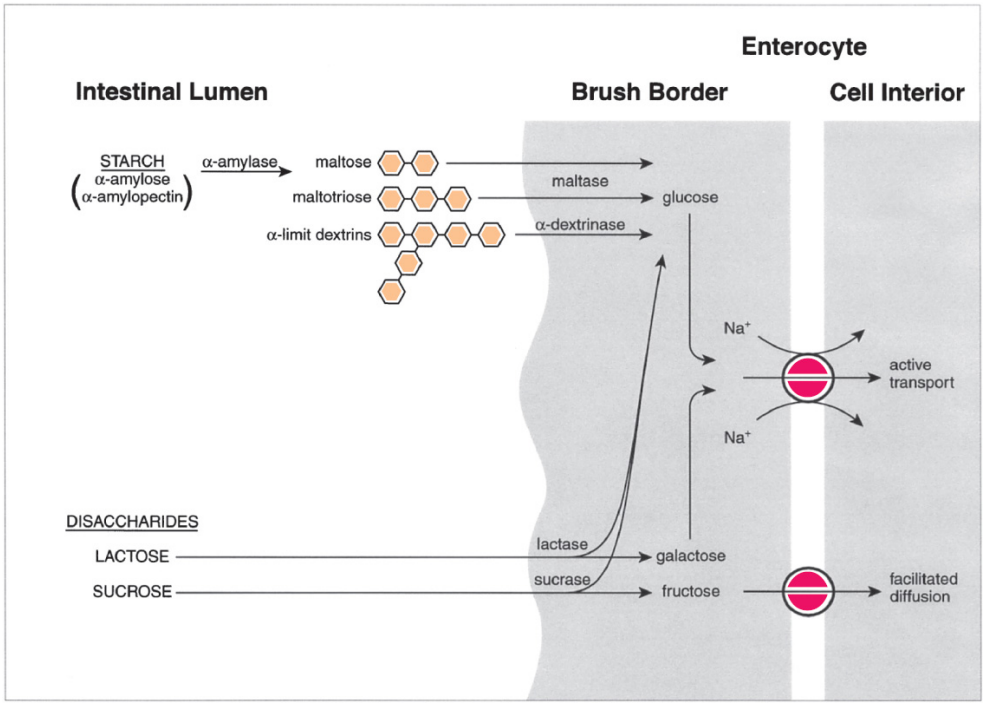

Figure 48.5 Digestion and absorption of carbohydrates.

Complex Starches: The storage carbohydrate of plants consisting mainly of sugars linked together, these account for approximately 60% of daily carbohydrate intake. The most common form is amylopectin. Amylose is a long linear grouping of glucose molecules connected with α(1,4)-glycosidic

bonds without branch points. Amylopectin and amylose are digested with the aid of salivary but mainly pancreatic amylase. This process yields maltose, which are glucose dimers with α(1,4)-glycosidic bonds, and maltotriose, which are glucose trimers with α(1,4)-glycosidic bonds. This digestive process is usually completed before the carbohydrate bolus leaves the duodenum. These small oligosaccharides along with ingested disaccharides, typically sucrose and lactose, are then further digested by the brush border saccharidases in the jejunum.

Disaccharides: Comprising mainly of sucrose (glucose–fructose dimers) and lactose (glucose–galactose dimers), but also maltose and trehalose, these are the next most common source of dietary carbohydrate representing nearly a third of daily intake. The brush border of the small bowel contains specific enzymes which, through catalytic reactions involving amylase, sucrase, and isomaltase, hydrolyze both oligo- and disaccharides into their component monosaccharide moieties such as glucose, galactose, and fructose.

Monosaccharides: These simple sugars of glucose, galactose, and fructose can be transported across the apical cell membrane of the small intestine. A sodium-dependent hexose transporter (SLGT1) actively transports glucose and galactose from the intestinal lumen utilizing energy from the Na^+–K^+-ATPase pump on the basolateral membrane to maintain a sodium gradient allowing for this influx. Fructose is transported in a carrier-mediated diffusion-dependent manner by GLUT5 and does not require sodium as a cotransporter.

The movement of monosaccharides into the cellular cytoplasm provides an additional gradient by which water is absorbed by the enterocytes from the intestinal lumen. The monosaccharides are then transported across the basolateral membrane by GLUT2. This hexose transporter allows for the diffusion of all three monosaccharides into the extracellular space and ultimately into the portal blood flow. A small portion of these monosaccharides may be used by the enterocyte (**Fig. 48.5**).

Nondigestible Carbohydrates (Dietary Fiber)

Dietary fiber, such as cellulose are thought to be an important part of a normal diet even though they do not provide dietary calories. Dietary fiber is present in grains, vegetables, and pulpy fruits. Dietary fiber helps decrease

bowel transit time by absorbing water in the intestinal lumen. In addition, fiber can absorb organic materials such as lipids and bile salts and inorganic minerals such as zinc, calcium, and magnesium. These actions of fiber are thought to play a role in preventing carcinogenesis and in helping to maintain normal serum lipid profiles. Unfortunately, fiber is underrepresented in most Western diets. Guidelines suggest a daily intake of 14 g of dietary fiber per 1,000 kcal.[34]

Protein

Protein consumption is essential to the daily diet. An average adult requires 0.75 g/kg of protein per day, although this requirement may be significantly increased during childhood, pregnancy, and times of significant illness. Protein provides an important caloric energy source as well as the essential building blocks for production of new proteins. A nearly equal amount of protein is ingested daily from dietary sources (70 to 100 g) as is provided by endogenous proteins (50 to 60 g of protein per day) in the small intestine from secreted enzymes, desquamated cells, and plasma protein leakage. Nearly 90% of this protein load is metabolized in a similar fashion to dietary proteins.

The initial digestion of protein begins with the activation of pepsinogen to pepsin in the acid environment of the stomach. Pepsin hydrolyzes protein into its component amino acids; however, this action only represents a small part of overall protein digestion. The majority of protein digestion occurs in the small intestine by pancreatic peptidases and proteases. Pancreatic enzymes flow into the duodenum, initiating this phase of protein digestion. These pancreatic proteases are initially released as proenzymes (zymogens). These zymogens are inactive and require a further catalytic process to occur for their activation. This is initiated by the brush border enzyme enteropeptidase (enterokinase) in the duodenum. Endopeptidase cleaves trypsinogen into the active enzyme trypsin. Trypsin in turn activates the other zymogens into their active endopeptidases (trypsin, chymotrypsin, and elastase) which hydrolyze internal peptide bonds. Additional protein digestion is performed by exopeptidases (caroxypeptidase A and B) which are able to cleave amino acids from the C-terminal ends of proteins.

Short oligopeptides are further digested by enzymes in the brush border of the small intestine or within the cell cytoplasm. Single amino acids, dipeptides, and tripeptides can diffuse through the apical membrane into the cytoplasm. Single amino acids are co-transported into the cytoplasm with sodium along an electrochemical gradient. This electrochemical gradient is maintained by the Na^+–K^+-ATPase pump on the basolateral cell membrane. Peptides greater than three amino acids in length are broken down into smaller peptides by enzymes in the brush border. The resultant dipeptides and tripeptides are then moved into the cytoplasm along with H^+ by a cotransporter PepT1, where they are hydrolyzed by specific peptidase into their component amino acids. Transport of amino acids into the cytosol provides an osmotic gradient by which water is further absorbed from the intestinal lumen. A small portion of the processed amino acids are utilized by the enterocyte, and the vast majority is shuttled into the portal blood flow via amino acid transporters on the basolateral membrane.

Fat

Forty percent of the average daily caloric intake (60 to 90 g) in a Western diet is in the form of fat. Ninety percent of these ingested fats are triglycerides, while the remainder is comprised of cholesterol, phospholipids, and fat-soluble vitamins. The initiation of lipid digestion occurs when CCK is stimulated by the presence of fatty acids on the duodenal mucosa. CCK in turn stimulates pancreatic secretion of lipase and its cofactor colipase. Lipase hydrolyzes triglycerides, yielding two fatty acids and a monoglyceride (a fatty acid esterified to glycerol). Cholesterol and fat-soluble vitamins are hydrolyzed by pancreatic cholesterol esterase and phospholipids by phopholipase A2. The products of lipolysis interact with bile salts to form water-soluble micelles. Mixed micelles are a combination of fatty acids, bile salts, and monoglycerides. The structure of a micelle is composed of an inward-facing hydrophobic region and a hydrophilic region facing outward toward the aqueous environment of the intestinal lumen. Due to the hydrophobic core, cholesterol, phospholipids, and fat-soluble vitamins can reside within the micelle structure. Micelles are able to interact with the mucosal cells and empty their contents into the cytoplasm. This occurs by the process of dissolution of the micelles into the

lipid bilayer of the mucosal cell. Once this is completed, the components of the micelle are ready to reform with new lipid components to repeat this process. There is no energy consumed directly in the transfer of lipids into the cell cytoplasm.

Once in the cytoplasm, long-chain fatty acids and β-monoglycerides are carried by cytosolic fatty acid–binding proteins to the smooth endoplasmic reticulum (SER). In the SER, resynthesis of triglycerides occurs. These triglycerides are further processed in the Golgi apparatus where a phospholipid and an apoprotein coat are added to form a chylomicron. Chylomicrons are 90% triglyceride; the remaining 10% is composed of phospholipid, cholesterol, and protein. Before exiting the Golgi apparatus, the chylomicrons are packaged into secretory vesicles. They exit the cell membrane by exocytosis and enter the central lacteal of the villus and the intestinal lymphatic system. In addition, enterocytes also produce smaller lipoprotein particles, very low–density lipoproteins, which contain a higher cholesterol/triglyceride ratio and provide the major route of entry for dietary cholesterol into the lymphatic system.

Short-chain fatty acids contain less than eight carbon atoms and are water soluble. This allows these molecules to enter and exit the enterocyte by simple diffusion independent of bile micelles or chylomicrons. Medium-chain triglycerides consist of 6 to 12 carbon atoms and can be absorbed by simple diffusion or through the previously mentioned process of transport of long-chained fatty acids via the formation of bile micelles and chylomicrons. Both short- and medium-chain fatty acids may enter the portal circulation without entering the lymphatics. Most of the dietary fat is processed and absorbed in the duodenum and upper jejunum.

Bile Salts

Approximately 95% of the bile salts secreted into the intestine are reabsorbed and returned to the liver through the portal circulation. Once in the liver, these bile salts are reprocessed and secreted and stored in the gallbladder in preparation for the next meal. This process of recycling of bile salts is referred to as the enterohepatic circulation. This reabsorption occurs by both passive and active means. A small amount of bile salts is passively reabsorbed along the entire length of the small intestine. The majority of bile

salts, however, are reabsorbed though an active Na^+-dependent transport mechanism in the terminal ileum. Bile, which is not reabsorbed, passes into the colon where it is deconjugated by bacteria. This process increases the solubility of the bile and promotes further passive absorption. High concentrations of bile salts within the colon inhibit sodium and water reabsorption, resulting in diarrhea. Patients who have undergone resection of their ileum may suffer from diarrhea due to this process. These patients may be treated with the bile-binding resin, cholestyramine, to help alleviate their symptoms.

Mineral

Mineral absorption is necessary for the proper form and function of the human body. These inorganic elements are responsible for approximately 4% to 6% of a person's mass. Many of these minerals are best absorbed in their ionized forms, which is aided by the presence of hydrochloric acid in the gastric lumen. Calcium accounts for approximately 50% of this mass, phosphate provides an additional 25%, and a variety of other minerals constitute the remaining 25%.

Macrominerals (major) have a daily requirement exceeding 100 mg/d while microminerals (trace) have a daily requirement of less than 15 mg/d. These two groups are equally important, and the amount needed in the body is not indicative of importance. A balanced diet usually provides all the essential minerals. However, certain pathologies, postsurgical states, or inadequate dietary consumption may necessitate supplementation to avoid pathologies secondary to deficiency. The following tables highlight the function and source of such elements (**Table 48.5**). Approximately 1 g of calcium is consumed per day, mainly from dairy products. Once in its ionized form, calcium is primarily absorbed in the duodenum, although this process occurs throughout the length of the small intestine. When calcium is present intraluminally at low levels, it is transported across the apical membrane of the enterocyte by carrier-mediated facilitated diffusion. Once calcium is in the cytoplasm, it is bound to calcium-binding proteins and delivered to the basal membrane. Calcium is then transferred into the interstitium by a Ca^{2+}-ATPase pump. This process is indirectly regulated by parathyroid hormone (PTH). PTH in low-calcium states promotes conversion of vitamin D to its

active form 1,25-$(OH)_2$ vitamin D. This activated form of Vitamin D causes an increase in the expression of both calcium-binding proteins and Ca^{2+} ATPase, causing an increase in the absorption of calcium by the small intestine.[35,36] When intraluminal calcium is in excess of its capacity to be actively transferred by the apical membrane's carrier-mediated mechanism, passive paracellular calcium absorption occurs in the distal small intestine. Absorbable dietary sources of iron are typically either contained within a protein, such as heme, or as a ferrous (Fe^{2+}) ion. Iron-containing proteins are usually from ingested meats, whereas ferrous forms are typically present in vegetables, grains, and fruits. Vitamin C (ascorbic acid) increases iron absorption by reducing the ferric (Fe^{3+}) ion into the more soluble ferrous state. Absorption of iron is facilitated by carrier-mediated translocation across the apical membrane of the enterocyte in the duodenum and proximal jejunum. Once in the cytoplasm, the ferrous ion is released by enzymatic cleavage. Ferrous ions may be stored intracellularly by ferritin or transported into the circulation by transferrin. The process of iron absorption is regulated in the enterocyte by hypoxia-inducible factor signaling and iron-regulatory proteins.

Table 48.5 Small Intestine Absorption of Minerals

Trace Element	Recommended Intake	Dietary Source	Route of Absorption	Function
Zinc	8–11 mg/d	Meat, chicken, nuts, lentils	Duodenum and jejunum	Part of many enzymes; genetic material and protein synthesis. Wound healing
Copper	900 mcg/d	Vegetables, grains, legumes, meat, fish, poultry	Stomach and proximal small intestine	Part of many enzymes; iron metabolism
Manganese	1.8–2.2 mg/d	Grains, dried fruits, vegetables	Small intestine	Part of many enzymes
Selenium	5 mcg/d	Seafood, kidney, liver	Small intestine	Antioxidant
Chromium	25–35 mcg/d	Processed meats, grains, cereals, vegetables, fruits	Small intestine	Works with insulin in regulating glucose levels
Iodine	150 mcg/d	Seafood, vegetables, drinking water	Proximal small intestine	Thyroid hormone
Fluoride	4 mg/d	Water, seafood, toothpaste	Stomach and small intestine	Bone and teeth metabolism
Molybdenum	45 mcg/d	Legumes, cereal grains, leafy vegetables, beef liver	Small intestine	Part of some enzymes
Cobalt	5–8 mcg/d	Milk, dairy, fish, shellfish	Small intestine	Red blood cell production
Iron	8–18 mg/d	Red meat, fish, poultry, shellfish, egg yolk, legumes	Duodenum and proximal jejunum	Hemoglobin molecule, energy metabolism

Table 48.6A and 6B Small Intestine Absorption of (A) Water-Soluble and (B) Fat-Soluble Vitamins

Water-Soluble Vitamin	Dietary Source	Route of Absorption	Resultant Deficiency
Vitamin C	Citrus; tomato; cantaloupe, strawberry	Carrier-mediated Na dependent	Scurvy
Vitamin B7 (Biotin)	Liver, egg yolks, soybeans, milk, meat	Carrier-mediated Na dependent	Seborrheic dermatitis, alopecia, myalgia, paresthesia
Vitamin B12 (Cobalamin)	Meats, fish, poultry, and eggs		Megaloblastic anemia (also due to lack of gastric intrinsic factor (IF) deficiency in atrophic gastritis)
Vitamin B9 (Folic Acid)	Vegetables, liver, oranges, cantaloupes, fortified breads	Specific folate carriers once unconjugated	
Vitamin B3 (Niacin)	Milk, eggs, meat, fish, whole grains	Specific carrier	Pellagra
Vitamin B6 (Pyridoxamine)	Meats, fish, potatoes, fruits, gut bacteria	Unknown	Irritability, depression, dermatitis, glossitis, cheilosis, peripheral neuritis, microcytic
Vitamin B2 (Riboflavin)	Dairy, eggs, meats, green leafy vegetables	Riboflavin transporters	Glossitis, corneal vascularization, and poor growth
Vitamin B1 (Thiamine)	Whole grains, nuts, dried legumes	Thiamine transporters	Megaloblastic anemia, encephalopathy

Fat-Soluble Vitamins	Route of Absorption	Daily Intake	Dietary Source	Result of Deficiency
Vitamin A	Small intestine micelles	3,000 IU	Meat, cheese, milk, fruit, vegetable	Night blindness (early), blindness (late), keratinization, infection, impaired wound healing
Vitamin D	Small intestine micelles	600–800 IU	UVB	Fatigue, depression, rickets (childhood), osteomalacia (adults)
Vitamin E	Ileum	15 mg	Sunflower oil, nuts	Peripheral neuropathy, immuno-deficiency, weakness, impaired vision
Vitamin K	Small intestine micelles	100–120 µg	Coagulation, bone formation	Bleeding

Vitamin Absorption

Fat-soluble vitamins (A, D, E, and K) are incorporated into micelles along with fats in order to pass into the enterocyte. These vitamins are then processed and packaged into chylomicrons so that they can exit into the lymphatic system. Water-soluble vitamins are absorbed in the jejunum and ileum through a variety of mechanisms. Vitamin C (ascorbic acid), biotin, and niacin are transported by Na^+-dependent mechanisms. Folate, vitamin B1 (thiamine), and vitamin B2 (riboflavin) are absorbed by Na^+ independent mechanisms and vitamin B6 is absorbed by passive diffusion.[37] Vitamin B12 (cobalamin) absorption is dependent on the presence of intrinsic factor, a glycoprotein produced by the gastric parietal cells. One molecule of intrinsic factor binds two molecules of cobalamin to form a complex which attaches

to a specific membrane receptor in the terminal ileum. Unbound cobalamin cannot be absorbed. Cobalamin becomes unbound from its complex in the enterocyte and exits from the cell into the portal circulation with the aid of B12-binding proteins called transcobalamins. Cobalamin is essential for DNA synthesis and a deficiency usually presents with megaloblastic anemia. Inability to absorb sufficient amounts of cobalamin may be due to lack of intrinsic factor after proximal or total gastrectomy, autoimmunity to gastric parietal cells or intrinsic factor, or atrophic gastritis. In addition, cobalamin-intrinsic factor complexes may fail to be absorbed due to distal ileal disease or resection, and cobalamin deficiency may occur from bacterial overgrowth due to bacterial overconsumption of cobalamin (**Table 48.6**).

Ileus and Bowel Obstruction

David I. Soybel and Amanda B. Cooper

Key Points

1. In simple obstruction the intestinal lumen is partially or completely occluded without compromise of intestinal blood flow. Simple obstructions may be complete, meaning that the lumen is totally occluded, or incomplete, meaning that the lumen is narrowed but permitting distal passage of some fluid and air. In strangulation obstruction, blood flow to the obstructed segment is compromised and tissue necrosis and gangrene are imminent.
2. Peritoneal adhesions are the most common cause of obstruction of the small intestine.
3. Four key symptoms variably associated with acute mechanical bowel obstruction include abdominal pain, vomiting, distention, and obstipation; abdominal pain out of proportion to physical findings should raise concern about rapidly evolving closed-loop obstruction and the need for urgent resuscitation and operation.
4. CT (computerized tomography) is the “go-to” imaging modality to detect and identify the likely site and source of obstruction.
5. Conservative management consisting of intravenous hydration, nasogastric decompression, and restoration of electrolyte balance is a cornerstone of initial management of any patient suspected of having intestinal obstruction.
6. Use of water-soluble contrast for patients with small bowel obstruction (SBO) may be both diagnostic and therapeutic.
7. Open exploratory laparotomy is the gold standard in the treating of unresolved SBO. Laparoscopic management may be considered in select group of patients. Types of intestinal obstruction that are more likely to lead to strangulation and the need for urgent/emergent operation include closed-loop obstructions, obstruction due to hernia, obstruction without a prior history of operation, and obstructions that occur after some laparoscopic procedures.
8. Ileus denotes underlying alterations in motility of the gastrointestinal tract, leading to functional obstruction.

9 Postoperative ileus (POI) can be differentiated from SBO with the use of contrast CT and enteroclysis imaging techniques. POI is often self-limiting; less frequent interventions are required for prolonged POI, if proper precautions have been taken during surgery.

10 Pseudoobstruction of the colon, also known as Ogilvie syndrome, can be complicated by perforation; it is treated with attention to underlying neurologic or metabolic disturbances and, as a first line of treatment, with decompressive colonoscopy.

INTRODUCTION

The purpose of this chapter is to provide an overview of the pathophysiology, natural history, diagnosis, and management of acute obstruction and ileus of the small and large intestines. Of note, the principles of early diagnosis, rapid intravenous fluid resuscitation, gastrointestinal decompression, and early operation to avoid intestinal gangrene and peritonitis, were established well before the advent of antibiotic therapy, invasive hemodynamic monitoring, and parenteral nutrition.[1] These early developments were critical in reducing morbidity and mortality of mechanical intestinal obstruction and ileus.[2,3]

MECHANICAL OBSTRUCTION OF THE INTESTINE

Terminology and Classification

The term *mechanical obstruction* means that luminal contents cannot pass through the intestine because the lumen is blocked. Mechanical causes of obstruction are contrasted with *neurogenic* or *functional* causes, in which luminal contents are prevented from passing because of disturbances in gut motility that prevent coordinated peristalsis from one region of the gut to the next. This latter form of obstruction is commonly referred to as *ileus* in the

small intestine and *pseudoobstruction* in the large intestine. In *simple* obstruction, 1 the intestinal lumen is partially or completely occluded without compromise of intestinal blood flow. Simple obstructions may be *complete*, meaning that the lumen is totally occluded (**Fig. 49.1**), or *incomplete*, meaning that the lumen is narrowed but permitting distal passage of some fluid and air. In *strangulation* obstruction, blood flow to the obstructed segment is compromised and tissue necrosis and gangrene are imminent. Strangulation usually implies that the obstruction is complete, but some forms of partial obstruction can also be complicated by strangulation such as a Richter hernia.

As summarized in **Table 49.1**, causes of obstruction can include intraluminal objects such as foreign bodies or gallstones, intramural lesions such as tumors or intussusceptions, and extrinsic or extramural lesions such as adhesions. Adhesions are the most common cause of intestinal obstruction, accounting for more than half of all cases 2 .[4,5] It is equally instructive to classify obstruction according to the location of the obstructing lesion. Proximal or "high" obstructions involve the pylorus, duodenum, and proximal jejunum. Intermediate levels of obstruction involve the intestine from the mid jejunum to the mid ileum. Obstructions arising in the distal ileum, ileocecal valve, and proximal colon are considered "distal" whereas those termed as "low" arise in segments beyond the transverse colon. Obstructions in the colon will be discussed elsewhere in this volume. As outlined in **Table 49.2**, symptoms and signs of obstruction (pain, vomiting, abdominal distention, gas pattern on abdominal radiographs) vary with the level of obstruction.

It is also important, however, to distinguish between *open-* and *closed-loop* obstructions. An open-loop obstruction occurs when intestinal flow is blocked but proximal decompression is possible through vomiting. A closed-loop obstruction occurs when inflow to the loop of bowel and outflow from the loop are both blocked. This obstruction permits gas and secretions to accumulate in the loop without a means of decompression, proximally or distally. Examples of closed-loop obstructions are torsion of a loop of small intestine around an adhesive band (**Fig. 49.2**), incarceration of the bowel in a hernia, volvulus of the cecum or colon, or development of an obstructing carcinoma of the colon with a competent ileocecal valve. The primary symptoms of a closed-loop obstruction of the small intestine are sudden,

severe mid-abdominal pain and vomiting whereas symptoms of the large intestine are pain and sudden abdominal distention. Such pain often occurs before associated findings of localized abdominal tenderness or involuntary guarding. When signs of peritoneal irritation or frank peritonitis develop, there is a high level of suspicion that the viability of the bowel is compromised.

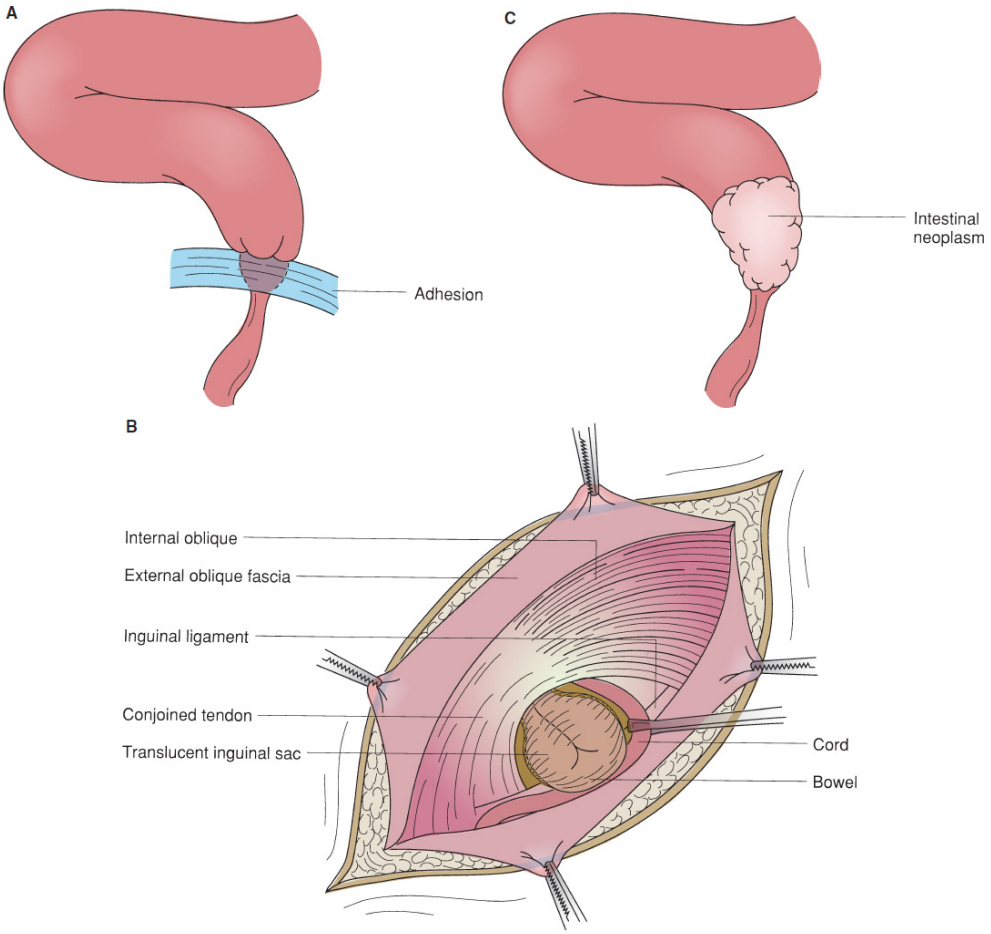

Figure 49.1 Schematic illustration of different forms of simple mechanical obstruction. Simple obstruction is most often due to adhesion, (**A**), groin hernia, (**B**), or neoplasm, (**C**). The hernia can act as a tourniquet, causing a closed-loop obstruction and strangulation.

Pathophysiology of Intestinal Obstruction

When a segment of intestine becomes obstructed, subsequent pathophysiologic events include (1) the accumulation of gas and fluid; (2) luminal stasis in association with release of microbe-generated toxins that

impair mucosal secretion and absorption, as well as translocation of bacteria to the gut wall, lymphatics, and systemic circulation; (3) a series of adaptive changes in intestinal motor function—at first relaxation to keep luminal pressures low, then hyperperistalsis in the effort to clear the blockage, and finally loss of organized motility patterns; and (4) alterations in blood flow to the mucosa and the gut wall, resulting not in ischemia, loss of mucosal integrity, inflammation, edema, and ultimately gangrene.[6,7] Ultimately it is the confluence of these disturbances that determines how quickly a simple obstruction evolves to cause symptoms and complications or a closed-loop obstruction to gangrene and perforation.

Table 49.1 Classification of Adult Mechanical Intestinal Obstructions

Intraluminal	Intramural	Extrinsic
Foreign Bodies Barium inspissation (colon) Bezoar	Congenital (rare in adult) Atresia, stricture, or stenosis Web Intestinal duplication Meckel diverticulum	Adhesions Congenital: Ladd or Meckel bands Postoperative Postinflammatory (after pelvic inflammatory disease)
Inspissated feces Gallstone ileus Meconium (cystic fibrosis)	Inflammatory Process Crohn disease Diverticulitis Stricture from ischemia Radiation enteritis or stricture Medication induced (NSAIDs, KCl tablets)	Hernias Abdominal wall Internal Groin Volvulus External mass effect Abscess
Parasites (ascaris, diphyllobothrium) Enterolith Intussusception	Neoplasms Primary intestinal or colon (malignant or benign) Secondary (metastasis or carcinomatosis)	Annular pancreas Pancreatic pseudocyst Carcinomatosis Endometriosis
Polypoid and exophytic lesions	Trauma (e.g., intramural hematoma)	Pregnancy

Complications and Systemic Effects of Bowel Obstruction

Closed-Loop Obstructions

The onset of obstruction is often caused by twisting of the bowel around the axis of its mesentery induced by an adhesive band or due to incarceration in a hernia (internal or external). Reflex hyperperistalsis and twisting of the mesentery occur early and are associated with intense pain and reflex nausea and vomiting. In a relatively short segment of intestine, and depending on region involved, continued secretion of mucus to high intraluminal pressures, stasis, bacterial overgrowth, mucosal disruption, and elevation of luminal pressures convert intermittent cramps to constant and worsening pain. When luminal pressure exceeds mural venous pressure and then capillary perfusion pressures, inflammatory cells are recruited from surrounding peritoneal structures. This sequence of events leads to intense inflammation, release of exudate and the first localization of pain from the umbilicus to the area of peritoneum lying nearest the involved segment of intestine. Peritoneal findings (localized tenderness, involuntary guarding, rebound or referred tenderness) and fevers appear. Subsequently, 20 to 24 hours into the illness, the blood supply of the appendix is compromised. Gangrene and perforation follow and, if not contained by surrounding structures, free perforation leads to release of intestinal fluid containing toxic microbes as well as the influx of fluid from the circulation due to intense peritoneal inflammation. Toxins from necrotic intestinal tissue and bacterial overgrowth are released resulting in circulatory collapse and shock.

Open-Loop Obstructions

Complications in open-loop obstructions do not necessarily evolve as rapidly as in closed-loop obstructions. Not uncommonly, an open-loop obstruction located in the proximal jejunum can be decompressed by the patient's ability to vomit. Proximal obstruction is characterized by vomiting and loss of gastric, pancreatic, and biliary secretions, with resulting electrolyte disturbances. These disturbances include dehydration, metabolic alkalosis, hypochloremia, hypokalemia, and usually hyponatremia. In contrast, obstructions of the distal ileum may lead only to a slowly progressing distention of the small intestine, with accommodation by

intestinal myoelectrical function and minor alterations in fluid and electrolyte balances. Open-loop obstructions located in the midgut are often complicated by events similar to those seen in closed-loop obstructions or by combinations of events seen in proximal and distal obstructions (**Table 49.2**). Patients with distal jejunal obstruction tend to present with a combination of complications resulting from loss of intestinal contents from vomiting, as well as distention and compromise of intestinal wall perfusion.

Table 49.2 Symptoms and Signs of Bowel Obstruction

Symptom/ Sign	Prox. Small Bowel (Open Loop)	Dist. Small Bowel (Open Loop)	Small Bowel (Closed Loop)	Colon/Rectum
Pain	Intermittent, intense, colicky, often relieved by vomiting	Intermittent to constant	Progressive, intermittent to constant; rapidly worsens	Continuous
Vomiting	Large volumes, bilious, and frequent	Low volume and frequency, progressively feculent with time	May be prominent (reflex)	Intermittent, not prominent; when present, feculent
Tenderness	Epigastric or periumbilical; quite mild, unless strangulation is present	Diffuse and progressive	Diffuse, progressive	Diffuse
Distention	Absent	Moderate to marked	Often absent	Marked
Obstipation	May not be present	Present	May not be present	Present

Adapted from Schuffler MD, Sinanan MN. Intestinal obstruction and pseudo-obstruction. In: Sleisenger MH, Fordtran JS, eds. *Gastrointestinal Disease, Fifth Edition*. Philadelphia, PA: W. B. Saunders Co.; 1993:898–916.

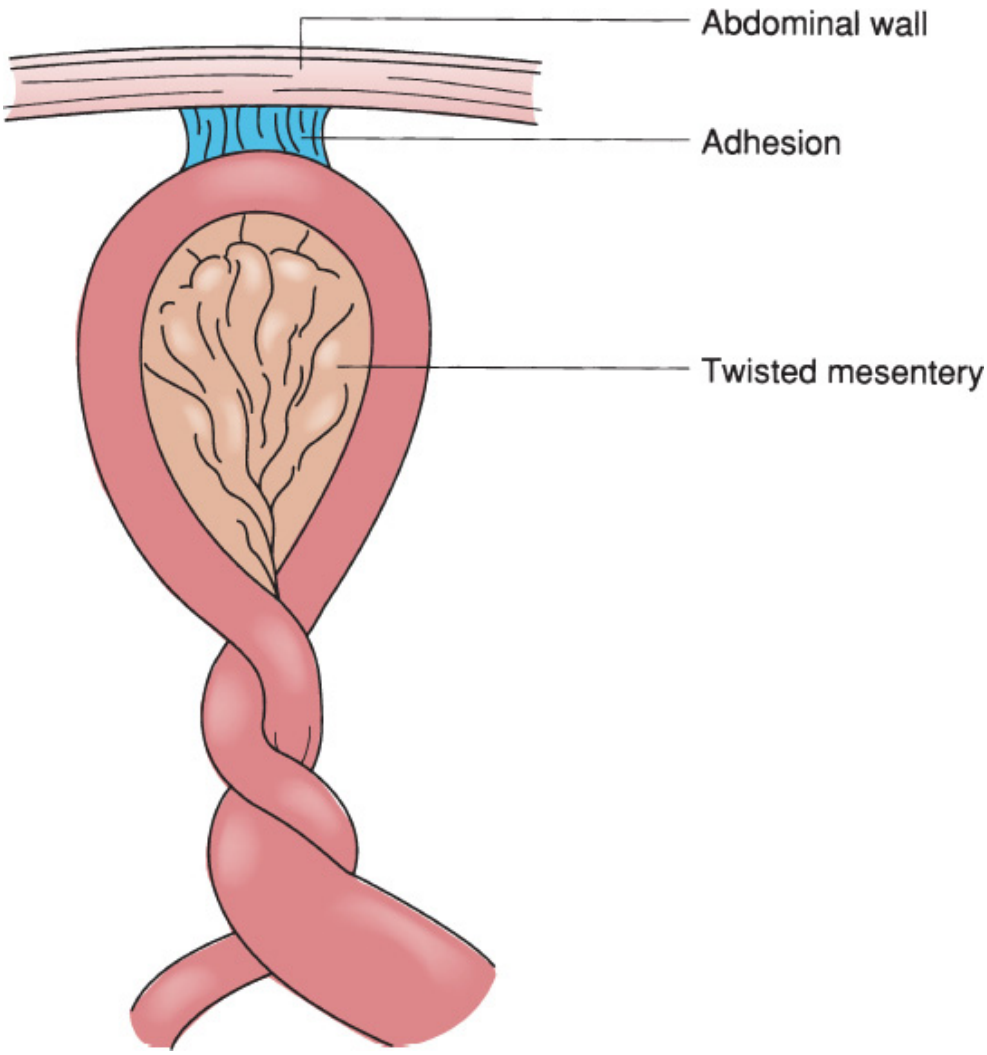

Figure 49.2 Schematic illustration of a closed-loop obstruction. The small intestine twists around its mesentery, compromising inflow and outflow of luminal contents from the loop. Also, the vascular supply to the loop may be compromised due to the twisting of the mesentery. The risk of strangulation is high.

Clinical Presentation and Diagnosis of Small Bowel Obstruction

Acute Obstructions: Symptoms and Signs

Four key symptoms associated with acute mechanical obstruction of the small intestine include *abdominal pain, vomiting, distention, and obstipation.* When a patient presents with abdominal pain that is evolving but not associated with other signs—that is, "pain out of proportion to physical findings," the differential diagnosis includes closed-loop obstruction, along with entities such as mesenteric ischemia, pancreatitis, ureteral colic, a

leaking or ruptured aortic aneurysm, as well as metabolic disturbances. The diagnosis of closed-loop obstruction must be excluded by expeditious testing and imaging or acted on as a surgical emergency 3 . Other consequential factors in the history and clinical examination[8,9] include previous abdominal surgery, quality of pain (colic/intermittent vs. steady), abdominal distention, and hyperactivity of bowel sounds (**Tables 49.2** and **49.3**). In addition, it is important to focus on symptoms that may reflect underlying malignancy as the cause, including fatigue, deconditioning, anorexia, and weight loss; and useful to consider a history of prior malignancies. In simple obstruction, laboratory studies do not play a direct role in diagnosis, but aid in understanding the likelihood of complications such as dehydration, strangulation, and sepsis. Plain abdominal radiographs and other imaging studies with enhancements are useful in confirming the clinical diagnosis of simple obstruction and in differentiating obstruction that is partial in contrast to obstruction associated with intestinal ischemia or gangrene.

Strangulation: Symptoms and Signs

The presentation usually involves an evolving picture of abdominal pain as well as physical signs and laboratory tests that suggest peritonitis, large fluid shifts, and ultimately systemic toxicity (**Table 49.3**). Such signs include abdominal tenderness or involuntary guarding localizing to the area of the strangulated loop of small bowel, decreasing urine output, fever, and tachycardia. The likelihood of strangulation is low if such signs are not present.[10] It should be stressed, however, that when complete obstruction is present, no satisfactory clinical criteria are available to reliably exclude the possibility of strangulation.[6,11,12]

Strangulation: Laboratory Testing

Different laboratory tests have been advocated for early detection of strangulated intestine. Metabolic (i.e., lactic) acidosis and increases in serum amylase, inorganic phosphate, hexosaminidase, intestinal fatty acid–binding protein, serum D-lactate levels and procalcitonin have all been associated with intestinal ischemia.[13–16] Such laboratory abnormalities may be helpful in diagnosing established strangulation in a small group of patients where the diagnosis of necrotic bowel is not clear. However, a noninvasive and rapid

assay has not yet been developed that can provide information to suggest that tissue necrosis is imminent but not yet established.[12]

Obstruction and Strangulation: Differential Diagnosis

Other abdominal conditions, such as appendicitis, diverticulitis, perforated peptic ulcer, cholecystitis or choledocholithiasis can usually be distinguished from small bowel obstruction (SBO), by clinical history, examination, and basic laboratory data. Obstruction of the colon is usually accompanied by varying levels of pain with massive abdominal distention and obstipation. It should also be emphasized that the presence of another abdominal process does not exclude the complication of SBO.

Obstruction and Strangulation: Radiographs and other Imaging Modalities

The role of imaging is to confirm the diagnosis of bowel obstruction while excluding other diagnoses, locate the site of obstruction, and gain insight into the lesion responsible for the obstruction.

Plain Radiographs

A plain, supine abdominal radiograph provides evidence of dilated loops of small bowel (>3 cm) proximal and clearance of fluid and air distal to the point of obstruction (**Fig. 49.3**), while upright or lateral decubitus films classically reveal multiple air–fluid levels located at different levels on the upright film or lateral decubitus film (**Fig. 49.4**). When the clinical symptoms and signs make a simple obstruction likely, plain abdominal radiography can be diagnostic in 67% to 80% of patients.[17,18] It should be emphasized, however, that plain radiographs can miss SBO in patients without air–fluid levels because of fluid-filled distended loops.[19] If there is air in the colon, the obstruction may be complete, but early in the clinical course, or it may be incomplete. Free air in the peritoneal cavity, reflecting perforation of a viscus, is best diagnosed on upright or lateral views, and is easily missed on the supine view. These considerations underscore the importance of obtaining all three views but also should serve as a warning that plain films are not consistently accurate in localizing the specific site of obstruction or predicting clinical progression.

Table 49.3 Diagnosis and Decisions in Bowel Obstruction in Three Hypothetical Patients

	PATIENT I Early Closed-Loop Obstruction	PATIENT II Intestinal Obstruction with Strangulation	PATIENT III Open-Loop Obstruction of the Distal Small Intestine or Cecum
History/Symptoms	Crampy periumbilical pain rapidly evolving from colic to constant pain, with 2–3 episodes of emesis (sometimes dry emesis)	Diffuse, crampy abdominal pain over 24–48 hrs with many episodes of vomiting. Evolves to constant pain. Bowel movements or flatus not uncommon early in the illness, but not late.	Progressive abdominal distention over previous 2 wks. Mild discomfort. No vomiting. Few bowel movements and little flatus
Physical Findings/Signs	No distention, minimal flatus. Minimal disturbance in vital signs. Often with minimal or no tenderness. Peritoneal	Temperature >100 deg F, Heart Rate >100/min, dehydrated. Mild distention; local tenderness often present with focal	Distention prominent, mild tenderness, often with minimal localizing tenderness and no peritoneal findings

	findings absent	peritoneal signs. Strangulated segment may be palpable in thin individuals	
Lab	No leukocytosis, pH, or electrolyte disturbances	WBC 16K. Serum Na^+ low, K^+ low, Cl^- low, pH alkalotic	WBC normal, serum electrolytes mildly decreased
X-Ray	Nonspecific gas pattern on plain film	Multiple dilated loops and air–fluid levels. No gas in colon	Multiple dilated small bowel loops and air–fluid levels. Some gas and stool in proximal colon
Differential Dx	Broad: includes appendicitis, closed-loop SBO, pancreatitis, nonsurgical conditions	Narrow: Complete SBO likely, strangulation cannot be excluded	Narrow: distal small bowel or proximal colon obstruction likely, possibly incomplete
Initial Rx	Admit with q3–4 hr reevaluation by clinical examination, WBC. Repeat	Admit for rapid resuscitation with IVFs, IV antibiotics. Urinary catheter and	Admit for IVFs, NG intubation. Hypaque enema followed by

	films q8–12 hr. NG tube if vomiting persists. IVFs	NG intubation indicated	barium to evaluate colon. CT if malignancy suspected
Indications for Surgery	If pain worsens, local tenderness or peritoneal signs evolve, WBC rises, urine output falls	Already present. Patient should be scheduled and brought to O.R. after adequate resuscitation (dramatic improvement with resuscitation may permit observation for 4 hrs)	Surgery performed when evaluation is complete or if clinical course deteriorates during evaluation

Figure 49.3 Plain supine abdominal film of a patient with small intestinal obstruction. Note the multiple dilated loops of small intestine (*black arrow*) in the left upper quadrant characterized by complete markings of the plicae. Also note absence of air in colon and rectum.

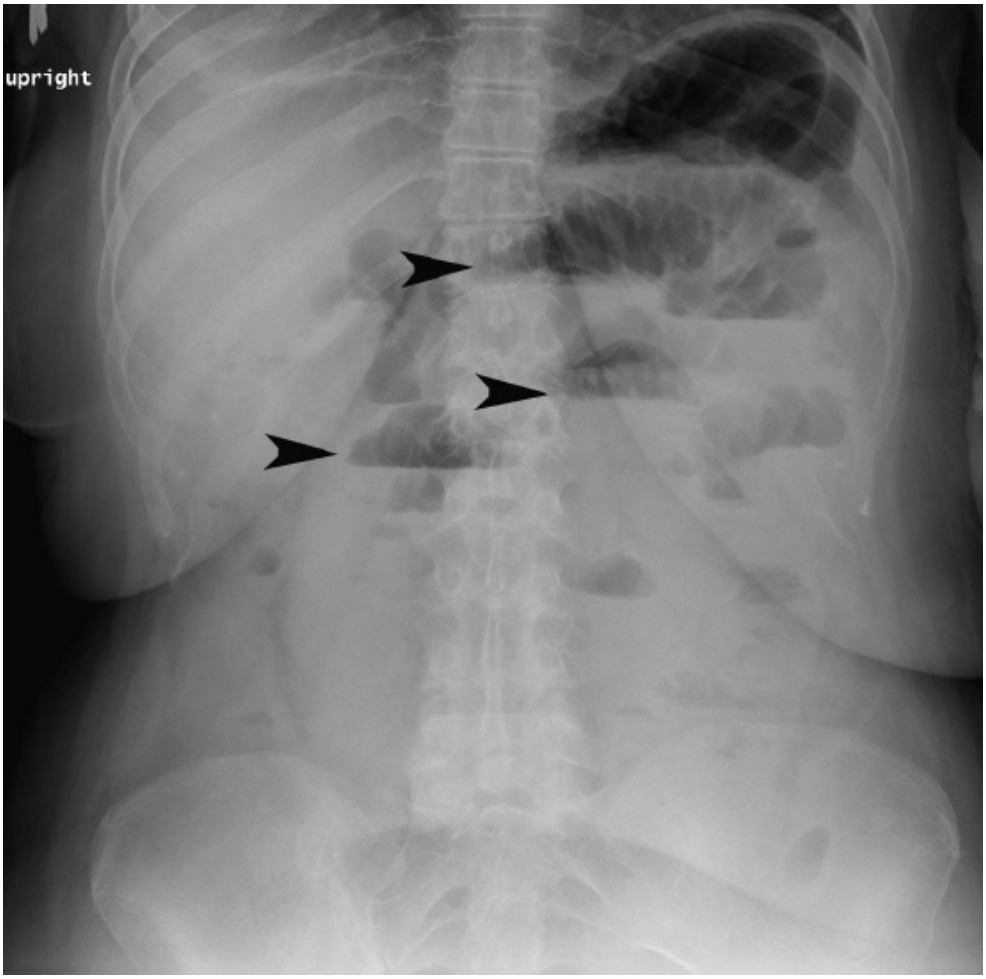

Figure 49.4 Plain upright abdominal film of a patient with small intestinal obstruction. Note the air–fluid levels in the stomach and multiple dilated loops of small intestine (*arrowheads*), and absence of air in the colon or rectum.

Contrast-Enhanced Radiography

Use of water-soluble contrast is diagnostic and can be therapeutic 6. Contrast studies (i.e., small bowel follow-through, enteroclysis, contrast enema) may provide specific localization of the point of obstruction and the nature of the underlying lesion. When obstruction of the small intestine is not progressing or resolving, a small bowel follow-through may be performed to confirm the presence and location of the obstruction. The choice of contrast materials includes water-insoluble suspensions of barium and water-soluble agents such as Gastrografin® or Hypaque™. Barium studies provide the clearest images, in both small bowel studies where the contrast is given from above and colon/rectum studies in which the contrast is given by enema. If

barium leaks into the peritoneum, however, it elicits intense peritonitis. If there is any possibility of bowel perforation or gangrene, barium should not be used. Water-soluble agents such as sodium amidotrizoate/meglumine amidotrizoate oral solution (Gastrografin) or diatrizoate sodium/diatrizoate meglumine (Hypaque) are hyperosmotic and can elicit fluid translocation into the gut.

When the obstruction of the small intestine is simple or incomplete, the use of these agents may also facilitate resolution. Gastrografin is hyperosmolar (1,900 mOsm/L). Its administration permits mobilization of fluid into the bowel lumen which decreases edema of the intestinal wall and increases the pressure gradient across obstructive site. It is thought that these fluid and pressure shifts can contribute to resolution in cases of incomplete obstruction. Thus, the appearance of contrast within 24 hours after administration clearly predicts resolution of the episode (>95%). It remains controversial whether the use of contrast alters the need for surgical intervention or reduces resource utilization when used routinely.[20–22] With respect to the protocol, the 2013 Bologna guidelines for diagnosis and management of adhesive SBO recommended a dosage of 50 to 150 mL of Gastrografin administered either orally or via NGT immediately on admission or after an attempt of conservative treatment for 48 hours.[23]

Computerized Tomography

The resolution and anatomic clarity afforded by computerized tomography (CT) provides several benefits, including improved localization of the obstructed segment and the points of transition, characterization of the completeness of obstruction, detection of ischemia and strangulation, and identification of the etiology of obstruction and exclusion or confirmation of other diagnoses. If the offending lesion is malignant, secondary information about local characteristics and stage can also be obtained.[24,25] The anatomic information obtained, particularly if other diagnoses such as hernia are present, is equally valuable. Attributes of impending ischemia include mesenteric edema, vascular engorgement, high-density fluid in the peritoneal cavity,[26] and moderate to severe intestinal wall thickening (greater than 2 mm) (**Fig. 49.5A,B**). High attenuation of bowel wall on unenhanced CT scans, low or reduced attenuation of bowel wall on intravenous contrast CT scans, and presence of intramural air (pneumatosis) or portal venous gas are

CT findings suggestive of strangulation. Using such criteria, CT scan has a >90% sensitivity and >90% specificity with a negative predictive value of 99% in diagnosing intestinal strangulation. Increasingly, CT scan is considered the "go-to" study for confirmation of the diagnosis, relevant anatomy, and complications.[22]4

Ultrasound and Magnetic Resonance Imaging

Ultrasound can be useful in excluding other diagnoses in the differential, especially lesions in the pelvis, and in detecting signs of mesenteric infarction, such as loss of bowel motility and presence of free peritoneal fluid.[22] MRI has comparable sensitivity to CT scan in diagnosing obstruction but limitations include limited availability after hours, poor definition of mass lesion, and poor visualization of colonic obstructions.[22] The use of MRI should be limited to patients who have contraindications to CT or are allergic to contrast material.[23] It is difficult to recommend the use of ultrasound, except in cases where CT is contraindicated and the sonographer very experienced.

Caveats to the Use of Imaging When Strangulation or Closed-Loop Obstruction Are Suspected

It should be emphasized that when the clinical picture provides strong suspicion for closed-loop obstruction complicated by strangulation, the decision for obtaining imaging studies should not lead to delay in resuscitation and timely operation. The information sought from imaging studies should be weighed against the risk of such delays. The message of the literature on imaging is that the clinical picture is usually correct, especially when multiple clinical signs (tenderness, peritoneal signs, leukocytosis, profound dehydration) of strangulation are present. An imaging study that provides the most rapid confirmation of diagnosis (plain film or CT) is usually sufficient, unless the surgical or medical histories are so extensive as to warrant concern for a complex cause of obstruction or signs that otherwise would be attributed to strangulation.

General Considerations in Management of the Patient with Bowel Obstruction

The Diagnosis Is Suspected

Patients with obstruction of the large bowel present with abdominal pain, distention, and obstipation. Vomiting and electrolyte imbalances are sometimes prominent, though usually delayed. Elderly patients are prone to dehydration. The presentation of SBO depends on level of obstruction, open- or closed-loop nature, and interval since onset of symptoms. Symptoms and signs of intermittent crampy abdominal pain, vomiting, obstipation, and distention are present in variable degrees. The overall picture, however, is usually one of a patient with abdominal symptoms that are evolving and getting worse. In the settings described previously, the following questions must be addressed as expeditiously as possible.

1. *Is the abdominal pain disproportionate to the physical findings and laboratory studies?*
2. *How rapidly are the symptoms and signs evolving: over minutes, hours, or less acutely?*
3. *Does the patient suffer from dehydration, electrolyte imbalance, and acid–base disturbance?*
4. *Is the obstruction complete or incomplete?*
5. *Is there a possibility of strangulation?*

Clinical data and basic laboratory studies will provide reliable information to answer the first three questions. Answering questions 4 and 5 will often depend on close clinical observation and reexamination in the first hours or days after presentation. Abdominal radiographs and imaging studies are frequently used to provide additional information to help answer these latter questions, as well as to provide information to identify the obstructing lesion.

Summarized in **Table 49.3** are thumbnail sketches of different, but typical, kinds of patients presenting with symptoms and signs consistent with obstruction of the small intestine. The principles of diagnosis and management of each of these patients begin with clinical information that indicates the likelihood of a bowel obstruction. Laboratory studies and plain abdominal films are used to confirm the diagnosis of obstruction and determine the extent of physiologic impairment. The patient's history and clinical course in the first few hours of observation are used to determine the likelihood of strangulation. Indications for surgery include rapid evolution of symptoms and signs and high suspicion/confirmation of closed-loop

obstruction. Contrast or imaging studies are used when symptoms are not evolving rapidly and when identification of the underlying lesion might alter the operative strategy.

Resuscitation

The initial management of all patients with suspected bowel obstruction includes designating the patient "NPO" and starting intravenous fluids comprised of isotonic Ringer or normal saline solutions. Restoration of fluid and electrolyte balance is a priority, often requiring frequent evaluation of serum electrolytes and pH[5] . In acute cases when significant dehydration is detected, an indwelling urinary catheter should be placed to monitor urine output. Hemodynamic monitoring may be necessary to monitor the response to fluid resuscitation in patients with severe cardiac, pulmonary, or renal insufficiency.

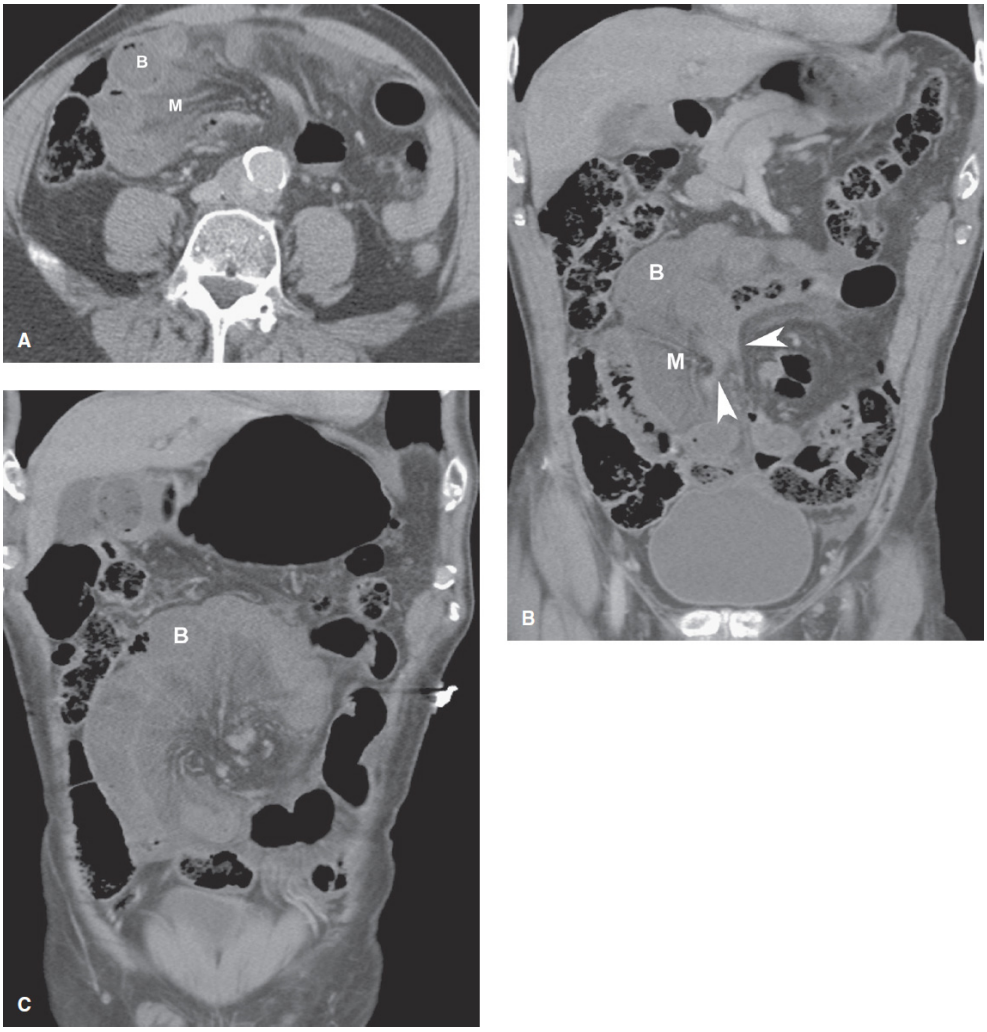

Figure 49.5 Axial, (**Panel A**), and coronal, (**Panel B**), images of a closed-loop obstruction with strangulated small bowel secondary to a volvulus from an adhesive band. Distended fluid-filled loops of small bowel (B) in a radial distribution converging toward the point of torsion (*white arrowheads*). There is edema within the mesentery (M). Shown in **Panel C** is a coronal view of vascular engorgement and mesenteric edema in a closed-loop obstruction.

Nasogastric Decompression

The nasogastric tube, typically a 16- or 18-French sump tube, serves to prevent distal passage of swallowed air and minimizes the discomfort of refluxing intestinal content. The use of longer tubes has been advocated in certain settings, especially for patients with chronic but intermittent obstruction arising from Crohn disease, peritoneal carcinomatosis, radiation enteritis, or many previous laparotomies for obstruction. The underlying rationale is that advancement of the tip of the long tube to the obstructed loop

would permit more effective decompression, perhaps resulting in relaxation of the loop and relief of the obstruction. While the use of long tubes has been reported to be of benefit in some settings[27] and has had its advocates over the year, there remains no clear consensus on indications for its use and its overall utility[22,28] for adhesive obstruction. An important caveat in the use of any form of nasogastric or nasoenteric tube decompression is the risk of aspiration pneumonia and other discomforts. Placement of decompressive tubes is indicated in the early phase of resuscitation and observation, with ongoing nausea, vomiting, distention; but can be avoided when symptoms are mild and quickly resolved.[29]

Antibiotics

It is well recognized, clinically, that bacterial overgrowth is a consequence of obstruction and, experimentally, that the presence of luminal bacteria accelerates the evolution of symptoms and signs of strangulation in closed-loop obstruction. In experimental studies, bacterial translocation to the lymph nodes, mesentery, and circulation has been demonstrated with obstruction; and release of bacterial toxins appears to play a role in mediating the mucosal epithelial and immune response to obstruction.[30–33] These considerations do not provide a rationale for using antibiotics to avoid operation, but they do provide a scientific basis for using antibiotics once the decision for operation has been made and if operation is unavoidably delayed. Nevertheless, the use of antibiotics in patients who have not yet been committed to operation has not been evaluated systematically. Giving antibiotics to patients who are being observed can obscure the underlying process and, in the end, delay optimal therapy. Once the decision has been made to proceed with surgery, broad-spectrum antibiotics, covering gram-negative aerobes and anaerobes should be given. A second-generation cephalosporin or a combination of a first-generation cephalosporin and metronidazole is a rational practice for perioperative coverage in both simple and strangulation obstruction.

Adjuncts to Resuscitation and Decompression

In addition to the use of oral water-soluble contrast, diverse adjunctive strategies have been reported in the effort to optimize resolution of simple adhesive obstruction and avoid surgical intervention. One such adjunct

included oral therapy with the laxative magnesium oxide (500 mg), a defoaming agent simethicone (40 mg) that dissipates large air bubbles, and the probiotic *Lactobacillus acidophilus* (0.3-g tablet) given three times daily via NGT. This appeared to be effective in hastening the resolution of the conservatively treated partial adhesive SBO and shortening the hospital stay with no difference in complication rate and recurrence.[27] Another strategy employed with a reported benefit was hyperbaric oxygen, testing the hypothesis that a high partial pressure of oxygen in blood would hasten evacuation of inert gases from the bowel lumen and reduce edema in the bowel wall.[34] A follow-up randomized controlled trial, however, failed to demonstrate any improvement in the need for operative intervention for SBO when hyperbaric oxygen was used.[35]

Indications and Timing of Operation

The decision to perform abdominal exploration to relieve intestinal obstruction should be made expeditiously, but not in the absence of critical information or before adequate resuscitation (**Algorithm 49.1**). Indications for surgery are outlined in **Table 49.3**, for each of the thumbnail vignettes. It should be emphasized that once a diagnosis of closed-loop obstruction or strangulation with obstruction, the safest course is to proceed to operation without undue delay. Conversely, when the diagnosis is uncertain (i.e., there is a possibility of a nonsurgical diagnosis or that the obstruction is not complete), a period of close observation is appropriate that includes resuscitation, restoration of electrolyte balance, serial examinations, and nasogastric suction when nausea, vomiting, and pain are prominent.

Current practice is in transition, with respect to the need for surgery when the obstruction is complete but not yet complicated by evidence of strangulation, peritonitis, or sepsis. Recent studies have provided evidence to challenge the well-established principle of early operation in this situation. Thus, with management enhanced by administration of water-soluble contrast,[36] there are circumstances in which uncomplicated obstruction may safely be observed unless and until clinical follow-up indicates failure of resolution. Similarly, in patients with obstruction but without a history of prior operation, the so-called “virgin abdomen” may safely be observed to resolution.[37–40] Under circumstances such as these, it is important to recognize the circumstances under which scheduling for surgery

may not be urgent but should not be unduly delayed. Such circumstances would include obstruction due to nonreducible hernia (internal or external) or malignancy amenable to curative resection. A decision to observe, rather than early operation, may also be influenced by resources, expertise, and ancillary services that are available.[41]

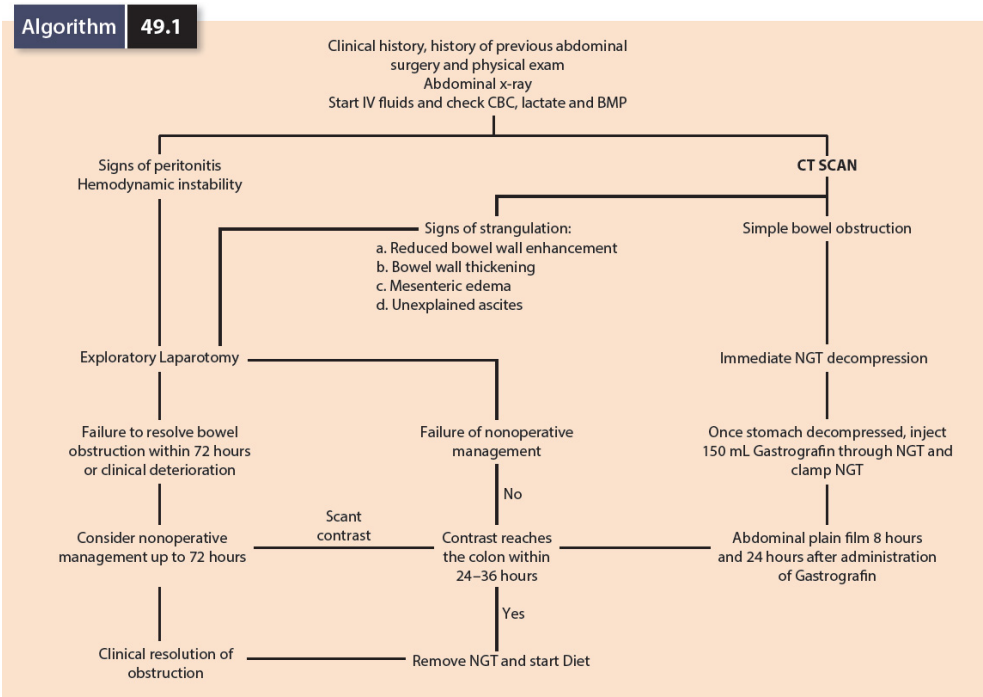
Specific Types of Bowel Obstruction

Chronic Adhesions

Peritoneal adhesions account for more than half of SBO cases. Lower abdominal procedures such as appendectomy, hysterectomy, colectomy, and abdominoperineal resection are common precursor operations to adhesive obstruction. Adhesions may form after any abdominal procedure, however, including cholecystectomy, gastrectomy, and abdominal vascular procedures. In long-term follow-up, about 5% of patients undergoing laparotomy will develop adhesive obstruction[42]; of these, 10% to 30% will suffer from additional episodes. Over 80% episodes of SBO due to adhesions may resolve nonoperatively.[6,22,28] An index episode and three recurrences indicate a likelihood of over 80% that there will be more recurrences.[43] The critical question, then, is whether outcomes, complications, and costs, on balance, favor operative intervention or observation and follow-up in cases where either strategy for management could be chosen. In a series of recent reports, utilizing retrospective administrative data from all acute care hospitals in Ontario, Canada, it would appear that early surgical intervention with an index case of obstruction is associated with less frequent recurrence[44] and comparatively long-term survival.[45] A clear message from this set of reports is that boundaries should be set on the interval for expectant management (**Algorithm 49.1**), so as to avoid the higher morbidity and mortality caused by undue delays.[46]

The pathobiology of adhesion formation has been the subject of considerable investigation.[6] Histologic examination of chronic adhesions reveals foreign-body reaction, usually to talc, starch, lint, intestinal content, or suture. Talc and starch are found less commonly now than previously, because of improvements in techniques of manufacture and sterilization of surgical gloves, and the increasing applications of laparoscopy for intra-

abdominal operations. Mesothelial cells are the presumed origin of tissue plasminogen activator (TPA). TPA binds fibrin and plasminogen, thereby preventing adhesion formation. In early studies, inflammatory cells, including mast cells, were implicated in the process that produces adhesions, along with macrophages which secrete cytokines and chemokines that drive inflammation, resolution, and formation of scar. Ischemia, injury, and rough handling of tissues also play a role to incite local inflammatory response, and recent studies[47] have highlighted the role of various proinflammation cytokines in exacerbating or inhibiting adhesion formation in different animal models. It also seems likely that genetic variants, perhaps among the various cytokines and their receptors,[48] will be found to modify the risk of developing adhesions that lead to obstruction.



Algorithm 49.1 Approach to recognition and management of early postlaparotomy obstruction of the small intestine.

Current strategies to prevent adhesions at a first, or subsequent laparotomy, include first and foremost, minimizing tissue manipulation and injury to the peritoneal surfaces, meticulous attention to hemostasis and surgical technique, use of laparoscopic approaches where safe and feasible, and removal of any foreign material whenever possible. Adjuncts to prevent

adhesions after a first laparotomy include targeting of the fibrinolytic system in order to enhance rapid healing and minimize formation of peritoneal adhesions.[49] Popular strategies have also included the effort to develop temporary barriers that can be placed intraperitoneally at the time of laparotomy in order to prevent adherence of loops of bowel to each other and to other peritoneal surfaces.[50] Such barrier compounds include hyaluronic acid–carboxymethylcellulose membrane (Seprafilm, Genzyme, Cambridge, MA), icodextrin solution, hydrogen adhesion spray, and lyophilized human peritoneal membranes. Such barrier compounds may be useful in preventing adhesions at an initial laparotomy,[51] but only one (icodextrin) has been tested in a trial setting of preventing recurrence following an index episode of adhesive SBO.[52]

Early Postoperative Obstruction and Adhesions

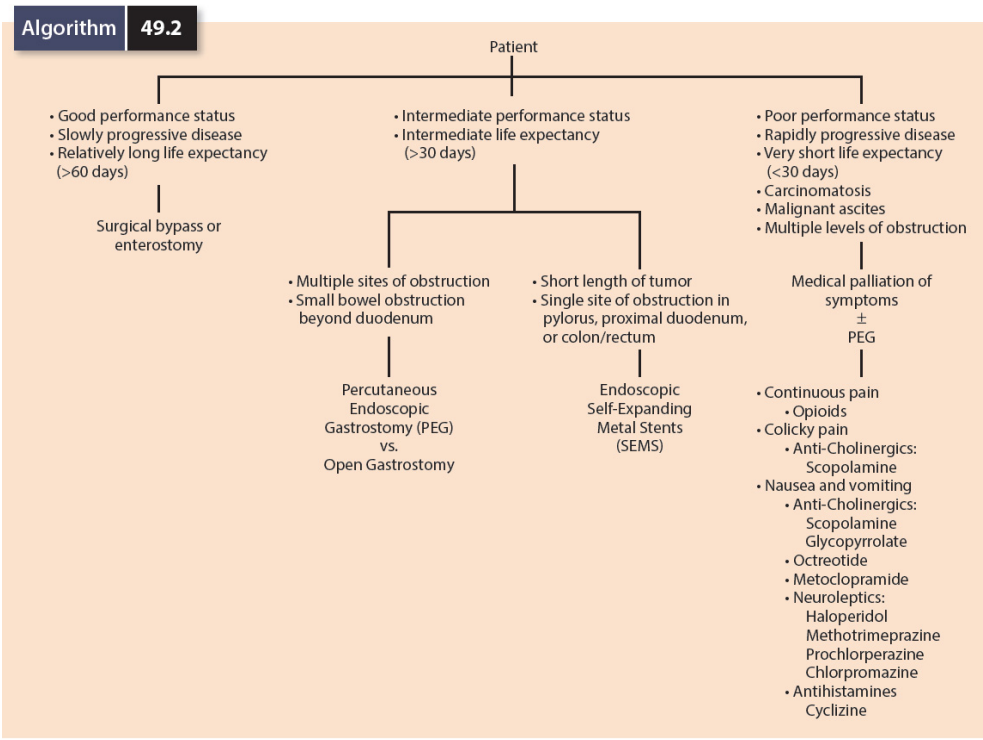
Early Obstruction after Open Operations

Obstruction in the immediate period following open abdominal surgery is uncommon but may occur in up to 1% of patients in the 4 weeks following laparotomy. Adhesions are responsible for approximately 90% of such cases and hernias for approximately 7%.[53] Intussusception, internal herniation, inflammation, abscess, intramural intestinal hematoma, or technical errors may be responsible for the remainder of cases.[54–56] Most cases occur after surgery of the colon, especially abdominoperineal resections, or operations in the lower abdomen. It is rare for upper abdominal surgery to cause such obstructions. A common scenario is that a patient will undergo colectomy uneventfully, pass flatus, and have bowel sounds by postoperative day 3. On the fourth postoperative day the patient will suddenly become distended and uncomfortable, and with cessation of flatus and stool. Patients with acutely evolving symptoms and signs should be suspected of having a complete obstruction and should be managed as such. In this latter setting, the mortality may be as high as 15% due to delays in recognition and operative intervention.[54,57] The loss of bowel sounds after a short period of normal or hyperactive activity is worrisome for ischemia of the obstructed segment. The great majority of such cases may be treated as partial intestinal obstruction; nasogastric suction and intravenous fluids will help resolve symptoms within a few days (**Algorithm 49.2**). When the clinical course

does not demand earlier intervention, a nonoperative approach may be tried for 10 to 14 days and will resolve the obstruction in over 75% of such cases.[57] Patients who experience early postoperative obstruction from adhesions have a higher risk of subsequent adhesive SBO (26.5% vs. 7.5% at 5 years, $P < 0.001$).[56]

Early Obstruction After Laparoscopic Procedures

Requires a different kind of vigilance, in order to determine whether early operative intervention is warranted. In general, laparoscopic procedures are associated with lower short- and long-term risks for intestinal obstruction.[5,58–61] Individual laparoscopic procedures do, however, have individual complication profiles,[57,62,63] reflecting differences in etiology. A port-site hernia is common to all laparoscopic procedures, but the risk likely varies with the site and diameter of port placement. Thick adhesions are a risk where there is localized inflammation, and more likely to occur when procedures involve viscera of the lower abdomen (appendicitis, diverticulitis); but also in cases where there are extensively dissected surfaces, surgically stapled surfaces or intraperitoneally placed prosthetics such as occurs during hernia repair. Internal hernias are a risk when windows are opened in mesentery, such as in bariatric procedures or intestinal/colon resections. Based on these considerations, it is recommended that imaging be obtained when the etiology of obstruction is unclear and that patients with early postlaparoscopy obstruction be followed closely when a decision is made for expectant management rather than expeditious operation.



Algorithm 49.2 Algorithm for management of malignant obstruction.

Bowel Obstruction after a Bariatric Procedure

The obesity epidemic has seen the growth in the number of bariatric procedures which includes gastric banding, sleeve gastrectomy, gastric plication, Roux-en-Y gastric bypass, and biliopancreatic diversion with or without duodenal switch. Band slippage can occur in 15% to 20% of patients and typically presents with a history of upper abdominal symptoms of reflux, regurgitation, and dysphagia. Upper GI study is the preferred method of diagnosing band slippage, showing evidence of malposition of the band and proximal pouch dilatation with obstruction. The initial management is urgent band deflation using a Huber needle and if this is unsuccessful or patient is acutely unwell, necrosis, abscess, or erosion must be considered, which may require surgery. Intestinal obstruction occurs in 4.4% of patients after Roux-en-Y gastric bypass. The etiology of obstruction includes internal hernia (53%), roux limb compression due to scarring (20%), adhesion (14%), stricture at gastrojejunal anastomosis, kinking of the alimentary limb, incisional hernia, and intestinal intussusception. The most common site of internal herniation is the mesojejunal mesenteric window, followed by Petersen window (the defect between the small bowel limb, the transverse

mesocolon, and the retroperitoneum), and the mesocolic window.[64] Obstruction in the postbariatric surgery patient is thus different in its likely etiologies and presentations than in other patients. Thus, while early postoperative intestinal obstruction in the latter patients generally resolves without operation, surgery is required more than 50% of the time in the former and the acute presentation leads to reoperation more quickly, usually within 24 hours after the onset of obstructive symptoms.[65]

Hernia

Indications and Timing of Surgery

Hernias of all types are second only to adhesions as the most frequent causes of obstruction in western countries. External hernias such as inguinal (**Fig. 49.6A,B**) or femoral hernias may present with the symptoms of obstruction and will not be diagnosed unless sought.[66] Femoral hernias are particularly prone to incarceration and bowel necrosis due to the small size of the hernia inlet.[66] Other hernias such as umbilical, incisional, parastomal, or lumbar hernias are obvious. Still others, such as internal hernias are usually diagnosed at laparotomy for obstruction. These include obturator hernias, paraduodenal hernias, and hernias through the foramen of Winslow (posterior to the porta hepatis) or mesenteries. When hernia has been identified as the cause of the obstruction, the patient is quickly resuscitated, given antibiotics, and taken to the operating room. The hernia is reduced and the viability of the bowel assessed. If viable, the bowel is left alone; if not, it is resected. The hernia defect is then repaired. One important consideration is the Richter hernia (**Fig. 49.7**).[67] In this variant, only a portion of the wall of the bowel is incarcerated and thus incarceration and strangulation may not be associated with complete obstruction. These most frequently occur in association with femoral or inguinal hernias. Complete obstruction can occur if more than half of the bowel circumference is incarcerated.

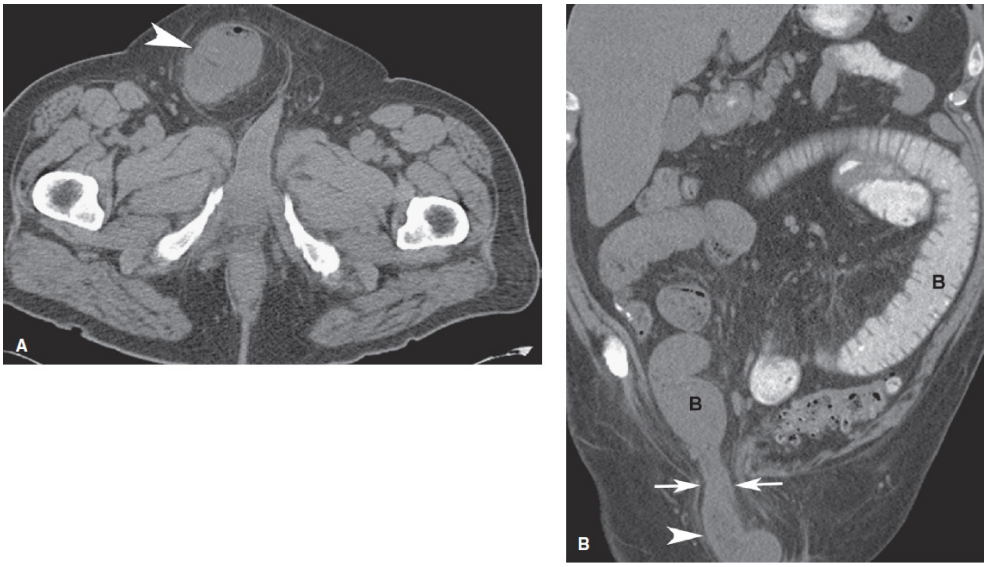


Figure 49.6 CT images of groin hernia. **Panel A:** Axial view. **Panel B:** Coronal view. *White arrowheads* identify the herniating segment. White *arrows* indicate the location of the hernia orifice.

Use of Mesh in Repair in Obstruction-Associated Hernia

Inguinal Hernia

With respect to inguinal hernia, current recommendations do not treat the use of mesh as contraindicated or as a preferred method for repair.[68] A recent large institutional experience confirms the higher likelihood of short-term complications and recurrence in emergency open hernia repairs and found no benefit in using mesh.[69] Based on these considerations, it seems most prudent to perform open tissue repair, saving mesh for recurrences should they occur. Laparoscopy, or laparotomy if necessary, is useful to assist in reduction and assess viability of bowel as needed. The laparoscopic approach to a nonreducible hernia, with reduction and placement of mesh, has been reported with acceptable results; in cases where there was significant contamination or when bowel required resection, a two-stage approach was utilized, with repair delayed until healing after reduction, washout, and resection.[70]

Ventral Hernia

It remains uncertain whether repair of a ventral hernia can safely include use of permanent prosthetic mesh. Recent studies suggest that obstruction without

ischemia or gangrene poses no special risk for postoperative wound occurrence or mesh infection.[71] Complication rates increase if contamination occurs during hernia repair, due to perforation advertent enterotomy, or intestinal resection, risks of postoperative wound infection, fistula, reoperation, and mortality.[72] At the same time, recent studies have shown that, in expert hands, such contamination need not lead to complication rates that are higher even when permanent synthetic meshes are used.[73] These considerations suggest that the approach to hernia complicated by intestinal obstruction should be tailored to the experience of the surgeon and the specific details of the case.

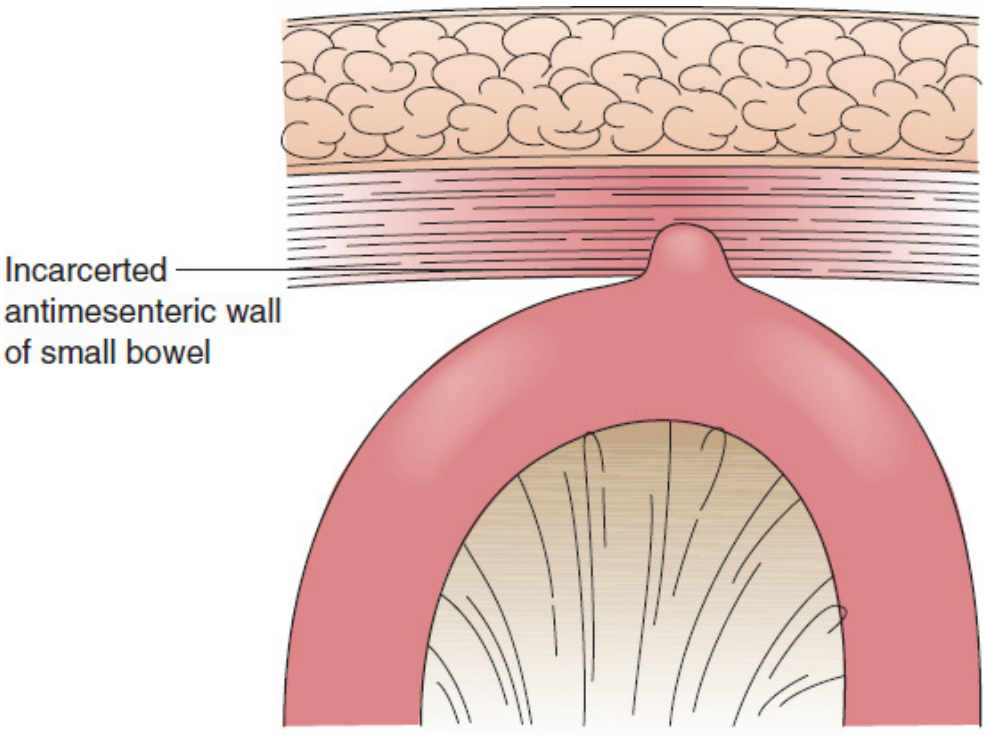

Figure 49.7 Schematic diagram showing Richter hernia, in which the antimesenteric border (but not the whole wall) of the intestine is incarcerated.

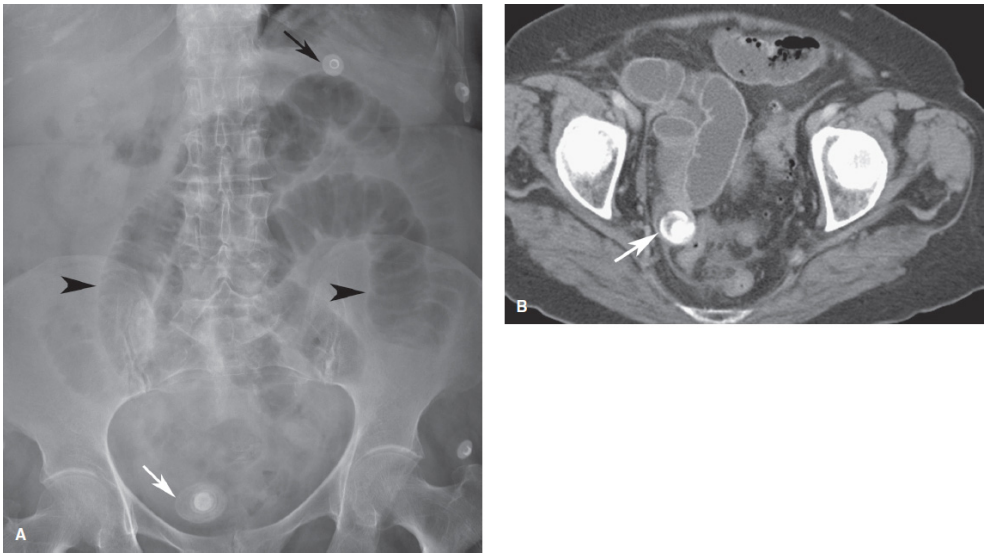

Figure 49.8 Gallstone ileus: **Panel A:** Plain film showing dilated loops of small intestine (*black arrowheads*), with air visible in biliary tree characteristic of biliary enteric fistula. **Panel B:** CT scan showing gallstone (*white arrow*) in the distal ileum and fecalization of luminal content adjacent to the stone.

Preoperative Reduction of Hernia to Relieve Obstruction (Taxis)

Reduction of the hernia is often successful but can occasionally result in reduction of the contents of the hernia still within its peritoneal sac, also known as reduction en masse. This can lead to persistence of a pre-existing obstruction or development of a new obstruction due to twisting of the loop of bowel in the sac. This is one reason for using circumspection in relying on taxis as a mode of treatment for incarcerated inguinal, femoral, and incisional hernias. In general, taxis should be followed by an expeditious operative repair.[74–76]

Gallstone Ileus

As a result of intense inflammation surrounding a gallstone, a fistula may develop between the biliary tree and the small or large intestine. Most fistulae develop between the gallbladder fundus and duodenum. If the stone is greater than 2.5 cm in diameter, it can lodge in the narrowest portion of the terminal ileum, which is just proximal to the ileocecal valve. This condition is rare, accounting for no more than 3% of cases of intestinal obstruction. Typically, the patient is elderly and female and presents with intermittent symptoms over several days, as the stone tumbles distally toward the ileum.

The classic findings on plain radiographs include those of intestinal obstruction, a stone lying outside the right upper quadrant, and air in the biliary tree (**Fig. 49.8A,B**). Treatment includes removal of the stone (via a proximal enterotomy) and resection of the obstructed segment only if there is evidence of tissue necrosis. The risk of a recurrent gallstone ileus is about 5% to 10%.[77,78] Such recurrences usually occur within 30 days of the initial episode and are usually due to stones in the small intestine that were missed at the original operation. Concurrent disconnection of the fistula and cholecystectomy is associated with higher morbidity[79] but can be performed selectively in good-risk patients. The current consensus is that cholecystectomy should not be performed at the initial operation for gallstone ileus, except in highly selected patients. A careful search of the entire intestine should be performed to exclude the possibility of additional large stones which can occur in up to 25% of patients.[80,81] For patients with Bouveret syndrome (duodenal obstruction due to an intraluminal gallstone), particularly those with high operative risk, an endoscopic approach may be considered as lithotripsy can often successfully relieve the obstruction. It should be noted, however, that up to 15% of these patients may go on to require laparotomy due to the development of a more distal obstruction due to migration of a stone fragment.[81,82]

Intussusception

About 5% of intussusceptions occur in adults. An intussusception occurs when one segment of bowel telescopes into an adjacent segment, resulting in obstruction and ischemic injury to the intussuscepting segment (**Fig. 49.9A**) and the obstruction may become complete, particularly if tissue inflammation and necrosis occur. Of adult cases, 90% are associated with pathologic processes.[83,84] Tumors, benign or malignant, act as the lead point of intussusception in more than 65% of adult cases. A significant proportion of cases have been reported to occur after abdominal surgery for lesions other than neoplasm. In cases not associated with neoplasm, Sarr et al.[85] reported that approximately 20% were related to the suture line, approximately 30% to adhesions, and approximately 60% to intestinal tubes. Intussusception related to long tubes can occur when the tube is withdrawn, but most frequently occurs with the tube in place. Perioperative intussusception

frequently subsides without intervention. It should also be noted, that as CT scans have become more widely used, transient intussusceptions without evidence of bowel obstruction are not infrequently identified and do not typically require intervention.[84,86]

Four types of intussusception are recognized: enteric, ileocolic (**Fig. 49.9B,C**), ileocecal, and colonic. In the ileocolic form, the ileum telescopes into the colon past a fixed ileocecal valve. In the ileocecal form, the valve itself may be the lead point of the intussusception. Radiographic features of intussusception are not specific. Plain films reveal evidence of partial or complete obstruction. Occasionally, a sausage-shaped soft tissue density will be seen, outlined by two strips of air. In both pediatric and adult cases ultrasonography may be useful in diagnosis. Nevertheless, in adult patients the mainstays of diagnosis are contrast studies or CT scan. Because of the high incidence of tumors, surgery has generally been recommended. Reduction by hydrostatic pressure, which is the standard of care in pediatric cases, is not usually attempted in adults.

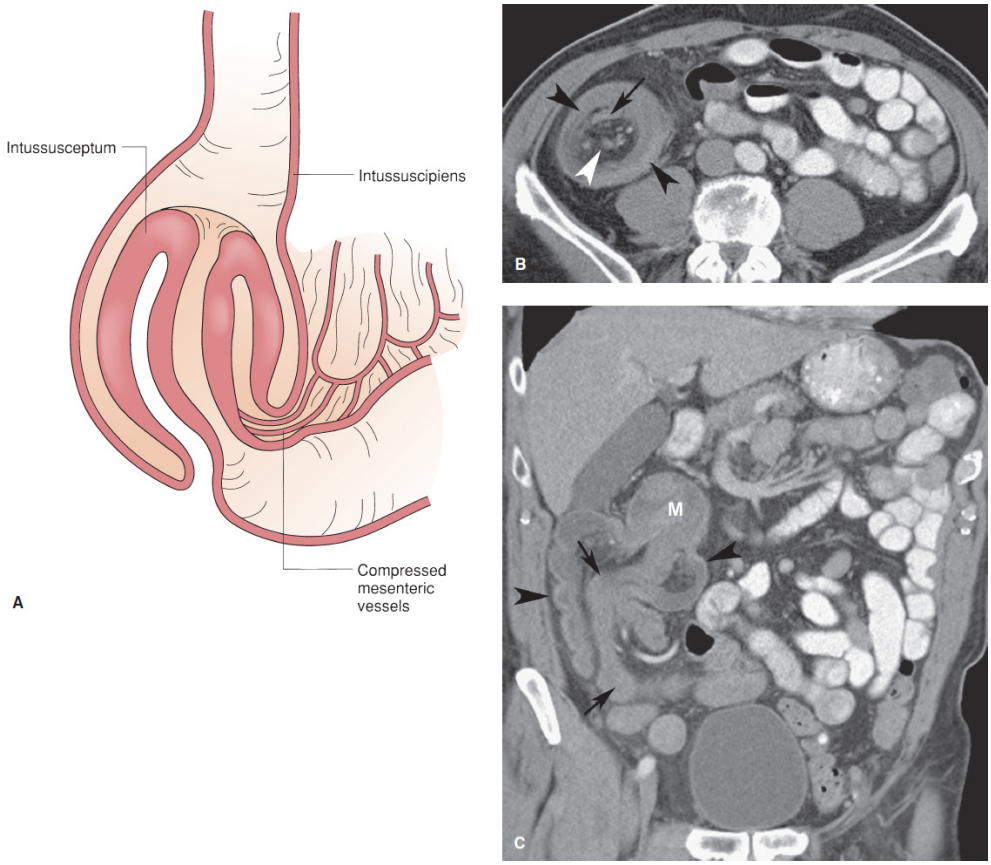

Figure 49.9 Anatomy and CT views of intussusception. **Panel A:** The intussusceptum is the segment of bowel that invaginates into the intussuscipiens. Axial view, (**Panel B**), *white arrowhead* shows the lumen, *thin arrow* shows the intussuceptum, and *thick black arrowheads* show the intussuscipiens. Coronal view, **(Panel C)**, M indicates the mesentery of the intussusceptum, while *black arrows* indicate the intussuscipiens. The *black arrowhead* indicates the edematous wall of the intussuscipiens.

In adults, preoperative reduction with barium or endoscopic insufflation might be successful in about one-third of patients, while intraoperative reduction is successful in another one-third.[83,84,87] Preoperative reduction has several benefits, including avoidance of emergency surgery, allowing radical surgery for cancer, reducing the extent of intestinal resection, and allowing time for preoperative preparation of the patient.[87] Clear indications for operation include long length and wide diameter of the intussusception, presence of a lead point, or evidence of bowel obstruction.[83,86] When malignancy is detected, preoperative reduction is inadvisable.[83] In the absence of malignancy, recent studies have called into question the need to operate in all cases detected on sensitive imaging studies such as CT scan,

arguing that a number of these patients can be safely managed without operation.[86] Given the possibility occult and potential malignant lesions such as gastrointestinal stromal tumor or carcinoid, expectant management should probably not be initiated without additional studies such as enteroscopy or capsule endoscopy.

Crohn Disease

Indications for surgery in Crohn disease are discussed elsewhere in this book. In this disease, obstruction occurs under two different sets of circumstances.[88] When the disease has flared acutely, the lumen may be narrowed by a reversible inflammatory process. The result is an open-loop obstruction that may respond, first to intravenous hydration and nasogastric decompression, and ultimately to therapy with corticosteroids or other anti-inflammatory regimens.[89] Alternatively, obstruction may occur in the setting of a chronic stricture. Such strictures may respond temporarily to conservative measures but, once diagnosed, operative therapy should not be delayed. One important clinical point is that perhaps 7% of Crohn strictures in the colon and an uncertain but smaller number in small bowel may harbor malignancy.[88] Extent of resection of a Crohn stricture is thus based on intraoperative findings, that is, to margins beyond visibly diseased bowel. If there is suspicion for malignancy, a lymphadenectomy is performed but not otherwise.

Malignant Obstruction

Obstruction can complicate malignancies of the small and large bowel in a number of settings. Studies have documented that 10% to 28% of patients with colorectal cancer and 20% to 50% of patients with ovarian cancer will present with a malignant bowel obstruction at some point during the course of their disease.[90] Most commonly, a primary lesion such as an adenocarcinoma or lymphoma will enlarge until the lumen of the intestine is blocked. The lesion then presents with symptoms and signs associated with the level of obstruction and is managed accordingly.

A second setting involves a patient who previously has undergone surgery for malignancy and now returns with evidence of bowel obstruction. The

likelihood that that the obstruction is due to recurrent disease is based on several factors, including the origin of the primary malignancy, the stage of the primary malignancy, and the designation of the original surgery as curative or palliative. Gastric and pancreatic carcinomas often present with or are subsequently complicated by peritoneal carcinomatosis and thus the subsequent obstruction is most likely due to malignancy. With respect to colon and rectal carcinomas, as many as 50% of cases presenting with obstruction after resection of the primary may be due to adhesions and not recurrent malignancy.[90,91] In addition, even if the obstruction is due to now unresectable disease, significant palliation can be obtained through bypass or enterostomy in up to 75% of patients (**Fig. 49.10**). However, the underlying diagnosis of cancer in this patient population mandates careful attention be paid to patient selection prior to any surgical intervention and risk factors for poor outcome (**Table 49.4**).

Management of incurable malignant obstruction may require an approach that moves away from classical surgical teaching of nothing by mouth (NPO), nasogastric tube, intravenous fluids, and serial radiographs.[92] Patients with advanced malignant obstruction in the absence of a solitary or correctable obstructing lesion are generally managed without surgery. Patients are managed without a nasogastric tube if possible. They are encouraged to eat as soon as obstructive symptoms resolve using a low-fiber diet. Antiemetics and opioids via continuous subcutaneous infusions are used to manage nausea, vomiting, and colic, respectively. In addition, octreotide, a somatostatin analog, is used in palliation of refractory malignant intestinal obstruction by improving intestinal mucosal absorption, improving motility, reducing gastrointestinal hormone levels and intestinal secretions, and having a direct antineoplastic effect on the obstructing tumor.[93] This may allow true palliative care outside a hospital setting saving patients the pain, discomfort, and complications of hospitalization and unproductive surgery.[92] In patients presenting with gastroduodenal and colorectal obstructing lesions who are not candidates for surgical bypass or enterostomy, endoscopic management options including percutaneous endoscopic gastrostomy tube (PEG) placement and self-expanding metallic stent (SEMS) placement, are available (**Algorithm 49.2**). These options have been associated with symptomatic relief in greater than 75% of patients.[90]

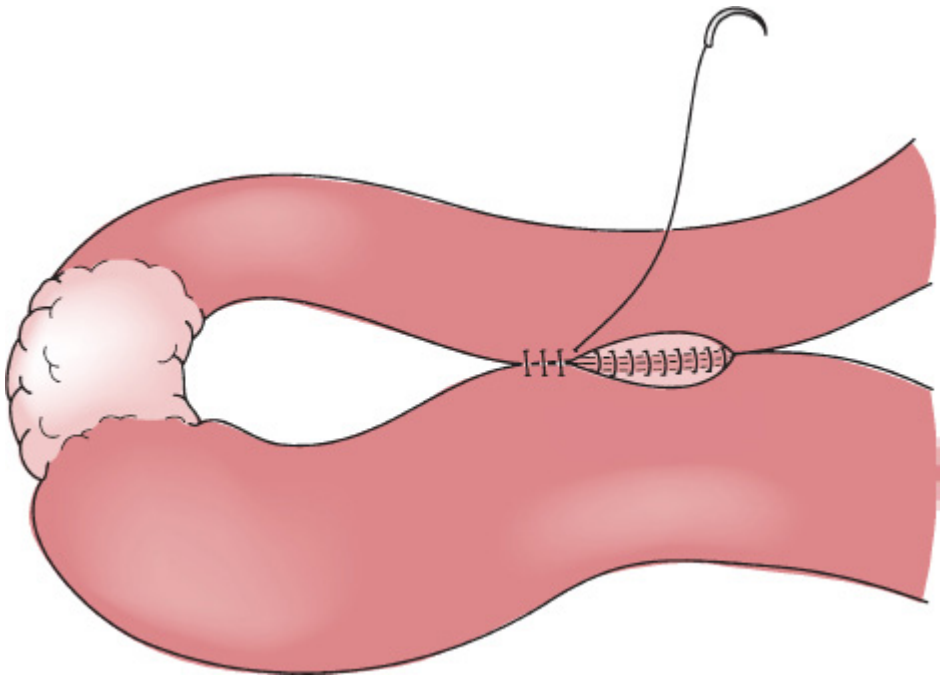

Figure 49.10 Significant palliation can be achieved in a patient with obstructing, but unresectable malignancy. Enteroenterostomy is performed to bypass the obstructing segment.

Table 49.4 Management of Malignant Obstructions: Risk Factors for Unfavorable Outcome

Advanced age (biologic/physiologic)
Poor performance status
Advanced stage of primary malignancy (previous treatments, availability of anticancer options, life expectancy)
Malnutrition/cachexia
Comorbidities
Absence of psychosocial support
Ascites (>100 cc associated with poor outcome)
Single vs. multiple sites of obstruction
Carcinomatosis (believed to respond poorly to surgical intervention)

Volvulus

The term *volvulus* indicates that a loop of bowel is twisted more than 180 degrees about the axis of its mesentery. Volvulus has been reported for the cecum, transverse colon, splenic flexure, and sigmoid colon. A special variant of volvulus, complicating a condition known as *Chilaiditi syndrome*, can occur when redundant loops of the transverse colon slip between the liver and diaphragm and then torse.[94] Generally, the condition is asymptomatic, but when associated with volvulus must be relieved surgically.

The most common site for volvulus is the sigmoid colon, accounting for 65% of cases. Volvulus occurs less often when an unusually mobile cecum, or rarely the transverse colon twists around their mesenteries.[95,96] A volvulus is a form of closed-loop obstruction of the colon. Air is always present in the colon and rectum, and thus volvulus of any segment of the colon is associated with abdominal distention and, usually, severe abdominal pain. As shown in **Figure 49.11**, the most common radiographic feature is the "bent inner tube" appearance of the sigmoid, which is usually visualized in the upper abdomen. The preferred method of management involves endoscopic decompression. A rigid or flexible proctosigmoidoscope is advanced gently into the rectum until a rush of air and feces indicates that the loop has been untorsed. A rectal tube is then advanced well into the loop as a stent to prevent retorsion. Gangrene of the colon does not usually complicate the picture if the patient is seen and treated promptly. This conservative approach resolves the volvulus in 85% to 90% cases and elective resection or fixation of the redundant segment can then be planned. Following endoscopic decompression alone, recurrence of the volvulus is higher than 60%.[97] Thus, an operation to remove the sigmoid should be performed if the patient is fit for surgery.[98] However, a majority of these patients are elderly and infirm and approximately 15% have a history of psychiatric disorder. As a result, the patient may present with peritoneal findings, sepsis, and shock. In this setting, rapid resuscitation followed by urgent resection and colostomy is warranted. Other forms of volvulus generally cannot be detorsed without operation. Fixation of the torsed segment (e.g., via cecostomy or cecopexy) is not as effective as resection of the involved segment and is not generally recommended.[95,96]

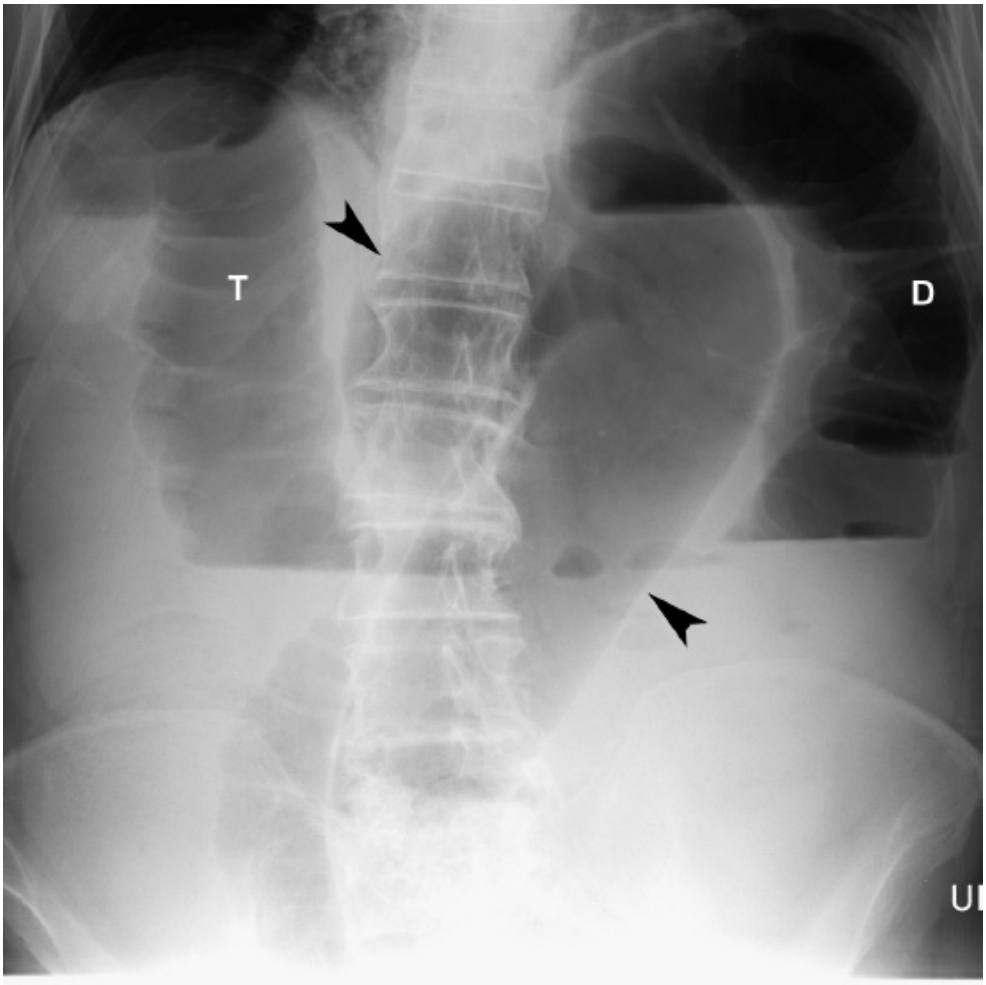

Figure 49.11 Plain supine abdominal film of a patient with sigmoid volvulus (*black arrowheads*). The centrally located sigmoid loop is outlined by trapped air. The proximal small intestine is dilated as well suggesting that the volvulus has been present for sufficient time to cause accumulation of air and fluid proximally.

Radiation Enteritis

After asymptomatic periods lasting at least 10 years, chronic intestinal obstruction can result. Radiation injury elicits an underlying vasculitis and fibrosis that lead to chronic, recurring low-grade partial obstruction of the small intestine or stricturing and bleeding in the colon and rectum. Operation is indicated for incapacitating symptoms and obstruction not resolved by conservative management.[99,100] Recurrence of the original tumor as a cause of obstruction should be considered and excluded. However, the diffuse nature of the injury and pathologic responses can lead to massive resections that leave the patient with short-bowel syndrome. Attempts to suture scarred

loops can also result in chronic inflammation and formation of interloop abscesses and fistulae. The incidence of suture line leak is high.[101] A critical feature is preoperative malnutrition and diarrhea that is often associated with radiation enteritis, due to both malabsorption and maldigestion,[100] leading to deficiencies in fat-soluble vitamins (especially Vitamin B_{12}) and interruption of the enterohepatic circulation. Surgical approaches include resection, when structuring disease is localized to distal segments and the intestinal loops not too densely adherent to each other or other structures such as major blood vessels. When resection is not feasible, it may be possible to perform a bypass of the obstructing segment (**Fig. 49.10**).

Open and Laparoscopic Operation in the Management of Small Bowel Obstruction

General Principles of Open Laparotomy and Lysis of Adhesions

Currently, open laparotomy is the preferred method for managing SBO complicated by strangulation or perforation, or in the setting of complex abdominal conditions such as malignancy, inflammatory bowel disease, or hernia. It is also generally the safest approach for operative management when multiple operations have been performed previously. An incision is made, usually in the midline and starting, if possible, cephalad to any prior incisions. The technique of adhesion lysis requires patience and gentle traction on structures to reveal opportune planes of dissection. Sharp dissection, in some cases using a scalpel blade, is used on very dense adhesions in order to avoid unnecessary crush or tear injuries. When areas of dense adherence are visualized, it is wise to tease the less densely adherent structures on all sides—cephalad, caudad, and lateral to the most difficult areas. Moist sponges are used to as much as possible when handling the bowel in order to prevent desiccation. Areas of serosal abrasion or tear are imbricated and covered with uninjured serosa, while full-thickness enterotomies are closed, resected with enteroenteral anastomosis, or converted to enteroenterostomy. In general, the longer a lysis of adhesions takes, the more physiologic disturbance and the slower the recovery. Exploration of the peritoneal cavity for obstruction requires unhurried but steady progress, conscious of the clock but not driven by it.

General Principles of Laparoscopically Assisted Lysis of Adhesions

Over the past two decades, technical advances have permitted laparoscopy to enter the mainstream of surgical management for intestinal obstruction.[102] Such approaches have been used, with varying degrees of success, to manage obstruction from a number of different etiologies.[103–105] The benefits of laparoscopic management include faster recovery of bowel function, shorter hospital stay, less postoperative pain, reduced recovery time and earlier return to full activity, and fewer postoperative complications including a decreased incidence of wound infection and pneumonia. Additionally, laparoscopy is associated with decreased incidence, extent, and severity of intra-abdominal adhesions compared with open surgery. Thus laparoscopic management of bowel obstruction may result in a decreased lifetime risk for recurrent bowel obstruction. According to a systematic review and meta-analysis, laparoscopic adhesiolysis was associated with reduced overall complication rate with no significant difference in the occurrence of intraoperative injury to bowel and overall mortality.[106] The predictive factors for a successful laparoscopic adhesiolysis are fewer than two previous laparotomies, nonmedian previous laparotomy, appendectomy as prior surgery, unique band adhesion as the mechanism of SBO, early laparoscopic management (within 24 hours of the onset of symptoms), no signs of peritonitis on physical examination, and experience of surgeon.[107] Reasons for conversion from laparoscopic to open operation include the overall burden of dense adhesions, inadvertent enterotomy, and inability to determine the underlying cause of obstruction.[102]

In adults, the most common indication for laparoscopic management of bowel obstruction is adhesive bowel obstruction.[7,22,102] Studies of laparoscopic lysis of adhesions for SBO indicate that it is feasible, with acceptable operative times, length of hospital stay, as well as conversion and complication rates. Studies directly comparing laparoscopic to open surgical management of adhesive SBO highlight the benefits of the laparoscopic approach as indicated by statistically significant decreases in complication rates, time to return of bowel function, length of hospital stay, and even overall cost.[102,108,109]

Laparoscopic management of bowel obstruction should be approached with caution and individualized to specific clinical situations.[110]

Laparoscopy is discouraged when the surgeon is uncomfortable with the technique or in patients presenting with peritonitis, hemodynamic instability, severe comorbid conditions, complete and distal obstruction, or when contraindications to pneumoperitoneum exist. Recently, consensus guidelines have been published emphasizing its role in selected group of patients.[111] Laparoscopically assisted lysis of adhesions may be attempted in case of first episode of SBO or anticipated single band lesion. In addition, it is safe to approach the patient with intestinal obstruction in the setting of a prior history of uncomplicated laparoscopically assisted procedures such as appendectomy or cholecystectomy. Under these circumstances, success in using laparoscopy to confirm the diagnosis of obstruction is between 60% and 100%; its success in therapeutic resolution of the obstruction is lower, perhaps 40% to 80%.

Operative technique plays a paramount role in the success of laparoscopic approach. In obtaining laparoscopic access, an open access (Hasson) technique, entry into the left upper quadrant, and ultrasound-guided site entry are recommended.[23,111] It is also important to point out the need for adhesion quantification in future research. Coccolini et al. proposed a Peritoneal Adhesion Index ranging from 0 to 30, providing a more precise and standardized system for describing findings at operation.[112] Such standardization would enable integration of the results of different studies, permitting a better understanding of circumstances where treatments may be standardized and those where individualization is important.[5]

7 Open exploratory laparotomy is the gold standard in treating unresolved SBO but laparoscopic management should be considered in select groups of patients. Types of intestinal obstruction that are more likely to lead to strangulation and the need for urgent/emergent operation include closed-loop obstructions, and obstructions that occur after laparoscopic procedures.

ILEUS AND PSEUDOOBSTRUCTION

Ileus

Etiologic Factors

An *ileus* or *"eileos"* (Greek for "twisting") reflects a loss of forward peristalsis and coordination of the motility of the different regions of the gastrointestinal tract causing a functional obstruction 8 .[113] Clinically, bowel sounds, passage of flatus, and bowel movements have been used to signal the return of bowel function and coordination of peristalsis. Liquid contrast and radiolabeled marker studies suggest that duration of motor dysfunction varies in different regions of the alimentary tract.[114,115] Ileus is a known consequence of systemic metabolic disturbances such as sepsis or ketoacidosis, activation of reflexes after injury to the central nervous system, direct contact of bowel with inflammation and infection (peritonitis), or inflammation or bleeding in the retroperitoneum caused by conditions such as pancreatitis, aneurysm rupture, or pelvic fracture.

A postoperative ileus (POI) may last for 0 to 24 hours in the small intestine, 24 to 48 hours in the stomach, and 48 to 72 hours in the large bowel.[116,117] The overall duration of ileus, however, is determined by the coordination of motor function along the length of the gastrointestinal tract. Ileus is most commonly associated with operations of the abdomen; it is also observed in the setting of major orthopedic operations such as hip reconstruction or spine surgery.[118,119] Duration of ileus is primarily dependent on the return of colonic motility and its coordination with other regions of the gastrointestinal tract. A typical period of ileus is self-limited and easily tolerated.[120,121]

Neurohumoral Factors

Implicated in the pathogenesis of ileus (**Table 49.5**) is a diverse array of circulating peptides and neurotransmitters, some that enhance gastrointestinal motility and others that inhibit myoelectric function. Among them are acetylcholine, calcitonin gene related peptide (CGRP), Substance P released through vagal pathways (activate motor function) and catecholamines released by sympathetic neurons and the adrenal medulla (dampen motor function).[122] Among the most clinically consequential are the opioids, both synthetic and endogenous, which delay gastric emptying and promote nonperistaltic contractions that increase intraluminal pressure along the length of the gastrointestinal tract.[123,124]

Inflammation

A relatively recent series of experimental and clinical investigations have focused attention on the role of inflammatory cells and mediators of inflammation in the development of prolonged ileus. Surgical intervention results in activation of mast cells and macrophages within the gut wall, leading to release of proinflammation cytokines and activation of their receptors, including interleukins 1, 6, and 10; activation of cyclooxygenase isoform-2 (COX-2) and inducible nitric oxide (iNOS).[125–127] Thus, the hypothesis has evolved that focal manipulation of the bowel results in a pan-enteric inflammation and modulation of the enteric nervous system that leads to ileus.[126,128–130]

Diagnosis

Clinically, it is important to distinguish between normal POI, pathologic, or the so-called paralytic ileus and early postoperative mechanical obstruction. POI is self-limited, usually lasting 2 to 4 days, predominantly a reflection of colon dysmotility. Paralytic ileus lasts longer, and reflects dysmotility of the small intestine. Symptoms and signs of normal POI include mild nausea and perhaps vomiting with mild distention and sparse but not absent bowel sounds. A prolonged postoperative ileus (PPOI) is manifest in protracted signs or symptoms of abdominal distention, bloating, diffuse and persistent and constant abdominal discomfort, nausea, vomiting, and inability to pass flatus or tolerate an oral diet. In contrast, mechanical obstruction is characterized by intense colicky pain, feculent emesis, or rapidly progressing pain or distention is more suggestive of SBO than PPOI. Classically, localized tenderness, fever, tachycardia, and peritoneal signs suggest bowel ischemia or perforation.[10,131–133] Differentiation of ileus from obstruction is often difficult without objective confirmation through imaging and systematic, serial clinical observations.

Table 49.5 Etiologies of Prolonged Ileus after Abdominal Operations

Neurogenic	Metabolic	Pharmacologic	Infectious
Spinal cord lesions or injury	Hypokalemia Uremia	Anticholinergics Opiates	Systemic sepsis Pneumonia
Retroperitoneal process hematoma, tumor	Ca^{++}, Mg^{++} imbalance	Autonomic blockers	Peritonitis
Ureteral colic	Hypothyroidism Diabetic coma or ketoacidosis	Antihistamines Psychotropics Phenothiazines Haloperidol Tricyclic antidepressants Clonidine Vincristine	Herpes Zoster Tetanus Bacterial overgrowth (blind-loop)

A variety of clinical circumstances and laboratory tests may also increase suspicion for prolonged ileus and lessen concern for mechanical obstruction and associated complications. In addition to opiates, diverse medications have been associated with slow recovery of intestinal motor function (**Table 49.5**). Isolated metabolic disturbances such as ketoacidosis, hypomagnesemia, hypercalcemia, hypokalemia can prolong ileus.[134,135] Ileus can be caused and perpetuated by systemic inflammatory responses to sepsis, abscess, pneumonia, pancreatitis, and major burns. In addition, there is some clinical and experimental evidence to suggest that when there are pre-existing micronutrient abnormalities that lead to systemic inflammation, recovery of intestinal motor function may be delayed.[136,137]

When the patient's POI has extended beyond the expected period, plain films of the abdomen reveal gas in segments of both small and large bowel (**Fig. 49.12**). At this point, the patient may begin to experience some

discomfort and distention, as swallowed air fills loops that do not have effective peristalsis. Bowel sounds may be present, if hypoactive. The differential diagnosis now includes the possibility of mechanical obstruction from early postoperative adhesions (see earlier).9 To differentiate early postoperative obstruction from ileus, contrast studies or CT scans are helpful. The latter may be useful if other abdominal pathology such as an abscess could be contributing to the clinical picture. *CT with oral contrast has a sensitivity and specificity of 90% to 100% in distinguishing ileus from a complete postoperative SBO.*[138] However, it is less reliable in distinguishing ileus from a partial SBO.[138] If the diagnosis is uncertain after CT, upper GI contrast studies (enteroclysis) with water-soluble radio-opaque contrast material (e.g., Gastrografin) are especially helpful in distinguishing ileus from partial SBO (which more closely mimics ileus than complete SBO) and in identifying the severity of partial obstruction.[138] POI is usually self-limited.

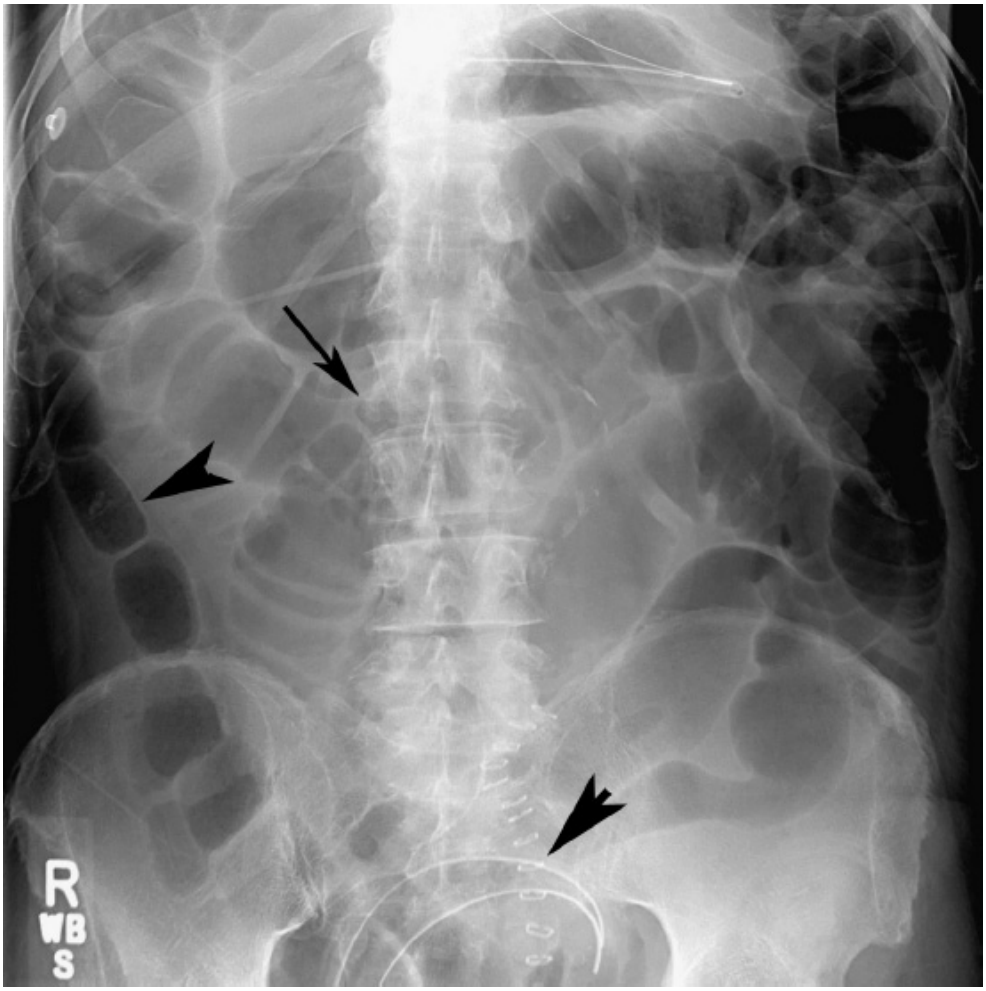

Figure 49.12 Plain upright abdominal radiograph of a patient with ileus. Air–fluid levels are present in the small intestine (*thin black arrow*). Air is also seen in the ascending colon (*black arrowhead*) and the distal colon (*arrowhead with short stem*). These findings are characteristic of, but not specific for, ileus.

Management

The principal goal in managing a normal POI is to prevent uncomfortable distention, vomiting, and aspiration. A secondary goal is to limit its duration. Passage of flatus is used, in reliable patients, as the index indicating coordination of all segments of the gastrointestinal tract and resolution of ileus. For many years, the mainstay of therapy was the use of nasogastric suction to prevent accumulation of swallowed air and secreted fluids in an alimentary tract not yet coordinating flow distally. Subsequent studies have demonstrated that the putative benefit does not compensate for risks of aspiration and discomfort of the tube.[139,140] Thus, following moderately

complex abdominal operations such as colectomy or complex abdominal wall reconstruction, nasogastric suction is not used; resolution of ileus is encouraged with preoperative preparation that includes resolution of any preoperative electrolyte and metabolic disturbances, carbohydrate loading, and protocols for avoidance of fluid overload. Nasogastric suction is used selectively, mainly to relieve the discomforts associated with nausea and distention. In individual cases, use of nasogastric suction may be extended, when in the surgeon's judgment the ileus is likely to be prolonged because of intraoperative findings such as peritonitis or because of extensive manipulation of the bowel due to widespread adhesions. Serial and standardized examinations will usually reveal that ileus is resolving as evidenced by normalization of bowel sounds and passage of flatus. Until the patient's bowel functions are clearly restored, close attention to fluid and electrolyte balance is important.

In recent years, considerable attention has been given to identifying and systematically addressing the multiple and potentially interacting risk factors for prolongation of POI (**Table 49.6**).[113,134,141,142] Such risk factors include perioperative fluid overload, electrolyte disturbance, and transient acute kidney injury; and taking measures to standardize fluid management in the perioperative period. Early mobilization and walking is encouraged directly with physical therapy and indirectly by removing barriers to mobility such as nasogastric tubes and urinary catheters; mobilization stimulates bowel function, reducing the risk of pulmonary complications and possibly improving cognition. Adjuncts such as gum chewing or use of hard candy theoretically stimulate vagal function and have been studied extensively, without strong evidence for or against their routine use. Use of epidural catheters and regional nerve blocks, when appropriate, have been shown to accelerate return of bowel function after laparotomy, not only by decreasing pain and use of opioid medications but also potentially by interfering with motility-inhibiting influences of the sympathetic nervous system. Early feeding also stimulates secretions, coordinated propulsive activity and likely improves immune function, thereby reducing the risk of postoperative infection and metabolic disturbance.[143–146]

Based on experimental studies, pharmacologic interventions have been proposed to shorten recovery of gastrointestinal motility and coordination between different regions of the gastrointestinal tract. Thus, opioid

antagonists, somatostatin analogs, sympatholytics, injection of local anesthetics into mesenteric nerve roots, or nonsteroidal anti-inflammatory agents, such as ketorolac, all appear to promote faster recovery to normal myoelectric activity and intestinal transit times. Over the years, prokinetic agents that target vagal or other components of the enteric neuroendocrine system and including metoclopramide, erythromycin, and cisapride (currently not permitted for use in the United States) have also been studied but without clear, demonstrable benefit in accelerating resolution of POI and shortening hospital lengths of stay.[147] Laxatives have no proven benefit for earlier resolution[113] of POI, although anorectal stimulation with suppositories can facilitate passage of flatus.

Table 49.6 Management Treatment for Postoperative Ileus

Treatment	Benefit	Drawback
Nasogastric tube	Possible relief of vomiting and bloating	Does not shorten duration of ileus May contribute to fever, atelectasis, and aspiration Discomfort
Early postoperative feeding	Stimulates reflex for propulsive bowel motility and enzyme secretion Stimulates immune system Reduces postoperative and posttraumatic infectious complications Reduces risk of anastomotic dehiscence, wound infection, pneumonia	Patients may not tolerate feeding
Opioid antagonists (alvimopan)	Peripheral acting FDA approved to hasten postoperative ileus following partial large or small bowel resection with primary anastomosis	Possible cardiovascular or neoplastic risk Currently restricted to in-patient use only

Laparoscopic procedures	Earlier return of bowel function and discharge from hospital Minimal skin incision, minimal mechanical bowel manipulation	Not all patients and procedures are amenable to the laparoscopic approach
Epidural anesthetics/analgesics	Reduced duration of ileus vs. systemic opioid Increases splanchnic blood flow Anti-inflammatory	Risks associated with epidural catheter placement
Gum chewing	May shorten duration of ileus Simple and inexpensive	Limited data
Laxatives	May shorten duration of ileus Inexpensive	Limited data on efficacy
Nonsteroidal anti-inflammatory drugs (COX-2 inhibitors)	Decreases opioid needed for pain control May increase motility by acting as an anti-inflammatory	Possible increased risk of postoperative bleeding Other adverse effects

Adapted from **Table 49.2** Luckey A, Livingston E, Taché Y. Mechanisms and treatment of postoperative ileus. *Arch Surg* 2003;138(2):206–214. Prepared by Zain Khalpey.

Of special interest, however, are strategies that target the μ-opioid receptor or serotonin-receptor 5-HT_4. Thus the opioid μ-receptor antagonist alvimopan (Entereg™) has been reported to reduce GI recovery time and to

facilitate hospital discharge following major abdominal operations,[148,149] as well as operations outside the abdomen.[108] More recently, benefit in resolving POI has been observed with selective 5-HT_4 blockers, mosapride and prucalopride[150,151] and herbal supplements such as Escin, a natural mixture of triterpene saponins extracted from dried seeds of horse chestnut (*Aesculus hippocastanum* or *A. chinensis*).[152] Short-term use, such as that utilized in trials for patients with POI, has not been associated with clinically irreversible side-effects such as cardiotoxicity, but it is important to be mindful of the toxicities of longer-term, or off-label use.

Along with pharmacologic measures, it should be emphasized that, in otherwise routine laparotomy or laparoscopy, gentle handling of tissues, meticulous attention to hemostasis, and applications of sound principles of wound management are likely to have the greatest impact on optimizing recovery from ileus and minimizing the incidence of prolonged ileus. Efforts to reduce incision size and time spent handling the intestines through the use of laparoscopic approaches clearly improve recovery from ileus in some if not all patients undergoing standardized intra-abdominal procedures such as appendectomy,[153] and colectomy.[154] Even in open procedures,[155] standardization of management and effective communication help expedite clinical fast-track pathways and facilitate earlier recovery of bowel function and discharge from hospital.[113,156,157] Currently proposed measures to minimize the prolongation of ileus are summarized in **Table 49.7**.

Colonic Pseudoobstruction (Ogilvie Syndrome)

Etiologic Factors

Acute pseudoobstruction of the colon, also known as *Ogilvie syndrome*,[158] is a paralytic ileus of the large bowel, characterized by rapidly progressive abdominal distention, often painless.[159] Although the distention of the colon is not due to mechanical obstruction, the wall of the bowel, particularly that of the cecum, can become sufficiently distended so that its blood supply is compromised. Gangrene, perforation, peritonitis, and shock can follow. In

95% of the cases, there are underlying diseases.[159,160] Less than 5% of the cases occur in the absence of other conditions.

Table 49.7 Management Measures to Prevent Prolongation of Ileus
Minimization of trauma to tissues; using proper technique in the operating room with gentle handling of bowel during surgery.
Minimal use of narcotics for analgesia, for any route of administration (intravenous, intramuscular, epidural)
Use of opioid antagonists (alvimopan)
Generous use of mid-thoracic epidural anesthesia with local anesthetic use
Use of nonsteroidal anti-inflammatory (COX-2 inhibitors) agents for analgesia
Early feeding
Correction of any electrolyte or metabolic imbalances
Early recognition of septic complications (e.g., abdominal abscess, pneumonia, central line sepsis) that may contribute to prolongation beyond the expected period for ileus

Major risk factors for development of Ogilvie syndrome include traumatic injury (11%), infections such as pneumonia, sepsis (10%); obstetric/gynecologic conditions (10%); myocardial infarction and congestive heart failure (10%); abdominal and pelvic surgery (9%); neurologic conditions such as Parkinson disease, spinal cord injury, multiple sclerosis, and Alzheimer disease (9%); orthopedic procedures (7%); other medical conditions including metabolic imbalances, for example, hypokalemia, hypocalcemia, hypomagnesemia (32%); other surgical conditions (12%).[158,160] Evidence suggests that Ogilvie syndrome is thought to be related, at least in part to sympathetic nervous overactivity or interference with sacral parasympathetic efferents.[159,161] It is postulated that the distal colon becomes atonic due to interruption of the S2 to S4 parasympathetic nerve fibers. Other theories about the pathophysiologic

causes include autonomic dysfunction, reduced colonic ganglion cells, and loss of intrinsic nitric oxide activity but the cause remains unknown.[159]

Diagnosis

This syndrome is commonly encountered in patients hospitalized over 3 to 7 days, often in men greater than 60 years of age. Primary manifestations variably include gastrointestinal symptoms such as nausea, vomiting, abdominal pain, constipation, and diarrhea.[159,160] Labored breathing, caused by abdominal distention, may be observed as part of the clinical picture. Other than distention, there are no characteristic physical or laboratory findings for this syndrome. On percussion, the abdomen is resonant due to the presence of air in dilated segments of small intestine and colon. Sounds from the small intestine are present and may not be high pitched, as they are in intestinal obstruction.

Laboratory findings associated with this syndrome may include hypokalemia, hypocalcemia, hypomagnesemia, and hypophosphatemia, which are implicated as etiologic factors. Leukocytosis, elevation of sedimentation rate, or C-reactive protein is also present if low-grade systemic inflammation is present or perforation is impending.

The diagnosis is usually apparent from plain films. Radiographs of the abdomen may reveal air in the small bowel and distention of discrete segments of the colon (i.e., cecum or transverse colon often up to splenic flexure) or the entire abdominal colon. Haustral markings disappear with increasing distention. In doubtful cases and when bowel necrosis is not a significant worry, a Hypaque contrast enema can establish the nonmechanical nature of the dilatation. Alternatively, colonoscopy can be diagnostic as well as therapeutic. Features suggesting the complication of bowel ischemia may include localized tenderness, worsening leukocytosis, metabolic acidosis, evidence of sepsis, or a rapidly deteriorating clinical course.

It is important to differentiate this syndrome from toxic megacolon and mechanical obstruction before establishing a final diagnosis. Mechanical obstruction of the colon, occurring in volvulus or obturator obstructions from cancer or diverticular disease, presents with acute pain along with distention. In contrast, pseudoobstruction is less often associated with acute pain and more likely to present with discomfort due to distention. However,

lack of pain in postoperative patients on opiates or elderly patients cannot exclude mechanical obstruction. On plain x-rays, the pathognomonic signs of mechanical obstruction such as lack of gas in the distal colon or rectum, or air fluid levels in small intestine on x-ray can also be seen in Ogilvie syndrome. CT scan is currently the standard method for identifying colon pseudoobstruction and excluding other forms of obstruction.[159] Patients with toxic megacolon may manifest typically with symptoms such as fever, tachycardia, abdominal tenderness, bloody diarrhea or other manifestations of chronic inflammatory bowel disease along with "thumb printing" on the appearance of the abdomen on plain x-ray film in upright posture. Flexible sigmoidoscopy is contraindicated if toxic megacolon is thought likely. If toxicity is not likely, flexible sigmoidoscopy and/or contrast enema can be useful diagnostically and therapeutically.

Management

Initial management includes resuscitation and correction of any underlying metabolic or electrolyte imbalances (**Table 49.8**). Patients should have physical examination and plain abdominal radiographs serially to follow colonic diameters in order to determine which cases need colonoscopic decompression or surgery. If the patient is not very uncomfortable and the colonic distention is no greater than 12 cm, conservative treatment can be continued for 1 to 2 days. It may be helpful to place the patient in a prone position or in the knee to chest position with hips held high, alternating right and left lateral decubitus position each hour. A nasogastric tube is helpful if the patient is vomiting and will prevent swallowed air from passing distally. When bowel ischemia is suspected, surgery is indicated. If bowel necrosis is found, the affected segment is resected and an ileostomy or colostomy should be performed. If the bowel is viable, a cecostomy is placed to vent the colon and prevent distention.

Table 49.8 Management Treatment for Pseudoobstruction

Treatment	Benefit
Nasogastric tube	Prevention of swallowed air from passing distally
Neostigmine	Increase motility through its parasympathomimetic action Premedication with colonoscopic decompression adding benefits
Erythromycin	Increases intestinal motility through motilin receptors in intestinal wall
Colonoscopic decompression	Prevention of complications such as perforation
Surgical interventions: total colectomy, Hartmann procedure, percutaneous endoscopic cecostomy	Required in case of refractory medical therapy

If, initially, the distention is painless and the patient shows no signs of toxicity or bowel ischemia, expectant management is successful in 50% of cases.[159,162] The risk of spontaneous perforation is approximately 3%, with an attendant mortality of 50%. In most patients, acute colonic pseudoobstruction usually resolves within 3 days.[159,163] If the clinical picture is worsening and the cecal diameter increases beyond 10 to 12 cm or if it persists for more than 48 hours, intervention is recommended. The duration of distention may be more important than the absolute size of the cecum with respect to spontaneous perforation. Colonoscopy should only be performed by experienced endoscopists. Endoscopic decompression is successful in 60% to 90% of cases, but the condition can recur in up to 40% of patients. This rate of recurrence may be decreased by placement of a decompressive tube. Recurrence requires repeat colonoscopic decompression in approximately 40% of cases after initial successful decompression. The

placement of a decompression tube with the aid of a guidewire at the time of colonoscopy may reduce the need for repeated colonoscopic decompression. Rectal tubes are ineffective as primary modalities in managing distention of the proximal colon. Such tubes may be useful in promoting passage of air and feces after colonoscopy but should not be used as a substitute for colonoscopic decompression. Percutaneous endoscopic left-sided colostomy (PEC), a minimally invasive technique, can be used to treat pseudoobstruction provided these cases are carefully selected in the hands of a skilled endoscopist because of a high failure rate caused by infection.[164]

In anecdotal reports, prokinetic agents such as cisapride and erythromycin have been used to treat Ogilvie syndrome with some success. Erythromycin acts by binding to motilin receptors in the small intestine, causing intestinal smooth muscle contraction and perhaps better coordination with colonic motor function. Anecdotal reports have suggested the success of erythromycin treatment by either intravenous route for 3 days or oral route for 10 days.[165,166] However, the relative paucity of motilin receptors in colon smooth muscle may explain why erythromycin is only anecdotally effective in relieving colonic pseudoobstruction. Successful resolution of pseudoobstruction has been reported with sympatholytic agents or spinal sympathetic block. The efficacies of these modalities have not been systematically evaluated.[159,167]

Neostigmine, a parasympathomimetic, is used in the treatment of acute colonic pseudoobstruction. Decompression with this drug has been achieved in 80% to 100% of patients with a recurrence rate of 5%.[159,168] Neostigmine may be a viable alternative to colonoscopy in pregnant women, provided mechanical obstruction is excluded. The administration of a polyethylene glycol electrolyte balanced solution after initial resolution of colonic dilatation may reduce the recurrence rate with use of neostigmine.[169]

Neostigmine has expected cardiovascular side effects such as bradycardia, hypotension, and dizziness; and is excreted via the kidneys. The few relative contraindications to its use in treatment of acute colonic pseudoobstruction are a baseline heart rate of less than 60 beats/min or systolic blood pressure of less than 90 mm Hg; active bronchospasm requiring medication; a history of colon cancer or partial colonic resection; active gastrointestinal bleeding; pregnancy; or a serum creatinine concentration of more than 3 mg/dL (265 μmol/L). Other side effects include mild to moderate crampy abdominal

pain, excessive salivation, and vomiting. Side effects, such as increasing airway secretions and bronchospasm, can be reduced by concomitant use of glycopyrrolate without reduction of colonic response.[170,171] Ponec et al.[172] recommend use of neostigmine prior to colonoscopy, based on its easy administration, lower expense, and superior results in comparison to colonoscopy. Reported rates of response to treatment with neostigmine are 91% (single administration) and 100% (second administration).[159,161,172,173] While earlier recommendations suggested that colonoscopy would prove superior to neostigmine as first-line treatment,[168] more recent studies have suggested that neostigmine therapy should be used initially and this is now the recommended sequence of therapeutic intervention.[161,173]

In the absence of signs of clinical deterioration, a nonoperative or "conservative course" of therapy can be continued safely for several days, with resolution of acute colonic pseudo-obstruction in 70% to 90% of patients.[161,173] It should be emphasized, however, that patients should undergo immediate exploration if they exhibit signs of clinical deterioration or bowel perforation (peritoneal signs on physical examination or free air on radiographs). Surgery is reserved for patients not responding to medical and endoscopic management and for patients who develop signs of peritonitis or perforation. Percutaneous endoscopic cecostomy can also be performed if conservative measures fail.[174] Cecostomy tubes are often poorly tolerated because of issues related to skin breakdown; in the authors' opinion, this approach is advisable only when more extensive surgical procedures are considered too risky. Procedures such as total colectomy, ileostomy, and Hartmann procedure are taken into consideration in cases of perforation.[159,168] Pseudoobstruction 10 of the colon, also known as Ogilvie syndrome, is usually benign but it can be complicated by bowel gangrene or perforation. Initially it is treated with attention to underlying neurologic or metabolic disturbances, followed in sequence by use of neostigmine and then decompressive colonoscopy. Surgery is reserved for patients with evidence of ischemic bowel, perforation, peritonitis, or clinical deterioration.

Crohn Disease

Anuradha R. Bhama and Scott R. Steele

Key Points

1. Crohn disease can affect the entire gastrointestinal (GI) tract from mouth to anus and is likely from a multifactorial etiology.
2. Crohn disease may manifest in the GI tract in one or more disease patterns—fistulizing, inflammatory, and fibrostenotic—resulting in fistulas, abscess/phlegmons, and/or obstruction, respectively.
3. Crohn disease is associated with an increased long-term risk of developing colorectal cancer compared to the general population. Patients should be screened accordingly, and surgical treatment is typically more aggressive in the setting of underlying microscopic colorectal dysplasia or dysplastic lesions.
4. Several classes of medications are available for Crohn disease, depending on the spectrum of disease, ranging from topicals and aminosalicylates to steroids, immunosuppressants, and/or biologic agents.
5. The indications for operating on a patient with Crohn disease involve managing complications of the disease, not achieving cure.
6. Preservation of functional bowel length is paramount in this patient population, given the high need for future resections and potential for diseased/nonfunctioning bowel.
7. The decision making for embarking on surgical intervention must account for the patient's clinical presentation, concomitant medical therapy, underlying continence, anatomy, and overall nutritional status.
8. Anorectal conditions in Crohn patients must be managed with special considerations given the potential for poor wound healing, incontinence, and worsened quality of life with aggressive surgical intervention.

INTRODUCTION

Crohn disease is a chronic, inflammatory condition of the alimentary tract. To date, the underlying mechanism of disease is not known, and it can manifest with a wide spectrum of presentations and severity. A number of Crohn patients may respond well to medications, while others are recalcitrant to multiple high-dose biologics or steroids. Therefore, treatment options must be individualized for each patient with Crohn disease. Basic tenets of Crohn disease include that it may occur anywhere along the alimentary tract, has no "curative" operation, and is hallmarked by periods

of flares and quiescent disease. Despite improvements in medical therapy, upward of 75% of patients will still require at least one operation during their lifetime to treat complications associated with the disease or nonresponsiveness to medical therapy.[1] As such, careful consideration must be given to each individual patient's future function when weighing therapeutic options in order to resolve the current problem at hand. Surgeons must be exceedingly aware of the indications, surgical options, and expected outcomes for patients with Crohn disease. In order to maximize the latter, it is crucial to also have a thorough understanding of not only the principles guiding surgical treatment, but also the medical therapies that may either allow avoidance of surgery altogether. This chapter will cover the clinical presentation, diagnostic evaluation, medical therapies, and surgical treatment for Crohn disease.

EPIDEMIOLOGY

The a 1 ge of onset of Crohn disease follows a bimodal distribution, either in the second to fourth decades of life or in the sixth decade.[2] Systematic reviews have found an annual incidence of Crohn disease ranging from 20.2 per 100,000 person-years in North America and 12.7 per 100,000 person-years in Europe to 5.0 person-years in Asia and the Middle East.[2] Males and females tend to be affected equally, though whites and certain ethnic groups such as Ashkenazi Jewish descent have higher overall rates.[3] Given the geographic and temporal variation in the epidemiology of Crohn disease, recent research has focused on environmental and genetic factors that may be driving these shifts.[4–6]

ETIOLOGY

Despite tremendous progress in the overall understanding of the disease and advancements in comprehension of various phenotypical manifestations, the exact etiology of Crohn disease remains unknown. The development of the disease is thought to be a result of environmental triggers acting upon a combination of genetic and intestinal factors that drive the development of compromised intestinal immune response followed by mucosal inflammation.

Approximately 2% to 14% of patients report a family history of Crohn disease and is higher in those of Jewish ancestry.[7,8] The concordance rate for monozygotic twins ranges from 20% to 50%, suggesting that genetics plays a role and the disease is not entirely dependent on environmental and/or acquired factors.[9] Over 200 alleles have been associated with inflammatory bowel disease (IBD), though only 37

are specific for Crohn disease.[10,11] Several of the genes involved and linked to Crohn disease are related to the host's ability to sense bacterial, or control innate immunity, Th17-cell function, and can result in an altered mucus layer of the GI tract.[10,12] Attention has revolved around the NOD2 (formerly CARD15) gene on chromosome 16, a region felt to be involved host interactions with bacterial lipopolysaccharide to activate NF-κB, which correlates to Crohn disease phenotype.[13,14] Genome-wide association studies have provided insight that polymorphisms in genes such as ATG16L1 and IRGM play a role in autophagy in Crohn patients. This process involves the regulation of cell development and differentiation, senescence, and ultimately the inflammatory system response to what the body deems is normal and abnormal.[15] Impaired recognition and processing in this aspect results in a deregulation and ultimately disease pathogenesis. In addition, other genes such as TLR4, HLA, and IRF5 that are involved in the innate and adaptive immune system response are seen to be altered in Crohn patients.

Theories regarding a host–microbiome connection have been evolving over the past few decades. The gut microbiome is the largest reservoir of microbes in the entire body and functions in digestion, immunity, and suppression of harmful organisms.[16] The state of an individual's microbiome is influenced by a variety of elements including genetics, age, geography, hygiene, diet, drugs, smoking, and potentially many others.[17] An interplay between the immune system and the microbiome has been identified in IBD, and various microbes may be either protective against or increase susceptibility to the development of the disease. *Escherichia coli*, in particular the adherent-invasive strains, have been found in higher concentrations in patients with ileal Crohn disease and can induce granuloma formation—a pathognomonic feature of Crohn disease.[18–20] Conversely, there is evidence to suggest that certain microbes are protective in IBD. *Bacteroides* and *Clostridium* have been shown to reduce intestinal inflammation through upregulation of regulatory T cells as well as regulate NF-kB activation to decrease mucosal inflammation.[21,22] *Bifidobacterium, Lactobacillus,* and *Faecalibacterium* have been shown to be protective against mucosal inflammation through a downregulation of inflammatory cytokines and an upregulation of IL-10.[23,24] Although the beneficial effects of antibiotics in the treatment of Crohn disease provide indirect evidence for a bacterial etiology, no distinct organism has been identified to date. Similarly, several viruses, such as EBV, CMV, and measles, have been postulated to have an association with the development of Crohn disease; however, multiple reports have found little evidence to support this notion.[25] Other causative immune factors have included overexpression and dysregulation of tumor necrosis factor, an imbalance between proinflammatory and anti-inflammatory cytokines, and an impaired mucosal

susceptibility in sampling gut antigens.[26] Combined, these all contribute to regulatory mechanisms that may be altered and play a role in the pathogenesis of Crohn disease.

Environmental factors may also play a role, highlighted by the well-established link between smoking and an increased susceptibility to Crohn disease as well as a worsened clinical course with higher recurrence rates. While patients with Crohn disease frequently have concomitant food intolerances, the role of dietary habits remains debatable.[27] Taken together, rather than a causative effect, it is felt that the microbiome in the human gastrointestinal (GI) tract is heavily influenced by dietary intake, leading to a local environment ripe to foster susceptibility to Crohn disease. This remains an area of increasing discovery and rapid change that is certain to evolve as the etiology and underlying reasons for such wide variability in phenotypical manifestations and clinical course in this disease are explored.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis for Crohn disease is wide and includes both benign and malignant processes (**Table 50.1**). Crohn disease has certain traits that are highly suggestive of its presence (e.g., noncontiguous multisite disease, fistulas, creeping fat) versus other disorders. Yet, a variety of abdominal processes may mimic Crohn disease. For example, ileocolic Crohn disease can be misdiagnosed as acute appendicitis, right-sided diverticulitis, an infectious process, or a perforated malignancy. Radiologic studies may demonstrate patterns of bowel inflammation consistent with Crohn disease, and laboratory examination may reveal elevated CRP and/or white blood cell count. Careful consideration of the differential diagnosis must be taken both preoperatively and intraoperatively.

Table 50.1 Differential Diagnosis of Crohn Disease

Ulcerative colitis
Irritable bowel syndrome
Acute appendicitis
Diverticulitis
Malignancy
Infectious colitides (CMV, *Yersinia*, *Escherichia coli*, *Salmonella*, etc.)
***Clostridium difficile* colitis**
Ischemic colitis
Pancreatitis
Meckel diverticulum
Tuberculosis
Radiation enteritis
Behçet disease

When disease is isolated to the colon, the major differentiation involves distinguishing Crohn colitis from ulcerative colitis, though other infectious and inflammatory colitides remain in the differential. Both diseases share common histopathologic traits, which contributes to the diagnostic dilemma. Perianal Crohn disease differential diagnosis includes traditional cryptoglandular abscess and fistulas, skin tags may mimic routine hemorrhoids and/or tags, and infectious causes such as HIV, syphilis, and tuberculosis may share phenotypical manifestations with Crohn. Ultimately, it is the entire evaluation of the individual disease presentation including information taken from history, laboratory, pathologic, endoscopic, radiologic, and clinical examinations that will help clarify the picture and aid in diagnosis.

DIAGNOSTIC EVALUATION

Crohn disease and ulcerative colitis both fall under the umbrella of inflammatory bowel disease and no specific tests at present permit a definitive diagnosis of either condition. The diagnosis is established using a combination of history and physical examination, laboratory values, radiographic findings, and endoscopic findings. Even so, 5% to 15% of patients with ulcerative colitis are eventually diagnosed with Crohn disease or indeterminate colitis when new concerning symptoms arise.[28,29] There are several available classification schemes available for Crohn disease. Classification based on phenotypic manifestations includes fibrostenotic disease

(stricturing), fistulizing disease (penetrating), and inflammatory disease (phlegmonous). Patients may have one, two, or all three, as evidenced by the high rate of strictures with proximal fistulas. Location is also frequently used to classify disease, with the distal ileum having the highest rate of disease incidence (**Fig. 50.1**). Localized inflammation in the ileocecal region occurs in approximately 45% of patients, colonic in 25% to 33%, proximal small-bowel disease in 25%, <10% will have isolated upper GI or isolated perianal disease, with many patients having disease in more than one location. In general, patients with concomitant perianal disease tend to have a more severe clinical course, and perianal disease in the setting of Crohn may precede abdominal manifestations in up to 45% (**Fig. 50.2**).[30,31] Identification of suspicious perianal disease should prompt an investigation into more proximal disease.

Figure 50.1 Terminal ileitis.

Due to the chronic and heterogeneous nature of the disease, different classification manifestations may occur independently, concomitantly, or may even vary along the longitudinal course of the disease. Fibrostenotic pattern may occur in any location, though most commonly occurs in the terminal ileal region, where patients present with obstructive-type symptoms such as nausea, vomiting, and decreased oral intake. More proximal disease (e.g., gastroduodenal) can often present with obstructive-type symptoms such as nausea, vomiting, and early satiety. Inflammatory disease may

present with a wide range of symptoms such as abdominal pain, fever, an abdominal mass, change in bowel habits, and/or weight loss. Finally, penetrating or fistulizing disease may be completely asymptomatic (e.g., enteroentero fistula of adjacent bowel), present with anorectal abscesses and/or fistulas, or more commonly complain of symptoms depending on the involvement of the secondarily involved organ; for example, recurrent urinary tract infections, pneumaturia, vaginal discharge, or diarrhea.

Figure 50.2 Perianal fistulas.

CLINICAL EVALUATION

Upper Gastrointestinal

Gastroduodenal Crohn disease is rare, occurring in only 0.5% to 4% of all Crohn patients and typically asymptomatic.[32] Yet up to 40% of these patients will demonstrate early subclinical evidence of Crohn disease on radiologic or endoscopic evaluation.[33] When present, symptoms typically represent a gastric outlet obstruction and include epigastric abdominal pain, nausea, vomiting, early satiety, bloating, weight loss, and anorexia. Crohn disease of the esophagus is exceedingly rare, involving <0.5% of patients and extraesophageal disease is nearly always present.[34] A high index of suspicion should lead to diagnostic testing such as contrast imaging (e.g., fluoroscopic upper GI, small-bowel follow-through) and endoscopy that will confirm the diagnosis (**Fig. 50.3**).

Small Bowel

2 The distribution of disease and phenotypic classification dictates the clinical presentation, with ileocecal disease the most commonly affected site. Patients with disease in this location will classically present with slow onset of right lower quadrant abdominal pain, fatigue, nausea, vomiting, abdominal mass, and pain with hip extension from psoas muscle involvement. Obstructive symptoms may also occur in patients with either fibrostenotic or acute inflammation (**Fig. 50.4**). Diarrhea tends to be nonbloody, though heme-positive stools may occur, and rarely gross blood is a manifestation from a small-bowel source.

Colonic

Colonic involvement may occur in isolation in approximately 25% of patients, though it is most often seen concomitantly with perianal (associated with left-sided colonic inflammation) or terminal ileal (associated with cecal and ascending colon inflammation) disease.[35] Within the colon, the distribution is somewhat variable, with approximately one-third of patients having total colonic involvement, 40% showing segmental disease, and left-sided only in up to 30%.[36] Regardless of the exact location within the large intestine, patients with colonic involvement may experience abdominal pain, mucus drainage, and malnutrition. Unlike ulcerative colitis, rectal bleeding is not routine, and bowel movements are often nonbloody, except in those with moderate to severe colitis. Diarrhea is often of smaller volume and may be from several sources—malabsorptive (e.g., salt/water and bile acid malabsorption), infectious (e.g., CMV superinfection), or as a result from an enterocolonic fistula.[37,38] In addition, similar to disease in the small bowel, patients can experience hip or back pain from fistulas, cramping, and obstructive symptoms. Patients with penetrating disease may also experience symptoms with associated involvement of the secondary organ (e.g., feculent vaginal drainage from a

colovaginal fistula, pneumaturia or fecaluria from bladder involvement, or skin drainage from an enterocutaneous fistula).

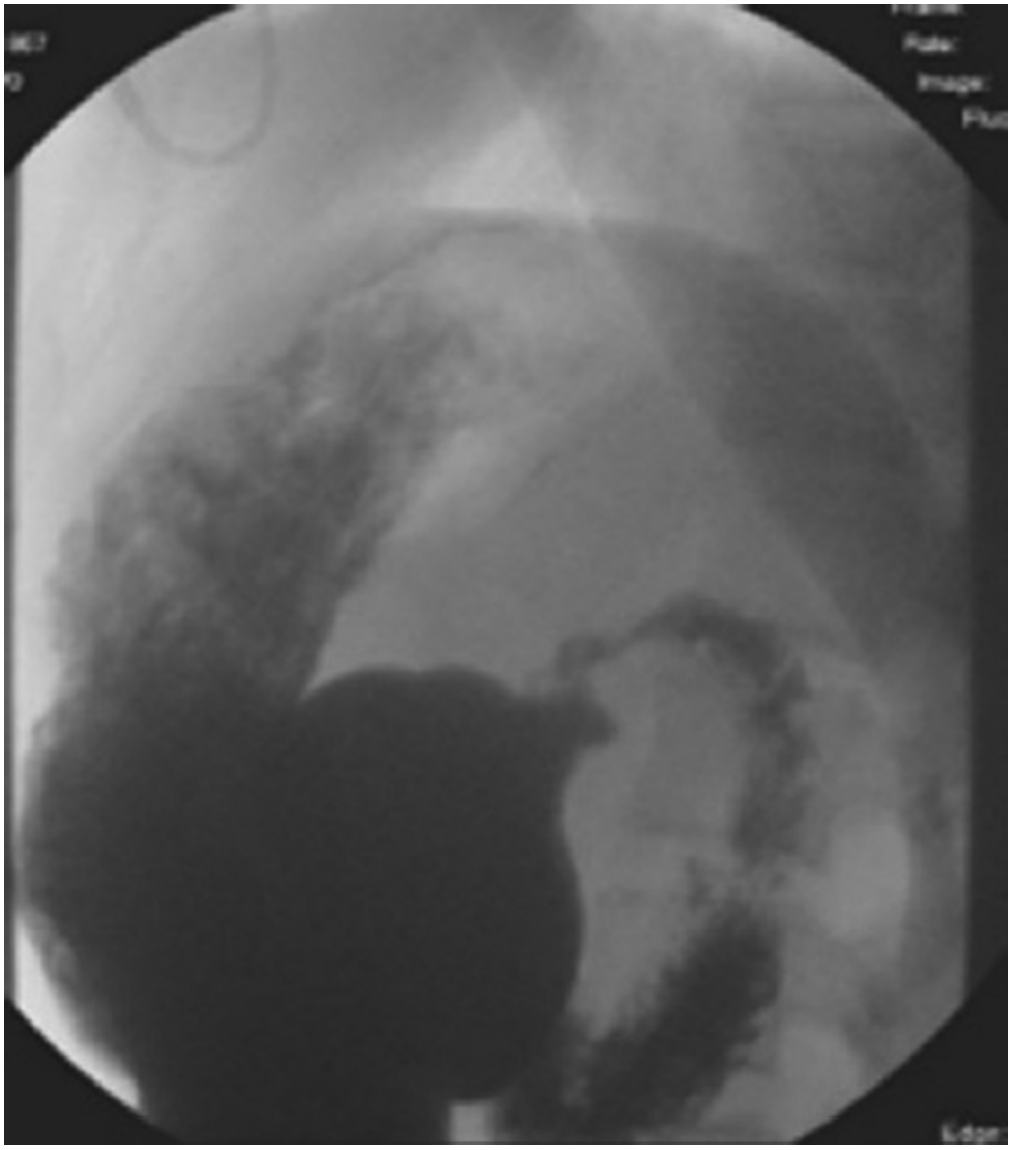

Figure 50.3 Upper GI contrast study demonstrating a stricture in the duodenum.

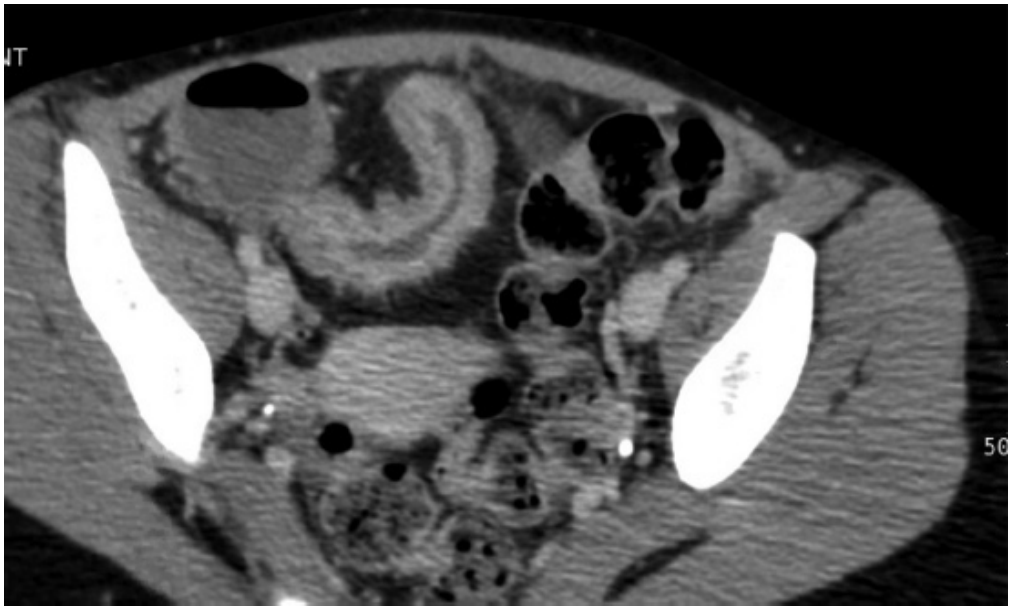

Figure 50.4 CT enterography demonstrating terminal ileal disease resulting in obstructive symptoms.

Anorectal

Despite advances in the understanding of many features of Crohn disease, perianal complaints have been recognized as one of its most challenging aspects. Isolated perianal disease is the presenting symptom in 5% to 15% of Crohn patients; though upward of 25% to 80% may experience symptoms at some point. Perianal involvement is more common in those with concomitant rectal or colonic disease.[39,40] In addition, active disease in the perineum is felt to act as a harbinger of an overall more virulent course.[41] Patients with Crohn disease may also have "traditional" anorectal complaints, the most common being perianal skin tags. These tend to be large, flat, with a bluish hue and classically described as an "elephant ear" appearance. Perianal abscesses, fistulae, and fissures that do not follow the typical pattern of cryptoglandular disease should raise suspicion for a diagnosis of Crohn disease. Fissures tend to be deeper, off the midline, and much more painful than routine hypertonic-associated fissures (**Fig. 50.5**). Patients presenting with perianal findings consistent with or concerning for Crohn disease should undergo a thorough physical examination and full endoscopic and radiologic evaluation. Finally, patients with long-standing Crohn may develop anal stenosis or an anal stricture at the verge secondary to repeated bouts of chronic inflammation.

Extraintestinal Disease

Similar to ulcerative colitis, patients with Crohn disease may have manifestations from the disease process that extend outside of the GI tract (**Table 50.2**).

Extraintestinal disease (EID) has been reported in 6% to 47% of patients with inflammatory bowel disease, and has an increased concordance among siblings and first-degree relatives—suggesting a genetic component that has been linked to the major histocompatibility complex (MHC) on chromosome 6.[42,43] EID occurs secondary to the systemic inflammatory process associated with the underlying disease and affects a wide range of organ systems. While the GI tract may be the primary source, the dysfunction in immune regulation incites a pathologic response that may occur in nearly every location in the body simultaneous with, preceding, or following GI manifestations.[44] Overall, rheumatologic/joint problems (e.g., peripheral or sacroiliac arthritis, arthralgias) are the most common, occurring in up to one-third of patients. Other more frequent sites of involvement include the skin, eyes, and hepatobiliary system; while the renal, pulmonary, nervous, and coagulation systems are involved to a lesser extent. It is important to distinguish between manifestations that parallel bowel disease activity (episcleritis, peripheral arthritis, erythema nodosum) from those that do not (ankylosing spondylitis, pyoderma gangrenosum, primary sclerosing cholangitis) (**Fig. 50.6**). In these cases, EID may flare prior to the bowel (or in the setting of asymptomatic active bowel disease) and necessitate adjustments in medical management. Conversely, surgical intervention directed at the bowel may occasionally be required for recalcitrant extraintestinal disease that may go into remission following bowel resection.[45]

Figure 50.5 Anal fissure in Crohn disease.

Table 50.2 Classification of Extraintestinal Manifestations of Crohn Disease

Organ System	Extraintestinal Manifestation
Musculoskeletal	Arthralgias, peripheral arthritis, ankylosing spondylitis, sacroiliitis, myopathy, metabolic bone disorders
Ocular	Uveitis, iritis, episcleritis, conjunctivitis, optic neuritis
Renal	Glomerulonephritis, amyloidosis, urolithiasis
Skin/Mucocutaneous	Erythema nodosum, pyoderma gangrenosum, aphthous ulcers
Hematologic	Thromboembolic disease, anemia
Pulmonary	Bronchitis, pleuritis, tracheal stenosis
Hepatobiliary	Hepatitis, primary sclerosing cholangitis, primary biliary cirrhosis, pancreatitis, cirrhosis, cholangiocarcinoma, portal vein thrombosis
Cardiac	Pericarditis, myocarditis
Neurologic	Demyelinating disease, neuritis

Figure 50.6 Pyoderma gangrenosum surrounding an ileostomy.

DIAGNOSTIC METHODS

Radiology

Over recent years, the radiographic assessment of Crohn disease has developed dramatically. Previously, fluoroscopic imaging, including small-bowel follow-through or retrograde contrast studies, with the use of barium or gastrografin contrast was essential. These studies were used to identify ulcerations that create cobblestone and nodular patterns, mucosal granularity, loss of villous morphology, skip lesions, strictures, and fistulas (**Fig. 50.7**).[46] Contrast studies can still provide a wealth of information regarding anatomy and aid in operative planning. Over the

years, the utilization of computed tomography enterography (CTE) and magnetic resonance imaging enterography (MRE) has become the most effective method for the evaluation of Crohn disease and these imaging modalities have been shown to alter treatment course and evaluate response to treatment (**Figs. 50.8** and **50.9**).[47–49] Both modalities have high sensitivity (>90%) and specificity (>90%) for diagnosing active small-bowel disease.[47,50] In regard to identifying and quantifying small-bowel disease activity, CTE and MRE are equally sensitive and specific, although CTE has the advantage of better-quality images[51–57] while MRE has been shown to be superior to CTE in the identification of fistulas and strictures.[53,57,58] The radiographic findings of transmural healing on CTE and MRE have been shown to correspond to mucosal healing on endoscopic examination in the majority of settings.[59–61] Although CTE and MRE will include imaging of the pelvis and sphincter complex, if imaging is deemed necessary for perianal fistula or abscess, a standard pelvic MRI should be obtained.[62–64] Positron emission tomography (PET) and PET-MRI are other modalities that have shown some promise for the evaluation of Crohn disease, though not currently used routinely.[65]

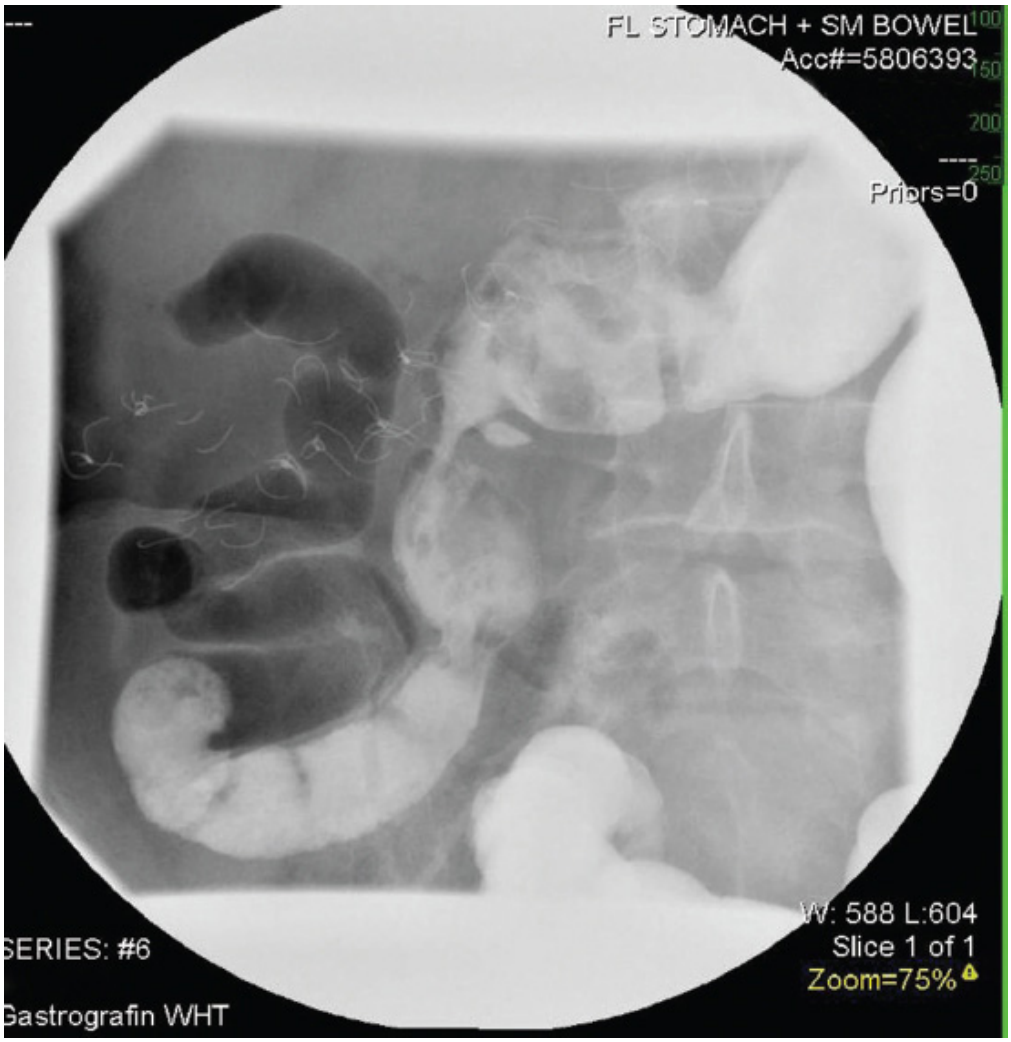

Figure 50.7 Contrast study demonstrating Crohn stricture.

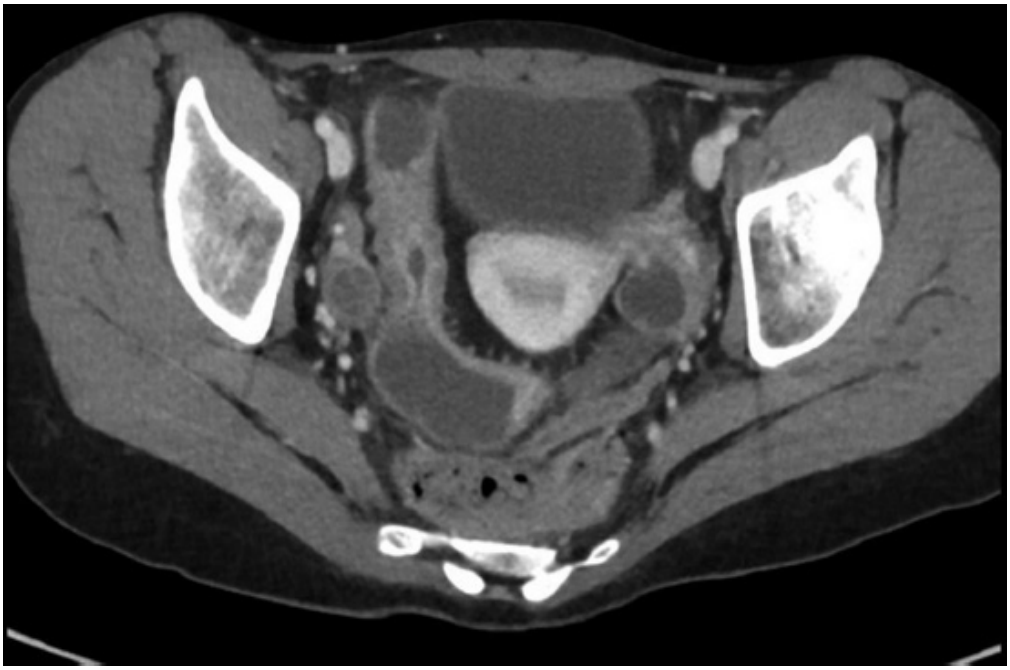

Figure 50.8 CT enterography demonstrating small-bowel stricture.

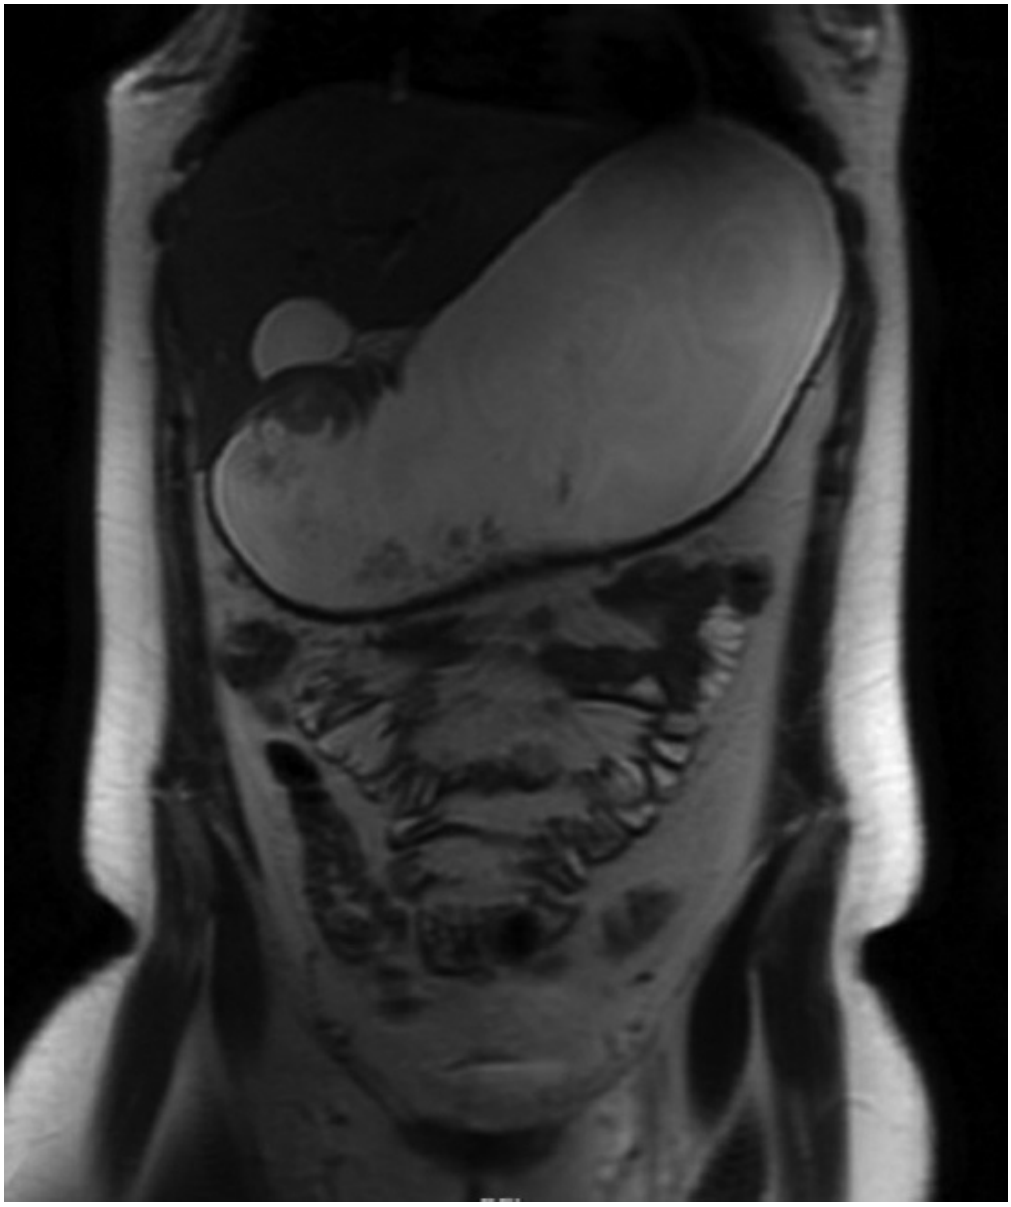

Figure 50.9 MR enterography demonstrating terminal ileal disease in the setting of multifocal disease. This patient also has a duodenal stricture resulting in marked gastric dilation.

Endoscopy

Endoscopy is an indispensable tool used to identify the extent and severity of the disease and perform biopsies to aid in diagnosis.[66] Endoscopic evaluation of the entire colon, including the terminal ileum along with appropriate biopsies, is required in patients suspected of Crohn disease. Early changes seen in the mucosa include aphthous ulcerations, erosions, and serpiginous ulcers that occur in a skip-type pattern. As the full-thickness inflammatory cycle continues, these ulcerated

areas progressively enlarge and coalesce forming the cobblestone-type pattern. The presence of rectal sparing and active terminal ileal disease may help differentiate Crohn disease from ulcerative colitis, although the latter may demonstrate similar characteristics due to medical therapy and backwash ileitis, respectively.[67] Finally, the presence of strictures or associated masses may indicate the need for surgical or therapeutic intervention (**Fig. 50.10**).

3 Patients with Crohn disease should undergo more aggressive malignancy surveillance compared to the general population. Screening colonoscopy should start 8 to 10 years after the onset of colitis and have repeat examinations every 1 to 2 years.[68–70] Previous recommendations supported routine biopsies in four quadrants every 10 cm throughout the colon. While high-definition white light endoscopy remains the current recommendation for neoplasia screening in IBD, recently there has been a shift toward the use of chromoendoscopy.[71–74] When compared to white light endoscopy, chromoendoscopy using methylene blue or indigo carmine demonstrate higher rates of both adenoma detection and dysplasia detection.[74–77] Narrow-band imaging (NBI) can be helpful for adenoma detection in a healthy colon; however, due to the presence of background inflammation in the setting of Crohn disease, NBI is not recommended as an adjunct for endoscopic surveillance in these patients.[71,78–80] Patients with chronic disease may demonstrate pseudopolyps on endoscopic examination (**Fig. 50.11**). Pseudopolyps are masses of scar tissue that represent the formation of granulation tissue that result from alternating cycles of ulceration and regeneration.[70] In general, they are benign, and do not warrant intervention, but will make for increasing difficulty with screening for colorectal cancer with more severe incidence.

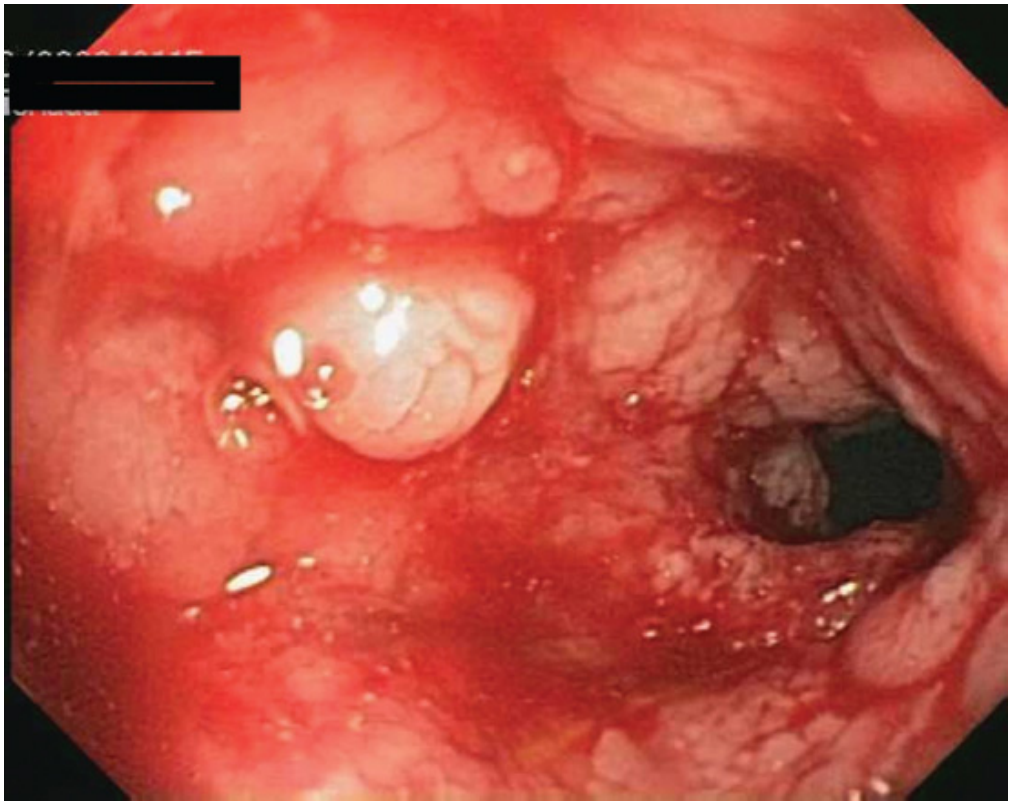

Figure 50.10 Endoscopic view of terminal ileal stricture.

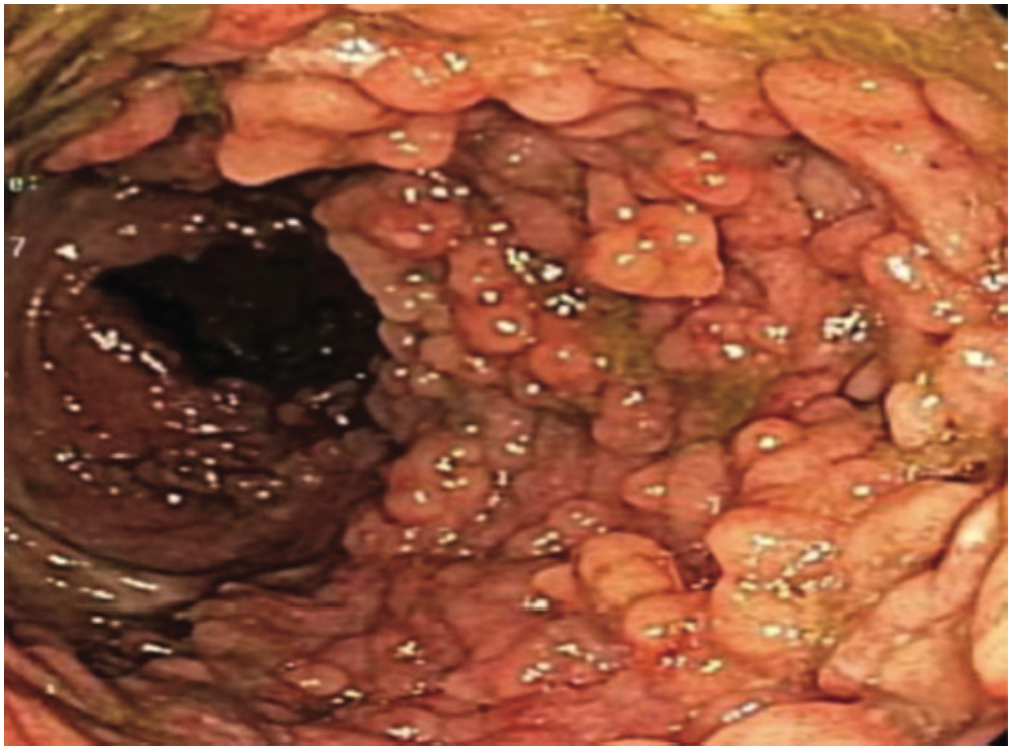

Figure 50.11 Colonic pseudopolyps.

Esophagogastroduodenoscopy (EGD) also plays a role for patients with suspected or known proximal disease and can identify ulcers, fistulas, and strictures that may be responsible for various upper GI symptoms. In addition, through the scope, therapeutic interventions (e.g., dilation, needle-knife) can be performed. Overall, both upper and lower endoscopy are relatively safe procedures with complications in IBD patients occurring in <5%, and generally consist of bleeding—though perforation remains a very small risk of every endoscopic procedure.[81] Additionally, endoscopic evaluation provides an ability to track and quantify disease activity by use of the scoring systems such as the Crohn Disease Endoscopic Index of Severity (CDEIS) or Simple Endoscopic Score for Crohn Disease (SES-CD) (**Table 50.3**).[82]

Video capsule endoscopy uses wireless technology to capture continuous images of the upper GI tract mucosa to help determine disease presence and activity that are beyond the reach of endoscopy and the limitations of traditional small-bowel imaging. While the diagnostic yield may not be as high, it has been shown to be comparable to ileocolonoscopy and better than small-bowel follow-through for the detection of small-bowel inflammation.[83] Furthermore, negative predictive values range from 96% to 100%, essentially ruling out the diagnosis of Crohn disease when the results are normal.[84] Of note, it is imperative to exclude the presence of moderate–severe strictures prior to its use, as their presence can result in bowel obstruction from the capsule becoming lodged at the point of stenosis (**Fig. 50.12**).

Pathology

The presence of noncaseating granulomas on pathologic examination is pathognomonic of Crohn disease. However, they are only found in 25% to 42% of patients, and may simply be a marker of more virulent disease.[85] In addition, a small subset of long-standing ulcerative colitis patients may have granulomas on biopsy.[86] Routine depth endoscopic biopsies may miss granulomas and often they are only visible on resected full-thickness specimens. Other histologic evidence of Crohn disease includes architectural distortion of the crypts (size, shape, symmetry), ulcerations, pseudopolyps, and skip areas—some of which may also be found in ulcerative colitis (**Fig. 50.13**). Other discriminating features of Crohn disease on gross examination include the potential for full-thickness involvement of the bowel wall, and the presence of "creeping fat," where the mesenteric fat extends over the serosal surface of the bowel wall—"creeping" over the normally distinct mesenteric/bowel wall interface (**Fig. 50.14**). Furthermore, gross pathologic examination of Crohn disease specimens may range from acutely inflamed, edematous, hyperemic bowel to thickened, fibrotic, and "woody." Finally, the mesentery is classically thickened, with increased edema, friability, and vascularity.

Table 50.3 Clinical Endoscopic Scoring Systems for Crohn Disease

Simple Endoscopic Score for Crohn Disease (SES-CD)

Severity	0	1	2	3
Size of ulcers	None	<0.5 cm	0.5–2 cm	>2 cm
Ulcerated surface	None	<10%	10–30%	>30%
Inflamed surface	None	<50%	50–75%	>75%
Stenosis	None	Single, passable	Multiple, passable	Not passable

Each segment of bowel is assigned values for all four severity variables.

Crohn Disease Endoscopic Index of Severity

	Rectum	Sigmoid and Left Colon	Transverse Colon	Right Colon	Ileum	Total	
Deep ulceration (0 = absent; 12 = present)						1	
Superficial ulceration (0 = absent; 6 = present)						2	
Surface involved by the disease (cm)						3	
Ulcerated surface measured (cm)						4	
						Total 1 + total 2 + total 3 + total 4 =	A
						Number (n) of segments explored =	n
						Total A divided by n	B
						Ulcerated stenosis anywhere: 0 = absent, 3 = present	C
						Nonulcerated stenosis anywhere: 0 = absent; 3 = present	D
						Total score = B + C + D	CDEIS

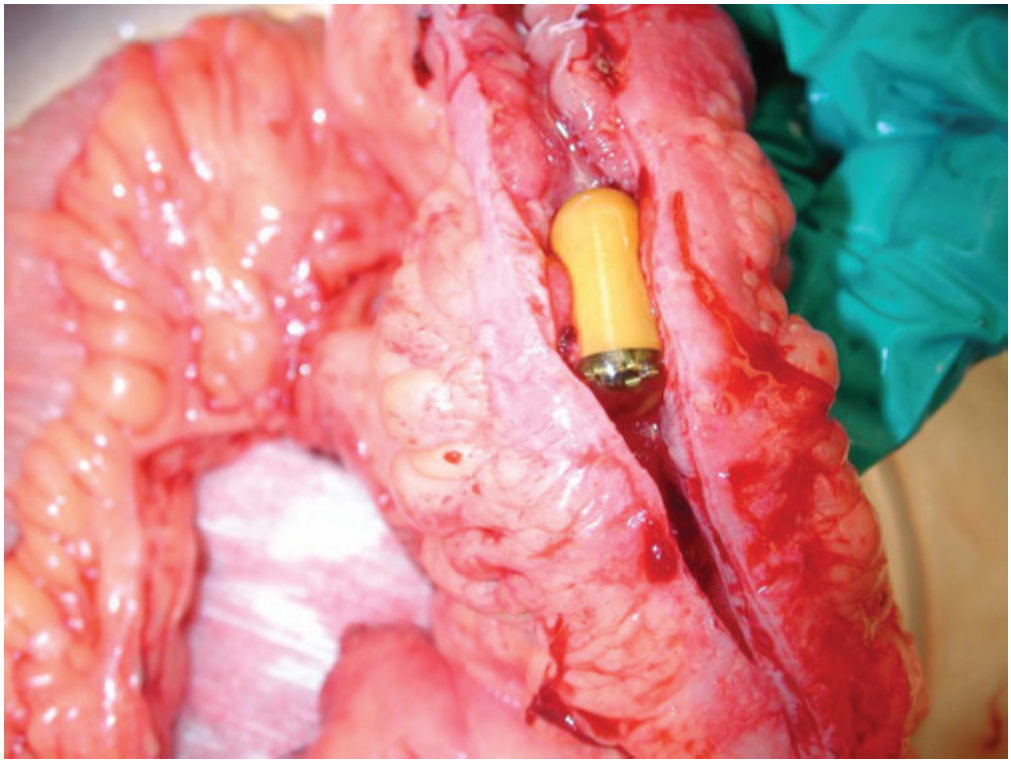

Figure 50.12 Capsule endoscopy pill lodged in small-bowel stricture.

Laboratory Analysis

No single laboratory examination will provide a definitive diagnosis of Crohn disease; yet, there are tests available to help discriminate between Crohn and other processes. Though not recommended for routine use, serum measurements of perinuclear antineutrophil cytoplasmic antibodies (p-ANCAs) and anti-Saccharomyces cerevisiae antibodies (ASCAs) can been used to help differentiate Crohn disease from ulcerative colitis.[71,87,88] The former is a known marker associated with ulcerative colitis, whereas elevated levels of ASCA are associated with Crohn disease. Unfortunately, only 30% to 50% of Crohn patients will test positive for ASCA, and up to 10% of healthy individuals will also have elevated serum levels.[89]

C-reactive protein is a nonspecific marker for inflammation that has been useful in tracking disease activity and response to treatment. More recently, fecal biomarkers such as fecal calprotectin,[71,90] lactoferrin, and neopterin[91] are used to monitor intestinal inflammation and have been shown to reliably correlate with endoscopic disease activity and response to anti-TNF therapy.[92–94] While nonspecific, elevations in fecal biomarkers have been shown also to correlate with higher levels of recurrence following surgical resection.[95,96]

TREATMENT

Medical Management

4 While an in-depth discussion of medical management of Crohn disease is beyond the scope of this chapter, a few points are worth noting. First, despite the spectrum of disease presentations, Crohn remains one hallmarked by inflammation (i.e., abdominal pain) and diarrhea. As such, supportive care to include antidiarrheal and antimotility agents, along with a bland diet, are good first-line approaches to provide symptomatic control. It is important to exclude the concomitant presence of "superinfections" such as cytomegalovirus or *C. difficile* infection, as antimotility medications may result in the onset of toxic megacolon and a rapidly progressive clinical deterioration. These can be ruled out by endoscopic biopsies in addition to stool studies. Simple over-the-counter, readily available medications such as loperamide and bismuth, along with prescription medications such as diphenoxylate, codeine, and tincture of opium often provide tremendous relief to abdominal pain, cramping, and loose stools.

Figure 50.14 Creeping fat along terminal ileum.

Nutritional support in all patients with Crohn disease is paramount. Ideally, preservation of oral feeding in any form is crucial for maintenance of the absorptive and protective mechanisms provided by the GI mucosal lumen villi and microvilli. Exclusive enteral nutrition involves a completely liquid diet using formula per nasal tube or orally for 6 to 8 weeks followed by slow reintroduction of other foods. This is the first-line therapy for treatment of Crohn disease in the pediatric patient as it avoids growth suppression associated with steroids and has been shown to result in complete mucosal healing in adults as well.[97–99] When enteral intake is not possible, parenteral nutrition is invaluable in preserving nutritional stores, maintaining positive nitrogen balance, preventing weight loss, and improving perioperative

outcomes.[100] This must be weighed against the potential complications involved with intravenous routes to include infectious complications and thromboembolic events.

When considering the treatment strategy for patients with Crohn disease, it is important to keep in mind the goals of treatment, which include resolution of current inflammation and resultant symptoms and to prevent the risk of long-term complications. With these goals at the forefront, it is necessary to take into account several patient-specific factors such as age, extent of inflammation, severity of symptoms, nutritional status, and long-term function. Treatments are aimed at the induction and maintenance of remission, with surgery reserved for patients with complications from, or refractory to, the disease.

There are several classes of medications used to treat Crohn disease including probiotics, antibiotics, 5-aminosalicylate (5-ASA) compounds, glucocorticoids, immunomodulators, and biologic agents with differing mechanisms of action and purpose of use (**Table 50.4**).

Probiotics, which are typically not harmful, may have the effect of altering the gut microbiome; however, no randomized control trials or meta-analyses have demonstrated this consistently. The influence of antibiotics on maintenance of remission of Crohn disease remains unclear.[101] Though there currently are no antibiotics approved by the Federal Drug Administration specifically for the treatment of inflammation in Crohn disease, they may aid in remission and decrease relapse. Metronidazole can be used for the treatment of symptoms of perianal Crohn disease and there are some data to suggest that rifaximin may be beneficial in maintaining remission.[102–106]

Table 50.4 Available Medications for Crohn Disease

Class of Medication	Examples	Role in Therapy
Antibiotics	Metronidazole	Induction of remission Treatment of infection
5-ASA	Mesalamine Olsalazine Sulfasalazine	Maintenance of remission in mild cases
Steroids	Budesonide[a] Methylprednisolone Prednisone Prednisolone	Induction of remission
Immunomodulators	6-Mercaptopurine Azathioprine Cyclosporine[b] Methotrexate Tacrolimus	Induction and maintenance of remission
Biologics	Adalimumab Certolizumab Infliximab Natalizumab Ustekinumab Vedolizumab	Induction and maintenance of remission

[a]Budesonide is taken enterally and has only topical effect, no systemic effect.

[b]Cyclosporine can be used as rescue therapy/induction in refractory cases, but has not been supported by evidence in the treatment of Crohn disease.

5-ASA compounds are released at various locations along the digestive tract and control apoptosis, cell proliferation, inflammation, and metabolite function. These drugs must be taken with folic acid supplementation. Previously these drugs were the standard therapy for treatment of Crohn disease; however, several trials have not shown benefit over placebo.[107–109] There is no role of 5-ASA drugs in the induction of remission in Crohn disease, though these drugs can be used in the setting of mild to moderate active colonic Crohn disease.[71] Side effects of 5-ASA compounds include GI upset, headache, bone marrow suppression, hemolytic anemia, hepatitis, fever, hypersensitivity reactions, pancreatitis, pneumonia, and rash. For patients with mild disease, they may still be useful as a frontline agent.

Glucocorticoids are frequently used for the induction of remission, but not a preferred treatment for the maintenance of remission. They function by modulating the immune response inhibiting expression of adhesion molecules, and decreasing inflammatory cells infiltrating the intestine. The side effect profile of these drugs limits their use to acute episodes. Budesonide is an oral glucocorticoid with minimal systemic absorption that works topically in the terminal ileum and proximal colon. Induction of remission is achieved at a dose of 9 mg daily for 8 weeks and then tapered to a maintenance dose of 6 mg/day. Prednisone is a systemically absorbed glucocorticoid that can be used for induction of remission at a dose of 40 to 60 mg/day and tapered down after 2 to 6 weeks until discontinuation of the medication. Side effects include acne, hyperglycemia, hypertension, mood disruption, moon facies, weight gain, glaucoma, cataract, insomnia, osteonecrosis, osteoporosis, and adrenal suppression. Patients should be closely monitored for symptom response as they may develop "steroid-resistant" or "steroid-dependent" disease and should be considered for additional therapies, including surgery.

Immunomodulators, such as thiopurines and methotrexate, are another class of medications used for induction and maintenance of remission. The addition of these medications can also allow for tapering of glucocorticoids. Thiopurines, 6-MP and its precursor azathioprine, interfere with nucleic acid metabolism and a clinical improvement can typically be seen 6 to 12 weeks following initiation of therapy. Prior to starting therapy, thiopurine methyltransferase (TMPT) levels should be measured, and the drug should not be given if levels are deficient. Side effects include nausea, vomiting, increase in liver enzymes, pancreatitis, leukopenia, and lymphoma. A complete blood count should be monitored routinely. Methotrexate is a folic acid analogue used for both induction and maintenance of remission that has inhibitory activity against enzymes in the metabolic pathway of folic acid. This leads to decreased production of inflammatory mediators via accumulation of adenosine by way of thymidylate, purine, and methionine inhibition. Patients must take folic acid supplementation along with the medication. Side effects include GI upset, stomatitis, leukopenia, hepatic fibrosis, hypersensitivity reactions, and pneumonitis.

The introduction of biologic agents dramatically changed the landscape of medical management of Crohn disease. These medications include anti-TNFα agents, integrin receptor agonists, and interleukin agonists**.** The anti-TNF agents infliximab, adalimumab, and certolizumab are the most widely used and are now considered first-line agents in the treatment of Crohn disease. Infliximab is given by intravenous infusion with a loading dose followed by maintenance doses either biweekly or monthly. Adalimumab and certolizumab are given as subcutaneous injections. All three drugs have similar response rates.[110] Drugs should be monitored closely as side effects and the development of antibodies can occur. Side effects of these

medications include a risk of infection, tuberculosis autoimmune reactions, liver dysfunction, heart failure, lymphoma, and multiple sclerosis. Prior to starting these medications, patients should be tested for tuberculosis and hepatitis.

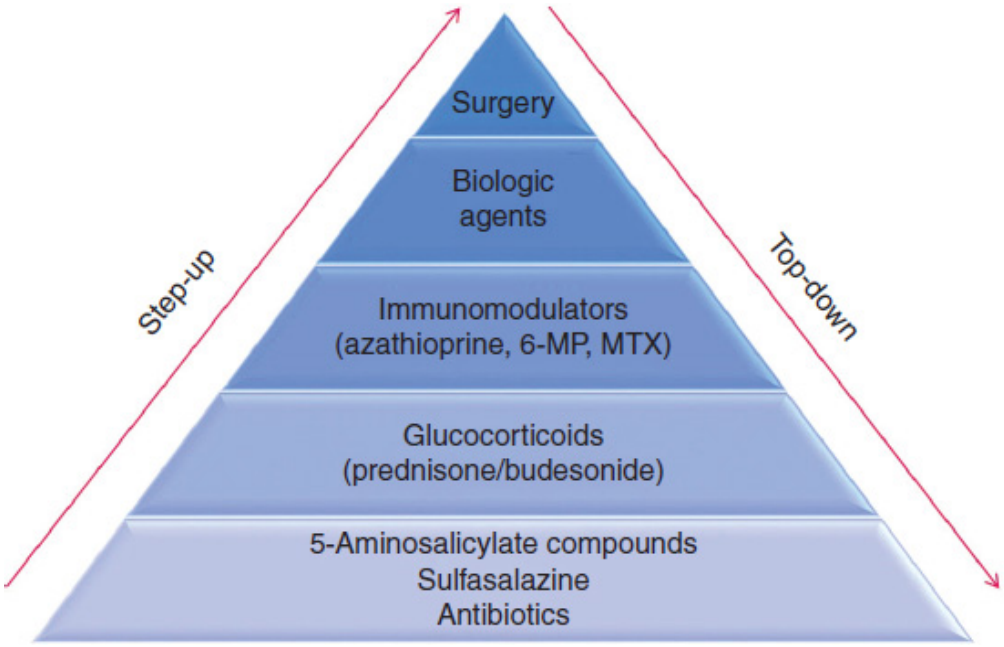

Figure 50.15 Step-up and top-down treatment strategies for Crohn disease.

Integrin receptor agonists are a newer class of medications that include natalizumab and vedolizumab. Both drugs are useful for the induction and maintenance of remission. These drugs must also be monitored closely. Natalizumab is FDA approved for the treatment of Crohn disease after the failure of anti-TNF agents. This medication has been shown to have the potential for progressive multifocal leukoencephalopathy and should be monitored closely. Vedolizumab is an anti-inflammatory drug that works through inhibition of cell adhesion molecules. This medication is well tolerated and has been shown to not have an increased risk of infectious complications or lymphoma.

Ustekinumab, an inhibitor of IL-12 and IL-23, has been shown to have efficacy in induction and in maintenance of disease with a limited side effect profile. The infection profile of this medication is similar to that of placebo and the risk of malignancy mirrors that of the general population.[111,112]

There are two general approaches to treatment of Crohn disease (**Fig. 50.15**). Traditionally, a "step-up" approach was taken where less effective medications are started first with an incremental increase to more effective medications, which are potentially riskier (**Table 50.5**). The other approach is a "top-down" approach, in which the more aggressive medications are initiated despite the potential for greater

risk. There are advantages and disadvantages to both approaches and must be individually weighed for each patient with close monitoring for safety. This may include monitoring of serum drug levels of biologic agents, which recently has become clinically useful for guiding therapy. Drug levels of adalimumab >8.5 μg/mL have been shown to be associated with decreased levels of serum CRP, fecal calprotectin levels, and endoscopic mucosal healing.[113–115] Multidisciplinary management and close discussion with medical colleagues, primarily gastroenterology, are extremely useful in this aspect—especially when patients may require surgical therapy while on certain medications that could affect decision making and outcomes.

OPERATIVE MANAGEMENT

Indications for Surgery

The basic tenet in the management of Crohn disease is that surgery is typically reserved either for disease refractory to medical 5 therapy or complications from the disease. Refractory disease is still the most common reason for surgery in patients with Crohn disease. Complications resulting in a potential need for operative intervention include fistula, abscess, obstruction (stricture), growth retardation, perforation, extraintestinal disease, bleeding, and malignancy. Of note, hemorrhage in Crohn disease is a rare event and is more commonly seen in ulcerative colitis or diverticular disease. Despite improvements in medical therapy, over 70% of all Crohn patients will require surgery at some point in their lives, with almost half of those requiring additional procedures. Therefore, having a firm understanding of the general principles and technical specifics is important for surgeons who care for these patients.

General Principles

6 Certain overarching principles guide the planning and operative management. First, Crohn disease is a process marked by lifelong potential for recurrence; therefore, preservation of intestinal length is paramount during the planning phase.[116] This translates to not only maximizing bowel length, but also ensuring functional bowel. Next, the extent of resection versus intestinal sparing procedures is dependent on multiple factors, including location and duration of disease, indication for surgery, ability to exclude malignancy, and prior resections that may have resulted in shortened small bowel. In addition,7 as the stools tend to be loose, consideration must be given to rectal compliance and sphincter function during

surgical planning to avoid a "perineal colostomy," whereby continuity is preserved but the patient has no sphincter control—significantly affecting quality of life. Furthermore, unlike ulcerative colitis where removal of the entire colon and rectum is a curative operation, in Crohn disease, a segmental resection for both small and large bowel is often sufficient with ileocolonic, colocolonic, and rectal anastomoses, all playing a role in avoiding a permanent stoma while maximizing functional bowel.[117] Crohn patients with pancolitis may undergo a total abdominal colectomy with ileorectal anastomosis (for those with rectal sparing) or total proctocolectomy with end ileostomy.[118] While there are select patients with Crohn disease whose manifestations are more on the spectrum of ulcerative colitis and may do well with a total proctocolectomy with ileal pouch–anal anastomosis, this is typically discouraged, and is normally the result of an initial misdiagnosis of ulcerative colitis.

Table 50.5 Medications for the Induction of Remission of Crohn Disease

	Ileum	Colon	Upper GI
Mild	Budesonide	Sulfasalazine Systemic steroids	Systemic steroids Immunomodulators
Moderate	Budesonide or systemic steroids Antibiotics if sepsis Consider anti TNF	Systemic steroids If relapse: anti TNF +/− immunomodulators Discuss surgery	Systemic steroids If relapse: anti TNF +/− immunomodulators Discuss surgery
Severe	Systemic steroids If relapse: anti TNF +/− immunomodulators Discuss surgery Infrequent relapse: steroid + immunomodulator	Systemic steroids If relapse: anti TNF +/− immunomodulators Discuss surgery	Systemic steroids + immunomodulators If relapse: anti TNF +/− immunomodulators

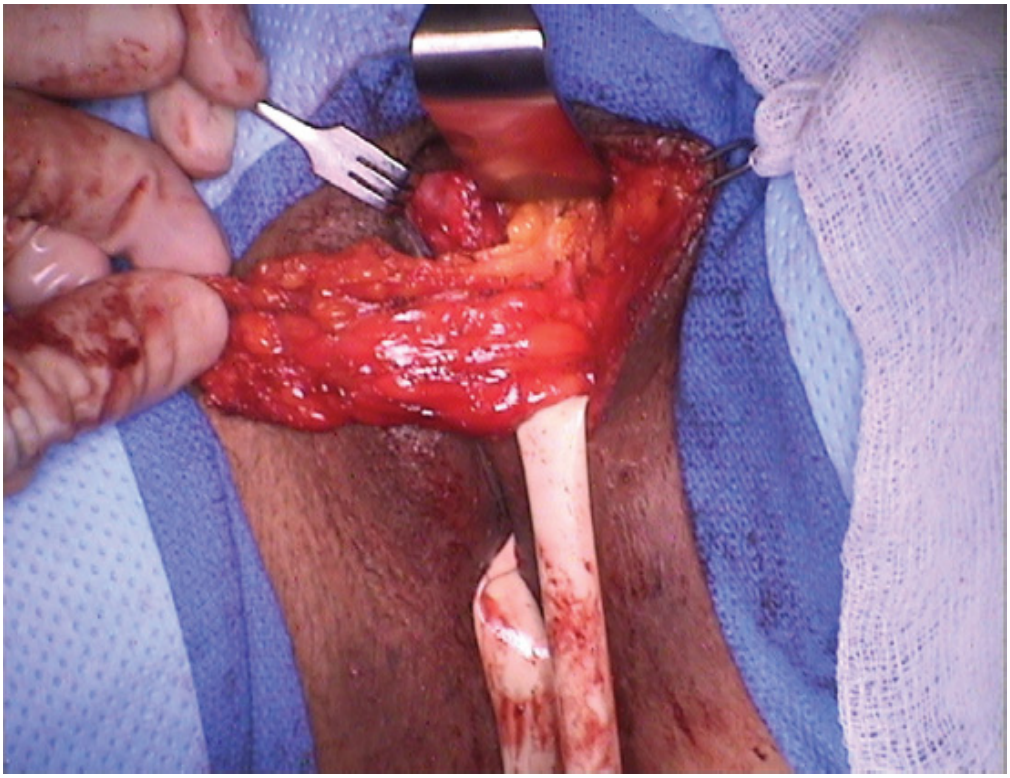

Figure 50.16 Bulbocavernosus flap for rectovaginal fistula (Martius flap).

Technical tips also come into play when planning for Crohn resections. For example, when performing a proctectomy, it is important to consider the potential for a delayed or nonhealed perineal wound. An intersphincteric dissection, which maximizes the amount of healthy muscle/tissue remaining, helps avoid this complication. Some patients will require more extensive procedures such as flaps (i.e., gracilis, myocutaneous thigh), and may require plastic surgeon involvement (**Fig. 50.16**).[119] As with small-bowel resection, length of resection margin does not influence the risk of risk of relapse and resection to grossly normal bowel is all that is required.[120] Finally, diversion is more commonly used due to both the presence of active disease as well as the potential negative healing effects of the Crohn medications.

Given the advances in imaging, unexpected inflammatory bowel disease is less frequently encountered in the operating room. In the case of suspected acute appendicitis in a patient with unknown Crohn disease, careful consideration should be paid to the extent of resection–ileocectomy versus appendectomy alone. Traditional teaching recommends performing an appendectomy alone if the cecum is normal, or to withhold on resection and undergo medical treatment only. Performing an appendectomy in the setting of cecal inflammation leaves the patient at risk of developing a perforation and/or fistula at that site. However, ileocolonic resection

for isolated disease may be in the patient's long-term best interests, with one series reporting almost half of patients required no further surgery, compared to 92% of those undergoing appendectomy only.[121] A complete evaluation of the GI tract should be performed at the time of surgery.

Strictures in Crohn disease most commonly occur in the terminal ileum, but may arise anywhere along the GI tract (**Fig. 50.17**). Due to the transmural inflammation, it is not uncommon to have luminal narrowing within the bowel especially with repeated flares. However, the underlying cause of obstruction may be from external compression from a phlegmonous/inflammatory process or secondary to the fibrostenotic pattern of disease. In the former, medical management may be successful by decreasing the inflammation and resolving the compression on the bowel wall, though surgery may still be required if symptoms are refractory to medical therapy. Patients with fibrotic strictures typically have little to no response to medical management and most often require surgery.[122–124] Emerging evidence suggests that early treatment of strictures with aggressive biologic therapy may aid in preventing the onset of fibrosis, especially in patients under 40.[125]

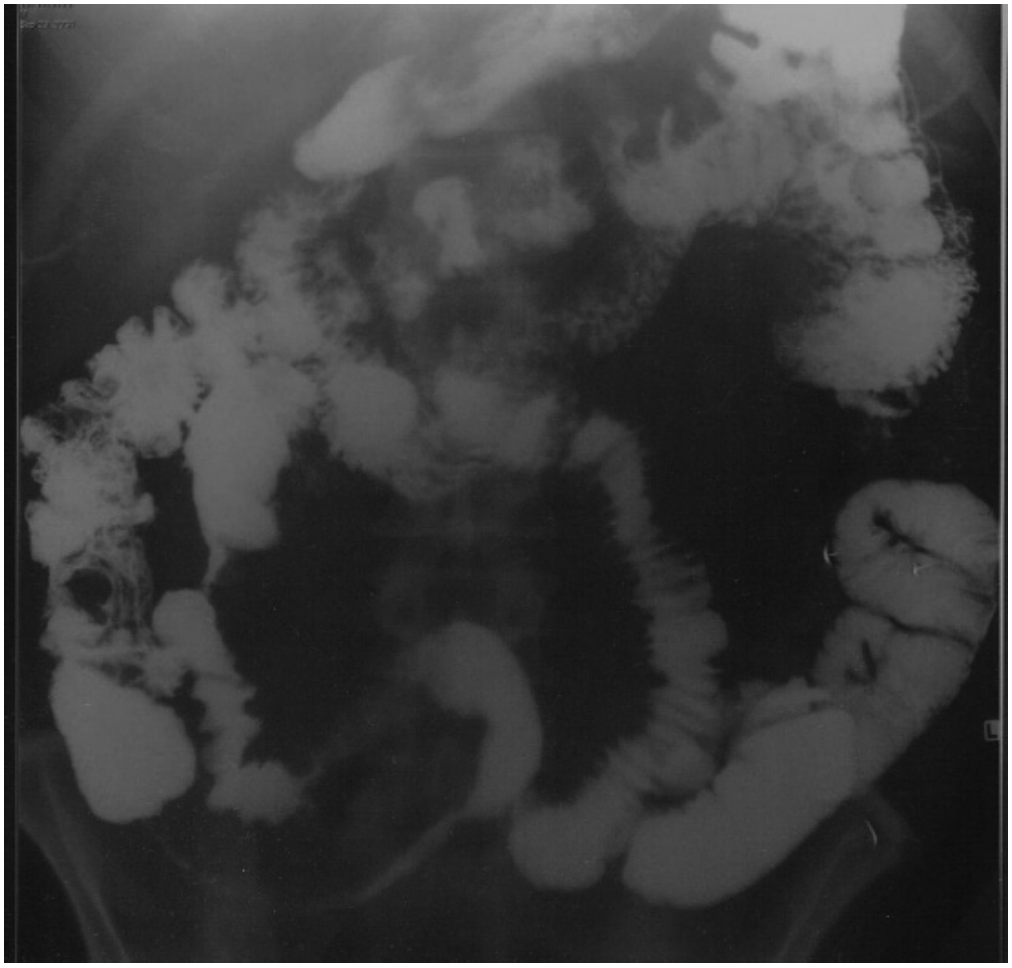

Figure 50.17 Multiple strictures demonstrated on small-bowel follow-through.

Strictures also differ based on their location. The rate of colonic strictures has been reported to be as high as 7% to 17%.[126] In general, these benign strictures are responsive to medical management as well as endoscopic dilation for moderate- to high-grade stenosis. EGD allows for therapeutic intervention such as dilation for those with gastric outlet obstruction.[127] Malignancy has been shown to be present in approximately 7% of all colonic strictures, and Crohn disease carries an increased risk of colorectal cancer above the general population.[128] It is very difficult to differentiate malignant from benign strictures clinically, therefore all colonic strictures should typically undergo endoscopic evaluation and biopsy. If malignancy is suspected, a standard oncologic resection should be performed (**Fig. 50.18**). For those that are clearly benign and nonresponsive to medical management, endoscopic dilation has been shown to provide symptomatic relief in over 80% of patients, with most patients with colonic strictures requiring repeated dilations.[129]

Strictures of the small bowel have been reported in 20% to 40% of Crohn patients.[130] Treatment typically consists of medical management; though depending

on the severity of obstructive symptoms, many patients will require intervention. Small-bowel strictures are often amenable to dilation if accessible via double-balloon enteroscopy.[131,132] Symptomatic relief occurs in 75% to 90% following the first dilation, while approximately 30% to 40% will require repeated intervention. For those with initial success, the cumulative dilation-free rate at 3 years is 40% to 50%.[133] Overall complications occur in 10% to 15% (<5% major complications), and include pain, fistula, fevers, bleeding, and perforation.[134] Despite this success, many will require operative intervention when symptoms fail to resolve, repeated bouts occur, or when a stricture is associated with a nonresolving inflammatory process, malnutrition, immunosuppression, or fistula. Surgical options then include stricturoplasty or resection.

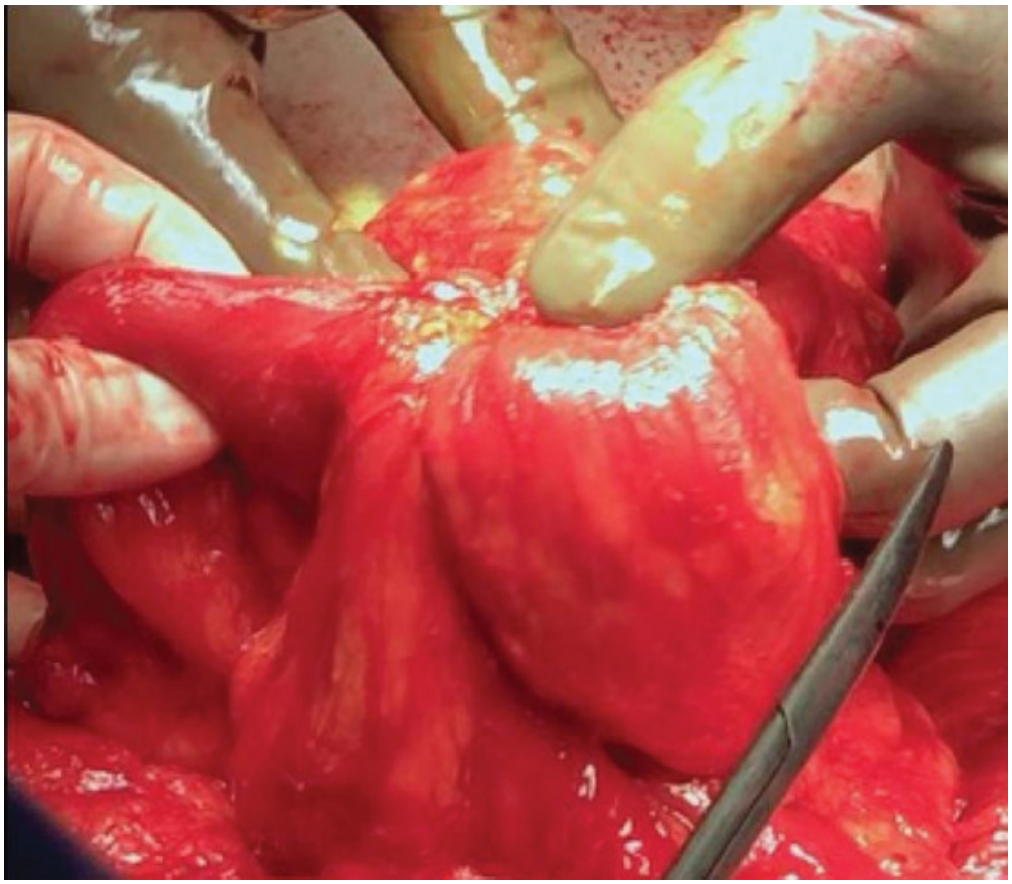

Figure 50.18 Colonic stricture.

Stricturoplasty can be performed to address fibrostenotic disease in the absence of inflammation and acts to preserve bowel length by avoiding resection altogether (**Fig. 50.19**). There are several surgical techniques based on the length of the stricture. The Heineke–Mikulicz method involves a longitudinal incision along the antimesenteric border of the bowel with a transverse closure and is useful for

shorter segments of bowel. The Finney stricturoplasty, classically used for longer strictures of 7 to 15 cm in length, involves a longitudinal enterotomy along the length of the diseased segment of intestine. The bowel is then folded upon itself and a full-thickness anastomosis is created. Finally, for longer strictures, the Michelassi stricturoplasty involves dividing the stricture and its associated mesentery in the middle of the length of the stricture. The intestine is overlapped in an isoperistaltic fashion and longitudinal enterotomies are created along the length of the strictured bowel and anastomosed together. Complications have been reported in 4% to 15% in large series, and include obstruction, bleeding, sepsis, perforation, and death.[135,136] Contraindications to stricturoplasty include malnutrition, presence of a phlegmon/perforation/fistula at the site, multiple strictures within a small segment, and suspicion of a malignancy.[137]

Figure 50.19 Small-bowel stricturoplasty.

Strictures at prior anastomotic sites may occur from recurrent disease or secondary to technical problems. They are often amenable to dilation,[138] yet failure is high, thus requiring resection for symptomatic strictures. There are some data to suggest that side-to-side stapled ileocolic anastomoses have a decreased rate of postoperative complications including leak, recurrence, and reoperation when compared to handsewn end-to-end anastomoses.[139,140]

Intra-abdominal fistulas may arise from either the small or large bowel and affect any adjacent structure. It is important to determine the site of origin of the fistula, as

this section of bowel will typically require a formal resection. On the other hand, the adjacent organ may simply be involved in the process secondarily without primary disease involvement. Therefore, it is important to evaluate the adjacent organ when possible (such the colon in an ileosigmoid fistula) to ensure there is no active disease that will need to be addressed (**Fig. 50.20**). The preferred treatment is to take the fistula down, resect the diseased segment of bowel, and primarily repair the adjacent site. If there is concern for active disease in the adjacent site, such as in the above example with the ileosigmoid fistula, the preferred strategy would be to perform a concomitant colonic resection.[141] Transmural bowel inflammation and communication can also occur with the skin, bladder, or vagina. Once again, the bowel is the offending organ and should be resected, while ligation of the fistula and closure of the secondarily involved organ is adequate treatment. These organs do not have potential for active Crohn disease and they can often be simply repaired. If the inflammatory process is severe or there is a concern for concomitant malignancy, the entire process should be resected en bloc with appropriate reconstruction. When an abscess is present, it is often preferable to percutaneously drain the abscess first and ensure adequate medical therapy prior to embarking on abdominal exploration.[142] Finally, asymptomatic enteroenteric or enterocolonic fistulas do not require surgery and medical treatment, especially with biologic agents that have relatively good success.[143]

Treatment for malignancy in the Crohn patient is similar to that of the general population, with resection following standard oncologic principles. As synchronous and metachronous lesions have been reported in up to 10%, consideration should be given to a subtotal colectomy with ileorectal anastomosis in the absence of rectal lesions, though segmental colectomy has been well described in Crohn disease.

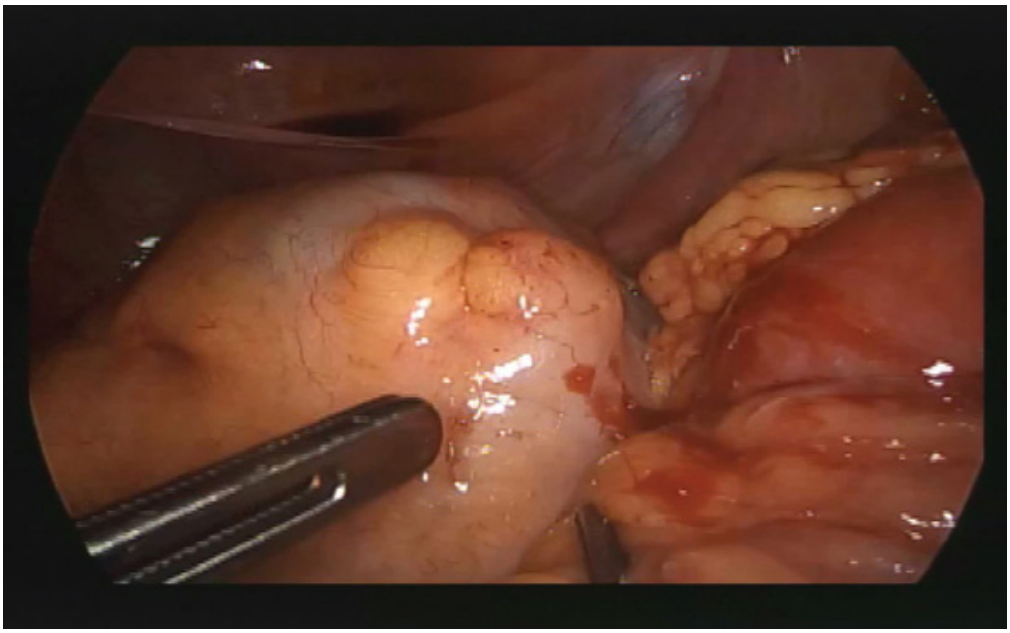

Figure 50.20 Ileosigmoid fistula.

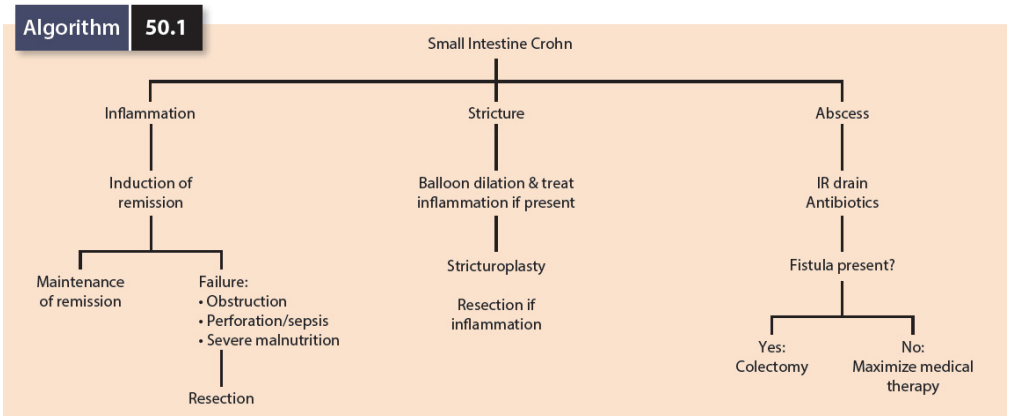

Algorithm 50.1 Management of small-bowel disease in Crohn disease.

SPECIFIC CONSIDERATIONS

Small-Bowel Disease (Algorithm 50.1)

Following resection, consideration should be given to the nutritional status of the patient, medications, and overall physiologic state, as diverting stoma may be required to minimize the incidence and consequences of an anastomotic leak. As the rate of perioperative complications tends to be higher in this population, a minimally invasive approach has been associated with improved short-term outcomes in Crohn

disease patients, including decreased morbidity and shorter length of stay for both primary and recurrent disease (**Table 50.6**).[144]

The mesentery in active Crohn disease always presents a particular challenge for surgeons. Due to its thick, edematous nature with increased neovascularization, adequate hemostasis is a particular concern. Safe division involves techniques such as overlapping clamps with both mass and individual vessel suture ligation where appropriate. Minimally invasive approaches typically rely on advanced vessel-sealing devices for hemostasis, though they may be inadequate in the Crohn disease patient and conversion to an open procedure may be necessary to control hemorrhage. Avoidance of mesenteric hematomas is crucial, as these may result in continued bleeding and may as well compromise the blood supply to the healthy remaining bowel. Recently, wide resection of the mesentery in Crohn disease, similar to that of an oncologic resection, has been shown to have decreased need for reoperation and decreased future recurrence of Crohn disease.[145,146]

Table 50.6 Perioperative Complications of Bowel Resection in Crohn Patients[a]

Complication[a]	Incidence (%)
Bleeding	1–5
Anastomotic leak	1.3–17[b]
Anastomotic stricture	6–13
Anastomotic recurrence of disease	15–39
Bowel obstruction/ileus	5–23
Abscess/intra-abdominal sepsis (excluding leak)	2.1–15
Surgical site infection	10–33
Venous thromboembolic event	1.4–3.3

[a]Risk factors: malnutrition, obesity, emergent surgery, immunosuppressant use, smoking, older age, open approach, stoma surgery.

[b]Depending on location and definition (clinical vs. radiologic).

The recommended type of anastomosis used to restore continuity following resection is variable. Options include stapled or handsewn, antiperistaltic, isoperistaltic, end to end, and end to side. The Kono-S–type anastomosis is a novel

antimesenteric end-to-end handsewn anastomosis thought to prevent recurrence of Crohn disease (**Fig. 50.21**).[147]

Colorectal Conditions

Toxic colitis may occur in Crohn disease patients similar to those with ulcerative colitis (**Algorithm 50.2**).[148] Following resuscitation and intravenous steroids or immunosuppressants, emergent surgical intervention is required for those with recalcitrant disease, perforation, or a deteriorating clinical state. The operative procedure of choice is a subtotal colectomy with end ileostomy. Debate exists as to the handling of the rectal stump, though options include a distal mucus fistula with remnant sigmoid, implantation into the subcutaneous space, or local reinforcement of the stump. Proctocolectomy should be avoided in this situation due to the prolonged operative time and increased risk of morbidity and mortality.

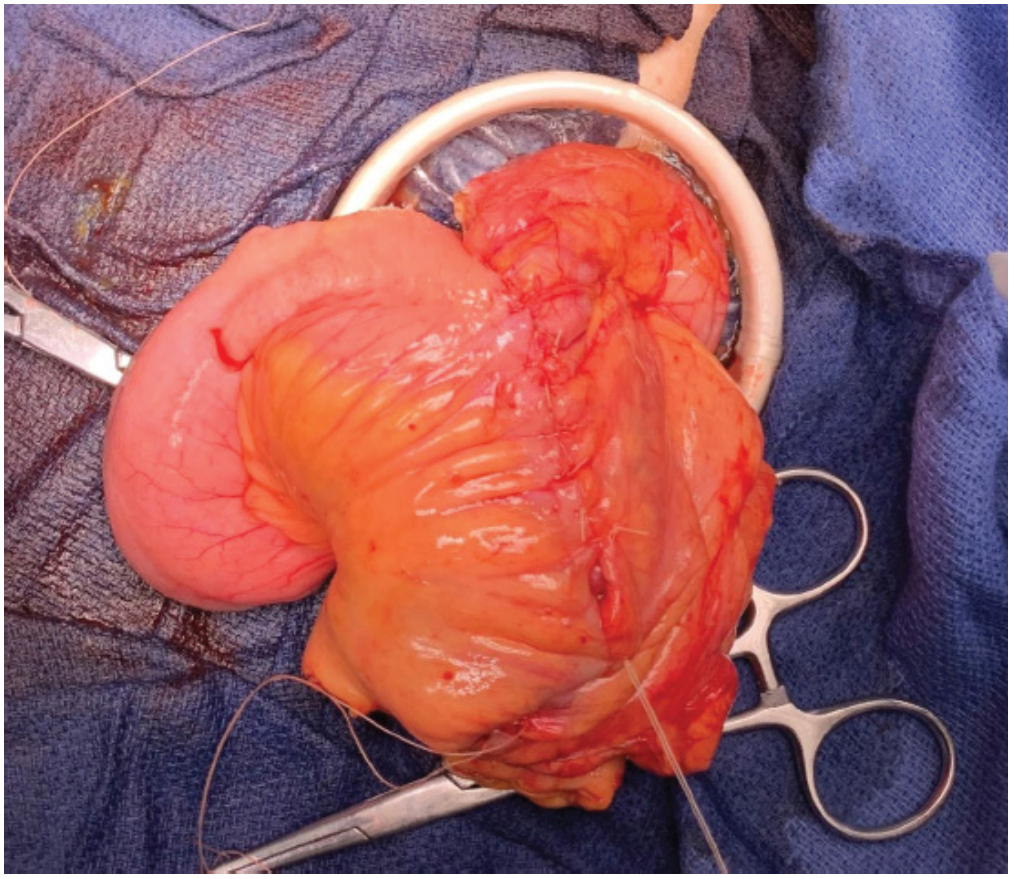

Figure 50.21 Kono-S–type anastomosis.

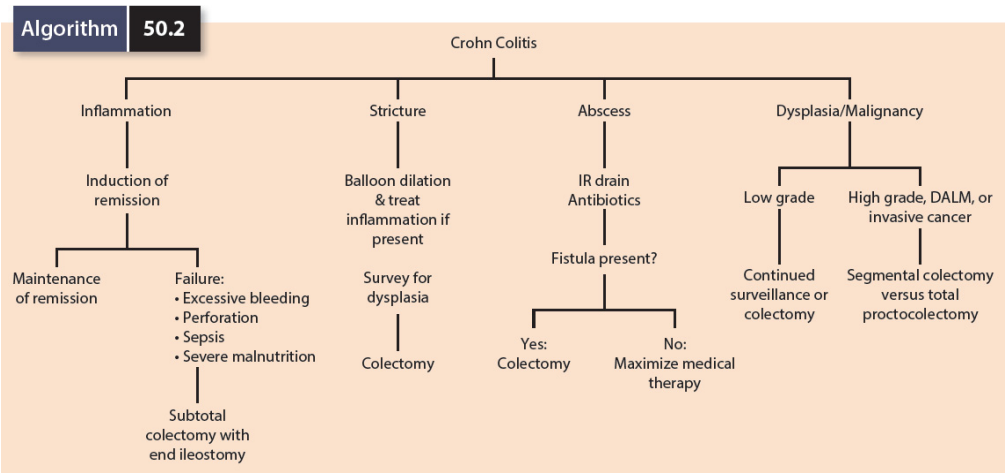


Algorithm 50.2 Management of colitis in Crohn disease.

An ileoanal pouch in the patient with Crohn disease is mostly commonly encountered in the setting of an initial diagnosis of ulcerative colitis with manifestations of Crohn disease at a later stage. While certain expert centers may advocate total proctocolectomy and ileal pouch construction for highly select patients with Crohn disease, in general, this is to be discouraged. Retrospective studies have reported 35% to 93% of patients will have Crohn-related complications such as pouchitis, abscesses, and pouch–anal fistulas, with another 10% requiring pouch excision or permanent diversion.[149] Furthermore, roughly half of patients will experience urgency or continence issues. Of those patients with a functioning pouch, over half will continue to require medication to treat active Crohn disease.[126,150,151]

Colorectal Malignancy

The risk of developing malignancy is elevated in the setting of Crohn disease and the management of dysplasia and invasive cancer remains controversial.[152] In the setting of inflammatory bowel disease, the type of lesion must be taken into consideration and a sporadic adenoma is managed differently than a nonadenomatous dysplasia–associated lesion or mass (DALM). Traditional sporadic adenomas can be managed with polypectomy and surveillance.[153–155] A DALM is a raised dysplastic lesion that does not have the appearance of a traditional sporadic adenoma. In general, the presence of a DALM raises consideration for total proctocolectomy given the high incidence of synchronous dysplastic lesions and metachronous colorectal cancers.[156] Absolute indications for surgery include high-grade dysplasia, multifocal dysplasia, and invasive cancer. Low-grade dysplasia and high-grade dysplasia are both risk factors for invasive cancer as they are associated with the identification of synchronous cancer in 19% and 42%, cases respectively.[157] In the setting of invasive

cancer, the extent of resection is controversial—segmental colectomy can be considered for select patients with Crohn disease, although total proctocolectomy remains the traditional recommendation.[156,158] Ileoanal pouch anastomosis can be considered in only highly selected patients.

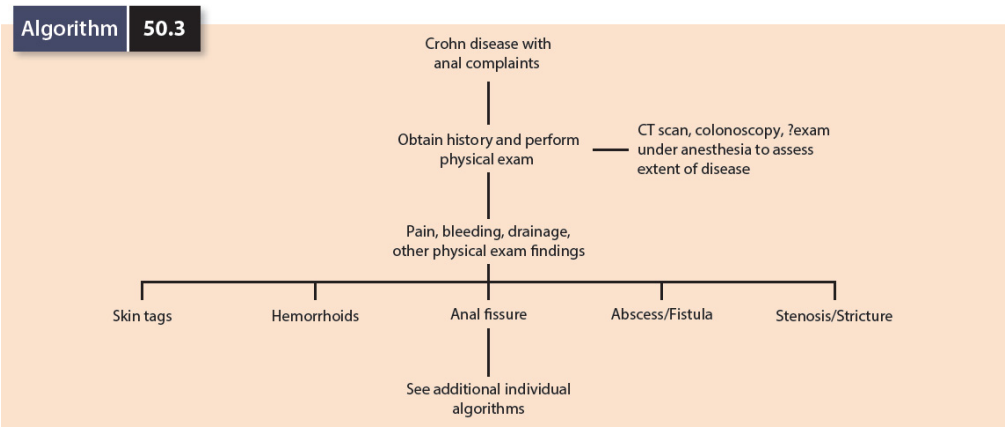
Influence of Immunosuppressive Medications on Surgical Outcomes

A strong consideration when operating on patients with Crohn disease is the potential for adverse postoperative outcomes in patients on immunosuppressive medications such as steroids and biologic agents. Patients undergoing colectomy for inflammatory bowel disease have been shown to have higher rates of infections when compared to those undergoing colectomy for cancer.[159] The main postoperative complications of concern are anastomotic leak, superficial surgical infection, and deep-organ space infection. Currently, no strict guidelines exist regarding the preoperative management of steroids and biologic agents. Several studies have demonstrated that anti-TNF agents are associated with higher rates of surgical site infection but not higher rates of anastomotic leak, and newer biologic agents are still under investigation.[160–166] However, the administration of immunosuppressive medications must be taken into consideration regarding surgical intervention. Decision making must balance the risk of holding these medications (such as disease flares and antibody development) with the benefit of decreasing postoperative morbidity. Furthermore, a combination of biologic medications, steroids, and malnutrition must be considered intraoperatively, potentially leading to higher rates of diversion.

Steroids are typically unable to be stopped due to steroid-dependent disease control. In general, anti-TNF agents are held for 4 weeks preoperatively, vedolizumab for 4 to 8 weeks preoperatively, and ustekinumab for 4 weeks preoperatively.[167] It is generally recommended to schedule surgery as far from the last dose of medication, around the time of what would be the next scheduled dose.

Venous Thromboembolism Prophylaxis

Patients undergoing surgery for inflammatory bowel disease experience higher rates of postoperative venous thromboembolism (VTE). The rate of postoperative VTE in patients with Crohn disease ranges from 0% to 4.9%.[168] Seventy-four percent of patients who experience VTE present during the initial postoperative hospitalization and 61% within the first 2 weeks postoperatively.[169] Standard perioperative VTE prophylaxis should be administered while patients are hospitalized and patients should be considered for extended prophylaxis upon discharge.[170]



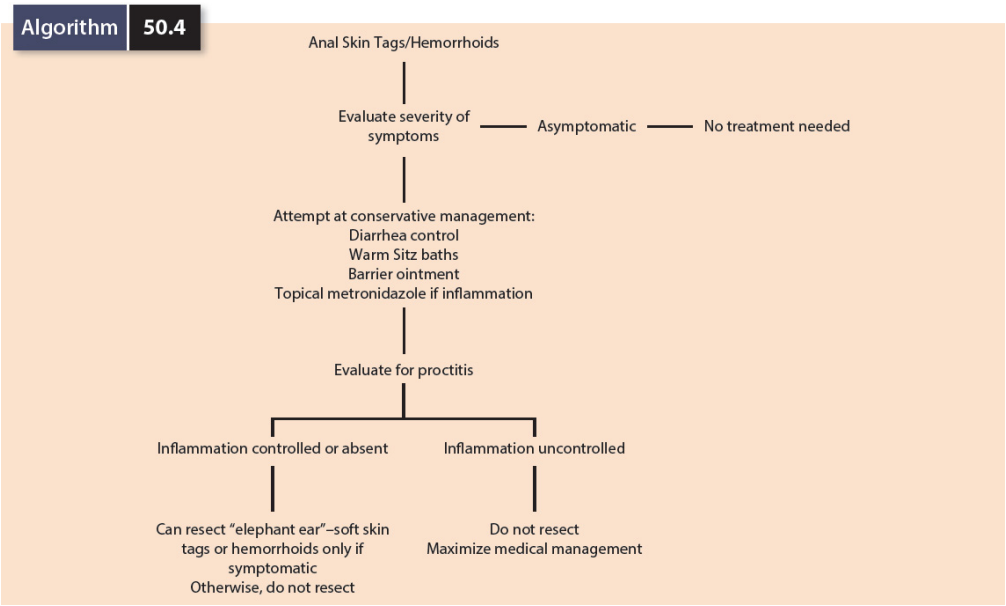
Algorithm 50.3 Crohn disease with anal complaints.

Treatment of Anorectal Conditions (Algorithm 50.3)

8 A distinguishing characteristic of the surgical treatment for anorectal Crohn disease is to first consider whether or not they are symptomatic. As a follow-on principle, aggressive intervention in the asymptomatic patient is unwarranted and potentially dangerous.

Anal Skin Tags and Hemorrhoids (Algorithm 50.4)

There are two types of skin tags associated with Crohn disease. The first type is a result of lymphedema due to concomitant intestinal disease and is hard, blue-colored, edematous, and tender (**Fig. 50.22A**). The other type is often referred to as "elephant ear" skin tags and are broad based, soft, and painless (**Fig. 50.22B**). When considering surgical intervention for these tags, it is important to keep in mind that Crohn disease patients have the propensity for poor healing, especially in the face of diarrhea. Patients should be counseled as to the risk of nonhealing wounds, continence problems, and mucus drainage.[171] An initial attempt at conservative treatment with warm Sitz baths and control of diarrhea is warranted. During this time, medical therapy toward Crohn disease should also be optimized, as active inflammation/proctitis will lead to increased morbidity. In the absence of proctitis, the "elephant ear"–type skin tags may be excised if personal hygiene is particularly bothersome, and wound healing can ensue normally.



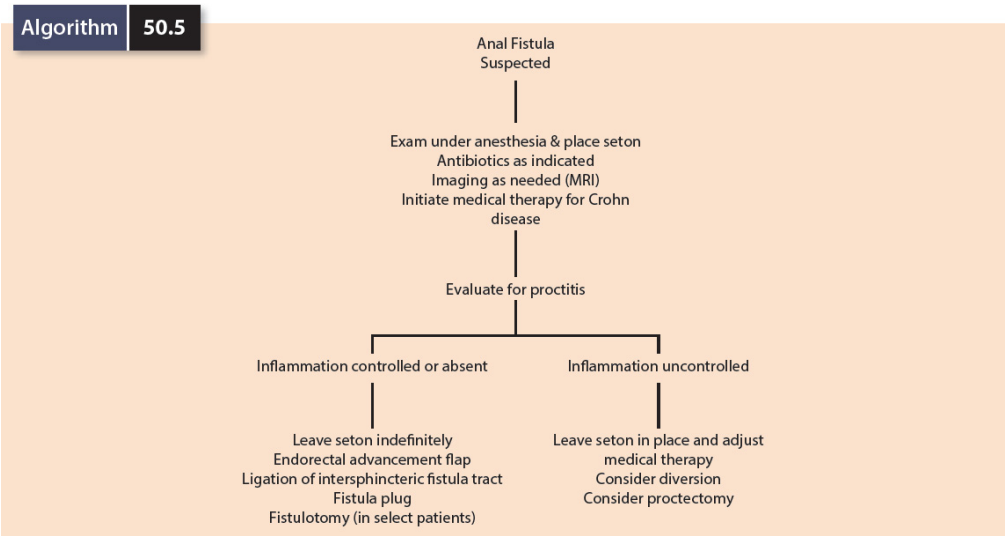
Algorithm 50.4 Management of anal skin tags and hemorrhoids in Crohn disease.

Figure 50.22 **A:** Crohn skin tags: elephant ear–type skin tags. **B:** Type of Crohn skin tags that should not be excised.

Internal hemorrhoids are not common in the setting of Crohn disease and patients that present with rectal bleeding should initially be evaluated for a flare of the underlying disease. However, if present, in the absence of proctitis and/or active perianal disease, they may be treated in a similar manner as a patient without Crohn disease, with conservative management of proper bowel hygiene, fiber supplementation, and band ligation, reserving surgical management as a last resort after failure of nonsurgical treatment.

Anorectal Abscess/Fistula (Algorithm 50.5)

Upward of 30% of patients with Crohn disease will develop perianal abscess or fistula and the treatment remains controversial. Perianal abscesses and fistulas in the setting of active perianal Crohn disease do not typically follow the traditional patterns of routine cryptoglandular-based disease (**Fig. 50.23**). The primary goal of treatment is the same, however, to control sepsis and maintain continence. The best treatment course depends on individual patient and fistula characteristics.



Algorithm 50.5 Management of anal fistula in Crohn disease.

Figure 50.23 Perianal fistulas in Crohn disease with "watering-can perineum." Hydrogen peroxide is injected through an external opening, with bubbles coming from multiple other openings.

When presenting initially as an abscess, incision and drainage is indicated and it is important to place the incision as close to the anal verge as possible while still achieving adequate drainage, considering the possibility of fistula development.[172] Alternatively, a small mushroom-tipped catheter may be placed in the cavity close to the anal verge, thus evacuating the abscess and allowing the cavity to close around the catheter, while allowing continued drainage.

If there is suspicion for a fistula, determining the anatomy of the tract is required, and attention must be paid to the presence of proctitis, status of the sphincter, prior anal operations, and potential for chronic diarrhea. In the setting of a fistula, a seton should be placed initially until further workup can be completed (**Fig. 50.24**). The goal of the seton is to allow for continuous drainage and prevent abscess formation. In addition, it has the potential of turning a chronic inflammatory tract into a more chronic fibrotic one. After the acute situation is handled, patients should then be evaluated thoroughly for the presence of intestinal disease and considered for medical treatment.

In the absence of proctitis, treatment is determined based on the characteristic of the fistula. A low-lying fistula in the absence of overt proctitis can often be treated

safely with fistulotomy.[173] Care must be given, even in these situations, as decreased continence may still ensue. When the fistula is higher or more complex, the initiation of anti-TNF agents has been reported to heal fistulas in up to 60% of patients.[174] Other treatment options include fibrin glue (not recommended), fistula plugs (success rates <20%), endorectal advancement flaps, or the LIFT procedure (ligation of the intersphincteric fistula tract). Meta-analysis of endorectal advancement flap versus LIFT procedure for Crohn disease demonstrates no difference in healing rates, with both procedures achieving success in approximately 50% to 60% of cases.[175]

Figure 50.24 Seton drains made of Penrose drains placed through fistula.

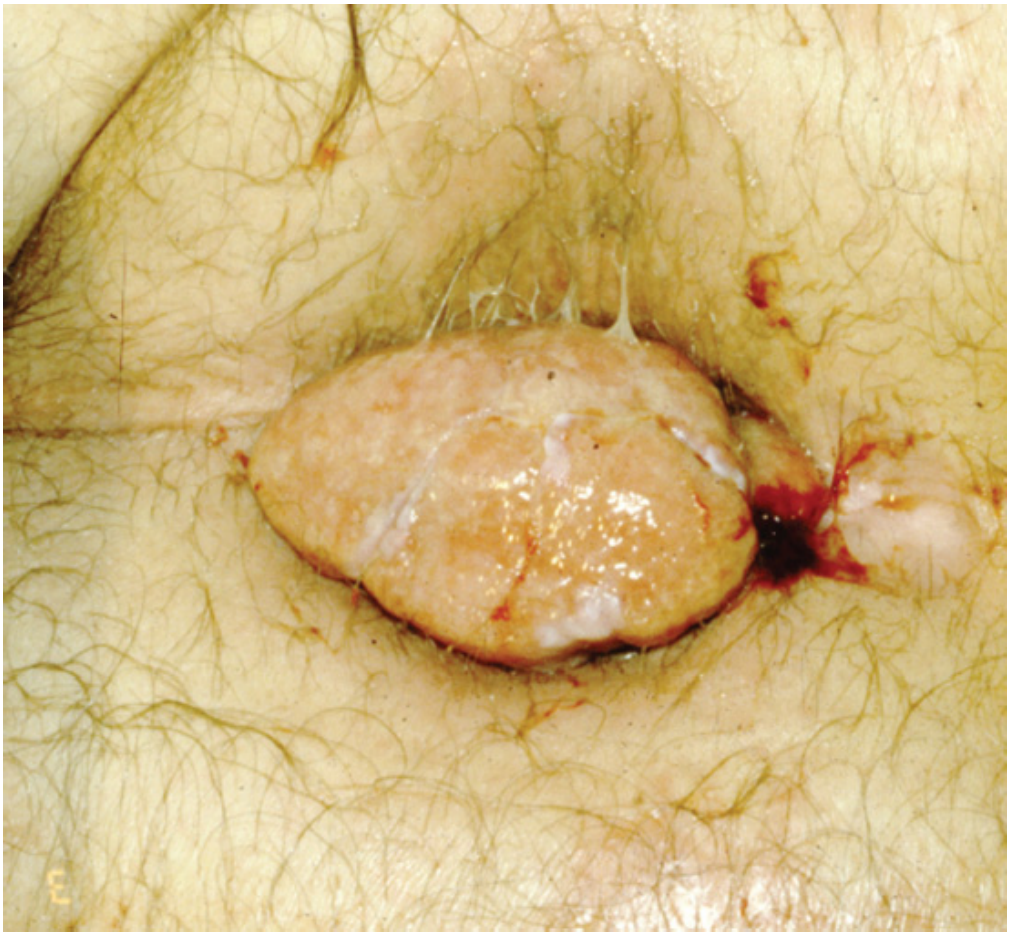


Figure 50.25 Anal cancer arising in perianal Crohn disease.

In the presence of active proctitis, typically the best way to proceed is to place a seton and initiate medical therapy. Setons can remain indefinitely, but patients should be periodically reexamined both to ensure that there is adequate drainage and to screen for the development of squamous cell carcinoma and adenocarcinoma arising in a fistulous tract (**Fig. 50.25**). Unfortunately, fistulas and fistula procedures all vary in their outcomes, with healing rates ranging from 15% to 97% and morbidity rates 3% to 78%, making it difficult to accurately compare results. As such, consideration should be given for a diverting stoma for recurrent or complex fistulas and upward of 68% of patients may require permanent diversion or even proctectomy.[176–179]

Rectovaginal/Anovaginal Fistula

Rectovaginal fistulas are particularly problematic in the Crohn disease patient. Passage of air and/or stool from the vagina can be extremely disturbing to the patient, but rarely constitutes a surgical emergency (**Fig. 50.26**). Clearance of active sepsis should take first priority with drainage of any abscess and initiation of antibiotics. After sepsis is controlled, the anatomy should be defined and medical

therapy with immunologic and/or biologic therapy should be initiated. The mainstay of management of these patients is medical therapy, with surgical therapy taken into consideration with caution. Recurrence rates are high and even with optimal treatment, upward of 20% of patients will eventually require proctectomy with permanent stoma.[180] Surgical options include fistula plug, endorectal advancement flap, LIFT procedure, episioproctotomy, sphincteroplasty, tissue interposition, and proctectomy.[181] Diversion is used liberally to improve healing. In certain situations, a lifelong seton may be necessary.

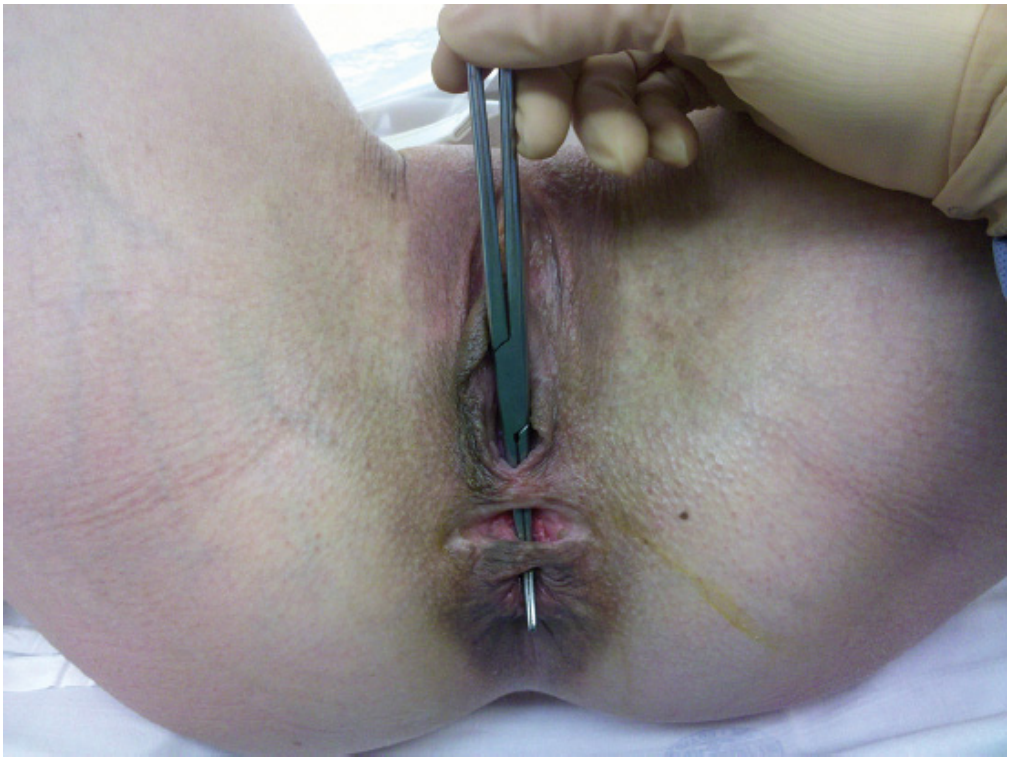

Figure 50.26 Rectovaginal fistula.

Anal Fissure (Algorithm 50.6)

Patients with Crohn disease can present with routine typical fissures associated with anal sphincter hypertonicity versus atypical fissures that are the result of the Crohn disease itself. All patients should be evaluated for the extent and severity of active intestinal Crohn disease. Excessive pain should raise the suspicion for an underlying abscess and prompt an examination under anesthesia.

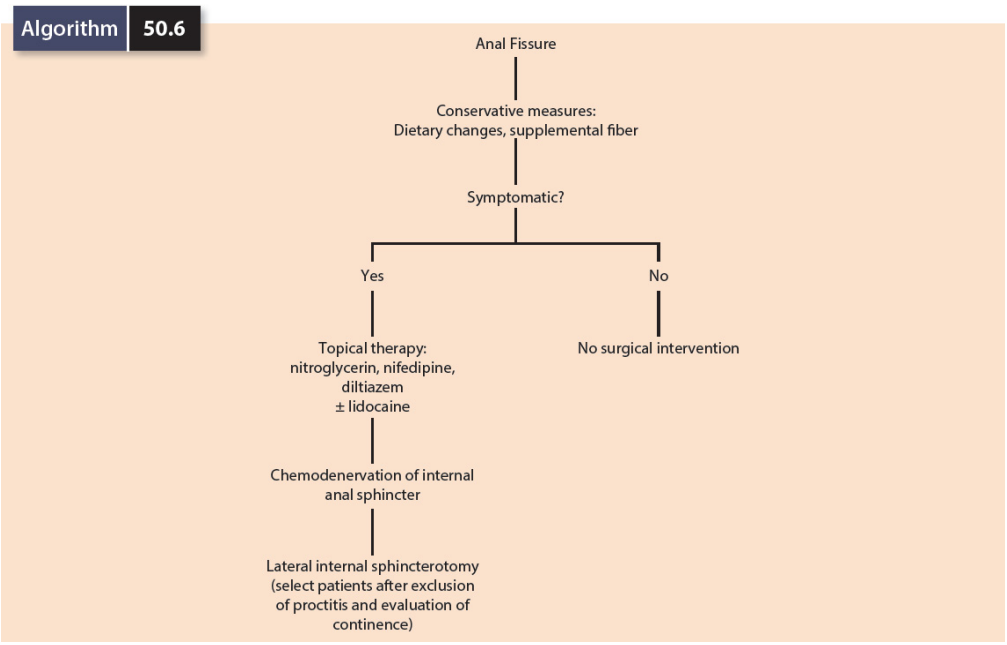
Routine typical fissures in the absence of active perianal disease can be treated in the standard fashion. Bowel habit management with high-fiber diet, stool softeners, fiber supplementation, and topical calcium channel blocker ointment are first-line treatments. Botulinum toxin injection and sphincterotomy can also be considered if

medical therapy fails, though sphincterotomy should minimize the wound as much as possible.

Crohn disease–associated fissures are hallmarked by deep, burrowing, off the midline, and sometimes multiple wounds. Many anal fissures are fortunately painless and require no intervention. Initial attempts at conservative therapy with topical metronidazole, smooth muscle relaxants, and local anesthetics may be attempted to palliate symptoms and help with healing.[182] For particularly symptomatic fissures, botulinum toxin has also been used. In contrast, other authors have advocated a more aggressive surgical approach in Crohn disease patients, with one report citing 67% of patients who were treated surgically with either lateral internal sphincterotomy or fissurectomy ultimately healed.[183] Given the continence risks associated with surgery, medical management directed toward Crohn disease is the preferred initial therapy in patients with Crohn-related fissures. Surgical intervention with a tailored lateral internal sphincterotomy should be reserved for those patients with minimal active anorectal inflammation who fail all reasonable conservative therapy, and still sphincter muscle division should be kept to a minimum.

Anorectal Malignancy

Risk factors in patients with Crohn disease include the presence of chronic inflammation, long-standing open wounds, and use of immunosuppressant medication. Both squamous cell carcinoma (Marjolin ulcer) and adenocarcinoma, and their variants may occur.[184] Patients, especially those with long-term indwelling setons, should be periodically examined at least annually to exclude the presence of malignancy or other pathology. All suspicious lesions should undergo biopsy and any malignancy identified should undergo proper staging and treatment.



Algorithm 50.6 Management of anal fissure in Crohn disease.

SUMMARY

Crohn disease remains a complex disease process with many different manifestations in the GI tract as well as extraintestinal locations. Although advances in medical therapy continue to evolve and significantly alter the way patients are managed, surgeons still play a large role in the medical and surgical therapy of the disease, though multidisciplinary care with gastroenterologists is crucial to achieve optimal therapy. Due to its recurring nature, providers must adhere to the principles of preventing and managing disease complications versus aiming for cure. By focusing on the maximization of functional outcomes, surgeons can optimize outcomes through a multimodal approach and minimize additional complications.

James W. Fleshman Jr and Steven G. Leeds

Key Points

1. The main types of primary small bowel tumors include adenoma, adenocarcinoma, neuroendocrine (carcinoid), lymphoma, and sarcoma (GIST). Surgical resection remains the treatment of choice for all except lymphoma (only needed for symptomatic lesions causing obstruction or bleeding).
2. There is a rising incidence of small bowel tumors, directly caused by a relative increase in the incidence of neuroendocrine tumors (NETs) over adenocarcinoma of the small bowel. This trend is occurring globally.
3. Research is now focused on the molecular cause of the discrepancy between the number of small bowel and colorectal adenocarcinomas.
4. Size and location influence the symptoms caused by tumors within the small bowel. The majority of tumors found incidentally are asymptomatic.
5. Capsule endoscopy (CE) is helpful for diagnosis but lack of spatial orientation, inability to biopsy, and capsule retention causing obstruction limits its usefulness. Small bowel enteroscopy, device-assisted enteroscopy (DAE), or deep enteroscopy (DE), are excellent alternative modalities.
6. Even though small NETs can metastasize, the risk of metastasis correlates with the size of the primary tumor.
7. There are three common radiographic modalities used to diagnose small bowel tumors which include CT scan, MRI and CT, or MR enterography. NETs also benefit from octreotide scanning as a functional scan to detect metastasis.
8. Chromogranin A tends to be the most sensitive indicator of recurrence during surveillance of NET, and sensitivity and specificity depends on the functionality of the tumor.
9. Gastrointestinal stromal tumors (GISTs) arise from pacemaker cells (interstitial cells of Cajal) of the small intestine and, based on mutations in the c-kit protooncogene region of the tyrosine kinase

gene, respond to imitinib (tyrosine kinase inhibitor) monoclonal antibody. Surgical resection remains the only curative method of treatment.

10 Melanoma is the most common extraintestinal malignancy with predilection to metastasize to the small bowel.

INTRODUCTION

The small bowel comprises about 75% of the entire length of the gastrointestinal tract and provides about 90% of its mucosal surface area. Small intestinal neoplasms represent less than 5% of the cancer affecting the entire gastrointestinal tract (**Table 51.1**).[1] The main types of malignancy include adenocarcinoma (40%), neuroendocrine (carcinoid), lymphoma (17%), and sarcoma (gastrointestinal stromal tumor [GIST]) (32%). [1] Several benign neoplasms such as lipomas, hamartomas, leiomyomas, and desmoid tumors are found in the small intestine. Recent large database queries have demonstrated that the most common malignancy is now neuroendocrine tumors (NETs) (6.98 per 100,000). Metastatic tumors to the small bowel are rare, but direct invasion and carcinomatosis tend to be the common presentation for nonprimary tumors. Operative treatment with extended resection is not possible with the small bowel. Treatment modalities and multidisciplinary approaches which do not rely on wide resection may offer improved survival.

EPIDEMIOLOGY

The National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program estimates that 10,590 new cases of small bowel cancer will be seen in 2019 with an estimated 1,590 deaths.[2] The incidence increased from 2007 to 2016 for small intestine cancer by 1.6% and mortality increased by 1.3%. At the same time cancer from all sites has decreased by 1.3 annual percent change and mortality dropped 1.5% (all races, both genders, age stratified). This may be due to an increased incidence of

neuroendocrine small intestine tumors to 1.05 per 100,000 in 2012. 2 This trend is occurring not only in the United States, but across the world. The same rising incidence is demonstrated in the United States in patients 65 years or older with proximal distribution of the neuorendocrine tumors (3.56 per 100,000 in gastropancreatic sites and 1.05 per 100,000 in small intestine).[3]

In the population below the age of 40, the incidence of small bowel neoplasms is low. The incidence for males and females is essentially the same. Sporadic, nonfamilial cancer occurs rarely in young patients.

PATHOGENESIS

The small intestine is the portion of the GI tract with the largest surface area, but has the lowest rate of cancer. Several factors have been identified as potential explanations: (1) The small bowel has liquid contents with an alkaline pH exposing the mucosa to a decrease in mechanical and chemical inflammation; (2) transit through the small bowel is rapid, thus shortening the time carcinogens are in contact with the mucosal surface; (3) there is a rapid turnover in epithelial cells in the mucosa outpacing the potential growth and development of neoplastic cells; (4) there is lower luminal bacterial load, particularly of anaerobes, which results in less total production of potential carcinogens; (5) the small bowel mucosa has an apparent enhanced ability to metabolize and/or detoxify certain dietary components or breakdown products that may be carcinogenic; and (6) the elaborate lymphoid tissue network surrounding the small bowel, and in particular, its ability to secrete immunoglobulin A, which might confer an increased immunologic-related tumor control (**Table 51.2**).[1]

Table 51.1 Small Intestinal Neoplasms

	Duodenum (%)	Jejunum (%)	Ileum (%)
Small bowel adenocarcinoma[1]	55–82	11–25	7–17
NETS[43]	11.4	6.3	49.9
Lymphoma[69]	6.5	25	65
Small intestine	4–5%	15%	15%

Small bowel adenocarcinoma is a molecularly unique intestinal cancer with a relatively high incidence of genomic alterations 3 predictive of response to targeted and immunotherapies. It has demonstrated distinct genomic differences compared with colorectal adenocarcinoma and gastric adenocarcinoma, including variations in the frequency and types of alterations of P53, KRAS, *APC, SMAD4, BRAF, ERBB2/HER2, EGFR, PIK3CA, ATM*, and a number of other genes (**Table 51.3**).[4] Small bowel adenocarcinoma has a higher percentage of microsatellite instability-high (MSI-H)/mismatch repair–deficient (dMMR) tumors compared with colorectal cancer.[5] Universal MMR or MSI testing is recommended in all patients with a personal history of small bowel adenocarcinoma to identify individuals with hereditary nonpolyposis colorectal cancer (HNPCC).

PREDISPOSITION TO SMALL BOWEL CANCER

There are several predisposing risk factors for development of small bowel cancers. These include genetic and environmental factors. The pathway to small bowel adenocarcinoma is the polyp–cancer pathway common to large intestinal cancer and as such the risk of small bowel adenocarcinoma is increased in all of the inherited polyposis syndromes (**Table 51.4**).

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) patients have hundreds, and even thousands, of adenomas in their gastrointestinal tract, and have a 100% transformation rate to colorectal cancer if untreated. Interestingly, the leading cause of death for patients with FAP is not the progression of colorectal cancer, due to the fact that most of the patients undergo a total colectomy. It is actually the malignant transformation of the periampullary adenoma to adenocarcinoma.[1]

Table 51.2 Protective Features of Small Intestine[1]

1. Liquid alkaline contents limit mechanical and chemical inflammation
2. Rapid transit to cecum (<1½ hrs)
3. Rapid turnover of epithelium
4. Lower bacterial load and less potential carcinogens
5. Epithelium detoxifies dietary components
6. Secreted IgA to give immunologic-related tumor control

[a]Targetable genetic alterations.

Crohn Disease

Crohn disease is a significant risk factor for small bowel adenocarcinoma. The duration of disease, distal jejunal or ileal disease, early age of diagnosis, fistulizing-type disease, and male gender all contribute to a higher risk for development of small bowel adenocarcinoma.[7] The relative risk was reported as 33 (95% CI: 15.9–60.9).[8] The areas of the small intestine that are particularly susceptible are where long-standing inflammation has caused

stricture formation. In these areas, the tumor tends to occur after at least 10 years of inflammation (0.2% cumulative risk) and commonly contains signet-ring cell features similar to those found in colon cancer due to ulcerative colitis.[9]

Table 51.4 Genetic Syndromes Predisposing for Small Bowel Adenocarcinoma

Familial adenomatous polyposis (FAP)
Crohn disease
Celiac disease
Peutz–Jeghers syndrome
Lynch syndrome
Multiple endocrine neoplasia type I (MEN-1)
Von Hippel–Lindau syndrome
Neurofibromatosis—type I

Celiac Disease

There is an increased risk for small bowel lymphomas as well as small bowel adenocarcinoma in patients affected by celiac disease. Lymphomas tend to be both T-cell and non-Hodgkin lymphomas.[10] The relative risk for small bowel adenocarcinoma in patients with celiac disease has been estimated 10 to 13.[11,12]

Peutz–Jeghers Syndrome

This is an autosomal dominant syndrome characterized by hamartomatous polyps in the gastrointestinal tract and mucocutaneous melanin pigmentation. The increased risk of cancer is for breast, ovarian, testicular, pancreas, stomach, esophagus, and others. The mutation has been identified on the serine/threonine kinase 11 (STK 11) gene. Meta-analysis of Peutz–Jeghers

syndrome indicated a relative risk for small bowel cancer of 520 when compared to the general population.[13]

Lynch Syndrome

Lynch syndrome or HNPCC is an autosomal dominant gene that is associated with the mutation of mismatch repair genes. There is an increased risk to develop small bowel cancer with a relative risk of greater than 100 in carriers for the gene mutation.[14] Other affected organs include uterus, ovaries, and urothelium.

Other Familial Syndromes

Multiple endocrine neoplasia type 1 (MEN-1), von Hippel–Lindau syndrome, and neurofibromatosis type 1 all carry increased risk for developing NETs.[10]

Dietary and Lifestyle Predisposition

There are several indicators to the increased risk of developing small bowel cancer including cigarette smoking, increased BMI/obesity, red meat (saturated fats), low-fiber diet, and alcohol consumption (**Table 51.5**).[12,13]

CLINICAL PRESENTATION

4 The majority of small bowel tumors, whether benign or malignant, are typically asymptomatic and are encountered incidentally. The biggest factor relating to the way small bowel tumors present is the size and location within the small bowel. Generally, tumors less than 4 cm are asymptomatic. This is even truer with benign lesions. The most common presenting symptoms are weight loss (30% to 50%), nausea, vomiting, anemia, and abdominal pain.[12] Late detection of asymptomatic malignant tumors results in metastases in about 50% of patients at the time of diagnosis.[15] Ulceration, perforation (in cases of lymphoma), obstruction, and bleeding are other common presenting symptoms.[16] Intussusception or volvulus can occur rarely. NETs can present

as functional syndromes, such as "carcinoid syndrome" with flushing, diarrhea, and tachycardia with late valvular dysfunction due to fibrotic scarring induced by serotonin (**Table 51.6**).

Table 51.5 Modifiable Risk Factors for Small Bowel Adenocarcinoma

Diet (high fat, low fiber)
Alcohol
Smoking
Obesity
Biliary tract disease
Occupational exposure (organic solvents, nuclear waste)
Vitamin D deficiency

Table 51.6 Complications Resulting from Small Bowel Tumors

Complication	Details
Weight loss	30–50% of patients History and physical examination of the patient
Nausea/vomiting	Nonspecific finding
Obstruction	Include in differential for patients never undergoing an abdominal surgery Diagnosis made with radiographs or CT scan
Ulceration/bleeding	Commonly with lymphoma Mass can be seen on CT scan, but ulceration and bleeding found with capsule endoscopy or deep endoscopy
Perforation	Emergent surgical management May see free air on radiographs or CT scan
Metastasis	50% metastasis with incidence of malignant small bowel tumors at time of diagnosis

DIAGNOSIS

Examining the small bowel with accuracy is a difficult process. Upper and lower gastrointestinal endoscopy provides little information because of the limited access to the vast amount of mucosal surface. Colonoscopic intubation of the ileocecal valve is ideal but is not possible in about 5% to 10% of the patients.[17] Even with this intubation, only the most distal 25 cm of the terminal ileum can be surveyed. During upper endoscopy (EGD), the

duodenum is visualized in the proximal portion typically leaving the distal duodenum and the rest of the small bowel unevaluated. In certain cases, and with maximal effort, the endoscope can be advanced beyond the ligament of Treitz. However, the risk of duodenal injury increases due to pressure in the curve of the duodenum. Nevertheless, both of these procedures are indicated to begin the workup. The entire small bowel needs to be evaluated for a source of the symptoms. Endoscopic gastroduodenoscopy (EGD) with endoscopic ultrasound is recommended during initial workup and staging for detection and pathologic sampling when a duodenal malignancy is suspected. If obstruction is detected during imaging, palliative diversion or stenting may be considered.[6,18]

CAPSULE ENDOSCOPY

5 Capsule endoscopy (CE) uses a miniature camera introduced orally that is capable of producing images throughout the small bowel to depict its entire mucosal lining as the first-line method to evaluate the small bowel for a source of occult gastrointestinal bleeding (OGIB).

Generally, CE is safe and widely used as a diagnostic test.[19] The only contraindications to its use are patients having swallowing disorders or bowel obstruction, with the possibility of capsule retention. There is a 2% capsule retention rate in most series.[20] Other limitations to CE are that it is time consuming; there is no biopsy potential, and no therapeutic capability. The European Society of Gastrointestinal Endoscopy (ESGE) endorses CE for small bowel investigation in overt obscure gastrointestinal bleeding.[18]

A large meta-analysis completed by Triester et al.[21] demonstrated the incremental yield of CE over enteroscopy and small bowel barium radiography to be 35% and 59%, respectively. CE's ability to evaluate more mucosal surface area than other modalities yields a higher rate of lesion detection.[22] The 50,000 images must be manually reviewed.[23]

SMALL BOWEL ENTEROSCOPY

Device-assisted enteroscopy (DAE) (double-balloon enteroscopy [DBE], single-balloon enteroscopy [SBE], spiral enteroscopy [SE], and balloon-guided enteroscopy) utilizes a fixation point provided by the scope and the small bowel is brought to the viewing tip of the scope. Traditional endoscopy utilizes pushing the endoscope through the gastrointestinal tract which is impossible without external intraoperative manipulation of the bowel over the scope. The disadvantages of CE are difficulty with orientation, inability to biopsy, possible obstruction, and capsule retention.

DAE allows the operator to obtain biopsies and to perform therapeutic interventions. There are four methods for DAE available today.

Double-Balloon Enteroscopy

The double-balloon endoscope consists of a balloon at the tip of an endoscope that has a length of 140 cm. An overtube, also containing a balloon at the tip, fits over the scope to employ a push-and-pull technique.[24] This allows for examination of 240 to 360 cm. Scope diameters are 8.5 mm to 9.3 mm with working channels of 2.2 mm and 2.8 mm. The working channels allow for the therapeutic and diagnostic options provided by these systems.

Double-balloon enteroscopy has a diagnostic yield of 60% to 80% in patients with OGIB and other small bowel pathologies.[25] Success rates vary from 16% to 86%.[26] The complication rate overall is reported as 0.8% but can be higher while performing therapeutic procedures such as electrocautery for a GI bleed, polypectomy, or dilation. The main complications are pancreatitis, ileus, and perforation.[27–29]

Single-Balloon Enteroscopy

SBE uses a balloon on the overtube placed over the scope. The scope tip is hooked to hold the scope fixed to aid in the advancement of the overtube. The overtube is referred to as the splinting tube which has a hydrophilic coating that is activated with application of 30 mL of water. Radiopaque material is present at the tip to aid in the advancement with fluoroscopy.

Spiral Enteroscopy

SE provides potential benefits with regard to shorter procedure time. A raised spiral on the exterior of the scope pulls the small bowel over the scope as it advances. This scope is 118 cm in length and has a diameter of 9.8 mm. The raised spiral grooves are 16 mm high. Clockwise rotation of the scope will advance the scope and counterclockwise rotation will withdraw the scope. Studies for SE demonstrate shorter insertion depths with faster procedure times. There is variation in the insertion depth varying from 176 cm to 262 cm.[30,31] The complication rate is noted to be 0.3% with a perforation rate of 0.27%.[25] Overall, the device is simple to use with a learning curve of five cases.[25,32] The ESGE endorses DAE to confirm findings of CE and possible biopsy or treatment of identified lesions.[18]

Exploratory Laparoscopy for Small Bowel Neoplasms

The role of laparoscopy has improved the management of small bowel lesions over the last decades.[33,34] There are distinct advantages to laparoscopy. Direct visualization of the small bowel on the extraluminal side adds significant value to the management of small bowel tumors. Complete evaluation of the small bowel can be obtained laparoscopically by examining the entire small bowel in a systematic approach in order to visualize all aspects of the small bowel including the mesentery. In conjunction with endoluminal approaches, like small bowel enteroscopy, lesions can be located, biopsied, and if needed, resected.

Small bowel enteroscopy can tattoo the lesion to provide evidence of the lesion on the extraluminal side. This would also facilitate a sound oncologic resection of the tumor. Hand-assisted laparoscopy is also helpful if palpation is essential and a small incision is desired.

A laparoscopic case should be converted to an open technique if conditions prevent oncologically sound technique in order to provide the patient with the best outcome.

Imaging

A prospective study comparing computed tomography enterography (CTE) to magnetic resonance enterography (MRE) in 150 patients with suspected small bowel disease, but negative findings on endoscopy, reported that MR enterography was more accurate than CT enterography, particularly for neoplastic diseases.[35]

CTE and MRE have clinical value in small bowel examination and tumor detection. They can be used with video CE, sequentially or complementarily. DAE might be better employed for endoscopic treatment or biopsy after CE or MRE/CTE detection of a small bowel tumor.[36]

MANAGEMENT

Benign

Adenomas are benign lesions that have malignant potential and are most commonly seen in the periampullary region due to the exposure to bile.[37] The most common location is immediately distal to the papilla in the second portion of the duodenum.[38]

Hamartomas are benign vascular tumors with a low malignant potential and usually associated with Peutz–Jeghers syndrome.[16] Lipomas are encountered incidentally as a single mass. Hemangiomas are rare benign tumors in the small bowel that present as GI bleeding.

Operative management may be required to control symptoms of a benign small bowel lesion. Mass effect causing intussusception or obstruction, hemorrhage, or a questioned presence of malignancy generates the need for segmental resection of the lesion. The "diagnostic dilemma" is a common reason for resection of an incidentally found mass on contrast study or endoscopy. Hemangiomatous lesions can usually be managed with angiographic embolization. The use of angiographic isolation with intraoperative angiographic methylene blue injection can be very helpful to guide resection in a field of bleeding small bowel hemangiomas which cannot be embolized.

Malignant

Cancers of the small intestine account for 5% of all gastrointestinal cancer. Within the group of malignant tumors found in the small bowel, there are four main types. The most recent data from a single-institution tumor registry show that neuorendocrine tumors of the small bowel have surpassed the incidence for adenocarcinomas of the small bowel.[1] Small intestinal tumors include NETs (40%), adenocarcinomas (40%), lymphoma, GIST, and sarcoma account for the remaining 20%.

Neuroendocrine Tumors

Diagnostic techniques such as device-assisted and capsule enterography, CT and MRI enterography have increased the NET diagnosis rates and accuracy of staging.[39] The most dramatic rise in incidence of GI tumors was in patients 65 or older (3.56/100,000 gastropancreatic, 1.02/100,000 in small intestine) in a recent SEER program review.[3]

NETs arise from secretory cells, called enterochromaffin cells, which produce vasoactive substances. NETs, formerly known as carcinoid tumors, can be almost benign or very aggressive. The increased production of serotonin causes systemic effects such as diarrhea, flushing, bronchospasm, cutaneous vasomotor symptoms, and right heart valvular dysfunction (Carcinoid syndrome). Serotonin is derived from its precursor tryptophan, and when in circulation, it elicits particular symptoms. The liver inactivates serotonin, to make 5-hydroxyindoleacetic acid (5-HIAA) which is excreted by the kidney, and only tumors outside the portal vein drainage system will produce the carcinoid syndrome.[40]

Tumor size can elicit effects such as obstructive symptoms or abdominal pain especially if mesenteric implants and a desmoplastic, fibrotic scar causes retraction and eventual constriction of the vascular supply to the small intestine. Small intestinal NETs have increased in incidence over the last 40 years, likely due to improved imaging and endoscopic techniques (1.05 per 100,000). Most commonly these tumors metastasize to the liver, mesentery, and peritoneum.[41]

Metastasis of small bowel NETs is related to primary tumor size; tumors >2 cm versus tumors less than 1 cm, there was 12% 6 nodal metastasis and 5% distant metastasis.[42] The risk of metastases correlates with size, grade, site, and differentiation of the primary tumor. This is influenced by the early

invasion of bowel wall lymphatics and blockage of the lymphatics in the mesentery, forcing cells to flow retrograde into lymphatics along the bowel to produce nodal and distant metastases (**Table 51.7**).

Table 51.7 Prognostic Factors Influencing Overall Survival (OS) in NETs

Good Prognosis (OS)	Poor Prognosis (OS)
Localized to bowel	Distant Spread
30+ yrs	1 yr
Grade 1	Grade 4
16.2 yrs	0–1 yr
Rectum	Pancreas
25 yrs	3.6 yrs
Appendix	Small intestine
30 yrs	14 yrs
Well differentiated	Poorly differentiated
Size <1 cm	Size >2 cm

Table 51.8 Pathologic Classification of Neuroendocrine Tumors[40]

Pathologic Classification of Neuroendocrine Tumors		
Differentiation	**Grade**	**Criteria**
Well differentiated	Low (typical)	<2 mitoses/10 HPF and ≤2% Ki67 index
Intermediate (atypical)	2–20 mitoses/10 HPF or 3–20% Ki67 index	
Poorly differentiated	High	>20 mitoses/10 HPF or >20% Ki67 index

The mitotic rate and Ki-67 index are measured in order to provide the histologic grade of these tumors, which correlates closely with clinical behavior (**Table 51.8**). These measurements categorize the tumors into one of four categories by grade; low (1) to high (4). Grades 1 and 2 typically fall into the well-moderately differentiated category and grades 3 and 4 are considered poorly differentiated or anaplastic. Resection to maximally debulk the tumor, or maximize cytoreduction, is the only chance for cure in NETs, but peptide receptor radionuclide therapy which attaches indium, yttrium, or lutetium to octreotide to seek out somatostatin-binding tumor receptors may have a role in the future.[43]

A formal Tumor Nodes Metastasis (TNM) staging classification stratifies tumors into localized, locally advanced, and metastatic categories with associated 5-year survivals of 95%, 84%, and 51%, respectively (**Table 51.9**). The American Joint Committee on Cancer TNM staging system utilizes tumor size, depth of bowel wall invasion, regional nodes, and distant metastasis.[44]

Table 51.9 AJCC TNM Classification for Neuroendocrine Tumors of Lower Jejunum and Ileum

T-Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
T1	Tumor invades mucosa or submucosa and size <1 cm
T2	Tumor invades muscularis propria or size >1 cm
T3	Tumor invades subserosa
T4	Tumor invades peritoneum/other organs
For any T, add (m) for multiple tumors	
N Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis
M	Distant metastasis
MX	Distant metastasis cannot be assessed
M0	No distant metastases
M1	Distant metastasis

Table 51.10 5-Year Survival Rates by Neuroendocrine Tumor Location (1973–1997)[a]

Site	All Stages (%)	Local Stage (%)	Regional Stage (%)	Distant Stage (%)
Stomach	75.1/55.3	90.2/69.6	40.4/27.2	18.0/9.0
Small bowel	76.1/54.6	94.5/70.4	84.4/64.1	51.2/32.4
Appendix	76.3/65.0	95.6/87.8	80.0/67.6	37.5/26.8
Colon	69.5/41.8	94.1/77.1	72.5/35.3	27.8/4.1
Rectum	87.5/77.8	94.9/86.2	53.7/42.1	14.6/13.1

Survival rates are all age-adjusted to standard 2000 population.
[a]Cancer-specific survival/relative overall survival.
From Maggard MA, O'Connell JB. Updated population-based review of carcinoid tumors. *Ann Surg* 2004;240(1):117–122, with permission.

Several factors influence survival of NETs from small intestine, which has the best survival behind rectal NET and is similar to lung NET. Localized NETs in the small intestine have a median overall survival of 14 years. Distant spread from small intestine NETs reduced median overall survival to 5.83 years. Higher-grade NETs from the small intestine (grade 3 or 4 histology—poor or anaplastic differentiation) have median overall survival of 30 months. Survival has been improving over recent years (**Table 51.10**).[3]

Diagnosis of NETs

Generally, diagnosis is made based on radiographic findings in conjunction with tumor markers. There are three common radiographic modalities used to diagnose these tumors, which include CT scan and MRI enterography and octreotide scanning.

7 Three-phase CT should be used for optimal evaluation of vascular liver metastasis in patients with active serotonin-based symptoms.[45]

NETs often express somatostatin receptors rendering them detectable by imaging with radiolabeled octreotide or SRS (somatostatin receptor scintigraphy). Five subtypes of somatostatin receptors have been identified and the somatostatin analogs from the octreotide scan bind with subtypes 2 and 5 which are present in 70% to 90% of NETs.[46] Single-photon emission computed tomography (SPECT) can enhance the detection of pathologic and

physiologic uptake in the abdomen. This is a full-body scan that enables visualization of somatostatin uptake throughout the entire body.

Positron emission tomography with use of functional radiotracers provides higher spatial resolution than the octreotide scanning and detects smaller lesions than other scanning methods. Octreotide, metaiodobenzylguanidine (MIBG), and positron emission tomography (PET) scanning are used for follow-up of patients and staging of patients for distant disease when planning aggressive, multiorgan resections. Serum levels of chromogranin A is a sensitive indicator of NET 8 persistence when the NET was found to produce chromogranin A. Because of false positives in non-NET settings, it is not appropriate for screening.[40,47,48]

Surgical excision of the primary tumor and local node metastasis is still the only curative therapy for these patients.[49] Several management options are available once any functional disorder is controlled. These include close surveillance of indolent tumors, radiofrequency ablation (RFA) therapy for liver metastases, systemic therapy with somatostatin analogs, interferon, or cytotoxic or molecular targeted therapies. These have never been compared in a controlled trial, making these therapies highly individualized based on underlying symptomatology.

Surgical management with complete resection and the use of RFA for liver disease still provide the best survival benefit for patients with advanced NET.[50,51] Debulking procedures have been shown to be effective in improving symptoms with greater than 90% resection.[50] A two-step approach for radical resection to achieve complete resection has been shown to be effective.[52] Recurrence rates can be as high as 81%.[53] Transarterial chemoembolization (TACE) has been shown to be highly effective against nonresectable diffuse liver lesions to reduce symptoms.[51]

Medical management of NET includes a wide variety of agents including somatostatin analogs (octreotide) and peptide receptor radionucleotide therapy (PRRT), chemotherapeutic agents (doxorubicin–streptozotocin, dacarbazine, temozolomide, oxaliplatin, or interferon), monoclonal antibody therapy (bevacizumab), mTOR inhibitors (temsirolimus and everolimus), and multikinase inhibitors (sunitinib, sorafenib, and pazopanib).[3]

A combination of both medical and surgical management is outlined in **Algorithm 51.1**.

Since NETs can develop in all areas of the intestine, surveillance with endoscopy is important. Scanning with CT/MRI of the liver can guide reexploration and resection. Octreotide scanning, MIBG, or PET scanning can be helpful in controversial cases of possible metastases.

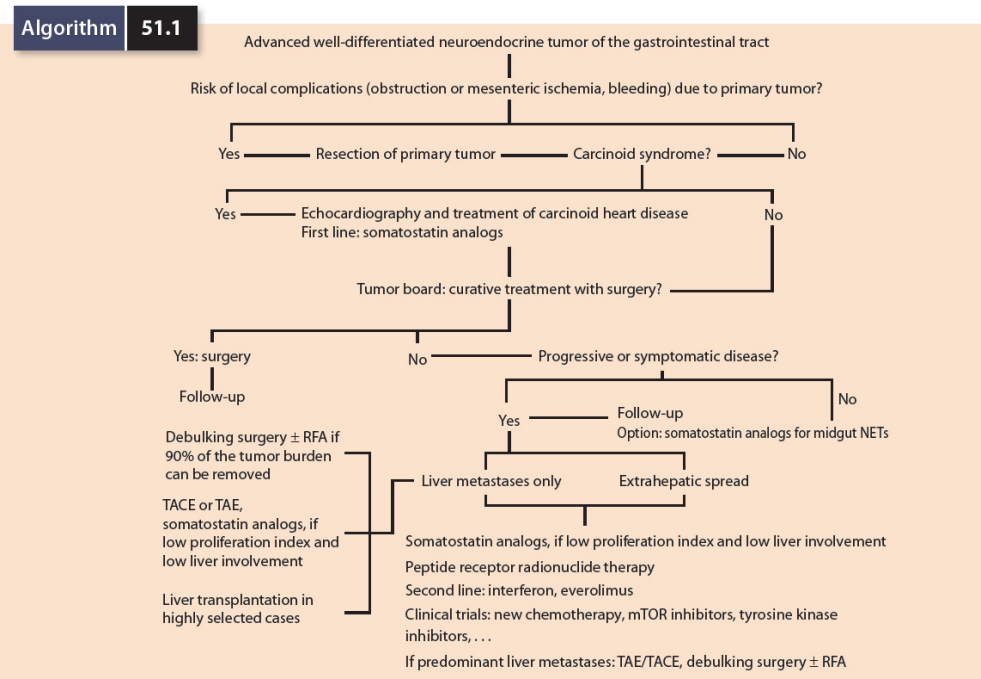
Small Bowel Adenocarcinoma

Small bowel adenocarcinomas represent the second-most common cancer of the small bowel with an incidence of 7.3 cases per million worldwide.[54,55] Small bowel adenocarcinoma, along with colorectal cancer, is more common in developed countries, and has higher incidence rates in North America and Western Europe.[56] Black populations have an age-adjusted incidence rate of about twice the rate of white individuals, and the Hispanic population follows. The lowest incidence is in the Asian/Pacific Islander population.[57]

Small bowel adenocarcinomas, which comprise an estimated 30 to 40% of small bowel cancer diagnoses, have until recently lacked many established guidelines for management. A French intergroup recently published 2018 clinical practice guidelines.[58]

Presentation for small bowel adenocarcinoma is very nonspecific with the most common symptom on presentation being abdominal pain (45% to 76%).[55] Other common symptoms include nausea and vomiting, weight loss, fatigue and anemia, and GI bleeding.[59,60] Interestingly, with the indolent presentation of these cancers, patients can recall symptoms for long periods of time prior to diagnosis. Talamonti et al. were able to identify a mean duration of symptoms at presentation for 10 months, reflecting the need for a high index of suspicion.[60]

Carcinoembryonic antigen (CEA) and carbohydrate antigen 19-9 (CA 19-9) are elevated in only about 30% to 40% of patients.[61] Radiologic and endoscopic modalities provide the best method for detecting small bowel adenocarcinoma but often fail to make a diagnosis given the nonspecific nature of the presenting symptoms.



Algorithm 51.1 Management algorithm for patients with advanced neuroendocrine tumors (NETs) of the gastrointestinal tract. mTOR, mammalian target of rapamycin; PPI, proton pump inhibitor; RFA, radiofrequency ablation; TAE, transarterial embolization. (Walter T, Brixi-Benmansour H, Lombard-Bohas C, et al. New treatment strategies in advanced neuroendocrine tumours. *Dig Liver Dis* 2012;44(2):95–105.)

Upper GI swallow study with small bowel follow-through or enteroclysis are unable to assess extraluminal spread. CT enterography has 84.7% sensitivity rate for detecting small bowel tumors and a specificity of 96.9%.[62] MRE has a sensitivity of 91% and a specificity of 95%.[63]

Endoscopic evaluation with DAE plays an important role in detecting small bowel adenocarcinomas when the symptom is anemia.

Prognosis after treatment is directly related to the tumor staging.[59] Poor differentiation, positive margins after resection, duodenal location, male gender, elderly age, and black ethnicity all drive poor prognosis.[55] Lymph node harvest at the time of surgery should yield 8 or 10 or more nodes for accurate assessment.[64,65] Patients can be staged (**Table 51.11**) and their disease-specific survival rates can be assessed based on the tumor site (**Fig. 51.1**) and change based on the number of lymph nodes examined (**Fig. 51.2**) and the number of positive lymph nodes (**Fig. 51.3**).

Longer survival after resection is strongly associated with a lower ratio of positive-to-negative lymph nodes as well as with a higher number of regional

lymph nodes assessed during surgery.[65–68] Two of these analyses, which considered duodenal and jejunoileal adenocarcinomas separately, concluded that, for adequate staging, a minimum of five lymph nodes should be retrieved for duodenal tumors and a minimum of nine lymph nodes for jejunal or ileal tumors.[67,68] Based on these studies, a goal for all small bowel adenocarcinoma resections should be the removal of at least eight regional lymph nodes for evaluation.

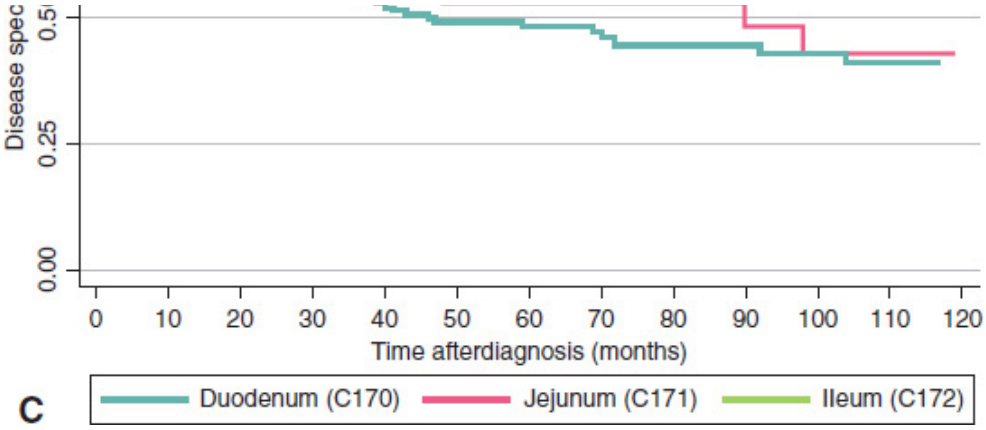

Figure 51.1 These Kaplan–Meier curves illustrate disease-specific survival for small bowel adenocarcinoma stratified by (**A**) disease stage, (**B**) subsite in the small bowel for stage I and II diseases, and (**C**) subsite in the small bowel for stage III disease. Codes for the duodenum (C17.0), jejunum, (C17.1), and ileum (C17.2) are from the International Classification of Diseases for Oncology and Related Health Problems, 10th Revision. (Overman MJ, Hu CY, Wolff RA, et al. Prognostic value of lymph node evaluation in small bowel adenocarcinoma: analysis of the surveillance, epidemiology, and end results database. *Cancer* 2010;116(23):5374–5382.)

Surgical management is the mainstay of therapy for small bowel adenocarcinoma with locoregional disease.[55] It has been known for almost two decades that resection of duodenal adenocarcinomas yields a 56% survival at 5 years with complete surgical resection and 0% survival at 5 years without resection.[69] Duodenal adenocarcinomas can be managed with pancreaticoduodenectomy or with segmental resection for the distal third and fourth portions for resectable tumors. Nodal involvement should prompt adjuvant therapy, but otherwise observation is sufficient (**Algorithm 51.2**). Jejunal and ileal adenocarcinomas should be managed with similar principles of segmental resection and regional lymph node dissection, with a right hemicolectomy for tumors involving the distal ileum.[55]

Adjuvant and Neoadjuvant Therapy

Adjuvant therapy is aimed toward controlling recurrence of adenocarcinoma at distant sites. Distant recurrence predominates over locoregional recurrence for duodenal adenocarcinomas.[55] After pancreaticoduodenectomy for duodenal adenocarcinoma, the first site of recurrence was predominantly distant (59%) followed locoregional (19%) or both (22%).[70] Adjuvant therapies involve 5-fluorouracil/capecitabine, FOLFOX/CAPOX, FOLFIRI, or gemcitabine.

The ongoing international phase III BALL Trial (or 5-FU/LV plus oxaliplatin (FOLFOX) compared with observation alone) for patients with stage I–III small bowel adenocarcinoma will determine the usefulness of adjuvant chemotherapy for local regional disease.[6,71,72]

Microsatellite instability/mismatch repair (MSI/MMR) is an important piece of information to consider when deciding whether to use adjuvant chemotherapy in patients with stage II small bowel adenocarcinoma.[6,73] Tumors related to Lynch syndrome with high MSI do not respond to 5-fluorouracil–based chemotherapy.

For some patients with locally unresectable or medically inoperable small bowel adenocarcinomas, conversion to resectable disease may be a goal.[6] A retrospective study of patients with unresectable or recurrent duodenal adenocarcinoma who were treated with neoadjuvant chemotherapy or chemoradiation found that 9 of 10 patients showed conversion to resectable disease after neoadjuvant therapy.[74] Based on these data, patients with locally unresectable or medically inoperable small bowel adenocarcinoma may undergo neoadjuvant therapy, during which they should be routinely monitored for conversion to resectable disease.

Lymphoma

Lymphomas account for about 15% to 20% of small intestine neoplasms.[15] SEER database analysis from 1975 to 2003 shows a distribution of 60% to 65% in the ileum, followed by 20% to 25% in the jejunum, and 6% to 8% in the duodenum (**Table 51.1**).[75] Secondary lymphoma is much more common than primary lymphoma because the gastrointestinal tract is the most common site for extranodal disease.[16]

The typical clinical presentation of small bowel lymphoma is nausea, vomiting, abdominal pain, anemia, and weight loss. Severe symptoms such as obstruction, intussusceptions, or perforation are rare.[15]

The most common intestinal lymphoma is diffuse large B-cell lymphoma. Despite the incidence of lymphoma in the small intestine, surgery is typically not the method for management. These patients should undergo resection in situations of obstruction or bleeding, and should still receive chemotherapy.[15] Immunoproliferative small intestinal disease (IPSID) occurs

in patients who are chronically immunosuppressed, as a result of infection by *Helicobacter pylori* and *Campylobacter jejuni*. Antibiotic therapy for these bacteria usually results in regression of immunoproliferative small intestinal disease. Most of these patients relapse and will need radiation and chemotherapy with nutritional support.[76,77]

Gastrointestinal Stromal Tumor

GISTs are the most common mesenchymal tumors of the small bowel. GISTs are found in the stomach (60% to 70%), small intestine (20% to 30%), and in the duodenum (4% to 5%).[78] GISTs are known to arise from the interstitial cells of Cajal, which are described as the gastrointestinal pacemakers.[79] Hirota et al. recognized the c-kit protooncogene which codes for a tyrosine kinase inhibitor, as the genetic mutation leading to GISTs.[80]

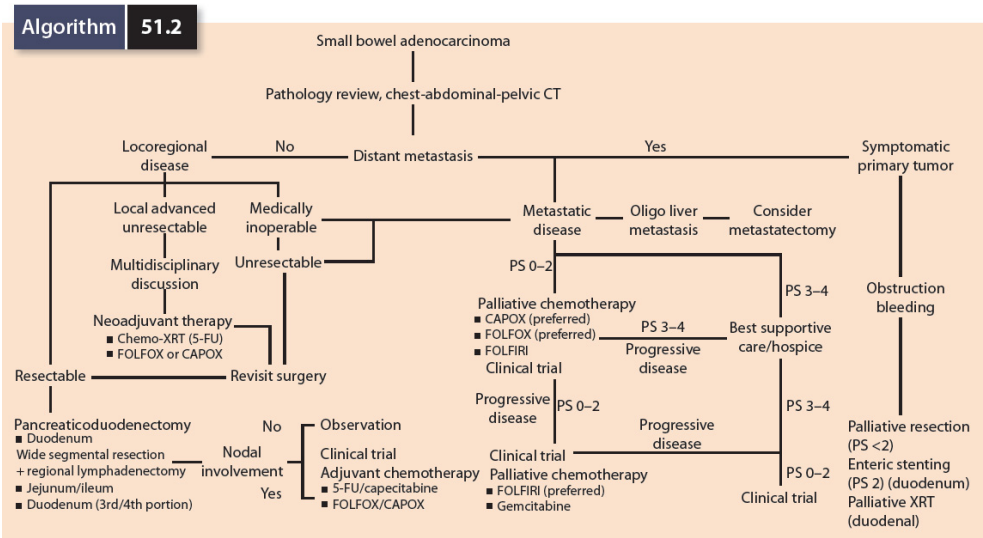
GIST is unique with regard to the submucosal origin and its likelihood to grow in size away from the lumen of the small bowel. This makes it difficult to make a diagnosis with intraluminal biopsy. Bümming demonstrated that only one-third of diagnoses are made with biopsies, and that the most common method of detection was endoscopy and CT scan.[81] Patients with GISTs present with vague abdominal symptoms, pain, GI bleeding from a mucosal erosion, or an abdominal mass.[82]

9 GISTs do not have the malignant pattern predicted in other types of cancers based on histopathology alone. Several factors influence malignant behavior including tumor size, mitotic rate, tumor location, kinase mutational status, and occurrence of tumor rupture. Mitotic rate and tumor size are the most commonly acceptable indices for prognosis.[78]

Complete surgical resection remains the only method for curative treatment, and simple negative margins are needed, as wide margins have not shown significant benefit. Small segmental resection of the small bowel is adequate because GISTs rarely metastasize to lymph nodes. Lymph node dissection is not warranted. En bloc resection should be done for locally advanced GISTs. Overall 5-year survival rate for patients with complete resection of GISTs is 50% to 65%.[78–84]

Patients have a defined risk for recurrence and may benefit from adjuvant therapy. The Modified NIH–Fletcher GIST Risk Assessment Criteria is presented in **Table 51.12**. Other risk assessment tools are available such as

Armed Forces Institute of Pathology Classification and the Memorial Sloan-Kettering Cancer Center Prognostic Nomogram. Adjuvant therapy utilizes imatinib (Gleevec). This drug is used in the treatment algorithms for patients with advanced or metastatic GIST (**Algorithm 51.3A**) or with resectable GIST (**Algorithm 51.3B**). Imatinib is a competitive inhibitor for multiple tyrosine kinase inhibitors and was originally recommended for chronic myelogenous leukemia treatment. It became first-line adjuvant treatment for GIST once it was recognized to disrupt the KIT oncogene in GISTs.[85] Shortly after that, imatinib was approved for use in unresectable or metastatic disease shown in **Algorithm 51.3A**.[86,87] Imatinib adjuvant therapy yields 98% 5-year recurrence-free survival.[88] The management of GISTs benefits from a standard algorithm.[89]



Algorithm 51.2 Algorithm showing the management of patients with small bowel adenocarcinomas. The treatment strategy depends on disease stage and involves en bloc resection for locoregional disease and systemic chemotherapy for metastatic disease. All current recommendations are based on case series, retrospective reviews, or nonrandomized prospective trials because of an absence of any randomized data. 5-FU, 5-fluorouracil; CAPOX, capecitabine and oxaliplatin; FOLFIRI, 5-FU, leucovorin and irinotecan; FOLFOX, 5-FU, leucovorin and oxaliplatin; KRAS-WT, *KRAS* wild-type; PS, performance status; XRT, radiation therapy. Hepatic metastases from neuroendocrine tumors with a "thin slice" pathological examination: they are many more than you think. *Ann Surg* 2010;251(2):307–310.)

METASTATIC TUMORS TO THE SMALL BOWEL

Metastasis to the small bowel occurs in two different ways, either from distant spread or direct invasion from a nearby organ malignancy. The most common extra-abdominal metastases are from breast cancer and melanoma. Melanoma is the most common extraintestinal malignancy with predilection to metastasize to the small bowel (**Fig. 51.4**).[90] 10 Patients with metastatic melanoma to the small bowel often present with other extraintestinal metastasis.[91] Primary tumors of intraperitoneal organs such as colon, ovary, uterus, and stomach metastasize to the small bowel.[84]

Patients with small bowel metastasis are usually offered palliative systemic chemotherapy. Other palliative measures can be considered on a case-by-case basis including surgical resection, internal bypass, or usage of an endoscopically placed stent.[9]

Table 51.12 Modified NIH–Fletcher GIST Risk Assessment Criteria

Risk Category	Tumor Size (cm)	Mitotic Index (/50 HPF)	Primary Tumor Site
Very low risk	<2.0	≤5	Any
Low risk	2.1–5.0	≤5	Any
Intermediate risk	2.1–5.0	>5	Gastric
	<5.0	6–10	Any
	5.1–10.0	≤5	Gastric
High risk	Any	Any	Tumor rupture
	>10	Any	Any
	Any	>1G	Any
	>5.0	>5	Any
	2.1–5.0	>5	Nongastric
	5.1–10.0	≤5	Nongastric

Section G: PANCREAS

52

Pancreas Anatomy and Physiology

Teviah E. Sachs and Jennifer F. Tseng

Key Points

1. The pancreas is an endocrine and exocrine organ which lies in the retroperitoneum whose primary functions are to regulate carbohydrate metabolism and secrete enzymes to aid in digestion.
2. Its head lies in the second and third portions of the duodenum, its body lies behind the stomach and its tail terminates in the hilum of the spleen. It abuts several highly critical organs and blood vessels along its course.
3. Embryologically, the pancreas is derived from a ventral and dorsal bud which rotate with the duodenum and fuse together to create a single gland. Abnormal rotation or fusion can lead to variant pancreatic anatomy including pancreatic divisum and annular pancreas.
4. The exocrine pancreas makes up 90% of the mass of the gland, and can primarily be divided into the central acinus, which secrete fluid and enzymes for digestion, and the ductal network through which the enzymes are flushed into the duodenum.
5. The central acinus is made up of acinar cells which produce and secrete enzymes, and the centroacinar and terminal duct cells which secrete sodium bicarbonate solution.
6. The endocrine pancreas makes up 1% to 2% of the pancreatic mass but accounts for 15% of its blood flow. Its main functional unit is the islets of Langerhans which are composed of a multitude of cells including α (alpha) cells which secrete glucagon, β (beta) cells which secrete insulin, and δ (delta) cells which secrete somatostatin.
7. Insulin and glucagon act opposite one another to maintain glucose homeostasis, with insulin-increasing glucose uptake by cells and glucagon-stimulating gluconeogenesis and glycogenolysis from the liver. Somatostatin acts on both α and β cells and slows intestinal transit.
8. The superior mesenteric artery runs behind the neck of the pancreas, as does the superior mesenteric vein, which joins the splenic vein behind the pancreatic neck to form the portal vein. Understanding this anatomy, as well as the multiple variants that exist, is crucial for all who operate in the abdomen and retroperitoneum.

INTRODUCTION

- The 1 pancreas is a soft, tan-colored organ which is found in the retroperitoneum, and has two main functions: the regulation of serum glucose and the production of pancreatic enzymes 2 critical for digestion. It lies in close proximity to a multitude of upper abdominal organs and major vasculature, making the understanding of its anatomy of utmost importance to the surgeon.
- The pancreas is considered an upper gastrointestinal organ that acts in an exocrine, paracrine, and endocrine capacity.[1,2] The exocrine portion of the gland is comprised of acinar and ductal cells and accounts for up to 95% of the mass of the pancreas. The function of these cells is to produce and secrete an array of enzymes which are essential for absorption of nutrients in the small intestine. The endocrine function of the pancreas is carried out by the islets of Langerhans, which are distinct groupings of endocrine cells found throughout the pancreas. As opposed to the exocrine portion of the gland, these cells make up less than 1% of pancreatic tissue. However, despite their diminutive volume they receive nearly 15% of pancreatic blood flow, which substantiates their importance.[3] These cells secrete a variety of hormones, most notably insulin, glucagon, and somatostatin, in order to regulate carbohydrate metabolism.[1,4] These endocrine hormones act not only systemically, but upon the islets themselves in a paracrine fashion as well, in order to maintain a relatively consistent serum glucose.[2] The sequelae of insult to the pancreas, whether it be surgical, traumatic, acute or chronic disease, can be devastating to the patient, and therefore a thorough understanding of pancreas physiology is paramount.

EMBRYOLOGY OF THE PANCREAS

- The pancreas develops from two distinct primordia: the dorsal 3 and ventral pancreatic buds. These are derived from the endoderm and form at the junction of the foregut and midgut at the septum transversum. The majority of the pancreas arises from the dorsal bud, to eventually include the superior aspect of the head, the neck, the body, and the tail of the pancreas. The remainder of the head of the pancreas and the uncinate process derive from the ventral bud, which arises laterally beside the growing biliary tract. As the duodenum matures and rotates, the ventral bud follows, rotating clockwise to fuse with the dorsal bud. At the junction of the ventral and dorsal buds of the pancreas, the ducts of each bud fuse, and the duct which lies in the distal and main body of the dorsal bud empties via the ventral duct through the ampulla of Vater (major papilla) and into the duodenum. The remaining proximal duct of the dorsal bud empties directly into the duodenum more proximally, via the minor papilla (**Fig. 52.1**). The main pancreatic duct is known as the duct of Wirsung, while the minor pancreatic duct is known as the duct of Santorini.

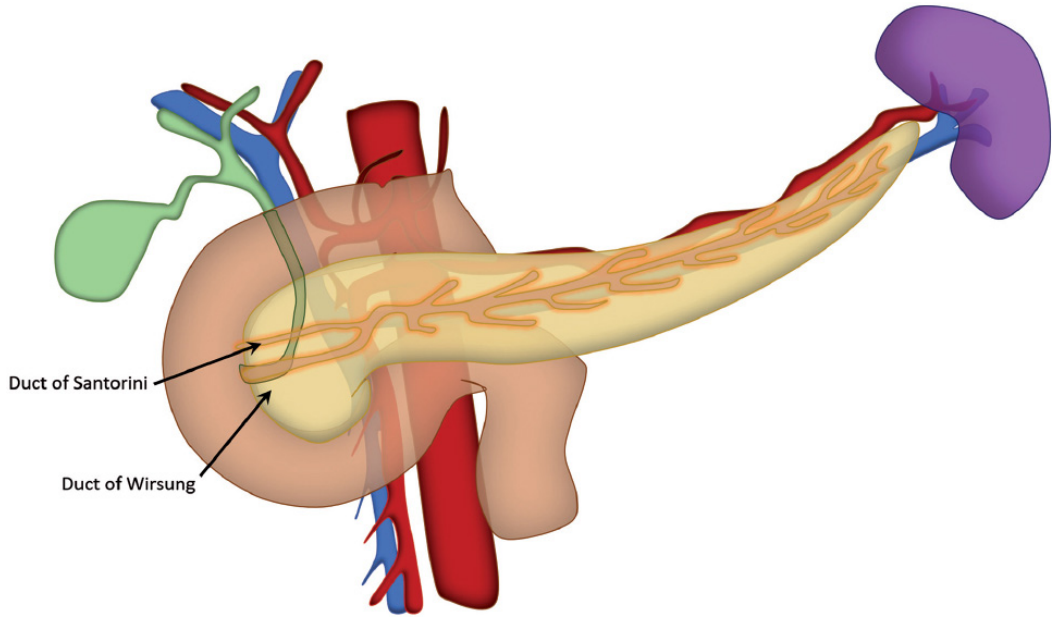

Figure 52.1 Pictorial demonstration of normal pancreatic ductal anatomy.

- While it is not clearly understood what roles the endocrine cells have in early development, endocrine function can be measured as early as 10 weeks of gestation. Glucagon-producing α cells differentiate first, followed by δ cells (somatostatin) and β cells (insulin).

VARIANT EMBRYOLOGIC ANATOMY

- The variants in anatomy that come with improper embryologic development may occur in up to 30% of patients, however, most are inconsequential.

Pancreas Divisum

- When there is incomplete fusion of the ventral and dorsal pancreatic buds, the intrapancreatic ducts also fail to fuse, leading to drainage of the main pancreatic (dorsal) duct through the minor papilla. Pancreatic divisum, as it is called, occurs in less than 5% of patients,[5] and only about 5% of those affected will develop symptoms. There are three types of pancreatic divisum. The first type (type 1) is the most common and occurs when there is complete separation between the dorsal and ventral pancreatic ducts. Type 2 (absent ventral pancreatic duct) and type 3 (small communication between dorsal and ventral pancreatic ducts) are far more rare, and of little clinical significance.[6] The most common associated symptom of pancreatic divisum is acute and/or chronic pancreatitis, and is most often seen in young women. Whether pancreas divisum itself is the cause of the pancreatitis, or merely a cofactor with other genetic predisposition, remains to be clearly understood.[7]

Annular Pancreas

- Annular Pancreas may occur when a bifid or dual ventral bud forms (**Fig. 52.2A**). These two ventral buds may rotate in opposite directions (**Fig. 52.2B**) around the septum, leading to a circumferential ring of pancreatic tissue around the second portion of the duodenum (**Fig. 52.2C**). It

is rare, although more common than previously thought, with an incidence of approximately 1 per 1,000.[8] It is thought to occur slightly more commonly in females and is usually an incidental finding in adults. When symptomatic, it can cause a range of symptoms from chronic abdominal pain to acute pancreatitis.[9] In neonates and children, symptoms can be more severe and will often present with duodenal obstruction. In these cases, operative intervention is usually necessary to bypass the obstructed segment of intestine.

- When annular pancreas is encountered incidentally in the operating room, care should be taken to avoid transection, as the pancreatic duct may lie within this tissue and transection can lead to leak or even a chronic pancreatic fistula.
- In some cases, the distal common bile duct traverses the pancreas at the region of the annular pancreas in such a way that it can lead to biliary obstruction and jaundice. These cases commonly require intervention either endoscopically or operatively to relieve the obstruction.

Ectopic or Heterotopic Pancreas

- In ectopic or heterotopic pancreas, pancreatic tissue forms elsewhere in the gastrointestinal tract. These pancreatic rests are devoid of vascular or anatomic communication to the actual pancreas.[10] There are four types of pancreatic heterotopia, depending on the type of tissue identified histologically (**Table 52.1**).[11] Heterotopic pancreatic tissue can occur anywhere within the GI tract but is most commonly found in the stomach followed by the duodenum, jejunum, and gallbladder. These lesions may cause symptoms including abdominal pain and fullness, or—when large enough—obstruction. In rare cases there can be malignant degeneration, and endoscopic ultrasound with biopsy can be helpful in establishing a diagnosis when these lesions are encountered.

Table 52.1 Types of Heterotopic Pancreatic Tissue as Defined by the Type of Tissue Identified on Histologic Examination

Type of Heterotopia	Distinction	Tissue Identified
I	Normal pancreas	Acini, ducts, and islet cells
II	Canalicular	Pancreatic ducts
III	Exocrine	Acini
IV	Endocrine	Islet cells

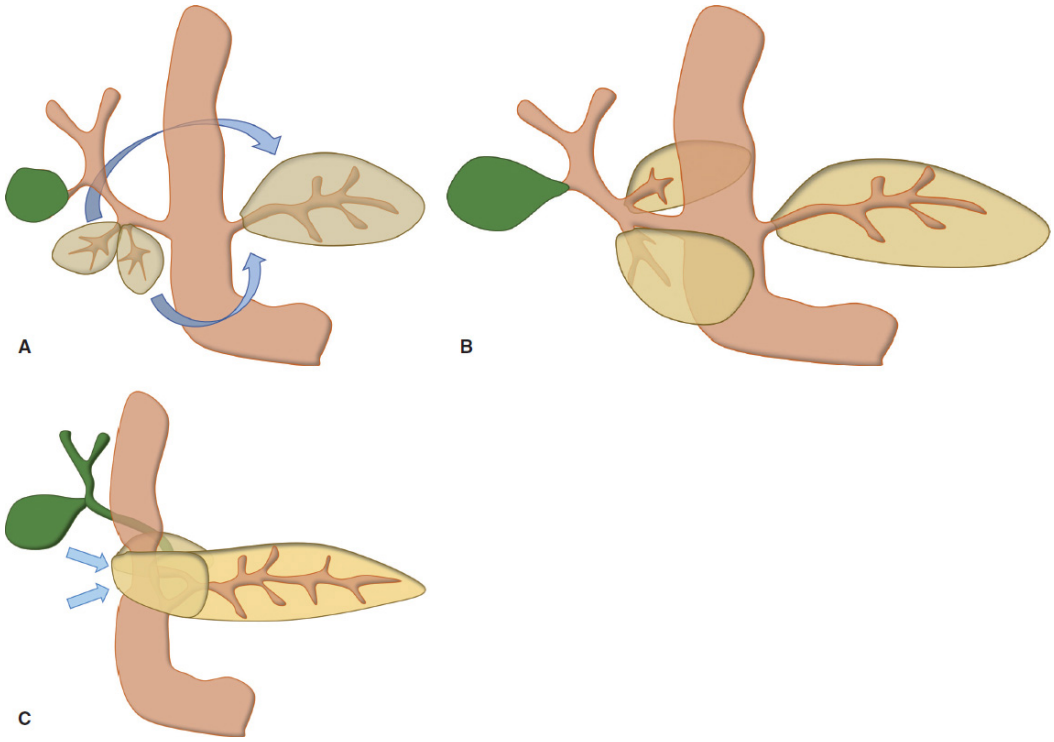

Figure 52.2 Annular pancreas can occur when two ventral buds form instead of one (**A**). These ventral buds then rotate in opposite directions around the growing duodenum (**B**). As they fuse with the dorsal duct, they can cause narrowing or stricturing of the duodenum (**C**), (*blue arrows*).

CELLULAR ORGANIZATION OF THE PANCREAS

- 4 The pancreas can be thought of as one gland with exocrine and endocrine functions. The cellular arrangement of the pancreas facilitates these functions. Up to 90% of the pancreatic tissue is exocrine in nature while only 1% to 2% of the pancreas is considered endocrine. The remaining tissue consists of pancreatic stroma and vasculature.

Exocrine Pancreas

- 5 The exocrine pancreas has two main functions: to produce enzymes for digestion and to deliver them into the intestine. The first function is carried out by the acini which produce all the enzymes and zymogens necessary to break down proteins, carbohydrates, and lipids for absorption by the small intestine. The acinus is the functional unit of the exocrine pancreas and consists of clusters of between 30 and 40 pyramidal cells that are arranged circumferentially around a central lumen, with their apices pointing toward the duct. These cells create the proenzymes (enzymes in their inactive form) and package them into zymogen granules for eventual secretion into the ductal network. Also important are the centroacinar cells, which secrete the fluid in which the proenzymes are delivered through the duct, and which keeps these proenzymes in their inactive form, at an alkaline pH around 8.0. The acinar cells and centroacinar cells deliver their secretions into the intercalated ducts, which then coalesce to form interlobular ducts. These interlobular ducts, in turn, empty through a network of secondary ducts and eventually into the main pancreatic duct for secretion into the duodenum.

Endocrine Pancreas

- The islets of Langerhans are the functional unit of the endocrine 6 pancreas. These islets can contain anywhere from a few hundred to several thousand cells. The dominant cells in the islets are the β cells, which primarily produce insulin.[2] The β cells account for up to 70% of the mass of the islet and are clustered toward its center. Further out from the β cells are the α and δ cells, which are arranged more circumferentially around the β cells. These cells make up as much as 20% of the pancreas.[12] The α cells produce glucagon which has a counter-regulatory effect to insulin. The δ cells produce somatostatin and vasoactive intestinal peptide (VIP). F cells (also known as PP cells) which produce pancreatic polypeptide (PP) and can account for up to 10% of the volume of the islet itself.[13] The remaining cells include epsilon (ε) cells which produce ghrelin, and C cells which produce substance P and serotonin.[12]
- The islets are well vascularized compared to their size, and account for 15% of the pancreatic blood flow.[3] The islets have an afferent arteriole and efferent venule, between which a rich capillary bed allows for transmission of the islet hormones into circulation.
- The cellular distribution of the islets is disproportionate throughout the gland. The islets in the tail of the pancreas are dominated by β and δ cells, whereas the proximal portion of the gland has more F cells. The glucagon-producing α cells are more evenly spread throughout the gland (**Table 52.2**).

Table 52.2 Pancreatic Endocrine Cell Types

Cell Type	% Islet Cell Mass	Major Hormone Secreted	Location within Islet	Location within Pancreas	Associated Tumor Syndrome
A (α)	10%	Glucagon	Peripheral	Evenly distributed	Glucagonoma: necrolytic migratory erythema, diabetes, hypoaminoacidemia
B (β)	70%	Insulin	Central	Body/Tail	Insulinoma: hypoglycemia and associated symptoms
D	5%[a]	Somatostatin	Evenly distributed	Body/Tail	Somatostatinoma: diabetes, gallstones, steatorrhea
D_2	5%[a]	Vasoactive intestinal peptide (VIP)	Evenly distributed	Body/Tail	VIPoma: high-volume secretory diarrhea, hypokalemia, metabolic acidosis, hypochlorhydria
F	15%	Pancreatic polypeptide	Peripheral	Head and uncinate process	Treatment directed at presenting symptoms
E C	<1%	Substance P, serotonin	Evenly distributed	Evenly distributed	None
G	Not present in normal physiologic state	Gastrin, ACTH-related peptides	Not applicable	Head, uncinate process, duodenum	Gastrinoma: acid hypersecretion, gastric/duodenal ulcers, diarrhea

[a]Combined D and D_2 mass.

- 7 The main function of the exocrine pancreas is to regulate serum glucose, through the secretion of glucagon and insulin. These hormones act in a paracrine fashion on the exocrine pancreas. As serum insulin rises, exocrine functions are stimulated, leading to increased enzyme and protein synthesis, and amino acid transport.[14] Glucagon acts in the opposing fashion, to downregulate pancreatic exocrine function. Somatostatin may act on β cells and the acinar cells in order to

downregulate pancreatic insulin secretion as well as pancreatic exocrine secretions, while VIP acts to increase water secretion in the pancreatic duct, decrease gastric secretion, and increase small intestine motility.[15]

PHYSIOLOGY OF THE PANCREAS

Exocrine Physiology

- The pancreas produces between 1.5 and 3 L of alkaline (pH 7.1 to 8.2) fluid per day, in which the secretory enzymes of the pancreas are delivered to the duodenum.[16] Maintaining a consistent alkaline pH is necessary for proper enzymatic function and provides a means to neutralize the acidic effluent of the stomach as it enters the duodenum.

Enzymatic Secretions

- Vagal innervation of the pancreas through cholinergic fibers acts as the primary stimulus for the acinar cells to increase the production and secretion of enzymes. Unlike classical synapses, neurotransmitters are released next to the islet cells, and norepinephrine and acetylcholine act on the islet cells themselves to stimulate or inhibit secretion of hormones.[17]
- Enzymes produced in the acinar cells can be grouped into those which act on carbohydrates (amylolytic), lipids (lipolytic), and proteins (proteolytic) (**Table 52.3**). Amylolytic enzymes, like amylase, break down carbohydrates into more easily digestible sugars such as maltose. Lipolytic enzymes such as lipase break down triglycerides into their main components: fatty acids and glycerols. Phospholipases break down cell membranes into arachidonic acids and phospholipids. The proteolytic enzymes (endopeptidases, exopeptidases, elastases, and nucleases) break down proteins into amino acids and nucleotides.
- Endopeptidases, like trypsinogen and chymotrypsinogen, are proenzymes, or zymogens, which are inactive forms of the enzymes. They are secreted by the acinar cells via the zymogen granules and into the apical duct lumen. They are not activated until they enter the duodenum, where enterokinase is secreted by the duodenal mucosa. The enterokinase then cleaves the endopeptidase, trypsinogen, initiating the proteolytic enzyme cascade where the remaining inactive precursor endopeptidases are converted into their active forms.
- The proportion of each of these groups of enzymes will fluctuate based on a variety of stimuli from neuropeptides, gastric acid secretion, and hormonal influences. Exocrine pancreatic secretion can be divided into three phases: cephalic, gastric, and intestinal (**Table 52.4**). The cephalic phase occurs with sensory stimulation, where the sight or smell of food triggers parasympathetic pathways via the vagal innervation to the acinar cells of the pancreas. The acinar cells, in response to acetylcholine and other neurotransmitters increase production of enzymes and zymogens which are brought toward the center of the acinus. The gastric phase occurs when food enters the stomach, stimulating additional cholinergic activation and further production of pancreatic enzymes and zymogens. Upon food entering the duodenum, the intestinal phase begins, primarily mediated by cholecystokinin (CCK), VIP, and secretin, which flood the ductal network with sodium bicarbonate solution and flush the products of the acinar cells into the main pancreatic duct for secretion through the ampulla of Vater and into the duodenum.

Table 52.3 Most Common Enzymes Secreted by the Exocrine Pancreas

Enzyme	Category	Target of Action	End Product
Amylases	Amylolytic	Carbohydrates	Oligosaccharides/Maltose
Lipases	Lipolytic	Lipids	Fatty acids/Glycerols
Phospholipases/Phospholipase B	Lipolytic	Phospholipids/Cell membranes	Arachidonic acids
Cholesterol esterases	Lipolytic	Cholesterol esters	Unesterified cholesterols/Fatty acids
Trypsin/Chymotrypsin	Proteolytic	Peptides	Amino acids
Carboxypolypeptidase	Proteolytic	Peptides	Amino acids
Nucleases	Proteolytic	DNA/RNA	Nucleotides

Bicarbonate Secretion

- Sodium bicarbonate solution is made up of water and sodium bicarbonate and is secreted by the centroacinar and terminal duct cells. The content of bicarbonate in pancreatic secretions can be as high as 145 mEq/L, as compared to bile (45 mEq/L) and serum (27 mEq/L).[18]
- When gastric acid enters the proximal duodenum, the cells of the duodenal mucosa release secretin. In addition, the presence of long-chain fatty acids and essential amino acids in the proximal small intestine leads to the release of CCK. Secretin, and to a lesser extent VIP and CCK, accelerate the uptake of bicarbonate from plasma and into the centroacinar and terminal duct cells of the acini.[19] Secretin increases cyclic AMP (cAMP) in these cells and activates the cystic fibrosis transmembrane conductance regulator (CFTR). The CFTR is primarily responsible for the exchange of bicarbonate for chloride, which is excreted back into the plasma in order to maintain anion balance.[18]
- Just as bicarbonate production by the centroacinar and terminal duct cells is activated via vagal stimulation it also inhibited by the vagus via the release of atropine, and further dampened in a paracrine fashion by the hormonal effects of glucagon, PP, and somatostatin.[3,4]
- Surgical transection of vagal innervation to the upper gastrointestinal tract via truncal vagotomy can decrease the production of sodium bicarbonate solution by as much as half.[20]

Exocrine Insufficiency

- Exocrine function can be impaired by a variety of means, including loss of functional pancreatic parenchyma (surgical resection, chronic pancreatitis) or secondary loss of exocrine pancreatic function or enzyme activity. Exocrine pancreatic insufficiency occurs when enzymatic production falls below 10% of normal.[21] Pancreatic exocrine insufficiency commonly presents with steatorrhea from insufficient lipase production.[22]
- Differentiating intestinal malabsorption from pancreatic exocrine insufficiency is the first step and can be done with a variety of tests with varying efficacy (**Table 52.5**). The most accurate tests are also the most invasive, often requiring duodenal intubation via Dreiling tube or endoscopy. Less invasive testing such as fecal fat and breath testing are easier, but less specific.
- Serum tests for amylase, lipase, and other enzymes are not useful in the diagnosis of pancreatic insufficiency as these enzymes are not elevated at baseline. Amylase, lipase, and trypsinogen are

all useful, however, in the diagnosis of acute pancreatitis, discussed elsewhere in this book.

- The etiology of exocrine pancreatic insufficiency must be determined in order to treat the patient properly.

Testing for Pancreatic Exocrine Insufficiency

Pancreatic Effluent Testing

- The secretin stimulation test is the gold standard test for pancreatic exocrine insufficiency. Historically this was done via a Dreiling tube. After fasting overnight, patients would undergo fluoroscopic placement of the tube and basal aspirate of duodenal contents were taken. Additional aspirates were taken every 20 minutes after secretin bolus (2 units/kg) for four successive measurements. Analysis of pancreatic secretions including total volume, amylase, and bicarbonate concentrations are used for diagnosis. More recently, endoscopic techniques have been employed to assess pancreatic output.[23] In endoscopic pancreatic function testing (ePFT), patients are given an intravenous bolus of secretin (0.2 µg/kg). Via endoscopic intubation, pancreatic secretions are aspirated and quantified at 30 and 45 minutes post injection. Peak bicarbonate concentrations less than 80 mmol are considered abnormal.[24] While easier for the patient, the endoscopic technique requires sedation and does not yield as much information as total volumes are not obtained, nor are basal rates for comparison. The results of secretin stimulation testing can differentiate between various causes of pancreatic exocrine insufficiency (**Table 52.5**).

Table 52.4 Three Phases of Pancreatic Exocrine Secretion

Phase	Initiated by	Mediated by	Action on	Result
Cephalic	Sensory stimuli (sight, smell, taste, etc.)	Vagus nerve	Acinar cells to produce digestive enzymes	Enzymes and zymogen granules are produced in the acini
Gastric	Food within the stomach	Vagus nerve	Acinar cells to produce and secrete digestive enzymes	Enzymes and zymogens accumulate in the ductal network
Intestinal	Emptying into duodenum	Secretin and cholecystokinin	Ductal cells secrete aqueous bicarbonate solution	Enzymes and zymogen granules are washed through the ductal network and into the duodenum for activation

Table 52.5 Differential Diagnosis of Intestinal and Pancreatic Steatorrhea

Parameter	Intestinal Steatorrhea	Pancreatic Insufficiency
24-hr fecal fat	<20 g; soapy consistency	>20 g; only seepage
D-xylose	Abnormal (low)	Normal
Secretin test	Normal	Abnormal
Small bowel series	Abnormal	Normal
Small bowel biopsy	Abnormal	Normal
PABA test	Normal	Abnormal
PP response to meal	Normal	Abnormal
Vitamin B_{12} and folate	Abnormal (low)	Normal
Treatment with pancreatic enzymes	No change	Improvement

- The Lundh test is a direct measurement of enzyme secretion. Similar to the secretin stimulation, patients fast overnight and the duodenum is then fluoroscopically intubated. A protein-, fat-, and carbohydrate-rich meal enters the stomach and duodenal aspirates are taken at 30-minute intervals for 2 hours.[25] Often, a promotility agent such as metoclopramide is given intravenously to stimulate gastric motility and emptying. The activity of trypsin, amylase, and lipase are analyzed. In patients with abnormal secretion of CCK or secretin, this test may yield a false-positive result.
- The most invasive of enteral access testing, the dimethadione (DMO) test is done over a period of 3 days and measures the pancreatic metabolism of trimethadione to dimethadione in the setting of secretin stimulation.[26] While highly sensitive and specific for pancreatic exocrine insufficiency, it is rarely employed.

Serum Testing

- While serum testing of amylase and lipase are not useful in diagnosing pancreatic exocrine insufficiency, serum testing of PP can be useful. This test is performed after a period of overnight fasting. A meal rich in carbohydrate, fat, and protein is given enterally. Basal and postingestion serum values of PP are obtained. If both basal levels and response levels are low (less than 100 pg/mL and less than 250 pg/mL, respectively) then a diagnosis of exocrine pancreatic insufficiency is appropriate. However, because PP release is dependent upon vagal innervation, prior gastric resection, truncal vagotomy, or chronic enteroneuropathic disease states such as diabetic gastropathy can lead to a false positive.

Urine Testing

- The BT-PABA test is much less invasive than those above. A 1-g bolus of N-benzoyl-1-tyrosyl paraaminobenzoic acid (BT-PABA) is given to the patient enterally. BT-PABA is cleaved by chymotrypsin in the intestine and the resultant PABA is excreted in the urine. Urine is collected over a 6-hour period and the total volume is analyzed. Concentrations less than 60% of the initial dose of BT-PABA given are consistent with exocrine pancreatic insufficiency.

Fecal Testing

- Quantitative analysis of fecal fat calls for patients to maintain a strict diet of 100 g of fat per day for 5 consecutive days and collect the full volume of feces for a period of 3 consecutive days. The coefficient of fat absorption is then quantified.[22] While accurate at diagnosis, it is cumbersome, unpleasant, and rarely utilized in clinical practice. A 24-hour fecal fat testing measures total volume of fat. In pancreatic insufficiency, this volume will be greater than 20 g. More often, a qualitative analysis or “spot” sample is procured and the acid stain of fat within the sample is analyzed. Fecal elastase has shown to be useful in the diagnosis of pancreatic exocrine insufficiency in chronic pancreatitis, but not in postpancreatic resection.[27] While useful in cases of severe pancreatic insufficiency, all fecal testing is less sensitive in mild and moderate cases.

Breath Testing

- This is a noninvasive test which is often used in conjunction with urinary or fecal elastase testing in the initial workup of steatorrhea. The mixed triglyceride (MTG) breath test involves giving the patient a small oral bolus of the radioactive isotope C^{14} bound to corn oil. Normal enzymatic digestion and absorption should produce carbon dioxide, which retains the radiolabeled carbon, and this can be quantified at the 4-hour mark in the patient’s breath. A more recent advent is the use of C^{13} which is not radioactive and therefore safer for patients, especially children.[27] It provides similar results to the C^{14} MTG test, with high sensitivity and specificity for steatorrhea,[28] but it cannot differentiate between intestinal malabsorption and true pancreatic exocrine insufficiency. However, in the latter case, patients should show improved excretion with oral pancreatic enzyme replacement.

All of these tests can aid in the diagnosis of exocrine pancreatic insufficiency. In practice, however, when there is a high suspicion, improvement with the addition of oral pancreatic enzyme replacement can be both diagnostic and therapeutic.

Endocrine Physiology

- The islet cells produce hormones that act in an endocrine and paracrine fashion to regulate serum glucose and affect carbohydrate metabolism. The two most important hormones are insulin (β cells) and glucagon (α cells), which act in opposition to one another. Insulin activates transport of glucose into cells and inhibits the breakdown of glycogen into glucose in the liver and muscle cells. It similarly inhibits the metabolism of fatty acids from the adipose tissues. Glucagon acts to increase serum glucose and simulate glycogen and fatty acid metabolism in the tissues. Somatostatin (δ cells) causes secondary hormone activation in the intestine, and likely plays a paracrine role on the other islet cells in response to hormone.[12] There is some evidence that endogenous somatostatin stimulates growth of pancreatic tissue.[29]

Endocrine Insufficiency

- Endocrine insufficiency is generally related to insulin. A loss of β cells, as occurs in type I diabetes, is most often due to autoimmune destruction. In these patients, the sensitivity to insulin is unaffected, and serum glucose homeostasis can be compensated with exogenous insulin. A loss of greater than 80% of β cells in the pancreas will generally lead to type I diabetes.[30] In type II diabetes, the islet cells produce insulin normally, but there is a loss of function or affinity for insulin on the cell surface, leading to elevated plasma glucose levels. Increased endogenous insulin stimulation, such as occurs with sulfonylureas, can be effective in type II diabetes, in addition to exogenous insulin.

Insulin

- Produced in the β cells, insulin is comprised of two small polypeptide chains, A and B, which are 21 amino acids and 30 amino acids long, respectively. These two chains are bound covalently via two disulfide bridges creating a 51 amino acid structure. The structure of bovine and porcine insulins is very similar to that of humans, making them the mainstay of treatment for diabetes up until synthetic insulin was created.
- Preproinsulin is synthesized in the endoplasmic reticulum, where it is cleaved to form proinsulin, the precursor to insulin. Proinsulin is cleaved by a protease in the secretory vesicles, forming active insulin and C-peptide, both of which are secreted into blood.
- Serum levels of exogenous insulin can be differentiated from endogenous insulin by the presence of C-peptide in the bloodstream.
- The exocytosis of cytoplasmic insulin occurs in a biphasic manner.[14] The first phase occurs with the release of prepackaged insulin at the plasma membrane. This occurs quickly, within the first 10 minutes of stimulation. The second phase is characterized by the synthesis of new hormone, and is slow, lasting as long as serum glucose remains elevated.
- Insulin has a half-life of 8 to 10 minutes and is metabolized quickly by nearly all cells in the body, the exceptions being red blood cells and cells of the brain, both of which depend on glucose constantly and cannot be dependent on insulin activation for its metabolism. In the liver, uptake and storage of glucose by hepatocytes can also be completed independent of insulin.
- Insulin receptors on the cell surface are activated with elevated serum insulin, leading to activation of glucose transporters in the plasma membrane facilitating the uptake of glucose into the cell.

- Insulin resistance is the hallmark of type II diabetes and can be due to a decrease in the number of insulin receptors or a loss of affinity for insulin. Similarly, reduced numbers and impaired activity of glucose transporters contribute to cellular insulin resistance and the further development of diabetes mellitus.[31]
- The enteroinsular axis, as described by Unger, demonstrates in increased activity of a variety of enteric hormones to glucose.[32] Gastric inhibitory peptide, CCK, glucagon, and glucagon-like peptide-1 (GLP-1) all stimulate insulin production and secretion, while somatostatin and pancreastatin are inhibitory.

Glucagon

- The preproglucagon gene encodes the precursors of glucagon as well as both GLP-1 and GLP-2. These latter two products are secreted in their inactive forms, while glucagon is secreted as a 29 amino acid polypeptide in its active form. Interestingly, in the small intestine, the reverse occurs, with GLP-1 and GLP-2 being secreted as active peptides and stimulating insulin secretion, while proglucagon remains inactive.[17]
- Glucagon is stimulated in direct response to hypoglycemia via three mechanisms: direct effects of hypoglycemia on the α cells, a release of suppression by the β cells, and autonomic stimulation of the α cells. The first two mechanisms are likely small, and it is the autonomic stimulation that is thought to be the major driver of glucagon secretion.
- Autonomic stimulation can occur via direct parasympathetic fibers that innervate the islet cells, or via direct or indirect sympathetic stimulation. Indirect sympathetic stimulation occurs from circulating epinephrine in response to stress.[33]
- Whereas insulin is an anabolic hormone, glucagon is highly catabolic. Its main effects are on the liver, as one might expect. Glucagon is secreted into the pancreatic venules and from there enters the portal circulation, acting on hepatocytes and causing an increase in glycogenolysis and gluconeogenesis in the liver.
- Glucagon oversecretion, as can happen with functional pancreatic neuroendocrine tumors, can lead to profound hyperglycemia. The opposite is true in patients who have undergone total pancreatectomy, where the absence of glucagon can cause hypoglycemia that can be difficult to control.

Somatostatin

- Secreted by δ cells, somatostatin is primarily secreted in response to rising serum glucose, as well as amino acids leucine and arginine.[34] Only 5% of somatostatin that is found in circulation, however, is from the islet cells, with the remainder coming from the gastrointestinal tract and hypothalamus.[12] This difference in distribution is why the majority of effects of somatostatin are seen either centrally or in the proximal GI tract, where somatostatin inhibits gastric, pancreatic, and biliary secretion.
- Somatostatin analogs, such as octreotide, are commonly used to slow intestinal transit and limit the effects of neuroendocrine tumors. It has also been variably shown to reduce fistula output in patients after pancreatic resection.[35]
- Less well understood are the paracrine effects of somatostatin. Somatostatin inhibits both insulin and glucagon from β and α cells, respectively. How this is accomplished is multifactorial but involves direct mediation via gap junctions as well as somatostatin receptors on the cells themselves.[12] It also has been shown to regulate islet cell growth. The dysregulation of somatostatin may affect hyperglycemia seen in diabetics.

Ghrelin and Pancreatic Polypeptide

- ε Cells produce ghrelin, known as the "hunger hormone" which acts in a paracrine fashion to stimulate somatostatin thereby inhibiting insulin and glucagon.[36] Its effects systemically are less well understood.
- PP has been shown to have numerous functions, the best known of which are its effects to decrease glucagon and hepatic gluconeogenesis and glycogenolysis. It has also been shown to decrease pancreatic and biliary secretions.

PANCREATIC ANATOMY

- Understanding 8 of the anatomic relationships of the pancreas with other organs is paramount for the surgeon.
  - Location: The pancreas is a retroperitoneal organ running somewhat obliquely from where its head, surrounded by the second and third portions of the duodenum, to its tail in the hilum of the spleen. Physiologically, the pancreas empties its exocrine contents from the tail, along the body and neck and through the head into the duodenum. However, anatomically we distinguish the head and uncinate process of the gland as proximal and the body and tail as distal.

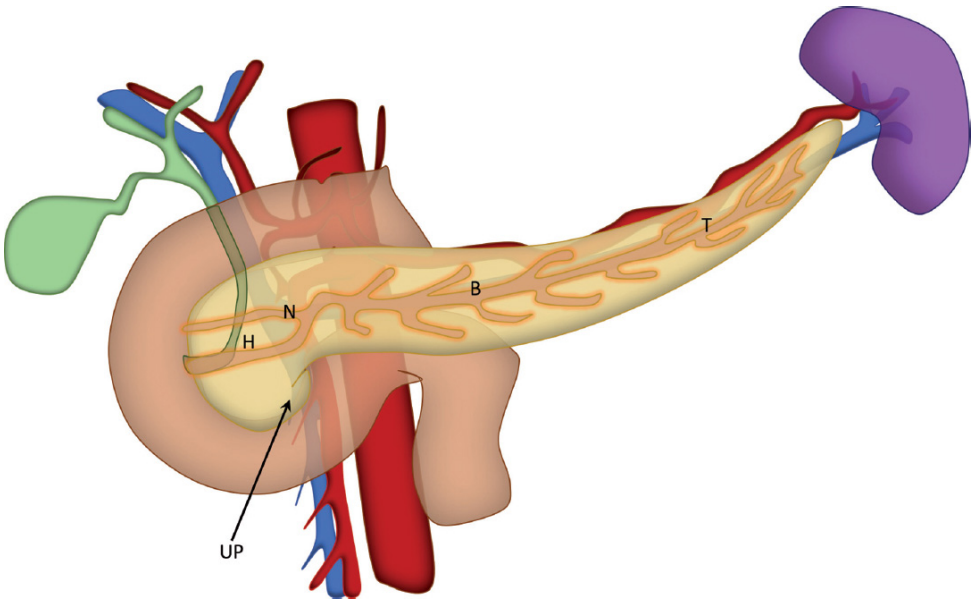

Figure 52.3 Pictorial demonstration of zones of the pancreas. H, head; UP, uncinate process; N, neck; B, body; T, tail.

  - Zones: The pancreas is often thought of as having four zones of significance: the head/uncinate process, the neck, the body, and the tail. However, there is little anatomic distinction between these areas, other than their relationship to adjacent organs and vasculature.
    - Head/Uncinate Process: The head of the pancreas is nestled within the second and third portions of the duodenum. It anatomically begins just to the right of the superior mesenteric vein. It is fused with the uncinate process which wraps inferiorly and posteriorly around the superior mesenteric vein and superior mesenteric artery (**Fig. 52.3**). Posteriorly the head and uncinate process lie atop the medial half of the inferior vena cava and the distal left renal vein, as well as the right renal artery. The common bile duct runs through the head of the pancreas and joins the pancreatic duct as they empty through the ampulla of Vater and into the duodenum.

- Neck: The neck of the pancreas is the region under which the superior mesenteric vein joins the splenic vein and empties into the portal vein. The superior mesenteric vein exits the aorta behind the neck and proximal body of the pancreas, running medially and slightly posterior to the superior mesenteric vein. During proximal pancreatic resection, the neck of the pancreas is divided.
- The body and tail of the pancreas lie posterior to the body of the stomach. Their anterior surface has a peritoneal layer, acting as the posterior reflection of the lesser sac. The posterior body and tail have no such layer, and lie in direct contact with the aorta, left adrenal gland, superior portion of the left kidney and the left renal vein and artery. The tail of the pancreas is variably intimate with the splenic hilum. The splenic vein and artery run posteriorly along its course prior to entering and exiting the spleen, respectively (**Fig. 52.4**). The distal transverse colon and splenic flexure lie along its anterio-inferior border.

- Vasculature: The arterial blood supply to the pancreas comes from the celiac axis.
  - The head/uncinate process and the neck of the gland are supplied by the gastroduodenal artery (GDA) which arises from the common hepatic artery as it leads into the proper hepatic artery. The GDA then produces the superior pancreaticoduodenal artery which has anterior and posterior branches. The inferior pancreaticoduodenal artery arises from the proximal superior mesenteric artery, and similarly divides into anterior and posterior branches. Together, these arteries form an intricate and well-collateralized supply to the proximal pancreas as well as the distal common bile duct and the duodenum. The ampulla of Vater receives its blood supply from the superior and inferior pancreaticoduodenal arteries, which produce three small branches at the 11, 1, and 6 o'clock positions (**Fig. 52.5**).
  - The body and tail of the pancreas receive blood from the splenic artery as it courses first posterior and then slightly superior to the gland. Along its course are several branches to the pancreas, the three most important of which being the dorsal pancreatic artery (proximal body), the great pancreatic artery (midbody), and the caudal pancreatic artery (pancreatic tail).
  - The venous drainage of the pancreas follows a similar distribution as the arterial supply. The superior aspect of the head of the pancreas drains via the superior venous arcade and into the portal vein. The inferior head and uncinate process drain into the superior mesenteric vein via the anterior and inferior venous arcades. The body and tail of the pancreas drain directly into the splenic vein via several branches, the most important of which are the caudal pancreatic vein, the great pancreatic vein, and the inferior pancreatic vein.
  - The inferior mesenteric vein does not receive blood from the pancreas, but lies behind the body of the pancreas, where it most commonly drains into the splenic vein, although it may also drain into the superior mesenteric vein or at the inferior confluence of the superior mesenteric vein and splenic vein.
  - Aberrant arterial anatomy exists in approximately 20% to 30% of patients (**Fig. 52.6**). The most common anomaly is a replaced or aberrant right hepatic artery arising from the superior mesenteric artery, which can occur over 20% of the time.[37] In these cases, the right hepatic artery courses posterior to the head of the pancreas and along the posterolateral aspect of the bile duct. Palpation of this border of the bile duct is paramount prior to any dissection to avoid unnecessary injury or transection. The second most common anomaly is the replaced left hepatic artery, which most commonly is supplied by the left gastric artery. In these cases, which occur in 5% to 10% of patients, the vessel can be found along the anterior border of the caudate lobe, entering the liver between segments 3 and 4, alongside the round ligament. It should be noted that either of these anomalies can present as an accessory artery, whereby there is some degree of duplication of the arterial inflow. In some cases the accessory artery

is more or less diminutive than the true artery. Care should be taken to avoid injuring these accessory vessels, even so, as they may provide important inflow to segments of the liver. Less commonly than the other two variants is the replaced common hepatic artery, whereby all the inflow to the liver is supplied by a common trunk arising from the superior mesenteric artery. This can occur up to 5% of the time. Unlike the replaced right hepatic artery, these course more medially, between the neck and head of the pancreas, and along the posteromedial border of the common bile duct.

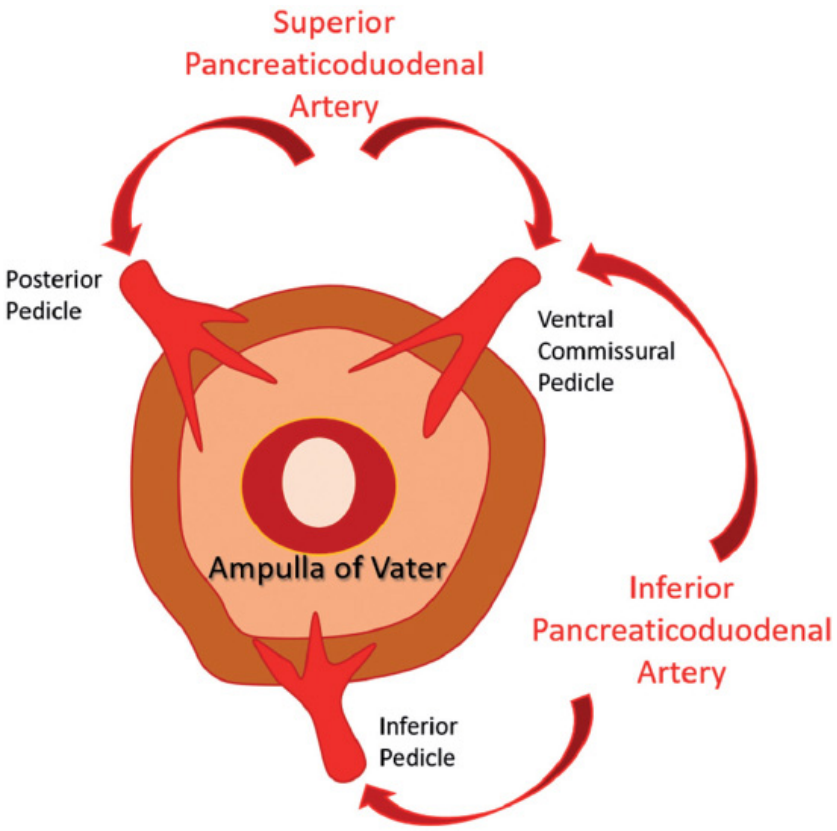

Figure 52.5 Pictorial demonstration of blood supply to the ampulla of Vater.

Lymphatics

- Due to its rich vascular supply and drainage, the pancreas has a similarly prominent lymphatic drainage. There are five major drainage patterns of the pancreas:
  - Superior: drain superior portion of pancreas head and neck
  - Inferior: drain inferior portion of pancreas head and uncinate
  - Anterior: drain prepyloric and infrapyloric regions
  - Posterior: portions of the head, distal common bile duct and, ampulla
  - Splenic: drain the pancreatic body and tail
- The 18 nodal stages as described by the Japanese Pancreas Society are presented in **Table 52.6**.

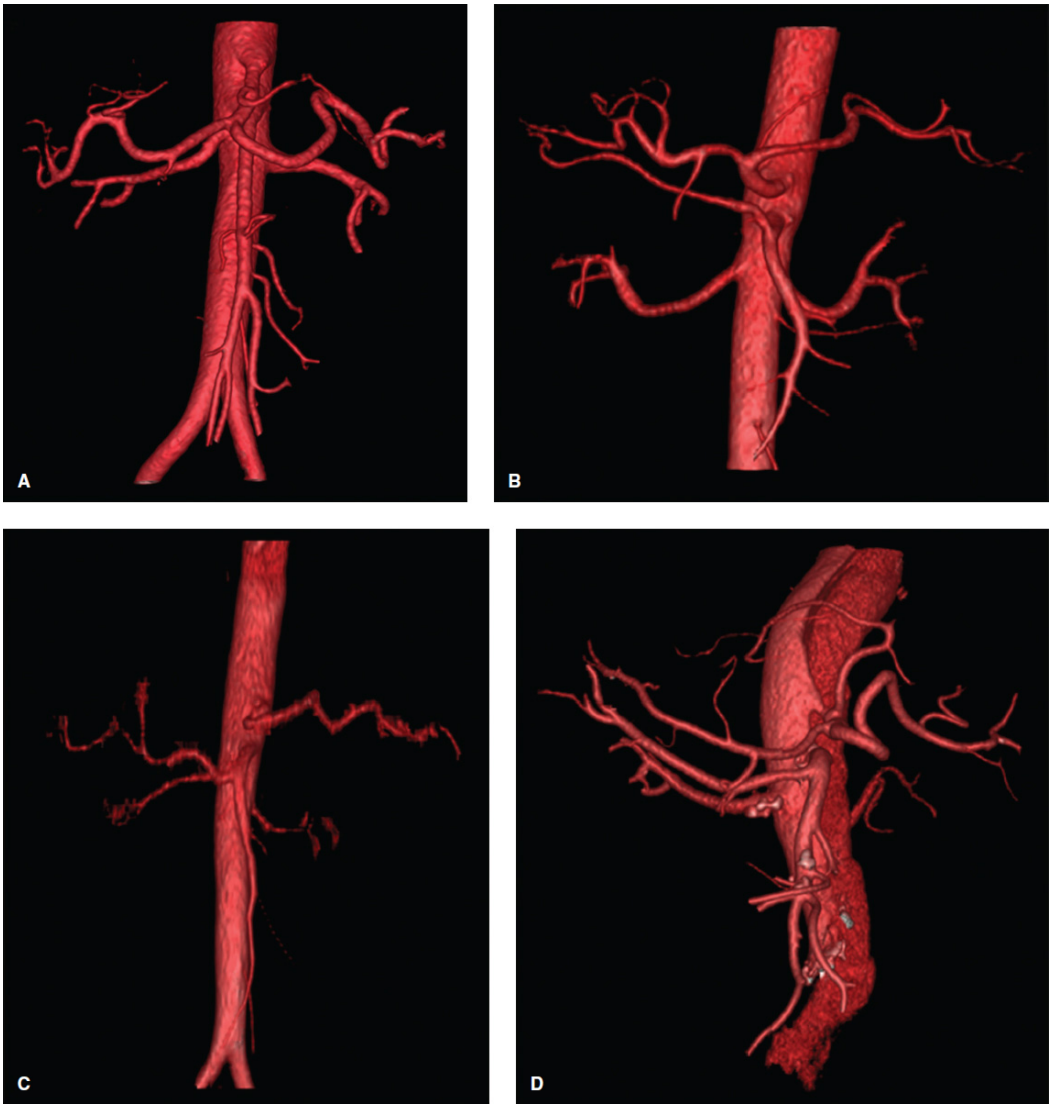

Figure 52.6 3D CT reconstructions of (**A**) Normal arterial supply to the pancreas, (**B**) Replaced right hepatic artery arising from the superior mesenteric artery, (**C**) Replaced common hepatic artery arising from the superior mesenteric artery, and (**D**) Replaced left hepatic artery arising from the splenic artery.

Innervation

- As previously noted, the pancreas is innervated via the vagus nerve as well as the thoracic splanchnic nerves. The sympathetic and parasympathetic nerves travel from the ganglia of the celiac axis and the proximal superior mesenteric artery. The sympathetic nerves inhibit exocrine and endocrine function while the parasympathetic nerves stimulate these functions. In addition to direct stimuli, the vagal branches also have secretory neurons which secrete both stimulatory and inhibitory hormones to the islets and acini. Sensory fibers from the pancreas track toward the celiac and superior mesenteric artery ganglia, which can be an important focus for pain control in patients with pain from pancreatic disease.

Table 52.6 Japanese Lymph Node Stations

Station Number	Name	Standard	Radical
3	Gastric lesser curve	No[a]	Yes[b]
4	Gastric greater curve	No[a]	Yes[b]
5	Superior pyloric	No[a]	Yes
6	Inferior pyloric	No[a]	Yes
8	Common hepatic artery	No	No
9	Celiac origin	No	Yes[c]
12	Hepatoduodenal ligament		
12a2	Proper hepatic artery near GDA	No[d]	No[d]
12b2	Bile duct below cystic duct	Yes[e]	Yes[e]
12c	Around cystic duct	Yes	Yes
12p2	Retro portal vein below cystic duct	No[d]	No[d]
13	Posterior pancreaticoduodenal	Yes	Yes
14	SMA and SMV nodes		
14a	Origin of SMA	No	No
14b	Right side of SMA	Yes[e]	Yes[e]
14c	Anterior SMA at middle colic	No	No
14d	Left side of SMA at first jejunal branch	No	No
14v	SMV nodes	Yes[e]	Yes[e]
16	Aortocaval nodes		
16a2	Celiac to left renal vein	No	Yes[f]
16b1	Left renal vein to IMA	No	Yes
17	Anterior pancreaticoduodenal	Yes	Yes

[a]Unless a distal gastrectomy is performed as part of standard resection.

[b]Some of these nodes may accompany the distal gastrectomy specimen.

[c]Sampled only.

[d]Not formally resected.

[e]Some of these nodes may accompany the pancreaticoduodenectomy specimen.

[f]Some of these nodes, cephalad to the left renal vein, but not required to dissect the celiac axis origin.

Acute Pancreatitis

Elizabeth Pando Rau, Rogier Voermans, Casper van Eijck, Hjalmar van Santvoort, and Marc Besselink for the Dutch Pancreatitis Study Group

Key Points

1. The annual incidence of acute pancreatitis (AP) varies from 13 to 45 per 100,000 persons.
2. In most Western countries, gallstones and/or bile sludge are the most frequent cause (up to 80%) of AP.
3. Diagnosis of AP according to the 2012 Revised Atlanta Classification (RAC) requires at least two of the following three criteria: (1) abdominal pain compatible with pancreatitis, (2) serum amylase and/or lipase of at least three times greater than the upper limit of the normal serum value, or (3) imaging findings consistent with AP.
4. Among the many methods to predict the severity of AP, the SIRS criteria are preferred.
5. The two most accepted classifications for the severity of AP are the three-tiered RAC and the four-tiered Determinant-Based Classification (DBC).
6. The use of crystalloid solutions such as Ringer lactate, or balanced saline solutions (Plasmalyte) are currently recommended in the early phase of AP, since they have advantages over the use of colloid solutions.
7. As current evidence is limited, pain can be managed according to general pain protocols.
8. The use of antibiotics in AP is justified as treatment of suspected or documented infection of necrosis, whereas prophylactic use in sterile necrosis is not recommended.
9. No benefits for the use of enteral probiotics were found; a higher mortality potentially related to nonocclusive mesenteric ischemia was observed.
10. Early oral nutrition is advocated in AP. Enteral nutrition (EN) can be used “on demand” when patients have no sufficient oral intake after 48 to 72 hours of AP. Early tube feeding within 24 hours holds no health benefits.

11 For infected peripancreatic collections, it is recommended to wait with percutaneous or endoscopic transluminal drainage until the collections have become walled off (which usually occurs after 3 to 4 weeks).

12 In almost 30% of patients, pancreatic (peri)necrosis will become infected, requiring invasive intervention in the vast majority of patients. Upfront open surgical necrosectomy is associated with high morbidity and mortality; it should be avoided if possible.

13 Laparotomy may still be indicated during AP in case of mesenteric ischemia or abdominal compartment syndrome (ACS). In both scenarios it is advised to leave the retroperitoneum intact to prevent spread of activated pancreatic enzymes into the peritoneal cavity and infect sterile retroperitoneal necrosis.

14 The treatment of choice for infected peripancreatic collections is the "step-up approach" in which the necrotic collections are drained mainly by catheter drainage first (percutaneous or endoscopic transluminal), and in the absence of clinical improvement, step up toward minimally invasive necrosectomy (e.g., video-assisted retroperitoneal debridement [VARD] or endoscopic transluminal). For percutaneous catheter drainage, ideally drains are placed just over Gerota fascia trough the retroperitoneum to facilitate retroperitoneal debridement.

15 If technically feasible and available, endoscopic drainage is preferred over the percutaneous route for drainage of (infected) walled-off necrosis (WON).

16 All patients with severe (acute) necrotizing pancreatitis should be treated by a multidisciplinary team consisting of HPB surgeon, gastroenterologist, and interventional radiologist.

EPIDEMIOLOGY

Acute pancreatitis (AP) is one of the most common gastrointestinal diseases requiring acute hospitalization in the Western world. 1 The annual incidence of AP varies from 13 to 45 per 100,000 persons.[1] Approximately 15% to 20% of patients develop a moderate–severe or severe form of the disease. In almost one-third of patients, pancreatic necrosis becomes secondarily infected, which is associated with mortality ranging from 15% to 39%.[2–4]

Approximately half of AP deaths occur within the first 2 weeks of illness, primarily due to multiple organ failure as a result of a severe systemic inflammatory response. The other patients die later due to complications secondary to pancreatic (peri)necrosis infection and subsequent interventions.[5,6]

AETIOLOGY

2 In most Western countries, gallstones and/or bile sludge are the most frequent cause (up to 80%) of AP.[1,7] With approximately 10% to 15% of cases, alcohol is the second most frequent cause of AP in most countries. Less common causes of AP include medication, endoscopic retrograde cholangiopancreatography, hypercalcemia, hypertriglyceridemia, surgery, and trauma (**Table 53.1**). Idiopathic acute pancreatitis (IAP) occurs in around 16% to 26% of patients, requiring additional diagnostic modalities in the follow-up (repeat transabdominal ultrasound, endoscopic ultrasound [EUS] or magnetic resonance cholangiopancreatography).[8] Meta-analyses show that in about 60% of patients with IAP, EUS can establish aetiology. This includes the detection of microlithiasis or biliary sludge (41%), chronic pancreatitis, or pancreatic tumors in up to 7% of IAP.[9]

Table 53.1 Etiology of Acute Pancreatitis

Gallstones
Alcohol
Iatrogenic causes ERCP Abdominal and nonabdominal surgery Cardiopulmonary bypass
Trauma
Neoplasms (e.g., pancreatic cancer, IPMN)
Pancreas divisum
Sphincter of Oddi spasm
Medications
Toxins Parathion Scorpion venom
Hyperlipidemia
Hypercalcemia
Infectious agents Viruses (e.g., mumps and Coxsackie B viruses; HIV) Bacteria (e.g., *Salmonella* and *Shigella* species; hemorrhagic *Escherichia coli*) Biliary parasites (e.g., *Ascaris lumbricoides*)
Genetic causes Cationic trypsinogen *PRSS1* mutations Pancreatic secretory trypsin inhibitor *SPINK1* mutations Cystic fibrosis transmembrane conductance regulator *CFTR* mutations
Autoimmune pancreatitis (lymphoplasmacytic sclerosing pancreatitis)
Vasculitis (e.g., systemic lupus erythematosus and polyarteritis nodosa)
Ischemia

Pregnancy

ERCP, endoscopic retrograde cholangiopancreatography.

AP, both alcoholic and nonalcoholic, may also develop into chronic pancreatitis. This progression may also be related to genetic mutations in the protease gene (PRSS1) that can present an autosomal dominant mutation. Other identified mutations that increase the risk of PC are mutations in the CFTR, SPINK1 and CTRC genes.[10–12]

In rare cases, AP can be the first presentation in patients with pancreatic cancer.[1,2] We recently found a 0.4% risk of pancreatic cancer during a median follow-up of 55 months after the first episode of AP. The median time between the first episode of AP and the detection of pancreatic cancer, in patients free from chronic pancreatitis, was 12 months. After a first episode of AP without a clear cause, physicians should be aware of the possibility of pancreatic cancer as the underlying disease and patients should undergo follow-up with endoscopic ultrasonography and computed tomography (CT).[13–15]

BILIARY PANCREATITIS

The prevalence of gallstones in Western countries is around 20%.[16] In 1901, Opie postulated that obstruction of pancreatic outflow causes pancreatitis, which triggered acinar cell damage.[17] In experimental studies, damage from bile reflux could not be demonstrated in the early stages of AP, only in cases of potentially infected bile.[18–20] Therefore, in acute biliary pancreatitis, sustained obstruction of the ampulla of Vater would ultimately trigger an increase in pressure in the pancreatic duct, which would ultimately be the source of acinar damage in biliary AP.[20–22]

ALCOHOLIC PANCREATITIS

Alcohol consumption is a known risk factor for AP. A meta-analysis showed a high risk of AP with a consumption of more than four alcohol units per day (RR = 2.5, 95% CI: 2.0 to 3.1).[23] Despite this, in animal models it has not

been possible to reproduce acute alcohol-mediated pancreatitis, requiring the addition of other factors such as cerulein, lipopolysaccharide, and ductal obstruction.[23] It is postulated that pancreatic toxicity is mediated by the oxidative and nonoxidative metabolism of ethanol, which ultimately favors the deposition of fatty acid ethyl esters "FAEEs" in acinar cells. This leads to an increase in the release of "Ca^{2+}" from the endoplasmic reticulum, with the activation of a compensatory mechanism of Ca^{2+} entry into the cytoplasm, which increases cellular damage. Similarly, the hydrolysis of the FAEES into fatty acids within the mitochondria favors mitochondrial damage. All of these events trigger cell death.[24,25]

CLINICAL PRESENTATION

AP presents as severe abdominal pain, usually sudden onset which may be associated with vomiting. The pain usually radiates to the back. Most patients seek hospital within 12 to 24 hours of the onset of symptoms. The abdominal examination shows epigastric sensitivity, with signs of peritonitis because of the retroperitoneal location of the pancreas.

PHYSIOLOGY

Following the acinar cells' necrosis, there is a release of activated pancreatic enzymes into the cellular interstitium, activating local vasoconstriction–dilation mechanisms. Infiltration of inflammatory cells occurs in the pancreatic parenchyma with the consequent increase of cellular necrosis.

In the most severe forms of AP, an aggressive cellular and humoral response develops, similar to septic shock, multiple trauma, and extensive burns. The magnitude and continuation of such events are attributed to the development of systemic inflammatory response syndrome (SIRS), which could lead to multiorgan failure in 30% of patients. Within the mediators involved are several cytokines, such as interleukin-1 (IL-1), IL-6, IL-8, tumor necrosis factor (TNF), and platelet activation factor (PAF). All of these mediators are remarkably elevated in the first 24 hours of the disease,

associated with a decrease in anti-inflammatory cytokines (IL-2, IL-10). As a result, activation of neutrophils, monocytes, lymphocytes, platelets, and endothelial cells occurs. There is an increase in the expression of cell adhesion molecules and integrins in neutrophils, favoring distant organ damage (especially the lungs); polymorphonuclear leukocytes appear causing extensive tissue destruction.[26,27]

Regardless of the aetiology of AP, there is an activation in very early stages of the disease of the protease precursor enzymes (trypsinogen). This favors the release of activated enzymes in the cellular cytosol, favoring mechanisms of cellular necrosis.[28–32]

Additionally, in recent years, the "gut-lymph concept" has gained interest, as a factor contributing to systemic multiorgan failure in AP mediated by an increase in the permeability of the intestinal barrier, favoring the translocation of primed neutrophils and intestinal toxic factors through circulation through the thoracic duct, in early stages, promoting multiorgan dysfunction syndrome.[33]

SEVERITY CLASSIFICATION AND PREDICTION

Revised Atlanta Classification

3 Diagnosis according to the 2012 Revised Atlanta Classification (RAC): the diagnosis of AP requires at least two of the following three criteria: (1) abdominal pain compatible with pancreatitis, (2) serum amylase and/or lipase of at least three times greater than the upper limit of the normal value, or (3) findings consistent with acute imaging pancreatitis (contrast-enhanced CT [CECT], MRI, or ultrasound).[34] For typical clinical and laboratory findings, no additional CECT or other imaging is required to confirm the diagnosis. The severity of AP is classified as mild, moderate, or severe: mild when no local or systemic complications are present; moderate in case of local (e.g., collections of peripancreatic fluid) or systemic (e.g., exacerbation of chronic disease) or transient organ failure (48 hours); severe in case of persistent organ failure (more than 48 hours).

Laboratory Test and Scores

Among the methods of predicting the severity of AP are several clinical and laboratory scores. One of the most used is the APACHE-II score (acute physiology and chronic health evaluation II), where a value equal to or greater than 8 is considered a high risk of developing a severe AP. Others are the BISAP score (bedside index for severity AP), the Ranson score, the modified 4 Glasgow/Imrie score, the presence of SIRS, the value of C-reactive protein, and recently the increased in blood urea nitrogen (BUN) and procalcitonin.[35–38] The IAP/APA treatment guidelines advise the use of the SIRS criteria built up from (1) temperature <36°C (96.8°F) or >38°C (100.4°F), (2) heart rate >90/min, (3) respiratory rate >20/min, and (4) white blood cells <4 × 10^9/L or >12 × 10^9/L.[39]

Clinical-Based Classifications: Atlanta Classification and Determinant-Based Classification

The two most accepted classifications are the three-tiered RAC and the four-tiered Determinant-Based Classification (DBC) (**Table 53.2**).[34,40]

In the RAC, severity is divided into three degrees: mild, moderate, and severe, based on the presence of transient or persistent organ failure, as well as the existence or absence of local 5 complications. The DBC includes the presence of organ failure and the existence or absence of necrosis infection, adding a severity level, critical AP, by combining persistent organ failure and infected necrosis. Both systems (RAC and DBC) are capable of accurately classifying the severity of the AP.[41]

TREATMENT

EARLY PHASE

Currently, in the absence of curative treatment, the management of the early stages of AP is based on supportive care, consisting of pain management, adequate fluid resuscitation, as well as optimal nutritional support. Interventions to reduce the inflammatory response have not achieved beneficial results and are therefore discouraged.[39,42]

Table 53.2 Definition of Severity of Acute Pancreatitis According to Current Classification Systems

Revised Atlanta Classification[35]
Mild AP ▪ No organ failure ▪ No local or systemic complications
Moderate severe AP ▪ Transient organ failure (<48 hrs) AND/OR local or systemic complications OR exacerbation of pre-existing comorbidities
Severe AP ▪ Persistent organ failure (single or multiple)
Determinant-Based Classification[36]
Mild AP ▪ No organ failure ▪ No peri(pancreatic) necrosis
Moderate AP ▪ Sterile (peri)pancreatic necrosis AND/OR transient organ failure
Severe AP ▪ Infected (peri)pancreatic necrosis OR persistent organ failure
Critical AP ▪ Infected (peri)pancreatic necrosis AND persistent organ failure

FLUID RESUSCITATION

Adequate fluid resuscitation is justified by the state of a systemic inflammatory response, which increases fluid extravasation to the third space, favoring hypovolemia and organ hypoperfusion, which is associated with organ failure in cases of severe AP.

The use of crystalloid solutions such as Ringer lactate, or balanced saline solutions (Plasmalyte) are currently recommended, since 6 they have advantages over the use of colloid solutions, which have been associated with increased mortality.[39,43,44] On the other hand, all fluid therapy must be closely monitored. The target measures include a heart rate <120/min, mean blood pressure between 64 and 85 mm Hg, and a urine output of at least 0.5 mL/kg/hr, a decrease in serum creatinine and hemoconcentration (less than 44%), the use of rapid or aggressive hydration not being recommended since both are associated with higher mortality and risk of abdominal compartment syndrome (ACS).[45,46]

PAIN MANAGEMENT

Pain is the predominant symptom of AP and should be treated promptly 7 and adequately. Frequent reassessment of pain scores and, if indicated, adjustment of analgesic types and/or dosages is needed to assure proper pain management. Several RCTs compared different types of analgesia in AP.[47–50] A systematic review on opioid use in AP and a recent meta-analysis reported that the quality of most of these RCTs is low, and no particular analgesic strategy is superior.[51,52] As current evidence is limited, pain can be managed according to general state-of-the-art pain protocols.

ANTIBIOTICS AND PROBIOTICS AS PROPHYLAXIS

Secondary infection of pancreatic or peripancreatic necrosis is one of the deadliest complications of AP.[53]

Bacterial translocation from the intestinal barrier is postulated as one of the mechanisms of necrosis infection.[54] Various RCTs have assessed the use of prophylactic antibiotics, without 8 conclusive evidence that this can

reduce the rate of infected necrosis but with increased risk of antibiotic resistant microorganisms.[55–59] Therefore, the use of antibiotics in AP is justified only if there is a documented infection of necrosis or because there is sufficient clinical suspicion.

Several RCTs investigated whether the use of enteral probiotics could influence the intestinal microbiome, reducing bacterial translocation, with initially promising results.[60,61] However, 9 in a subsequent larger multicenter RCT with 296 patients with predicted severe AP, no mortality benefits were found; on the contrary, higher mortality was observed, potentially related to nonocclusive mesenteric ischemia. Currently, the use of probiotics in severe AP is not recommended.[62]

NUTRITION

Enteral Nutrition

The use of enteral nutrition (EN) has been shown to be useful in AP, when compared to routine parenteral nutrition.

EN helps to maintain the integrity of the intestinal barrier, preventing bacterial translocation and bacterial overgrowth, which would ultimately prevent infection of the pancreatic necrosis (INP).[63,64] It is postulated that the benefits of EN are based on an immunomodulatory effect on the intestinal mucosa and on the systemic level, having an effect on the maturation and function of lymphocytes at the level of intestinal epithelial cells (IECs).[65] In experimental models, glutamine infusion decreased inflammatory activity at the IEC level, through the production of cytoprotective enzymes.[66,67]

Benefits have also been shown with respect to the decrease in the rates of multiorgan failure, and mortality, when compared with the use of routine total parenteral nutrition.[68,69]

10 The nasojejunal and nasogastric feeding routes are equivalent, with no differences in adverse effects compared to the nasogastric route.[70–72] In cases of mild AP, the oral route can be used when abdominal pain decreases.[73]

PORTO-SPLENO-MESENTERIC THROMBOSIS IN AP

The incidence of porto-spleno-mesenteric thrombosis (PSMVT) in AP varies from 1.8% to 57%, according to the literature.[74–76] The development of PSMVT is associated with the presence, location, and extent of pancreatic necrosis and the severity of AP. The rate of complications related to the PSMVT over the course of AP, is usually low.[76,77] Complications of PSMVT include: gastric variceal bleeding, splenomegaly, and less frequently, liver failure after progression of portal vein thrombosis. Systemic anticoagulation is advised, however, the recanalization rates vary from 11% to 86%, irrespective of the use of systemic anticoagulation.[75,77,78] It is unknown which patients are at risk to develop a progression of thrombosis; hypothetically, in this group of patients, the use of systemic anticoagulation would have a potential role.[79] Routine splenectomy after splenic vein thrombosis and splenomegaly is not recommended due to the low rate of complications in this group of patients.[74,76]

ENDOSCOPIC RETROGRADE CHOLANGIOGRAPHY IN ACUTE BILIARY PANCREATITIS

Several studies have investigated the role of routine endoscopic retrograde cholangiography (ERC) with sphincterotomy in biliary pancreatitis.[80] It is widely accepted that ERC is indicated in patients with concurrent cholangitis and pancreatitis. In patients with mild AP, early ERC is not indicated because of the lack of potential benefit, compared with the risk for complications.[39,81]

Recently, the results of a multicenter randomized trial showed that in patients with predicted severe acute biliary pancreatitis without cholangitis, early ERC with biliary sphincterotomy within 24 hours after presentation at the emergency department did not reduce the primary end point of death or major complications.[82]

LOCAL COMPLICATIONS OF AP

The RAC classifies local complications into four groups (**Fig. 53.1**).[34]

Collections associated with acute interstitial edematous pancreatitis: (1) acute collections of peripancreatic fluid, which are extrapancreatic and fluid; (2) pancreatic pseudocysts are typically extrapancreatic, encapsulated, contain fluid with no solid components, and develop after 4 weeks; they are rare after severe AP.

Collections associated with acute necrotizing pancreatitis: (3) acute necrotic collections, of early appearance, without clear delimitation, and (4) walled-off necrosis (WON), with encapsulated and thick walled necrosis.

The onset of WON is usually only after 3 to 4 weeks. A recent study found that WON developed in 40% of patients in the first 3 weeks.[83]

Pancreatic necrosis is observed in 5% to 10% of patients with AP and is characterized by the absence of intravenous contrast uptake of the pancreatic parenchyma on abdominal tomography. The computed tomography severity index (CTSI) classifies the percentage of pancreatic parenchymal necrosis and the presence of local alterations, giving a score of 1 to 10, finding an association of higher mortality for scores between 7 and 10.[84]

Extrapancreatic necrosis (EXPN): This involves the involvement of the peripancreatic tissues, generally peripancreatic, retroperitoneal, and mesenteric fat. The presence of EXPN has a better prognosis than pancreatic parenchymal necrosis. However, in cases of EXPN infection, a complication and mortality rate similar to pancreatic parenchymal necrosis was found.[85]

It is recommended that the abdominal CT be carried out 72 hours after the first symptoms of AP because in the first hours the necrosis is unlikely to have been established.

Performing pancreatic magnetic resonance imaging (MRI) can be useful for studying pancreatic fluid collections where the differential diagnosis of disconnection of the pancreatic duct is suspected, in addition to identifying the presence of solid components within the cyst cavity.[86]

MANAGEMENT OF LOCAL COMPLICATIONS

Peripancreatic Fluid Collections

Over the years, the treatment of peripancreatic collections and pancreatic necrosis has evolved. The current best practice is that conservative management should be used in most cases. There is wide acceptance that peripancreatic collections that are infected, or present symptoms that do not subside after a period of conservative treatment, should be drained.[39] Among the symptoms or complications of peripancreatic fluid collection (PFC) are abdominal pain, gastrointestinal obstruction, vascular compression, and biliary obstruction.[53]

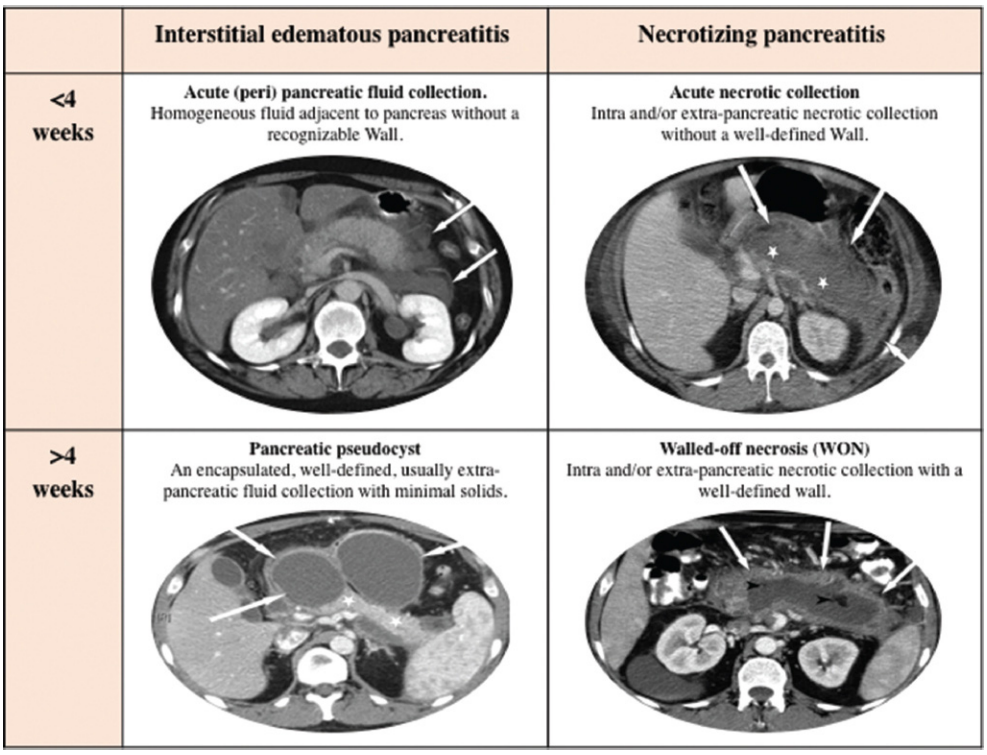

Figure 53.1 Collections associated with AP, according to revised Atlanta classification. (Adapted from Juneja D, Gopal PB, Ravula M. Scoring systems in acute pancreatitis: which one to use in intensive care units? *J Crit Care* 2010;25[2]:358.e9–358.e15.)

Generally, it is recommended to postpone drainage of infected collections until the stage of WON has been reached, this may take several weeks as mentioned earlier. This facilitates the approach of the collection, with a lower probability of bleeding and a greater probability of successful drainage due to greater adherence of the collection to the gastrointestinal

lumen for the endoscopic approach, for example.[87] Early intervention on infected PFC is associated with increased mortality, due to a lowering in the proinflammatory response in critically ill patients, reduced postoperative complications, and reduced number of procedure-related adverse events.[88,89]

Many collections deemed pancreatic pseudocysts on a CT scan in a patient with severe AP actually contain necrosis and should be diagnosed as WON or acute necrotic collection. Ultrasound or an MRI scan is better capable of detecting necrosis in a fluid predominant collection. This is relevant since the treatment of an infected or symptomatic pseudocyst is different from a collection with necrosis as the latter is easily infected when drained sterile.

Pancreatic pseudocysts can often be treated conservatively. Only in case of symptoms or infection is intervention needed. The spontaneous resolution of the pancreatic pseudocysts varies from 8% to 70% and depends on several factors: the presence of multiple locations, location in the pancreatic tail, communication with the main pancreatic duct and coexistence of stenosis, and increase in size during the follow-up.[90–92] There is no absolute size at which intervention is required; however, an increased risk of complications of cysts >5 cm in diameter has been reported, especially in the absence of decreased cyst size for 6 weeks.[34,92,93] Symptoms include persistent abdominal pain, pain in the side or back, partial or complete obstruction of the gastric or duodenal outlet with early satiety, anorexia, weight loss, bloating, vomiting or reflux, biliary obstruction, and jaundice. As mentioned, the most serious complications include infection, bleeding in the cyst, rupture, and erosions of the gastroduodenal and/or splenic artery, where intervention is necessary. Regarding the technique of drainage, the studies comparing different techniques (surgery, endoscopy, percutaneous drainage), do not demonstrate a clear superiority of one technique over another. In general, endoscopic transmural drainage is preferably used, especially when there is a favorable location of the pancreatic pseudocyst (perigastric or periduodenal), in addition to the lower risk of cutaneous pancreatic fistula compared to percutaneous drainage. It has also been described that surgical drainage seems to have a high clinical success rate; however, subsequent studies have shown similar results using endoscopy or percutaneous approaches.[94–96]

MANAGEMENT OF PANCREATIC NECROSIS AND ITS COMPLICATIONS

During the first 3 to 4 weeks after the appearance of acute necrotic 11 collection, it will resolve or encapsulate. Most of the necrotic collections are sterile and will resolve with conservative treatment, but in cases of infection, will mostly require an additional invasive intervention.[39]

Regardless of its size, an asymptomatic WON does not require intervention, since it mostly resolves spontaneously over time.[4,97] A larger size of WON, such as with extension into the paracolic gutter, and the extent of necrosis have been shown to be associated with the need for intervention.[75,90,98,99]

Intervention in a sterile collection carries the risk of secondary iatrogenic infection, with all its associated morbidity and mortality. A sterile necrotic collection without symptoms (e.g., abdominal pain or mechanical obstruction) may require intervention; however, due to the risk of secondary iatrogenic infection, attention should be focused on conservative treatment and interventions should be delayed for 6 to 8 weeks or longer.[4]

12 In almost 30% of patients, peripancreatic collections will become infected, requiring intervention in the vast majority of cases. A small percentage of patients can be treated just with antibiotics.[100,101] Since early open surgery is associated with high morbidity and mortality, it should be avoided whenever possible.[102]

13 There are exceptional indications for early urgent laparotomy such as the presence of mesenteric ischemia and ACS as a direct consequence of AP, which are indications for open surgery.[103]

STEP-UP APPROACH

14 Necrosect omy in the first 2 weeks of AP carries a high risk of morbidity and mortality and should therefore be avoided.[88,89,102] However, percutaneous drainage can be performed early in the course of infected necrotizing pancreatitis.

Previously, a primary open necrosectomy was the preferred treatment. This was associated with high mortality and morbidity rates. Currently, the treatment of choice is the "step-up approach" in which the necrotic collections are drained mainly by less invasive methods (percutaneous drainage, or endoscopic drainage through stents), and in the absence of clinical improvement, there is a "step-up" toward surgical necrosectomy (minimally invasive initially).[104] This intensive approach reduces rates of new-onset multiple organ failure, morbidity, serious adverse events, and lower costs compared to primary open necrosectomy, which has since been largely abandoned.[105] In the step-up approach, almost half of patients can be treated with drains alone, while the other half requires additional different procedures for the final treatment, including percutaneous, endoscopic, open, or minimally invasive surgery.[42,104]

Percutaneous catheter drainage can be a sufficiently definitive treatment in up to 56% of patients.[106] An analysis showed that percutaneous drainage with antibiotics alone was a successful treatment in 50% of patients.[107] Upgrading percutaneous drains toward larger calibers (i.e., upsizing) facilitates the drainage of the collection.[104] Currently, the multicenter POINTER trial is underway to study the immediate drainage by percutaneous catheter of infected necrosis in comparison to the standard conventional approach (step-up approach).[108]

MINIMALLY INVASIVE NECROSECTOMY

If the patient with infected pancreatic necrosis does not recover with drainage alone, a necrosectomy will be required. Traditional open necrosectomy has largely been replaced by minimally invasive techniques. Of these, the most widely used techniques include sinus tract endoscopy and video-assisted retroperitoneal debridement (VARD),[109,110] see **Figure 53.2**. As part of the "step-up approach," a 12- to 14-Fr percutaneous drain is placed in the pancreatic (peri)collection through the left retroperitoneum. If drainage does not lead to clinical improvement, surgical intervention is considered necessary and VARD is proposed. This technique can be considered a hybrid between pure endoscopic retroperitoneal necrosectomy and the open translumbar approach (20-cm incision). In VARD, the small

incision allows the surgeon to remove larger pieces of necrosis, with shorter operation time and less need for repetitive procedures. These minimally invasive techniques showed reduced morbidity and mortality, especially in high-risk patient groups.[111]

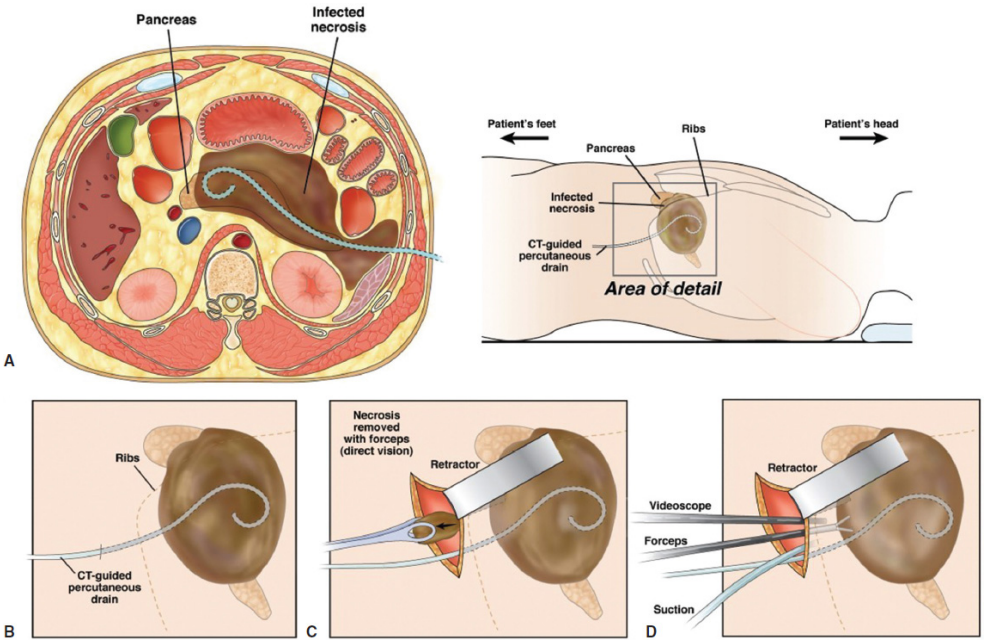

Figure 53.2 Surgical step-up approach. **A:** Cross-sectional image and torso depicting a peripancreatic collection with fluid and necrosis. The first step of the surgical step-up approach is percutaneous catheter drainage. The preferred access route is through the left retroperitoneal space between the left kidney, dorsal spleen, and descending colon. If necessary, percutaneous catheter drainage is followed by a minimally invasive surgical necrosectomy, for example, videoscopic-assisted retroperitoneal debridement. **B:** Enlargement of the area of detail shown in part A of the figure. **C:** A 5-cm subcostal incision is made, and the previously placed percutaneous drain is used as a guide into the retroperitoneum to enter the necrotic collection. The first necrosis is removed under direct vision with a long grasping forceps. **D:** Further debridement is performed under videoscopic assistance. (Reprinted from van Brunschot S, van Grinsven J, Voermans RP, et al. Transluminal endoscopic step-up approach versus minimally invasive surgical step-up approach in patients with infected necrotising pancreatitis (TENSION trial): design and rationale of a randomised controlled multicenter trial [ISRCTN09186711]. *BMC Gastroenterol* 2013;13[1]:161. *Open access*.)

15 ENDOSCOPIC NECROSECTOMY

In recent decades, transmural (i.e., transgastric) endoscopic management of acute necrotizing pancreatitis is increasingly used. Various endoscopic techniques are used for the treatment of WON, all of which include EUS-guided transmural access to the cavity, **see Figure 53.3**. EUS-guided drainage and/or necrosectomy has had an advantage over the conventional transmural endoscopic approach due to greater technical success.[92,93,107] Compared to surgical necrosectomy, an endoscopic approach significantly reduces the proinflammatory response and improves the clinical outcome in patients with ANP.[112] However, when used as a single-modality approach, it requires more necrosectomy sessions for definitive treatment than in combination with other interventional procedures.[113] A meta-analysis found that endoscopic necrosectomy has a success rate of 81% as a single treatment modality, with a complication rate of 36%.[114] The multicenter randomized controlled TENSION trial, compared the endoscopic step-up approach with the surgical step-approach. Both procedures were found to have similar mortality and morbidity rates. However, the endoscopic step-up group had a lower incidence of pancreatocutaneous fistula and shorter hospital stay.[111]

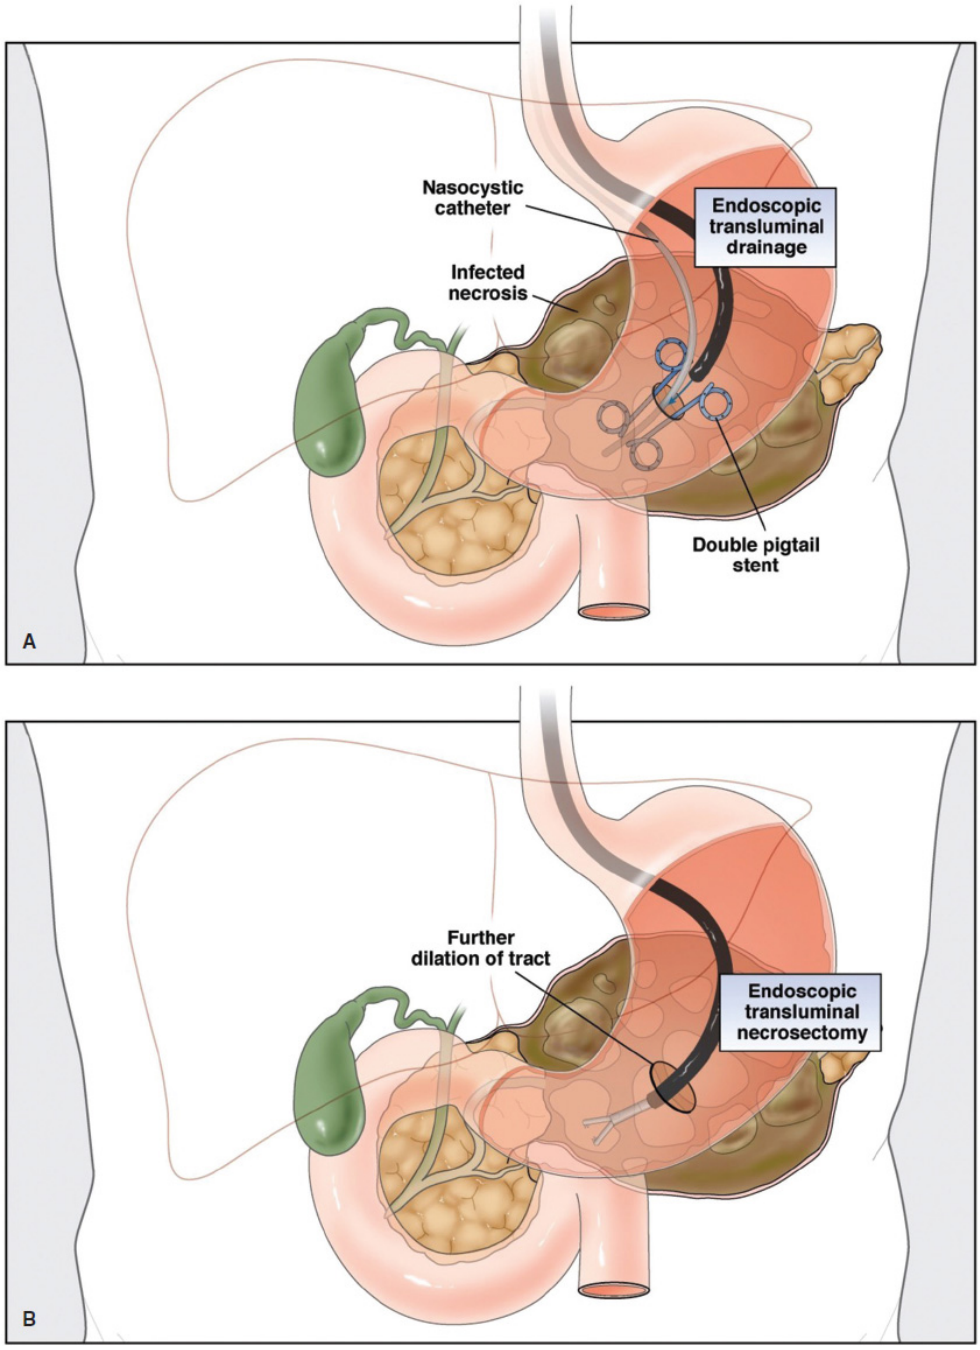

Figure 53.3 Endoscopic step-up approach. **A:** The first step of the endoscopic step-up approach is endoscopic transluminal drainage. The preferred access route for endoscopic transluminal treatment is through the posterior wall of the stomach. The necrotic collection often bulges into the stomach, facilitating endoscopic transluminal treatment. The collection is punctured through the gastric wall, followed by balloon dilatation of the tract. Two double-pigtail stents and a nasocystic catheter are placed for continuous postoperative irrigation. **B:** If necessary, the cystostomy tract is further dilated, the collection is entered by a forward-viewing endoscope, and necrosectomy is performed. (Reprinted from van Brunschot S, van Grinsven J, Voermans RP, et al. Transluminal endoscopic step-up

approach versus minimally invasive surgical step-up approach in patients with infected necrotising pancreatitis (TENSION trial): design and rationale of a randomised controlled multicenter trial [ISRCTN09186711]. *BMC Gastroenterol* 2013;13[1]:161. *Open access*.)

Endoscopic drainage of infected pancreatic necrotic collection has evolved, from the use of a small plastic stent to lumen-apposing metal stent (LAMS), with a specific biflanged design that facilitates the creation of a stable and sealed fistula between the gastric or duodenal wall and the WON. Retrospective series showed very promising results with clinical success in up to 89% of cases. However, LAMS is related to a significant rate of adverse events (25.4%).[115,116] The only randomized controlled trial comparing plastic double pigtail stents showed no difference in clinical important outcome parameters. Ongoing trials will show the definite role of LAMS for drainage of WON.[117]

16 All patients with severe (acute) necrotizing pancreatitis should be treated by a multidisciplinary team consisting of HPB surgeon, gastroenterologist, and interventional radiologist.

Chronic Pancreatitis

Katherine A. Morgan

Key Points

1. Chronic pancreatitis (CP) is heterogeneous in etiology with an increasingly recognized role of genetic factors and smoking.
2. The most common indication for intervention in CP is severe, debilitating abdominal pain.
3. Medical and endoscopic therapies are frontline management of CP, but are often unsuccessful.
4. Surgical intervention is aimed at achieving durable pain relief with least perioperative and long-term morbidity.
5. Innovative surgical therapies for CP, including minimally invasive approaches and total pancreatectomy with islet autotransplantation (TPIAT), have gained increasing enthusiasm.

INTRODUCTION

The surgical management of chronic pancreatitis (CP) has evolved significantly in the modern era. The increasing recognition of genetic mechanisms for pancreatitis and the role of smoking in pathophysiology of

CP have changed the patient demographic as well as treatment strategies, including the surgical algorithm. Additionally, potentially field-altering research is currently being undertaken on genetics, molecular pathways, and clinical outcomes in CP.

CP is a benign inflammatory disorder of the pancreas, resulting in progressive fibrotic replacement of parenchyma. The most notable clinical presentation is severe, debilitating, and unremitting abdominal pain, often with associated nutritional failure. CP leads to progressive endocrine failure due to islet loss (type 3c diabetes mellitus)[1] and exocrine failure (malabsorption). Importantly, patients have significant impairments in quality of life.

EPIDEMIOLOGY

CP is a significant public health concern. Its prevalence and annual incidence are estimated at 0.2% to 0.6% and 7 to 10/100,000, respectively in the United States and Europe.[2] The economic impact is notable, with estimated annual healthcare expenditures for pancreatitis in the United States in 2004 at $3.7 billion.[3]

ETIOLOGY

Historically, alcohol use has been the most commonly implicated etiologic factor in CP in the Western world. A more recent multi-institutional observational study by the North American Pancreatitis Study 2 (NAPS2) Group revealed a lesser contributory role for alcohol.[4] Dose and duration of alcohol consumption have been demonstrated to be contributory to CP development, although several more recent studies suggest that alcohol alone is not sufficient to cause CP. Byproducts from ethanol metabolism injure acinar cells and can activate pancreatic stellate cells (PSCs) to form extracellular matrix. Recent investigation suggests an association between alcoholic pancreatitis and a locus on the X chromosome.[5]

1 Smoking is a significant risk factor in the development of CP. Tobacco consumption has been associated with pancreatic calcifications

radiographically.[6] Synergistic effects of smoking and alcohol have been described.[7] More recently, NAPS2 has shown that smoking is an independent risk factor for CP in a dose-dependent fashion.[4] In addition, tobacco use has been shown to be a strong risk factor for the progression of acute pancreatitis to CP, suggesting a role for smoking in pancreatic fibrogenesis.[8]

Genetic causes for pancreatitis have been a major focus of advancement in the evolving understanding of CP in the current era. In 1952, Comfort and Steinberg described hereditary pancreatitis (HP),[9] and in 1996, Whitcomb and colleagues delineated a mutation in the cationic trypsinogen gene PRSS1, which results in the inappropriate activation of trypsin and is responsible for HP.[10] HP is an autosomal dominant disorder with 80% penetrance, marked by recurrent acute pancreatitis beginning in early childhood, progression to CP in many, and a greatly (50×) increased risk of pancreatic cancer beginning in the fifth decade. Since, several other mutations in the PRSS1 gene have been identified. In addition, multiple other genetic foci have been implicated as contributing agents in CP as well, primarily related to the inappropriate activation of trypsin. Pancreas secretory trypsin inhibitor (serine protease inhibitor, Kazal type 1, and SPINK1),[11] cystic fibrosis transmembrane conductance regulator (CFTR) gene, chymotrypsin C (CRTC),[12] calcium-sensing receptor (CASR) gene,[13] and gamma-glutamyltransferase 1 (GGT1) gene[14] have all been elucidated as conferring a susceptibility to CP development. Conversely, the anionic trypsinogen gene PRSS2 may confer a protective advantage against the development of pancreatitis.

Clearly, the etiology of pancreatitis is variable, complex, and incompletely understood.

PATHOPHYSIOLOGY

The pathophysiology of CP is not well elucidated. A theory known as the "three-hit hypothesis" holds that (1) a stochastic event occurs resulting in (2) inappropriate trypsin activation causing acute pancreatitis. The patient then has (3) an unfavorable immunologic response to the inflammation resulting in fibrosis and CP (**Fig. 54.1**).[15] Environmental factors (e.g., alcohol) are

common inciting events in the cascade, with key modulating factors being genetics and the histologic milieu.

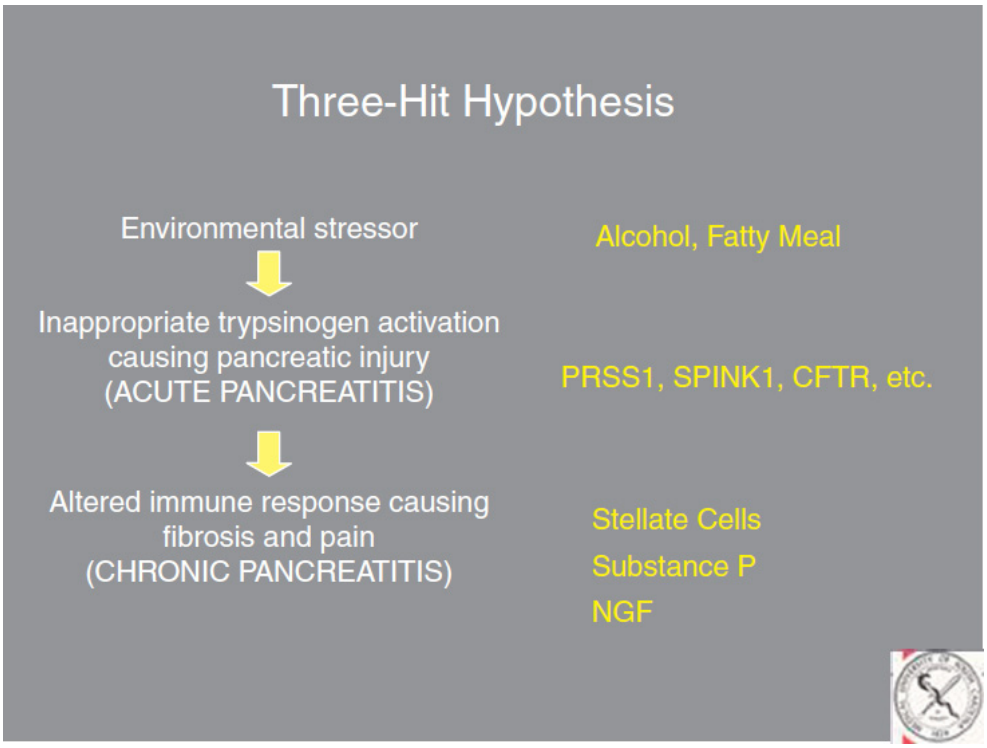

Figure 54.1 Three-hit hypothesis for pathophysiology of chronic pancreatitis. NGF, nerve growth factor. (Adapted from Whitcomb DC. Genetic risk factors for pancreatic disorders. *Gastroenterology* 2013;144:1292–1302.)

Insights into pathophysiology of pancreatitis have occurred through advances in cellular basic science. PSCs are causative in pancreatic fibrogenesis. PSCs are residents of the healthy pancreas that become activated by inflammatory cytokines during pancreatitis to become myofibroblast-like cells, producing extracellular matrix in the interstitial space.[16] In addition, several matrix metalloproteinases are implicated in altering extracellular matrix remodeling and collagen degradation, enhancing fibrogenesis and irreversibly altering the organ architecture to a diseased, fibrotic pancreas.[17]

The CP pain syndrome has complex pathophysiology. Classical theory holds that pancreatic ductal obstruction due to fibrosis results in elevated intraductal and intraparenchymal pressures which cause pain. More recent theories focus on peripancreatic neuropathy. On a histologic level, peripancreatic neuronal hypertrophy as well as infiltration of the periaxonal

tissue with inflammatory cells is evident.[18,19] Increased presence of the "pain neurotransmitters" is identified, including calcitonin gene-related peptide and substance P, stimulated by nerve growth factor.[20] These changes in the peripancreatic neuronal milieu may contribute to peripheral neural remodeling and central neural sensitization that make the CP pain syndrome uniquely severe and vexing to manage.

CLINICAL PRESENTATION

2 The primary presentation of CP is severe, intractable epigastric abdominal pain that radiates into the back. The classic pain is constant with periods of exacerbation. Patients often have associated gut dysfunction, with nausea, emesis, and difficulty tolerating a diet consistently, particularly during pain episodes. Patients may develop endocrine failure (pancreatogenic diabetes, type 3c) and exocrine pancreatic insufficiency (EPI) over time. Less often, patients may present with an acute complication of CP such as biliary or duodenal obstruction, a pancreatic pseudocyst, pancreatic ascites, mesenteric venous thrombosis, or mesenteric arterial pseudoaneurysm (**Table 54.1**).

On physical examination, patients generally appear malnourished. Abdominal tenderness in the epigastrium may be elicited. Significant laboratory values to note include chemistries to assess dehydration and acidosis, a hepatic panel to investigate biliary obstruction or malnutrition, and serum amylase and lipase which may be elevated or may be normal in advanced disease.

RADIOGRAPHIC EVALUATION

Radiography is important in both diagnosis and management of CP. Multiphase, contrast enhanced abdominal computed tomography (CT pancreas protocol) can show pancreatic parenchymal changes of pancreatitis including edema, fibrosis, and atrophy. Pancreatic ductal dilation may be evident, as well as intraductal or intraparenchymal calcifications (**Fig. 54.2**). CT can be helpful in identifying complications of pancreatitis such as biliary

or duodenal obstruction, pseudocysts or ascites, or mesenteric vascular complications. Magnetic resonance pancreatography (MRP) can be useful in revealing parenchymal changes in enhancement and secretion (T1-weighted images) and ductal changes (T2-weighted images), particularly with the addition of secretin stimulation (**Fig. 54.3**). With increased capabilities of MR technology, MR imaging has largely replaced endoscopic retrograde cholangiopancreatography (ERCP) in diagnosis of CP. In the modern era, ERCP is utilized for therapeutic means including endoscopic sphincterotomy, dilation, and stenting. Endoscopic ultrasound (EUS) is useful for evaluation of pancreatic parenchyma and ductal anatomy. EUS has a grading system to objectify and document pancreatitis disease severity, although the system is flawed by interobserver variability (**Table 54.2**).[21]

Table 54.1 Complications of Chronic Pancreatitis

Pain	90%
Pseudocyst	25–30%
Biliary stricture	10–15%
Mesenteric venous thrombosis	5–10%
Duodenal stricture	4–5%
Pseudoaneurysm	2–3%
Pancreatic adenocarcinoma	2–4%[a]
Extrapancreatic malignancy	10–15%

[a]Risk of pancreatic cancer is 2% after 10 years and 4% after 20 years with chronic pancreatitis.

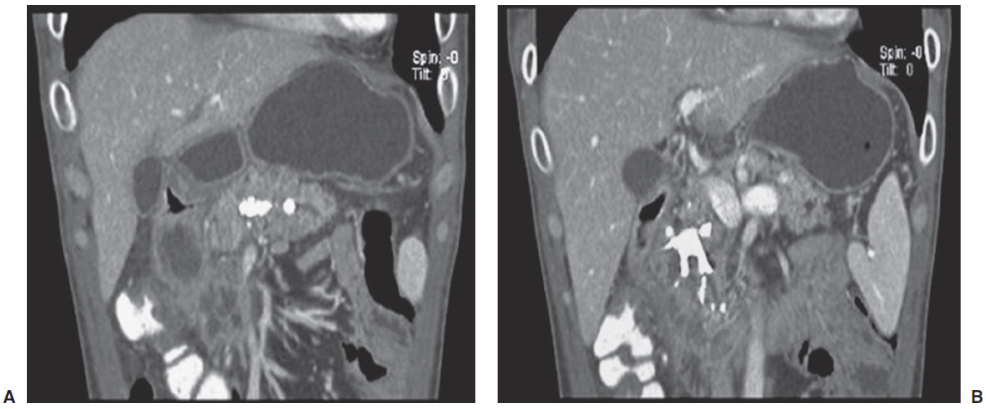

Figure 54.2 Contrasted CT scan in venous phase; coronal images showing (**A**) dilated main pancreatic duct with intraductal stones and (**B**) significant fibrotic disease burden in the head of the pancreas with intraparenchymal and intraductal calcifications.

CONSIDERATIONS IN MANAGEMENT

3 Frontline management of CP includes risk factor modification, such as alcohol and tobacco cessation. Primary medical interventions entail pain management, including adjunctive behavioral therapy, and nutritional optimization, including pancreatic enzyme replacement therapy. Behavioral therapy is a keystone of therapy in CP and is effective in modulating pain perceptions and in managing opioid misuse.[22]

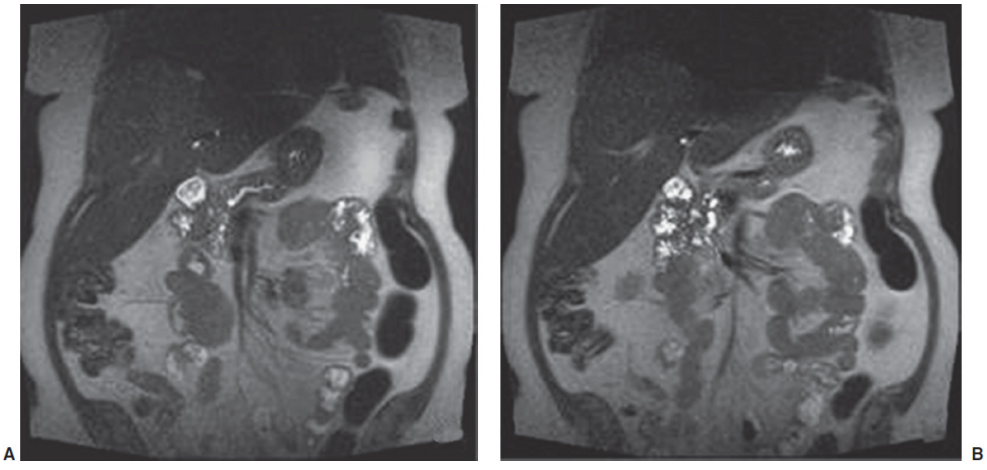

Figure 54.3 T2-weighted magnetic resonance imaging with secretin stimulation demonstrate a pathologically dilated pancreatic duct in the body of the pancreas (**A**) and cystic changes and dilated ducts in a fibrotic and inflammatory head of the pancreas (**B**).

ENDOSCOPIC MANAGEMENT

ERCP is the primary endoscopic modality for therapy in CP, with the goal of relieving obstructive pathology. Potential maneuvers include sphincterotomy, stone extraction, stricture dilation, and stenting.

EUS can be utilized for endoscopic pseudocyst drainage procedures and for celiac plexus neurolysis. Percutaneous and endoscopic-guided celiac nerve blockade has been utilized to manage CP pain. Meta-analysis studies of EUS-guided celiac plexus blockade found short-term pain relief in about one-half of the subjects.[23]

Table 54.2 EUS Criteria for Chronic Pancreatitis

Parenchymal Criteria
Hyperechoic foci

EUS, endoscopic ultrasound.

From Wallace MB, Hawes RH, Durkalski V, et al. The reliability of EUS for the diagnosis for chronic pancreatitis: Interobserver agreement among experienced endosonographers. *Gastrointest Endosc* 2001;53:294–299.

In general, the endoscopic approach is undertaken prior to consideration of surgery, given the perceived advantages of lower morbidity with a less invasive approach. Two prospective, randomized, controlled trials have compared endoscopy and surgery in patients with obstructive CP. Dite and colleagues randomized 72 patients with CP, pancreatic duct obstruction, and pain to endoscopic or surgical intervention. At 5-year follow-up, the surgical group had a greater proportion of patients that were pain free (34% vs. 15%).[24] Cahen and colleagues randomized 39 patients and found the surgical group had a greater proportion of patients that had pain relief (80% vs. 38%, $p = 0.001$), had greater improvements in quality of life, and underwent fewer procedures, despite equivalent morbidity, length of stay, and preserved pancreatic function at 5 years.[25]

SURGICAL MANAGEMENT

Approximately two-thirds of patients with debilitating pain from CP fail medical and endoscopic managements 4 . The goals of surgery are to effectively relieve pain while minimizing morbidity, including minimizing perioperative complications and preserving pancreatic parenchyma. The pancreatic anatomy is the primary determinant in surgical planning. Patients with a dilated (greater than 6 to 7 mm diameter) main pancreatic duct are assumed to have obstructive pathology and are candidates for a drainage-type procedure (lateral pancreaticojejunostomy, Frey procedure). Patients with a small-diameter main pancreatic duct are considered for resection of fibrotic and poorly drained parenchyma. Patients with head-predominant or tail-centered disease can undergo a directed partial resection. In patients with diffuse parenchymal involvement, a TP with islet autotransplantation may be appropriate (**Algorithm 54.1**).

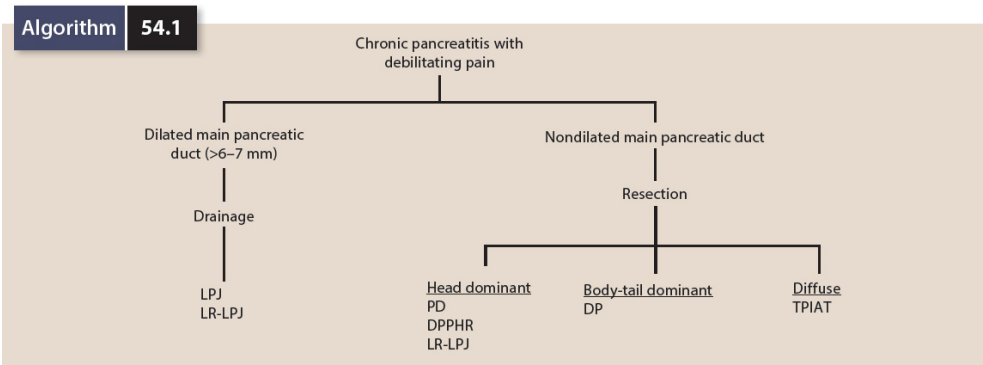
Lateral Pancreaticojejunostomy

Retrograde pancreatic drainage for relapsing pancreatitis was described by Puestow and Gillesby in 1958.[26] A modification of this original drainage procedure that more closely resembles the modern-day technique of the lateral pancreaticojejunostomy (LPJ) was reported by Partington and

Rochelle in 1960.[27] LPJ is the classic operation for pancreatic drainage and entails opening the pancreatic duct anteriorly along its length, medially to the level of the gastroduodenal artery and laterally into the tail. The opened pancreatic duct is then cleared of stones, including into the head, and anastomosed to a Roux-en-Y jejunal limb for drainage.

Procedure-specific complications of note include intraoperative hemorrhage (due to splenic vein or gastroduodenal artery injury), postoperative hemorrhage (often from the gastroduodenal artery), and anastomotic leak (seen in 10% of cases).

Multiple retrospective single-institution case series have been reported evaluating outcomes with LPJ, with pain-relief rates of 48% to 91%.[28–30] Morbidity rates are low (20% on average) and endocrine and exocrine function is often preserved.[31] LPJ is an effective and safe procedure for pain relief in many patients with dilated duct pancreatitis. Recurrent pain does occur after LPJ, however, likely due to pathology in the head of the pancreas. Intraductal stone disease in the head of the pancreas can be cleared with intraoperative pancreatoscopy and electrohydraulic lithotripsy, which has been shown to improve outcomes (reduced readmissions, increased pain-relief rates).[32] Alternatively, combining a localized head resection with LPJ can help to reduce recidivism.



Algorithm 54.1 Algorithm for operative decision-making in chronic pancreatitis. LPJ, lateral pancreaticojejunostomy; LR-LPJ, local pancreatic head resection with lateral pancreaticojejunostomy; PD, pancreatoduodenectomy; DPPHR, duodenum preserving pancreatic head resection; DP, distal pancreatectomy; TPIAT, total pancreatectomy with islet autotransplantation.

Localized Pancreatic Head Resection with Lateral Pancreaticojejunostomy

In 1987, Frey and colleagues described a local pancreatic head resection with lateral pancreaticojejunostomy (LR-LPJ) with the goal of achieving pancreatic ductal drainage, removal of damaged and poorly drained parenchyma in the head of the pancreas, and preservation of the duodenum to minimize postoperative gastrointestinal dysfunction. Frey reported initially on 50 patients, describing a morbidity of 22% and a pain-relief rate of 84%.[33] His outcomes have been validated in modern series, both at his own institution and at others, with pain-relief rates of 62% to 88%.[34,35]

Pancreatic Head Resection

Pancreatoduodenectomy (PD) for CP was described as early as 1946 by Whipple.[36] In the modern era, PD is the operation of choice for patients with complicated CP and head-dominant disease. Patients may present with duodenal or biliary obstruction as well as obstructive pancreatopathy from an inflammatory mass in the head of the pancreas. Outcomes for PD include pain relief in 70% to 89% of patients, morbidity in 16% to 53%, and mortality in less than 5% in high-volume centers.[30–37]

The pylorus-preserving pancreatoduodenectomy (PPPD) was popularized by Traverso and Longmire in an effort to maintain the physiologic benefits of a functional pylorus.[38] PPPD has been well adopted into pancreas surgery although the purported nutritional advantages have not been evidenced.[39–41] Some authors, however, have reported improved professional rehabilitation and quality of life after PPPD as compared to classic PD.[42]

Duodenum-preserving pancreatic head resection (DPPHR) was developed by Beger and colleagues in the 1970s in an effort to decrease the morbidity of pancreatic head resection for CP. Pain relief is reported in 77% to 88% of patients, with professional rehabilitation rates of 63% to 69% (**Fig. 54.4**). Morbidity and mortality are acceptable at 28.5% and 1%, respectively.[43,44] The ChroPac trial, a recent multicenter European trial, randomized 226 patients to PD (or PPPD) versus DPPHR. Perioperative morbidity was lower in the PD group and at 2 years follow-up, there was no difference in

the development of endocrine or exocrine failure or quality of life between the groups.[45]

Distal Pancreatectomy

In patients with CP and disease localized to the body and tail of the pancreas or in patients with a main pancreatic duct stricture in the neck or body, distal pancreatectomy (DP) can be an effective means of pain relief. The majority of CP patients who are candidates for DP have severe inflammatory changes in the region of the splenic hilum, making concomitant splenectomy necessary. Pain-relief rates of 57% to 84% are reported, with 15% to 32% morbidity.[46,47] Postoperative pancreatic fistula after DP is the primary morbidity of this operation and appears to be related to patient-specific factors rather than to operative technique.[48]

Total Pancreatectomy

5 TP for CP was performed as early as 1944 by Clagett at the Mayo Clinic. Perhaps tellingly, his patient died 10 weeks after surgery of a hypoglycemic event. TP can be an effective means of pain relief in patients with diffuse small-duct pancreatitis, as salvage therapy in patients who have failed lesser surgeries, and in patients with genetic pancreatitis. There is a requisite brittle type 3c pancreatogenic diabetes that follows TP, however, with severe, potentially life-threatening hypoglycemic episodes. With TP, there is loss of not only insulin-producing beta cells but also of the alpha cells and other composite cells of the islet that produce hormones to maintain glucose homeostasis. As a result, patients may demonstrate an unpredictable response to exogenous insulin and, importantly, may develop hypoglycemic unawareness.

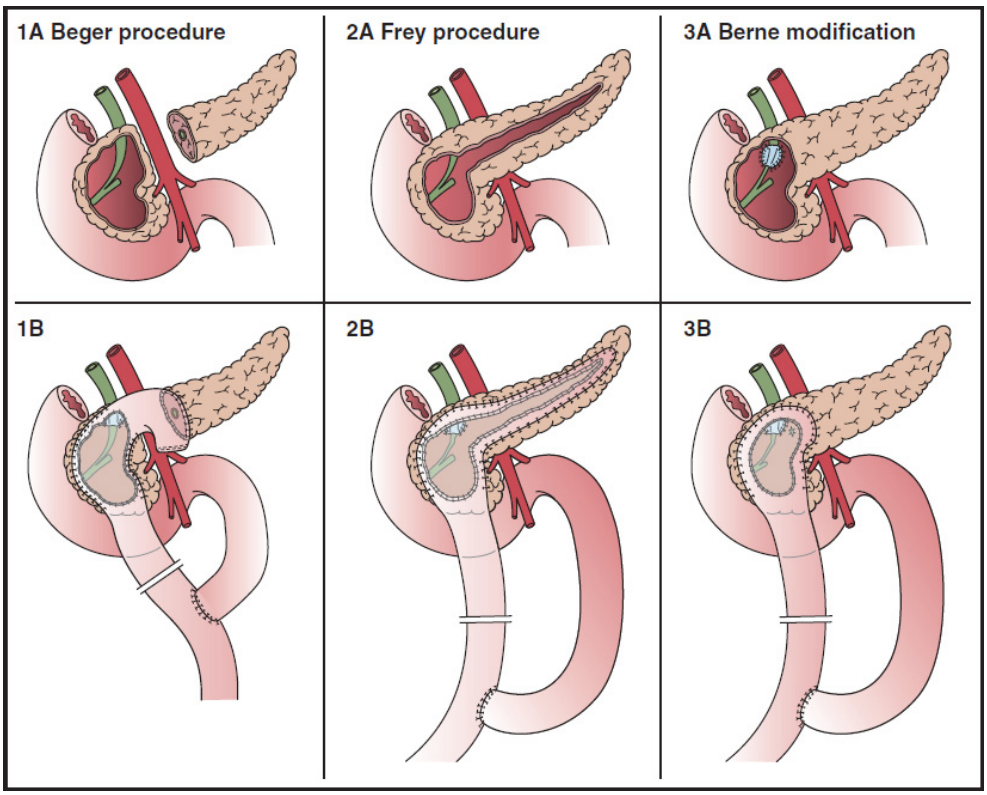


Figure 54.4 Schematic drawings of extent of resection (**A**) and method of reconstruction (**B**) for a Beger procedure (*1*), Frey procedure (*2*), and a Berne modification of the Beger procedure (*3*). (Reproduced from Müller MW, Freiss H, Leitzbach S, et al. Perioperative and follow-up results after central pancreatic head resection (Berne technique) in a consecutive series of patients with chronic pancreatitis. *Am J Surg* 2008;196:364–372.)

Total pancreatectomy with islet autotransplantation (TPIAT) was described by Sutherland and colleagues at the University of Minnesota in 1978, with the goal of ameliorating the brittle diabetes after extensive pancreatectomy.[48] TPIAT has been increasingly accepted over the past decade, and understanding of long-term outcomes is evolving. Pain-relief rates of 72% to 86% have been reported and patients have a significantly improved quality of life. Morbidity rates of 47% to 55% are reported, with 1.4% to 6% mortality, and insulin independence in 10% to 40% long term after islet transplant.[49–51] Insulin independence after TPIAT correlates with the number of islet equivalents per kilogram harvested,[52] and transplanted islet function appears to be durable, with outcomes reported for more than 13 years.[53] Genetic pancreatitis patients have the most favorable outcomes,[51] whereas patients with alcohol-related pancreatitis fare poorly with TPIAT.[54]

A multicenter prospective observational outcomes study evaluating TPIAT is currently in progress.

Minimally Invasive Surgery for Chronic Pancreatitis

Minimally invasive pancreas surgery encompasses laparoscopic and robotic approaches. Laparoscopy began in pancreas surgery with laparoscopic staging for pancreatic cancer. The development of endoscopic stapler technology in the mid 1990s allowed for more complex pancreatic resections to emerge, and the epidemic of incidentally discovered low-grade pancreatic neoplasms allowed for the evolution of laparoscopy as the standard approach to DP. Single and multicenter comparative studies,[55,56] and now several single and multicenter randomized controlled trials[57–59] have demonstrated the efficacy of minimally invasive pancreas surgery. Minimally invasive DP has been shown to have lower blood loss, length of stay, and morbidity compared to open DP, with equivalent operative times and pancreatic fistula rates.[55,57] Minimally invasive PD has been demonstrated to have equivalent outcomes to open DP at expert centers.[56] A recent evidence-based consensus statement on minimally invasive pancreatic surgery reviewed available evidence.[60] Importantly, much of the reported experience in minimally invasive pancreas surgery is for low-grade pancreatic neoplasms and pancreatic cancer. Minimally invasive surgical approaches to CP are technically more challenging due to fibrotic distortion of anatomy and obliteration of normal tissue planes.

CONCLUSIONS

CP is a complex disease, challenging in management. Notable recent progress has been made in understanding the underlying pathophysiology, including genetic causes and cellular and biochemical mechanisms, with much still to be learned. Surgery can be beneficial in many patients with debilitating pain from CP. Evolving surgical therapies, such as TPIAT and minimally invasive techniques, are promising.

Neoplasms of Exocrine Pancreas

Motaz Qadan and Cristina R. Ferrone

Key Points

1. The incidence of pancreatic cancer continues to rise around the world. Risk factors include smoking, obesity, diabetes mellitus, chronic pancreatitis, and germline mutations in *BRCA2* and *CDKN2A.*
2. The most common mutations identified in PDAC are *KRAS, CDKN2A, TP53,* and *SMAD4*.
3. Intraductal papillary mucinous neoplasms (IPMNs) are important recognized precursor lesions for pancreatic ductal adenocarcinoma and are subclassified as main-duct, branch-duct, or mixed type depending on location.
4. Pancreatic protocol contrast-enhanced computed tomography (CT) is commonly utilized for staging and surveillance. Endoscopic ultrasonography (EUS) with biopsy is essential if neoadjuvant therapy is being considered.
5. A Whipple pancreaticoduodenectomy is performed for head, neck, and uncinate tumors of the pancreas and a distal pancreatectomy (with splenectomy) for body and tail lesions.
6. Systemic therapy utilizing 5-FU/leucovorin/oxaliplatin/irinotecan (FOLFIRINOX) and gemcitabine/abraxane have significantly improved the overall survival of patients with resectable and metastatic PDAC.
7. Palliation of patients with incurable pancreatic cancer may require endoscopic and/or surgical interventions to establish biliary drainage and prevent or relieve gastric outlet obstruction.

INTRODUCTION

Pancreatic cancer is the fourth leading cause of cancer-related death in the United States in men and women. Overall 5-year survival for patients with pancreatic cancer is 9%.[1] The majority of tumors are exocrine adenocarcinomas (93%) and fewer are pancreatic neuroendocrine tumors

(7%). Surgical resection offers the only chance for long-term cure. Unfortunately, because of the late presentation and early disease dissemination, only 15% to 20% of patients present with resectable disease. Five-year survival after pancreaticoduodenectomy (PD) is improving as systemic therapy becomes more effective. The absence of symptoms associated with early pancreatic cancer, inaccessibility of the pancreas to examination, aggressive tumor biology associated with the disease, and technical difficulties associated with pancreatic surgery render pancreatic cancer as one of the most challenging diseases treated by surgeons and oncologists.

In recent years, significant advances have been made in our understanding of the pathogenesis and clinical management of pancreatic cancer. This chapter reviews the epidemiology and risk factors associated with pancreatic cancer, discuss recent developments in the field of molecular genetics, and provide an update on the current clinical and oncologic management of pancreatic cancer.

EPIDEMIOLOGY AND RISK FACTORS

In the United States, it is estimated that nearly 57,600 new cases of pancreatic cancer will be diagnosed with almost 47,050 people dying of the disease in 2020. Pancreatic cancer accounts for 3% of all cancers in the United States and is responsible for 7% of all cancer deaths. The incidence of pancreatic cancer in the United States is 12.4 per 100,000 populations. The lifetime risk for developing pancreatic cancer is 1.5%.[1] The incidence of pancreatic cancer has slowly been increasing, with an average increase of 0.8% per year over the last 10 years (**Fig. 55.1**). The risk of development of pancreatic cancer is related to age, race, sex, tobacco use, diet, and specific genetic syndromes (**Table 55.1**). The incidence increases with advancing age. More than 80% of cases occur in persons between the ages of 60 and 80 years, and pancreatic cancer is rare in people younger than 40 years. The incidence and mortality rates for pancreatic cancer in African Americans of both sexes are higher than those in whites. The gender differences in pancreatic cancer have been diminishing in recent years with 30,400 cases

predicted in men compared with 27,200 among women. Similarly, 24,640 deaths are predicted in men in 2020 compared with 22,410 among women.

Environmental and dietary factors have also been implicated as risk factors for the development of pancreatic cancer. The most consistently observed environmental risk for the development of pancreatic cancer remains cigarette smoking. It has been estimated that cigarette smoking can increase the risk for pancreatic cancer between 1.5 and 5 times. The mechanism is unknown, but carcinogens in cigarette smoke have been shown to produce pancreatic cancers in experimental studies. In addition, autopsy studies have documented hyperplastic changes in pancreatic ductal cells with atypical nuclear patterns in smokers. Alcohol consumption does not seem to be a risk factor for pancreatic cancer despite conflicting prior data. Recent studies suggest that past studies linking pancreatic cancer to alcohol use may have, in fact, been confounded by tobacco use. Similarly, coffee consumption and exposure to ionizing radiation have been shown not to be associated with an increased pancreatic cancer risk.

Several epidemiologic investigations have suggested that diet may play an important role in the development of pancreatic cancer. An apparent association has been noted between pancreatic cancer and an increased consumption of total calories, carbohydrates, cholesterol, meat, salt, dehydrated food, fried food, refined sugar, soybeans, and nitrosamines. The risks are unproven, however, for the ingestion of fat, beta-carotene, and coffee. A protective effect has been reported for dietary fiber, vitamin C, fruits, and vegetables.[2]

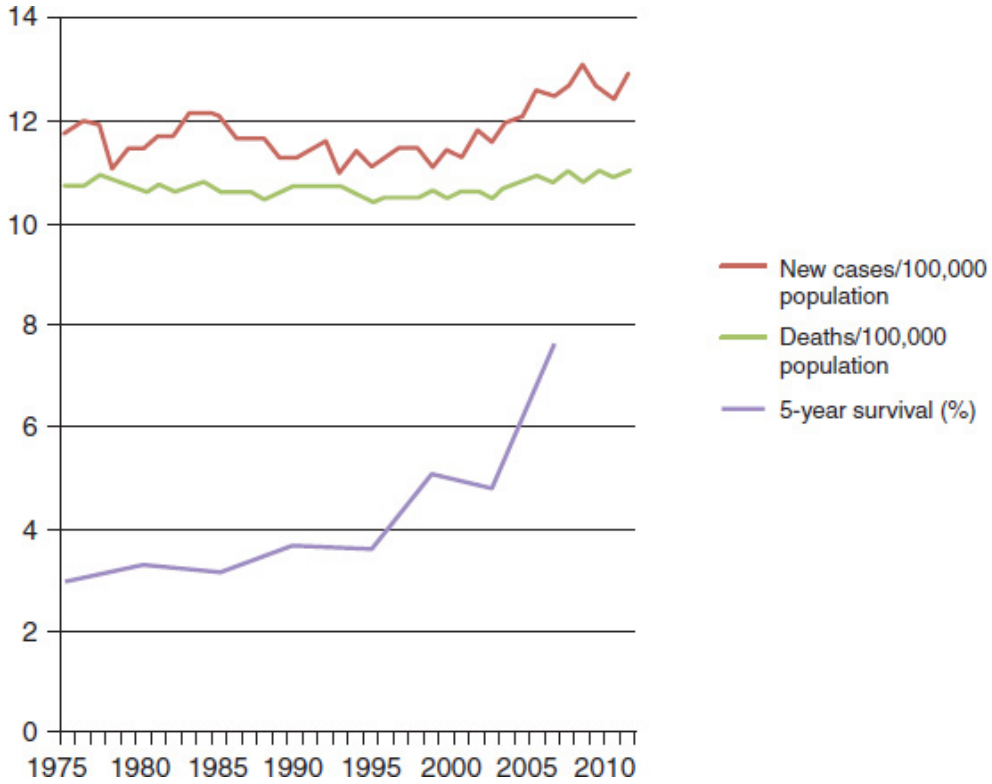

Figure 55.1 U.S. pancreatic cancer new cases, death rate, and 5-year survival. (Adapted from *EER Cancer Statistics Factsheets: Pancreas Cancer*. Bethesda, MD: National Cancer Institute. Available at http://seer.cancer.gov/statfacts/html/pancreas.html. Accessed March 10, 2016.)

In addition to well-defined genetic syndromes, a number of common conditions constitute etiologic factors in the development of pancreatic cancer. An apparent association between diabetes and pancreatic cancer has been suggested. Approximately 80% of patients diagnosed with pancreatic cancer have impaired glucose metabolism, impaired glucose tolerance, or diabetes mellitus. It is unclear if alterations in glucose tolerance/metabolism are a causative factor for pancreatic cancer or represent reaction to an enlarging malignancy in the pancreas. Among patients with newly diagnosed diabetes, 0.85% went on to be diagnosed with pancreatic cancer within 3 years.[3] Type II diabetes of at least 5 years duration has been associated with a twofold increase in pancreatic cancer.

The risk of pancreatic cancer has also been shown to increase as body mass index increases. Examination of data from the Nurses' Health Study and the Health Professional's follow-up study previously demonstrated a 1.72

relative risk (95% CI 1.19–2.48) of pancreatic cancer in patients with a BMI >30 kg/m^2 as compared to individuals with a BMI <23 kg/m^2.

Table 55.1 Risk Factors for Pancreatic Cancer

	Increased Risk	Possible Risk	Unproved Risk
Demographic factors	Advancing age Male sex Black race	Geography	Socioeconomic status Migrant status
Host factors	Hereditary nonpolyposis colorectal cancer Familial breast cancer Peutz–Jeghers syndrome Ataxia–telangiectasia Familial atypical multiple-mole melanoma Hereditary pancreatitis		Peptic ulcer surgery
Environmental factors	Tobacco	Diet Occupation	Alcohol Coffee Radiation

Modified from Gold EB, Goldin SB. Epidemiology of and risk factors for pancreatic cancer. *Surg Oncol Clin North Am* 1998;7:67.

Chronic pancreatitis of any cause has been associated with a 25-year cumulative risk for the development of pancreatic cancer of approximately

4%. Other conditions for which a possible association with pancreatic cancer has been demonstrated include thyroid and other benign endocrine tumors, cystic fibrosis, and pernicious anemia.

Most cases of pancreatic cancer have no obvious predisposing factors. However, it is believed that between 5% and 10% of pancreatic cancers are associated with a familial predisposition. Six genetic syndromes have been associated with an increased risk for the development of pancreatic cancer (**Table 55.2**).

1 MOLECULAR GENETICS

Invasive pancreatic ductal adenocarcinoma (PDAC) tumors are genetically complex, with wide-spread chromosome abnormalities, numerous losses and gains of large segments of DNA, and, on average, more than 60 exomic alterations in each tumor.[4] PDAC harbors an average of 63 genome alterations, of which the majority are point mutations. Four key genes that are frequently altered in PDAC include *KRAS, CDKN2A, TP53,* and *SMAD4* (**Table 55.3**). The most common gene alteration is in *KRAS*, where mutations occur in codons 12, 13, and 61. More than 90% of PDAC tumors possess *KRAS* mutations. Point mutations of the K-*ras* oncogene impair the intrinsic guanosine triphosphatase activity of its gene product. The result is a protein that is constitutively active in signal transduction *and* activates various downstream signaling pathways, including the mitogen-activated protein kinase (MAPK) cascades. Ras proteins are involved in a variety of cellular functions, including proliferation, differentiation, and survival. Cyclin-dependent kinase inhibitor 2A gene (*CDKN2A*) is also inactivated in up to 90% of PDAC due to intragenic mutations in association with allelic loss, homozygous deletion, or hypermethylation of the gene promoter. *CDKN2A* encodes a cyclin-dependent kinase inhibitor that controls G1–S transition in the cell cycle. Inactivation of *CDKN2A* leads to the loss of an important cell cycle checkpoint, thereby resulting in unchecked cellular proliferation. *TP53* is one of the most frequently mutated genes in many cancers, and is inactivated in about 75% of PDAC, mainly due to point mutations or small deletions. The *p53* gene product is a DNA-binding protein that acts as both a cell-cycle checkpoint and an inducer of apoptosis. Inactivation of the *p53*

gene in pancreatic cancer therefore leads to the loss of two important controls of cell growth including regulation of cellular proliferation and induction of cell death. *SMAD4* (*DPC4,* SMAD family member 4 gene). *SMAD4* encodes a transcription factor that mediates signaling of the transforming growth factor-β (TGF-β) superfamily. *SMAD4* is a tumor-suppressor gene that has been identified on chromosome 18q. This chromosome has been shown to be absent in nearly 90% of pancreatic cancers. The *SMAD4* gene is inactive in almost 50% of pancreatic carcinomas. The mutation appears to be a homozygous deletion in 30% of pancreatic cancers, and a point mutation in another 20% of tumors. *SMAD4* mutations are more specific than *p53* or *p16* mutations for pancreatic cancer.

Table 55.2 Genetic Syndromes Associated with Hereditary Pancreatic Cancer

Syndrome	Mode of Inheritance	Gene	Fold Increase in Risk	Manifestation of Pancreatic Cancer
Peutz–Jeghers	AD	*STKll*	140×	Hamartomatous polyps of the gastrointestinal tract; mucocutaneous melanin macules
Hereditary pancreatitis	AD	*PRSSl*	60×	Recurrent episodes of severe pancreatitis starting at a young age
Familial pancreatic cancer	Unknown	Unknown	18×	At least one pair of first-degree relatives with pancreatic cancer
FAMMM	AD	p16	20×	Multiple nevi, atypical nevi, and melanomas
Familial breast cancer 2	AD	*BRCA2*	10×	Breast, ovarian, and pancreatic cancer
HNPCC	AD	*MSH2 HLHl*	Unknown	Colonic, endometrial, and gastric cancers; mutator phenotype

AD, autosomal dominant; FAMMM, familial atypical multiple mole melanoma; HNPCC, hereditary nonpolyposis colorectal cancer.

Germline mutations in *BRCA2* and *CDKN2A,* and less frequently in *BRCA1, PALB2*, and *ATM* have been identified in a small subset of patients with familial pancreatic cancer. The inactivation of *BRCA2,* which encodes a protein involved in DNA damage repair, is associated with a 3.5- to 10-fold increased risk of pancreatic cancer, in addition to the widely referenced increased risk of breast and ovarian cancer. In addition, patients with Lynch syndrome (caused by germline mutation in one of the mismatch repair genes *MLH1, MSH2, MSH6,* or *PMS2*) and Peutz–Jegher syndrome (caused by germline mutation of the *STK11* gene) are at increased risk of pancreatic cancer. Approximately 4% of pancreatic cancers can be characterized by

disorders of DNA mismatch–repair genes with potential implications in responses to immunotherapeutics.[5]

Table 55.3 Genetic Alterations in Pancreatic Adenocarcinomas

Gene	Chromosome Locus	Frequency (%)
Oncogenes	12	90
K-*ras*

2 PATHOLOGY

Tumors of the exocrine pancreas can be classified according to their cell of origin (**Table 55.4**). The most common neoplasms of the exocrine pancreas are ductal adenocarcinomas. Approximately 65% of PDACs arise in the head, neck, or uncinate process of the pancreas; 15% originate in the body or the tail of the gland; and 20% diffusely involve the whole gland.

Table 55.4 Histologic Classification of 645 Cases of Primary Nonendocrine Cancer of the Pancreas

Classification	Number
Duct cell origin	572 (89%)
Duct cell adenocarcinoma	494
Giant cell carcinoma	28
Adenosquamous carcinoma	20
Microadenocarcinoma	16
Mucinous carcinoma	9
Mucinous cystadenocarcinoma	5
Acinar cell origin	8 (1%)
Acinar cell carcinoma	7
Cystadenoma	1
Uncertain histogenesis	61 (9%)
Pancreaticoblastoma	1
Papillary and cystic neoplasm	1
Mixed type—duct and islet cells	1
Unclassified	58
Connective tissue origin	4 (1%)

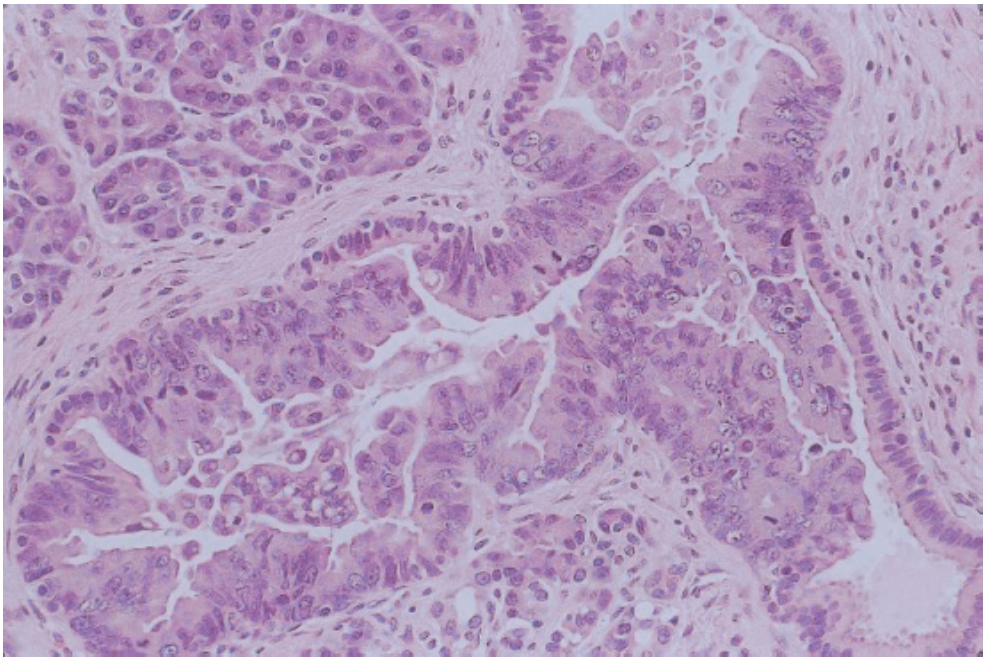

Figure 55.2 Microscopic appearance of ductal adenocarcinoma of the head of the pancreas demonstrating glands from an adenocarcinoma embedded in a fibrous matrix.

Solid Epithelial Tumors of the Pancreas

Ductal Adenocarcinomas

Ductal adenocarcinomas account for more than 75% of all nonendocrine pancreatic cancers. Grossly, they are pale, poorly defined, hard masses that often obstruct the distal common bile duct and/or main pancreatic duct. They are often associated with a biologically-intimate desmoplastic reaction that causes fibrosis and chronic pancreatitis. Microscopically, they contain infiltrating glands of varying size and shape surrounded by dense, reactive, fibrous tissue (**Fig. 55.2**). The epithelial cells sometimes form papillae and cribriform structures, and they frequently contain mucin. The nuclei of the cells can show marked pleomorphism, hyperchromasia, loss of polarity, and prominent nucleoli.

Ductal adenocarcinomas tend to infiltrate into vascular, lymphatic, and perineural spaces. At the time of resection, most ductal carcinomas have already metastasized to regional lymph nodes. In addition to regional lymph nodes, these tumors frequently metastasize to the liver (80%), peritoneum

(60%), and lungs and pleurae (50% to 70%). They also directly invade the duodenum, stomach, transverse mesocolon, spleen, and adrenal glands. Distant nodal involvement is also common.

The histologic examination of a pancreas resected for cancer frequently reveals the presence of precursor lesions in the pancreatic ducts and ductules adjacent to the cancer. This suggests that much like colon cancer, which arises from benign adenoma precursors, pancreatic cancer may also demonstrate progression to malignant disease from benign precursor lesions. Known precursor lesions include pancreatic intraepithelial neoplasia (PanIN). Briefly, PanIN-1A and PanIN-1B are proliferative lesions without remarkable nuclear abnormality that possess flat and papillary architecture, respectively. PanIN-3 is associated with severe architectural and cytonuclear abnormalities, but invasion through the basement membrane is absent. PanIN-2 is an intermediate category between PanIN-1 and PanIN-3 and is associated with a moderate degree of architectural and cytonuclear abnormality.[6] Older data suggest that PanINs are precursors of infiltrating pancreatic cancer: PanINs are often found in association with ductal adenocarcinomas, three-dimensional mapping techniques that demonstrated a stepwise transformation from mild dysplasia to severe dysplasia in pancreatic duct lesions, and PanINs demonstrate some of the same genetic changes seen in infiltrating adenocarcinomas, most notably activating point mutations in codon 12 of K-*ras* and mutations in the *p16* and *p53* tumor-suppressor genes.

Adenosquamous Carcinomas

Adenosquamous carcinoma is a rare variant of ductal adenocarcinoma that shows both glandular and squamous differentiation. This variant appears to be more common in patients who have undergone previous radiation therapy, although the exact etiology is not known. The biologic behavior of adenosquamous carcinoma appears to be similar to that of ductal adenocarcinoma, with similar rates of perineural invasion, lymph node metastases, and distant disease dissemination.

Acinar Cell Carcinomas

Acinar cell carcinomas account for only 1% of pancreatic exocrine tumors. Acinar tumors are typically smooth, fleshy, lobulated, hemorrhagic, or necrotic. Histologically, they form acini, and the cells display an eosinophilic and granular cytoplasm. Immunohistochemical staining demonstrates expression of trypsin, lipase, chymotrypsin, or amylase. These tumors are more common in males with a male-to-female predominance of approximately 3:1. The age of diagnosis is usually in the fifth to seventh decades. These tumors tend to be substantially larger than ductal adenocarcinomas, with improved prognosis compared with patients with ductal carcinoma.[7] Surgical resection is the curative treatment of choice.

Solid-Pseudopapillary Neoplasms

Solid-pseudopapillary neoplasms (SPN), also termed solid and cystic tumors, papillary cystic tumors, *Hamoudi* tumors, and *Frantz* tumors occur primarily in women in their third to fourth decades of life. Grossly, the masses range from 5 to 15 cm in diameter. Radiologically, they present as a well-demarcated heterogeneous mass with solid and cystic components, with a peripheral capsule which rarely shows calcifications. EUS-guided fine needle aspiration (FNA) or core biopsy is often diagnostic, showing uniform cells forming microadenoid structures, branching, and papillary clusters with delicate fibrovascular cores. Most SPNs exhibit benign behavior, and even the less than 20% of tumors that have vascular or perineural invasion, lymph node involvement, or liver metastases frequently have an indolent course. The 5-year overall survival is close to 97% in patients who undergo complete surgical resection.

Pancreatoblastoma

Pancreatoblastomas occur primarily in children ages 1 to 15 years. Pancreatoblastomas contain both epithelial and mesenchymal elements. The epithelial component appears to arise from acinar cells. The tumors are typically larger than 10 cm and often contain areas of degeneration and hemorrhage. The prognosis appears to be more favorable than that for typical ductal adenocarcinoma if the tumor can be resected.

Cystic Epithelial Tumors of the Pancreas

Cystic neoplasms also arise from the exocrine pancreas. Cystic neoplasms are less common than ductal adenocarcinomas; tend to occur in women, and are, on the whole, evenly distributed throughout the gland. Many pancreatic and peripancreatic cysts are still benign inflammatory pseudocysts. It is important to identify cystic neoplasms which require careful surveillance and potential surgical resection. With advancements in imaging technology and increased utilization, cystic lesions of the pancreas are being detected with increased frequency. The majority of pancreatic cysts are often detected incidentally.[8] Although many of these lesions are small and asymptomatic, they can have malignant potential and mucinous lesions are premalignant by nature. The management of these patients is complex, and knowledge of pancreatic cyst natural history and predictors of neoplasia are important.

Serous Cystic Neoplasms

Serous cysts are epithelial neoplasms composed of uniform cuboidal glycogen-rich cells that usually form numerous small cysts containing serous fluid. Serous cystadenomas, or microcystic adenomas, are more common in women than in men (3:1 preponderance). These tumors can vary from a few centimeters to more than 10 cm in size. Twenty-five percent to 30% of patients are asymptomatic. However, most patients present with symptoms such as abdominal or epigastric pain, dyspepsia, nausea, or vomiting. Serous cystadenomas can be located anywhere in the pancreas and usually do not communicate with the pancreatic ducts. Plain computed tomography (CT) shows a honeycomb pattern of microlacunae, with thin septa separating different segments. Serous cystic neoplasms can have a sunburst pattern of central calcification, which is seen in 10% to 30% of cases. Grossly, they appear as spongy, well-circumscribed, multiloculated cysts. Microscopically, they consist of a layer of simple cuboidal cells separated by dense fibrous bands. Serous cystic neoplasms are benign. However, symptomatic cysts or cysts that cannot be differentiated from other potentially malignant cysts should undergo surgical excision.

Mucinous Cystic Neoplasms

Mucinous cystic neoplasms (MCNs) are neoplasms composed of mucin-producing epithelial cells associated with a pathognomonic "ovarian-type" stroma. These cysts usually do not communicate with the larger pancreatic ducts. MCNs are relatively uncommon but account for almost 30% of all cystic neoplasms. The mean age at diagnosis is between 40 and 50 years. MCNs are more common in women with a female-to-male ratio of 9:1. Most patients with MCNs present with vague abdominal symptoms that include epigastric pain or a sense of abdominal fullness. The majority (70% to 90%) of MCNs arise in the body or tail of the pancreas, and only a minority (10% to 30%) involve the head of the gland. Microscopically, these cysts are lined by tall columnar mucin-producing epithelium. These columnar cells have basal nuclei and abundant intracytoplasmic apical mucin and can form flat sheets or papillae. The stroma is composed of densely packed spindle cells with sparse cytoplasm and uniform elongated nuclei. MCNs are premalignant lesions and should be cleanly resected to prevent progression to malignancy. Variable degrees of premalignant transformation are encountered, ranging from low- to high-grade dysplasia based on the degree of architectural and cytologic atypia of the epithelial cells.

Invasive mucinous cystadenocarcinomas are MCNs that are associated with invasive carcinoma secondary to progression. In surgical series, between 15% and 30% of all MCNs are associated with invasive carcinoma. Naturally, patients with mucinous cystadenocarcinomas tend to be 5 to 10 years older than patients with benign MCNs. The extent of invasive carcinomas and high-grade dysplasia in MCNs can be very focal. Therefore, a benign working diagnosis cannot be established on biopsy alone due to sampling error, and lesions, including precursors, should also be completely excised. The prognosis for patients with resected benign/premalignant tumors is excellent. Patients with mucinous cystadenocarcinoma also perform better than patients with conventional ductal adenocarcinoma, with 5-year overall survival rates nearing 50%.

Intraductal Papillary-Mucinous Neoplasms

Intraductal papillary-mucinous neoplasms (IPMNs) are intraductal mucin-producing neoplasms with tall, columnar, mucin-containing epithelium with or without papillary projections. These neoplasms extensively involve the

main pancreatic ducts (main-duct IPMN) and/or major side branches (branch-duct IPMN). While radiologic distinction from MCNs may be challenging, IPMNs critically lack the ovarian stroma characteristic of MCNs on biopsy sampling, and are therefore distinct lesions. Similar to the well-defined adenoma–carcinoma sequence in PDAC (PanIN to invasive ductal carcinoma), IPMNs seem to follow a similar pattern of progression from IPMN with low-grade dysplasia to high-grade dysplasia to invasive carcinoma. Microscopically, IPMNs consist of papillary projections lined by columnar mucin-secreting cells. They show varying degrees of cellular atypia. Invasive IPMNs are either colloid or tubular, with the latter having a worse prognosis. Further histologic subtyping of epithelial differentiation is based on cell lineage, morphology of the papillae, and immunophenotype, and includes classification into intestinal, gastric, pancreaticobiliary, and oncocytic subtypes with variable prognosis.

IPMNs are subclassified as main-duct, branch-duct, or mixed type depending on their location. Main-duct IPMNs are characterized by involvement of the duct of Wirsung, which is dilated either focally or diffusely throughout the gland. Branch-duct IPMN originates in the side branches of the pancreatic ductal system and appears as a multilobular cystic lesion communicating with a nondilated main pancreatic duct. If the main duct is dilated with synchronous involvement of the branch ducts, it is described as a mixed IPMN.

IPMNs are usually found in individuals in their 60s to 80s. Some patients may experience symptoms that include abdominal pain, steatorrhea, weight loss, jaundice, diabetes, and chronic pancreatitis. However, the majority are detected as incidental findings on cross-sectional imaging studies performed for other indications. Interestingly, the presence of diabetes in IPMNs is more likely to be associated with high-grade dysplasia and invasive carcinoma and is worthy of more aggressive surveillance if no evidence of malignancy is present.[9] IPMNs appear to be more common in the head, neck, and uncinate process of the pancreas but can be found diffusely throughout the whole gland. Computed tomography (CT) scans often provide the initial modality by which these lesions are noted, but are better characterized, and surveillance conducted, using magnetic resonance imaging (MRI). In approximately 20% of lesions, IPMNs may contain areas of calcifications.[10] In a recent report, the presence of calcifications correlated with larger cyst

sizes and were more commonly seen when pancreatic ductal dilatation was found. However, there was no association between presence of calcifications and malignancy, epithelial subtype, or other clinic data, unless the calcification was noted to be "coarse" in nature (compared with punctate or eggshell). On endoscopy, mucin can be seen oozing from the ampulla of Vater in cases of main-duct IPMN with a classic fish mouth opening of the pancreatic duct at the ampulla. Endoscopic retrograde cholangiopancreatography (ERCP) can be used to confirm that the cysts communicate with the pancreatic ducts.

MCNs are the main entity to consider in the differential diagnosis of IPMNs (**Table 55.5**). Aside from the ovarian-stroma of MCNs, two radiologic features distinguish IPMNs from MCNs; IPMNs communicate with ducts whereas mucinous cysts do not. In addition, MCNs are usually seen in the tail of the pancreas and occur in middle-aged women, whereas IPMNs are more frequently seen in the head of the pancreas and occur in older individuals of either gender. Finally, on molecular analysis, MCNs are devoid of *GNAS* mutations compared with IPMNs, and both may possess *KRAS* mutations in their profile, which, importantly, does not necessarily represent an in-situ or invasive malignant component.

Table 55.5 Comparison between Mucinous Cystic Neoplasm (MCN) and Intraductal Papillary Mucinous Neoplasm (IPMN)

	MCN	IPMN
Age (years)	40–50	60–80
Gender	More common in females	More common in males
Location	Body/tail	Head
Communicates with pancreatic duct	No	Yes
Mucin at ampulla	No	Yes
Ovarian like stroma	Yes	No

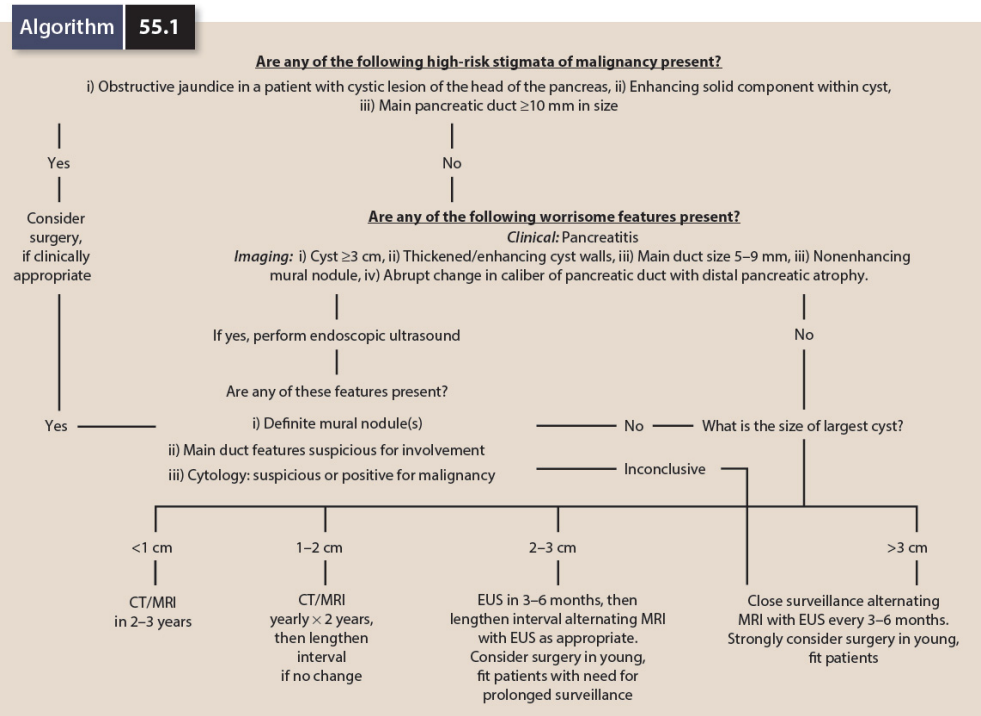
As noted, IPMNs represent a continuum of disease from benign to malignant. In a large series of 851 resected cystic lesions from the Massachusetts General Hospital over a 33-year period, 38% of lesions were noted to be IPMNs.[11] The series also included MCNs, serous cystadenomas, and cystic neuroendocrine tumors. The series highlighted several important findings, including the increase in incidentally-discovered lesions over time, representing the increase in cross-sectional imaging, a decrease in malignancy rate within resected lesions over time, highlighting the ability to detect premalignant lesions more effectively, and an overall high rate of survival for all mucinous lesions (5-year overall survival of 87%).

Several international consensus guidelines for the management of IPMNs have been developed, and range in their assessment of malignant transformation.[12] Traditionally, the International Association of Pancreatology (IAP) guidelines (Sendai and Fukoka) have been followed by surgeons with conservative approaches toward risk of malignant transformation. These guidelines, therefore, incorporate more stringent surveillance recommendations. Conversely, the American Gastroenterology Association (AGA) guidelines underestimate the risk of malignant transformation, and, thus, carry more liberal recommendations for surveillance and discontinuation of long-term follow-up in the event cysts remain unchanged after 5 years.

In attempts to better predict IPMNs with "imminent" malignant potential, IPMNs may possess features of "high-risk stigmata" or "worrisome features." High-risk stigmata in the most recent 2017 iteration include obstructive jaundice in the setting of a cyst in the head of the pancreas, a main duct >10 mm, or a cyst with a solid enhancing component >5 mm in the wall. Worrisome features include cyst >3 cm, thickened and enhancing cyst walls, enhancing mural nodules <5 mm, main duct size between 5 mm and 9 mm, abrupt change in the caliber of the main pancreatic duct with distal pancreatic atrophy, lymphadenopathy, cyst growth >5 mm in 2 years, and elevated serum levels of CA 19-9. All cysts with "worrisome features" should undergo endoscopic ultrasonography (EUS), and all cysts with "high-risk stigmata" should be resected in healthy patients. If no "worrisome features" are present, no further initial work-up is recommended. However, serial surveillance is still necessary (**Algorithm 55.1**). Of note, however, cysts that remain smaller than 1.5 cm for more than 5 years might possess

very low risk for progression to malignancy (<1%) and may be considered for less aggressive surveillance.[13]

The goal of surgical therapy for IPMNs should include complete surgical resection with absence of invasive carcinoma or high-grade dysplasia at the transection margin. In addition, main-duct IPMNs may pose a more challenging situation if disease extends across the entire length of the gland, where total pancreatectomy may be indicated. The presence of focal invasive malignancy and condition of the patient are important determinants of the decision to perform total pancreatectomy. Perioperative management requires specialized care, often with the assistance of endocrinology, and informed discussion with patients in the preoperative phase.



Algorithm 55.1 International consensus guidelines for the management of IPMNs. (From Tanaka M, Fernandez-del Castillo C, Adsay V, et al. International consensus guidelines 2012 for the management of IPMN and MCN of the pancreas. *Pancreatology* 2012;12:183–197.)

Unlike those patients with completely resected noninvasive MCNs (who are routinely cured), patients with completely resected IPMNs should undergo careful follow-up and surveillance for the development of recurrent disease. Furthermore, patients with resected IPMNs should also undergo

careful follow-up and surveillance as they are at higher risk for the development of distinct PDACs elsewhere in the gland.

3 CLINICOPATHOLOGIC STAGING

Accurate pathologic staging of pancreatic cancer is important for providing prognostic information to patients and for comparing the results of various therapeutic trials. The American Joint Committee on Cancer (AJCC) staging for pancreatic cancer evolves every few years (currently 8th edition), and is shown in **Table 55.6**. This system, based on the TNM classification, takes into account the extent of the primary tumor (T), the presence or absence of regional lymph node involvement (N), and the presence or absence of distant metastatic disease (M).

Table 55.6 Staging of Pancreatic Cancer

Stage	T	N	M
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T3	N0	M0
IIB	T1, T2, T3	N1	M0
III	T4 (or any T if N2)	N2 (or any N if T4)	M0
IV	Any T	Any N	M1

Tumor (T)
TX: Primary tumor cannot be assessed
T0: No evidence of primary tumor
Tis: Carcinoma in situ
T1: Maximum tumor diameter ≤2 cm
T2: Maximum tumor diameter >2 cm but ≤4 cm
T3: Maximum tumor diameter >4 cm
T4: Tumor involves the celiac axis or the superior mesenteric artery

Regional Lymph Nodes (N)
NX: Regional lymph nodes cannot be assessed
N0: No regional lymph node metastasis
N1: Regional lymph node metastasis in 1–3 nodes
N2: Regional lymph node metastasis in ≥4 nodes

Distant Metastasis (M)
MX: Distant metastasis cannot be assessed
M0: No distant metastasis
M1: Distant metastasis

DIAGNOSIS

Clinical Presentation

Many of the difficulties associated with the management of pancreatic cancer result from an inability to make the diagnosis at an early stage. The early symptoms of pancreatic cancer include anorexia, weight loss, abdominal discomfort, and nausea. Unfortunately, the nonspecific nature of these symptoms often leads to a delay in the diagnosis. Specific symptoms usually develop only after invasion or obstruction of nearby structures has occurred. Most pancreatic cancers arise in the head of the pancreas, and obstruction of the intrapancreatic portion of the common bile duct leads to progressive jaundice, acholic stools, darkening of the urine, and pruritus. Pain is a common symptom of pancreatic cancer. The pain usually starts as a vague upper abdominal or back pain that is often nonspecific, gnawing in nature, worse at night at time, and frequently attributed to some other cause. It is usually worse in the supine position and is often relieved by leaning forward. Pain may be caused by invasion of the tumor into the splanchnic plexus and retroperitoneum, or by obstruction of the pancreatic duct and potential pancreatitis. Other digestive symptoms are also common in pancreatic cancer (**Table 55.7**).

Table 55.7 Symptoms of Pancreatic Cancer

Symptom	Patients (%)
Head	
Weight loss	92
Jaundice	82
Pain	72
Anorexia	64
Dark urine	63

Nausea	43
Vomiting	37
Anorexia	33
Constipation	27
Hematemesis	17
Melena	17
Jaundice	7
Fever	7
Diarrhea	3

Occasionally, pancreatic cancer may be discovered in an unusual manner. The onset of diabetes may be the first clinical feature in 10% to 15% of patients. An episode of acute pancreatitis may also be the initial presentation of pancreatic cancer if the tumor partially obstructs the pancreatic duct. It is important to consider a pancreatic cancer in patients presenting with acute pancreatitis, especially those without an obvious cause for their pancreatitis (alcohol or gallstones).

The most common physical finding at the initial presentation in head tumors is jaundice (**Table 55.8**). Hepatomegaly and a palpable gallbladder may be present in some patients. In cases of advanced disease, cachexia, muscle wasting, or a nodular liver, consistent with metastatic disease, may be evident. Other physical findings in patients with disseminated cancer include left supraclavicular adenopathy (Virchow node), periumbilical adenopathy (Sister Mary Joseph node), and pelvic drop metastases (Blumer shelf). Ascites can be present in 15% of patients.

Laboratory Studies

In patients with cancer of the head of the pancreas, laboratory studies usually reveal a significant increase in serum total bilirubin and alkaline phosphatase, indicating bile duct obstruction. The transaminases can also be elevated but usually not to the same proportion as the bilirubin and alkaline phosphatase. In patients with localized cancer of the body and tail of the pancreas, laboratory values remain normal early in the course. Patients with pancreatic cancer may also demonstrate a normochromic anemia and hypoalbuminemia secondary to the nutritional consequences of the disease. In patients with jaundice, the prothrombin time can be abnormally prolonged. This usually is an indication of biliary obstruction, which prevents bile from entering the gastrointestinal tract and leads to malabsorption of fat-soluble vitamins (A, D, E, and K) and decreased hepatic production of vitamin K–dependent clotting factors. The prothrombin time can usually be normalized by the administration of parenteral vitamin K. Serum amylase and lipase levels are usually normal in patients with pancreatic cancer.

A wide variety of serum tumor markers have been proposed for use in the diagnosis and follow-up of patients with pancreatic cancer. The most extensively studied of these is CA 19-9, a Lewis blood group–related mucin

glycoprotein. Approximately 5% of the population lacks the Lewis gene and therefore cannot produce CA 19-9. When a normal upper limit of 37 U/mL is used, the accuracy of the CA 19-9 level in identifying patients with pancreatic adenocarcinoma is only about 80%. When a higher cutoff value of more than 90 U/mL is used, the accuracy improves to 85%, and increasing the cutoff value to 200 U/mL increases the accuracy to 95%.[14] The combined use of CA 19-9 and ultrasonography, CT, or ERCP can improve the accuracy of the individual tests, so that the combined accuracy approaches 100% for the diagnosis of pancreatic cancer. Levels of CA 19-9 have also been correlated with distant spread, prognosis, and tumor recurrence. In general, higher CA 19-9 values before surgery indicate an increased size of the primary tumor and increased rates of disease dissemination and localized unresectability. In addition, the CA 19-9 level has been used to monitor the results of neoadjuvant and adjuvant chemoradiation therapy in patients. Increasing CA 19-9 levels usually indicate recurrence or progression of disease, whereas stable or declining levels indicate a stable tumor burden (lack of progression/response), absence of recurrence on imaging studies, and an improved prognosis.

Radiologic Investigations

Radiologic imaging plays a crucial role in the diagnosis, staging, and follow-up of patients with pancreatic cancer. In addition to identifying the primary tumor, the goals of imaging include the assessment of local and regional invasion, evaluation of lymph nodes and vascular structures, identification of distant metastatic disease, and the determination of tumor resectability. Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are all useful noninvasive tests in patients suspected of having a pancreatic cancer.

Table 55.8 Signs of Pancreatic Cancer

Sign	Patients (%)
Head	
Jaundice	87
Palpable liver	83
Palpable gallbladder	29
Tenderness	26
Ascites	14
Abdominal mass	13
Body and Tail	
Palpable liver	33
Tenderness	27
Abdominal mass	23
Ascites	20
Jaundice	13
Diarrhea	3

Transabdominal ultrasonography (US) will reveal a pancreatic mass in 60% to 70% of patients with cancer. Pancreatic cancer typically appears as a hypoechoic mass on US. Ultrasonography may also demonstrate dilated intrahepatic and extrahepatic bile ducts, liver metastases, pancreatic masses, ascites, and enlarged peripancreatic lymph nodes. Because helical CT is just as sensitive as ultrasonography and provides more complete information about surrounding structures and the local and distant extent of the disease, transabdominal ultrasonography has been largely replaced by CT.

CT scanning is currently the preferred noninvasive imaging test for the diagnosis of pancreatic cancer. Pancreas protocol CT should be performed with rapid injection of intravenous iodinated contrast. Slices should be reconstructed at less than or equal to 3 mm with overlap. At least two postcontrast acquisitions, in the late arterial (or parenchymal) and venous phases are useful to assess the arteries (celiac, common hepatic, peripancreatic, and superior mesenteric arteries) and veins (portal, splenic,

and superior mesenteric veins [SMVs]). The parenchymal phase best shows the tumor as an ill-defined hypodense mass in the pancreatic parenchyma (**Fig. 55.3**), while the venous phase is best for detecting liver metastases. Neutral enteral contrast, such as water, is used, since this allows for better identification of the duodenal wall and results in artifact-free reformations. In many centers, no oral contrast is used. Coronal and sagittal reformations in both arterial and venous phases increase the sensitivity for determining local invasion. In addition to determining the primary tumor size, CT is used to evaluate invasion into local structures or metastatic disease.

4 In general, MRI offers no significant advantages over CT because of a low signal-to-noise ratio, motion artifacts, lack of bowel opacification, and low spatial resolution. MRI can be considered an alternative preoperative staging examination in patients with allergies to iodinated contrast agents and in patients with renal insufficiency. On MRI, a typical pancreatic adenocarcinoma appears hypointense on T1-weighted, unenhanced images, and has a variable appearance on T2-weighted sequences. The T2 signal of the tumor is often dependent on the amount of desmoplastic response associated with the tumor. On dynamic imaging following a gadolinium contrast injection, an adenocarcinoma enhances relatively less than the background pancreatic parenchyma in the early phase and then reveals progressive enhancement in the subsequent phases. Magnetic resonance imaging with MRCP is currently indicated for noninvasive diagnostic imaging to evaluate the biliary and pancreatic ducts and may be the optimal method to survey patients with IPMN and the pancreatic remnant after surgery.

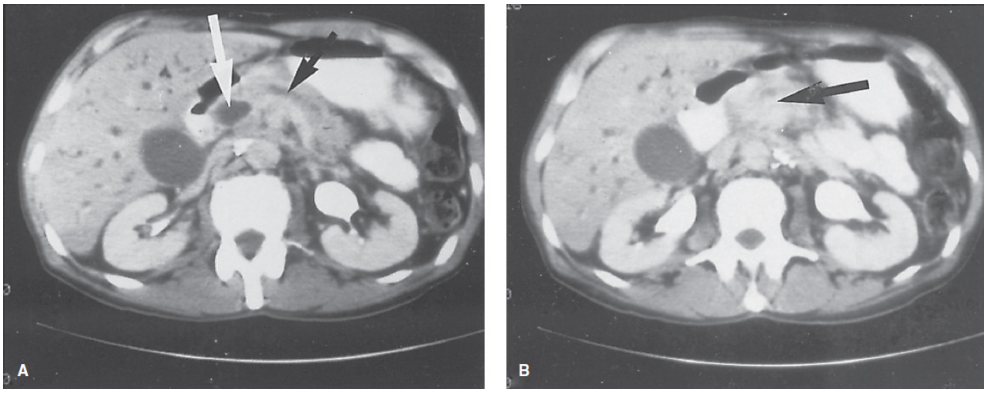

Figure 55.3 Computed tomogram of the abdomen of a patient with adenocarcinoma of the pancreas. **A:** The obstructed and dilated common bile duct (*light arrow*) and pancreatic duct (*dark arrow*) can be seen. In the adjacent cross section **B,** a large mass is present in the head of the pancreas (*arrow*).

Traditionally, the next step in the evaluation of the jaundiced patient has been cholangiography, either by the endoscopic or by the percutaneous route. If the endoscopic approach is used, the duodenum and ampulla can be visualized and biopsy brushing specimens obtained if necessary. In addition, ERCP allows for direct imaging of the pancreatic duct. The sensitivity of ERCP for the diagnosis of pancreatic cancer approaches 90%. The finding of a long, irregular stricture in an otherwise normal pancreatic duct is highly suggestive of a pancreatic cancer (**Fig. 55.4**). Often, the pancreatic duct will be obstructed with no distal filling. Although ERCP is reliable in confirming the presence of a clinically suspected pancreatic cancer, it is not routinely necessary, unless obstructive jaundice is present and relief with stent placement is pursued.

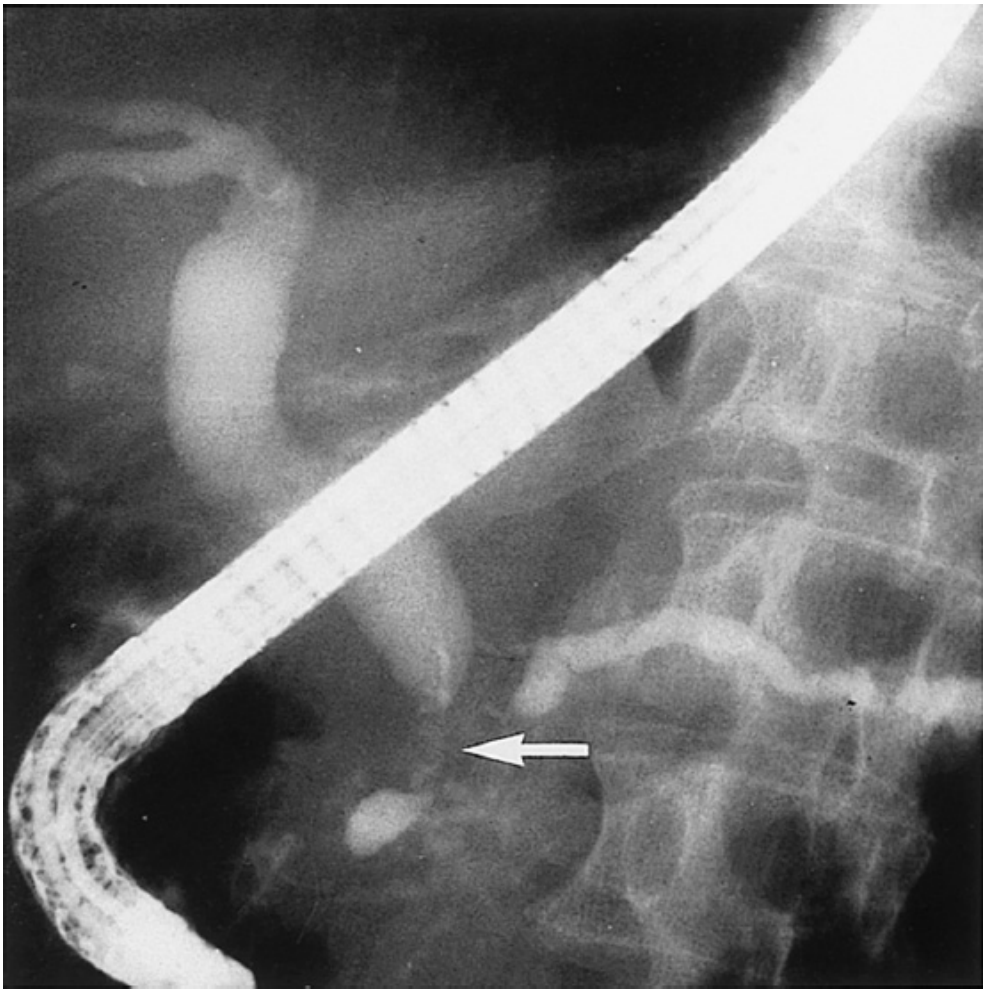

Figure 55.4 Endoscopic retrograde cholangiopancreatography in a patient with adenocarcinoma of the pancreas demonstrates a stricture of both the distal common bile duct and the pancreatic duct (*arrow*).

EUS is a minimally invasive technique in which a high-frequency ultrasonographic probe is placed into the stomach and duodenum endoscopically and the pancreas is imaged. Tumors appear as hypoechoic areas in the pancreatic substance (**Fig. 55.5**). The advantages of EUS for pancreatic cancer include characterization of small lesions (<2 cm) when CT findings are questionable or negative, detection of malignant lymphadenopathy, detection of vascular involvement, and the ability to perform EUS-guided FNA and core biopsies for definitive diagnosis and staging. EUS is not effective in assessing metastatic disease to the liver, although lesions in the left lateral segment overlying the stomach can sometimes be seen and biopsied too. EUS-guided biopsy has been used to

acquire tissue samples for cytologic analysis. This approach may avoid the risks of tumor seeding from percutaneous biopsy. The accuracy of EUS for detection of pancreatic tumors is extremely high at 94%, despite operator dependence, which makes this modality the most sensitive modality for detection, including for subcentimeter lesions where sensitivity is greater than 80%.[15] The addition of FNA biopsy extends sensitivity of detection to up to 92% and specificity up to 98%. Interestingly, while the analysis of regional nodes is frequently unnecessary given the lack of change in management of these tumors, the presence of pathologic celiac or para-aortic disease is different, given that extension of tumor within these nodes is considered nonregional metastatic disease. The sensitivity and specificity of EUS FNA of these nodes is 96.7% and 100%, respectively, highlighting the superior diagnostic power provided by EUS.

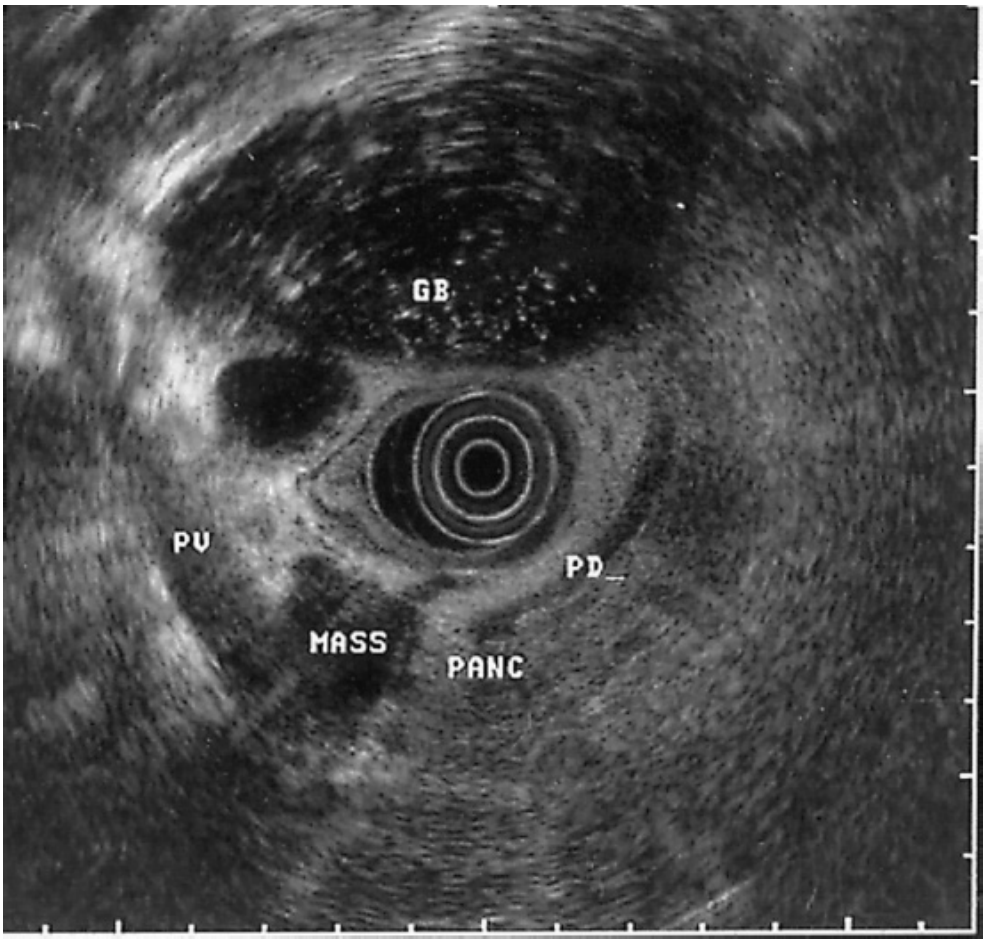

Figure 55.5 Endoscopic ultrasonogram of a 2.2-cm mass in the head of the pancreas. The transducer tip is located in the duodenum. The dilated common bile duct and gallbladder (GB) can be seen at the top of the image. The pancreatic duct (PD) is also dilated. The mass involves the portal vein (PV).

Percutaneous FNA of pancreatic masses is helpful in selected patients. The technique is safe and generally reliable but use of percutaneous biopsy has greatly diminished in recent years, and EUS is the preferred technique when possible. With the advent of EUS in recent years, few lesions of the pancreas today will undergo surgical resection without biopsy first, particularly in the absence of classical signs such as jaundice. This ensures that resection of nonsurgical diseases such as pancreatic lymphoma and autoimmune pancreatitis is avoided. In addition, with the advent of neoadjuvant therapy for treatment of PDAC, tumor biopsy is mandated prior to commencement of chemotherapy and/or radiation regimens.

PREOPERATIVE STAGING

The goal of preoperative staging of pancreatic cancer is to determine the feasibility of surgery and the optimal treatment for each individual patient. Specific anatomy-based CT criteria can stratify patients into four distinct groups (**Table 55.9**): (1) Resectable, (2) Borderline resectable, (3) Locally advanced unresectable, or (4) Metastatic. However, following neoadjuvant therapy, cross-sectional imaging is no longer reliable when determining extent of the local cancer given the inability to distinguish treatment response and fibrosis from tumor.[16]

Table 55.9 Preoperative Staging Based on CT Findings

Metastatic Evidence of metastatic spread (typically to the liver, peritoneum, or lung)
Resectable ▪ No involvement of the SMA, celiac, or CHA ▪ <180° interface between tumor and vessel wall of the PV or SMV and patent portal vein/splenic vein confluence ▪ No evidence of metastatic disease
Borderline resectable ▪ Tumor-vessel interface ≥180° of venous wall circumference and/or reconstructable occlusion ▪ <180° of SMA or celiac wall circumference, or reconstructable short-segment CHA ▪ No evidence of metastatic disease
Locally advanced ▪ Tumor-vessel interface ≥180° of venous wall circumference and/or reconstructable occlusion ▪ >180° of SMA or celiac wall circumference, or reconstructable short-segment CHA ▪ No evidence of metastatic disease

STAGING LAPAROSCOPY

Liver and peritoneal metastases are the most common sites of distant spread of pancreatic cancer. The patient's overall survival continues to be limited once distant intra-abdominal metastases have developed. Currently there is no clinical trial data to support resection of the primary pancreatic cancer and visible metastases. Despite improvements in modern imaging, diagnostic laparoscopy identifies occult metastases in 17% of treatment-naïve patients who appear to be resectable on imaging.[17] These occult metastases are often 1 to 2 mm lesions on the liver or peritoneum. In a series from the Massachusetts General Hospital of 151 patients the median overall survival for the staging laparoscopy group (11.4 months) was significantly longer than the laparotomy group (8.3 months, $p < 0.001$). There was no difference in the 30 day or lifetime incidence of postoperative cholangitis, gastric outlet obstruction, or biliary stent placement between groups, highlighting a role for diagnostic laparoscopy in treatment-naive patients. Patients who only underwent laparoscopy started palliative chemotherapy earlier (17.9 days vs. 39.9 days in the laparotomy group, $p < 0.001$), possibly contributing to the improved survival.

RESECTION OF PANCREATIC CARCINOMA

Carcinoma of the Head, Neck, or Uncinate Process

In 1912, Kaush[18] reported the first successful resection of the duodenum and a portion of the pancreas for an ampullary cancer. In 1935, Whipple[19] described a technique for radical excision of a periampullary carcinoma. The operation was originally performed in two stages. A cholecystogastrostomy to decompress the obstructed biliary tree and a gastrojejunostomy to relieve gastric outlet obstruction comprised the first stage. The second stage was performed several weeks later when the jaundice had resolved, and the nutritional status had improved. During the second stage, an en bloc resection of the second portion of the duodenum and head of the pancreas was performed without reestablishing pancreatic–enteric continuity. Although

earlier contributions had been made, the report by Whipple triggered the modern-day approach to the treatment of pancreatic carcinoma.

5 The operative management of pancreatic cancer consists of 2 phases that include tumor extirpation and then restoration of gastrointestinal continuity with anastomotic reconstruction. After the abdomen has been opened through an upper midline or an extended subcostal incision, a careful search for tumor outside the limits of a pancreaticoduodenal resection should be carried out. The liver, omentum, and peritoneal surfaces are inspected, palpated, and suspect lesions are sampled and specimens submitted for frozen-section analysis. While experience with resection of metastases is growing, the resection of metastatic disease remains unconventional and should be conducted under controlled research or clinical trial settings in specialized centers.

Once distant metastases have been excluded, the primary tumor is assessed for resectability. Local factors that generally preclude pancreaticoduodenal resection include retroperitoneal extension of the tumor to involve the inferior vena cava or aorta or direct involvement or encasement of the superior mesenteric artery, hepatic artery, and celiac axis. Involvement of the SMV or portal vein can be managed with venous resection and reconstruction in select cases. The technical aspects of determining local resectability begin with a Kocher maneuver and mobilization of the duodenum and head of the pancreas from the underlying inferior vena cava and aorta. Once the duodenum and head of the pancreas are mobilized sufficiently, the surgeon's hand can be placed under the duodenum and head of the pancreas to palpate the relationship of the tumor mass to the superior mesenteric artery. Inability of the surgeon to identify a plane of normal tissue between the mass and the arterial pulsation indicates direct tumor involvement of the superior mesenteric artery, and the possibility of complete tumor resection is ordinarily eliminated.

In the setting of resection following neoadjuvant therapy, institutional practice is variable, ranging from no resection when vessels continue to exhibit involvement radiologically to complete vascular resections and reconstructions including both arterial and venous resection. At the authors' institution, the surgical approach involves sampling suspicious areas involving the vessels based on preoperative radiologic assessment to confirm whether viable tumor persists on frozen analysis, including

commencement of surgery with a left-sided SMA first approach if needed to provide biopsies. In the event frozen samples are positive for cancer, palliation is pursed. If frozen specimens confirm only the presence of fibrosis, then planned resection continues, including venous resections and reconstructions as necessary. It should be noted while the principles and steps of the operation are unchanged following neoadjuvant therapy, operations tend to be more complicated due to adhesions and fibrosis, and frequently necessitate tedious and meticulous dissections of the arterial structures to safely resect the specimen.

Following Kocherization of the duodenum, the lesser sac is entered, and the pancreatic body is identified. By separating the mesenteric leaves of the stomach and colon, the right gastroepiploic vein and middle colic vein can be traced to the inferior border of the pancreas. The inferior border of the pancreas should be further dissected and entry of these vessels into the SMV identifies the inferior portion of the SMV–pancreas tunnel. Alternatively, following extensive Kocherization, the first structure that one encounters anterior to the third portion of the duodenum is the SMV, which can be traced toward the inferior aspect of the pancreas. Obliteration of the tunnel by tumor may restrict the surgeon from being able to proceed, although maneuvers such as moving to the left aspect of the field to create a tunnel initially over the splenic vein that is then used to identify the confluence may be helpful. Once the tunnel is exposed from below, dissection of the porta ensues, and early exposure and division of the right gastric artery and gastroduodenal artery expose the portal vein superiorly. It is always important to confirm, before ligation of the gastroduodenal artery, that the structure to be ligated is indeed the gastroduodenal artery and not a replaced right hepatic artery, and that pulses persist in the proper hepatic artery persist on clamping. Once the anterior portion of the vein is cleanly dissected, the tunnel is then completed from above, under the pancreas. The common hepatic duct is then dissected and the gallbladder and cystic duct taken. The stomach is then divided using a linear stapler in the classic approach to include 30% to 40% of its distal component, or the duodenum dissected and divided approximately 2 cm distal to the pylorus in the pylorus-sparing approach. The jejunum is divided 10 to 15 cm distal to the ligament of Treitz. The proximal jejunum and fourth portion of the duodenum are passed under the superior mesenteric vessels to the right, to allow the uncinate process to be dissected from the superior

mesenteric artery clearing all of the tissue along the right border of the artery. The course of the superior mesenteric artery should be clearly identified to avoid injury to this structure. The pancreatic neck is next carefully divided and, subsequently, the common hepatic duct. Once the hepatic duct has been divided, the posteriorly located portal vein can be seen across its length to facilitate dissection of the uncinate process from the vein. Small branches from the SMV should be carefully controlled. Gentle retraction of the specimen away from the vein along with leftward retraction of the vein will ensure that the specimen is meticulously resected in line with the SMA and without leaving behind residual pancreatic, adipose, or nodal tissue.

At this point, the specimen consisting of the gallbladder and common bile duct, the pancreatic head, neck, and uncinate process, and the entire duodenum and proximal jejunum (and the distal stomach for a traditional Whipple procedure) is freed completely and removed from the operative field (**Fig. 55.6**). Margins should be inked to facilitate pathologic analysis of the specimen.

Following resection of the specimen, there are a total of three anastomoses required for restoration of gastrointestinal continuity. These include the pancreaticojejeunostomy, hepaticojejunostomy, and gastrojejunostomy, or duodenojejunostomy if a pylorus-sparing operation is pursued. While reconstruction techniques can vary, our preferred technique is to bring the end of the divided jejunum through the transverse mesocolon in a retrocolic fashion and perform an end-to-side pancreaticojejeunostomy. The anastomosis is carried out in 2 layers, using either an interrupted silk outer layer, or a Blumgart anastomosis that is fashioned using an absorbable monofilament synthetic suture. These techniques rely on an internal duct-to-mucosal anastomosis. A small enterotomy is made in the jejunum to match the size of the pancreatic duct and an inner layer of interrupted 5-0 absorbable monofilament sutures are used to create the anastomosis. Some surgeons prefer to stent this anastomosis with either a short indwelling pancreatic stent or an externalized pancreatic stent when a small duct is encountered. An alternative to this duct-to-mucosa technique is to create an enterotomy approximately the same size as the pancreatic neck and to complete a running anastomosis circumferentially around the entire gland to permit invagination of the neck 1 to 2 cm into the lumen of the bowel by the outer anterior layer of the anastomosis. The biliary–enteric anastomosis is performed 8 to 10 cm

distal to the pancreaticojejeunostomy. An end-to-side hepaticojejunostomy is performed with a single interrupted radial layer of 4-0 absorbable synthetic suture material. Approximately 20 cm distal to the biliary–enteric anastomosis, a 2-layer end-to-side gastrojejunostomy (or duodenojejunostomy) is performed in an antecolic manner with an inner continuous layer of 3-0 absorbable synthetic suture material. The final reconstruction is shown in **Figure 55.6C**.

Several technical aspects of PD remain controversial. These controversies include whether (1) a radical lymph node dissection is necessary, (2) the pylorus should be preserved, and (3) a role exists for minimally-invasive pancreatic resections.

Several nonrandomized retrospective studies have recommended performing a radical (extended) retroperitoneal lymph node dissection to PD in an attempt to improve survival. However, results from four randomized prospective trials (**Table 55.10**)[20–24] have not proven any benefit associated with extended nodal dissections. The prospective trial performed by Pedrazzoli et al.[20] suggested a survival advantage to extended retroperitoneal lymph node dissection in patients with positive lymph nodes. Eighty-one patients with pancreatic adenocarcinoma were randomized to either standard or radical lymphadenectomy over 3 years at six different institutions. While the two groups were similar with respect to preoperative parameters, operative morbidity, and overall survival, a subgroup analysis of the 48 patients with positive lymph nodes showed a statistically significant survival advantage for patients undergoing the extended lymph node dissection. However, the largest prospective randomized trial from the Johns Hopkins Hospital failed to demonstrate a survival advantage for a radical resection compared with a classic PD.[21] Two hundred and ninety-four patients undergoing resection for periampullary adenocarcinoma were randomized between a standard resection (pylorus preserving PD with en bloc resection of the anterior and posterior pancreaticoduodenal lymph nodes, lower hepatoduodenal lymph nodes, and nodes along the right lateral aspect of the superior artery and vein) and a radical resection (standard resection plus distal gastrectomy and retroperitoneal lymph node dissection extending from the right renal hilum to the left lateral border of the aorta and from the portal vein to the inferior mesenteric artery). The groups did not differ with respect to age, gender, site of primary tumor, lymph node status, or margin status.

There were no significant differences in 1-, 3-, or 5-year and median survival when comparing the standard and radical groups (**Fig. 55.7**). However, the radical group had a higher overall morbidity (43% vs. 29%) with significantly higher rates of delayed gastric emptying and pancreatic fistula in addition to a longer postoperative hospital stay.

Pancreaticoduodenectomy with or without distal gastrectomy and extended retroperitoneal lymphadenectomy for periampullary adenocarcinoma, part 2: randomized controlled trial evaluating survival, morbidity, and mortality. *Ann Surg* 2002;236:355–366; discussion 366–368, with permission.)

In 1978, Traverso and Longmire[25] popularized the pylorus-preserving modification of the Whipple procedure. Preserving antral and pyloric

function, the pylorus-preserving Whipple procedure reduces the incidence of troublesome postgastrectomy symptoms. A number of studies have documented that gastrointestinal function may be better preserved in the pylorus-sparing modification than in the traditional operation. Concerns exist in the use of the pylorus-preserving Whipple procedure for the management of periampullary tumors because of the possibility of compromising the already small proximal surgical margin of resection in addition to anecdotal increased rates of delayed gastric emptying. This question has been addressed by a number of authors, and no difference appears to be found in survival or emptying rates among those patients treated with the pylorus-sparing Whipple procedure and those managed by the traditional Whipple resection.[26–28]

In recent years, significant advances have been made in the application of minimally invasive techniques to the management of both benign and malignant pancreatic disorders. Initially, laparoscopic pancreatic surgery was limited to diagnostic staging in patients with pancreatic cancer prior to resection. More recently, minimally invasive techniques have been used to manage benign and malignant lesions of the pancreas.[29] Laparoscopic or robotic PD is a technically demanding procedure due to the retroperitoneal location of the pancreas, its intimate association with surrounding gastrointestinal and major vascular structures, and the need for three separate anastomoses to complete the reconstruction. The procedures are performed as either robotic, pure laparoscopic, hand assisted, or as laparoscopic-assisted procedures.

Carcinoma of the Body and Tail

The surgical management of adenocarcinoma of the body and tail of the pancreas may be more limited than that of the head of the pancreas owing to late presentation secondary to the absence of presenting signs such as jaundice. The exploration should be started with a search for evidence of either metastatic disease to the liver or peritoneal implants, which is frequently done using diagnostic laparoscopy. The operation itself is also amenable to a minimally-invasive laparoscopic or robotic approach. In the absence of distant disease, the lesser sac is opened, and the SMV is identified as it passes under the neck of the pancreas in most cases, except if

the tumor is in the very distal portion of the pancreatic tail. The short gastric vessels are ligated sequentially extending to the right diaphragmatic crus, including the superior splenic attachments, and the splenic flexure is then mobilized. These maneuvers completely expose the distal pancreas, and the superior and inferior borders are next dissected. A retropancreatic tunnel is then easily created, and the splenic artery and vein are identified and dissected separately from the pancreas. The splenic artery and then splenic vein are divided near their proximal origins. The splenic vein is ligated close to the SMV or just distal to the insertion of the inferior mesenteric vein (IMV) in order to prevent venous thrombosis and propagation of clot within the vascular stump. The pancreas is divided proximal to the tumor to ensure a negative resection margin. The specimen is removed in a medial-to-lateral fashion above the retroperitoneal plane to remove the distal pancreas and spleen. Removal of the spleen constitutes a complete oncologic resection of tumors of the distal pancreas and associated regional lymph nodes. The transected pancreas is oversewn or stapled, frequently with reinforced staple loads. The bed is carefully inspected for residual disease and bleeding, and hemostasis ensured.

Postoperative Results

During the 1960s and 1970s, many centers reported operative mortality following PD in the range of 20% to 40%, with postoperative morbidity rates as high as 40% to 60%. During the last three decades, a dramatic decline in operative morbidity and mortality following PD has been reported at a number of centers, with operative mortality rates in the range of 2% to 3%.[30–32] The reasons behind this decline appear to be due to (1) increased specialization and expertise of surgeons performing the operation, (2) improvements in preoperative and postoperative care in specialized centers, (3) improvements in anesthetic management, and (4) large numbers of patients being treated at high-volume centers.[33]

Although the operative mortality rates for pancreatic cancer have been reduced significantly, the complication rates approach 40% (**Table 55.11**). Pancreatic fistula remains the most frequent serious complication following PD, with an incidence ranging from 5% to 15% following Whipple resections. In the past, the development of pancreatic fistula after PD was

associated with mortality rates of 10% to 40%. Although the incidence of pancreatic fistula following PD remains stable, the overall associated mortality rate has diminished owing to improved management, which largely includes percutaneous drainage of intra-abdominal collections. Despite many different closure techniques of the pancreatic stump following distal pancreatectomy, the pancreatic fistula rate continues to range from 20% to 30%.[34] Variation in patterns of intraoperative drainage exist, ranging from no drain placement with expectant management postoperatively to placement of dual anterior and posterior anastomotic drains. Similarly, much variation exists with respect to timing of removal of intraoperatively-placed surgical drains. Finally, the role of newer somatostatin analogs has been established in randomized-controlled settings, although widespread adoption has been limited by prohibitive costs across many clinical centers.[35] Most surgeons today continue enteral nutrition with, or without, antibiotics following complete drainage and adequate source control, and are able to manage pancreatic leaks using outpatient surveillance strategies.

Long-Term Survival

Historically, 5-year survival rates for patients undergoing resection for adenocarcinoma of the head of the pancreas were reported to be in the range of 12% to 19% from high-volume centers.[36–38] Factors found to be important predictors of survival in these series were negative margins and nodal positivity on a consistent basis. With the evolution of modern systemic chemotherapy, the median overall survival is 54 months and the 3-year

overall survival is 63% for resected patients who receive adjuvant therapy (**Figure 55.8**).[39]

ADJUVANT AND NEOADJUVANT THERAPY

Surgical and perioperative care after pancreaticoduodenectomy has not changed significantly over the last decade. However, there have been dramatic improvements in systemic therapy. Over the past two decades 5-year overall survival was 15% to 20% for resectable disease, with a median survival of 20 to 24 months.[40] With the development of novel chemotherapeutic regimens the median survival has increased to 54.4 months.[39]

The results of the most important randomized prospective trials of adjuvant therapy for pancreatic cancer are summarized in **Table 55.12**.

Table 55.12 Randomized Prospective Trials of Adjuvant Therapy for Pancreatic Cancer

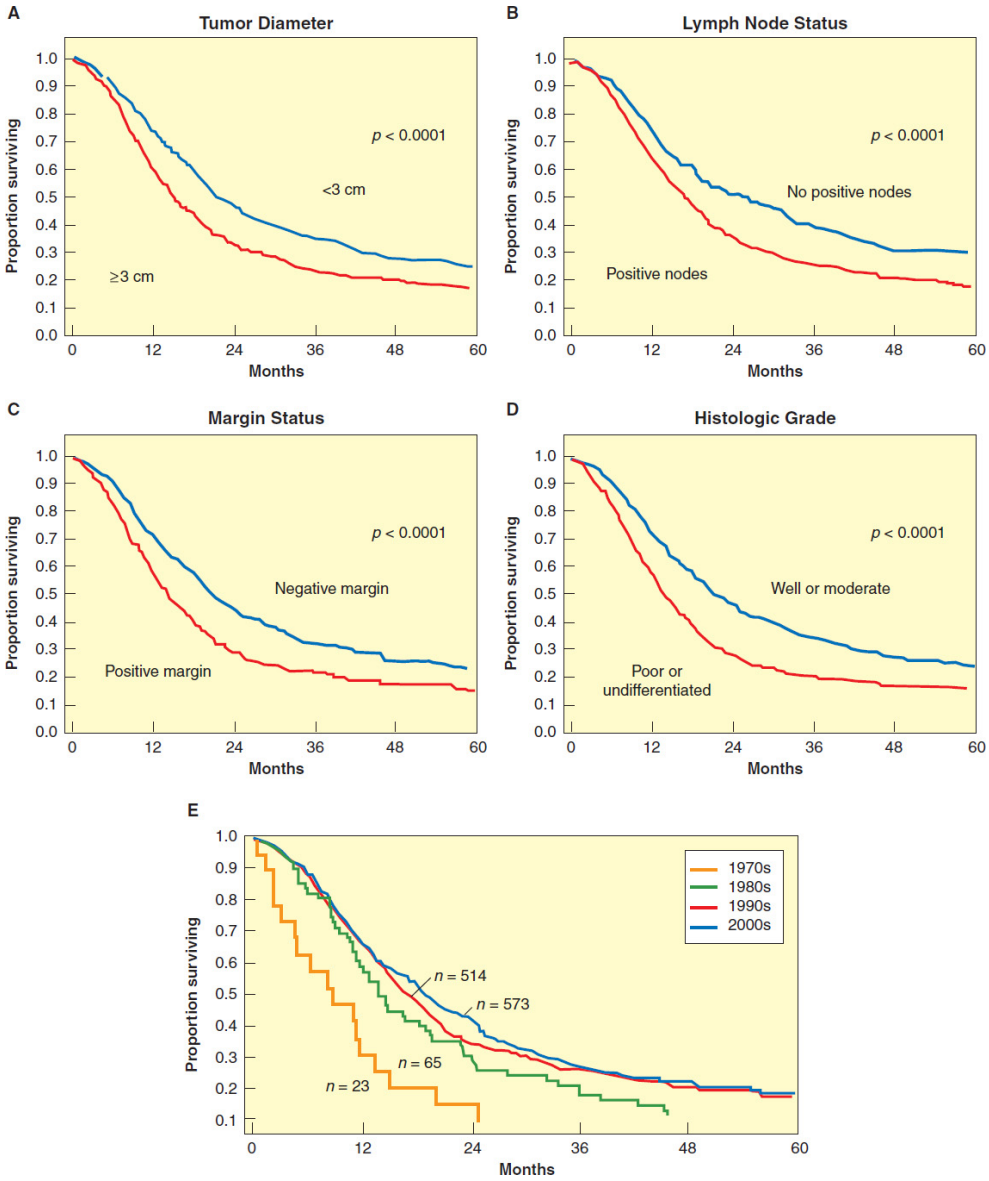

Figure 55.8 Survival of patients with pancreaticoduodenectomy based on tumor size **(A),** lymph node status **(B),** margin status **(C),** histologic grade **(D),** and historical context **(E)**. (From Winter JM, Cameron JL, Campbell KA, et al. 1423 pancreaticoduodenectomies for pancreatic cancer: a single-institution experience. *J Gastrointest Surg* 2006;10:1199–1211, with permission.)

The first randomized clinical trial in PDAC was in 1985 evaluating adjuvant chemoradiation. The role of radiation in the treatment of PDAC continues to be actively debated with significant differences in practice patterns around the world. However, most significantly the landscape of systemic therapy has changed resulting in significant improvements in survival.

In 1985, the Gastrointestinal Tumor Study Group reported encouraging results from a prospective, randomized trial to evaluate the efficacy of adjuvant radiation and chemotherapy following curative resection for adenocarcinoma of the head of the pancreas.[41] Forty-three patients were randomized to either adjuvant therapy with radiation and 5-fluorouracil (5-FU) or no adjuvant therapy. The median survival for the 21 patients who received adjuvant therapy was 20 months, and 3 (14%) survived 5 years or longer. For the 22 patients who received no adjuvant therapy, the median survival was 11 months, and only 1 patient (4.5%) survived 5 years.

The randomized trial conducted by the European Organization for Research and Treatment of Cancer (EORTC),[42] sought to recapitulate the results of the GITSG study in 114 patients with pancreatic head lesions (observation, $n = 54$ and adjuvant treatment, $n = 60$). However, chemotherapy (5-FU) given during radiation was given as a continuous infusion (rather than via bolus) during each radiation sequence, depending on toxicity, for up to 5 days. No chemotherapy was given post chemoradiation. Fifty-six percent of patients received the intended chemotherapy dose during radiation. Patients in the chemoradiation arm had a median survival of 17.1 months versus 12.6 months in the observation arm ($p = 0.099$); 2- and 5-year overall survivals were 37% and 20%, respectively, for the experimental arm and 23% and 10%, respectively, for the control arm.

The first trial evaluating systemic chemotherapy and chemoradiation was the ESPAC-1 trial published in 2004. The trial analyzed 289 patients recruited from 53 hospitals in a 2 × 2 factorial design.[43] The four study groups included (1) surgery only ($n = 69$); (2) chemotherapy only ($n = 73$) consisting of 5-FU, 425 mg/m^2, and leucovorin, 20 mg/m^2, given daily for 5 days every 4 weeks for six cycles of treatment; (3) radiation therapy and 5-FU given ($n = 75$) according to the original GITSG method; and (4) both treatments ($n = 73$, chemoradiation followed by chemotherapy). The major study conclusions were that the 5-year overall survival comparisons between patients who received chemotherapy versus those that did not (21% vs. 8%, $p = 0.009$) and those that received radiation therapy versus those that did not (10% vs. 20%, $p = 0.05$). The authors concluded that adjuvant chemotherapy had a beneficial effect in resected pancreatic cancer, whereas chemoradiation had a deleterious effect. A quality-of-life questionnaire showed no difference between those that received chemotherapy and those

that did not, and those that received chemoradiation and those that did not. Thus, the survival benefit of adjuvant chemoradiation for pancreatic cancer patients remains unclear, and the optimal regimen has yet to be determined.

The RTOG 9704 trial, presented in abstract form in 2006,[44] contained 442 eligible patients who received adjuvant chemoradiation (5,040 cGy) given as continuous fractions with radiosensitizing doses of 5-FU. The comparisons were with the addition of either three cycles of 5-FU (one prechemoradiation, two postchemoradiation for 12 weeks) versus four cycles of gemcitabine (one prechemoradiation, three postchemoradiation). Although the study showed no overall difference in aggregate survival, when pancreatic head lesions only were considered (eliminating study results from resected lesions in the pancreatic body or tail), both median survival (16.7 vs. 18.8 months) and overall survival at 3 years (21% vs. 31%) favored the gemcitabine arm ($p = 0.047$). The study concluded that the addition of adjuvant gemcitabine to postoperative 5-FU chemoradiation was superior to the addition of 5-FU.

The trial which made adjuvant gemcitabine the standard of care for PDAC was the CONKO-1 trial,[45] conducted in Germany and Austria. The trial randomized 368 patients following R0 or R1 resection to either observation or gemcitabine. After a median follow-up time of 53 months, the median disease-free survival was 13.9 months in the gemcitabine arm versus 6.9 months in the observation arm ($p < 0.001$). There was no difference in overall survival for the gemcitabine arm versus the control group; median survival was 22 versus 20 months. Although survival was not different, the authors concluded that postoperative gemcitabine significantly delayed the development of recurrent disease after complete resection of pancreatic cancer compared with observation alone.

The ESPAC-4 trial[46] enrolled 732 patients and compared adjuvant gemcitabine with a combination of adjuvant gemcitabine and capecitabine. After a median follow-up of 43.2 months the median overall survival was 27.9 months for gemcitabine and 30.2 months for the combination ($p = 0.03$).[47] The 5-year survival estimates were 17.1% in the gemcitabine group and 28% in the combination group. Both groups had similar recurrence patterns after a median of 12.7 months with 49.7% presenting with local recurrence, 40.3% with distant only, and 10% with local and distant recurrence.

Phase III trials showing significant improvement in overall survival in patients with metastatic disease utilizing FOLFIRINOX or gemcitabine/abraxane provided the rationale for the most successful adjuvant trial.[9,10,13]

The Phase III PRODIGE 24-ACCORD trial from France and Canada[39] was a landmark trial that consisted of 493 patients with resected PDAC. Patients were randomized to receive modified FOLFIRINOX (oxaliplatin [85 mg per square meter of body-surface area], irinotecan [180 mg per square meter, reduced to 150 mg per square meter after a protocol-specified safety analysis], leucovorin [400 mg per square meter], and fluorouracil [2,400 mg per square meter] every 2 weeks) or gemcitabine (1,000 mg per square meter on days 1, 8, and 15 every 4 weeks) for 24 weeks. After a median follow-up of 33.6 months, the median disease-free survival was 21.6 months in the modified-FOLFIRINOX group and 12.8 months in the gemcitabine group ($p < 0.001$). Disease-free survival at 3 years was 39.7% in the modified-FOLFIRINOX group and 21.4% in the gemcitabine group. This trial demonstrated the longest median overall survival for resected PDAC of 54.4 months in the modified-FOLFIRINOX group and 35.0 months in the gemcitabine group ($p = 0.003$). The overall survival rate at 3 years was 63.4% in the modified-FOLFIRINOX group and 48.6% in the gemcitabine group. This improvement in overall survival does come at a cost to patients with adverse grade 3 or 4 events in 75.9% of patients in the modified-FOLFIRINOX group and in 52.9% in the gemcitabine group. This trial set the new standard of care for PDAC patients.

6 Neoadjuvant strategies for PDAC continue to evolve (**Table 55.13**). Neoadjuvant therapy, which refers to treatment delivered prior to surgical resection, offers several potential benefits including: (1) delivery of treatment to well-oxygenated tissue which may enhance the efficacy, (2) downstaging can enhance the ability to achieve a negative-margin resection and thereby reduce local recurrence, (3) ability to avoid treatment postoperatively, particularly given the high rate of postoperative complications following pancreatectomy, and (4) avoidance of an operation in patients with rapidly progressive disease.

The majority of investigative work performed in the neoadjuvant treatment field has been with chemoradiation therapy. Multimodality treatment was administered to 142 consecutive patients with localized adenocarcinoma of

the pancreatic head.[48] A subset of 41 patients treated by preoperative chemoradiation and pancreatoduodenectomy were compared with 19 patients who underwent pancreatoduodenectomy and postoperative adjuvant chemoradiation. Surgery was not delayed for any patient who received preoperative chemoradiation because of chemoradiation toxicity, but 24% of the eligible patients did not receive their intended postoperative chemoradiation because of delayed recovery following resection. The patients treated with rapid fractionation were reported to have a significantly shorter duration of treatment (median, 62.5 days) than patients who received postoperative chemoradiation (median, 98.5 days). In early follow-up, no patient who received preoperative chemoradiation experienced a local recurrence, and peritoneal recurrence developed in only 10% of these patients. Local or regional recurrence developed in 21% of patients who received postoperative chemoradiation. The overall survival curves were similar for both cohorts.

Table 55.13 Selected Neoadjuvant Trials for Potentially Resectable Pancreatic Cancer

Author	Year	*n*	Regimen	Resected (%)	Median Survival (Months)
Spitz et al.[48]	1997	91	XRT, 5-FU	45	19

Wolff et al.[51] examined 86 patients treated with weekly gemcitabine at a dose of 400 mg/m^2 and 30 Gy of radiation. Sixty-one patients ultimately underwent resection (71%). The median survival in the resected patients was 36 months which is significantly longer than those seen in regimens using 5-

FU or paclitaxel as the radiation sensitizer. Analysis of the specimens revealed two pathologic complete responses and more than 50% nonviable tumor cells in 36 (59%). A gemcitabine-based regimen was also used in a multi-institutional study of 20 patients reported by Talamonti et al.[52] This group used full-dose gemcitabine and limited field radiation to 36 Gy (2.4 Gy/fraction). The authors described 14 patients as resectable and 6 as borderline resectable. Ultimately, all patients were explored and 17 resected (85%), again representing a high rate of resectability. A single pathologic complete response was observed and, in 24% of tumors, greater than 90% of the tumor cells were felt to be nonviable. Also notable was the low incidence (6%) of margin positivity in this trial. The median survival in the resected patients was 26 months. Based on the results of these initial trials, gemcitabine-based neoadjuvant regimens remain of considerable interest.

The most recent Phase III trial evaluating preoperative chemoradiotherapy to immediate surgery in resectable and borderline resectable patients is the Dutch PREOPANC trial.[57] The trial randomized 246 patients. Among patients who underwent neoadjuvant therapy, 61% underwent resection, while 72% of the patients who went directly to the operating room underwent resection. The intent to treat analysis demonstrated no difference in overall survival; 16 months in the neoadjuvant therapy arm versus 14.3 months in the surgery first group, ($p = 0.96$).

The utilization of total neoadjuvant therapy with FOLFIRINOX followed by chemoradiation is expanding. Two Phase II trials have been completed at the Massachusetts General Hospital for borderline and locally advanced disease.[55,56] The Phase II trial for borderline resectable PDAC enrolled 48 patients who received neoadjuvant FOLFIRINOX followed by chemoradiotherapy. Among the 32 patients who underwent resection, the R0 resection rate was 97%, 38% had N1 disease, and median progression-free survival was 48.6 months.[16] The second phase II trial enrolled 49 patients with newly diagnosed locally advanced PDAC who received neoadjuvant FOLFIRINOX and losartan followed by 50.4 Gy of chemoradiotherapy. Among the 34 patients who underwent resection, the R0 resection rate was 88%, 26% had N1 disease, and median progression-free survival was 17.5 months. Median overall survival was 33 months.[17]

UNRESECTABLE PANCREATIC CARCINOMA

For patients with persistently unresectable, but localized pancreatic adenocarcinoma, there are two main treatment modalities including intraoperative high-dose radiation and irreversible electroporation.

Intraoperative therapy is administered with a cone <8 cm in size with an average dose of 15 Gy. No substantial increase in morbidity was identified.[58] For the 64 patients who received TNT with FOLFIRINOX, the median progression-free survival was 14.7 months and the 12-, 24-, 48-, and 60-month survival rates were 98%, 49%, 13%, and 9%, respectively.[59] A gastrojejeunostomy was routinely performed at the time of treatment to avoid gastric outlet obstruction due to edema of the duodenum from radiation of the pancreatic tumor.

Irreversible electroporation is performed utilizing 2 to 6 operator-controlled, monopolar, single-use, disposable electrode probes, with >90 pulses consisting of 80 to 90 ms pulses to transmit energy to the target ablation area.[60] The AHPBA registry collected 152 patients, and after a median follow-up of 19 months from diagnosis, 9 (6%) patients exhibited local recurrence and 27 (18%) patients demonstrated distant recurrence. From diagnosis median overall survival was 30.7 months (range: 0.2 to 68.3 months), median progression-free survival was 22.8 months (range: 0.2 to 68.3 months) and median time to progression was 27.3 months (range: 0.2 to 68.3 months).[61]

PALLIATION

An increasing proportion of patients continue to become resectable as neoadjuvant therapy improves. However, a significant proportion of patients continue to present with locally advanced or metastatic disease that requires palliation. Symptom palliation via operative and nonoperative approaches can significantly improve the quality of life of patients. However, the decision to perform nonoperative versus surgical palliation for pancreatic cancer is influenced by a number of factors, including the patient's symptoms, overall health status, predicted procedure-related morbidity and mortality, location and size of the tumor, and projected survival. Surgical palliation can

be completed with acceptable perioperative morbidity and mortality and postoperative length of stay. The avoidance of late complications of recurrent jaundice, duodenal obstruction, and disabling pain would strengthen the argument in favor of surgical palliation in those patients expected to survive 6 months or more. [7] Nonoperative methods of palliation should be considered for patients in whom life expectancy is short and patients who are not candidates for operative intervention.

Table 55.14 Prospective Randomized Trial of Prophylactic Gastrojejunostomy in Patients with Unresectable Periampullary Cancer

	Patients (No.)	Morbidity (%)	Mortality (%)	Postoperative Length of Stay (Days)	Late Gastric Outlet Obstruction (%)
Gastrojejunostomy	44	32	0	8.5	0
No gastrojejunostomy	43	33	0	8.0	19

Adapted from Lillemoe KD, Cameron JL, Hardacre JM, et al. Is prophylactic gastrojejunostomy indicated for unresectable periampullary cancer? *Ann Surg* 1999;230: 322–330.

Biliary Obstruction

Jaundice, from obstruction of the common bile duct, is often the main presenting sign for patients with pancreatic cancer. Failure to decompress the biliary system can result in progressive liver dysfunction. Symptomatically, deposition of bile salts in the skin and tongue results in significant alterations of taste and refractory pruritus, respectively. Nonoperative palliation with a stent placed during ERCP is the preferred method. If endoscopic stent placement fails, a less desirable option is transhepatic catheter placement with external catheters that are converted to internal stents to permit biliary drainage. With these two options at high volume centers, operative bypass, such as hepaticojejunostomy, has become nearly obsolete.

Endoscopic stents can be plastic, metal or covered metal stents. Plastic stents are thinner stents which are less durable, resulting in more frequent endoscopies and stent changes. Metal stents can be uncovered or covered. In a randomized controlled trial of 119 patients undergoing neoadjuvant therapy for PDAC there was no significant difference in sustained biliary drainage,

however the reasons for stent failure differed significantly.[62] Covered metal stents had a higher rate of stent migration, while uncovered stents had a higher rate of tumor ingrowth. The rate of acute cholecystitis did not differ significantly (4.8% to 9.3%) in patients with their gallbladder in situ.

When patients undergo exploration for possible cure and are found to have unresectable disease, a biliary bypass can be performed or the patient can have an endoscopic metal stent placed. Traditionally, surgeons have performed either choledochojejunostomy or cholecystojejunostomy for the relief of malignant biliary obstruction. Both procedures are effective in relieving jaundice, but it appears that the rate of recurrent jaundice after cholecystojejunostomy is approximately 10%. Therefore, our preference for the palliation of obstructive jaundice is a hepaticojejunostomy or choledochojejunostomy reconstructed with a Roux-en-Y limb of jejunum. The surgical palliation of jaundice can be accomplished safely, with a mortality rate of less than 3% and an overall morbidity rate of 30% to 40%.[63] Nonoperative palliation appears to be associated with lower complication rates, lower procedure-related mortality rates, and shorter initial periods of hospitalization in comparison with surgical palliation. However, the rate of recurrent jaundice is higher.

Duodenal Obstruction

At the time that pancreatic cancer is diagnosed, approximately one-third of patients have symptoms of nausea or vomiting. Although true mechanical obstruction of the duodenum seen by radiologic or endoscopic examination is much less frequent, duodenal obstruction develops in almost 20% of patients before they die as the disease progresses.[64] Duodenal obstruction can be caused in the C-loop by cancers of the head/uncinate or at the ligament of Treitz by cancers of the body and tail. In patients with evidence of duodenal obstruction or impending obstruction, a minimally invasive gastrojejunostomy is indicated for palliation and improvement in quality of life. If patients have a significant burden of disease and a short life expectancy of only a few months an endoscopic duodenal stent can be considered. However, duodenal stents can obstruct due to tumor ingrowth and can jail the ampulla, which prevents exchange of the biliary stent. For patients with a longer life expectancy a minimally invasive isoperistaltic

loop gastrojejunostomy with a loop of jejunum 20 to 30 cm distal to the ligament of Treitz should be performed. If patients have long-standing obstruction and a dilated stomach, it may take weeks before the stomach regains tone and the patient is able to take in adequate calories. This population may benefit from a gastrojejeunal feeding tube which can vent the stomach and feed the jejeunum. This allows patients to avoid a long-term postoperative nasogastric tube and shorten their days in the hospital.

In patients who are explored and found to have unresectable pancreatic cancer we prefer to perform a gastrojejeunostomy. A prospective, randomized trial of prophylactic gastrojejunostomy in 44 patients were randomized and compared to 43 who did not undergo gastric bypass.[65] In this study, no difference was observed in either the complication rate, mortality, or the postoperative length of stay (**Table 55.14**). However, late duodenal obstruction developed in 19% of the patients who did not undergo bypass. A recent multicenter prospective randomized controlled trial has confirmed these results.[66] Therefore, we believe that a prophylactic gastrojejunostomy should be performed in patients undergoing surgical palliation for unresectable pancreatic carcinoma.

Novel approaches to perform endoscopic gastric bypasses using specialized stents are becoming increasingly possible. These procedures provide effective gastric decompression, however, their diameter is significantly smaller than an operative gastrojejeunostomy, limiting the amount and types of food a patient can eat. The endoscopic bypass is twice as likely to require an additional intervention (9%) when compared to a surgical gastrojejeunostomy (19%) in a shorter time interval (64 days vs. 93 days, $p < 0.01$) (Fisher AV HPB in press). Randomized data are required to provide accurate data regarding safety and efficacy.

PAIN

Tumor-associated pain can be incapacitating in patients with unresectable pancreatic cancer. The postulated causes of tumor-associated pain are many and include tumor infiltration into the celiac plexus, increased parenchymal pressure caused by pancreatic duct obstruction, pancreatic inflammation, gallbladder distention resulting from biliary obstruction, and gastroduodenal

obstruction. The management of pain in patients dying of carcinoma of the pancreas is one of the most important aspects of their care. The appropriate use of oral agents can be successful in most patients. Patients with significant pain should receive their medication on a regular schedule and not on an "as-needed" basis. The use of long-acting morphine derivative compounds appears to be best suited for such treatment. Percutaneous neurolytic block of the celiac axis, performed under either fluoroscopic or CT guidance, is also successful in the majority of patients in helping eliminate pain. Patients with unresectable cancer at the time of surgical exploration should receive a chemical splanchnicectomy, with 20 mL of 50% alcohol injected on either side of the aorta at the level of the celiac axis.[67]

CONCLUSION

Pancreatic adenocarcinoma is a complex disease requiring multi-disciplinary care. Significant improvements in the surgical management and systemic therapy have contributed to an improvement in overall survival.

Neoplasms of the Endocrine Pancreas

Jordan M. Cloyd and George A. Poultsides

Key Points

1. Pancreatic endocrine neoplasms (PENs) originate from multipotent stem cells in pancreatic ductules. Therefore, use of the older terms *islet cell tumor* and *islet cell carcinoma* is now discouraged, in favor of the terms *pancreatic neuroendocrine neoplasms* or *pancreatic neuroendocrine tumors*.
2. PENs have traditionally been classified according to the size and the mitotic rate of the tumor into one of three categories: pancreatic endocrine microadenomas, well-differentiated PENs, and poorly differentiated or high-grade endocrine carcinomas.
3. The most recent World Health Organization classification uses the combination of a proliferative index (Ki-67), mitotic rate, and morphologic features (degree of differentiation) to grade PENs.
4. The best initial imaging technique for a PEN is a high-quality multidetector computed tomography (CT) scan while novel NET-specific positron emission tomography (PET) scans provide important diagnostic and staging information.
5. Insulinomas may present with either neuroglycopenic and/or hypoglycemic-induced symptoms. Ninety percent are solitary, 90% are sporadic, and 90% are benign with their location evenly distributed throughout the pancreas. Ten percent are familial, typically associated with multiple endocrine neoplasia type 1 (MEN-1) syndrome, and commonly multifocal in the pancreas.
6. Most gastrinomas are located in the gastrinoma triangle. Seventy-five percent are sporadic, while 25% are associated with MEN-1 syndrome. They typically have malignant behavior including locally invasive growth and metastatic spread.
7. Glucagonomas usually present with a characteristic severe dermatitis (necrolytic migratory erythema) and are typically large and bulky and often with metastatic disease.
8. The majority of PENs are nonfunctional and surgical resection of localized tumors or those with limited hepatic metastases is standard treatment.

9 Liver-directed therapies including transarterial embolization or ablation may be considered for patients with hepatic metastases that are not amenable to resection.

10 Numerous systemic therapies exist for patients with metastatic PENs including somatostatin analogs, traditional chemotherapy such as temozolomide and capecitabine, targeted therapies such as everolimus or sunitinib, and peptide receptor radionuclide therapy (PRRT).

INTRODUCTION

Epidemiology

Pancreatic endocrine neoplasms (PENs) are rare tumors that account for 3% of pancreatic neoplasms and 7% of all neuroendocrine tumors (NETs).[1] Their incidence has increased nearly fivefold over the past 30 years, corresponding to the dramatic rise in the use of cross-sectional imaging in modern medicine. This has led to an increase in the rate of incidentally diagnosed tumors in asymptomatic patients.[2] First described by Nicholls in 1902 as a tumor arising from pancreatic islet cells, these "islet cell adenomas" were long thought to arise from the islets of Langerhans.[3] Recent investigations have revealed that PENs more likely originate from multipotent stem cells in pancreatic ductules.[4,5] This non–islet cell origin hypothesis has been further supported by the presence of tumors arising in patients with multiple 1 endocrine neoplasia type 1 (MEN-1).[6] Therefore, use of the older terms *islet cell tumor* and *islet cell carcinoma* is now discouraged, in favor of the terms *pancreatic endocrine neoplasms, pancreatic neuroendocrine tumors*, *pancreatic neuroendocrine neoplasms,* or *pancreatic endocrine tumors*.[7,8]

Classification

Traditionally, PENs were classified according to their size and the mitotic rate of the tumor. This system placed PENs into one of three categories: **pancreatic endocrine microadenomas**, 2 **well-differentiated PENs**, and **poorly differentiated** or **high-grade endocrine carcinomas**. PENs are also differentiated by the presence or absence of symptoms due to hormone

production, with nonfunctional PENs (91%) significantly more common than functional tumors (9%).[9,10] The production of certain hormones by functional tumors and their resulting symptoms lead to well-described clinical syndromes, which are detailed later in this chapter.

PENs less than 0.5 cm in diameter are classified as **pancreatic endocrine microadenomas**. Oncologically, they are considered to be benign lesions. Their prevalence is estimated to be as high as 10% of the population in autopsy series.[11,12] Most pancreatic endocrine microadenomas are noted as incidental findings in pancreata resected for other indications and, by definition, produce no neoplastic syndromes (i.e., are nonfunctional). PENs measuring greater than 0.5 cm in diameter but with low-grade histology are referred to as **well-differentiated PENs**. This group comprises the large majority of clinically relevant PENs but are still relatively rare.[13,14]

Table 56.1 2017 World Health Organization Classification of Pancreatic Neuroendocrine Tumors

	Ki67 Index	Mitotic Index
Well-Differentiated NENs	<3%	<2/10 HPF
G1 NET	3–20%	2–20/10 HPF
G2 NET	>20%	>20/10 HPF
G3 NET		
Poorly Differentiated NENs	>20%	>20/10 HPF
NEC G3		
Small Cell Type		
Large Cell Type		

NEN, neuroendocrine neoplasm; NET, neuroendocrine tumor; NEC, neuroendocrine carcinoma; HPF, high-power fields.

The classification of PENs has in the past been controversial, with no single dominant staging system in existence.[15] Multiple varying staging schemes (including those by the European Neuroendocrine Tumor Society [ENETS] and the American Joint Committee on Cancer [AJCC])[16,17] have been put forward, attempting to establish prognostic characteristics such as size, mitotic count,

presence of necrosis, extrapancreatic invasion, vascular and perineural invasion, 3 nuclear polymorphisms, and nodal involvement.[18–21] In 2017, the **World Health Organization (WHO)** updated their classification of PENs into **well-differentiated NETs** and **poorly differentiated neuroendocrine carcinomas (NECs)** based on tumor morphology with further stratification based on tumor grade as measured by the Ki-67 proliferation index and mitotic rate (**Table 56.1**). By convention, the tumor is assigned the higher grade if the Ki-67 index and mitotic rate differ.

Well-differentiated PENs can also be classified as **functional** or **nonfunctional** based on the presence or absence of a clinically recognizable syndrome (**Table 56.2**). These syndromes are the result of the secretion of biologically active hormones by the tumors and are confirmed by measurable elevations of the hormones in the blood. The most common functional PENs include insulinomas, gastrinomas, vasoactive intestinal polypeptide-omas (VIPomas), glucagonomas, and somatostatinomas. The incidence of these lesions ranges from 1 per 1 million for insulinomas to 1 per 40 million for somatostatinomas.[22] Even less common PENs secreting calcitonin,[23,24] parathyroid hormone–related protein,[25] growth hormone–releasing factor, and adrenocorticotropic hormone[26] have been reported. Nonfunctional PENs are classified as such due to their lack of an associated clinical syndrome. Some of the tumors in this group do secrete elevated amounts of hormones, including chromogranin A, which can be detected in either the serum or in surgical specimens using immunohistochemistry.[27] These secreted hormones either produce no clinical syndromes, as is seen with tumors that secrete pancreatic polypeptide (PP),[28] or secrete hormones in subclinical amounts or inactive forms. Traditionally, functional PENs were reported to comprise the majority of PENs. As methods of detecting these lesions and patterns of presentation have evolved, due primarily to the widespread use of high-quality cross-sectional imaging, nonfunctional PENs now comprise the vast majority of surgically resected cases.[18,29]

MOLECULAR GENETICS

Whole-Exome Sequencing of PENs

In 2011, a seminal whole-exome sequencing study of 68 sporadic PENs[30] identified frequent somatic mutations in *MEN-1* as well as the chromatin-

remodeling complex, *DAXX* (death-domain–associated protein) and *ATRX* (alpha thalassemia/mental retardation syndrome X linked). A subset of samples had mutations in genes involved in the mammalian target of rapamycin (mTOR) pathway including phosphatase and tensin homolog (PTEN), tuberous sclerosis complex 2 (TSC2), and phosphatidylinositol-4,5-bisphosphate 3-kinase, catalytic subunit α (PIK3CA). Other studies have correlated *DAXX* and *ATRX* mutations, activation of alternative lengthening of telomeres, and global chromosomal alterations with pathologic features and outcomes.[31] A more recent whole-exome sequencing of 102 PENs samples has clarified four distinct signaling pathways in which somatic mutations were commonly found: (1) chromatin remodeling, (2) DNA damage repair, (3) mTOR signaling, and (4) telomere maintenance.[32]

Familial Syndromes

The majority of PENs are sporadic. Some of them, however, occur as part of inherited familial syndromes such as MEN-1, von Hippel–Lindau (VHL) syndrome, neurofibromatosis (NF-1), and tuberous sclerosis (TS) (**Table 56.3**).[33]

Table 56.2 Classification of Functional Pancreatic Endocrine Tumors

Tumor (Syndrome)	Clinical Features	Extrapancreatic Location	Malignancy Rate
Insulinoma	Hypoglycemia	Rare	10%
Gastrinoma (Zollinger–Ellison)	Peptic ulcer Diarrhea	Frequent	50%
VIPoma (Verner–Morrison; WDHA; Pancreatic Cholera)	Watery diarrhea hypokalemia achlorhydria/acidosis	10%	Most
Glucagonoma	Hyperglycemia Dermatitis	Rare	Most
Somatostatinoma	Hyperglycemia Steatorrhea Gallstones	Rare	Most

WDHA, watery diarrhea, hypokalemia, and either achlorhydria or acidosis.

Table 56.3 Familial Genetic Syndromes Associated with Pancreatic Endocrine Neoplasms (PENs)

Syndrome	Chromosomal Location	Gene Product	PEN Type
MEN-1	11q13	Menin	Gastrinoma Nonfunctional
VHL	3p25-26	VHL	Various
NF-1	17q11.2	Neurofibromin	Somatostatinoma
TS	9q34 (TSC1) 16p13.3 (TSC2)	Tuberin	Various

MEN-1, multiple endocrine neoplasia 1; VHL, von Hippel–Lindau; NF, neurofibromatosis; TS, tuberous sclerosis; TSC, tuberous sclerosis complex.

MEN-1, also known as Wermer syndrome, is an autosomal dominant disorder caused by germline mutations in the tumor suppressor gene *MEN-1*. Chromosomal linkage studies have localized the genetic defect to the 11q13 locus, and studies of DNA markers have localized the MEN-1 gene between PYGM and D11S97. The gene contains 10 exons that code for a 610-amino-acid protein called menin, which is involved in DNA replication, transcription, repair, and chromatin remodeling. Although more than 20 endocrine tumors have been associated with MEN-1 syndrome, the most common include tumors of the parathyroid, anterior pituitary, and endocrine pancreas.

Less frequently than MEN-1, PENs may be associated with **VHL** syndrome. VHL syndrome is another autosomal dominant inheritance disease that includes many clinical disorders[34] including retinal hemangioblastomas, cerebellar and medullary hemangioblastomas, and PENs. PENs are found in a small percentage of patients with VHL syndrome, although pancreatic cysts are commonly encountered. A mutation in the VHL gene, a tumor suppressor located on chromosome 3p25–26, which regulates hypoxia-induced cell proliferation, is responsible. Although germline mutations with loss of heterozygosity (LOH) are associated with this disease, it has been proposed that other tumor suppressors most likely cooperate with VHL in order to form PENs. VHL-mutated PENs

have been shown to have specific defects in angiogenesis and hypoxia-inducible factor pathways.[35]

NF-1 (von Recklinghausen disease) is an autosomal dominant disorder that produces a well-described clinical syndrome characterized by café-au-lait spots and neurofibromas. These patients may develop pancreatic somatostatinomas, often near the ampulla of Vater. The NF-1 gene is a tumor suppressor gene located on 17q11.2 that encodes for neurofibromin, a regulator of the mTOR pathway. Loss of NF-1 results in mTOR activation and tumor development.[36,37]

TS is a rare autosomal dominant disorder associated with mutations in *TSC1* or *TSC2* which encode the protein tuberin. It is a neurocutaneous disorder associated with characteristic skin lesions, central nervous lesions including hamartomas, and rarely PENs. Note that patients may also develop pancreatic angiomyolipomas.

Molecular Targeting of PENs

In summary, PENs are becoming easier to characterize molecularly (and clinically) due to large-scale sequencing efforts and a better understanding of the molecular biologic aspects of these pancreatic tumors. Indeed, the molecular characterization of these tumors have helped to pave the way for clinical trials targeting tyrosine kinases (e.g., sunitinib) and the mTOR pathways (e.g., everolimus). Future molecular interrogation of PENs combined with these types of preclinical targeting approaches should continue to move the field closer to a personalized approach to treating PENs with more effective targeted therapies.

DIAGNOSTIC EVALUATION

Presentation

There are three primary ways by which patients with PENs come to clinical attention: the incidental discovery of a mass in the pancreas during cross-sectional imaging, symptoms secondary to the mass effect of a lesion in the pancreas (i.e., obstructive jaundice or pain), or, as a consequence of the symptoms of a syndrome associated with a functional PEN. As mentioned previously, incidentally detected nonfunctional PENs currently comprise the majority of clinically relevant tumors.

Biochemical

If a nonfunctional PEN is suspected, baseline serum levels of chromogranin A and PP can be useful diagnostic markers prior to surgical resection. Chromogranin A is a 49-kDa protein contained within the neurosecretory vesicles of PENs. The chromogranin A levels can be tracked over time to document tumor recurrence, often before the lesions become visible on cross-sectional imaging studies.[38] PP is secreted by the PP cells of the islets of Langerhans and can also be used to track patients with PENs, though its sensitivity (63%) is lower than that of chromogranin A.[39] Neuron-specific enolase is another tumor marker that is elevated in approximately 50% of PENs, most commonly in patients with pulmonary metastases.[40]

For those in whom a functional PEN is suspected, confirmatory testing of the relevant serum hormone should be performed. Assays are readily available for measuring insulin, gastrin, VIP, and glucagon. Assays for somatostatin, PP, prostaglandins, and other hormonal markers are less commonly available but can be obtained from certain laboratories. Genetic testing may be indicated for those in whom a clinical syndrome is suspected both for diagnostic confirmation but also to guide subsequent personal and family screening.

Computed Tomography

Cross-sectional imaging with thin-cut multiphasic computed tomography (CT) or magnetic resonance imaging (MRI) is typically indicated for all patients with confirmed or suspected PENs.[41] The accuracy of CT in detecting primary PENs ranges from 64% to 82% and depends largely on the size of the tumor.[42,43] PENs are typically hyperdense on arterial phases of imaging. Lesions that are obvious during the early arterial phase can become isodense on later phases of imaging. 4 Therefore, a multiphase approach is typically recommended.[44,45] CT is useful in assessing size and location of the primary tumor, proximity to visceral vessels, peripancreatic lymph node involvement, and the presence or absence of liver metastases (**Fig. 56.1**).

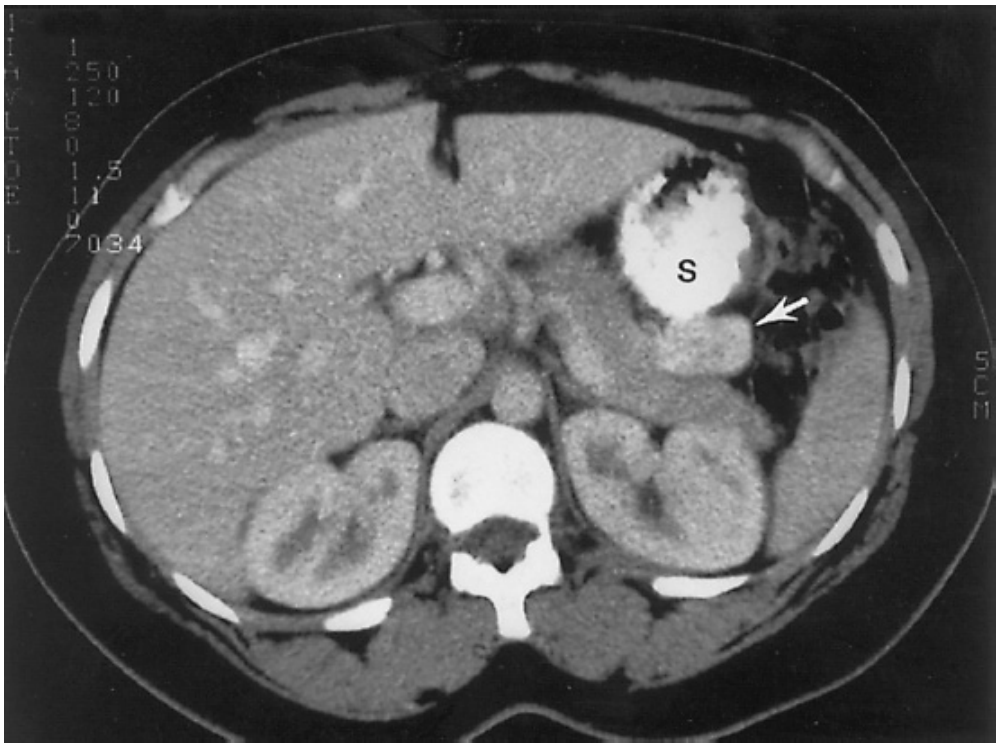

Figure 56.1 Computed tomography with oral and intravenous contrast in a patient with biochemical evidence of insulinoma. The neoplasm (*arrow*) is seen as a contrast-enhancing structure, 3 cm in diameter, in the tail of the pancreas posterior to the stomach (S). (From Yeo CJ. Islet cell tumors of the pancreas. In: Niederhuber JE, ed. *Current Therapy in Oncology*. St. Louis, MO: Mosby; 1993:272, with permission.)

Magnetic Resonance Imaging

MRI is increasingly used in the detection of PENs, particularly small lesions. They are especially well visualized on T1- and T2-weighted images with fat suppression. MRI has the advantage of increased soft tissue contrast without the administration of intravenous contrast when compared to CT.[35] PENs characteristically have high signal intensity on T2-weighted images.[46] On dynamic contrast-enhanced T1-weighted images, the tumors show the same typical enhancement pattern as on CT scan. The sensitivity of MRI has been reported to be between 74% and 100%.[42,43]

Somatostatin Receptor Scintigraphy

Somatostatin receptor scintigraphy (SRS) also plays an important role in imaging patients with PENs given that over 90% of NETs express somatostatin receptors. Traditionally, the octapeptide analog of somatostatin (octreotide)

labeled with indium-111 (known as Octreoscan) was the standard method of staging and characterizing NETs (**Fig. 56.2**).

This imaging modality has been largely replaced by positron emission tomography (PET)–based techniques. The most common used today is gallium Ga-68 DOTATATE which was approved by the FDA in 2016 and offers several benefits compared to traditional Octreoscan including improved sensitivity, less radiation, and enhanced convenience given the shorter scanning time required (**Fig. 56.3**). This method of SRS utilizes 3D PET fused with contrast-enhanced CT to provide improved spatial resolution and better sensitivity. In one seminal prospective study, the addition of Ga-68 DOTATATE to CT/MRI and Octreoscan led to a clinically significant change in management among 33% of the patients.[47]

Consensus guidelines generating appropriate use criteria have suggested that SRS-PET should replace in-pentetreotide scintigraphy for essentially all indications in which the latter was previously being used.[48]

Figure 56.2 Octreotide scan (*anterior view*) in a patient with a large endocrine tumor in the tail of the pancreas (large dark mass, upper right) and several hepatic metastases (upper left quadrant). A small amount of the tracer is seen in the bladder (lower midline).

Endoscopic Ultrasound

Endoscopic ultrasonography (EUS) is an important adjunct in the evaluation and localization of PENs.[49–53] Rösch et al.[51] were able to localize 32 of 39 tumors (82%) correctly with EUS after CT had failed to locate the tumor (**Fig. 56.4**). In their experience, EUS was more sensitive than the combination of CT and visceral angiography. A more recent study by Proye et al.[54] evaluated preoperative EUS and SRS in 41 patients with insulinoma and gastrinoma. The sensitivity and positive predictive value of EUS were 77% and 94%, respectively, for pancreatic tumors; 40% and 100%, respectively, for duodenal gastrinomas; and 58% and 78%, respectively, for metastatic lymph nodes.

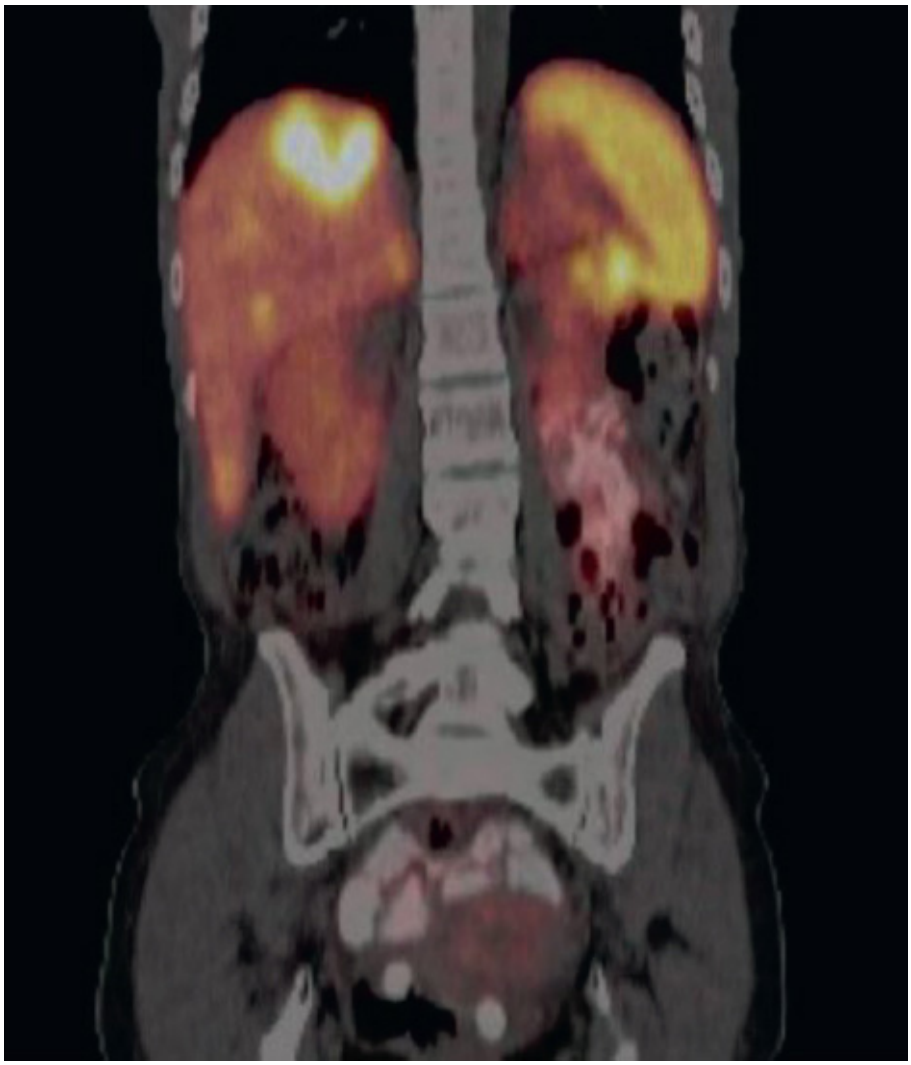

Figure 56.3 Gallium 68 dotatate PET/CT scan of a patient with a pancreatic endocrine tumor with several bulky hepatic metastases.

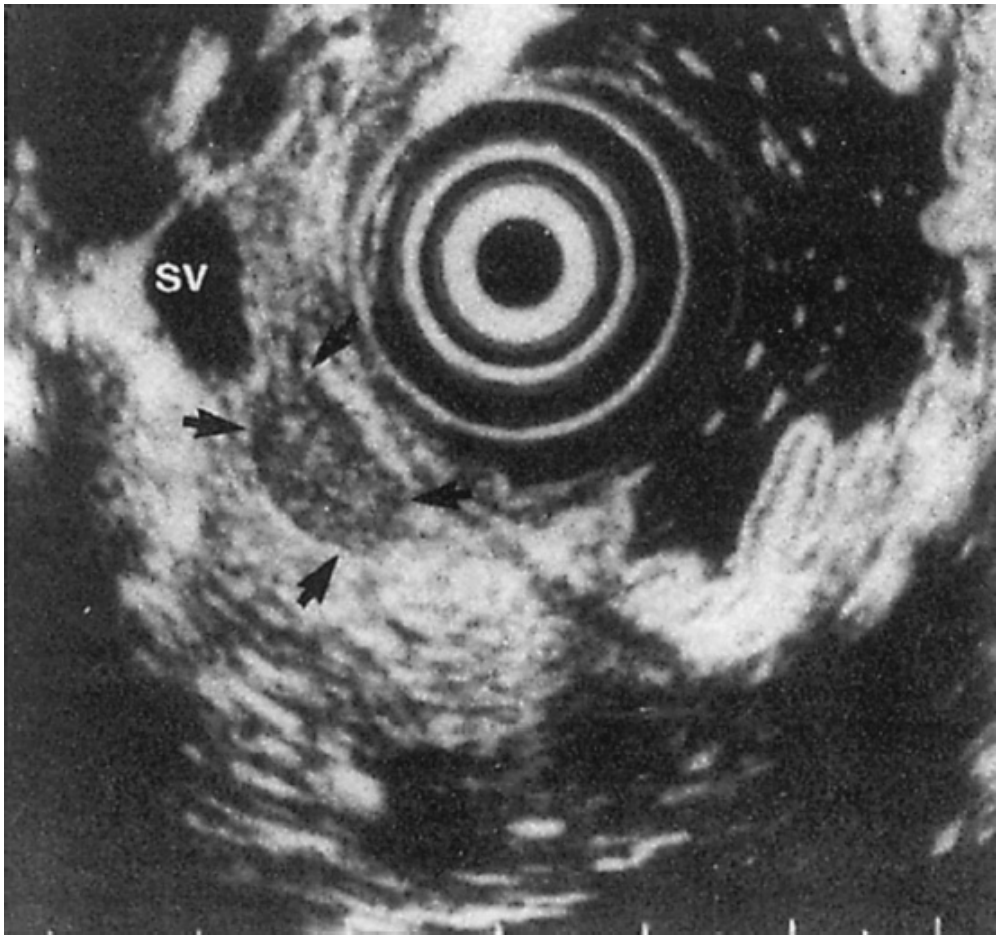

Figure 56.4 Endoscopic ultrasonographic image from a patient with an insulinoma (*arrows*) in the body of the pancreas. SV, splenic vein. (From Rösch T, Lightdale CJ, Botet JF, et al. Localization of pancreatic endocrine tumors by endoscopic ultrasonography. *N Engl J Med* 1992;326[26]:1721–1726, with permission.)

Venous Sampling

Percutaneous transhepatic portal venous sampling (PTPVS) and arterial stimulation with venous sampling (ASVS) are two techniques that are used exclusively for the diagnosis and localization of PENs. Although rarely used, PTPVS and ASVS can be helpful in localizing functional PENs when CT, MRI, SRS, and EUS are unsuccessful. Specifically, when insulinoma or gastrinoma are suspected, PTPVS may help in localizing the occult neoplasm.[55–59] The technique involves placing a catheter percutaneously through the liver into the portal vein and then sequentially sampling for hormone levels in the splenic vein, superior mesenteric vein, and portal vein, thereby regionalizing the location of hormone production (**Fig. 56.5**). The overall accuracy of this test

ranges from 70% to greater than 95% depending on the number of samples obtained, the persistence of autonomous hormone production by the tumor, and the careful handling and assaying of all samples. ASVS involves the selective visceral arterial injection of secretin or calcium with concurrent hepatic venous sampling for either gastrin or insulin.[60,61] Gastrinoma cells are known to respond to secretin by releasing gastrin,[62,63] and insulinoma cells are known to respond to calcium by releasing insulin. The provocative secretogogue is serially injected through an arterial catheter into at least three sites—the splenic, gastroduodenal, and inferior pancreaticoduodenal arteries. Samples are drawn from a hepatic vein catheter before and immediately after each injection. The arterial supply to the occult tumor can then be deduced based on which selective secretogogue injection is followed by a large increase in hepatic vein hormone concentration (**Fig. 56.6**). This technique, particularly when combined with intraoperative ultrasonography, results in a sensitivity of greater than 90%, essentially obviating the need for blind resection in unlocalized insulinomas.[64,65] Additionally, ASVS can differentiate the 5% of patients with nesidioblastosis from those with insulinoma.[66,67]

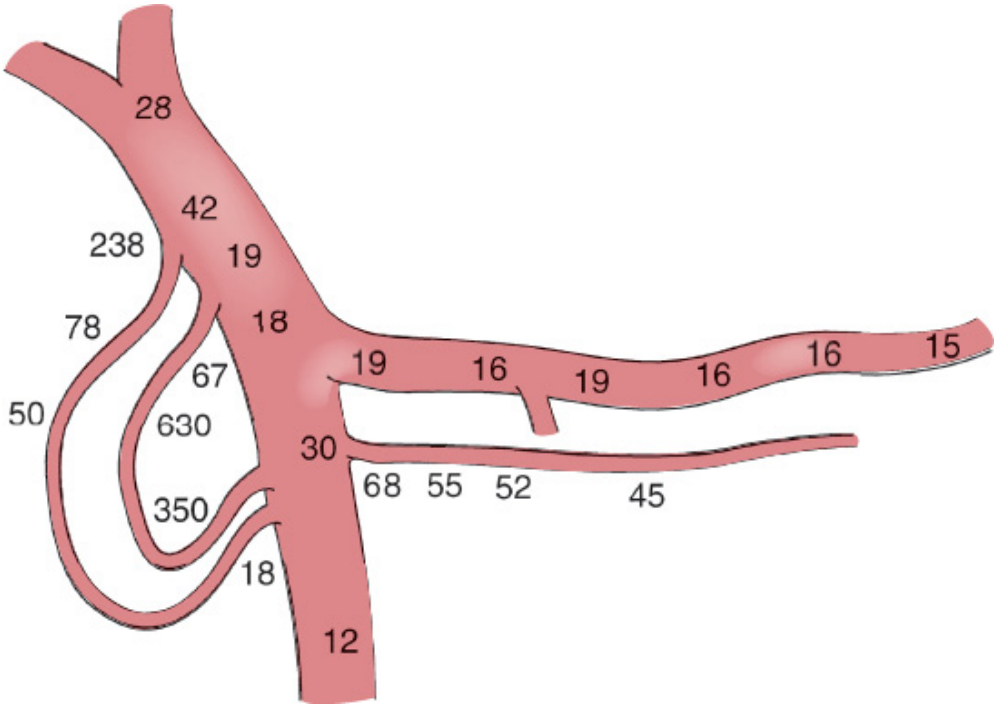

Figure 56.5 Schematic depiction of data from percutaneous transhepatic portal venous sampling (PTPVS) in a patient with an insulinoma. Insulin levels are given in microunits per milliliter. These data localize the neoplasm to the head of the pancreas. (Adapted from Norton JA, Sigel B, Baker AR, et al. Localization of an occult insulinoma by intraoperative ultrasonography. *Surgery* 1985;97:381–384.)

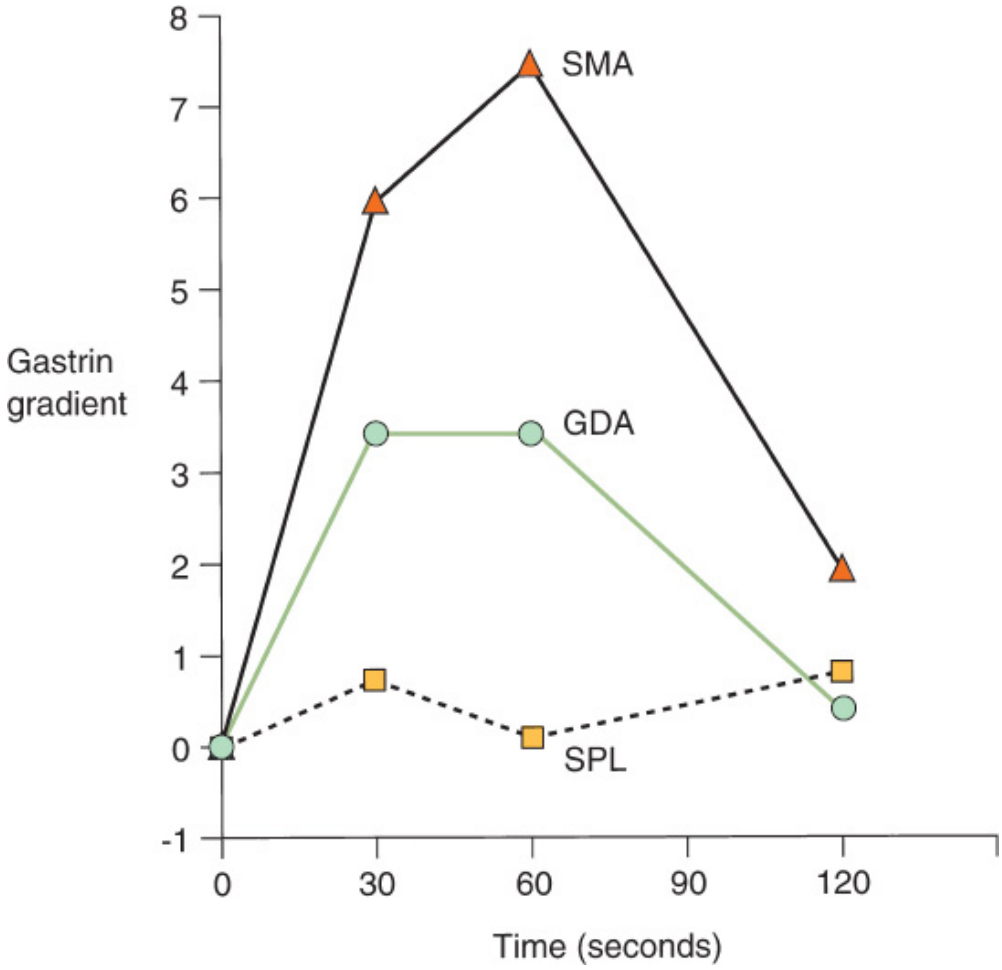

Figure 56.6 Graphic depiction of the results of arterial stimulation with venous sampling (ASVS) in a patient with gastrinoma. The rise in hepatic vein gastrin concentration (gastrin gradient) is plotted on the y-axis, and basal values are plotted on the x-axis: 1, 100% rise; 2, 200% rise; and so forth. A rise in the hepatic vein gastrin concentration observed after the injection of secretin into the superior mesenteric artery (SMA) and gastroduodenal artery (GDA) localizes the neoplasm to the head of the pancreas or duodenum. SPL, splenic artery. (Adapted from Thom AK, Norton JA, Doppman JL, et al. Prospective study of the use of intra-arterial secretin injection and portal venous sampling to localize duodenal gastrinomas. *Surgery* 1992;112:1002–1028; discussion 1008–1009.)

SURGICAL EXPLORATION

With modern diagnostic tools, surgical exploration without preoperative tumor localization is rarely needed. Regardless, at the time of surgical exploration for PEN, a complete evaluation of the pancreas and peripancreatic regions is performed. The body and tail of the pancreas are exposed by dividing the

gastrocolic ligament and entering the lesser sac. This portion of the pancreas can be partially elevated out of the retroperitoneum by dividing the inferior retroperitoneal attachments to the gland. After the second portion of the duodenum has been elevated out of the retroperitoneum by means of the Kocher maneuver, the pancreatic head and uncinate process are palpated bimanually. The liver is carefully assessed for evidence of metastatic disease. Intraoperative pancreatic and hepatic ultrasound can be helpful in identifying occult primaries or metastatic disease with sensitivities reported between 75% and 90%.[64,68]

NONFUNCTIONAL PANCREATIC ENDOCRINE NEOPLASMS

Surgical Resection

Overall, nonfunctional tumors tend to grow more slowly and have a more indolent course than pancreatic ductal adenocarcinoma, yet the 5-year survival rate for PENs after resection remains only 65%, with a 10-year survival of 45%.[10] Size is an important determinant of outcome and can be used to guide surgical decision making. PENs <1 cm typically have low malignant potential and can be safely observed while PENs >2 cm have prohibitive risks for lymph node and hepatic metastases that warrant resection.[69–71] PENs between 1 and 2 cm are controversial and require individualized decision making regarding resection or observation.[72] In general, patients with localized disease who are surgical candidates should undergo formal resection for potential cure via pancreaticoduodenectomy or distal pancreatectomy, depending on tumor location. Tumor enucleation, without formal resection may be appropriate for patients with small tumors in which the lesion is far from the pancreatic duct as to minimize the risks of pancreatic fistula. Patients with locally advanced disease involving the mesenteric vasculature may be candidates for radical mesenteric vascular resection (**Fig. 56.7**) or can be treated with neoadjuvant therapies in an attempt to downstage to resectability. With successful treatment, these patients can expect to enjoy a median survival in excess of 5 years.[73,74]

Lymphadenectomy

The role of lymphadenectomy for PENs remains controversial. PENs frequently metastasize to regional lymph nodes and therefore a lymph node dissection at the time of surgical resection provides important prognostic information as well as local disease control. The rate of lymph node involvement also correlates with tumor size.[75] While consensus guidelines are lacking, most recommend performing a regional lymphadenectomy at the time of resection for most PENs.[72]

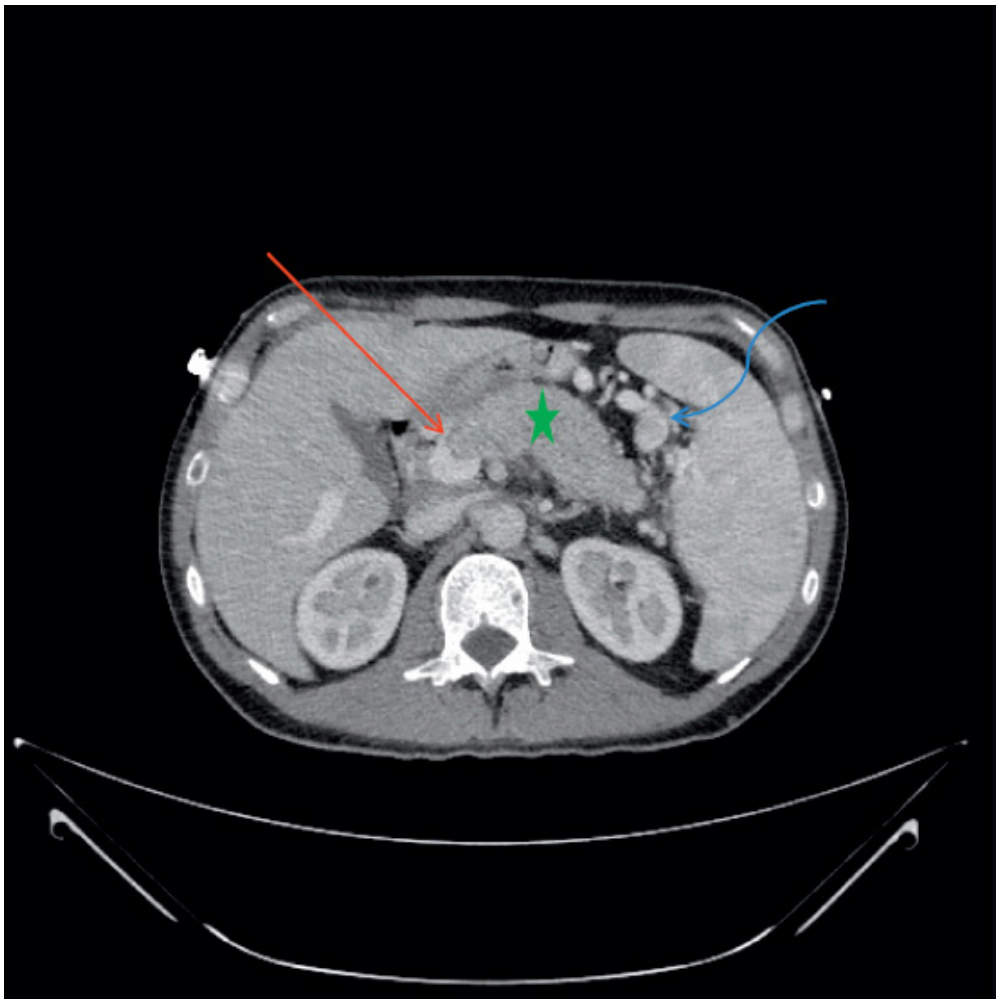

Figure 56.7 Computed tomography of a patient with a large PEN (*green star*) replacing the pancreatic body and tail, with splenic vein occlusion, perigastric varices (*blue line*), and tumor thrombus (*red line*) growing into the portal vein. This patient underwent a distal pancreatectomy, splenectomy, and partial portal vein resection with tumor thrombectomy, with complete surgical extirpation of the malignancy.

Table 56.4 Insulinoma

Parameter	Description
Symptoms	Neuroglycopenia causes confusion, personality change, coma Catecholamine surge causes trembling, diaphoresis, tachycardia Anabolic state: weight gain
Diagnostic tests	Monitored fast Insulin-to-glucose ratio
Anatomic localization	Evenly distributed throughout pancreas

INSULINOMA

5 Insulinoma is the most common functional neoplasm of the endocrine pancreas (**Table 56.4**). Patients typically present with the following features, known as **Whipple triad**[76]:

1. Symptoms of hypoglycemia during fasting
2. Documentation of hypoglycemia, with a serum glucose level typically below 50 mg/dL
3. Relief of hypoglycemic symptoms following administration of exogenous glucose

Autonomous insulin secretion in insulinomas leads to spontaneous hypoglycemia, with symptoms that can be classified into two groups. Neuroglycopenic symptoms include confusion, seizure, obtundation, personality change, and coma. Hypoglycemia-induced symptoms, related to a surge in catecholamine levels, include palpitations, trembling, diaphoresis, and tachycardia. In most cases, patients consume carbohydrate-rich meals and snacks to relieve or prevent these symptoms and typically gain weight.

Insulinoma is most reliably diagnosed by means of a **monitored fast** (via the withholding of exogenous glucose). During a monitored fast, blood is sampled for glucose and insulin determinations every 4 to 6 hours and when symptoms appear. Hypoglycemic symptoms typically occur when glucose levels are below 50 mg/dL, with concurrent serum insulin levels often exceeding 25 microunits/mL. Additional support for the diagnosis of insulinoma comes from the calculation of the insulin-to-glucose ratio at different times during the monitored fast. Healthy individuals have insulin-to-glucose ratios below 0.3, whereas patients with insulinoma typically demonstrate insulin-to-glucose ratios above 0.4 after a prolonged fast.

Other measurable β-cell products synthesized in excess in patients with insulinoma include **C peptide** and **proinsulin**. Elevated levels of both are typically found in the peripheral blood of patients with insulinoma. The possibility of the surreptitious administration of insulin or oral hypoglycemic agents should be considered in all patients with suspected insulinoma. Levels of C peptide and proinsulin are not elevated in patients who self-administer insulin. Additionally, patients self-administering either bovine or porcine insulin may demonstrate anti-insulin antibodies in circulating blood. The ingestion of oral hypoglycemic agents, such as sulfonylureas, can be assessed by means of standard toxicologic screening.

Insulinomas are evenly distributed throughout the pancreas, with one-third found in the head and uncinate process, one-third in the body, and one-third in the tail of the gland.[77] Less than 3% are located outside the pancreas, with these lesions located in the peripancreatic area.[78] Ninety percent are found to be solitary **sporadic** adenomas amenable to surgical cure, while approximately 10% are associated with the **MEN-1 syndrome**. In patients with MEN-1, the possibility of multiple insulinomas must be considered, and recurrence rates following surgery are higher. After the diagnosis of insulinoma has been confirmed biochemically, the appropriate localization and staging studies described earlier are performed (typically CT and EUS). Once the lesion has been localized,[79] patients undergo surgical exploration, where the pancreas is assessed not only by operative palpation but also by intraoperative ultrasonography. This allows for confirmation of preoperative localization and evaluates for the presence or absence of multiple primary tumors. Small tumors that are not close to the main pancreatic duct can be removed by enucleation (**Fig. 56.8**).[80] Larger tumors in the neck or proximal body may be resected via central pancreatectomy.[81–83] In the body and tail of the pancreas, insulinomas

more than 2 cm in diameter and those close to the pancreatic duct are most commonly removed via distal pancreatectomy. Large lesions in the head or uncinate process of the gland may not be amenable to local resection and may occasionally require pancreaticoduodenectomy for complete excision.[84,85] Increasingly, experienced surgeons are utilizing a minimally invasive approach to these tumors. Both laparoscopic and robotic pancreatectomy or enucleation are now performed on a routine basis with good results.[86–90]

Approximately 10% of insulinomas are malignant, presenting with lymph node or liver metastases. In the presence of hepatic metastases, resection of the primary tumor and metastases should be considered to reduce hypoglycemic symptoms and improve long-term survival.[91–93] In patients with unresectable disease, medications such as diazoxide and octreotide can be used to reduce insulin secretion from the tumor, minimizing hypoglycemia. Furthermore, the mTOR inhibitor everolimus, in addition to its antiproliferative effects, may improve glycemic control for patients with metastatic insulinoma.[94] Dietary manipulations, including judicious spacing of carbohydrate-rich meals and the consumption of night-time snacks, can also reduce the number of hypoglycemic episodes. Multiple chemotherapeutic regimens have been used including streptozocin, dacarbazine, doxorubicin, and 5-fluorouracil.[95–97] Combination chemotherapy has yielded the highest response rates but has not been shown to be curative.

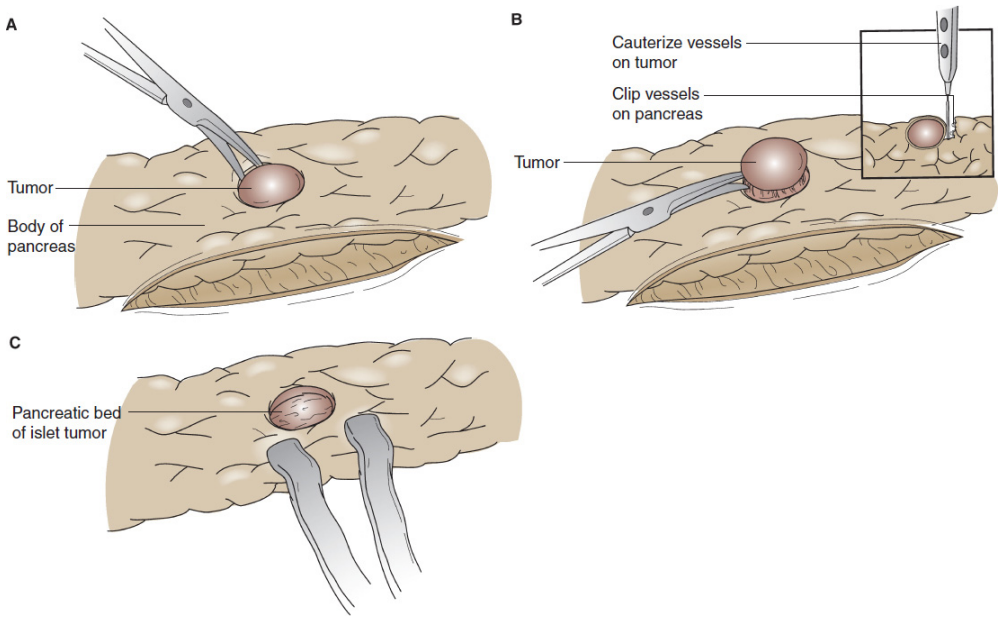

Figure 56.8 The technique for enucleating a benign pancreatic endocrine neoplasm with scissors (**A**) or electrocautery (**B**). **C:** After enucleation, the site of excision is drained.

GASTRINOMA (ZOLLINGER–ELLISON SYNDROME)

In 1955, Zollinger and Ellison described two patients with severe peptic ulcer disease and pancreatic endocrine tumors and postulated that an ulcerogenic agent originated from the pancreatic tumor.[98–100] It has been estimated that approximately 1 in 1,000 patients with primary duodenal ulcer disease and 2 in 100 patients with recurrence after peptic ulcer surgery harbor gastrinomas.[101] Seventy-five percent of gastrinomas occur sporadically, and 25% are associated with the MEN-1 syndrome. Historically, the majority of gastrinomas were found to be malignant, with metastatic disease present at the time of initial workup. With increased awareness and screening for hypergastrinemia, the diagnosis of gastrinoma is made earlier and a higher percentage of patients present with earlier stage and potentially curable neoplasms.[102]

The **clinical symptoms** of patients with gastrinoma are a direct result of increased levels of circulating gastrin (**Table 56.5**). Abdominal pain and peptic ulceration of the upper gastrointestinal (UGI) tract are seen in up to 90% of patients. Diarrhea is seen in 50% of patients, with 10% having diarrhea as their only symptom. Esophageal symptoms or endoscopic abnormalities resulting

from gastroesophageal reflux are seen in up to half of patients. The diagnosis of gastrinoma should be suspected in several clinical settings, including the initial diagnosis of peptic ulcer disease, recurrent ulcer after medical or surgical therapy, postbulbar ulcer, family history of ulcer disease, ulcer with diarrhea, prolonged undiagnosed diarrhea, MEN-1 kindred, nongastrinoma pancreatic endocrine tumors (high association of secondary hormone elevations), and prominent gastric rugal folds on UGI examination. Serum gastrin levels should be obtained in all of these settings.

DIAGNOSIS

Table 56.5 Gastrinoma

Parameter	Description
Symptoms	Peptic ulcer disease Diarrhea Esophagitis
Diagnostic tests	Serum gastrin measurement Gastric acid analysis (or pH testing) Secretin stimulation test
Anatomic localization	Duodenum and head of pancreas (gastrinoma triangle)

In most patients with gastrinoma, the **fasting serum gastrin** level is greater than 200 pg/mL. Gastrin levels greater than 1,000 pg/mL in the setting of documented hyperacidity and ulcer disease are virtually pathognomonic for gastrinoma. Because hypergastrinemia can occur in other pathophysiologic states (**Table 56.6**), fasting hypergastrinemia alone is not sufficient for the diagnosis of gastrinoma. **Gastric acid analysis** (or at least **gastric pH testing**) is critical in differentiating between ulcerogenic (high levels of acid) and nonulcerogenic (low levels of acid) causes of hypergastrinemia. To obtain an accurate gastric acid analysis, patients must not be taking antisecretory medications including histamine (H_2)-receptor antagonists or proton pump inhibitors (PPIs). The diagnosis of gastrinoma is supported by a basal acid output above 15 mEq/hr in nonoperated patients, a basal acid output exceeding 5

mEq/hr in patients with previous vagotomy or ulcer operations, or a ratio of basal acid output to maximal acid output exceeding 0.6.

After documenting that hypergastrinemia and excessive acid secretion exist, provocative testing with secretin should be performed to differentiate between gastrinoma, antral G-cell hyperplasia or hyperfunction, and the other causes of ulcerogenic hypergastrinemia. This is achieved with a **secretin stimulation test** (**Fig. 56.9**). A baseline gastrin level is drawn. The patient is then stimulated with 2 units/kg of secretin as an intravenous bolus and subsequent gastrin samples are collected at 5-minute intervals for 30 minutes. An increase in the gastrin level by more than 200 pg/mL above the basal level supports the diagnosis of gastrinoma.

DIAGNOSIS

Table 56.6 Disease States Associated with Hypergastrinemia

Nonulcerogenic causes (normal to low gastric acid secretion)
Atrophic gastritis
Pernicious anemia
Previous vagotomy
Renal failure
Short-gut syndrome
Ulcerogenic causes (excess gastric acid secretion)
Antral G-cell hyperplasia or hyperfunction
Gastric outlet obstruction
Retained excluded gastric antrum
Zollinger–Ellison syndrome

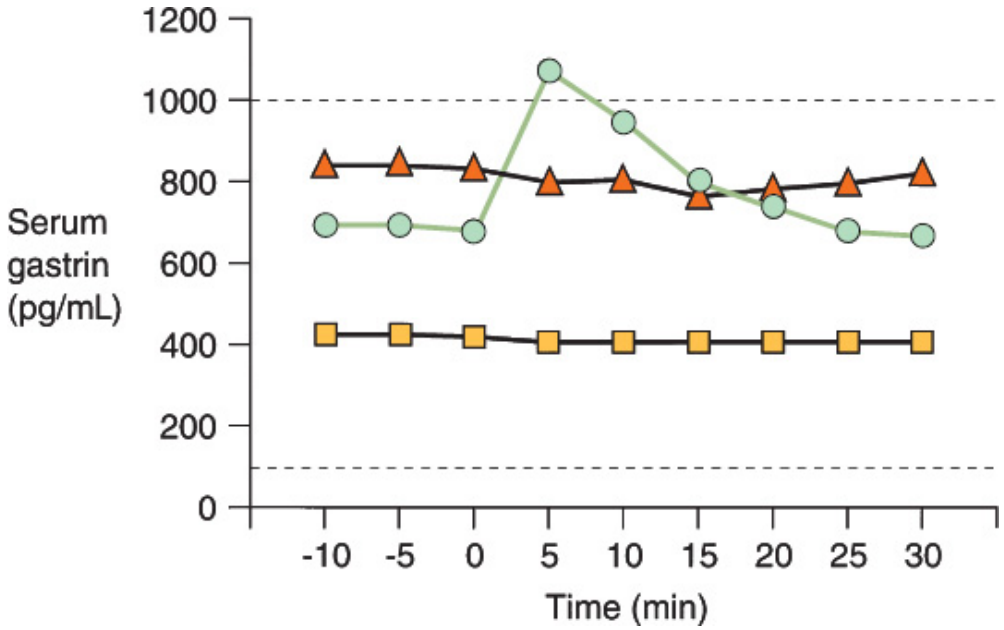

Figure 56.9 Results of intravenous secretin stimulation tests in patients with atrophic gastritis (*triangles*), gastric outlet obstruction (*squares*), and gastrinoma (*circles*). A positive test result, consistent with the presence of gastrinoma, is indicated by an increase over basal serum gastrin levels of at least 200 pg/mL. (Adapted from Wolfe MM, Jensen RT. Zollinger-Ellison syndrome: current concepts in diagnosis and management. *N Engl J Med* 1987;317:1200–1209.)

After the biochemical diagnosis of gastrinoma has been made, the gastric acid hypersecretion should be pharmacologically controlled. PPIs are now considered the drug of choice for this purpose.[103,104] The dose is adjusted to achieve a nonacidic pH during the hour immediately before the next dose of the drug. Typically, PPI doses needed for acid control exceed usual dosing levels. After the initiation of antisecretory therapy, all patients should undergo imaging studies to localize the primary tumor and to assess for metastatic disease.

6 For patients with resectable disease, surgical exploration with curative intent should be offered. On exploration, the entire abdomen should be assessed for areas of extrapancreatic and extraduodenalgastrinomas. Most gastrinomas are found in the **gastrinoma triangle** (**Fig. 56.10**),[77,105] the area to the right of the superior mesenteric vessels, in the head of the pancreas or in the duodenal wall. Both intraoperative ultrasound and intraoperative upper endoscopy may be helpful in tumor localization.

Transillumination of the duodenum may help identify small duodenal gastrinomas.[106,107] If the tumor is still not identified, a longitudinal **duodenotomy** should be performed at the level of the second portion of the duodenum in search of duodenal wall microgastrinomas, which can be palpated

between two fingers.[108,109] Small gastrinomas in the duodenal wall can be locally resected with primary closure of the duodenal defect. The routine use of duodenotomy increases the short- and long-term cure rates in patients with sporadic gastrinoma.[110] In a small percentage of patients, gastrinoma is found only in peripancreatic lymph nodes, with these lymph nodes harboring the apparent primary tumor. Resection of these apparent lymph node primary gastrinomas has been associated with long-term eugastrinemia and biochemical cure in up to half of cases.[111] A review from the National Institutes of Health identified likely primary lymph node gastrinomas in 26 of 176 gastrinoma patients (14.7%), with 69% being eugastrinemic at a mean of 10 years after resection.[112]

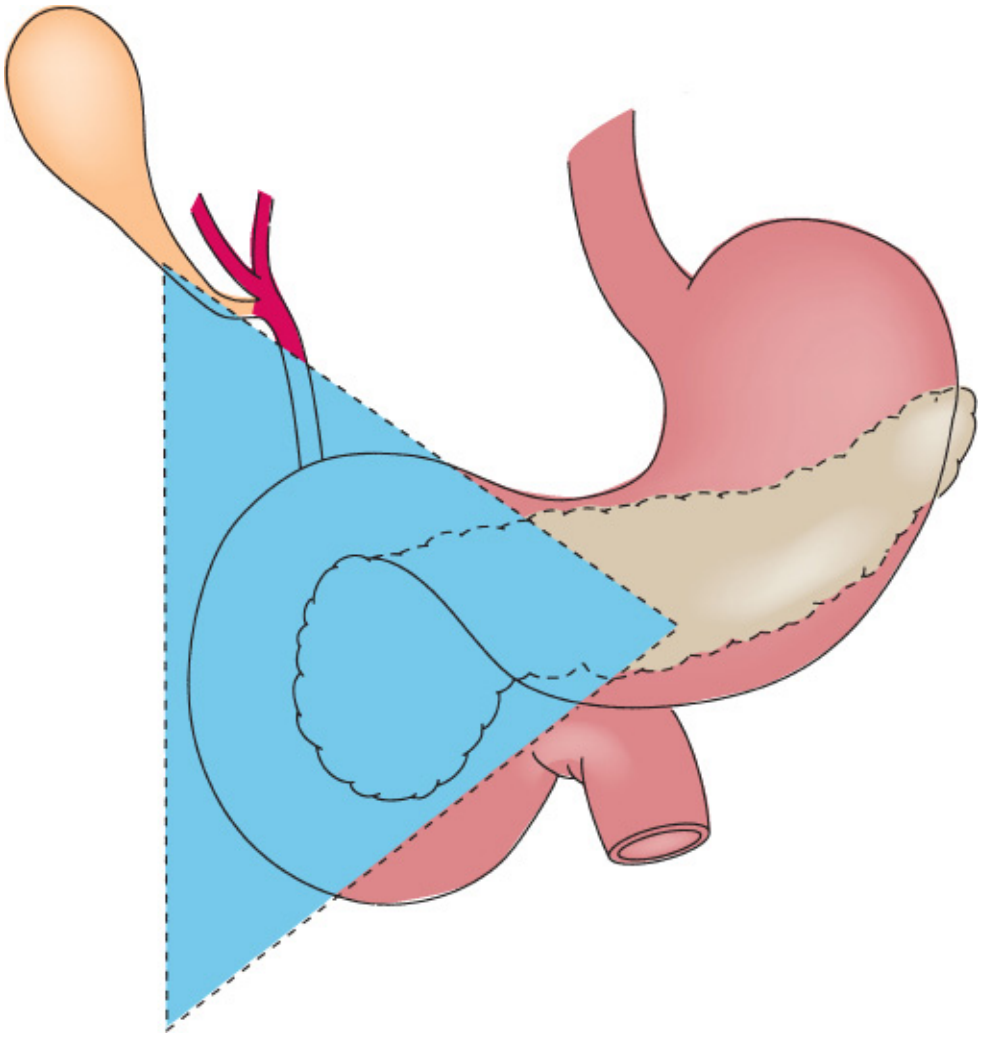

Figure 56.10 Most gastrinomas are found within the gastrinoma triangle.

The management of **gastrinoma in MEN-1** is not as clear given the multifocality of these lesions. Patients with sporadic gastrinomas tend to experience significantly improved disease-free survival following resection compared to those with MEN-1.[113] In patients with MEN-1, gastrin-secreting tumors are often multicentric and associated with lymph node metastases. Although some groups have favored resection only when MEN-1 gastrinoma tumors exceed 3 cm, some have posited that earlier intervention may be warranted.[114,115] The surgical **treatment of hypercalcemia** caused by parathyroid hyperplasia should precede any surgery for hypergastrinemia in patients with MEN-1.

For patients with unresectable metastatic disease, multiple modalities have been used. Chemotherapy including streptozocin, 5-fluorouracil, and doxorubicin provides response rates of less than 50%.[116] Hormonal therapy with octreotide may relieve symptoms, reduce hypergastrinemia, and diminish hyperchlorhydria.[117,118] In patients with hepatic metastases, aggressive surgical cytoreduction,[119–122] hepatic transplantation,[123] hepatic artery chemo- or radioembolization, and interferon therapy have all been used, with variable results.

VIPOMA (VERNER–MORRISON SYNDROME)

Synonyms for VIPoma include WDHA syndrome (watery diarrhea, hypokalemia, and either achlorhydria or acidosis) and pancreatic cholera syndrome (**Table 56.7**). Verner and Morrison[124] characterized this secretory diarrheal syndrome in a 1958 report. Patients characteristically present with intermittent severe, watery diarrhea averaging up to 5 L/d. Hypokalemia results from fecal loss of large amounts of potassium. Low serum potassium levels lead to lethargy, muscle weakness, and nausea. A metabolic acidosis may be present, due to loss of bicarbonate in the diarrhea. Half of the patients may have hyperglycemia or hypercalcemia, and cutaneous flushing can be observed in a minority. The diagnosis of VIPoma is made after other common causes of diarrhea have been excluded (**Table 56.8**)[125] and an elevated serum VIP level is documented.

Table 56.7 VIPoma

Parameter	Description
Symptoms	Watery diarrhea Weakness Lethargy Nausea
Diagnostic Tests	Hypokalemia Achlorhydria Metabolic acidosis Serum VIP levels elevated
Anatomic Localization	Most in body and tail of pancreas, with liver metastases

VIP, vasoactive intestinal peptide.

Table 56.8 Differential Diagnosis of Verner–Morrison Syndrome

Entity	Workup
Villous Adenoma	Lower GI endoscopy
Laxative Abuse	Stool examination for phenolphthalein
Celiac Disease	Fecal fat measurement D-xylose tolerance test Small bowel biopsy
Parasitic and Infectious Diseases	Stool culture Ovum and parasite analysis *Clostridium difficile* toxin assay
Inflammatory Bowel Disease	Lower GI endoscopy Upper GI and small bowel series
Carcinoid Syndrome	Urinary 5′-HIAA Upper GI and small bowel series Abdominal CT Serum serotonin measurement
Gastrinoma	Serum gastrin measurement Gastric acid analysis Secretin stimulation test

CT, computed tomography; GI, gastrointestinal; 5′-HIAA, 5′-hydroxyindoleacetic acid.

VIP secretion can be episodic, so repeated fasting levels should be measured if there is a strong clinical suspicion. Preoperative tumor localization is critical, because 10% of patients may have extrapancreatic tumors located in the retroperitoneum or chest. Most tumors are located in the distal pancreas where they are amenable to resection via distal pancreatectomy. In most cases, hepatic metastases accompany the primary tumor. Therapies directed at these metastases, such as resection or ablative strategies, are appropriate.

Surgical excision is appropriate in nearly all patients with VIPoma. Prior to surgery, fluid and electrolyte imbalances must be corrected. Octreotide can serve as a treatment adjunct, reducing the levels of circulating VIP, with a resultant decrease in the volume of diarrhea. Octreotide is also useful for

symptom control in the setting of unresectable disease. Chemotherapy specific for this disease has not been well studied.

GLUCAGONOMA

7 The most common findings in the glucagonoma syndrome are severe dermatitis, mild diabetes, stomatitis, anemia, and weight loss (**Table 56.9**). The dermatitis manifests as a characteristic skin rash termed **necrolytic migratory erythema**. This rash exhibits cyclic migrations, and it has been theorized that the hypoaminoacidemia accompanying glucagonoma is the cause.

DIAGNOSIS

Table 56.9 Glucagonoma

Parameter	Description
Symptoms	Dermatitis manifested as necrolytic migratory erythema Stomatitis Catabolic state: weight loss
Diagnostic tests	Hyperglycemia Hypoproteinemia Serum glucagon measurement Serum amino acid profile
Anatomic localization	Most in body and tail of pancreas, with liver metastases

The diagnosis of glucagonoma is suggested by the clinical presentation and biopsy of the skin lesions but is secured by the documentation of high fasting levels of serum glucagon. Most glucagonomas are located in the body and tail of the gland. These tumors are typically large and bulky, and surgical resection requires distal pancreatectomy (**Fig. 56.11**). Metastases are found in most patients and safe debulking of these should be considered.[126] As in patients with VIPoma and insulinoma, octreotide can be useful in controlling the signs and

symptoms (hyperglycemia and dermatitis) associated with incurable glucagonoma.

SOMATOSTATINOMA

The somatostatinoma syndrome is the least common of the five generally accepted functional PEN syndromes, occurring in less than 1 in 40 million people. The clinical features are nonspecific including steatorrhea, diabetes, hypochlorhydria, and cholelithiasis (**Table 56.10**). Fasting plasma somatostatin levels of greater than 100 pg/mL can be used to confirm the diagnosis.

Most somatostatinomas are located in the pancreatic head or periampullary region.[127] Tumors are of variable size and are often easily localized. Metastatic disease may be present at the time of diagnosis. Safe resection of the primary tumor (often via pancreaticoduodenectomy) and careful debulking of hepatic metastases are indicated.

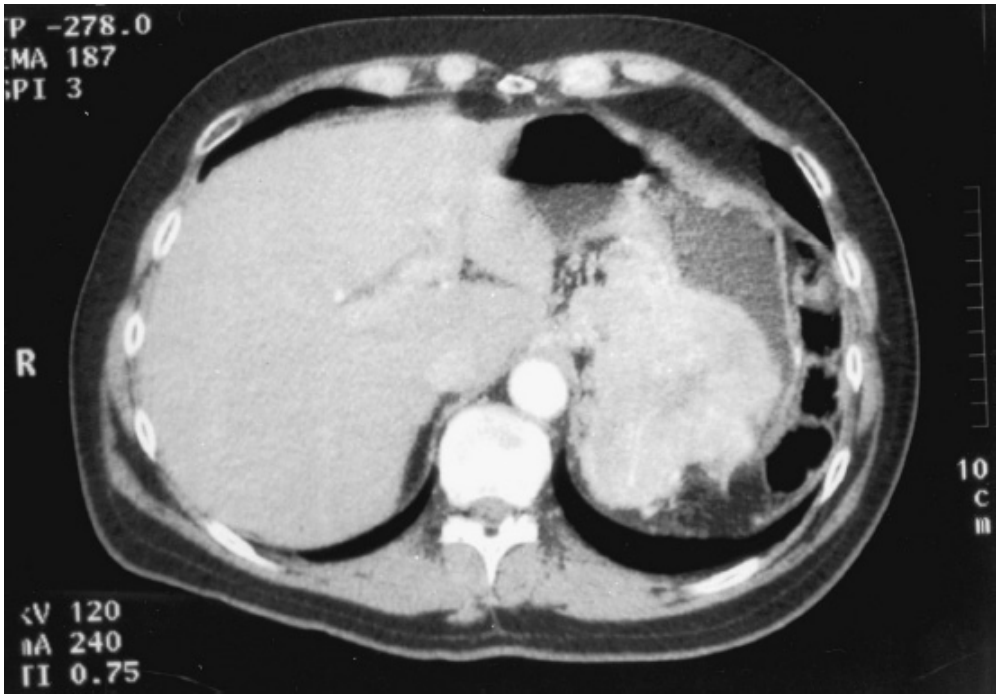

Figure 56.11 Computed tomography with oral and intravenous contrast in a patient with a glucagonoma. The large tumor appears to be posterior to the stomach and to the right of the aorta from the viewer's perspective.

Table 56.10 Somatostatinoma

Parameter	Description
Symptoms	Steatorrhea Right upper quadrant pain
Diagnostic tests	Hyperglycemia Hypochlorhydria Gallstones Serum somatostatin level
Anatomic localization	Most in head or uncinate process of pancreas; often periampullary

METASTATIC PANCREATIC ENDOCRINE TUMORS

Liver-Directed Therapies

At least one-third of patients with malignant PENs present with synchronous liver metastases at the time of diagnosis.[128] A subset of these patients remain asymptomatic and experience 8 prolonged survival even without aggressive therapy.[95] However, overall 5-year survival with liver metastases is less than 50%.[129] PENs are one of the few tumors for which a survival advantage for surgical debulking has been shown.[120,128,130–132] In those selected patients where safe surgical resection of greater than 90% of the tumor burden can be achieved, 5-year survival rates of 60% to 75% have been reported.

Those with unresectable disease to the liver may be candidates for a variety of liver-directed therapies for locoregional control 9 and symptom palliation. Transarterial embolization (TAE), chemoembolization (TACE) or radioembolization (TARE) with yittrium-90 are the most frequently used.[133] For patients with solitary or oligometastatic disease, percutaneous or surgical ablation, either with radiofrequency or microwave ablation techniques, are good options.[134]

Somatostatin Analogs

Since the majority of NETs express somatostatin receptors, somatostatin analogs (SSAs) are widely used for patients with metastatic PENs. SSAs not only lead to effective symptom control of carcinoid syndrome, they are also associated with improved progression-free survival (PFS). Both the PROMID and CLARINET trials were prospective randomized controlled trials demonstrating PFS superiority of long-acting SSAs to placebo among patients with metastatic well-differentiated gastroenteropancreatic NETs.[135,136] Based on these results and the indolent nature of well-differentiated PENs, SSAs are often the initial treatment for patients with slow-growing metastatic NETs. Newer more broadly binding SSAs are being investigated but have not shown superiority compared to traditional SSAs.

Systemic Therapies

A number of systemic therapies have been developed over the past decade for patients with metastatic PENs (**Table 56.11**). 10 While historically only streptozocin-based chemotherapy regimens were available,[96] advances in the molecular understanding of PENs have led to newer targeted therapies which offer improved response rates with better side effect profiles. For example, both **sunitinib malate**, an oral, small molecule, multitargeted tyrosine kinase inhibitor initially approved for the treatment of advanced renal cell carcinoma and refractory gastrointestinal stromal tumors, as well as **everolimus**, an oral inhibitor of the mTOR, are specifically approved for use in metastatic PENs.[137,138] Recent evidence has suggested the combination chemotherapy **temozolomide and capecitabine** is effective for PENs. Finally, **peptide receptor radionuclide therapy (PRRT)** is an exciting therapy recently approved for use in the United States which binds radionuclides to SSAs. In the landmark NETTER-1 trial, PRRT using ^{177}Lu-DOTA^{0},Tyr^{3}octreotate led to improved response rates and overall survival among patients with metastatic midgut NETs.[139] Ongoing research is currently investigating novel radiopharmaceuticals as well as targeted therapies, checkpoint inhibitors, and oncocytic viruses.[140]

Table 56.11 Seminal Randomized Controlled Trials of Systemic Therapies for Patients with Neuroendocrine Tumors

Trial	Intervention	Mechanism of Action	Control	Population	Median PFS Improvement (Mo)
Promid[16]	Octeotide LAR	SSA	Placebo	Midgut NET ($n = 84$)	14.3 vs. 6.0
Clarinet[17]	Lanreotide	SSA	Placebo	GEP-NET ($n = 204$)	38.5 vs. 18.0
Radiant-3[26]	Everolimus	mTOR inhibitor	Placebo	PEN ($n = 420$)	11.0 vs. 4.6
Raymond et al.[137]	Sunitinib	TKI	Placebo	PEN ($n = 171$)	11.4 vs. 5.5
Netter-1[45]	^{177}Lu-DOTATATE	PRRT	Octreotide LAR (60 mg)	Midgut NET ($n = 230$)	NA vs. 8.4

PFS, progression-free survival; SSA, somatostatin analog; NET, neuroendocrine tumor; GEP, gastroenteropancreatic; PEN, pancreatic endocrine neoplasm; mTOR, mammalian target of rapamycin; TKI, tyrosine kinase inhibitor; PRRT, peptide receptor radionuclide therapy.

Section H: HEPATOBILIARY AND PORTAL VENOUS SYSTEM

57

Hepatobiliary Anatomy

Alice C. Wei

Key Points

1. Couinaud classification divides the liver into eight anatomic segments based on hepatic portal inflow and hepatic vein outflow.
2. Classic hepatic arterial anatomy is present in only approximately 50% of patients, with a replaced or accessory right hepatic artery arising from the superior mesenteric artery and a replaced or accessory left hepatic artery arising from the left gastric artery as the most common variants.
3. The modern Calot triangle (hepatocystic triangle) is bounded by the common hepatic duct medially, the cystic duct inferiorly, and the undersurface of the liver, superiorly. The cystic artery can be identified in this triangle during cholecystectomy.
4. There are three major hepatic veins; most patients have a right hepatic vein that joins the right anterior wall of the inferior vena cava (IVC) and middle and left hepatic veins that converge into a common trunk before joining the IVC.
5. Multiphase computed tomography (CT) with intravenous contrast is the mainstay for preoperative liver imaging. CT scans provide anatomic details of the hepatic vasculature and characterize many hepatic lesions, often without the need for biopsy.
6. Magnetic resonance cholangiopancreatography (MRCP) can be used to visualize intra- and extrahepatic biliary anatomy and provides complimentary information to a CT for indeterminant liver lesions.
7. Intraoperative ultrasonography is used liberally to confirm the anatomy of the hepatic vessels, biliary system and localize lesions during surgery.
8. The steps in major hepatectomy include exposure, vascular inflow control, vascular outflow control, and parenchymal transection.

Liver anatomy is complex, often with variations in the hepatic vessels and biliary tree that may not be apparent at the time of surgery. For safe hepatobiliary surgery, surgeons must have a thorough understanding of each

patient's unique liver anatomy and the relationship of lesions to major structures prior to any operation.

TOPOGRAPHIC AND SURFACE ANATOMY

The liver is a large, wedge-shaped organ situated in the right upper quadrant of the abdomen ventral to the inferior vena cava (IVC). Most of the liver sits in the subcostal space and is bounded superiorly, laterally, and posteriorly by the diaphragm and retroperitoneum, and anteriorly by the abdominal wall. The liver lies anterior to the stomach, gallbladder, hepatoduodenal ligament, and duodenum, and its lower extent lies adjacent to the hepatic flexure of the colon, right adrenal gland, and kidney (**Fig. 57.1**). On the liver's inferior aspect, the gallbladder sits in the gallbladder fossa, and the hepatic portal structures enter encapsulated by the Glissonean capsule by means of the hepatoduodenal ligament. Rouviere sulcus on the right inferior aspect delineates the border between the anterior and posterior right liver. On the left inferior aspect, Arantius cleft runs between the base of the left portal vein and the vena cava, separating the caudate lobe from the left liver. Within the Arantius cleft, the ligamentum venosum (obliterated left umbilical vein) lies between the left portal vein at the base of the falciform ligament and the left hepatic vein.

The visceral peritoneum invests most of the liver surface apart from the posterior bare area and the gallbladder fossa. The bare area is bound by the right triangular and coronary ligament (**Fig. 57.2**). In addition to these ligaments, the left triangular and the falciform ligament, which extends from ligamentum teres to the suprahepatic vena cava, connects the liver to the anterior abdominal wall. The gastrohepatic ligament connects to the ligamentum venosum (obliterated ductus venosus) in Arantius cleft. These ligaments, as well as the hepatoduodenal ligament, which arises between the pancreatic head and the liver hilum (known as the porta hepatis), comprise the ligamentous attachments of the liver. The hepatoduodenal ligament contains the portal vein, hepatic arteries, extrahepatic bile duct, and portal lymphatics (**Fig. 57.3**).

MORPHOLOGIC AND FUNCTIONAL ANATOMY

1 Over the past 100 years, a variety of anatomic models of the liver have been developed and debated. Couinaud classification of liver segments is the most often used by hepatobiliary surgeons (**Fig. 57.4**).[1,2] In this classification, eight segments of the liver are delimited by portal inflow and hepatic venous outflow. The right and left hemilivers are divided by a plane through the middle hepatic vein and the IVC (**Fig. 57.5**) along Cantlie's line. The left and right hepatic veins subdivide their respective hemilivers each into two sectors (alternatively called sections). The sectors are further divided into segments by portal pedicles. This results in the left liver segments II, III, IVa, and IVb and right liver segments V, VI, VII, and VIII. Segment I, the caudate lobe, arises posterior to the portal pedicle and anterior to the IVC. Segment I receives both left and right portal inflow, and caudate veins drain directly into the IVC.

The Glissonean capsule is the connective tissue that invests the hepatic arteries, portal vein, bile duct, nerves, and lymphatics. The structures within the Glissonean capsule enter the liver centrally at the porta hepatis via the hepatoduodenal ligament.

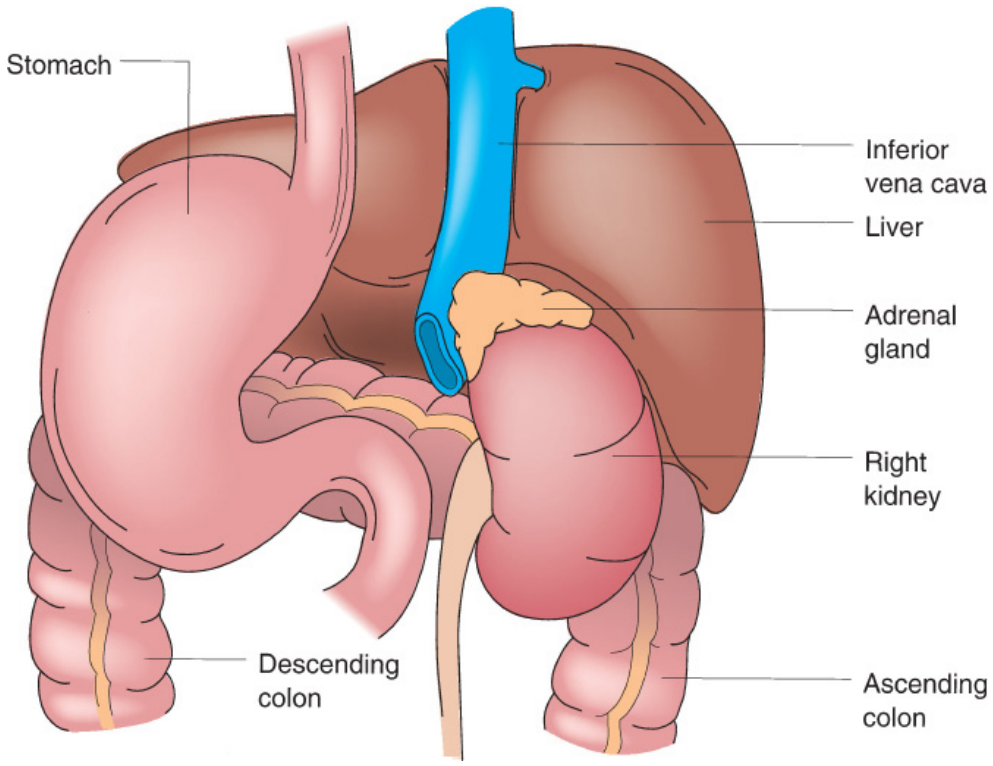

Figure 57.1 Posterior view of the liver, showing organs that produce impressions on its inferior surface.

Variations from the canonical anatomy occur frequently; hepatic artery variation is most common, followed by biliary tract and portal vein variants.[2] Variations often occur concomitantly. When anatomic variation is seen in one of the portal structures, the surgeon should be aware that variation in other structures may be present, and additional investigation to confirm anatomy may be indicated.

Hepatic Arteries

The common hepatic artery arises from the celiac axis and becomes the proper hepatic artery as it turns cephalad in the hepatoduodenal ligament after giving off the right gastric and gastroduodenal artery branches. It lies ventral and medial in the hepatoduodenal ligament and gives off the right and left hepatic arteries. Variations in hepatic artery anatomy are common in up to 40% of individuals (**Fig. 57.6**).[3,4] This variation can be in 2 the origin, branches, or course of the hepatic artery vasculature. Replaced or accessory right and left hepatic arteries occur in 13% and 11% of patients,

respectively.[4] Typically, accessory right hepatic arteries arise from the superior mesenteric artery (SMA) and travel posterior to the common bile duct and lateral to the portal vein. Left accessory or replaced hepatic arteries most often arise from the left gastric artery and course to the liver via the gastrohepatic ligament. The cystic artery can arise either directly from the common hepatic artery or from the right hepatic artery. Variations in the takeoff, size, and number of small vessels, including the cystic artery (**Fig. 57.7**) are common and must be considered when operating. Further, the location, relationship between the hepatic artery branches and other portal and biliary structures, and vessel of origin vary in the anterior and posterior planes with some regularity.

Portal Veins

The main portal vein is formed by the confluence of the superior mesenteric and splenic veins. The coronary vein (left gastric vein) joins the portal vein which travels in the posteromedial aspect of the hepatoduodenal ligament to enter the liver. At the porta hepatis, the main portal vein splits into the right and left portal branches which enter the parenchyma of their respective hemilivers at its first division (**Fig. 57.8**). The short right portal vein enters the liver obliquely and at its second division, gives of the anterior pedicle which supplies segments V and VIII, and a posterior pedicle which supplies segments VI and VII. The longer left portal vein courses outside the liver and turns to lie in the umbilical fissure prior to giving off branches into the left liver. The left second division gives off segment IV branches, also known as the “recurrent branches”; the segment II and III branches supply the left lateral section of the liver (to the left of the falciform ligament). The terminal end of the left portal vein merges with the ligamentum teres as the obliterated umbilical vein. Both the right and left portal veins give off small branches to supply segment I.

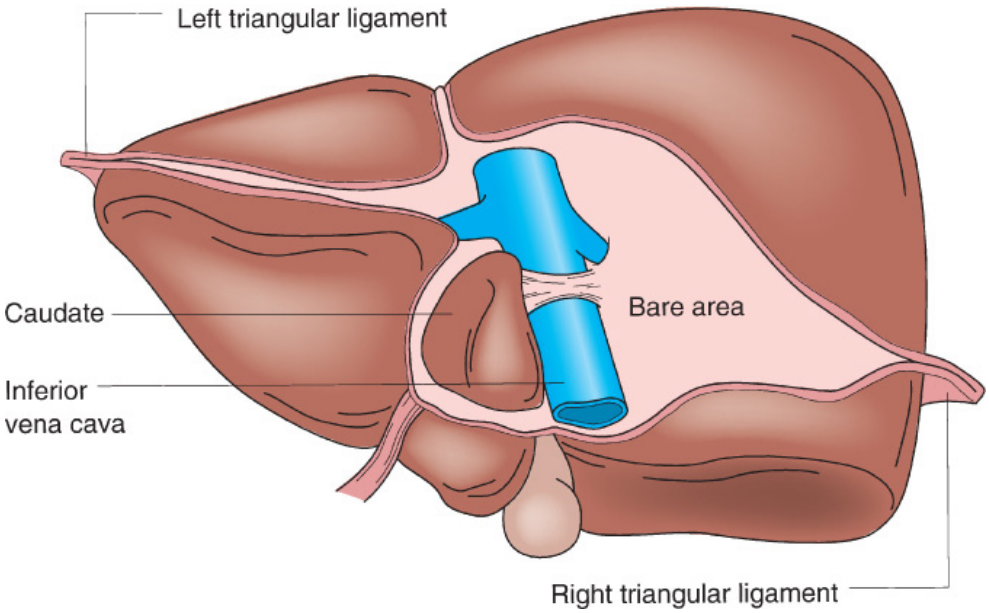

Figure 57.2 Posterior view of the liver, showing the level of peritoneal reflections.

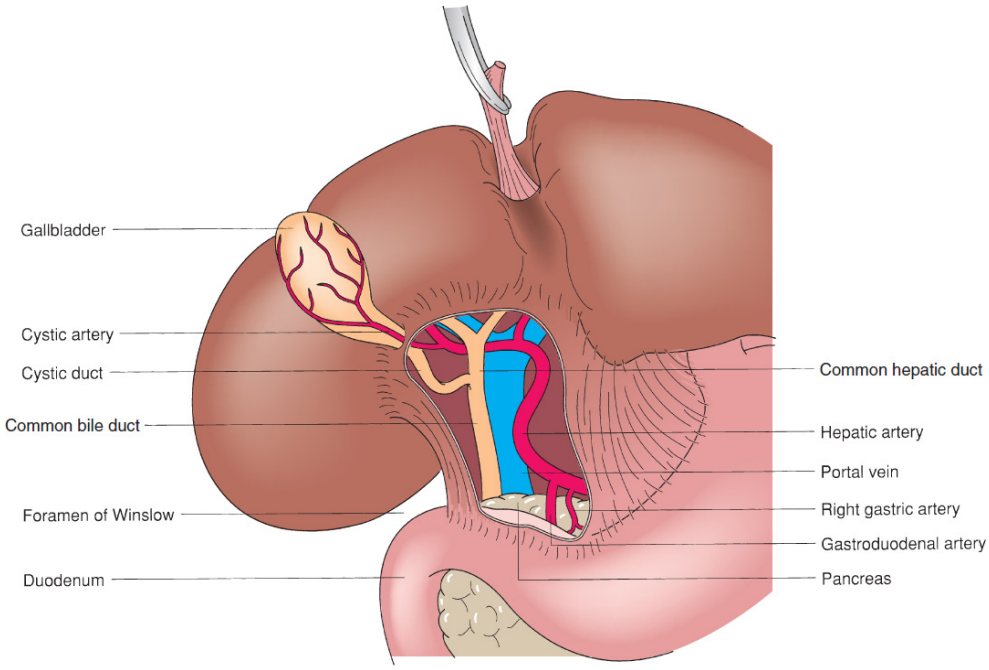

Figure 57.3 Relationship of structures within the hepatoduodenal ligament.

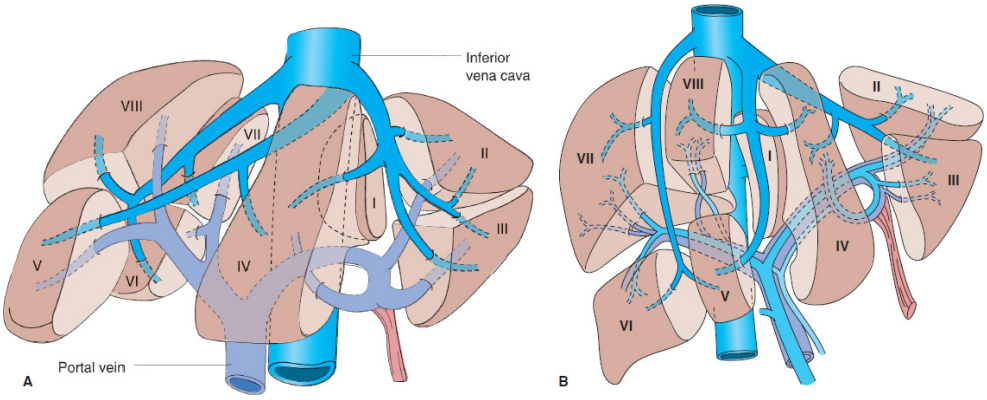

Figure 57.4 Functional divisions of the liver and liver segments according to Couinaud nomenclature with the liver in the natural position (**A**) and after it is mobilized (**B**).

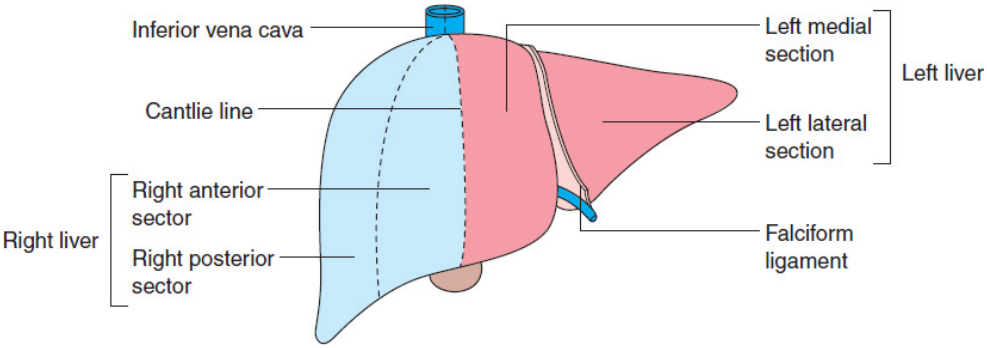

Figure 57.5 Anatomic division of the liver into right and left halves by a plane extending from the gallbladder fossa posteriorly to the inferior vena cava.

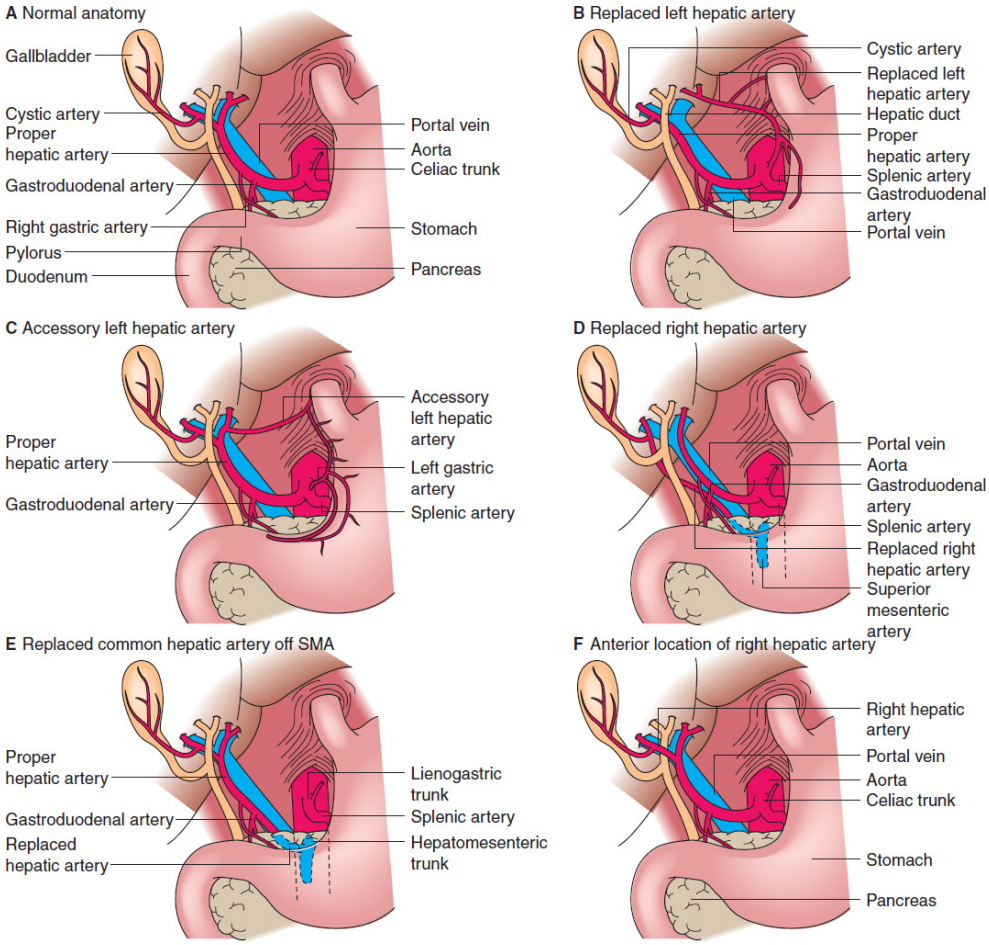

Figure 57.6 Variations in hepatic arterial anatomy.

Biliary System and Gallbladder

The common bile duct lies ventral and lateral in the hepatoduodenal ligament. The right and left liver drain their respective hemilivers into right and left bile ducts which merge to form the common hepatic duct extrahepatically in the liver hilum (**Figs. 57.9** and **57.10**). Variations in the confluence of the biliary system occur with regularity. Common variants include a right posterior (segments VI/VII) duct draining directly into the common hepatic duct, or a right posterior system draining into the left bile duct.

The gallbladder is a pear-shaped organ that lies on the undersurface of the liver and drains into the cystic duct. The cystic duct usually runs parallel to the common hepatic duct for a variable distance before joining the common hepatic duct to form the common bile duct, which then travels through the

pancreatic head and terminates at the ampulla of Vater. The cystic duct can vary in length, and when long, can take a circuitous route, either anterior or posterior, to the common bile duct prior to its insertion on either the lateral or medial side of the common bile duct (**Fig. 57.11**).

Calot triangle was originally described in 1891 as a triangle bound inferiorly by the cystic duct, medially by the common hepatic duct, and superiorly by the cystic artery. In the modern era, the working definition of Calot triangle differs from the original description.[2,3] The modern Calot triangle, should be referred 3 to as the hepatocystic triangle, is larger and is delineated by the cystic duct inferiorly, the common hepatic duct medially, and the undersurface liver superiorly.[3] In this larger triangle the cystic artery can be usually found. Calot's triangle is an important landmark when performing cholecystectomies. Variability in the origin, number, and location of the cystic artery is common (**Fig. 57.7**).

The surgeon should be aware of potential variations when operating in the porta hepatis, regardless of whether the procedure is a simple cholecystectomy or a more complex procedure, such as a living-donor liver transplant. Preoperative and/or intraoperative cholangiography may be required to avoid inadvertent injury to the biliary radicals.

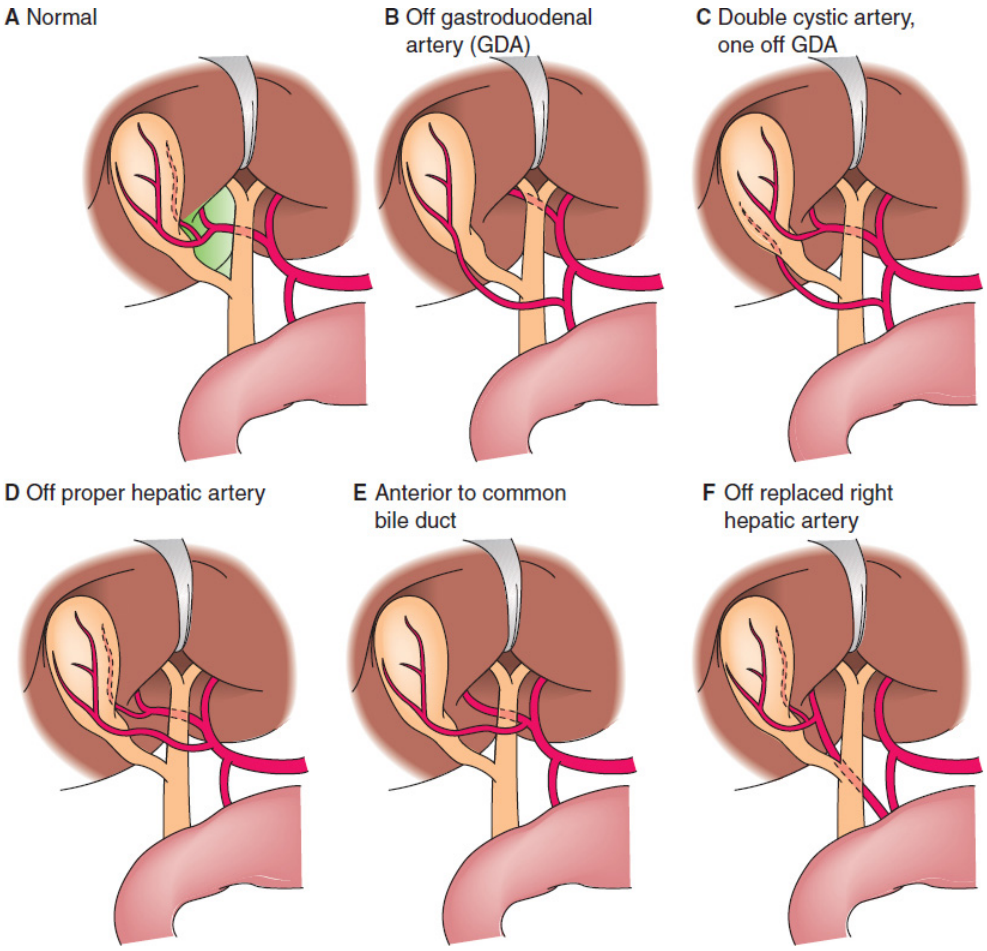

Figure 57.7 Variations of the cystic artery. The modern Calot's triangle (also known as the hepatocystic triangle) is marked in green (**A**).

Hepatic Veins

Liver outflow to the IVC progresses to the suprahepatic IVC via the major hepatic veins, the right, middle, and left hepatic veins. The 4 right hepatic vein usually joins as a single branch on the anterolateral aspect of the suprahepatic IVC. The middle and left veins can either drain individually into the IVC through separate orifices or merge intraparenchymally into a short, conjoined vein prior to entering the IVC.

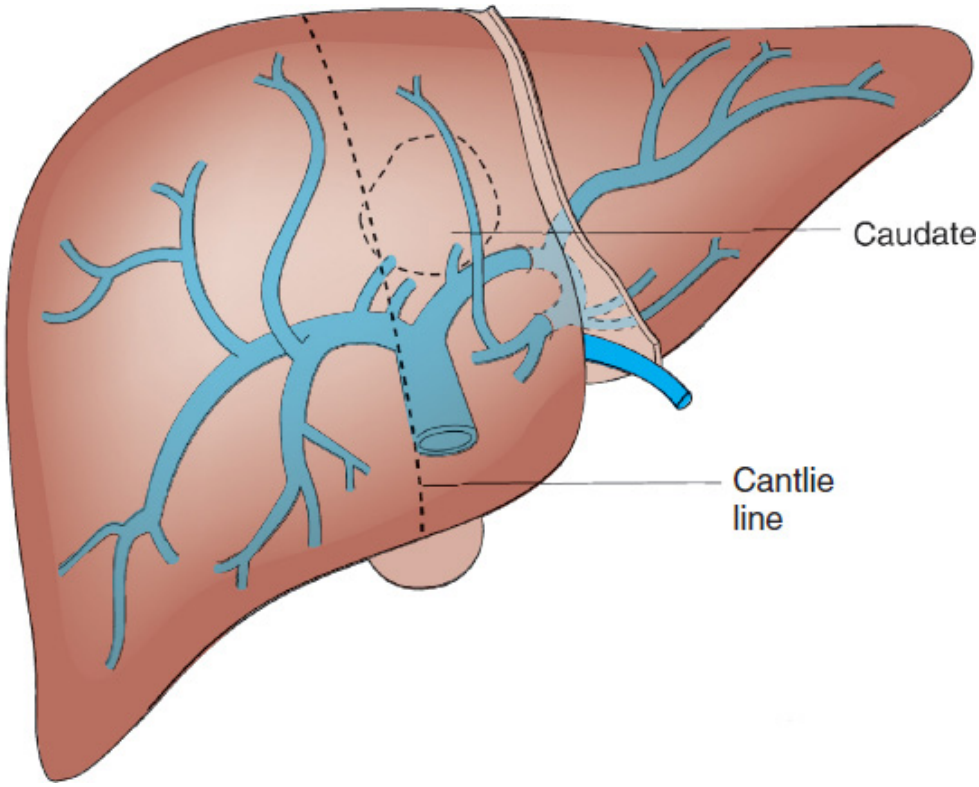

Figure 57.8 Intrahepatic divisions of the portal vein.

The hepatic veins divide the liver into sectors and drain their respective parenchyma. The right hepatic vein separates the posterior sector of the liver (segments VI/VII) from the anterior sector (segments V/VIII) and drains blood from these segments into the IVC (**Fig. 57.12**). Similarly, the middle and left hepatic veins mark the border between the left medial sector segment IV, and from the left lateral sector (segments II/III).

In addition to the named major draining veins, a variable number of accessory veins drain the caudate lobe and right hepatic lobe directly into the retrohepatic IVC. Some accessory veins can be sizable, particularly those from segment VI of the liver. On occasion, an accessory vein may be a major source of liver drainage. When present, large accessory veins must be considered in any planned procedure. For example, in living-donor liver transplantation, major accessory veins may require implantation, and for major liver resections that involve the outflow tract, drainage may be possible through a large accessory segment VI vein (**Fig. 57.13**).

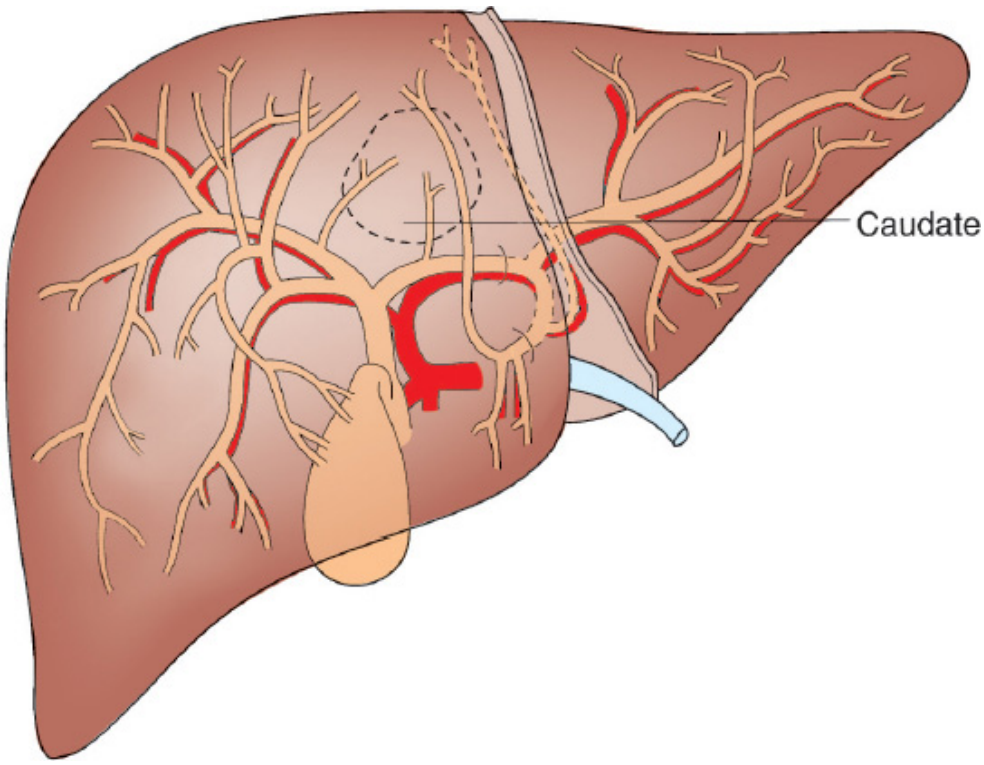

Figure 57.9 Intrahepatic divisions of the bile ducts and hepatic arteries.

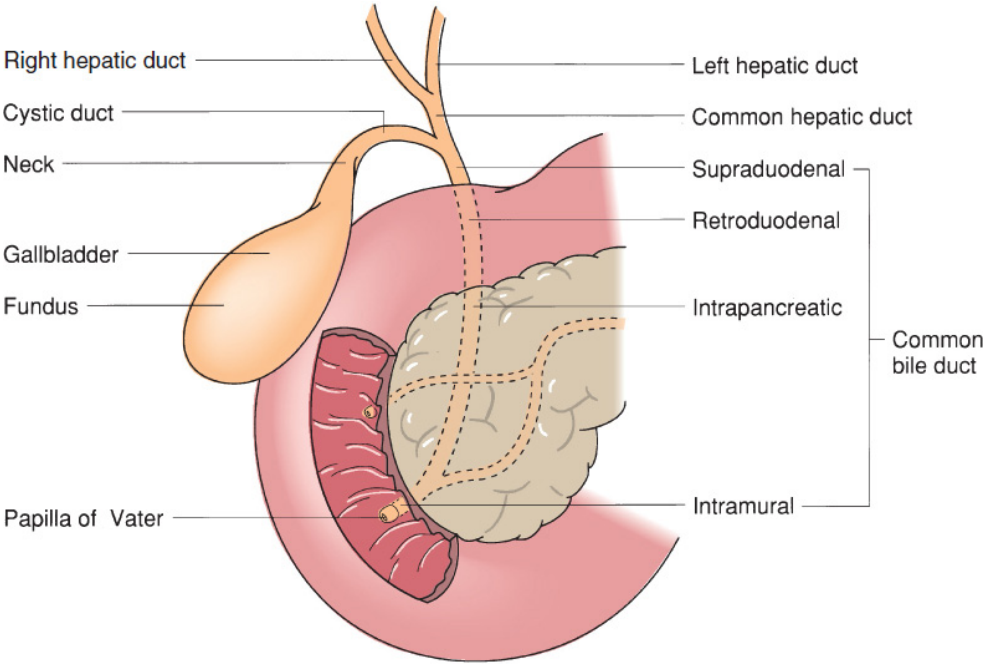

Figure 57.10 Anatomy of the extrahepatic biliary tree and pancreatic duct.

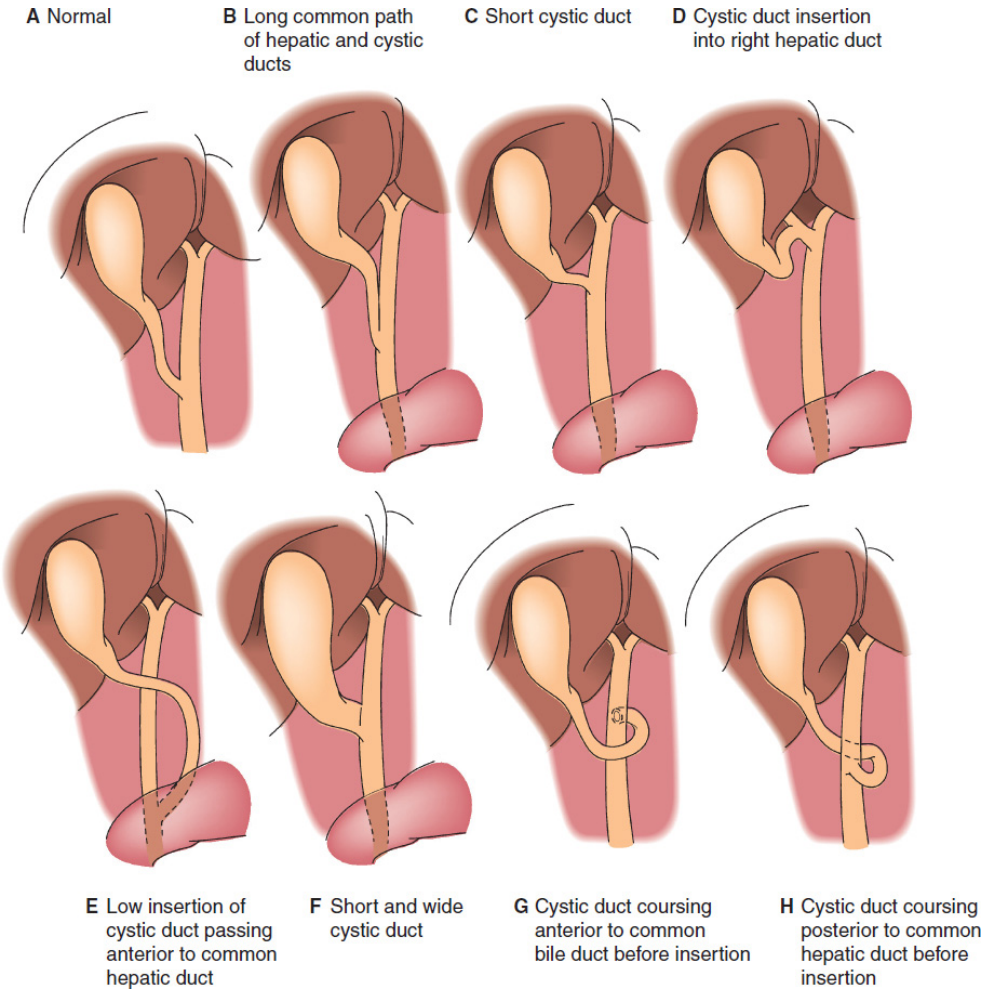

Figure 57.11 Variations in the junction of the cystic duct and common hepatic duct.

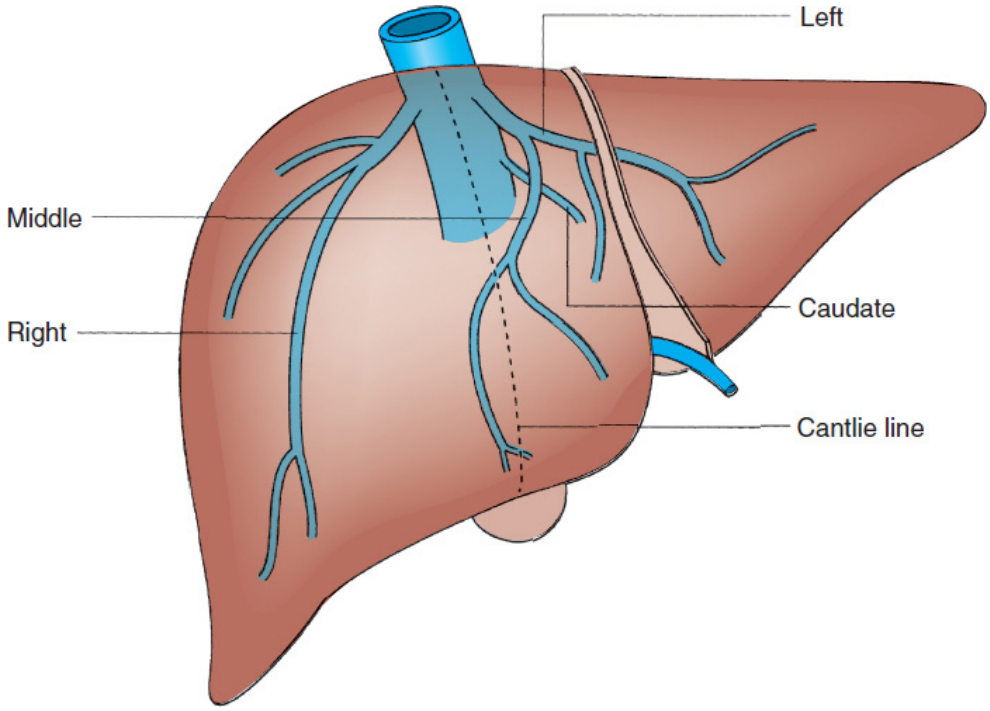

Figure 57.12 Three major hepatic veins drain the liver. The caudate segment of the liver usually drains directly into the inferior vena cava.

LIVER IMAGING

High-quality liver imaging is essential for preoperative assessment of the anatomy of major hepatic structures. The size, number, and location of the intraparenchymal vessels and bile ducts can be mapped preoperatively. Axial, coronal, and/or sagittal reconstruction scans are helpful in providing a three-dimensional model of the liver. For complex procedures, such as living-donor liver resection, careful preoperative mapping of the intra- and extraparenchymal structures are paramount for safe resection and reconstruction. For resections, tumor characteristics and relationship to major structures should be evaluated. Each patient's unique anatomy must be well understood prior to any hepatectomy.

Computed Tomography

Cross-sectional imaging with computed tomography (CT) with liver-specific phases is the mainstay of liver imaging. Well-timed 5 vascular contrast in

the arterial, portal, and venous phases provides excellent detail of the parenchyma and vascular anatomy of the liver (**Fig. 57.14**). In the appropriate clinical context, morphologic and contrast features of the tumor can be diagnostic without the need for liver biopsy (**Fig. 57.15**).

CT angiography plots the arterial anatomy of the liver and should be used liberally to plan complex resections. Three-dimensional reconstructions can be performed for surgical planning. For establishing suitability of living-donor liver transplantation, these reconstructed images are particularly important (**Fig. 57.16**). In addition, specialized CT protocols are available for different tumor types, including hepatocellular carcinoma and cholangiocarcinoma, and can help improve diagnostic accuracy of indeterminate lesions and/or aid in the visualization of small tumors.

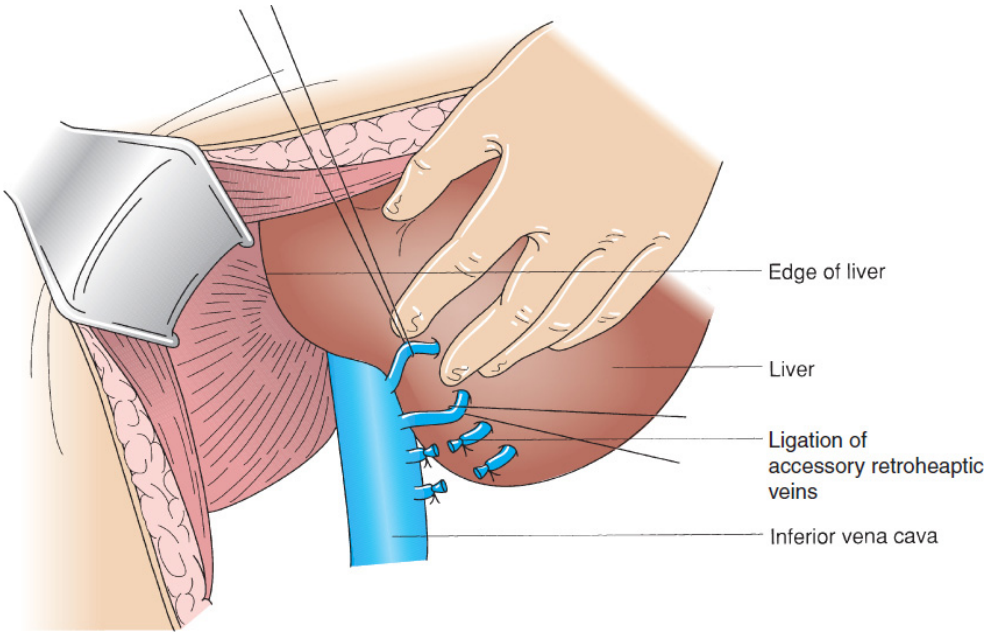

Figure 57.13 Retraction of right liver medially exposes small venous tributaries that drain the right liver directly into the retrohepatic vena cava. Several branches are ligated.

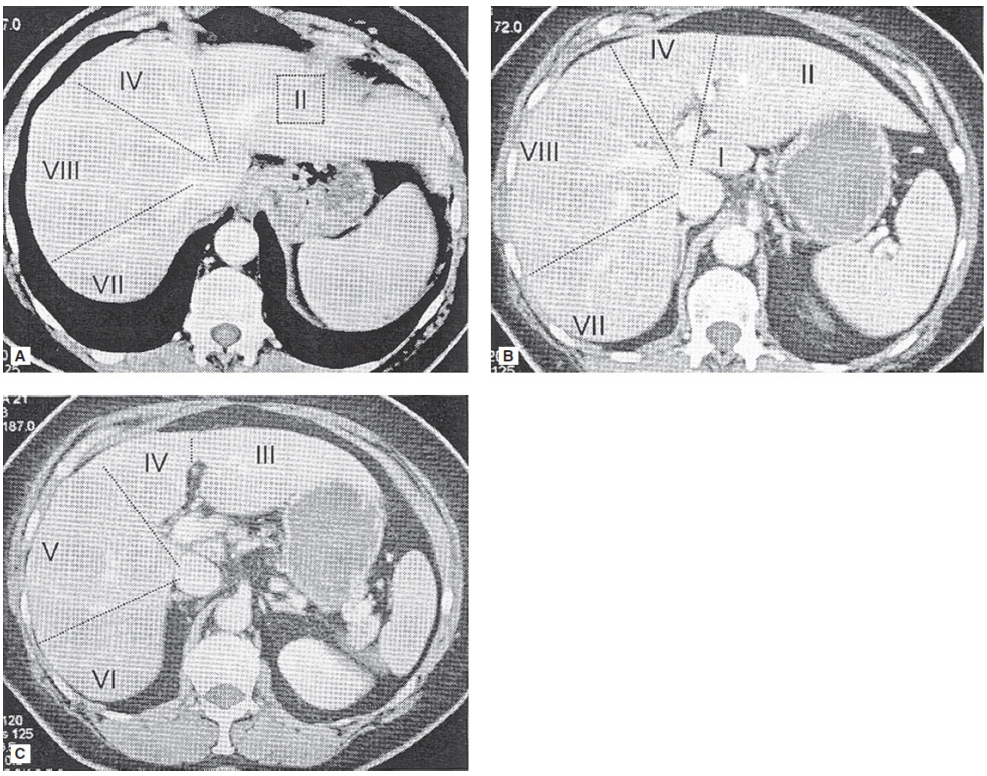

Figure 57.14 Computed tomography scan demonstrating segmental anatomy of the liver with cuts through the dome (**A**), just above the portal bifurcation (**B**), and below the portal bifurcation (**C**).

Further advantages of CT scans are that they can provide staging information to rule out the presence of extrahepatic disease and can provide insight into the presence or absence of underlying liver disease.

Magnetic Resonance Imaging/Magnetic Resonance Cholangiopancreatography

Magnetic resonance imaging (MRI) is a complementary imaging modality to CT and can provide additional information for small or indeterminant liver tumors (**Fig. 57.15**). In particular, MRI with gadolinium-based vascular or hepatobiliary contrast agents has improved sensitivity and specificity for characterizing many liver lesions. Benign lesions, such as hemangiomas, focal nodular hyperplasia, and liver cysts, can often be definitively characterized by MRI. MRI can have higher sensitivity in detecting small tumors in patients with hepatic steatosis or underlying liver disease, particularly if hepatobiliary contrast agents are used.

6 Unlike conventional CT scans, magnetic resonance cholangiopancreatography (MRCP) using T2-weighted imaging has high sensitivity for biliary structures and has largely replaced endoscopic retrograde cholangiopancreatography (ERCP) for diagnostic evaluation of the biliary tree (**Fig. 57.17**). MRCP is noninvasive and can resolve both intra- and extrahepatic biliary structures.

The disadvantages of MRI include the extended time required to obtain the scans, which can be difficult for patients who have claustrophobia or are unable to lie still for long periods of time; the inability to fully stage the other organs in the thoracoabdominal region in the same scan; and the associated additional costs. As a result, MRI should be reserved to provide complementary information that is not obtainable by CT scan.

ULTRASOUND AND INTRAOPERATIVE LIVER ASSESSMENT

Transcutaneous ultrasound (US) can be used as a screening test for liver disease and may be an option for noninvasive surveillance of liver lesions. Routine use of transcutaneous US for preoperative assessment has been supplanted by CT and/or MRI scans.

Nevertheless, US remains an important modality for intraoperative, real-time assessment of liver anatomy (**Fig. 57.18**). US at the 7 time of laparoscopy and/or laparotomy is used in combination with visual inspection and palpation to evaluate the liver. Intraoperative US should be used liberally throughout the procedure for diagnostic purposes and to localize deep lesions and intraparenchymal structures.

Newer modalities, including near-infrared visualization of indocyanine green (ICG) fluorescence, are increasingly being used to provide real-time imaging guidance of anatomic structures. However, experience is still accumulating on the role of these modalities in intraoperative assessment. ICG may be particularly useful in minimally invasive liver resection, as palpation and visual inspection are more limited.

PREOPERATIVE EVALUATION OF HEPATIC RESERVE

Accurate evaluation of the hepatic reserve is imprecise. For patients with underlying liver disease, a variety of different scores and tests have been developed that measure either static or dynamic liver function (**Table 57.1**). However, no single test is able to confidently predict the hepatic reserve of the future liver remnant (FLR) that will remain following liver resection in a patient with impaired liver function.

Liver function and volume of the FLR are the most commonly used methods to evaluate hepatic reserve in North America. For cirrhotic patients, the Child–Pugh score incorporates albumin, bilirubin, INR, as well as the presence or absence of ascites and/or encephalopathy as a measure of hepatic reserve (**Table 57.2**). Only Child–Pugh score A and highly selected B patients are candidates for liver resection. The presence of portal hypertension, manifested by splenomegaly, varices, ascites, or thrombocytopenia, is an independent predictor of postoperative liver failure, and patients with these comorbidities are usually not candidates for resection. Other scores of liver function, including the Model of End-Stage Liver Disease (MELD) score, have limited use for predicting liver failure following resection and are not routinely used to determine suitability for liver resection (**Table 57.3**). For patients with liver cancer or end-stage liver disease, the MELD score is useful for establishing eligibility for liver transplant, and MELD is currently used by the United Network for Organ Sharing (UNOS) for prioritizing organ allocation for liver transplants.

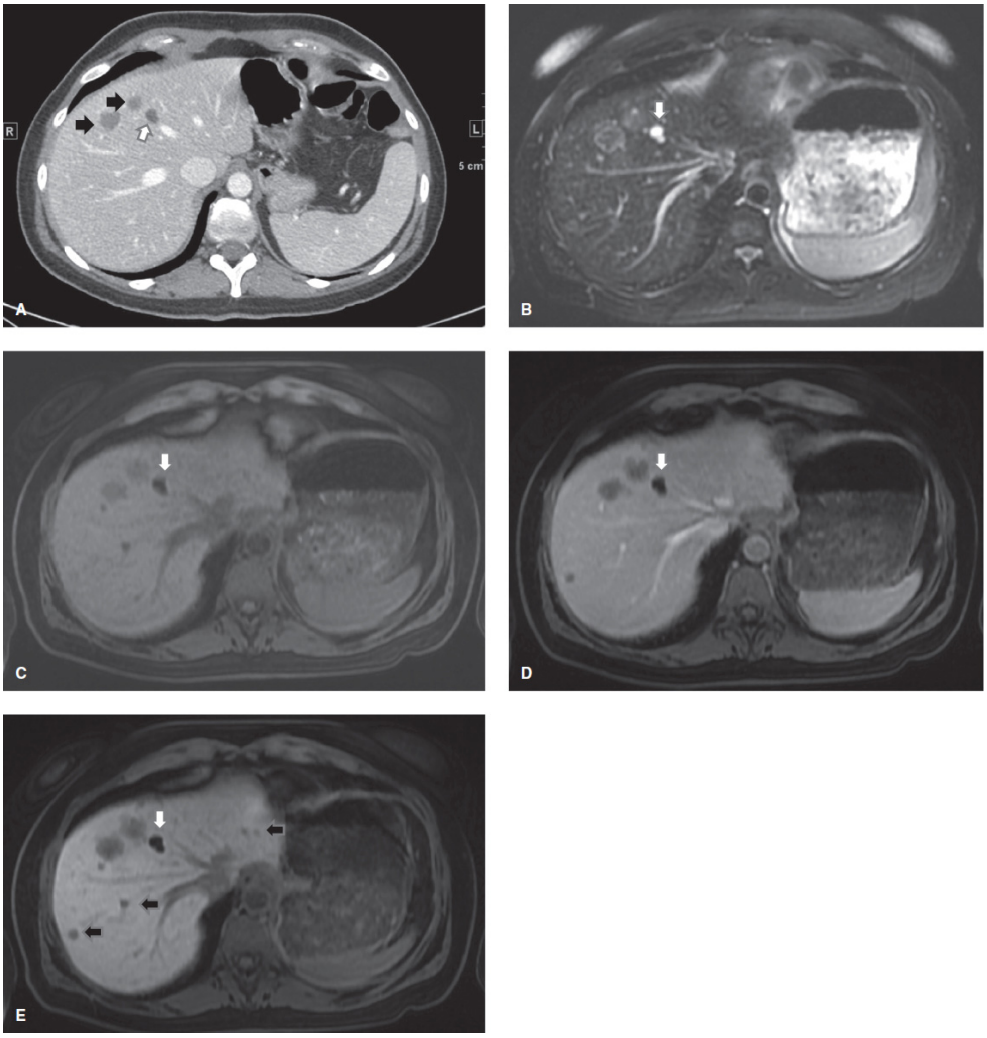

Figure 57.15 Cross-sectional imaging for a patient with colorectal liver metastases and hepatic cysts. The CT scan in portal venous phase (**A**) demonstrates two irregular hypoattenuated lesions consistent with metastases (*black arrows*). A third lesion adjacent to the middle hepatic vein (*white arrow*), lower in attenuation compared to the liver metastases is noted and indeterminant. MRI imaging of the same patient in different phases (**B**–**E**). MRI with fat-suppressed T2-weighted imaging (**B**), and precontrast fat-suppressed T1-weighted imaging (**C**). Same cyst as prior CT (*white arrow*), with markedly T2 bright signal and low T1 signal. MRI with postcontrast fat-suppressed T1-weighted imaging during the portal venous phase (**D**) and delayed hepatobiliary phase with Gd-EOB-DTPA (Eovist) contrast agent (**E**). Same cyst as prior CT (*arrow*). Note the subcentimeter liver metastases now visible on delayed hepatobiliary phase in segments II and VII/VIII (*black arrows*).

Table 57.1 Strategies to Predict Hepatic Reserve

- Child–Pugh score (**Table 57.2**) to assess synthetic ability (albumin, prothrombin time, and ascites), bile conjugation and excretory function (total bilirubin), and metabolic function (changes in mental status from ammonia retention)
- Model for End-Stage Liver Disease (MELD) score estimates 3-mo mortality in patients with chronic liver disease (**Table 57.3**)
- Clearance of galactose or organic anionic dyes, such as indocyanine green
- Volumetric measurements of the liver and prediction of liver remnant after resection based on three-dimensional reconstructions from computed tomography and magnetic resonance imaging

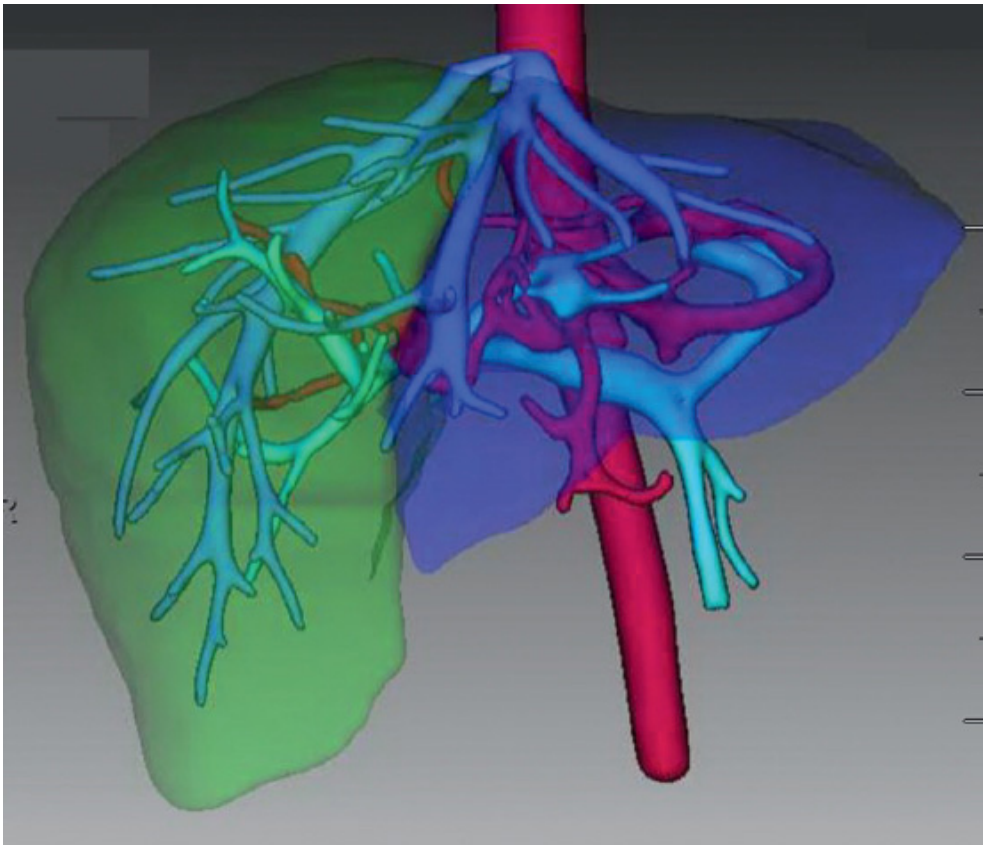

Figure 57.16 Three-dimensional reconstruction of the hepatic vasculature.

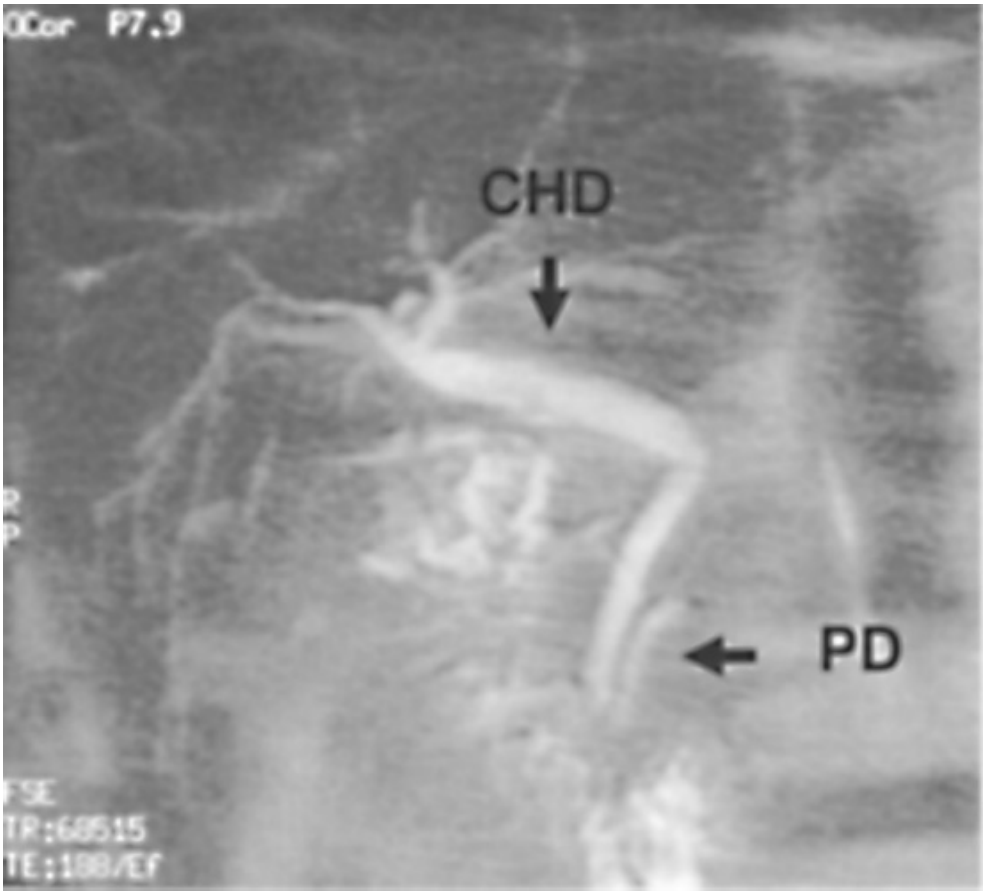

Figure 57.17 Magnetic resonance cholangiopancreatography (MRCP) of a patient after cholecystectomy with mild dilation of common hepatic duct (CHD). The pancreatic duct (PD) is also visible.

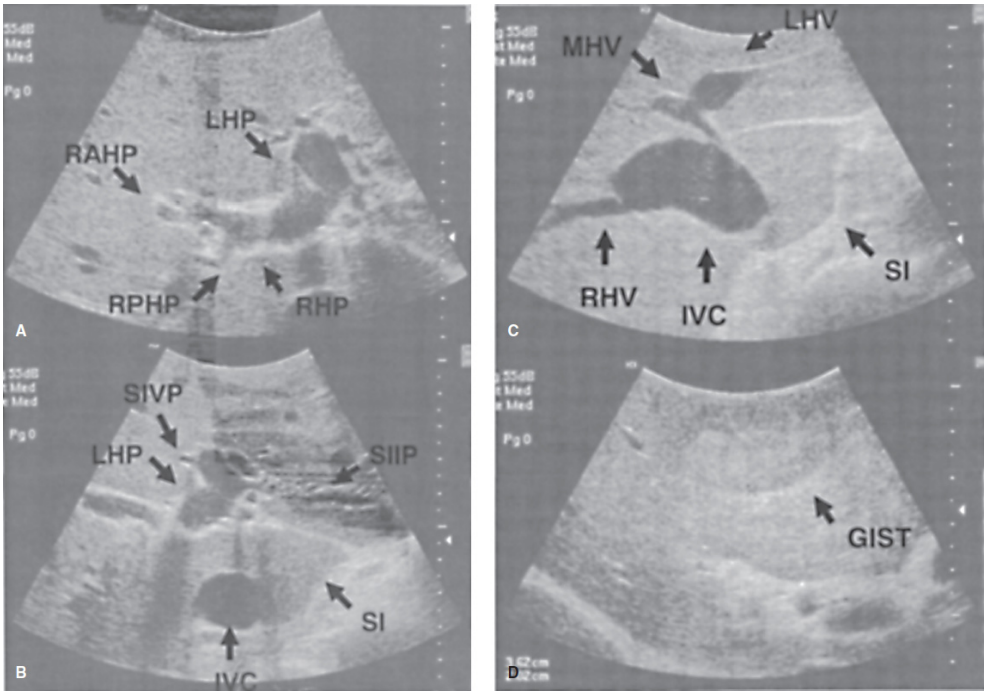

Figure 57.18 **A, B:** Intraoperative ultrasound images of liver demonstrating right hepatic pedicle (RHP), right anterior sector pedicle (RASP), right posterior sector pedicle (RPSP), left hepatic pedicle (LHP), segment II pedicle (SIIP), segment IV pedicle (SIVP), segment I (SI), and inferior vena cava (IVC). **C, D:** Intraoperative ultrasound images of liver demonstrating inferior vena cava (IVC), right hepatic vein (RHV), middle hepatic vein (MHV), left hepatic vein (LHV), segment I (SI), and a metastatic gastrointestinal stromal tumor lesion straddling segments IV and V of the liver.

Table 57.2 Child–Pugh Classification

	1 Point	2 Points	3 Points
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/dL)	>3.5	2.8–3.5	<2.8
Ascites	Absent	Moderate	Severe
Encephalopathy	Absent	Moderate	Severe
Prothrombin time			
Seconds prolonged	<4	4–6	>6
INR	<1.7	1.7–2.3	>2.3

INR, international normalized ratio; Child–Pugh Class A: 5–6 points; Class B: 7–9 points; Class C: 10–15 points.

Worldwide, ICG retention is a common dynamic test of hepatic reserve. ICG is a tricarbocyanine protein-bound dye that is rapidly eliminated by the liver. Impaired liver function results in slower elimination times, and thus ICG retention provides a dynamic measure of liver function. In a normal liver, ICG retention at 15 minutes (ICG-R15) is 1% to 10%. ICG-R15 of <10% is considered adequate hepatic reserve for major liver resection in cirrhotic patients. The acceptable ICG-R15 must be combined with additional clinical information, including the extent of the planned liver resection, the Child–Pugh score, and the presence or absence of portal hypertension, to estimate the risk of postoperative liver failure for an individual patient.

The volume of the expected FLR is associated with postoperative liver failure. For patients with normal background liver, an FLR >25% is adequate, as long as inflow/outflow and biliary drainage is preserved. For patients with liver disease, including cirrhosis, cholestasis, fatty liver disease, or prior chemotherapy, the threshold suggested for adequate FLR

should be higher, closer to 40%. However, the exact threshold is not agreed upon by all surgeons. For patients with small predicted FLR and/or in cases where there is underlying hepatic dysfunction, augmentation of the FLR is possible. Portal vein embolization or Associating Liver Partition and Portal vein Ligation for Staged hepatectomy (ALPPS) can be used to induce hypertrophy in the FLR prior to hepatectomy. Portal vein embolization on the side of the liver to be resected is performed 3 to 4 weeks prior to planned resection to induce compensatory hypertrophy. ALPPS combines operative portal vein ligation with parenchymal transection to induce rapid FLR hypertrophy. This is followed by planned early hepatectomy, days after ALPPS, once FLR volume is deemed adequate. The ALPPS approach remains experimental due to high rates of morbidity and perioperative mortality compared to percutaneous portal vein embolization.

Table 57.3 MELD Score

MELD = 3.78 × ln[serum bilirubin (mg/dL)] + 11.2 × ln(INR) + 9.57 × ln[serum creatinine (mg/dL)]
40 or more—71.3% 3-mo mortality
30–39—52.6% 3-mo mortality
20–29—19.6% 3-mo mortality
10–19—6.0% 3-mo mortality
<9—1.9% 3-mo mortality

INDICATIONS FOR LIVER RESECTION AND ONCOLOGIC CONSIDERATIONS

The indications for surgery include benign and malignant tumors, biliary conditions, and living-donor liver transplant. The vast majority of liver resections are performed for malignancy for curative intent. Colorectal liver metastases (CRLMs) and hepatocellular carcinoma are the most common malignant indications for hepatectomy. The evaluation of patients for

oncologic indications requires consideration of patient fitness for surgery, as well as oncologic and technical criteria. Oncologic principles for curative-intent surgery are that disease is limited to the liver, the resection can be performed for R0 intent, and an FLR with adequate volume/function, liver inflow, outflow, and biliary drainage can be achieved. The indications for surgery and the principles of surgery remain the same regardless of whether an open or minimally invasive approach is used.

For patients with CRLM, preoperative staging to rule out extrahepatic disease includes a CT scan of the chest, abdomen, and pelvis, and a recent colonoscopy to evaluate disease stage. MRI and PET scans are adjuvant tests that may be helpful to characterize the disease extent but are not routinely required. Also, prognostic variables, such as timing of liver metastases (synchronous vs. metachronous), nodal status of colorectal cancer, CEA levels, and number and size of liver metastases, may guide when or if liver resection is likely to provide a survival advantage.[5] The sequence of liver resection with respect to the timing of chemotherapy and management of the primary colorectal cancer must also be incorporated into a tailored approach for each patient. The goal of resection for CRLM is to obtain an R0 margin, optimally >1 cm, using parenchymal-sparing techniques when possible.[6] The rationale for a parenchymal-sparing approach is that it will preserve liver function and allow repeat liver resection for patients who develop recurrent CRLM. For patients with multiple CRLM, ablation may be combined with resection for small, central tumors where resection is not feasible in order to achieve disease control.

For patients with hepatocellular carcinoma, there is an additional requirement to understand the extent of underlying cirrhosis, which is often present. Poor liver function may preclude liver resection of otherwise technically resectable tumors due to the high risk of postoperative liver failure. As these patients may be candidates for liver transplantation, the decision for resection versus transplantation should be made in a multidisciplinary context. For patients undergoing liver resection for hepatocellular carcinoma, the optimal resection margin is controversial. However, a resection margin aimed at approximately 2 cm is associated with decreased postoperative recurrence rates and improved survival compared with a gross resection margin of 1 cm or less.[7] Some studies favor formal anatomic resections for improved outcomes.

For less common malignancies, a decision-making process analogous to those described above is applicable. Palliative debulking of liver tumors is rare but may be considered for select patients with metastatic neuroendocrine tumors, as these tumors are more indolent than most other malignancies. As a result, liver resection may provide symptomatic control, as well as a survival advantage. Liver metastasectomy for neuroendocrine metastases is based on the ability to debulk tumor volume. The threshold of tumor that needs to be removed for benefit remains controversial; generally, debulking may provide benefit if >90% tumor volume can be debulked safely.

NOMENCLATURE FOR HEPATECTOMIES

Standard terminology should be used to document the extent of liver resection performed. The International Hepato-Pancreato-Biliary Association has endorsed the Brisbane classification as the preferred nomenclature.[8] This naming system sorts liver resections based on first-, second-, or third-order divisions of the hepatic artery and bile ducts. Resections at the level of first-order divisions are termed *hepatectomies* or *hemihepatectomies* (**Fig. 57.19**). Thus, a left hepatectomy involves the removal of segments II, III, and IV, whereas a right hepatectomy involves removal of segments V, VI, VII, and VIII. Resections based on second-order divisions, which remove a named section, are termed *sectionectomies* based on the anatomic sections removed. As a result, there are left lateral (segments II and III), left medial (segment IV), right anterior (segments V and VIII), and right posterior (segments VI and VII) sectionectomies. *Trisectionectomy* is the preferred term for extended hepatectomies. Right trisectionectomy includes removal of three contiguous sections (segments IV, V, VI, VII, VIII), the right posterior, right anterior, and left medial sections. Similarly, left trisectionectomy includes a left hepatectomy and removal of the right anterior sections (segments II, III, IV, V, VIII). Single segment or two contiguous segment resections are termed *segmentectomies* and *bi-segmentectomies,* respectively.

INTRAOPERATIVE CONSIDERATIONS

8 The steps for performing liver resections include exposure and mobilization of the liver, inflow and outflow control, and parenchymal resection. Throughout any hepatectomy procedure, frequent use of US should be used to help map and visualize intraparenchymal structures and tumors, and to ensure the direction of parenchymal transection is appropriate.

Open hepatectomy requires unobscured access to the liver. This can be achieved with a right subcostal incision with or without midline extension. When additional access is required, the subcostal incision can be extended to the left side (**Fig. 57.20**). Retractors are used to elevate the costal margin and provide access to the entire right upper quadrant. On occasion, when suprahepatic access is required, intrathoracic extension or midline sternotomy can be used.

Mobilizing the liver requires dividing its ligamentous attachments between the abdominal wall and retroperitoneum. The liver can then be elevated off of the bare area, if required. The gastrohepatic ligament can also be divided to access the caudate lobe. During mobilization, accessory vessels should be noted and avoided. In particular, care should be taken to avoid an accessory or replaced left hepatic artery that runs in the gastrohepatic ligament. Palpation of the hepatoduodenal ligament can reveal an accessory or replaced right hepatic artery running posterior and medial to the common bile duct.

With the liver mobilized, visual inspection, palpation, and US of the liver and hepatoduodenal ligament should be performed to confirm preoperative findings and identify any new findings which may not have been noted on preoperative evaluation. This includes assessment of the background liver, as well as the number, size, and position of tumors. The location of lesions compared to the known hepatic anatomy should be assessed, and anatomic landmarks should be confirmed by US as the procedure progresses. Occasionally, operative cholangiography can supplement anatomy mapping of the biliary tree.

Safe hepatic surgery depends on the ability to minimize and control hemorrhage from the liver parenchyma during transection. Therefore hepatic arterial and portal venous vascular control are key technical steps in liver resection. Temporary inflow control can be obtained using the Pringle maneuver, which is usually performed in an intermittent manner with occlusion of the hepatic artery and portal inflow with compression of the

hepatoduodenal ligament. More selective inflow control can be obtained either with an intrahepatic Glissonean or an extrahepatic Glissonean approach to individual pedicles of interest.

Major hepatectomies based on first- or second-order divisions require removal of three or more segments. For these resections, exposure is obtained by taking down the liver attachments to fully mobilize and expose the lobe of interest. Permanent hepatic inflow control is obtained prior to parenchymal transection. For a conventional intra-fascial approach, the hepatic artery, portal vein, and bile duct of interest are exposed by incising the peritoneum of the hepatoduodenal ligament and entering the Glissonean capsule. Early ligation and division are performed to obtain permanent selective inflow control. An endovascular stapler can safely and efficiently divide major vessels and biliary pedicles and should be used liberally in liver surgery. The intra-fascial approach also allows identification of the extrahepatic biliary system. Division of the biliary system can be accomplished either intra- or extrahepatically depending on the length of the involved bile duct. Since the left biliary system has a long transverse-lying extrahepatic segment, it is usually straightforward to divide the left biliary system for a left hemihepatectomy. The right biliary system has a shorter extrahepatic component, and therefore it is sometimes necessary to divide the right bile duct intrahepatically for a right hemihepatectomy. For more extensive hilar dissections, dropping the hilar plate by incising the peritoneum of the hepatoduodenal ligament at the base of segment IV may allow access to the structures at the cephalad aspect of the hepatoduodenal ligament (**Fig. 57.21**).

1	*First-order division*		
Anatomical Term	**Couinaud segments referred to**	**Term for surgical resection**	**Diagram (pertinent area is shaded)**
Right Hemiliver **OR** *Right Liver*	*Sg 5–8(+/–Sg1)*	*Right Hepatectomy* **OR** *Right Hemihepatectomy* (stipulate +/–segment 1)	Left Hemiliver **OR** *Left Liver*	*Sg 2–4(+/–Sg1)*	*Left Hepatectomy* **OR** *Left Hemihepatectomy* (stipulate +/–segment 1)	
Border or watershed: The border or watershed of the first-order division which separates the two hemilivers is a plane which intersects the gallbladder fossa and the fossa for the IVC and is called the midplane of the liver.

2 *Second-order division*
(second-order division based on bile ducts and hepatic artery)

Anatomical Term	Couinaud segments referred to	Term for surgical resection	Diagram (pertinent area is shaded)
Right Anterior Section	*Sg 5, 8*	Add (-ectomy) to any of the anatomical terms as in *Right anterior sectionectomy*	Right Posterior Section	*Sg 6, 7*	*Right posterior sectionectomy*	Left Medial Section	*Sg 4*	*Left medial sectionectomy* OR *Resection segment 4* (also see Third order) OR *Segmentectomy 4* (also see Third order)	Left Lateral Section	*Sg 2, 3*	*Left lateral sectionectomy* OR *Bisegmentectomy 2, 3* (also see Third order)	
Other "sectional" liver resections

Sg 4–8 (+/–Sg1)	*Right Trisectionectomy (preferred term)* or *Extended Right Hepatectomy* or *Extended Right Hemihepatectomy* (stipulate +/–segment 1)	Sg 2,3,4,5,8 (+/–Sg1)	*Left Trisectionectomy (preferred term)* or *Extended Left Hepatectomy* or *Extended Left Hemihepatectomy* (stipulate +/–segment 1)	
Border or watershed: The borders or watersheds of the sections are planes referred to as the *right and left intersectional planes*. The left intersectional plane passes through the umbilical fissure and the attachment of the falciform ligament. There is no surface marking of the right intersectional plane.

3 *Third-order division*

Anatomical Term	Couinaud segments referred to	Term for surgical resection	Diagram (pertinent area is shaded)

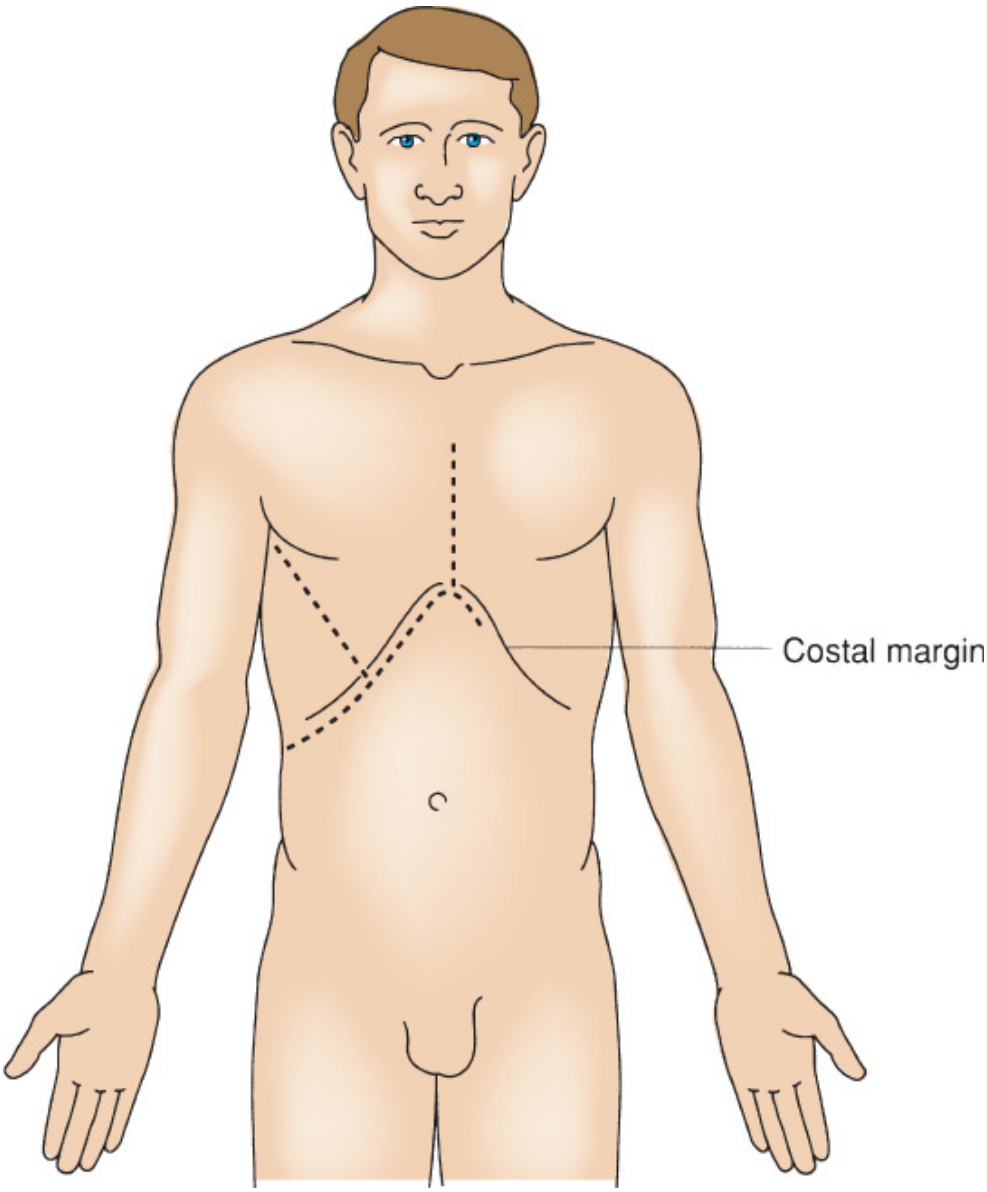

Figure 57.20 Incisions used for open hepatic resection.

Some surgeons prefer an extra-fascial Glissonean pedicle approach to isolate the portal structures. In this method, the portal pedicles are accessed by performing hepatotomies near the hilar plate to encircle the portal pedicles between the Glissonean capsule and Laennec capsule, the membrane that covers the liver parenchyma (**Fig. 57.22**). The extrahepatic Glissonean approach also allows selective inflow control, either on a temporary or permanent basis. In this method, the biliary structures are divided en masse with the vascular pedicle of interest. An advantage of this

approach is that variant biliary and hepatic artery anatomy lies within the Glissonean pedicle and is easily controlled using this method.

Using either approach, early inflow control allows ischemic demarcation of the liver along the anatomic lines, which is helpful to guide the extent of resection required.

Outflow control is then obtained. Small veins from the caudate lobe to the IVC are individually divided to mobilize the liver off of the IVC (**Fig. 57.13**). The hepatic vein of interest can then be encircled and divided with an endovascular stapler (**Figs. 57.23** and **57.24**). For left hepatectomies, formal division of the ligamentum venosum, which runs in Arantius cleft between the posterior left liver and the caudate lobe, provides easy access to the base of the left hepatic vein and facilitates control of this structure.

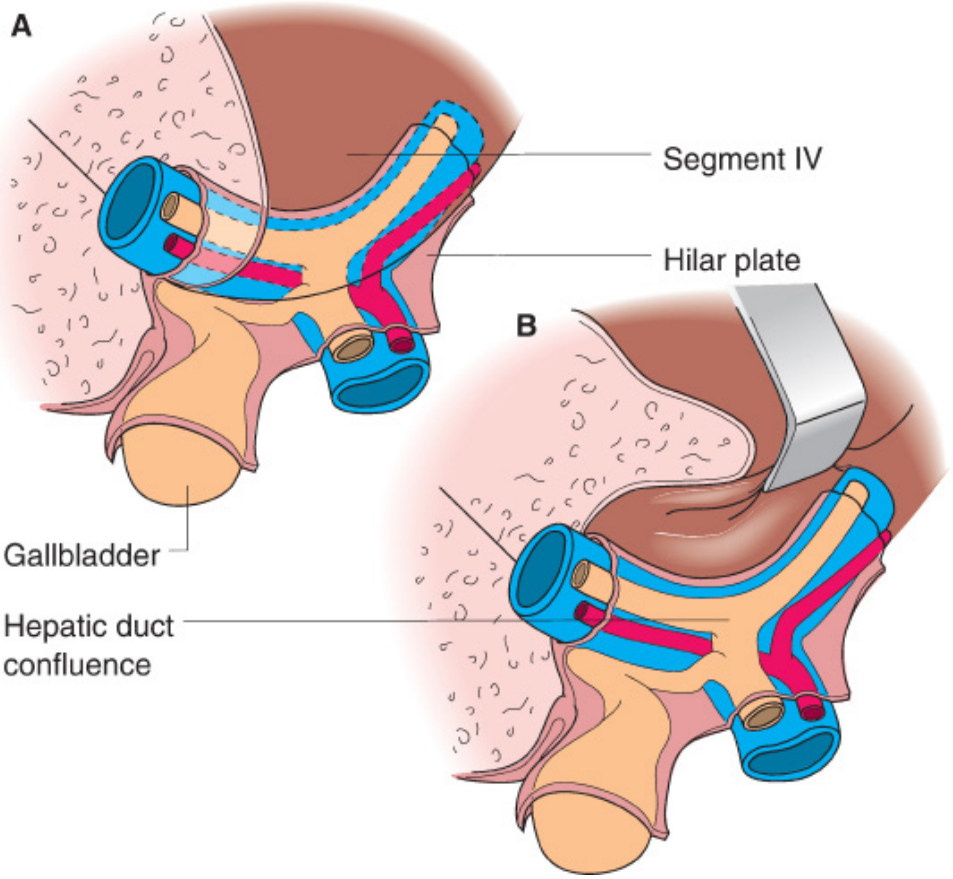

Figure 57.21 Lowering the hilar plate. **A:** The inferior border of segment IV overlies the hepatic duct confluence. **B:** Division of the connective tissue investment allows elevation of segment IV, which results in a "lower" hilar plate and surgical exposure to the hepatic duct confluence.

Parenchymal transection should be performed under low central venous pressure (CVP) conditions (<5 mm Hg) to minimize bleeding from the parenchymal surface.[9] The Pringle maneuver can also be used, either selectively or routinely, to further reduce blood loss and maintain clear visualization of the intraparenchymal structures during transection. Large intraparenchymal structures should be divided formally with sutures, clips, or staples to minimize bleeding and bile leak. A variety of techniques are used for parenchymal transection, including crush clamp, ultrasonic or water-jet dissectors, energy devices (monopolar, ultrasonic, or bipolar), and staplers. No single technique has been demonstrated to be clearly superior; thus, surgeons should use a technique that they are familiar with.

Minor hepatectomies include resection of smaller volumes of liver, but the name is a misnomer, as these resections are often technically challenging and require a more informed understanding of the intraparenchymal structures to ensure safe resection. In the modern era, a parenchymal-sparing approach is favored to preserve the FLR and allow repeat resection in the future and/or preserve liver function. In these cases, exposure and mobilization follow the same principles as discussed above, but unlike major hepatectomies, the vascular inflow and outflow structures are often within the liver. As a result, definitive inflow and outflow control is often not possible prior to parenchymal transection. Since parenchymal transection and vascular control occur concurrently, temporary inflow control with Pringle maneuver and low CVP conditions are even more important for these procedures. Parenchymal transection is performed to allow exposure and control of intrahepatic structures as they are encountered.

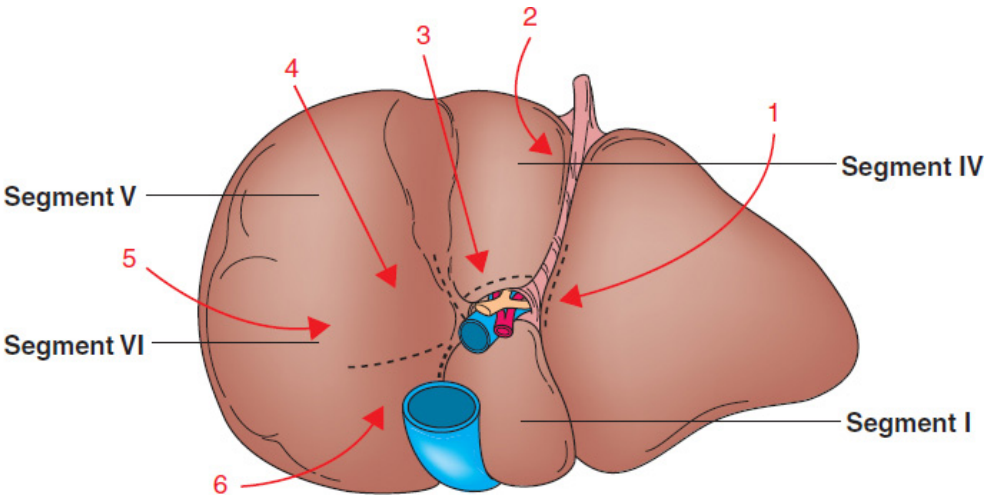

Figure 57.22 Hepatotomies to access pedicles for ligation: right hepatectomy, 4, 5 and 6 left lateral sectionectomy, 1 and 2; left hepatectomy, 1 and 3 right anterior sectorectomy, 4 and 5; and right posterior sectorectomy, 5 and 6.

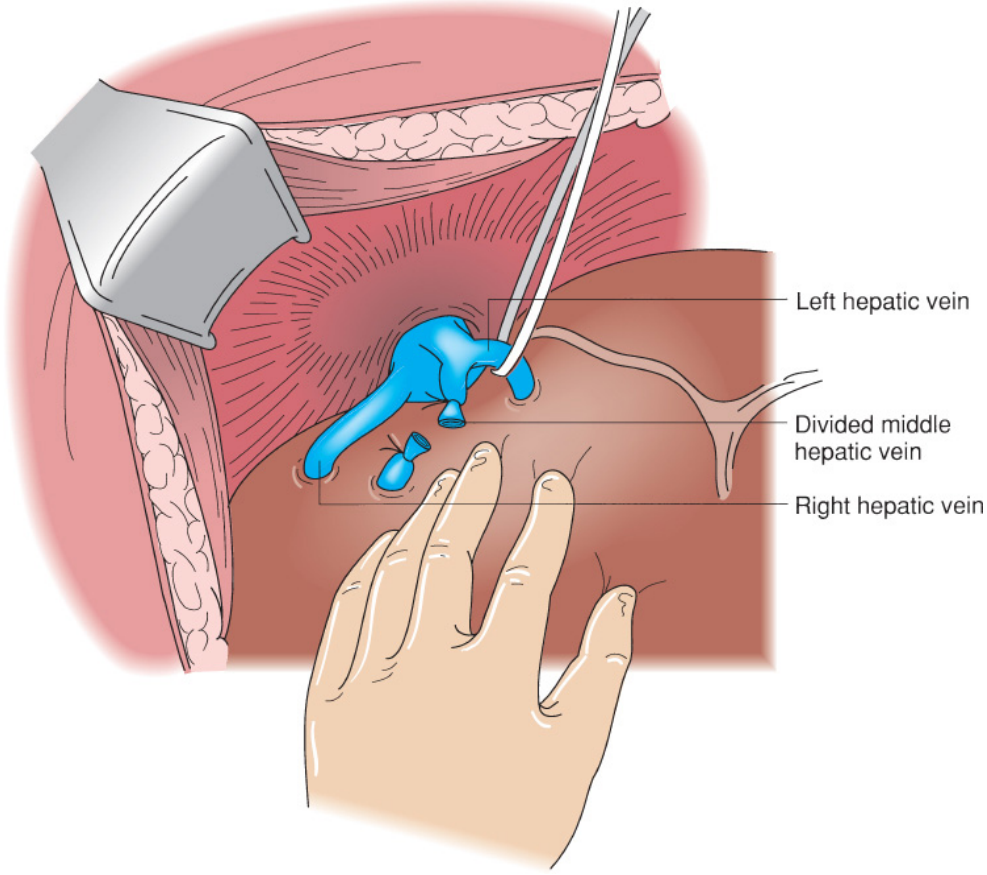

Figure 57.23 Caudal retraction of the left hepatic lobe with division of middle and left hepatic veins during left hepatic lobectomy. Often, the division of the middle and left hepatic veins is intraparenchymal.

Once resection has been completed, the FLR and the cut edge of the liver are inspected. Any bleeding points or open biliary radicals should be oversewn, and hemostasis along the cut surface should be confirmed. The falciform ligament should be reconstructed to avoid postoperative liver torsion.

There has been major advancement in liver surgery technique with the availability of minimally invasive hepatectomy.[10] Minor hepatectomies in safe zone areas—peripherally based lesions in segments II to VI—are now performed using a minimally invasive approach at many centers. As experience is gained, the use of minimally invasive techniques for formal hemihepatectomies, as well as posterior or superior lesions (segments I, IV, VII, VIII) is increasing. However, a minimally invasive approach provides a different anatomic view of the liver. Unlike an open procedure which provides a ventral approach to the liver, the liver is often seen in a caudal–cranial view during minimally invasive right hepatectomy.[11] As a result, surgeons performing minimally invasive major hepatectomies must be intimately familiar with how intraparenchymal structures appear from this perspective. There are several benefits of a minimally invasive approach, including improved postoperative recovery, decreased length of stay, and earlier return to full activity. Minimally invasive surgery can be approached using pure laparoscopic, hand-assisted, hybrid, or robotic-assisted approaches.

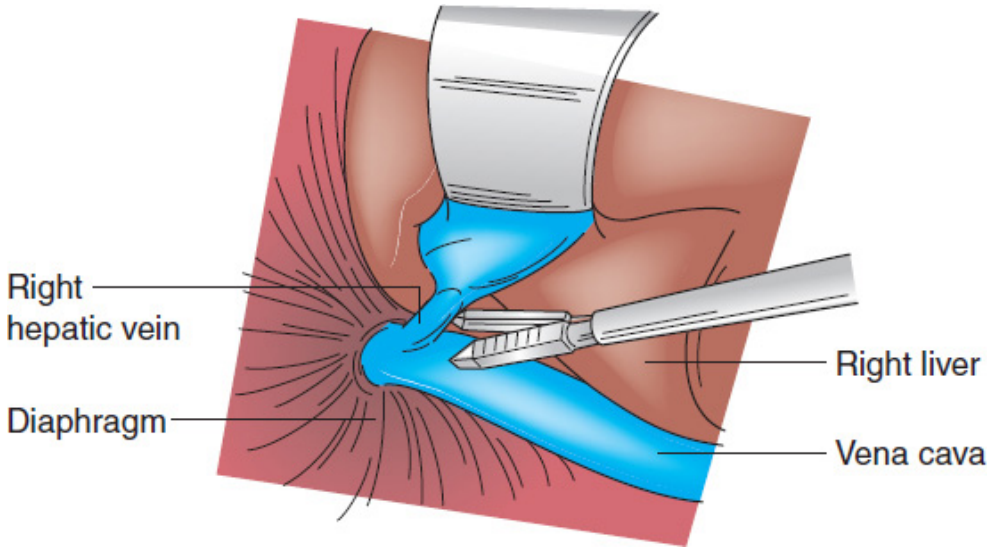

Figure 57.24 A vascular endoscopic stapling device is used to divide the right hepatic vein after the right side of the liver has been mobilized.

Hepatic Infection and Acute Liver Failure

Ola Ahmed and Maria B. Majella Doyle

Key Points

1. Liver abscesses are the most common type of visceral abscess.
2. Acute liver failure (ALF) is characterized by hepatic encephalopathy and impaired coagulation (INR >1.5) in the absence of any underlying or pre-existing liver disease.
3. Liver disease etiology influences management, outcomes, and overall prognosis.
4. Viral and acetaminophen are the most common causes of ALF in adults.
5. While biologic and nonbiologic liver support systems are still under experimentation, liver transplant is the only curative treatment of choice in cases of irreversible liver failure.

PYOGENIC LIVER ABSCESS

Prevalence and Pathogenesis

Pyogenic liver abscesses result from bacterial infections and most commonly develop from intra-abdominal contamination of bowel contents subsequently disseminating to the liver through portal circulation or contiguous spreading following biliary infections. Abscesses may also occasionally arise directly from 1 penetrating wounds or surgical procedures. These specific infections account for 13% of intra-abdominal abscesses, making them the most common type of visceral abscesses, with an annual incidence of 2.3 cases per 100,000 persons and a slight preponderance among male patients.[1,2]

Risk Factors

Common risk factors for abscess development include diabetes mellitus, liver transplantation, pre-existing hepatobiliary or pancreatic disease as well as invasive hepatic and intra-abdominal procedures. Loss of gastric acid production commonly seen in elderly patients or in cases of atrophic gastritis have also been associated with the increased risk of pyogenic infections, largely due to the consequential changes in bowel bacterial flora. Several studies from Taiwan reported a potential link between pyogenic liver abscesses and underlying colorectal cancer.[3–5] In some studies, the incidence of subsequent gastrointestinal malignancy was four-fold higher than in control groups, with *Klebsiella pneumonia* acting as the most implicating pathogen.

Clinical Manifestations

Fever is the most frequent presenting symptom of pyogenic liver abscesses, occurring in up to 90% of patients. Abdominal signs and symptoms occur in 50% to 75% of cases, commonly localizing to the right upper quadrant and manifesting as pain, guarding, and rebound tenderness. Hepatomegaly may occur in some scenarios and jaundice is frequently present. Other common symptoms are nausea, chills, anorexia, weight loss, malaise, and fatigue. Laboratory studies demonstrate leukocytosis and transaminitis with hyperbilirubinemia is evident in over 50% of cases, respectively. Hypoalbuminemia and normochromic, normocytic anemia may also be present.

Diagnosis

Abdominal imaging with ultrasound (US) and computed tomography (CT) are appropriate diagnostic modalities for abscess identification, though a chest x-ray may reveal a right pleural effusion or an elevated hemidiaphragm in 50% of cases. Abdominal US can diagnose pyogenic abscesses in almost 90% of cases and can guide diagnostic or therapeutic drainage. CT is more sensitive than US (95% vs. 85%), will reveal small abscesses, and further differentiate these lesions from other pathologies.[6] When CT scanning is done, intravenous contrast should be used if there are no patient contraindications (**Fig. 58.1**). Alternative diagnostic modalities include magnetic resonance imaging (MRI) or tagged white blood cell scans, which are less common.

Blood cultures are positive in up to 50% of cases and are important diagnostic elements. These should be ideally drawn prior to antibiotic therapy. Standard serum analyses such as complete blood counts, electrolytes, renal profiles, and liver function testing are also performed to determine the degree of systemic infection and for evidence of any potential concomitant organ injury. Serologic and fecal testing of *Entamoeba histolytica* is also considered in the diagnostic workup of patients with epidemiologic risk factors.

Image-guided drainage of suspected abscesses is performed to confirm the diagnosis and the involved bacterial pathogens. Aspirate material is sent for Gram staining and culture to help guide therapy.

Microbiology

Most pyogenic liver abscesses are polymicrobial, consisting of a combination of enteric and anaerobic pathogens. The most commonly identified pathogens are *Escherichia coli* and *K. pneumonia*. Streptococci species are also important causes of liver abscesses as well as *Staphylococcus aureus*. Candida coinfection can also arise in immunocompromised states.

Figure 58.1 Computed tomogram of a pyogenic hepatic abscess in a liver transplant recipient with occlusion of the hepatic artery.

Treatment

Multimodal treatment is essential for resolution of pyogenic liver abscesses. Drainage is both diagnostic and therapeutic and should always be considered when feasible. Drainage can be performed using CT/US-guided percutaneous techniques, surgical via an open or laparoscopic approach or by endoscopic retrograde cholangiopancreatography (ERCP). Drainage catheters should remain in place until output is minimal which is usually up to 7 days. Empiric antibiotic therapy should be administered pending microbiologic culture and sensitivity analysis. Coverage should be broad to include streptococci, enteric gram-negative bacilli and anaerobes and guided by microbiologic expertise. Once culture and sensitivity results are available, directed therapy should be initiated and duration is based on clinical response. A typical

course is 14 days of parenteral therapy followed by oral medication for a total of 6 weeks.[7]

AMEBIC LIVER ABSCESS

Prevalence and Pathogenesis

Amebic liver abscesses are the most common extraintestinal manifestations of amebiasis caused by the protozoan *E. histolytica*. Amebiasis is most prevalent in tropical and subtropical regions with poor sanitation and fecal–oral transmission is the most common route of infection. In developed countries, it can occur in migrants from endemic areas. Most infections are asymptomatic, but amebic dysentery and pulmonary, cardiac, and brain involvement can occur, along with hepatic abscess formation.

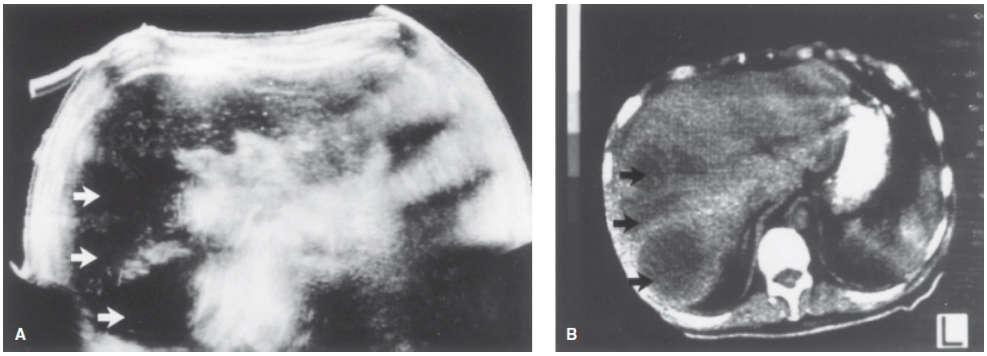

Figure 58.2 Sonogram **(A)** and computed tomogram **(B)** in a patient with multiple amebic abscesses (*arrows*).

Men are affected 10 times more commonly than women, with peak incidence in the third to fifth decade of life, and corticosteroid usage is a risk factor.[8] Ingested cysts pass through the stomach and reach the intestine. There, the cyst wall is degraded and trophozoites are released. These infective particles multiply in the colonic lumen and then may enter mesenteric veins and eventually the liver. Amebic trophozoites then cause obstruction of venules, thrombosis, and infarction of hepatic parenchyma, with resultant abscess formation.

Risk Factors

Risk factors predisposing to amebic liver abscesses are unclear, although immunocompromised states such as HIV may increase the likelihood of invasive disease.

Clinical Manifestations

Clinical presentation usually occurs within 8 to 20 weeks following return from endemic areas, manifesting as right upper quadrant pain and fever. Cough, sweating, malaise, weight loss, and hiccough may also be present. Diarrhea occurs in up to one-third of patients and jaundice is evident in 10%. Abscess rupture occurs in up to 7% of affected patients with direct extension into the peritoneal cavity often resulting in severe peritonitis and systemic infection. Leukocytosis is common with transaminitis and elevated alkaline phosphatase (ALP) levels evident in 80% of cases.

Diagnosis

Several imaging modalities can be utilized, specifically US, CT, or MRI (**Fig. 58.2**). Amebic abscesses are more common in the right lobe and tend to be singular. US typically demonstrates a round, well-defined, hypoechoic mass, while images on CT scan may show a low-density mass with an enhancing rim at it's periphery. On MRI, abscesses appear with a low-signal intensity on T1 weighted images and high signal intensity on T2 weighted images. Elevation of the right hemidiaphragm is evident on 50% of chest radiographs. *E. histolytica* is not always found in stool specimens of infected patients due to the intermittent appearance of organisms and the uncommon occurrence of simultaneous amebic liver and intestinal disease, but diagnostic antibodies are present in the serum 7 to 10 days after the onset of symptoms in over 90% of patients.[9] Needle aspiration with imaging modalities can be both diagnostic and therapeutic for large-sized abscesses. Abscess content is typically described as having an "anchovy paste" consistency and is acellular and proteinaceous in substance. Aspirates can be considered for antigen or PCR testing. Currently, PCR testing is understood to be the most sensitive method in identifying E. histolytica, and the sensitivity for aspirated material ranges from 75% to 100% with specificity rates over 90%, respectively.[10] A study by Parija reported a diagnostic

sensitivity of liver abscess analysis by PCR of 100% before treatment, comparing to 70.6% after treatment.[11] This is likely a result of DNA eradication and parasite destruction following treatment.

Treatment

Treatment is based on amebicidal drugs to eliminate liver organisms and a luminal agent to eradicate intraluminal cysts. Treatment can be initiated empirically pending further evaluation. Metronidazole 500 mg to 750 mg three times a day for 7 to 10 days is typically first line. Tinidazole 2 g orally for 5 days is an alternative treatment that is oftentimes better tolerated. To eradicate intraluminal cysts, the following regimens can be used: paromomycin (25 to 30 mg/kg/day orally three times a day for 7 days), diiodohydroxyquin (650 mg orally three times a day for 20 days), or diloxanide furoate (500 mg orally three times daily for 10 days for adults). Amebic abscesses can almost always be treated with medical therapy alone and abscess drainage can be considered in large abscesses or cases of a low or absent clinical response.

ECHINOCOCCUS (HYDATID DISEASE)

Prevalence and Pathogenesis

Echinococcal infection, also called hydatid disease, is a parasitic infection due to echinococcal tapeworms including *Echinococcus granulosus* or *E. multilocularis* in humans. The liver is most commonly affected by *E. granulosus* but this is typically asymptomatic. Dogs are the definitive host and the life cycle of the organism is such that when the canine host ingests infected viscera (from sheep or cattle) scoleces released in the intestine develop into adult worms. Humans, an intermediate host, acquire echinococcal eggs by ingestion of contaminated foods or with infected animals. The echinococcal egg is digested in the duodenum and yields an embryo (oncospheres). Embryos invade the intestinal wall and reach the liver via the portal circulation. Surviving embryos lodge in the hepatic

capillaries and develop into hydatid cysts. *E. multilocularis* is more commonly associated with alveolar disease.

Risk Factors

The disease is commonly associated with dog and sheep ownership and increasing age.[12]

Clinical Manifestations

Liver involvement with echinococcal cyst can lead to venous obstruction, portal hypertension, sepsis, and cholangitis. The right lobe is involved in most cases (60% to 85%) and symptoms typically develop when the cyst measures at least 10 cm. This can manifest as hepatomegaly, right upper quadrant pain, nausea, and vomiting. Cysts may grow at an annual rate of around 1 to 3 cm/yr. Enlarging cysts can cause symptoms of abdominal pain, biliary obstruction, and jaundice, or less commonly portal hypertension, resulting from mass or pressure effects. Occasionally, cysts may rupture into the peritoneal cavity causing abdominal pain and anaphylaxis.

Diagnosis

Hydatid cysts can be visualized using the previously mentioned imaging techniques: US, CT and MRI. US reaches a sensitivity of 90% to 95%[13] and typically demonstrates a smooth, anechoic, round cyst with a “hydatid sand” on patient movement.[14] CT imaging has an advantage over US through its ability to demonstrate intraperitoneal rupture and concurrent infection while MRI may further delineate the cyst capsule.[15] Serologic testing is also used during the initial diagnosis. Antibody testing with ELISA appears to be the most sensitive modality.[16]

Treatment

Surgical resection is the treatment of choice for large or complicated hydatid cysts (rupture, fistulae, compression). Surgical extirpation aims to remove the cyst intact without spillage of cyst contents. Aspiration of cyst contents

prior to resection may minimize the result of any cyst spillage. After aspiration injection with ethyl alcohol or 20% sterile saline is undertaken to kill remaining scoleces. In cases where the aspirate is bilious and a communication with the biliary tree is thus suspected the cyst should be resected without alcohol injection to prevent the occurrence of sclerosing cholangitis. Surgical excision can be performed through open or laparoscopic techniques depending on cyst features and location. Albendazole should be started 4 days prior to surgery and generally continued for at least 4 weeks postoperatively.[17] Mebendazole may be used as an alternative therapy but is less well absorbed and continued use for at least 3 months post surgery is advised.[18]

SCHISTOSOMA

Prevalence and Pathogenesis

Schistosoma mansoni, S. japonicum, S. haematobium, and *S. mekongi* are species of the trematode fluke that infects humans in endemic areas or visitors to these sites. Liver disease is especially severe with *S. mansoni, S. japonicum,* and *S. mekongi.* The life cycle of *Schistosoma* species alternates between sexual reproduction in humans and asexual multiplication in water snails. Cercariae enter the human host by penetrating the skin. An irritating maculopapular rash that lasts for several days is an early manifestation of infection. Schistosomes live in the intestinal lumen and eggs reach the liver via the portal circulation where they cause an inflammatory reaction manifesting as an inflammatory granuloma surrounding a schistosomal egg. The pathogen is most prevalent in central and subtropical areas of sub-Saharan Africa, the Middle East, India, and Southeast Asia.[19] Hepatocellular carcinoma (HCC), colon cancer, and follicular lymphoma of the spleen have been reported in association with hepatic schistosomiasis.[20]

Risk Factors

Acute schistosomiasis is seen typically in poor and rural communities exposed to infested waters and nonimmune visitors to endemic areas.

Clinical Manifestations

While hepatocellular functioning may not be impaired, physical examination may reveal a firm, nodular liver and features of portal hypertension such as splenomegaly and gastric varices.[21] It is usually asymptomatic until manifestations of portal hypertension declare themselves.

Diagnosis

Diagnosis requires serologic, microscopic, and biochemical analysis to detect infection and parasitic burden coupled with standard imaging modalities. Stool (Kato–Katz smears) and urine analysis can allow for microscopic egg detection while antigen testing can be performed on urine analysis to characterize parasitic burden. Serum transaminases are typically normal. Tissue biopsies are useful in the setting of inconclusive diagnostic tools and will show prominent granuloma formation and severe portal fibrosis. Imaging studies are not typically useful in the diagnosis of acute infection. In chronic cases US may show portal vein wall thickening.[22] Hypertrophy of the left lobe, splenomegaly, and engorged venous collaterals may all be observed as well. CT and MRI may show fibrosis around portal vein branches as well as low attenuation rings through the liver parenchyma.[23]

Table 58.1 Classification of Viral Hepatitis

	The Viral Hepatitides				
Virus	Hep A Picornavirus (RNA)	Hep B Hepadnavirus (DNA)	Hep C Flavivirus (RNA)	Hep D Viroid (RNA)	Hep E Calicivirus (RNA)
Transmission Acute disease Evolution to chronic disease	Fecal–oral Common Never	Parenteral Common Infrequent in adults	Parenteral Uncommon Frequent (70%)	Parenteral Common Yes	Fecal–oral Yes Described in organ transplant recipients
New cases/yr # Infected (U.S.)	1,400,000 6,700	22,100 862,000	44,300 2,400,000	Unknown, found in approximately 5% of cases of HBV infection	300 Unknown, uncommon
Treatment	None	Lamivudine Adefovir Entecavir	Interferon + Ribavirin	Treatment of HBV	Mainly sanitary preventative
Prophylaxis	Vaccine and Ig	Vaccine and Ig	None	Vaccinate against HBV	In development
Fulminant failure	Rare	Yes	Never	With HBV, as coinfection or superinfection	Especially in pregnant women

HBV, hepatitis B virus; Hep, hepatitis; Ig, immunoglobulin.

Treatment

Preferred treatment of schistosomiasis is praziquantel, with a cure efficacy of around 90%. Follow-up stool or urine microscopy should be performed at 6 weeks in endemic areas and 3 to 6 months following treatment in nonendemic areas. Repeat treatment with praziquantel may be warranted in persistent egg detection.

Viral Hepatitis

Viral hepatitis represents an important cause of acute and chronic liver disease, cirrhosis and hepatocellular cancer. In the United States, hepatitis A, B and C account for more than half of acute hepatitis cases with hepatitis C becoming a leading indication for liver transplantation and potential graft loss resulting from its reactivation.[24]

The mechanism of liver injury is largely a host inflammatory response to the virus. **Table 58.1** summarizes the current understanding and characteristics of the five viruses most commonly associated with clinical hepatitis, their modes of transmission, and the consequences of infection.

HEPATITIS A VIRUS

Epidemiology/Risk Factors for Transmission

Hepatitis A is generally self-limiting with no risk of chronic infection. This is usually transmitted via the fecal–oral route. Common risk factors for transmission include international travel, consumption of contaminated food and water, and intravenous drug use. The disease can occur sporadically or in epidemic form and outbreaks are not uncommon. However, incidence in the United States has declined with effective vaccination.

Clinical Features

Fulminant hepatic failure occurs in less than 1% of cases and mostly occurs in patients with underlying liver disease or coinfection. Symptoms are uncommon in children less than 6 years of age and more commonly manifest in adults, occurring in up to 70% of those infected. The incubation period is typically 28 days, ranging from 15 to 50 days. Initial symptoms are fatigue, malaise, nausea, vomiting, anorexia, fever, and right upper quadrant pain. The diagnosis may be missed in cases without jaundice, progressing to bilirubinuria, acholic stools, and jaundice in 40% to 70% of patients. In cases where jaundice becomes manifest, it persists for 1 to 6 weeks. Transaminitis (1,000 IU/mL), hyperbilirubinemia (>10 mg/dL), and elevated ALP (>400 U/L) may also occur (**Fig. 58.3**).

Treatment

Treatment is mainly supportive and infection control measures such as hand washing and isolation should be a top priority to prevent the spread of virus. Complete recovery typically occurs at 6 months in all patients. Vaccine protection for specific patient groups is warranted prior to hepatitis A exposure: all children at age one, individuals travelling to endemic areas, and those with chronic disease and HIV.

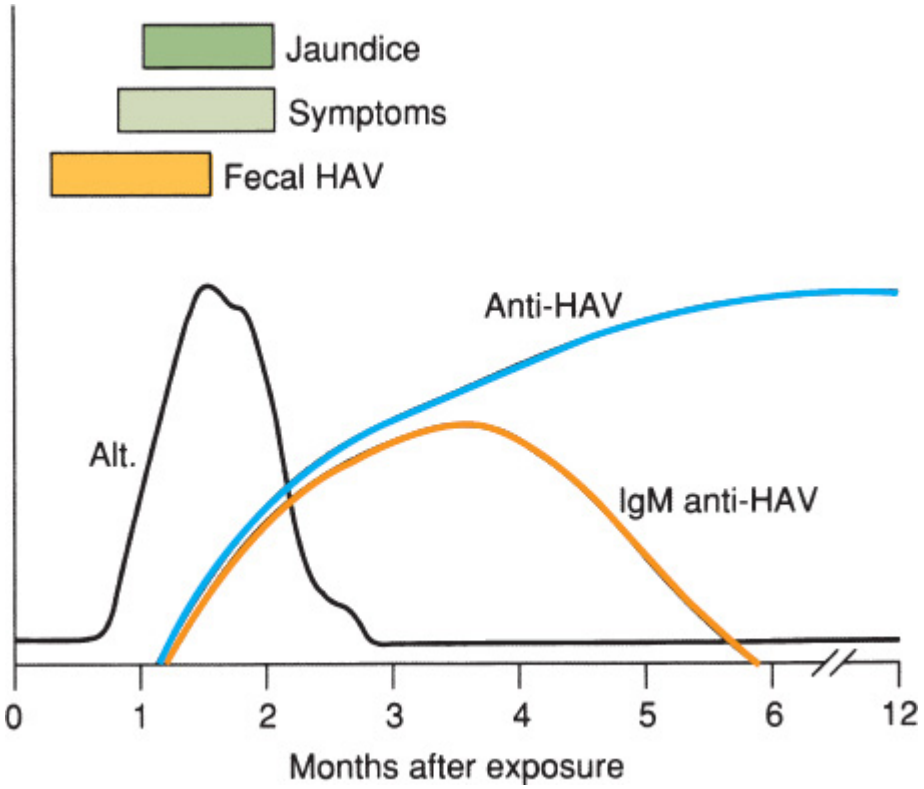

Figure 58.3 Clinical course of hepatitis A infection.

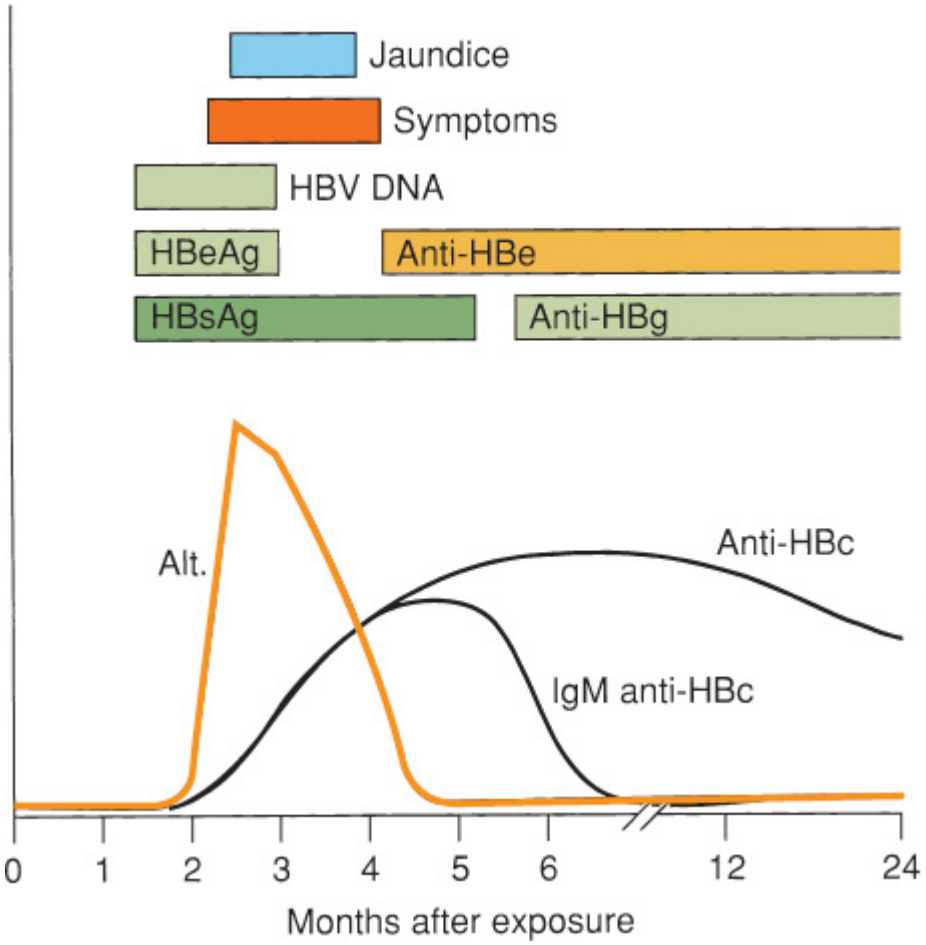

Figure 58.4 Clinical course of acute hepatitis B infection.

HEPATITIS B VIRUS

Epidemiology/Risk Factors for Transmission

It is estimated that nearly 2 billion people worldwide were previously or currently infected with hepatitis B and 248 million are chronic carriers.[25] In the developing world, mother-to-child infection is the most common mode of transmission. In the United States, transmission is primarily through sexual exposure. Infection from intravenous drug use and occupational infections due to percutaneous exposure may also occur. Liver injury is due to the resultant host immune response.

Clinical Features

The incubation period for hepatitis B virus (HBV) can last from 1 to 4 months. Clinical features of the virus vary in acute and chronic disease (**Fig. 58.4**). During the initial acute stage of disease, symptoms can range from subclinical to anicteric hepatitis. Icteric hepatitis occurs in 30% of patients while only 0.1% to 0.5% develop fulminant hepatic failure. The presence of serum hepatitis B surface antigen (HBsAg) may precede jaundice. Acute infection is associated with detectable serum HBV DNA, hepatitis B early antigen (HBeAg), and IgM to hepatitis B core. HBeAg is a useful marker of viral replication except in patients with mutant viruses where it may be undetectable despite active replication. In such cases detection of HBV DNA is diagnostic. The risk of liver failure is proportional to antibody titers of HBcAg and HBsAg. Serum anti-HBc IgM becomes detectable with the onset of jaundice and rapidly reaches peak concentrations. In most patients, when HBV does not develop into chronic hepatitis, anti-HBc IgM becomes undetectable after 6 months and for this reason is considered an accurate marker for differentiating acute hepatitis B from chronic hepatitis B reactivation or exacerbation. Chronic hepatitis can be asymptomatic but may ultimately progress to decompensated cirrhosis and other extrahepatic manifestations of disease such as skin rashes, arthralgias, and glomerular disease (**Fig. 58.5**).

Treatment

Treatment for acute HBV is mainly supportive. Further efforts should be taken to prevent exposure and transmission to other individuals. Vaccinations can be offered to high-risk individuals such as health care workers, visitors to highly endemic areas, men who have sex with men, sex workers, and intravenous drug users. The hepatitis B vaccine is given as a series of three intramuscular doses and has almost 100% efficacy among immunocompetent persons. Hepatitis B immune globulin has a reported efficacy of 90% in the prevention of newborn infections and approximately 75% in cases of needle sticks or sexual infections in people exposed to the virus with no prior immunity. It is administered as soon as possible after exposure together with the first dose of the hepatitis B vaccine series.

Additional treatment options include antiviral therapies such as lamivudine, adefovir dipivoxil, or entecavir as monotherapy. Therapy is

usually directed at HBeAg-positive cases that have an increased risk of cirrhosis and HCC. HBeAg-negative patients with a high viral load may also benefit from treatment. Treatment can be stopped following negative identification of HBsAg on two consecutive tests 4 weeks apart.

Liver transplantation is offered in cases progressing to cirrhosis. Recurrence of viral infection in the allograft can be as high as 80% in HBeAg-positive cases where no postoperative prophylaxis is administered. The combination of lamivudine and hepatitis B immune globulin post transplantation has reduced the reinfection rate to less than 10% and increased the 5-year survival rate to 80%.

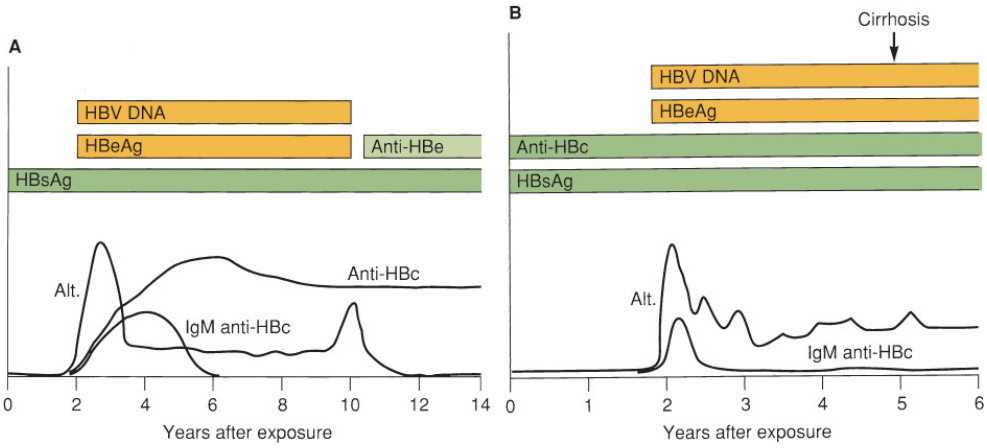

Figure 58.5 Clinical course of chronic hepatitis B. **A:** A benign chronic carrier has continued production of hepatitis B surface antigen but there is an absence of serum markers of viral replication. **B:** A pattern of continuing liver injury and serum markers of active viral replication.

HEPATITIS C VIRUS

Epidemiology/Risk Factors for Transmission

The estimated prevalence of hepatitis C worldwide is 177.5 million, almost 2.5% of the population.[26] In the United States alone, 44,300 new infections arise per year with an estimated 2.4 million people infected. Common risk factors are intravenous drug use, homelessness, incarceration, and sexual contact. In addition, the recent opioid epidemic has resulted in an increase in

hepatitis C virus (HCV) incidence as well as unhygienic and unsafe tattooing and body piercing.

Clinical Features

The HCV incubation period ranges from 15 to 150 days with symptoms commonly developing 5 to 12 weeks following exposure. Up to 80% of cases are asymptomatic. Nonspecific symptoms are seen in the remaining patients including nausea, diarrhea, abdominal pain, myalgia, and weight loss. Extrahepatic manifestations may arise in a subset of patients, including glomerular disease, autoimmune disorders, and dermatologic conditions.[27] Initial laboratory findings may reveal elevated ALT levels (500 to 1,000 IU/mL) and high HCV RNA titers (**Fig. 58.6**). Between 50% and 85% of patients remain chronically infected of which 5% to 30% progress to cirrhosis in the following two or three decades. Cirrhotic patients are at a further risk of developing HCC and decompensated failure.

The diagnosis of chronic hepatitis C is based on the serologic demonstration of persistent HCV RNA and HCV antibodies. HCV RNA can be detected weeks earlier than antibodies, which typically appear 2 to 8 weeks after the initial infection (**Fig. 58.7**).

Treatment

Similar to hepatitis B, treatment approaches include preventative measures for further hepatitis C transmission. Individuals are advised not to donate blood or share a toothbrush and are encouraged to take part in substance-abuse treatment facilities, and counseled regarding safer drug injection practices. Various antiviral treatment regimens are available depending on the viral phenotype and patient risk factors and should be considered in all patients with chronic HCV infection and a detectable HCV viral level for more than 6 months. Eradication is based on achieving a sustained virologic response (SVR) 12 weeks following the completion of therapy.

Interferon (IFN) has long been considered the drug of choice for hepatitis C treatment with its ability to reduce the rate of fibrosis progression. This can be used in combination with ribavirin for either 24- or 48-week courses, depending on the genotype present. SVR rates range from 29% to 62%.

Direct-acting antivirals (DAAs) have also been designed to specifically inhibit HCV proteins. These agents, including simeprevir, ombitasvir, and elbasvir, can be taken orally for 8 to 12 weeks with SVR rates approaching 90%.

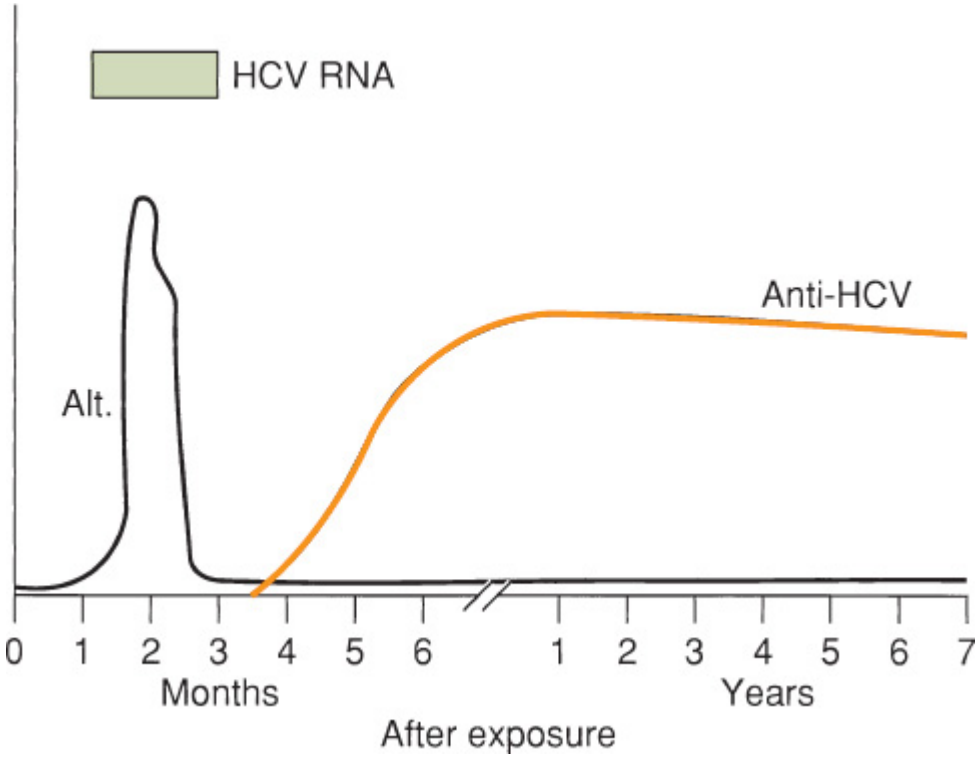

Figure 58.6 Clinical course in acute hepatitis C.

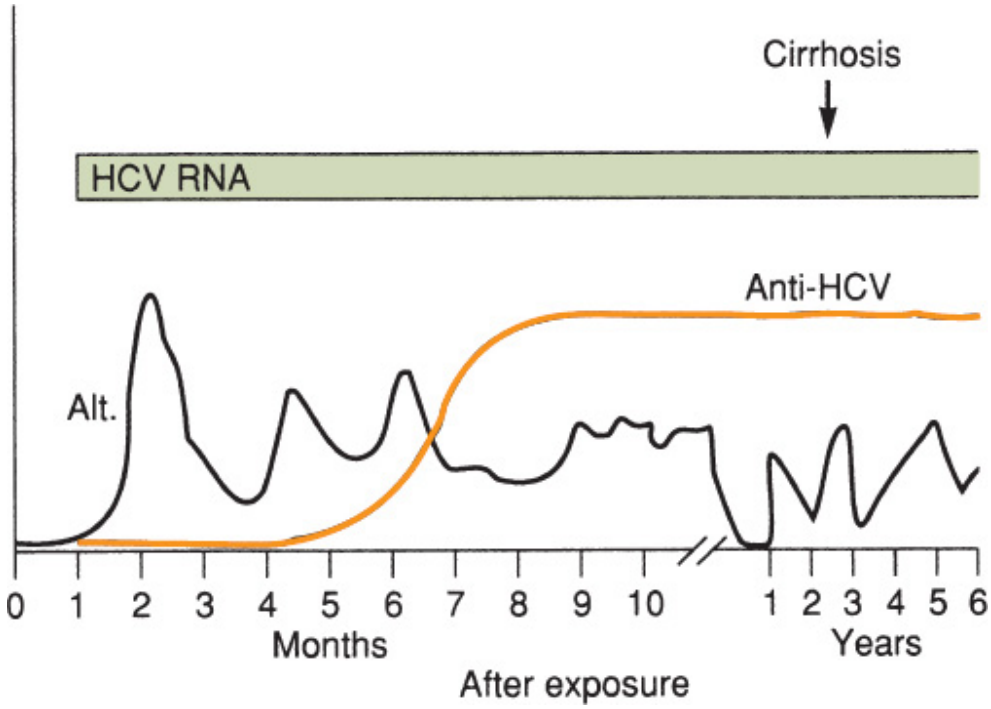

Figure 58.7 Clinical course in chronic hepatitis C.

Hepatitis C cirrhosis is a common indication for liver transplantation. However, reinfection and graft failure are almost inevitable if the virus is untreated during the pre- or posttransplant period. Five-year survival varies between 60% and 80%.

HEPATITIS D VIRUS

Epidemiology/Risk Factors for Transmission

Due to its dependence on HBV, patients with hepatitis D are always coinfected with hepatitis B. Transmission is similar to that of HBV, via parenteral or sexual exposure to blood or body fluids and hepatitis D virus (HDV) only occurs in HBsAg-positive patients.

Clinical Features

Acute infection is diagnosed by the presence of anti-HDV IgM. Coinfection with HBV generally produces a clinically indistinguishable disease with

clinical features similar to the acute hepatitis B infection (**Fig. 58.8**). Anti-HBc IgM distinguishes coinfection from superinfection which may manifest as a severe form of hepatitis or exacerbation of chronic HBV. The diagnosis in patients with chronic liver disease is made by the presence of HBsAg and antibodies against HDV in the serum and confirmed by the presence of HDV antigen in the liver or HDV RNA in the serum (**Fig. 58.9**). Cirrhosis may develop in up to 80% of coinfected patients compared to 15% to 30% of patients solely infected with HBV (**Fig. 58.10**).

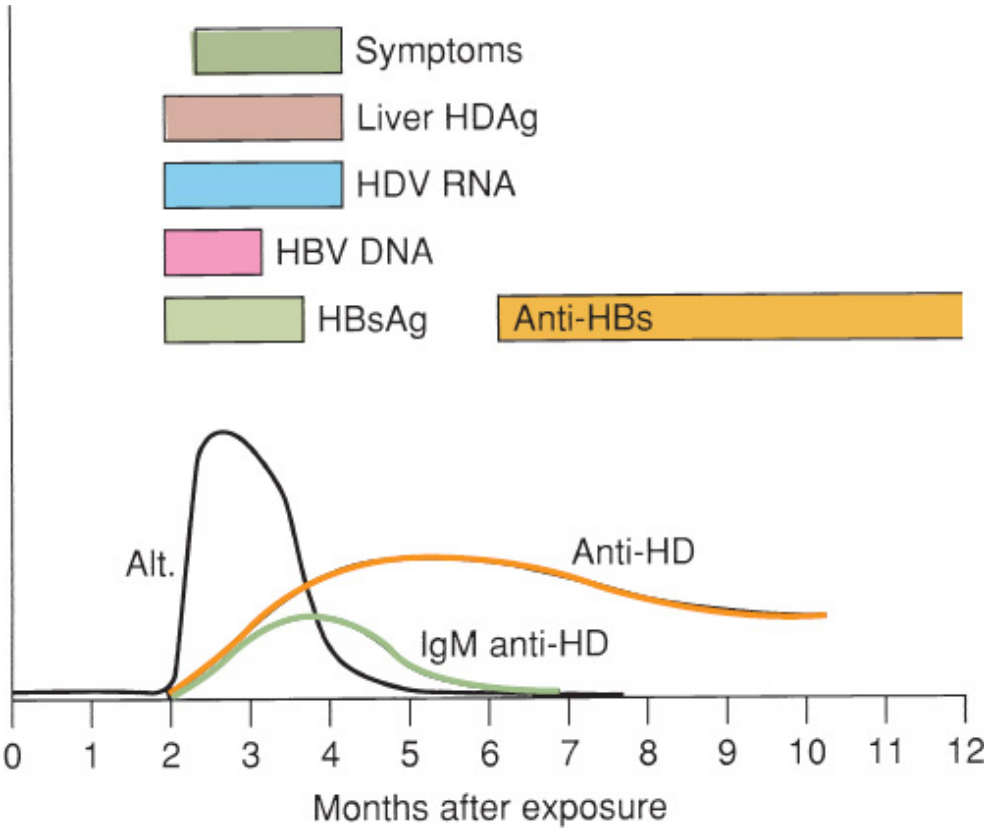

Figure 58.8 Synchronous infection with hepatitis B virus and hepatitis D virus.

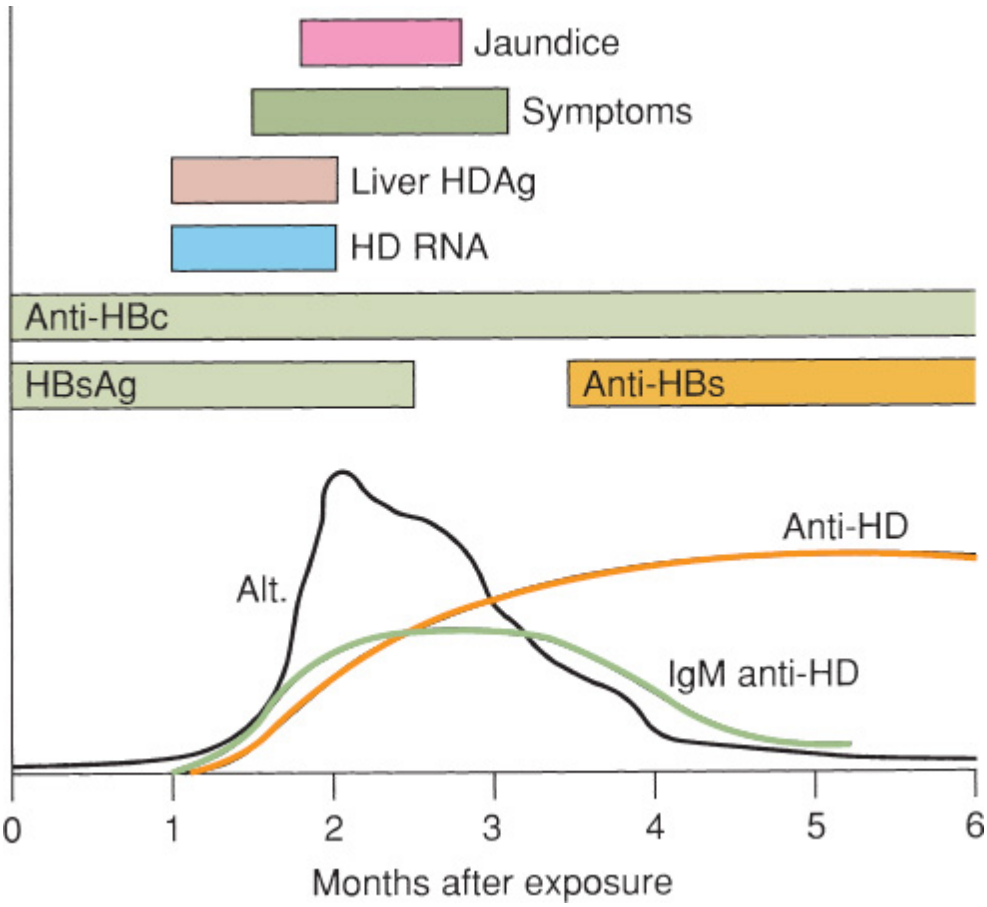

Figure 58.9 Superinfection of chronic hepatitis B carrier with hepatitis D.

Treatment

Treatment and prevention of HDV mirrors that seen with HBV and HCV. IFN is the treatment of choice and may be administered for up to 12 months. Mainstay prevention is dependent on HBV vaccination.

HEPATITIS E VIRUS

Epidemiology/Risk Factors for Transmission

Hepatitis E is one of the least diagnosed etiologies of acute viral hepatitis. There are an estimated 20 million new infections diagnosed every year according to the World Health Organization (WHO) and the virus is

distributed globally. Transmission occurs through the ingestion of fecally contaminated food and water, blood transfusions, and perinatal routes.

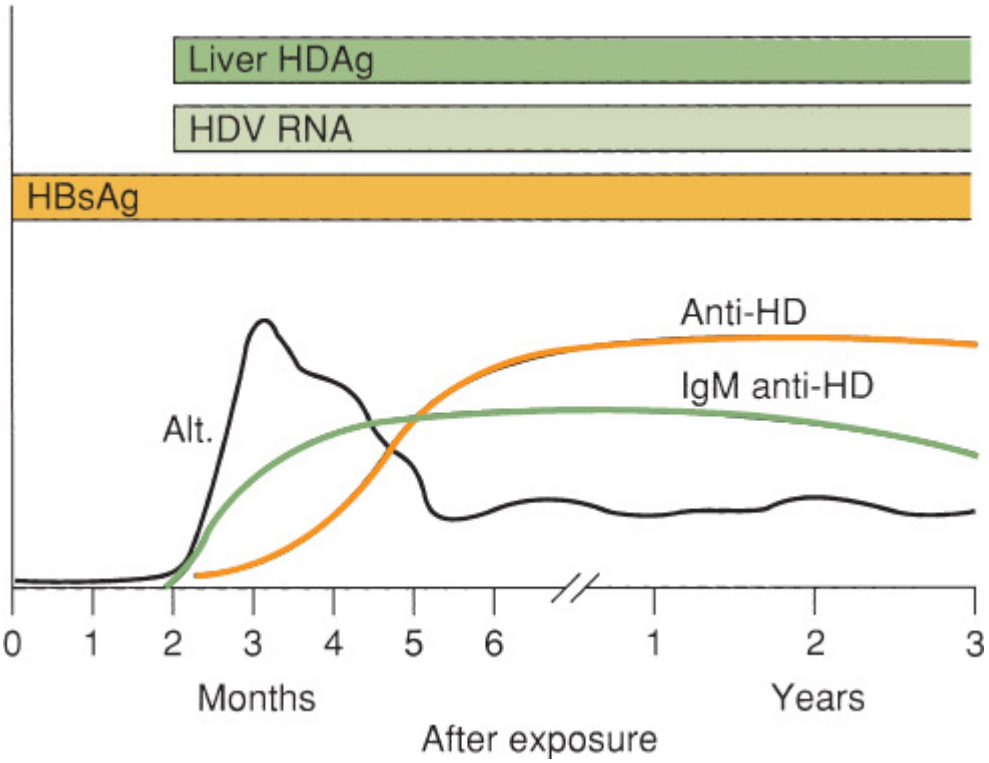

Figure 58.10 Clinical course of chronic hepatitis D infection.

Clinical Features

Most patients remain asymptomatic or develop mild symptoms such as jaundice, malaise, nausea, vomiting, and abdominal pain. The incubation period ranges from 15 to 60 days. In addition, several extrahepatic manifestations have been described including thyroiditis, hematologic anomalies, and neurologic diseases. Common biochemical findings are transaminitis and hyperbilirubinemia with resolution occurring 1 to 6 weeks following onset of the disease. While the disease is generally self-limiting, 0.5% to 4% of infected individuals may progress to fulminant hepatic failure, more likely affecting pregnant women, malnourished patients and those with underlying liver disease.[28]

Treatment

Management of hepatitis E virus (HEV) is mainly supportive, particularly in the acute phase. The disease may persist in immunocompromised patients (transplant recipients) and a 12-week course of antiviral therapy (ribavirin) can be considered. General precautions should be taken when travelling to endemic regions. A vaccine has been developed with a 96% protective efficacy over 12 months, however, this is not widely available.[29]

Cytomegalovirus

Cytomegalovirus (CMV) is a generally asymptomatic disease causing mild nonspecific symptoms in immunocompetent persons. Transmission can occur through close and/or sexual contact, blood exposure, and infected transplanted organs. Hepatic manifestations include mild hepatitis presenting as subclinical transaminitis in infected hosts, and may progress to ALF in immunosuppressed persons. Viral seroprevalence ranges from 30% to 100% and is dependent on age and ethnicity.[30] Infection is lifelong due to the latency of the virus and can be detected in up to 70% of individuals in U.S. cities. The diagnosis is confirmed by the identification of CMV-specific antibodies in serum samples. However, one limitation of this diagnostic technique is that IgM-specific CMV antibodies may be present for up to 6 months making it difficult to distinguish current infection from prior exposure. In addition, CMV antigenemia and PCR to detect CMV DNA have made diagnosis rapid. Histopathologic analysis with a liver biopsy may be necessary to further establish hepatitis.

Treatment is based on clinical course and viral load. The clinical effectiveness of antiviral therapies in immunocompetent persons is unclear and the disease is largely self-limiting. First-line treatment with ganciclovir or valganciclovir should be considered in immunocompromised persons. Treatment should be administered for a minimum 2 to 3 weeks or 2 to 3 months in high-risk patients.[30]

Epstein–Barr Virus

Epstein–Barr virus (EBV) is largely known as an important agent in infectious mononucleosis, but most infections are asymptomatic. The disease is spread through close contact and global seroprevalence rates are over

90%.[31] Deranged liver function tests are not uncommon and are generally self-resolving. In rare instances acute symptomatic hepatitis occurs as a sequelae of infectious mononucleosis. The presence of jaundice may reflect either more severe hepatitis or an associated hemolytic anemia and is present in less than 5% of infected persons.[32] Leukocytosis is usually present, with the presence of atypical lymphocytes being a hallmark. Detection of heterophile antibodies, or the "monospot test" is highly specific but can be negative during the first week of clinical illness. This can be repeated at a later date; however, if the test remains negative, the diagnosis can be further investigated through EBV-specific antibody testing. Treatment is largely supportive to alleviate symptoms. Acyclovir has been considered in the past, however the clinical benefit has not been conclusively established and is not generally recommended.[33]

Herpes Simplex Virus

Acute hepatitis is a rare complication of herpes simplex virus (HSV) infection, although both HSV-1 and HSV-2 have been described as causative agents. Hepatic involvement commonly occurs in immunocompromised patients, neonates, pregnant women, and patients taking steroids. The prevalence of antibodies to HSV-1 is around 75% in most populations and around 20% to HSV-2. Clinical manifestations include high fever, anorexia with nausea, abdominal pain, leucopenia, and coagulopathy.[34] Mortality rates over 70% have been described when the condition occurs and male gender, age over 40 years, coagulopathy, encephalopathy, and the absence of viral treatment are considered increased risks.[35] The diagnosis can be confirmed on histopathology demonstrating diffuse eosinophilic intranuclear inclusion bodies, multinucleated cells, widespread necrosis, and inflammation. Treatment with intravenous acyclovir should be initiated prior to confirmation of etiology given that progression of disease is extremely rapid and lethal.

Varicella Zoster Virus

Varicella zoster virus (VZV) infection is common and frequently presents as primary varicella in children. Hepatitis secondary to VZV infection is rare

but can be deadly, especially in immunocompromised individuals. In these individuals, clinical manifestations include fever, abdominal pain, and rash.[35] Fulminant liver failure may ensue. Reye syndrome may also develop from VZV infection in children leading to progressive encephalopathy and hepatic dysfunction. The diagnosis of VZV hepatitis can be distinguished from other diagnoses and confirmed on a liver biopsy. Disseminated VZV requires prompt treatment with antiviral medication usually in the form of acyclovir to decrease the high mortality rate. Varicella zoster immune globin should also be considered after exposure to the virus in immunocompromised or pregnant patients who lack immunity to VZV combined with strict contact precautions.

ACUTE LIVER FAILURE

Definition

2 ALF is a generally uncommon condition consisting of a rapid deterioration in liver function in the form of coagulopathy (INR >1.5) and hepatic encephalopathy in the absence of pre-existing liver disease. Incidence is low and the condition affects approximately 2,000 individuals in the United States per annum, but can be fatal if untreated. In 2012, a systematic review identified 41 different definitions for ALF, with onset of liver disease and interval between hepatic encephalopathy a largely differentiating factor.[36] Three specific time frames are applied to categorize and distinguish the different forms of ALF; hyperacute (<7 days), acute (7 to 21 days), or subacute (21 days to 26 weeks). The European Association for the Study of the Liver (EASL) characterizes disease duration beyond 28 weeks and before the onset of encephalopathy as chronic liver disease.[37] The most recent definition in hepatic failure nomenclature is “acute-on-chronic” liver failure which is characterized by an acute deterioration in liver function in patients with underlying chronic liver disease.[38,39]

Diagnosis

ALF can be diagnosed and confirmed using a variety of mediums. Following a thorough history and examination assessing for various stigmata of disease, initial testing includes serum liver function tests. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) are released when hepatocytes are damaged or killed. ALP is released when the biliary epithelium is injured such as in instances of biliary obstruction or cholangitis. γ-Glutamyltransferase is expressed by both hepatocytes and biliary epithelium and can be elevated in all conditions impacting liver function (**Table 58.2**).[40] A series of standard tests are considered in every patient and when the diagnosis still remains unclear, a liver biopsy is performed provided there are no absolute contraindications.

Table 58.2 Management in Acute Liver Failure: Initial Laboratory Evaluations
Serum chemistries Sodium, potassium, chloride, bicarbonate, calcium, magnesium, phosphate, glucose, BUN, creatinine, amylase, lipase
Hepatic panel AST, ALT, alkaline phosphatase, total bilirubin, albumin
Prothrombin time/INR
Complete blood count
Arterial blood gas, lactate, ammonia
Toxicology screen
Viral hepatitis serologies Anti-HAV IgM, Hep B surface Ag, Anti-HBV core IgM, anti-HCV, anti-HEV IgM (if indicated)
Anti-VZV IgM, Anti-HSV IgM
Autoimmune markers ANA, ASMA, IgG levels, SPEP
Pregnancy test
Serum ceruloplasmin level and 24-hr urine copper collection (if Wilson disease is suspected)

Ag, antigen; ALT, alanine aminotransferase; ANA, antinuclear antibody; ASMA, anti–smooth muscle antibody; AST, aspartate aminotransferase; BUN, blood urea nitrogen; HAV, hepatitis A virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HEV, hepatitis E virus; HSV, herpes simplex virus; IgM, immunoglobulin M; INR, international normalized ratio; SPEP, serum protein electrophoresis; VZV, varicella zoster virus.

Etiology

3 The cause of liver failure influences the management approach and prognosis and for this reason ever effort is made to establish the correct underlying cause. ALF can arise from a variety of causes. 4 In the United

States, United Kingdom, and Australia, acetaminophen overdose is the most common cause, accounting for 45.7% to 65.4% of all cases. In Asia, viral hepatitis contributes to the majority of cases.[41] The cause is unclear in 15% of patients.

Drug-Induced Liver Injury

Acetaminophen hepatotoxicity occurs in a dose-dependent manner which can occur following consumption of a single dose or staggered over multiple time points.[42] The former is more commonly seen in suicide attempts rather than instances of therapeutic misadventure.[43] ALF more commonly develops in malnourished patients, a history of alcoholism, or in late presenting cases.[42] Full hepatic recovery is seen in 93% of patients and patients are less likely to proceed to poor outcomes than in instances of non–paracetamol-related hepatic failure.[44]

In contrast to the dose-dependent interactions of acetaminophen, idiosyncratic drug reactions are dose independent and generally occur within 6 months of drug treatment.[45] Stevens–Johnson syndrome caused by phenytoin, amoxicillin-clavulanate, carbamazepine, or halothane is a form of hypersensitivity idiosyncratic responses, while isoniazid, valproate, and amiodarone mainly cause metabolic idiosyncratic reactions.

Viral Hepatitis

Hepatitis A virus infection is generally mild accounting for less than 3% of ALF cases. Up to 70% of cases recover completely with little to no intervention and a better overall outcome is seen than in other causes of viral hepatitis.[46,47] HBV accounts for 8% of all cases of ALF in Europe and the United States.[43] The majority of cases of hepatitis B are caused by new infection while the remaining cases of ALF may develop following reactivation of previously in active disease.[43,48] Hepatitis C does not confer a significant risk of ALF in the absence of hepatitis B coinfection.[49] Similarly, HDV infection can lead to ALF in the setting of concurrent hepatitis B coinfection or pre-existing chronic hepatitis B infection.[50,51] HEV is a worldwide infection and can cause fulminant hepatic failure in specific high-risk groups.[52] Hepatitis E infection accounts for 20% to 40% of ALF

cases in developing countries but is a rare case in Western societies.[53,54] VZV, HSV, and CMV are other rare viral causes (see previous sections).

Other

Other causes of ALF include heat stroke, pregnancy-related injuries (HELLP), metabolic/autoimmune diseases, and hepatic ischemia.[42,43]

Clinical Features, Management, and Treatment

The initial symptoms of ALF are generally nonspecific and may include right upper quadrant pain, nausea, malaise, fatigue, and vomiting.[55] Encephalopathy is one of the hallmarks of ALF and is graded from I to IV (**Table 58.3**). Cerebral edema accompanies 25% to 35% of patients with grade III and 75% of patients with grade IV.[56] Altered mental status in the form of lethargy, confusion, or disturbed sleep may eventually progress to a coma. As liver failure worsens, so does jaundice, transaminase and prothrombin time elevations, and thrombocytopenia. Acute kidney injury occurs in approximately 30% to 70% of patients.[57] Other common electrolyte derangements are hypophosphatemia, hypokalemia, hypomagnesemia, and hypoglycemia.

General management of patients should be in specialist units with liver transplantation services. Up to 40% of patients recover spontaneously. Serial laboratory tests are essential to monitor the patient's clinical course and for the development of any complications. Hemodynamic stability needs to be accurately followed and deviations need prompt responses. Intravascular volume depletion and a low systemic vascular resistance are likely the result of decreased oral intake and fluid extravasation. Hypotension can usually resolve with normal saline and in cases of acidosis, half-normal saline can be considered.[43] In cases of hypoglycemia, dextrose can be added to carefully titrated fluid regimens, avoiding the risk of overhydration that may worse cerebral edema. Mean arterial pressure should be maintained at least 75 mm Hg and if this is not achievable with sole fluid management; norepinephrine with or without vasopressin can be used.[58]

Acetaminophen toxicity can be treated with the administration of N-acetylcysteine, which may also be beneficial in other causes of ALF.[59] Patients with grade III or IV encephalopathy are at a high risk for developing cerebral edema and intracranial pressure monitoring could be utilized to guide treatment. Elevating the head of the bed and prophylactic hypertonic saline should be considered in high-risk patients. In cases of elevated intracranial pressure, mannitol therapy is typically first-line treatment to maintain intracranial pressures below 20 to 25 mm Hg and cerebral perfusion pressures above 50 to 60 mm Hg.[60] Hyperventilation can be considered in patients, although the clinical benefits are transient. It may, however, be effective in patients with impending herniation. Coagulopathy should be monitored and patients should receive stress ulcer prophylaxis to reduce potential gastrointestinal bleeding.

Table 58.3 Stages of Hepatic Encephalopathy

Stage	Clinical Signs
I	Mild confusion, slurred speech, disordered sleep
II	Moderate confusion, lethargy, disorientation
III	Marked confusion, sleeping but arousable, slurred speech
IV	Coma

Table 58.4 King's College Criteria of Poor Prognostic Indicators

Acetaminophen-induced ALF: Arterial pH <7.3 irrespective of coma grade *OR all of the following:* INR >6.5, creatinine >3.4 mg/dL (300 µmol/L), grade III/IV encephalopathy
Non–acetaminophen-induced ALF: INR >6.5 *OR any three of the following:* Age <10 or >40, drug toxicity or undetermined etiology, jaundice >7 days before encephalopathy, INR >3.5, bilirubin >17 mg/dL (300 µmol/L)

ALF, acute liver failure; INR, international normalized ratio.

Liver Transplantation

5 Liver transplantation is the only definitive cure in the setting of irreversible liver failure. Identifying which patients are likely to benefit from liver transplantation and which are likely to spontaneously recover is an important and challenging step. Spontaneous recovery depends on several factors including patient age, degree of encephalopathy, and disease etiology. The King's College criteria are an effective tool applied to determine prognosis in acetaminophen-induced fulminant hepatic failure and is used to predict survival outcomes for alternative etiologies and as an adjunct to prediction tools when proposing candidacy for liver transplantation.[59] Positive predictive values for acetaminophen and non–acetaminophen-induced ALF are 84% and 98%, respectively. Negative predictive values are 86% and 82% for acetaminophen and non–acetaminophen-induced ALF (**Table 58.4**).[61] The model for end-stage liver disease (MELD) system is another validated scoring system commonly used for chronic liver disease severity scoring. In terms of ALF, the King's College criteria appear more specific while the MELD score is more sensitive in predicting mortality. MELD scores greater than 30.5 predict a need for transplantation.[62]

Life Support Systems

Artificial liver support systems have been proposed in an effort to delay or preclude the need for transplantation. The two major categories are biologic and nonbiologic support systems. The mostly commonly investigated systems are the molecular adsorbents recirculating system (MARS) and the Prometheus system. Both systems are based on the removal of albumin-bound toxins. Results in ALF have been variable, and the devices are not widely available outside of clinical trials.

Similarly, bioartificial systems have yet to break into routine clinical practice. In this setting, a patient's blood is perfused through a bioreactor of human or porcine hepatocytes and undergoes detoxification.[63] While these emerging technologies have given some hope and promise to the transplant community, they are still mainly utilized in an experimental setting and liver transplantation remains the only curative option for ALF.

Prognosis

Overall survival rates for ALF are greater than 60% and up to 55% can survive without transplantation.[64] Hepatic encephalopathy development and progression is a key prognostic indicator. However, prognosis can vary between etiologic agents and appears more favorable in acetaminophen-associated toxicity than alternative causes. Mortality also increases with the occurrence of cerebral edema, renal failure, coagulopathy, infection, and mechanical ventilation. Additional indicators of poor prognosis have been further developed in King's College in London to include the presence of three of the following: age less than 11 and greater than 40 years, jaundice present longer than 1 week before encephalopathy occurrence, serum bilirubin greater than 300 μmol/L, prothrombin time greater than 50 seconds, fulminant hepatitis secondary to non–A, B, or C virus, idiosyncratic drug reactions, and halothothane hepatitis.[65]

QUIZ

1. Which of the following is the most accurate regarding the presentation of patients with liver abscesses?

a. Fever is the most common feature of pyogenic liver abscesses caused by bacterial infections.
b. Blood cultures are positive in over 95% of patients.
c. Abdominal ultrasound is rarely diagnostic and always requires an additional radiologic modality to support the diagnosis.
d. Multiple hepatic abscesses is a typical feature of candida infection.

2. The King's College Criteria require the presence of an INR > 6.5 or at least three other variables prior to determining patient candidacy for liver transplantation in nonacetaminophen causes of ALF. Which of the following is not a recognized requirement?

a. Duration of jaundice before onset of encephalopathy >7 days
b. Drug toxicity or undetermined etiology
c. Bilirubin >17 mg/dL (300 µmol/L)
d. Age <10 or >40
e. Hyponatremia

3. Which of the following viruses is likely to proceed to chronic hepatic failure?

a. EBV
b. Hepatitis B
c. Hepatitis C
d. Hepatitis D
e. VZV

Cirrhosis and Portal Hypertension

Russell N. Wesson and Andrew M. Cameron

Key Points

1 Chronic injury and inflammation due to ongoing oxidative stress is a common pathway leading to cirrhosis, regardless of etiology. Removal of the inciting agent can stop progression of disease.

2 Acetaldehyde mediates injury in alcohol-induced liver disease.

3 Nonalcoholic fatty liver disease (NAFLD) or nonalcoholic steatohepatitis (NASH) is associated with obesity, hyperlipidemia, and non–insulin-dependent diabetes. It is increasing in incidence and results in a spectrum of change from fatty infiltration to inflammation and cirrhosis.

4 Viral hepatitis is the most common cause of cirrhosis worldwide, accounting for at least 50% of cases. All genotypes of Hepatitis C can now be cured with direct-acting antivirals (DAAs). Hepatitis B is treatable with antivirals.

5 Budd–Chiari syndrome (BCS) is a rare disease characterized by obstruction of the hepatic veins by webs or membranes (most commonly in Asia and Africa) or thrombosis secondary to hypercoagulable states and neoplasms (most commonly in the West).

6 Hepatorenal syndrome (HRS) is a complication of cirrhosis, usually associated with ascites, characterized by progressive renal failure in the absence of intrinsic renal disease.

7 Hepatic encephalopathy is a neuropsychiatric syndrome occurring in the setting of liver disease. It is characterized by variable clinical manifestations ranging from subtle personality changes and sleep pattern derangement to confusion, lethargy, and coma.

8 Portal hypertension is defined as a portal pressure elevated above the normal range of 5 to 8 mm Hg. It is an important complication of cirrhosis (hepatic) and can also occur after portal vein thrombosis (prehepatic), or hepatic venous obstruction (posthepatic). Portal hypertension is responsible for the development of gastroesophageal varices and bleeding.

9 Important scoring systems include the Child–Turcotte–Pugh score which incorporates clinical and laboratory data as a means to assess

the functional status of the liver, estimate hepatic reserve, and predict morbidity and mortality of liver disease. The model for end-stage liver disease-sodium (MELD-Na) score is a highly reliable prognostic marker for cirrhosis, is calculated from standard laboratory tests, and has replaced the Child–Turcotte–Pugh score in liver transplant candidate stratification.

10 Transjugular intrahepatic portosystemic shunt (TIPS) has become first-line therapy for refractory or recurrent bleeding esophageal varices.

11 Surgical interventions for the treatment of variceal bleeding include liver transplantation, shunt procedures, and rarely performed devascularization procedures. Liver transplantation is the definitive treatment for decompensated cirrhosis.

12 Spontaneous bacterial peritonitis (SBP) is a potentially lethal infectious complication of cirrhosis with ascites. It occurs in up to 10% of patients.

CIRRHOSIS

Background and Definition

Cirrhosis is a chronic condition with a high mortality. It constitutes the fifth leading cause of adult deaths and ranks eighth in economic cost among the major illnesses in the United States.[1] A majority of adults with cirrhosis are unaware they have liver disease.

Described in the Greek myth of Prometheus, the ability of the liver to regenerate is legendary. The development of cirrhosis marks the beginning of a disease characterized by a dramatic decrease in the ability of the liver to function effectively and to recover from insults. Cirrhosis is the pathologic end result of repeated, chronic insults to the liver with subsequent repair. This continued cycle causes deranged hepatic architecture defined histologically by marked fibrosis, destruction of vascular and biliary elements with regeneration, and nodule formation (**Fig. 59.1**). It results in a

scarred, distorted nodular cirrhotic liver. Consequences include diminished hepatic function and reserve, portal hypertension, and complications of portal hypertension (**Table 59.1**). Portal hypertension can be prehepatic, intrahepatic, or posthepatic in origin. Importantly, the chronic, ongoing inflammation resulting in cirrhosis is carcinogenic, and hepatocellular carcinoma (HCC) may arise in livers affected by cirrhosis. HCC may occur in the absence of cirrhosis. The complications and causes of cirrhosis may be managed medically or via interventional radiologic techniques, and this may halt progression, improve quality of life, and increase survival. Liver transplantation, however, is the only definitive cure for decompensated cirrhosis at the current time.

1 Pathophysiology

Cirrhosis is caused by a range of pathologic entities. These include viral hepatitis, alcohol, metabolic disorders, drug toxicity, and biliary obstruction, among others (**Table 59.2**). These lead to injury, hepatocyte death, chronic inflammation, fibrosis, and subsequent loss of architectural integrity. The normal regenerative capacity of the liver is overcome, and there is resulting structural distortion. Cellular and molecular mechanisms underlying this shift from physiologic recovery to pathologic distortion after healing continue to be studied, and pathways of hepatic fibrogenesis and cirrhosis remain a central area of investigation in liver biology.[2,3] Significant progress in our understanding of the evolution of liver fibrosis, which ends with cirrhosis, has been gained in recent years.

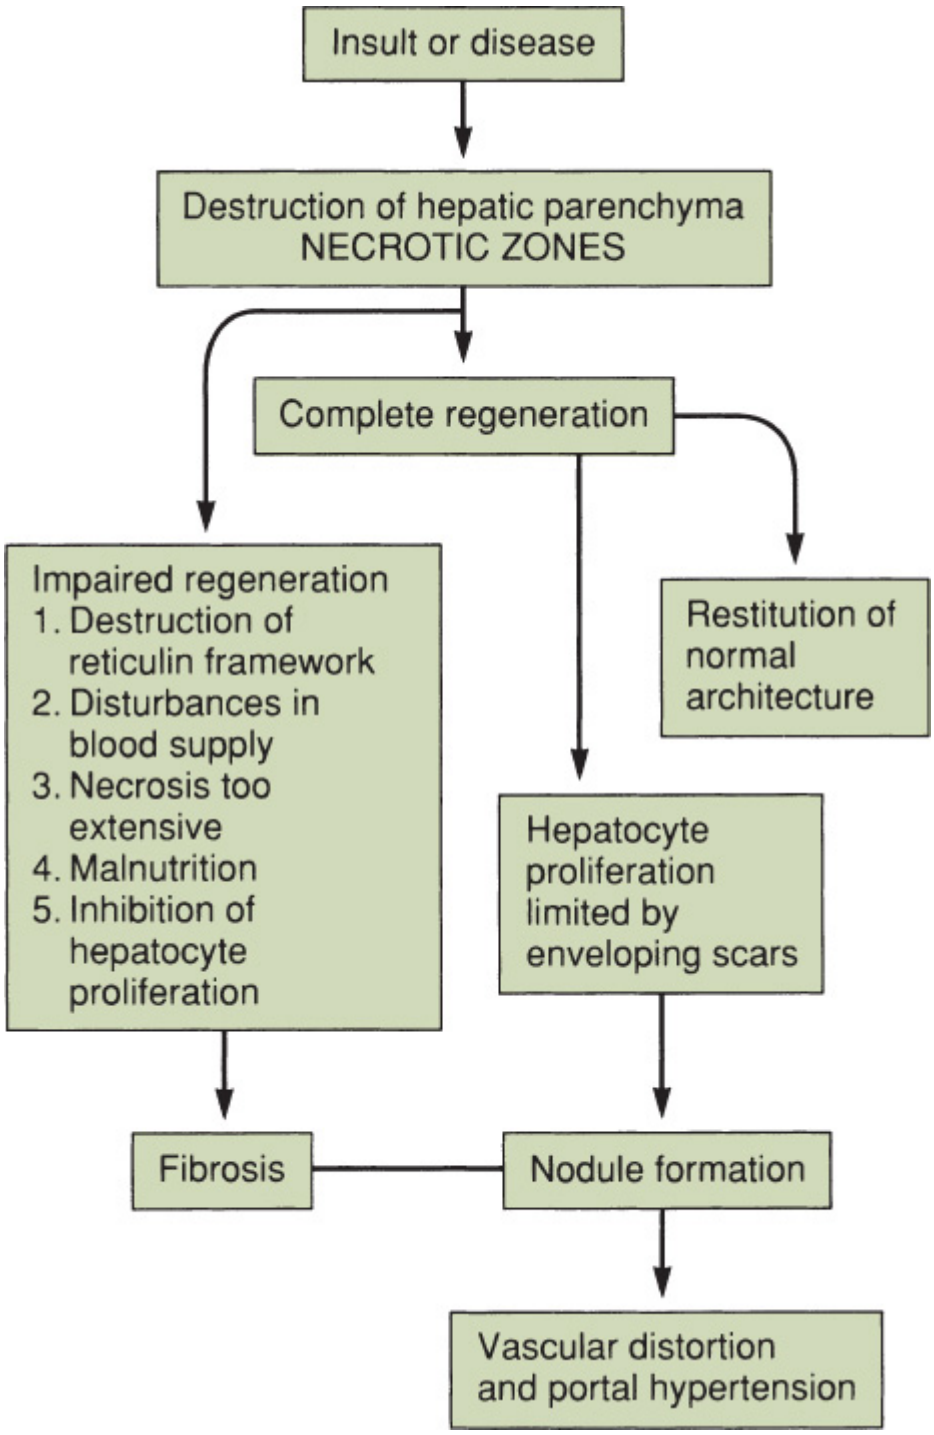

Figure 59.1 Evolution of cirrhosis. Fibrosis develops in nonregenerative necrotic areas, producing scars. The pattern of nodularity and scars reflects the type of response to injury (e.g., uniform vs. nonuniform necrosis) and the extent of injury.

Oxidative stress and chronic inflammation appear to be the final common pathway in the development of fibrosis and cirrhosis. Fibrosis is a wound

healing response in which damaged regions of liver are encapsulated by an extracellular matrix or scar. In chronic liver injury, it develops at variable rates depending in part upon the cause of liver disease and host factors. Fibrosis develops in regions where injury is most severe. For example, pericentral injury (perivenular fibrosis) is a hallmark of alcoholic hepatitis and will progress to panlobular cirrhosis if injury is ongoing.[4] As the liver becomes fibrotic, significant qualitative and quantitative changes occur in the extracellular matrix.[5] A low-density matrix is replaced by a high-density interstitial type matrix with consequences for the function of hepatocytes, hepatic stellate cells (HSCs), and endothelial cells. The high-density matrix activates HSCs leading to loss of hepatocyte microvilli and disappearance of endothelial fenestrations impairing solute transport from sinusoid to hepatocyte.[6]

Table 59.1 Major Complications of Cirrhosis

Portal hypertension and variceal hemorrhage
Ascites and volume overload
Spontaneous bacterial peritonitis
Hepatic encephalopathy
Hepatocellular carcinoma
Hepatorenal syndrome
Hepatopulmonary syndrome

Table 59.2 Causes of Cirrhosis

Most Common Causes (Developed Countries)
Alcohol
Chronic viral hepatitis (hepatitis B and C)
Hemochromatosis
Nonalcoholic fatty liver disease
Less Common Causes
Primary and secondary biliary cirrhosis
Primary sclerosing cholangitis
Veno-occlusive disease
Wilson's disease
Autoimmune hepatitis
Infection (brucellosis, syphilis, echinococcosis)
Drugs and toxins (e.g., methotrexate, isoniazid)
α_1-Antitrypsin deficiency
Cystic fibrosis
Glycogen storage disease
Other metabolic diseases
Sarcoidosis
Copper
Small-bowel bypass
Right-sided heart failure
Hereditary hemorrhagic telangiectasia
Idiopathic

HSCs (previously called the lipocytes, Ito, fat-storing, or perisinusoidal cells) play a central role in fibrogenesis and development of cirrhosis. Activation of HSCs occurs with ongoing inflammation, hepatocyte stress, and death (either via apoptosis or necrosis). These cells are located in the space of Disse between hepatocytes and sinusoidal endothelial cells (**Fig. 59.2**).[7] HSCs, which are normally quiescent and store vitamin A, appear to be the key mediator in the development of fibrosis and are the primary source of

extracellular matrix both in the normal and fibrotic liver.[8] Activated HSCs increase expression of "fibril-forming" collagen types I, III, and V[9] as well as heparan, dermatan, chondroitin sulfate,[10] laminin,[11] and fibronectin.[12]

A number of different stimuli result in initiation and perpetuation of the activation of HSCs. Paracrine stimulation by all neighboring cell types, including sinusoidal endothelium, Kupffer cells, hepatocytes, and platelets initiate activation. Mediators include transforming growth factor beta-1 (TGF-β1), platelet-derived growth factor (PDGF), and epidermal growth factor (EGF).[13] Apoptotic bodies (derived from hepatocytes) play a major role in the activation of HSCs and Kupffer cells.[14] Reactive oxygen species (ROS) are important in activating HSCs and are generated through lipid peroxidation of hepatocytes, macrophages, HSCs, and other cells.[15,16] In alcoholic and nonalcoholic steatohepatitis (NASH), ROS generation in hepatocytes results from induction of cytochrome P450 2E1, leading to pericentral, zone 3 injury.[17,18]

Activation of HSCs leads to further elaboration of proinflammatory and profibrogenic cytokines TGF-β1 and PDGF, creating a self-sustaining cycle.[13,14,19–22] TGF-β1 is derived from both paracrine and autocrine sources and remains the classic fibrogenic cytokine, with downstream signaling converging on Smad proteins resulting in HSC activation.[23,24] Activation of HSCs continues to be explored with roles for toll-like receptors (TLR4) being discovered, direct effects of hepatitis C on HSCs, and effects of hepatitis B on immune cells contributing to HSC activation. Ultimately, degradation and remodeling of the extracellular matrix by matrix metalloproteinases produced by HSCs as well as Kupffer cells occurs.[25,26] Importantly, regression of fibrosis can occur under the influence of certain macrophage subsets as well as dendritic cells. An increasing understanding of the role of inflammatory and immunomodulatory cells in liver disease may have led the way to new therapies in the future.[27–31]

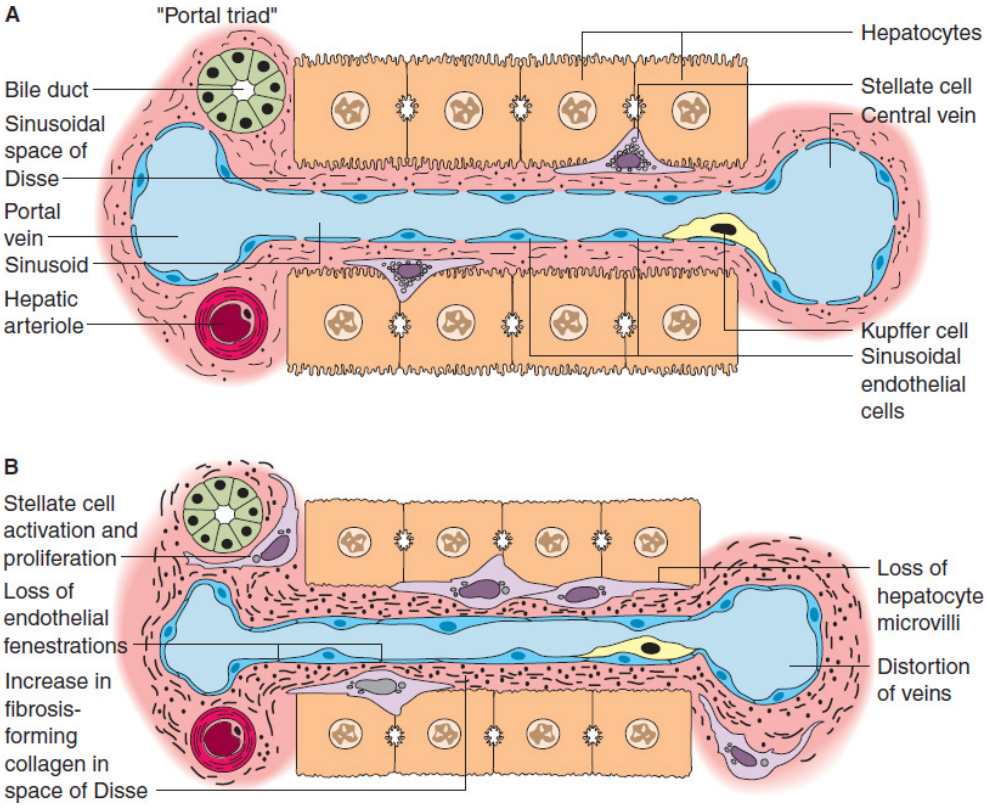

Figure 59.2 Matrix and cellular alterations in hepatic fibrosis. **A:** In normal liver, a modest amount of low-density matrix is present in the subendothelial space of Disse. **B:** In the fibrotic liver, the accumulation of fibril-forming matrix in this region leads to "capillarization" of the sinusoid and functional changes in all neighboring cell types.

Ultimately fibrosis causes architectural and functional disruption of the hepatic acinus. Collagen deposition and extracellular matrix synthesis leads to thickening of the space of Disse. "Capillarization" develops with loss of the fenestrated architecture of the sinusoidal endothelium.[32] This loss of fenestration may be an essential component of hepatocellular dysfunction in cirrhosis, preventing the normal flow of nutrients to hepatocytes and increasing vascular resistance.[33] In addition, endothelial and stellate cells produce endothelin-1, a potent vasoconstrictor, which causes contraction of the myofilaments within HSCs, influencing blood flow to injured areas and contributing to portal hypertension.[34] Fibrosis is reversible early if the inciting agents are removed. Sustained injury leads to irreversibility and progress to cirrhosis.

Treatment of Fibrosis

The point at which fibrosis becomes inexorable is unknown. Dense cirrhosis with nodule formation, portal hypertension, and early liver failure is irreversible, but less-advanced lesions can improve if injury is removed or possibly with therapy. In studies of hepatitis B, hepatitis C, and NASH, up to 70% of patients had reversal of early cirrhosis and fibrosis following successful antiviral therapies, and improvements in NASH and fibrosis after bariatric surgery.[35–37] Growing attention has been given to approaches that might disconnect hepatic injury from the inexorable path of fibrosis.[41] Targeting HSCs and mediators of fibrogenesis may complement therapies that treat the inciting factors of liver injury. **Removal of injurious stimuli** is most effective when initiated early. Examples include the removal of excess iron or copper in hemochromatosis or Wilson's disease, respectively. The potential success of treatment of HBV with **adefovir or entecavir**, treatment of delta hepatitis with interferon therapy, and the success of **direct-acting antiviral** (DAA) therapy against HCV are additional examples.

Suppression of hepatic inflammation has a role to play in some settings and is an active area of investigation. **Corticosteroids** are useful in many inflammatory liver diseases, in particular against autoimmune hepatitis. Duration of use is limited by the extensive side effects associated with prolonged use. **Ursodeoxycholic** acid has clear efficacy in primary biliary cirrhosis.[38,39]

Immune modulation, use of hepatoprotectants (such as hepatocyte growth factor), and the use of farnesoid X receptor ligands hold promise for future investigation. Bile acids such as obeticholic acid and chenodeoxycholic acid act as ligands to farnesoid X receptor. This nuclear receptor transcription factor downregulates HSC activation and contractility and may have other hepatoprotective effects. Cannabinoids and the cannabinoid receptors CB1 and CB2 are involved in fibrogenesis and have emerged as an attractive pathway for antagonizing hepatic fibrosis.

Among the most promising agents currently receiving the greatest attention in the treatment of fibrosis are the antioxidants.[14] A large randomized controlled trial (RCT) studied vitamin E as a therapy to suppress fibrogenesis. It showed benefit in reducing inflammation in adults, but not children.[40,41] N-acetylcysteine, metformin, and silymarin (a natural component of milk thistle that belongs to a group of flavonoid compounds) have been explored without clear evidence of clinical efficacy. Interruption

of the renin–angiotensin system using angiotensin-converting enzyme inhibitors or angiotensin II receptor antagonists, interference with TGF-beta signaling, and antagonism of endothelin receptors hold promise for decreasing fibrogenesis, but require further investigation.

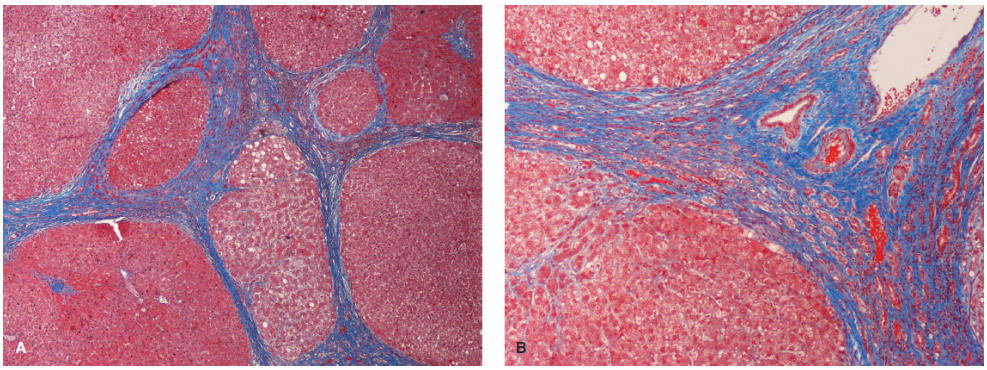

Figure 59.3 Photomicrographs A of cirrhotic liver tissue, showing irregular nodules of regenerating hepatocytes surrounded by dense fibrosis. **A:** Trichrome stain 2× magnification. **B:** Higher magnification (10×) showing portal triad surrounded by fibrosis. Etiology

Historically, cirrhosis has been divided into micronodular, macronodular, and mixed patterns. However, this World Health Organization (WHO) classification (created in 1977) has little utility in terms of defining etiology due to its low specificity (**Fig. 59.3**).

Alcohol

2 Alcohol abuse is common worldwide, with an estimated prevalence of 18% among adults in the United States. Excessive alcohol intake is associated with a range of liver disease, from fatty liver disease, alcoholic steatohepatitis, and ultimately cirrhosis and HCC. Cirrhosis due to alcohol is the second leading indication for liver transplantation overall, accounting for 19% of all liver transplants in Europe and 30% in the United States.[42,43] Once hepatic decompensation develops, the expected 5-year transplant-free survival rate is 60% for those who stop drinking alcohol and 30% if drinking continues.

Cirrhosis develops in 10% to 30% of heavy drinkers.[44] Consumption of at least 30 g of alcohol per day in women and 50 g of alcohol per day in men over at least 5 years is considered to the minimum threshold alcohol intake for cirrhosis to develop.[45] Why cirrhosis develops in some heavy drinkers but not others is unclear. Genetic predisposition, nutritional effects, concomitant drug use, and viral infection likely interact with alcohol abuse to result in cirrhosis. Advanced disease carries a poor prognosis: more than half of alcoholics with cirrhosis and two-thirds of patients with alcoholic hepatitis and cirrhosis die within 4 years of diagnosis.[46]

Histologic findings: Classically micronodular cirrhosis, the histology of alcoholic liver disease typically begins with the appearance of macrosteatosis of fatty liver disease. This progresses to alcoholic steatohepatitis when inflammation (neutrophil infiltration, generally in association with an elevated peripheral neutrophil count) and necrosis is present. Megamitochondria and Mallory–Denk bodies (eosinophilic accumulations of intermediate filaments with cytokeratin proteins, previously termed Mallory hyaline or Mallory bodies) are also characteristic. As disease duration and toxin exposure progress, fibrosis appears and progresses with architectural distortion occurring.

Alcoholic liver disease has long been known to be associated with consequences of oxidative stress in the liver with failure of homeostatic mechanisms.[47] The toxicity of alcohol is mediated through its metabolic product, acetaldehyde. Alcohol dehydrogenases are isoenzymes that catalyze the oxidation of alcohol (ethanol) to acetaldehyde. ALDH are located predominantly within the cytoplasm of hepatocytes. The microsomal ethanol oxidizing system (MEOS) cytochrome P450 2E1 (CYP2E1) is also responsible for approximately 10% of ethanol oxidation to acetaldehyde. Although alcohol may directly activate HSCs, the key mediator in alcohol-induced liver disease is acetaldehyde. CYP2E1 is largely in the perivenular/centrilobular zone 3 of the hepatic acinus. Zone 3 is also an area of relative hypoxia due of its distance from portal venous and hepatic arterial inflow, and levels of antioxidants such as glutathione are lowest in this zone. Activity of aldehyde dehydrogenases is also lower in zone 3. These factors contribute to the characteristic perivenular location of injury and histologic changes present in alcohol-induced liver disease.

Mechanisms of injury of acetaldehyde include the peroxidation of lipids in cell membrane. Macrosteatosis and the characteristic "ballooning degeneration" of alcohol-induced liver disease results. Acetaldehyde also increases the permeability of the intestinal barrier,[48,49] allowing delivery of bacterial endotoxin (LPS) to the liver. Kupffer cells activation by LPS via TLR4 may set off the inflammatory cascade responsible for the development of alcoholic liver disease.[50] The pathogenesis of alcoholic liver disease continues to be investigated, with roles for tumor necrosis factor-alpha (TNF-α), cyclo-oxygenase 2, dietary fat, oxidative stress, development of antigenic adducts (acetaldehyde binding to proteins creating antigenic adducts) among others being explored. Ultimately, continued alcohol-induced injury results in progression of fibrosis to cirrhosis.

Nonalcoholic Fatty Liver Disease/Nonalcoholic Steatohepatitis

3 Obesity and metabolic syndrome may produce hepatic injury and may potentiate the effects of viral injury.[51,52] Nonalcoholic fatty liver disease (NAFLD) describes the presence of hepatic steatosis (**Fig. 59.4**) when no other causes for secondary hepatic fat accumulation (e.g., heavy alcohol consumption) are present. NAFLD may progress to NASH and then fibrosis. Up to 20% of patients with NASH may progress to cirrhosis. This disease is now a major health problem in Westernized populations and in particular in the United States.[53] NAFLD is now the most common cause of chronic liver disease in the United States, affecting up to 30% to 46% of the population.[53–55] It is expected to surpass viral hepatitis as the leading indication for liver transplantation by 2025.[56] Initially, the liver becomes infiltrated with fat, with subsequent inflammatory infiltrate. Pathologic features are shared with alcohol-induced liver injury (**Fig. 59.5A,B**). NAFLD is associated with obesity, the metabolic syndrome, hyperlipidemia, cardiovascular disease, and noninsulin-dependent diabetes. Ninety percent of NAFLD patients have at least one of these risk factors and 30% have three or more.[57] Most patients traditionally diagnosed with cryptogenic cirrhosis in fact have NAFLD.[58] NAFLD is major risk factor for primary liver cancer (HCC) and in addition to hepatitis virus infection, accounts for the rapid rise in the incidence of HCC in Western countries.[59] More broadly considered, obesity is a major

risk factor for cancer deaths with a 4.5-fold increase of the relative risk for liver cancer in obese subjects.[60]

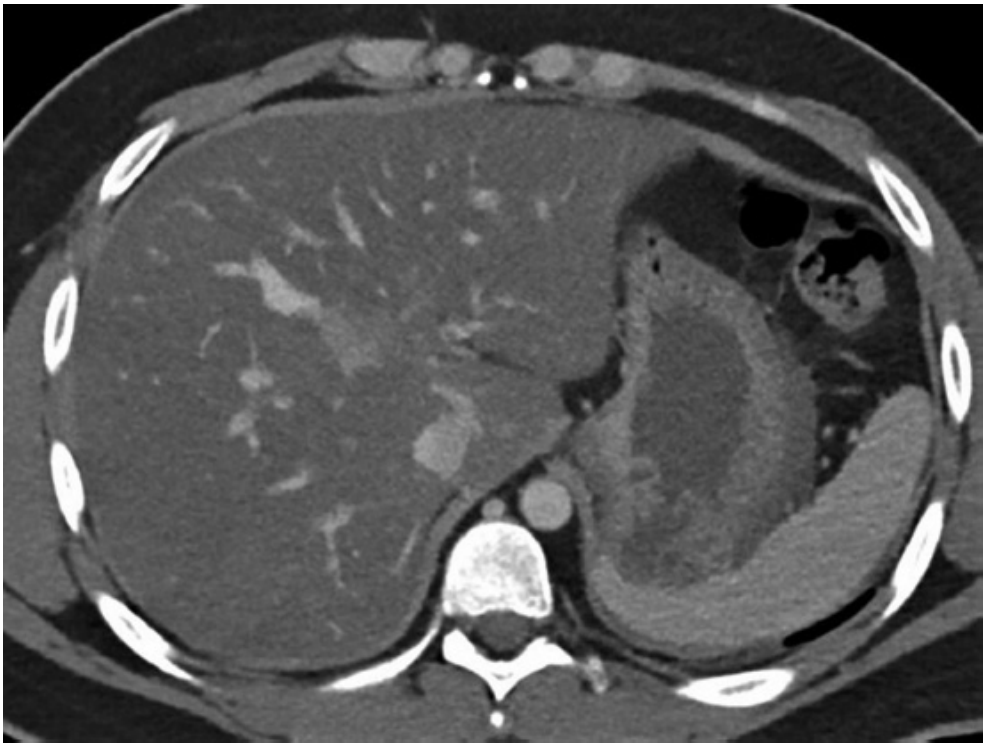

Figure 59.4 Venous-phase contrast-enhanced CT scan demonstrating a hypodense steatotic (fatty) liver. The liver is hypodense relative to the spleen. (Image courtesy of Dr. Ihab Khamel, Department of Radiology, Johns Hopkins Hospital.)

The current understanding of NAFLD with progression to NASH and cirrhosis involves a two-hit model.[56] This model proposes that insulin resistance leads to hepatic steatosis, which sensitizes the hepatic parenchyma to environmental and extracellular insults leading to oxidative injury, inflammation, necrosis, and fibrosis. Dietary fructose is an important culprit in the development of steatosis and steatohepatitis by decreasing intracellular ATP and transforming to lipid in the absence of insulin.[61] Ongoing hepatic insults lead to activation of the inflammasome and secretion of the proinflammatory cytokines IL-1β and IL-18. Inflammasome activation is further increased by gut-derived bacterial endotoxin, with stellate cell activation and fibrosis.[62]

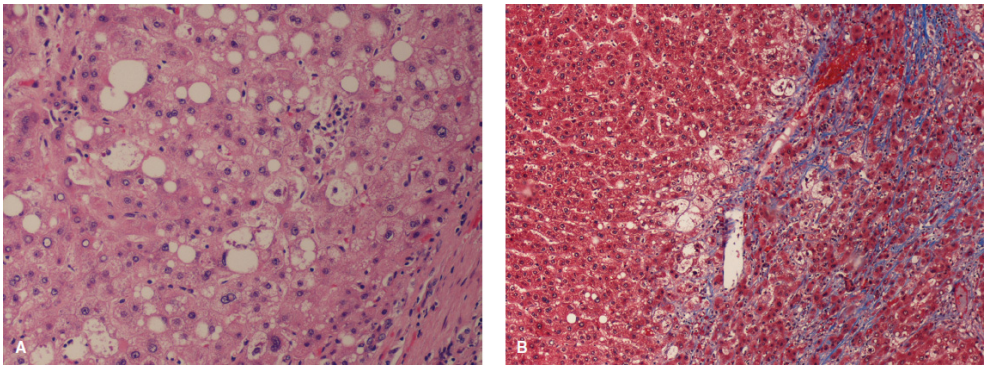

Figure 59.5 **A:** Steatohepatitis 20× magnification. Macrosteatosis, an inflammatory infiltrate and Mallory–Denk bodies are seen. **B:** Trichrome stain demonstrating steatohepatitis and fibrosis (10× magnification). (Images courtesy of Dr. Robert Anders, Department of Pathology, Johns Hopkins Hospital.)

Therapy for NASH centers on lifestyle modification and avoidance of ongoing or additional injury. General measures include avoiding other hepatotoxins including alcohol, and maintaining appropriate vaccinations against viral hepatitis as well as other standard vaccinations (such as against pneumococcus and influenza). Modification of cardiovascular disease risk factors is imperative. Modest weight loss of 5% to 10% is associated with significant histologic improvements in disease severity.[57] Weight loss may be achieved via bariatric surgery if exercise fails. Newer and experimental therapies are also being explored. The role of gut microflora is understood to play a major role in the pathogenesis of NASH (and in other liver diseases) and the use of probiotics, most commonly lactobacilli and bifidobacteria, is being explored in the treatment of NASH. A recent meta-analysis of four RCTs demonstrated probiotics significantly decreased transaminases, total cholesterol, TNF-α, and insulin resistance.[63]

Some, but not all randomized trials support the use of vitamin E as an antioxidant for NASH. A meta-analysis of five trials showed no histologic benefit with vitamin E.[64] This data may be due to heterogeneity of the included trials. The largest RCT included in this meta-analysis showed that patients with NASH without diabetes were more likely to have an improvement in their histology score when compared to placebo, and have an improvement in their ALT levels.[41,65]

Patients with NASH who also have diabetes may benefit from pioglitazone and liraglutide. Metformin use in the setting of NASH has not been shown to improve histology, whereas pioglitazone has been shown to improve fibrosis

as well as inflammation and steatosis in diabetics. Guidelines exist for the follow-up of patients with NASH. Patients should be followed clinically with serial noninvasive assessment of their liver fibrosis score (**Table 59.3**) if biopsy proven NASH is present.

Viral Hepatitis

4 Viral hepatitis is the most common cause of cirrhosis worldwide, accounting for at least 50% of cases. Hepatitis A, B, C, D, and E have all been proved to cause acute hepatitis. Histology is characterized by lymphocytic parenchymal and portal inflammation, focal necrosis, ballooning degeneration, and cholestasis. Kupffer cell and macrophage hypertrophy and hyperplasia are present with lobular disarray. Hepatitis B, C, and D may progress to chronic hepatitis, defined by persistent (>6-month) liver cell necrosis and inflammation.

Hepatitis B Virus: Less than 5% of patients who experience acute HBV infection develop chronic infection, and approximately 10% to 20% of chronically infected persons develop cirrhosis. Hepatitis B remains a major public health problem particularly in Asia and Africa where up to 10% of the population show evidence of chronic infection. Globally, it is estimated there are 248 million HBV carriers in the world, with 600,000 deaths annually from HBV-related disease.[66] In the United States, some data suggests there may be as many as 2.2 million chronically infected residents.[67] Vaccines and antiviral therapies exist. Antiviral medications effective against hepatitis B suppress viral replication to undetectable levels in up to 90% of patients and may reverse fibrosis and even early cirrhosis. Treatment suppresses viral replication, however, HBV remains incorporated into the host genome. This is important as HCC can still develop in the noncirrhotic liver of HBV-infected patients.[68] Public health strategies with systematic vaccination of newborns are able to substantially decrease the incidence of new infections.

Table 59.3 Comparability of Terms in Three Simple Systems for Histologic Grading and Staging of Chronic Hepatitis: IASL, Metavir, and Batts–Ludwig

IASL	Metavir	Batts–Ludwig
Grade (Activity, Inflammation)		
Minimal chronic hepatitis	A1	Grade 1
Mild chronic hepatitis	A1 A2	Grade 2 Grade 3
Moderate chronic hepatitis	A3	Grade 4
Severe chronic		
Stage (Fibrosis)		
Mild—portal fibrosis	F1	Stage 1
Moderate—periportal fibrosis or portal–portal septa	F1 F2	Stage 2 Stage 3
Severe—bridging fibrosis (few)	F3 F4	Stage 3 Stage 4
Severe—bridging fibrosis (many)		
Cirrhosis

Hepatitis C Virus: In contrast, HCV poses a much higher risk of chronic infection: 50% to 85% of persons exposed become chronically infected, and chronic hepatitis develops in 60% of these patients. A systematic review of 111 studies analyzing the natural history of HCV infection estimated the prevalence of cirrhosis 20 years after infection at 16%.[69] Among patients with compensated cirrhosis of viral origin, HCC developed in approximately 20% with HCV, 9% with HBV, and 41% with both HBV and HCV.[70] In the past, standard treatment for HCV was based on the combination of pegylated

interferon and ribavirin (a therapy associated with a high rate of adverse events that limited completion of therapy), with sustained viral response (SVR) rates of up to 80% in patients with genotypes 2 and 3.[71] Results for the more common genotype 1 were only 40% to 50%, with the best reporting an SVR rate of 65%.[72] The discovery of DAAs has revolutionized the treatment of HCV. Choice of antivirals has evolved rapidly and depends on multiple factors, including genotype, treatment history, comorbidities, presence and stage of cirrhosis, and potential drug interactions among other factors. Multiple effective drug combinations exist. Some combinations are effective against multiple HCV genotypes, and a few combinations have pangenotypic activity. Treatment recommendations and guidelines for DAA use are published by the American Association for the Study of Liver Diseases (AASLD) and Infectious Disease Society of America (IDSA) among others (European Association for the Study of the Liver [EASL], and the WHO).

In patients who respond to antiviral therapy, progression to cirrhosis is eliminated and it is generally thought that HCC does not develop. In patients who do not respond to therapy, cirrhosis develops in approximately 40%, and HCC develops in 16% of these patients.[73]

Hepatitis D Virus (Delta virus—HDV): It is an RNA virus. It is unusual in that it requires coinfection with HBV to be pathogenic. Superinfection of HBV-positive patients with HDV may lead to a more rapid clinical course, with progression to cirrhosis in 70% to 80% of patients.[74] The progressive increase in hepatitis-infected individuals in the United States precedes an epidemic in HCC, which has been well documented and is expected to peak over the coming decade.[75]

Cholestasis

Cholestasis may be caused by intrahepatic or extrahepatic biliary obstruction or defects in the ability of hepatocytes to excrete bile. Important causes are biliary atresia, primary sclerosing cholangitis (PSC) and primary biliary cholangitis (PBC—previously known as primary biliary cirrhosis) (**Table 59.4**). Prolonged biliary obstruction leads to proliferation of bile ducts, formation of bile lakes, fibrosis as a result of the direct toxic effects of

bile salts on hepatobiliary elements, and eventually secondary biliary cirrhosis.

Table 59.4 Causes of Cholestasis

Extrahepatic
Common bile duct stones
Cancers
  Pancreas
  Ampulla of Vater
  Bile duct
Cysts
  Pancreatic
  Choledochal
Infections
  Parasites
  Acquired immunodeficiency syndrome
Chronic pancreatitis
Bile duct strictures
  Benign
  Ischemic
Hodgkin disease
Biliary atresia

Intrahepatic
Primary biliary cirrhosis
Space-occupying lesions
  Primary or metastatic hepatic tumors
  Lymphoma
  Amyloidosis
Vanishing bile duct syndrome
  Allograft rejection
  Graft versus host disease
  Alagille syndrome
Idiopathic adult ductopenia
  Primary sclerosing cholangitis
  Hodgkin disease
Cystic fibrosis

Hepatocellular Cholestasis
Genetic

- α-Antitrypsin deficiency
- Benign recurrent intrahepatic cholestasis
- Byler syndrome
- Cholestasis of pregnancy
- Abnormal bile acid synthesis
- Porphyrias

Acquired
- Viral hepatitis
- Drugs

Alcoholic hepatitis
Bacterial infections
Total parenteral nutrition
- Renal carcinoma
- Hodgkin disease

Postoperative cholestasis

Primary Biliary Cholangitis

Several diseases characterized by cholestasis seem to be caused by underlying autoimmune or inflammatory disorders affecting either small (PBC) or large (PSC) bile ducts. PBC is a chronic, progressive autoimmune cholestatic disease that most commonly affects middle-aged women; family members of affected individuals are at a greatly increased risk of developing the disease. PBC is characterized by a T-lymphocyte mediated attack on small intralobular bile ducts and the bile duct cells. This portal inflammation and destruction of intrahepatic bile ducts ultimately results in cirrhosis. Almost all patients with PBC are women, and almost all of these women have antimitochondrial antibodies present in serum.[76] Antinuclear antibodies are present in up to 70% of patients. Hyperlipidemia, an elevated alkaline phosphatase and bilirubin are also present. In PBC, the autoimmune process directly damages the intrahepatic biliary tree. Toxicity of bile acids contributes to hepatocyte injury.[77]

Presentation is with fatigue, jaundice, and pruritus, however as many as 60% of patients may be asymptomatic.[78] PBC progresses in the majority of patients with median survival of 10 to 15 years in asymptomatic patients and 7 years in symptomatic patients.[79,80] Poor prognostic factors include

advanced age as well as those factors associated with advanced disease (hyperbilirubinemia, hepatosplenomegaly, and symptomatic disease).

Therapy for PBC includes the exogenous bile acid ursodeoxycholic acid. Treatment with ursodeoxycholic acid may reduce the expression of HLA class 1 antigens by hepatocytes and lessen the toxicity of retained naturally occurring bile acids. Complete response, as evidenced by normalization of liver enzymes without histologic progression, is seen in up to 30% of patients and may result in a normal life expectancy. Obeticholic acid (a farnesoid X receptor ligand) is recommended if response to ursodeoxycholic acid is inadequate. Liver transplantation is ultimately required as the definitive treatment in most patients who progress to decompensated cirrhosis. The parameters for liver transplantation and its timing are relatively predictable and have been well studied.

Primary Sclerosing Cholangitis

PSC is a chronic, progressive cholestatic liver disease of uncertain etiology characterized by diffuse segmental intrahepatic and/or extrahepatic biliary strictures with associated fibrosis and inflammation. The disease has no cure and leads to secondary biliary cirrhosis, portal hypertension, and hepatic failure. In addition, it carries a risk of cholangiocarcinoma. Median survival without liver transplantation after diagnosis of PSC is 10 to 12 years. PSC is strongly associated with inflammatory bowel diseases, particularly ulcerative colitis. There is likely a common underlying mechanism involving mucosal autoimmunity to the gastrointestinal (GI) tract. Around 70% of patients with PSC also have ulcerative colitis and up to 90% when rectosigmoid biopsies are routinely obtained.[81] Conversely, only approximately 5% of patients with ulcerative colitis have PSC, though more subtle forms of the disease may be present but asymptomatic. PSC is characterized by elevated levels of autoantibodies and an increased expression of human leukocyte antigen (HLA) class II molecules on biliary epithelial cells.[82,83] As opposed to PBC, in PSC two-thirds of patients are male and younger than 45 years of age at the time of diagnosis.[84] Patients with PSC may be completely asymptomatic with only abnormal liver function tests (up to 44%). Some may have signs of advanced disease at the time of diagnosis.[81] Commonly, the diagnosis is made in symptomatic patients after

endoscopic retrograde cholangiopancreatography (ERCP) has been performed to evaluate elevated liver enzymes, including alkaline phosphatase and γ-glutamyl transferase (GGT). Symptomatic patients have a waxing and waning course and may present with complaints of fatigue (75%), pruritus (25% to 70%), jaundice (30% to 69%), abdominal pain (16% to 37%), and weight loss (10% to 34%).[81] More advanced complications are due to the progression to cirrhosis, but also include episodes of acute cholangitis due to biliary strictures.

The diagnosis of PSC is suggested by a history of inflammatory bowel disease in the setting of elevated liver enzymes. Cholangiography (via MRCP, ERCP, or percutaneous cholangiography) may reveal the characteristic multifocal stricturing and dilatation of intrahepatic and/or extrahepatic bile ducts. Imaging may also reveal a single dominant stricture. Pathologically, bile ductular proliferation, periductal fibrosis and inflammation, ductopenia, and, less commonly, obliterative fibrous cholangitis may be present. Like ulcerative colitis, PSC confers a significant risk of malignant transformation of the biliary mucosa. Cholangiocarcinoma develops in 1% to 2% of patients per year after the diagnosis of PSC, with an overall risk of up to 10%.[85] PSC is a risk factor for both intra- and extrahepatic cholangiocarcinoma as well as gall bladder cancer. HCC risk is increased when cirrhosis is present. Surveillance for cancer with ultrasound, computed tomography (CT), or MRCP, and serum testing of CA19-9 has been recommended. When a dominant stricture, worsening symptoms or cholestasis is present, ERCP with brush cytology and fluorescence in situ hybridization (FISH) may be useful to increase sensitivity of cancer detection.

Unfortunately there is no generally accepted medical therapy effective against PSC. Therapies are directed toward the complications of the disease including biliary obstruction, cirrhosis, and cholangiocarcinoma. Dominant strictures, defined as stenosis less than 1.5 mm in the common bile duct or less than 1 mm in the hepatic duct, are readily treated endoscopically by means of dilation and/or stent placement.[86] A dominant stricture should raise concern for the development of cholangiocarcinoma. Transplantation should be performed before cancer develops. Historically the presence of cholangiocarcinoma was an absolute contraindication to transplantation because of poor outcomes. However, in highly selected patients with

localized tumors, liver transplantation may be achieved with an acceptable survival rate after intensive preoperative therapy radiation and chemotherapy, as proposed by Shaw and implemented on a larger scale by the Mayo group.[87]

Metabolic and Genetic Disorders

A description of all the metabolic and genetic disorders causing liver disease is beyond the scope of this chapter. Some of these diseases are listed in **Table 59.2**.

Hereditary Hemochromatosis: This is an autosomal recessive, inborn error of metabolism most commonly due to mutations in the hereditary hemochromatosis gene *HFE* and results in increased intestinal absorption of iron and subsequent total-body iron overload. Iron accumulates in the periportal regions of the liver and results in hepatotoxicity via lipid peroxidation. Kupffer cells subsequently phagocytose necrotic hepatocytes and activate stellate cells.[88] Over time, the reaction progresses to bridging fibrosis and eventually cirrhosis. Cardiac, endocrine, neurologic, and other systemic manifestations occur. Treatment includes reduction of iron intake, repeated phlebotomy, and liver transplantation.[89] As with other types of cirrhosis, there is a risk of HCC.

Wilson's Disease: Wilson's disease is an autosomal recessive disease caused by a mutation in the Wilson's disease protein resulting in deficient hepatocyte transport of copper into bile. The disease is characterized by a low serum ceruloplasmin level and manifests clinically as Kayser–Fleischer rings (corneal pigmentation), neuropsychiatric disease, and hepatic cirrhosis.[90] Liver manifestations of Wilson's disease vary widely from asymptomatic biochemical abnormalities and steatosis to fulminant hepatic failure, chronic hepatitis and cirrhosis. As copper accumulates in the liver, periportal inflammation develops that leads to piecemeal and lobular necrosis, bridging fibrosis, and ultimately a mixed micronodular–macronodular cirrhosis. A scoring system has been developed to assist with the diagnosis. Treatment options include chelating agents, such as penicillamine, trientine, zinc salts, and orthotopic liver transplantation.

Impaired Venous Outflow or Venous Outflow Obstruction

Cirrhosis may also result from chronic obstruction of the hepatic venous outflow. Causes include chronic right-sided heart failure as a result of severe tricuspid regurgitation, the Budd–Chiari syndrome (BCS), and the sinusoidal obstructive syndrome (hepatic veno-occlusive disease).

Hepatic dysfunction secondary to passive vascular congestion in the setting of right-sided heart failure and elevated right-sided heart pressures is caused by pressure transmission to the hepatic venous system. Sinusoidal congestion occurs and results in perivenular atrophy, hemorrhagic necrosis, and distortion and enlargement of sinusoidal fenestrations.[91] Perisinusoidal edema develops and exceeds the clearance capabilities of hepatic lymphatics, so that ascites develops. Grossly, the liver is described as having a "nutmeg" appearance in which areas of hemorrhage are interspersed with relatively normal yellowish parenchyma.[92] Histologically, perivenular fibrosis progresses to bridging fibrosis that spares the portal regions. This portal sparing is characteristic of "cardiac cirrhosis." In addition to causing ascites, chronic vascular congestion leads to fibrosis in the space of Disse, which compromises nutrient delivery and contributes to portal hypertension and zone 3 hepatocellular injury.[93]

5 **Budd–Chiari Syndrome** (see section on portal hypertension below) is a rare disease more common in women and usually presents in the third or fourth decade of life. It is caused by mechanical obstruction of the hepatic veins (**Table 59.5**). Obstruction may occur at the level of the terminal hepatic veins, the major hepatic veins, or the vena cava and may be caused by obstructing webs or membranes (most commonly in Africa and Asia) or thrombosis secondary to hypercoagulable states and neoplasms (most commonly in the West).

Table 59.5 Etiologic Factors in Budd–Chiari Syndrome

Idiopathic
Hematologic disorders Polycythemia vera Paroxysmal nocturnal hemoglobinuria Myeloproliferative disorders Antithrombin III deficiency Circulating lupus anticoagulants
Oral contraceptives
Pregnancy and postpartum
Tumors Hepatocellular carcinoma Renal cell carcinoma Adrenal carcinoma Leiomyosarcoma of the inferior vena cava
Vena caval webs
Infections Amebic abscess Aspergillosis Hydatid cyst
Phlebitis
Trauma
Veno-occlusive disease

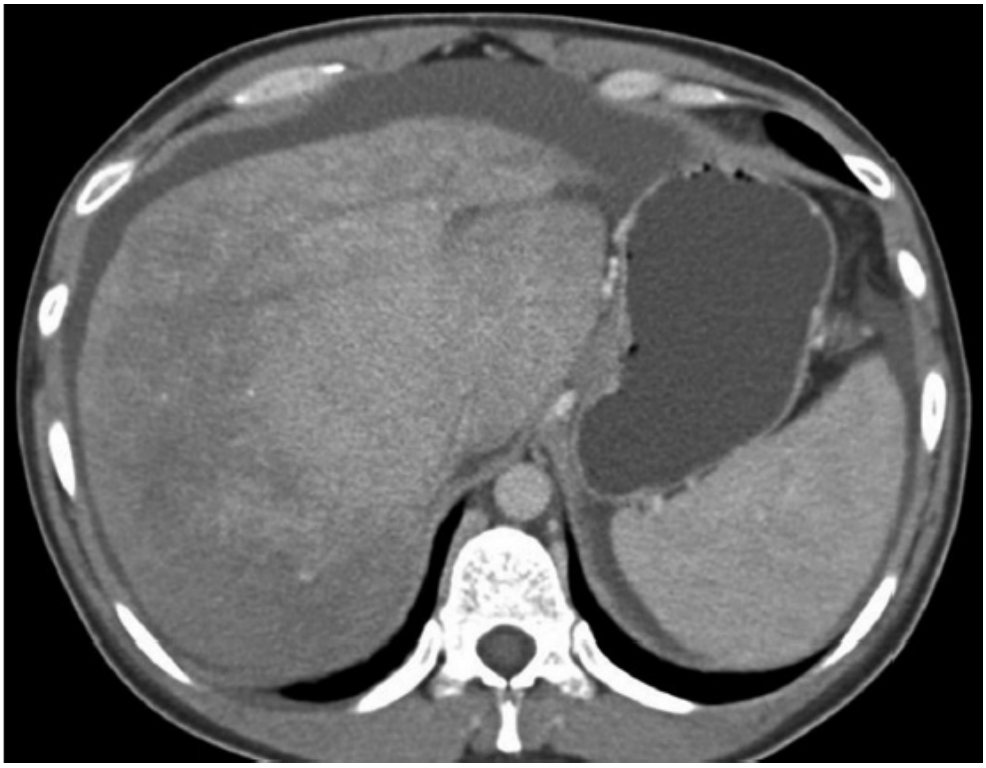

Figure 59.6 Contrast-enhanced CT of a patient with Budd–Chiari syndrome. This patient experienced an unprovoked thrombotic event which was found to be due to a myeloproliferative neoplasm positive for *JAK2 V617F mutation*. Massively hypertrophied caudate lobe is demonstrated. Also visible is ascites, compressed IVC, and splenomegaly. This patient was successfully treated with TIPS and lifelong anticoagulation and continued to have excellent hepatic function.[277] (Image courtesy of Dr. Ihab Khamel, Department of Radiology, Johns Hopkins Hospital.)

The range of presentations is wide: from asymptomatic to acute hepatic failure or cirrhosis.[94] Variation in symptoms and presentation is related to the degree and rate of progression of hepatic outflow obstruction. Patients classically present with abdominal pain, hepatomegaly, and ascites. The diagnosis can be made by duplex Doppler ultrasonography, which has a high sensitivity. Identification of collateral vessels to subscapular or intercostal vessels on ultrasound is a highly sensitive and specific finding.[95] CT and magnetic resonance imaging (MRI) (**Fig. 59.6**) delineate intrahepatic vascular anatomy and are used for the planning of complex interventions.[96] Medical management consists of anticoagulation and management of symptoms. Interventional radiologic procedures have now taken the forefront in management of BCS, in which accessible strictures may be treated with angioplasty or stenting. For patients unsuitable for reestablishment of hepatic

venous outflow through the above means, transjugular intrahepatic portosystemic shunting (TIPS) is able to decompress both the inferior vena cava (IVC) and the portal system. In patients with fulminant BCS or in those who develop chronic decompensated cirrhosis, liver transplantation is lifesaving.

Diagnosis

Although cirrhosis can be asymptomatic for decades, significant information can be obtained by performing a thorough history and physical examination. Symptoms may be nonspecific (anorexia, weight loss, weakness, fatigue). A history of chronic alcohol abuse, hepatitis or risk factors for virus transmission, jaundice, toxin or drug exposure, upper GI bleeding, enlarging hemorrhoids, infections, and alteration in mental status suggests the possibility of liver disease and decompensated cirrhosis. In women, chronic anovulation is common, while in men hypogonadism may develop. Physical findings associated with cirrhosis are listed in **Table 59.6**. In addition to these findings, fetor hepaticus, purpura and bruising, decreased body hair, and white nails (Muehrcke and Terry nails) are common. As cirrhosis progresses, a decrease in blood pressure is often present and contributes to the development of hepatorenal syndrome (HRS). Parotid enlargement may be present in alcoholic liver disease.

Table 59.6 Physical Findings in Cirrhosis

Physical Findings	Incidence (%)
Palpable liver	96
Jaundice	68
Ascites	66
Spider angiomas	49
Dilated abdominal wall veins (caput medusae)	47
Palpable spleen (splenomegaly)	46
Testicular atrophy	45
Palmar erythema	24
Noninfectious fever	22
Hepatic coma	18
Gynecomastia	15
Dupuytren contractures	5

Laboratory tests of liver function are indicated if liver disease is suggested by the history and physical examination. Although levels of bilirubin, aspartate aminotransferase, alanine aminotransferase, and alkaline phosphatase may be elevated in hepatic disease, the increases are not specific for liver pathology, and levels may be normal even in the setting of cirrhosis. A very common finding in patients with cirrhosis is thrombocytopenia, caused by hypersplenism and portal hypertension. The platelet growth factor thrombopoietin, which is produced by the liver, is decreased in patients with cirrhosis, and this deficit may lead to thrombocytopenia associated with hepatic disease.

Definitive diagnosis of cirrhosis usually requires biopsy, either percutaneous or operative, or gross inspection during laparoscopy or laparotomy. Regardless of the method selected, it is crucial to obtain a large enough specimen to make the diagnosis. Current recommendations suggest that at least 11 portal tracts need to be assessed.[97] Several staging systems exist for the grading of fibrosis and cirrhosis, including the International Association for Study of the Liver (IASL), Batts–Ludwig, and Metavir systems. The AASLD recommends use of the Batts–Ludwig or Metavir systems due to their simplicity (**Table 59.3**).[97]

Imaging classically reveals an atrophic, nodular liver and an enlarged spleen. Ultrasound is routinely used during the evaluation of cirrhosis. It is well tolerated, widely available, and noninvasive. Ultrasonographic criteria for cirrhosis include the demonstration of multiple nodular irregularities on the ventral liver surface that are clearly separate from the anterior abdominal wall. Parenchymal texture is altered in the setting of fibrosis, though this feature can be subtle. When these criteria are used, ultrasonography has been shown to have a sensitivity, specificity, and accuracy of approximately 90% in the diagnosis of cirrhosis.[98]

CT imaging provides similar information to ultrasound. Contrast administered with imaging during the portal phase can demonstrate the presence of portosystemic collaterals (if portal hypertension is present) and assess patency of the portal vein. MRI provides similar information and may contribute information about liver stiffness when elastography is performed. Contrast-enhanced CT and MRI are important in the characterization of the malignant potential of masses within the liver.

Measures of liver stiffness offer a noninvasive approach to the assessment of degree of fibrosis and may avoid the need to biopsy a liver. Elastography estimates liver stiffness by applying mechanical waves and measuring their propagation speed through tissue. Modalities include ultrasound and MRI among others. Ultrasound-based transient elastography (TE), a measure of liver stiffness, is playing an increasingly large role in the noninvasive assessment of fibrosis, with some studies demonstrating a 95% area under the receiver operating characteristic curve (AUROC) for diagnosing grade IV fibrosis (cirrhosis).[99] MR elastography (MRE) interrogates the whole liver (unlike ultrasound-based TE) and in some reports has a higher technical success rate and better diagnostic accuracy than ultrasound-based TE.

Several laboratory indices have been found to correlate well with histologic grade of cirrhosis.[99,100] The NAFLD fibrosis score, for example, consists of age, BMI, diabetes, platelet count, albumin level, and AST/ALT ratio.[101] The AUROC of this scoring system in diagnosing stage 3 or greater fibrosis was 85% in a recent meta-analysis.[102] The FibroSure (LabCorp) is a patented panel of biomarkers consisting of GGT, haptoglobin, bilirubin, apolipoprotein A1, and α-2-macroglobulin. The AUROC of FibroSure for fibrosis greater than or equal to stage 2 has been shown to be up to 87%.[103] Indirect evidence of cirrhosis includes endoscopically discovered varices of the esophagus and the presence of splenomegaly detected by CT or MRI.

Complications

The occurrence of major complications of cirrhosis signifies the occurrence of decompensated cirrhosis (**Table 59.1**).

Multiple factors can predispose to decompensation in a patient with cirrhosis. Risk factors for decompensation include bleeding, infection, alcohol intake, medications, dehydration, and constipation. In addition, patients with obesity are at increased risk of decompensation. Once decompensation has occurred, patients should be assessed for liver transplantation.

Renal

Renal complications in cirrhosis are intrinsic to functional dysregulation of vascular tone throughout the body.[104] Renal dysfunction is characterized by avid sodium retention despite normovolemia or hypervolemia, dilutional hyponatremia secondary to free water overload, ascites, and ultimately renal failure and the HRS. The paradoxical arterial vasoconstriction of the renal arterial bed in the face of global fluid overload is critical to the pathophysiology of HRS.[105] Among the complications of cirrhosis, HRS confers the highest risk of mortality.[106] Although HRS is the most dramatic renal complication of liver failure, renal dysfunction in patients with advanced liver disease is generally multifactorial.

Much progress has been made in the understanding of the pathophysiology of HRS focusing on the dysregulation of arterial tone in the end stages of

liver disease. Splanchnic arterial vasodilatation, which is triggered by portal hypertension, appears to play a central role in the hemodynamic changes and the decline in renal function in cirrhosis. Empiric observations that support a functional or "secondary effect" theory include the lack of anatomic renal abnormalities in patients with cirrhosis-related renal dysfunction, the normal function of previously dysfunctional kidneys transplanted into otherwise healthy recipients, and resolution of renal abnormalities after successful hepatic transplantation. Recent clinical studies have defined the critical role of optimizing colloid balance and regulating renal blood flow using agents such as terlipressin in counteracting the deranged vascular tone and physiology in cirrhotic patients.[107,108]

Sodium Retention

Patients with cirrhosis who do not have ascites have relatively normal sodium-handling capabilities. Patients in whom ascites develops have a marked inability to excrete sodium. Because of this deficit, sodium intake in excess of renal excretion contributes to fluid overload. The most accepted explanation for this development is the "arterial vasodilation hypothesis," which suggests that hypotension is the primary event. Arterial vasodilation in the splanchnic circulation leads to relative peripheral hypovolemia with activation of the renin–angiotensin–aldosterone and sympathetic nervous systems. This results in the release of antidiuretic hormone (arginine vasopressin), sodium and water retention, and an increase in effective circulating volume, with subsequent edema and ascites.[109–111]

Table 59.7 International Club of Ascites (ICA-AKI) Definitions for the Diagnosis and Management of AKI in Patients with Cirrhosis

Definition of AKI	Increase in sCr ≥0.3 mg/dL (≥26.5 μmol/L) within 48 hours; or a percentage increase sCr ≥50% from baseline which is known, or presumed, to have occurred within the prior 7 days		
Staging of AKI	Stage 1: increase in sCr ≥0.3 mg/dL (26.5 μmol/L) or an increase in sCr ≥1.5-fold to twofold from baseline Stage 2: increase in sCr >two to threefold from baseline Stage 3: increase of sCr ≥threefold from baseline or sCr ≥4.0 mg/dL (353.6 μmol/L) with an acute increase ≥0.3 mg/dL (26.5 μmol/L) or initiation of renal replacement therapy		
Progression of AKI	Progression: Progression of AKI to a higher stage and/or need for RRT		Regression: Regression of AKI to a lower stage
Response to treatment	No Response: No regression of AKI	Partial response: Regression of AKI stage with a reduction of sCr to ≥0.3 mg/dL (26.5 μmol/L) above the baseline value	Full response: Return of sCr to a value within 0.3 mg/dL (26.5 μmol/L) of the baseline value

sCr, serum Creatinine.

Evidence suggests that nitric oxide and prostaglandins are key mediators. Elevations in portal venous and systemic nitric oxide have been reported in both animal and human studies, and inhibitors of nitric oxide production have been shown to reduce vasodilatation and enhance renal hemodynamics.[112,113] Nitric oxide production may be stimulated by increased absorption of endotoxin from the intestine. Other studies have demonstrated that extracellular fluid volume expansion precedes vasodilation,[114] and that pathologic activation of intrahepatic vascular sensors is the key mediator for renal salt retention.[115] Fluid overload is an important landmark in the natural history of cirrhotic patients and the degree of sodium retention is inversely related to survival.

Water Retention and Hyponatremia

Water excretion is usually normal in patients with cirrhosis before the development of ascites. Patients with cirrhosis and ascites may have a markedly impaired ability to handle free water. An increased production of antidiuretic hormone, decreased delivery of fluid to the diluting segments of the nephron, and reduced renal production of prostaglandins all contribute.[116] Retention of water leads to dilutional hyponatremia (serum sodium 130 mEq/L), which can cause nausea, vomiting, lethargy, and seizures.[117] Severity of hyponatremia correlates with worsening survival.[118–120]

Hepatorenal Syndrome

6 Patients with refractory ascites are at risk for acute kidney injury (AKI). Early diagnosis of AKI is imperative because therapy impacts survival. AKI in cirrhosis can be caused by prerenal azotemia (PRA), HRS, or acute tubular necrosis (ATN). Diagnosis of AKI can be challenging given that patients with cirrhosis often have sarcopenia and a lower baseline creatinine. Criteria for AKI in cirrhosis were revised in 2015 by the International Ascites Club (IAC) (**Table 59.7**). HRS is a unique form of AKI that is a complication of cirrhosis characterized by progressive renal failure in the absence of intrinsic renal disease. It has also been described as occurring in acute liver failure. In patients with cirrhosis and ascites, HRS

occurs in up to 20% of patients at 1 year and 40% at 5 years. Two forms of HRS have been described. HRS-AKI (previously known as type 1 HRS) is characterized by a rapidly progressive decline in renal function associated with a high mortality. HRS-non-AKI (HRS-NAKI—previously known as Type 2) is a more chronic form of renal dysfunction that evolves over weeks to months. The development of HRS is a poor prognostic indicator: If liver transplantation cannot be performed, patients with HRS usually die within months of the development of severe disease.[106] Distinguishing HRS-AKI from other causes of AKI is paramount because treatment differs.

The pathogenesis of HRS is thought to be due to renal cortical vasoconstriction induced by activity of the renin–angiotensin–aldosterone system. The powerful endothelium-derived vasoconstrictor endothelin-1, combined with decreased renal production of vasodilator prostaglandins, also contributes. HRS is usually precipitated by an inciting event. Infection, use of nonsteroidal anti-inflammatory drugs, variceal hemorrhage, or excessive diuretic use may precipitate HRS. Manifestations of the disease include progressive oliguria, rising serum creatinine, increased cardiac output, and decreased arterial pressure.

Differential Diagnosis of HRS: This includes other causes of AKI and PRA. Excessive diuresis may lead to a rise in serum creatinine difficult to distinguish from HRS. A failure to respond to cessation of diuretics and fluid challenge suggests HRS. The disease, however, is virtually indistinguishable by laboratory testing from prerenal uremia. Both prerenal uremia and HRS are characterized by extremely low sodium concentrations in the urine, high urine osmolality, high urine-to-plasma ratios of creatinine, and normal urinary sediment (**Table 59.8**). Criteria for the diagnosis of HRS are listed in **Table 59.9**. Additional diagnostic biomarkers under study include urinary and serum neutrophil gelatinase-associated lipocalin (NGAL), urinary IL-18, urinary kidney injury molecule 1 (KIM-1) and fractional excretion of sodium (FeNa), among others.

Table 59.8 Differential Diagnosis of Acute Azotemia in Patients with Liver Disease

	Prerenal Azotemia	Hepatorenal Syndrome	Acute Renal Failure
Urinary sodium	<10 mEq/L	<10 mEq/L	>30 mEq/L
Urine/plasma creatinine ratio	>30:1	>30:1	<20:1
Urine osmolality	100 mOsm, or more than plasma osmolality	100 mOsm, or more than plasma osmolality	Equal to plasma osmolality
Urine sediment	Normal	Normal	Casts: cellular debris

Table 59.9 International Ascites Club (IAC) Diagnostic Criteria for Hepatorenal Syndrome Acute Kidney Injury (HRS-AKI)

1. Cirrhosis with ascites
2. Diagnosis of AKI according to IAC-AKI criteria
3. No improvement of serum creatinine after 2 days of diuretic withdrawal and volume expansion with albumin (recommended 1 g/kg of body weight per day, maximum 100 g/d)
4. Absence of shock
5. No current or recent treatment with nephrotoxic drugs
6. No macroscopic signs of structural kidney injury,[a] defined as:
   - absence of proteinuria (>500 mg/day)
   - absence of microhaematuria (>50 RBCs per high power field)
   - normal findings on renal ultrasonography

[a]Patients who fulfil these criteria may still have structural damage such as tubular damage. Urine biomarkers will become an important element in making a more accurate differential diagnosis between HRS and acute tubular necrosis.

Adapted from Angeli P, Gines P, Wong F, et al. Diagnosis and management of acute kidney injury in patients with cirrhosis: revised consensus recommendations of the International Club of Ascites. *Gut* 2015;64:531–537.

Management of HRS: Often there is a precipitating event that requires treatment. Diuretics should be stopped to prevent further injury. The most common inciting factor is spontaneous bacterial peritonitis (SBP) and infection. Up to 70% of cases of acute HRS have been linked to bacterial infections.[121] Volume contraction from multiple etiologies, including GI bleeding or the excessive treatment of ascites, is another major precipitator. HRS is treated with volume expansion with albumin (**Table 59.9**). Empiric antibiotics should be given until cultures are definitively negative.

Vasoconstrictors (by attenuating splanchnic vasodilatation) combined with albumin (volume expansion) significantly improve renal function in HRS. The vasopressin-analog terlipressin is commonly used outside the United States, and lead to reversal in over 56% of patients in one recent RCT. The oral vasopressor midodrine is commonly used in the United States. Use of terlipressin has not been approved for use by the FDA. Midodrine is sometimes in combination with octreotide, however terlipressin is superior

to the combination of midodrine and octreotide in the reversal of HRS. Others have examined norepinephrine as a substitute for terlipressin with slightly improved reversal rates in the norepinephrine group (43% vs. 39%), although this was not statistically significant.[122] A meta-analysis of all RCTs of vasopressor use in the treatment of HRS has found a reduction in all-cause mortality when vasopressors are utilized.[123] Medical therapy may reverse HRS in some patients, however many will ultimately require liver transplantation or combined liver kidney transplantation.

Pulmonary

Many pathologic processes in patients with cirrhosis affect pulmonary function. Some diseases affect both hepatic and pulmonary systems (i.e., cystic fibrosis, α_1-antitrypsin deficiency); others are primary pulmonary processes, such as interstitial lung disease, primary pulmonary hypertension (portopulmonary hypertension [PPHTN]), and obstructive airway disease. Three important pulmonary manifestations of cirrhosis are discussed: The first relates to the volume effect of ascites and effusion when present: diaphragmatic excursion is reduced, affecting the total lung capacity. Intrapulmonary shunting is less common and is known as the hepatopulmonary syndrome. Finally, PPHTN is another cause of respiratory insufficiency.

Ascites and Hepatic Hydrothorax: The presence of copious ascites can lead to compromised diaphragmatic excursion secondary to increased intra-abdominal and intrapleural pressures. Ascites may also induce hepatic hydrothorax (typically right sided pleural effusion) via transdiaphragmatic lymphatic communication.[124] Compression of lung parenchyma by the effusion impairs gas exchange, and results in ventilation–perfusion mismatch with subsequent hypoxemia. Decreased functional residual and total lung capacity are the end result. Volume removal, either via diuresis, large-volume paracentesis, or thoracentesis can ameliorate symptoms and reduce work of breathing.[125] For patients refractory to the above measures, strategies such as TIPS, indwelling pleural catheter placement, and pleurodesis have been described. Liver transplant is definitive.[125]

Hepatopulmonary Syndrome. HPS is characterized by abnormal arterial oxygenation caused by intrapulmonary vascular dilatations in the setting of

liver disease or portal hypertension. It occurs in patients with mild to severe hepatic disease and is present in approximately 4% to 47% of patients with chronic liver disease (depending on criteria used and population studied).[126,127] Symptoms include dyspnea, platypnea (worsening dyspnea with movement from a supine to an erect position), and orthodeoxia (decreased oxygen tension from supine to erect). The basis for these symptoms is increasing shunt within dilated capillaries in the basal lung that occurs with standing. Spider nevi, clubbing, and cyanosis as well as evidence of impaired oxygenation (peripheral oxygen saturation <96% on room air) may be present on examination. Hypoxemic criteria for HPS in patients with cirrhosis include: 1. PaO_2 <80 mm Hg (<70 mm Hg in patients over the age of 65 years) or 2. Alveolar–arterial gradient ≥15 mm Hg (≥20 mm Hg over the age of 65 years).[128]

Although the underlying mechanism of hypoxemia in these patients is right-to-left intrapulmonary shunting, ventilation–perfusion mismatch and impaired hypoxic vasoconstriction also play a role. Patients usually present with dyspnea and worsening hypoxemia without evidence of a primary pulmonary process. Initial diagnostic tools include pulse oximetry and arterial blood gas analysis. Pulmonary function testing excludes obstructive or restrictive airway disease as a cause of hypoxemia. A definitive diagnosis can be obtained by the use of contrast-enhanced echocardiography (bubble study) or technetium labeled-macroaggregated albumin (MAA) scanning, which will confirm the presence of intrapulmonary vascular dilation.[129,130] Contrast echocardiography is the most sensitive test, whereby intrapulmonary vascular dilation is demonstrated by the late appearance of microbubbles in the left heart three to six cardiac cycles after injection.[131] MAA scanning revealing a shunt of >6% suggests HPS as the major contributor to hypoxemia.[132] The only effective therapy for this disease is orthotopic liver transplantation, and those with HPS and with a PaO_2 <60 mm Hg receive extra priority at listing.[131]

PPHTN refers to pulmonary arterial hypertension that is associated with portal hypertension. It is a complication of portal hypertension due to either chronic liver disease or extrahepatic causes. It is defined as a mean pulmonary arterial pressure of greater than 20 mm Hg at rest, normal or low pulmonary artery occlusion pressure <15 mm Hg at rest, and pulmonary

vascular resistance >240 dyn/s/cm^{-5} on right heart catheterization in the setting of documented portal hypertension.[128] It is a relatively uncommon complication of cirrhosis with prevalence rates of 2% in those with chronic liver disease, to rates of 16% in those listed for transplant. When severe, it carries a substantial risk of mortality and is a contraindication to liver transplantation.[133,134] Doppler echocardiography will suggest elevated right heart pressures (i.e., elevated peak tricuspid regurgitant velocity [TRV] >2.8 m/sec, or those with lower peak TRV but other signs of pulmonary hypertension), which is confirmed by right heart catheterization. The exact pathophysiology behind PPHTN is unknown, but portal hypertension is a necessary component of the disease process. The hyperdynamic state in portal hypertension may be the main contributory factor, although the severity of PPHTN does not correlate with the severity of portal hypertension.[135] Although the high flow state present in cirrhosis elevates right-sided pressures, the fixed obstruction present in the pulmonary microcirculation is highly lethal and is not likely to improve with liver transplantation.

Treatment is nearly identical to that for other types of pulmonary arterial hypertension. Beta-blockers should be avoided when feasible since they can worsen right heart failure and increase pulmonary vascular resistance. TIPS can increase right ventricle preload and worsen heart failure and should be used with caution if indicated for other reasons. Prolonged intravenous infusion of prostaglandins (e.g., epoprostenol) improves pulmonary hemodynamics but does not prolong survival.[134] The oral endothelin receptor antagonists such as bosentan and ambrisentan are also commonly used. Phosphodiesterase-5 inhibitors (sildenafil and tadalafil) are also commonly prescribed. As stated above, severe PPHTN (mPAP >50 mm Hg) is an absolute contraindication to liver transplantation. For patients in whom medical therapy can maintain mPAP under 35 mm Hg and PVR less than 400 dyn/s/cm^{-5}, MELD exception points for priority listing for liver transplantation are available.[136]

Hepatic Encephalopathy

Etiology

7 Hepatic encephalopathy is a neuropsychiatric syndrome due to liver disease that is characterized by variable alterations in mental status. The

manifestations (see clinical features below) range from subtle deficits detectable only by detailed psychometric tests to confusion, lethargy, and ultimately frank coma. The encephalopathy presents in association with acute hepatic failure, as a consequence of progression of chronic liver disease, or after the creation of a surgical portosystemic shunt. Usually, a precipitating event, such as an acute variceal hemorrhage, infection, deterioration in renal function, drugs (e.g., benzodiazepenes), or constipation can be found. Encephalopathy develops in 30% to 45% of patients with cirrhosis and in 10% to 50% of patients with TIPS.

The causative agent in hepatic encephalopathy has been the subject of much debate. Ammonia has been heavily implicated in the development of this condition. However, an elevated ammonia concentration in the serum is not required for diagnostic purposes, nor is it specific. Under normal circumstances, ammonia is produced by bacterial catabolism of nitrogenous sources (protein) in the intestine after which it is absorbed into the portal circulation to undergo degradation in the liver.[137] Ammonia and other bacterial degradation products are theorized to access the peripheral circulation as a result of both poor hepatic metabolism and portosystemic shunting. In patients with cirrhosis, the permeability of the brain to ammonia appears to be increased.[138] Other etiologic agents that have been suggested and include γ-aminobutyric acid (GABA), endogenous benzodiazepines,[139] branched-chain amino acids (BCAAs such as tryptophan),[140] neurotoxic short-chain fatty acids, mercaptans, phenols, and endogenous opiates.[141]

The following observations suggest that ammonia is the key mediator in hepatic encephalopathy: (a) ammonia levels are increased in 80% to 90% of patients with the condition,[142] (b) factors that precipitate hepatic encephalopathy cause increases in ammonia levels, and (c) treatments that relieve hepatic encephalopathy lower ammonia levels.[143] However, contrary to this hypothesis include the following arguments: (a) levels of ammonia correlate poorly with the severity of hepatic encephalopathy, (b) elevated ammonia levels alone do not cause encephalopathy, (c) administration of ammonia to patients with cirrhosis but not hepatic encephalopathy does not cause encephalopathy, and (d) treatments that reduce ammonia levels also reduce levels of other putative toxins.[143]

Clinical Features

A wide range of neurologic symptoms may occur in patients with hepatic dysfunction. Subtle changes may include changes in personality, memory loss, alterations in diurnal sleep variation, and minor decreases in intellectual function. The West Haven criterion describes the range of clinical stages. Neuromuscular impairment present may result in bradykinesia, asterixis, slurred speech and ataxia, and ultimately decerebrate posturing of coma. With progression of disease, asterixis may occur. Stigmata of liver disease are usually evident, including fetor hepaticus and spider angiomas. The combination of asterixis, elevated ammonia levels, and altered mental status in a patient with known liver disease strongly suggests the diagnosis. Electroencephalographic changes are nonspecific and may occur in patients with a variety of other conditions.

Treatment

Treatment options for hepatic encephalopathy include correction of the precipitating factors where possible. Treatments to reduce bacterial load of ammonia from the intestine are also instituted. A search for precipitating infection is extremely important. Pulmonary, urinary, and ascitic infections should be sought via appropriate cultures and ascitic fluid analysis. An assessment of overall volume status and drug history as well as a search for variceal bleed can be made (**Table 59.10**).

Treatment begins with general supportive care including resuscitation and rehydration via volume expansion as well as providing appropriate nutrition and correcting electrolyte abnormalities. The removal of nitrogenous compounds from the small and large bowel is the critical step in decreasing ammonia and other toxic substances from the blood. Orally administered cathartics and enemas can cleanse the bowel of protein and the source of ammonia. However, dietary restriction of protein is no longer recommended as it contributes to the skeletal muscle loss and malnutrition associated with cirrhosis. Dietary supplementation with BCAAs (only necessary in those intolerant of protein) improves the relative deficit of these compared to aromatic amino acids and improves the rate of recovery from episodic hepatic encephalopathy. L-carnitine supplementation has also been demonstrated to improve cognitive deficits and reduce ammonia levels.[144]

Table 59.10 Treatment of Hepatic Encephalopathy

Identify and treat precipitating factors: Disordered carbohydrate metabolism Drugs (benzodiazepines, barbiturates) Infection (spontaneous bacterial peritonitis, other) Hypotension Hypoxia Excess exogenous protein Gastrointestinal bleeding Electrolyte abnormalities Alkalosis Constipation
Supportive therapy: Eliminate dietary nitrogen Purge gastrointestinal tract to remove blood and other nitrogenous compounds Nonabsorbable antibiotics (Rifaximin) Lactulose (or lactitol)
Dopamine receptor agonists: L-dopa and bromocriptine[a]
Branched-chain amino acid[b]
Temporary liver support
Orthotopic liver transplantation

[a] Arousal effect in selected patients may be secondary to enhanced renal function.

[b] High cost and equivocal benefits of intravenous amino acid mixtures make it difficult to justify routine use.

Lactulose is a nonabsorbable disaccharide that acts as a cathartic when administered orally and is a mainstay of therapy. A dose of 45 to 90 g/d divided in two to four doses is generally effective and is adjusted to produce two to three bowel movements per day. Lactulose reaches the distal ileum

and colon where it is metabolized by intestinal bacteria and enhances the bacterial uptake of ammonia.[145] Hourly doses of 30 to 45 mL of lactulose can be administered to induce more rapid improvement during the initial phase of therapy and symptoms may abate within 24 hours to 48 hours. Side effects include flatulence, diarrhea, and electrolyte abnormalities.

Nonabsorbable antibiotics have also been used to decrease the number and concentration of ammonia-forming bacteria in the gut. Rifaximin is a minimally absorbed macrolide antibiotic. The addition of rifaximin to lactulose has been shown to result in a higher proportion of patients experiencing complete reversal of hepatic encephalopathy (76% vs. 50.8%) and decreased mortality (23.1% vs. 49.1%) compared to lactulose and placebo.[146] Based on current evidence, the treatment of hepatic encephalopathy should consist of treatment of any precipitating factors, followed by lactulose administration. Rifaximin should be added for patients without improvement in the first 24 hours. Following an episode of overt hepatic encephalopathy, maintenance therapy with lactulose with or without rifaximin should be administered indefinitely as secondary prophylaxis.[147]

Neomycin and metronidazole are antibiotics active against gram-negative anaerobes such as *Bacteroides*. Some studies have shown that neomycin for 4 days is equally as effective as lactulose,[148] and metronidazole for 7 days is as effective as neomycin.[149] In addition, for chronic hepatic encephalopathy, neomycin for 10 days was equal to lactulose.[150] However, other RCT evidence has shown no difference comparing neomycin versus placebo.[151] Due to the risk of nephrotoxicity and irreversible ototoxicity, neomycin therapy has fallen out of favor.[147] Metronidazole is associated with neurotoxicity.

PORTAL HYPERTENSION

8 Portal hypertension is defined as a portal vein pressure above the normal range of 5 to 8 mm Hg. It may also be defined by a hepatic vein–portal vein pressure gradient (HVPG) greater than 5 mm Hg.[152] Pressures in the portal venous system are usually measured indirectly via the wedged hepatic venous pressure using a technique similar to that used to determine

pulmonary capillary wedge pressure by pulmonary arterial (Swan–Ganz) catheterization.

Current guidelines recommend classification of cirrhosis into compensated and decompensated stages and further substaging compensated cirrhotic patients into those with mild portal hypertension and those with clinically significant portal hypertension (CSPH).[153] CSPH predicts the development of more advanced stages of disease. Patients with CSPH are divided into those with and without gastroesophageal varices. Treatment of portal hypertension differs depending on the stage and substages of cirrhosis, because prognosis, mechanisms of disease, and therapeutic targets are different. Clinically significant portal hypertension is defined by an HVPG equal to or greater than 10 mm Hg (the gold-standard method of assessment). If HVPG is unavailable, noninvasive testing resulting in a liver stiffness >20 to 25 kPa with low platelets, splenomegaly, or presence of portosystemic collaterals on imaging demonstrates CSPH. Ongoing screening endoscopy for varices should be performed in patients with CSPH.

Anatomy

The venous anatomy of the portal system is relatively constant, with the "usual" anatomy present in 98% of the population. The portal vein is formed by the confluence of the superior mesenteric and splenic veins behind the neck of the pancreas. The inferior mesenteric vein most often joins the splenic vein before the portal vein is formed. A third of people have the inferior mesenteric vein joining the superior mesenteric vein. Occasionally, the superior mesenteric vein is not present and the portal vein is formed by multiple smaller mesenteric branches which join the splenic vein.

Portosystemic Collaterals

As portal hypertension develops, portal pressure rises in tributaries of the portal vein. This elevated pressure results in the expansion and dilation of these tributaries as well as of the portosystemic collateral venous communications. The sites of portosystemic communication have important clinical consequences. Dilation of and increased flow through the coronary or left gastric vein becomes highly significant in portal hypertension. The

result is increasing portal blood flow to the veins of the lesser curve of the stomach and the esophagus, leading to the formation of esophageal and gastric varices as well as portal hypertensive gastropathy. The inferior mesenteric vein communicates with rectal branches that distend to form hemorrhoids; the umbilical vein remnant communicates with the left portal vein and dilates in portal hypertension to carry blood through the ligamentum teres of the falciform ligament to veins of the abdominal wall. This paraumbilical plexus dilates and becomes visible on examination as the "caput medusae." Splenic venous flow increases and dilates the short gastric veins further contributing to gastric varices. Retroperitoneal collaterals (**Fig. 59.7**) also form and can create large splenorenal shunts that decompress the portal system but are associated with severe encephalopathy.

Pathophysiology

Increased resistance to portal blood flow may occur at different levels, within the liver (intrahepatic) secondary to cirrhosis, prehepatic in situations of portal vein thrombosis, or posthepatic in hepatic venous obstruction. Normally, the porous hepatic venous sinusoids of the liver offer little resistance to portal flow. Moreover, the liver has limited control over portal blood flow; it is primarily a passive recipient of splanchnic flow which is regulated at the level of the splanchnic arterioles.[154] As discussed above, collagen deposition in the space of Disse and contractile stellate cells cause increased resistance within the liver to portal blood flow. Furthermore, splanchnic vasodilatation and increased splanchnic flow occurs as a response to cytokine and hormonal alterations.

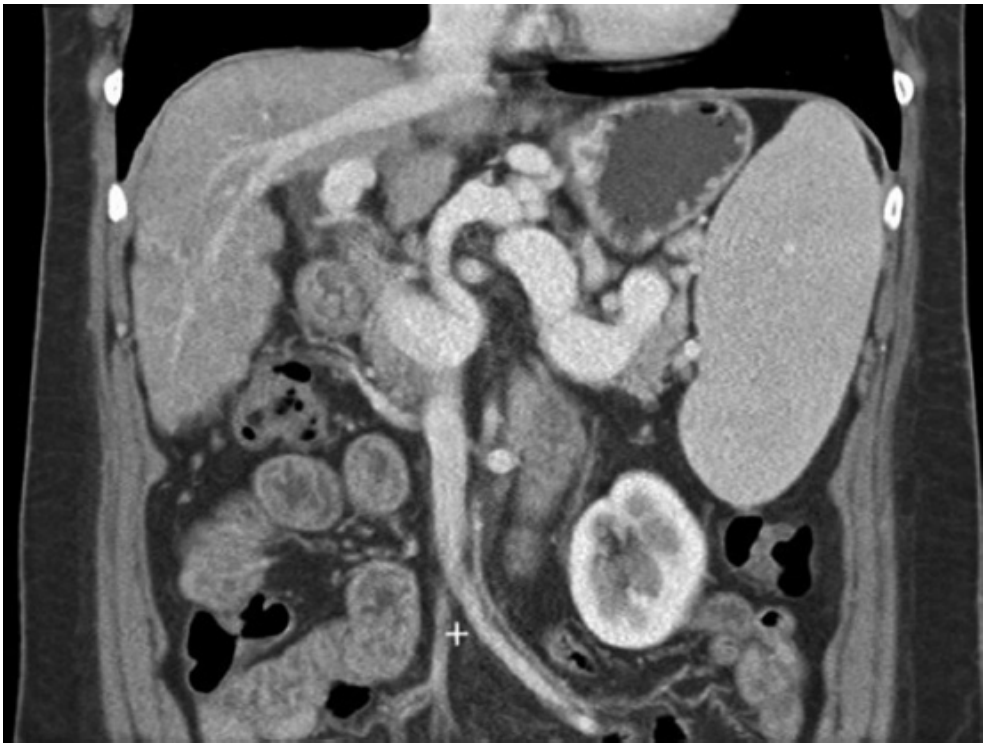

Figure 59.7 Coronal CT of a cirrhotic patient. Portal venous phase is shown demonstrating retroperitoneal collaterals and splenomegaly. (Image courtesy of Dr. Ihab Khamel, Department of Radiology, Johns Hopkins Hospital.)

The increased blood flow through collateral vessels and subsequently increased venous return cause the characteristic hemodynamic features of portal hypertension. An increased venous return via collateral vessels results in a subsequent increase in cardiac output and total blood volume and a fall in systemic vascular resistance.[155] Initially, blood pressure is normal, however with disease progression blood pressure falls.[156]

Nitric oxide, a potent vasodilator, as well as other vasodilators (prostacyclin, endotoxin, and glucagon) are elevated in patients with cirrhosis and portal hypertension.[157,158]

Etiology

Different pathologic processes cause portal hypertension (**Table 59.11**). These are classified as prehepatic, intrahepatic (presinusoidal, sinusoidal, or postsinusoidal), or posthepatic conditions. As noted above, in prehepatic and posthepatic conditions, portal hypertension is the result of mechanical venous

obstruction at the level of the portal or hepatic veins, respectively, whereas cirrhosis is the main cause of hepatic portal hypertension.

Budd–Chiari Syndrome and Veno-Occlusive Disease

Budd[159] described the classic presentation of BCS—abdominal pain, ascites, and hepatomegaly. Chiari[160] described the pathologic characteristics of the liver. Venous obstruction and hepatic venous occlusion causes an increase in pressure in the central veins with centrilobular congestion, necrosis, fibrosis, and cirrhosis with portal hypertension.

Common causes in Western populations are hypercoagulable states associated with polycythemia vera, myeloproliferative disorders, paroxysmal nocturnal hemoglobinuria, and hypercoagulable disorders.[161,162] In Eastern countries, the major causes of obstruction of the vena cava and hepatic veins are membranous webs that directly occlude the vessels. The etiology of these webs is unknown. Veno-occlusive disease is characterized by obliterative endophlebitis of the intrahepatic veins. Causes of veno-occlusive disease include medications, toxins, and pyrrolizidine alkaloids (naturally occurring alkaloids in some plant species).

BCS may present with acute, subacute, or chronic symptoms and is often misdiagnosed. Nearly 50% of patients have had symptoms for more than 3 months.[163] Early treatment prevents the development of hepatic fibrosis and the inevitable progression to end-stage liver disease. Acute symptoms include: hepatomegaly, right upper quadrant abdominal pain, nausea, vomiting, and ascites. Patients may present with the complications of cirrhosis and portal hypertension if presentation is late. In the chronic form, the liver atrophies except for the caudate lobe, which may hypertrophy. This is a classic hallmark of the disease and occurs because the caudate venous outflow into the vena cava is preserved. Compensatory hypertrophy of the caudate then occurs. The hypertrophied caudate lobe narrows the retrohepatic vena cava it surrounds. This may be completely obliterated with total obstruction of blood flow.

Although the diagnosis can be made by ultrasonographic evaluation of the liver and its vasculature with a sensitivity of 85% to 95%,[161] cross-sectional imaging assists in staging and planning therapy. Duplex ultrasound may reveal the location of the obstruction and characterize flow within the vena

cava and hepatic, portal, mesenteric, and splenic veins. Other common findings consistent with BCS include a lack of visualization of the hepatic veins, an enlarged caudate lobe with compressed vena cava, enlarged intrahepatic collaterals, splenomegaly, and ascites.[95] Thrombus within the hepatic veins or IVC may be seen.[164]

Because the vascular obstruction is usually well established at the time of presentation, anticoagulation alone is rarely sufficient therapy for BCS. Historically, major open operations, including mesoatrial shunting,[165,166] and liver transplantation[167] were favored. However, minimally invasive approaches are now preferred with percutaneous portacaval shunting effective in achieving decompression of the portal system.[168]

Table 59.11 Common Causes of Portal Hypertension

Prehepatic
Congenital atresia
Extrinsic compression
Schistosomiasis
Portal, superior mesenteric, or splenic vein thrombosis
Splanchnic arteriovenous fistula

Intrahepatic (Presinusoidal)
Schistosomiasis
Idiopathic noncirrhotic portal hypertension (including nodular regenerative hyperplasia)
Primary biliary cholangitis (PBC)
Sarcoidosis
Congenital hepatic fibrosis
Primary sclerosing cholangitis
Adult polycystic liver disease
Vinyl chloride toxicity
Neoplastic occlusion of portal vein

Intrahepatic (Sinusoidal)
Arsenic poisoning
Vinyl chloride toxicity
Drugs (e.g., amiodarone, methotrexate)

Chronic–Cirrhotic
NASH
Hepatitis B, C
Alcohol
α_1-Antitrypsin deficiency
Cryptogenic
Cystic fibrosis
Hemochromatosis
Wilson's disease

Chronic–Noncirrhotic
Congenital hepatic fibrosis
Focal regenerative hyperplasia

Hepatic veno-occlusive disease Gaucher disease Amyloid or light chain deposition in the space of Disse Mastocytosis Sarcoidosis
Intrahepatic (Postsinusoidal) Budd–Chiari syndrome Sinusoidal obstruction syndrome (veno-occlusive disease) Chronic radiation injury Vitamin A toxicity Epithelioid hemangioendothelioma Sarcoidosis
Posthepatic Cardiac disease (Chronic heart failure, constrictive pericarditis) IVC obstruction (e.g., Budd–Chiari syndrome) Vena cava webs

Creation of a mesoatrial shunt at surgery has been used to achieve decompression in the past in situations when bridging fibrosis was not present and transplant not indicated. This was first described by Cameron and Maddrey and involves decompressing the portal system by bypassing the hepatic veins and narrowed IVC.[165] After abdominal incision, the superior mesenteric vein is exposed. A 16-mm mesoatrial prosthesis (ring reinforced graft) is positioned and tunneled under the sternum into the right chest after a right lateral thoracotomy. The pericardium is opened and right atrium and appendage exposed. This graft is anastomosed first to the superior mesenteric vein and subsequently right atrial anastomosis completed.

Today, decompression of the portal system is achieved percutaneously via transjugular intrahepatic portosystemic shunt (TIPS) procedure. Contrary to TIPS in other settings of cirrhosis and portal hypertension, the rates of postprocedural encephalopathy are usually not increased in patients with BCS, because they have anatomically healthy livers that are able to recover fully if decompression is achieved early, prior to the establishment of cirrhosis. If BCS results in fibrosis and cirrhosis, liver transplantation may

be necessary. Postoperatively, patients require long-term anticoagulation to prevent recurrent thrombosis.

As noted, TIPS may be used as first-line therapy, and it has supplanted surgical shunting in the modern era.[169–171] One- and 5-year survival rates after TIPS have been demonstrated to be 93% and 74%, respectively.[171] Many patients develop shunt occlusion; however, further angiographic manipulation and long-term anticoagulation can be performed and maintain patency.

Portal Vein Thrombosis

Portal vein thrombosis is commonly associated with advanced cirrhosis, and may herald the occurrence of HCC. In children, portal vein thrombosis in the absence of cirrhosis is the most common cause of cirrhosis. However, this spontaneous portal venous thrombosis is uncommon in adults.[172,173] In contrast to patients with cirrhosis-induced portal hypertension, these patients have normal liver function and are not susceptible to the development of complications such as encephalopathy. Causes of portal vein thrombosis include umbilical vein infection (the most common cause in children), coagulopathies (protein C and antithrombin III deficiency), hepatic malignancy, myeloproliferative disorders, inflammatory bowel disease, pancreatitis, trauma, and previous splenorenal shunt.[174] In patients with cirrhosis, a rebalanced hemostasis system prone to hypercoagulability can also contribute. This is mostly due to decreased levels of protein C and elevated levels of factor VIII.[175] Most cases in adults are idiopathic.

Imaging shows an echogenic lesion in the lumen of the portal vein and an absence of portal venous flow on duplex examination. With time, cavernous transformation of the portal vein may occur, in which channels develop within the chronically thrombosed, recanalizing portal vein.[172] CT and MRI are also useful in establishing the diagnosis. Portal vein thrombosis in a noncirrhotic patient may manifest initially with variceal bleeding. Splenomegaly is an important clinical sign.

The initial therapeutic option for the control of hemorrhage caused by portal vein thrombosis is endoscopic esophageal variceal ligation. If unsuccessful, the distal splenorenal shunt has been the traditional surgical treatment for patients with isolated portal vein thrombosis. In patients whose

intrahepatic portal vein is patent (most commonly children), a shunt may be created between the superior mesenteric vein and the patent left portal vein within the parenchyma of the liver (Rex shunt). This may be performed with internal jugular vein and may be the optimal therapeutic procedure for reestablishing physiologic portal flow.[176] This solution reduces portal pressure by restoring blood flow to the liver, preventing chronic hepatic atrophy and dysfunction which would otherwise occur. Many consider the Rex shunt to be the first-line treatment with splenorenal shunting reserved for patients who have no remnant intrahepatic portal system to receive the shunted blood.

Splenic Vein Thrombosis

Splenic vein thrombosis is most often caused by disorders of the pancreas, including acute and chronic pancreatitis, trauma, malignancy and pancreatic pseudocyst. This association is related to the proximity of the splenic vein posterior to and abutting the pancreas. Other causes of thrombosis include retroperitoneal masses, abscesses, and inflammatory bowel disease; the remaining cases are idiopathic. The thrombosis results in isolated "sinistral" or "left-sided" portal hypertension. This increased venous pressure causes the development of gastric varices, which are present in approximately 80% of patients, and esophageal varices in 30% to 40%.[177] Patients, who are expected to have normal liver function, are readily cured with splenectomy, although observation for asymptomatic patients is acceptable. The main indication for splenectomy is variceal hemorrhage.

Complications of Portal Hypertension

9 The most important, potentially lethal complication of portal hypertension is GI bleeding secondary to esophageal and gastric varices. Ascites and hepatic encephalopathy are other debilitating complications. The mortality risk associated with portal hypertension is primarily related to the functional status of the cirrhotic liver. In 1964, Child and Turcotte introduced a scoring system of liver function for the purposes of assessing prognosis after portosystemic shunt surgery in patients with cirrhosis. This has been subsequently modified several times to the *Child–Turcotte–Pugh (CTP)*

score (**Table 59.12**). These indices incorporate clinical and laboratory data as a means to assess the functional status of the liver, estimate hepatic reserve, and predict morbidity and mortality. These criteria were adopted by the United Network for Organ Sharing (UNOS) as a tool for stratifying pretransplant mortality risk for patients on the waiting list for liver transplantation.[178] Over the last decade, the use of these criteria in transplant has been replaced by the model for end-stage liver disease (MELD) score, which uses serum bilirubin, creatinine, and the international normalized ratio (INR) to produce a surprisingly robust prediction of 90-day mortality for patients with cirrhosis on the transplant list.[179] Subsequently, the inclusion of serum sodium to create the MELD-Na score was introduced in 2016 into allocation of livers for transplantation, after it was demonstrated that hyponatremia is associated with increased mortality in patients with end-stage liver disease. Though the CTP score produces a more complete assessment of the patient, its use of subjective clinical components introduces potential variability by clinicians in the assessment of degree of liver disease and therefore makes it unreliable as a verifiable element in assessment of compliance with center behavior in national organ transplant policy.[180,181]

Table 59.12 Child–Turcotte Criteria for Hepatic Functional Reserve

Criterion	Class A	Class B	Class C
Encephalopathy	None	Minimal	Advanced
Ascites	None	Easily controlled	Poorly controlled
Bilirubin (mg/dL)	<2	2–3	>3
Albumin (g/gL)	>3.5	3–3.5	<3
Nutrition	Excellent	Good	Poor, "wasting"
Child–Turcotte–Pugh Grading of Severity of Liver Disease			
Score	**1**	**2**	**3**
Encephalopathy	None	1 or 2	3 or 4
Ascites	None	Mild	Moderate
Bilirubin (mg/dL)	1–2	2.1–3	≥3.1
Albumin (g/dL)	≥3.5	2.8–3.5	≤2.7
Prothrombin time (s)	1–4	4.1–6	≥6.1
or INR	<1.7	1.7–2.3	>2.3
Grade A, 5–6; grade B, 7–9; grade C, 10–15			

INR, international normalized ratio.

Adapted from Pugh RN, Murray-Lyon IM, Dawson JL, et al. Transection of the oesophagus for bleeding oesophageal varices. *Br J Surg* 1973;60(8):646–649, with permission.

While the MELD score was initially developed to determine prognosis of patients after undergoing TIPS, the CTP score has had long-standing use as a reliable predictor of mortality risk for shunt surgery and mortality risk of patients with cirrhosis undergoing other types of abdominal surgery.[182–184] Patients with normal function, termed "Child A," have adequate hepatic reserve and survival rates similar to those of noncirrhotic patients, whereas Child C patients have mortality rates in excess of 50% and may not tolerate any intervention except liver transplantation.

Varices

One of the most life-threatening complications of portal hypertension is bleeding from esophageal varices. Esophageal varices are dilated veins found most commonly in the distal 5 cm of the esophagus. In the normal esophagus, a venous plexus is located in the submucosa; in the distal esophagus, it becomes more superficial within the lamina propria.[185–187] This anatomy gives rise to the known increased incidence of bleeding occurring from distal esophageal varices. In addition, 5% to 33% of patients with portal hypertension have gastric varices.[188]

As portal venous system pressure increases, varices are more likely to develop. Varices generally do not develop in persons with HVPGs less than 12 mm Hg. Pressure gradients above 12 mm Hg are invariably present in patients with varices, but this pressure does not necessarily produce varices in all patients. Gastroesophageal varices are present in 40% of patients with Child A cirrhosis, and in up to 85% of patients with Child C cirrhosis.[153] Varices may also be present in chronic liver disease without frank cirrhosis. For example, 16% of patients with chronic hepatitis C and bridging fibrosis have varices.[189]

Esophageal varices are the cause of upper GI bleeding in approximately 10% of all patients presenting with acute bleeding. Conversely, cirrhotic patients bleed from sources other than varices (e.g., peptic ulcer disease) in up to 40% of cases. Risk of variceal bleeding increases with duration present and variceal size. Approximately half of patient with cirrhosis have esophageal varices, and one-third of all patients with varices will develop variceal hemorrhage with the highest risk during the first year after diagnosis.[153,190–192] Patients with large varices are at the greatest risk for an

initial bleed. Variceal bleeding ceases without intervention in up to 40% of patients, although the risk of mortality and recurrent bleeding remain high.[153] Of patients who survive an episode of bleeding, 30% rebleed within 6 weeks, and 70% at 1 year.[192,194] Mortality from bleeding varies, from 5% for Child's A, less than 25% for Child's B, and more than 50% for Child C patients, respectively.[194]

When combined with clinical data such as the presence of active alcohol consumption, certain endoscopic characteristics of varices have been correlated with initial episodes of bleeding. Variceal size, Child–Pugh class, and the presence of red wale markings (longitudinal dilated venules) are contributing factors. Direct and indirect measurements of portal pressure have been used to predict the likelihood of bleeding, with hemorrhage occurring only in patients with portal–hepatic venous gradients above 12 mm Hg.[195,196]

Diagnosis of Varices and Prevention of Initial Variceal Bleeding

Given the importance of variceal bleeding, methods to diagnose varices and to prevent both initial bleed (primary prophylaxis) as well as recurrent bleeding episodes (secondary prophylaxis) have been developed. Esophagogastroduodenoscopy (EGD) is the gold standard for the diagnosis of gastroesophageal varices, and is indicated upon the initial diagnosis of cirrhosis and after 2 to 3 years if none are present. If small (<5-mm) varices are present, EGD is repeated in 1 to 2 years, and if patients have decompensated cirrhosis, yearly endoscopic screening is recommended by the AASLD. After diagnosis of varices, primary and secondary bleeding prophylaxis is implemented and includes control of the underlying cause of cirrhosis (i.e., alcohol consumption or HCV treatment) and pharmacologic and surgical interventions to lower portal pressure.

Primary Prophylaxis for Prevention of Variceal Bleeding. In early-stage cirrhosis prior to the development of clinically significant portal hypertension, treatment aims to prevent progression, decompensation, and potentially allow for regression of cirrhosis. Elimination of the etiologic agent (e.g., alcohol, virus) at the current time is the mainstay of this strategy.

Beta Blockade: The use of nonspecific β-adrenergic blockade (NSBB) for prevention of variceal bleeding has been studied extensively in RCTs. There is no evidence that NSBB prevents the development of varices in patients without clinically significant portal hypertension.[153] NSBB such as propranolol and nadolol achieve β_1-adrenergic and β_2-adrenergic blockade which decreases cardiac output and increases splanchnic arteriolar vasoconstriction due to diminished β_2-adrenergic mediated dilation.[196,197] The end result is a decrease in portal blood flow and portal pressure (**Table 59.13**).

Whether portal hypertension is due to prehepatic, intrahepatic, or posthepatic conditions, these drugs are effective in pressure reduction.[198] The goal of therapy is to reduce the HVPG to less than 12 mm Hg or to more than 20% below baseline.[199] Meeting these goals decreases bleeding risk as well as the risk of developing ascites, SBP, and death.[200] Two meta-analyses evaluating seven RCTs show efficacy of propranolol or nadolol versus placebo in preventing initial bleeding: risk of bleeding is reduced by 40%, with a bleeding risk of 27% in placebo versus 16% in treated patients.[199,201,202] In patients with cirrhosis, both with and without ascites, who responded to lowering of portal pressure (based on reduction in HVPG), NSBB has also been shown to reduce events (ascites, variceal hemorrhage, SBP, HRS, encephalopathy), reduce mortality and requirement for liver transplantation.[203] Side effects of beta-blockers, however, may limit use, and it has been shown that they do not prevent the formation of varices in patients who do not yet have them.[204]

Surgical Intervention as Prevention. In the 1950s and 1960s, surgeons used surgical portosystemic shunts in an attempt to prevent variceal bleeding. Randomized trials showed that these procedures were effective in preventing variceal bleeding, but were associated with an increased incidence of hepatic failure and encephalopathy and had no effect on overall survival.[205,206] Indeed, these results provided clinical support for the notion that portal diversion accelerates the decline of liver function in patients with cirrhosis. These procedures are no longer performed for this indication.

Endoscopic Sclerotherapy and Variceal Ligation. While previously an accepted practice, due to technical challenges and the incidence of esophageal and pulmonary complications, endoscopic sclerotherapy (ES) as primary prevention of variceal bleeding is no longer practiced. Variceal ligation (EVL) as a method of primary prophylaxis to prevent initial bleeding in high-risk patients with varices initially reported mixed results.[207–209] Consensus recommendations regarding prophylaxis are now published in practice guidelines from the AASLD: patients with cirrhosis with small, high-risk varices (i.e., presence of red whale markings or occurring in a CTP-C patient) should be managed with beta-blocker prophylaxis; patients with medium or large varices should undergo EVL or beta blockade with NSBB or carvedilol as primary prophylaxis.[153]

Table 59.13 Primary Prophylaxis: Management for Patients with Varices That Have Not Bled

Drug	Dose	Therapy Goals	Maintenance/Follow-up
Propranolol	▪ 20–40 mg bid adjusted every 2–3 d to a maximum of 320 mg/d in patients without ascites (160 mg/d in patients with ascites)	▪ Resting HR of 55–60 bpm ▪ Systolic BP should not decrease <90 mm Hg	▪ Monitor HR to ensure on target at every outpatient visit ▪ Continue indefinitely ▪ No need for follow-up EGD
Nadolol	▪ 20–40 mg orally once daily adjusted every 2–3 d to maximum of 160 mg/d in patients with ascites (80 mg/d in patients without ascites)		
Carvedilol	▪ Start with 6.25 mg	Systolic BP should not	▪ Continue indefinitely

	once a day ▪ After 3 d increase to 6.25 mg twice a day ▪ Maximum dose 12.5 mg/d	decrease <90 mm Hg	▪ No need for follow-up EGD
Endoscopic variceal ligation	▪ Every 2–8 wks until the eradication of varices	▪ Variceal eradication	▪ First EGD 3–6 mo after eradication and every 6–12 mo thereafter

HR, heart rate; BP, blood pressure.

Esophageal Variceal Bleeding

Initial Management. Esophageal variceal bleeding (**Table 59.14**) is a life-threatening emergency requiring intensive care. Patients who recover from the first episode of variceal hemorrhage have a high rebleeding risk (60% in the first year) with a mortality of up to 33%.

Table 59.14 Guidelines for Management of Patients Presenting with an Acute Bleed

Resuscitation, intravenous access, endotracheal intubation, and ICU care as indicated
Performance of endoscopic evaluation within 12 hrs of bleed, and if variceal hemorrhage is suspected, variceal ligation should be performed
Intravenous vasoactive drugs should be initiated and continued for 2–5 d with addition of nonselective beta blockade once these are discontinued
TIPS is indicated if hemorrhage is not controlled or if bleeding recurs despite pharmacologic therapy and variceal ligation
Prophylactic antibiotics (ceftriaxone) should be initiated

Adapted from: Garcia-Tsao G, Abraldes JG, Berzigotti A, et al. Portal hypertensive bleeding in cirrhosis: Risk stratification, diagnosis, and management: 2016 practice guidance by the American Association for the study of liver diseases. *Hepatology* 2017;65(1):310–355.

Initial management is similar to any other emergency due to hemorrhage: The airway is immediately secured, attention is given to ensuring adequate oxygenation and ventilation, and secure large bore iv access is obtained. Laboratory studies aiding resuscitation include measurement of hemoglobin and hematocrit, coagulation status, liver function, electrolytes and renal function.

Resuscitation begins with administration of packed red blood cells (PRBCs), platelets, and fresh frozen plasma as well as intravenous crystalloid as appropriate, and care is transitioned to an intensive care setting. Transfusion using a restrictive strategy (initiating PRBC transfusion at a hemoglobin threshold of 7 g/dL and maintaining it at 7 to 9 g/dL) is associated with a significant decrease in mortality compared to a "liberal" transfusion strategy (initiating PRBC transfusion at a hemoglobin threshold of 9 g/dL and maintaining it at 9 to 11 g/dL). Lower rebleeding and mortality rates were seen in cirrhotic patients randomized to the restrictive strategy.[210] Transfusion and volume expansion in the individual patient should take into account other factors, such as age, cardiovascular disorders, ongoing

bleeding, and hemodynamic status. It should also be noted that INR is not a reliable indicator of coagulation status in the setting of cirrhosis. There are currently no recommendations regarding the administration of platelets or the administration of coagulation factors, while RCTs examining the effect of administration of factor VIIa have not shown a clear benefit.

Cirrhotic patients who bleed are at a high risk of developing bacterial infections, including SBP. RCTs have shown that the use of antibiotic prophylaxis leads to a decrease in the development of infections, recurrent bleeding, and death. Seven days of intravenous ceftriaxone (1 g every 24 hours) is a standard recommendation.

Pharmacologic Therapy. The administration of vasoactive medications should be commenced if variceal bleeding is suggested (**Table 59.15**). A meta-analysis of 30 RCTs shows that the use of vasoactive agents in acute variceal hemorrhage is associated with lower 7-day all-cause mortality and lower transfusion requirements.[211] Vasoactive decrease the rate of bleeding and enhance the endoscopist's ability to visualize the site(s) of bleeding.

Vasopressin (antidiuretic hormone) has potent splanchnic vasoconstrictive properties that decrease portal and collateral blood flow. Continuous intravenous administration of vasopressin has been shown to reduce variceal bleeding, an observation initially made in 1962 and confirmed on several occasions.[212–214] Compared to placebo, vasopressin stopped bleeding in 52% versus 18% of patients. However, rates of rebleeding as high as 45% were noted. Vasopressin should be used in combination with a vasodilator, such as nitroglycerin to protect against coronary artery constriction, decrease cardiac events, and decrease intrahepatic and collateral resistance.[215,216]

Table 59.15 Vasoactive Agents Used in the Management of Acute Variceal Hemorrhage

Octreotide (somatostatin analog)	50-mcg IV bolus (can be repeated in first hour for ongoing bleeding), followed by 50 mcg/h continuous infusion	2–5 d
Vasopressin (with nitroglycerin)	0.2–0.4 U/min can be increased to 0.8 U/min. It should always be accompanied by nitroglycerin IV at a starting dose of 50 mcg/min (max 400 mcg/min) titrated to maintain SBP at approximately 90 mm Hg	24 hrs
Somatostatin	Initial IV bolus of 250 mcg (can be repeated in first hour if ongoing bleeding) Continuous IV infusion of 250–500 mcg/hr	2–5 d
Terlipressin (Vasopressin analog)	Initial 48 hrs: 2 mg IV every 4 hrs until control of bleeding Maintenance: 1 mg IV every 4 hrs to prevent rebleeding	2–5 d

Adapted from Garcia-Tsao G, Abraldes JG, Berzigotti A, et al. Portal hypertensive bleeding in cirrhosis: Risk stratification, diagnosis, and management: 2016 Practice Guidance by the American Association for the Study of Liver Diseases. *Hepatology* 2017;65(1):310–355.

Somatostatin and octreotide, its longer-acting eight-amino acid derivative, have been used extensively for the treatment of variceal bleeding. These agents decrease splanchnic blood flow indirectly rather than by direct vasoconstriction.[217] Effects of somatostatin are limited to the splanchnic circulation, so that side effects are minimized.[218] In multiple studies, somatostatin and octreotide have proved to be as effective as vasopressin, sclerotherapy, and balloon tamponade.[219–221] A meta-analysis showed octreotide to be more effective than vasopressin in achieving hemostasis.[211] Octreotide is therefore the drug of choice in the United States. Dosing typically consists of a bolus of 50 µg followed by an infusion of 50 µg/hr, to

be initiated as soon as variceal bleeding is suspected and continued for 3 to 5 days after the diagnosis has been verified.[153]

Endoscopic Interventions. Esophageal variceal ligation is performed at urgent endoscopy when varices are the source of bleeding. Signs of variceal bleeding at endoscopy include: a visualized actively bleeding varix, a "white nipple" sign, and blood in the stomach within 24 hours of a bleed without any other evident cause. The endoscopist proceeds to suction the varix into the lumen of a plastic channel and a rubber band is fired over the varix to complete ligation (**Fig. 59.8**). The varix and bleed is controlled and the tissue sloughs after 1 to 3 days, leaving a shallow ulcer.

Success rates for variceal ligation range from 80% to 100%. Ligation compares favorably to sclerotherapy.[222] Sclerotherapy can be used if bleeding is profuse such that visualization is difficult.

Balloon Tamponade. Up to 20% of variceal hemorrhage episodes may be refractory to standard therapy, and in these circumstances balloon tamponade (**Fig. 59.9**) can bridge to a definitive therapy such a TIPS. Tamponade has high success rate in controlling bleeding but is also associated with a high rate of serious adverse events and a mortality rate near 20%. Tamponade entails the placement of a specialized nasogastric tube (the Sengstaken–Blakemore and Minnesota tubes) with two balloons that can be inflated separately to different pressures. These balloons compress varices present at the gastroesophageal junction and the esophagus. Once the mainstay in the initial management of variceal bleeding, use of these tubes is rare and the techniques involved in placing them are becoming a lost art. Incorrect use may cause fatal complications due to esophageal injury. The Sengstaken–Blakemore tube consists of a gastric and an esophageal balloon with a sump port for gastric suctioning. The Minnesota tube has an additional port above the esophageal balloon for aspiration of saliva and other material.

Prior to tube placement, patients undergo endotracheal intubation to maintain a safe airway. The tube is then passed through the nose and into the stomach. Imaging confirms placement of the tip of the tube in the stomach

before balloon inflation. This is critical to avoid inflation of the gastric balloon within the esophagus and subsequent esophageal perforation. The gastric balloon is inflated with 200 mL of air and firmly pulled backward against the gastroesophageal junction to tamponade any proximal gastric bleeding. The esophageal balloon is then inflated to a pressure of 30 to 40 mm Hg, and the tube is secured in position by means of a facemask or helmet to stabilize the tube and prevent inadvertent removal.

Complications of balloon tamponade include aspiration, esophageal and gastric perforation, and necrosis. These may occur in 10% to 20% of patients. Use is restricted to 24 hours to reduce the chance of these complications. Success rates for cessation of bleeding are 70% to 80%, but more than half of all patients rebleed when the balloons are deflated. Although this method is highly effective in the initial control of bleeding, because of its transient effect it is only a temporizing bridge to a more definitive procedure (e.g., TIPS, surgical shunting, or transplantation) and is used only after endoscopic and pharmacologic therapies have failed.

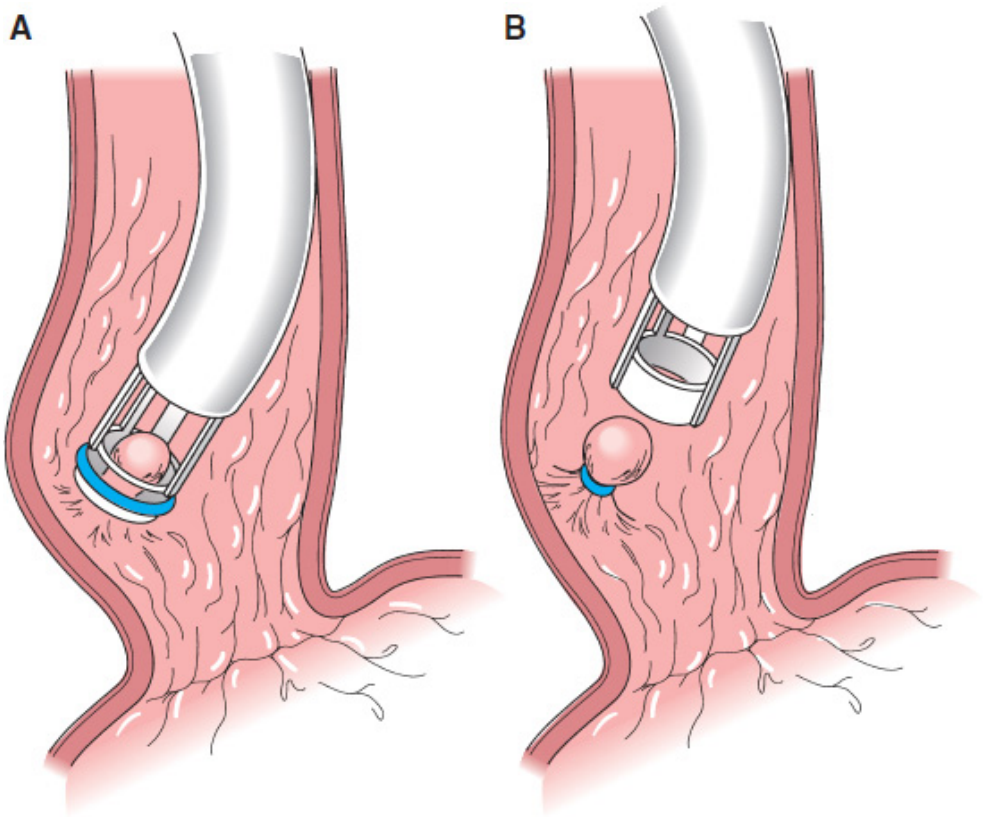

Figure 59.8 Endoscopic ligation of esophageal varices. The device used for ligation is based on the standard Barron-type ligator for the treatment of anal hemorrhoids. The esophageal varix is drawn up into the ligating device with suction (**A**), and the base of the varix is ligated with an O-ring (**B**). Up to six varices can be treated at a single session.

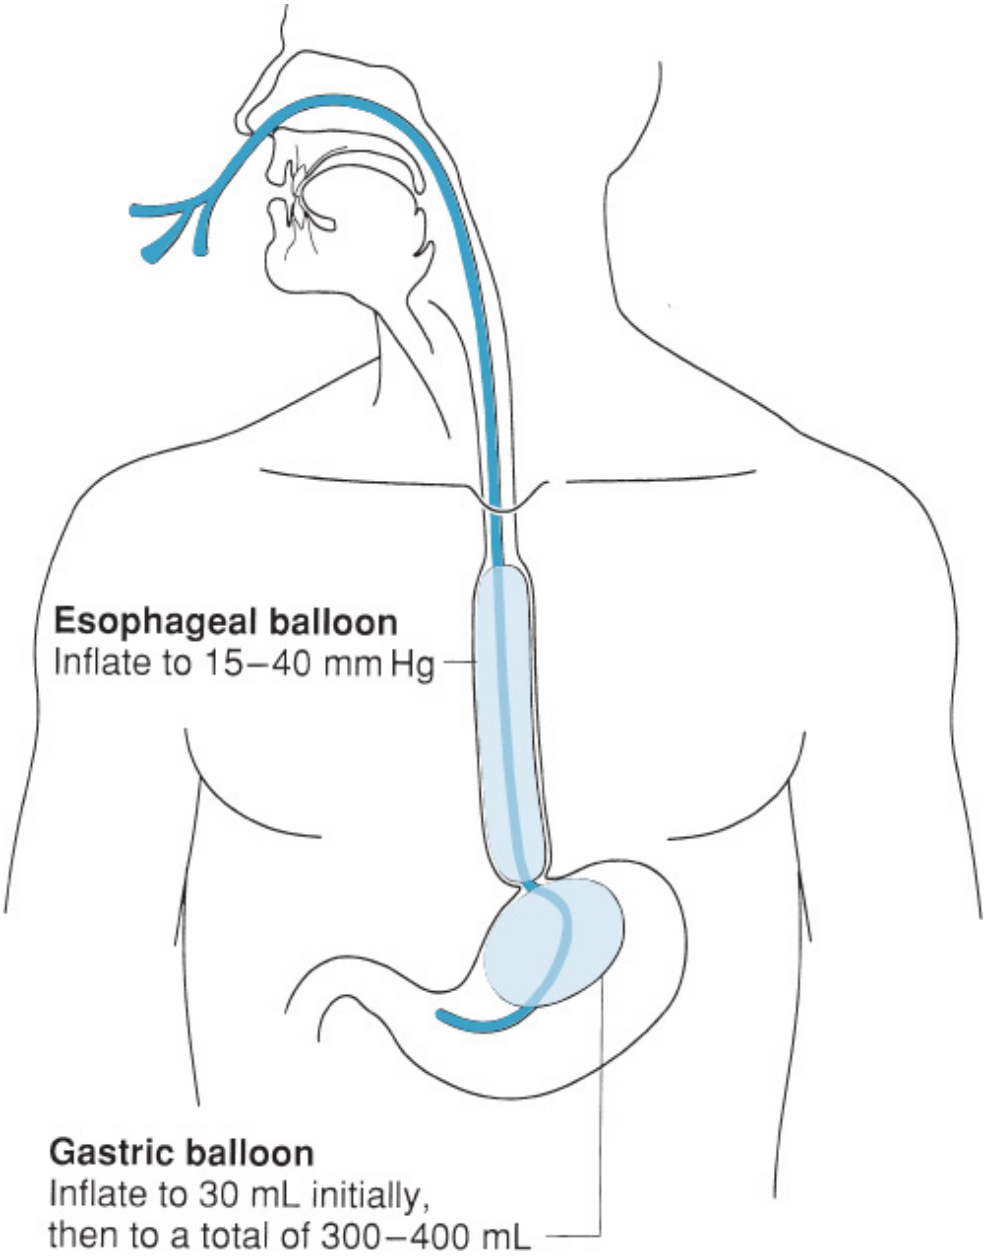

Figure 59.9 The Sengstaken–Blakemore tube is used to tamponade acutely bleeding gastroesophageal varices. The tube has three lumina—one to aspirate the stomach, another to inflate the gastric balloon, and a third to inflate the esophageal balloon. Patients treated with balloon tamponade should be in an intensive care unit, and endotracheal tubes should be placed in almost all to prevent aspiration.

Esophageal Stenting. Another technique that has recently been introduced is the endoscopic placement of self-expanding metal stents. This may achieve better control of bleeding with fewer side effects although no survival benefit has been shown compared to

balloon tamponade. An advantage to stenting is that the stent can stay in place for up to 7 days until definitive therapy.

Transjugular Intrahepatic Portosystemic Shunt. In the 10% to 20% of patients who continue to bleed or who have early rebleeding, additional procedures are indicated. Historically, surgical shunts were performed to bypass the high-pressure hepatic vascular bed. The mortality rate associated with failure to control bleeding can be in excess of 90%, and surgically created shunts in this setting were associated with a high morbidity and mortality rate.

10 TIPS (**Figs. 59.10** and **59.11**) has become first-line treatment for bleeding esophageal varices when the aforementioned attempts fail.[223] Absolute contraindications to TIPS include congestive heart failure, uncontrolled sepsis, multiple hepatic cysts, severe pulmonary hypertension, and uncontrolled biliary obstruction. Relative contraindications include HCC, hepatic vein obstruction, severe coagulopathy or thrombocytopenia, and moderate pulmonary hypertension.[224] After ultrasonographic confirmation of patency of the portal vein, the procedure is performed in the interventional radiology suite, where a stent (8 to 12 mm in diameter) is placed percutaneously over a wire into the jugular vein. The wire is then guided through the superior vena cava, right atrium, and IVC into a hepatic vein, after which the catheter traverses the hepatic parenchyma and connects the hepatic vein to a portal vein (usually the right portal vein). This connection creates a side-to-side portacaval shunt. Success rates in the cessation of variceal bleeding are as high as 90% to 100%, with an incidence of recurrent bleeding of approximately 10%.[225,226]

The ideal portosystemic shunt lowers the portal pressure without critically reducing liver perfusion. This avoids causing hepatic dysfunction, which would accelerate the progression of cirrhosis. It is possible to measure the portal pressure during TIPS, and this can guide optimal management of the TIPS to balance control of bleeding with hepatic perfusion. To control bleeding, the therapeutic goal is to reduce the hepatic venous pressure gradient (HVPG) to below 12 mm Hg. TIPS reduces the HVPG to a mean of approximately 9 to 15 mm Hg (average, 10 mm Hg) or to 40% to 62% below baseline.[227–229] A residual HVPG less than 5 mm Hg has been associated with a deleterious impact on hepatic flow.[230] Since well-validated

instruments predict the survival of patients after TIPS, the procedure should be used with caution in patients with high MELD scores, though TIPS has been used successfully to bridge to transplant.[231] The use of TIPS in massive variceal bleeding in a patient with a high MELD score who has contraindications to liver transplant should be regarded as a palliative intervention.

As with all portosystemic shunts, a significant complication of TIPS is the development of hepatic encephalopathy. The rate of encephalopathy following TIPS is 34%, compared to 19% following EVL for acute variceal bleeding, although the use of covered TIPS stents has reduced the rate of post-TIPS encephalopathy from when bare metal stents were used primarily.[232,233] Early series showed stenosis or occlusion of the TIPS stent developing in up to 50% to 60% of patients in the first year. Long-term patency is now maintained by ongoing surveillance of the shunt with redilatation, thrombolysis, or replacement as required. Current shunts are lined with polytetrafluoroethylene (PTFE) and have a much higher patency than the original permeable wall stents. Primary patency rates are 76% to 89% with shunt dysfunction occurring in 15% of patients at 1 year.[224] Patients are usually followed at 6-month intervals by ultrasonography to assess the patency of the shunt, with HCC screening at the same time. At 6 months of follow-up, 92% of patients had no episodes of rebleeding, and 82% were free of hemorrhage at 1 year. TIPS has become the standard procedure used to halt bleeding in patients who fail medical therapy. The ability to effectively decompress the portal circulation without open surgery in these critically ill patients has transformed clinical hepatology. Patients who become stable can be evaluated for transplantation electively.

Patients Who Have Recovered from an Episode of Acute Variceal Hemorrhage

Patients who recover from the first episode of variceal bleeding have a 60% chance of rebleeding in the first year with a mortality of up to 33%. These patients therefore must receive therapy to prevent rebleeding (**Table 59.16**). First-line therapy in these patients is the combination of NSBB and variceal ligation, with pharmacotherapy the cornerstone.[153] In a recent multicenter RCT, TIPS (using covered stents) when compared to endoscopic variceal ligation or glue injection plus NSBB, showed a lower rebleeding rate (0%

vs. 29%) in patients treated with covered TIPS. However, there was no difference in survival but a higher incidence of early encephalopathy in the TIPS group.[234]

In medically treated patients, the lowest rebleeding rates are observed in patients on secondary prophylaxis who are HVPG responders (defined as a reduction in HVPG below 12 mm Hg or >20% from baseline) on pharmacotherapy. An RCT of covered TIPS versus HVPG-guided therapy (propranolol and isosorbide mononitrate) showed lower rates of rebleeding in patients randomized to TIPS (7% vs. 26%) without differences in survival and with a higher incidence of encephalopathy in the TIPS group.[235] However, HVPG measurement is not available in all centers.

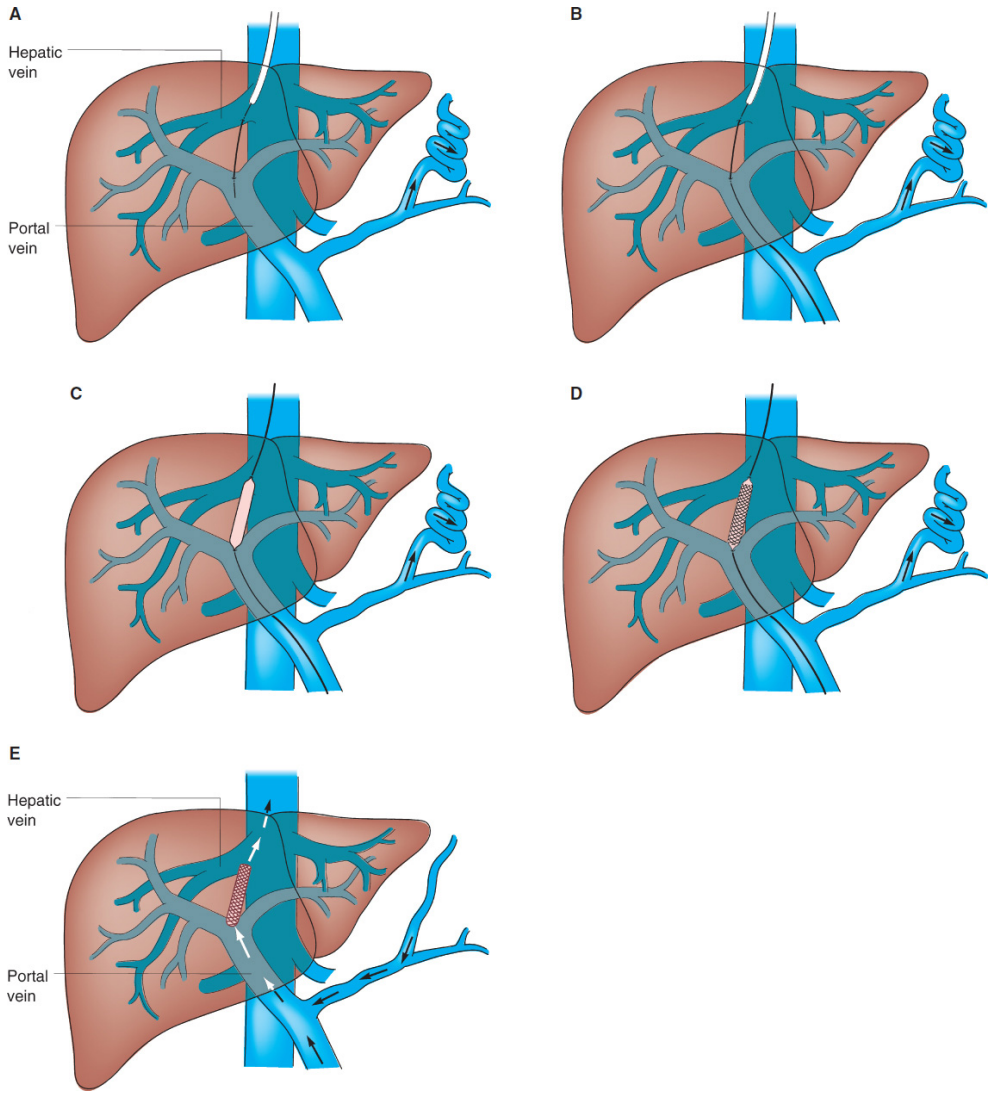

Figure 59.10 Schematic representation of the steps used to create a transjugular intrahepatic portosystemic shunt. **A:** A needle is directed from the IVC or hepatic veins into an intrahepatic portal venous branch. **B:** A guidewire is advanced into the portal venous system. **C:** The resulting tract is then balloon dilated. **D:** A stent is then placed into the dilated tract. **E:** Completed TIPS shunt. *Arrows* indicate direction of blood flow.

11 *Surgical Decompression*

Background. Orthotopic liver transplantation is the definitive treatment for portal hypertension caused by cirrhosis. As discussed above, most patients with bleeding esophageal varices are managed by TIPS or variceal band ligation and NSBB. The introduction and increased use of TIPS has virtually eliminated the need for

emergency portosystemic shunting. There is a small group of patients with portal hypertension whose bleeding cannot be controlled by endoscopy who may be candidates for shunting procedures if they have sufficient hepatic reserve that liver transplant is not indicated, or if patients have portal hypertension due to prehepatic conditions (e.g., portal vein thrombosis).

Shunts. Shunts can be classified by the degree to which they divert blood from the liver, which has important physiologic consequences. Surgical portosystemic shunts include (a) totally diverting (nonselective) shunts, (b) partially diverting shunts, and (c) selective shunts. Total shunts completely divert blood flow from the liver. Examples include both the end-to-side portacaval shunt (Eck fistula) (**Fig. 59.12**) and the large-diameter (>10-mm) side-to-side portacaval (**Fig. 59.13**), interposition mesocaval, and central splenorenal shunts. The mesoatrial shunt is described above in the section dealing with BCS.

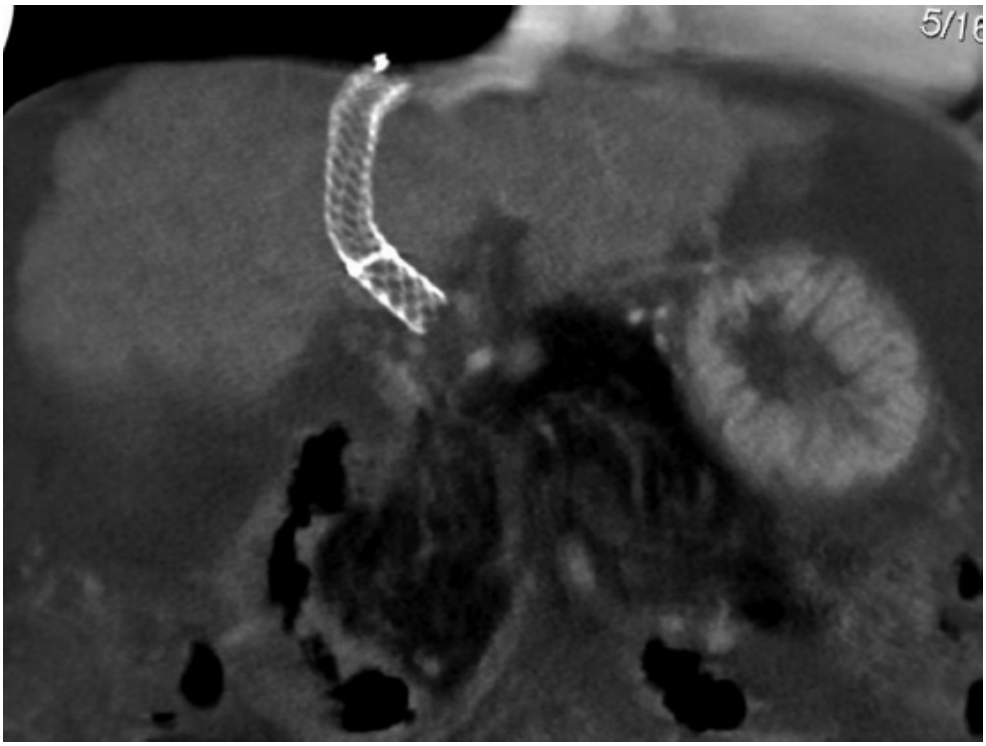

Figure 59.11 Liver MRI, coronal view showing TIPS in situ from right portal vein to right hepatic vein. (Image courtesy of Dr. Ihab Khamel, Department of Radiology, Johns Hopkins Hospital.)

In determining direction and degree of blood flow, the diameter of the anastomosis is critical. Resistance within the portal system in the liver is elevated as a result of cirrhosis. The portal pressure required to overcome this resistance is much higher than that present in the systemic venous system. Because of this pressure difference, large diameter side-to-side shunts divert virtually all blood flow into the low resistance systemic venous system via the IVC. Portal venous blood flow at the level of the liver may become reversed (hepatofugal) and total hepatic perfusion decreased. Ultimately, totally diverting, nonselective shunts result in complete portal blood flow diversion, a lower portal pressure, and are highly effective in treating bleeding varices. They may however accelerate hepatic decompensation via both diminished hepatic flow and removal of hepatotrophic substances present in mesenteric venous flow. Nonselective shunting also leads to hepatic encephalopathy, but may also be used to treat ascites.

When initially proposed, it was suggested that **partially diverting shunts** decompressed the portal venous system sufficiently while maintaining prograde, hepatopetal portal flow into the liver. This contention has been debated extensively. Initial shunts were created with a diameter larger than 10 mm, which maintained some antegrade hepatic flow. After shunt creation, however, in most instances complete or total shunting occurred over time as the shunt dilated and the gradient between portal pressure and IVC pressure disappeared. Smaller shunts were therefore created. Small-diameter (8-mm) side-to-side mesocaval (**Fig. 59.14**) and portacaval (Sarfeh or interposition "H" graft) (**Fig. 59.15**) shunts are performed with an interposition graft made of either expanded PTFE or dacron. The interposition "H" portacaval shunt involves ligation of portasystemic collaterals. The umbilical vein within the falciform ligament, the coronary (left gastric), the gastroepiploic along the greater curve of the stomach and inferior mesenteric veins are usually divided. Bleeding from varices resolves in more than 90% of patients. This smaller-diameter shunt has a higher resistance than the larger shunt, is synthetic and therefore does not dilate, can maintain hepatic perfusion, and is associated with a lower incidence of hepatic encephalopathy. Portal pressure gradients are reduced and hepatopetal flow is maintained in the majority of patients. Shunt thrombosis is a complication which may occurs in up to 16% of patients,[236] but can be treated angiographically.

Table 59.16 Secondary Prophylaxis: Guidelines for Prevention of Rebleeding after Variceal Hemorrhage

Maximal tolerated dosing of nonselective beta blockade with serial EVL until all varices are obliterated is performed, unless TIPS has been placed
Patients should then undergo surveillance EGD every 6–12 mo to evaluate for recurrent varices
Those patients who are candidates should be referred to a transplant center for timely evaluation

Adapted from Garcia-Tsao G, Abraldes JG, Berzigotti A, et al. Portal hypertensive bleeding in cirrhosis: Risk stratification, diagnosis, and management: 2016 practice guidance by the American Association for the study of liver diseases. *Hepatology* 2017;65(1):310–355.

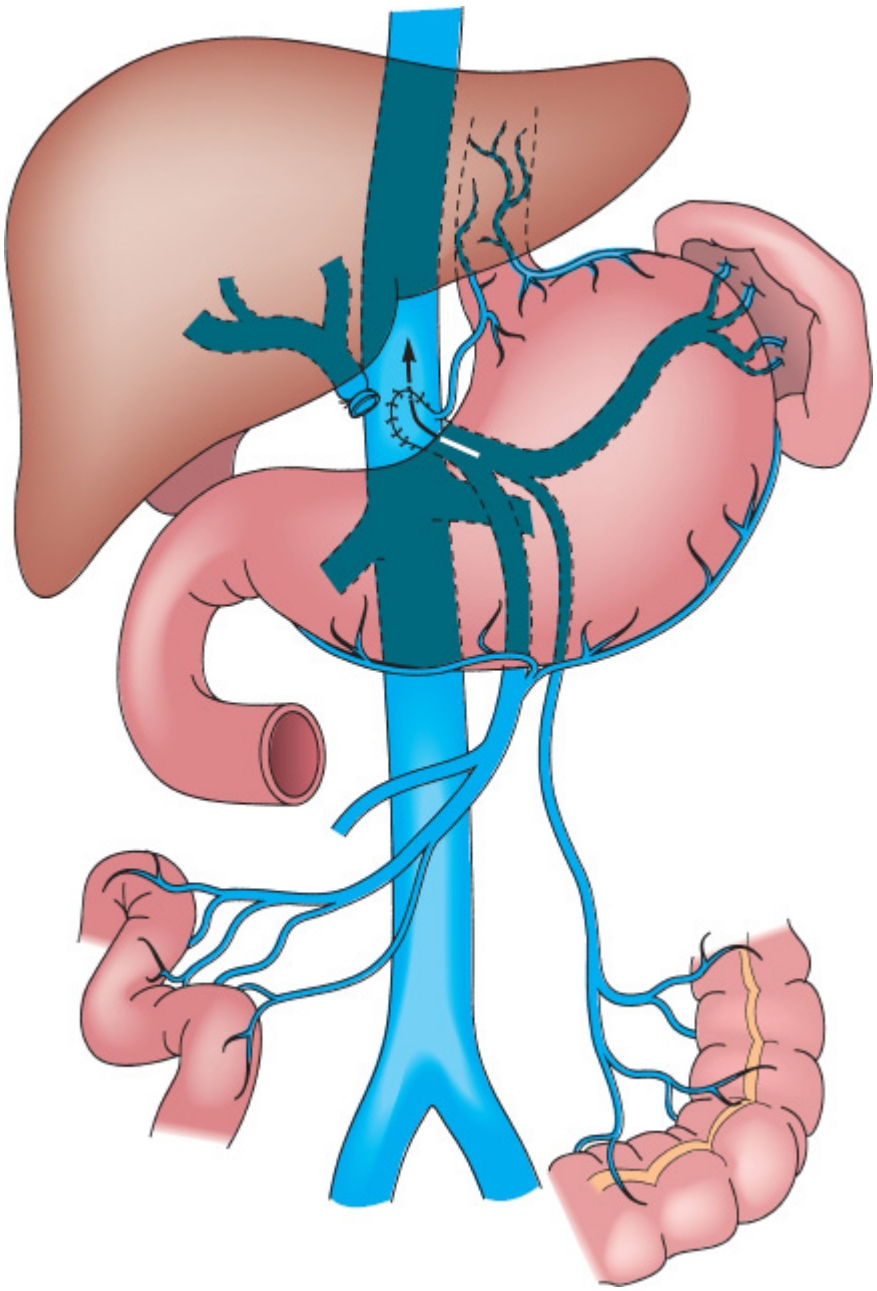

Figure 59.12 End-to-side, totally diverting portacaval shunt (Eck fistula). The portal vein is divided, the hepatic limb of the portal vein is ligated, and the splanchnic end of the portal vein is anastomosed end to side to the IVC. All portal blood is diverted into the IVC, and the hepatic limb of the portal vein cannot serve as an outflow tract.

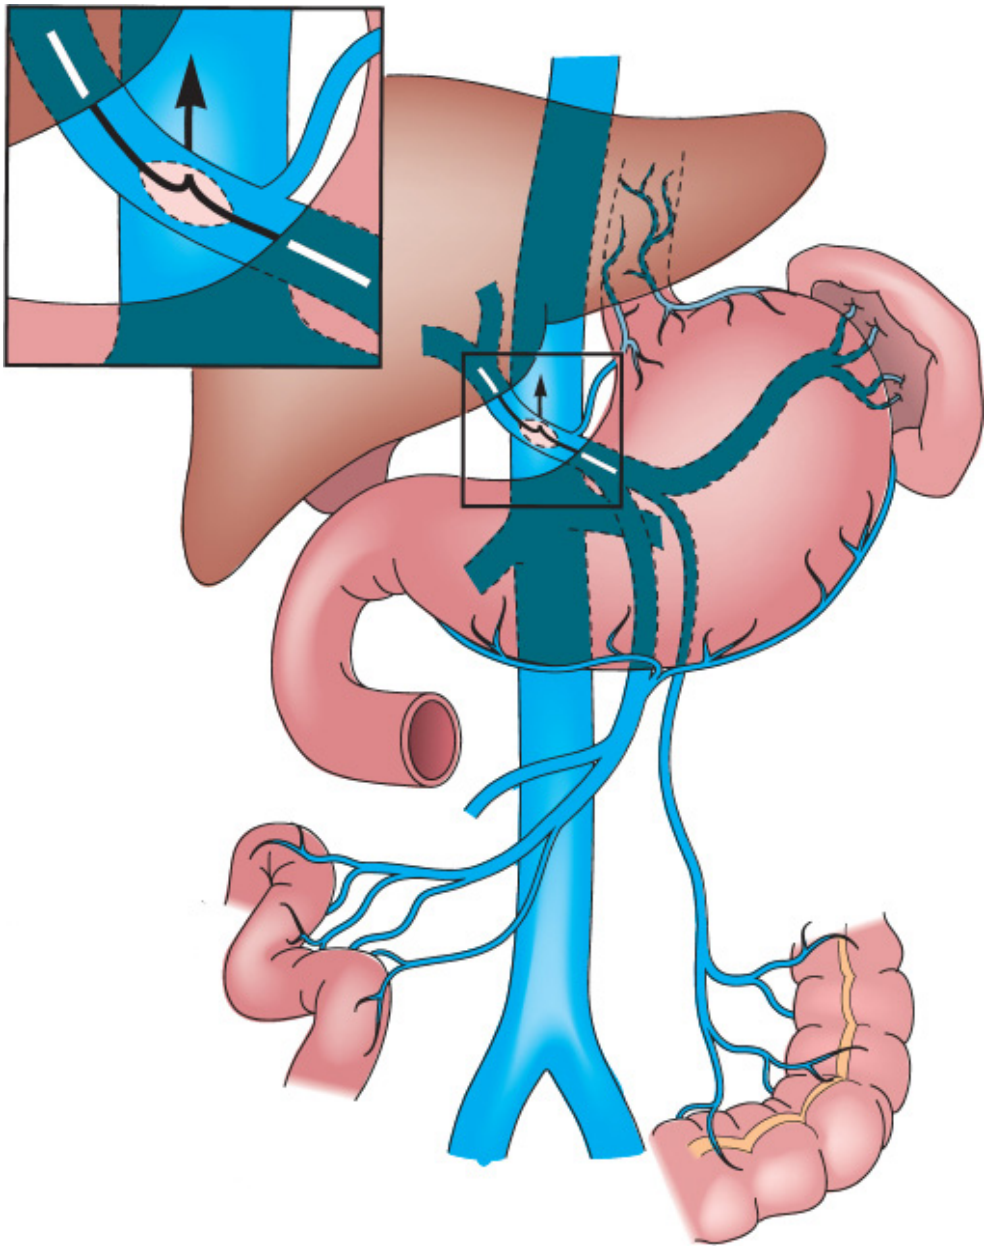

Figure 59.13 Side-to-side portacaval shunt. An anastomosis is made between the side of the portal vein and the side of the inferior vena cava. With a shunt of standard diameter, almost all splanchnic blood is diverted around the liver into the low-pressure vena cava. The hepatic limb of the portal vein serves as an outflow tract from the liver toward the low-pressure vena cava.

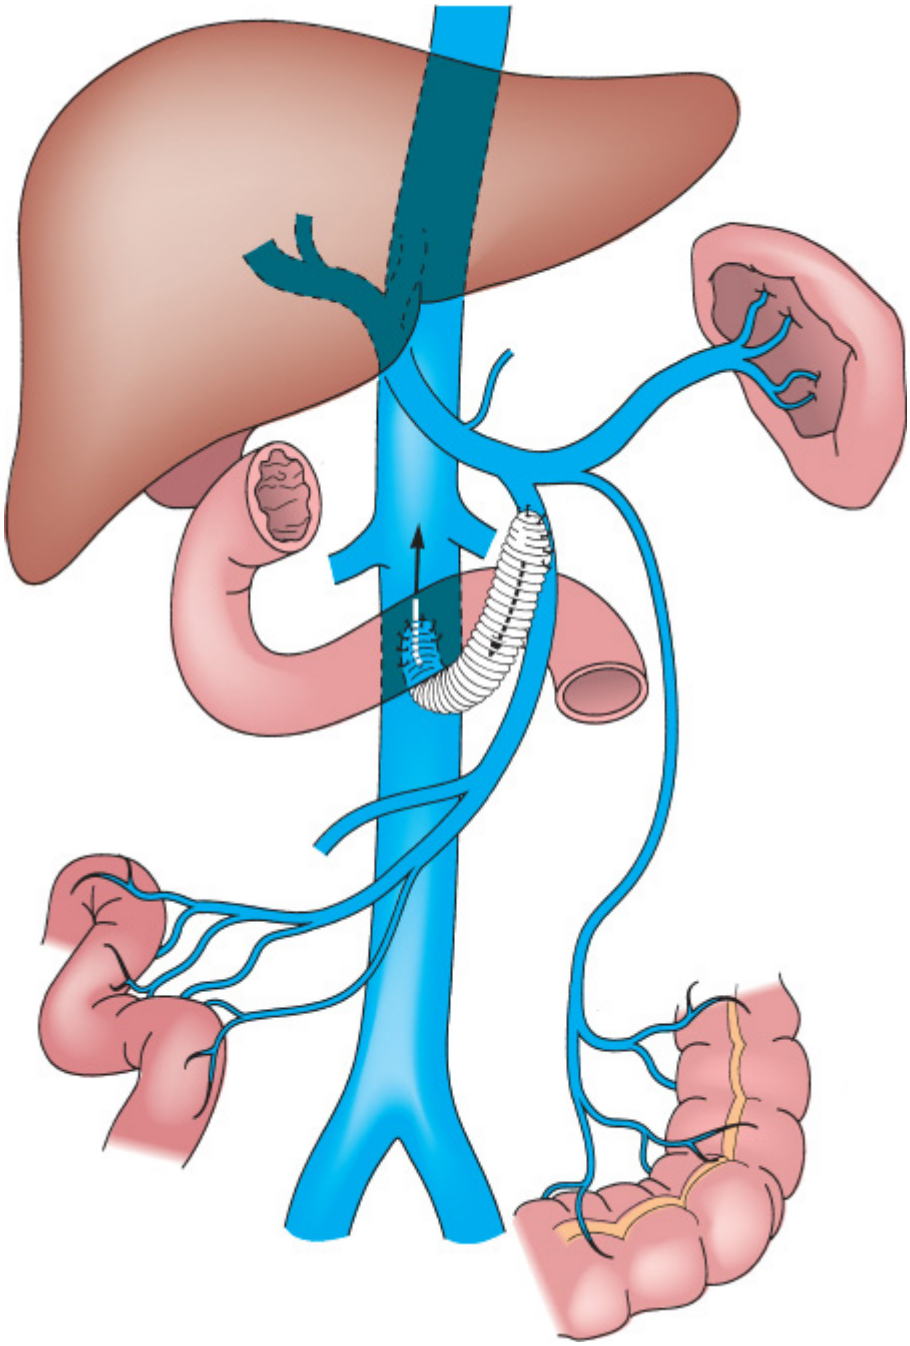

Figure 59.14 Interposition mesocaval shunt. A plastic prosthesis or an autogenous internal jugular vein is used for the shunt. One end is anastomosed to the inferior vena cava, and the other end is anastomosed to the trunk of the superior mesenteric vein. The shunt curves around the lower edge of the third portion of the duodenum and is sometimes called a C-shunt.

Selective shunts are designed to create two separate drainage systems within the portal venous network. High pressure is maintained within the mesenteric system and a low pressure is created in the esophagogastric

system by shunting blood from these varices into the systemic circulation without decompressing the mesenteric network. The most traditional and favored selective shunt is the distal splenorenal shunt. This technically demanding shunt (**Fig. 59.16**) decompresses the gastroesophageal venous system through an anastomosis between the distal splenic vein and the side of the renal vein. Decompression occurs through the vasa brevia (short gastric veins), which are in continuity with the splenic vein. In addition, as in the small side-to-side shunts described earlier, collateral veins must be ligated.

The distal splenorenal shunt was first introduced to reduce the portasystemic encephalopathy that results in some patients after a total shunt. The distal splenorenal shunt controls bleeding in more than 90% of patients and has the advantage of not requiring dissection of the portahepatis. Hepatopetal flow is maintained and the incidence of encephalopathy (5% to 24%) and risk of progressive liver failure are lower.[237,238] Loss of prograde portal flow occurs as a result of either portal vein thrombosis (approximately 10% of patients) or increased flow through collaterals located along the pancreas. It is possible to completely dissect the splenic vein from the posterior pancreas (splenopancreatic disconnection) and prevent flow through the pancreatic collaterals, but this technique adds to the complexity of the operative procedure and to the incidence of complications.[239] Since sinusoidal pressure is not decreased by the distal splenorenal shunt, massive ascites is not treated by the procedure and the distal splenorenal shunt is relatively contraindicated in patients with significant ascites. Ligation of collateral vessels and lymphatics during the procedure increases portal pressures and may actually increase ascites. The presence of a small splenic vein increases the incidence of shunt thrombosis.

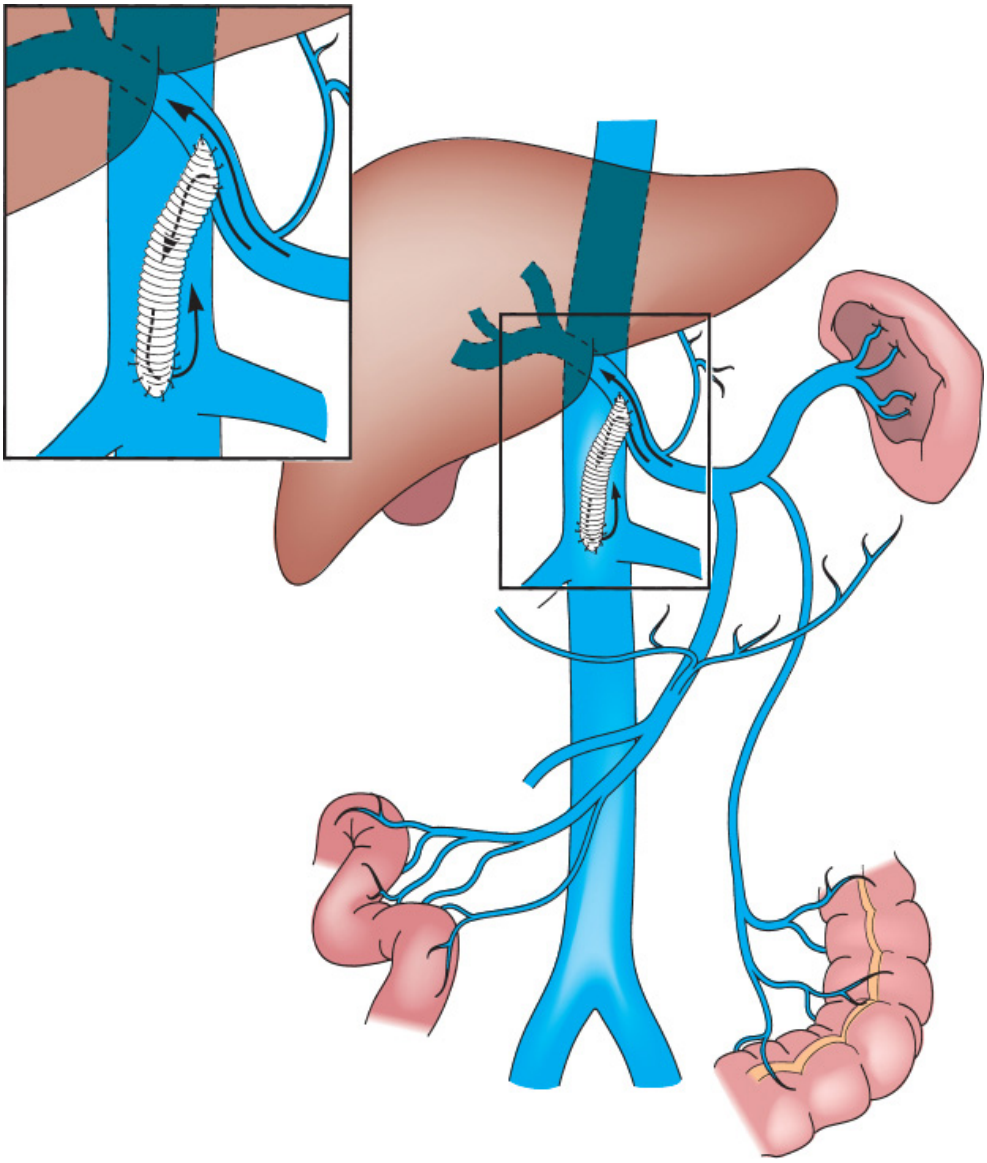

Figure 59.15 Small-diameter interposition portacaval Sarfeh shunt. A vascular prosthesis measuring 8 to 10 mm in diameter is interposed between the side of the vena cava and the side of the portal vein. The goal is to reduce portal pressure partially and thereby prevent variceal hemorrhage but still maintain sufficient pressure to permit the prograde flow of portal blood to the liver. This procedure is simpler to perform than that for the Warren shunt and theoretically avoids the problem of diversion of an increasing proportion of portal blood away from the liver over time, as occurs with the Warren shunt.

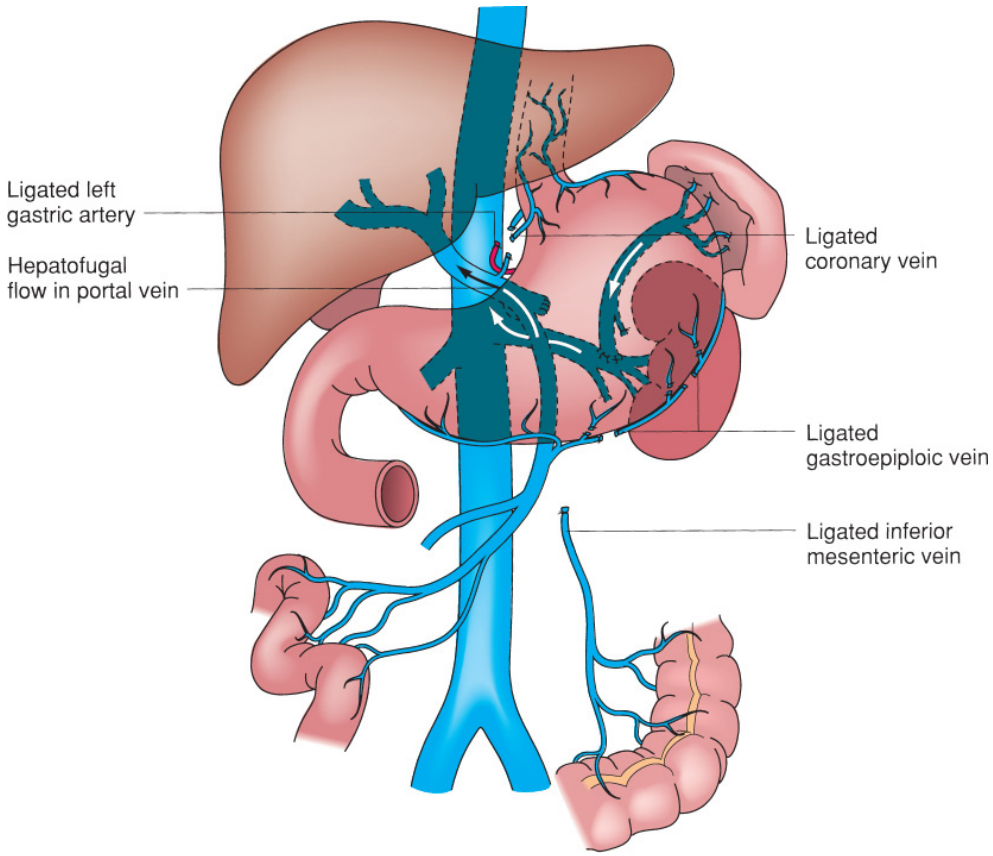

Figure 59.16 Distal splenorenal Warren shunt. The splenic vein is divided near its junction with the superior mesenteric vein. The distal end of the splenic vein is anastomosed to the renal vein. Varices are selectively decompressed through the stomach and short gastric veins into the splenic vein and then into the vena cava through the renal vein. Portal hypertension is maintained in the portal and superior mesenteric veins to provide enough pressure to drive portal blood through the diseased liver.

Trials comparing side-to-side total shunts with the distal splenorenal shunt found that both groups are equally effective (>90%) in the cessation of variceal hemorrhage.[240] The incidence of hepatic encephalopathy is lower after the distal splenorenal shunt, with rates of 36% and 15% for the total and selective shunts, respectively. Rates of rebleeding were similar and ranged from 0% to 30%, with no survival advantage for either procedure.

The side-to-side nonselective total shunt has also been used for the emergent treatment of bleeding varices. Cessation of bleeding occurred in all patients after surgery, and 99% of patients were completely free of episodes of rebleeding. The 5-year survival was approximately 80%, with the majority of deaths occurring during the first year after surgery as a result of

progressive hepatic failure. Hepatic encephalopathy requiring treatment occurred in 8% of patients. Of note, most of these patients had alcoholic liver disease, which recovers on withdrawal of alcohol.

Devascularization Procedures. Devascularization procedures are techniques in which the venous drainage of the stomach and esophagus is disconnected from the liver and intestinal vessels. These procedures are relatively less technically demanding than shunting procedures and can be performed in patients with extensive portal thrombosis. They do not interfere with hepatopetal blood flow and therefore do not increase the incidence of hepatic encephalopathy.

A range of procedures of varying complexity is possible. Esophageal transection with end-to-end reanastomosis (EEA) combined with ligation of the coronary vein (**Fig. 59.17**) is a relatively simple procedure. More complex is the Sugiura procedure (**Fig. 59.18**). This procedure involves splenectomy, devascularization of the proximal stomach and esophagus with esophageal transection and reanastomosis, and ligation of all gastroesophageal collaterals via abdominal and thoracic incisions.[241] A single abdominal incision procedure has been described.[242] Japanese researchers describe bleeding as recurring in fewer than 5% of patients in Japan, but rates of rebleeding are higher and range from 10% to 54% in other countries.[243] Operative mortality rates range from 10% to 35% and outcomes are certainly related to the severity of liver disease. Devascularization procedures are rarely performed today.

Hepatic Transplantation. Orthotopic liver transplantation is the definitive therapy for portal hypertension and cirrhosis. It is indicated for management of end-stage liver disease and has no role in the control of acute variceal bleeding. When successful, transplantation treats both the underlying disease many complications of end-stage liver disease.

In conclusion, open surgical intervention short of liver transplantation for patients with cirrhosis and portal hypertension is becoming a rarity. With the advent of TIPS, surgically created shunts are rarely indicated. While reintervention may be required after TIPS, the overwhelming efficacy and

safety of this procedure has essentially removed almost all need for open portal decompressive procedures.

Gastropathy and Gastric Varices

Approximately 20% of patients with cirrhosis also have gastric varices. The most commonly used classification for risk stratification and management of gastric varices is Sarin classification.[188] Location, size, presence of red spots, and severity of liver dysfunction influence bleeding risk. Cardiofundal varices should prompt investigation for portal or splenic vein thrombosis. Bleeding from gastric varices occurs in approximately 25% of affected patients and is usually more severe than bleeding from esophageal varices with rebleeding occurring in up to 30% of patients.[244] NSBB can be used to prevent bleeding from gastric varices, although data is not as robust. In a meta-analysis of three RCTs, sclerotherapy and EVL were found to be equally effective for initial hemostasis in controlling bleeding gastric varices, however cyanoacrylate injection is better at preventing rebleeding.[245] Other emerging endoscopic tools such as endoscopic ultrasound-guided insertion of coils or cyanoacrylate may provide more effective control but have not been well evaluated yet. Balloon tamponade may also be used as a temporizing measure. TIPS is highly effective as primary therapy for controlling gastric varices in patients who fail or cannot receive endoscopic therapy, with initial hemostasis rates of over 90% reported.[246] The distal splenorenal shunt is reserved for the rare patient who cannot receive TIPS.

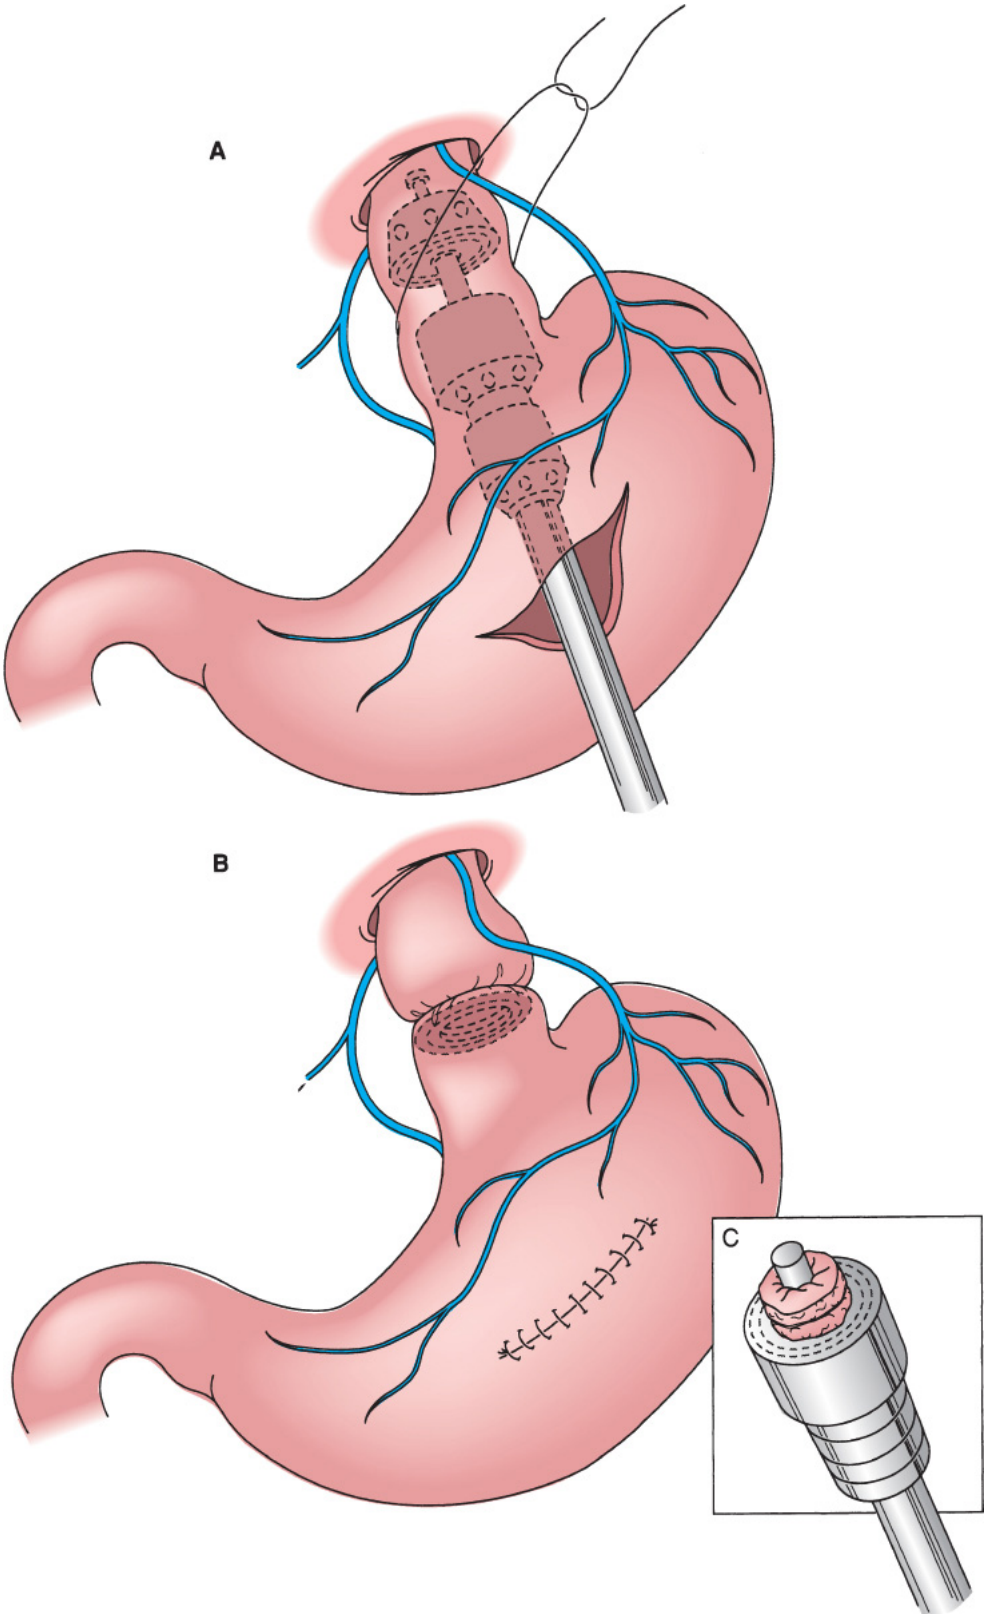

Figure 59.17 Transection and reanastomosis of the distal esophagus with the stapling device to control variceal hemorrhage. **A:** A stapling device is inserted

through a small gastrotomy incision. **B:** When the device is fired, the esophagus is simultaneously transected and reanastomosed with staples. **C:** If the device fires correctly, a complete ring of esophageal tissue is excised.

Balloon-occluded retrograde transvenous obliteration (BRTO) is a procedure for treatment of fundal varices associated with a large gastro/splenorenal collateral. In this procedure, blood flow to the liver is preserved but the large collateral is occluded using various techniques and the fundal varices are decompressed. A recent meta-analysis showed that BRTO and TIPS may have similar success rates in initial control of gastric variceal bleeding, but BRTO was associated with lower rates of rebleeding, hepatic encephalopathy, and mortality at 1 year.[247]

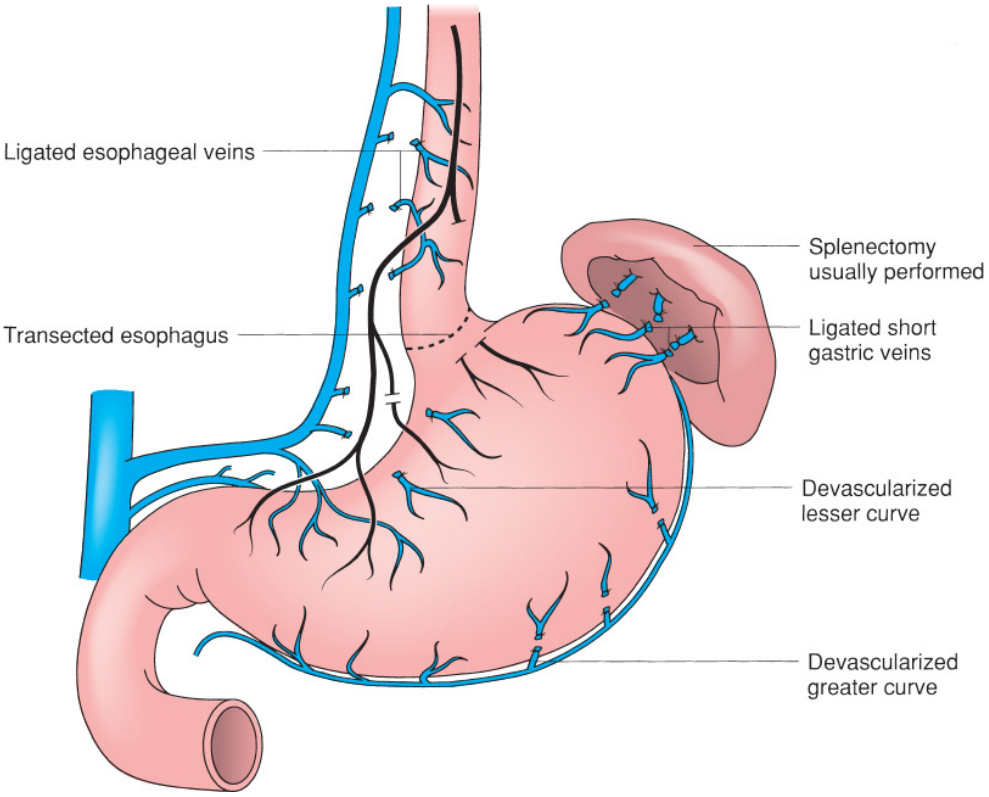

Figure 59.18 Sugiura esophageal transection and devascularization operation.

Portal Hypertensive Gastropathy. Portal hypertensive gastropathy is a condition characterized by dilation of the venules and capillaries of the gastric mucosa without associated inflammation. The major complication of gastropathy is bleeding; gastropathy accounts for 4%

to 38% of all episodes of acute bleeding in patients with cirrhosis.[248] TIPS may provide therapeutic decompression in this setting as well.

Ectopic Varices. Bleeding from ectopic varices is rare in cirrhotic patients, but more common in patients with prehepatic portal hypertension. Location and anatomy are variable, such that case-by-case assessment and management is necessary. Thin slice contrast-enhanced CT with portal venous phase imaging and large-volume diluted oral contrast will assist with diagnosis and delineation of anatomy. Frequent sites of ectopic variceal bleeding are surgically created stomas, duodenum, jejunoileum, and colon. A multidisciplinary approach to management is needed. Endoscopic therapy, TIPS, and BRTO may be useful therapies. Superficial stomal varices may be amenable to ultrasound-guided injection of cyanoacrylate or sclerosants.

Ascites

One of the most important consequences of hepatic dysfunction in cirrhosis and portal hypertension is ascites. Ascites is associated with markedly decreased survival rates. Unfortunately, it does not lead to any increased priority in organ allocation for transplant candidates. Ascites is defined as the accumulation of free fluid within the abdominal cavity (normally <150 mL). Causes of ascites are listed in **Table 59.17**. In cirrhosis, fluid is derived from a combination of hepatic (high in protein) and splanchnic (low in protein) lymphatic fluid that cannot be absorbed as a result of the increased hydrostatic pressures within the liver and splanchnic systems secondary to cirrhosis and capillarization of the space of Disse.[249] Because of the loss of sinusoidal fenestrations and a subsequent decrease in their permeability, splanchnic lymph is more abundant than hepatic lymph in patients with advancing cirrhosis, so that the protein content of ascitic fluid is relatively low.[250] The main underlying pathophysiology in the development of ascites is renal sodium and water retention, which leads to fluid overload.

Clinical and Laboratory Features

Ascites may be present in patients with cirrhosis who have no other overt signs or symptoms. Examination reveals shifting dullness to percussion (1.5

L of ascitic fluid), fluid waves (10 L), and bulging flanks.[251] Respiratory status may be compromised secondary to increased intra-abdominal pressure and pleural effusion (usually right). The progression may be slow or precipitated after an inciting event, such as a bleed or infection. Fluid filled umbilical and inguinal hernias may form and be present on examination.

DIAGNOSIS

Table 59.17 Differential Diagnosis of Ascites

Portal Hypertension
Cirrhosis and other intrahepatic diseases
Hepatic congestion
Congestive heart failure
Constrictive pericarditis
Inferior vena cava obstruction
Budd–Chiari syndrome
Portal vein occlusion
Hypoalbuminemia
Nephrotic syndrome
Protein-losing enteropathy
Malnutrition
Miscellaneous Disorders
Myxedema
Ovarian disease (Meigs syndrome, struma ovarii)
Peritoneal carcinomatosis
End-stage renal disease
Chylous ascites
Bile ascites
Urine ascites

From Sleisenger MH, Fordran JS. *Gastrointestinal disease: Pathophysiology. Diagnosis and Management*. 4th ed. Philadelphia, PA: WB Saunders; 1989:433.

Diagnostic Paracentesis

The differential diagnosis of ascites is presented in **Table 59.17**. Analysis of ascitic fluid obtained from patients with cirrhosis show it to be straw colored and clear; measurements of protein (usually <2 g/dL), quantitative cell counts, and microbiologic culture and determination of pH, amylase, glucose, and albumin levels should be obtained. The serum-to-ascitic fluid albumin gradient (SAAG) is calculated by subtracting the albumin concentration in ascites from the level found in serum and is helpful in determining the cause of ascites; high values (>1.1 g/dL) are associated with portal hypertension, whereas lower levels are associated with other disorders, including malignancy.[252]

Treatment

Initial management includes treating or removing the inciting factor. Where alcohol, autoimmune or HBV-related liver disease is present, ascites can resolve with treatment of these causes. In patients with cirrhosis, lower blood pressure is associated with worse survival. For this reason, and due to the central role of the renin–angiotensin–aldosterone axis in the pathogenesis of the hemodynamic disturbances of cirrhosis, angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers should be avoided in patients with ascites. In addition, propranolol may decrease survival in patients with refractory ascites. NSAIDs can inhibit prostaglandin synthesis and impair renal function.

Therapy is directed at renal sodium and water retention. A low-sodium diet is a critical part of the management of patients with cirrhosis (an upper limit of 2,000 mg/d or 45 to 90 mEq/d). Fluid restriction (1,000 to 1,500 mL of fluid/d) is also an essential component of therapy in patients in whom hyponatremia (sodium <125 mEq/L) develops. For the majority of patients who do not respond to fluid and salt restriction alone, diuresis is indicated (**Table 59.18**). Loop diuretics (furosemide) and potassium-sparing diuretic (spironolactone) are the two most widely used agents. They are often required in combination. A ratio of 40-mg furosemide to 100-mg spironolactone generally maintains potassium homeostasis. Diuresis of approximately 500 mL/d is the goal for patients with mild ascites and up to 1 to 2 L/d for patients with both ascites and peripheral edema. More than 90% of patients respond to dietary manipulation and diuretics.[251,253]

Table 59.18 Treatment of Ascites
Bed rest
Sodium restriction 1–2 g/d (45–90 mEq/d)
Fluid restriction 1–1.5 L/d
Diuretics Spironolactone 50 mg PO q8h Maximum of 100 mg q6h Furosemide 40–370 mg/d
Antibiotics Cefotaxime 2 g IV q12h Ofloxacin 400 mg PO q12h Prophylaxis Norfloxacin 400 mg/d while hospitalized Ciprofloxacin 750 mg PO weekly Norfloxacin 400 mg/d for 6 mo Trimethoprim/sulfamethoxazole One double-strength tablet five times a week

Important adverse effects of spironolactone include gynecomastia in males, hyperkalemia, and metabolic acidosis. Complications of furosemide include prerenaluremia, which occurs in approximately 20% of patients as a result of excessive diuresis, and hypovolemia. Additional complications include hyponatremia and encephalopathy.

Large-volume paracentesis (removal of 4 to 6 L of ascitic fluid per day) is performed for patients who are symptomatic due to massive ascites and who do not respond to diuretics. Patients requiring paracentesis usually have severe underlying liver disease and a 1-year survival of 25%.[254] Large-volume paracentesis involves placing a catheter into the abdominal cavity, either in the lower midline or in one of the lower quadrants. Entry lateral to the rectus muscle avoids the inferior epigastric artery. Albumin (6 to 8 g/L of ascites removed) is infused intravenously in the form of 25% albumin (12.5 g/50 mL). Patients who have less than 5 L of ascitic fluid removed do not usually require albumin replacement.[255] Repetitive large-volume paracentesis can be safely performed.

In an Italian multicenter RCT, long-term administration of albumin (40 g twice weekly, then weekly) plus standard of care treatment as chronic treatment of ascites in decompensated cirrhotic patients demonstrated improved transplant-free survival rates at 18 months as compared to standard of care therapy. However, this practice is not yet standard of care in the United States.

Peritoneovenous shunts are surgically placed tubes that connect the peritoneal cavity with the superior vena cava via the internal jugular vein. The two main types are the LeVeen and the Denver shunt. In both, a one-way valve allows unidirectional movement of ascitic fluid from the peritoneal cavity into the systemic circulation. Although these shunts are effective in decreasing the volume of ascitic fluid, a significant number of major complications have been noted, including disseminated intravascular coagulation, heart failure and sepsis, and associated mortality rates are high (approximately 20%).[256] Shunts patency is approximately 50% at 1 year.[254] The use of these shunts has greatly decreased with the development of the TIPS procedure.

Surgically created portosystemic shunts have been used in the past for the treatment of ascites. Because of high morbidity and mortality rates, an increase in encephalopathy and progression to liver failure, and the availability of TIPS as a treatment option, surgically created shunts are now used infrequently for this indication alone. In a study evaluating the use of TIPS for the treatment of medically refractory ascites, the ascites resolved completely in almost 75% of patients, and a partial response was noted in an additional 20%.[271] In addition, renal function improved during the 6 months

of follow-up. TIPS, however, was associated with an increase in encephalopathy.

12 SBP is a potentially lethal complication of portal hypertension with ascites that occurs in up to 10% of patients. The cause of SBP is unknown. Antecedent GI hemorrhage is common, and SBP in this setting may be related to bacterial translocation from the gut. Deficits in immune function, both systemically and within the abdomen, including depressed reticuloendothelial function, low ascitic protein concentration, and deficient ascitic opsonic activity, may play a role.[257–260] Patients often present with abdominal pain and fever, but 10% to 20% of cases are discovered on routine paracentesis.[261–263] In addition, patients may present with other signs not clearly related to SBP, including worsening encephalopathy and deteriorating renal function. The diagnosis is easily made by examination of the ascitic fluid obtained by paracentesis. An elevated absolute polymorphonuclear (PMN) cell count (>250/mm^3) is diagnostic. The majority of cases of SBP are caused by a single species of organism, most commonly a gram-negative enteric bacteria (**Table 59.19**). If more than one organism is present, the diagnosis of SBP should be questioned, and a search for intra-abdominal disease (secondary peritonitis), such as a perforated viscus or diverticulitis, should be performed.

Table 59.19 Bacteria Isolated from Ascitic Fluid in 519 Patients with Spontaneous Bacterial Peritonitis

Organisms	Percentage of Total
Escherichia coli	43
Klebsiella pneumoniae	11
Streptococcus pneumoniae	9
Other Streptococci	19
Pseudomonas	1
Enterobacteriaceae	4
Staphylococci	3
Miscellaneous	10

Adapted from McHutchison JG, Runyon BA. Spontaneous bacterial peritonitis. In: *Gastrointestinal and Hepatic Infections*. Surawicz CM, Owen RL (eds). Philadelphia, PA: WB Saunders; 1995:455.

The treatment of SBP consists of supportive care and broad-spectrum antibiotics. Cefotaxime, a third-generation cephalosporin, is commonly used as empiric therapy. Other antibiotics with proven efficacy include fluoroquinolones. Beta-blockers should be discontinued at presentation, and should not be restarted as they are associated with worse outcomes in patients with a history of SBP. Albumin infusion has been shown to significantly reduce mortality in patients with SBP and to reduce acute renal failure and is complementary to other interventions.[263] Infection-related mortality is low with appropriate treatment, but high if renal failure or septic shock develops, and worse with delay in therapy. Regardless of short-term outcome related to SBP, patients who have liver disease severe enough to develop SBP have in hospital mortality rates of 20% to 40%,[264] and 1- and 2-year mortality rates are approximately 70% to 80%, respectively.[265,266]

Prophylactic antibiotics are indicated for three groups of patients with cirrhosis with ascites: (a) those with GI hemorrhage, (b) those with low ascitic fluid protein (<1.5 g/dL) and either liver failure (defined as CTP score greater than or equal to 9 or a bilirubin above 3 mg/dL) or impaired

renal function (creatinine greater than or equal to 1.2 mg/dL or a BUN greater than or equal to 25, or a sodium below 130 mEq/L), and (c) those who have survived one or more episodes of SBP (recurrence rates are almost 70% at 1 year).[255,264] The preferred antibiotics to be initiated in patients with hemorrhage is 7 days of intravenous ceftriaxone. Norfloxacin, ciprofloxacin, and trimethoprim–sulfamethoxazole are oral alternatives once intravenous therapy is no longer required. These prophylactic antibiotics reduce the incidence of SBP and improve survival.[267–272]

Hernias and Ascites

Hernias of the anterior abdominal wall occur in up to 20% of patients with cirrhosis. The causes include increased intra-abdominal pressure and nutritional deficits, with muscular wasting and thinning of the anterior abdominal wall fascia. Untreated, complications include incarceration, rupture, strangulation, and leakage. Patients with hernias and decompensated cirrhosis need to be evaluated for liver transplantation. In patients with stable liver function, hernias should be treated electively, with pre- or intraoperative paracentesis to decrease intra-abdominal pressure. No increase in complication rates was noted in a study comparing the outcome of umbilical hernia repair in patients with and without ascites. A longer hospital stay and a significantly higher recurrence rate (73% vs. 14%) were noted, however, in the group of patients with ascites. Other studies have shown increased rates of complications with observation without morbidity in those who underwent repair.[273–276] Intra-abdominal drains may be used to remove ascites until the incision has healed, preventing ascites from leaking through the wound. Meticulous fluid management is essential during the postoperative period to prevent early reaccumulation of ascites.

In patients with severe ascites, TIPS may be performed before hernia repair to ensure a good result. Emergency repair of hernias complicated by skin breakdown with ascites leak, incarceration or strangulation is managed in a similar fashion with preoperative large-volume paracentesis, and aggressive control of ascites postoperatively.

Hepatic Neoplasms

Shishir K. Maithel

Key Points

1. Diagnostic principles and key imaging characteristics of benign, pre-malignant, and malignant hepatic neoplasms will be discussed.
2. General management principles and a histology specific guide to treating these neoplasms is provided.
3. The three tenets of surgical management of malignant hepatic neoplasms include assessing oncologic appropriateness, understanding the host condition, and determining technical resectability.
4. Techniques to expand and/or optimize resectability are reviewed.
5. Basic anatomy and classification systems of liver anatomy are discussed and illustrated.
6. A step-by-step approach to five common procedures is detailed.

INTRODUCTION

Improved access to and use of cross-sectional imaging have led to the more frequent discovery of hepatic tumors. In order to differentiate benign, potentially malignant, and malignant histologies, the most up-to-date imaging must be utilized. A complete clinical case analysis is required in order to determine an optimal strategy for patient treatment.

DIFFERENTIAL DIAGNOSIS

1 The most commonly diagnosed benign liver masses are listed in the top of **Table 60.1**. Most incidentally discovered liver masses in otherwise healthy individuals are benign. The most commonly diagnosed neoplasms include cavernous hemangiomas, focal nodular hyperplasia (FNH), hepatocellular adenomas (HCAs), and cystic disease. Cavernous hemangiomas are benign vascular lesions and are the most frequently seen benign liver neoplasms found in all age groups. Most patients are asymptomatic, despite their often large size, with the risk of rupture and hemorrhage being negligible. FNH is the second most common benign lesion and has a predilection in women between the ages of 30 and 50 years. In general, FNH is viewed as a hyperplastic but not neoplastic lesion that does not have malignant potential. The third most common, HCAs are also typically found in women between 30 and 50 years. They can enlarge, particularly with the use of oral contraceptives or during pregnancy. Both situations are associated with estrogen hormone stimulation. Although usually benign at diagnosis, HCAs do have the potential for malignant conversion and hemorrhage. It is this potential that guides indications for resection. While most cysts in the liver are simple, benign, and usually asymptomatic, mucinous cystic neoplasms (MCNs) and intraductal papillary neoplasms of the bile duct (IPNB) do have malignant potential. These cysts are similar to intraductal papillary mucinous neoplasms of the pancreas (IPMN).

Although the majority of liver masses are benign, the possibility of malignancy should be considered as well. These include both primary tumors, namely hepatocellular carcinoma (HCC) and intrahepatic cholangiocarcinoma (IHC), as well as the more commonly seen tumors that have metastasized to the liver. With respect to the most common primary tumor, HCC is the third most common cause of cancer-related death

worldwide. Cirrhosis underlies the development of HCC in nearly 90% of cases, with an annual HCC incidence of 3% to 4% in cirrhotic patients. Chronic infections from hepatitis B and hepatitis C viruses contribute to HCC development, albeit via distinct mechanisms. Excess alcohol consumption also frequently contributes to cirrhosis-related HCC. Nonalcoholic fatty liver disease (NAFLD) is increasingly becoming a risk factor for HCC, particularly in the West, with NAFLD now being the most common reason for liver transplantation in the United States. Patients with human immunodeficiency virus (HIV) represent a higher-risk population, as they have higher rates of HCC that occur at younger ages, and tend to be more frequently symptomatic, progresses more rapidly, and are associated with worse outcomes compared to HCC in non-HIV patients.

Table 60.1 Differential Diagnosis of Hepatic Neoplasms

Benign Liver Tumors
Cavernous hemangioma
Focal nodular hyperplasia (FNH)
Hepatocellular adenoma
Hepatic cysts
Intrahepatic abscess
Focal fat sparing
Primary Liver Malignancies
Hepatocellular carcinoma
Intrahepatic cholangiocarcinoma
Hilar cholangiocarcinoma
Gallbladder cancer
Metastatic Liver Malignancies
Colorectal cancer
Neuroendocrine tumors
Other (breast cancer, reproductive tract cancers, melanoma, adrenocortical carcinoma, renal cell carcinoma, sarcoma)

IHC is the second most common primary liver tumor, and its incidence has been steadily rising in European and North American countries over the last

30 years from 0.1 to 0.6 cases per 100,000. Most patients who present with IHC are asymptomatic and have no known risk factors, which often contributes to its late-stage presentation. Several risk factors have been identified, some of which are common to HCC. Chronic inflammation of the biliary epithelia is the final common pathway among them. These inflammatory conditions include primary sclerosing cholangitis, parasitic hepatic infections, hepatolithiasis, congenital biliary cystic disease, and cirrhosis. Other more general risk factors for IHC include diabetes, obesity, biliary-enteric bypass, and tobacco use.[1]

Metastatic liver tumors can originate from a variety of primary cancers, and should always be considered when evaluating a liver mass, as these are more common than a primary hepatic malignancy. The most common metastatic liver tumor originates from a primary colorectal cancer (CRC). The liver is the most common site for hematogenous spread from CRC. Roughly 25% of CRC patients present with synchronous liver metastases, and nearly 50% of CRC patients develop metachronous liver metastases after resection of their primary tumor. Neuroendocrine tumors (NETs) also commonly metastasize to the liver, usually originating from the midgut (small bowel or appendix) or pancreas and are the second most common source of metastatic liver tumors. Over 80% of patients with metastatic NETs have liver involvement. Noncolorectal, non-NET liver metastases represent a small, but important, group of liver tumors. These most commonly include primary breast cancer, reproductive tract cancers, melanoma, adrenocortical carcinoma, renal cell carcinoma, and sarcoma.

Workup

The algorithm for the evaluation of a patient with a liver mass can be complex. Laboratory evaluation includes a complete blood count, coagulation studies, hepatitis panel, liver function tests, and tumor markers (CEA, AFP, CA 19-9, chromogranin A).

Imaging is a critical part of the workup for liver masses, and various modalities may be used. These include right upper quadrant ultrasound (US), computed tomography (CT) scan, magnetic resonance imaging (MRI), positron emission tomography (PET) scan, and somatostatin receptor (SSR) scintigraphy. Although US can be useful in differentiating a cystic or solid

liver lesion, it is rarely sufficient in isolation to accurately characterize the lesion and make a diagnosis. A CT scan with a triphasic protocol that includes precontrast, arterial, and early and delayed venous images can identify and accurately characterize the majority of liver lesions.

A comprehensive MRI is the most sensitive and specific imaging modality to characterize liver lesions. The various series include fat-suppressed T1 pre- and postcontrast (arterial, portal venous, and 3- to 5-minute delay), T2 with and without fat suppression, MRCP, balanced-gradient sequence, dual-gradient echo in-phase and opposed-phase sequences, and diffusion-weighted images with a high B-value of approximately 800. The sensitivity for detecting small lesions on MRI can be enhanced by using hepatobiliary-specific contrast agents, such as gadoxetate sodium, and the specificity of MRI can be optimized with an extracellular agent. PET scan and SSR scintigraphy have limited use in the initial workup of incidental liver masses and are most helpful for assessing tumor burden, particularly extrahepatic, when metastases from PET-sensitive primary tumors and/or NETs are suspected.

If the diagnosis remains uncertain, a percutaneous core liver biopsy can be obtained. Biopsy should be performed only when the results will change management and should be avoided if HCC is suspected based on patient history and imaging characteristics. If a metastatic lesion is confirmed on biopsy, it is important to identify the primary tumor histology, as prognosis and the role of liver resection will vary greatly depending on tumor origin.

Diagnostic Principles

Upon obtaining adequate imaging, thorough review of all diagnostic studies should be performed. This will allow the most likely diagnosis and determine resectability. Benign lesions are most often associated with normal lab values and low serum tumor markers. Laboratory blood tests—such as elevated bilirubin, LFTs, and INR, as well as a low platelet count—are more suggestive of primary liver tumors that often develop in the background of underlying liver dysfunction and can cause biliary obstruction. Similarly, both primary and metastatic liver tumors can be associated with elevated tumor markers. However, laboratory studies and tumor markers primarily

play a supportive role in the diagnosis of incidental liver masses, and normal values do not exclude the possibility of a malignancy.

General imaging characteristics of liver tumors are shown in **Table 60.2**. Imaging is an integral part of the evaluation of hepatic neoplasms. The combination of radiologic characteristics and clinical features can often identify the etiology without the need for percutaneous biopsy. Specifically, for HCC the diagnosis with imaging in the correct clinical context is widely accepted and is sufficient to initiate both noninvasive and invasive treatments. Alternatively, if adenocarcinoma is detected on biopsy, further staining for specific markers, including TTF-1 (lung), ER/PR (breast), CK-20 (colon), and CK-7 (pancreatobiliary), can help identify the likely site of origin. If the diagnosis remains indeterminate after high-quality imaging and biopsy, excisional biopsy with resection may be necessary, although this is rarely required.

Table 60.2 Radiographic Features of Hepatic Neoplasms on Cross-Sectional Imaging (CT and MRI)

Precontrast Hypoattenuation
Hemangioma
Adenoma
Arterial Enhancement
Hepatocellular carcinoma (HCC)—with venous washout
Neuroendocrine tumors
Melanoma
Renal cell carcinoma
Focal nodular hyperplasia (FNH)
Colorectal cancer (slight)
+/− Hepatocellular adenoma
Early Venous Enhancement
Hemangioma (peripheral nodular enhancement)
Colorectal cancer (slight)
Delayed Venous Enhancement
Cholangiocarcinoma
Hemangioma (diffuse filling)
Colorectal cancer (increasing)
Other Notable Features
Central scar—FNH
Telangiectatic components—inflammatory adenoma

GENERAL TREATMENT GUIDELINES

2 Once a diagnosis is confirmed, an appropriate treatment plan should be developed. When determining the resectability of hepatic lesions, several key considerations should be addressed: the operative/oncologic indication, the surgical fitness of the patient, and the technical resectability of the tumor. In asymptomatic individuals, most benign lesions require no therapy, although this depends on the exact histology. If pain is the only symptom from

a benign liver tumor, in-depth discussion with the patient and careful patient selection are critical before proceeding with resection for this indication. The management of adenomas, however, is generally more aggressive than other benign lesions because rupture and hemorrhage have been reported to occur between 10% and 30%, and malignant transformation into HCC in up to 10% of lesions.

For malignant liver tumors, operative indication is ultimately governed by tumor biology which refers to the oncologic appropriateness of resection. For HCC and IHC, tumor size, multifocality, and vascular invasion should all be considered when determining resectability, however specific cutoffs are inconsistent, and guidelines are variable. HCC tumors, particularly in the background of cirrhosis, that meet the Milan Criteria (MC) should be considered for transplant evaluation. For colorectal liver metastases, hepatic resection has largely become the optimal treatment modality, although only feasible in 20% to 25% of patients. Determining oncologic appropriateness for resection involves balancing synchronous liver disease, primary tumor node status and histology, number and size of liver tumors, CEA level, and disease-free interval. However, there is no perfect stratification system. Liver resection for NETs may be associated with symptom improvement and prolonged progression-free survival, although its role is in flux with the continued expansion and increased efficacy of other management strategies. The role of liver resection for other metastatic tumors, such as breast cancer, melanoma, and sarcoma, is unclear and should be individualized to each clinical scenario. Regardless of the liver tumor being primary or metastatic, the presence of extrahepatic disease can be an indicator of aggressive tumor biology and the value of resection should be questioned. In any case where the oncologic appropriateness of resection is in question, a course of preoperative systemic or liver-directed therapy may help select more biologically favorable tumors prior to subjecting a patient to hepatic resection.

BENIGN/PREMALIGNANT LESIONS

Hemangioma

The prevalence ranges from 3% to 20% in the general population and has a female predominance.[2,3] As stated earlier in the introduction, these are most often "incidental" findings during an examination for some other etiology. Regardless of size, it is important to recognize and accept that most hemangiomas are *not* symptomatic. Even if patients undergo imaging for "pain," the etiology of that pain is usually due to something entirely different. This pain could be a result of biliary colic disease, dyspepsia, ulcer disease, or other similar upper GI ailments.[4] Rarely, a hemangioma can be symptomatic with compression of nearby structures, most commonly the stomach from a large hemangioma in the left lateral sector or diaphragmatic irritation from those located in the dome of the liver. Kasabach–Merritt syndrome, consisting of intravascular coagulation, clotting, and fibrinolysis within the hemangioma leading to systemic fibrinolysis and thrombocytopenia, is an exceptionally rare occurrence.[5]

The diagnosis of hemangioma relies on high-quality multiphase imaging, with a high-quality MRI representing the gold standard of care.[6] Most hemangiomas display "peripheral nodular enhancement with delayed central enhancement" with each progressive phase as the imaging progresses from arterial to venous to delayed venous phase (**Fig. 60.1**).[7] A "flash-filling" hemangioma can occur with small hemangiomas, usually measuring <2 cm, making it difficult to accurately and reliably distinguish from an arterial-enhancing tumor. Regardless, biopsy is not indicated and should be avoided, as imaging is usually diagnostic.

Given their benign, indolent, and asymptomatic nature, observation is the usual treatment strategy for patients with hemangioma. If "pain" is the primary patient complaint, efforts must be made to accurately assign the etiology of that pain and not assume that it is related to the incidentally discovered hemangioma. Most often, the presence of a hemangioma is actually unrelated to the pain.[8] If intervention is required, surgical resection remains the standard of care. Depending on the anatomic considerations of each individual case, both anatomic or nonanatomic resection and enucleation remain viable options.[9] Other liver-directed therapies including radiation, ablation, and arterial embolization have been reported but the lack of data supporting their efficacy makes it impossible to support their routine utilization.[10–12]

Focal Nodular Hyperplasia

FNH is the second most common benign lesion, is typically found in women between the ages of 30 and 50 years, and has a strong predilection in women compared to men approaching 9:1.[13,14] The vast majority of these are asymptomatic and are incidentally found on imaging ordered for some other pathology. Like hemangiomas, even when patients endorse abdominal pain, the etiology is usually something other than the incidental finding of an FNH. In the rare event that an FNH does cause pain, it is usually associated with a left-sided lesion resulting in pressure on the stomach. Additionally it may be a lesion near the surface of the liver that exerts pressure on Glisson capsule, or is pedunculated and is susceptible to intermittent torsion of the pedicle.[15]

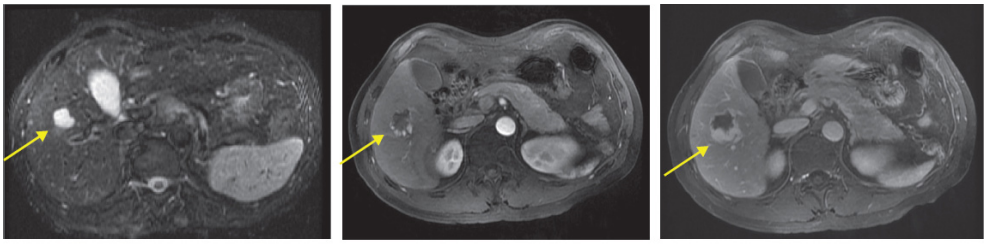

Figure 60.1 Hemangioma demonstrating bright appearance on T2 sequences and progressive peripheral nodular enhancement on delayed venous phase.

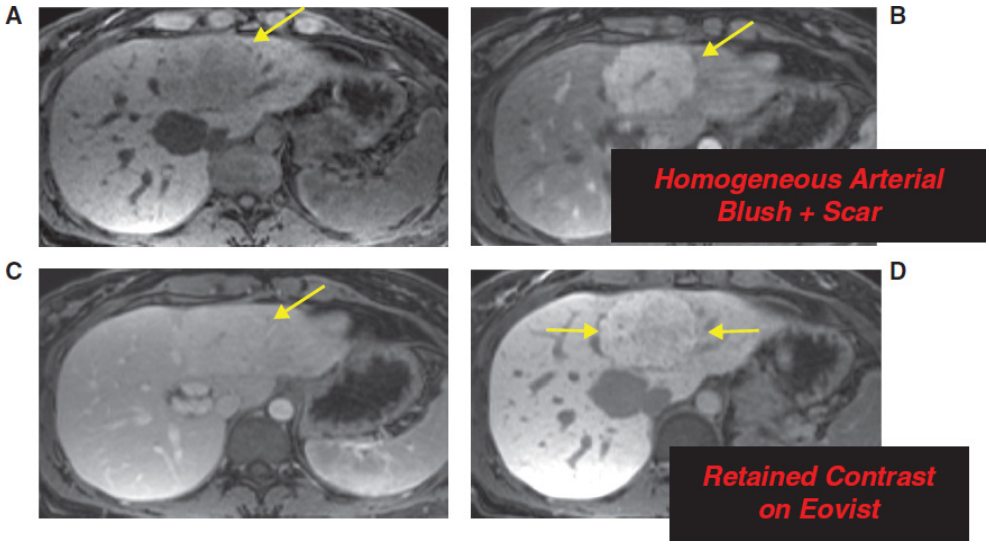

Figure 60.2 Typical appearance of FNH. **A:** Hypointense on precontrast phase. **B:** Bright with central scar on arterial phase. **C:** Homogenous and isointense appearance to liver background on venous phase. **D:** Retained contrast on delayed images with Eovist.

FNH is considered to be a hyperplastic reaction from an arterial malformation in the liver that in essence, hyperperfuses the local surrounding hepatic parenchyma leading to hepatocellular hyperplasia.[16] This phenomenon is usually isolated and thus most frequently presents as a solitary FNH, however multifocal FNH can occur in up to 20% of cases. FNH can also coexist with other benign lesions such as hemangioma or adenoma. Even though they do express estrogen receptors, tumor growth is not associated with oral contraceptive use or pregnancy.[17]

Obtaining the correct imaging is paramount to differentiate an FNH from an adenoma, which is a commonly encountered clinical scenario and carries potentially very different treatment strategies. Replacing the historic sulfur-colloid scan, an MRI with a hepatobiliary contrast agent (e.g., gadoxetate disodium [Eovist®]) is the standard of care to diagnose an FNH. Importantly, these contrast agents can exclude an adenoma. The retention of biliary elements in an FNH is a key distinguishing feature from adenomas that enables this typical imaging characteristic consisting of being hypointense on precontrast T1, isointense on T2, and becoming hyperintense on venous phase T1 images with progressive fading (**Fig. 60.2**).[18] Contrast-enhanced US is another modality that, although rarely utilized, has good diagnostic capability for FNH, particularly for small lesions.[19]

Given the lack of potential for malignant transformation, hemorrhage, or other complications, the treatment for FNH is observation. Patients should be reassured of their indolent nature and be counseled that serial imaging is not necessary. In the exceptionally rare instance of a symptomatic FNH, resection or other liver-directed therapy such as transarterial bland embolization or ablation can be pursued.[20]

Hepatocellular Adenoma

HCA is a rare benign liver neoplasm and similar to FNH; it has a strong tendency to form in women (female/male ratio—9:1).[21] Given this predominance of occurrence in females, the association of HCA with estrogen stimulation has long been studied. While most believe them to be linked, there is no data to support a "causal" relationship between the two.[22] Regardless, decreased size and spontaneous regression have been repeatedly observed in HCAs with cessation of hormonal therapy. This observation has led to cessation still being the first recommendation in patients with HCA. Although the association with estrogen stimulation is believed to be true, studies have demonstrated that most HCAs remain stable during pregnancy. As such, recommendations to avoid pregnancy for risk of growth, bleeding, and rupture are not warranted.[23] Importantly, the association of HCA with obesity and nonalcoholic steatohepatitis (NASH) has increasingly become more apparent. Obesity/metabolic syndrome is emerging as the dominant risk factor for HCA as opposed to oral contraception.[24,25] HCAs are also strongly associated with some rare genetic disorders, such as glycogen storage disease, maturity-onset diabetes of the young type 3, and McCune–Albright syndrome.[21]

Adenomas of the liver represent a heterogeneous disease as our molecular understanding of these lesions continues to evolve. There are four main subtypes, each of which carries its own profile of radiologic characteristics, typical host, and risk of hemorrhage and malignant transformation. The four subtypes include: HNF1α-mutated (HNF1A), inflammatory (telangiectatic—IHCA), β-catenin-mutated (b-HCA), and unclassified.[26] HNF1A has marked steatosis, IHCA is characterized by clusters of small arteries surrounded by extracellular matrix and inflammatory infiltrates, b-HCA contains pseudoglandular formations and cellular atypias such as enlarged, irregular,

and hyperchromatic nuclei. Unclassified adenomas include those not having a characteristic histologic pattern.[24,27]

The best diagnostic test, aside from a difficult-to-interpret tissue biopsy, is a high-quality MRI. As mentioned above, MRI with a hepatobiliary contrast agent will usually reliably distinguish an adenoma from an FNH. HNF1A adenomas are homogeneous and will demonstrate significant fat content. IHCA displays a strong hyperintense signal on T2-weighted images and often has persistent enhancement on the delayed venous phase. The other two types, b-HCA and unclassified, have less distinct imaging features, but usually resemble other hepatocellular tumors with arterial enhancement and venous washout (**Fig. 60.3**).[28,29] Tissue biopsy is best utilized if molecular characterization will inform management.

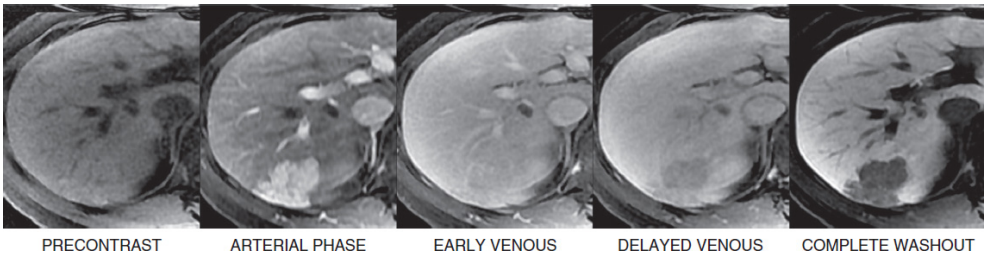

Figure 60.3 Series of images demonstrating the typical appearance of hepatocellular adenoma through the progressive phases of contrast-enhanced imaging.

The management of HCA is closely linked to the potential for complications—namely hemorrhage and/or malignant transformation. The risk assessment for the likelihood of these complications is mainly based on size, gender, and histologic type.[24] Importantly, the number of adenomas is not associated with an increased risk of complications. In general, 5 cm is the accepted "cutoff" for intervention, as the risk for bleeding and malignancy tends to increase with greater size.[24,30] However, these risks are still relatively low—hemorrhage occurs in less than 25% and malignant transformation in approximately 5%. Adenomas in males carry a significantly higher risk of malignant transformation and are most often the b-HCA subtype. As such, although uncommon, adenomas diagnosed in male patients should be removed.[24] When factoring in the histologic subtype, the HNF1A type is very indolent and rarely symptomatic and almost never transforms to HCC. IHCAs have a higher tendency to bleed. Other risk factors for bleeding

include visualization of arteries on imaging, location in the left lateral sector of the liver, and an exophytic growth pattern. The b-HCA subtype is characterized by a much higher risk of malignant transformation, particularly when >5 cm in size.[21,24] In general, size and gender are the main guiding principles for management, with greater than 5 cm and male gender requiring intervention.[24] The histologic subtype can help guide decision making, particularly in a borderline situation, where either resection or observation are equally being considered. For example a 4-cm b-HCA would likely undergo resection while a 5.5-cm HNF1A could likely safely be observed.

In terms of management, if relevant, the first step is cessation of oral contraception. Weight loss can be associated with spontaneous regression of adenomas as well.[24] When indicated, the standard of care for treatment is surgical resection. Bland arterial embolization is another option, particularly in difficult-to-resect lesions or in patients with significant comorbidities.[9,31] Liver transplantation, although previously considered in patients with adenomatosis, has recently fallen out of favor as the risk of complications is not increased with multiple compared to solitary adenomas and these lesions are most often the indolent HNF1A subtype. Instead, isolated treatment of lesions >5 cm can be undertaken and the other smaller adenomas can be observed, often displaying spontaneous regression.[24]

Simple Cysts

Simple cysts of the liver, originally believed to be quite rare, are visualized in up to 25% of patients who undergo MRI evaluation (**Fig. 60.4**). They are cystic formations that contain serous fluid and are lined by a single layer of cuboidal or columnar epithelial cells that resemble biliary epithelium, yet they do not have any direct communication with the biliary tree. Although they can be solitary, most of the time they are multiple. Prior to even considering any intervention, a simple cyst must be differentiated from polycystic liver disease (with or without autosomal dominant polycystic kidney disease—ADPKD), mucinous cysts (discussed below), and infectious etiology (hydatid cysts or echinococcal cysts). All of these other conditions have distinct management strategies that differ from that of simple cysts.

While most simple cysts are demonstrated in females, large, complicated, and symptomatic cysts are almost exclusively seen in women over the age of

50.[32] Outside of this demographic, most simple cysts are asymptomatic and are incidentally discovered during imaging for some other pathology. A carefully detailed history must be obtained in order to exclude other etiologies of pain. Large cysts located in the left lateral sector can compress the stomach. Large exophytic cysts can apply pressure on the liver capsule and/or diaphragm, and sometimes vascular structures and/or bile ducts can be compressed radiographically. The latter is rarely an indication for intervention as the radiographic appearance of compression is not usually clinically apparent or relevant. A trial of cyst fluid aspiration can be utilized to determine if the cyst is truly symptomatic, during which the symptoms should resolve temporarily. However, they will recur as the cyst refills with fluid.[33] Acute hemorrhage into the cyst can be accompanied by severe acute pain that usually resolves over a few days. Simple cysts do not have any malignant potential.

If truly deemed to be symptomatic, management of simple cysts can be pursued with either sclerotherapy or cyst fenestration. Sclerotherapy is most frequently accomplished with a 95% ethanol solution. After the cyst is percutaneously accessed and all the fluid is drained, it is vital to first inject contrast to ensure that no direct biliary or vascular communication is present.[34] Next, approximately 100 mL of 95% ethanol is infused into the cyst cavity and the patient is rolled in different positions to expose the alcohol to the entire cyst surface.[35] The procedure can be quite painful and blood alcohol levels can rise, thus underscoring the importance of limiting the amount of ethanol that is infused. Although the literature is sparse with reports of long-term follow-up after sclerotherapy, the symptomatic recurrence rate requiring additional treatment is believed to be low—less than 5%.[9]

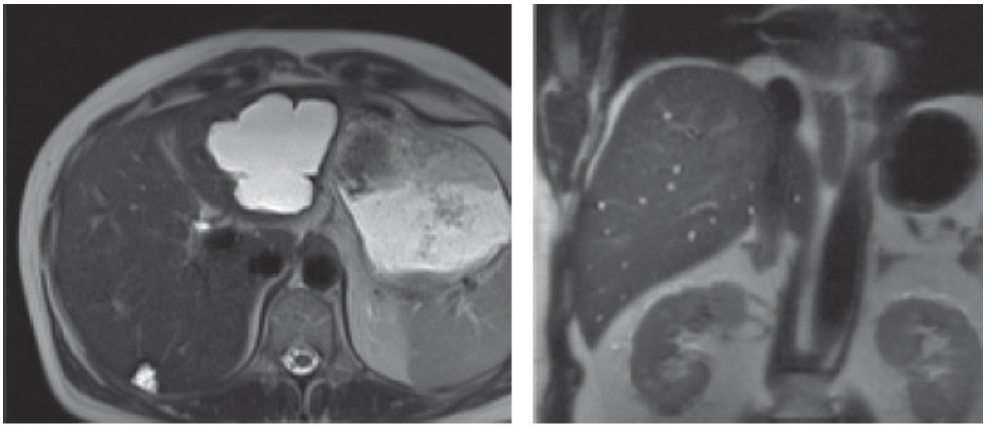

Figure 60.4 Typical appearance of a simple hepatic cyst on MRI T2 sequences.

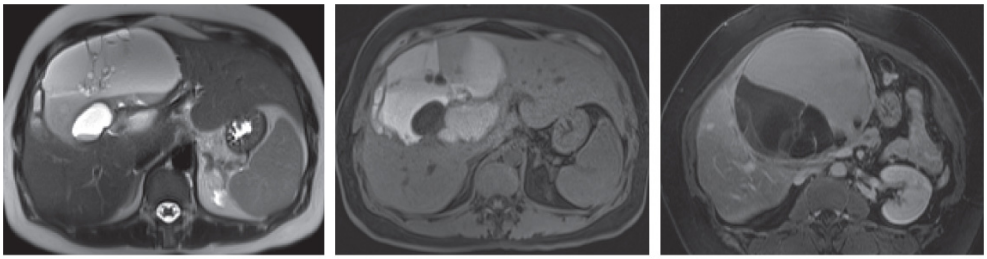

Figure 60.5 T2 sequences of an MRI demonstrating the bright appearance of mucinous cystic neoplasms that highlight the heterogeneous contents, septations, and nodularity that distinguish them from simple cysts.

If intervention is deemed appropriate, laparoscopic cyst fenestration is typically more commonly pursued than sclerotherapy.[36] Although the procedure is simple and straightforward with good results, it should only be utilized when needed. It should not lower the threshold for intervention. The procedure can be likened to taking the "ice cream off the cone." The ice cream represents the protruding cyst from the liver surface, presenting as the interface of the ice cream and the rim of the cone. Importantly, it is not necessary to remove the cyst lining that is embedded within the liver parenchyma. In fact, attempts to do this will greatly increase the risk of complications such as bleeding and bile leak, as these structures are often being compressed just below the cyst wall. Rather, the cyst should be opened approximately 1 cm above the liver surface. The fluid is drained out and then the cyst wall that is exterior to the liver parenchyma is removed with either an energy source or vascular staplers, leaving a crater of sorts. The

epithelium should be carefully cauterized and often an omental flap is created to place inside the cyst cavity. Any persistent fluid secreted from the base of the cyst wall is readily absorbed by the peritoneum and poses no risk to other organs. Success rates are high with this procedure and if done correctly, reintervention rates are low—less than 10%.[37]

Mucinous Cysts (MCN and IPMN-B)

While neoplastic mucinous lesions of the liver are exceedingly rare, it is paramount to differentiate them from simple or infectious cysts. They may have malignant potential and mandate complete resection most of the time. It is important to note that the terminology for these neoplastic cysts has evolved. The previous terminology of "cystadenoma" has been abandoned as the pathophysiologic understanding of these cysts has improved. As such, these cysts in the liver are believed to mirror those in the pancreas with similar rates of malignant potential. The term cystadenoma has been replaced with MCN and intraductal papillary mucinous neoplasm of the bile duct (IPMN-B).[38,39]

Much like MCN of the pancreas, MCNs of the liver are almost always solitary, occurring uniformly in younger women and do not communicate with the biliary tree. They are histologically defined as being lined with ovarian stroma.[40,41] The embryologic decent of the right ovary explains why most MCNs are found in segment IV of the liver, just as they are nearly always found in the body/tail of the pancreas due to the path of decent of the left ovary. Although many are asymptomatic and diagnosed incidentally, most are discovered during a workup of vague epigastric pain. If it reaches a large size, an MCN can progress to cause biliary obstruction and jaundice in the minority of cases.

A good-quality MRI is the best way to radiographically distinguish MCN from other cystic lesions of the liver. Most MCNs present as fluid-containing multilocular cysts with homogenous low or isosignal intensity on T1-weighted images and homogeneous high signal intensity on T2-weighted images (**Fig. 60.5**).[42] Nodularity of the cyst wall may be present as well. Unlike MCN of the pancreas, cyst fluid analysis of the hepatic counterpart is not well defined. Specifically, there is not a characteristic profile of CA 19-9 or CEA levels, partly since hepatic cyst fluid analysis is uncommonly

obtained. If suspected, given its malignant potential, complete resection is warranted, as cyst wall fenestration is not appropriate management.[43] Resection can consist of partial hepatectomy or enucleation, as there is a dissection plane between the MCN and normal hepatic parenchyma.

IPMN-B may macroscopically be divided into two variants: ductectatic type and cystic type. The ductectatic type can resemble main duct IPMN of the pancreas while the cystic type is analogous to side-branch IPMN.[44] The main distinguishing feature from MCN is that IPMN-B directly communicates with the biliary tree. This can often be visualized on MRI (**Fig. 60.6**) or on cholangiography. Given the mucin secretion into the biliary tree, IPMN-B can present with transient obstruction of the bile ducts. Unlike MCN, it is equally diagnosed in both genders and presents in the sixth decade of life. Given its malignant potential, resection is indicated.[39] Unlike the guidelines for resection of IPMN of the pancreas, no such detailed guidelines exist for IPMN-B. Even if malignant transformation has occurred, the prognosis is usually better than after resection of intrahepatic or hilar cholangiocarcinoma.

MALIGNANT LESIONS

3 Determining resectability of hepatic malignancies relies on three key concepts: oncologic appropriateness, host condition, and technical resectability.

Oncologic Appropriateness

Tumor biology dictates oncologic appropriateness. Adequately defining the extent of disease and understanding the nature of the tumor is critical before pursuing operative intervention. The surgeon's first responsibility is to determine those patients most likely to benefit from an operation, which is ultimately governed by tumor biology.

Host Condition

Host condition refers not only to the general health and surgical fitness of the patient, but also to the condition and functional status the liver. In most patients, this can be successfully evaluated through a careful history and physical examination. Other useful tools to further risk-stratify patients include indicated adjunct laboratory values and imaging.

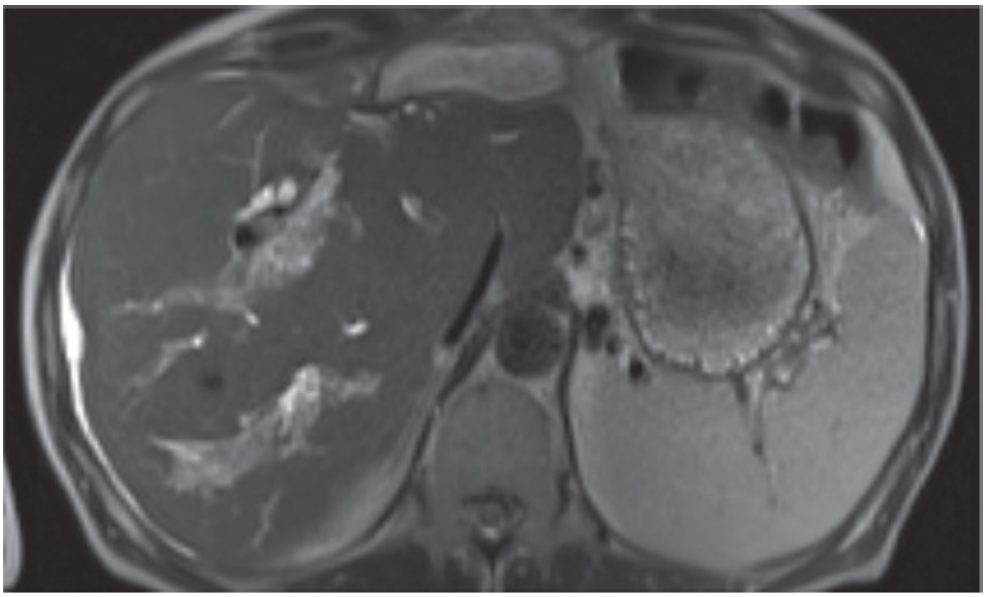

Figure 60.6 T2 sequences of an MRI demonstrating the biliary communication of IPMN-B.

Technical Resectability

Before pursuing any extent of hepatic resection, the remnant liver should be determined to have sufficient inflow, outflow, biliary drainage, and be of adequate quantity and quality to sustain hepatic function postoperatively during the regenerative period.

If surgery is determined to be reasonable from an oncologic perspective, the patient is deemed fit for surgery, and the extent of planned resection leaves an adequate functional liver remnant (FLR); nearly all patients should be candidates for liver resection. These three concepts will be elaborated upon within the context of specific liver tumors, both primary and metastatic, as well as discuss ways by which resectability rates can be potentially increased.

ONCOLOGIC APPROPRIATENESS

Determining resectability of a tumor from an oncologic perspective is paramount and should be the first consideration of any surgeon faced with a cancer patient prior to assessing technical resectability. This is based on the concept of nonmalfeasance, or "first, do no harm." When performed with curative intent, the value of surgery for malignancy is measured by its survival benefit. Tumor biology, however, ultimately dictates patient outcome. Thus, a thorough preoperative evaluation should be performed to assess the extent of spread, which, among other tumor-specific factors, can help predict the nature of disease. Whether a primary or metastatic liver tumor, extrahepatic spread is an indicator of aggressive tumor biology. While not always a preclusion of surgery,[45] the benefit of resection in these cases should be questioned. Improvements in imaging technology and, in appropriately selected patients, staging laparoscopy have increased our ability to identify those patients unlikely to benefit from surgery and avoid unnecessary hepatectomy. In certain cases where the oncologic appropriateness of surgery is in question, a trial of preoperative systemic or liver-directed therapy may help biologically select more favorable tumors for resection.

Preoperative Evaluation

Preoperative evaluation should focus on characterizing the lesion in question, defining the extent of disease, and determining its biologic behavior. Imaging modalities include a staging chest radiograph or chest CT, and either a CT or MRI of the abdomen and pelvis, with preference depending on the type of tumor being evaluated, institutional expertise, and patient-related factors. In many cases, however, both CT and MRI may be necessary.[46] PET scan can be a useful and important tool in evaluating the extent of disease in FDG-avid tumors, particularly when assessing for extrahepatic disease.[47–50] Preoperative biopsy for certain tumor types is often not necessary and should only be pursued in select cases where the information gained will alter the treatment plan, such as administering preoperative therapy.

Despite advances in various high-quality imaging modalities, still roughly 9% to 36% of patients are found to have occult metastatic disease at the time

of surgery.[51–55] Staging laparoscopy has been advocated by some to identify peritoneal metastases not detected on cross-sectional imaging, thereby avoiding unnecessary laparotomy.[54–58] However, its routine use is subject to debate, and may only be of benefit in patients already identified as high risk for having subradiographic metastatic disease.[59–61]

Hepatocellular Carcinoma

HCC is the most common primary liver tumor (**Fig. 60.7**) and the third most common cause of cancer-related death worldwide.[62] Although various nonoperative treatment options exist, surgery remains first-line therapy, with the choice between resection and transplantation generally dictated by the degree of underlying liver dysfunction and tumor burden.[63,64] From an oncologic perspective, four major clinical prognostic indicators have been identified—tumor size, multifocality, vascular invasion, and extrahepatic spread. These indicators serve as the basis for the Tumor–Node–Metastasis (TMN) staging system.[65,66] Since the widespread adoption of the MC, which utilized a selection cutoff using these clinical indicators, the identification of cirrhotic patients with HCC for transplantation has been simplified with consistently favorable results.[67,68] However, translating these clinical indicators into oncologic criteria for resection has proven difficult.

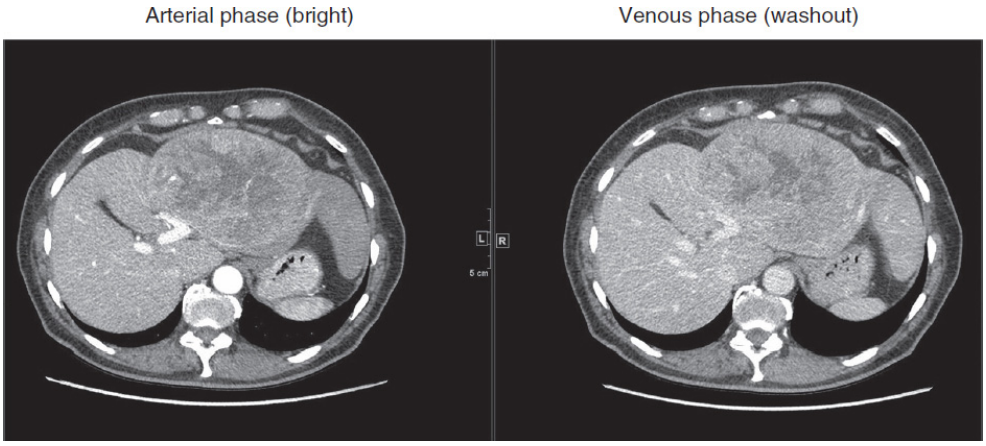

Figure 60.7 Hepatocellular carcinoma (HCC) has a bright appearance on arterial phase and tends to washout on venous phase.

Other clinical staging systems have been proposed using different clinicopathologic parameters with varying success in applicability, cancer-

specific focus, and prognostic value.[69–71] One commonly used system is the Barcelona Clinic Liver Cancer (BCLC) staging system. Stratification under BCLC is based on tumor stage, liver function, and performance status, therefore staging patients with HCC into four categories—early, intermediate, advanced, and terminal making treatment recommendations for each.[72,73] According to this staging system, hepatic resection is only indicated in patients with early-stage HCC (single tumor ≤5 cm or ≤3 tumors all <3 cm, without vascular invasion or extrahepatic spread; satisfactory liver function; and performance score of 0) with the oncologic appropriateness of resection mirroring that of MC.[67,72] While the BCLC system has gained increasing acceptance to guide resection, it continues to be controversial, as conflicting data regarding the prognostic value of these clinical indicators emerge.[74–80]

Historically, tumor size in HCC has been an important predictor of outcome following surgery. Readily measured preoperatively and shown to be inversely correlated with survival, tumors larger than 5 cm and 10 cm in diameter are particularly biologically aggressive.[76,81–84] However, several groups have demonstrated more acceptable and durable long-term survival following resection for large HCC, questioning the prognostic significance of tumor size alone.[77,80,85–87] Furthermore, when controlling for other factors, such as multiple tumors and presence of vascular invasion, size has demonstrated little impact on survival, even in tumors >10 cm in diameter.[65,80,88–90] In fact, the AJCC eighth edition staging classification does not use tumor size alone to stratify patients.[65,66] Increasingly, however, studies focusing on the link between tumor size and vascular invasion have shown that the frequency of microscopic and macroscopic vascular invasion drastically increases as tumor size increases.[78,80,91] This suggests that tumor size, rather than being an independent prognostic indicator, may serve as a surrogate marker for vascular invasion. Thus, while size alone should not dictate treatment, recognizing the link between size and more aggressive tumor biology is critical when discussing the oncologic appropriateness of resection in patients with HCC.

The presence of multiple tumors is another important independent prognostic factor in patients with HCC. The pathogenesis of multifocal HCC is thought to be due to at least two very different biologic mechanisms—multicentric hepatocarcinogenesis, meaning multiple de novo tumors of

independent origin, and intrahepatic metastasis, meaning multifocal dissemination of a common clonal origin.[92–94] While our ability to differentiate between these two pathways may have significant implications for understanding tumor biology and guiding management, reliable biomarkers are lacking and clinical applicability is not yet clear. However, as a whole, multifocal HCC incurs a worse prognosis than equally matched solitary tumors; this is reflected in the current AJCC staging system.[66,89,90] Although acceptable rates of survival have been shown following resection for multifocal HCC ≤5 cm in diameter, the oncologic benefit in patients with larger multifocal HCC is still subject to debate and a trial of preoperative therapy may be prudent prior to selecting these patients for resection.[65,89,90,95]

In multiple studies, vascular invasion has been shown to be one of the best predictors of outcome following surgery for HCC.[65,73,76–80,89–91] Patients presenting with macroscopic or major vascular invasion, defined as tumor involving a major branch of the portal or hepatic vein, have particularly dismal outcomes. This finding is associated with increased risk of intrahepatic and systemic metastases, and poor overall survival.[65,89,90,96–98] Left untreated, the reported median survival of patients with HCC and major vascular invasion is 9 to 10 weeks.[96,97] Several studies have reported an overall 5-year survival of only 10% to 11%, even after hepatic resection for HCC when major vascular invasion was present.[79,89,99,100] Although a small subset of patients may have more favorable outcomes than those previously reported,[79] the benefit of resection in patients with major vascular invasion remains doubtful and controversial, and should be pursued in only highly selected patients. Microscopic vascular invasion has also been shown to be a strong predictor of outcome, with its presence associated with earlier tumor recurrence, metastatic spread, and decreased overall survival.[76–78,80,91] Unfortunately, microscopic vascular invasion is difficult to anticipate and in isolation, is of little use in preoperatively determining resectability.

In patients with HCC, extrahepatic spread, including regional lymph node involvement and distant metastases, is considered stage IV disease. With few exceptions, it is a contraindication to resection in patients with HCC.[64,66,101]

Intrahepatic Cholangiocarcinoma

The second most common primary liver tumor is ICC (**Fig. 60.8**) with rising incidence seen in both European and North American countries.[102,103] Despite the rising occurrence in these countries, no currently available locoregional or systemic therapies have shown generalized therapeutic benefit, although advances in targeted therapy show great promise for select patients. Still, surgical resection remains the only potentially curative treatment for patients with ICC.[104] When the seventh edition AJCC staging system was developed, TMN staging for ICC was based on the same major prognostic criteria of HCC including tumor size, multifocality, vascular invasion, and extrahepatic spread.[105] Given its distinct tumor biology, underlying risk factors, and clinical behavior compared to HCC, several nomograms and staging systems have been developed. These is an attempt to differentiate relevant prognostic indicators and more accurately predict survival in patients with ICC.[106–111] The eighth edition of the AJCC staging system is unique to ICC and does not merely parallel that of HCC.

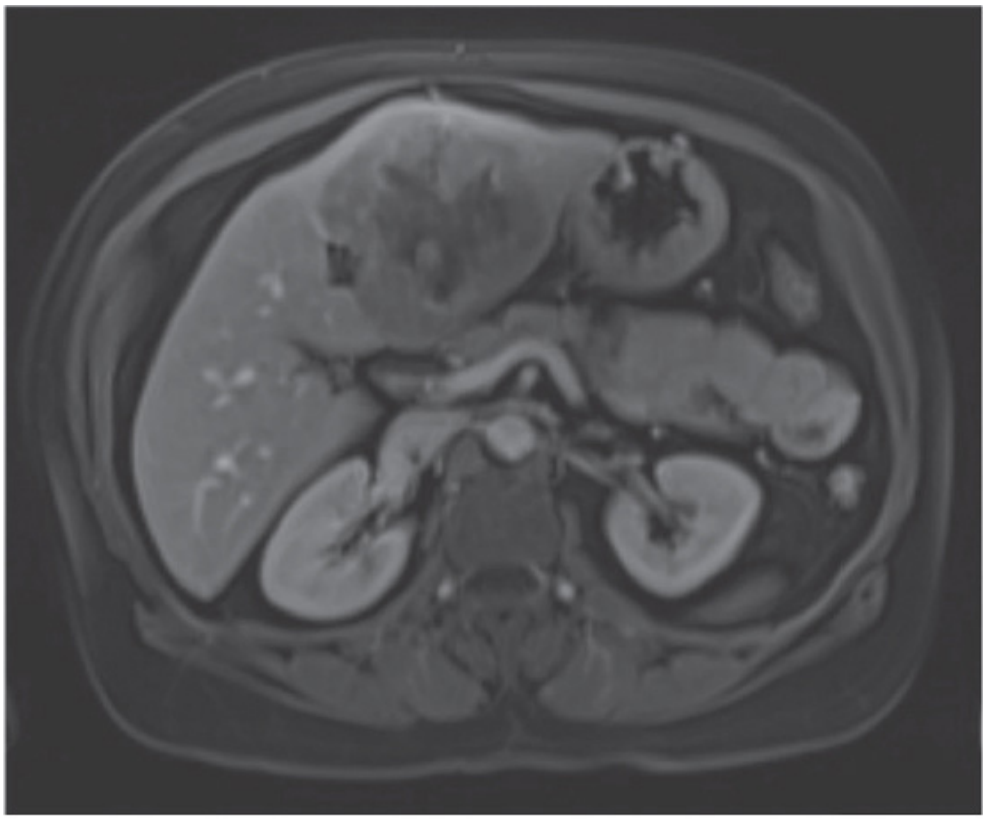

Figure 60.8 Cholangiocarcinoma typically depicts enhancement on delayed venous imaging.

The utilization of tumor size in patients with ICC as a prognostic indicator to stratify patients has been controversial. While used in previous versions of the AJCC staging system, the prognostic value of tumor size was refuted in one of the earliest proposed staging systems for ICC.[107] Supported by several groups, these authors found no independent association between tumor size and survival in ICC.[1,106,112,113] Indeed, tumor size is notably absent in the staging system proposed by Nathan et al., as well as in the seventh edition AJCC staging system addressing ICC independently.[106,110] On the other hand, the Liver Cancer Study Group of Japan (LCSGJ) found a worse prognosis in patients with ICC >2 cm in diameter. This size is used as a cutoff value in their commonly used staging system.[109] Similarly, others have shown a significant negative effect on recurrence and survival with increasing tumor size, particularly in tumors >5 cm and >7 cm. This is reflected by the fact that tumor size has been incorporated in two of the newer proposed nomograms.[108,111,114–116] More recently, increasing tumor size has been found to be associated with an increased incidence of nodal involvement, multiple tumors, vascular invasion, and poorly differentiated tumors.[117,118] The suggestion would be that larger tumor size may be indicative of more aggressive tumor biology. Though perhaps subtle, the role of size in determining resectability should not be entirely discounted. Accordingly, tumor size has been incorporated in the eighth edition AJCC staging system.

Multifocal intrahepatic disease is considered one of the most dominant clinicopathologic factors affecting survival in ICC. The pathophysiology of multiple ICC tumors, similar to HCC, is thought to be due to either satellitosis, multicentric hepatocarcinogenesis, or intrahepatic metastases. However, the clinical significance of these is unclear. Still, there is very little debate that patients with ICC presenting with multiple tumors face a grim prognosis, particularly with ≥3 tumors.[1,108,111,114–117] While most patients with multifocal disease never reach resection, the median survival for the minority that do ranges from 12 to 19 months, with one study observing no survival benefit over patients treated nonoperatively.[1,114,116] Thus, in patients with multiple intrahepatic ICC tumors, nonoperative therapies should be the first consideration. Resection should be reserved for only highly selected cases.

The presence of vascular invasion is often cited as an important risk factor for disease recurrence and decreased survival in patients with ICC.[1,106,108,113]

Its utility as an independent prognostic indicator, however, is less clear. Indeed, when taking into account other factors, such as positive lymph node status and multiple tumors, vascular invasion frequently failed to maintain significance.[1,112,114,117,119] Furthermore, microscopic vascular invasion is difficult to identify on preoperative imaging, giving it little value in determining resectability. Even when faced with major vascular invasion, however, several groups have advocated a more aggressive surgical approach, citing increased resectability rates and comparable or better overall survival when major vascular resection was performed in order to obtain negative margins.[117,119,120] Thus, hepatic resection in the setting of major vascular invasion can be oncologically appropriate in select patients with ICC, particularly after a favorable response to a course of preoperative therapy.

Extrahepatic disease is considered stage IV and these tumors should be deemed unresectable, except in highly select cases. Regional lymph node disease, in the latest eighth edition AJCC staging system, is deemed stage IIIB as opposed to previously being designated stage IV disease.

Figure 60.9 Typical appearance of colorectal cancer liver metastases on venous phase imaging.

Colorectal Liver Metastases

CRC is the most common cancer worldwide and the second most common cause of cancer-related death in the United States.[62] Approximately 25% of patients with CRC present with metastatic disease and 50% will eventually develop metastases, with the majority being located in the liver (**Fig. 60.9**).[121,122] In patients with metastases confined only to the liver, hepatic resection is the goal, with a 5-year survival of approximately 50% in most modern series and a 10-year disease-free survival reaching nearly 20%.[123,124] Unfortunately, resection is only possible in 20% to 25% of patients.

Selecting the patients for resection that are likely to achieve these survival benchmarks, however, has been challenging. Several risk factors have been identified and used in various combinations to develop clinical risk scoring systems to predict long-term survival and guide therapy in patients with

colorectal liver metastases. Examples of these factors include synchronous liver disease, primary tumor node status and histology, number and size of liver tumors, CEA level, disease-free interval, and the presence of extrahepatic disease.

While most studies agree as to the general importance of these factors and their cumulative effect on survival, there is little standardization in their individual cutoff values and prognostic strengths, and no one factor has unanimously been shown to affect outcomes.[125–129] In fact, one study focusing on patients cured of disease at 10 years showed that well over half of them originally had at least one, and 43% had at least three, of these poor prognostic factors—synchronous disease (7%), node-positive primary (51%), CEA >200 (7%), disease-free interval <12 months (37%), multiple hepatic tumors (40%), and size of hepatic tumor >5 cm (36%).[124] Even in the setting of extrahepatic disease, a scenario traditionally considered a contraindication to resection, acceptable 5-year survival rates up to 28% have been shown in select patients undergoing hepatic resection.[130–132] Certainly, there is little question that patients with many risk factors do worse than patients with few to none. However, the line that separates the biologically resectable from the biologically unresectable patients with colorectal liver metastases continues to evade us.

Neuroendocrine Liver Metastases

Although a rare tumor, when metastatic, the liver is involved in the majority of cases, with midgut (small bowel and appendiceal) and pancreatic location being the primary sites of disease.[133] Before considering liver resection, the full extent of disease burden must be evaluated. This can be accomplished with high-quality cross-sectional imaging (**Fig. 60.10**), usually in combination with SSR scintigraphy. While Indium-111 (octreotide scan) is useful, the Gallium-68 Dotatate scan offers greater sensitivity for detecting small-volume disease and is the preferable modality. Indications for resection include not only eradication of disease, but also control of symptoms related to the carcinoid syndrome. Surgical cytoreduction of disease, on the order of 70% to 90%, has been deemed adequate to be associated with improved survival and/or symptom relief.[134,135] As the medical and nonoperative liver-directed therapy armamentarium (including

transarterial embolization, ablation, and transarterial radioembolization) for treating advanced NETs continues to evolve and expand, the role and benefit of resection must be carefully weighed against its potential morbidity. Furthermore, with the FDA approval of Peptide Receptor Radionuclide Therapy (PRRT) with Lutetium 177 Dotatate in January 2018 based on the results of the Netter-1 trial, the role of hepatic resection has been called into question, especially in patients with extrahepatic disease.[136] That being said, liver resection should always be discussed and considered in multidisciplinary tumor boards when determining the therapeutic plan for each individual patient.

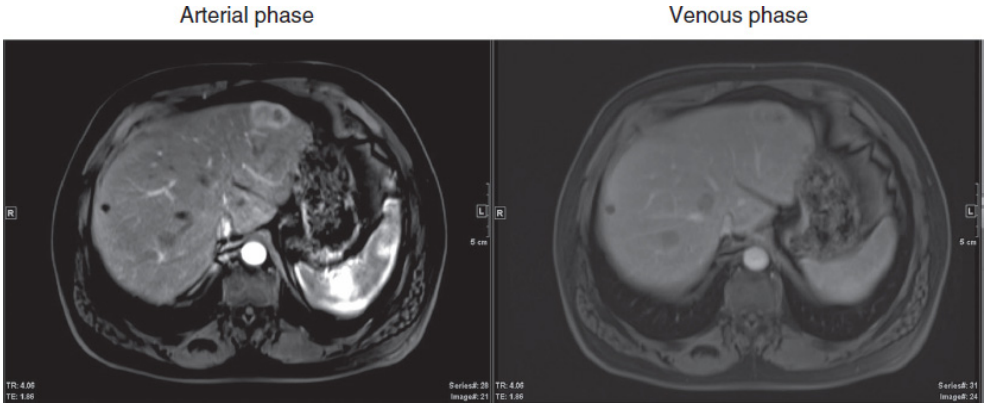

Figure 60.10 Neuroendocrine liver metastases are typically bright on arterial phase imaging and tend to wash out during the venous phase.

Noncolorectal, Nonneuroendocrine Liver Metastases

This group of patients represents a small minority of patients who are candidates for and undergo liver resection. Primary histologies that comprise this cohort of patients include melanoma, renal cell carcinoma, sarcoma, breast cancer, lung cancer, and gynecologic malignancies. Each individual scenario must be evaluated thoroughly in a multidisciplinary setting, as there are no general guidelines that dictate the appropriateness of hepatic resection for this group of patients. One must weigh the magnitude of resection and its potential morbidity, the extent of hepatic and extrahepatic disease, the systemic therapy options and their projected efficacy, and the anticipated survival of the patient.[137]

HOST CONDITION

A patient's general health status and their ability to tolerate surgery, or surgical fitness, is a critical component of determining resectability of hepatic malignancies. A thorough history and physical examination, and any other indicated adjunct workup, should be performed preoperatively on all patients. Because determining the surgical candidacy of a patient is often subjective, several risk indices have been developed to aid in patient assessment, decision making, and provide a more objective way to risk-stratify patients. Those commonly used by anesthesiologist and surgeons include the American Society of Anesthesiologists (ASA) scale, the Eastern Cooperative Oncology Group (ECOG) Performance Status, the Charlson Comorbidity Index (CCI), and the Revised Cardiac Risk Index (RCRI).[138–141] More recently, the concept of frailty has been introduced as an important surgical risk assessment tool and forms the basis of the Hopkins Frailty Score, which was later validated in a large multidisciplinary prospective study examining outcomes of patients undergoing major intraabdominal surgery.[142,143]

TECHNICAL RESECTABILITY

4 In liver surgery, the technical resectability of a tumor is defined not only by what can be removed, but more importantly by what is subsequently left behind. Thus, hepatic arterial and portal venous inflow, venous outflow, biliary drainage, and the quantity and quality of the future liver remnant (FLR) should all be deemed adequate to sustain function and support regeneration in the postoperative period. Patients with underlying liver dysfunction pose a unique challenge when considering hepatic resection and understanding the degree of dysfunction and its effect on prognosis is crucial. In select patients, the use of remnant-optimizing techniques and staged procedures can increase resectability and should be considered whenever possible.

Vascular Inflow/Outflow and Biliary Drainage

One of the major dilemmas in determining the technical resectability of liver tumors is balancing the appropriate operation required in order to completely remove the tumor and obtain negative margins while maintaining adequate vascular inflow, outflow, and biliary drainage of the FLR. Thus, mapping out the tumor location in relation to the patient's hepatic vascular and biliary anatomy is critical. In most patients, this can be done successfully with good-quality cross-sectional imaging, including a CT scan, MRI, or both. Even with centrally located tumors, which more frequently involve major vascular structures close to the hilum, improvements in high-quality cross-sectional imaging have allowed for better visualization and characterization of tissue planes. When biliary obstruction is suspected, cholangiography may help delineate biliary involvement, and can be done endoscopically, percutaneously, or using MRI. Given the advances in imaging, invasive cholangiography is rarely necessary.

Historically, tumor involvement of the portal vein or inferior vena cava has been considered a contraindication to surgery, as resection of these tumors incurred significant perioperative morbidity and mortality risk. However, improvements in surgical technique and perioperative management have expanded our definition of resectability. Indeed, several studies have demonstrated that in select patients, hepatectomy combined with major vascular resection or thrombectomy can be safe, with low postoperative morbidity and mortality, and that major vascular or biliary involvement should not necessarily preclude resection.[79,120,144–148] In highly select patients whose tumor involves the IVC, the hilum, or the confluence of the IVC and hepatic veins, and would otherwise be considered unresectable by any other resection techniques, ex vivo resection with autotransplantation may be an option.[149–153] However, data regarding this approach is sparse, limited to case reports and small series, and the survival benefit is unclear.

FLR QUANTITY AND QUALITY

Volumetric Assessment of the Liver

As the liver has a tremendous capacity for functional compensation and regeneration, healthy livers, without cirrhosis, can tolerate resection of up to

80% of their parenchymal volume. However, the segmental distribution of the liver's functional capacity is not uniform. It can vary from person to person, thus making it difficult to estimate the volume of the FLR needed to sustain function based on traditional anatomic nomenclature.[154] Preoperative volumetric analysis can be an important tool to assess the actual volume and predict the function of the FLR. This is particularly important when considering major and extended hepatic resections.

In the most basic sense, the FLR is standardized to total liver volume (TLV) and is expressed as the percentage of the TLV that is to be left unresected. Various methods for measuring liver volume have been proposed. One method is using CT and three-dimensional CT volumetry. This has been shown to be accurate and reproducible in calculating TLV and FLV values.[155–157] However, direct measurement of TLV on imaging can be problematic as large tumors, biliary dilatation, and underlying liver disease may affect the accuracy of the measurements. In addition, accurately measuring TLV requires that the tumor volume be excluded or subtracted, which can be particularly difficult in the setting of multiple tumors and can lead to user discrepancies and mathematical error.

An alternative approach is to estimate the TLV using a mathematical formula based on body surface area (TLV [cm^3] = −794.41 + 1267.28 × body surface area [m^2]), which has been validated in a meta-analysis and found to be superior to other similar formulas.[158,159] An FLR volume ≤20% has been found to be the strongest independent predictor of postoperative liver insufficiency, as well as a significant risk factor for postoperative liver failure and death.[160–162] Thus, an FLR volume >20% has been proposed as a cutoff for safe hepatic resection in healthy, noncirrhotic livers.

However, many patients undergoing liver resection do not have healthy livers. Although the exact pathogenesis is not entirely understood, liver injury is a known risk of chemotherapy, and increasing duration of preoperative treatment has been shown to increase the risk of postoperative complications.[163–169] Longer durations of preoperative chemotherapy (>12 weeks) have been associated with higher rates of liver injury and postoperative hepatic insufficiency.[167,170] In patients who receive short-duration preoperative chemotherapy, it has been suggested that an FLR of at least 20% to 30% is sufficient to undergo hepatic resection.[170,171] However, those receiving long-duration (>12 weeks) preoperative chemotherapy

should have an FLR volume of at least 30%, although some suggest that an FLR of 40% is necessary to prevent postoperative hepatic insufficiency.[170,172,173] In patients with hepatic fibrosis or cirrhosis, the FLR volume is suggested to be at least 40% to 50% of TLV.[174,175]

Functional Assessment of the Liver

One of the most important assessments when determining resectability of liver malignancies involves the preoperative evaluation of liver function. The perioperative morbidity and mortality risk has been shown to increase with worsening degree of hepatocellular compromise in cirrhotic patients undergoing hepatic resection.[176–179] Although a long list of functional studies, imaging techniques, and serum markers exists, the multiple and diverse functions of the liver make comprehensive evaluation difficult, and no single study has been consistently proven to be the best measurement of preoperative liver function or predictor of postoperative hepatic insufficiency and failure prior to resection.

The model for end-stage liver disease (MELD) is one of two major clinical scoring systems frequently used to evaluate liver function in cirrhotic patients. MELD is based on a patient's bilirubin, international normalized ratio (INR), and creatinine.[180] Traditionally used to predict survival in cirrhotic patients awaiting liver transplantation, the utility of the MELD score has been expanded to a variety of clinical settings, including the assessment of patients being considered for partial hepatectomy.[180–183] For patients with cirrhosis undergoing hepatic resection, a MELD score ≥9 has been shown as an independent predictor of perioperative complications and mortality.[182,183] As such, a MELD score <9 can be considered reasonably safe for hepatic resection.

The other frequently used clinical scoring system, the Child–Turcotte–Pugh (CTP) score, can be used to predict liver-related mortality in cirrhotic patients. CTP takes into account both clinical measures and laboratory values, including presence of ascites, encephalopathy, total serum bilirubin, INR, and serum albumin.[184] An elevated CTP score has been associated with increased morbidity and mortality following liver resection.[177,179,185] In fact, a Child B classification (score 7 to 9) is considered a relative contraindication to resection, particularly for major hepatectomy. A Child C

designation is an absolute contraindication, even for most minor resections.[186] In addition, the presence of encephalopathy, independent of the other factors, is generally considered a contraindication to resection.

An additional method of identifying cirrhotic patients at risk for postoperative complications involves an assessment for the presence of portal hypertension. Splenomegaly and/or varices present on imaging are both reliable signs of portal hypertension. However, they are rarely present in patients being considered for resection, therefore reliance on radiographic evidence of these signs is inadequate. Portal venous wedge pressure can be used for the direct measurement of portal pressure. However, the routine use of this invasive technique is impractical. Alternatively, for patients with underlying liver dysfunction, thrombocytopenia has been shown to be a good surrogate marker for the presence of portal hypertension. It tends to be indicative of increased platelet sequestration due to portal hypertension–induced hypersplenism. Although portal hypertension is not an absolute contraindication to hepatic resection, thrombocytopenia has been associated with increased morbidity and mortality in patients undergoing resection.[187–190] Specifically, a preoperative platelet count <150/nL has been independently associated with major postoperative complications, postoperative hepatic insufficiency, and 60-day mortality in patients with HCC undergoing hepatic resection.[185] In fact, a modified Child score based on this data has been proposed, which replaces encephalopathy in the traditional CTP scoring system with preoperative platelet count. This modified Child score was found to be independently associated with major postoperative complications and 60-day mortality, and the only factor independently associated with postoperative hepatic insufficiency.[185] This modified scoring system is particularly clinically relevant as the presence of encephalopathy is uniformly a contraindication to resection and thus does not contribute greatly to a preoperative risk scoring system. Rather, a simple lab value such as the platelet count can give insight into the presence of portal hypertension. Bone marrow suppression from chemotherapy leading to a decreased production of platelets must also be considered when interpreting the meaning of thrombocytopenia.

Indocyanine green (ICG) clearance is another assessment tool used preoperatively to evaluate liver function in cirrhotic patients being considered for hepatic resection. ICG is an anionic organic dye that is

selectively taken up by hepatocytes and excreted in bile. It is usually measured as a percent serum clearance at 15 minutes and indirectly reflects hepatocyte blood flow and functional capacity.[191] An ICG cutoff of <10% at 15 minutes has been reported to be safe for extended resection, a cutoff of 10% to 20% for hemihepatectomy, 20% to 30% for segmentectomy, and only enucleation for those with >40% ICG clearance.[192] However, the utility of ICG clearance over other well-established functional measures is debated, and it is rarely used in the United States.[188,193]

INCREASING TECHNICAL RESECTABILITY

Portal Vein Embolization

Portal vein embolization (PVE) is a percutaneous procedure performed preoperatively in select patients as a means to increase the volume of the anticipated FLR, which has been shown to subsequently improve liver function, thereby decreasing the risk of postoperative complications associated with small FLR size.[194–197] The portal vein of the intended specimen is embolized and occluded to induce a hypertrophic response in the FLR. The efficacy of PVE has been well documented, with a reported average increase of 12 ± 5% in FLR volume following PVE.[160,161,172,197] In fact, FLR growth due to PVE has been shown to increase resectability in almost 60% of patients who previously would have been considered unresectable due to inadequate FLR size.[171,198] Furthermore, it has been demonstrated that those patients whose FLR growth following PVE enabled them to undergo resection had no difference in postoperative morbidity and mortality compared to those who underwent resection upfront without the need for PVE.[160,198,199] Overall and disease-free survival has also been shown to be similar among these two groups in patients undergoing resection for colorectal liver metastases.[172,198] Thus, it does not seem that increasing technical resectability utilizing PVE sacrifices adherence to the principle of biologic selection.

More recent studies have found the kinetic growth rate of the FLR following PVE to be a strong predictor of postoperative liver insufficiency, liver failure, and death.[200,201] Using cutoff values of ≥2% and >2.66% FLR

growth per week, patients in this group from both studies had significantly lower postoperative morbidity and none developed liver failure or suffered liver-related death. This suggests that growth rate of the FLR, rather than the absolute standard volumetric measurements, may be a better marker for determining resectability of liver tumors following PVE, although further evaluation is still needed.

Although its application is not standardized, studies have warned against the routine use of PVE, citing a large percentage of patients in whom PVE had no effect on morbidity or mortality following hepatic resection.[171,199] Furthermore, PVE is not entirely without risk. Between 2% and 20% of patients fail to demonstrate remnant hypertrophy following PVE, and roughly 10% of patients suffer adverse events following the procedure.[197,202] Tumor progression following PVE may also be a concern, and has been documented in 17% to 25% of patients with colorectal liver metastases.[198,203]

Therefore, it has been suggested that PVE be reserved for an FLR volume ≤20% of TLV in patients without underlying liver dysfunction.[160,171,198,204] Among patients with or at high risk for liver injury (e.g., those who have received extensive preoperative systemic chemotherapy), PVE is recommended for an FLR volume ≤30% of TLV.[160,172,204] In patients with severe hepatic fibrosis or cirrhosis, an FLR ≤40% is the suggested cutoff value for performing PVE.[174,175,204]

Two-Stage Hepatectomy

Initially described by Adam et al. in 2000, a two-stage hepatectomy (TSH) is a potentially curative operative strategy in patients with multiple bilobar colorectal liver metastases that traditionally would be considered unresectable via a single operation, even in conjunction with systemic and local therapies.[205] The first stage of the procedure consists of resection of metastases from only one hemiliver, which is the designated FLR after the second stage is complete. Thus, it is important that parenchymal-sparing techniques be used during the first operation. In most patients, PVE of the contralateral liver is performed following the first stage. During the second-stage operation, all remaining metastases in the contralateral hemiliver are then resected. Although data examining TSHs are limited to single-institution studies with small patient cohorts and widely variable patient selection

criteria, a recent meta-analysis found that in select patients with initially unresectable colorectal liver metastases, TSH resulted in low postoperative morbidity and mortality and acceptable survival outcomes.[206] In particular, these patients fared significantly better than their counterparts who received systemic chemotherapy alone. In one study examining long-term outcomes following TSH, despite higher postoperative morbidity, comparable 5-year survival was seen between patients undergoing completed TSH and those who underwent a single-stage hepatectomy during the same time period.[207]

Associating Liver Partition with Portal Vein Ligation for Staged Hepatectomy

Associating liver partition with portal vein ligation for staged hepatectomy (ALLPS) is a relatively aggressive, and disputed, approach to managing traditionally unresectable liver tumors. More specifically, it was developed to overcome several limitations of PVE, including the potential for disease progression during the 4- to 6-week waiting period, and inadequate FLR hypertrophy following PVE. The procedure involves in situ splitting of the liver with portal vein ligation during the first stage, inducing rapid FLR hypertrophy, followed by a short-interval (<7 days) second stage in which the hemiliver containing the tumor is removed.[208,209] While several case series have reported its technical feasibility, complications can be high. Long-term data is minimal, and its use is highly controversial and debated.[210–216]

ANATOMY AND CLASSIFICATION

5 In order to perform partial hepatectomy, precise knowledge and mastery of the surgical anatomy of the liver, blood vessels, and biliary channels is essential. The liver is divided into sectors that comprise liver segments, each supplied by branches of the portal triads and drained by hepatic veins. Partial hepatectomy involves removal of one or more segments by isolation of the relevant portal venous and arterial inflow, severance of the relevant

hepatic veins and biliary drainage channels, and removal of the associated liver tissue.

The anatomic division between the right and left hemiliver follows a line projected through a plane found at the principal plane or Cantlie line—running from the medial margin of the gallbladder bed to the left of the IVC posteriorly, not at the falciform ligament.[217] Each hemiliver is then subdivided into sectors, sections, and segments.

The Brisbane terminology dictates that the hepatic veins form the boundaries between the different sectors of the liver.[218] Specifically, the medial margin of the right posterior sector is the right hepatic vein and comprises segments VI and VII. The right anterior sector is bordered by the right hepatic vein laterally and middle hepatic vein medially, coursing along the principal plane, comprising segments V and VIII. These are also termed the right posterior *section* and right anterior *section* according to Brisbane terminology. Based on this same terminology system, the area of liver that comprises segments IVa, IVb, and III forms the left medial sector as it is bound by the middle and left hepatic veins. Segment II forms the left lateral sector, because the left hepatic vein divides segment II from III. From a clinically relevant perspective, however, en bloc resection of segments III, IVa, and IVb cannot be performed since this area of liver encompasses the umbilical fissure where the left portal vein is situated. Thus, according to Brisbane terminology, segment IVa/b is referred to as the *left medial section,* and it is bordered by the middle hepatic vein and umbilical fissure. The left lateral sector, according to the slightly modified terminology that is being presented here, is comprised of segments II and III. This represents the portion of liver to the left of the ligamentum teres and falciform ligament and is termed the *left lateral section* according to Brisbane terminology. Essentially, the left liver is divided into a medial and lateral sector along the line of insertion of the ligamentum teres and the falciform ligament. This modified terminology will be utilized for the remainder of this chapter as it is clinically relevant and applicable. The term "section" will not be used. The portal venous and hepatic arterial branches conform to the segmental organization and run within the segments, and the draining hepatic veins converge posteriorly toward the inferior vena cava (**Fig. 60.11**).

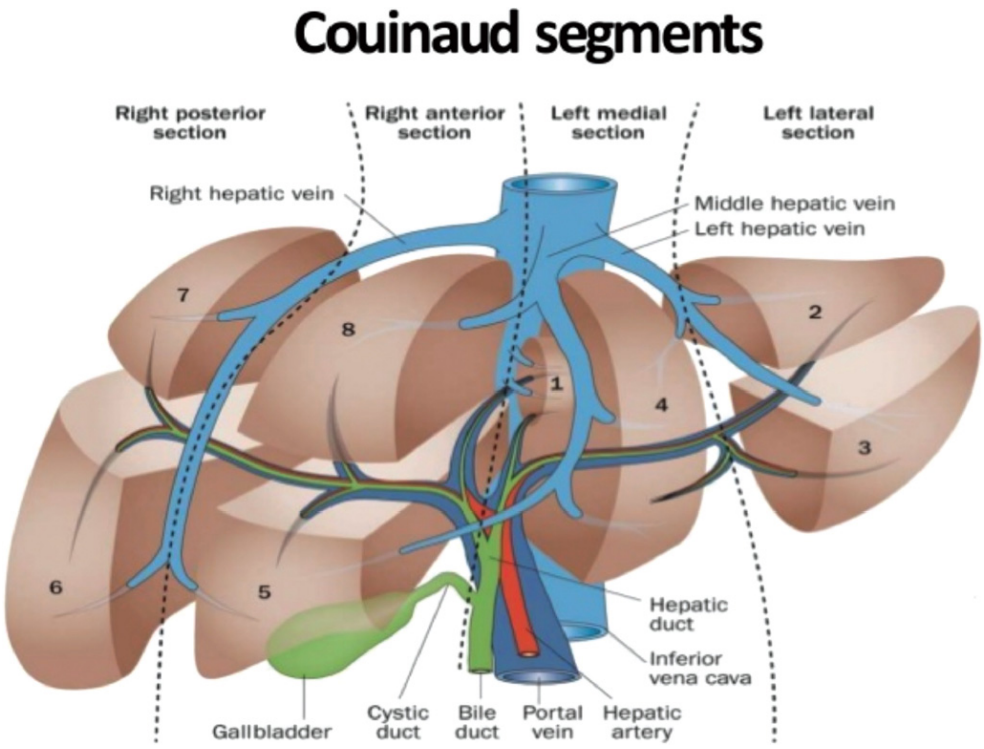

Figure 60.11 Segmental anatomy of the liver utilizing the Brisbane terminology of "sections."

6 Practically, five types of hepatic resections are performed relatively routinely. The five different resections include (1) right hepatectomy, (2) left hepatectomy, (3) left lateral sectorectomy, (4) right posterior sectorectomy, and (5) segmentectomy/nonanatomic resection. A simple step-by-step algorithm for performing these procedures is detailed in **Tables 60.3** to **60.7**. The portal vein and hepatic artery divide into major right and left branches outside the liver parenchyma below the hilus. Here, when the overlying peritoneum is incised, it is usually possible to dissect each major branch beyond its bifurcation, unless significant variations in anatomy exist. The confluence of the right and left hepatic ducts also occurs outside the liver. At the hilum of the portal vein, the right portal vein is short, and often has an early branch to the caudate process prior to its bifurcation into the right anterior and posterior portal veins. In contrast, the left branch of the portal vein and the left hepatic duct pursue a longer, more horizontal extrahepatic course beneath segment IV and are more easily dissected free along their length.

The ligamentum teres (round ligament) runs into the umbilical fissure of the liver, at the base of which the main vascular and biliary pedicles branch to the segments of the left liver (II, III, IVa, IVb). After entering the umbilical fissure, the left branch of the portal vein curves caudally and gives branches not only to the left lateral sector (segments II and III) but together with branches of the left hepatic artery, it also supplies the left medial sector—segments IVa and IVb of the left liver, also known as the *quadrate lobe*. These branches course from left to right, starting in the umbilical fissure and supplying segments IVa/IVb.

Outside of the liver substance, there is not a distinct sheath around the portal triad structures, and they can be dissected separately. The structures of the portal triad—the portal vein, hepatic artery, and bile duct—are covered with Glisson capsule as they enter the liver parenchyma such that within the liver, they are contained in well-formed branching fibrous sheaths often referred to as *pedicles*, each containing a vein, artery, and bile duct. Pedicles are strong structures that contain the constituents of the portal triad, and intrahepatic dissection of these pedicles enables isolation and control of vascular and biliary elements without the need to individually expose each structure outside the liver.

Table 60.3 Right Hepatectomy (Segments V–VIII)

1. Explore the abdomen to ensure no subradiographic metastatic disease.
2. Ligate the round ligament and leave the suture long and place a hemostat on it.
3. Divide the falciform back toward IVC, staying about 1 cm off the surface to enable resuspension of the left liver.
4. Open the lesser sac through the pars flaccidum and clear the area over the caudate lobe and feel for enlarged lymph nodes. This will enable control of the porta hepatis.
5. Ultrasound the entire liver, especially the left liver remnant, to ensure no subradiographic disease.
6. Perform a cholecystectomy, but leave a long tie on the cystic duct stump. This will facilitate a safe dissection in the porta hepatis.
7. Mobilize the right liver. The right phrenic vein will mark the location of the right hepatic vein.
   a. Incise the right anterior coronary ligament.
   b. When visualization becomes difficult, incise the inferior attachments to the liver to drop the kidney and adrenal gland. Stay just lateral to the IVC.
   c. Incise the triangular ligament.
   d. This will give good exposure to retract the right liver toward the left and incise the right posterior coronary ligament.
   e. Do not divide the left coronary/triangular ligament to prevent kinking of the left inflow and outflow vessels postoperatively.
8. Ligate and divide the venous tributaries to the IVC from the caudate lobe to expose and clear off the anterior aspect of the IVC.
   a. Clips, energy devices, or staplers can be used for this depending on the size of the veins.
9. Divide the caval (caudate) ligament with a vascular load stapler.
10. Find and develop the “notch” at the dome of the liver to find space between the right and middle hepatic vein. This will facilitate extrahepatic control of the right hepatic vein.
11. With the cystic duct stump retracted medially to the left, dissect out and control the right hepatic artery. Test clamp to ensure good left hepatic arterial flow before dividing. It can either be tied or stapled.

12. Once artery is divided, dissect out the right portal vein. Test clamp to ensure the left portal vein is intact with US. Place an umbilical tape around the right portal vein and retract to the left to protect the left portal vein. Divide with an endovascular stapler.
13. Now that inflow is controlled, divide the right hepatic vein outflow with an endovascular stapler.
14. Mark out the line for parenchymal transection along Cantlie line, staying just right of the middle hepatic vein.
15. Divide the hepatic parenchyma down to the right bile duct.
16. Encircle the right bile duct intrahepatically, making sure to stay to the right of the cystic duct stump and biliary hilum to avoid injury to the contralateral biliary system. Divide the right bile duct with an endovascular stapler.
17. Complete the parenchymal transection.
18. Hydrate the patient to a status of euvolemia.
19. Ensure hemostasis and biliary stasis along the cut surface of the liver.
20. Resuspend the left liver by sewing the falciform ligament to the diaphragm with interrupted figure-of-eight 2-0 Vicryl sutures.

Table 60.4 Left Hepatectomy (Segments II–IV)

1. Explore the abdomen to ensure no subradiographic metastatic disease.
2. Ligate the round ligament and leave the suture long and place a hemostat on it.
3. Divide the falciform back toward IVC.
4. Open the lesser sac through the pars flaccida and clear the area over the caudate lobe and feel for enlarged lymph nodes. This will enable control of the porta hepatis.
5. Ultrasound the entire liver, especially the right liver remnant, to ensure no subradiographic disease.
6. Perform a cholecystectomy.
7. Mobilize the left liver by incising the left coronary and left triangular ligaments.
   a. Place a laparotomy pad over the stomach and spleen to avoid injury.
   b. Do not injure the diaphragm or left phrenic vein.
8. Divide the entire length of the lesser omentum, being careful to ligate a replaced or accessory left hepatic artery if present.
9. Dissect out the left hepatic artery at the medial aspect of the porta hepatis at the base of the umbilical fissure. Test clamp it to ensure good flow in the right hepatic artery. Divide the left hepatic artery either with ties or an endovascular stapler.
10. Dissect out and control the left portal vein at the base of the umbilical fissure. Test clamp it and ensure good flow in the right portal vein using US. Divide the left portal vein with an endovascular stapler. Divide it distal to the takeoff of caudate lobe branches to preserve caudate inflow.
11. Mark out the plane of transection, staying left of the middle hepatic vein.
12. Divide the parenchyma. Make sure to curve to the left as the transection plane approaches the porta hepatis to prevent injury to the right bile duct or right-sided inflow structures.
13. Encircle the left bile duct at the base of the umbilical fissure and divide it with an endovascular stapler.
14. Complete the parenchymal transection superiorly by dividing the left hepatic vein with an endovascular stapler.
15. Hydrate the patient to a status of euvolemia.

16. Ensure hemostasis and biliary stasis along the cut surface of the liver.

Table 60.5 Left Lateral Sectorectomy (Segments II–III)

1. Explore the abdomen to ensure no subradiographic metastatic disease.
2. Ligate the round ligament and leave the suture long and place a hemostat on it.
3. Divide the falciform back toward IVC.
4. Open the lesser sac through the pars flaccida and clear the area over the caudate lobe and feel for enlarged lymph nodes. This will enable control of the porta hepatis.
5. Ultrasound the entire liver, especially the right liver remnant and segment IV, to ensure no subradiographic disease.
6. Perform a cholecystectomy. This is not absolutely necessary to perform a left lateral sectorectomy but is conventional to perform at the time of liver resection.
7. Mobilize the left liver by incising the left coronary and left triangular ligaments.
   a. Place a laparotomy pad over the stomach and spleen to avoid injury.
   b. Do not injure the diaphragm or left phrenic vein.
8. Mark out the line of parenchymal transection just left of the falciform ligament and umbilical fissure.
9. Divide the parenchyma.
10. Encircle the segment III pedicle as it is exposed during parenchymal transection. Divide it with an endovascular stapler.
11. Encircle the segment II pedicle as it is exposed during parenchymal transection. Divide it with an endovascular stapler.
12. Complete the parenchymal transection superiorly by dividing the left hepatic vein with an endovascular stapler.
13. Hydrate the patient to a status of euvolemia.
14. Ensure hemostasis and biliary stasis along the cut surface of the liver.

Table 60.6 Right Posterior Sectorectomy (Segments VI–VII)

1. Explore the abdomen to ensure no subradiographic metastatic disease.
2. Ligate the round ligament and leave the suture long and place a hemostat on it.
3. Divide the falciform back toward IVC, staying about 1 cm off the surface to enable resuspension of the left liver, should it be necessary.
4. Open the lesser sac through the pars flaccida and clear the area over the caudate lobe and feel for enlarged lymph nodes. This will enable control of the porta hepatis.
5. Ultrasound the entire liver, especially the left liver remnant and right anterior sector, to ensure no subradiographic disease.
6. Perform a cholecystectomy.
7. Mobilize the right liver. The right phrenic vein will mark the location of the right hepatic vein.
   a. Incise the right anterior coronary ligament.
   b. When visualization becomes difficult, incise the inferior attachments to the liver to drop the kidney and adrenal gland. Stay just lateral to the IVC.
   c. Incise the triangular ligament.
   d. This will give good exposure to retract the right liver toward the left and incise the right posterior coronary ligament.
   e. Do not divide the left coronary/triangular ligament to prevent kinking of the left inflow and outflow vessels postoperatively.
8. Divide the caval (caudate) ligament with a vascular load stapler.
9. Find and develop the “notch” at the dome of the liver to find space between the right and middle hepatic vein. This will facilitate extrahepatic control of the right hepatic vein. This step is not always necessary depending on the location of the tumor and whether or not the right hepatic vein needs to be divided to obtain a negative margin.
10. Mark out the line for parenchymal transection along the right hepatic vein using US. The line of transection will be either to the right or left of the right hepatic vein depending on whether or not it needs to be ligated to obtain a negative margin resection. The line of transection is along a transverse plane of the liver.
11. Divide the hepatic parenchyma down to the right posterior sector pedicle.

12. Encircle the right posterior pedicle and test clamp it and ensure preservation of flow in the right anterior pedicle with US. Divide the right posterior pedicle with an endovascular stapler. Extrahepatic control and division of the right posterior portal vein and right posterior hepatic artery is also feasible and commonly performed.
13. If necessary for the procedure, divide the right hepatic vein with an endovascular stapler.
14. Complete the parenchymal transection.
15. Hydrate the patient to a status of euvolemia.
16. Ensure hemostasis and biliary stasis along the cut surface of the liver.
17. If necessary, resuspend the left liver by sewing the falciform ligament to the diaphragm with interrupted figure-of-eight 2-0 Vicryl sutures. Given that the right anterior sector is left in situ, this step is often not necessary.

Table 60.7 Partial Hepatectomy/Segmentectomy

1. Explore the abdomen to ensure no subradiographic metastatic disease.
2. Ligate the round ligament and leave the suture long and place a hemostat on it.
3. Divide the falciform back toward IVC.
4. Open the lesser sac through the pars flaccida and clear the area over the caudate lobe and feel for enlarged lymph nodes. This will enable control of the porta hepatis.
5. Ultrasound the entire liver, especially the future liver remnant, to ensure no subradiographic disease.
6. Perform a cholecystectomy.
7. Depending on what segment or what area of the liver is to be removed, the right or left liver should be mobilized as described in **Tables 60.3** and **60.4**.
8. Mark out the line for parenchymal transection using US to ensure an adequate margin. If a segmentectomy is to be performed, US should be utilized to define the inflow and outflow.
9. Divide and complete the hepatic parenchyma. It is helpful to use US to guide the resection to ensure a negative margin and remnant inflow during the dissection.
10. Complete the parenchymal transection.
11. Hydrate the patient to a status of euvolemia.
12. Ensure hemostasis and biliary stasis along the cut surface of the liver.

The liver straddles the IVC immediately below the diaphragm, and the hepatic veins have a short extrahepatic course to empty into the vena cava. This superior portion of the vena cava with the draining hepatic veins is covered with a fold of peritoneum that extends from the cephalad aspect of the falciform ligament to the right and left triangular ligaments. This fold of peritoneum comprises the anterior and posterior coronary ligaments, which converge to form the right and left triangular ligaments, respectively. The right hepatic vein usually enters the vena cava separately. By contrast, the left hepatic vein runs in the left scissura between segments II and III and is often joined by the middle hepatic vein, which occupies the principal scissura,

before entering the vena cava. Thus, the middle and left hepatic veins most often empty into the IVC as a common trunk. The right and left phrenic veins, which are easily visible on the surface of the diaphragm, empty into the right and left hepatic veins, respectively, and serve as a reliable landmark to mark the location of the right and left hepatic veins. Several smaller veins from the posterior surface of the liver and the caudate lobe drain directly into the IVC, termed the short hepatic veins or "caudate veins."

The umbilical vein runs beneath the falciform ligament and empties into the left hepatic vein. This vein is important in right-sided resections that remove segment IVa because it provides drainage of segment IVb if the procedure mandates ligation of the middle hepatic vein.

OPERATIVE PROCEDURES

Patient Positioning and Incision

For open procedures, the patient should be positioned supine with both arms extended at a right angle to the body. It is not necessary to place the patient in a lateral decubitus position, as adjusting the operating table allows for adequate exposure during the operation. This exposure is adequate for most hepatic resections. The abdomen should be widely exposed from midaxillary line to midaxillary line to allow adequate space for a bisubcostal incision, should one be necessary or preferred. It is the author's preference to do all resections through a simple midline laparotomy incision. A self-retaining retractor to elevate the costal margin provides ample visualization and exposure to complete the procedure safely.

Ultimately, the incision depends on body habitus and tumor location, and the surgeon should not hesitate to extend or enlarge the wound to gain adequate access. For most hepatic resections, a midline incision will suffice with appropriate costal margin and side-wall retraction. A midline incision is often most comfortable for the patient. An extended right subcostal or a bilateral subcostal with a vertical extension are other common incision choices. A slight variation of these incisions that affords excellent exposure for most resections is an upper midline incision from the xiphoid process to approximately 2 to 3 cm above the umbilicus with right lateral extension

toward a point midway between the inferior costal margin and anterior superior iliac spine. A small upper midline incision may be made first to allow preliminary manual and visual exploration to exclude obviously unresectable disease or the presence of extrahepatic spread. Particularly for left-sided resections, a midline incision is adequate. Large tumors of the right side of the liver, especially those lying posteriorly and involving the IVC, may require a right thoracoabdominal approach, but this is rarely necessary. This can usually be avoided with either right lateral extension of an upper midline incision with good costal margin retraction or a generous midline incision.

Exposure, Mobilization, and Assessment

After the abdomen is opened, the entire peritoneal cavity should be explored to assess for evidence of subradiographic metastatic disease. In particular, periportal lymph nodes along the hepatic artery, celiac axis, or in the portacaval groove should be assessed. Exploration of the lower abdomen through an upper abdominal incision may be difficult in patients who have had previous pelvic surgery. When direct access is limited, palpation in conjunction with preoperative cross-sectional imaging (CT or MRI) and/or PET scans is sufficient.

Prior to exploration of the liver, the ligamentum teres (round ligament) is divided, and the falciform ligament is incised and separated from the anterior abdominal wall. The falciform ligament is divided as far cephalad as the subdiaphragmatic IVC. Vessels running within the falciform ligament are usually controlled with bovie electrocautery. When performing a major right-sided resection, the transection plane of the falciform ligament should be approximately 1 cm off the surface of the liver to enable resuspension of the left liver remnant should it be necessary. A long suture should be left on the round ligament to act as a handle during subsequent exploration and dissection for manipulating the liver.

Elevation of the round ligament facilitates examination of the undersurface of the liver, the porta hepatis, and umbilical fissure. Bimanual palpation should be performed, as lesions located deep within the parenchyma may be missed or underestimated with simple surface examination. The transparent tissue of the lesser omentum, or pars flaccida, should be incised to facilitate

manual palpation of the caudate lobe (segment I) and the celiac lymph node basin. If the gastrohepatic ligament needs to be further divided to facilitate an adequate evaluation, attention should be directed to the possible presence of an accessory or replaced left hepatic artery. Complete assessment and palpation of the right lobe requires mobilization of the right liver from the diaphragm and retroperitoneum. This may be delayed until US examination of the liver in conjunction with initial palpation indicates that the lesions are resectable.

Mobilization of the right liver begins with complete division of the falciform ligament and identification of the right hepatic vein as the right coronary ligament is incised. As the falciform ligament fibers begin to splay at the back, one must be careful, as the hepatic vein confluence is in close proximity. Early identification of the right hepatic vein prevents subsequent injury during the lateral and inferior mobilization. The location of the right hepatic vein is marked by the right phrenic vein insertion. Once the right vein is visualized, the anterior and posterior coronary ligaments are incised to expose the entire bare area of the liver until the depth of the posterior ligament prevents adequate visualization. At this point, the inferior peritoneal attachments to the liver are incised, which is usually met with a rush of air, in order to separate and drop the adrenal gland. Releasing the inferior attachments facilitates leftward retraction of the liver and exposure of the triangular ligament. The triangular ligament is incised. With the right hepatic vein already visualized, the dissection can now safely proceed medially to complete the division of the posterior coronary ligament toward the inferior vena cava in order to fully mobilize the right hemiliver.

Next, the short retrohepatic veins draining directly from the caudate lobe to the IVC are serially divided, progressing from the inferior aspect up toward the hepatic veins. Complete exposure of the IVC and right hepatic vein requires division of the fibrous tissue, or the vena caval ligament, which usually obscures the right side or the upper part of the retrohepatic vena cava. This division can be done with an energy device or an endoscopic gastrointestinal anastomosis vascular stapler (Endo GIA; US Surgical, Norwalk, CT). It is the author's practice to routinely divide this ligament with a stapler in order to seal the blood vessels contained within this structure. The vena caval ligament also extends behind the vena cava posteriorly as a fibrous extension from the caudate lobe on the left. Rarely,

the caudate lobe circumferentially wraps around the IVC such that the vena cava runs through a tunnel of liver parenchyma. Although this thin plate of liver tissue can be a source of difficulty, it can similarly be divided to expose the IVC completely with minimal consequence. Dividing this ligament is a necessary step in order to safely gain extrahepatic control of the right hepatic vein.

Similarly for a planned left-sided resection, the left coronary and triangular ligaments are incised to mobilize the left lateral sector. Care must be taken not to damage the stomach and spleen at the far left of the triangular ligament, and placing a laparotomy pad under the ligament helps to protect these structures while incising the ligament. Extrahepatic control of the middle/left hepatic vein confluence is a challenging maneuver. The ligamentum venosum must be divided near its attachment to the left hepatic vein in order to expose the anterior surface of the IVC just proximal to the hepatic vein confluence. The notch in between the right and middle vein is developed and this plane is carefully extended to exit anterior to the IVC at the level of where the ligamentum venosum was divided. Placing an umbilical tape through this space controls the middle/left hepatic vein confluence extrahepatically. This maneuver should only be performed if the location of the tumor mandates extrahepatic division of these veins to facilitate an oncologic margin-negative resection.

Intraoperative Ultrasound

Intraoperative ultrasound (IOUS) is an integral and necessary component for planning and performing hepatic resections. It is used to confirm what was seen on preoperative imaging and to assess for other lesions that may not have been seen previously or have developed in the interval time period between imaging and resection. IOUS also further delineates the exact anatomic relationship of lesions with the major vascular and biliary structures within the liver parenchyma. US guidance is also utilized to perform a needle biopsy of small, deeply placed lesions and for ablative procedures. Examination is carried out with a B-mode, real-time system and a T-shaped probe is the most ergonomic for direct application of the probe to the liver surface and in the author's opinion, provides the best images. Examination should be carried out in a systematic fashion, starting with

assessing the outflow and inflow vessels, the biliary tree, and then finally the hepatic parenchyma. In case of doubt, further examination may be done after mobilization of the right or left liver, particularly for posteriorly located tumors. The probe also may be placed on the inferior surface of the liver. IOUS can help plan and guide large segmental resections traversing narrow planes between the tumor edge and major vascular structures. Thus, it is paramount that the surgeon has the ability to use and interpret IOUS in order to safely maneuver inside the liver.

GENERAL PRINCIPLES OF HEPATIC RESECTIONS

All hepatic resections mandate control of the inflow and outflow vasculature and biliary drainage to the portion of liver to be resected, with preservation of adequate hepatic arterial and portal venous blood supply and intact biliary drainage to the liver remnant. Depending on the type of resection being performed, the inflow and outflow can be controlled either outside the liver substance or within the liver parenchyma. Launois and Jamieson have historically advocated for control of the intrahepatic pedicles when oncologically feasible in order to avoid contralateral injury.[219] In practice, most surgeons use a combination of techniques in hepatic resection, doing both pedicle ligation within the liver and extrahepatic dissection to expose the individual corresponding artery and portal vein. Biliary drainage from the remnant liver must be preserved without injury, including both leakage and stricture, to the biliary tract. The hepatic venous outflow should be controlled after inflow division, and the liver parenchyma must be transected to provide tumor adequate clearance in cases of malignancy.

Inflow Control and Preservation of the Integrity of the Biliary Tree

The hepatic arterial and portal venous blood supply to the portion of liver to be removed can be controlled and ligated either by extrahepatic dissection or by transecting the relevant pedicles within the liver parenchyma.

Extrahepatic vascular dissection may be accompanied by extrahepatic dissection and control of the relevant biliary radicles as well. However, this is associated with a higher risk of biliary injury, particularly during dissection on the right side, where anatomic variations in biliary anatomy are common. Thus, the right hepatic artery and right portal vein are typically divided utilizing an extrahepatic dissection for vascular control of right-sided lesions, while the corresponding biliary structures are divided within the pedicles at the time of hepatic parenchymal transection. This is not possible, however, for tumors that are close to the hilar structures, such as hilar cholangiocarcinoma. In these cases, extrahepatic biliary dissection is required, as making an intrahepatic approach would be impossible without compromising tumor clearance. For left-sided resections, although a pedicle approach is possible, dissection is most often carried out within or at the base of the umbilical fissure, and far left of the hilar bifurcation. Typically, the left hepatic artery and left portal vein are isolated and individually divided and the left bile duct is divided at the base of the umbilical fissure, thus minimizing the risk of injury to the right liver biliary drainage into the common duct.

Outflow Control

When performing a right hepatectomy, intrahepatic control of the right hepatic vein during parenchymal transection is feasible and acceptable for tumors that allow clearance superiorly with adequate tumor margins and with safe intrahepatic access to these vessels. However, extrahepatic control of the right hepatic vein is also safe and provides the added benefit of controlling the main outflow and disconnecting the specimen from the vena cava prior to parenchymal transection. This can potentially help reduce blood loss during parenchymal transection. For the difficult tumors lying high and posteriorly, extrahepatic control and ligation also facilitates an adequate oncologic margin. Because the middle hepatic vein usually merges with the left hepatic vein prior to draining to the IVC, the middle hepatic vein is usually taken within the liver substance when performing an extended right hepatectomy. During an extended left hepatectomy for a superiorly situated tumor, the middle and left hepatic veins are often controlled as a single unit outside the liver. For a standard left hepatectomy, the middle hepatic vein is preserved

and the left hepatic vein is divided within the liver, often as the last step of parenchymal transection. If isolated extrahepatic left hepatic vein control is needed, a small hepatotomy is usually needed to dissect the plane between the middle and left hepatic veins. This is seldom needed or performed.

Parenchymal Transection

Once the inflow and outflow are controlled, parenchymal transection ensues. It is important to maintain a state of low central venous pressure (CVP) in order to minimize bleeding. Central venous access for CVP monitoring is not necessary as long as intravenous fluids are tightly restricted. Several methods may be used to transect the liver parenchyma. The author's preference has been to use a simple crushing technique where Glisson capsule is scored with diathermy along the line of proposed transection, and a Kelly clamp is used to crush the liver tissue and expose small vessels, biliary channels, and larger pedicles. These structures can then be secured and divided using a variety of techniques. The most simple and economic method is to use clips and suture ligation. However, a variety of energy devices can be used that include (1) computer-controlled bipolar cautery (LigaSure; Valleylab, Boulder, CO); (2) a saline-linked radiofrequency ablation monopolar device (TissueLink; TissueLink Medical, Dover, NH), or a bipolar variation (Aquamantys, TissueLink Medical); (3) a Harmonic Scalpel (SonoSurg; Olympus Key Med, New York, NY). All of these devices have been used with success by a variety of investigators.[220–222] They also have been used successfully in the performance of laparoscopic partial hepatectomy. Larger structures can be controlled with sutures or vascular staplers.

The technique of using a Kelly clamp to crush the tissue is rapid and efficient. Although some surgeons choose to apply intermittent inflow occlusion to control blood flow to the remnant, this is most often not necessary if low CVP is maintained.[223] Should inflow occlusion still be necessary, intermittent 15-minute periods of occlusion, interspersed by 5-minute periods of relief to allow perfusion of the remnant and decompression of the bowel, is usually a safe technique. Prolonged occlusion during hepatic resection in patients with jaundice or cirrhosis should be avoided. Prolonged portal inflow occlusion is unnecessary, and for major hepatic resections,

complete parenchymal transection is usually accomplished in 20 to 30 minutes. During the short breaks between applications of the Pringle maneuver, the argon beam coagulator (Force GCU System; Valleylab) can be used to control small vessel oozing on the side of the remnant. Avitene (Davol, Warwick, RI), Surgicel (Ethicon, Somerville, NJ), or fibrin sealants also may be applied to the cut surface of the liver to achieve final hemostasis after transection is complete.

Alternate options for the Kelly clamp technique to expose the intrahepatic vascular and biliary anatomy include an ultrasonic dissector or a water-jet dissector.[224] The ultrasonic dissector has some advantages in dissecting liver parenchyma away from delicate vascular and biliary structures, particularly when a margin-negative resection is dependent on the precise dissection of that area. A disadvantage of the ultrasonic dissector is that it can be time consuming and offers no apparent advantage during the majority of parenchymal transection. No published data are available to indicate that any one technique is associated with decreased blood loss.

Some have described the use of broad coagulation devices, an example of which is the Habib 4X (AngioDynamics, Latham, NY). It uses radiofrequency energy to coagulate liver parenchyma widely along the planned transection plane with or without the use of vascular staplers; this method does not clearly expose the internal structures of the liver. The author does not advocate for such an approach and strongly believes that parenchymal transection should be a controlled dissection to avoid serious damage to the liver remnant and minimize bleeding and risk of bile leak.

The basic steps to performing common hepatic resection procedures are listed in **Tables 60.3** to **60.7**.

CONCLUSION

The nuances of determining resectability for liver tumors can be difficult to master, owing to the variety of primary and secondary malignancies involving the liver, the diversity of patient-specific factors to consider, and the hepatic anatomic and functional variability that represents the norm. The basic principles, however, are simple—if surgery is deemed appropriate from an oncologic standpoint, the patient is in reasonably good health and

can withstand the operation, and the tumor can be safely removed without compromising the viability of the future remnant, nearly all patients will be candidates for resection. However, as our understanding of tumor biology improves, diagnostic and operative techniques evolve, and systemic and local therapies improve, the selection of patients for resection will continue to both expand and simultaneously be refined.

Calculous Biliary Disease

Salila S. Hashmi and Elijah Dixon

Key Points

1. Gallstones are classified by their cholesterol content as either cholesterol (70% to 80%) or pigment (20% to 30%), with pigment stones further classified as black or brown.
2. The pathogenesis of cholesterol gallstones is multifactorial but essentially involves four factors: (a) cholesterol supersaturation in bile, (b) crystal nucleation, (c) gallbladder dysmotility, and (d) gallbladder absorption/secretion.
3. Prophylactic cholecystectomy is generally not indicated in patients with asymptomatic gallstones.
4. Laparoscopic cholecystectomy is a safe procedure even when performed for acute cholecystitis.
5. Choledocholithiasis (Common Bile Duct stones) can have an asymptomatic course or may present with mild biliary colic to fulminant sepsis from acute cholangitis, biliary pancreatitis, or hepatic abscesses.
6. Endoscopic cholangiography with sphincterotomy allows for the diagnosis of CBD stones in the vast majority of cases. It also allows for therapeutic intervention if stones are identified. ERCP with stone extraction is effective in removing stones in 85% to 95% of cases but is associated with postprocedural complications (pancreatitis and cholangitis).
7. Common bile duct exploration may be required to remove stones that cannot be removed via ERCP.

INTRODUCTION

There are two types of gallstones—cholesterol or pigment stones. Cholesterol stones are most common accounting for 70% to 80% of gallstones. The pathogenesis of cholesterol gallstones is multifactorial' essentially involving four factors: (a) cholesterol supersaturation in bile, (b) crystal nucleation, (c) gallbladder dysmotility, [1] and (d) gallbladder

absorption/secretion. These are not purely 2 made up of cholesterol but in fact have a core of calcium salts. The pigmented stones can be black or brown and are made up of calcium bilirubinate. Black stones are exclusively found in the gallbladder whereas brown stones can also be found in the biliary tree (both intra and extrahepatic). While cholesterol stones are more common in the Western world, pigmented stones especially brown stones are more common in Asia.

RISK FACTORS FOR GALLSTONE FORMATION

Cholelithiasis is a result of an interplay between genetic and environmental factors.

Age: The incidence of gallstones increases with age. Most pediatric patients with gallstone disease have an association with a hemolytic disease.

Gender: Females are at a higher risk—mostly secondary to hormonal effects of estrogen, oral contraceptive use or hormonal therapy after menopause. Pregnancy also increases the risk of biliary sludge formation.

Genetics: There has been an implication of a genetic component in up to 30% of patients in some population studies. Cholesterol stones are found in ratios of 3:1 in family members. Genetic mutations have been identified in the hepatic cholesterol metabolism and hemolysis has been identified to play in a role in development of gallstone formation.

Physical activity, diet: Obesity is a major risk factor for gallstone development. Patients receiving parenteral nutrition are also at risk of developing biliary stasis and gallstones.

Other disease processes/medications: Cirrhosis can induce gallstone formation in about 25% to 30% of the patients. Inflammatory bowel disease, ileal resection, cystic fibrosis interferes with bile reabsorption and can lead to cholelithiasis. Medications including estrogen, thiazide diuretics increase biliary cholesterol secretion

whereas ceftriaxone—a third-generation cephalosporin—can also induce biliary stasis and therefore gallstone formation.

NATURAL HISTORY OF GALLSTONES

Eighty percent of people with cholelithiasis will remain asymptomatic. Two percent to 3% per year of those with known gallstones will develop symptoms and 1% to 2% will develop more complex problems (such as cholecystitis, pancreatitis, or cholangitis) annually. Symptoms can be described as right upper quadrant (RUQ) pain, mostly postprandial (usually after a fatty meal) and will often recur. Half of the patients with symptoms will develop a second symptomatic attack within a year. These symptoms correspond to intermittent impaction of gallstones at the gallbladder neck as the gallbladder contracts in order to deliver its contents into the common bile duct (CBD).

GALLSTONES AND GALLBLADDER CANCER

There is limited data to suggest that large gallstones (>3 cm) increase the risk for gallbladder cancer but this may be secondary to chronic inflammation. Therefore, there is no role for prophylactic cholecystectomy for asymptomatic cholelithiasis to 3 decrease cancer risk except for certain populations where the incidence of gallbladder cancer is unusually high (Chileans, Pakistani women, Pima Indians). Calcification of gallbladder is encountered in 0.8% of patients. The risk of gallbladder cancer with porcelain gallbladder was thought to be much higher.[1] The rate of gallbladder malignancy was only 6% compared to 1% in a matched cohort of patients without gallbladder wall calcification. Multivariate analysis identified the presence of a gallbladder mass as the only independent prognostic factor for harboring gallbladder malignancy. Even though it is a small but significant chance of gallbladder cancer with porcelain gallbladder a cholecystectomy is recommended in the setting of a calcified gallbladder.

Table 61.1

Imaging Modality	Findings	Advantages	Disadvantage
Transabdominal US	▪ Gallbladder wall thickening >4 mm ▪ Enlarged gallbladder (long axis ≥8 cm, short axis ≥4 cm) ▪ Pericholecystic fluid ▪ Presence of gallstones/sludge ▪ Murphy sign	▪ Quick, readily available ▪ Inexpensive ▪ No radiation exposure ▪ Sensitivity and specificity 80–85%	▪ User dependent
Biliary scintigraphy (HIDA)	▪ Lack of visualization of gallbladder implies obstructed cystic duct ▪ Ejection fraction <35%—signifies biliary pathology	▪ Sensitivity 95–98% and specificity 90% ▪ Diagnostic yield is higher than US	▪ False positive after prolonged fasting or a after a heavy meal ▪ Not readily available ▪ Radiation exposure
CT	▪ Gallbladder wall thickening ▪ Presence of gallstones ▪ Complications of cholecystitis—gangrenous cholecystitis, liver abscess/perforation		▪ Typically, less helpful for diagnosis for acute cholecystitis ▪ Radiation exposure
MRI/MRCP	▪ Gallbladder wall thickening ▪ Stones in the common bile duct	▪ Sensitivity 86% and specificity 82%	▪ Overestimate the presence of

	gallbladder inflammation ▪ Quality of images depends on patient's cooperation to hold the breath ▪ Radiation exposure

See references [34–36].

CHOLECYSTITIS

Cholelithiasis begets cholecystitis which can present as acute inflammation or more ongoing, intermittent inflammation leading to chronic cholecystitis.

Acute Cholecystitis

Acute cholecystitis develops when the bile flow is obstructed secondary to an impacted gallstone(s) in the gallbladder neck (infundibulum) or in the cystic duct. This obstruction leads to biliary stasis, gallbladder wall edema, venous obstruction, and in extreme cases, eventual arterial obstruction causing necrosis of the gallbladder wall. Acute inflammation may be complicated by secondary biliary infection, gram negatives such as *Klebsiella* and *Escherichia coli* being the most common organisms.

Clinical Manifestations

Clinical course can vary from mild epigastric/RUQ pain with fever/chills to frank sepsis secondary to perforation or development of emphysematous/gangrenous cholecystitis. Inflammation results in midepigastric or RUQ pain with localized peritoneal irritation. Murphy sign which is defined by cessation of inspiration secondary to pain, due to the

presence of an inflamed gallbladder during deep abdominal palpation at the midclavicular line of the RUQ, is pathognomonic for acute cholecystitis.

Imaging

According to the Tokyo guidelines ultrasound (US) is recommended as the first-choice imaging method for the morphologic diagnosis of acute cholecystitis.[2] US findings of gallbladder wall thickening >4 mm, enlarged gallbladder, pericholecystic fluid, presence of gallstones, and/or positive Murphy sign (pain and cessation of inspiration when the probe is pressed over the gallbladder) are consistent with acute cholecystitis.

Criteria for diagnosis of acute cholecystitis on other imaging modalities are listed in Table 61.1. Of note, combined modalities do not appear to add sensitivity or specificity for detection of acute cholecystitis, although they may provide additional morphologic information.

Diagnosis

Criteria for diagnosis for acute cholecystitis are listed in the **Table 61.2**. When compared to pathologic samples the diagnostic accuracy is between 94% and 60%. The World Society of Emergency Surgery guidelines for acute calculous cholecystitis recommend the combined use of clinical, laboratory, and imaging findings for diagnosis.[3]

Table 61.2 Tokyo Guidelines for Diagnosis of Acute Cholecystitis

A. Local signs of inflammation (1) Murphy sign (2) RUQ mass/tenderness
B. Systemic signs of inflammation (1) Fever (2) elevated C-reactive protein (CRP) (3) elevated white blood cell (WBC) count
C. Imaging findings characteristic of acute cholecystitis Suspected diagnosis: one item in A + one item in B Definite diagnosis: one item in A + one item in B and C

See references 2, 41.

Table 61.3 Grades of Acute Cholecystitis (Tokyo Guidelines)

Grade I	Grade II	Grade III
No organ dysfunction and mild inflammatory gallbladder changes	Elevated WBC RUQ tenders/palpable tender mass Duration of complaints >72 hrs Marked local inflammation (gangrenous cholecystitis, pericholecystic abscess, hepatic abscess, biliary peritonitis, emphysematous cholecystitis) Duration of complaints >72 hrs	Cardiovascular dysfunction requiring vasopressor support Neurologic dysfunction—decreased level of consciousness Respiratory dysfunction—PaO_2/FiO_2 ratio <300 Renal dysfunction—oliguria, Cr > 2 Hepatic dysfunction Hematologic dysfunction platelets <100,000/mm^3

Three grades of severity have been described with grade III (severe) acute cholecystitis causing systemic symptoms due to organ damage (Table 61.3). These grades have been validated in multiple studies and are significantly associated with prognosis, length of hospital stay, conversion to open surgery and medical costs.[4–6] However, these grades cannot be used to assess surgical difficulty.

Treatment

Initial medical treatment involves parenteral hydration and antibiotics against enteric bacteria. Despite symptom resolution, the patient should undergo

cholecystectomy as the definitive treatment given that the likelihood of a second biliary-related complication is high.

Cholecystectomy is the standard surgical therapy for patients with acute cholecystitis. Laparoscopic and more recently robotic cholecystectomy (at limited centers) has become standard of care. The timing of the cholecystectomy—early versus delayed has been much debated. Early cholecystectomy removes the pathologic source and helps resolve the acute inflammatory response, potentially making the surgery safer with fewer complications and morbidity. No significant differences in patient outcomes between early and delayed surgeries with respect to bile duct injuries, bleeding, laparoscopic-to-open conversions, postoperative infection, and patient death have been reported. However, 4 23% of delayed patients presented with complications requiring emergent cholecystectomy. In addition, total length of stay in the hospital, including the index admission and subsequent admission either for biliary complications and/or later cholecystectomy, was significantly longer for these patients. A 2013 Cochrane Review included six randomized trials with 488 patients; this study compared early (within 7 days of presentation) to late (>6 weeks after initial treatment) cholecystectomy and found similar results.[7] Multiple studies demonstrate that *early* should be within the index admission and the 72-hour limit is a relative rule given improved skills of surgeons with laparoscopic surgery and the understanding that surgery delayed to a different admission could potentially lead to worse complications. Tokyo guidelines recommend early (within 7 days, within 72 hours even better) laparoscopic cholecystectomy for grade I patients. In grade II (moderate) patients, consider urgent/early laparoscopic cholecystectomy if patient performance status is good. If the patient's condition is poor, urgent/early biliary drainage and delayed/elective cholecystectomy should be considered. In grade III (severe) patients with high surgical risk, urgent/early biliary drainage should be performed. In selected patients with no negative predictive factors (total bilirubin ≥2, neurologic dysfunction, respiratory dysfunction) or with cardiovascular or renal system failure that is rapidly reversible after admission early laparoscopic cholecystectomy can be considered.[8]

CHRONIC CHOLECYSTITIS

Cholelithiasis is the causative factor of chronic cholecystitis in most (>90%) patients. This leads to recurrent episodes of cystic duct obstruction manifesting as recurrent biliary colic. These recurrent attacks lead to scarring and a nonfunctioning, noncontracting gallbladder. A patient with chronic cholecystitis presents similarly to those with biliary colic and it is often difficult to distinguish between the two conditions. Diagnosis is accomplished with a US showing circumferential thickened gallbladder wall with gallstones in the setting of recurrent episodes of RUQ abdominal pain. In some patients the gallbladder may be shrunken and small. Chronic cholecystitis is treated with cholecystectomy. A subtype of chronic cholecystitis is called xanthogranulomatous cholecystitis that can present as gallbladder mass. Inflammation of gallbladder wall leads to permeation of bile within the wall, bile in engulfed by macrophages and the resulting lipid-laden macrophages lead to a chronic granulomatous inflammatory response. Histology shows diffuse or focal mural changes in the form of xanthoma cells (foamy histiocytes containing lipids and bile pigment), giant multinucleate histiocytes, and acute or chronic inflammatory cells. Microabscesses may also form in the gallbladder wall and a fibrous reaction may lead to adhesions with adjacent liver, duodenum, and transverse colon.[9] Studies have shown that contrast enhanced US may be a better diagnostic modality in differentiating xanthogranulomatous cholecystitis than gallbladder cancer.[10]

ACUTE ACALCULOUS CHOLECYSTITIS

Acute acalculous cholecystitis presents with major illness and therefore its incidence is significantly higher in intensive care unit patients. It is associated with increased bile stasis and decreased gallbladder emptying and function which leads to bile being inspissated and the formation of biliary sludge. The diagnosis requires a high index of clinical suspicion given that most critically ill patients are sedated and mechanically ventilated which makes reliable physical examination difficult. Late or missed diagnosis may lead to gallbladder ischemia and progression to gangrene and eventual perforation resulting in a mortality rate of up to 15% to 30%. Diagnosis may be made using bedside ultrasonography following similar criteria as used for acute calculous cholecystitis, except for lack of calculi. The sensitivity of US in

this setting ranges from 50% to 100% with a specificity of 90% to 94%. A hepatobiliary iminodiacetic acid (HIDA) scan with morphine amplification can be used to increase bile secretory pressure and allow bile to reflux through a contracted gallbladder neck, thereby decreasing false-positive rates, providing sensitivity rates of 67% to 100% and specificity rates of 69% to 100%. A negative US in a patient with a high clinical suspicion for acute acalculous cholecystitis may benefit from a HIDA scan to improve diagnostic yield. Treatment includes a percutaneous cholecystostomy (PC) tube in critically ill and/or unstable patients and a cholecystectomy for a stable patient. PC tube may be the definitive treatment for acute acalculous cholecystitis given there is no mechanical obstruction secondary to cholelithiasis.

OTHER CONDITIONS

Gangrenous Cholecystitis

Gangrenous cholecystitis is more commonly found in diabetic patients who have acute cholecystitis. The most common site for necrosis is the fundus as it is the furthest from the blood supply. Usually full-thickness necrosis is present in patients with gangrenous cholecystitis, but this does not necessarily result in frank perforation in all cases. CT findings include irregular thickening of the gallbladder wall, poor contrast enhancement of the wall (interrupted rim sign), increased density of fatty tissue around the gallbladder, gas in the gallbladder lumen or wall, membranous structures within the lumen (intraluminal flap or intraluminal membrane), and peri-gallbladder abscess.[11] Contrast enhanced CT or MRI are recommended for diagnosing gangrenous cholecystitis as these findings may be under appreciated on US alone.[12]

Emphysematous Cholecystitis

Emphysematous cholecystitis results from gas-forming bacteria in the bile. This can result in perforation, intra-abdominal abscess, generalized peritonitis, necrotizing fasciitis of abdominal wall. Given that intramural gas can be difficult to identify on US, CT is the modality of choice for diagnosis

and can also help to assess perforation and/or intra-abdominal abscess. Treatment includes antibiotic coverage for Clostridium and cholecystostomy tube placement for unstable, sick patients and a cholecystectomy for clinically stable patients.[2]

Of note the grading severity according to the Tokyo guideline classifies bother gangrenous and emphysematous cholecystitis as moderate.

Mirizzi Syndrome

Biliary obstruction secondary to cholecystitis is called Mirizzi syndrome. There are two types of Mirizzi syndrome. Type I involves compression of the CBD secondary to an impacted stone in the infundibulum or cystic duct. Type II involves a cholecystocholedochal fistula. Open cholecystectomy is the standard of care given that high laparoscopic to open conversion rates have been reported. Given the degree of inflammation a subtotal/partial cholecystectomy or a biliary reconstruction may also be required.

Cholecystoenteric Fistulae

Cholecystoeneteric fistula formation is a rare complication which occurs in approximately 1% to 2% of all patients with cholecystitis. The most common site of fistula is to the duodenum or transverse colon. This happens when the gallbladder decompresses into a bowel loop during an episode of cholecystitis. Complications of a cholecystoenteric fistula are rare, but a large gallstone may pass into the bowel and cause a mechanical bowel obstruction, usually distally in areas of narrow caliber, such as the ileocolic valve or sigmoid colon. This obstruction is known as a *gallstone ileus*. If this complication occurs, the initial management involves removal of the gallstone through an enterotomy with possible bowel resection. Decision to proceed with removal of the biliary enteric fistula and cholecystectomy at the time of index operation depends on patient's clinical condition and the degree of tissue inflammation. An association between the presence of a cholecystoenteric fistula and gallbladder cancer has been suggested, therefore clinical suspicion for cancer is warranted in this scenario.

CHOLECYSTECTOMY

Laparoscopic cholecystectomy was first performed in 1985 and is now the most common gastrointestinal surgical procedure performed in the U.S. and Canada. It is the gold standard operative technique given significant decreases in operative time, patient comfort, length of stay, and overall costs. True contraindications to the laparoscopic approach to cholecystectomy include (i) patient inability to tolerate pneumoperitoneum, (ii) bleeding diatheses, (iii) decompensated cirrhosis with ascites and varices.

TECHNIQUE—LAPAROSCOPIC CHOLECYSTECTOMY

The abdomen is typically entered near the umbilicus. This can be done with an open Hasson or a closed veress needle technique. We prefer the open Hasson technique and recommend a good finger sweep before inserting the Hasson port. This helps to sweep away any bowel or adhesions. The abdomen is then insufflated with CO_2. Even a blunt finger can injure bowel and therefore once the camera is placed through the port a thorough look in this area should be performed to rule out any inadvertent injuries before proceeding to the RUQ. If the patient has had a previous midline surgery or there are significant adhesions in the midline one should consider entering the peritoneal cavity under direct vision using optiview in the right or the left upper quadrant and then place the other ports under direct vision. Three additional operating ports are placed under direct visualization: one 10-/12-mm port in the epigastric/subxiphoid area, one 5-mm port in the RUQ in the anterior axillary line, in a position to grasp the fundus of the gallbladder and retract it cephalad and another 5-mm port in the midclavicular line in a position to grasp the infundibulum. Care should be taken to place ports at least a hands breadth away from each other to operate without the instruments clashing with each other.

Typically, the fundus is retracted cephalad (10 o'clock position), however depending on the length of the gallbladder this retraction may be appropriate

to apply below the fundus. The infundibulum is grasped and needs to be retracted toward the right lower quadrant to expose the triangle of Calot.

A few minutes should be spent to orient to the anatomy at this time. The dissection in the triangle should be performed above the Sulcus of Rouviere to avoid being too close to the duodenum. The hepatic artery may or may not be clearly visible but spending a few seconds may delineate a pulsation. Usually part of the bile duct can also be seen. Also, if the dissection will be below the umbilical fissure this means that one is too far out to the left in the porta and need to readjust retraction.

Hook cautery is used for dissection on the surface in the triangle and separate the lymphatic and fatty tissue. The blunt tip of the laparoscopic suction device is also a great tool especially in an inflamed field, allowing for dissection and suctioning of blood at the same time. Dividing the peritoneum on either side of the gallbladder wall helps expose the triangle even better. We recommend doing this before dissecting deep in the triangle. The goal is to identify two distinct structures entering the gallbladder (the cystic artery and cystic duct) creating the critical view of safety (Strasberg). This is done with a combination of hook cautery, suction catheter, and Maryland forceps. Sometimes the artery is very anterior to the triangle and may need to be clipped to complete the dissection in the triangle before the cystic duct can be clipped and divided confidently, especially if the dissection is difficult secondary to inflammation. This should be done with extreme caution and only in select cases. We recommend placing two clips on the staying side of the artery and the duct and one clip toward the gallbladder and then divided.

The peritoneum surrounding the gallbladder is then incised further and using electrocautery the gallbladder is then taken off the cystic plate. If bleeding is encountered electrocautery should be used to control it immediately before the visibility is lost once the gallbladder has been taken off the cystic plate. Inadvertent excursion into the deep plane here can lead to bleeding from tributaries of the middle hepatic veins.[13]

Once the gallbladder is free it is placed in an impermeable bag and removed through the umbilical port. This may need to be enlarged in the setting of large calculi. All ports are removed under direct visualization. The fascia at the umbilical port site is then closed using 0-Vicryl sutures and then the skin is closed with Monocryl sutures.

Intraoperative Cholangiogram

If the anatomy is unclear, a cholangiogram is a useful adjunct. This can be performed laparoscopically via access of the proximal cystic duct. A ductotomy is made on the anterior wall of the proximal cystic duct. The duct proximal to this is ligated with a clip. A cholangiocatheter is then threaded through this ductotomy and a radio-opaque contrast agent is injected, and under fluoroscopy the biliary ductal anatomy is defined. The role of routine cholangiography in prevention of bile duct injury is controversial. A complete and adequate cholangiogram includes identification of the cystic duct, visualization of both the right and left hepatic ducts, smooth tapering of the CBD, and presence of contrast into the duodenal lumen.

Newer techniques of fluorescent-assisted biliary system identification using systemically injected near-infrared dyes, such as indocyanine green, may assist in identification of the critical structures without requiring intraoperative catheter placement. Fluorescent imaging requires a special camera system and allows continuous biliary mapping throughout the procedure. Intraoperative US is another adjunct that can be utilized to define anatomy during laparoscopic cholecystectomy.

OTHER APPROACHES TO CHOLECYSTECTOMY

Single-Incision Laparoscopic Approach

The desire for minimally invasive surgery led to the development single-incision approach to laparoscopic cholecystectomy (SILS). This is generally performed by placing a multiport access device through the umbilicus and inserting various instruments through the single port in order to dissect the critical structures and the gallbladder. The safety of SILS in elective cholecystectomies has been proven in various clinical trials, however increased operative time and hernia rates have been reported.

Robotic Cholecystectomy

With the emerging use of robot technology in various surgical procedures, robotic cholecystectomy has also been gaining popularity. Studies have shown that even though this is a safe approach and the outcomes of robotic and laparoscopic approach are comparable, the cost to the healthcare system continues to be an issue. Further investigations are needed to determine its role in acute settings and its cost-effectiveness.

Open Cholecystectomy

Open cholecystectomy is now a rare operation. It is usually performed if there is another concurrent procedure or when a laparoscopic cholecystectomy is converted to an open procedure. This may be due to inability to identify anatomy or an inadvertent injury. Conversion to open cholecystectomy in the setting of acute cholecystitis is not protective of bile duct injury. Open cholecystectomy can be performed through either an upper midline or right subcostal (Kocher) incision. Typically, dissection is performed in a top-down fashion, from the fundus toward Calot triangle with identification of the cystic artery and duct at the gallbladder neck. Dissection can still be started in the triangle as described above to obtain the critical view, divide the duct and the artery. The duct and artery can be divided between clips and sutures. The gallbladder is then taken off the cystic plate using electrocautery either in a top-down approach, or from the infundibulum upward to the fundus.

SUBTOTAL CHOLECYSTECTOMY

Subtotal cholecystectomy is an option to avoid biliary tract injury in cases where anatomy cannot be delineated clearly or when there is an impaction of a large stone at the cystic duct. This can be performed with laparoscopic or open approach. It involves opening the gallbladder above the neck, removing all the stones leaving the neck of the gallbladder in situ to protect the critical structures. In some cases, the posterior wall of the gallbladder may be left attached to the liver bed as well. The neck of the gallbladder may be closed with suture or stapler (subtotal reconstitution). If left open the lumen of the cystic duct is closed with a purse-string suture (subtotal fenestration).

Omentum can be placed within the neck of the gallbladder as well. While the reconstituting technique can lead to stone reformation and recurrent symptoms, the fenestrating technique has a higher likelihood of bile leak or biliary fistula. A similar proportion of patients have been shown to require reintervention after fenestrating versus reconstituting subtotal cholecystectomy (32% vs. 26%), more completion cholecystectomy was required after fenestrating subtotal cholecystectomy (9% vs. 4%). A closed suction drain should be placed in the gallbladder fossa after a subtotal cholecystectomy to evacuate any bile leak, which will generally resolve spontaneously.

Percutaneous Drains after Cholecystectomy

There is no current evidence in support of leaving drains after an uncomplicated cholecystectomy or even open cholecystectomy. They seem to increase harm to the patient without providing any additional benefit. Drain placement should be deferred onto a case-to-case basis and can be considered if the gallbladder is necrotic or in cases of subtotal cholecystectomy with high risk for bile leak postoperatively. Even in these cases drains may assist in the early diagnosis of bile leaks but do not prevent it.[14,15]

COMPLICATIONS OF CHOLECYSTECTOMY

Serious complications of laparoscopic or open cholecystectomy are rare and the associated mortality rate is <0.3%. The most severe complication of cholecystectomy is a biliary duct injury. The incidence of bile duct injury following laparoscopic cholecystectomy is between 0.3% and 0.6% (vs. 0.2% to 0.3% for open surgery). Cystic artery stump leak is rare but may happen if the clips are dislodged. Major vascular injuries, especially to the right hepatic artery, may occur in association with bile duct injuries due to their close anatomic relationship. Spillage of stones into the peritoneal cavity during laparoscopic cholecystectomy occurs in 5% to 40% of cases. Intra-abdominal abscess, subcutaneous abscess, and fistulation of stones through the abdominal wall have all been described and therefore every attempt

should be made to remove spilled stones. Large stones or massive spills should be removed as best possible to prevent delayed complications.

PROPHYLACTIC CHOLECYSTECTOMY

Asymptomatic cholelithiasis can be managed expectantly without surgical intervention. Prophylactic cholecystectomy may, however, be indicated in certain circumstances (Table 61.4). Patients who have a higher risk of cancer in the setting of gallbladder disease, such as Native Americans, presence of large gallstones (>2.5 cm), or calcification of gallbladder wall ("porcelain gallbladder") are commonly offered prophylactic cholecystectomy. Patients who are more likely to have recurrent symptoms or complications secondary to gallstone disease may also undergo prophylactic cholecystectomy; examples of these conditions include hereditary spherocytosis, sickle cell disease, other hemoglobinopathies, the bariatric patients, and pediatric patients.

Table 61.4 Indications for Prophylactic Cholecystectomy

Pediatric gallstones associated with sickle cell disease
Congenital hemolytic anemia
Gallbladder polyp >10 mm
Calcifications
Acalculous cholecystitis/biliary dyskinesia
Concern for gallbladder malignancy
Cholelithiasis and no access to medical care

PERCUTANEOUS CHOLECYSTOSTOMY

PC tubes can be used as a bridge to cholecystectomy or a definitive treatment of acute cholecystitis in critically ill patients or those who are not good

surgical candidates. There is no data to suggest any difference in outcomes for transhepatic versus transperitoneal cholecystostomy tube placement.[16] The technical success for radiologically guided cholecystostomy tubes is 98% to 100%. Potential complications include intrahepatic hematoma, pericholecystic abscess, biliary peritonitis, and biliary pleural effusion. Once the patient is doing clinically better a cholangiogram should be performed to ensure there is no obstruction at the level of the cystic duct and if no evidence of obstruction the tube can be clamped for 10 to 14 days to confirm that the patient will tolerate removal. If clamping is tolerated it can be safely removed. If clamping trial is not tolerated a cholecystectomy should strongly be considered or the tube may need to be left for a longer duration.[17] Patients who have a persistent obstruction secondary to gallstones and are still not good surgical candidates may need upsize of tube and/or removal of stones percutaneously.

It is recommended to wait at least 8 weeks after placement of PC tube before proceeding with laparoscopic cholecystectomy. Early cholecystectomy (less than 8 weeks) has been shown to be associated with higher risk of complications and longer hospital length of stay.[18,19] This may be secondary to maximal medical optimization preoperatively.[20] When doing a laparoscopic cholecystectomy with a cholecystostomy tube in place it is usually easier to remove the cholecystostomy tube at the outset of the operation so that the fundus can be retracted normally. The suction catheter can be used to remove all the bile to prevent leakage. Alternatively, a clip can be placed at the site where the tube was entering the gallbladder, or a grasper can be used retract the fundus cephalad and cover the hole to prevent leakage of bile, sludge and stones. There is data to suggest that the rate of CBD injury during a subsequent laparoscopic cholecystectomy after PC tube may be higher than general population.[17] There is no difference in risk of CBD injury in the early cholecystectomy versus late group after placement of PC tube.

Other Therapies

Ursodeoxycholic acid (ursodiol) works by dissolving cholesterol crystals and decreasing hepatic secretion of biliary cholesterol thereby decreasing the number of stones and is thought to decrease the number of biliary colic

attacks. Unfortunately, most stones recur (>50% at 5 years) and in a prospective randomized study of ursodiol therapy the authors found that it did not decrease the number of attacks nor gallstone-related complications during the waiting period for cholecystectomy. An additional therapy is extracorporeal shock wave lithotripsy (ESWL). This therapy uses energy ("shock") waves to dissolve stones. ESWL can dissolve small calculi or decrease the size of larger calculi and make them potentially extractable by endoscopic or percutaneous techniques, especially if in the CBD or distal cystic duct. It is a relatively safe procedure with rare complications, including hematoma (biliary or otherwise), bowel perforation, and necrotizing pancreatitis.

SPECIAL CONSIDERATIONS

Gallstone Pancreatitis

Gallstone pancreatitis is the most common form of acute pancreatitis, thought to be secondary to obstruction of the ampulla secondary to a stone and reflux of bile into the pancreatic duct. In most cases the obstruction is transient and urgent biliary decompression is needed. Once the pancreatitis is settled these patients should undergo cholecystectomy. There is no data to support any differences between early endoscopic retrograde cholangiopancreatography (ERCP) and conservative management of pancreatitis of any severity. However, in patients with concurrent cholangitis or continuous biliary obstruction early ERCP reduced mortality and systemic complications.[21]

Gallbladder Cancer

A gallbladder containing an unsuspected cancer is removed in 0.2% to 2% of all laparoscopic cholecystectomies. If cancer is suspected preoperatively a complete staging workup with CT of chest, abdomen/pelvis or CT chest, and MR abdomen should be completed before cholecystectomy and better still the patient should be referred to a specialist hepatobiliary surgeon. During surgery extreme caution should be taken to avoid bile spillage as this is associated with worse outcomes if cancer is found on final pathology.[22,23] If

the suspicion is very high then an en bloc hepatic resection (parts of segment 4b and 5) should also be performed. This can be done with laparoscopic energy (Harmonic or Ligasure) devices. The gallbladder is taken off with the cystic plate in continuity, being careful to ensure a negative margin. If suspicion is high a portal lymphadenectomy should be performed as well. This is all done for appropriate staging. The gallbladder with en bloc liver should be extracted in an impermeable bag to reduce the risk of seeding the peritoneum and/or port sites. If a gallbladder cancer is incidentally discovered on pathology, these patients should be referred to hepatobiliary surgery expertise for further management. They will require additional hepatic resection, portal lymphadenectomy, and possible bile duct resection (if cystic duct margin is positive). The optimal time interval for re-resection for incidentally discovered gallbladder cancer appears to be between 4 and 8 weeks after the initial cholecystectomy.

Cholecystitis during Pregnancy

After appendicitis, biliary disease is the second most common gastrointestinal disease requiring surgical consideration during pregnancy. The safety of laparoscopic cholecystectomy is well established in the second trimester. Chances of spontaneous abortion and preterm labor prohibits this procedure being undertaken in the first and third trimester. If acute cholecystitis cannot be managed with antibiotics in either of these trimesters, PC tube should be considered as a bridge to cholecystectomy in second trimester or post delivery. The periumbilical port site may need to be adjusted based on the gestational age.

Cholecystitis and Cirrhosis

Cholecystitis in the presence of liver cirrhosis should generally be treated with PC tube placement. Even though incidence of complications may be higher in these patients this does not preclude them from getting a cholecystectomy in selected patients. Higher MELD score, Child's B and C, operative time, intraoperative blood loss, lower platelet count, and high INR are all prediDifferent Techniques for Common Bile Duct Explorationolecystectomy in patients with cirrhosis. Laparoscopic approach

is associated with shorter operative time, reduced length of stay, and reduced complication rates.[24–26] Therefore, patient selection is of utmost importance; elective surgery in patients with varices and ascites should be avoided. They should be treated with PC tubes if they develop acute cholecystitis. If varices are found on the gallbladder wall intraoperatively subtotal cholecystectomy and stone retrieval is an option to avoid bleeding.

CHOLEDOCHOLITHIASIS

Choledocholithiasis is defined as the presence of stones in the extrahepatic biliary tree. CBD stones can be defined as primary or secondary stones based on the location of their origin. Primary CBD stones originate within the bile duct. These tend to develop in conditions associated with bile stasis, such as: (i) benign biliary strictures, (ii) bile duct cysts (choledochal cysts), or (iii) sphincter of Oddi dysfunction. They can also occur in patients with congenital 5 absence of gallbladder or those whose CBD was clear at the time of cholecystectomy. These are predominantly brown-pigment (calcium bilirubinate) stones. Secondary stones originate from the gallbladder and migrate into the bile duct. They are the most common type of CBD stones. Majority of these stones are cholesterol stones. Ten percent to 15% of patients with symptomatic gallstones will have CBD stones and the vast majority of patients with secondary CBD stones will have gallstones.[27]

Clinical Presentation

Clinical presentation of CBD stones can vary from an asymptomatic course to biliary colic, jaundice, cholangitis, and pancreatitis. CBD stones can pass spontaneously into the duodenum without clinical consequence. The incidence and frequency in which this occurs is unknown. In patients with a low index of suspicion (nonjaundiced patients with nondilated bile ducts on US), the incidence of CBD stones at the time of cholecystectomy is approximately 5% with one-third of these patients passing the stone(s) spontaneously. Biliary colic is the most common presentation. Intermittent obstruction of CBD and passage of stones can also cause varying fluctuations in the bilirubin and liver function enzymes. Persistent CBD obstruction can lead to cholangitis and

present as Charcot triad—fever/rigors, jaundice, RUQ pain or Reynaud pentad—hypotension and mental status changes in addition to Charcot triad. Pancreatitis is the second most common presentation of CBD stones. CBD stones can be found in about 50% of patients with pancreatitis depending on the timing of the cholangiography. If left untreated symptomatic CBD stones can lead to serious complications therefore diagnosis and ultimately their treatment is of utmost importance.

Diagnosis

Without the presence of any clinical signs (cholangitis or pancreatitis) the diagnosis rests on a combination of biochemical and radiologic tests. Numerous studies have assessed the predictive value of serum liver biochemical tests. Although liver biochemical tests have a strong negative predictive value (97%), they only have a positive predictive value of 15% to 50% when they are abnormal in patients with suspected CBD stones. ϒ-Glutamyltransferase has been suggested to be the most sensitive and specific.[28] Imaging modalities consist of both invasive and noninvasive techniques. Transabdominal US alone has a poor sensitivity of 22% to 60% in detecting CBD stones and is highly operator dependent. Presence of gallstones or CBD diameter greater than 6 mm can be predictive of CBD stones. Like US, computed tomography (CT) scans also have a low sensitivity. Magnetic resonance cholangiopancreatography (MRCP) is the gold standard noninvasive imaging modality to detect duct stones. It has a sensitivity of 81% to 100% and specificity of 92% to 100%. Small stones less than 5 mm can still be missed with MRCP. Its accuracy is comparable to ERCP and an intraoperative cholangiogram (IOC). Certain treatment algorithms recommend an endoscopic ultrasound (EUS) as first approach prior to ERCP in patients at intermediate risk of CBD stones, when the diagnosis of choledocholithiasis is unclear, or in patients with severe gallstone pancreatitis. If no stones are seen on EUS, an ERCP can be avoided. Laparoscopic intraoperative US using a high-frequency probe allows for successful evaluation of the CBD in 88% to 100% of cases with a sensitivity of detecting CBD stones of 71% to 100%. In addition, laparoscopic US, like EUS, allows for the adequate evaluation of the distal bile duct for stones. Given the invasive nature of ERCP and the risks of

bleeding, perforation, ascending cholangitis, and postprocedure pancreatitis it is now best reserved as a therapeutic measure rather than a diagnostic test. When routine IOC was being performed at the time of open cholecystectomy choledocholithiasis was discovered in 10% to 15% of patients and those that were clinically significant were even less. Use of IOC at the time of laparoscopic cholecystectomy has yielded similar results. It has been shown that only 2.2% of patients with positive IOC required ERCP 6 weeks post cholecystectomy for symptomatic choledocholithiasis.[27]

The American Society for Gastrointestinal Endoscopy has proposed a risk stratification scheme to detect duct stones based on common predictive factors previously identified (Table 61.5).[29] This has been validated in a large cohort of multi-institutional patient cohort.

Management

Management of choledocholithiasis includes endoscopic, surgical (open and/or laparoscopic), and percutaneous approaches. Sequence of events for management of choledocholithiasis varies depending on the local expertise of a multidisciplinary team (surgery, gastroenterology, and radiology). For acutely sick patients with cholangitis or severe gallstone pancreatitis and persistent choledocholithiasis ERCP prior to cholecystectomy should be performed.

Table 61.5 The American Society for Gastrointestinal Endoscopy Predictors of Choledocholilithiasis

Predictors of Choledocholithiasis	
Very strong	
CBD stone on transabdominal US	
Ascending cholangitis	
Bilirubin >4 mg/dL	
Strong	
Dilated CBD (>6 mm) on US	
Bilirubin elevated (1.8–4 mg/dL)	
Moderate	
Abnormal liver biochemical test (other than bilirubin)	
Age >55	
Clinical gallstone pancreatitis	
Likelihood	
Presence of any very strong predictor	High
Presence of both strong predictors	High
No predictors	Low
All other patients	Intermediate

See reference 29.

Table 61.6 ERCP Prior to Cholecystectomy vs CBD Exploration for Choledocholithiasis

ERCP prior to cholecystectomy for suspected choledocholithiasis	▪ High-risk group, especially those needing decompression for cholangitis ▪ Severe gallstone pancreatitis and persistent choledocholithiasis
Common bile duct exploration at the time of cholecystectomy	▪ Large, impacted stones ▪ Multiple failed endoscopic attempts ▪ Anatomy precluding endoscopy such as previous gastric bypass ▪ Intermediate preoperative risk for choledocholithiasis with IOC confirming choledocholithiasis

ERCP, Endoscopic retrograde cholangiopancreatography; CBD, common bile duct; IOC, intraoperative cholangiogram.

Table 61.6 elicits timing and sequence of interventions based on some relevant clinical scenarios.

There is some evidence to support a single-stage laparoscopic cholecystectomy with IOC and CBD exploration in those with choledocholithiasis versus preoperative ERCP followed by laparoscopic cholecystectomy. Prospective randomized trials have concluded equivalent duct clearance rates, 6 morbidity, but shorter length of stay with single-stage procedure.[30] This 7 is dependent on the surgeon's comfort level with laparoscopic or open CBD exploration. Management of patients with high and low risk of choledocholithiasis is generally agreed upon. It is the management of patients with intermediate risk that poses a challenge. Randomized clinical trial has shown shorter length of stay and difference in morbidity with upfront cholecystectomy and IOC compared to preoperative ERCP and subsequent ERCP.[31]

Endoscopic Approach

A cholangiogram is performed after a deep biliary cannulation to define anatomy and confirm choledocholithiasis. Endoscopic sphincterotomy is the first therapeutic step in stone extraction. If there is a large impacted stone sometimes a precut sphincterotomy is required to complete the sphincterotomy. Balloon baskets and Fogarty-type balloon catheters are employed for stone extraction. Large stones may also mandate dilatation of the papilla using endoscopic balloon dilation. Mechanical lithotripsy, intracorporeal lithotripsy with laser or electrohydraulic probes can help reduce stone size and facilitate retrieval. ERCP is successful in about 90% of cases, the chances of retention increase with stone size >15 mm. Complications of ERCP include acute pancreatitis, cholangitis, bleeding from sphincterotomy, perforation (duodenal and biliary).

Percutaneous Approach

This involves (i) a rendezvous procedure and (ii) a complete percutaneous procedure. Rendezvous involves passage of a guidewire percutaneously through the bile ducts and into the duodenum. This guidewire is then used by endoscopists for an ERCP. This is beneficial is cases with altered anatomy (Bilroth II) or large duodenal diverticulum precluding ERCP. Complete percutaneous approach requires multiple sessions. A transhepatic fistula is created, allowed to mature for 7 to 8 days and then used for stone retrieval.

Table 61.7 Different Techniques for Common Bile Duct Exploration

	Transcystic	Transcholedochal
Success	80–90%	83–96%
Morbidity	Bile leak 1% Acute pancreatitis 0.5% Cystic duct rupture 6.8%	Bile leak 14% Pancreatitis 7.3% Reoperation 7.3% Mortality 1%

Refs. [37–40].

7 SURGICAL TECHNIQUES FOR CHOLEDOCHOLITHIASIS

Laparoscopic Surgical Approach

Laparoscopic Common CBD Exploration (LCBDE)

Concomitant LCBDE at the time of laparoscopic cholecystectomy allows for management of choledocholithiasis as a single stage procedure. It is ideal for patients with CBD stones incidentally identified at the time of IOC. LCBDE can be performed via a transcystic or transcholedochal technique (Table 61.7). Transcystic LCBDE is used for small stones (1 cm). Usually the same port sites as a laparoscopic cholecystectomy can be used, with potentially an additional 5-mm port along the midclavicular line on the left. The gallbladder is left in situ for traction. A cystic ductotomy is made like the one for IOC. To relax the Sphincter of Oddi 1 mg of glucagon is administered intravenous and after 3 minutes with the guide wire in place, a cholangiocatheter is advanced from the ductotomy into the CBD, which is then saline irrigated to flush small stones and debris out of the bile duct under fluoroscopic guidance. A choledochoscope can be used for direct visualization and stone extraction can be accomplished with the use of a basket. The ampulla may need dilatation which can be performed with a long ureteral balloon over a guide wire. This technique can also be used for cystic duct dilatation if needed. At the completion the cystic duct can be ligated using an Endoloop, clips or suture.

CBD exploration via choledochotomy is performed only when CBD >1 cm in diameter and it is typically reserved for larger stones (>1 cm). An anterior longitudinal choledochotomy below the cystic duct is made between two stay sutures on the CBD using fine absorbable sutures. The same techniques as mentioned above can be used for stone retrieval. If all the stones are removed and CBD is clear the choledochotomy should be closed primarily. However, if there are concerns for recurrent/retained stones, the choledochotomy should be closed over a T-tube. The T-tube preparation and management is detailed below.

Laparoscopic Biliary Enteric Bypass

If there is risk of recurrent stones or distal biliary stricture (malignancy excluded) a choledochoduodenotomy or a Roux-en-Y hepaticojejunostomy should be considered. In the past there were concerns for sump syndrome with choledochoduodenotomy, which implied food debris blocking the bile flow. But it is really thought to be a technical error secondary to narrow anastomosis. This anastomosis allows for easy endoscopic access to the biliary tree if needed. In cases where duodenum cannot be mobilized secondary to inflammation a Roux-en-Y hepaticojejunostomy should be performed. The downside is that in future direct endoscopic access to the biliary tree is not available with this anastomosis.

Laparoscopic-Assisted Endoscopic Retrograde Cholangiopancreatography

Patients who have had previous Roux-en-Y gastric bypass accessing the ampulla can be difficult even with balloon endoscope. In this situation laparoscopic access to the gastric remnant can provide an easier access for ERCP. Stomach is brought up to the wall, a gastrostomy is made, and a radially dilating trocar is placed through the gastrostomy. An endoscope is then passed down through this trocar to perform ERCP.[32] Once ERCP is completed the gastrostomy can be closed with sutures or an endoscopic stapler.

Open Surgical Approach

Open Common Bile Duct Exploration

In the current era open CBD exploration is infrequently performed, mostly when other approaches fail. Presence of large impacted stones causing Mirizzi syndrome, patients in whom anatomy precludes endoscopic treatment such as prior gastric resection/bypass, duodenal diverticula, or presence of biliary enteric fistula, are some of the instances where open CBD exploration may be required.

A wide Kocher maneuver is performed to allow for exposure and palpation of the entire bile duct. A supraduodenal longitudinal choledochotomy is made between two stay sutures with fine absorbable sutures. This should be as distal as possible; this (i) allows easy creation of

an anastomosis if needed, (ii) leaves maximal amount of CBD for additional future procedures, (iii) allows the use of a rigid choledoscope since it measure about 7 cm. Fogarty cannulation is performed, passing the catheter into the duodenum (can be easily palpated with fingers). The balloon is then inflated very carefully while the catheter is being retracted against the papilla so the stones from the duct can be cleared. Care is taken to avoid passage of stones into the proximal duct. This can be done for stones in the proximal duct as well. Inflation in balloon needs to be precise—where underinflation can miss stones overinflation can lead to duct damage. After a choledochotomy is made a choledoscope (rigid or flexible) can also be used to remove stones. Use of rigid instruments including grasping forceps should be avoided as they can damage the bile duct and lead to late strictures. The duct should be flushed with saline; this allows for small stones and sludge to be flushed out. Use of T-tubes is falling out of favor and therefore the choledochotomy can be closed with interrupted fine absorbable sutures but if needed (high risk patients) a 12-French T-tube can be left in place and secured with interrupted fine absorbable sutures, taking care not to catch the T tube with the sutures.

A T-tube needs to be prepared before being placed in the CBD. This involves cutting the two limbs and removing half the diameter of the part that will be in the CBD. This will prevent obstruction in the bile duct and allow easy removal. Once the T tube is placed completion cholangiography should be performed to assess for CBD clearance. The T-tube it is left to straight drainage until postoperative day 5 to 7 when a T-tube cholangiogram is performed. If no obstruction is present the tube can be clamped and eventually pulled after 4 to 6 weeks (once the tract has matured). T-tubes do not prevent bile leakage and should usually be deployed with a closed suction drain in proximity. If retained stones are identified, the biliary tree can be accessed percutaneously via the T-tube, once the tract has matured, and the stones can be removed.

Transduodenal Sphincteroplasty

Patients with impacted stones at the ampulla or with primary bile duct stones, recurrent stones, intrahepatic stones, or a benign distal bile duct stricture may require an open biliary drainage procedure, such as a transduodenal sphincteroplasty. This involves a wide Kocher maneuver followed by a

lateral duodenotomy. A transcystic Fogarty can be helpful in identify the papilla if not readily visible. If the papilla is identified a Fogarty can be passed through it to be used as a guide for the sphincteroplasty. The sphincteroplasty is then performed for 4 to 5 mm at 11 o'clock position superiorly to avoid the duct of Wirsung which is present medially; this is done with sharp electrocautery. Sphincteroplasty in then extended to a longer length to allow instrumental exploration of the CBD with forceps for extraction of stones. Sutures are placed on the outer wall between the duodenal mucosa and the CBD wall, taking care to avoid the duct of Wirsung. Stones can also be removed using Fogarty, saline irrigation, and a choledoscope.

Choledochoduodenostomy and Roux-en-Y Hepaticojejunostomy

The consideration for one versus the other are the same as described above in the laparoscopic biliary enteric bypass section.

T-TUBES

Historically T tubes were commonly used after CBD exploration. However, these appear to increase operating time and hospital length of stay without any evidence of benefit after open or laparoscopic CBD exploration. The increased complication rate is primarily attributed to the placement of the T-tube, and is due to (i) bile leakage, (ii) wound issues at T-tube insertion site, (iii) dislodgement or displacement of T-tube leading to biliary obstruction, and (iv) persistent biliary fistula. Therefore, their use has decreased over the years. A Cochrane Review in 2013 called for more randomized trials to be conducted with low risk of bias and assessing the risk–benefit effect of these tubes.[33]

INTRAHEPATIC STONES

Hepatolithiasis or intrahepatic stones are defined as stones present above the confluence of the left and right hepatic ducts. The etiology remains unknown

in most patients, but these can occur secondary to chronic biliary stasis and in the presence of choledochal cysts, biliary strictures, and/or biliary parasites. Majority of these patients (70%) do not have gallstones. The two most commonly referred classifications are listed in **Table 61.8**, these are based on distribution of stones and presence of biliary stricture.

Most patients with hepatolithiasis present with cholangitis with wide range of severity. According to a Japanese survey 20% of patients with hepatolithiasis can remain asymptomatic. There are numerous diagnostic modalities including US, CT, MRCP. Endoscopic and percutaneous cholangiography are invasive and therefore used less readily. Initial management for symptomatic patients revolves around resuscitation and treatment for cholangitis. Biliary drainage can be performed via percutaneous or endoscopic technique depending on the location of stricture and distribution of stones. Definitive treatment may require hepatectomy especially if there is concern for cholangiocarcinoma. Depending on the location of strictures hepatectomy and hepaticojejunostomy with anchoring jejunal limb to the abdominal wall may also be performed. This allows percutaneous access in the future if stone retrieval may be needed. Recurrence rates are high even when intrahepatic stones are completely removed. Recurrence rates are variable (0% to 50.8%) and depend on presence of bile duct strictures and treatment modality. Incidence of intrahepatic cholangiocarcinoma in patients with hepatolithiasis has been reported to be 5% to 10%.

Table 61.8 Classification of Intrahepatic Stones

Japanese Classification	Takada Classification
Type I: Intrahepatic stones alone	Type I: No stricture, mild biliary dilatation
Type IE: Intra- and extrahepatic ductal stones	Type II: Distal CBD/ampullary stricture
Type L: Left-sided intrahepatic ductal stones	Type III: Hilar stricture
Type R: Right-sided intrahepatic ductal stones	Type IV: Unilateral hepatic duct stricture
Type C: Caudate stones	Type V: Multiple bilateral strictures

Biliary Injury, Strictures, and Sclerosing Cholangitis

Rory L. Smoot and Sean P. Cleary

Key Points

1. Bile duct injury remains a common complication of cholecystectomy.
2. The method and timing of bile duct injury repair depends on he location and extent of the injury, presence of concomitant vascular injury, the presence of sepsis and the timing of recognition.
3. Management of benign biliary strictures is dependent on etiology. Treatment strategies include medical management, endoscopic stenting as well as surgical bypass or resection.

While the etiology of injuries and acquired or autoimmune-based strictures of the bile ducts are diverse (see Table 62.1), a basic understanding of biliary anatomy and physiology as well as its impact on liver homeostasis can guide management decisions. The recognition and initial management of biliary injury and/or stricture are important skills for general surgeons to have, as appropriate initial therapeutic approaches can have a significant impact on the outcome of definitive management. Based on the published frequency of biliary injuries and the ubiquitous nature of cholecystectomy,

statistics suggest that the majority of general surgeons will face a biliary injury over the course of their career.[1] While the acute and chronic nature of injuries and strictures, respectively, impacts their presentation, the principles of management remain similar: (1) control any associated infection/sepsis (due to intraperitoneal leak or cholangitis); (2) restoration of biliary drainage (internally or externally); (3) assessment of malignant potential; (4) timely definitive management; and (5) continue appropriate surveillance and reintervention. For each subset of conditions, the options are slightly different and will be discussed in detail further. As with the majority of medical/surgical care, the approaches have become less invasive over time.

BILE DUCT INJURY

1 Bile duct injuries have been reported at a frequency of up to 0.6% and 0.1% for laparoscopic and open cholecystectomy, respectively.[2] Less well recognized is the potential for bile duct injury during other RUQ operations including distal gastric/proximal duodenal procedures and liver resection. This chapter will focus on cholecystectomy as the initiating factor; however the workup and management listed can be applied regardless of the index operation. For cholecystectomy, factors that have been implicated as elevating the risk of associated injuries include obesity, acute inflammation, and anatomic abnormalities among others (Table 62.2). The etiology of bile duct injuries are variable but generally fall into one of two categories: (1) misinterpretation/misidentification of pertinent anatomy[3] or (2) aberrant anatomy. Misinterpretation of visual cues during cholecystectomy can result in the "classic" pattern of injury in which the surgeon visualizes/interprets the common bile/hepatic duct as the cystic duct secondary to excessive cranial traction, adherence of the cystic duct to the common hepatic duct in parallel, or initiation of dissection in an inappropriate plane medial to the common bile/hepatic duct (Fig. 62.1). In this scenario, the common duct is clipped and divided. Alternatively, aberrant biliary anatomy including either low cystic duct insertion and parallel course of the cystic duct and common bile duct has been reported in up to 25% of patients, and aberrant drainage of the right posterior sectoral duct directly into the common bile duct occurs up to 6% of the time; this unconventional segmental biliary drainage pattern can

place these ducts at risk for injury (Fig. 62.2).[4] Finally, other mechanisms such as traction injury or inadvertent dissection into the common hepatic duct have been described more commonly with open procedures and a "top-down" approach, respectively. Independent of the underlying etiology, classification systems for bile duct injury have been developed. The most commonly utilized classification used historically to describe location rather than extent (Table 62.3).[5] Practically speaking, classification of biliary injuries is important only in that the ultimate definitive management is dependent on the pattern of injury. A special category of injury that bears mentioning is combined vascular and biliary injury, typically termed vasculobiliary injuries.[6] These most commonly involve stricture or occlusion of the right hepatic artery, although portal vein injuries are also described. Vasculobiliary injuries significantly increase the risk of stricture following definitive surgical management due to the resulting compromise in biliary blood supply.

Several strategies for mitigating the risk of bile duct injury have been proposed including obtaining the "critical view of safety," intraoperative cholangiogram, and various forms of subtotal cholecystectomy. The critical view of safety describes the view obtained following clearance of tissue within the triangle of Calot such that only two structures (cystic duct and artery) are connecting the gallbladder to the central hepatoduodenal structures. An important aspect in obtaining this view is initiating dissection on the infundibulum of the gallbladder, not on the triangle of Calot itself. This minimizes the possibility of inadvertently initiating the dissection on the medial side of the common duct, which can lead to misinterpretation of the common duct as the cystic duct. The routine use of IOC during cholecystectomy is practiced by a minority of general surgeons, and the most recent population-based data would suggest it does not impact the rate of bile duct injury, but may be beneficial in selected use.[7–9] However, identification of a biliary injury is facilitated at the index operation when IOC is performed which may expedite management and reduce morbidity.[10] Finally, while conversion to an open procedure should be considered in all patients in whom anatomic landmarks cannot be clearly defined, this may not provide significantly reduced risk of biliary injury if the operating surgeon is not accustomed to routine open cholecystectomy. Two alternative strategies have been described; the perforating and fenestrating partial cholecystectomy.[11]

Partial cholecystectomy has gained in acceptance as an alternative to conversion for surgeons less comfortable in open gallbladder surgery who are confronted with significant portal inflammation and difficulty identifying relevant structures. The risk of postoperative biliary fistula is relatively low and emphasis should be placed on clearing all stones to prevent recurrent symptoms.

Table 62.1 Causes of Benign Biliary Strictures

Postoperative Strictures

Post-Biliary Surgery/Intervention

Laparoscopic Cholecystectomy

- Transection
- Occlusion (w/ clip)
- Laceration

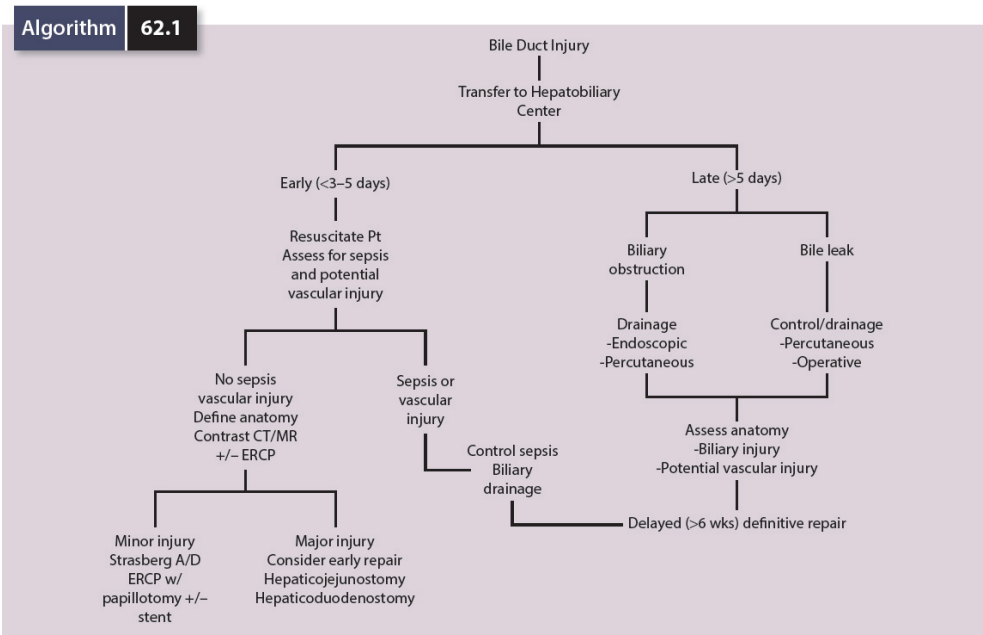
E3 Stricture of Common Hepatic Duct with Right and Left Hepatic Ducts Still in Communication
E4 Stricture of Common Hepatic Duct with Right and Left Hepatic Ducts Separated
E5 Stricture of the Common Hepatic Duct and Right Posterior Sectoral Duct Occlusion



Algorithm 62.1 Bile duct injury.

Clinical Presentation

The presentation of biliary injuries varies considerably from intraoperative identification, to acute presentation secondary to bile leak or jaundice, and subacute presentations related to stricturing, cholestasis, and/or cholangitis. The timing of presentation, signs and symptoms are frequently linked to the type of injury (i.e., partial vs. complete, occlusion vs. transection, and the presence of ischemic injury). Intraoperative identification of biliary injury occurs when bile leakage is noted or when identification of a third structure emanating from the gallbladder is noted after transection of the duct, typically indicating that the common duct has been mistaken for the cystic duct. Acute presentations can occur several hours to several days following surgery. The presenting signs and symptoms can include nausea, fever, increasing pain, and/or jaundice. Patients in whom symptoms are worsening following cholecystectomy should be evaluated with the possibility of biliary injury in mind. Subacute presentations can occur months to years later when stricturing can lead to obstructive jaundice and/or cholangitis. Patients with significant delay in identification can present with biliary cirrhosis from chronic obstruction and the sequelae of advanced liver disease including portal hypertension.

Evaluation

Evaluation of the patient with a suspected biliary injury begins with a focused history and physical examination. Intraoperative details of the index operation including approach, structures identified, placement of clips, and hemostatic techniques used should be clearly documented. Ideally, confirmation of the details of the case and intraoperative events with the primary surgeon should take place by direct communication. The timing of their symptoms as it relates to cholecystectomy should be noted and signs of systemic illness (sepsis) such as fever, tachycardia, and hypotension should be assessed. Basic lab testing including complete blood count, liver transaminases, alkaline phosphatase, and coagulation parameters should be obtained. Imaging studies typically consist initially of CT scanning with IV contrast. Images are evaluated for the presence of dilated biliary tree, undrained fluid collection, and whether the inflow vasculature of the liver is intact. Assessment of the biliary tree continuity and the level of injury can be obtained by ERCP or MRI/MRCP. If delayed repair is planned and undrained collections are present, then image-guided drainage is performed. Drainage of collections or bilomas should be performed prior to ERCP if bile leak is suspected to reduce the risk of postprocedural sepsis, ideally via percutaneous route. If a tangential injury is suspected, then ERCP has the advantage of providing not only diagnostic information, but also the ability to intervene therapeutically typically with sphincterotomy with or without stenting. If a complete transection/occlusion is suspected, then ERCP will have little diagnostic value and has the disadvantage of being an invasive modality. In these scenarios, MRI with MRCP is the preferred diagnostic modality.

Treatment

2 For complex injuries identified intraoperatively or early postoperatively, where there is no significant sepsis, transfer to a hepatobiliary surgeon and evaluation can be performed expeditiously, and early repair within the first 3 to 4 days can be considered. For injuries recognized >4 to 5 days postoperatively or if there is significant associated sepsis, delayed repair should be given strong consideration (**Algorithm 62.1**). The principles of

delayed management are as follows: (1) control sepsis/drain undrained collections, (2) establish biliary drainage, and (3) definitive management/repair by a surgeon with significant hepatobiliary experience once sepsis and inflammation has resolved. As noted above, patients with undrained fluid collections in the porta hepatitis should have image-guided drainage often after initiating fluid resuscitation and broad spectrum antibiotics targeting enteric organisms. For partial injuries, most typically a lateral laceration of the duct and/or cystic duct stump leak, then endoscopic stenting is often successful as definitive management. For complete transection +/− occlusion with delayed presentation, percutaneous biliary drainage is required. Occasionally if the duct has not been occluded, PTC cannulation of unobstructed ducts can be challenging. If the duct can be cannulated, ideal management would be to span the defect with a PTC, otherwise external drainage of the duct alone can improve the control of bile flow and sepsis. If the duct is occluded, the establishment of external drainage is achieved with a catheter secured at or above the level of the injury. If an ongoing bile leak is present, this will most typically stop following biliary drainage and the biloma drainage catheter can be removed while continuing external drainage of the biliary tree via PTC. The patient will need to be instructed on care of the biliary drainage catheter, and furthermore the patient will need to be cautioned about the risk of dehydration and instructed to increase oral fluid intake while the external drain is in place. The timing of definitive management will depend on several factors but typically can be considered from 6 to 12 weeks following control of the local sepsis. Factors affecting timing include the presence of significant infection/inflammation at the index operation in which the injury occurred, the overall medical condition of the patient, the presence of a concomitant vascular injury, and tolerance of external biliary drainage. For patients with significant infection/inflammation and/or a concomitant vascular injury at the index operation, delaying definitive management until 12 weeks may be prudent given the significant risk of postoperative anastomotic stricture.

Definitive surgical management most typically consists of a biliary–enteric anastomosis. This can be performed to the duodenum if mobility will allow it, but most typically is performed to a Roux-en-Y limb of the jejunum. Perioperative planning and optimization considerations include the potential

for nutritional deficiencies with extended external biliary drainage including vitamin K deficiency which may impact the risk of perioperative hemorrhage. The position of the right hepatic artery in relation to the bile duct must be noted as this typically runs posterior to the duct, however can course anteriorly, and in this position is at high risk for injury during subsequent definitive operative repair as the porta hepatis can be scarred and the structures obscured. Therefore location as well as patency of the right hepatic artery should be confirmed on imaging prior to definitive repair. Identification of the bile duct can be aided by intraoperative ultrasound with identification of the PTC catheter marking the bile duct. Utilization of a small gauge needle and a syringe to probe with aspiration of bile can also be used to definitively identify the duct. After identification, the anterior wall of the duct can be opened longitudinally as the arteries run at the 3 and 9 o'clock positions laterally. If the injury is near or at the biliary confluence, then a right angle or probe can be inserted into the bile duct and the ductotomy extended onto the left hepatic duct to provide for a larger anastomosis. The biliary–enteric anastomosis can be done in a side-to-side fashion if the posterior wall of the bile duct cannot be safely mobilized or in an end-to-side fashion if it is mobilized. Surgeon choice dictates interrupted versus running stitches, however absorbable monofilament sutures are typically utilized. It may be helpful to leave the PTC across the anastomosis if this is possible and it is common to place a drain near the anastomosis. Optimal long-term outcomes are obtained when the repair of bile duct injuries is undertaken by a surgeon with significant hepatobiliary training and/or experience, with risks of poor long-term results highest when the repair is undertaken by the index surgeon.[12,13] The timing of repair is a subject of significant controversy, with early (<3 to 5 days) and late (>6 weeks) repair associated with the better outcomes than repairs attempted in the intermediate period (6 days to 6 weeks) or in the presence of sepsis.[14,15]

The management of concomitant biliary and vascular injury requires special consideration. The most common concomitant vascular injury is to the right hepatic artery, with injury to the hepatic artery proper and portal vein less common. Of note, arterial collaterals exist through the hepatic duct confluence so that arterial supply to the right biliary tree may be maintained in the presence of the right hepatic artery injury if the confluence is not disrupted. Repair of arterial injuries is rarely successful unless identified

and repaired immediately, but repair of significant portal vein injuries should be considered. Early repair of biliary injury in the presence of isolated right hepatic artery injury can be considered, however, if vascular integrity of the biliary system is in question, delayed repair is preferred and in the most dramatic cases may require hepatic resection.

Outcomes

The short- and mid-term outcomes of definitive operative repair have been reported in a number of retrospective series.[12–15] There remains debate regarding the optimal timing of repair, however a recent large systematic review and meta-analysis evaluating data pooled from 32 individual studies demonstrated a benefit to early referral and delayed repair. Repair failure, which was typically defined as diagnosed stricture or need for imaging/intervention secondary to suspected stricture/cholangitis, was noted to be 37.7% in repairs undertaken before 6 weeks and 8.9% in repairs after 6 weeks. Early referral to a hepatobiliary surgeon was associated with a decrease in postoperative complications and biliary stricture.[16]

Follow-Up

Following definitive repair, the patients are at risk long term for stricture of the anastomosis. We recommend annual ultrasound and liver function testing to assess for the development of strictures which may be associated with a rising alkaline phosphatase level or the development of progressive intrahepatic duct dilatation. Early identification of strictures is essential and can typically be dilated either endoscopically or percutaneously prior to the development of secondary biliary cirrhosis and liver failure.

BILIARY STRICTURE

3 The etiology of benign biliary strictures include iatrogenic/postoperative and various other infectious/inflammatory conditions (Table 62.1). Postoperative biliary strictures due to bile duct injuries have been addressed above. The approach to nonneoplastic biliary strictures is dependent on the

etiology and location within the biliary tree and ruling out neoplastic processes are a vital component of the evaluation.

Clinical Presentation

Patients with benign biliary strictures often present with either cholangitis or jaundice. Patients with cholangitis typically present with some combination of fever, right upper quadrant pain, and jaundice. Patients with sepsis secondary to cholangitis will have hypotension and tachycardia at presentation. This may be in the setting of known predisposing factors such as recurrent pancreatitis, previous biliary surgery, and primary sclerosing cholangitis (PSC). Alternatively patients may present absent known risk factors.

Evaluation

Similar to patients with bile duct injury, evaluation begins with a focused history and physical examination with special attention to predisposing factors including a history of biliary intervention/surgery, recurrent pancreatitis, and history of inflammatory bowel disease. Laboratory evaluation includes complete blood count, liver function testing, and coagulation profile. IgG4 levels should be considered, however negative results do not rule out this as a diagnosis, as tissue IgG4 levels are far more sensitive than serum levels for diagnosis. For patients with signs and symptoms of cholangitis and/or sepsis, fluid resuscitation and broad spectrum antibiotics should be initiated as part of the evaluation and the remainder of the workup performed while hospitalized. Patients without infection/sepsis can be evaluated as an outpatient. Typically the next step in evaluation includes CT scan of the abdomen with IV contrast. The presence of a mass requires evaluation for neoplastic processes. Without an obvious mass, the typical next step in a combination of ERCP, EUS, and biliary endoscopy (if available). EUS is performed to further assess for neoplastic changes, while ERCP is performed for both diagnostic (cholangiography and brushings) as well as therapeutic reasons as stenting is often required. Brushings should be evaluated by cytology and, if available, fluorescence *in situ* hybridization (FISH). If endoscopic stenting with drainage of as many

relevant hepatic segments as possible cannot be achieved, percutaneous biliary drainage (PTC) should be considered.

Treatment

The treatment for benign biliary strictures is dependent on the etiology and ranges from medical management to endoscopic and/or operative management. Conditions that can be treated medically include IgG4 cholangiopathy or pancreatitis which can typically be temporized with stenting and treated with corticosteroids. Duodenal Crohn's is another condition that may be able to be managed medically with stenting to temporize until the inflammation improves, and similarly nonneoplastic duodenal ulcers leading to ampullary/biliary stricture can be treated medically while temporized with endoscopic biliary drainage. Patients with pancreatitis-related biliary strictures may be managed with stenting if the stricture is related to acute inflammation. For patients with chronic inflammatory changes and stricturing, definitive management may require operative intervention. In this setting, two options for benign strictures are possible including Whipple pancreaticoduodenectomy or biliary bypass typically to a Roux limb. The choice of approach depends whether or not there is head-dominant pancreatitis likely to benefit from resection and the ability to safely perform such an operation. A resective approach should be considered if malignancy cannot be excluded. PSC represents a unique situation that will be discussed in detail in the next section. Postoperative biliary strictures can be balloon dilated and stented, which is successful in select patients, however definitive management often will require operative bypass which can be accomplished by bilioenteric anastomosis as described above.

Outcomes

The data regarding successful outcomes following endoscopic management of biliary strictures reports variable rates depending on retrospective versus prospective evaluation, plastic versus fully covered self-expanding metal, and etiology (most commonly pancreatitis vs. posttransplant anastomotic stricture vs. postcholecystectomy). In a prospective trial of metal versus

plastic stenting, the stricture resolution rate (at 12 months) was 92.6% versus 85.4% and fewer procedures were required during the treatment period (2.14 vs. 3.24).[17] Similarly, a meta-analysis also demonstrated fewer ERCPs required with metal stenting and a stricture recurrence rate of 16%.[18] As might be expected, longer-term follow-up of prospective stenting trials with covered metal stents have demonstrated stent-free probabilities of 61.6% for chronic pancreatitis at a median of 58 months, and 84.6% in postcholecystectomy strictures at 5-year poststent follow-up. The stent dwell time at the index treatment was 10 to 12 months in these studies.[19,20]

Follow-Up

Patients undergoing endoscopic stenting +/− balloon dilation for biliary stricture may require repeated procedures, the timing of which typically will be dictated by the choice of plastic versus covered metal stenting. For patients undergoing bilioenteric bypass, we recommend annual ultrasound and liver function testing as discussed above.

Pancreatitis with biliary obstruction
Choledocholithiasis Recurrent pyogenic cholangitis Postoperative stricture Hepatic ischemia
Tumors

SCLEROSING CHOLANGITIS

Sclerosing cholangitis can be primary (PSC) or secondary. Secondary sclerosing cholangitis is most commonly associated with recurrent episodes of cholangitis from a variety of causes (Table 62.4) which can lead to scarring and strictures. Management of the underlying etiology is required for treatment/prevention of secondary sclerosing cholangitis and may include

medical, endoscopic, or operative intervention based on the etiology. In contrast, PSC is an autoimmune disease without a known inciting factor. It is associated with ulcerative colitis (approx. 2/3 of patients with PSC will have ulcerative colitis), and carries a markedly increased risk of cholangiocarcinoma (400- to 1,000-fold increase compared to the general population).[21] A finding of diffuse strictures throughout the biliary tree is pathognomonic of the disease (although segmental involvement is possible) and progressive disease often leads to chronic cholestasis and eventual liver failure requiring transplant. The presence of a dominant stricture with or without an associated mass in a patient with PSC requires workup to rule out cholangiocarcinoma. Surgical intervention on the biliary tree other than transplant or cholecystectomy is uncommon while endoscopic management is the mainstay of therapeutic and surveillance strategies.

Clinical Presentation

Clinical presentation is a spectrum from incidental findings (alkaline phosphatase/bilirubin elevations and/or imaging changes), to painless jaundice, to cholangitis and sepsis. The initial diagnosis of PSC may be at the time of cholangiocarcinoma diagnosis.

Evaluation

The initial evaluation is similar to those noted above for biliary stricture, with a focused history and physical examination, followed by bloodwork, resuscitation as indicated, and imaging studies. Specific to PSC, the diagnosis is made based on clinical presentation and imaging findings. Either ERCP or MRCP can be utilized to evaluate the biliary anatomy, and diagnostic features include diffuse areas of structuring/beading throughout the biliary tree. Imaging characteristics of cirrhosis and/or portal hypertension should also be assessed. ERCP allows stenting and brushing/biopsy of any dominant strictures. Evaluation of cytology for malignancy is complicated in the setting of PSC and adjunctive studies such as FISH specifically evaluating the specimens for polysomy is recommended. A high index of suspicion should be maintained for malignancy in these patients and surveillance should be undertaken at a specialized center.

Treatment

For secondary cholangitis, treatment is targeted at the underlying etiology. In this setting, endoscopic and/or operative intervention on the liver/biliary tree may be undertaken. For example, in patients with recurrent pyogenic cholangitis (RPC), there often is selective involvement of the left lateral sector of the liver with progressive sclerosis and recurrent episodes of cholangitis secondary to intraductal stone formation. Resection of the involved liver segments can provide durable management. For other indications, such as IgG4 cholangiopathy, the treatment is medical. For PSC, the treatment modality for symptomatic strictures is endoscopic dilation, brushing, and stenting with close surveillance; the timing of which is dictated by the findings on cytology and FISH. Progressive liver failure or cholangiocarcinoma are treated with liver transplant in appropriately selected patients with PSC, although recurrence of PSC in the transplanted liver is possible.

Biliary Neoplasms

Kaitlyn J. Kelly, Yuman Fong, and Sharon Weber

Key Points

1. Surgery remains the only curative option for biliary malignancies.
2. Gallbladder cancer is a rare malignancy with a dismal prognosis because of its insidious onset, propensity for local invasion, and rapid disease progression.
3. The association of gallstones with carcinoma is probably related to chronic inflammation.
4. Patients with choledochal cysts have an increased risk of carcinoma developing anywhere in the biliary tree, but the incidence is highest in the gallbladder.
5. The only curative option in patients with gallbladder cancer is complete surgical resection.
6. Nonoperative palliative biliary decompression can be accomplished with percutaneous or endoscopic stenting, depending on the level of obstruction.

INTRODUCTION

1 Tumors arising in the gallbladder and biliary tree are rare, with approximately 10,650 cases per year in the United States and 140,000 per year worldwide.[1,2] These tumors are often asymptomatic until late in the course of the disease. Consequently, these tumors commonly present in an advanced, often unresectable stage. Surgery remains the only curative option for biliary malignancies. Complete resection of biliary neoplasms, however, often requires radical resections and complex biliary reconstructions that are only routinely safe at specialized, high-volume centers. Both the late diagnosis and the complex operative techniques required for potentially curative resection contribute to the challenge of these cases. This chapter reviews the incidence, diagnosis, and therapy of these malignancies as well as the outcomes of treatment.

GALLBLADDER CARCINOMA

2 Gallbladder cancer is a rare malignancy with a dismal prognosis because of its insidious onset, propensity for local invasion, and rapid disease progression. Overall, most series report a 5-year survival of less than 5%.

Incidence

Gallbladder cancer is the most common biliary tract malignancy, but there are only 6,000 to 7,000 new cases diagnosed nationally each year. Attesting to the rarity of this lesion, after routine screening of abdominal ultrasounds in asymptomatic patients in Japan, only 19 out of 194,767 patients (0.01%) were found to have gallbladder cancer.[3] This tumor occurs more frequently in women (female:male ratio = 3:1), and peak incidence is in the seventh decade.[4] There is a tremendously increased risk of gallbladder cancer in particular indigenous populations, including Mapuche Indians in South America (12.3 cases/100,000 males and 27.3/100,000 females), and Native Americans in New Mexico (8.9 cases/100,000 people).[5,6]

The increased risk of gallbladder cancer with cholelithiasis is well established; 70% to 90% of all patients with carcinoma also have gallstones. However, less than 0.5% of patients with gallstones are found to have gallbladder cancer.[5] In recent series of patients undergoing elective

cholecystectomy for gallstones, gallbladder cancer is found incidentally in <0.5% of patients.[7] The association of gallstones with carcinoma is probably related to chronic inflammation. Larger stones (>3 cm) are associated with a 10-fold increased risk of cancer.[6,8]

3 The association of gallbladder cancer with gallstone disease has led some investigators to question whether all patients with gallstones should undergo cholecystectomy. The argument against this approach is that the use of cholecystectomy only for symptomatic patients, thus leaving the gallbladder in place in patients with asymptomatic gallstones, has not led to an increase in the prevalence of gallbladder cancer over time. Also, epidemiologic studies have found that the 20-year risk of developing cancer in patients with gallstones is less than 0.5% for the overall population and 1.5% for high-risk groups.[5] Thus, routine cholecystectomy for asymptomatic gallstones because of concern for gallbladder cancer does not appear to be warranted.

In the past, the finding of a calcified gallbladder wall, called "porcelain gallbladder" (**Fig. 63.1**), was associated with a high risk of cancer, in some series ranging from 25% to 60%.[9] Thus, the recommendation was for all patients with porcelain gallbladder to undergo open cholecystectomy, even if asymptomatic. Recent series evaluating this issue suggest that the risk of gallbladder cancer in patients with porcelain gallbladder has likely been greatly overestimated. In fact, although patients with limited areas of calcification of the wall may have a higher incidence of gallbladder cancer (7%), patients with diffuse calcification of the gallbladder wall, the classic presentation for porcelain gallbladder, do not appear to have an increased risk of cancer.[10,11]

4 Patients with choledochal cysts have an increased risk of carcinoma developing anywhere in the biliary tree, but the incidence is highest in the gallbladder. This risk increases with age. Therefore, cholecystectomy is recommended for all patients with choledochal cysts at the time of diagnosis.

Pathology and Staging

More than 80% of gallbladder cancers are adenocarcinomas; there are several histologic subtypes, including papillary, nodular, and tubular. Papillary tumors, which grow predominantly into the gallbladder lumen,

have an improved prognosis compared with the other subtypes.[12] Poor prognostic signs in gallbladder cancer include grade, and vascular invasion.[12,13] The most important prognostic factor may be lymph node status, although 5-year survivors with nodal involvement have been documented.[14,15] Less than 5% of cases are squamous cell carcinomas, with the remaining 10% being anaplastic lesions.

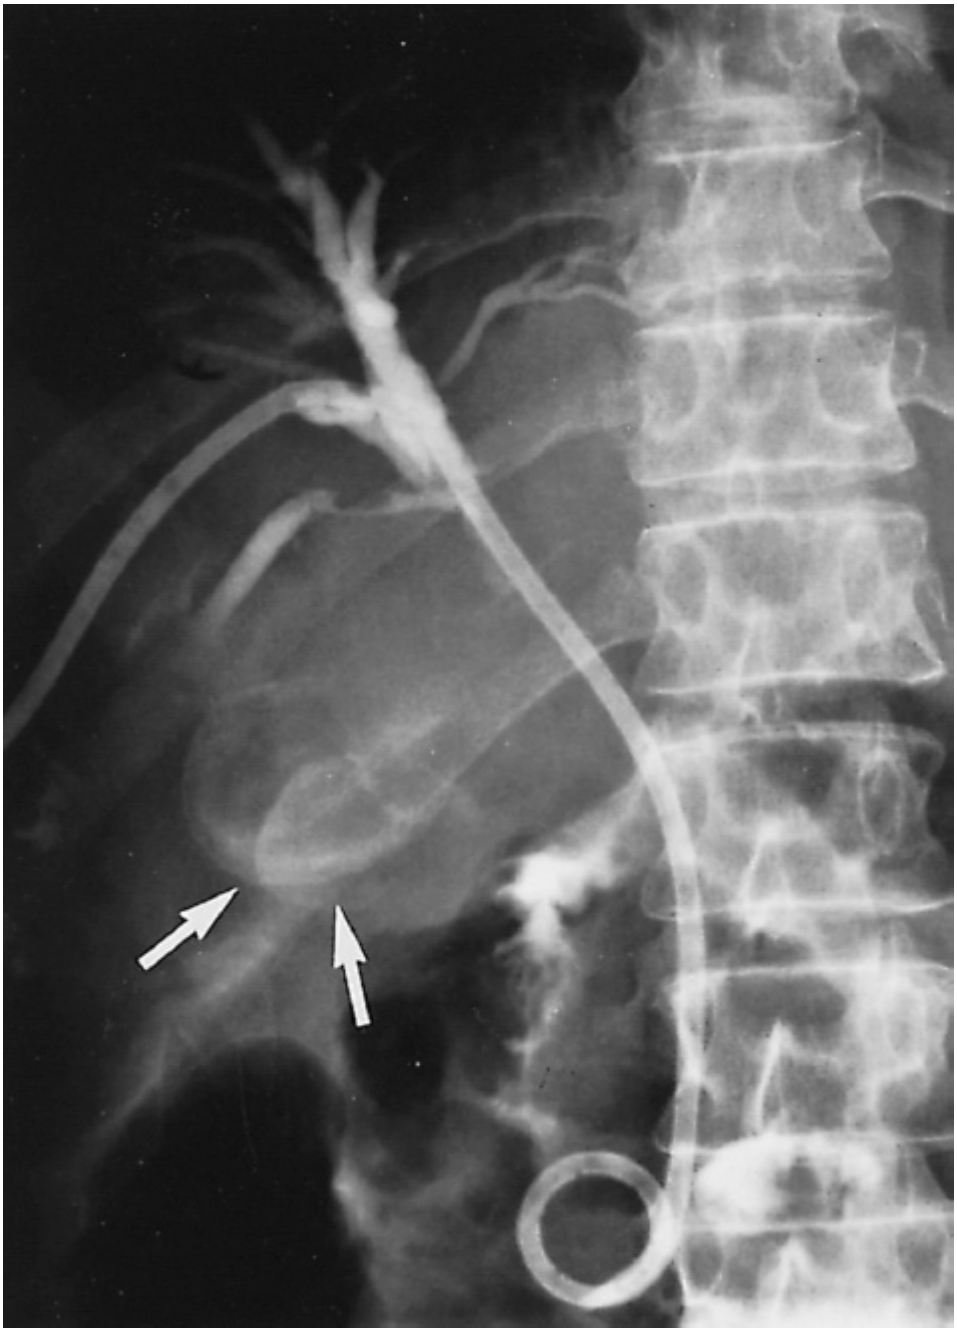

Figure 63.1 Unresectable gallbladder cancer demonstrating palliative transhepatic percutaneous stent placed to relieve jaundice. Porcelain gallbladder is present (*arrows*).

Gallbladder cancer spreads via the lymphatic and venous drainage. Because of drainage of the cholecystic veins directly into the adjacent liver, these tumors often involve hepatic parenchyma, most often portions of segments IV and V. Lymphatic spread is first to the cystic duct (Calot) node,

then to pericholedochal and hilar nodes, and finally to peripancreatic, duodenal, periportal, celiac, and superior mesenteric artery nodes. Nodal disease in the porta hepatis often causes common bile duct (CBD) obstruction and resultant jaundice, which is the first clinical symptom in 30% of patients. Jaundice may also be caused by tumors arising in the infundibulum, which may spread directly to the cystic duct and common hepatic duct. Although peritoneal metastases are frequent, distant extraperitoneal metastases are not.

Limited information exists regarding the genetic changes in gallbladder cancer. Recently reported gene abnormalities associated with gallbladder cancer include p53, K-ras, CDKN2 (9p21), FGFR, and PI3 kinase pathway aberrations.[16–20] The finding that patients with an anomalous pancreaticobiliary junction have a greater frequency of K-ras mutations has led investigators to believe that reflux of pancreatic enzymes into the biliary tree may contribute to the development of cancer.[16] Because of our limited knowledge of the sequence of molecular changes, there are no known detectors of early disease or of risk assessment. Clearly, this is an area that needs improvement, particularly in endemic areas.

The American Joint Committee on Cancer's (AJCC) eighth edition of its tumor, node, metastasis (TNM) staging system (**Table 63.1**) reflects prognostic characteristics of tumor depth, regional nodal disease, and distant spread. The gallbladder differs histologically from the rest of the gastrointestinal tract in that it lacks a muscularis mucosa and submucosa. The gallbladder wall is composed of (a) a single layer of columnar cells, the mucosa, and lamina propria; (b) a fibromuscular layer; (c) a perimuscular, subserosal layer containing lymphatics and neurovascular structures; and (d) a serosal surface, except where the gallbladder is embedded in the liver. Because lymphatics are present in the subserosal layer only, tumors invading less than the full thickness of the muscular layer have minimal risk of nodal spread. Thus, disease invading into, but not through, the muscular layer of the gallbladder is T1b disease (stage I), whereas invasion into the perimuscular connective tissue is T2 (stage IIa or b). If on the peritoneal side, it is T2a, and if on the hepatic side, T2b. Stage III disease includes tumors that have perforated the serosa or have directly invaded the liver or other surrounding structures (T3), which are clearly more advanced but still potentially resectable. Tumors that invade the main portal vein, hepatic artery, or two or

more extrahepatic organs/structures are classified as T4 (stage IVA) and are typically unresectable. Lymph node metastasis to one to three regional nodes is N1, and to four or more regional nodes is N2. N1 nodal metastasis is classified as stage IIIB and N2 as stage IVB. In line with other pancreaticobiliary malignancies, the stage III grouping refers to locally advanced disease and stage IV indicates locally advanced unresectable or metastatic disease.

Clinical Findings and Diagnosis

Most patients are found to have gallbladder cancer during workup or treatment of cholelithiasis or choledocholithiasis. In patients with symptoms, abdominal pain consistent with biliary colic or acute cholecystitis is most common. Patients also present with jaundice, weight loss, anorexia, or an increase in abdominal girth secondary to ascites. Physical findings may include right upper quadrant tenderness or a palpable mass, hepatomegaly, and ascites. Laboratory investigation, if abnormal, is most often consistent with biliary obstruction. Because of its nonspecific presentation and the lack of reliable screening tests, gallbladder cancer is not diagnosed preoperatively in more than half the cases.

Imaging evaluation often reveals a thickened gallbladder wall or a mass within or replacing the gallbladder on ultrasound examination. Because polyps, asymmetric wall thickening from cholecystitis (especially xanthogranulomatous type), and carcinoma can have an echogenicity similar to the gallbladder wall, these lesions are often difficult to distinguish. This is even more difficult when inflammation is present from gallstones. At times, ultrasound can visualize invasion of the liver, adjacent adenopathy, and a dilated biliary tree. The ability of ultrasound to differentiate benign from neoplastic disease is enhanced using endoscopic ultrasound, and may be more specific than computed tomography (CT) or magnetic resonance imaging (MRI).[21–23]

A dynamic contrast-enhanced CT scan may identify a gallbladder mass or invasion into the liver parenchyma or adjacent organs. The classic finding in a patient with gallbladder cancer is asymmetric thickening of the gallbladder wall. Staging of gallbladder carcinoma using CT, however, is limited by poor sensitivity in identifying nodal spread.[24]

In patients who are jaundiced, direct cholangiography may be useful to delineate the extent of biliary involvement as well as to palliate symptoms of biliary obstruction. A mid–bile duct obstruction not caused by gallstones is gallbladder cancer until proved otherwise (**Fig. 63.2**). More recently, with improvements in MRI technology, diffusion-weighted imaging and magnetic resonance cholangiopancreatography (MRCP) have evolved into a single, noninvasive imaging modality that allows complete assessment of biliary, vascular, hepatic parenchymal, and nodal involvement, as well as involvement of adjacent organs (**Fig. 63.3**).[25–27]

STAGING

Table 63.1 American Joint Committee on Cancer, 8th Edition, Staging System for Gallbladder Carcinoma

Stage	Tumor	Nodes	Metastasis
0	Tis	N0	M0
I	T1	N0	M0
IIA	T2a	N0	M0
IIB	T2b	N0	M0
IIIA	T3	N0	M0
IIIB	T1–3	N1	M0
IVA	T4	N0–1	M0
IVB	Any T	N2	M0
	Any T	Any N	M1

Definition of TNM	
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ
T1	Tumor invades lamina propria or muscular layer
T1a	Tumor invades lamina propria
T1b	Tumor invades muscular layer
T2	Tumor invades perimuscular connective tissue; no extension beyond serosa or into liver
T2a	On peritoneal side, without involvement of serosa
T2b	On hepatic side, without extension into liver
T3	Tumor perforates the serosa (visceral peritoneum) and/or directly invades the liver and/or one other adjacent organ or structure, such as the stomach,

	duodenum, colon, pancreas, omentum, or extrahepatic bile ducts
T4	Tumor invades main portal vein or hepatic artery or invades two or more extrahepatic organs or structures
Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis to one to three regional nodes
N2	Metastasis to four or more regional nodes
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

Figure 63.2 Endoscopic retrograde cholangiopancreatogram obtained from a patient with gallbladder cancer. Mid–bile duct obstruction (*arrow*) is caused by direct extension of tumor to the cystic and common hepatic duct.

In patients who present with incidentally discovered gallbladder cancer following cholecystectomy, staging should be performed with high-quality CT or MRI of the chest, abdomen, and pelvis. There is no clear role for PET/CT in this setting.[28]

Surgery

5 It is clear that the only curative option in patients with gallbladder cancer is complete surgical resection. It is essential for optimal patient care that patients with gallbladder cancer be recognized before laparoscopic cholecystectomy is performed, because of the risk of bile spillage, with its potential for subsequent carcinomatosis.[29]

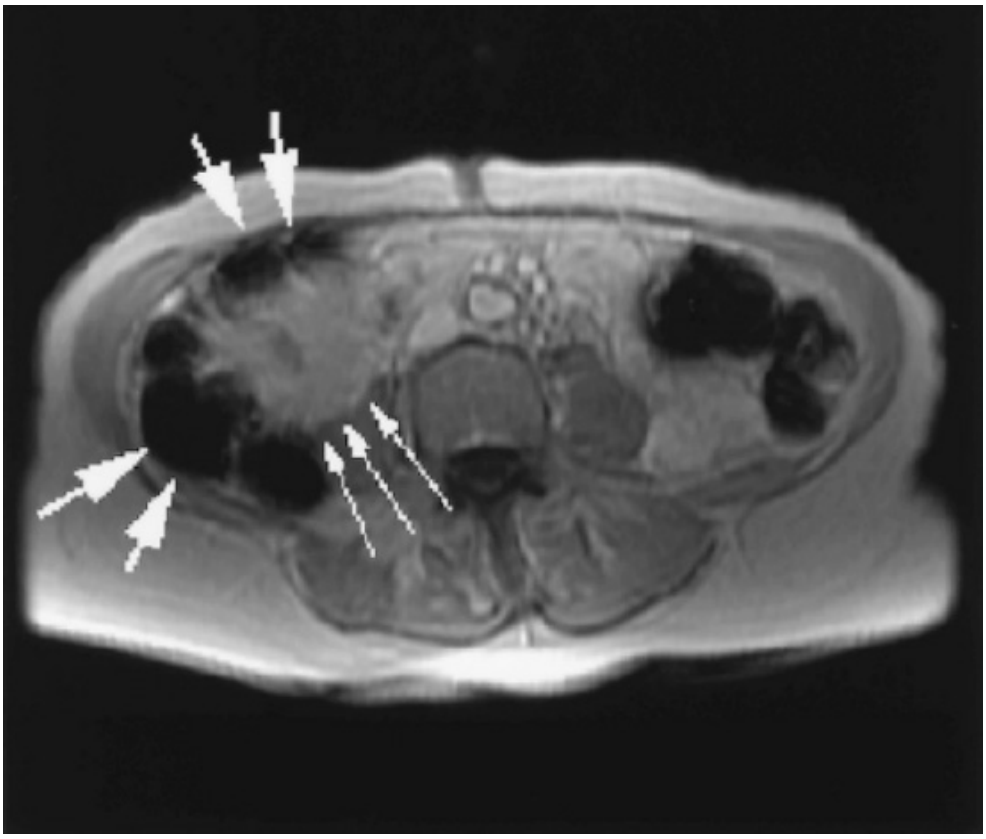

Figure 63.3 T1-weighted magnetic resonance imaging scan of a patient with gallbladder cancer (*small arrows*) with extension into the duodenum and the hepatic flexure of colon (*large arrows*).

Role of Staging Laparoscopy

Because a large percentage of patients with gallbladder cancer are found to have occult, unresectable disease at the time of surgical exploration, several authors have investigated the use of initial staging laparoscopy for this disease.[30–33] Because gallbladder cancer has such a propensity to spread intra-abdominally, this tumor is ideal for detection of intra-abdominal metastases with laparoscopy. This is demonstrated by the fact that up to 50%

of patients are found to have unresectable disease at the time of laparoscopy.[34,35] Patients who are found to have unresectable disease at laparoscopy can begin other forms of systemic therapy earlier and may undergo the procedure as an outpatient. Particularly because patients with unresectable disease have a median survival of only 6 months, the impact on quality of life, including decreased length of stay in the hospital, cannot be overemphasized.

Cholecystectomy with or without Partial Hepatectomy

Gallbladder cancer, if not completely surgically removed, results in rapid local progression and death. In a collected review of 5,836 patients with gallbladder cancer, the overall mean survival was between 2 and 5 months, whereas the 5-year survival was 4%.[5]

There is little doubt that the results of treatment, as well as the scope of operation, are related to depth of tumor penetration (**Table 63.2**). For tumors limited to the muscular layer of the gallbladder (T1), there is near-universal agreement that simple cholecystectomy is adequate.[15,36–38] T1 tumors have not yet invaded the subserosal layer, which contains lymphatics, and therefore lymphadenectomy is not required. Attesting to the fact that early gallbladder carcinoma is completely curable, simple cholecystectomy has resulted in 90% to 100% survival when early cancer is an incidental finding after elective cholecystectomy.[15,39]

The extent of surgical resection for T1b tumors is controversial, with recommendations ranging from simple cholecystectomy to radical excision, including hepatectomy. For T2 or greater tumors, extended resection with cholecystectomy combined with resection of liver segments IVb and V and portal lymphadenectomy is recommended.[40]

To understand the rationale for extensive resections, it is also important to understand the pattern of spread of gallbladder cancer. Direct extension to the adjacent liver parenchyma often occurs first, followed by adjacent organ involvement, including duodenum, colon, and stomach (**Fig. 63.2**). Lymphatic spread of gallbladder cancer is routine, often involving nodes in the porta hepatis, peripancreatic region, celiac axis, and the aortocaval nodal basins. There is currently no consensus on the extent of lymphadenectomy that is appropriate for gallbladder cancer. Extensive lymphadenectomy including

para-aortic nodes is advocated in the East, but is not universally accepted. Recently, a technique of intraoperative nodal staging was proposed that entails sampling the highest peripancreatic lymph node for frozen section. This is the lymph node situated between the N1 and N2 nodal stations at the junction of the bile duct and the superior border of the head of the pancreas (**Fig. 63.4**). Metastatic disease to this node has been shown to be a poor prognostic factor.[41]

Dissection of lymph nodes should include all tissues from the bifurcation of the hepatic ducts to the distal CBD. Proponents of this approach advocate liver resection on the basis that it is the only way to obtain an adequate margin on the hepatic side of the gallbladder and resection of the regional nodes allows the best chance for complete tumor clearance. For all of these reasons, simple cholecystectomy is inadequate for T2 or greater tumors. When larger anatomic hepatic resections have been performed in patients with T2 tumors, it has increased the 5-year survival from 25% to 40% after simple cholecystectomy to 70% to 100% after radical resection.[14,36–38,42,46,47,49,50]

RESULTS

Jensen et al.[47]	29	42	—	—
Mayo et al.[48]	16	53	8	11

[a]No significant difference.

For T3 and T4 lesions, there is a high likelihood of intraperitoneal and hematogenous spread and significant morbidity from the radical procedures that are often necessary for excision of local disease. Recent series, however, support an aggressive approach to resection of these large tumors, particularly if no indication of nodal involvement is found (**Table 63.3**) and negative margins can be achieved. For T3 and resectable T4 tumors, a minimal resection includes segments IVb and V, and in many cases an extended right hepatectomy (segments IV, V, VI, VII, and VIII) may be necessary to obtain complete resection. With aggressive resection, long-term survival can be achieved even for patients with these more advanced tumors.[14,15,36,37,43,51]

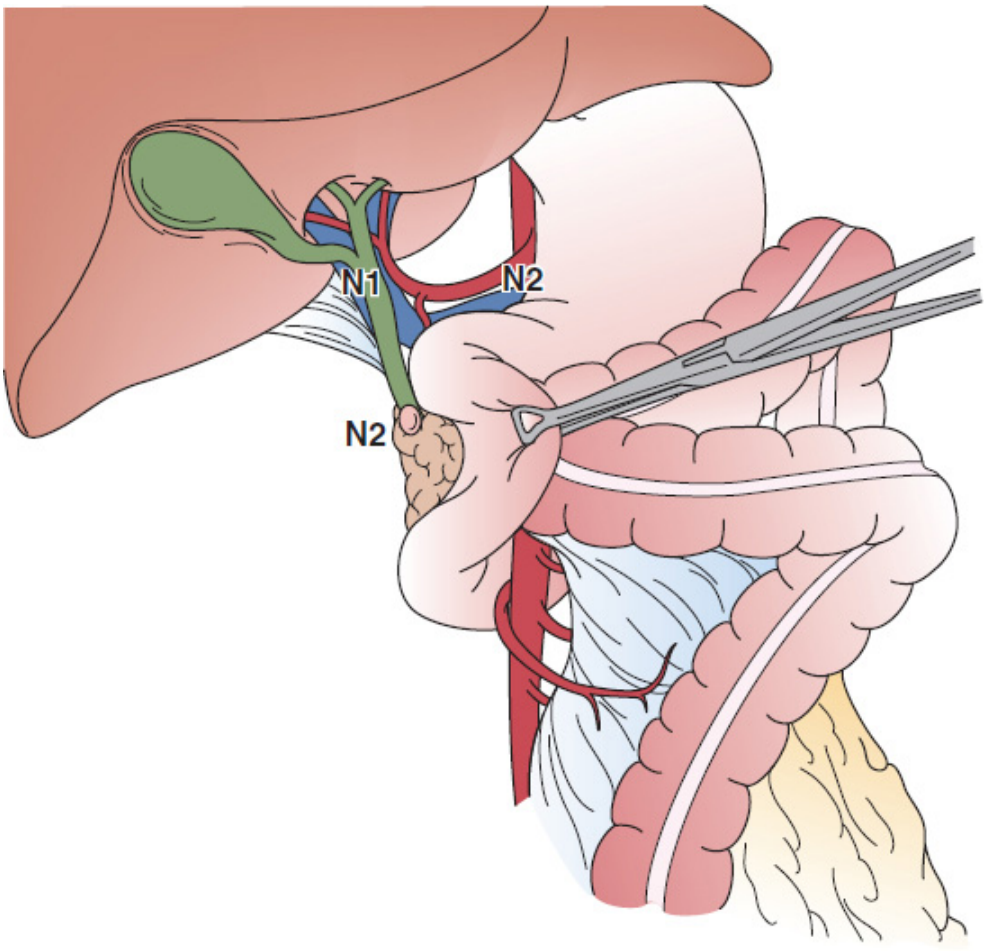

Figure 63.4 Illustration of the highest peripancreatic lymph node.

Surgical exploration should be performed for all patients without medical contraindications. If a T1 tumor is suspected, a cholecystectomy and biopsy of regional nodes should be performed after thorough examination of the abdominal cavity for any signs of tumor dissemination. The pathology and depth of penetration should be confirmed by frozen section, and the procedure terminated if a T1 tumor with negative margins is confirmed. For T2 lesions, a radical cholecystectomy (with resection of segments IVb and V) with lymphadenectomy should be performed.[14] For T3 lesion and resectable T4 lesions, a segment IVb and V resection or extended right hepatectomy is performed if needed to obtain negative margins. Similarly, bile duct resection should only be performed if necessary to achieve negative margins.

RESULTS

Table 63.3 Results after Radical Resection for Gallbladder Cancer

Mayo et al.[48]	202	2	—

Complete regional lymphadenectomy should be performed, skeletonizing the CBD, hepatic artery, and portal vein. Short-term postoperative outcomes following resection of gallbladder cancer have remained relatively stable over time, with postoperative morbidity occurring in 30% to 40% of patients, and mortality occurring in <5% (**Table 63.4**).

Table 63.4 American Joint Committee on Cancer, 8th Edition, Staging System for Intrahepatic Bile Duct Carcinoma

Stage	Tumor	Nodes	Metastasis

Incidentally or Laparoscopically Discovered Gallbladder Cancer

Gallbladder cancer is often discovered during pathologic examination after cholecystectomy for presumed benign disease. Because of the popularization of laparoscopic cholecystectomy in the past decade, an increasing number of patients with gallbladder cancer are found incidentally. The role of reresection in this setting is controversial. In a series of 135 patients who underwent re-exploration following laparoscopic cholecystectomy, 61% of all and 36% of those with T1b primary tumors were found to have residual disease.[52] In this study, survival following reresection of residual locoregional disease was extremely poor and was not different from that of patients with metastatic disease. Improved survival has been demonstrated following reresection to achieve negative margins, however, especially in patients with T2 or T3 disease.[49,53,54] While laparoscopic port-site recurrence has been reported, it is associated with peritoneal-based disease. Port-site excision at the time of re-exploration is no longer recommended as recent data have shown that it is not associated with decreased recurrence or improved survival.[55,56]

Reresection after recent cholecystectomy is often technically challenging. Postoperative inflammation in the right upper quadrant often hinders distinction of tumor from normal tissue. Determination of ductal or nodal involvement by tumor is always difficult at the time of reoperation. In addition, postoperative fibrosis often encases the right hepatic artery, which crosses behind the bile duct in most patients. Because of this, during a second operation for incidentally discovered gallbladder cancer, an extended right hepatectomy along with excision of the extrahepatic biliary tree and portal lymphadenectomy is often necessary. This resection allows adequate exposure for lymphadenectomy and greater confidence of a negative margin

on the bile duct, and also permits biliary reconstruction to only one side of the liver. The disadvantage is that a large portion of normal liver parenchyma is sacrificed, and consequently, transient postoperative liver dysfunction is common. Although it may be more difficult to curatively resect disease in patients with incidentally discovered gallbladder cancer after laparoscopic cholecystectomy, there is no difference in overall survival between patients with incidentally discovered gallbladder cancer who are submitted to curative resection and those patients who undergo initial curative resection.[57]

When a patient presents with T1a gallbladder cancer discovered after simple cholecystectomy, the pathology should be reviewed to determine if the entire gallbladder has been removed and if the cystic duct margin is clear of tumor. If all margins are negative, no further therapy is warranted. If the tumor is proved to be T1b or greater, and in the absence of metastatic disease, patients should be counseled regarding reresection to attempt complete staging and margins, chemotherapy with or without radiation, or observation. Patients with a known or suspected early gallbladder carcinoma should be referred to an experienced center where curative-intent resection can be performed at the initial operation.

Neoadjuvant and Adjuvant Therapy

Very few randomized trials have been completed to inform the role of neoadjuvant and adjuvant therapy for gallbladder cancer. Given the relative rarity of these malignancies in the United States, large-scale, randomized trials are feasible only in the context of a multi-institutional or cooperative group setting. Consensus guidelines state that neoadjuvant therapy should be considered for patients with locally advanced gallbladder cancer, although there is little data supporting any one regimen. Commonly used regimens include combinations of gemcitabine with oxaliplatin, cisplatin, or capecitabine, or 5-fluorouracil-based regimens. A meta-analysis published in 2019 identified 474 patients with gallbladder cancer treated in 8 studies with neoadjuvant therapy and surgery or surgery alone and concluded that data were insufficient for routine use of neoadjuvant therapy.[58]

In 2002, a randomized phase III trial of adjuvant chemotherapy with 5-fluorouracil and mitomycin C versus surgery alone for patients with pancreaticobiliary malignancies having resection found that in the subset of

patients with gallbladder cancer (n = 112), the 5-year survival rate was significantly better in the adjuvant group (26%) versus the control group (14%).[59] Similarly, the 5-year disease-free survival rate was 20.3% versus 11.6%, clearly favoring the adjuvant therapy group. A recent review of the SEER database also reported an association between adjuvant chemoradiation therapy and improved survival in patients with locoregionally advanced disease.[60] This finding prompted a multi-center phase II trial of adjuvant capecitabine and gemcitabine followed by concurrent capecitabine and radiation therapy for patients with resected gallbladder cancer or extra hepatic cholagiocarcinoma. The results of this study were published in 2015 and showed promising findings of 65% 2-year survival.[61] These studies suggest that patients with gallbladder cancer with high risk for recurrence (T2 or greater, node-positive, or margin-positive) should be considered for adjuvant treatment with systemic chemotherapy or chemoradiation.

Prognosis

The 5-year survival rate for all patients with gallbladder cancer is less than 5% in most series, with a median survival of 6 months. This is primarily because most patients present with unresectable disease. Of those patients undergoing resection, survival is dependent on depth of penetration and nodal status. Nearly 100% survival is reported after simple cholecystectomy for T1a disease, whereas patients with T2 and T3 tumors without nodal disease have a 5-year survival greater than 50%.[14,15,43,50] Node positivity is an ominous finding, with few series reporting 5-year survivors.

Follow-up after Resection for Gallbladder Cancer

The most common sites of recurrence after resection of gallbladder cancer include carcinomatosis, intrahepatic metastases, or nodal recurrence in the retroperitoneum. For most tumors, local recurrence is found synchronously with diffuse intra-abdominal spread. When jaundice or cholangitis is the presenting symptom of possible recurrence, a nonsurgical palliative

approach using percutaneous transhepatic cholangiogram (PTC) and stenting is usually favored unless a benign postsurgical stricture is suspected. Because of the rapid growth of tumor in patients with recurrence, the hospitalization and recovery time from a surgical bypass is usually not justified for recurrences resulting in biliary obstruction.

The routine follow-up of a patient after resection of gallbladder cancer includes office visits every 3 months with physical examination and measurement of liver function tests, and cross-sectional imaging every 3 to 6 months for the first 2 years. In patients who remain free of disease at 2 years, follow-up should be continued on an individualized basis. Although CA19-9 may be elevated in patients with gallbladder cancer, the sensitivity and specificity are poor and, thus, is optional for screening for recurrence.[62] If recurrence is identified, systemic therapy with gemcitabine and cisplatin should be considered as it has been shown to prolong survival in the setting of metastatic disease.[63] For patients who cannot tolerate this regimen, alternatives include single-agent gemcitabine or gemcitabine plus capecitabine.[64] Lastly, molecular profiling to identify targeted agents, including immunotherapy, that may be effective is recommended.

Issues for the Future

Clearly, improving our ability to recognize early gallbladder cancer in high-risk geographic areas would have an important impact on outcome in these patients. This will likely require implementation of screening programs in high-risk areas, which could result in prophylactic cholecystectomy.[65] Additionally, standardization of minimum pathologic assessment of gallbladder specimens in high-risk areas is important to allow for accurate diagnosis, staging, and treatment of patients.

Further studies on characterization of molecular aberrations in gallbladder cancer by next generation sequencing and other technologies may lead to the discovery of targetable mutations and lead to the development of novel therapies. Additionally, there is a theoretical role for neoadjuvant therapy for patients with locoregionally advanced gallbladder cancer given their poor prognosis following surgery. Clinical trials in this area are needed.

BILE DUCT CARCINOMA

Bile duct carcinomas may arise within the liver (intrahepatic cholangiocarcinoma [ICC] or peripheral cholangiocarcinoma), at the liver hilum (hilar cholangiocarcinoma or Klatskin tumor), or in the extrahepatic bile duct (extrahepatic cholangiocarcioma [ECC]). While all arise from the biliary epithelium, the location of these tumors affects prognosis as well as the potential for curative resection.

Resection of biliary neoplasms, particularly hilar cholangiocarcinoma, often requires radical resections and complex biliary reconstructions that should be performed only at high-volume, experienced centers. There is also a role for surgery in palliation for these cancers by providing biliary bypass for jaundiced patients with unresectable tumors. Because disease is often diagnosed late in the course and because complex operative techniques are required for potentially curative resection, these tumors represent one of the greatest challenges for definitive treatment.

INCIDENCE

The incidence of ICC in the United States is approximately 0.7/100,000 with a similar mortality. During the last 30 years, it appears that both the incidence and mortality in the United States are increasing.[66] The overall incidence of hilar cholangiocarcinoma, the most common type, is 1.0/100,000 per year in the United States, although rates are higher in other geographic regions such as Israel and Japan.[67] Recent population studies have noted a trend toward a relative increased incidence of ICC compared to ECC.[4,68,69] Using the Surveillance, Epidemiology and End Results-Medicare databases, Welzel et al.[69] noted HCV infection, chronic nonalcoholic liver disease and obesity, and smoking being associated only with ICC and not ECC, possibly explaining the divergent trends in incidence. Cholangiocarcinomas arise slightly more often in males, with a male-to-female ratio of 1.3:1 and an average age of 50 to 70 years.

Known risk factors for cholangiocarcinoma include primary sclerosing cholangitis, ulcerative colitis, choledochal cysts, and biliary tract infection, either with *Clonorchis* or in chronic typhoid carriers.[70] Some industrial

chemicals (e.g., nitrosamines, dioxin, asbestos, and polychlorinated biphenyls) have also been implicated in the pathogenesis of cholangiocarcinoma. Although there has been some suggestion of an increased risk of cholangiocarcinoma arising after transduodenal sphincteroplasty,[71] it is difficult to determine if this is caused by the surgical intervention or the underlying disease leading to sphincteroplasty.

Pathology and Staging

More than 90% of bile duct cancers are adenocarcinomas. They are morphologically described as nodular, which is the most common, scirrhous, diffusely infiltrating, or papillary. Histologic subtypes include acinar, ductular, trabecular, alveolar, and papillary. Papillary tumors have an improved outcome. Much less common types of bile duct tumors include cystadenocarcinomas, hemangioendotheliomas, and mucoepidermoid carcinomas. In patients with ICC, negative prognostic signs include vascular invasion, multiple tumors, and lymph node metastases.[72]

Historically, ECCs have been classified according to their location in the upper (60%), middle (15% to 20%), or lower third (15% to 20%) of the bile duct. Middle-third lesions arise between the cystic duct and the superior border of the duodenum. Lower-third lesions are found below the superior border of the duodenum but above the ampulla. The problem with this classification is that the anatomic landmarks are somewhat arbitrary and not clinically useful. A more useful classification is to divide these lesions into upper-half or lower-half tumors, based on the location of the cystic duct as it enters the common duct (in the case of normal anatomy). The usefulness of this classification scheme is that it allows the surgeon to delineate whether a hepatic or pancreatic resection will be required for clearance of tumor. The AJCC TNM staging system (eighth edition) for bile duct cancers is described in **Tables 63.4** to in **63.6**.

Table 63.5 American Joint Committee on Cancer, 8th Edition, Staging System for Perihilar Bile Duct Carcinoma

Stage	Tumor	Nodes	Metastasis
0	Tis	N0	M0
I	T1	N0	M0
II	T2a–b	N0	M0
IIIA	T3	N0	M0
IIIB	T1–3	N1	M0
IVA	T4	N0–1	M0
IVB	Any T	N1–2	M0
	Any T	Any N	M1

Definition of TNM	
Primary tumor (T)	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ/high-grade dysplasia
T1	Tumor confined to bile duct, with extension up to the muscle layer or fibrous tissue
T2a	Tumor invades beyond the wall of the bile duct to surrounding adipose tissue
T2b	Tumor invades adjacent hepatic parenchyma
T3	Tumor invades unilateral branches of the portal vein or hepatic artery
T4	Tumor invades main portal vein or its branches bilaterally; or the common hepatic artery; or the second-order biliary radicals bilaterally; or unilateral second-order biliary radicals with contralateral portal vein or hepatic artery involvement

Regional lymph nodes (N)	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	One to three positive lymph nodes typically involving the hilar, cystic duct, common bile duct, hepatic artery, posterior pancreatoduodenal, and portal vein lymph nodes
N2	Four or more positive lymph nodes from the sites described for N1
Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

Table 63.6 American Joint Committee on Cancer, 8th Edition, Staging System for Distal Bile Duct Carcinoma

Stage	Tumor	Nodes	Metastasis
0	Tis	N0	M0
IA	T1	N0	M0
IB	T2	N0	M0
IIA	T3	N0	M0
IIB	T1–3	N1	M0
III	T4	Any N	M0
IV	Any T	Any N	M1
Definition of TNM			
Primary tumor (T)			
TX	Primary tumor cannot be assessed		
T0	No evidence of primary tumor		
Tis	Carcinoma in situ/high-grade dysplasia		
T1	Tumor invades the bile duct wall with a depth of <5 mm		
T2	Tumor invades the bile duct wall with a depth of 5–12 mm		
T3	Tumor invades the bile duct wall with a depth of >12 mm		
T4	Tumor involves the celiac axis, superior mesenteric artery, and/or common hepatic artery		
Regional lymph nodes (N)			
NX	Regional lymph nodes cannot be assessed		
N0	No regional lymph node metastasis		
N1	Metastasis to one to three regional nodes		
N2	Metastasis to four or more regional nodes		

Distant metastasis (M)	
M0	No distant metastasis
M1	Distant metastasis

Other staging systems have been created that attempt to incorporate clinically important indicators of resectability for hilar cholangiocarcinoma that are defined preoperatively, including hepatic lobe atrophy or portal vein involvement.[73] With the increasing acceptance of major hepatic resection for these tumors, this preoperative staging system attempts to define whether there is ipsilateral involvement alone, because tumors with bilateral extension past the primary biliary radicles are not resectable.

Clinical Findings and Diagnosis

The presentation of patients with cholangiocarcinoma is variable. Patients with hilar or extrahepatic tumors most commonly present with painless jaundice. Symptoms of mild right upper quadrant pain, pruritus, anorexia, malaise, and weight loss may also be reported. Cholangitis is the presenting symptom in 10% to 30% of patients. Some patients, particularly those with ICC may be asymptomatic and have their tumors discovered incidentally or on evaluation for elevations of alkaline phosphatase and gamma-glutamyl transferase. Many of these patients will present to the surgeon with a biopsy showing adenocarcinoma without a known primary tumor. The standard evaluation in these patients should include tumor markers including carcinoembryonic antigen (CEA) or α-fetoprotein (AFP); upper and lower endoscopy to evaluate for a gastrointestinal source; CT scan to assess for a primary tumor in the gastrointestinal tract or pancreas; and, in women, a mammogram. If no site of primary disease is found, in most patients, the diagnosis is ICC.

On CT, cholangiocarcinomas most often appear as hypodense masses with irregular margins on precontrast phase images, with peripheral rim enhancement on arterial phase, followed by progressive hyper-attenuation on venous and delayed phases.[74] Intrahepatic lesions often exhibit associated

capsular retraction and segmental/lobar atrophy and ductal dilatation. Hilar and proximal extrahepatic lesions demonstrate dilated intrahepatic biliary ducts with a normal, collapsed gallbladder, and, depending on the level of the tumor, a nondilated or partially dilated extrahepatic biliary tree (**Fig. 63.5**). While conventional CT is useful for assessment for extrahepatic, metastatic disease and perihilar adenopathy, high-resolution CT and/or MRI are required for accurate assessment of the tumor and for determination of respectability (**Figs. 63.6** and **63.7**).[74] Portal vein patency can be determined with ultrasound, CT, or MRI. Particularly for hilar tumors, signs of hepatic lobar atrophy should be carefully sought, because this indicates ipsilateral portal vein involvement by tumor. MRCP offers the potential of evaluating parenchymal, vascular, biliary, and nodal involvement with a single noninvasive examination.[25,27,75]

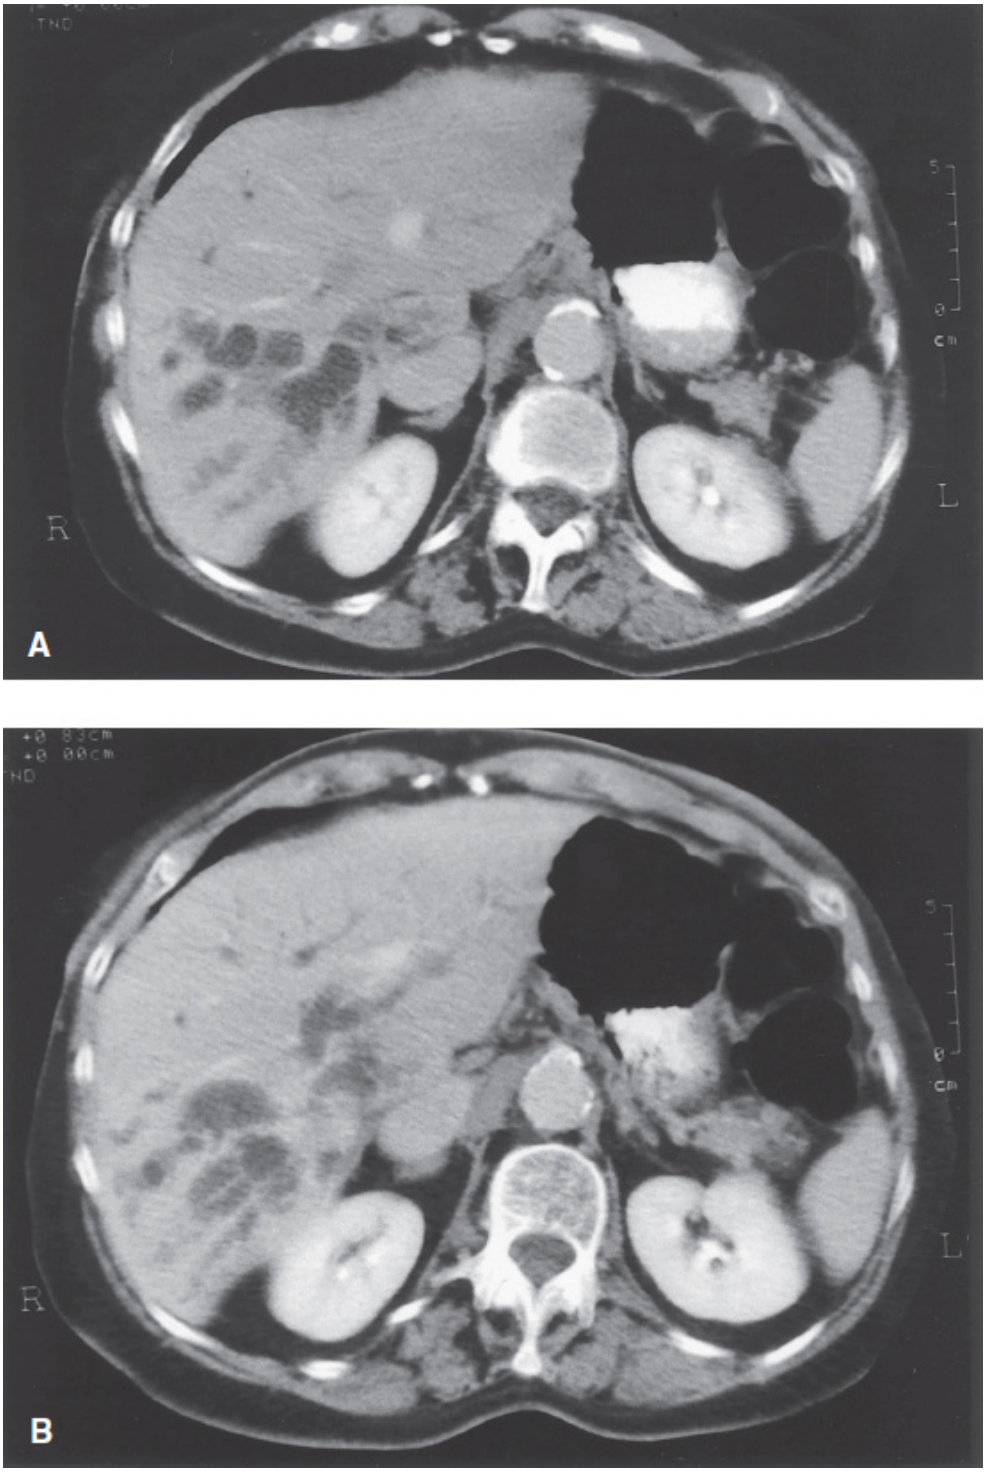

Figure 63.5 Computed tomography scan in a patient with hilar cholangiocarcinoma, demonstrating dilated intrahepatic ducts in the right lobe (**A** predominantly posterior sector, **B** both anterior and posterior sectors) but inability to directly visualize tumor.

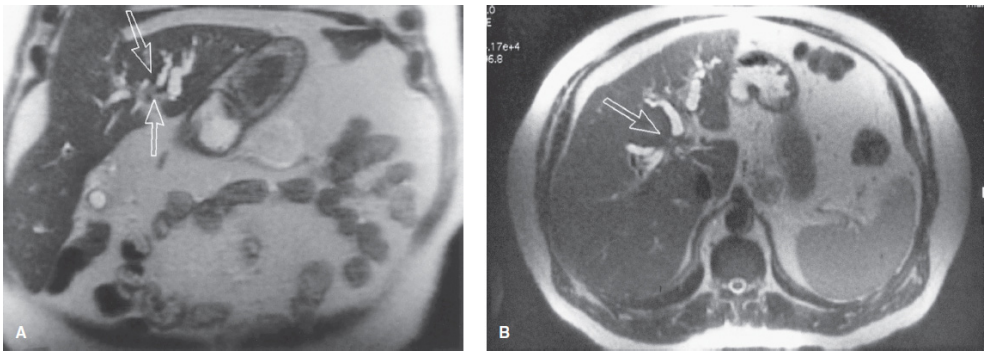

Figure 63.6 Coronal (**A**) and axial (**B**) magnetic resonance imaging in a patient with hilar cholangiocarcinoma. Dilated intrahepatic ducts are present with a soft tissue density consistent with tumor (*arrows*).

In most centers, direct cholangiography is used to evaluate the extent of biliary involvement and provide palliation for jaundice. Endoscopic retrograde cholangiopancreatography (ERCP) has little role to play in high biliary obstruction because opacification of the proximal biliary tree is difficult. ERCP, however, can be effectively used to image more distal lesions. At the time cholangiography is performed, some authors advocate the routine preoperative placement of biliary drainage catheters to aid in intraoperative identification of the bile ducts.[76,77] Others have found a higher incidence of infectious complications and mortality, and a longer hospital stay, after preoperative placement of biliary drainage catheters.[78–80] The difficulty in making the decision regarding preoperative stenting is that many patients are severely symptomatic because of jaundice and pruritus and require palliation, thus if the operation is delayed, many patients require palliation.

In many cases, it is difficult to obtain pathologic confirmation of cholangiocarcinoma, even with the use of biliary brushings and cytology obtained at the time of direct cholangiography. Oftentimes, patients are offered surgical therapy based on clinical suspicion and radiographic appearance. In patients with ICC, cross-sectional imaging with CT scan is usually sufficient. Tumors may be mass-like or may have cystic areas.

Surgery

Untreated, most patients with bile duct cancers die within a year of diagnosis.[80,81] Surgical excision is the treatment of choice, with no other

potentially curative therapy available. The immediate causes of death are most commonly hepatic failure or cholangitis related to tumor growth and inadequate drainage of the biliary tree.[82] Therefore, the goals of surgery are complete removal of tumor with R0 margins while leaving a sufficient liver remnant, and establishing adequate biliary drainage. Patients with ICC require additional consideration. Those patients with multifocal and especially bilobar intrahepatic tumors, even if technically resectable with negative margins and adequate remnant liver, should not be considered for resection. These patients have very poor prognosis indicating that bilobar hepatic spread represents hematogenous metastasis.[83] What remains controversial is whether peritumoral satellite lesions also represent metastatic disease. Because this is unknown and surgery is the only potentially curative therapy for these patients, satellite lesions are not currently considered an absolute contraindication to resection.

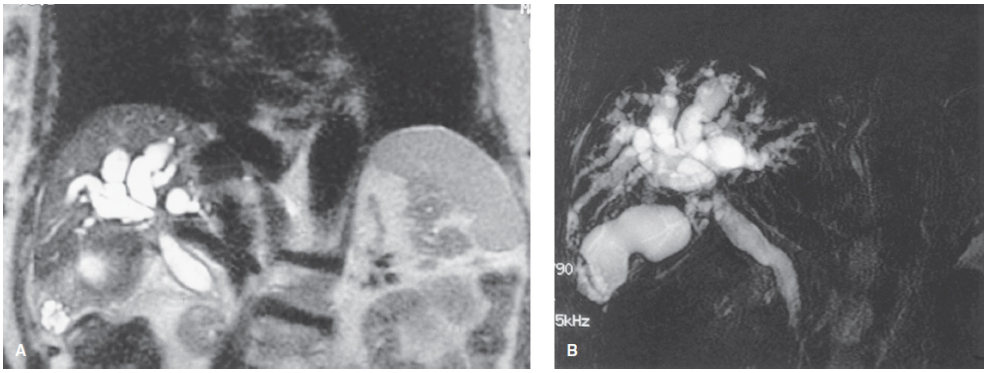

Figure 63.7 Coronal (**A**) magnetic resonance imaging and magnetic resonance cholangiopancreatography (**B**) in a patient with hilar cholangiocarcinoma, demonstrating dilated intrahepatic ducts narrowing at the area of obstruction.

Hilar cholangiocarcinoma is often unresectable due to local factors. These include invasion of the main portal vein or both the right and left portal veins and hepatic arteries and tumor extension into second-order biliary radicals of both right and left hepatic lobes. By contrast, tumors extending into second- or third-order biliary radicles on one side of the liver without vascular involvement can be resected for cure. It has become clear over the last three decades that curative treatment for patients with tumors of the hilum or those involving the upper half of the bile duct depends on aggressive excision that often requires a major liver resection. Until as recently as one decade ago,

treatment of hilar cholangiocarcinoma was associated with mortality as high as 30%.[84–88] Recently, major improvements in the safety of these operations have been demonstrated, and resection of hilar tumors now results in mortality of less than 10%, even when liver resections are required.[84,85,87,89]

Role of Staging Laparoscopy

Because of the potential morbidity of a laparotomy that has no therapeutic benefit, staging laparoscopy has been advocated to save patients from unnecessary laparotomy. In patients with hilar cholangiocarcinoma, up to 25% will benefit from staging laparoscopy because of detection of occult extrahepatic disease.[33,34] Laparoscopy is a very sensitive means to detect peritoneal metastases or additional intrahepatic disease through the use of laparoscopic ultrasound but is less sensitive in detecting nodal metastases or locally invasive tumors.

Partial Hepatectomy with or without Bile Duct Resection

The extent of hepatectomy required for resection of cholangiocarcinoma is dependent on the tumor location in relation to the portal inflow and venous outflow of the liver. Intraoperative ultrasound is a useful adjunct for assessment of tumor extent and for small satellite lesions that may not be apparent on cross-sectional imaging.

Small ICCs may be removed by segmentectomy or sectorectomy, but these tumors are often large and require extended right or left hepatectomy. For hilar and proximal hepatic duct lesions, complete resection usually requires combined biliary and hepatic resection with or without major vascular reconstruction. Additionally, caudate resection is often required because of direct extension into caudate biliary radicles or parenchyma.[73,88,90] Resection of the extrahepatic bile duct with Roux-en-Y hepaticojejunostomy to the remnant duct is required in these cases. Intraoperative assessment of the bile duct resection margin should be performed if additional duct can potentially be taken. If not, assessment on permanent sectioning is sufficient.

Lymphadenectomy

Regional lymphadenectomy is essential for accurate staging of cholangiocarcinoma, and may be important for locoregional disease control, but has historically been underperformed for intrahepatic and hilar tumors.[72,91] Recent data have shown that lymph node metastases are present in 30% to 40% of patients.[72,91–93] Regional lymph nodes include those along the porta hepatis, the hepatoduodenal ligament, the hepatic artery for essentially all patients. In addition, for those with primary tumors of the right hemiliver, retropancreatic nodes should be removed. For those with primary tumors of the left hemiliver, perigastric lesser curve nodes (levels 1, 3, and 5) should be removed.[94] A recent study utilizing the SEER database found that removal of at least six lymph nodes is recommended for accurate staging of ICC.[95]

Pancreaticoduodenectomy

For cholangiocarcinoma of the lower half of the extrahepatic bile duct, pancreaticoduodenectomy is requiring for complete tumor extirpation. The proximal bile duct margin should be assessed by frozen section to ensure tumor clearance. Regional lymphadenectomy is inherent in this procedure.

Liver Transplantation for Hilar CC and the Mayo Protocol

Orthotopic liver transplantation (OLT) was thought to hold promise for patients with hilar CC, because of the ability to achieve adequate margins by complete hepatectomy. Unfortunately, when used as a single treatment modality, results have been poor. Three- and 5-year survival rates have been reported at 25% to 30%.[96–98] Because of this poor outcome, the Mayo Clinic developed a protocol combining neoadjuvant therapy with liver transplant, based on a strategy initially developed by the University of Nebraska. This protocol uses high-dose neoadjuvant 5-fluorouracil and brachytherapy followed by liver transplantation.[99,100] Inclusion criteria include (i) locally advanced unresectable disease with either positive intraluminal brush cytology, positive intraluminal biopsy, or CA19-9 $\geq$100 in the setting of a radiographic malignant stricture; (ii) primary sclerosing cholangitis with resectable disease; and (iii) absence of medical contraindications for OLT. Since 2003, biliary aneuploidy as demonstrated by digital image analysis

(DIA) and fluorescent in situ hybridization have been considered equivalent to cytology.[101,102] Exclusion criteria include (i) extrahepatic disease including regional lymph node involvement; (ii) uncontrolled infection; (iii) prior attempt at resection; (iv) prior treatment with radiation or chemotherapy; and (v) previous malignancy within 5 years. In this protocol, patients receive external beam radiotherapy to a target dose of 4,500 cGy with concomitant fluorouracil (5-FU). Following this, transcatheter iridium-192 brachytherapy with a target dose of 2,000 to 3,000 cGy is administered. Thereafter, patients receive oral capecitabine as tolerated until transplantation. It is important that, prior to transplantation, patients undergo a staging laparotomy, at which time biopsy of perihilar lymph nodes as well as any lymph nodes or nodules suspicious for tumor is performed. Only patients with negative staging operations remain eligible for transplantation.[99]

The prolonged course of neoadjuvant therapy, staging laparotomy, and time on the OLT waiting list provides an opportunity to exclude patients demonstrating disease progression. This highly rigorous selection bias in favor of patients with biologically favorable disease is reflected in the early outcomes published from the Mayo group. In a recent review of 71 patients enrolled in this transplant protocol, only 38 underwent transplantation (38%). These patients were compared to 26 patients (of 54 explored, 48%) who underwent successful resection. When compared to those undergoing resection (some with node-positive disease), patients undergoing transplantation were younger ($p < 0.001$) and more likely to have inflammatory bowel disease ($p < 0.03$) and PSC ($p < 0.001$). It is important that only 58% of patients had histologically proven cancer. In these highly disparate groups, 5-year survival was 82% after transplantation (38 patients) compared to 21% after resection of 26 patients ($p = 0.022$).[103] There were also fewer recurrences in the transplant patients (13% vs. 27%), and recurrences became apparent later after transplantation than after resection (mean 40 months vs. 21 months). Direct comparisons are difficult with this study given the differences between groups. A recent meta-analysis of patients with unresectable hilar cholangiocarcinoma reported 5-year overall survival of 65% for those who underwent neoadjuvant therapy followed by transplantation, versus 32% for those who had transplantation alone.

At present, OLT cannot be considered a standard form of therapy for hilar cholangiocarcinoma for patients with resectable disease, but it does offer a potential option for patients with underlying PSC or those with unresectable tumors who fit the rigorous inclusion and exclusion criteria of these protocols.

RESULTS

Prognosis after Resection

Results of major studies on resection of hilar cholangiocarcinoma are summarized in **Table 63.7**. In patients amenable to curative resection, the median survival is 35 months with a 5-year survival rate of 10% to 30%.[78,86,87,96,100,112] Surgical resection provides both improved survival and improved quality of life. The greatest risk factors for recurrence include the presence of positive margins, and node-positive tumors.[113]

In patients with ICC, expected 3-year survival rates as high as 60% have been reported, with 5-year survival rates of 30% to 45%.[35,113,114] Patients with unresectable disease have a median survival of 12 months.[35,115] Thus,

completely resected ICC appears to have an improved prognosis over proximal (hilar) cholangiocarcinoma. Patients with cholangiocarcinomas arising in the distal bile duct have both an increased resectability rate and improved prognosis over those with hilar cholangiocarcinomas.[89] Patients with resectable distal bile duct cancer have a 5-year survival rate of 30% to 50%, with a decreased survival if nodes are involved with tumor.[116,117]

Unresectable Cholangiocarcinoma

6 For patients with unresectable hilar cholangiocarcinomas, biliary drainage is necessary.

Nonoperative palliative biliary decompression can be accomplished with percutaneous or endoscopic stenting, depending on the level of obstruction. Proximal lesions are usually approached percutaneously with placement of expandable stents or drainage catheters (**Fig. 63.8**). Internal stents result in fewer electrolyte abnormalities and improvement in patient comfort, although morbidity and mortality occurs in up to 30% of patients and stent occlusion is common.[118–120] There is a significant risk of cholangitis with external and internal drainage, occurring in more than 90% of patients with metallic expandable internal stents in one series.[119] Bleeding and bile leaks are also frequent complications. More recent techniques (e.g., photodynamic therapy) have been used to palliate patients with biliary obstruction and may hold some promise for the future.[121]

Palliative surgical bypass can also be performed, however is less often necessary with current availability of advanced endoscopic and percutaneous techniques. A partial excision of the left lateral segment and biliary-enteric anastomosis to the left hepatic duct (Longmire procedure) was used commonly in the past, but more recently surgical techniques have become less complicated and do not require hepatic parenchymal transection. One technique involves biliary decompression through the left duct, approached through the round ligament, a segment III bypass (**Fig. 63.9**). Opening the bridge of tissue just beneath the ligamentum teres allows access to the duct. In this position, a long anastomosis can be performed from the segment III duct to a jejunal limb because of the horizontal course of the duct in this location. Although less commonly used, the right hepatic duct can be

approached at the base of the gallbladder fossa. This is technically more difficult and results in a higher rate of late bypass failure.[122]

Because patients with unresectable disease have a relatively short median survival, those whose disease is clearly unresectable on preoperative imaging should undergo percutaneous internal or external drainage. In patients who undergo exploratory surgery and whose disease is found to be unresectable, surgical bypass offers fewer episodes of cholangitis, with an improved quality of life. In some series, surgical bypass for patients with unresectable disease is the only biliary drainage procedure ever required by the patient.

In patients with unresectable distal cholangiocarcinomas, palliation can be achieved with surgical bypass, percutaneous biliary drains, or ERCP-placed stents. The simplest and most effective way to relieve jaundice is usually with an ERCP stent. Although surgical bypass offers improved patency and fewer episodes of cholangitis, the morbidity of the procedure is not warranted in patients with these aggressive tumors.

Liver-directed therapies such as transarterial chemoembolization (TACE), transarterial radioembolization (TARE), and ablation are also potential treatment options for patients with ICC who are not candidates for resection. These therapies have not been evaluated in the format of a randomized prospective trial, but have shown promising results in both retrospective and early phase prospective studies (REFS).

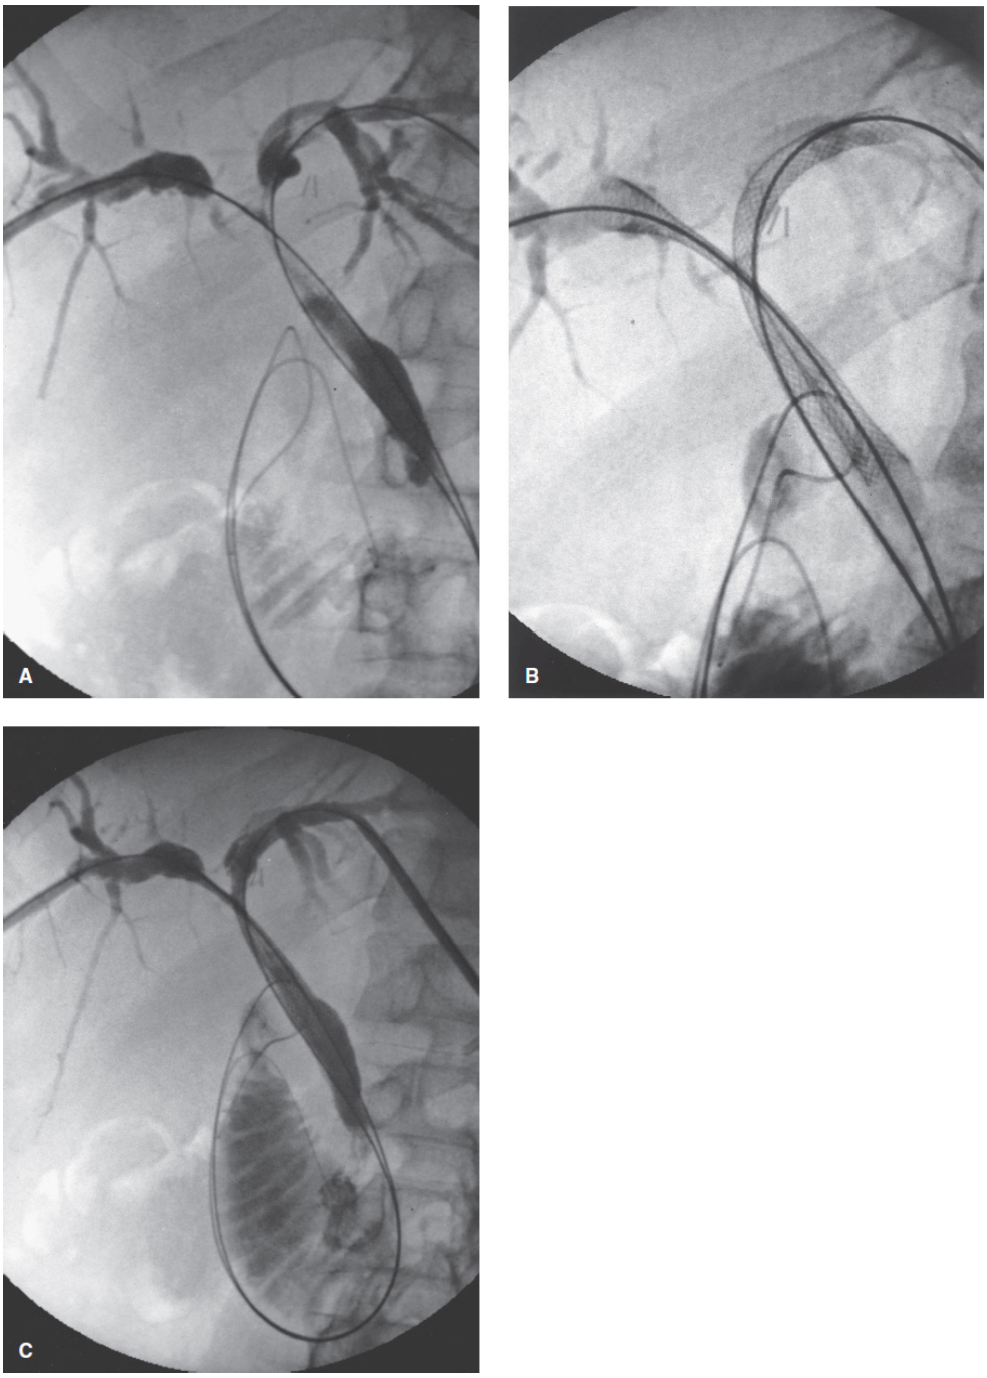

Figure 63.8 **A:** Percutaneous transhepatic cholangiogram in a patient with hilar cholangiocarcinoma, demonstrating biliary obstruction at the confluence. The patient has previously had placement of internal/external stents for biliary drainage. **B:** Film demonstrates appearance of wall stents after deployment into the left and right biliary ducts. **C:** After stenting, the cholangiogram demonstrates adequate biliary drainage, with contrast filling the duodenum.

Adjuvant Therapy

To date, no chemotherapeutic regimen has consistently shown activity against cholangiocarcinoma. Many of the issues that pertain to chemotherapy trials in gallbladder cancer are directly relevant to the interpretation of trials for cholangiocarcinomas. Studies performed to date have typically been small, single-institution trials, including patients with both gallbladder and bile duct cancers.[123]

Although 5-fluorouracil (5-FU)–based chemotherapy is often offered to patients with unresectable disease, the likelihood of response is less than 10%. Capecitabine as a single agent may have some modest activity in cholangiocarcinomas.[124] When capecitabine was used in combination with gemcitabine in a recent prospective study, overall survival was 14 months.[64] Gemcitabine and cisplatin combination therapy has also been tested in phase II studies of patients with advanced biliary tract carcinoma.[125,126] Results of these studies demonstrated response rates of 27% to 34.5%, and overall survival of 9.7 to 11 months. The use of mitomycin C and doxorubicin (Adriamycin), in combination with 5-FU, has resulted in combined response rates of less than 30%, with higher toxicity than 5-FU alone.[127]

With the exception of extrahepatic disease, there is no clear role for adjuvant chemotherapy in the treatment of cholangiocarcinoma. The previously mentioned phase II trial from 2015 showed a promising 2-year survival for patients with extrahepatic cholangiocarinoma treated with adjuvant capecitabine/gemcitabine and concurrent capecitabine and radiation therapy.[61] Aside from this study, however, previous data suggested no difference in overall survival (36% vs. 42%, $p = 0.6$) or loco regional recurrence (38% vs. 37%, $p = 0.13$) in patients who underwent R0 resection alone versus those with high loco regional recurrence risk who received adjuvant chemoradiation therapy.[128] Similar to the recommendations for gallbladder cancer, patients with extra-hepatic cholangiocarcinoma who undergo R0 or R1 resection should be considered for adjuvant capecitabine/gemcitabine and concurrent capecitabine and radiation therapy.

(Courtesy of Dr. L. H. Blumgart.)

In cases of unresectable cholangiocarcinoma, the use of external beam radiation therapy has been explored.[90,129–132] To date, no study has clearly demonstrated efficacy for this modality. Anecdotal reports of long-term survivors after external beam radiotherapy show that some individuals may benefit from such treatment, but this must be weighed against the potential complications (e.g., duodenal or bile duct stenosis and duodenitis). The most encouraging results involve use of intraoperative or interstitial radiation.[129,130,132,133] In patients whose disease is resected and have node- or margin-positive disease, systemic therapy with gemcitabine or 5-FU, or 5-FU–based chemoradiation, or enrollment in a clinical trial should be strongly encouraged.

Follow-up after Resection of Cholangiocarcinoma

Recurrence following resection of ICC is within the liver in 60% of patients. While data are lacking, there is some evidence to suggest that there is a role for reresection in highly selected patients. The most likely site of recurrence after resection of hilar cholangiocarcinoma is locally within the bile duct, regional lymph nodes, or liver. Therapy for recurrence is palliative. Surgical re-excision is usually impossible because of the challenging anatomic location and the radical procedures that are required for resection of the primary tumor. The main symptoms of recurrence that demand palliation are pruritus or cholangitis associated with jaundice. For biliary drainage to relieve jaundice or cholangitis, either surgical drainage or drainage by PTC can be effective. Endoscopic drainage has little role in the relief of jaundice in patients who have had Roux-en-Y biliary reconstruction. For limited recurrences, intraluminal brachytherapy or external beam radiotherapy may improve palliation and, potentially, survival.[134]

Routine follow-up consists of office visits every 3 months with physical examination and measurement of liver function tests. Although a rising alkaline phosphatase level is a reliable indicator of evolving biliary obstruction, patients recovering from liver resection and biliary obstruction can have persistent elevations of alkaline phosphatase. Up to 10% of patients with biliary surgical reconstruction, however, may develop a benign anastomotic stricture. Most patients with recurrence or a benign stricture will present with jaundice or cholangitis. Surveillance cross-sectional imaging is recommended every 3 to 6 months for the first 2 years following resection and should be individualized thereafter.

Issues for the Future

Further studies are needed to develop effective adjuvant, and potentially neoadjuvant, therapies for cholangiocarcinoma. Continued assessment of novel drugs and radiosensitizers, and biologic agents is warranted. A better understanding of the molecular pathogenesis and genetics of bile duct cancers

may lead to new therapeutic strategies and possibly preventive strategies for high-risk populations.

BENIGN GALLBLADDER NEOPLASMS

Incidence

Benign tumors of the biliary tract are rare, but have been reported more frequently as imaging modalities (e.g., ultrasound and CT scan) have come into widespread and frequent use. In patients undergoing cholecystectomy, the reported incidence of benign gallbladder tumors is less than 3%.

Pathology

Polyps and Pseudotumors

Benign gallbladder tumors are most frequently polyps or polypoid lesions. The incidence of polyps in asymptomatic patients is about 5%.[3] Cholesterol polyps (cholesterolosis), accounting for half of all gallbladder polypoid lesions, result from epithelium-covered, cholesterol-laden macrophages in the lamina propria.[135] These lesions are likely a result of an error in cholesterol metabolism. They extend from the mucosa on a narrow stalk, grossly appearing as yellow spots on the mucosal surface. Nearly all are multiple, and most are less than 10 mm in size.[135,136] When a polyp is pedunculated, it is benign in most cases; alternatively, sessile "polyps" are more often malignant (**Fig. 63.10**). Inflammatory polyps result from chronic inflammation and extend by a narrow vascularized stalk into the gallbladder lumen. None of these lesions are considered premalignant, although isolated cases of cholesterolosis associated with in situ carcinoma have been reported.[137]

Figure 63.10 T2-weighted magnetic resonance imaging scan showing a sessile polyp within the gallbladder (*arrow*) that was malignant on histologic examination.

Adenomas

Gallbladder adenomas are found infrequently. They may be tubular or papillary, both arising from the epithelial layer of the gallbladder. Multiple papillary adenomas, or papillomas, are called *papillomatosis*. A direct association between benign adenoma, adenoma containing carcinoma in situ, and invasive carcinoma has been demonstrated; thus these lesions are considered premalignant.[138] Malignant transformation, however, has only rarely been reported, primarily from large adenomas. In one series, all benign adenomas were less than 12 mm in diameter, whereas the adenomas with cancerous foci were greater than 12 mm.[137]

Adenomyomatosis

Adenomyomatosis of the gallbladder is characterized by localized or diffuse hyperplastic extensions of the mucosa into, and often beyond, a hypertrophied gallbladder muscular layer. Hyperplasia occurs at outpouchings of the

mucosa of the gallbladder through the wall (Rokitansky–Aschoff sinuses) and through the crypts of Luschka. This can result in focal thickening of the gallbladder wall, resembling gallbladder adenocarcinoma. The etiology is unknown. This lesion may be premalignant, because cases of adenocarcinoma arising in or near adenomyomatosis have been reported, but this relationship is unclear.[129,139,140]

Other Benign Gallbladder Tumors

Other benign lesions include tumors arising from the tissue of the gallbladder wall, such as leiomyomas, lipomas, hemangiomas, granular cell tumors, and heterotopic tissue, including gastric, pancreatic, or intestinal epithelium.

Clinical Findings

Patients with benign gallbladder tumors typically present with symptoms consistent with choledocholithiasis, including right upper quadrant pain, fatty food intolerance, and nausea. Many benign gallbladder lesions are also discovered incidentally after elective cholecystectomy. Therefore, symptoms caused by benign lesions are difficult to separate from those caused by gallstones. Most lesions, however, are asymptomatic and are discovered incidentally during imaging for other abdominal conditions.

Diagnosis

Diagnosis of benign gallbladder polyps is usually made when an ultrasound study is obtained to evaluate a patient for symptoms consistent with gallstones. On ultrasound, a filling defect that does not change with position is likely a polyp or carcinoma and not a gallstone. Cholesterol polyps are typically small, submucosal, multiple, and hyperechoic on ultrasound because of their high cholesterol content. Other than this typical appearance and the fact that malignant polyps are usually more than 1 cm in size, it is difficult to differentiate benign from malignant polyps.

Both intravenous contrast-enhanced and unenhanced CT may be important in distinguishing benign from malignant polyps. In a recent series examining 31 polypoid lesions of the gallbladder, contrast-enhanced CT detected all of

the lesions. Benign polyps were not visualized with unenhanced CT, unlike neoplastic tumors, thus improving the ability to distinguish these lesions when both enhanced and unenhanced CT scans were obtained.[9] Endoscopic ultrasound has also been used to image these lesions, and may be more accurate than transabdominal ultrasound in differentiating benign from malignant tumors.[22]

Treatment

Large polyps, greater than 10 mm, have the greatest malignant potential.[9,135,136] Without the evidence of invasion or metastatic disease, however, no radiologic test can reliably differentiate benign from malignant lesions. Therefore, if large (>1 cm) polyps are present, even in asymptomatic patients without stones, cholecystectomy is warranted.[141] Additionally, resection is recommended for smaller pedunculated lesions with evidence of a vascularized stalk. Small pedunculated lesions with the gross characteristics of a benign cholesterol polyp may be observed and resected only if symptomatic. Although these lesions have routinely been followed with ultrasound, a recent prospective study suggested that polyps smaller than 1 cm do not progress to carcinoma.[142] Cholecystectomy, however, is still considered the standard of care if there is any increase in size.

BENIGN BILE DUCT NEOPLASMS

Incidence

Benign bile duct tumors, at times clinically resembling hilar cholangiocarcinoma, are less common, occurring in less than 1% of patients.[4]

Pathology

Attesting to the rarity of these lesions, only two cases of benign extrahepatic bile duct disease occurred in 4,200 biliary tract operations in one institution.[143] The most common benign tumors of the extrahepatic biliary tree arise from the glandular epithelium lining the ducts; about two-thirds of benign tumors are polyps, adenomatous papilloma, or bile duct adenomas.

Most are found in the periampullary region, but they can be distributed throughout the entire biliary tree (**Fig. 63.11**). Multiple papillomas also have been reported throughout the intrahepatic and extrahepatic biliary tree, termed *multiple biliary papillomatosis.* Although local recurrence and progression to death from obstructive jaundice and cholangitis occur frequently in these rare cases, these tumors have little, if any, malignant potential. Other benign tumors (e.g., cystadenoma, granular cell myoblastoma, leiomyoma, heterotopic tissue) have also been reported.

One condition that deserves consideration is the case of "malignant masquerade," an inflammatory, fibrotic lesion clinically resembling hilar cholangiocarcinoma, but pathologically consisting only of extensive fibrosis and inflammatory cells without evidence of dysplasia or preneoplastic change.[144–146] In patients being considered for palliative treatment alone with presumed hilar cholangiocarcinoma, it is essential to obtain a tissue diagnosis. It is inappropriate to treat benign lesions by percutaneous stenting because of the excellent outcome after resection of these lesions.

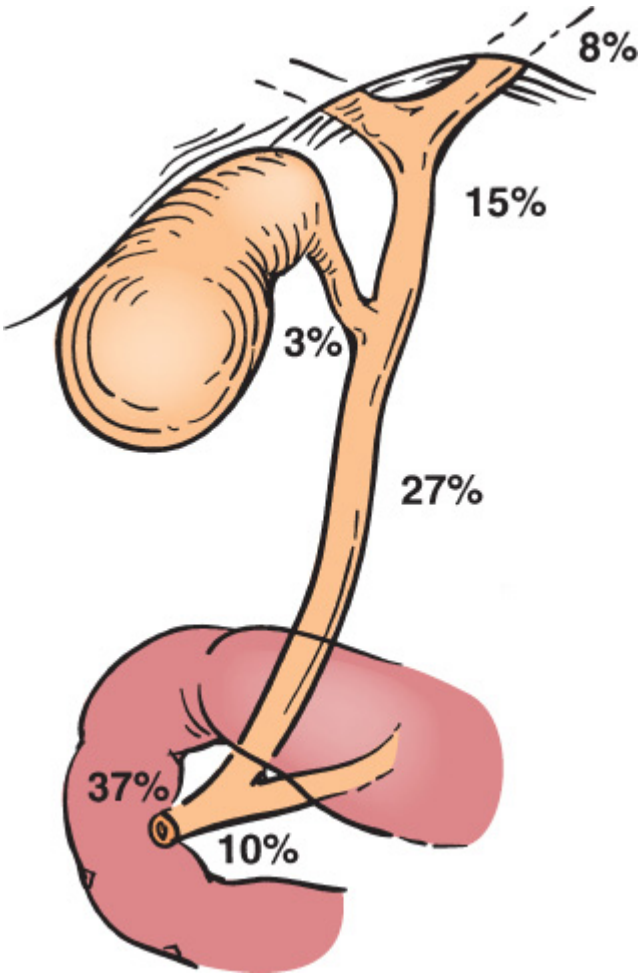

Figure 63.11 Distribution of papillomas and adenomas of the biliary tree. The ampulla and common bile duct are the most frequent sites.

Clinical Findings

Biliary obstruction, with resultant jaundice or cholangitis, is frequently the presenting symptom in patients with benign bile duct tumors. Symptoms may also include epigastric pain or nausea. Because these tumors are indolent, symptoms may be intermittent or gradually progressive.

Diagnosis

Because of the presence of jaundice, benign bile duct tumors are usually initially evaluated with ultrasound. Many patients then undergo ERCP or PTC and CT scan. A diagnosis of malignant masquerade should be suspected

in patients with mass lesions that resemble hilar cholangiocarcinomas, but without lobar atrophy or portal vein involvement.

Treatment

Resection and reconstruction are performed to relieve jaundice and cholangitis. The preferred reconstruction is a Roux-en-Y choledochojejunostomy to decrease the risk of postoperative biliary stricture or recurrent cholangitis.

Section I: COLON AND RECTUM

64

Anatomy and Physiology of the Colon, Rectum, and Anus

Elise H. Lawson and Elizabeth C. Wick

Key Points

1. The mesorectum is invested by the fascia propria of the rectum.
2. The ileocolic branch of the superior mesenteric artery supplies the right colon and the proximal transverse colon.
3. The inferior mesenteric artery supplies the distal transverse colon, sigmoid colon, and rectum.
4. The inguinal lymph nodes drain the lymphatics from the anal canal below the dentate line.
5. The colon has 10^{13} bacteria, which promote mucosal immunity, help digest complex nutrients, and protect against pathogenic organisms.
6. Alterations in the colonic flora have been associated with inflammatory bowel disease and colorectal cancer.

INTRODUCTION

While the complex coordination of stool through the colon, rectum, and anus is the main function of the colon, it also plays a role in the complex digestion and absorption of carbohydrate and protein residue, creates a balanced environment for bacteria, and lubricates stool for transit. Understanding the anatomy and physiology of the colon, rectum, and anus is important to treating the pathology associated with it.

EMBRYOLOGY

Knowledge of embryologic origins is helpful for understanding gastrointestinal function as well as pathophysiology. In addition, it is useful to remember when mobilizing the colon in order to identify appropriate planes of dissection and prevent injury to retroperitoneal structures. The primitive gut is derived from endoderm and is divided into three segments (foregut, midgut, and hindgut) by the third week of gestation. The small intestine distal to the ampulla of Vater and the colon proximal to the splenic flexure are formed from the midgut, while the remaining colon (distal to the splenic flexure), rectum, and anal canal (proximal to the dentate line) are formed from the hindgut. This has implications for arterial blood supply, as structures formed by the midgut are supplied by the superior mesenteric artery, while structures formed by the hindgut are supplied by the inferior mesenteric artery.

The midgut undergoes a three-stage process of rotation and fixation starting in the sixth week of gestation. In the first stage, the midgut elongates over the superior mesenteric artery, herniates out of the abdominal cavity through the umbilical cord, and then rotates 90 degrees in a counterclockwise direction. In the second stage, which starts in the tenth week of gestation, the midgut returns to the abdominal cavity while continuing to rotate an additional 180 degrees counterclockwise around the superior mesenteric artery. This results in the colon lying anterior to the duodenum. In the third stage, the cecum migrates inferiorly to the right lower quadrant, and then fixation of the ascending and descending colon begins. Major anomalies of rotation typically occur during the second stage, and include nonrotation, malrotation, reversed rotation, omphalocele, and internal hernia.

The terminal end of the hindgut is termed the cloaca. During development, the intestinal and urogenital tracts are joined at the cloaca until the urorectal septum migrates caudally, dividing the cloaca into the urogenital plate anteriorly and the anal plate posteriorly. The dentate line represents the fusion plane of the endodermal and ectodermal tubes, with the anal transition zone referring to the cloacal part of the anal canal which includes both endodermal and ectodermal components.

GROSS ANATOMY

The colon is a tubular organ measuring on average 150 cm, though overall length is highly variable. Typically, the colonic diameter decreases over its course, with the cecum measuring about 7.5 to 8.5 cm and the distal sigmoid colon about 2.5 cm. As described above, the ascending and descending colon are fixed to the lateral peritoneal wall, with the posterior aspects fused to the retroperitoneum. In contrast, the transverse and sigmoid colon are intraperitoneal strictures that are fixated only at their proximal and distal aspects.

The colon is distinguished from the rest of the gastrointestinal tract by three unique anatomic features: taeniae coli, haustra, and appendices epiploicae (**Fig. 64.1**). The three taeniae coli are continuous condensations of the outer longitudinal muscle layer of the colon and are named according to their attachments: taenia mesocolica (posteromedial, attached to the mesocolon), taenia omentalis (posterolateral, attached to the greater omentum), taenia libera (anterior, no attachments). The three taeniae originate at the base of the appendix, course along the length of the colon, and then converge at the rectosigmoid junction, marking the anatomic beginning of the rectum. They are one-sixth shorter than the rest of the bowel wall, resulting in outpouchings between the taenia called sacculations or haustra, which are separated by the plicae semilunares. Finally, the appendices epiploicae are antimesenteric fat appendages that protrude from the colonic serosa and vary in size.

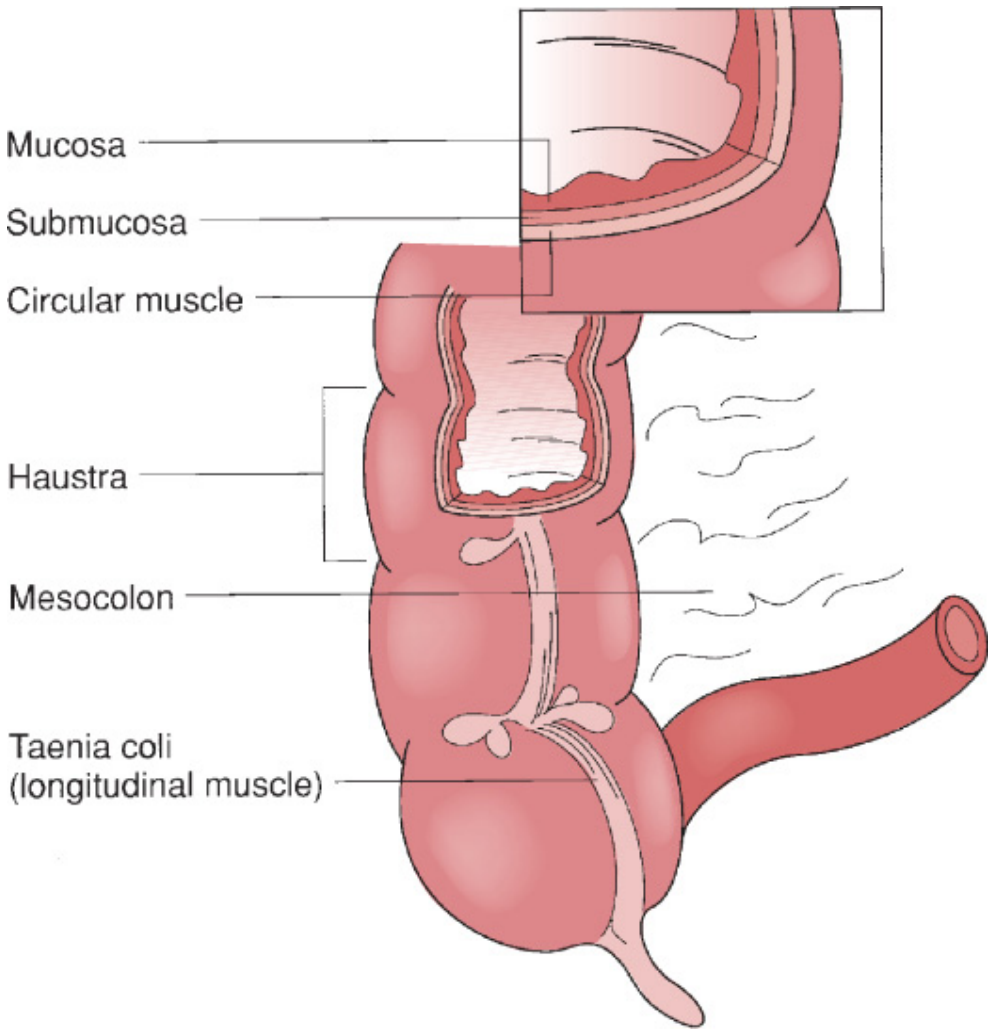

Figure 64.1 Layers of the colonic wall.

The colon begins in the right lower quadrant with the cecum. The cecum extends approximately 6 to 8 cm below the ileocecal valve, which is located at posteromedial aspect of the cecum (**Fig. 64.2**). The ileocecal valve is formed by angulation between the ileum and cecum via the superior and inferior ileocecal ligaments and prevents reflux of stool back into the ileum.[2] The cecum is the widest portion of the colon, has the thinnest wall, and is entirely enveloped by peritoneum.

The origin of the appendix can be identified by following the converging taeniae at the most proximal portion of the cecum. In the vast majority of people (85% to 95%), the appendix lies posterior to the cecum, lateral and in line to the terminal ileum. Other variants in position include retrocecal (toward the psoas muscle), pelvic, and retroileal.[3] Visualization and

documentation of the appendiceal orifice and ileocecal valve is important for ensuring complete colonic examination during colonoscopy.

From the cecum, the right colon ascends approximately 15 cm to the hepatic flexure, which is anterior to the inferior pole of the right kidney and overlies the second portion of the duodenum. When the right colon and mesentery are mobilized during a colectomy, care must be taken to visualize and avoid injury to the underlying duodenum and right ureter. Only the anterior surface of the right colon is invested with peritoneum; laterally, the white line of Toldt marks the extent of the peritoneal covering and serves as an important landmark during surgical mobilization of the colon.

The transverse colon stretches from the hepatic flexure to the splenic flexure and is the longest segment of colon (between 30 and 60 cm). The transverse colon is suspended by the transverse mesocolon and is completely intraperitoneal. It is the most mobile portion of the colon and may descend to the level of the iliac crests or deep into the pelvis. The greater omentum descends from the greater curve of the stomach in front of the transverse colon and then ascends to attach to the transverse colon on its anterosuperior edge. To mobilize the transverse colon or enter the lesser sac, the fusion plane of the omentum to the transverse colon must be dissected.

The splenic flexure is situated high in the left upper quadrant, more cephalad than the hepatic flexure, and abuts the lower pole of the spleen. There are attachments from the colon to the diaphragm at the level of the 10th and 11th ribs and spleen (phrenocolic and splenocolic ligaments), and these must be carefully divided during mobilization of the flexure to avoid splenic injury.

The descending colon is approximately 25 cm long and courses from the splenic flexure to its junction with the sigmoid colon at the pelvic brim. It lies anterior to the left kidney and, like the right colon, the anterior, lateral, and medial portions of the descending colon are covered by peritoneum.

The sigmoid colon extends from the pelvic brim to the sacral promontory, where it continues as the rectum and generally measures 15 to 50 cm in length. It is completely invested by peritoneum. The sigmoid colon is extremely mobile and has a generous mesentery that extends along the pelvic brim from the iliac fossa across the sacroiliac joint to the second or third sacral segment. Because of its mobile mesentery, the sigmoid colon can twist, forming a volvulus which causes obstruction. The left ureter runs in the

intersigmoid fossa, which is at the base of the mesosigmoid. When a high ligation of the inferior mesenteric artery is performed during a cancer operation or the sigmoid colon is being mobilized along the white line of Toldt, the left ureter should be identified to avoid inadvertent injury. Preoperative placement of urinary stents can be useful for locating the ureter intraoperatively in complex, reoperative pelvic surgery.

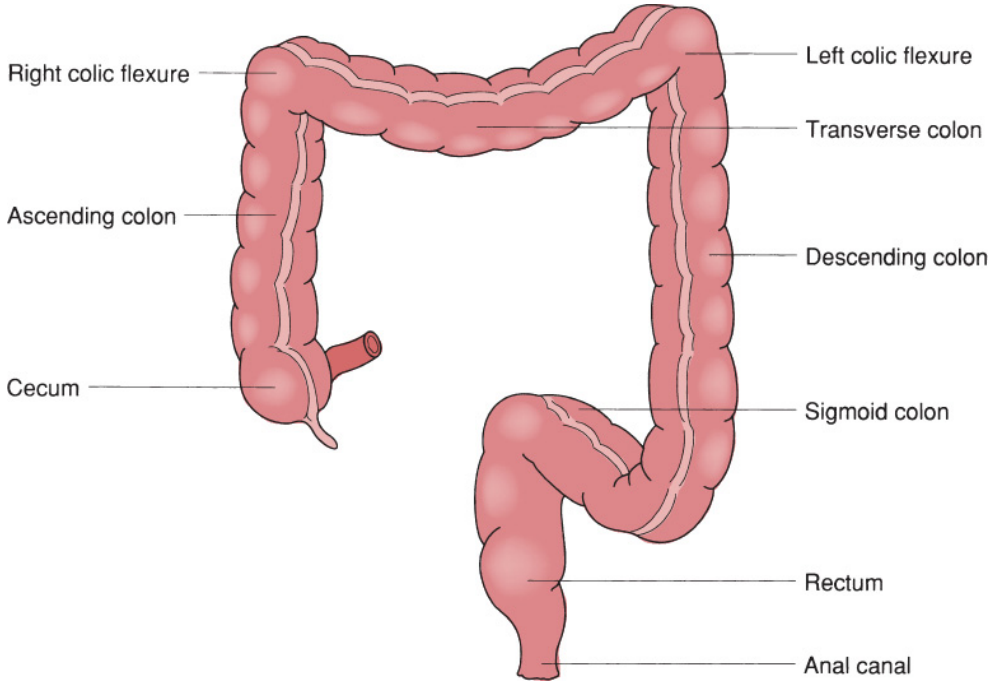

Figure 64.2 General anatomic components of the colon.

At the sacral promontory, the colon becomes the rectum. The rectosigmoid junction is marked by the convergence of the colonic taenia. The outer layer of the rectal wall is composed of the longitudinal muscle, where the three teniae splay. The rectum measures 12 to 15 cm in length. It proceeds posterior and caudal along the curvature of the sacrum and coccyx, passing through the levator ani muscles, at which point it turns abruptly caudal and posteriorly at the anorectal ring, becoming the anal canal. Anterior to the rectum are the uterine cervix and posterior vaginal wall in women, and the bladder and prostate in men. Posteriorly, the rectum occupies the sacral concavity where the median sacral vessels, presacral veins, and sacral nerves run, all of which are invested in the presacral fascia. The rectum is marked by three curves. The upper and lower curves are convex and to the

right, while the middle is convex and to the left. Within the lumen, these correspond to the valves of Houston, which separate the lower third, middle third, and upper third of the rectum—important landmarks when the location of a rectal abnormality is established endoscopically (the lower rectal valve is at 7 to 8 cm from the anal verge, middle rectal valve at 9 to 11 cm, and upper rectal valve at 12 to 13 cm).[4] The valves do not contain all layers of the bowel wall and thus biopsy at this location carries minimal risk of perforation. The middle valve of Houston is the internal landmark corresponding to the anterior peritoneal reflection. The anterior and lateral surfaces of the upper third of the rectum are intraperitoneal, whereas only the anterior surface of the middle third of the rectum is intraperitoneal in location. The lower third of the rectum is entirely extraperitoneal. The mesorectum is 1 the term used to describe the areolar tissue surrounding the rectum that contains nerves, lymphatics, and terminal branches of the superior hemorrhoidal branch of the inferior mesenteric artery. Although it invests the rectum circumferentially, the mesorectum is most prominent posterior to the rectum. It is invested by the fascia propria of the rectum, a continuation of the parietal endopelvic fascia (**Fig. 64.3**). The fascia propria (investing fascia) includes the distal two-thirds of the posterior rectum and the distal one-third of the anterior rectum, where it is no longer intraperitoneal. A total mesorectal excision entails removal of the entire rectum without violating the fascia propria of the rectum. This is accomplished by mobilizing the rectum using the plane between the fascia propria of the rectum and the presacral fascia. Anterior to the investing fascia (fascia propria) is a delicate layer of connective tissue known as Denonvilliers fascia, which separates the rectum from its anterior structures. Waldeyer fascia (rectosacral fascia) is the presacral fascia that is an extension of the parietal pelvic fascia from the periosteum of sacral segment four to the posterior wall of the rectum. It contains branches of the sacral splanchnic nerves. Below Waldeyer fascia is the supralevator or retrorectal space.

The surgical anal canal begins at the anorectal ring or levator ani muscles and extends to the anal verge. It measures 2 to 4 cm and is usually longer in men than in women. The internal anal sphincter (continuation of the circular smooth muscle of the rectum) and the external anal sphincter (continuation of the puborectalis muscle) encircle the anal canal and control fecal continence.

The internal anal sphincter relies on autonomic innervation, while the external anal sphincter uses somatic innervation. The median length and thickness of the female anterior external sphincter are 11 and 13 mm and thus a small tear sustained during vaginal delivery may cause fecal incontinence.[5] There are three layers of the external sphincter—subcutaneous (traversed by the conjoined longitudinal muscle with some fiber attachments to the skin), superficial (connective tissue attaches posteriorly, forming the anococcygeal ligament), and deep (continues with the puborectalis muscle). Between the internal and external anal sphincters, the longitudinal muscle of the rectum joins fibers of the levator ani and puborectalis muscles to form the conjoined longitudinal muscle.

The dentate line marks the transition between the columnar epithelium of the intestine and the squamous epithelium of the anal canal. The transition between these two epithelia is called the anal transitional zone. The Columns of Morgagni are the 6 to 14 longitudinal folds located at the dentate line. Small pockets between these columns called anal crypts contain glands, which may become obstructed with foreign material to cause an infection. Below the dentate line is the anoderm, which extends to the anal verge and does not contain accessory skin structures, such as hair, sebaceous and sweat glands. The autonomic nervous system innervates proximal to the dentate line and the somatic nervous system supplies the anoderm and distally.

Pelvic Floor

The perineal body is the tendinous insertion of the external anal sphincter, bulbocavernosus, and superficial and deep transverse perineal muscles. It supports the perineum and separates the vagina from the anus. Three striated muscles that attach to the pubic bone make up the pelvic floor or levator ani muscles: iliococcygeus, pubococcygeus, and puborectalis. The pelvic floor muscles are supplied by branches from the third sacral nerve, while the external anal sphincter is supplied by nerve fibers traveling with the pudendal nerve on the levator's undersurface.

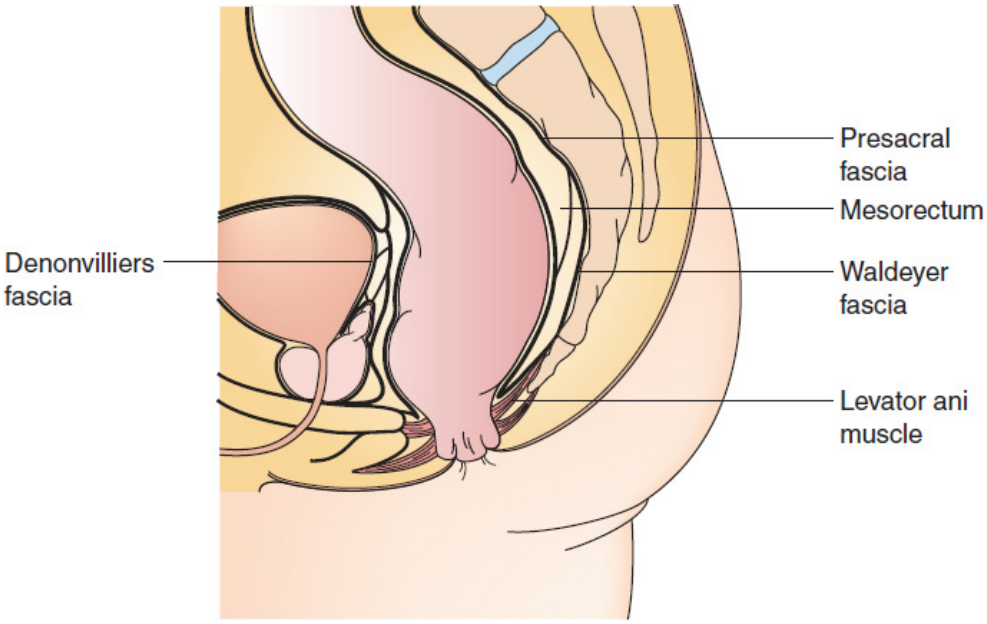

Figure 64.3 Fascial relationships of the pelvis.

The puborectalis originates from the back of the symphysis pubis and forms a U-shaped sling as it joins the opposite muscle posteriorly. The iliococcygeus muscle arises from the ischial spine and posterior part of the obturator fascia and travels inferiorly, posteriorly, and medially to insert into the last two segments for the sacrum and coccyx. The pubococcygeus muscle arises from the anterior half of the obturator fascia and the posterior pubis. Its fibers are directed backward, downward, and medially, where they decussate with fibers of the opposite side. The decussation is called the anococcygeal raphe.

Anorectal Spaces

The perianal space surrounds the anal canal superficially and contains the external hemorrhoidal plexus. The ischioanal space extends laterally and goes superiorly to the levator ani from the skin on the perineum. The levator ani and external sphincter muscles form the medial boundary, while the lateral wall is formed by the obturator fascia. The superficial postanal space connects the perianal spaces with each other posteriorly below the anococcygeal ligament, while the deep postanal space lies above the anococcygeal ligament. The ischioanal and perianal spaces make the ischioanal fossa. The deep postanal and ischiorectal spaces form a horseshoe

configuration that may be involved in a horseshoe abscess. Below the perianal space between the sphincter muscles is the intersphincteric space. The submucosal space contains the internal hemorrhoidal plexus and lies between the internal anal sphincter and the mucosa distal to the dentate line. Proximally, it becomes the submucosa of the rectum. Above the levator complex is the supralevator space, which extends superiorly to the peritoneum at the rectosacral fascia. The retrorectal space extends above the rectosacral fascia and lies between the upper two-thirds of the rectum and sacrum.

Arterial Blood Supply

The arterial blood supply to the colon, rectum, and anus is highly variable. The superior mesenteric artery typically arises from the aorta, runs posterior to the pancreas, and passes anterior to the third portion of the duodenum (**Fig. 64.4**). In addition to supplying the small bowel 2 through jejunal and ileal branches, the superior mesenteric artery gives rise to the ileocolic, right colic, and middle colic branches that supply the cecum, ascending colon, and proximal transverse colon. The right colic arterial anatomy is particularly variable and can be absent or arise from the ileocolic or the superior mesenteric artery. The middle colic artery has a right branch that supplies the hepatic flexure and the right portion of the transverse colon, while the left branch supplies the left 3 portion of the transverse colon. The inferior mesenteric artery arises from the anterior surface of the aorta, typically 3 to 4 cm above the aortic bifurcation, and supplies the distal transverse colon, descending colon, sigmoid colon, and upper rectum. The inferior mesenteric artery gives rise to the left colic artery and sigmoidal branches, then continues in the sigmoid mesentery, and after crossing the left iliac vessels, is renamed the superior rectal/hemorrhoidal artery. The inferior mesenteric artery may also function as an important collateral vessel to the lower extremities during instances of distal aortic occlusion. The superior hemorrhoidal artery descends behind the rectum and splits into right and left branches in the mesorectum. It is the main blood supply of the rectum. The middle and inferior rectal/hemorrhoidal arteries arise from either the internal pudendal arteries or the hypogastric arteries and supply the distal two-thirds

of the rectum. The presence of the middle rectal artery, in particular, can be variable.

Venous Drainage

The veins that drain the large intestine bear the same terminology and follow a course similar to that of their corresponding arteries (**Fig. 64.5**). The veins from the right colon and transverse colon, along with the veins draining the small intestine, drain into the superior mesenteric vein. The superior mesenteric vein runs slightly anterior to and to the right of the superior mesenteric artery. The superior mesenteric vein courses beneath the neck of the pancreas, where it joins with the splenic vein to form the portal vein. The inferior mesenteric vein is a continuation of the superior rectal vein and drains blood from the left colon, sigmoid colon, rectum, and superior anal canal. The inferior mesenteric vein follows a course of its own, starting at the left colic artery, and ascends over the psoas muscle in a retroperitoneal plane. The vein courses under the body of the pancreas to drain into the splenic vein. During an anterior resection of the rectum, division of the inferior mesenteric vein at the inferior border of the pancreas can provide additional mobility of the left colon to facilitate a coloanal anastomosis. The superior hemorrhoidal (rectal) veins drain blood from the rectum and upper part of the anal canal, where the internal hemorrhoidal plexus is situated, into the portal system via the inferior mesenteric vein. The middle hemorrhoidal (rectal) veins drain the lower part of the rectum and upper part of the anal canal into the systemic circulation via the internal iliac veins. The inferior hemorrhoidal (rectal) veins drain blood from the lower rectum and anal canal, where the external hemorrhoidal plexus is located, via the internal pudendal veins into the systemic venous circulation via the internal iliac veins. In the setting of portal hypertension, the superior, middle, and inferior hemorrhoidal veins interact to shunt venous blood from the portal system into the systemic circulation.

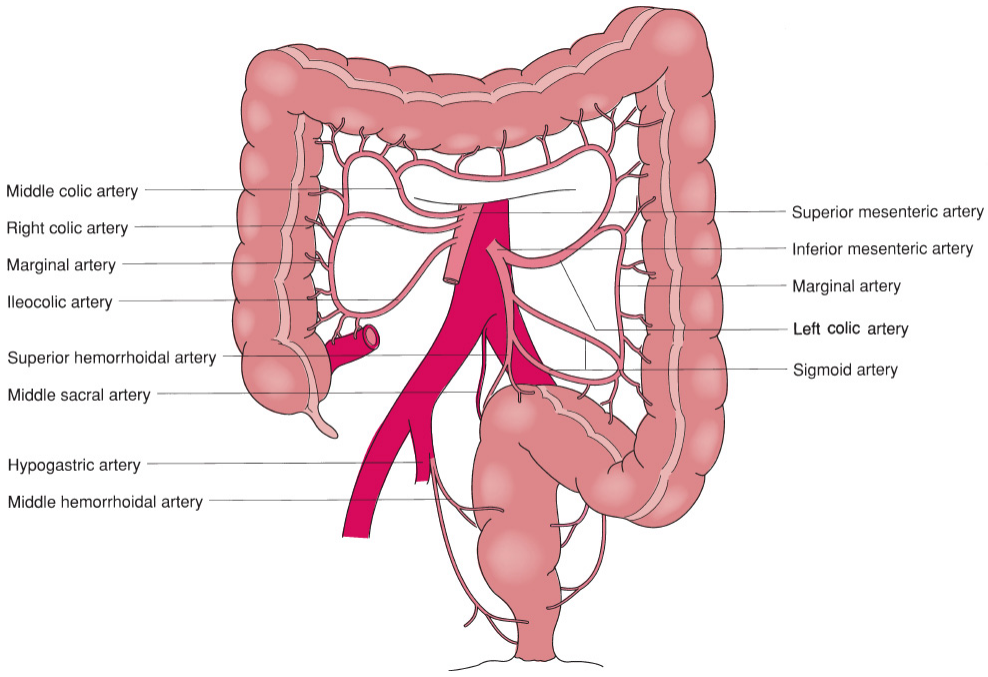

Figure 64.4 Arterial blood supply of the colon.

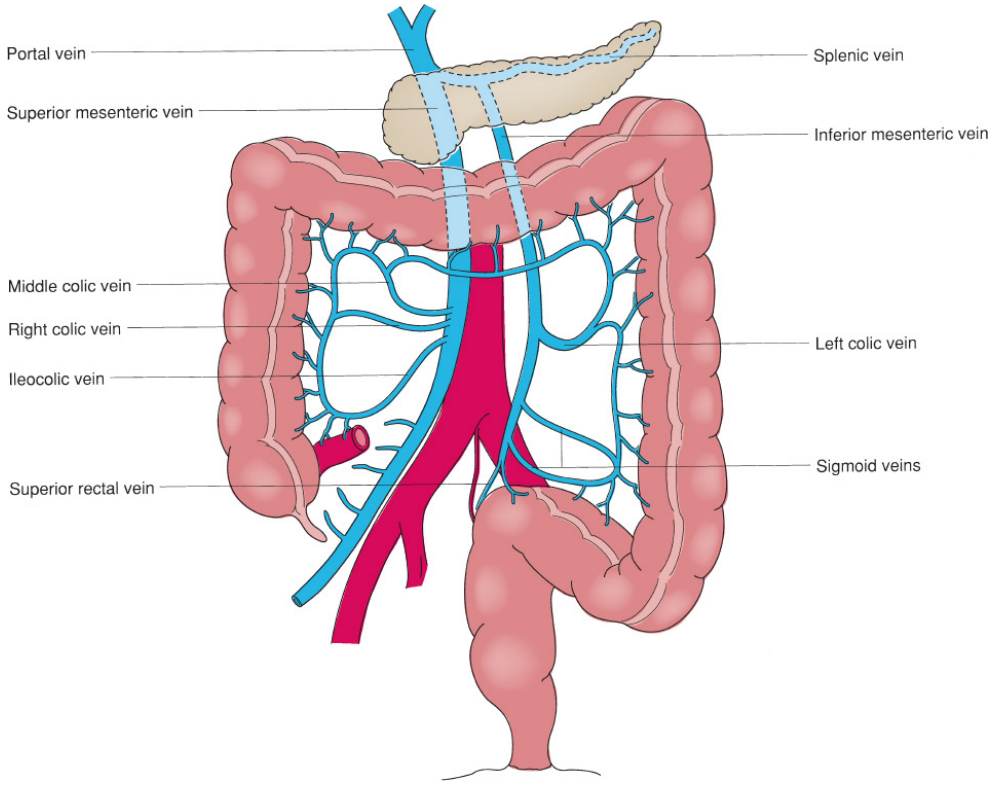

Figure 64.5 Venous drainage of the colon by the portal vein.

Lymphatic Drainage

4 Lymphatic drainage generally follows the arterial blood supply of the colon and rectum. As such, performing a high ligation of the feeding artery during oncologic segmental colon resection should ensure adequate lymph node harvest. In the anal canal, lesions above the dentate line drain into the inferior mesenteric lymph nodes while lesions below the dentate line drain into both the internal iliac lymph nodes and the inferior mesenteric lymph nodes.

Neural Components

The colon possesses extrinsic and intrinsic (enteric) neuronal systems. The extrinsic system consists of sympathetic and parasympathetic nerves that inhibit or stimulate colonic peristalsis, respectively. The sympathetic innervation to the right colon originates from the lower thoracic segments of the spinal cord and travels in the thoracic splanchnic nerves to the celiac and superior mesenteric plexuses. Postganglionic fibers emerge from here and course along the superior mesenteric artery and its branches to the right side of the colon. The parasympathetic nerves originate from the right vagus nerve and travel along with the sympathetic nerves to the right side of the colon. The left side of the colon and the rectum receive sympathetic fibers that arise from L1 through L3 segments of the spinal cord. This passes through the ganglionated sympathetic chains and leaves as a lumbar sympathetic nerve to join the preaortic plexus. It extends along the inferior mesenteric artery as the mesenteric plexus and then becomes the presacral nerve or superior hypogastric plexus. These hypogastric nerves are identified at the sacral promontory 1 cm lateral to the midline. The key zones of sympathetic nerve damage are during ligation of the inferior mesenteric artery and during initial posterior rectal mobilization adjacent to the hypogastric nerves. The parasympathetic supply to the left side of the colon and the rectum comes from S2 through S4 spinal cord segments. The sacral nerve fibers become the nervi erigentes, which join the pelvic plexus at the pelvic side walls. To prevent injury during full mobilization of the rectum, the lateral ligament should be cut close to the rectal side wall. Both the sympathetic and parasympathetic nervous systems play a role in erection, in that damage to

the parasympathetics can lead to erectile dysfunction, while retrograde ejaculation can occur with damage to sympathetic nerve injury.

The intrinsic, or enteric, nervous system consists of two groups of plexuses that are identified by their location within the colon wall. This system can function independently of the central nervous system and controls motility as well as exocrine and endocrine functions of the gut, and is involved in intestinal immune regulation and inflammatory responses. The Meissner plexus is located in the submucosa between the muscularis mucosae and the circular muscle of the muscularis propria and is important in secretory control. The myenteric plexus, also known as the *Auerbach plexus,* is located between the inner circular muscle and outer longitudinal muscle layers of the colon and primarily controls intestinal motility.[4]

The internal anal sphincter is supplied by the sympathetic and parasympathetic nerves that supply the lower rectum. The parasympathetic nerves are inhibitory. The external sphincter is supplied by the inferior rectal branch of the internal pudendal nerve and the perineal branch of S4. Sensation of the anal canal is from the inferior rectal nerve, which is a branch of the pudendal nerve.

PHYSIOLOGY

Nutrient digestion and absorption primarily occurs in the small bowel. The primary function of the colon is to absorb water, electrolytes (sodium and chloride), undigested starches and bile salts. The physiologic control of colonic water and electrolyte transport requires careful integration of neural, endocrine, and paracrine components. Although colonic epithelium does not actively absorb glucose or amino acids as the small-intestinal epithelium does, the colon does absorb short-chain fatty acids and vitamins that are produced by bacterial breakdown of nonabsorbed carbohydrates and amino acids. These short-chain fatty acids, which include acetate, butyrate, and propionate, are absorbed in a concentration-dependent fashion. They are a major energy substrate for colonic epithelial cells and represent the major fecal anions.[6]

Approximately 1,500 mL of ileal effluent reaches the cecum in a 24-hour period, 90% of which is reabsorbed in the colon. The colon has a

tremendous capacity that allows it to absorb as much as 5 to 6 L of water within a 24-hour period. When colonic capacity is exceeded, diarrhea results.[7] Normally formed feces consists of 70% water and 30% solid material. Almost half of the solid material is made up of bacteria and the other half is composed of undigested food material and desquamated epithelium. Water absorption in the colon is a passive process that depends primarily on the osmotic gradient established by the active transport of sodium across the colonic epithelium. The composition of ileal effluent and luminal flow rates also plays an important role in water absorption. Upsetting the balance of these three factors results in diarrhea. The absorptive capacity is not the same throughout each segment of the colon. Salt and water absorption is greatest in the right colon. Patients undergoing a right hemicolectomy should therefore be counseled preoperatively that they may experience loose bowel movements in the early postoperative period. Patients should also be reassured that this will resolve with time as the remaining colon adapts.

Colonic Flora

The bacterial flora of the colon is established soon after birth and is largely dependent on dietary and environmental factors. 5 The colon is populated by approximately 10^{13} commensal bacteria.[10] The vast majority of the normal colonic flora consists of anaerobic bacteria, with *Bacteroides* species being most prevalent, particularly *Bacteroides fragilis*.[11] Aerobic colonic bacteria are mainly coliforms and enterococci, with *Escherichia coli* being the most predominant coliform. The colonic flora is important for (a) digestion and absorption of complex macromolecules, (b) protecting the colon against invasion by noncommensal bacteria, and (c) development of mucosal immunity. Fermentation of carbohydrates generates short-chain fatty acids, including acetic acid, propionic acid, and butyrate, which is the primary nutrient for the colonic mucosa. Colonic bacteria also produce certain vitamins, such as vitamins K and B_{12}, which are absorbed by the host. The enterohepatic circulation of bilirubin and bile acids depends on bacterial enzymes produced by fecal flora. The degradation of bile pigments by colonic bacteria gives stool its characteristic brown color. Colonic bacteria

also play an important role in preventing infection by controlling the growth of potentially pathogenic bacteria such as *Clostridium difficile*.

Host and colonic flora have a mutualistic relationship; however, disturbances of this coexistence can lead to human disease.[12] [6] Changes in diet and use of antibiotics can dramatically alter the microbiome. Dysregulation of the flora has been implicated in the pathogenesis of inflammatory bowel disease, obesity and, to a lesser extent, colorectal cancer. Increasingly, dysregulation has also been linked to nongastrointestinal diseases including autism and other neurologic conditions. In animal studies, mice with certain immune deficiencies that make them prone to colitis fail to develop colitis when raised under germ-free conditions. Analysis of the microbiota of patients with inflammatory bowel disease revealed markedly different flora compositions in ulcerative colitis, Crohn disease, and healthy control patients. Similarly, certain genetically altered mice with a propensity to develop colorectal cancer fail to develop tumors in germ-free conditions. Although studies of human flora and colorectal cancer are limited, preliminary studies have raised interest in modulating the colonic flora as a way to treat and/or prevent colitis and other diseases of the colon.

Colonic Motility

Motor activity varies greatly throughout the colon. There are two patterns of colonic motility: segmental contractions, which are single or clustered contractions, and propagated activity, which is either high-amplitude (>100 mm Hg) propagated contractions (HAPCs) or low-amplitude (<60 mm Hg) propagated contractions (LAPCs). *Segmental contractions* are intermittent contractions of the longitudinal and circular muscles that result in the segmented appearance of the colon.[13] These contractions propel luminal contents in a back-and-forth pattern over short distances, slowing aboral transit and allowing for water reabsorption.[14] *Propagated activity* consists of strong, propulsive contractions of the smooth muscle that involve a long segment of colon.[15] The LAPCs move luminal contents forward at a rate of 0.5 to 1.0 cm/s and typically last for 20 to 30 seconds.[13] HAPCs occur three to four times per day, primarily after awakening, exercise, and after meals.

The orderly progression of colonic luminal contents from cecum to anus requires the coordination of smooth muscle contractions. Calcium-dependent

cyclic depolarization and repolarization of the colonic smooth muscle cell membrane generates a basic electrical pattern of slow-wave activity. This activity allows each smooth muscle cell to control its own contraction and to couple with adjacent smooth muscle cells.[16] The extrinsic (autonomic) and intrinsic (enteric) neuronal systems also interact to influence colonic motility.

Defecation

When fecal matter enters the rectum, the internal anal sphincter relaxes (rectoanal inhibitory reflex, or RAIR), while the external anal sphincter contracts to maintain continence. Distention of the rectum in this setting is the primary stimulus for defecation to begin. At this point, the urge to defecate may be suppressed by conscious contraction of the external anal sphincter. Receptive relaxation of the rectal ampulla accommodates the fecal mass and the urge to defecate passes unless the volume of feces is extremely large or the sphincter mechanism is impaired. If the subject voluntarily accedes to the urge to defecate, a Valsalva maneuver occurs, which increases the intra-abdominal pressure to overcome the resistance of the external anal sphincter. Relaxation of the pelvic muscles causes the pelvic floor to descend and the anorectal angle to straighten. Conscious inhibition of the external anal sphincter then allows passage of the feces. On completion, the pelvic floor returns to its resting position and the anal sphincter muscles return to their resting activity, closing the anal canal. Under normal circumstances, this process occurs once every 24 hours; however, the interval between bowel movements may vary between 8 and 12 hours and 2 to 3 days in normal subjects.

Anal Continence

There are varying degrees of anal continence, with a spectrum from complete control to complete lack of control. Maintaining continence is complex, as both voluntary and involuntary mechanisms play a role in anal continence. The most important mechanisms involve the internal anal sphincter, which contributes 52% to 85% of the pressure generated to maintain continence.[17,18] The remaining anal basal pressure is comprised of the external anal sphincter (30%) and the hemorrhoidal cushions (15%). The internal sphincter is

supplied by dual extrinsic innervation: sympathetic outflow (S5) via the hypogastric nerve provides motor supply and parasympathetic outflow (S1–S3) provides inhibition. The external sphincter nerve supply is dependent on the pudendal nerve (S2–S4) and maintains tonic activity at rest. When stool enters the rectum, the contents of the rectum are sampled by sensors in the anal canal to determine whether the contents are solid, liquid, or gas. By discriminating between the consistency of the stool, the pelvic floor and sphincter muscles are able to coordinate a complex mechanism through angulation of the pelvic floor and contraction of the anal sphincter muscles. Other mechanisms contributing to continence include stool consistency and volume.

CONCLUSIONS

Understanding the basic principles of colorectal anatomy and physiology is an essential foundation for proficiency in colorectal surgery. Many of the colorectal diseases represent derangements in colorectal physiology such as colonic pseudo-obstruction, colonic inertia, pelvic floor dysfunction, or fecal incontinence. Furthermore, much of the foundation of optimal colorectal oncologic surgery is related to the anatomy of the colon and rectum.

Gastrointestinal Bleeding

Richard H. Turnage and Benjamin L. Davis

Key Points

1. Gastrointestinal (GI) bleeding is classified as upper, lower, or mid-GI bleeding based on the accessibility of the bleeding site to endoscopic imaging.
2. Esophagogastroduodenoscopy (EGD) is the initial diagnostic test of choice in almost all cases of upper GI bleeding.
3. Hemodynamically stable patients with hematochezia should undergo colonoscopy after resuscitation and bowel preparation.
4. As many as 15% of hemodynamically unstable patients presenting with hematochezia will be bleeding from an upper GI source.
5. About 70% of patients with overt GI bleeding in whom an EGD and colonoscopy failed to identify a site of hemorrhage will be bleeding from the small intestine.
6. Video capsule endoscopy is the diagnostic test of choice for hemodynamically stable patients suspected to be bleeding from the small intestine.
7. Endoscopic therapy significantly reduces the rate of recurrent bleeding and the need for urgent surgical intervention in patients with high-risk lesions, such as those that are actively bleeding or have a nonbleeding visible vessel.
8. Patients bleeding from lesions not amenable to endoscopic therapy or who fail endoscopic therapy are managed by angiographic embolization or surgery.

NOMENCLATURE

Bleeding from the gastrointestinal (GI) tract is classified as overt or occult based on the presence or absence of visible signs of blood loss. Patients with overt GI bleeding present with hematemesis (the vomiting of blood), melena (the passage of black tarry stools), and/or hematochezia (the passage of bright red blood). Patients with occult GI bleeding present with iron

deficiency anemia and/or a positive fecal occult blood test without signs of overt bleeding. This chapter focuses on the clinical features, evaluation, and management of patients with overt GI bleeding.

1 Traditionally, overt GI bleeding has been classified as upper or lower based on the location of the bleeding relative to the ligament of Treitz. Advances in endoscopic imaging of the small bowel and the distinct nature of small bowel bleeding have established a new model of nomenclature for GI bleeding that is based on accessibility of the bleeding site to endoscopic imaging. Bleeding proximal to the ampulla of Vater, and within reach of a standard esophagogastroduodenoscope (EGD), is termed upper GI bleeding. Bleeding from the colon, rectum, or anus and within reach of the colonoscope is defined as lower GI bleeding and bleeding between the ampulla of Vater and the ileocecal valve, visualized by video capsule endoscopy (VCE) and/or device-assisted enteroscopy (DAE), is defined as mid-GI (or small bowel) bleeding.[1,2] The term "obscure GI bleeding" is used to identify those instances in which no source of bleeding is found despite endoscopic examination of the entire GI tract.

About 40% to 60% of patients hospitalized with overt GI bleeding are bleeding from the upper GI tract, 5% to 10% are bleeding from the small bowel, and 25% to 32% are bleeding from the lower GI tract. The site of bleeding is unknown in 29% to 35% of patients.[2–4] The most common causes of overt GI bleeding and their relative frequencies are shown in Table 65.1.

EPIDEMIOLOGY

Bleeding is the most common indication for hospitalization for GI diseases in the United States. In 2014, GI bleeding caused more than 500,000 hospitalizations, 2.2 million days of hospitalization, $5 billion in direct costs, and nearly 11,000 deaths. Overall, the mortality rate for patients hospitalized with GI bleeding is about 2%, although the number varies widely based on the severity of bleeding and the patient's comorbidities.[3]

The incidence of upper GI bleeding in the United States is about 67 cases per 100,000 population.[5] Worldwide, the incidence varies from 48 to 160 cases per 100,000 population.[14] The incidence of upper GI bleeding has declined over the past 30 years.[5,15–17] For example, a study in the United

States documented a 21% reduction in the incidence of upper GI bleeding between 2002 and 2012[5]; changes attributed to decreased bleeding from peptic ulcer disease and gastritis.[4,15]

The incidence of lower GI bleeding (as traditionally defined) is about 33 cases per 100,000 population. The age- and sex-matched incidence of hospitalizations for lower GI bleeding decreased by 15% in the United States between 2001 and 2009.[4] In contrast, Lanas et al. reported an increased incidence of lower GI bleeding in Spain between 1996 and 2005.[16]

Although overt GI bleeding can occur at any age, it is particularly prevalent in the elderly. The median age of patients hospitalized for upper and lower GI bleeding is 67 and 74 years, respectively.[5,10] Upper GI bleeding is slightly more common in males (55%)[5,17] and lower GI bleeding is slightly more common in females (52%).[10]

CLINICAL PRESENTATION

A thorough medical history, physical examination, and basic laboratory tests provide important information regarding (1) the site and cause of bleeding, (2) risk factors for GI bleeding, and (3) the severity of bleeding. Clinical scenarios associated with various causes of GI bleeding are shown in Table 65.2.

Table 65.1 Causes of Overt Gastrointestinal Bleeding and Their Relative Frequencies

Cause	Relative Frequency (%)
Upper GI Bleeding[4–7]	
Peptic ulcer disease	27–68
Erosive disease (gastritis, esophagitis, duodenitis)	11–30
Mallory–Weiss tear	4–8
Esophageal/gastric neoplasm	3–5
Vascular lesions (angioectasias, Dieulafoy lesion)	2–10
Gastroesophageal varices/portal gastropathy	2–9
Mid-GI Bleeding[8,9]	
Vascular lesions (angioectasias, telangiectasias)	16–20
Ulcerations/erosions	11–18
Small bowel neoplasm	4–11
NSAID enteropathy	4–8
Crohn disease	3–5
Small bowel diverticulum (diverticulosis, Meckel's)	1–3
Other disease	2–9
Obscure GI bleeding	39–48
Lower GI Bleeding[10–13]	

Diverticulosis	26–31
Internal hemorrhoids	14–19
Neoplasm	6–20
Colon ischemia	6–12
Postpolypectomy	3–8
Inflammatory bowel disease	2–9
Angioectasias	1–6
Rectal ulcer	0–6
Infectious colitis	0–2
Radiation colitis/proctitis	0–3

GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug.

Site and Cause of Bleeding

Patients with upper GI bleeding will usually present with hematemesis or melena. Hematemesis is the vomiting of bright red blood or dark heme-positive material, termed coffee-ground emesis. The latter is blood that has been partially degraded and suggests that the bleeding has stopped. The vomiting of bright red blood suggests recent or ongoing bleeding. Melena is the passage of black, tarry stools with a characteristic pungent odor. It is caused by bacterial degradation of blood and occurs with as little as 50 mL of blood in the upper GI tract, small bowel, or proximal colon. Clinical findings most suggestive of an upper GI source of bleeding include melena, nasogastric lavage fluid containing blood or coffee grounds, and a serum urea nitrogen to creatinine ratio of more than 30.[18]

Hematochezia is the passage of bright red blood, maroon-colored blood, or blood clots from the rectum. It is usually caused by bleeding in the colon or rectum, but may occur with rapid blood loss anywhere in the GI tract. Fifteen percent of patients with hematochezia will have severe upper GI bleeding,[19] most of whom are hemodynamically unstable. The clinical finding most predictive of lower GI bleeding is the passage of blood clots per rectum.[18]

Risk Factors for GI Bleeding

Important risk factors for overt GI bleeding include advanced age, nonsteroidal anti-inflammatory drug (NSAID), and aspirin (ASA) use, treatment with antiplatelet agents and anticoagulants, and the presence of chronic illnesses, especially renal failure, cirrhosis, and cardiac disease.[2,5,10,14,15] Many risk factors have a synergistic effect on a patient's risk of bleeding. For example, the combination of NSAIDs and anticoagulants is more than double the risk of upper GI bleeding compared with NSAIDs or anticoagulants alone.[15] GI bleeding is also an important complication of patients hospitalized for common acute and chronic illnesses such as sepsis, stroke, myocardial infarction, renal failure, cirrhosis, and cancer.[10,15,20,21]

Table 65.2 Clinical Scenarios Associated with Various Causes of Overt Gastrointestinal Bleeding

Upper GI Bleeding
Peptic ulcer disease
Epigastric pain followed by hematemesis/melena in a person taking aspirin or NSAIDs
Esophagitis/esophageal ulceration
Hematemesis/melena in a person with a history of gastroesophageal reflux, heartburn, and/or odynophagia
Mallory–Weiss tear
Vomiting/retching followed by hematemesis and/or melena
Gastroesophageal varices
Painless, massive bleeding in a cirrhotic
Mid-GI Bleeding
Angioectasias
Recurrent GI bleeding in an elderly patient with chronic renal failure or aortic stenosis
Meckel diverticulum
Painless, large-volume GI bleeding in a child or young adult
Aortoenteric fistula
GI bleeding in patient with a history of abdominal aortic aneurysm repair
Lower GI Bleeding
Diverticulosis
Painless, intermittent large-volume hematochezia
Internal hemorrhoids
Intermittent low-volume bleeding with bright red blood on the tissue or dripping into the toilet water
Colon ischemia
Abdominal pain and hematochezia in an elderly patient with cardiovascular disease
Hematochezia or bloody diarrhea shortly after abdominal aortic aneurysm repair

GI, gastrointestinal; NSAIDs, non-steroidal anti-inflammatory drugs.

Severity of Bleeding

GI bleeding varies from minor, self-limited episodes of blood loss to massive hemorrhage with shock. The medical history, physical examination, and basic laboratory tests provide important information regarding the severity of bleeding and the patient's hemodynamic response. Basic laboratory tests should include a complete blood count with platelet count, electrolyte measurements, liver function tests, a basic coagulation profile, and a type and crossmatch.

In addition to hematemesis, melena, and/or hematochezia, patients with GI bleeding may present with symptoms of acute blood loss including light-headedness, dizziness, orthostatic syncope or near syncope, shortness of breath, and/or tachycardia. Severe bleeding is associated with the physical features of hypovolemic shock including cool, clammy, mottled skin, tachycardia, tachypnea, flat jugular veins, oliguria, and perhaps hypotension. Advanced age, chronic illnesses, and various medications may obscure these hemodynamic responses. Clinical findings most predictive of severe upper GI bleeding include bright red blood in the nasogastric lavage fluid, tachycardia with a heart rate greater than 100 beats per minute, and a hemoglobin level less than 8 g/dL.[18]

Table 65.3 Clinical Variables Used in Risk Assessment Tools for Patients with Upper GI Bleeding

Glasgow-Blatchford Score[22]	Admission Rockall Score[23]	AIMS65 Score[24]
Systolic blood pressure	Systolic blood pressure	Albumin
Heart rate	Heart rate	INR
Hemoglobin	Liver failure	Mental status
Melena at presentation	Renal failure	Systolic blood pressure
Syncope at presentation	Disseminated malignancy	Age
Blood urea nitrogen	Other major comorbidities	
Hepatic disease	Age	
Cardiac disease		

GI, gastrointestinal; INR, international normalized ratio.

RISK ASSESSMENT AND TRIAGE

Most patients with overt GI hemorrhage will stop bleeding spontaneously. Those who do not stop and those who rebleed are likely to require endoscopic, angiographic, or surgical intervention and are at a high risk to suffer a complication or die. Accurate estimation of the severity of bleeding and the patient's hemodynamic response guides the triaging of patients for diagnostic studies and therapeutic interventions. Minor, self-limited bleeding in hemodynamically normal patients may be managed in an ambulatory

setting whereas patients with ongoing or severe bleeding require urgent endoscopic evaluation and treatment in an intensive care unit. A number of tools employing clinical and endoscopic criteria are used to estimate the severity of bleeding and the likelihood of continued or recurrent hemorrhage and death.

Risk Assessment Tools for Upper GI Bleeding

The most widely validated risk assessment tools for predicting recurrent upper GI bleeding and mortality are the Glasgow-Blatchford score (GBS),[22] Rockall score,[23] and the AIMS65 score.[24] The clinical variables used in these risk assessment tools are shown in Table 65.3. The GBS is superior at predicting a combined endpoint of hospital-based intervention or death compared with the other two tools[25] and is promulgated by clinical guidelines from the European Society of Gastrointestinal Endoscopy,[26] the International Consensus Group,[27] and the Asia-Pacific Working Group.[28] A GBS score ≥7 predicts the need for endoscopic control of bleeding and a score ≤1 allows for the safe discharge and outpatient management of patients at very low risk of adverse outcomes.[25–29]

Risk Assessment Tools for Lower GI Bleeding

Unlike upper GI bleeding, there is no generally accepted risk prediction tool for patients with lower GI bleeding. A number of tools have been studied; however, heterogeneity of populations and outcomes has limited comparison and generalizability. The primary outcomes examined included severe bleeding, 30-day mortality, and adverse events.[30–32] The Oakland score[33] predicts safe discharge from the emergency department. The GBS has also been used to identify patients with lower GI bleeding who are at risk for adverse outcomes (rebleeding, need for transfusion, and in-hospital death).[34] As shown in Table 65.4, there is considerable overlap in the variables used in these models, particularly with regard to measures of blood loss and patient hemodynamics, the presence of comorbidities, and the use of

antithrombotic drugs. Unfortunately, the predictive ability of most of these tools for their primary outcome is only fair.[35]

RESUSCITATION

Airway Management

The initial step in the resuscitation of an acutely bleeding patient is to ensure that the airway is secure. Patients with severe GI bleeding who are inadequately ventilating or who are unable to protect their airway should undergo endotracheal intubation to optimize gas exchange and reduce the risk of aspiration. Prophylactic endotracheal intubation is not indicated as it is associated with the development of cardiopulmonary complications such as pneumonia.[36]

Table 65.4 Clinical Variables Used in Risk Assessment Tools for Patients with Lower GI Bleeding

Strate et al.[30]	Sengupta and Tapper[31]	Kollef et al. (BLEED)[32]	Oakland[33]
Heart rate	Age	Ongoing bleeding	Age
Systolic blood pressure	Dementia	Systolic blood pressure	Gender
Syncope	Metastatic cancer	Prothrombin time	Prior admission for lower GI bleeding
Nontender abdominal examination	Chronic renal disease	Altered mental status	Blood on digital rectal examination
Bleeding in first 4 hrs of hospitalization	Chronic lung disease	Unstable comorbid disease	Heart rate
Aspirin use	Anticoagulant use		Systolic blood pressure
>2 comorbid conditions (Charlson Index)	Admission hematocrit Admission albumin		Hemoglobin

GI, gastrointestinal.

Volume Resuscitation

Intravenous access is obtained by placing two large-bore catheters into antecubital veins. Intravascular volume resuscitation is started with an isotonic saline solution. Most patients will stop bleeding spontaneously and crystalloid resuscitation is all that is required. The decision to transfuse

blood or blood products depends on the specific needs of the patient. A number of randomized controlled trials[37,38] and published clinical guidelines[26–28,39,40] support a restrictive transfusion strategy which withholds the transfusion of packed red blood cells (PRBC) until a hemoglobin threshold of 7.0 to 8.0 g/dL is reached. A higher threshold (8 to 10 g/dL) is used for patients with ischemic cardiac disease. Patients with massive GI bleeding should receive a balanced hemorrhagic resuscitation regimen (e.g., a 1:1:1 ratio of PRBC, fresh frozen plasma, and platelets) to restore intravascular volume, oxygen-carrying capacity, and coagulation factors.

Hemodynamic Monitoring

Prompt, adequate resuscitation and diligent observation are the cornerstones of managing these potentially critically ill patients. Patients with evidence of active bleeding, those who have sustained significant blood loss, and those with risk factors for adverse outcomes should be admitted to an intensive care unit for close monitoring of their vital signs and evidence of continued or recurring blood loss. The placement of a urinary catheter and frequent monitoring of heart rate, blood pressure, oxygen saturation, urine output, and mental status are minimum necessary to monitor patients who have suffered significant GI bleeding. The presence of comorbidities such as cardiac, renal, or hepatic disease may necessitate invasive cardiac monitoring in order to optimize intravascular volume replacement therapy.

Nasogastric Lavage

The placement of a nasogastric tube in patients with suspected GI bleeding is controversial and the practice is highly variable.[18,26,27] Blood or coffee grounds in the nasogastric lavage fluid increases the likelihood of upper GI bleeding and the presence of bright red blood in the lavage fluid increases the probability of severe bleeding requiring urgent endoscopic hemostasis.[18] However, nasogastric lavage does not affect mortality, length of hospital stay, or the need for transfusions or surgery.[41] Furthermore, nasogastric tube insertion is an uncomfortable procedure with patients rating its discomfort comparable to fracture reduction or abscess drainage.[42]

Management of Antithrombotic Drugs

Twenty-nine percent to 44% of patients with severe GI bleeding are taking antithrombotic drugs (antiplatelet agents, anticoagulants).[10,43] The management of these patients balances the effect of the antithrombotic drug on the severity of bleeding with the risk of thromboembolic events should the agent be withdrawn. The treatment of patients who develop severe GI bleeding while receiving antithrombotic medications is the subject of numerous evidence-based guidelines[26–28,39,40] including those promulgated by the American Society for Gastrointestinal Endoscopy[44] and a joint task force of the Asian Pacific Association of Gastroenterology, and the Asian Pacific Society for Digestive Endoscopy.[45] Selected recommendations from these guidelines are shown in Table 65.5.

Table 65.5 Management of Patients with Overt Gastrointestinal Bleeding Who Are Taking Antithrombotic Medications

Patients receiving vitamin K antagonists (e.g., warfarin)

1. Patients with overt GI bleeding should have their anticoagulation managed in consultation with a cardiologist[26,40,44,45]
2. Patients with serious, life-threatening bleeding should have their coagulopathy corrected with 4-factor prothrombin complex concentrate (PCC) plus vitamin K or fresh frozen plasma if PCC is unavailable[26,28,40,44,45]
3. Endoscopy and endoscopic hemostasis should not be delayed awaiting correction of the coagulopathy,[27,28,45] especially if the international normalized ratio is less than 2.5[26,29,39,44]
4. Patients at high risk for thromboembolic events (e.g., patients with a mechanical mitral heart valve) should resume warfarin once hemostasis has been achieved.[29,45] These patients should receive unfractionated heparin as a bridge to anticoagulation with warfarin[44,45]

Patients receiving direct oral anticoagulants (DOACs; e.g., apixaban, dabigatran, rivaroxaban, edoxaban)

1. Patients with overt GI bleeding should have their anticoagulation withheld.[26,27,44,45] Because of their short half-lives and predictable loss of anticoagulant effect, “time is the most important antidote against DOACs”[26]
2. Endoscopy and endoscopic hemostasis should not be delayed by treatment of the coagulopathy[27,28]
3. Idarucizumab may be administered to patients with life-threatening bleeding who are anticoagulated with dabigatran[28,45]
4. Once the bleeding has been controlled, the DOAC should be resumed within 1–2 days and in consultation with the patient’s cardiologist[28,45]

Patients receiving single agent antiplatelet therapy with aspirin

1. Antiplatelet therapy for cardiovascular prophylaxis should be managed in collaboration with a cardiologist, neurologist, or cardiovascular specialist[28,29,44]
2. Patients receiving aspirin monotherapy for primary cardiothrombotic prophylaxis[a] should have the aspirin withheld at

least temporarily, with consideration given to permanent discontinuation[26,29,46]

3. Patients receiving aspirin monotherapy for secondary cardiothrombotic prophylaxis[b] should have the aspirin continued.[40,46] If it is stopped, it should be resumed upon obtaining hemostasis[28] or at least within 72 hours of achieving hemostasis[26,29,45]

Patients receiving dual agent antiplatelet therapy (aspirin, clopidogrel, prasugrel, ticlopidine, ticagrelor, vorapaxar)

1. Antiplatelet therapy for cardiovascular prophylaxis should be managed in collaboration with a cardiologist, neurologist, or cardiovascular specialist[26,28,29,40,44]
2. Patients at high risk for cardiothrombotic events should have both antiplatelet agents continued because of the high risk of thrombosis and death[29,40,45,46]
3. Patients at low risk for continued or recurrent bleeding (e.g., those with low-risk endoscopic stigmata) should have both antiplatelet agents continued[28]
4. Patients with severe bleeding and lower risk for cardiothrombotic events should have at least one of the agents continued, generally aspirin[26,28,40,45] with the P2Y12 receptor inhibitor restarted within 5 days of achieving hemostasis[26,28,40,45,46]

[a]In the absence of known cardiovascular disease.

[b]In the presence of known cardiovascular disease.

DIAGNOSTIC ALGORITHMS

Upper GI Bleeding

2 The initial diagnostic test in almost all cases of upper GI bleeding is EGD. This procedure will identify the site of bleeding in 95% of cases, provide information regarding the likelihood of continued or recurrent bleeding, and be therapeutic. Multiple evidence-based clinical guidelines recommend that patients undergo EGD after appropriate resuscitation and

within 24 hours of presentation.[26–28] Early endoscopy allows for the safe discharge of low-risk patients, improves outcomes for high-risk patients, and reduces resource utilization. Patients with ongoing bleeding and persistent hemodynamic instability despite volume resuscitation should undergo EGD within 12 hours.[26,28] Patients with cirrhosis and suspected variceal bleeding should also undergo EGD within 12 hours of presentation.[47,48] Patients must be appropriately resuscitated prior to endoscopy as inadequate resuscitation is associated with adverse outcomes, including in-hospital mortality.[49]

Computed tomographic (CT) angiography is an appropriate diagnostic test in those instances in which (1) the patient is actively bleeding and remains hemodynamically unstable despite volume resuscitation or (2) EGD has documented evidence of hemorrhage but the site of bleeding could not be identified.[50] CT angiography can be performed expeditiously and will detect rates of bleeding as low as 0.3 mL/min. It will also identify sources of bleeding outside the reach of a standard endoscope thus facilitating therapeutic endoscopic or angiographic interventions. In actively bleeding patients, the sensitivity and specificity of CT angiography is 85% and 92%, respectively. The sensitivity of CT angiography is only about 50% in patients with lower rates of bleeding.[50,51]

Visceral angiography is indicated in those instances in which endoscopy or CT angiography has identified a site of active bleeding that is not amenable to endoscopic hemostasis. In this setting, visceral angiography has a high diagnostic accuracy and is effective in achieving hemostasis with catheter-based embolization techniques in about 80% of cases.[50,52] Visceral angiography will detect arterial or capillary bleeding at rates of 0.5 to 1.0 mL/min, a rate of bleeding that correlates with the need for ongoing volume resuscitation to maintain hemodynamic stability. If the bleeding has stopped, or is intermittent, the bleeding site will not be visualized by angiography, an important limitation of this study.

Lower GI Bleeding

The timing and manner of diagnostic studies for patients with lower GI bleeding depends upon the severity of bleeding and the hemodynamic status of the patient. A diagnostic algorithm for the evaluation of patients with lower GI bleeding is shown in Figure 65.1. Patients with minor self-limited

episodes of bleeding and no other indication for hospitalization (such as those with an Oakland score ≤8) may be discharged from the emergency department and evaluated by colonoscopy in an outpatient setting.[39,40]

3 Hemodynamically stable patients with suspected lower GI bleeding should undergo colonoscopy. The timing of the procedure is controversial. Two systematic reviews found that colonoscopy performed within 24 hours of presentation was associated with improved detection of a definite site of bleeding, increased rates of endoscopic treatment, and shorter hospital stays.[53,54] However, a recent multicenter, randomized controlled trial comparing early versus elective colonoscopy failed to demonstrate a difference in the rate of rebleeding or the ability to identify stigmata of recent hemorrhage.[55] Patients should undergo bowel preparation prior to colonoscopy in order to optimize visualization of the colonic mucosa and improve diagnostic yield which is 42% to 100% in patients with hematochezia.[10,39,40] CT angiography is indicated in those instances in which colonoscopy documents evidence of bleeding but is unable to identify the source.

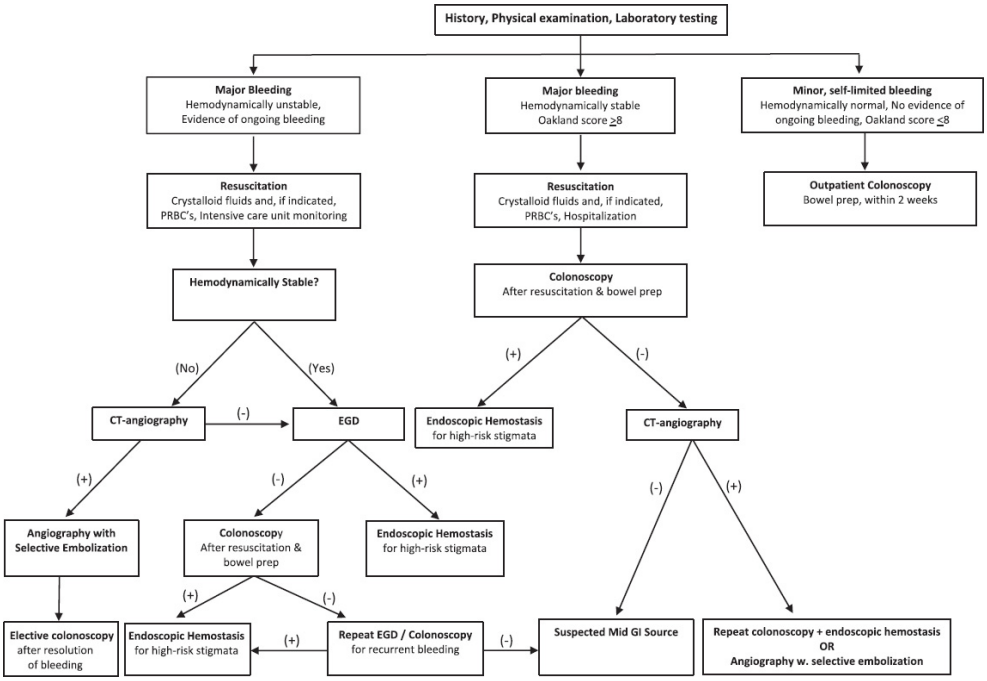

Figure 65.1 Diagnostic algorithm for patients presenting with hematochezia. PRBCs, packed red blood cells; EGD, esophagogastroduodenoscopy; GI, gastrointestinal; CT, computed tomography; (+), diagnostic; (−), nondiagnostic.

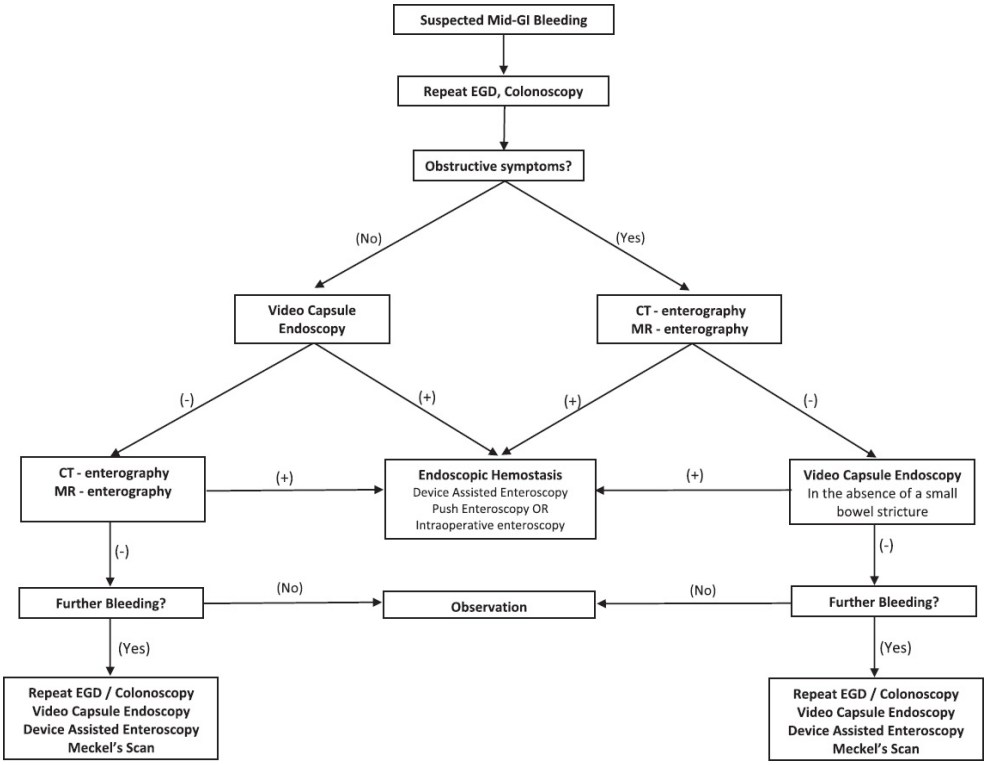

Figure 65.2 Diagnostic algorithm for hemodynamically stable patients with suspected overt mid-gastrointestinal bleeding. GI, gastrointestinal; CT, computed tomography; MR, magnetic resonance; (+), diagnostic; (−), nondiagnostic.

Hemodynamically unstable patients with hematochezia who have not responded to volume resuscitation should undergo urgent CT angiography as the initial diagnostic test since these patients are unlikely to tolerate bowel preparation and colonoscopy.[39,40] If a source of bleeding is identified by CT angiography, the patients should undergo visceral angiography with superselective embolization of the bleeding site. If a source of bleeding is not identified by CT angiography, an EGD 4 should be performed given the high rate of upper GI bleeding in unstable patients presenting with hematochezia (15%).[19,39,40,46,56]

Mid-Gastrointestinal Bleeding

5 About 70% of patients with overt GI hemorrhage in whom an EGD and colonoscopy fail to identify the source of bleeding are bleeding from the small intestine.[57] A diagnostic algorithm for the evaluation of patients with mid-GI bleeding is shown in Figure 65.2. If the patient is hemodynamically unstable, he/she should undergo CT angiography to identify the site of

bleeding and guide subsequent endoscopic or angiographic hemostasis. Hemodynamically stable patients with potential small bowel bleeding should undergo repeat EGD and/or colonoscopy since these studies will identify a site of bleeding in 30% to 40% of instances.[58]

6 VCE is the diagnostic test of choice for hemodynamically stable patients with potential small bowel bleeding. It allows the noninvasive examination of the entire length of small bowel in 80% to 90% of cases and has a diagnostic yield of 80% in patients with suspected small bowel bleeding, especially if performed within 2 to 3 days of the hemorrhage.[2,58,59] Recurrent bleeding after a negative VCE is infrequent (6% to 11%).[59,60] The primary risk of VCE is capsule retention which occurs in about 1% of examinations.[61] The most common cause of capsule retention is a small bowel stricture. Thus patients with suspected small bowel bleeding and obstructive symptoms should undergo CT enterography prior to VCE.[58,59]

DAE includes balloon-assisted enteroscopy and spiral enteroscopy. The diagnostic yield of DAE in patients with suspected mid-GI bleeding is about 60% and increases to 75% in the setting of a positive VCE.[62,63] DAE facilitates the endoscopic treatment of patients in whom VCE has identified a site of bleeding within the small intestine. A detailed description of the role of DAE in the management of patients with small bowel disorders is provided in Ref. [64].

Multiphase CT enterography uses intravenous contrast and large-volume oral contrast to detect inflammatory lesions, neoplasms, and vascular abnormalities within the small bowel. The diagnostic yield of CT enterography for patients with suspected small bowel bleeding is 40% to 57%.[65,66]

Pertechnetate scintigraphy is performed in young adults or children suspected to be bleeding from a Meckel diverticulum. Intravenous Technetium-99m pertechnetate is taken up by the mucoid cells of ectopic gastric mucosa located within the Meckel diverticulum and presents as a focus of abnormal radioactivity in the right lower abdomen. The diagnostic accuracy is greater than 90% in children[67] but is less than 50% in adults.[68]

7 **Table 65.6** Endoscopic and Medical Management of Patients with Peptic Ulcer–Related Upper GI Bleeding According to the Endoscopic Appearance of the Ulcer[26–29]

Endoscopic Stigmata	Type[a]	Endoscopic Treatment	Medical Management
High-Risk Stigmata			
Spurting ulcer	Ia	Endoscopic hemostasis	High-dose PPI (bolus + continuous infusion) for 72 hrs
Oozing ulcer	Ib	Endoscopic hemostasis	High-dose PPI (bolus + continuous infusion) for 72 hrs
Nonbleeding visible vessel	IIa	Endoscopic hemostasis	High-dose PPI (bolus + continuous infusion) for 72 hrs
Adherent clot	IIb	Clot removal + endoscopic hemostasis if underlying high-risk stigmata	High-dose PPI (bolus + continuous infusion) for 72 hrs
Low Risk Stigmata			
Flat pigmented spot	IIc	None	Once daily oral PPI
Clean ulcer base	III	None	Once daily oral PPI

[a]Forrest classification.[72]

GI, gastrointestinal; PPI, proton pump inhibitor.

UPPER GASTROINTESTINAL BLEEDING

Peptic Ulcer Disease

Peptic ulcer disease is the most common cause of upper GI bleeding, accounting for about 50% of cases. *Helicobacter pylori* and gastroerosive drugs, especially NSAIDs and ASA, are independent and synergistic risk factors for peptic ulcer–related bleeding and account for about 80% of cases.[15,69] NSAIDs potentiate the effect of other risk factors for peptic ulcer–related bleeding such as advanced age, anticoagulants, corticosteroids, and selective serotonin reuptake inhibitors.[15] About 30% of patients will present with bleeding as the initial symptom of their disease and about 50% of patients will have antecedent upper abdominal pain.[70,71]

The Forrest Classification is an endoscopic scoring system that identifies patients at high risk for continued or recurrent bleeding and death.[72] High-risk endoscopic stigmata include active ulcer bleeding and a nonbleeding visible vessel. Low-risk endoscopic stigmata includes ulcers with flat pigmented spots or clean ulcer base. An adherent clot is defined as a blood clot over an ulcer that is resistant to jet water irrigation. The management of patients with peptic ulcer–related bleeding based on the endoscopic appearance of the ulcer is shown in Table 65.6.

Endoscopic hemostasis can be achieved with injection, thermal or mechanical methods.

Thermal devices (contact and noncontact), injectable agents (i.e., sclerosing agents, thrombin/fibrin glue), and endoscopic clips are all effective methods for achieving hemostasis, with no single modality being superior.[26,27,29,73] Epinephrine injection alone is effective at achieving primary hemostasis, but is associated with a high rate of rebleeding.[74] Therefore, if epinephrine is used to treat peptic ulcer bleeding, it should be used in combination with another endoscopic modality.[26]

Following successful endoscopic therapy, patients with ulcers with high-risk endoscopic stigmata should receive high-dose proton pump inhibitor (PPI) therapy administered as an intravenous bolus followed by continuous infusion for 72 hours post endoscopy. This regimen has been demonstrated to reduce rebleeding, the need for surgery, and mortality.[26,73] Daily oral PPI therapy is then continued for 4 to 8 weeks.[75] Patients with low-risk lesions

(clean base, flat spot) should receive oral PPIs once a day from the time of diagnosis.[29] All patients should be tested for *H. pylori* in the acute setting and appropriate antibiotic therapy initiated if *H. pylori* is detected.[26]

Patients who rebleed following initial endoscopic control should undergo repeat endoscopic hemostasis.[26,29] One randomized controlled trial comparing endoscopic re-treatment to surgery found that endoscopic re-treatment controlled bleeding in 73% of patients and was associated with a lower rate of adverse events compared with surgery.[76] Emerging data suggest that hemostatic powder may provide temporary hemostasis in patients in whom standard endoscopic techniques are unsuccessful.[26,28,77] Additionally, over-the-scope clips, which are much larger than standard endoscopic clips, may allow successful treatment of some ulcers in which standard endoscopic treatment has been unsuccessful.[26,78]

8 If the bleeding is unable to be controlled at the second endoscopy or if the patient rebleeds, the patient should undergo angiographic embolization or surgery.[20,26,79,80] Three meta-analyses have compared embolization to surgery in patients who failed endoscopic hemostasis. All three studies found that embolization is associated with higher rates of rebleeding and two of the three reported a trend toward higher mortality rates with emergency surgery. These data are summarized in Table 65.7.[81–83]

The surgical choice depends on the location and extent of the ulcer, the patient's medical status, and the experience of the surgeon. For favorably located gastric ulcers, such as those along the greater curvature, excision of the ulcer with closure of the gastrotomy will suffice. If the ulcer is unfavorably located, for example, near the gastroesophageal junction, simple oversewing of the bleeding vessel may adequately control the hemorrhage. Biopsy of the ulcer margin, either at the time of operation or at follow-up endoscopy in 4 to 8 weeks, is important to rule out malignancy. Extensive gastric resections such as subtotal or total gastrectomy are generally not performed in these potentially medically complex and unstable patients.

Table 65.7 Results of Three Meta-Analyses Comparing Embolization to Surgical Hemostasis for Remedial Treatment of Bleeding Peptic Ulcers[81–83]

	Angiographic Embolization (% of Events)	Surgery (% of Events)
Rebleeding	25–35	15–18
Mortality	19–24	22–25
Need for additional intervention	18–33	8–18
Complications	31	50

Most duodenal ulcers requiring surgical control are large, posterior lesions bleeding from the gastroduodenal artery. A longitudinal incision in the duodenal bulb will allow visualization of the bleeding gastroduodenal artery in the base of the ulcer which should be oversewn proximally and distally to the bleeding site with figure-of-eight stitches. A U-stitch is placed underneath the bleeding site to control the transverse pancreatic artery which enters the gastroduodenal artery posteriorly. The performance of a vagotomy and drainage procedure (usually a Heineke-Mikulicz pyloroplasty) is associated with lower mortality rates compared with oversewing the ulcer alone.[84] Operations for peptic ulcer disease including truncal vagotomy and pyloroplasty are described in detail in Chapter 44.

Stress Ulceration

Stress ulceration is characterized by diffuse bleeding from erosions and superficial ulcers in the stomach, and to a lesser extent the duodenum, of critically ill patients. The clinical spectrum of this disease varies from asymptomatic, superficial gastroduodenal erosions to deep mucosal and submucosal ulcerations with overt upper GI bleeding and hemodynamic instability.

The incidence of overt upper GI bleeding in critically ill, hospitalized patients is between 0.9% and 5.0%.[20,85,86] The risk is much higher in critically ill patients requiring specialized care such as mechanical ventilation, renal replacement therapy, and extracorporeal life support.[20,87] The risk of stress-related upper GI bleeding in hospitalized patients who are not critically ill is much lower (0.29%).[88]

The most salient factor in the pathophysiology of stress ulcerations is disruption of the gastroduodenal mucosal barrier. Critical illness or injury reduces gastric blood flow and causes mucosal ischemia and reperfusion injury. This in turn impairs mucosal barrier defenses and ultimately disrupts mucosal integrity. The pathophysiology of stress ulcerations is reviewed in Ref. [20].

The principal nonpharmacologic method to decrease stress-related upper GI bleeding is the administration of enteral nutrition. It is postulated that enteral nutrition buffers gastric acid, enhances protective mucosal prostaglandin production, and improves regional perfusion.[20] Acid suppression with PPIs is the predominate means of prophylaxis against stress ulceration.[20,85,88,89] PPIs significantly reduces the risk of upper GI bleeding in critically ill patients when compared to no prophylaxis or placebo, histamine H_2-receptor antagonists, or sucralfate.[20] There is increasing evidence linking acid suppression with the occurrence of nosocomial infections in critically ill patients, especially ventilator-associated pneumonia and *Clostridium difficile* colitis.[90,91] These observations and others have created a growing concern that the adverse effects of acid suppression outweigh the risk of stress-related upper GI bleeding. At the very least, it calls into question the use of acid suppression in patients at low risk for stress ulceration, such as hospitalized patients who are not critically ill or those patients in the intensive care unit who lack well-defined risk factors for GI bleeding.[20]

The management of patients with stress-related upper GI bleeding is similar to that of patients with other nonvariceal causes of upper GI bleeding. Endoscopy should be performed within 12 to 24 hours of presentation depending on the severity of the bleeding. The presence of high-risk endoscopic stigmata identifies lesions that may be amenable to endoscopic hemostasis. Hemostatic powders may be useful for diffusely bleeding lesions. High-dose PPI therapy is the mainstay of treatment for patients

whose lesions are not amenable to endoscopic hemostasis. It is also prescribed after successful endoscopic therapy.

The need for surgical management of severe bleeding from stress ulceration is extremely rare. Most of the published experience is more than 40 years old. A number of surgical procedures have been used to control bleeding ranging from suture ligation of specific bleeding sites to total gastrectomy for diffuse hemorrhage. Rebleeding is common for procedures less extensive than total gastrectomy and the mortality rate is high regardless of the operative approach. Stress-related upper GI bleeding is further discussed in Chapter 44.

Esophagitis

Severe esophagitis causes 6% to 15% of cases of upper GI bleeding[5,6,92,93] with an adjusted incidence of 4 to 12 cases per 100,000 population per year.[3,5] Gastroesophageal reflux disease is the most common cause of esophagitis associated with overt upper GI bleeding. Fungal (candida) and viral (herpes simplex, Cytomegalovirus) esophagitis may also cause upper GI bleeding in immunocompromised individuals. Gastroesophageal reflux disease and esophagitis are discussed in Chapter 41.

Patients bleeding from esophagitis present with hematemesis (43% to 86%) and/or melena (38% to 52%).[6,92] A minority of patients will have symptoms of gastroesophageal reflux such as heartburn (23% to 38%).[92,94] Massive bleeding with hematochezia (2%) and hemodynamic instability (5%) is uncommon.[92,94] In general, patients bleeding from esophagitis have more stable vital signs, higher hemoglobin and hematocrit levels, and lower Rockall scores than patients with other causes of upper GI bleeding.[92]

Most patients respond well to treatment with PPIs with few requiring endoscopic hemostasis (3%). These patients have an extremely low risk of rebleeding and mortality. Many patients with bleeding from esophagitis can be triaged to early discharge once the diagnosis is made with endoscopy. Patients with cirrhosis who are bleeding from severe esophagitis are at higher risk for rebleeding (17%) and mortality (33%).[92]

Mallory–Weiss Syndrome

Mallory–Weiss syndrome is upper GI bleeding caused by a longitudinal laceration of the distal esophagus and proximal stomach after vomiting, retching, coughing, or straining. Extension of the laceration into the submucosa disrupts esophageal venous and arterial plexuses with hemorrhage. A history of heavy alcohol use is commonly described, as is the presence of a hiatal hernia.

Patients characteristically have an episode of nonbloody emesis, retching or coughing followed by hematemesis. This "classic" presentation occurs in slightly more than 50% of cases.[95] About 10% of patients will present with melena in the absence of hematemesis.[96] The amount of bleeding is variable with severe bleeding described in patients with cirrhosis and portal hypertension.

The mortality rate associated with bleeding from a Mallory–Weiss tear is about 5%. Risk factors for poor outcomes include advanced age, medical comorbidities, and active bleeding at the time of endoscopy.[6,97] Endoscopic mechanical hemostasis is effective in controlling active bleeding and preventing rebleeding.[26,98] Patients without high-risk stigmata are treated with high dose PPIs as are those patients whose bleeding is controlled endoscopically.[26] Surgical treatment, consisting of oversewing the bleeding site through an anterior gastrotomy, is rarely necessary.

Dieulafoy Lesion

A Dieulafoy lesion is an abnormal enlarged artery that courses through the submucosa of the stomach (70%), duodenum (15%), esophagus (8%), colon (2%), rectum (2%), or small intestine (1%).[99] Severe GI bleeding is caused by erosion of the arterial wall through a small superficial defect in the overlying mucosa.

Dieulafoy lesions typically occur in older individuals with 90% of patients more than 60 years of age. Males are affected more commonly than females and medical comorbidities are common. The use of NSAIDs, aspirin, or anticoagulants is also common among patients with bleeding Dieulafoy lesions.[99–101]

Patients present with hematemesis and melena. Most patients are actively bleeding at presentation. One-third of patients are hemodynamically unstable

and two-thirds require blood transfusions. Recurrent bleeding occurs in about 20% of patients.[99,100]

Greater than 90% of patients with bleeding Dieulafoy lesions can be managed endoscopically.[26,102] There is similar efficacy with thermal, mechanical, or combination hemostasis techniques.[100,103] Recurrent bleeding after initially successful endoscopic hemostasis is managed with repeat endoscopic therapy.

Patients who fail endoscopic hemostasis are treated with angiographic embolization or surgery. The operative management of gastric Dieulafoy lesions is laparoscopic or open wedge resection of the lesion after preoperative endoscopic localization. Lesions in the small bowel or colon are treated with resection of the involved bowel and lesions in the rectum are managed by oversewing the bleeding vessel.

Gastroesophageal Varices

Cirrhosis is the fifth leading cause of adult deaths in the United States and ranks eighth in economic cost among major illnesses.[104] About 50% of patients with cirrhosis develop gastroesophageal varices (GEV)[105] and 10% to 15% of these patients will bleed from their varices each year.[106]

Cirrhosis may be classified into two main prognostic stages, compensated and decompensated, depending on the presence or absence of decompensating events such as ascites, variceal bleeding, or encephalopathy.[48] Up to 85% of patients with decompensated cirrhosis will have GEV compared with 30% to 40% of patients with compensated cirrhosis.[105] Patients with compensated cirrhosis develop varices at a rate of 7% to 8% per year[107] and progress from small to large varices at a rate of 10% to 12% per year.[108]

Portal hypertension is an early and important consequence of cirrhosis and is responsible for the majority of its complications, including variceal hemorrhage. The development of portosystemic collaterals, such as those through the coronary and short gastric veins which cause GEV, is an early consequence of portal hypertension. The risk of variceal bleeding depends on the severity of liver disease, size of the varices, and the presence of red wale marks, which are due to thinning of the variceal wall.

The risk of variceal bleeding and death directly relates to the degree of elevation of portal venous pressure. Each 1 mm Hg increase in portal pressure predicts a 3% increase in the risk of death with a median follow-up of 19 months.[109] The relationship between portal pressure and complications of portal hypertension[48,110,111] is shown in Table 65.8.

Patients with variceal bleeding present with effortless and recurring hematemesis of large volumes of dark red blood. The history and physical examination will identify risk factors for cirrhosis (e.g., alcoholism, obesity, hepatitis) and associated physical findings (e.g., jaundice, ascites, spider angiomas, palmar erythema, gynecomastia, ascites, and visible portosystemic collaterals within the abdominal wall, termed "caput medusa"). Splenomegaly is a sensitive, but nonspecific sign of portal hypertension and may be identified on physical examination and/or imaging with ultrasound or CT. Thrombocytopenia is the most common laboratory sign of portal hypertension, although it lacks the accuracy to either diagnose or exclude clinically significant portal hypertension or GEV. Other laboratory tests may document evidence of hepatic synthetic dysfunction (prolonged prothrombin time, hypoalbuminemia, hyperbilirubinemia) and/or hypersplenism and bone marrow suppression (thrombocytopenia, leukopenia).

Table 65.8 Relationship between Elevated Portal Pressure and Complications of Portal Hypertension[48,110,111]

HVPG[a] (mm Hg)	Complication of Portal Hypertension
3–5	Normal
5–10	Mild portal hypertension
>10	Clinically significant portal hypertension
>12	At risk for variceal bleeding
>16	At higher risk of death
>20	Predicts failure to control bleeding, early rebleeding, and death

[a]Portal pressure is most commonly estimated by catheterizing the hepatic vein with a balloon catheter and measuring the difference between the wedged (or occluded) hepatic venous pressure and free hepatic venous pressure (hepatic venous portal gradient, HVPG).

Noncirrhotic causes of portal hypertension include schistosomiasis, extrahepatic portal vein thrombosis, and idiopathic portal hypertension. Additionally, as many as one-third of cirrhotics with upper GI hemorrhage will be bleeding from a cause unrelated to portal hypertension, the most common of which is peptic ulcer disease.[112]

The immediate goals of therapy for patients bleeding from GEV is to control the hemorrhage, prevent early recurrence, and prevent 6-week mortality.[48] Acute variceal bleeding is a medical emergency requiring prompt, intensive care. A restrictive PRBC transfusion strategy (described earlier) is associated with lower rates of early rebleeding and mortality in cirrhotics with upper GI bleeding than are more liberal transfusion strategies.[37,48] Patients with cirrhosis who present with upper GI bleeding are at a high risk of developing bacterial infections. The administration of prophylactic antibiotics decrease the risk of infections, recurrent hemorrhage, and death.[113] The antibiotic of choice in most centers is ceftriaxone administered for a maximum of 7 days.[48] The intravenous infusion of vasoactive agents (such as octreotide) should be started as soon

as possible and before diagnostic endoscopy in patients suspected of bleeding from GEV. A recent meta-analysis of 11 trials showed that the administration of octreotide significantly improved control of acute variceal bleeding.[114]

Endoscopy should be performed as soon as possible following resuscitation and not more than 12 hours after presentation. If a variceal source of bleeding is confirmed or suspected, endoscopic variceal ligation (EVL) should be performed. Once EVL have been performed, "early" transjugular intrahepatic portosystemic shunt (TIPS) has been shown to lower treatment failure and mortality rates in high-risk patients. For patients in whom early TIPS is not performed, intravenous vasoactive drugs (e.g., octreotide) should be continued for 2 to 5 days and nonselective beta blockers (e.g., propranolol) should be started once the vasoactive drugs have been discontinued. Rescue TIPS is indicated in those patients in whom hemorrhage cannot be controlled by vasoactive drug infusion and EVL, or if bleeding recurs.[48]

Patients who recover from the first episode of variceal hemorrhage have a 60% chance of rebleeding in the first year and a mortality rate of up to 33%. Patients who had TIPS performed during the initial bleeding episode do not require additional specific therapy, but should be referred for liver transplant evaluation. The first-line therapy for patients who do not undergo TIPS initially is nonselective beta blockers plus EVL.[48] If the patient bleeds while on first-line therapy, he/she should undergo TIPS. A multicenter randomized controlled trial comparing TIPS to EVL plus nonselective beta blockers found that TIPS was associated with a significantly lower rate of rebleeding but had a higher rate of early encephalopathy. There were no differences in survival.[115] The evaluation and surgical management of patients with complications of cirrhosis is discussed in Chapter 58.

Clinical Outcomes for Upper GI Bleeding

Overall, the mortality rate for patients with upper GI bleeding is 2.0% to 2.5%.[3,5,17] The mortality rate for patients bleeding from GEV is more than twice that of patients bleeding from nonvariceal causes.[17] Patients who develop upper GI bleeding while they are hospitalized for another condition

have a mortality rate that is 3 to 4 times higher than that of patients who present to the hospital with GI bleeding.[21]

LOWER GASTROINTESTINAL BLEEDING

Diverticular Disease

Diverticular disease is the most common cause of lower GI bleeding, accounting for about 30% of cases.[10,11,116] The age- and sex-adjusted incidence of diverticular bleeding in the United States is 19 to 24 cases per 100,000 population per year.[4,117] The cumulative incidence of lower GI bleeding in patients with known diverticular disease is 2.2% at 5 years.[117]

Diverticular bleeding originates most commonly from the right colon despite the fact that in Western population diverticular disease predominantly affects the left colon. Bleeding is caused by perforation of a vasum rectum located at the neck or apex of the diverticulum. The vasa recta penetrate the colon wall through obliquely oriented connective tissue septa. Protrusion of the mucosa and submucosa through this tissue plane forms the diverticulum and causes apposition of the colonic mucosa and the vasum rectum. This is illustrated in Figure 65.3. Ulceration of the mucosa of the diverticulum and disruption of the arterial wall cause hemorrhage into the bowel lumen.

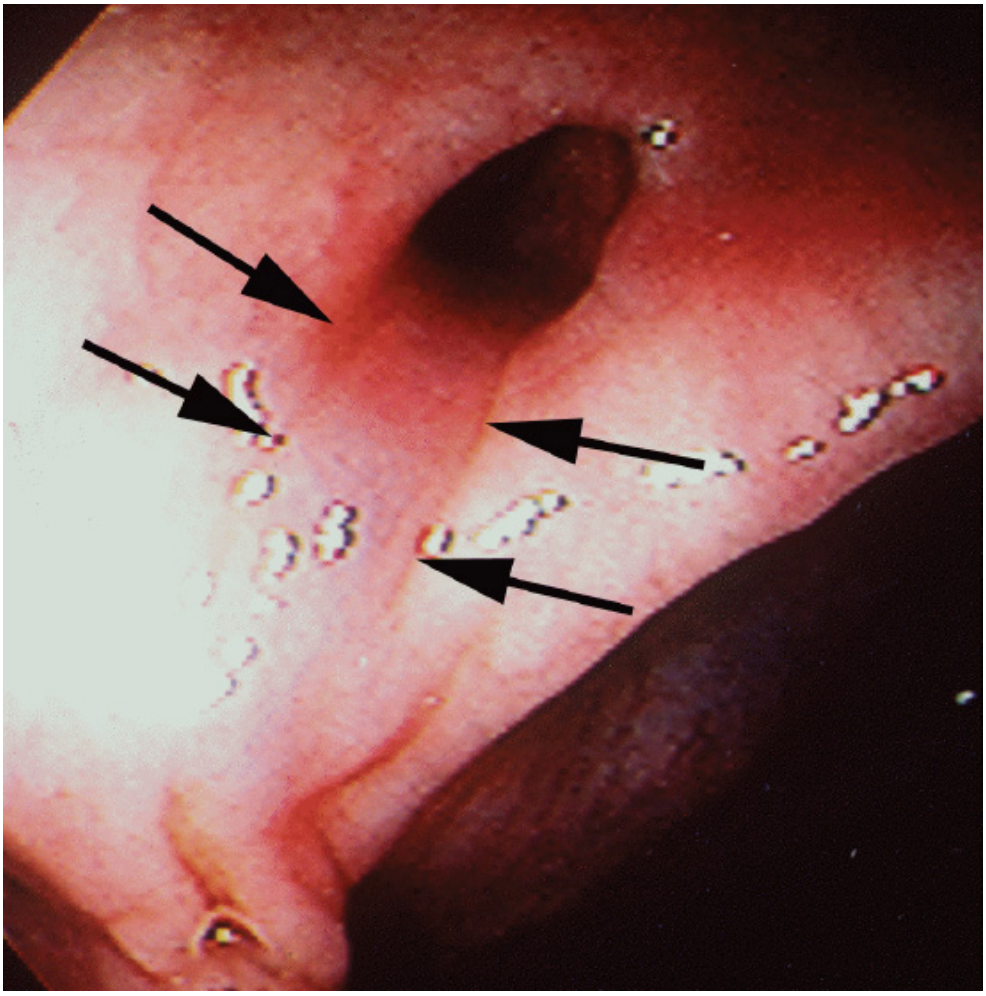

Figure 65.3 Endoscopic view of a colonic diverticulum showing a vasum rectum underneath the colonic mucosa at the neck of the diverticulum (*arrows*).

Patients with diverticular bleeding present with painless, intermittent, large-volume hematochezia. The color of the blood varies from dark maroon to bright red blood clots depending on the location and intensity of the bleeding. Patients with diverticular bleeding do not typically exhibit small amounts of bleeding. Important risk factors for diverticular bleeding are age greater than 70 years, pancolonic disease, the use of NSAIDs, ASA, or anticoagulants, and a previous episode of diverticular bleeding.[117–119]

Most patients (75% to 80%) with diverticular bleeding will stop bleeding spontaneously, although recurrence is common. The incidence of a second episode of bleeding is 3,626 per 100,000 person-years and the median time between the first and second episodes is 1.2 years. The incidence of recurrent bleeding is higher for individuals who have the index bleed at an

older age and those individuals taking antiplatelet agents. If a person has had two prior episodes of diverticular bleeding, the annual risk of recurrent hemorrhage is about 11%.[117]

Endoscopic hemostasis is an effective treatment for patients with diverticular bleeding and high-risk endoscopic stigmata (active bleeding, nonbleeding visible vessel). The particular technique depends upon the location of the bleeding, the ability to access the bleeding site, and the operator's experience.[53,120] The use of endoscopic clips (with or without epinephrine injection) has the advantage of reducing the potential for transmural injury and perforation associated with contact thermal modalities, especially in the thin-walled right colon.[53,120] A review of endoscopic treatment of 137 patients with diverticular bleeding reported successful hemostasis in 92% of patients and no reported complications.[12]

Patients with severe bleeding who cannot tolerate colonoscopy should undergo CT angiography to identify the site of bleeding followed by selective visceral angiography. Superselective embolization with microcoils, polyvinyl alcohol particles, or water-insoluble gelatin (gel foam) has improved the success rate of this procedure and reduced the risk of adverse events, especially bowel infarction. Reports of embolization as first-line therapy for patients with overt lower GI bleeding documented successful initial hemostasis in 85% to 96% of patients with early rebleeding in 22% of patients.[12,121]

The indications for surgical treatment of patients with diverticular hemorrhage include: (1) bleeding that has been unresponsive to endoscopic hemostasis and angiographic embolization, (2) recurrent bleeding that is refractory to endoscopic or angiographic hemostasis, and (3) massive hemorrhage in which the patient has been unresponsive to resuscitation. Preoperative localization of the bleeding site is important and allows the surgeon to limit the extent of resection to a partial colectomy, reduces the likelihood of recurrent bleeding, and improves short- and long-term outcomes. A subtotal colectomy is indicated in rare instances in which the site of bleeding cannot be localized. The rate of recurrent bleeding after a subtotal colectomy is less than 4% and the perioperative mortality rate is 2% to 6%.[122,123] The surgical management of complications of diverticular disease is discussed in Chapter 69.

Internal Hemorrhoids

Hemorrhoids are dilated submucosal veins located in the anus above (internal hemorrhoids) or below (external hemorrhoids) the dentate line. Although usually asymptomatic, patients with first-degree hemorrhoids (i.e., internal hemorrhoids bulging into, but not out of, the anal canal) may present with painless, recurrent episodes of bleeding that cause coating or streaking of the stool with bright red blood, the dripping of blood into the toilet, or staining of tissue with blood. Severe bleeding requiring transfusion is uncommon except in patients taking anticoagulants and those with portal hypertension.

Anoscopy should be the initial diagnostic study for all patients with lower GI bleeding. It will identify internal hemorrhoids as the cause of rectal bleeding and facilitate their treatment by banding. Even if internal hemorrhoids are present, colonoscopy is still necessary to exclude another more serious source of bleeding.

Mild hemorrhoidal bleeding can be successfully managed with diet and lifestyle modification. Dietary changes include fiber supplementation and increased water consumption with the goal of reducing straining during defecation. Other lifestyle modifications include the avoidance of prolonged sitting or straining on the toilet, improved perianal hygiene, and avoiding triggers of constipation or diarrhea.

Banding is effective in controlling hemorrhoidal bleeding in more than 90% of patients. Patients who have failed banding or other forms of endoscopic treatment, those with symptomatic combined internal/external hemorrhoids (grades III/IV), and patients who are coagulopathic may require operative treatment. Although more effective than endoscopic hemorrhoidal banding, operative treatment is associated with a higher rate of complications such as anal stenosis and postoperative bleeding. The management of complications of hemorrhoids is discussed in Chapter 70.

Colon Ischemia

Colon ischemia (also referred to as ischemic colitis) is an acute condition caused by transient ischemia and reperfusion of a segment of the colon that leads to localized inflammation, mucosal ulceration, and bleeding. The

severity of the injury ranges from reversible localized inflammation to transmural infarction and necrosis. In the United States, colon ischemia accounts for 7% to 12% of hospital admissions for lower GI bleeding.[11,116] The left colon is most commonly affected (33%).[124] The vascular watershed areas of the colon, such as the splenic flexure and the sigmoid colon, are particularly susceptible to ischemic injury.

Colon ischemia is more common in females (57% to 76%) than males and the prevalence increases with age.[125,126] Colon ischemia typically presents with sudden cramping, mild, left lower abdominal pain, an urgent desire to defecate, and the passage of bright red or maroon-colored blood or bloody diarrhea.[127] Abdominal pain (87%), rectal bleeding (84%), and diarrhea (56%) are the most common symptoms.[128] Physical examination demonstrates a soft abdomen with tenderness and voluntary guarding over the affected segment of colon. Peritonitis suggests full-thickness ischemia, perforation, or an alternate diagnosis. The acute onset of symptoms is an important feature of colon ischemia and distinguishes it from other causes of colitis in which the onset of symptoms is more gradual.

Risk factors for the development of colon ischemia include cardiovascular and pulmonary diseases, irritable bowel syndrome, diabetes mellitus, and collagen vascular diseases.[125,126,129] Vasoactive drugs, including cocaine and amphetamines, have also been associated with the development of colon ischemia.[125] Surgical procedures, especially those that require ligation or occlusion of the inferior mesenteric artery such as abdominal aortic aneurysm repair, are also associated with the development of colon ischemia.[126] The rate of colon ischemia following abdominal aortic aneurysm repair is about 2%.[130]

Most episodes of colon ischemia are benign, self-limited, and cause mild rectal bleeding. Severe hematochezia occurs in about 12% of patients and is more frequent in women and in patients with severe lung disease, elevated creatinine and glucose levels, and those receiving anticoagulants.[131] Severe bleeding is also more commonly associated with gangrenous colon ischemia (10%) and fulminant pancolitis (2%).[126,127]

Patients with suspected colon ischemia should undergo CT with intravenous and oral contrast as the initial diagnostic test. This study can suggest the diagnosis, identify areas of affected colon, and exclude other serious (and more common) causes of abdominal pain (e.g., diverticulitis,

appendicitis). CT findings (segmental wall thickening, mucosal thumbprinting, and pericolonic fat stranding) are not specific enough to differentiate colon ischemia from other causes of colitis such as diverticulitis, infectious colitis, or inflammatory bowel disease.

Colonoscopy should be performed within 48 hours of presentation. On endoscopic examination, the colonic mucosa will appear erythematous, edematous, and friable. Mucosal ulcerations may also be present. In instances of gangrene, the bowel wall will appear dusky with blue-black nodules.[126,127] The mucosa should be biopsied except in instances of gangrene. Patients with peritonitis or evidence of irreversible ischemic injury should not undergo colonoscopy.

Most cases of colon ischemia resolve spontaneously without diagnosis or specific treatment. Patients with more significant clinical findings require hospitalization for general supportive measures including fasting, intravenous fluid resuscitation, and broad-spectrum antibiotics. Patients with rectal bleeding usually respond to medical treatment alone. Surgical management is required in about 14% of patients.[131] The most common indications for surgery are peritonitis, clinical deterioration, fulminant colitis, or other evidence of necrotic bowel. The mortality rate for patients needing operative management is 37% to 47%.[126]

Inflammatory Bowel Disease

Clinically significant GI bleeding is rare in patients with inflammatory bowel disease. Overt GI bleeding is more common in patients with Crohn disease (1.2%) than ulcerative colitis (0.1%).[132] In patients with Crohn disease, the site of bleeding is equally distributed between the small bowel, ileocolonic region, and the colon. Severe bleeding from ulcerative colitis is usually caused by pancolitis.[132,133] There are no specific clinical or epidemiologic factors predictive of severe bleeding in patients with either Crohn disease or ulcerative colitis.

Colonoscopy will identify the site of bleeding in 60% to 80% of cases. In most instances, the bleeding originates from diffuse areas of active inflammation or ulcerations.[132–134] Most patients respond favorably to fluid resuscitation and medical treatment of their disease (89%) although recurrent bleeding is common (26%). Relatively few of these lesions are amenable to

endoscopic therapy (10% to 15%).[132,133] The need for surgical treatment for initial control of the bleeding or for recurrent bleeding is common in patients bleeding from Crohn disease (20%) and uncommon for patients with ulcerative colitis.[132,134] The clinical presentation, diagnostic evaluation, and management of complications of inflammatory bowel disease are discussed in Chapters 49 and 65.

Infectious Colitis

Overt lower GI bleeding can occur with infections caused by *Campylobacter jejuni*, *Salmonella*, *Shigella*, Shiga toxin–producing *Escherichia coli*, Cytomegalovirus, or *C. difficile*. Diarrhea along with fever and bloody stools suggests an invasive bacterial etiology (e.g., *Salmonella*, *Shigella*, *Campylobacter*, Shiga toxin–producing *E. coli),* enteric viruses (e.g., Cytomegalovirus), or a cytotoxic organism such as *C. difficile*. Immunocompromised patients, such as those receiving chemotherapy or immunosuppressants, are particularly susceptible to Cytomegalovirus colitis. Treatment consists of fluid resuscitation and targeted antibiotics or antiviral agents.

MID-GASTROINTESTINAL BLEEDING

Five percent to 10% of patients with overt GI bleeding will be bleeding from lesions in the small intestine. The bleeding is vascular (24%), inflammatory (16% to 18%), or neoplastic (11%) in etiology.[2] Recurrent bleeding is common, occurring in about one-third of patients.[135] The differential diagnosis is strongly influenced by the patient's age and medical history. Patients under the age of 40 years are more likely to be bleeding from Crohn disease or a Meckel diverticulum, whereas patients older than 40 years are more likely to be bleeding from angioectasias and NSAID ulcers. A history of a bleeding diathesis (such as von Willebrand disease), medication usage (such as ASA, NSAIDs, anticoagulants, and other antiplatelet agents), valvular heart disease, chronic renal failure, and cirrhosis are important risk factors for small bowel bleeding.[2,136]

Angioectasia

Vascular lesions of the GI tract may be classified into three broad categories: (1) vascular tumors, which may be benign (e.g., hemangioma) or malignant (e.g., Kaposi sarcoma, angiosarcoma), (2) vascular anomalies associated with congenital or systemic diseases (e.g., Klippel–Trenaunay–Weber syndrome, hereditary hemorrhagic telangiectasias), and (3) acquired and sporadic lesions (e.g., angioectasias, gastric antral vascular ectasias, radiation-induced vascular ectasias, and Dieulafoy lesions).

Angioectasias are the most common vascular abnormality of the GI tract. They are characterized by abnormal, ectatic, dilated, tortuous, and usually small blood vessels located within the mucosa and submucosa of the GI tract. The affected vessels are lined by vascular endothelium with little or no smooth muscle. There is no associated inflammation or fibrosis. They are most commonly located in the jejunum (80%) followed by the duodenum (51%), stomach (23%), and right colon (11%). Sixty percent of patients with angioectasias will have lesions in multiple sites within the GI tract.[137]

Most angioectasias are asymptomatic and discovered incidentally during endoscopy for other indications. For example, Fouch et al. reported finding angioectasias in 8 of 964 healthy, asymptomatic patients undergoing screening colonoscopy for colon cancer. None of these patients bled from these lesions when followed for 3 years.[138] Most symptomatic patients present with clinical evidence of chronic well-compensated occult blood loss. Patients with overt GI bleeding may present with hematemesis, melena, or hematochezia depending on the location of the lesion and the intensity of the hemorrhage. Most patients with angioectasias are 60 years of age or older. Risk factors include advanced age, chronic renal disease, and cardiovascular disease.[137] Bleeding from angioectasias in patients with aortic stenosis, termed Heyde syndrome, is postulated to result from an acquired von Willebrand factor deficiency.[8]

VCE is the preferred first-line diagnostic test for patients suspected to be bleeding from the small bowel. Patients with active bleeding on VCE are treated with endoscopic hemostasis using DAE and argon plasma coagulation.[2,58,59] Unfortunately, recurrent bleeding is common (34% to 45%). Risk factors for recurrent bleeding include the number of vascular lesions, age over 65 years, presence of lesions in the jejunum, cardiac

valvular disease, chronic renal disease, use of anticoagulants, and the need for transfusion.[139]

A number of medical treatments have been proposed for patients bleeding from angioectasias. Octreotide has been shown to reduce the transfusion requirements of patients bleeding from angioectasias as has low-dose thalidomide.[139–141] Hormonal therapy (estrogen plus progesterone) has been abandoned because of lack of efficacy in randomized controlled trials.

Hemodynamically unstable patients with active bleeding should undergo CT angiography followed by angiographic embolization of the bleeding site. Superselective embolization will control the bleeding in 70% to 80% of cases, with recurrent bleeding in about 12% of cases.[142,143] Surgical management is reserved for those instances in which endoscopic and angiographic hemostasis have been unsuccessful. Laparotomy with intraoperative enteroscopy will identify the site of bleeding in patients with overt hemorrhage and facilitates endoscopic hemostasis.[144] Aortic valve replacement reduces the risk of bleeding from angioectasias in patients with Heyde syndrome.[8]

Meckel Diverticulum

Meckel diverticulum is the most common GI congenital anomaly, occurring in 0.3% to 2.9% of the population.[145] About 4% of Meckel diverticula are symptomatic.[145–148] Symptomatic Meckel diverticula can present at any age but predominantly occur in children and young adults. More than half of all symptomatic patients are younger than 10 years of age[149–151] and most are males (1.5:1 to 4:1).[145,152] Twenty-five percent to 35% of symptomatic patients present with GI bleeding[145,152] in which case it is postulated that heterotopic gastric oxyntic glands located within the Meckel diverticulum cause peptic ulceration of adjacent small bowel mucosa with resulting hemorrhage.

A Meckel scan (pertechnetate scintigraphy) will detect a bleeding Meckel diverticulum with a high degree of accuracy in children (>90%).[67] Unfortunately, the diagnostic accuracy of a Meckel scan in adults is less than 50%.[68] The diagnostic accuracy of balloon-assisted enteroscopy in patients with bleeding Meckel diverticula is 85% to 90%.[68,153] Treatment consists of

resecting the diverticulum with adjacent bowel. Diverticulectomy alone will allow persistence of the ulcer and possibly recurrent bleeding.

Small Bowel Diverticula

Diverticular disease of the small intestine is an uncommon cause of GI bleeding. About 80% of small bowel diverticula are located in the jejunum and multiple diverticula are common (67%). Small bowel diverticula are pseudodiverticula (like colonic diverticula) and may be complicated by diverticulitis, obstruction, and bleeding. The pathogenesis of bleeding is the same as that of colonic diverticula with erosion of a vasum rectum through the diverticular wall with the acute onset of massive hemorrhage.

Patients present with hematemesis, melena, or hematochezia depending on the location of the diverticulum and the intensity of bleeding. CT angiography will localize the site of bleeding in actively bleeding patients and DAE or visceral angiography will facilitate endoscopic hemostasis or selective microembolization, respectively. Surgical resection of the involved bowel is the treatment of choice in those instances in which endoscopic hemostasis or angiographic embolization is unavailable or has been unsuccessful.

Aortoenteric Fistula

Although communication between the aorta and the intestine may occur as a result of aneurysmal disease or infectious aortitis (*primary aortoenteric fistula*), most aortoenteric fistulas result from erosion of an aortic vascular prosthesis through the wall of the distal duodenum (*secondary aortoenteric fistula*). The incidence of aortoenteric fistula following aortic reconstructive surgery is about 1% with most of these fistulas arising from the proximal graft anastomosis. This may occur after open or endovascular aortic procedures.

Patients may present with massive GI hemorrhage and exsanguination. Others may have an initial episode of GI bleeding (i.e., herald bleed) that is followed in hours, days, or weeks by catastrophic hemorrhage. Patients may also complain of back or abdominal pain and less commonly have fever or signs of sepsis from infection of the graft.

The diagnosis of an aortoenteric fistula must be considered in any patient with an aortic prosthesis or an abdominal aortic aneurysm who presents with GI hemorrhage. If the patient is hemodynamically stable, the initial diagnostic study should be CT angiography. This test may demonstrate evidence of an aortoenteric fistula such as perigraft infection. If CT angiography is negative or nondiagnostic, EGD should be urgently performed to identify evidence of the aortoenteric fistula (such as the blood, clot or graft material in the distal duodenum) or another cause of bleeding, such as peptic ulcer disease. Care should be taken to avoid dislodging fresh thrombus in the distal duodenum as it can induce massive hemorrhage. In patients who are actively bleeding, exploratory laparotomy with exposure of the proximal graft should be undertaken. Identification of an aortoenteric fistula requires repair of the duodenal wall and resection of the graft with aortic reconstruction or extra-anatomical bypass. The complications of abdominal aortic operations including aortoduodenal fistulas and their management are discussed in Chapter 94.

Gastrointestinal Stromal Tumors

Gastrointestinal stromal tumors (GISTs) are infrequent causes of overt GI bleeding. These tumors occur most commonly in the stomach (36%) and small intestine (18%), but may be found anywhere within the GI tract. The age-adjusted incidence of GISTs is 0.7 to 1.2 cases per 100,000 population per year. The median age of patients with a GIST is 65 years with a slight predominance in females (M/F ratio = 0.8). Most GISTs (97%) are sporadic and associated with a mutation of the C-kit (71%) or platelet-derived growth factor receptor alpha (15%) gene.[154]

GI bleeding is a common and important clinical manifestation of GISTs.[155,156] About one-third of patients with GISTs will present with evidence of GI bleeding such as hematemesis, hematochezia, or the passage of melena. Fewer patients will present only with occult blood loss, for example, iron-deficiency anemia or a positive fecal occult blood test.[156,157] CT (e.g., CT angiography, CT enterography) or endoscopy (e.g., EGD, VCE, DAE, colonoscopy) is diagnostic in the majority of cases. The specific diagnostic modality depends upon the suspected site and magnitude of hemorrhage.

The treatment of choice for patients bleeding from a GIST is surgical resection with a 1- to 2-cm macroscopically normal margin. Postoperative tyrosine kinase inhibitor therapy with imatinib is useful for patients at high risk of recurrence. The molecular biology, clinical presentation, and management of patients with a GIST are discussed in detail in Chapter 50.

Ulcerative Colitis

Aaron J. Dawes and Arden M. Morris

Key Points

1. Ulcerative colitis (UC) is a form of inflammatory bowel disease (IBD) characterized by mucosal and submucosa inflammation of the colon and rectum. This process is continuous and homogenous, beginning in the rectum, and extending proximally for a variable distance.
2. The acute indications for surgical intervention include fulminant disease, toxic megacolon, and uncontrolled bleeding. Failure of medical management, dysplasia, and cancer are indications for elective surgery.
3. Intestinal and some extraintestinal manifestations of UC can be cured by complete removal of the colon and rectum.
4. Current surgical options depend on the acuity of presentation of the disease; minimally invasive methods should be employed when clinically indicated and technically feasible.
5. Ileal pouch-anal anastomosis (IPAA) can provide patients with a continent reservoir for stool; however, permanent end ileostomy remains a viable option for patients who do not qualify or do not wish to undergo pouch construction.
6. Although perioperative and late complications after IPAA are common, the vast majority of patients enjoy a high quality of life after surgery.

INTRODUCTION

Ulcerative colitis (UC) is a nonspecific and idiopathic inflammatory bowel disease (IBD) affecting nearly 600,000 Americans of both sexes and all ages groups, although peak onset occurs between the second and fourth decade of life.[1] Unlike Crohn disease (CD)—a related, but distinct entity affecting the entire gastrointestinal (GI) tract—UC primarily affects the mucosa and submucosa of the colon and rectum through recurrent episodes of inflammation, ulceration, and healing. While chronic UC increasingly has

been managed successfully via medical and biologic therapy, surgery continues to play a role in the treatment of acute severe disease, medically refractory disease, dysplasia, and cancer.

EPIDEMIOLOGY

Although the exact incidence and prevalence of UC remains difficult to determine due to its relative infrequency and the fact that mild cases might never be reported, several trends have emerged. First, the disease appears to demonstrate a North/South gradient, with the highest incidence and the prevalence occurring in northern Europe (24.3 per 100,000 person-years and 505 per 100,000 people) and Canada (19.2 per 100,000 person-years and 248 per 100,000 people) and the lowest in Asia and the Middle East.[2–4] American estimates indicate a slightly lower prevalence than Europe or Canada, ranging from 214 to 238 per 100,000 people.[5,6] Second, despite slightly higher rates of CD among women, there appears to be no sexual predominance in UC.[2,6] Third, the age-specific incidence of UC appears to be bimodal with the largest peak between 15 and 40 years old followed by a separate, smaller peak at 50 to 75 years old (**Fig. 66.1**).[6,7] Finally, after a steady increase throughout the industrialized world over the last 20 years, both the incidence and prevalence of UC appear to have stabilized in North America and Europe, with continued growth being limited to newly industrialized areas in Africa, Asia, and South America.[3,8]

ETIOLOGY AND RISK FACTORS

The etiology of UC remains unknown. Extensive investigations have failed to isolate a specific gene, environmental exposure, or immunologic dysfunction.[9] Instead, the origin is believed to be multifactorial. That is, patients are born with an underlying genetic predisposition that is activated via the interaction or dysregulation of a variety of environmental and microbial risk factors.

Genetics

Familial clustering has been identified since the earliest descriptions of UC. Between 10% and 20% of UC patients have at least one other family member with IBD, particularly UC as opposed to CD, further suggesting the two diseases represent separate clinical entities.[10] Interestingly, parent–child and sibling–sibling pairings appear to be more common than pairings involving more distant relatives despite no clear Mendelian inheritance pattern.[11] Monozygotic twin concordance varies, but has been reported to be between 10% and 19%.[12–14] In addition, certain ethnic groups, particularly Ashkenazi Jewish populations, have significantly higher rates of UC compared to geographic controls.[15] Overall, first-degree relatives of a patients with UC have a four-fold increase in their risk of developing the disease.[16]

Over 200 separate gene loci have been associated with an increased risk of developing IBD. The vast majority are located in genes involved in inflammatory signaling or mucosal barrier function and confer a risk for both UC and CD, although several disease-specific relationships have been identified.[17–19] For example, certain human leukocyte antigen haplotypes and alteration in cell–cell junction signaling appear to be more associated with UC than CD.[20–22] However, currently identified genetic features explain only 7.5% of disease variance in UC and do not reliably predict disease activity.[23,24]

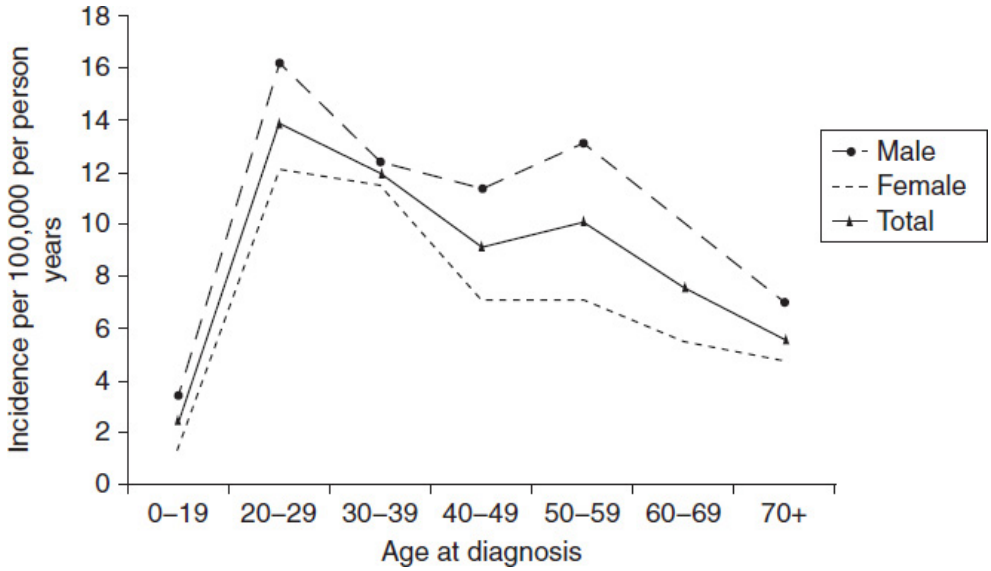

Figure 66.1 Age-specific incidence of UC in Midwestern U.S. population. (Adapted from Loftus CG, Loftus EV Jr, Harmsen WS, et al. Update on the incidence and prevalence of Crohn's disease and ulcerative colitis in Olmsted County, Minnesota, 1940–2000. *Inflamm Bowel Dis* 2007;13[3]:254–261.)

Environment

Although none have proven causal, multiple environmental exposures have been associated with a higher incidence of UC. Diets high in fats, meats, and refined sugar or low in vegetables appear to be associated with an increased risk of developing UC.[25–28] There is some evidence that breast feeding is protective against the development of both UC and CD, including a dose-dependent response with the lowest rates among children who were breastfed for at least 12 months compared to 3 or 6 months.[29]

Exposure to microorganisms and antibiotics also appears to play some role given that both the temporal and geographic incidence of IBD parallel trends in urbanization.[30] The odds of developing IBD are 2.9 times higher among children exposed to antibiotics within their first year of life and 2.8 times higher among children treated at least once for otitis media between 2 and 5 years old.[31,32] Whether the trigger is the exposure to a pathogenic bacteria or the lack of exposure to normal, nonpathogenic bacteria that promote immune regulation—the so-called "hygiene hypothesis"—remains unknown.[33]

Cigarette smoking plays a complex role in the development of IBD. In contrast to CD, active smokers have a lower incidence of UC than nonsmokers. Former smokers, however, are at higher risk than individuals who have never smoked.[34–36] The apparent protective effect of smoking extends to some of the extraintestinal manifestations of UC, in particular lower rates of primary sclerosing cholangitis (PSC).[37,38] Interestingly, appendectomy also appears to be protective against developing UC, with up to a 30% to 45% risk reduction in large, retrospective studies.[39–43] Although the mechanism remains unknown, some have suggested that responding to an inflammatory process like appendicitis stimulates the immune system to perform self-regulatory functions that prevent the inappropriate inflammatory cascade that characterizes UC.

Microbiome

The newest line of inquiry into the pathogenesis of IBD involves the influence of the microbiome, both on its own and through its interaction with other risk factors. Animal studies have demonstrated that mice with a genetic susceptibility do not develop colitis if kept in a germ-free environment while healthy mice that are inoculated with microbiota from IBD patients go on to develop colonic inflammation.[44,45] Humans predominantly develop IBD in areas of the body with high bacterial loads (colon) and fecal stasis (terminal ileum and rectum).[30] Moreover, fecal diversion, the use of antibiotics, and even fecal microbial transplantation have been associated with disease remission in select UC patients.[46–49]

In addition, the microbiome appears to mediate the influence of other epidemiologic risk factors. Patients with defects in NOD2, the gene encoding an intracellular pattern recognition receptor that interacts with bacterial peptidoglycan, appear to have both higher levels of proinflammatory bacteria and a more aggressive phenotype of CD.[50–52] Breast milk contains anti-inflammatory microbiota as well as prebiotic oligosaccharides that promote immune tolerance. Similarly, cigarette smokers have more proinflammatory and less anti-inflammatory bacteria in their gut lumen when compared to nonsmokers and there is some evidence of normalization upon smoking cessation.[53]

CLINICAL FEATURES

UC symptoms are dynamic and typically parallel the severity of disease. Inflammation classically begins in the rectum and extends proximally in a homogenous and continuous fashion. The degree of colonic involvement is variable, ranging from the rectum alone (proctitis) to the rectosigmoid (proctosigmoiditis) to the entire colon and rectum (pancolitis) in approximately 20% of patients.[54] Unlike in CD, the small intestine is spared, aside from the final few inches of the terminal ileum, which can experience a reversible "backwash ileitis" from the reflux of diarrheal stool (**Table 66.1**). Heterogenous inflammation, rectal sparing, and significant ileal or proximal small bowel disease raise the possibility of CD and require further evaluation.

The classic symptoms of UC are diarrhea and rectal bleeding, although patients may present anywhere along the spectrum from chronic low-grade disease to fulminant colitis. The diarrhea is typically small volume, consisting of mostly blood and mucus, and can be as frequent as every 1 to 2 hours. Paradoxically, patients with isolated rectosigmoid disease may experience constipation and incomplete evacuation (tenesmus) as a result of rectal spasm.[24] The bleeding is also typically a slow, low-volume ooze from diseased mucosa rather than the massive hemorrhage that can be seen with vessel injury. Many patients experience diffuse, crampy abdominal pain, especially in the left lower quadrant, that is relieved or improved by defecation.[55] Persistent or severe pain is uncommon and should raise concern for severe disease with inflammation extending to the serosa.[56]

Disease severity is typically calculated using the Mayo Clinic Score, although other scales exist (**Table 66.2**).[57] Worsening abdominal distention along with signs of systemic involvement, including fever, tachycardia, and leukocytosis, are worrisome for fulminant colitis or toxic megacolon and require immediate surgical evaluation. Chronic signs of illness, including weight loss, fatigue, anemia, and anorexia, must be identified and addressed as a part of a comprehensive treatment plan, ideally prior to any surgical intervention, if possible.

Table 66.1 Clinicopathologic Features of Ulcerative Colitis versus Crohn Disease

Common Clinicopathologic Characteristics of IBD		
Manifestation	**UC**	**CD**
Bleeding	Common	Rare
Crypt abscesses	Common	Rare
Rectal involvement	Common	Rare
Small bowel involvement	Rare	Common
Transmural inflammation	Rare	Common
Bowel wall fissures	Rare	Common
Fibrosis	Rare	Common
Fistulas	Rare	Common
Perianal disease	Rare	Common
Ulcers	Rare	Common
Cobblestoning	None	Common
Pattern of involvement	Continuous, distal to proximal, mucosal	Skip lesions, transmural

Table 66.2 The Mayo Clinic Score

Stool Frequency (3-day average)
(Total number of stools/day)
0 = Normal number of stools for this patient
1 = 1–2 stools/d more than normal for this patient
2 = 3–4 stools/d more than normal for this patient
3 = >5 stools/d more than normal for this patient

Rectal Bleeding (3-day average)
0 = No blood seen
1 = Streaks of blood with <50% of stools
2 = Obvious blood seen with >50% of stools
3 = Blood alone passed

Physician's Global Assessment (PGA)
0 = Normal
1 = Mild disease
2 = Moderate disease
3 = Severe disease

Finding of Flexible Proctosigmoidoscopy (Endoscopic Subscore)
0 = Normal or inactive disease
1 = Mild disease (erythema, decreased vascular pattern, mild friability)
2 = Moderate disease (marked erythema, absent vascular pattern, friability, erosions)
3 = Severe disease (spontaneous bleeding, ulceration)

Table 66.3 Extraintestinal Manifestations of UC by Disease Activity

Parallel Disease Activity	Independent of Disease Activity	Variable Course
Erythema nodosum	Polyarticular peripheral arthritis/arthropathies	Primary sclerosis cholangitis
Pauciarticular peripheral arthritis/arthropathies	Axial arthropathies (sacroiliitis, ankylosing spondylitis)	Pyoderma gangrenosum
Acute synovitis	Uveitis/iritis	
Episcleritis	Aphthous ulceration	

Adapted from Vavricka SR, Schoepfer A, Scharl M, et al. Extraintestinal manifestations of inflammatory bowel disease. *Inflamm Bowel Dis* 2015;21(8):1982–1992.

Extraintestinal Disease

Hepatobiliary

Asymptomatic transaminitis is the most common hepatobiliary abnormality in UC, affecting nearly 50% of patients. Although much less common—occurring in only 3% to 7% of UC patients—PSC is the most feared hepatobiliary manifestation of UC since there is no effective medical therapy short of liver transplantation.[58,59] PSC is independent of colonic disease activity, may precede colonic symptoms of UC by up to 7 years, and persists even after proctocolectomy (**Table 66.3**). In addition, PSC patients are at four to five times higher risk of developing colorectal cancer than patients with UC alone; as such, they require more intensive endoscopic surveillance.[60]

Cutaneous

Erythema nodosum is the most common cutaneous manifestation of IBD, occurring in 10% to 15% of cases.[61] Patients develop tender, raised, and red-violet nodules in their subcutaneous tissue that represent

lymphohistocytic infiltrates responding to an unknown antigen. The number and severity of lesions tightly parallels colonic disease activity and persistence can be interpreted as a sign of inadequate disease control.[62] Pyoderma gangrenosum occurs less frequently, but is more difficult to treat and does not reliably parallel disease activity. Lesions begin as erythematous plaques in the pretibial region, but progress into ulcerative, painful wounds with ragged borders (**Fig. 66.2**). Topical or intralesional steroids, topical tacrolimus, and systemic tumor necrosis factor-alpha (TNF-α) antagonists produce some response, although aggressive wound care is essential to healing.[63,64] Peristomal lesions can be particularly difficult to treat. Although occasionally necessary, re-siting should be performed with caution as lesions are known to recur at the new stoma site.[65]

Musculoskeletal

Peripheral and axial arthropathies occur in a minority of UC patients, but can be particularly debilitating.[66] Pauciarticular peripheral arthritis is acute and parallels colonic disease activity while polyarticular disease persists and follows an independent course.[67] Patients with a family history and the HLA-B27 haplotype are at higher risk of developing axial disease, including sacroiliitis and ankylosing spondylitis, which can unfortunately progress to significant disability. NSAIDs and exercise programs remain the mainstays of management, although anti-TNF and, more recently, anti-IL-17 agents appear to provide some relief in severe cases.[68,69]

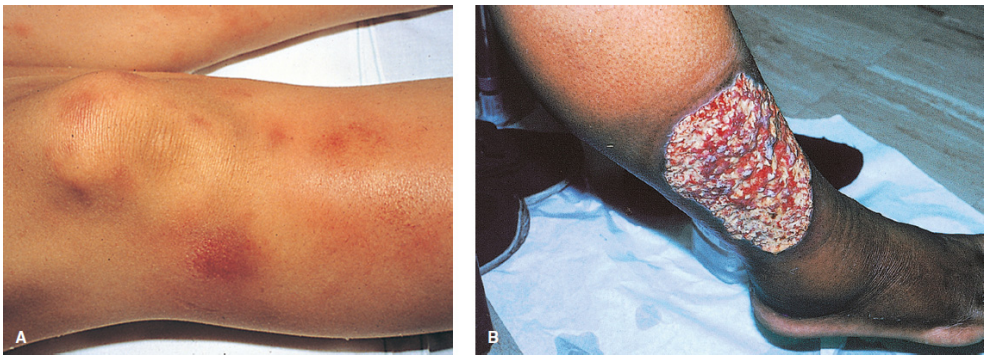

Figure 66.2 **A:** Erythema nodosum. **B:** Pyoderma gangrenosum. (Reproduced with permission from Goodheart HP. *A Photoguide of Common Skin Disorders: Diagnosis and Management*. Baltimore, MD: Lippincott Williams & Wilkins; 1999.)

Ophthalmologic

Although UC patients frequently report ophthalmologic symptoms, fewer than 10% actually develop ocular inflammation, including, episcleritis, iritis, and uveitis.[70,71] Episcleritis is the most common and is characterized by redness without vision changes. Both iritis and uveitis are less common, but can produce pain, blurry vision, and eventually blindness if not treated promptly with steroids or immunomodulatory medications.[72]

DIAGNOSIS

Physical examination is often nonspecific, although worsening abdominal distention and generalized abdominal pain are often indicators of severe disease. As with other septic conditions, the triad of tachycardia, fever, and leukocytosis suggests systemic toxicity and should prompt rapid resuscitation and surgical evaluation.

Laboratory Testing

There is no specific diagnostic test for UC. In the acute setting, a complete blood count will evaluate for systemic toxicity and anemia. Serum albumin and prealbumin provide a measure of protein loss and malnutrition. Erythrocyte sedimentation rate or C-reactive protein levels can be drawn and followed as markers of disease activity. Stool studies and a *Clostridium difficile* assay should be sent to rule out bacterial and parasitic infections.

Calprotectin, a calcium-binding protein expressed by neutrophils, can be measured in the stool as a marker of colonic mucosal inflammation. Meta-analyses report an 80% to 95% sensitivity and a 76% to 96% specificity for distinguishing IBD from non-IBD diagnoses, including patients with irritable bowel syndrome.[73–75] In fact, patients with levels of <50 μg/g have only a 1% to 4% chance of having IBD. Fecal calprotectin levels also appear to correlate with endoscopic findings, degree of mucosal healing, and risk of relapse at 3 and 6 months.[76]

Serum antibodies, such as anti–*Saccharomyces cerevisiae* antibody (ASCA) and atypical perinuclear antineutrophil cytoplasmic antibody

(pANCA), are often elevated in IBD, but do not reliably distinguish UC from CD or predict disease activity in UC, although ASCA+ may be a marker for complex disease in CD. Patients who are ASCA+/pANCA−have the highest positive predictive value for UC (77% to 95%), although the sensitivity for this combination is only 30% to 38%.[77]

Imaging

Conventional x-rays are quick and can be useful in the rare case of frank perforation or toxic megacolon. Classically, barium enema was performed in the diagnosis of chronic UC, although it has largely been replaced by more modern imaging modalities. Colonic foreshortening, loss of haustral markings, and linear, "collar button ulcers" are signs of long-standing colonic inflammation (**Fig. 66.3**).

Computed tomography (CT) of the abdomen and pelvis with IV and occasionally oral and/or rectal contrast has become the technique of choice in evaluating acute disease. CT can be obtained rapidly, can demonstrate the extent and severity of inflammation, and can rule out extraintestinal air or other signs of perforation.

Magnetic resonance imaging (MRI), especially specialized enterographic protocols involving biphasic oral contrast agents (magnetic resonance enterography; MRE), is often used for evaluating chronic disease (**Fig. 66.4**).[78]

Both MRE and its CT equivalent (CTE) can document both intra- and extramucosal disease activity, including the presence of fistulae, phlegmons, masses, or abscesses that might suggest a disease process other than UC.[79] Importantly, MRE and CTE are both 90% to 95% sensitive for small bowel CD, a diagnosis that must be excluded, if at all possible, prior to any elective surgical intervention.[80,81] MRI has the advantage of limiting ionizing radiation exposure, which can benefit younger patients who may require multiple imaging studies over their lifetime.

Endoscopy

Endoscopy with biopsies remains the gold standard for the diagnosis of UC. Limited evaluation with flexible sigmoidoscopy or rigid proctoscopy is often sufficient given the near universal involvement of the rectum and may be safer in the setting of acute inflammation when full colonoscopy may pose an increased risk of perforation. Mucosal inflammation is typically graded on the Mayo Endoscopic Subscore, a component of the Mayo Score (**Table 66.3**), which has shown strong correlation with microscopic findings and good interrater reliability.[82–84] Biopsies should also be taken to confirm histologic evidence of IBD, rule out concomitant cytomegalovirus (CMV) infection, and evaluate for dysplasia.

Surveillance and management of dysplasia in IBD has evolved in recent years. In short, surveillance colonoscopy should begin within 8 to 10 years of the onset of symptoms and should be performed every 1 to 2 years. Patients with a family history of colorectal cancer or PSC should be surveilled more frequently.[85] At least 32 random biopsies must be performed throughout the colon—typically eight each in the right, transverse, left, and sigmoid colon—to achieve a 90% sensitivity for ruling out dysplasia.[86] Any polyps that are discovered should be removed endoscopically, if possible, and biopsies should be taken of the surrounding tissue to rule out persistent dysplasia.[87]

Pathology

Macroscopic Appearance

UC starts in the rectum and progresses proximally in a continuous fashion, with the most severe inflammation typically occurring in the most distal regions (**Fig. 66.5**). Inflamed mucosa generally appears granular, friable, and congested when viewed endoscopically. This pattern can dissipate either gradually or abruptly as one moves proximally, but is never interrupted by areas of normal mucosa ("skip lesions"). Rectal mucosa in UC may be "burned out" or may demonstrate local treatment effect, but it is never spared, as in seen in CD.

Ulcers, superficial fissures, and pseudopolyps may be present in more severely inflamed areas, however, unlike in CD, fibrosis and strictures are uncommon (**Table 66.2**). In fact, the presence of stricturing disease in

suspected UC should raise concern for malignancy until proven otherwise, especially if symptomatic, proximal to the splenic flexure, or late in the course of the disease.[88] The presence of fistulizing disease indicates CD rather than UC.

Microscopic Appearance

Histology should confirm evidence of both colitis and chronicity. Biopsies demonstrate inflammation, including neutrophils within the surface epithelium, lamina propria, and crypts. Although inflammation in UC is traditionally confined to the mucosa and submucosa, the colon wall can be inflamed transmurally in the setting of acute severe disease, mimicking CD. Neutrophilic infiltration of the crypts ("cryptitis") can lead to aggregation ("crypt abscesses") and eventually ulceration (**Table 66.2**). As these findings are also present in acute non-IBD colitis, additional evidence of chronicity (irregularities in crypt size, shape, and spacing) or regeneration (mucin depletion, hyperchromatic nuclei, Paneth cell metaplasia) is required to make the diagnosis of UC.

Differential Diagnosis

Bloody diarrhea is a hallmark of acute colitis from any etiology. Infectious sources, such as *C. difficile,* Campylobacter, Salmonella, *Escherichia coli* 0157:H7, and Entamoeba, should specifically be excluded via stool studies. Biopsies should be tested for CMV, regardless of whether an underlying diagnosis of IBD is made. Persistent diarrhea with a normal or relatively normal colonoscopy warrants biopsies to rule out microscopic colitis. Segmental inflammation may be due to ischemic colitis (splenic flexure or rectosigmoid) or diverticular disease (sigmoid colon).

In nearly 10% of the cases, it is impossible to definitively classify the source of the colitis. Over time, a portion of these cases will declare themselves as either CD or UC, while others will remain indeterminate, especially if the serologic assessment is inconclusive.[89] As has been mentioned throughout, distinguishing UC from CD can be a challenge, particularly in the setting of CD colitis (25% of CD cases).[90] Upper GI symptoms, small bowel involvement, perianal disease, and patchy colonic

involvement should elicit some pause before proceeding with definitive surgical interventions.

MANAGEMENT

Medical Management

Medical therapy for UC is separated by disease severity. In general, patients with mild-to-moderate colitis are treated in the outpatient setting with oral and/or rectal medications while patients with fever, tachycardia, or significant abdominal tenderness are admitted to the hospital for intravenous resuscitation and steroids. All treatment regimens have the same goals, regardless of the medications used: induction of clinical remission with improvement or elimination in symptoms, promotion of mucosal healing ("endoscopic remission"), maintenance of steroid-free remission, and prevention of complications and, where possible, colectomy.

Mild-to-Moderate Colitis

Aminosalicylates continue to be the first-line treatment of mild UC and can be used both for induction and maintenance of remission.[91] Mesalamine (5-ASA) is the active compound, but is metabolized by proximal intestinal cells and requires either specialized coating or azo bonding to another compound to reach more distal disease. Alternatively, oral and rectal preparation can be used concomitantly.[92] Noncompliance with 5-ASA maintenance therapy is associated with a five-fold increase in disease recurrence.[93] Occasionally, budesonide, a topical corticosteroid, is required to help achieve remission, however, it appears to be less effective as monotherapy than 5-ASA alone and is typically weaned in favor of other immunomodulatory medications during maintenance.[94,95]

Moderate-to-Severe Colitis

Patients with more severe disease (Mayo Clinic Score 6–12 with Mayo Endoscopic Subscore 2–3) are at higher risk of failure, recurrence, and colectomy, if remission cannot be achieved and maintained medically. Younger patients (<40 years old), more extensive disease, deep ulcers on

endoscopy, steroid dependence, and infection with either *C. difficile* or CMV have all been identified as predictors of increased 3-month colectomy rates.[96–100] Although the evidence is limited, experts have moved toward recommending more aggressive upfront treatment in moderate-to-severe disease rather than waiting to start immunomodulatory medications or biologics until after a patient has failed 5-ASA.[101] This shift in management partially reflects increasing evidence for "top-down" as opposed to "step-up" medical management in CD, but also the lack of evidence for 5-ASA in severe UC and the concern that any delay in achieving remission may increase both the likelihood and risks of surgery due to prolonged inflammation and progressive physiologic decline.

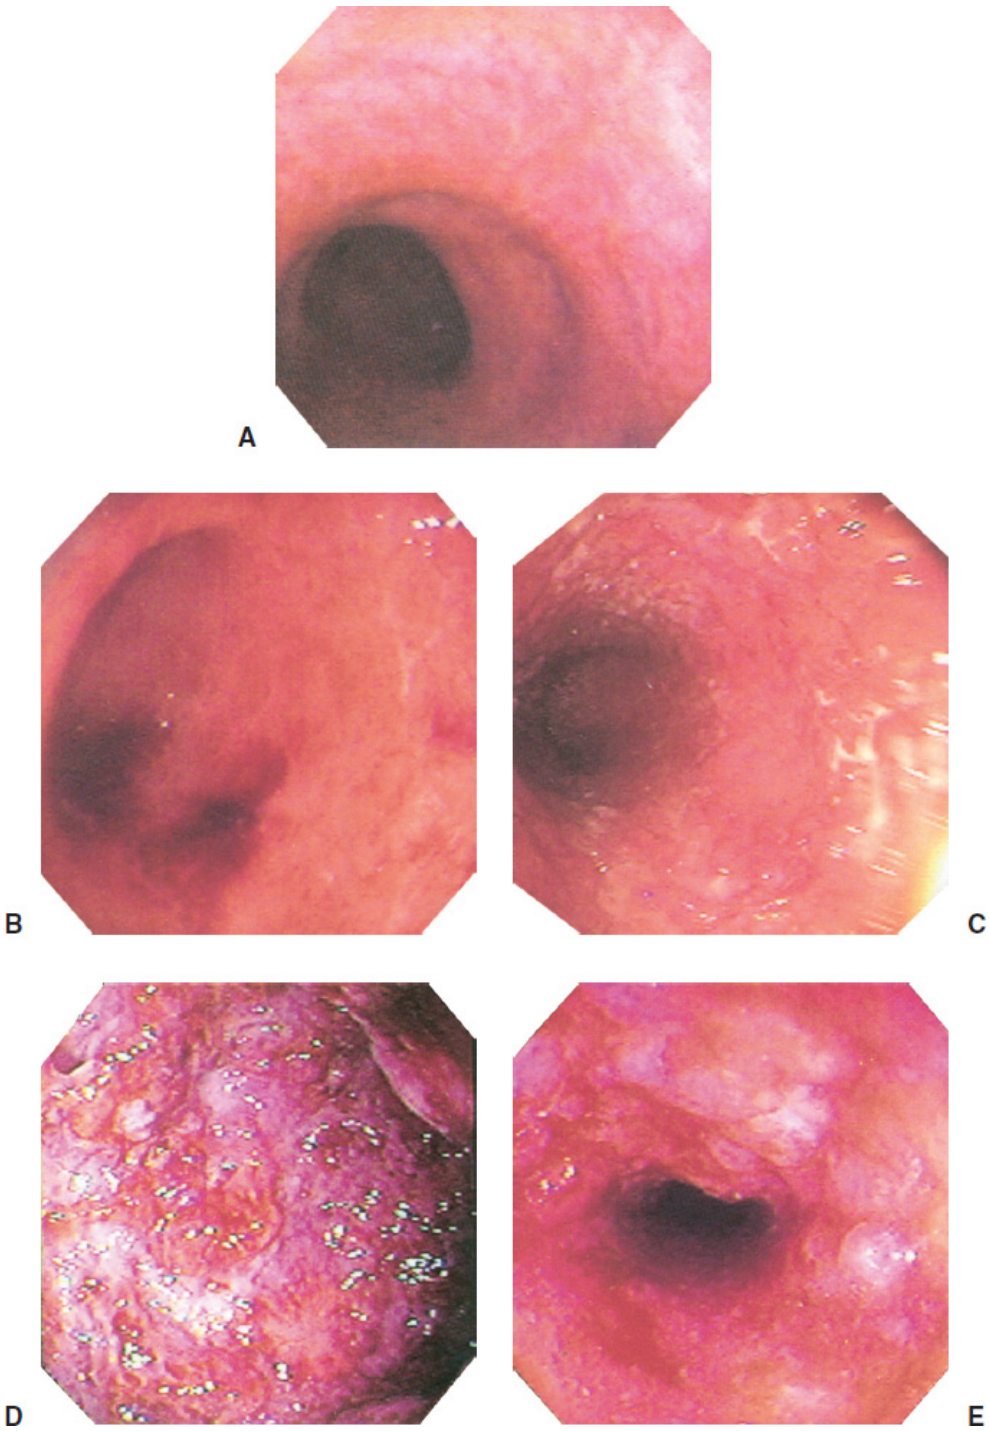

Figure 66.5 UC endoscopic findings with (**A**) Loss of normal vascular pattern. **B:** Contact bleeding. **C:** Granularity. **D:** Ulceration and friability. **E:** Colonic stricture. (Reproduced with permission from Corman ML. *Colon and Rectal Surgery*. 5th ed. Philadelphia, PA: Lippincott Williams & Wilkins; 2005.)

Corticosteroids remain the primary treatment of acute UC flares, with remission rates approaching 70%.[102,103] In the outpatient setting, oral

prednisone doses of 40 mg or higher per day are common and are typically followed by either a short or more prolonged taper as symptoms improve and other medications are introduced. Overall, the use of corticosteroids has decreased in recent years, largely due to the increase in the number and effectiveness of available biologic agents. Corticosteroids should not be used for maintenance of remission due to their side-effect profile, including osteoporosis, diabetes, glaucoma, and an increased risk of infection, among others. In fact, long-term corticosteroids use in IBD is associated with an increase in mortality.[104]

Thiopurines, including 6-mercaptopurine and its prodrug azathioprine, have been used extensively in the treatment of moderate-to-severe UC, however, their slow onset of action makes them more appropriate for maintenance therapy than for induction. In fact, azathioprine was found to be superior to 5-ASA in maintenance of remission and may be equivalent to some biologics, although no head-to-head trials exist.[105] Skin cancers, lymphoma, and severe infections have been reported with the use of these medications.[106,107] Liver enzyme elevations, pancreatitis, and cholestasis have also been seen, although the most commonly reported side effects are headaches, hypersensitivity, and abdominal pain.

Infliximab, a chimeric mouse–human monoclonal antibody targeting TNF-α, was approved for the treatment of CD in 1988 and shortly afterward for UC. Infliximab successfully induced remission in over 60% of patients in the ACT 1 and 2 trials and significantly increases the likelihood of mucosal healing on endoscopy.[108,109] Extended follow-up has demonstrated that 15% of patients who initially respond to infliximab subsequently have to discontinue therapy due to side effects or loss of efficacy.[110] Newer TNF-α antagonists, including adalimumab, certolizumab, and golimumab, have also been shown to induce and maintain remission in UC, although none seem as effective at inducing remission as infliximab.[108,111,112] Vedolizumab, a monoclonal antibody targeting integrin α4β7, prevents neutrophilic translocation in intestinal capillaries, thereby modulating the immune response in a gut-specific fashion. In head-to-head trials, vedolizumab was more successful than adalimumab at inducing clinical remission, at least among biologic naïve patients.[113] There was no difference among patients who had previously been treated with a TNF-α antagonist. Based on this evidence, the American Gastroenterological Association recommends initial

biologic treatment with either infliximab or vedolizumab followed by ustekinumab, a monoclonal antibody targeting IL-12 and IL-23, in primary nonresponders.[101]

Overall, biologic agents are well tolerated. Infection, including reactivation of dormant mycobacterial and fungal infections, as well as certain autoimmune reactions remains a persistent concern.[114–116] The data regarding malignancy risk with anti-TNF agents are mixed, although there appears to be an increased risk of lymphoma.[117] More recently, biologics have been used in combination with either thiopurines or methotrexate as "dual therapy" in order to improve their pharmacokinetics (higher drug levels) and decrease their immunogenicity (lower rates of antidrug antibodies). A multiarmed randomized controlled trial found no difference in corticosteroid-free remission or mucosal healing between azathioprine and infliximab monotherapy, but did find significantly better rates among patients receiving both medications.[118] Patient selection is key, however, as combination therapy also appears to increase the rate of adverse drug reactions.[119]

Acute Severe Colitis

Patients with acute severe colitis require hospitalization for bowel rest, fluid resuscitation, pain control, and intravenous immunosuppression. IV corticosteroids, such as methyl-prednisolone, are first-line therapy with daily doses of 40 to 60 mg or higher being common. There is no evidence to support any particular steroid preparation, dose, or dosing strategy over another. Antibiotics are not required unless there is evidence of perforation.[101] All patients with IBD are at substantively increased risk for venous thromboembolism and should be treated during a flare with prophylactic heparinoids unless contraindicated.

Failure to improve within 48 to 96 hours of appropriate medical therapy should prompt reevaluation with either the addition of a second-line "rescue" medication or surgery. As mentioned previously, infliximab induces remission in roughly 60% of patients and may allow up to 90% of steroid-refractory patients to avoid colectomy in the urgent setting.[120] Cyclosporine can also be used as a second-line medication and may be more effective that steroids alone, however, serial lab draws to determine levels and close

monitoring for toxicity is required.[121] Two randomized controlled trials demonstrated no difference in short-term colectomy rates for steroid-refractory patients treated with infliximab versus cyclosporine.[122,123] Both medications have mean response times of 5 to 7 days, after which surgery should strongly be considered as sequential "rescue" therapy is ineffective.[124]

Surgical evaluation should take place early in the course of the hospitalization to ensure that important discussions regarding the risks and benefits of surgery are not rushed.[125] If available, an enterostomal therapist should also meet with patients to answer questions, discuss stoma care, and begin the adjustment process.

SURGERY

Indications

Approximately 20% to 30% of UC patients will ultimately require surgery.[126,127] While the short-term colectomy rate appears to have decreased in the biologic era,[128] the long-term rate remains roughly the same, suggesting that current medical therapies may be more successful at shifting surgery to an elective setting than at obviating it completely.[120,129] Two population-based studies report conflicting data on changes in the indication for surgery in the biologic era, with one Japanese study finding a relative increase in surgery for dysplasia and cancer while a Finnish study found no significant differences over time.[130,131]

Whether prior exposure to biologics increases the risk of surgery remains somewhat debatable. Daily prednisone doses of >40 mg clearly increase the risk of infection, anastomotic leak, and pelvic sepsis in patients undergoing proctectomy or ileal pouch-anal anastomosis (IPAA).[132] There is mixed evidence with respect to TNF-α antagonists, with some studies finding higher short-term infectious and anastomotic complications while others do not.[133–135] Meta-analyses separating patients by their underlying diagnosis found a trend toward higher postoperative complications for CD patients on anti-TNF-α agents, but not for UC.[136,137] Several experts have postulated that this effect may be moderated by higher drug levels among CD patients and

observational studies appear to demonstrate a dose–response effect.[138] There is no evidence to suggest that vedolizumab exposure increases postoperative complications rates.[139–141] Given the conflicting data, some authors support performing IPAA regardless of biologic exposure while others recommend waiting at least 4 weeks after anti-TNF-α dosing and 4 to 8 weeks after vedolizumab dosing before performing elective surgery.[142,143]

Fulminant Colitis and Toxic Megacolon

Fulminant colitis, as defined by Truelove and Witts, is an aggressive form of acute severe colitis characterized by fever, tachycardia, abdominal tenderness, greater than 10 bloody bowel movements per day, anemia requiring transfusion, elevated erythrocyte sedimentation rate, and colonic dilatation on radiography.[144]

Toxic megacolon occurs when severe colonic inflammation results in dilatation of the transverse colon beyond 6 cm (**Fig. 66.3**). Toxic megacolon is not specific to UC and can occur in the setting of colitis from other sources, including infection and ischemia. Toxic megacolon from UC is seen most often in new diagnoses, but can occur in acute exacerbations of chronic UC. As with fulminant colitis, patients experience severe colonic and systemic inflammation, as demonstrated by high fevers, tachycardia, severe abdominal pain, and leukocytosis or leukopenia.

Aggressive resuscitation and broad-spectrum antibiotics should be started immediately. All opiates and antidiarrheal agents should be discontinued to avoid worsening colonic distention. Steroids should be started as soon as an infectious source is ruled out. Primary nonoperative treatment should not be prolonged due to high risk of perforation and decompensation. In one study, patients experiencing more than eight stools per day or three to eight stools per day with a C-reactive protein >45 mg/mL after 3 days of rescue therapy had an 85% chance of requiring colectomy during their hospitalization.[145] Moreover, early surgical intervention is associated with a decrease in the mortality rate among patients failing medical therapy.[146,147]

Uncontrolled Bleeding

Less than 5% of UC patients have life-threatening GI bleeding. In this rare circumstance, a total abdominal colectomy is necessary to remove the

inflamed and friable mucosa. Operations for bleeding represent only 10% of emergent colectomies performed in UC patients.[148]

Dysplasia and Cancer

Patients with UC are at an increased risk of developing colorectal cancer compared to the general population, with younger patients and patients with pancolitis, longer disease duration, family history of IBD, or PSC at the highest risk. Meta-analyses report 10-, 20-, and 30-year rates of colorectal cancer at 2%, 8%, and 18%, respectively,[149] although newer population-based cohorts suggest that the actual risk may be lower.[150,151]

Cancer in the setting of UC appears to have the same stage-specific prognosis, but is often detected at a later stage than in the general population. In fact, nearly 20% of colorectal carcinomas in the setting of UC are unresectable at the time of diagnosis.[152,153] Given the fact that patients with UC undergo colonoscopy more frequently than the general population, such a pattern of disease indicates that cancer development in UC patients may be accelerated or may follow a different progression from dysplasia to carcinoma.

As mentioned above, the guidelines have changed in response to growing evidence that the majority of dysplasia is visible and potentially resectable, even in the setting of IBD.[154] The traditional recommendation for total proctocolectomy in the setting of dysplasia was based on elevated risk of malignant transformation throughout the colon or rectum. Under the new guidelines, visible polypoid lesions that are completely removed endoscopically with biopsies of the surrounding tissue that demonstrate no evidence of dysplasia can be managed as they would in patients without IBD.[154] In addition, rather than mandating colectomy, “invisible” dysplasia on random biopsies may instead be followed using close-interval chromoendoscopy, which has demonstrated higher detection rates and lower incidence of metachronous colorectal cancer when compared to white light.[87,155] Still, any dysplasia in the setting of UC warrants further evaluation by a specialist and may still prompt total proctocolectomy in the setting of unresectable, unsurveyable, or multifocal disease.

Failure of Medical Management

Inability to fully control UC symptoms or to do so without the chronic use of steroids remains the most common indication for surgery. Proctocolectomy can also improve many of the extracolonic manifestations of UC and can be considered in particularly debilitating or recalcitrant cases of erythema nodosum, large joint arthritis, aphthous ulceration, or episcleritis.[156]

Surgical Management

Unlike for CD, surgery with total proctocolectomy is curative for UC. Multiple surgical options are available and the ultimate choice of operation should be determined by the indication, urgency, continued need for immunosuppressive medications, and medical and nutritional condition of the patient. In general, the decisions regarding colectomy, proctectomy, and IPAA should be made independently, given that proctectomy can often be postponed safely after abdominal colectomy and that patients with permanent end ileostomy have both lower long-term complication rates and can have equivalent quality of life to those with a restorative IPAA.[157,158]

Total Abdominal Colectomy with End Ileostomy

For urgent indications, including fulminant colitis, toxic megacolon, uncontrolled bleeding, and perforation, the operation of choice is a total abdominal colectomy with preservation of the rectum and an end ileostomy (**Fig. 66.6**). Resection of the rectum in the urgent setting should be avoided, if possible, to both allow for continent reconstruction at a later time and to avoid a perineal dissection under conditions in which the perineal wound is likely to break down or become infected. Mobilizing the rectum unnecessarily disrupts the mesorectal planes, making later reconstruction more difficult. In addition, active inflammation and anasarca can obscure dissection planes, putting the ureters and pelvic nerves at unnecessary risk. In addition, consideration should be given to the level of ileal transection proximally, keeping in mind that pouch reach is dependent on the available bowel and the length of its mesentery. Under certain circumstances, the ileocolic artery must be preserved to allow for back filling of the arcades if the superior mesenteric artery must be divided to enable the ileal pouch to reach the anus.

The location of stoma should be marked preoperatively by an enterostomal therapist, if possible. Managing a poorly placed stoma is a major source of preventable frustration for patients. If there is concern regarding visualization of the ureters, stents should be placed prior to beginning the operation. Although they do not reduce the rate of ureteral injury, they do aid in intraoperative identification of any injury and can help facilitate prompt repair.[159]

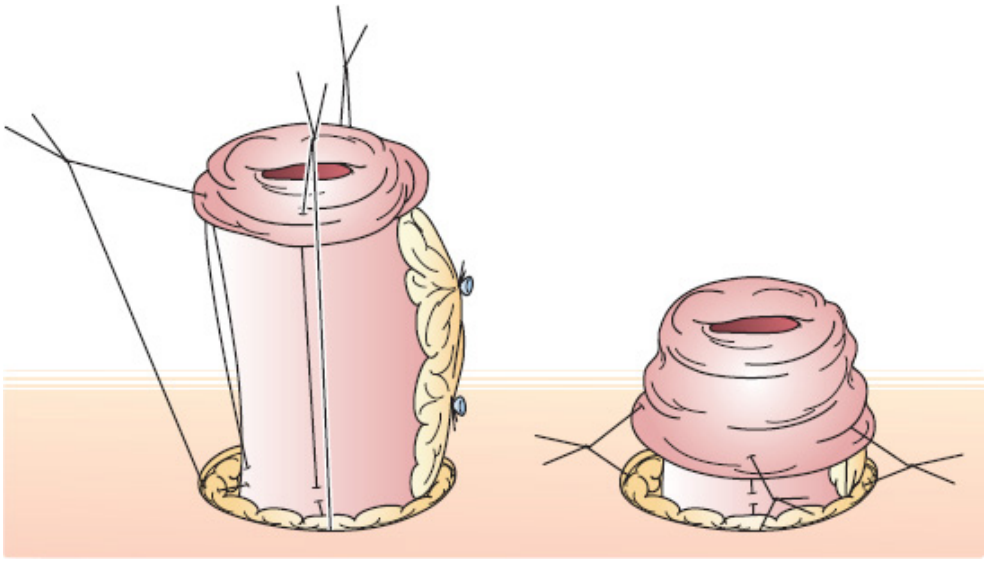

Figure 66.6 Brooking ileostomy.

A minimally invasive approach should be attempted, if the patient is stable and the surgeon is sufficiently comfortable with such an approach.[160,161] After establishing pneumoperitoneum and placing additional ports, the colon is mobilized systematically in either a medial-to-lateral or lateral-to-medial fashion (**Figs. 66.7** and **66.8**). Although the sequence of the operation varies from surgeon to surgeon (e.g., right colon first vs. left colon first), a systematic technique should be employed. Unless there is concern for cancer, the vessels can be transected close to the bowel wall to avoid the risks of high ligation. Particular attention should be paid to the splenic flexure, as a splenic tear will unnecessarily complicate the operation.

Once the colon has been completely mobilized and the vessels divided, the rectosigmoid junction can be transected, either laparoscopically or through a Pfannenstiel or lower midline incision. The distal ileum is either similarly divided and the specimen is extracted through the lower incision, or the

entire specimen is extracorporealized through the ileostomy aperture, with division of the terminal ileum, followed by creation of an end ileostomy (**Fig. 66.6**). It is critical to make sure that the small bowel mesentery is not twisted before maturing the ileostomy.

Depending on the level of inflammation, the rectal stump may be at substantial risk of staple line disruption and leakage. If possible, it is prudent to leave a long enough rectal stump to be able to tack it anterior to the fascia but deep to the skin. In the event of a rectal stump leak, tacking to the fascia effectively creates a mucous fistula rather than allowing leakage of stool into the pelvis or peritoneal cavity. Other strategies for managing the rectal stump include oversewing the staple line, decompressing the rectum from below with a soft drain that is removed several days postoperatively, or purse-stringing the proximal end around a transabdominal drain, if an early return to the operating room is anticipated.

Completion Proctectomy/Total Proctocolectomy

Hospitalized patients who do not respond to medical management, cannot achieve steroid-free remission, or are medically or nutritionally depleted should undergo total abdominal colectomy (rather than proctocolectomy) to remove the bulk of disease, break the inflammatory cycle, and allow time for rehabilitation prior to considering any additional surgery. After recovery, patients who have persistent rectal symptoms (pain, tenesmus, bleeding, discharge), do not want to undergo continued surveillance, or desire restoration of continuity can proceed with completion proctectomy with or without IPAA. Short of persistent symptoms requiring steroids, an inability to perform surveillance of the rectum, or evidence of dysplasia/cancer, proctectomy is not mandatory and patients can live full lives with a permanent ileostomy and their remaining rectum in place, as long as they continue surveillance.[157] Unfortunately, proctectomy is required for restoration of continuity as ileorectal anastomosis has not demonstrated favorable outcomes in UC and should be avoided outside of specific clinical situations (e.g., palliation and young women considering future pregnancy).[162]

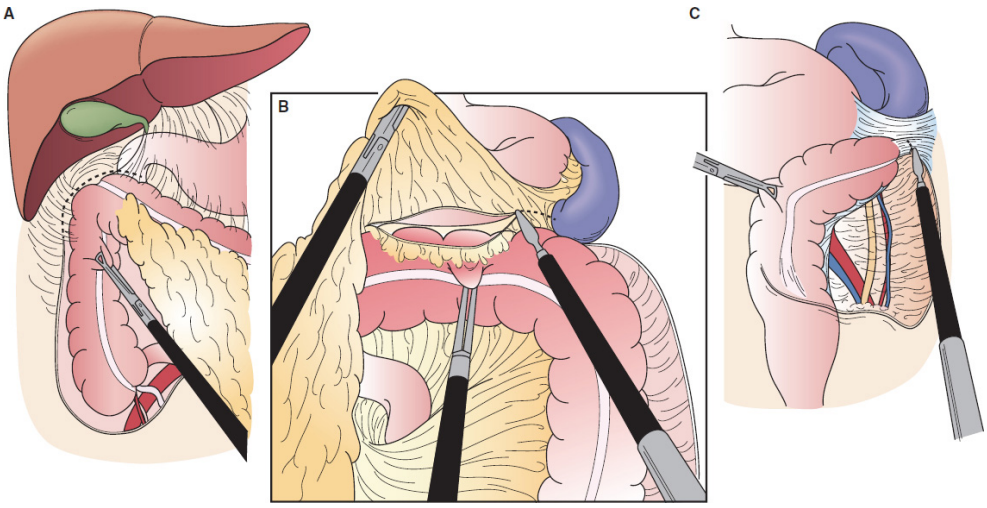

Figure 66.7 Colon mobilization. **A:** right colon. **B:** transverse colon. **C:** left colon.

Abdominal colectomy is performed as above, either at a prior operation or during the initial phase of total proctocolectomy. As with total abdominal colectomy, proctectomy can be performed via an open or minimally invasive approach, depending on the surgeon's training and comfort. The patient is placed in a steep Trendelenburg position and the small bowel is displaced into the upper abdomen. The remaining sigmoid and rectum are placed on tension and the peritoneum is incised over right side of the rectum, medial to the ureters and the pelvic nerves. The embryologic plane between the mesentery and the retroperitoneum is followed cephalad just posterior to superior rectal artery to identify the inferior mesenteric artery (IMA). Careful dissection near the IMA pedicle toward the left pelvic sidewall will reveal the left ureter through the retroperitoneal fascia; its location is almost always higher than expected. After the ureter is identified, the IMA can be skeletonized and divided. In the absence of neoplasia, it is unnecessary to perform a high (proximal) ligation of the IMA.

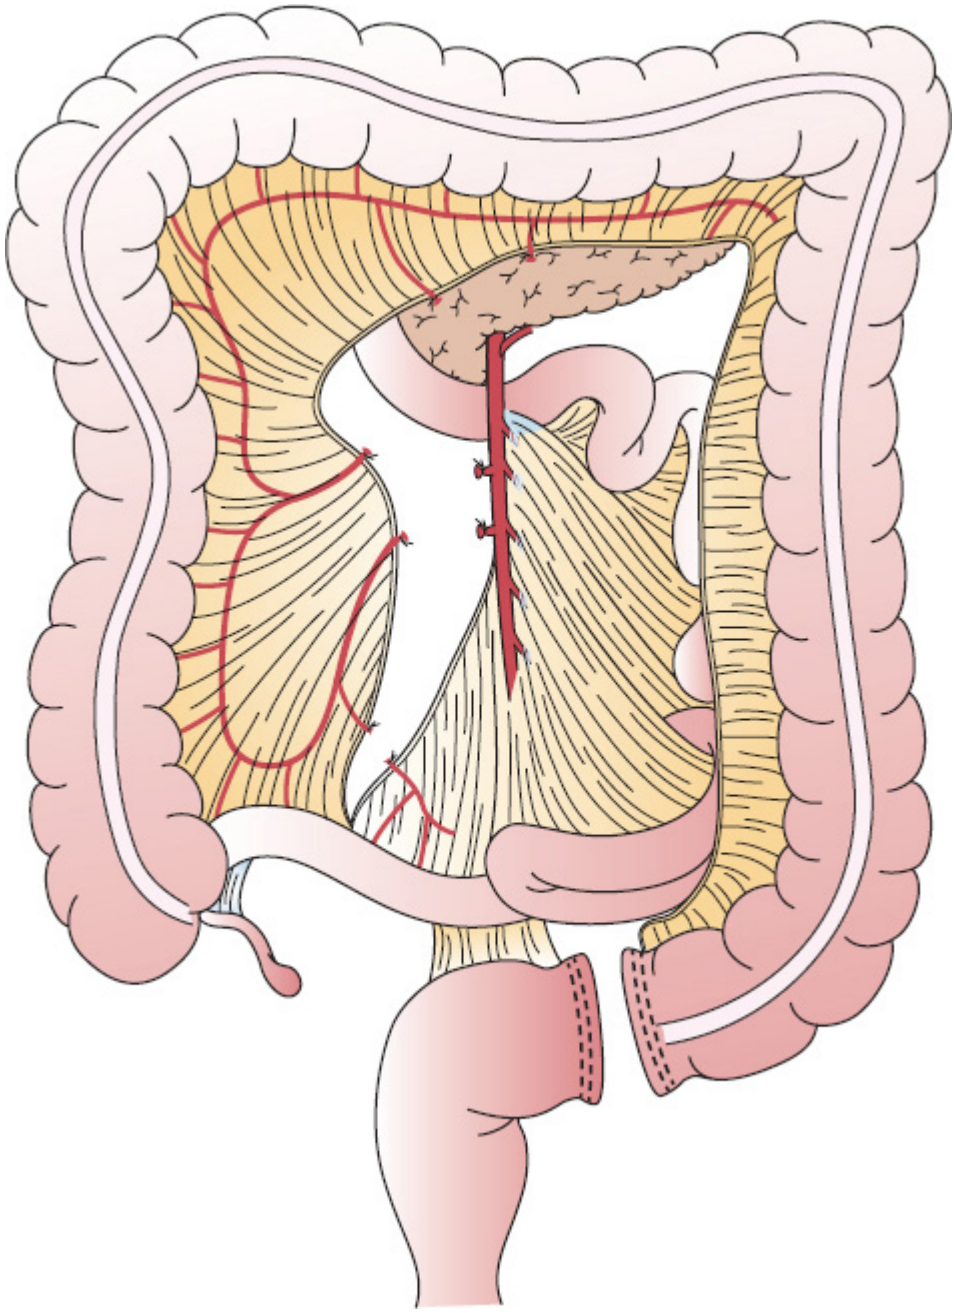

Figure 66.8 Mobilized colon with vessels divided, and stapled at the rectum. This specimen is ready for extraction; the ileum can be transected intracorporeally, or after specimen is extracorporealized.

The dissection is carried distally into the pelvis along the posterior mesorectal plane. The "wishbone" of the superior hypogastric plexus should be clearly identified and protected. Meticulous dissection can be done relatively bloodlessly as long as one stays in the correct embryologic plane. Dissection posteriorly through the presacral fascia risks injuring the

presacral veins, which can result in troublesome and sometimes life-threatening bleeding. All effort should be made to complete the dissection posteriorly, prior to dividing the anterior peritoneal reflection and entering either the rectovaginal or rectoprostatic plane. Denonvilliers fascia should not be violated in order to avoid contributing to sexual dysfunction, particularly in men.

Once the dissection is carried down to the pelvic floor circumferentially, the distance from the anal verge can be assessed via digital rectal examination. In patients undergoing IPAA, the rectum is transected using a stapler and removed from the field. In patients undergoing total proctectomy and permanent ileostomy, a perineal dissection is begun, either in the lithotomy or prone position. Unlike an abdominoperineal resection for cancer, the perineal dissection begins in the intersphincteric groove and extends proximally in the relatively bloodless plane between the sphincters until the abdominal cavity is entered. Performing an intersphincteric dissection leaves the external sphincter in situ, allowing it to be incorporated into a layered perineal closure thereby improving the chance of complete wound healing.

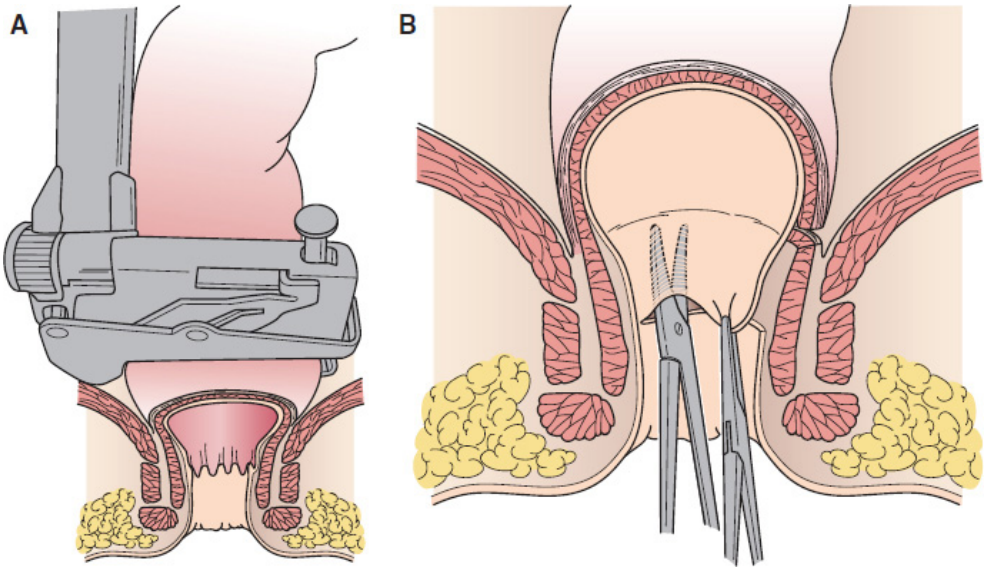

Figure 66.9 Distal rectal transection, (**A**) stapled above the dentate line, or (**B**) a mucosectomy in preparation for a hand-sewn anastomosis.

Ileal Pouch-Anal Anastomosis

Total proctocolectomy with IPAA is the most commonly performed elective operation for UC, typically in the setting of persistent mild-to-moderate disease or dysplasia. While higher than end ileostomy, IPAA has an acceptable morbidity rate (20% to 30%) and produces a quality of life that approaches normal controls.[125] IPAA is not appropriate in patients with poor anal sphincter function, a history of anorectal disease, or an inability to tolerate the increased risk of pelvic sepsis that exists in the setting of an ileoanal anastomosis. All prior pathology should be reviewed to confirm the diagnosis of UC as IPAA in CD carries a higher risk of post-operative complications and pouch failure.[163–165]

Colectomy and mesorectal mobilization are performed as described above except the rectum is transected approximately 1 cm above the anorectal ring with the stapler (**Fig. 66.9A**). Alternatively, a mucosectomy can be performed from below, although this necessitates hand-sewn ileoanal anastomosis (**Fig. 66.9B**). Overall, there is no difference in perioperative complications between double-stapled and hand-sewn IPAA anastomoses.[166–169] Some studies suggest leaving a small rectal cuff improves defecatory function,[170] although any residual rectal mucosa poses some risk of dysplasia or recurrent proctitis ("cuffitis").[171,172]

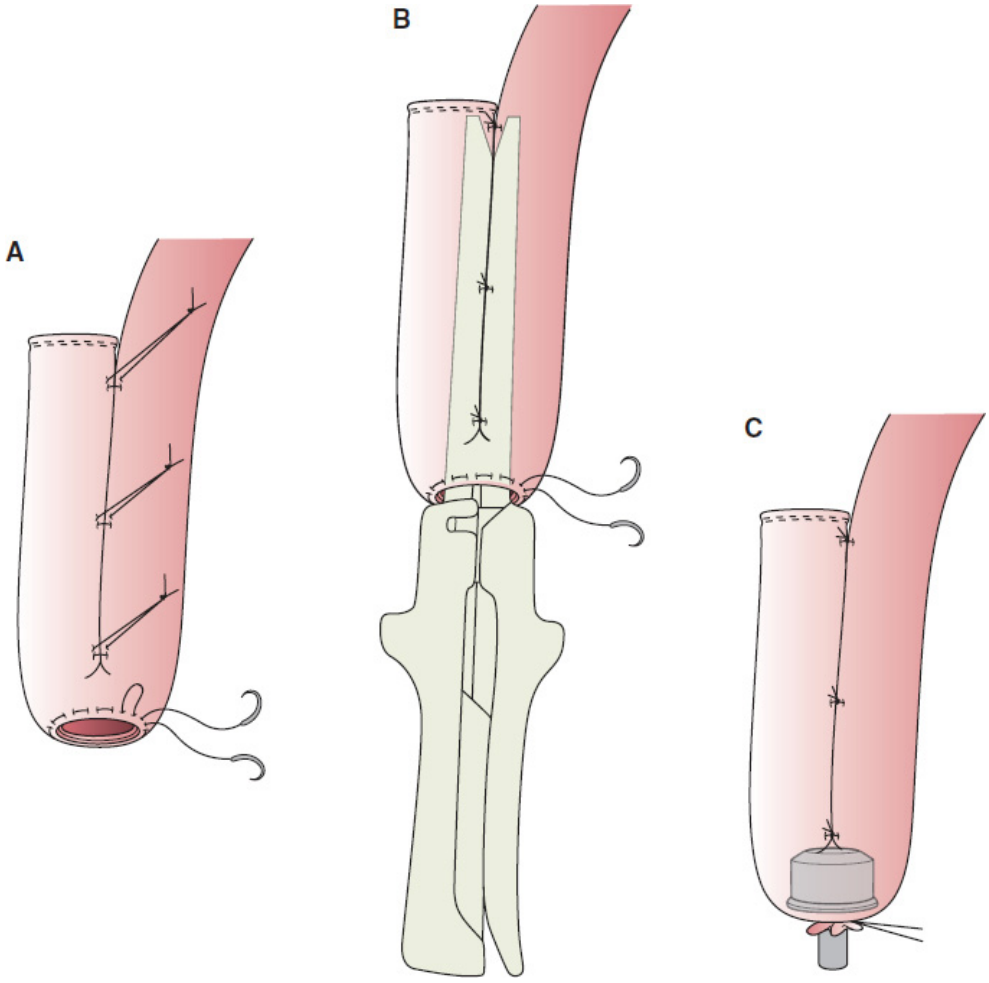

Figure 66.10 IPAA construction and anastomosis, (**A**) terminal ileum alignment for (**B**) common channel creation. **C:** EEA anvil attachment at the apex of the pouch.

After the proctectomy has been completed, a pouch is fashioned from the terminal ileum. Multiple pouch configurations exist, although there is no evidence to support one over another[173,174]; the double-loop J-pouch configuration is the most popular in the United States (**Fig. 66.10**). A portion of the distal or terminal ileum is pulled toward the anus to align the bowel in a "J" configuration. Before committing to pouch formation, it is necessary to confirm that the apex will reach the rectal cuff or anus without tension, which is typically done by stretching the apex slightly beyond the pubic symphysis. Multiple maneuvers can be performed to "lengthen" the reach of the pouch, if necessary, and are beyond the scope of this discussion. Once the apex location is decided on, the two limbs of the ileum are aligned with interrupted suture to create a pouch of 15 to 20 cm in length. An enterotomy

is made at the apex of the pouch and a GIA stapler is used to fashion a common channel between the two limbs. The pouch can then be anastomosed to the distal segment either by using an EEA stapler (placing the anvil in the J pouch and firing pin through the rectal pouch) or via a hand-sewn anastomosis (**Fig. 66.11**).

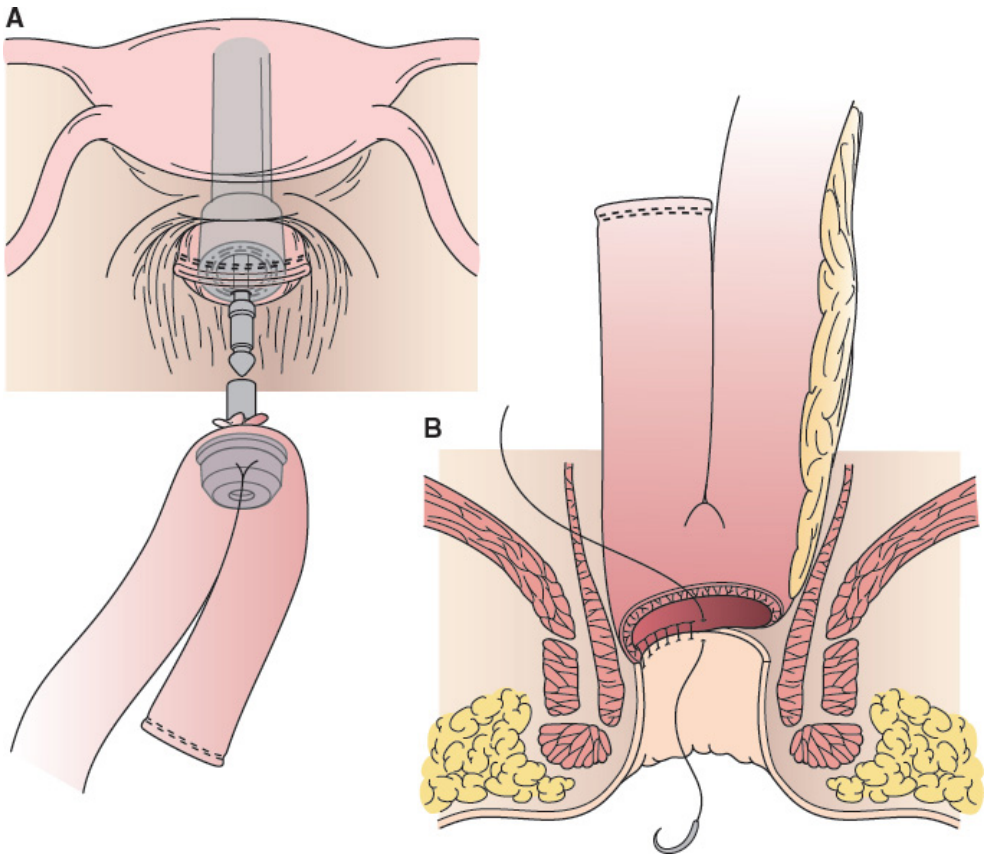

Figure 66.11 Anastomosis of the J-Pouch with (**A**) stapled anastomosis and (**B**) hand-sewn anastomosis.

IPAA-Postoperative Complications

The majority of patients who have an IPAA report a high quality of life after surgery. As with any abdominal or pelvic operation, patients are at risk for bleeding, infection, bowel obstruction, sexual or bladder dysfunction, and changes to fertility. Up to 60% of IPAA patients experience a perioperative complication.[175] Small bowel obstruction occurs in 15% to 20% of patients and is most commonly managed nonoperatively.[176] Sexual function after surgery is variable.[177] Between 10% and 20% of patients describe an increase in dyspareunia while 2% to 19% of men report retrograde

ejaculation or erectile dysfunction.[178–180] Women with UC who have surgery appear to have lower conception rates and higher rates of infertility or need for fertility treatment compared to women with UC who do not have surgery, although there is no difference between patients with IPAA versus end ileostomy.[181]

Recent series have also called into question the long-term bowel function of IPAA patients. In a large U.S. study, the majority of IPAA patients reported having between 6 and 10 bowel movements per day after a median follow-up of 4 years, however, 90% still reported difficulties delaying a bowel movement for 15 minutes, 56% reported having to have a second bowel movement within 15 minutes of evacuating, and 19% reported fecal leakage on some to most days.[175]

Pouch-specific complications include persistent, nonspecific inflammation of the pouch ("pouchitis"), and anastomotic issues, including stricture, abscess, fistula, and pelvic sepsis. Pouchitis occurs in 40% to 50% of the patients and is the most common complication after IPAA.[175,182] It is generally treated with oral antibiotics (ciprofloxacin or metronidazole), but may require evaluation with endoscopy and biopsy, if symptoms persist. Other medications that have been shown to help treat pouchitis include corticosteroids, budesonide, 5-ASA, and allopurinol.[183] Up to 10% of IPAA patients experience a frank anastomotic leak and 12% develop a persistent fistula tract. Antibiotics, drainage, and salvage procedures can be performed, however, between 7% and 8% eventually require pouch excision.

Colonic Polyps and Polyposis Syndromes

Emily Steinhagen and Neil Hyman

Key Points

1. Colonic polyps are common and may have adenomatous, serrated, hyperplastic, or inflammatory histology; dysplasia is inherent to adenomas and serrated polyps.
2. Colorectal cancer may develop in polyps via the classical pathway, driven by APC gene mutations, the microsatellite instability pathway, or the CpG island methylation pathway.
3. Screening and surveillance decrease the risk of colorectal cancer by detecting and removing polyps before they develop into cancer with colonoscopy representing the gold standard.
4. Multi-disciplinary management of hereditary polyposis syndromes is optimal.
5. Patients with hereditary polyposis syndromes require screening and surveillance for colonic and extracolonic malignancies as they have increased risks that vary by genetic syndrome.
6. The role for prophylactic surgery in adenomatous polyposis syndromes should be individualized to patients and disease phenotype.

Polyps occur frequently in the colon and rectum, and may represent precursor lesions to colorectal cancer (CRC). As such, identification and removal of these lesions may decrease an individual's risk of developing CRC. There are three main pathways through which CRC can develop, and each involves a precursor lesion. The classical pathway, characterized by chromosomal instability, is most common and consists of adenomas developing progressive mutations eventually leading to CRC. The microsatellite instability (MSI) pathway and hypermethylation pathways occur due to failure to repair DNA errors of replication, and are associated more frequently with serrated type polyps (**Fig. 67.1**).

Approximately 5% to 10% of CRC has a hereditary basis.[1] For patients and families with a hereditary predisposition to CRC, there are typically other at-risk organ systems for neoplasia, and progression to cancer may

occur more quickly compared to sporadic cases. Recognition of these syndromes enables appropriate screening and surveillance.

Polyps may be classified by their shape as well as their histology. Polyps may be sessile, protruding directly from the bowel wall with a broad base; pedunculated, on a fibrovascular stalk; or flat, which may be the most difficult to recognize endoscopically (**Fig. 67.2**). Polyps may also be considered as neoplastic, with malignant potential, or nonneoplastic. Neoplastic polyps typically include adenomas and serrated lesions. Nonneoplastic polyps include hyperplastic polyps (HPs), hamartomatous polyps such as juvenile polyps or inflammatory polyps. Submucosal lesions such as lipomas, leiomyomas, lymphoid aggregates, or other lesions may appear polypoid as well.

COLONIC POLYPS

Adenomatous Polyps

1 Adenomas are epithelial lesions that typically appear smooth but may become nodular as they grow and their histology advances. They are generally asymptomatic and are found in up to half of individuals who undergo screening colonoscopy. Because they are by definition precancerous, removing them via screening and surveillance is generally thought to be the major factor accounting for the decreasing incidence of CRC in the United States.

Epidemiology

Traditionally, adenoma rates have been higher in the United States and Western countries compared to parts of Asia, South America, and Africa. However, as the "Western" lifestyle has spread, the incidence of adenoma and CRC has increased in these regions. Studies evaluating the incidence of adenomas on screening or surveillance colonoscopies suggest that the rate may approach 50%.[2] The incidence of adenomas increases with age in all populations. It is estimated that in a patient with an adenoma, there is a 30% to 50% chance that they have at least one additional adenoma.[3]

Even outside of defined hereditary syndromes that predispose to polyps and CRC, heredity plays a role in adenoma and CRC risk. There is a two- to threefold risk of CRC among those with a first-degree relative who has adenomas or CRC. The more affected family members, the higher the risk. However, the risk may be impacted by the shared environment as well as shared genetics.

It was previously thought that adenomas were uniformly distributed throughout the colon with larger polyps more prevalent on the left side. However, the reported incidence of right-sided polyps has increased over time.

Histology

Adenomatous polyps are characterized by their physical features, size, glandular structure, and degree of dysplasia (**Fig. 67.3**). Tubular adenomas consist of at least 80% dysplastic tubules that are arranged in a tightly packed network and extend toward the normal lamina propria. Villous adenomas have at least 80% villous fronds that consist of a core of lamina propria surrounded by adenomatous epithelium; these fronds are elongated crypts. Tubulovillous adenomas have features of both.

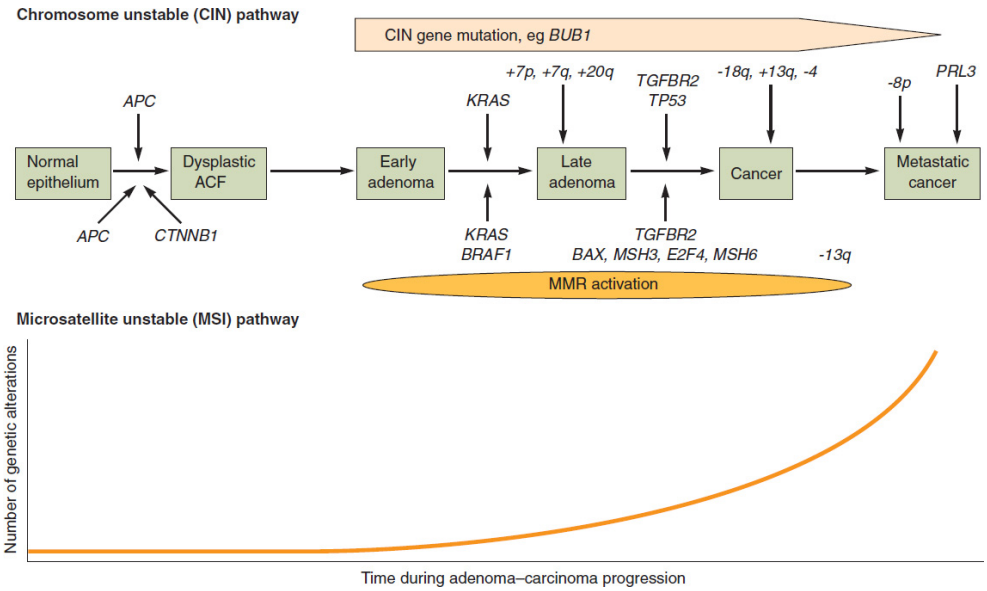

Figure 67.1 Proposed sequence of genetic events in the development of colon cancer. Carcinomas arise from an accumulation of events whose sequence has been defined for two of the carcinogenesis pathways. Tumors progress through the adenoma-to-carcinoma sequence along pathways marked by chromosomal instability (CIN) or microsatellite instability (MSI). At least one more pathway, characterized by promoter methylation of tumor-suppressor genes, serrated polyps, and cancers with variable degrees of microsatellite instability, is incompletely understood, and not shown here. ACF, aberrant crypt focus; TGF, transforming growth factor.

Adenomas are, by definition, dysplastic. The degree of dysplasia depends on the degree of abnormality in the crypt architecture as well as the appearance of the nuclei. Abnormalities in crypt architecture may be described as irregular branching, crowding, or "back-to-back" configurations (**Fig. 67.4**). Signs of nuclear atypia include larger size, pleomorphism, and hyperchromatic appearance. There may be multiple mitoses and pseudostratification within the cells. Dysplasia is graded as mild, moderate, or severe. Severe, or high-grade dysplasia, indicates that the basement membrane has not yet been invaded; extension into the lamina propria defines intramucosal carcinoma; invasion into the muscularis mucosa denotes invasive carcinoma. Polyp size often correlates with the extent of villous morphology and degree of dysplasia and is therefore associated with an increased risk of cancer.

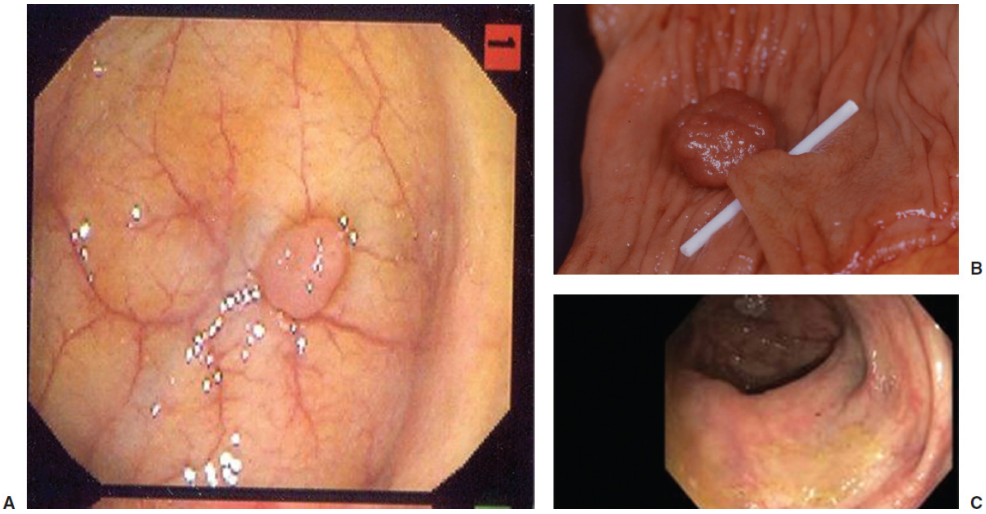

Figure 67.2 Appearance of (**A**) sessile polyp, (**B**) pedunculated polyp, and (**C**) flat polyp.

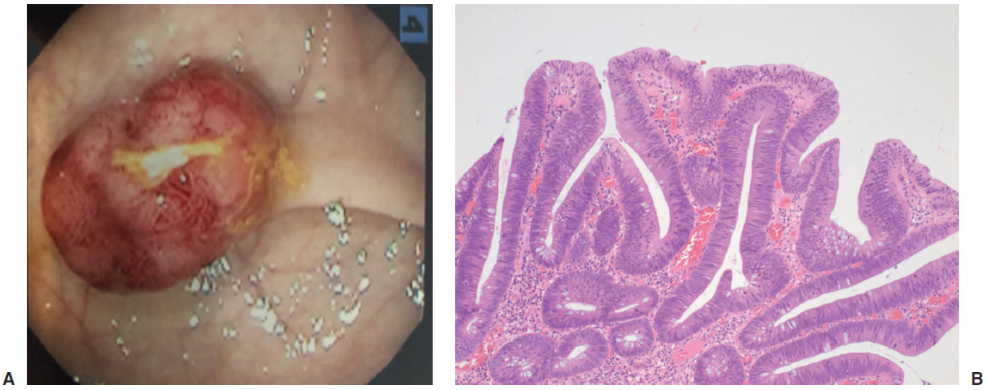

Figure 67.3 Adenomas. **A:** Colonoscopic appearance. **B:** Histologic appearance.

Etiology/Molecular Pathways

Classical Pathway

2 Adenomas develop through a progressive sequence of molecular alterations that lead to proliferation, cellular accumulation, and atypia. The vast majority of CRC develops along this chromosomal instability, or classical pathway, during which there is a process of multistep carcinogenesis. In sporadic cases (those not associated with a hereditary mutation), there are spontaneous changes that occur during DNA replication. The frequency of CRC compared to other types of cancer is likely a result of frequent cell turnover. Mutation of the *APC* gene, located on chromosome 5q, is an early event in the adenoma to carcinoma sequence. This tumor

suppressor gene can act as a gatekeeper of sorts, and once it is mutated, cellular proliferation can occur without regulation.

The protein produced by the *APC* gene is β-catenin. Once *APC* is mutated, there is a loss of phosphorylation of β-catenin, which is important for crypt proliferation. Mutations in *KRAS*, the prototypical oncogene in CRC, are frequently seen in polyps as well; as they become more advanced, *KRAS* mutation frequency increases. Proto-oncogenes function in signal transduction to regulate normal cell growth; they turn on when growth is stimulated and turn off when sufficient growth has occurred. When mutated, there is unregulated growth signaling and excessive cellular proliferation. The tumor suppressor gene *p53* must be inactivated to transition from adenoma to carcinoma. The *p53* gene typically prevents cells with DNA damage from replicating by stopping mitosis progression from the G1 to S phase.

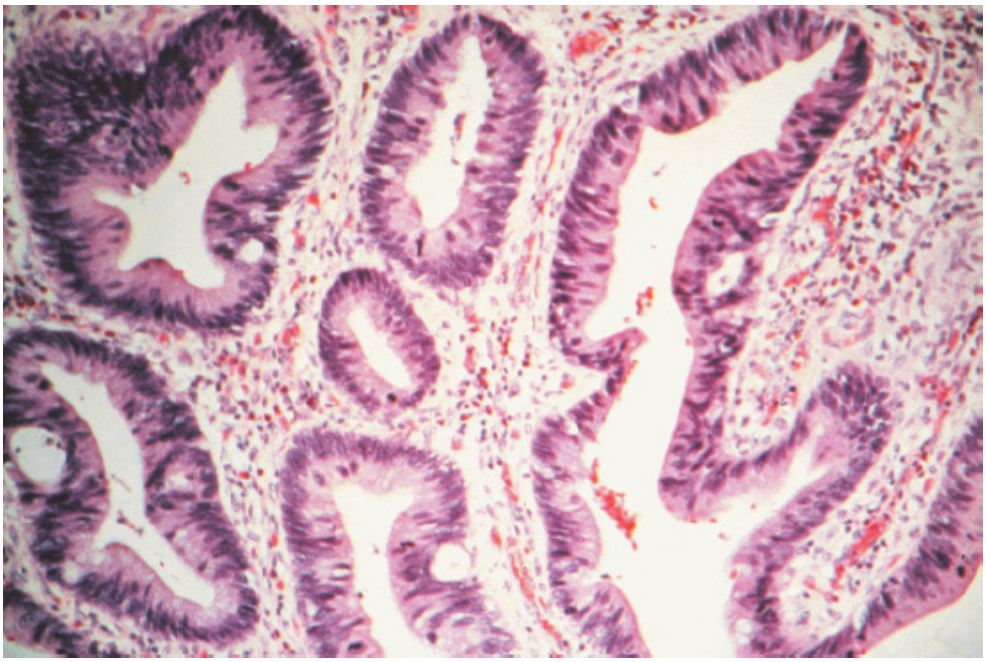

Figure 67.4 Histologic appearance of adenoma. There are crowded, irregular glands and cells. The nuclei are hyperchromatic and nonuniform in size and shape.

Microsatellite Instability Pathway

Approximately 15% to 20% of adenomas and carcinomas develop along a different molecular pathway; the so-called MSI pathway. This occurs when there is hypermethylation of one of the genes controlling the mismatch repair

(MMR) pathway. The most frequent MMR genes are *MLH1, MSH2, MSH6,* and *PMS2*. While in Lynch syndrome (LS) these genes have germline mutations, sporadic methylation of the promoter gene of *MLH1* (sometimes referred to the *BRAF* V600E mutation) accounts for the majority of sporadic MSI-high CRCs. The normal function of MMR genes is to repair DNA damage that occurs as a consequence of replication; without it, MSI can occur. Specific genes that maintain normal cellular behavior may be affected such as *transforming growth factor B receptor II (TGF-BII)*. When TGF-β receptors are inactivated, cells no longer have normal growth regulation control. One of the more notable features of the MSI pathway is that the progression may occur more rapidly (1 to 2 years) compared to the classical pathway. Cancers that develop along this pathway are more likely to occur on the right side of the colon, with histology notable for poor differentiation, signet ring or mucinous tumor subtypes, and an abundance of tumor-infiltrating lymphocytes. Compared with tumors developing along the classical pathway, prognosis is improved.

CpG Island Methylation Pathway

The CpG island methylator pathway (CIMP) describes a subset of CRC that develops along a pathway of epigenetic instability. The hallmark of this mechanism is hypermethylation of CpG islands, which inactivates tumor suppressor genes. More than half of human genes are regulated by promoters; CpG islands represent one type of promoter. When they are hypermethylated, the genes are inappropriately silenced and this can deregulate key genes involved in carcinogenesis.

Figure 67.5 Large polyp harboring invasive carcinoma.

Cancers with a high degree of methylation represent a clinically distinct group of tumors with a different histology and potentially different behavior. Typically, promoter regions of tumor suppressor genes are involved. Tumors notably have high rates of mutations in *KRAS* or *BRAF*, wild type p54, are located in the proximal colon, have mucinous features, are poorly differentiated, occur at an older age, and are more frequent in female patients.[4]

Progression to Cancer

Though nearly all CRCs originate from adenomas or serrated lesions, most polyps do not develop into cancer. Malignant potential is related to size and histology, with larger size and villous components in adenomas representing higher-risk lesions for progression. Adenomas that are 0.5 cm or less very rarely contain severe dysplasia or carcinoma (<0.5%) and only 1% to 2% of

adenomas less than 2 cm contain carcinoma (**Fig. 67.5**). In autopsy studies, up to 40% of adenomas >2 cm harbor an associated cancer. The risk of cancer in adenomas larger than 1 cm, with villous components, and severe dysplasia are estimated at 3%, 17%, and 37%, respectively, but may increase with age. The rate of transition to cancer is estimated at 2.6% in patients aged 55 to 59, and 5.1% in those over 80.[5] It is generally estimated that it takes 5 to 10 years to go from normal mucosa to cancer. This explains the findings of The National Polyp Study, which demonstrated the protective effect of screening colonoscopy for at least 10 years.

Clinical Features

Most patients with adenomatous polyps are asymptomatic. However, hematochezia may be present when larger polyps are in the distal colon or rectum, and right-sided polyps may cause melenic stools. In addition, iron deficiency anemia (with or without associated systemic signs and symptoms) can result from occult bleeding related to polyps. Polyp size is directly related to bleeding risk and volume; those less than 2 cm typically lose less than 1 mL of blood daily. Secretory diarrhea may be associated with large, villous adenomas in the distal colon and rectum and can also be associated with hypokalemia and hypochlorhydria. When polyps are particularly large, they can also lead to obstructive symptoms or alterations in bowel function.

Serrated Polyps

Incidence

Serrated polyps appear to be less common than other histologic types, occurring in approximately 5% of individuals undergoing screening and making up only 7% of polyps detected on colonoscopy.[6] They occur more frequently on the right side of the colon and are frequently flat and covered with a mucous cap, which can make them difficult to identify endoscopically (**Fig. 67.6**). Over 75% occur on the right side of the colon.

Histology

Serrated polyps are characterized by the saw-tooth pattern of the colonic crypts. The crypt base is serrated and dilated, and the proliferative zone has migrated to the side of the crypt rather than the base. Sessile serrated adenomas (SSAs) represent 3% to 20% of serrated polyps. The two most frequent serrated polyps, traditional serrated adenomas and SSAs, are associated with *BRAF* mutations and the CIMP or MSI pathways.

Progression to Cancer

Serrated lesions follow MSI or hypermethylation pathways to evolve into carcinoma. The time sequence appears to be shorter than that of traditional adenomas, but has not been well described.

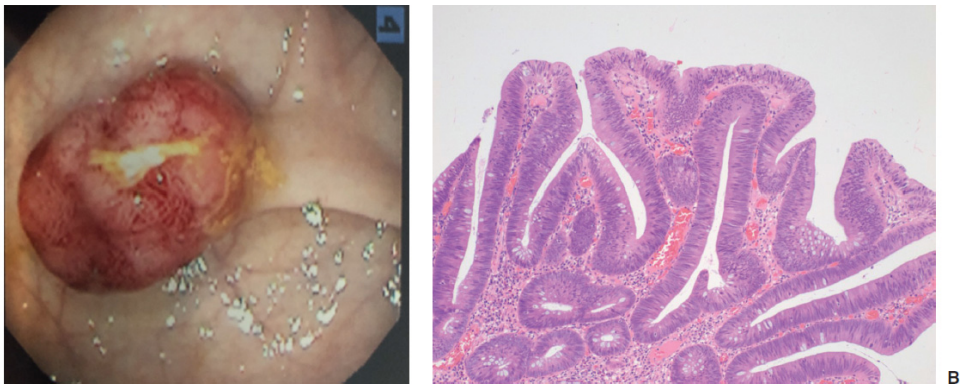

Figure 67.6 Sessile serrated adenoma (SSA), (**A**) colonoscopic appearance; this is a flat lesion that often has a mucous cap and can be difficult to identify on colonoscopy. **B**: Histologic appearance of SSA.

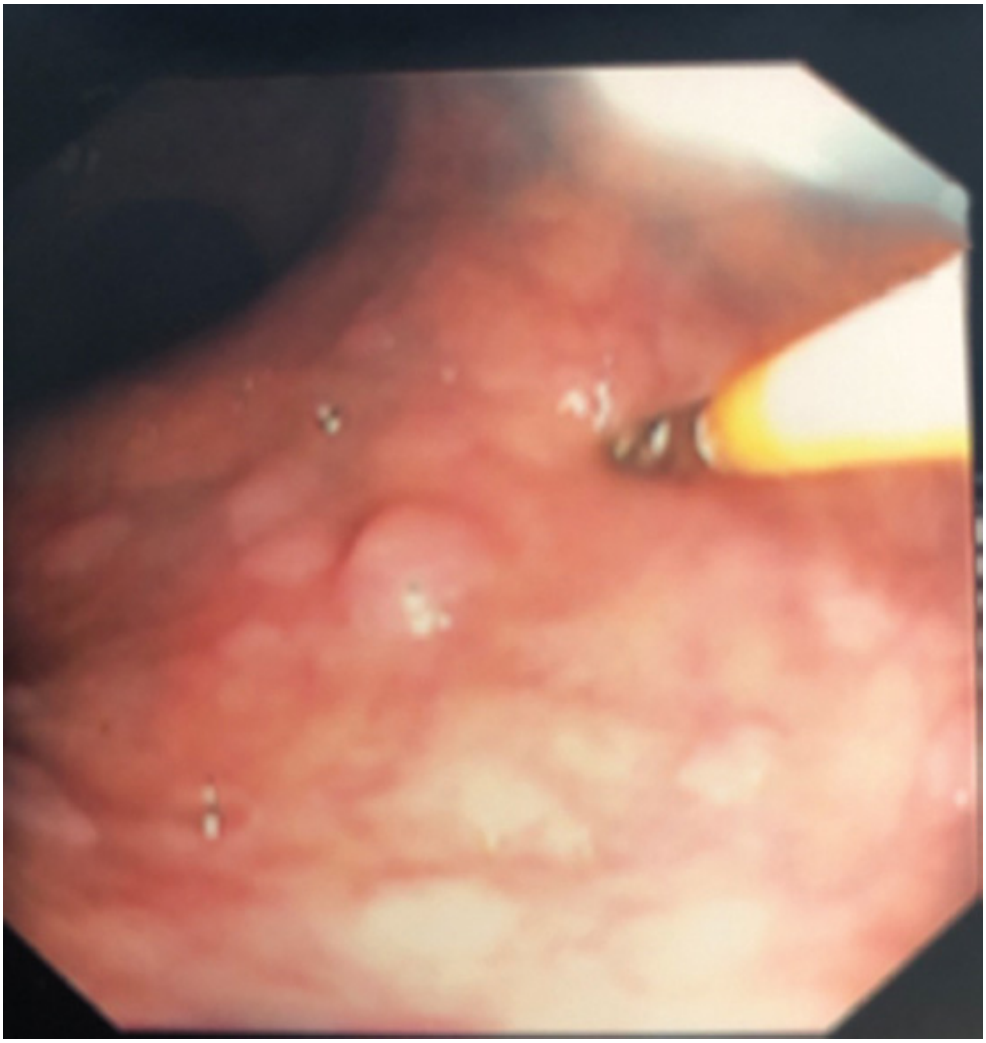

Figure 67.7 Colonoscopic appearance of hyperplastic polyp.

Hyperplasic Polyps

HPs appear as pale, broadly based, flat, smooth nodules. Usually, they are less than 5 mm in size. Most occur in the rectosigmoid and typically multiple are present (**Fig. 67.7**). They arise from faulty epithelial maturation and a failure of apoptosis.

Incidence

HPs are found in more than 30% of individuals over age 50. They may coexist with other types of polyps. There is no evidence of malignant potential once they have been distinguished from adenomas and serrated lesions. The presence of HPs on colonoscopy does not change future

screening recommendations unless they are thought to be part of a polyposis syndrome.

Histology

While HPs are the most common type of serrated polyp, they do not have malignant potential. Histologically, they are characterized by elongated, nonbranching mucosal crypts and hyperplasia without atypia. The main component is mature goblet cells. HPs are generally considered to be nonmalignant, though adenomatous changes can occur. HPs are distinct from SSAs.

"Mixed" hyperplastic and adenomatous or serrated polyps can also occur. When HPs occur as part of a polyposis syndrome, they are associated with an increased risk of malignancy.

Hamartomatous Polyps

Hamartomatous polyps are localized overgrowths of mature intestinal epithelial cells. They appear as smooth, pedunculated lesions with intact-appearing mucosa on endoscopy (**Fig. 67.8**).

They are usually lined with normal epithelium over a submucosal core that does not involve the muscularis mucosa. The pathogenesis is thought to be a mucosal ulceration or inflammation that blocks colonic glands. This leads to proliferation and dilation of the glands, followed by the growth of granulation and connective tissue in the area. Histologic examination demonstrates vascularity, cystica dilation, and a prominent fibrous stroma. Sporadic hamartomatous polyps do not have malignant potential unless they contain adenomatous components.

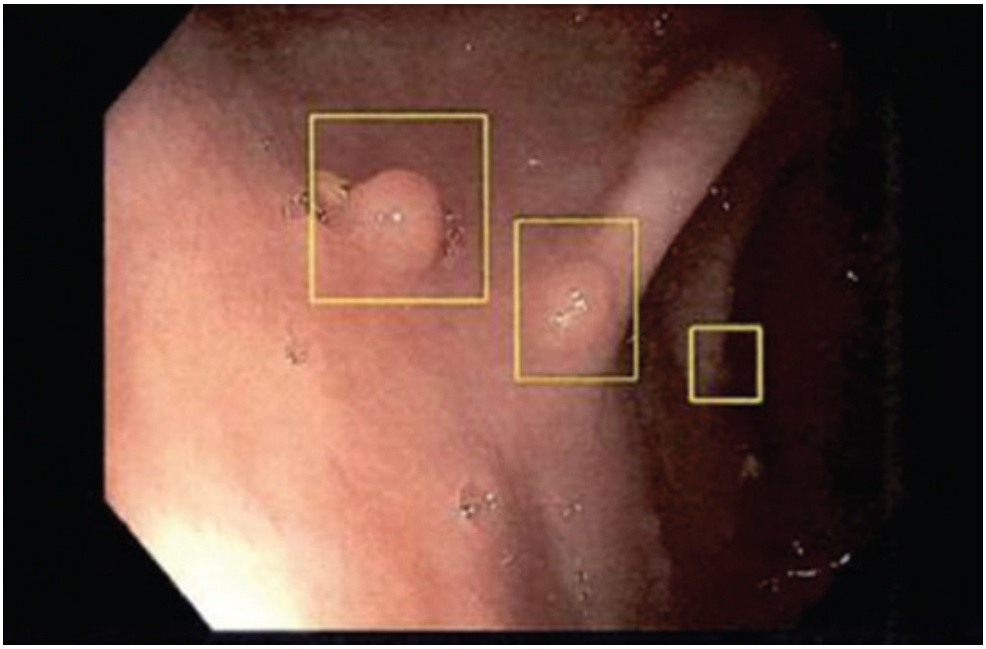

Figure 67.8 Colonoscopic appearance of hamartomatous polyps from a patient with a PTEN mutation.

However, hamartomatous polyps can cause symptoms such as abdominal pain, bleeding from ulceration, diarrhea, intussusception, or prolapse in the case of rectal polyps. When more than three hamartomatous polyps are found in a single patient, a polyposis syndrome should be considered.

Juvenile polyps can occur sporadically or as part of a syndrome. They are made up of dilated mucous-filled glands with abundant lamina propria. Unlike other polyps, these typically occur in children under age 10. Most frequently, a child will have a single pedunculated polyp with a smooth surface. They are thought to occur in about 2% of children. They often present with hematochezia due to their vascular nature. If they occur distally, they may prolapse (**Fig. 67.9**). More proximal lesions can cause intussusception. They have no malignant potential and are removed when symptomatic.

Inflammatory Polyps

Inflammatory polyps are sometimes referred to as pseudopolyps, occurring in areas of mucosal damage and repair. They are most frequently found in patients with ulcerative colitis, but may be found in other types of colitis as

well. Inflammatory polyps are uniform in width from the base to the head and consist of islands of inflamed regenerating mucosa surrounded by ulceration. Since they arise in areas of inflammation, multiple inflammatory polyps may develop in the affected area. The polyps themselves require no specific treatment and do not need to be removed unless there is uncertainty about the diagnosis.

Figure 67.9 Prolapsed hamartomatous polyp protruding through the anus.

SCREENING AND SURVEILLANCE MODALITIES FOR COLONIC POLYPS

3 A number of strategies to screen average- and high-risk individuals are available. Screening can be based on examination of the colonic mucosa, or stool-based tests looking for blood or genetic changes suggestive of advanced adenomas or cancers.

Flexible Sigmoidoscopy

Flexible sigmoidoscopy visualizes the rectum and parts of the sigmoid and descending colon. In general, it does not require a full bowel preparation and polypectomy may be completed at the time of the procedure; if precancerous polyps are identified, full colonoscopy is typically recommended. Though flexible sigmoidoscopy does not visualize all at-risk mucosa, it has been demonstrated to reduce mortality from CRC approximately 26% to 31% compared to no screening.[7] Even when performed once at age 60, a 33% reduction in CRC has been observed.[8] However, with the rightward migration of adenomas and cancer over recent decades, the applicability of this data derived from earlier decades may be limited.

Colonoscopy

Colonoscopy involves direct visualization of the entire colorectal mucosa while facilitating synchronous removal of polyps, biopsies of larger polyps/masses, and has been demonstrated to reduce CRC mortality. Colonoscopic polypectomy is associated with a 53% reduction in CRC mortality.[9] A SEER-Medicare database study also confirmed via case-control study that colonoscopy is associated with a significant reduction in CRC-related death; interestingly, the association was stronger with left-sided cancers, which is consistent with other European and Canadian studies.[10] These findings suggest that right-sided lesions are not detected as frequently and/or that they grow at different rates. Colonoscopy remains the gold standard test for detecting adenomas and CRC. Colonoscopy requires patients to complete a bowel preparation with cathartics and sedation and carries risks such as bleeding or perforation.

CT Colonography

CT colonography, also referred to as "virtual colonoscopy," involves high-resolution cross-sectional images of the abdomen and pelvis. It is a rapid and safe method of evaluating the colon. The National CT Colonography Trial, a multicenter study that compared CT colonography with same day colonoscopy in 2,600 patients, found that the sensitivity of CT colonography for polyps >10 mm was 90% and the negative predictive value was 99%. However, patients still require mechanical bowel preparation for the test and

those with abnormal findings then typically need to undergo colonoscopy for biopsy or polypectomy. One area of concern is the ability to detect serrated lesions, which are typically flat and more likely to be located in the right colon. Additionally, extracolonic findings are not infrequent; this may result in early diagnosis of occult disease but often leads to unnecessary additional testing for incidental findings.

Stool-Based Tests

Stool-based tests are noninvasive screening modalities that detect blood or shed cellular debris from polyps or cancer. Patients can often complete these tests at home and avoid the risks of sedation, and the potential discomfort or risks of an invasive procedure. While they do not require mechanical bowel preparation, some dietary changes in days leading up to the test may be necessary for optimal results.

Fecal occult blood test (FOBT) assesses for the presence of peroxidase in stool. It is a qualitative test that can be altered by the presence of peroxidase from red meat, certain fruits and vegetables, or inactivated by high doses of vitamin C. Patients must comply with dietary restrictions for several days prior to testing to improve the accuracy of the results and typically three samples are utilized to complete the test with appropriate sensitivity and specificity. Importantly, only 15% of polyps <1 cm are detected with this modality, while 80% of polyps >2 cm result in a positive FOBT. Annual or biannual testing reduces CRC-related deaths by 15% to 30%.[7]

Fecal immunohistochemical test (FIT) is an immunohistochemical, semi-quantitative test that measures hemoglobin in a stool sample. The premise is that adenomas and cancers are prone to minor bleeding and therefore the presence of blood in the stool may suggest their presence. Compared to FOBT, FIT test is quantitative. It has improved sensitivity and specificity compared to FOBT. However, FIT tests are less effective at detecting adenomas as compared to carcinomas. FIT testing is intended to be repeated every year. If the test is positive, colonoscopy is recommended. The sensitivity of FIT is estimated at 79%, with a specificity of 94%, though depending on the threshold for a positive test, these numbers can vary.[1] There is no high-quality evidence evaluating the impact of FIT testing on CRC mortality in the United States.

Stool DNA testing (multitarget stool DNA, MT-sDNA, Cologuard®) has also been introduced as a noninvasive screening test. The sensitivity for CRC is 92.3% and 42.4% for adenomas. Stool DNA testing generally has higher sensitivity but lower specificity compared to FIT.

While colonoscopy remains the gold standard for screening and surveillance for CRC, many patients do not wish to undergo this procedure, and the best screening test is the one that the patient will have. A number of societies offer evidence-based guidelines that are updated regularly to enable practitioners to counsel patients about the appropriate age to screen for CRC and the suggested interval depending on the patient and modality utilized.

POLYPOSIS SYNDROMES

There are a number of syndromes associated with colonic polyps and an increased risk of CRC (**Table 67.1**). Importantly, nearly all patients with a hereditary polyposis syndrome are at risk of extracolonic manifestations and require heightened screening and surveillance. The adenomatous polyposis syndromes include familial adenomatous polyposis (FAP) as well as the attenuated form, aFAP; LS; *MUTYH*-associated polyposis (MAP), familial colorectal cancer type X (FCC-X); as well as a number of newly described syndromes that have been found in a small number of families. HP syndrome is characterized by hyperplastic, and sometimes serrated and adenomatous polyps. Hamartomatous polyposis syndromes are characterized by gastrointestinal hamartomas, and include juvenile polyposis syndrome (JPS), Peutz–Jeghers syndrome (PJS), and *PTEN* hamartoma syndromes (Cowden disease and Bannayan–Riley–Ruvalcaba syndrome [BRRS]). Hereditary mixed polyposis syndrome is characterized by both hamartomatous and adenomatous polyps of the gastrointestinal tract.

4 Patients who are suspected of having a hereditary syndrome should be referred to a medical geneticist, genetic counselor, or another healthcare professional with specialized expertise and experience in cancer genetics for consideration of genetic testing. If there is a family history of a CRC syndrome, the decision to refer is straightforward. In addition, patients with ten or more adenomas, two or more hamartomas, and five or more serrated

polyps proximal to the sigmoid should also be considered for further evaluation. The reason for referral prior to testing is to take a more detailed family history, to provide risk counseling, psychosocial assessment and support, education, and a detailed discussion about genetic testing prior to obtaining informed consent.

Table 67.1 Genetic Syndromes

	Gene/Chromosome		Colon Phenotype	Extracolonic Features
Familial adenomatous polyposis (FAP)	*APC* 5q21	Autosomal Dominant	Dozens to hundreds of polyps Early age of onset CRC	Upper GI neoplasia, hepatoblastoma, thyroid cancer, desmoid tumors, supranumerary teeth, osteomas, fibromas, cysts
Lynch syndrome	*MLH1, MSH2, MSH6, PMSH2*	Autosomal dominant	Increased risk CRC, early age of onset CRC	Small bowel cancer, urothelial cancer, endometrial and ovarian cancer, breast cancer, gastric cancer
MUTYH-associated polyposis (MAP)	*MUTYH* 1p35	Autosomal recessive	Dozens to hundreds of polyps Early age of onset CRC	Same as FAP
Peutz–Jeghers syndrome	*LKB1/STK11* 19p13.3	Autosomal dominant	Hamartomatous polyps Higher than average risk CRC	Small bowel polyps, mucocutaneous pigmentation; cancers of bowel, pancreatic cancer, ovarian cancer, cervical cancer, breast cancer
Juvenile polyposis	*SMAD4/MADH4, BMPR1A, ENG* 10q21.1, 10q22.3, 9134.11	Autosomal dominant	Hamartomatous polyps; few to hundreds 10–50% risk of CRC	15% with malrotation, heart or brain abnormalities, cleft palate, polydactyly, genitourinary tract abnormalities
Bannayan–Riley–Ruvalcaba	*PTEN* (60% of cases) 10q23 Unknown	Autosomal dominant	Hamartomas, increased risk of CRC	Macrocephaly, macrosomia at birth, genital freckling in males, developmental delay/intellectual disability, hemangiomas, hypotonia
Cowden syndrome	*PTEN* 10q23 Unknown	Autosomal dominant	Hamartomas, increased risk of CRC	Hamartomas of mucous membranes, breast cancer, thyroid cancer, endometrial cancer, renal cancer, melanoma (all early onset)
Serrated polyposis syndrome/Hyperplastic polyposis syndrome	*RNF43* Unknown	Unknown	Few to hundreds of hyperplastic and serrated polyps; increased risk CRC	Multiple other cancers reported; not enough data to conclusively determine
Hereditary mixed polyposis	*GREM1* 15q13.3	Autosomal dominant	Adenomas, hyperplastic polyps, hamartomas, serrated polyps	Unknown

Adenomatous Polyposis Syndromes

Lynch Syndrome

LS is defined by germline mutation in one of the MMR genes: *MLH1, MLH2, MSH6,* and *PMS2*. Patients with LS are at increased risk for a number of cancers including CRC, endometrial, urothelial, and small bowel; the risk varies based on which gene is mutated.

Incidence

LS accounts for approximately 3% to 5% of all CRCs, though the frequency may be higher in younger patient groups. It is estimated to occur in 1:370 to 1:2,000 individuals.

Genetics/Molecular Pathways

LS is an autosomal dominant syndrome with varying penetrance. It is caused by a mutation in an MMR gene. LS-associated CRC develops via the MSI pathway. Additionally, deletions in the *EPCAM* gene cause hypermethylation of the *MSH2* promoter, which leads to silencing of the gene and causes LS. Rarely, if two parents carry mutations to the same MMR gene, their offspring will be at risk of constitutional MMR deficiency (CMMRD); in this situation, the cancer risk is extremely elevated and occur at even earlier ages.

Diagnosis

Previously, LS patients were identified by family history utilizing the Amsterdam Criteria, and subsequently, the Bethesda criteria. More recent studies have shown that family history is neither sensitive nor specific and germline testing is required; tumor-based testing can be suggestive of LS but is not diagnostic. Identification of LS is important because of the high risk of metachronous cancers, and because it enables affected family members to benefit from potentially lifesaving early detection or prevention of the characteristic cancers.

Although not necessarily sufficient for diagnosis, patient or family history may suggest that further evaluation is necessary. A family history that meets either the Amsterdam II criteria or Bethesda criteria should prompt further evaluation. Amsterdam criteria include an individual with one or more first-degree relative diagnosed with CRC or endometrial cancer under age 50, more than one first-degree relative with CRC or endometrial cancer plus another LS-related cancer, more than two first- or second-degree relatives

with LS-related cancers including more than one diagnosed before age 50, or more than three first- or second-degree relatives with LS-related cancers regardless of age. The Bethesda criteria include: colorectal or endometrial cancer prior to age 50, or at any age in an individual with another LS-related cancer, with more than one first- or second-degree relative who has an LS-associated cancer under age 50, or more than two first- or second-degree relatives with LS-related cancers regardless of age.

There are several models available online that predict risk for LS including PREMM5, MMRpro, and MMRpredict, which are based on individual and family history. If an individual has a greater than 5% risk of having a pathogenic mutation based on a predictive model, genetic testing is generally recommended.

There are also certain histologic findings in CRC that may prompt genetic testing: MSI-H histology, absence of staining for one or more MMR proteins, the presence of tumor-infiltrating lymphocytes, Crohn's like lymphocytic reaction, mucinous/signet ring differentiation, or medullary growth pattern are all suggestive of LS (**Fig. 67.10**).

There are two options for tumor-based testing for LS; immunohistochemistry (IHC) and MSI testing. IHC uses antibodies to stain for the four most common MMR proteins; their absence is suggestive of LS. MSI testing uses PCR to assess for five microsatellites. If three or more are unstable, the tumor is considered MSI-high and suggestive of LS. There is high concordance between the two techniques. However, 10% to 15% of CRCs will display MSI-H and absence of staining for *MLH1* due to hypermethylation of the promoter region of *MLH1*; these represent the sporadic CRCs that develop along the MSI pathway. Absence of *MLH1* on staining should trigger assessment for the *BRAF* V600E variant that accounts for nearly all of these sporadic cases; if it is mutated, the cancer is likely sporadic rather than suggestive of LS. Neither IHC nor MSI is sufficient to diagnose LS and germline testing is necessary for definitive diagnosis.

While adenomas can be evaluated via IHC, sensitivity is decreased compared to CRC, especially with smaller-sized lesions. Therefore, while positive results may be useful, a negative result does not rule out LS. Another important caveat is that neoadjuvant therapy in rectal cancer may lead to falsely positive IHC staining on subsequent biopsy. Whenever possible, biopsy specimens prior to treatment should be obtained. Because tumor-

based testing is not definitive, it should not be used alone to guide surgical decision making. In most cases, germline testing can be expedited to enable informed decision making about the extent of surgery.

Colon Cancer Risks

Not all patients with LS will develop CRC; the overall lifetime risk is between 52% and 82%, but varies by mutation. Individuals with *MSH6* and *PMS2* mutations have a risk of 10% to 22% while those with *MLH1* and *MSH2* mutations represent the higher end of the spectrum, with a 40% to 80% lifetime risk as noted in consensus guidelines.

CRC Surveillance

Patients with LS are at high risk for a large number of malignancies and therefore may require complex surveillance regimens. Colonoscopy should begin at age 20 to 25 (or 2 to 5 years younger than the earliest family member with CRC), with surveillance intervals of 1 to 2 years. This approach has been demonstrated to decrease the risk of CRC in LS patients.

It appears that aspirin may decrease the risk of CRC in patients with LS; the benefit may also extend to other LS-associated cancers.[11] The optimal dose and duration of treatment are not yet clear.

Extracolonic Cancers and Surveillance

5 Patients with LS are at high risk for extracolonic malignancies. The risk by gene mutation compared to the general population and the average age at diagnosis is found in **Table 67.2**.

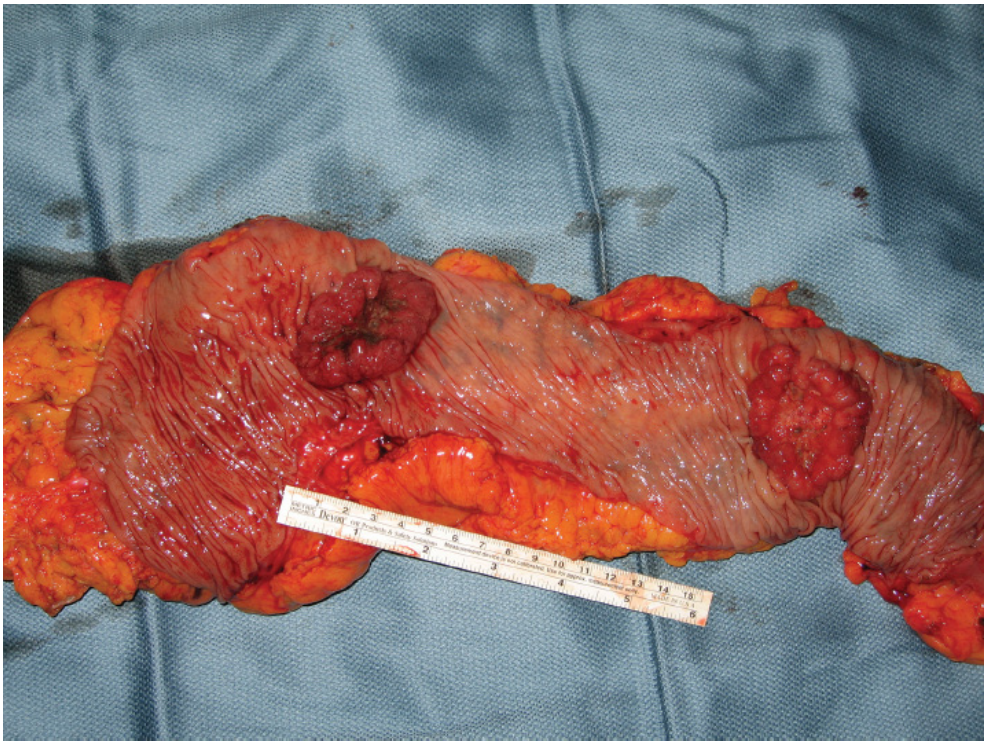

Figure 67.10 Colon resection from a patient with Lynch syndrome demonstrates synchronous cancers.

Table 67.2 Summary of Surveillance Guidelines for Lynch Syndrome Patients

Organ System	Surveillance Test	Frequency
Skin	Skin Exam	Annually
Gynecologic	Endometrial Biopsy Consider TVUS, CA-125	Annually
Small bowel	Capsule endoscopy	No recommendation
Stomach	EGD	1–3 yrs
Hepatobiliary/Pancreas	Consider ultrasound	No recommendation
Urologic	Urinalysis/Cytology	Annually
Breast cancer	Mammogram	Per general population guidelines

Gynecologic Cancers. The lifetime risk of endometrial cancer may be even higher than CRC in some cases. While the risk of endometrial cancer in the general population is about 3%, for women with LS it is approximately 18% to 60% for those with an *MLH1* mutation, 21% to 60% for *MSH2* mutation, 16% to 71% with mutations in *MSH6*, and 13% to 24% for those with *PMS2* mutations. The mean age at endometrial cancer diagnosis in women with LS is 46 to 54 years, compared with a mean age of 60 years otherwise. Up to 20% of Lynch-associated endometrial cancers are diagnosed before age 40. Similar to sporadic cases, endometrial cancer in LS tends to be diagnosed early and have a good prognosis. Women with LS who have atypical bleeding should be evaluated promptly. In addition, endometrial biopsy should be performed every 1 to 2 years for surveillance as it is highly sensitive and specific. Transvaginal ultrasound in postmenopausal women may also be used, although supportive evidence is generally lacking.

The lifetime risk of ovarian cancer for women with LS is 7% to 24%, again varying by mutation. The mean age at diagnosis is 43 to 50 years compared to 60 years in the general population. It is not clear that screening for ovarian cancer reduces the morbidity or mortality of ovarian cancer in women with LS, as also observed with sporadic cases.

Based on the high risk of gynecologic malignancies, hysterectomy with or without salpingoophorectomy should be considered in women who have completed childbearing and are fit for surgery.

Small Bowel Cancer. The risk of small bowel carcinoma in LS is highest in those with *MSH2* and *MSH6* mutations, who have a lifetime risk between 0.6% and 7%. Tumors are found throughout the small intestine at a median age of 39 to 53 years.[12] There are no specific guidelines for routine screening. The use of enteroscopy as well as video capsule endoscopy have not been demonstrated to decrease rates of small bowel cancer in LS patients. While there are no clear data to support screening for small bowel cancer, EGD with visualization at the duodenum at the time of colonoscopy every 3 to 5 years starting at age 40 is suggested by consensus guidelines.

Gastric Cancer Some studies have estimated the lifetime risk of gastric cancer in LS to be as high as 13% in Asian populations. But the lifetime risk in North America and Western Europe is likely closer to 5%; the mutation

with the highest frequency is *MSH2*. A carefully conducted time-trend study of gastric cancer found an 8.0% and 5.3% lifetime risk of this malignancy in males and females with MMR gene mutation, respectively, and a lack of familial clustering.[13] There are no studies that have evaluated the effectiveness of screening and surveillance for gastric cancer in LS patients, but EGD with gastric antrum biopsy every 3 to 5 years starting at age 40 is considered reasonable. If *Helicobacter pylori* is detected, it should be treated.

Hepatobiliary and Pancreatic Cancer Compared to other cancers, hepatobiliary cancer and pancreatic cancer are rare in LS. The lifetime risk of each is estimated at 0.2% to 4%, respectively. Median age at diagnosis is 62 years. The benefit of screening for these cancers in LS has not been evaluated. An international pancreas consensus panel recommended that MMR gene mutation carriers with one affected first-degree relative (FDR) should be considered for annual PC surveillance with magnetic resonance imaging (MRI) and/or endoscopic ultrasound based on early data in other cohorts with comparable risk.[14]

Urothelial Cancer Patients with LS, particularly *MSH2* and *MSH6* mutations are at increased risk of urothelial cell cancer at a rate of 20 times the general population, or a lifetime risk of 0.4% to 20%. The median age at diagnosis is 56 years. The current recommendation is for annual urinalysis and cytology starting at age 30 to 35 though some also recommend cystoscopy or CT urogram, particularly in those with a prominent family history of urothelial cancer in the context of LS.

Prostate Cancer The relative risk of prostate cancer is 3.6 times the general population, but there are no specific screening guidelines or evidence to suggest earlier onset or higher stage at diagnosis compared to average-risk populations.

Breast Cancer While there is an increased risk of breast cancer in LS patients, there is insufficient evidence to support increased screening above the recommendations for average-risk individuals.

CNS Cancer Other than annual physical examination and neurologic examination beginning at 25 to 30 years, no additional testing is recommended.

Surgical Treatment of CRC in LS

When LS is suspected preoperatively, testing should be considered to diagnose or rule out LS unless there are compelling reasons for more urgent surgery. There is clear evidence that patients with LS who have colon cancer should be offered total abdominal colectomy with ileorectal anastomosis; in rectal cancer, decisions are individualized, based on patient and tumor factors.[15] After segmental resection, the rates of metachronous adenomas and carcinomas are 33% and 25% even with excellent follow-up, compared to 11% and 8% after total abdominal colectomy.[16] There is a clear benefit in terms of cost effectiveness, probability of being alive and cancer free, and quality-of-life years with more extensive surgery in many circumstances.[17]

In women with LS, it is recommended that they undergo prophylactic hysterectomy and bilateral salpingoophorectomy by age 40. When women have completed childbearing earlier than age 40, it is reasonable to contemplate prophylactic surgery. In addition, when women with LS who still have their uterus, tubes, and ovaries undergo surgery for CRC, synchronous prophylactic hysterectomy and salpingoophorectomy are recommended.

Familial Adenomatous Polyposis/Attenuated FAP

Incidence

FAP is an autosomal dominantly inherited syndrome that occurs in 1 in 10,000 births. The penetrance and presentation can vary even within the same family who share a mutation. It accounts for less than 1% of all CRC. Importantly, up to one-third of cases of FAP are de novo mutations, meaning that there is no family history of the syndrome. It is the second most common inherited CRC syndrome. FAP is characterized by hundreds to thousands of polyps throughout the colon as well as a variety of extracolonic manifestations (**Fig. 67.11**). The median age for adenoma development in patients with classical FAP is 17 years. Untreated patients develop CRC at a median age of 40, with death at a mean age of 44.

Figure 67.11 Colon resection from a patient with FAP with thousands of polyps throughout the colon.

Genetics/Molecular Pathways

The *APC* gene is located on chromosome 5q21. Its most well-described function is in the Wnt signaling pathway, in which the APC protein forms a complex with c-myc, GSK3, axin, and casein that allows the degradation of β-catenin. When it is nonfunctional, β-catenin accumulates and enters the nucleus where it induces transcription of cellular growth factors. Cell proliferation, enhanced cell-to-cell adhesion, and cell migration result. The APC protein also stabilizes microtubules and help organize cell migration; it also binds cytoskeletal regulators and when not present, mis-segregation of chromosomes during mitosis can occur.

A number of different mutations in the *APC* gene can lead to FAP; there are truncating mutations that lead to a dysfunctional protein as well as missense mutations. When there is a germline mutation in one copy of the *APC* gene, it creates a situation where there is loss of heterozygosity in which a so-called "second-hit" leads to the classical adenoma to carcinoma sequence. While there are correlations between specific genetic mutations and phenotypic features, the phenotype can still vary between individuals with the same

mutation, even within the same family (**Fig. 67.12**). These differences may be a result of other genes, environmental influences, or other factors. When the *APC* gene mutation occurs in the "mutation cluster" region of exon 15, it predicts a more virulent form of FAP with thousands of colonic polyps and an earlier age of onset of CRC. Mutations at the 3′ end of the gene, in contrast, tend to have a milder phenotype.

Diagnosis

Many patients are diagnosed based on screening or genetic testing, prompted by a family history of FAP. Up to one-third of FAP patients represent de novo mutations; they do not have a parent with FAP. However, each child of an affected patient with FAP has a 50% chance that they will inherit the mutation and therefore develop the manifestations of disease.

Some patients without a family may also be referred for testing based on extracolonic findings such as supranumerary teeth, osteomas, or congenital hypertrophy of the retinal pigment epithelium (CHRPE). Others present with symptoms from polyposis that may include bleeding, change in bowel habits, and abdominal pain. FAP can be diagnosed on a clinical basis when more than 100 colonic adenomas are identified. However, genetic testing should always be performed to confirm the diagnosis. Up to 90% of individuals with a suggestive clinical phenotype will have a mutation identified.

Genetic counseling is an important part of genetic testing for FAP and other hereditary syndromes. Screening panels can sometimes identify one or more mutations of uncertain significance that must be interpreted. Patients may also misunderstand their results and subsequent cancer risk, as well as the implications for family members. There are frequently psychosocial implications with testing both of affected and unaffected family members that should be considered and addressed. With the frequent availability of panel-based testing, more than one gene alteration may be identified. Therefore, informed counseling is critical and should be performed by an experienced genetic counselor.

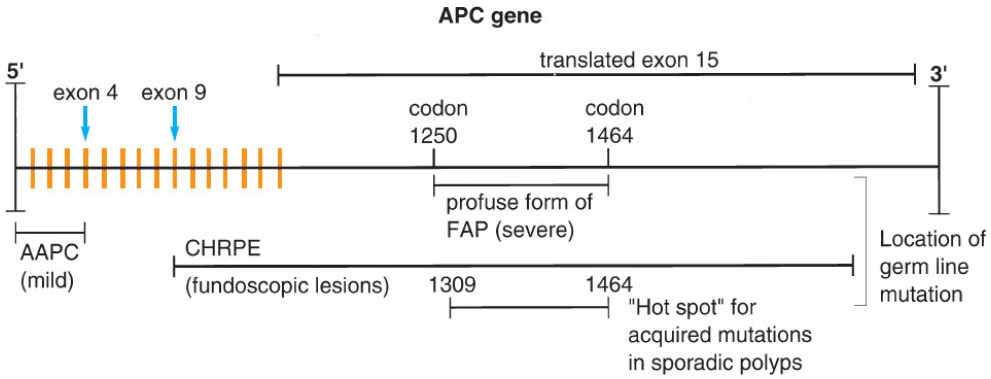

Figure 67.12 This scheme of the APC (adenomatous polyposis coli) gene illustrates the genotype–phenotype correlations. Most mutations of APC result in premature stop codons; therefore, the site of the mutation usually indicates the relative length of the mutant protein product. Mutations at the 5′ end of the gene produce "attenuated" FAP, a milder form of the disease. The retinal lesions (congenital hypertrophy of retinal pigmented epithelium [CHRPE]) occur when the mutations are between exons 9 and 15. The portion of the *APC* gene that binds to other cytoskeletal elements in the cell is represented at the 3′ end of the 15th exon. Mutations in a hot spot immediately downstream from the β-catenin–binding site (between codons 1250 and 1464) result in a more virulent, profuse form of familial adenomatous polyposis. This site is also the location of most of the acquired mutations in sporadic colorectal neoplasms.

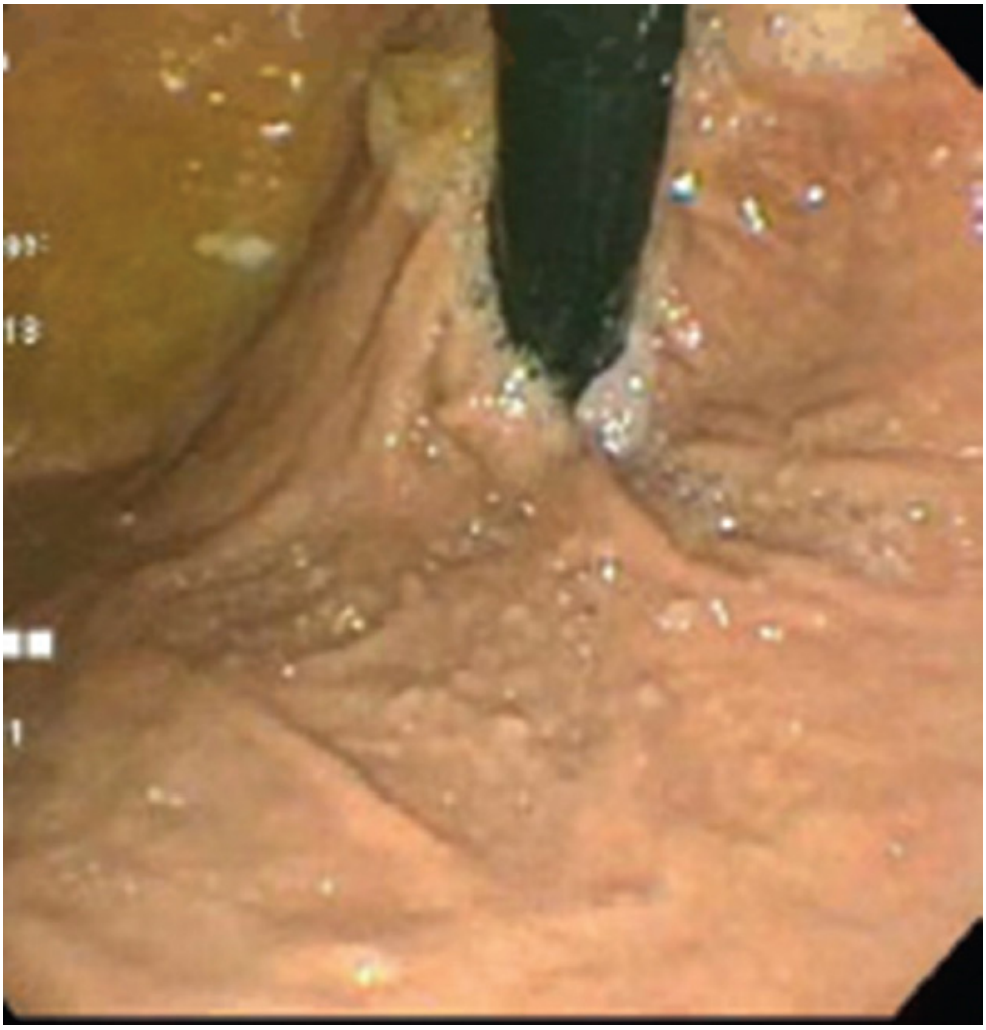

Figure 67.13 Endoscopic appearance of fundic gland polyps from a patient with FAP.

Colon Cancer Risks and Surveillance

Virtually all patients with classical FAP will develop CRC if untreated. The incidence of CRC rises dramatically after age 30. Typically, risk-reducing surgery is recommended once an individual reaches physical and emotional maturity in their late teens or early 20s. However, polyp burden or symptoms may necessitate earlier intervention. Patients with fewer than 20 polyps, and none larger than 10 mm may continue to be surveyed with colonoscopy and polypectomy.

Patients with known or suspected FAP, or those in families with a known *APC* mutation who have not undergone genetic testing should undergo annual colonoscopy at age 10 to 15 years. Most patients with FAP will develop

polyps by their early 20s. Flexible sigmoidoscopy may be an option, but would miss the onset of polyps in the right side of the colon, where they are more likely to occur in attenuated cases.[15]

Extracolonic Features

Gastroduodenal polyps. More than 90% of FAP patients will have upper GI lesions. The most frequent finding is fundic gland polyps, which are benign and have no malignant potential (**Fig. 67.13**). Histologically, they are hamartomatous. However, gastric adenomas and carcinomas may be found, particularly in Japanese and Korean patients. In Western populations, the risk of gastric cancer is less than 1%. Factors associated with an increased risk include carpeting of the stomach, larger polyp size (>20 mm), polypoid appearing mounds, and adenomas. Duodenal and periampullary polyps and carcinoma are also a common feature in FAP patients; the lifetime risk of duodenal cancer is 3% to 5% and half of all duodenal polyps occur in the periampullary location. The duodenal polyps tend to occur later than the colonic lesions and there tend to be fewer polyps compared to the more diffuse colonic polyposis. Duodenal polyps are classified by the Spigelman system (**Table 67.3**) which estimates the risk of carcinoma and determines the appropriate surveillance protocol.[18] It is based on the number, size, and histologic features of the polyps.

CHRPE is a common and completely benign feature present in some FAP patients. The lesions are well demarcated and gray-brown or oval; they are sometimes described as "bear claws." While small, isolated lesions occur in the retinal epithelium of nonaffected patients, the presence of multiple or bilateral lesions is highly suggestive of FAP. CHRPE lesions can be seen on slit lamp examination but are otherwise not seen on routine ophthalmologic examinations. Mutations between codons 543 and 1309 of the *APC* gene are associated with a higher incidence of CHRPE. In some families, the presence of CHRPE can be used to identify affected family members.

Osteomas and fibromas are benign, slow-growing neoplasms of the bone. The classical description in FAP is in the jaw or skull, but they can be present in any bone. They may be detected on physical examination if they are large, or on x-rays, particularly those done for dental indications. Osteomas are associated with a subtype of FAP known as Gardner syndrome and they may precede the development of gastrointestinal polyposis. Other

manifestations of Gardner syndrome include epidermoid cysts, supernumerary teeth, and desmoids. In addition, other benign lesions such as epidermoid cysts, fibromas, and lipomas occur much more frequently in the FAP population. Epidermoid cysts occur in mid to late adolescence and often occur in atypical locations such as the face, scalp, and extremities. Supernumerary teeth, dentigerous cysts, and secondary retention of teeth are all associated with FAP. Supernumerary teeth are usually present before age 10, and should be removed only if they impede the development of normal dentition. Dentigerous cysts develop from the epithelium of the enamel organ and develop before teeth erupt from the jaw. They can grow and occupy a significant portion of the jaw.

Table 67.3 Spigelman Classification for Duodenal Adenomas in FAP

Points	1	2	3
Polyp number	1–4	5–20	>20
Polyp size (mm)	1–4	5–20	>20
Histology	Tubular adenoma	Tubulovillous	Villous
Dysplasia	Mild	Moderate	Severe
Interval to next EGD			
Stage 0 (0 points)	5 yrs		
Stage I (1–4 points)	5 yrs		
Stage II (5–6 points)	3 yrs		
Stage III (7–8 points)	1–2 yrs		
Stage IV (9–12 points)	EUS or surgery		

Thyroid cancer has been recognized at increased rates in FAP patients. The rates range from 1% to 12% and more frequently affects female patients.

Thyroid cancer is diagnosed at a mean age of 27 years. In most cases, the histology is papillary but the cribriform-morular variant is closely associated with FAP. Multicentric thyroid cancer is more frequent in FAP patients compared to sporadic cases. As with sporadic thyroid cancer, outcomes are excellent and treatment is similar. Screening for thyroid cancer is now typical for FAP patients.

Hepatoblastoma. Unlike other FAP-associated cancers which typically occur in adulthood, hepatoblastoma tends to occur in young children. The incidence in FAP patients is 1.6% and is more common in males. Screening can be performed using ultrasound as well as alpha-fetoprotein levels every 3 to 6 months from birth until 5 or 10 years of age. However, genetic testing is usually deferred until adolescence in individuals from FAP families; in order to decide about screening for hepatoblastoma, genetic testing must be performed in infancy to determine if the child is at risk.

Desmoids are slow-growing mesenchymal tumors made of well-differentiated fibroblasts and myofibroblasts with abundant collagen. Up to one-third of FAP patients develop desmoids; however, the rate is more than 1,000 times the rate in nonaffected populations. While the tumors are technically benign and do not metastasize, they do tend to be locally aggressive and infiltrate surrounding tissues. Additionally, recurrence rates are high after removal. Desmoids may occur in any part of the body, but the intra-abdominal desmoids tend to be most clinically significant; up to 80% of FAP-related desmoids are found in the mesentery with the remainder occurring primarily in the abdominal wall (**Fig. 67.14**). In addition to mass-like desmoids, flat-white desmoplastic plaques may also be found. They can affect the mesentery and lead to ischemic bands or obstructions.

Desmoid tumors are a major source of both morbidity and mortality following risk-reducing colectomy. Though these tumors are not technically malignant, complications including obstruction, necrosis, and fistulization can be extremely problematic. They represent one of the more common reasons for FAP-related mortality in patients who have undergone risk-reducing colectomy and therefore are unlikely to get CRC. Typically these lethal desmoids occur in the mesentery and this can make resection extremely treacherous. High recurrence rates are observed after attempted excision. Previously, some authors had suggested that ileorectal anastomosis (IRA) was better than ileal-pouch anal anastomosis (IPAA) to avoid desmoids but

this does not necessarily appear to be the case. In particular, this management strategy has been proposed for women who are concerned about desmoids affecting fertility but will ultimately require completion proctectomy.

The clinical presentation of desmoids ranges from asymptomatic plaques or masses discovered incidentally on imaging or during prophylactic surgery, or with nonspecific symptoms. Large or locally aggressive desmoids may lead to abdominal pain, bowel obstruction, ischemia, venous thrombosis via compression, motor or sensory deficits from nerve compression, ureteric obstruction, sepsis from enteric fistula, and gastrointestinal hemorrhage.

One of the major risk factors for desmoid development is surgical trauma. Desmoids are identified at the time of initial surgical intervention in <5% of patients. Other risk factors for desmoid disease include female gender, the presence of other extraintestinal manifestations of FAP, and a family history of desmoids.[19] Mutations toward the 3′ end of the *APC* gene are associated with the development of desmoid tumors, but family history is a risk factor for the development of disease, independent of genotype.

Intra-abdominal desmoid staging takes into account tumor size, symptoms, behavior, and the presence of complications.[20] This can help in evaluating desmoids over time and determining treatment options. Stage I desmoids are asymptomatic and not growing. They are usually found incidentally at the time of surgery or CT scan performed for other reasons. Stage II tumors are symptomatic and 10 cm or less, but not growing. These tumors may require treatment because of symptoms. Stage III desmoids are symptomatic tumors that are 11 to 20 cm in size, or asymptomatic and slow growing. Treatment may also be recommended for these large desmoid tumors. Finally, Stage IV desmoids are symptomatic and more than 20 cm in size, display rapid growth, or cause significant complications. Tumors that cause life-threatening complications such as sepsis, free bowel perforation, or massive bleeding require urgent treatment. Other features of desmoids that are taken into account include their shape (mass, nodular, or flat), the number of tumors present, the location, whether they occur before or after operative intervention, and hormone receptor status. These can all help guide management.

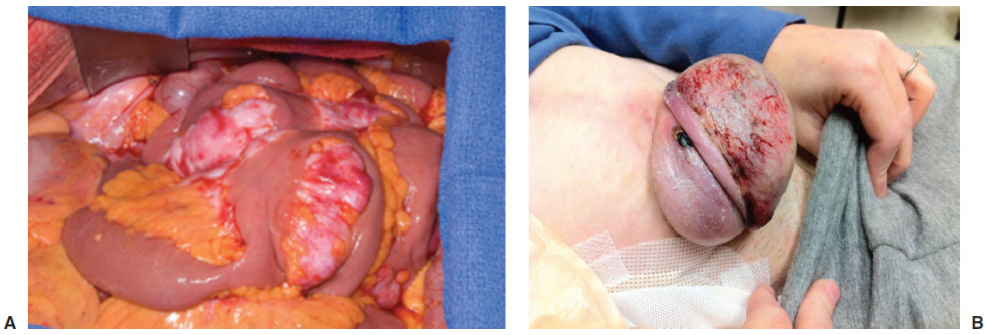

Figure 67.14 **A:** Mesenteric desmoids may limit the ability to perform colon resection or to create a pouch that reaches the pelvis for a restorative procedure. **B:** Abdominal wall desmoid in a young woman with FAP. This is a source of significant morbidity for the patients despite the nonmalignant nature of the desmoid tumor.

There are both nonsurgical and surgical treatments for desmoids. Nonsteroidal anti-inflammatory drugs (NSAIDs) such as sulindac and indomethacin are considered first-line therapy for desmoids. Antiestrogens, primarily tamoxifen and raloxifene may be similarly effective to NSAIDs, and the two may be used together. Chemotherapy typically aimed at sarcoma may also be utilized, as well as tyrosine-kinase inhibitors. Radiation therapy is another option for local control, particularly after surgery or when the tumor is unresectable; but there are substantial risks as the small bowel is likely to be present in the field of radiation in these cases.

Surgery for intra-abdominal desmoids may not be feasible when they are in their common location in the root of the mesentery. In addition, high recurrence rates following resection limit the utility of surgery to carefully selected cases. Often, the characteristic infiltrating growth pattern makes complete resection impossible without extensive small bowel resection. Major complications have been reported in up to 50% of patients with intra-abdominal desmoids treated with surgical resection. In addition, extensive resection may lead to short bowel syndrome and its attendant management challenges. Abdominal wall desmoids may be treated with surgical resection, including 2-cm margins. Reconstruction with prosthetic mesh or a myocutaneous flap may be required for larger tumors.

Surveillance Protocols

Patients with FAP should undergo annual colonoscopy starting at age 10 to 12. Upper endoscopy with a side-viewing endoscope to optimize

visualization of the ampulla is performed by age 20 to 25. Subsequent intervals depend on findings and are typically based on the Spigelman classification. Annual thyroid examination should be performed; many experts recommend that FAP patients undergo thyroid ultrasound in the late teenage years, and that the examination be repeated potentially up to every 3 years, particularly for women. The surveillance for desmoids may include annual abdominal examination or routine imaging with either CT, MRI, or ultrasound if dictated by personal or family history after colectomy; this should begin within 1 to 3 years of colectomy and be repeated every 5 to 10 years. There is no specific protocol for evaluating the small bowel beyond the duodenum in FAP. There is no evidence supporting routine enterography or video capsule endoscopy. In cases where screening for hepatoblastoma is desired, AFP levels can be measured every 3 to 6 months for the first 5 years of life and along with abdominal ultrasound and palpation (**Table 67.4**).

Table 67.4 Summary of Surveillance Guidelines for FAP Patients

Organ System	Surveillance Test	Frequency
Stomach/duodenum	EGD	At least every 3 yrs depending on findings
Thyroid	Ultrasound	Annually
Liver (hepatoblastoma) *controversial	Ultrasound and alpha-fetoprotein	Every 6 mo until 5–10 yrs of age
Adrenal	Ultrasound	Not recommended

*This is to note that surveillance of the liver is a controversial recommendation.

Surgical Treatment of FAP

6 Patients with classical FAP are destined to develop CRC unless they undergo risk-reducing colectomy. Surgical options depend on the number and distribution of polyps; timing also depends on the number and size of polyps, symptoms, patient age, and maturity. Ideally, surgery should occur when

patients have reached physical maturity as well as the ability to cope psychologically with their diagnosis and consequences of surgical treatment.

Total proctocolectomy is appropriate for patients with diffuse polyposis involving the colon and rectum, as well as those with primary colonic disease who prefer a more definitive operation. Patients may choose to have a permanent ileostomy, but restorative proctocolectomy with IPAA is typically performed in suitable candidates. Continent ileostomy, or Kock pouch, may also be an option in selected individuals with FAP.

In the setting of restorative proctocolectomy, the role of mucosectomy is debated in FAP. The idea behind mucosectomy is that by removing all at-risk mucosa, the chance of polyps and cancer developing is eliminated. However, even with a mucosectomy, it is possible to leave behind microscopic islands of mucosa that are at risk for neoplasia. Adenomas occur in the anal transition zone at a rate of 28% to 51% after stapled anastomosis and 10% to 22% after mucosectomy with hand-sewn anastomosis. Cancer is rare, but does occur at a rate of 1% to 2% following either approach, so continued surveillance is necessary.

When polyp distribution is primarily colonic and there are less than 20 to 30 polyps in the rectum that can be managed endoscopically, patients can be considered for colectomy with IRA. With appropriate patient selection, the risk of subsequent proctectomy is less than 2%.

Patients must have regular surveillance of either their IRA or ileal pouch following risk-reducing surgery. It is generally recommended than an IRA be evaluated with flexible endoscopy every 6 to 12 months, depending on the rectal polyp burden. Pouchoscopy should be performed every 1 to 3 years.

Attenuated FAP

Attenuated FAP (aFAP) is a milder phenotype of FAP; it is characterized by fewer colonic polyps with a later age of onset and a lower risk of CRC. The typical range of polyps in aFAP is 10 to 100 adenomas. The distribution is more likely to be right sided than pan-colonic compared to FAP. The onset of CRC tends to occur later in life compared to classic FAP but the risk of cancer may be up to 80% by age 70. Routine colonoscopy and polypectomy may decrease the risk. The extracolonic tumor spectrum is similar to FAP and therefore screening and surveillance regimens are also similar.

Some patients with mild, attenuated FAP may be managed endoscopically and avoid colectomy. If their colon and rectum can be endoscopically cleared of polyps and they are willing to submit to frequent follow-up, they may be able to forego surgery. Most patients with aFAP are well suited to colectomy with IRA.

MUTYH-Associated Polyposis (MAP)

MAP is an autosomal recessive polyposis syndrome caused by mutations in the base-excision repair gene, *MUTYH*. Patients tend to have a milder form of colonic polyposis compared to FAP. Most patients have fewer than 100 adenomas. Other polyp types such as hyperplastic or serrated lesions may also be present. Because of the autosomal recessive inheritance pattern, the family history may not be as obvious as in FAP. Polyps typically develop in the third to sixth decades of life.

Incidence

Between 1% and 2% of the Caucasian population carry a single-mutated copy of the *MUTYH* allele; the most frequent alterations are Y179C, G396D, and E480X. The Y179C variant is less active than G396 and therefore represents the most severe phenotype. For non-European descent individuals, the genetic alterations may be different and occur at different frequencies but this has not yet been well described.

Genetics/Molecular Pathways

Germline mutations in *MUTYH* permit excess number of acquired mutations in the *APC* gene, which is why MAP is phenotypically similar to FAP. The *MUTYH* gene encodes a specific DNA glycosylase excision repair protein that is responsible for excising adenine nucleotides that are mismatched with 8-oxo-guanine, which is a product of oxidative damage to DNA. The mutations are typically G:C → T:A transversions. MAP is an autosomal recessive syndrome, so the individual must inherit two mutated alleles of the gene.

Extracolonic Features

The spectrum of extracolonic features and cancers in MAP is similar to FAP. However, they occur less frequently and are not as well characterized in this

syndrome. Consequently, the surveillance protocols are similar in the two syndromes.

Cancer Risks

The estimated lifetime risk of CRC for patients with MAP is approximately 60%. The typical age of onset is between ages 45 to 59, slightly older than in FAP. Monoallelic carries of *MUTYH* gene mutations may be at increased risk of CRC. The estimated risk is two to three times higher than the general population.[21]

Surveillance Protocols and Management

Patients with MAP should undergo colonoscopy every 1 to 2 years with polypectomy as indicated. Surveillance should be initiated by age 25 to 30. Those with unresectable polyps or a large polyp burden should be referred for surgical consideration. Similar to those patients with FAP, the extent of surgery (total abdominal colectomy with IRA vs. total proctocolectomy) depends on the polyp burden in the rectum. In a patient with an IRA, the rectum should be surveyed with flexible sigmoidoscopy every 6 to 12 months. Monoallelic carriers of *MUTYH* mutations should also have colonoscopies every 5 years beginning at age 40, or 10 years prior the earliest diagnosis of CRC in the family.

Because of the risk of upper GI neoplasia, baseline upper endoscopy including visualization of the ampulla of Vater should be performed by age 30 to 35. Surveillance examination interval is determined by the Spigelman stage in the same way it is used for FAP. The overall risk of duodenal cancer in MAP is approximately 5%.

Novel Genes or Syndromes (NTHL1, CRAC1)

With advances in genetic testing, a number of newer syndromes have been described. Polymerase proofreading-associated polyposis is an autosomal dominant syndrome characterized by mutations in the polymerase proofreading genes *POLE* and *POLD1*, which results in a highly penetrant syndrome of tens to hundreds of polyps and a high risk of CRC. The carcinomas are microsatellite stable, follow the chromosomal instability or classical pathway to development from adenomas, and are a result of unrepaired DNA replication errors. Patients may have family histories suggestive of LS. Female patients may be at increased risk for endometrial,

breast, and ovarian cancers. There are also descriptions of small bowel cancer and brain tumors associated with this syndrome.

The *NTLH1* gene, which encodes for a base excision repair protein, has been implicated in an autosomal recessive syndrome that is similar to MAP. It has been described in a cluster of Dutch families with a single founder mutation. The suspected carrier frequency in that population is 1 in 75,000. In a different individual with two separate mutations in the gene, the constellation of CRC, carcinoma of the bladder, meningioma, breast carcinoma, intradermal nevi, and basal cell carcinoma has been described. This suggests that the range of DNA lesions affected by this protein is broader than in MAP. The phenotype in affected families is consistent with an attenuated colorectal polyposis.

A mixed polyposis syndrome is described in patients with mutations to the *CRAC1* gene. Polyps may be serrated, hamartomatous, and adenomatous. CRC risk appears to be elevated. This gene is described in the Ashkenazi Jewish population. The gene was identified via linkage analysis and appears to be a single, founder mutation.

Because these syndromes are just being defined in small groups and clusters of families, the spectrum of the phenotype is not well known. There is insufficient evidence for specific screening, surveillance, or surgical treatment. As in cases without an identifiable genetic mutation, the individual and family phenotype should guide treatment decisions.

Familial CRC Type X and Undefined Syndromes

Families that meet the Amsterdam II criteria but do not have a pathogenic variant in an MMR gene identified are referred to familial CRC Type X. Compared to LS, it appears that the risk of extracolonic cancers are decreased. However, surveillance at short intervals is still recommended.

There are patients who phenotypically meet criteria for a polyposis syndrome and/or have a family history that is extremely suggestive of a polyposis syndrome, but do not have an identifiable genetic mutation. Management, therefore, is based on phenotype. Those individuals with dozens to hundreds of polyps should be managed in the same way as FAP patients, though their risk of extracolonic features may be less. The more common scenario, however, is a patient with 11 to 20 polyps; these patients

are managed individually based on specifics of the phenotype and clinical judgment. The patient must be willing to undergo frequent surveillance at 1- to 3-year intervals and polypectomy should be performed to clear the colon. If it becomes impossible to safely survey the colon endoscopically or advanced lesions are found, colectomy is appropriate.

Serrated Polyposis Syndrome

Serrated polyposis syndrome (SPS) was previously referred to as HP syndrome. It is rare, even compared to other hereditary CRC syndromes, and less well understood. It does appear to have an autosomal dominant inheritance pattern; 40% of first-degree relatives of SPS patients also have serrated polyps.

Genetics

Some patients who meet the clinical criteria for SPS have pathogenic variants in the *RNF43* gene but the majority of patients do not have an identifiable genetic mutation. The *RNF43* gene regulates *AMTIATR* (ataxia-telangiectasia mutated/ataxia-telangiectasia and Rad3-related protein) response to DNA damage.

Diagnosis

The clinical diagnosis for SPS includes at least five serrated polyps proximal to the sigmoid colon with at least two greater than 1 mm in size, any number of serrated polyps in an individual with a first-degree relative with SPS, or 20 or more serrated polyps anywhere in the colon. While small HPs are frequently found in the distal sigmoid and rectum of normal individuals, SPS represents a distinct phenotype.

Cancer Risk

Individuals with SPS are at higher than average risk for CRC, with a range of 16% to 35% reported in the limited literature that addresses the topic.[22,23]

Surveillance

If endoscopic management is feasible, all polyps 5 mm or greater in size should be removed. Subsequently, patients should undergo surveillance colonoscopies at 1- to 3-year intervals. If the number and/or size of polyps

renders endoscopic management impossible, or if there are advanced lesions, patients should be referred for surgery.

Because most patients do not have an identifiable genetic mutation, management of their relatives presents a challenge. It appears that first-degree relatives, even those without an SPS phenotype, have an increased risk of CRC.[24] Consensus guidelines recommend that first-degree relatives should be screened at the youngest age of onset of SPS in the family, 10 years earlier than the diagnosis of CRC, or by age 40—whichever is earliest in the case of an individual family. Colonoscopy should be repeated at least every 5 years and more frequently if indicated by findings.

Hamartomatous Polyposis Syndromes

Peutz–Jeghers Syndrome

PJS is an autosomal dominant syndrome associated with GI polyps and characteristic skin pigmentation. There are two genetic alterations associated with PJS, *LKB1,* and *STK11*, both of which encode serine/threonine kinase.

The GI polyps in PJS are hamartomatous. They are nonneoplastic but histologically distinct from other hamartomatous polyps such as juvenile polyps. They may be found in the stomach, small intestine, or colon. Polyps may cause bleeding, intussusception, or obstruction.

PJS is also characterized by distinctive cutaneous manifestations. The dark, macular lesions on the mouth and buccal mucosa as well as on the nose, lips, hand, feet, genitals, and anus tend to be more prominent early in life and then less obvious by puberty (**Fig. 67.15**). They are different than typical freckles in that they are present at birth and the buccal mucosa may be involved in PJS; the lesions also extend within the vermilion border of the lips.

Patients with PJS are at increased risk of cancers within and outside the GI tract. At-risk organs include the stomach, small intestine, colorectum, breast, pancreas, and biliary tree. Ovarian cysts, sex cord tumors, and sertoli cell testicular tumors may also be present. Small bowel cancer and CRC are relatively rare in PJS.

Management of PJS is aimed toward removal of polyps in the GI tract. Traditional upper and lower endoscopy are utilized, but more advanced

techniques such as double balloon or push enteroscopy may also be required. Surgery is utilized in cases where endoscopic management is not feasible. Combined laparoscopy and endoscopy may also be useful to enable treatment of the entire small bowel. There is no prophylactic surgery recommended for PJS.

Figure 67.15 Perioral hyperpigmentation associated with PJS.

Juvenile Polyposis Syndrome

JPS has been described with three distinct phenotypes: JPS limited to the colon, JPS limited to the stomach, and JPS throughout the GI tract. There are two genetic alterations associated with the syndrome, involving the *SMAD4* and *BMPR1A* genes. Each are thought to account for 20% of JPS cases; the remainder of cases have an unknown genetic etiology. When JPS occurs in conjunction with hereditary hemorrhagic telangiectasia, it is typically associated with *SMAD4*. In addition, some *PTEN* mutations have also been linked to JPS, but this is rare.

Clinical manifestations include bleeding, intussusception, obstruction, and autoamputation of polyps that then pass through the GI tract. Rarely, protein-losing enteropathy may develop. Approximately 15% of patients with JPS

have other abnormalities such as malrotation, heart or brain abnormalities, cleft palate, polydactyly, or genitourinary tract abnormalities.

Cowden Syndrome

Cowden Syndrome, also known as PTEN hamartoma tumor syndrome, is associated with a mutation on chromosome 10q23.3. Mutations are found in about 85% of patients diagnosed with Cowden syndrome. The PTEN gene is a tumor suppressor gene that acts as a negative regulator of the Akt/PKB signaling pathway, which in turn regulates levels of phosphoinositol triphosphate. It is also involved in regulating cell cycle, apoptosis, and angiogenesis. While intestinal polyps are important features, the extracolonic manifestations are more prominent. Though hamartomatous intestinal polyps occur in 30% to 85% of cases, there is no strong evidence of an increased risk for CRC from the hamartomatous polyps related to this syndrome. Patients may also have benign hamartomas and malignant tumors of the breast, thyroid, uterus, brain, and mucocutaneous tissue.

Diagnosis is based on meeting pathognomonic major and minor criteria developed in consensus guidelines. Testing should be offered to patients who have a family history of the syndrome if they meet the diagnostic criteria or if they have Lhermitte–Duclos disease. Major criteria include breast cancer, endometrial cancer, follicular thyroid cancer, multiple GI hamartomas or ganglioneuromas, macrocephaly, macular pigmentation of the glans penis, or mucocutaneous lesions including trichilemmoma, palmoplantar keratoses, multifocal or extensive oral mucosal papillomatosis, or multiple cutaneous facial papules. Minor criteria include autism spectrum disorder, CRC, more than three esophageal acanthoses, lipomas, intellectual disability, certain forms of thyroid cancers or benign lesions, renal cell carcinoma, single GI hamartoma or ganglioneuroma, testicular lipomatosis, or vascular malformation. In an individual with a relative who meets the clinical diagnosis criteria but who has not been tested, testing is appropriate if they meet any “major” or two “minor” criteria.

Breast cancer rates in women with Cowden syndrome are between 30% and 50%; men are also at risk. Benign breast conditions are also common in Cowden syndrome. Thyroid abnormalities including goiter, thyroglossal duct

cysts, and thyroid cancer are an important feature of Cowden syndrome. Renal cell cancer has also been described.

Because of the broad spectrum of tumors, patients with Cowden syndrome are recommended to undergo surveillance of their breast, endometrium, kidney, and thyroid. In terms of CRC risk, it is recommended that colonoscopy be started at age 35 or 5 to 10 years prior to the first known CRC in the family. Patients should undergo colonoscopy at least every 5 years for surveillance.

Bannayan–Riley–Ruvalcaba Syndrome

BRRS is a hamartomatous polyposis syndrome that also includes a constellation of macrocephaly, hypotonia, developmental delays in about half of all cases, pigmented speckling of the penis in men, hypermobile joints, and lipomas and hemangiomas in addition to the hamartomas of the intestine. More than two-thirds of patients with BRRS have a mutation in the PTEN gene. It is a rare disorder with dozens of cases reported in the literature but it may be underdiagnosed in milder phenotypes The incidence of gastrointestinal polyps is 45%.[25] The cancer risks associated with this syndrome are not well defined but many authors consider it analogous to Cowden syndrome. Most authors suggest considering individuals with BRRS at higher than average risk for malignancy, similar to Cowden syndrome.[26]

CONCLUSIONS

Polyps are an extremely common finding on colonoscopy, particularly as individuals age. Screening and surveillance with polypectomy has the potential to decrease both the risk and the mortality related to CRC. Polyposis syndromes are complex clinical problems that require coordinated care from multiple specialists; patients are often at higher risk for cancer in multiple organ systems. Optimal care is given in the context of a registry or organized program to ensure that all screening and surveillance guidelines are followed.

Colorectal Cancer

Julio Garcia-Aguilar and Emmanouil P. Pappou

Key Points

1. Incidence and overall mortality for colorectal cancer (CRC) are declining, especially among those aged 65 years or older, likely due to increased screening and improvement in treatment modalities. However, a surge in incidence among young adults, particularly those younger than 50 years has been recently noted. The cause of increase in young-onset CRC is currently unknown.
2. Our greater understanding of the molecular biology of CRC and the identification of disease biomarkers has allowed the introduction of targeted therapies, including immunotherapy into clinical practice.
3. Advances in imaging techniques have improved risk stratification via more accurate baseline tumor staging and treatment selection.
4. Improved risk stratification and neoadjuvant therapy have enabled physicians to tailor therapeutic components of treatment.
5. Use of laparoscopic and robotic surgical techniques in combination with enhanced recovery programs has accelerated patient recovery, reduced length of hospital stay, and reduced postoperative complications.
6. While long-term survival for patients with stage IV disease remains low, median survival for these patients has improved significantly in recent years, probably due to more effective chemotherapy and more aggressive surgery.
7. Multidisciplinary treatment involving surgical oncologists, medical oncologists, radiation oncologists, as well as liver surgeons, gastroenterologists, and stoma therapists improves outcomes and quality of life in patients with CRC.

INTRODUCTION

Colorectal cancer (CRC) kills more than 50,000 people every year in the United States. If diagnosed at an early stage, however, it is one of the most curable malignancies. Identification of populations at risk and screening of asymptomatic patients are therefore crucial imperatives. This chapter provides

a comprehensive overview of the disease, including epidemiology, risk factors, molecular characteristics, progression, staging, screening, diagnosis, and treatment.

EPIDEMIOLOGY

CRC is the third most common malignancy and the second most common cause of cancer death in the United States. It is estimated that in 2020, a total of 147,950 people will be diagnosed with CRC in the United States, and 53,200 will die from the disease.[1] Approximately 1 in 20 Americans will be diagnosed with CRC in their lifetime. Death from CRC could be reduced significantly by implementing screening for cancer prevention and early diagnosis, as well as adherence to standards of cancer care. The incidence and mortality rates for CRC have been decreasing for the last three decades, with a large drop in the late 2000s thought to be reflective of the nationwide adoption of CRC screening with colonoscopy. Most recently, however, there has been a deceleration in the decline of CRC incidence and mortality (**Fig. 68.1**).[2]

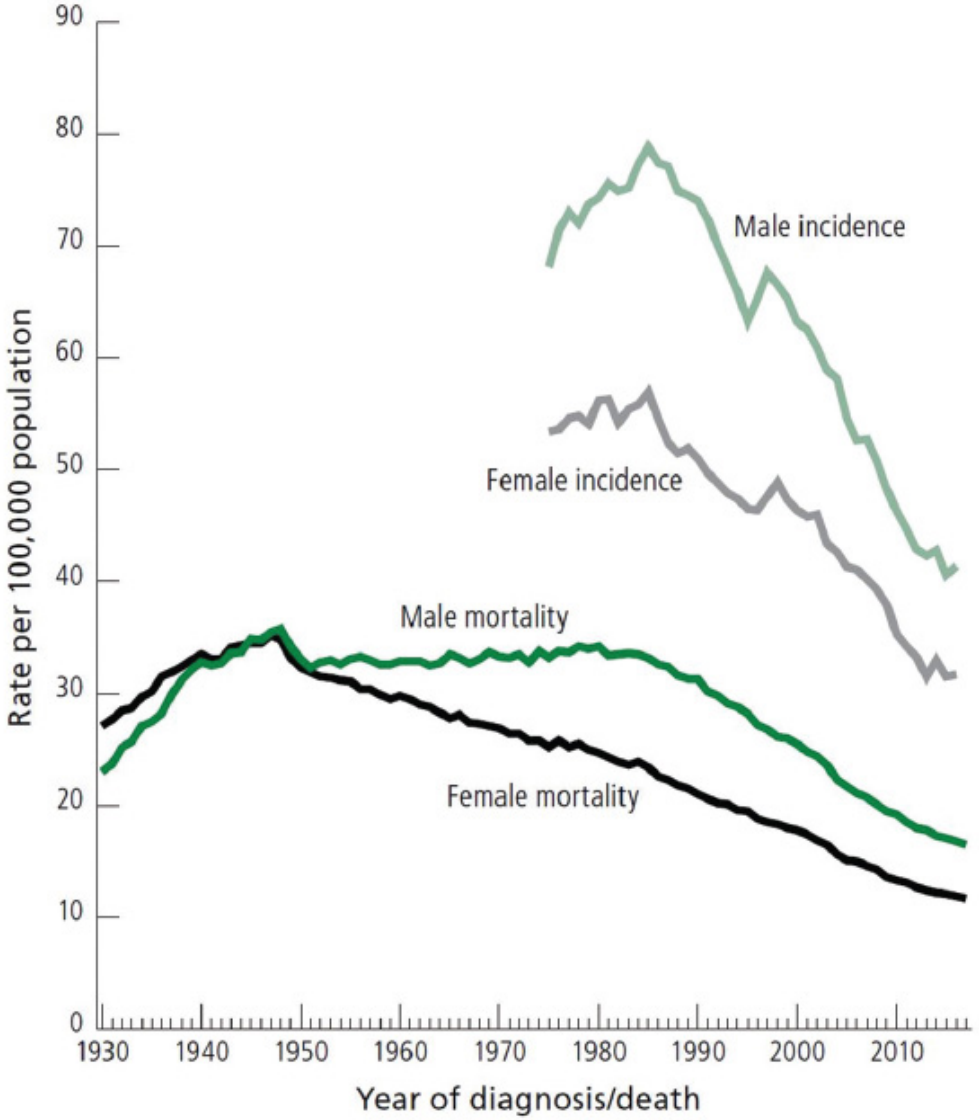

Figure 68.1 Trends in Colorectal Cancer Incidence and Death Rates by Sex, USA, 1930–2017. (Reproduced with permission from The American Cancer Society, Colorectal Cancer Facts and Figures 2020–2022. Atlanta: American Cancer Society, Inc.)

The incidence and mortality rates for CRC vary with age. The median age at colon cancer diagnosis is 67 years in men, and 71 years in women; for rectal cancer, 62 years in men and 63 years in women.[2] While the incidence and mortality for CRC have decreased in older adults (50+ years old), they have 1 increased in younger adults (<50 years old) (**Fig. 68.2**). This change in trend is especially worrisome, as the incidence is occurring in patients younger than the recommended screening age.[2] Both, the incidence and mortality for CRC are 30% to 40% higher in men than in women. The reasons for these differences are

not completely understood but probably reflect an interaction between risk factors and hormonal differences. There are also gender differences in the distribution of CRC, with a higher proportion of proximal tumors in women.

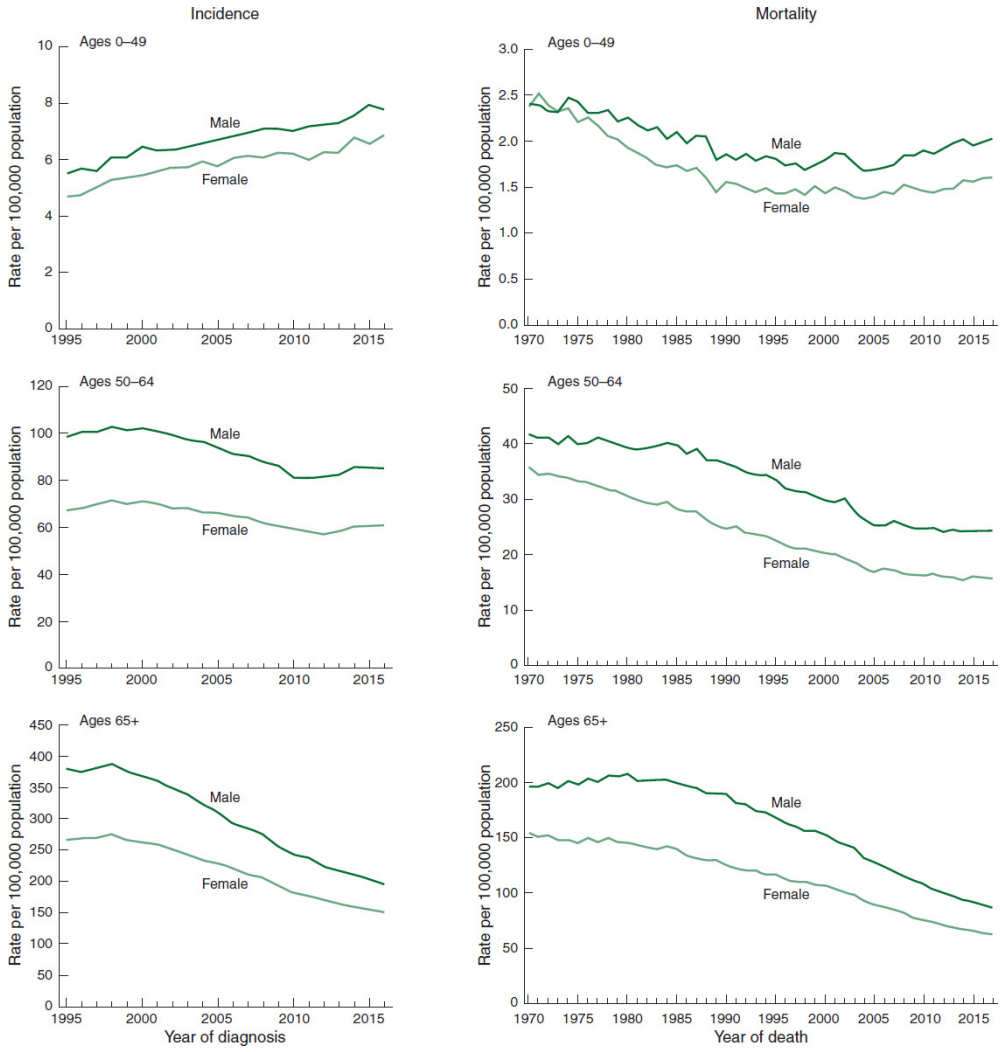

Figure 68.2 During the most recent five data years (2012–2016), incidence rates of CRC increased by 2.2% annually in individuals younger than 50 years and by 1% annually in those ages 50 to 64 years, a sharp contrast to declines of 3.3% per year in adults ages 65 and older. Reasons for the increasing CRC trend in younger age groups are unknown. (Reproduced with permission from The American Cancer Society, Colorectal Cancer Facts and Figures 2020–2022. Atlanta: American Cancer Society, Inc.)

There are great disparities in CRC incidence and mortality between ethnic and racial groups. Both are highest for African Americans and lowest for Asians/Pacific Islanders, but the differences in mortality are proportionally larger compared to the differences in incidence. The decline in mortality for

CRC that began in the 1980s did not start affecting African Americans until the 1990s. Since the mid-2000s, CRC incidence rates decreased by 1% to 3% per year in all racial groups.[2]

CRC is the third most common cancer in men and the second most common cancer in women worldwide, with an estimated 1.8 million new cases diagnosed in 2019.[3] It is responsible for 9% of cancer deaths worldwide. The age-standardized incidence of CRC varies significantly by country. It is decreasing in developed countries that have implemented screening programs (U.S., Israel, and Japan) or have modified factors known to be associated with increased risk of CRC (Australia and New Zealand). However, the incidence rates are increasing in both developed and developing countries with changes in unfavorable risk factors such as adoption of a western diet, obesity, and smoking. Despite the increase in incidence, mortality for CRC is decreasing in many countries, most likely because of improvements in both screening and treatment.[3]

RISK FACTORS

There are numerous factors associated with the risk of CRC (**Table 68.1**). Some are behavioral, and potentially modifiable. Others are genetic or hereditary, and therefore nonmodifiable. Information about individual risk factors can be used to reduce incidence and mortality through behavior modification and screening programs.[4] Except for the relatively uncommon hereditary syndromes with known patterns of inheritance, the relative contribution of inherited and environmental factors to the development of CRC is controversial. Analysis of cohorts of twins from Scandinavian countries suggests a significant but relatively minor contribution of hereditary factors to the development of sporadic CRC; the environment seems to play a larger role in the development of sporadic cancers.[5]

Table 68.1 Relative Risks for Established Colorectal Cancer Risk Factors

Factors that Increase Risk:	Relative Risk[a]
Behavioral, Modifiable	
Heavy alcohol use (daily average >3 drinks)	1.3
Obesity (body mass index ≥30 kg/m^2)	1.3
Colon, male	1.5
Colon, female	1.1
Rectum, male	1.3
Rectum, female	1.0
Red meat (100 g/day)	1.1
Processed meat (50 g/day)	1.2
Smoking	
Current vs. never	1.5
Former vs. never	1.2
Hereditary, Nonmodifiable	
Family History	
Family history of CRC	
1 or more first-degree relatives	2.2
1 or more first-degree relatives diagnosed before age 50	3.6
2 or more first-degree relatives	4.0
1 or more second-degree relatives	1.7
Family history of adenoma	
1 or more first-degree relatives	2.0
Medical History	
Inflammatory bowel disease (Crohn disease, ulcerative colitis)	1.7
Type 2 diabetes mellitus	
Male	1.4
Female	1.2
Factors that Decrease Risk:	
Physical activity	0.7

Dairy (400 g/day)	0.9

[a]Relative risk for dietary factors compares the highest with the lowest consumption. If the relative risk is more than 1.0, then risk is higher among exposed than unexposed persons. Relative risks less than 1.0 indicate a protective effect.

Reproduced with permission from The American Cancer Society, Colorectal Cancer Facts and Figures 2020–2022. Atlanta: American Cancer Society, Inc.

The list of behavioral or modifiable factors that increase CRC risk includes obesity, smoking, diet, and alcohol intake. More than half (55%) of CRCs in the United States are attributable to potentially modifiable risk factors.[3] Physical activity and dairy products reduce CRC risk.[2] Obesity is associated with increased risk of developing CRC in both men and women.[6] Abdominal obesity, measured as waist size, seems to be more important than excess weight, particularly in men. Being overweight increases the risk of CRC, independent of the level of physical activity. The most physically active people have a 25% lower risk of developing CRC, compared to the least active people. Both recreational and occupational physical activity reduces CRC risk, and sedentary people who become physically active later in life do reduce their CRC risk.[7] An increased risk of CRC has been associated with high consumption of red or processed meats.[8] On the other hand, the risk of CRC is inversely correlated with the intake of fiber and whole grains, fruits and vegetables, dairy products and calcium, vitamin D, and folates.[8] Heavy alcohol consumption (more than 3 drinks/day) is associated with the development of CRC, and the effect seems to be dose dependent. The risk seems to be higher for men than for women. There is no difference in the effect with regard to the type of alcohol.[9] Smoking increases the incidence and mortality from CRC, and in particular, rectal cancer.[10,11]

Three-quarters of CRCs occur in people who do not have any particular predisposing factors, and are therefore considered to be at average risk. The remaining 25% of patients have hereditary risk factors that predispose them to the development of CRC: either a well-defined hereditary CRC syndrome (5%) or a close relative who has been diagnosed with the disease (20%). People with one or more first-degree relatives with CRC have between a 1.9 and 4.4 relative risk of developing CRC, compared to the average population. The risk is higher when the affected relative was diagnosed at an early age, or when several relatives have been affected.[12,13] Recent population-based studies have found a greater familial aggregation of early-onset CRC among first-degree

relatives diagnosed before the age of 40, compared to patients diagnosed after the age of 41. This age-of-onset effect could not be attributed solely to known hereditary CRC syndromes.[14] CRC survivors have four times the lifetime risk of developing a new (metachronous) CRC, compared with people at average risk. The estimated mean annual incidence of metachronous CRC is 0.3%, with a cumulative incidence of 3.1% at 10 years.[15] A personal history of adenomatous colorectal polyps also increases the risk of CRC, in particular for patients with larger or multiple polyps and an early age at diagnosis.[16]

Patients with chronic inflammatory bowel disease, both ulcerative colitis and Crohn disease, are at increased risk of developing CRC.[17] The risk increases with the duration of the disease. It is estimated that, after 10 years of disease, the risk of developing CRC increases by around 1% each year. Thus, it is estimated that patients with 30 years of inflammatory bowel disease have an 18% risk of developing CRC. The risk is higher for patients diagnosed with inflammatory bowel disease at an early age and with disease extending proximal to the splenic flexure. A high cumulative burden of inflammation, that takes into consideration the intensity and the duration of inflammation, has been associated with a higher risk of colorectal neoplasia.[18] However, the incidence of CRC in patients with ulcerative colitis seems to be decreasing. A recent meta-analysis of population-based cohort studies reported a 1.7 increased risk of CRC among inflammatory bowel disease patients, compared to the general population, after adjusting for age, gender, and duration of disease.[19] These changes are probably due to more effective treatments and the efficacy of surveillance programs.[20]

Patients with type II diabetes have a higher risk of developing CRC compared to the nondiabetic individual, even when adjusting for factors such as obesity and sedentary lifestyle.[21] In addition, CRC survival rates are lower for diabetic patients compared to nondiabetic patients.[22] The relationship between diabetes and CRC seems to be stronger for men than for women.

MOLECULAR CHARACTERISTICS

The traditional model of CRC tumor development is often represented as a linear and sequential progression from normal epithelium to small adenoma, to large adenoma, to invasive carcinoma, and finally to metastatic disease.[23] This so-called adenoma–carcinoma sequence has been deemed the result of the

progressive accumulation of alterations in the genome. This model has shaped our understanding of key genetic alterations that result in colorectal tumorigenesis and has had an enormous clinical impact by highlighting the importance of screening and surveillance. Whole genome analysis with high-throughput technologies has added new information that is broadening our understanding of colorectal carcinogenesis. Every CRC has a multitude of distinct genetic alterations that perturb a number of molecular pathways. This genetic heterogeneity ultimately has a bearing on the speed of growth, local invasiveness, metastatic potential, and response to therapy. As our understanding of these molecular changes improves, we anticipate 2 that we will be able to provide better screening and prognostic tools and discover new tumor-specific therapies.

The most comprehensive molecular analysis of CRC to date has been conducted by The Cancer Genome Atlas (TCGA) Consortium.[24] They have used state of the art technology to elucidate the mutational spectrum, the chromosomal and subchromosomal changes, the epigenetic regulation and transcriptional alterations in a large number of CRCs. A key finding that has helped frame our molecular understanding of CRC is the wide variation in the number of somatic mutations present in most tumors. According to the number of mutations, CRC can be effectively classified as hypermutated, harboring a median of 728 nonsilent mutations per tumor, and nonhypermutated, with a median of 58 nonsilent mutations (**Fig. 68.3**). Nonhypermutated tumors comprise 84% of CRCs, and are characterized by chromosomal instability (CIN). CIN is the result of missegregation of chromatids in tumor cells, resulting in gains and losses of entire chromosomes or chromosomal segments; manifesting as aneuploidy and copy number alterations (CNAs).[25] Common patterns of aneuploidy and CNAs in nonhypermutated CRC include amplifications in chromosome arms 1q, 7p and q, 8q, 13q, 17q, and 20p/q, and deletions in 8p, 14q, 15q, 17p, and 18p/q. Some of these CNAs could account for the loss of important tumor suppressors such as TP53 (on 17p), DCC, and SMAD4 (on 18q), and the amplification of oncogenes such as ERBB2 (on 17q). In short, CIN in nonhypermutated tumors can activate critical oncogenes, and inactivate tumor suppressors that contribute to the acquisition of tumorigenic traits.

The hypermutated tumors, representing 16% of all CRCs, are deficient in the mismatch-repair (MMR) mechanisms controlling the correction of errors that occur during DNA replication. The end result of MMR deficiency (dMMR) is a

form of genetic instability characterized by the accumulation of mutations throughout the genome, primarily in repetitive sequences known as microsatellites; this is known as microsatellite instability (MSI).[26] The mutational burden ultimately provides these MSI tumors with their malignant potential. Unlike CIN tumors, also known as microsatellite stable or MSS, MSI tumors generally remain diploid or near-diploid. They are less likely to have KRAS, TP53, SMAD4 mutations, and more likely to have BRAF and TGFBR2 mutations. MSI can arise from either the germline inactivating mutations or the epigenetic silencing of one of several MMR genes (MLH1, MLH3, MSH2, MSH3, and MSH6). Research into the mechanisms of epigenetic silencing of MSI tumors has helped elucidate the CpG Island Methylator Phenotype (CIMP), whereby the methylation of CpG sequences in the promoter region of MMR genes (most commonly MLH1) leads to their transcriptional silencing.

The classification of CRC according to the type of genomic instability is clinically relevant.[27] MSI tumors tend to be preferentially right sided, have a solid or cribriform histologic pattern, and contain a large number of tumor-infiltrating lymphocytes.[28] Nonmetastatic MSI tumors have a better prognosis, compared to MSS tumors.[29] However, in a metastatic setting, MSI tumors are associated with a worse survival compared to MSS tumors.[30] MSI tumors are less responsive to fluoropyrimidines, but most responsive to immune checkpoint inhibitors (ICIs), compared to MSS tumors.[31]

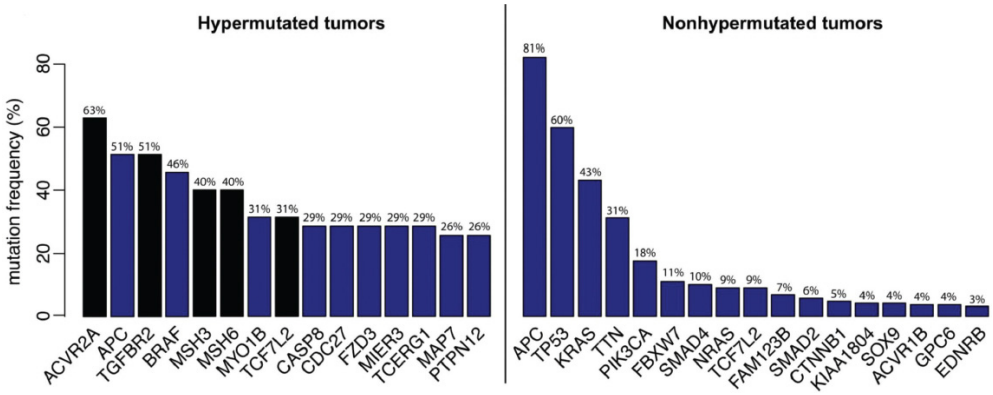

Figure 68.3 Mutation frequencies in hypermutated and nonhypermutated tumors in CRC. *Blue bars* represent genes identified by MutSig and genes in *black bars* are identified by manual examination of sequence data. (Reproduced with permission from Comprehensive molecular characterization of human colon and rectal cancer. The cancer genome atlas network. *Nature* 2012;487(7407):330–337.)

The genomic instability that characterizes CRC is associated with alterations in a number of key pathways; among others, the WNT, MAPK, PI3K, TGF-β, and p53 pathways.[24] The WNT signaling pathway contributes to the tightly regulated homeostasis of intestinal epithelial crypts, and its alteration is considered an initiating event in colorectal carcinogenesis. It is altered in more than 90% of both hypermutated and nonhypermutated CRCs. The most prevalent alteration leading to dysregulation of the WNT pathway occurs through biallelic inactivation of the tumor suppressor adenomatous polyposis coli (APC) gene.[32] Patients with familial adenomatous polyposis (FAP) have a germline mutation in one allele of the APC gene, and their risk of developing CRC is virtually 100%. The WNT pathway is also commonly altered as a result of stabilizing mutations of the CTNNB1 gene coding for β-catenin, a protein normally targeted for degradation by APC. The accumulation of β-catenin as a result of APC loss or stabilizing CTNNB1 mutations leads to its translocation to the nucleus, where it interacts with transcription factors of the TCF/LCF family, turning them into transcriptional activators. The end result is an increase in the transcription of genes that are normally important for stem cell renewal and differentiation but, when inappropriately expressed at high levels, can cause cancer.

Mutational inactivation of the TGF-β pathway, important in regulating cell growth arrest and apoptosis, is a common event in CRC.[33] Downstream effectors of this pathway such as the transcription factor SMAD4, and associated proteins SMAD2 and SMAD3, are also inactivated by mutation or homozygous deletion of chromosomal segment 18q. Another member of this pathway, deleted in CRC (DCC), is also commonly inactivated by deletion of chromosome 18q.

A common theme of the WNT and TGF-β signaling pathways is the increased activity of c-Myc, a regulator gene that codes for a multifunctional transcription factor which plays a role in cell cycle progression, apoptosis, and cellular transformation. c-Myc seems to play a central role in colorectal carcinogenesis.[34]

The TP53 gene is a member of a pathway of regulators of cell cycle arrest and cell death in response to a variety of genotoxic stresses. Mutations in the TP53 tumor suppressor gene occur in more than half of nonhypermutated CRCs. In most tumors, both alleles of the gene are inactivated by a combination of a mutation in one allele, and loss of the second allele by deletion of the chromosomal segment 17p. Loss of the TP53 tumor suppressor gene is

generally considered an early event that plays a role in the transition from adenoma to invasive carcinoma.[35] In hypermutated tumors, the TP53 pathway may be attenuated by mutations in other genes, such as the proapoptotic BAX.

The MAPK pathway consists of a cascade of tightly coordinate kinases that work together to regulate cell division and proliferation. KRAS, a protooncogene that becomes constitutively activated by mutation, resulting in uncontrolled cell proliferation, is mutated in 37% of CRC. Interestingly, a number of studies from model organisms reveal that KRAS mutation by itself is not sufficient to initiate tumorigenesis; in order to have oncogenic potential it requires a previous APC mutation. The MAPK pathway is the molecular pathway that has successfully been therapeutically targeted in CRC. Inhibition of this pathway using antibodies against the epidermal growth factor receptor (EGFR) reduces progression in wild-type KRAS/NRAS metastatic CRC.[36] Activating mutations of BRAF, also an effector member of the MAPK pathway downstream of KRAS, are seen in 13% of CRC. The BRAF mutation is associated with poor prognosis, specifically in MSI tumors.[37]

The PI3K/AKT/mTOR signaling pathway, with important roles in cell proliferation and apoptosis, is abnormally activated in nearly half of all CRCs. Moreover, in the TCGA cohort, PI3K and RAS pathways are simultaneously affected by mutations in one-third of all CRCs, suggesting that simultaneous inhibition of both pathways may be required to achieve a therapeutic effect.[38]

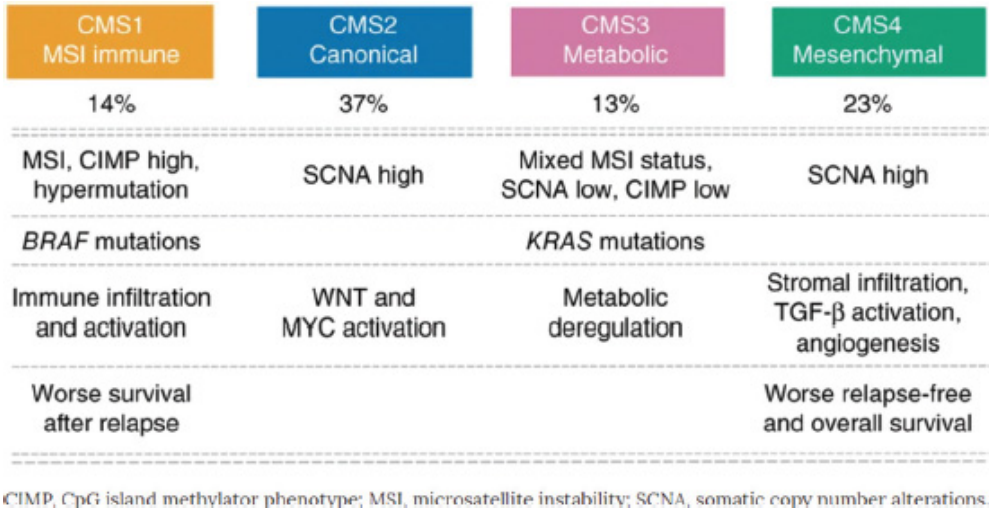

Figure 68.4 The consensus molecular subtypes. CMS1 displays subtype clusters that involve hypermutation and microsatellite instability along with increased immune cell infiltrates consisting of Th1 lymphocyte, cytotoxic T cell, NK cell infiltration, and upregulated immune checkpoints such as PD-1. CMS2 clustering involves the upregulation of canonical pathways including WNT and MYC downstream targets. CMS3 clustering is defined by dysregulation of metabolic pathways including carbohydrate and fatty acid oxidation and the loss of TH17 cells. CMS4 clustering is referred to as a mesenchymal subtype that involves the upregulation of EMT pathways. CMS4 clustering also shows elevated TGF-β signaling, matrix remodeling, angiogenesis, complement activation as well as integrin-β3 upregulation, stromal infiltration, immune upregulation, and platelet signatures. (Reproduced with permission from Guinney J, Dienstmann R, Wang X, et al. The consensus molecular subtypes of colorectal cancer. *Nat Med* 2015;21(11):1350–1356.)

Gene expression has been linked to tumor phenotype and biologic behavior in CRC. Recently, an international consortium of six groups that examined shared, large-scale high-throughput gene expression data was able to create a transcriptomic-based molecular classification of CRC. This novel classification distinguishes four consensus molecular subtypes (CMS) of CRC, with distinct genomic and clinical features (**Fig. 68.4**).[39] The CMS group classification is currently considered the most robust molecular system connected to distinct biologic and clinical characteristics, and serves as a framework for molecularly targetable interventions. CMS2 was named the canonical subtype that made up 37% of all clusters observed and exhibited epithelial characteristics with marked WNT and MYC activated pathway signaling. CMS1 made up 14% of the categorized molecular clustering and displayed MSI along with significant immune activation and hypermutated features. The CMS3 subtype made up 13% of the molecular clustering and showed features of epithelial and metabolic dysregulation. The CMS4 subtype

was found in 23% of the molecular clusters with epithelial mesenchymal transformation (EMT) characteristics accompanied by prominent stromal invasion and angiogenesis, hallmarked by transforming growth factor-β (TGF-β) activation. The remaining 13% of tumors had molecular features that were mixed and are thought to reflect a transition phenotype or intratumoral heterogeneity, typically with characteristics of multiple CMS.[40] The identification of molecularly distinct subtypes can provide distinct subsets of patients on which to test new treatments, and may provide insight into specific biologic pathways to target for these subgroups.

HISTOPATHOLOGY AND PROGRESSION

CRC is an adenocarcinoma arising from the epithelial lining of the large bowel. Some CRCs may develop de novo, but most result from malignant transformation of adenomatous polyps. In the past, only tubular and villous adenomas were considered to develop into invasive adenocarcinomas. However, recent evidence suggests that serrated polyps can also develop into CRCs. Polyps arise from normal mucosa, and gradually increase in size. Some polyp characteristics—size larger than 1 cm, tubulovillous or villous histology, multiple occurrences—are associated with a high risk of malignant transformation. Most screening programs are designed to recognize the presence of polyps, or early malignant change in polyps or the surrounding mucosa.

Table 68.2 Histopathologic Types of Colorectal Cancer

Carcinomas
Adenocarcinoma
Medullary carcinoma
Mucinous adenocarcinoma (greater than 50% mucinous content)
Signet ring cell carcinoma (greater than 50% signet ring cells)
Neuroendocrine adenocarcinoma
Squamous cell carcinoma
Adenosquamous carcinoma
Small cell carcinoma
Undifferentiated carcinoma
Other Tumors
Carcinoid
Lymphoma
Sarcomas

The majority of CRCs are typically adenocarcinomas that form glandular structures resembling the normal colonic epithelium. However, there are several histologic types of adenocarcinoma (**Table 68.2**). Colorectal adenocarcinomas are assigned to one of four histologic grades according to their histologic resemblance to the normal colonic epithelium. The histologic grade is associated with oncologic outcome independent of other risk factors, including tumor staging.

CRC is locally invasive, potentially spreading through the full thickness of the bowel wall into adjacent tissues. From the primary site, CRC often extends to the regional lymph nodes and to other organs. CRC can metastasize to almost any organ, but the most common sites are the liver and lungs. Approximately 20% to 34% of patients have metastases at the time of diagnosis, and another 30% of those initially treated with curative intent will subsequently develop distant metastases. Other sites of distant metastasis are the brain and bones, but these are unusual in the absence of liver metastases. Patients may also develop peritoneal spread, with the formation of malignant ascites. The risk of nodal metastasis increases with the depth of tumor invasion into the bowel wall, and the risk of distant metastasis is higher for patients with nodal metastasis.

STAGING AND PROGNOSIS

The anatomical extent or stage of the tumor at the time of diagnosis is a key factor in deciding upon treatment and defining prognosis in patients with CRC. The tumor–node–metastasis (TNM) classification developed by the UICC/AJCC is firmly established as the preferred staging system (**Table 68.3**).[41] It classifies CRC according to the extent of the primary tumor (T), the involvement of the regional lymph nodes (N), and the presence or absence of distant metastasis (M). The TNM classification is important for both clinical and pathologic staging. Most colon cancers, and many rectal cancers, are staged after surgery and pathologic examination of the surgical specimen (pTNM). Many rectal cancer patients, and a small but growing number of colon cancer patients, do not receive surgery as the initial therapy, which makes clinical TNM (cTNM) staging based on medical history, physical examination, endoscopy, and imaging, increasingly important. As tumors experience a variable degree of regression with preoperative chemotherapy and/or radiation, it is important that patients receiving neoadjuvant therapy are assigned an accurate cTNM stage before starting treatment. For patients who have received neoadjuvant therapy, a modified pathologic staging is generated after surgical resection, annotated by the prefix y (ypTNM). The 8th edition of the AJCC Cancer Staging Manual incorporates a four-tier tumor regression grading (TRG) system for patients receiving neoadjuvant therapy. In this grading system TRG 0 represents Complete Response, no viable tumor cells or complete pathologic response (pCR); TRG 1, Near-complete Response; TRG 2, Partial Response; and TRG 3, Poor Response. Tumor regression seems to correlate closely with prognosis and long-term oncologic outcome.[41]

The AJCC staging system is updated periodically in response to newly acquired clinical data and understanding of the biology of the tumor. The 8th edition of the AJCC Cancer Staging Manual, for all cancers diagnosed after January 1, 2018, was updated based on observed survival outcomes obtained from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) program. Relative survival in CRC patients decreases according to the depth of tumor penetration into the bowel wall and number of lymph nodes involved, but the presence of distant metastasis is the single most important predictor of survival in these patients (**Table 68.3**). Other tumor and treatment-related prognostic factors, in addition to the TNM stage, are listed in **Table 68.4**.

Quantitative parameters of lymph node evaluation—number of positive lymph nodes, total number of lymph nodes examined, and lymph node ratio—have prognostic implications in CRC. The number of nodes involved by tumor is included in the N category of the TNM system. The current staging system recommends examining a minimum of 12 lymph nodes for adequate staging.[41] The total number of lymph nodes retrieved is lower in rectal cancer patients treated with preoperative chemotherapy and radiation, but the minimal number of nodes required for adequate staging in these patients is unknown. The total number of nodes examined has an important impact on outcome in patients with colon and rectal cancer; in patients with all T and N combinations, the probability of survival increases linearly with the number of lymph nodes examined. The lymph node ratio, defined as the number of positive lymph nodes divided by the total number of retrieved nodes, has also been considered an independent predictor of survival.[42] However, the results have not been extensively validated and the lymph node ratio is not currently included in staging. Irregular tumor deposits in the mesocolon or mesorectum without surrounding lymph node tissue, are considered peritumoral tumor deposits; they are not counted as lymph nodes but are classified as N1c, and contribute to stage III.[41] These are considered to represent large vessel or perineural invasion. The significance of micrometastasis detected by immunohistochemistry (usually with anticytokeratin antibodies) in H&E negative nodes of patients with stage II disease is controversial. Although some studies have reported an association between micrometastasis, increased recurrence and reduced survival, the detection of micrometastasis has not been incorporated into clinical practice, and at the present time should be considered investigational.[43]

Tumor sidedness has prognostic implications that are probably related to epidemiologic, clinical and biologic factors. In general, patients with right-sided tumors tend to be older, more frequently women, have more advanced histologic grade and more advanced disease stage at diagnosis. Right-sided tumors are more likely to be MSI and have more BRAF mutations. Stage I and II right-sided cancers have better cancer-specific survival compared to left-sided tumors, but stage III and specially stage IV right-sided tumors have worse specific survival compared to left-sided tumors.[44] In patients with rectal cancer, tumors located in the distal rectum have worse prognosis compared to tumors located in the upper rectum.

Table 68.3 American Joint Committee on Cancer (AJCC) TNM Staging Classification for Colorectal Cancer 8th ed., 2017

Definitions for T, N, M

T Primary Tumor	
TX	Primary tumor cannot be assessed
T0	No evidence of primary tumor
Tis	Carcinoma in situ: intramucosal carcinoma (involvement of lamina propria with no extension through muscularis mucosae)
T1	Tumor invades the submucosa (through the muscularis mucosae but not into the muscularis propria)
T2	Tumor invades muscularis propria
T3	Tumor invades through muscularis propria into the pericolorectal tissues
T4	Tumor invades the visceral peritoneum or invades or adheres to adjacent organ or structure
T4a	Tumor invades through the visceral peritoneum (including gross perforation of the bowel through tumor and continuous invasion of tumor through areas of inflammation to the surface of the visceral peritoneum)
T4b	Tumor directly invades or adheres to adjacent organs or structures
N Regional Lymph Nodes	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	1–3 regional lymph nodes are positive (tumor in lymph nodes measuring ≥0.2 mm), or any number of tumor deposits are present and all identifiable lymph nodes are negative
N1a	1 regional lymph node is positive
N1b	2–3 regional lymph nodes are positive
N1c	No regional lymph nodes are positive, but there are tumor deposits in the subserosa, mesentery, or nonperitonealized pericolic or perirectal/mesorectal tissues

N2	4 or more regional lymph nodes are positive
N2a	4–6 regional lymph nodes are positive
N2b	7 or more regional lymph nodes are positive

M Distant Metastasis	
M0	No distant metastasis by imaging etc.; no evidence of tumor in distant sites or organs
M1	Metastasis to one or more distant sites or organs or peritoneal metastasis is identified
M1a	Metastasis to one organ or site (e.g., liver, lung, ovary, nonregional lymph node) is identified without peritoneal metastasis
M1b	Metastases to two or more sites or organs or metastasis to one organ or site (e.g., liver, lung, ovary, nonregional lymph node) is identified without peritoneal metastasis
M1c	Metastasis to the peritoneal surface is identified alone or with other site or organ metastases

Prognostic Groups

Stage	T	N	M
0	Tis	N0	M0
I	T1	N0	M0
	T2	N0	M0
IIA	T3	N0	M0
IIB	T4a	N0	M0
IIC	T4b	N0	M0
IIIA	T1–T2	N1/N1c	M0
	T1	N2a	M0
IIIB	T3–T4a	N1/N1c	M0
	T2–T3	N2a	M0
	T1–T2	N2b	M0
IIIC	T4a	N2a	M0
	T3–T4a	N2b	M0

	T4b	N1-N2	M0
IVA	Any T	Any N	M1a
IVB	Any T	Any N	M1b
IVC	Any T	Any N	M1c

Note: cTNM is the clinical classification, pTNM is the pathologic classification. The y prefix is used for those cancers that are classified after neoadjuvant pretreatment (e.g., ypTNM). Pathologic complete response ypT0N0cM0 may be similar to Stage 0 or I. The prefix r is to be used for those cancers that have recurred after disease-free interval (rTNM).

Table 68.4 Colorectal Cancer Prognostic Factors

Pathologic Features
TNM stage
Total number of nodes examined
Extramural non-nodal tumor deposits
Tumor location
Circumferential resection margin
Local residual disease (R status)
Tumor regression after neoadjuvant therapy
Lymphovascular invasion
Perineural invasion
Histologic type, grade, and presence of mucin
Host immune response (presence of tumor-infiltrating lymphocytes within tumor)
Clinical Features
Preoperative serum CEA levels
Bowel obstruction and/or perforation
Molecular Features
Microsatellite instability
KRAS mutation
BRAF mutation

The quality of the surgery and the completeness of tumor resection also provide important prognostic information. The distance of tumor to the

circumferential resection margin (CRM)—defined as the surgically dissected nonperitonealized surface of the specimen—provides important prognostic information in both colon and rectal cancers.[45,46] The CRM is considered positive if tumor is found within 1 mm of the resection margin (rather than 0 mm). In rectal cancer patients, involvement of the CRM (i.e., the margin created by the surgeon around the rectum and mesorectal fat) occurs most frequently anteriorly, where the mesorectum is at its thinnest. The presence of tumor at the CRM, because of advanced stage or inadequate resection, is associated with a high rate of recurrence and decreased probability of survival.[47]

The AJCC has established codes for completeness of the resection, which should be reported for each procedure.[41] A resection is defined as R0 when the entire tumor is resected and the margins are histologically negative; R1 when the margins are grossly uninvolved but histologically positive; and R2 when the tumor is not completely resected, and there is gross residual tumor at the primary site, regional lymph nodes, or metastatic sites.

Other factors associated with worse outcomes include elevated CEA levels before surgery, high histologic grade, signet ring cell and small cell histopathologic type, lymphatic and blood vessel invasion, and perineural invasion.[41] Vascular invasion is considered a sign of aggressive behavior in CRC, and has been associated with a higher risk of disease progression and poor prognosis. Capillary invasion is often associated with lymphatic invasion, and these are commonly designated as lymphovascular invasion. Large vessel invasion, detectable on magnetic resonance imaging (MRI), has been shown to be an adverse risk factor in rectal cancer.[48]

While the TNM staging system provides important prognostic information, it is inadequate for individual prognostication. Outcomes for individual patients within each tumor stage are variable. Recently, nomograms using a number of clinical and pathologic characteristics have been designed to improve prediction and survival beyond TNM staging in patients with colon or rectal cancer, particularly in the setting of stage II tumors (**Fig. 68.5**).[49] In addition to providing prognostic information, nomograms may potentially guide clinical decisions, such as the use of adjuvant chemotherapy or the regularity of surveillance. However, nomograms have not been routine part of clinical decision making.

A number of molecular markers such as MSI, 18q loss of heterozygosity, KRAS, and BRAF, among others, have been associated with prognosis in CRC patients. In addition, some of these markers are now used to make treatment

decisions, particularly in metastatic CRC. For example, MSI tumors are likely to respond to PD-1 blockade, KRAS wild-type tumors are likely to respond to anti-EGFR therapy, and BRAF V600E mutant tumors are likely to respond to a combination of BRAF, MEK, and EGFR inhibitors.[50–53]

Increasing evidence demonstrates that the evolution of cancer is strongly dependent on the complex tumor microenvironment in which it develops, comprised of a variety of elements including fibroblasts, lymph vessels, and cells of the immune system. The presence of tumor infiltrating lymphocytes (TILs), usually seen in MMRd patients, is associated with good prognosis in patients with CRC, regardless of mismatch repair (MMR) status.[54] Quantification of lymphocyte populations, in particular CD3- and CD8-positive T cells, has led to the development of a score referred to as Immunoscore, a score highly reproducible across institutions, with increasing score correlating with longer patient survival.[55]

Based on recent advances in the molecular characterization of CRC, a number of multigene molecular signatures (Oncotype DX, Coloprint, and ColDx) have been designed as prognosticators of recurrence and outcomes. While these molecular signatures seem to determine risk of recurrence independent of other well-established risk factors, they have not been fully incorporated into clinical practice.[56–58]

SCREENING AND PREVENTION

The slow development of CRC from a benign polyp to an invasive cancer provides a window of opportunity for the detection and removal of premalignant adenomatous polyps and early-stage cancers. Removal of adenomatous polyps reduces the incidence of cancer, and the diagnosis of CRC at earlier stages reduces mortality.[59,60] A number of prospective studies have proven that screening for colorectal polyps and cancer using a variety of methods reduces CRC mortality, and the reduction in mortality persists long-term after screening.[61–64] There is good evidence that screening has contributed significantly to the drop in CRC mortality rates from a peak a few decades ago. Screening for CRC is cost-effective, in terms of the quality-adjusted life-years gained, compared to nonscreening. In the United States, screening for CRC is recommended for men and women over age 50, although the guidelines are currently changing due to the recent rise in young onset CRC. While overall

uptake of CRC screening is improving, it remains relatively low among individuals with lower socioeconomical status and without a usual source of health care.[65]

Screening Tests

Numerous screening methods for CRC have been used over the years (**Tables 68.5** and **68.6**). These fall into one of two categories: stool tests, which detect the presence of blood or altered DNA in the stool; and structural tests, which identify polyps and cancers. Efficacy in detecting CRC, cost-effectiveness as a screening tool, supporting evidence, and patient acceptability vary for each of these tests.[66]

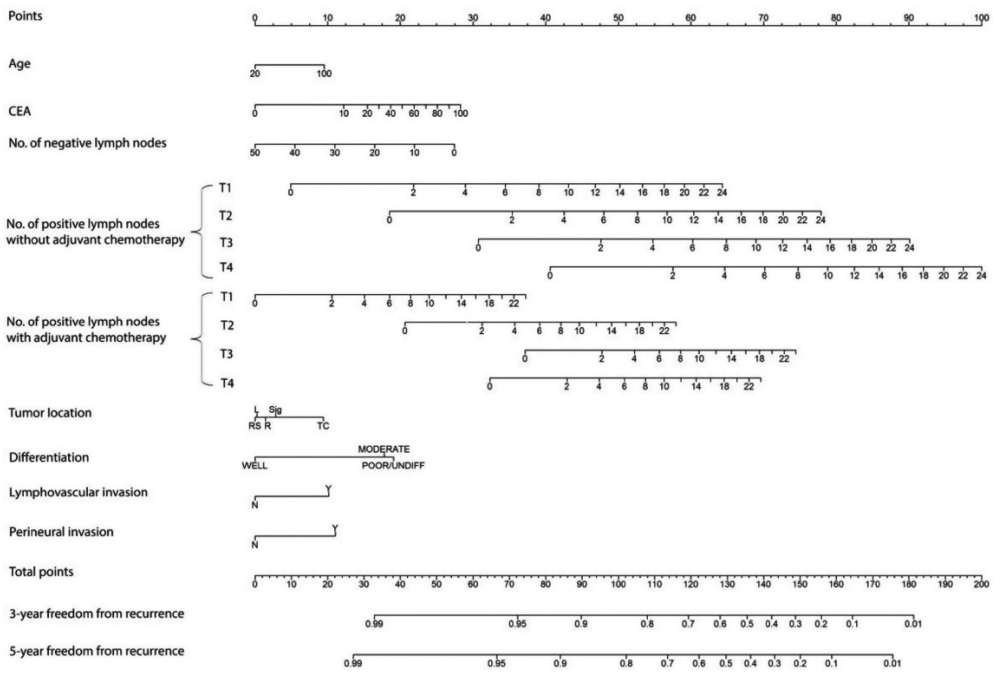

Figure 68.5 Colon cancer nomogram for freedom from recurrence. Locate the patient's preoperative level of carcinoembryonic antigen (in nanograms per milliliter) on the CEA axis. Draw a straight line up to the Points axis to determine how many points toward recurrence the patient should receive. Repeat this process for each of the remaining axes, drawing a straight line each time to the Points axis. Sum the points received from each prognostic variable and locate this number on the Total points axis. Draw a straight line from the total points down to the 3- or 5-year freedom from recurrence axis to ascertain the patient's specific risk of remaining free from recurrence for either 3 or 5 years. CEA, carcinoembryonic antigen; L, left colon; R, right colon; RS, rectosigmoid colon; Sig, sigmoid colon; TC, transverse colon. (Reproduced with permission from Konishi T, Shimada Y, Hsu M, et al. Contemporary validation of a nomogram predicting colon cancer recurrence, revealing all-stage improved outcomes. *JNCI Cancer Spectr* 2019;3(2):pkz015.)

Stool Tests

CRCs and polyps bleed more than the normal mucosa and detecting occult blood in the stool is the basis of the most widely used screening tests. Blood is detected by searching the stool for hemoglobin using chemical or immunologic methods; patients found to have blood in the stool should then undergo colonoscopy. The original fecal occult blood tests (FOBTs) relied on guaiac-based detection of the pseudoperoxidase activity of hemoglobin. However, as pseudoperoxidase activity is not specific to human hemoglobin, foods such as red meat can produce false positives. Additionally, medications, such as aspirin and nonsteroidal anti-inflammatory drugs, and foods, such as those rich in vitamin C, should be avoided due to the risk of an inaccurate test. These drugs

and foods should be avoided 2 to 3 days prior to the FOBT. As most tumors bleed slowly and intermittently, the sensitivity of this test remains low. Rehydration of the test cards increases sensitivity, at the cost of reducing specificity. The sensitivity of the test increases with the number of samples tested; testing two samples per stool on three consecutive bowel movements is recommended. Several prospective, randomized trials have demonstrated that screening by FOBT, followed by total colonic evaluation with colonoscopy in individuals with a positive test, reduces mortality from CRC.[67–70]

Table 68.5 Tools for Colorectal Cancer Screening

a. Fecal tests—detect primarily cancer
   Guaiac-based fecal occult blood test (gFOBT)
   Fecal immunochemical test (FIT)
   Stool DNA test (sDNA)
b. Structural examinations—detect polyps and colorectal cancer
   Flexible sigmoidoscopy (FSIG)
   Optical-colonoscopy (OC)
   Double–contrast barium enema (DCBE)
   Computed tomography colonoscopy (CTC)

Fecal immunochemical tests (FITs) rely on antibodies that are specific to human hemoglobin, and the analysis of samples by automated quantification methods. FITs are as sensitive as the guaiac-based tests, but more specific in detecting human hemoglobin in stool. As this avoids the false-negative results in the presence of vitamin C and false-positive results in the presence of red meat, the test does not require any dietary modification prior. As with any fecal test, a positive result with FIT requires a complete colonoscopic examination. FIT has better screening performance, compared to FOBT.[71–75] As an additional consideration, FIT may be more easily implemented as a screening regimen, compared with sole usage of colonoscopy.[76] Based on this evidence, a number of countries have introduced screening programs utilizing these tools.

Table 68.6 Screening and Surveillance for Colorectal Cancer According to Risk[a]

Risk Category	Age to Begin	Recommendation	Comment
Average Risk			
	45–50	Annual gFOBT/FIT/ FIT-DNA every 1–3 yrs OR flexible sigmoidoscopy every 5 yrs OR flexible sigmoidoscopy with FIT every 10 and 1 yrs OR Colonoscopy every 10 yrs OR CTC every 5 yrs	If positive, colonoscopy is indicated. Screening is recommended up to 75 yrs of age (with individual risk assessment up to 85 yrs old)
Increased Risk—Patients with History of Polyps at Prior Colonoscopy			
Patients with small rectal hyperplastic polyps	—	Colonoscopy or other screening options at intervals recommended for average-risk individuals	An exception is patients with a hyperplastic polyposis syndrome. They are at increased risk for adenomas and colorectal cancer and need to be identified for more intensive follow-up

Patients with 1 or 2 small tubular adenomas with low-grade dysplasia	5–10 yrs after the initial polypectomy	Colonoscopy	The precise timing within this interval should be based on other clinical factors (such as prior colonoscopy findings, family history, and the preferences of the patient and judgment of the physician)
Patients with 3–10 adenomas, 1 adenoma ≥1 cm, or any adenoma with villous features or high-grade dysplasia	3 yrs after the initial polypectomy	Colonoscopy	Adenomas must have been completely removed. If the follow-up colonoscopy is normal or shows only 1 or 2 small tubular adenomas with low-grade dysplasia, then the interval for the subsequent examination should be 5 yrs (7–10 yrs

			for 3–4 small adenomas)
Patients with ≥10 adenomas on a single examination	1 yr after the initial polypectomy	Colonoscopy	Consider the possibility of an underlying familial syndrome
Patients with adenomas (≥20 mm) that are removed piecemeal	2–6 mos to verify complete removal	Colonoscopy	Once complete removal has been established, subsequent surveillance needs to be individualized based on the endoscopist's judgment. Completeness of removal should be based on both endoscopic and pathologic assessments
Increased Risk—Patients with Colorectal Cancer			
Patients with colon and rectal cancer should undergo high-quality perioperative clearing	3–6 mos after cancer resection, if no previous colonoscopy, and if no unresectable metastases are	Colonoscopy	In the case of nonobstructing tumors, this can be done by preoperative colonoscopy. In the case of

	found during surgery; alternatively, colonoscopy can be performed intraoperatively		obstructing colon cancers, CTC with intravenous contrast or DCBE can be used to detect neoplasms in the proximal colon
Patients undergoing curative resection for colon or rectal cancer	1 yr after the resection (or 1 yr following the performance of the colonoscopy that was performed to clear the colon of synchronous disease)	Colonoscopy	This colonoscopy at 1 yr is in addition to the perioperative colonoscopy for synchronous tumors. If the examination performed at 1 yr is normal, then the interval before the next subsequent examination should be 3 yrs. If that colonoscopy is normal, then the interval before the next

		subsequent examination should be 5 yrs. Following the examination at 1 yr, the intervals before subsequent examinations may be shortened if there is evidence of HNPCC or if adenoma findings warrant earlier colonoscopy. Periodic examination of the rectum for the purpose of identifying local recurrence, usually performed at 3–6-mo intervals for the first 2 or 3 yrs, may be considered after low

			anterior resection of rectal cancer
Increased Risk—Patients with a Family History			
Either colorectal cancer or adenomatous polyps in a first-degree relative before age 60 yrs or in 2 or more first-degree relatives at any age	Age 40 yrs, or 10 yrs before the youngest case in the immediate family	Colonoscopy	Every 5 yrs
Either colorectal cancer or adenomatous polyps in a first-degree relative age 60 or older or in 2 second-degree relatives with colorectal cancer	Age 40 yrs. Screening options at intervals recommended for average-risk individuals	Screening options at intervals recommended for average-risk individuals	Screening should be at an earlier age, but individuals may choose to be screened with any recommended form of testing
High Risk			
Genetic	Age 10–12 yrs	Annual FSIG to	If the genetic test

diagnosis of FAP or suspected FAP without genetic testing evidence		determine if the individual is expressing the genetic abnormality and counseling to consider genetic testing	is positive, colectomy should be considered
Genetic or clinical diagnosis of HNPCC or individuals at increased risk of HNPCC	Age 20–25 yrs, or 10 yrs before the youngest case in the immediate family	Colonoscopy every 1–2 yrs and counseling to consider genetic testing	Genetic testing for HNPCC should be offered to first-degree relatives of persons with a known inherited MMR gene mutation. It should also be offered when the family mutation is not already known, but one of the first three of the modified Bethesda criteria is present
Inflammatory bowel disease, chronic ulcerative	Cancer risk begins to be significant 8 yrs after the onset of pancolitis or	Colonoscopy with biopsies for dysplasia	Every 1–2 yrs; these patients are best referred to a center with

colitis, and Crohn colitis	12–15 yrs after the onset of left-sided colitis	experience in the surveillance and management of inflammatory bowel disease

[a]Summary estimation of published guidelines.

gFOBT, guaiac-based fecal occult blood test; FIT, fecal immunochemical test; FIT-DNA, multi targeted stool DNA test; CRC, colorectal cancer; CTC, computed tomographic colonography; DCBE, double-contrast barium enema; FAP, familial adenomatous polyposis; FSIG, flexible sigmoidoscopy; HNPCC, hereditary nonpolyposis colon cancer; MMR, mismatch repair.

Detection of altered DNA from exfoliated tumor cells has been investigated as a screening test for CRC for years. Similar to the detection of hemoglobin, detection of altered DNA triggers patient referral for colonoscopy. Large, prospective studies of this test show fair sensitivity in detecting CRC and low sensitivity in detecting large adenomas, compared with colonoscopy.[77,78] Two recent studies found stool DNA testing sensitivity to be at the high end of the reported FIT range, but at the low end of the typical FIT range for specificity in detecting CRC and advanced precancerous lesions.[79,80] The most recent United States Preventive Task Force (USPTF) guidelines have included stool DNA testing as a screening option; however, they caution about the potential for overly intensive surveillance due to clinician and patient concerns in patients with a negative colonoscopy after an abnormal stool DNA test.[81]

Structural Tests

Two-thirds of CRCs and polyps are located in the sigmoid colon and rectum and can be reached with a 60-cm flexible sigmoidoscope. Flexible sigmoidoscopy is safe, fast, does not require sedation, and allows biopsying suspicious lesions. It has a minimal risk of perforation (approximately 1 in 20,000). The effectiveness of flexible sigmoidoscopy as a screening modality requires examination to at least 40 cm from the anal verge. The main limitations of flexible sigmoidoscopy are discomfort which can deter some patients from undergoing future examinations and that it is does not examine the entire colon. However, the presence of distal adenomatous polyps increases the probability

of finding additional polyps or cancers in more proximal segments of the large bowel. If an adenomatous polyp is found during flexible sigmoidoscopy, the patient should undergo complete colonoscopy. Due to differences in the distribution of colorectal neoplasia in patients of different age, gender, and racial groups, the efficacy of flexible sigmoidoscopy may vary. Several case-control studies have demonstrated that screening by sigmoidoscopy reduces mortality from CRC by two-thirds in the setting of tumors located within reach of the sigmoidoscope.[82,83] More recently, several prospective studies have demonstrated that screening with flexible sigmoidoscopy reduced CRC incidence and mortality by approximately 25%.[84–86] Furthermore, at least two prospective trials demonstrated a reduction in CRC incidence and mortality with only one flexible sigmoidoscopy screening between 55 and 64 years of age.[86,87] The long-term follow-up of these trials (15 to 17 years) demonstrated sustained reduction in CRC mortality.[88–90] The optimal testing frequency is still controversial. The USPTF currently recommends repeating surveillance every 5 years.[81]

The evidence for combining stool tests (FIT or FOBT) and flexible sigmoidoscopy is mixed. Some studies have shown that the combination of these two screening methods is more effective in detecting colorectal neoplasia than each method used individually, whereas one prospective study looking at flexible sigmoidoscopy with and without FOBT found no benefit in detection, but improvement in CRC mortality.[85,91] This screening strategy may be of benefit to patients who desire direct endoscopic visualization but wish to avoid a full colonoscopy.[81]

Colonoscopy is considered the most accurate test for the early diagnosis and prevention of CRC. It allows direct visualization of the mucosa of the entire colon and rectum, simultaneously allowing the biopsy or removal of suspicious lesions. Colonoscopy is also used to evaluate patients who have tested positive on other screening tests. However, colonoscopy is inconvenient, requires dietary modification and bowel preparation beforehand, is usually performed under conscious sedation, and carries a risk of complications of 1–2 per 1,000. Colonoscopy is also more expensive compared to other screening methods. Overall, patient acceptability of colonoscopy seems to be higher compared to other invasive screening methods, and it is now the most commonly used screening method in the United States. There is evidence to suggest that colonoscopy reduces CRC mortality.[91–95] Comparative studies show that colonoscopy is more effective in detecting advanced colonic neoplasia, in both

men and women, than a single FOBT combined with sigmoidoscopy. Colonoscopy is more likely to detect preneoplastic polyps, but just as likely to detect invasive CRC as FITs. In addition, colonoscopy provides the protective benefit of screening the proximal colon.[96] Several randomized control trials to assess long-term outcomes of CRC site-specific incidence and mortality for colonoscopy are currently underway.

Computed tomography colonography (CTC), also referred to as virtual colonoscopy, involves thin-section, multidetector, helical CT, and three-dimensional viewing for interpretation.[97] It has largely replaced double-contrast barium enema as it has been shown to be superior.[98,99] A meta-analysis of studies looking at CTC compared to colonoscopy found CTC to have a high sensitivity for adenomas ≥10 mm with somewhat lower sensitivity for adenomas ≥6 mm.[100] Besides the challenge of identifying small lesions, CTC has been shown to be less accurate with flat lesions and sessile serrated polyps.[101,102] CTC obviates some of the drawbacks of colonoscopy, such as the need for sedation and recovery time. However, it still requires standard bowel preparation and gaseous distension of the colon. New methods of tagging and subtracting residual stool are trying to obviate the need for bowel preparation. Furthermore, patients found to have lesions on CTC still require full visualization of the colon with colonoscopy. CTC has downstream consequences including radiation exposure and detection of incidental extracolonic findings that may trigger expensive and, sometimes, unnecessary diagnostic tests.

Risk Categories

Patients with symptoms of CRC should undergo the appropriate diagnostic studies; they are not candidates for screening. Screening recommendations for the general population are based on individual risk assessment. Based on the past medical history and family history of CRC or polyps, individuals are assigned to one of three risk categories, with different screening recommendations (**Table 68.6**).[103] Several different groups provide guidelines for CRC screening including the USPTF, American Cancer Society, and United States Multi-Society Task Force.[81,99,104]

Average Risk

Most guidelines define average risk as asymptomatic, without family history of CRC or familial CRC syndromes, without personal history of CRC or adenomatous polyps or IBD, and at the age of 50. However, in response to the increase in young onset CRC, the American Cancer Society has recently changed the age to start screening to 45. Furthermore, most recommend cessation of screening at 75 years old, with the option of screening up to 85 years based on comorbidities, life expectancy, and individualized discussion with each patient, as the benefit of early detection of and intervention declines after age 75 years. Acceptable forms of screening include FIT, FOBT, stool DNA testing, flexible sigmoidoscopy, CTC, or colonoscopy. The most recent American Cancer Society and USPTF guidelines do not offer a preferred or ranked order of screening strategies, but rather offer various choices, with the goal to maximize overall screening uptake. Digital rectal examination (DRE) should be performed at the time of sigmoidoscopy or colonoscopy in all individuals. People found to be positive on stool testing, CTC, or flexible sigmoidoscopy should undergo entire colon and rectum examination by colonoscopy.

Increased Risk

Family History

Individuals with a first-degree relative (parent, sibling, or child) with CRC or adenomatous polyps diagnosed before 60 years of age or two first-degree relatives diagnosed at any age should start screening with colonoscopy at 40 years of age or 10 years younger than the earliest diagnosis in their family, whichever comes first. The test should be repeated every 5 years. Individuals with one first-degree relative with CRC or adenomatous polyp diagnosed at 60 years of age or older, or with two or more second-degree relatives (grandparent, grandchild, aunt, uncle, niece, nephew, half-sibling) with CRC or adenomatous polyps at any age, should undergo screening as average-risk individuals—but starting at 40 years of age. Patients with one second-degree relative or one or more third-degree relatives (first cousin) affected are considered to be at average risk.

History of Polyps at Previous Colonoscopy

Patients undergoing endoscopic excision of 1–2 small (<1 cm) adenomatous polyps should have the entire colon examined at the time of the polypectomy.

Colonoscopy should be repeated 7 to 10 years later. If the test is negative, they should then follow the screening recommendations for average risk.[106]

Patients with more than three small adenomas (<10 mm), adenomas with villous features or high-grade dysplasia, or a large adenomatous polyp (>1 cm) who have the entire colon examined at the time of polypectomy, should undergo complete colonoscopy 3 years later—and, if normal, every 5 years thereafter (except in patients with more than three small adenomas—they can go back to 10 years).

A complete colonic examination should be carried out before surgery in any patient undergoing a planned curative resection for CRC. The colonoscopy should be repeated at 1 year to exclude metachronous lesions. If the examination at 1 year is normal, it should be repeated after 3 years, and every 5 years thereafter if the previous one was normal.

Patients with Colorectal Cancer

Patients with colon and rectal cancer should undergo high-quality perioperative clearing of polyps with colonoscopy 3 to 6 months after resection, if not performed before surgery. Surveillance after curative resection is described in detail in Surveillance after Curative Resection for Colon and Rectal Cancer section.

High Risk

This category includes individuals from families diagnosed with hereditary forms of CRC as noted in consensus guidelines. At-risk members of families with hereditary cancer syndromes should be informed about the benefits and limitations of genetic counseling and genetic testing.

Familial Adenomatous Polyposis

Once the diagnosis of FAP is established, the patient should undergo colectomy, or a yearly colonoscopy until colectomy. Upper gastrointestinal endoscopy should be performed regularly at intervals of 6 months to 4 years based on the extent of the duodenal polyposis. Siblings and children of a patient with FAP should start surveillance by flexible sigmoidoscopy at puberty.

MYH-Associated Polyposis

Depending on the individual, age of presentation, and number and size of polyps, the patient may be advised to undergo a prophylactic colectomy or yearly colonoscopy beginning at 25 years of age. Upper gastrointestinal

surveillance should be performed following the guidelines for patients with FAP.

Lynch Syndrome

Individuals from families fitting the Amsterdam criteria for HNPCC should have a colonoscopy at 21 years of age, then every 2 years until 40 years of age, and yearly thereafter. Genetic counseling and testing should be considered.

Consequences of Screening

The full spectrum of clinical consequences of screening, other than the prevention of deaths from CRC, is difficult to predict because every screening strategy initiates a cascade of events, each one with uncertain probability. The rate of false-positive tests, the number of colonoscopies performed, the complications of the screening and diagnostic tests, and the number of patients who may require surveillance as a consequence of screening, are complex factors that arise at different times over several decades. However, cost-effectiveness analysis in the United States has demonstrated that screening for CRC in average-risk patients, according to the strategies outlined above, compares favorably with other healthcare interventions such as mammography or treatment of mild hypertension.[108,109] It is important to understand that screening does not completely eliminate the risk of CRC. Up to 9% of CRCs are diagnosed within 6 to 36 months after a screening colonoscopy.[110,111] These interval cancers tend to be preferentially located in the proximal colon. This may be related to failure to reach the proximal colon, residual stool obscuring the view in the proximal colon, or different characteristics of the proximal lesions that makes them more difficult to detect or remove.

Implementation of Guidelines

The general population has limited awareness of the risks of CRC or its symptoms; as a result the number of individuals participating in screening programs has been low. The dissemination of information to patients is an essential part of the screening program. Primary care physicians have a responsibility to inform their patients about their risk of CRC, the benefits of screening and different screening strategies, and to set up a system for implementing these guidelines.[109,112,113] Through such efforts, the proportion of

adults 50 to 75 years of age having colonoscopy has increased steadily over the past decades: from 19.1% in 2000 to 55% in 2010, and to 68.8% in 2018.[114]

DIAGNOSIS

While the proportion of CRCs diagnosed through screening is increasing, most are still diagnosed after patients become symptomatic. CRC can cause a myriad of symptoms, many of which are nonspecific and highly prevalent among healthy individuals. Therefore, the diagnosis of colorectal carcinoma often requires a high index of suspicion.

Symptoms and Signs

The most common symptoms in patients with CRC are abdominal pain, change in bowel habits, rectal bleeding, anemia, anorexia, and weight loss. The clinical manifestations of CRC differ depending on the location and stage of the tumor.

Abdominal pain is nonspecific; it may be localized to any quadrant of the abdomen, or may be diffuse. When the pain is persistent and colicky, it is more likely to represent obstructive symptoms resulting from a left-sided lesion. More localized tenderness with signs of localized peritonitis indicates local invasion of the adjacent peritoneum or perforation. It can be difficult to distinguish the pain associated with diverticular disease from that due to a carcinoma in the sigmoid or descending colon. Patients with diverticular disease may also have an underlying carcinoma. Abdominal pain may occasionally be related to extensive metastatic disease in the liver or retroperitoneal lymph nodes. Rectal cancer can also cause perineal discomfort and is often associated with tenesmus, the sensation of incomplete defecation. A locally advanced rectal cancer can also cause sacral or sciatic pain.

An unexplained change in bowel habits lasting more than 2 weeks requires investigation for CRC. Constipation associated with colicky abdominal pain is a common manifestation of partially obstructing tumors. Abdominal pain, constipation, and abdominal distension suggest a complete colonic obstruction, which is more common in tumors located in the sigmoid colon and rectum. Some patients with sigmoid or rectal cancer may also complain of diarrhea, which may sometimes be bloody.

Bleeding from tumors in the sigmoid colon and rectum is often wrongly attributed to hemorrhoids or other benign anal conditions. However, blood from hemorrhoids is usually bright red and is accompanied by anal discomfort; the bleeding is intermittent and splashes the toilet pan. Anal fissure is also a common cause of rectal bleeding; the blood is often bright, occurring after defecation, and is typically associated with sharp anal pain triggered by defecation. Painless defecation with rectal blood that is darker in color and mixed in with stool is more likely to be secondary to an underlying carcinoma. Rectal bleeding, particularly when associated with tenesmus, requires a thorough diagnostic investigation to exclude an underlying rectal tumor.

The development of nonspecific anemia of unknown origin is a common manifestation in patients with a carcinoma in the proximal colon. Patients with unexplained microcytic anemia should be examined initially with colonoscopy. Anorexia and weight loss frequently accompany CRC, and are often associated with advanced disease. The differential diagnosis in these patients is a gastric carcinoma, but when investigations are negative it is important to exclude a large-bowel malignancy. As the bowel lumen is larger and the stools overall looser in the proximal colon, obstructive symptoms are uncommon; therefore, patients with tumors proximal to the splenic flexure often present with advanced disease.

It should be remembered that the presence of colon cancer can also be identified incidentally during investigations for other pathologies such as gallstones, gynecologic, or urinary conditions. A complete family history, with emphasis on past history of CRC or polyps, is essential to diagnose some hereditary cancer syndromes. A family history of endometrial, gastric, urologic, or other HNPCC-associated cancers is also important because it may help in diagnosing Lynch II syndrome.

The evaluation of patients suspected of CRC requires a complete physical examination. Features that should arouse suspicion of malignancy include pallor, palpable abdominal mass, and a palpable mass on DRE. Hepatomegaly indicates advanced disease with extensive liver metastases, and consequently a very poor prognosis. A hard mass in the pouch of Douglas felt on DRE may indicate peritoneal carcinomatosis. Other signs of an underlying CRC include pneumaturia, ischiorectal or perineal abscesses, or even deep venous thrombosis.

The differential diagnosis of CRC includes diverticulitis, irritable bowel syndrome, inflammatory bowel disease, ischemic colitis, and benign anorectal

conditions such as hemorrhoids or rectal mucosal prolapse.

Diagnostic Evaluation

Patients with symptoms suggesting CRC should have a colonoscopy to evaluate the entire colon (**Fig. 68.6**). The examination should be complete, as up to 4% of patients with CRC have synchronous cancers and many more have colorectal polyps.[115,116] Up to one-third of these synchronous cancers are in locations requiring a different surgical resection, further emphasizing the importance of complete colonoscopy. As many patients undergo minimally invasive surgery, the endoscopist should mark the vicinity of the tumor with India ink to help locate the lesion intraoperatively. CT colonography and DCBE are less effective in investigating patients with symptoms suggestive of CRC, but they are useful in patients with partially obstructive tumors, in whom colonoscopy cannot be completed. In patients with obstructive lesions, the proximal colon can be examined either by preoperative imaging studies such as PET-CT, or intraoperatively by direct palpation of the colon. In any case, patients with a complete colonoscopy before surgery should have a surveillance colonoscopy 6 months after surgery.

Assessment of the extent of disease at the time of diagnosis is important because clinical stage, particularly in rectal cancer, dictates treatment decisions. A CT scan of the chest, abdomen, and pelvis with intravenous and oral contrast is important in order to locate the tumor, detect mesenteric nodes, 3 and exclude liver metastasis and gross peritoneal carcinomatosis (**Fig. 68.6**). In addition, preoperative imaging helps the surgeon plan the resection. In patients with iodine allergy, and in patients with undetermined lesions on CT, a PET-CT or an abdominopelvic MRI may provide additional information.

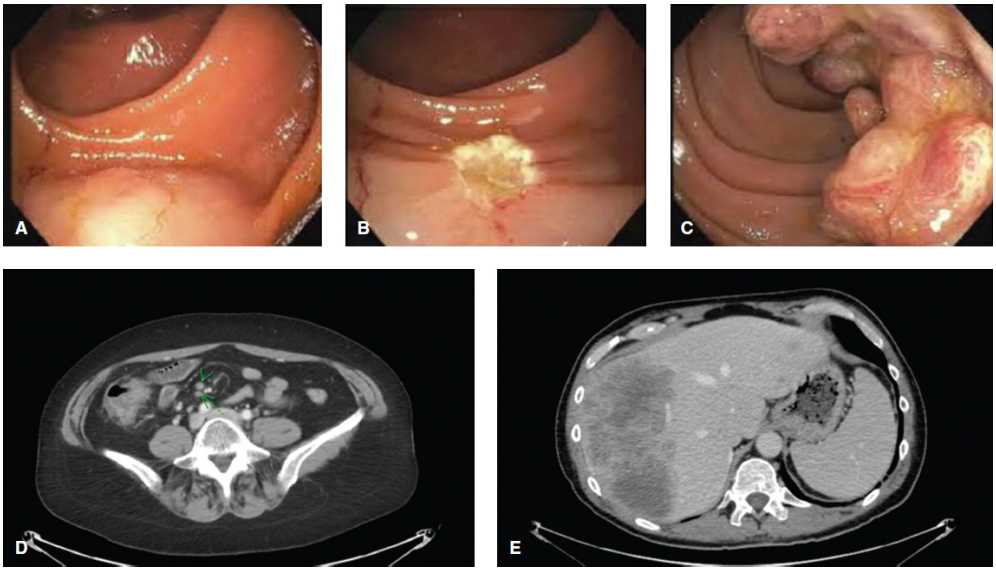

Figure 68.6 Staging modalities for colorectal cancer. **A:** Sessile polyp. **B:** Polyp removed at colonoscopy with hot snare technique. **C:** Sigmoid colon cancer at colonoscopy. **D:** Circumferential ascending colon tumor with regional lymphadenopathy (*arrowheads*). **E:** Liver metastases of colorectal origin.

Laboratory evaluation includes complete blood cell count, coagulation parameters, and chemistry panel. Preoperative CEA should be measured because it provides prognostic information, and can be useful during patient surveillance.

TREATMENT

Surgery is the primary treatment for CRC, but for many patients surgery is not the initial form of treatment and some do not require surgery at all. Treatment is different for colon than for rectal cancer, and depends also on the clinical stage of the tumor. Treatment decisions must also take into account the patient's performance status, comorbidities, hereditary CRC predisposition, as well as desires and expectations.

Preoperative Preparation

All patients undergoing surgery for colon and rectal cancer require similar preoperative preparation aimed at optimizing the technical success of the procedure and avoiding perioperative complications. Surgical site infection

(SSI) is the most common complication after colon and rectal cancer resection, occurring in 4% to 26% of cases.[117,118] In addition to causing patient suffering, SSIs lengthen hospital stay and increase costs.[119] The institutional rate of SSI after colorectal surgery is now an important quality metric for several benchmarking programs. A number of federal and state-wide initiatives aimed at improving surgical care recommend implementing measures to reduce the rate of SSI and other complications in patients undergoing elective colorectal surgery.[120,121]

The colon has the largest concentration of bacteria in the human body. A gram of feces contains 10^{11} polymicrobial bacteria, mostly gram negatives and anaerobes.[122] Oral mechanical bowel preparation using polyethylene glycol to reduce the bacterial load and risk of intraoperative fecal spillage has been considered an axiom in colon and rectal surgery. However, a number of prospective trials have failed to demonstrate benefit from mechanical bowel cleansing in preventing SSIs.[123,124] Combination of mechanical bowel preparation with oral antibiotics, usually neomycin and erythromycin, may be more effective than mechanical bowel preparation alone. A large retrospective study of more than 27,000 patients undergoing elective colorectal resection compared the use mechanical bowel preparation with and without oral antibiotics, oral antibiotics alone, or no preparation. Dual preparation was associated with lower rates of SSI, organ space infection, wound dehiscence and anastomotic leak compared to no preparation, and lower rates of SSI than antibiotic bowel preparation alone. Dual preparation was not associated with an increased risk of *Clostridium difficile* infection.[125]

High-quality evidence indicates that antibiotics covering aerobic and anaerobic bacteria, delivered orally or intravenously (or both) prior to elective colorectal surgery, reduce the risk of postoperative surgical wound infection by as much as 66%.[126] For patients without penicillin allergy, a second-generation cephalosporin (cefotetan, or cefoxitin) is often administered intravenously within 30 minutes of the surgical incision, with redosing during the procedure as required according to the half-life of the drug and the duration of surgery. For penicillin-allergic patients, metronidazole or clindamycin combined with either ciprofloxacin or gentamicin is acceptable, as are aztreonam and fluoroquinolones.[127] Ertapenem, a long-acting carbapenem active against gram negatives and anaerobes, is an accepted alternative to second-generation cephalosporins for prophylaxis in CRC. Ertapenem has a long life and does not require redosing in prolonged procedures, but has been associated with

increasing risk of *C. difficile* infection.[128] Other measures that prevent SSI include tight glucose control in diabetic patients, smoking cessation, clipping rather than shaving the skin of the abdominal wall, and maintaining normothermia and adequate oxygenation during anesthesia.[129]

Patients undergoing surgery for CRC are also at risk of venous thromboembolism (VTE), and should have thromboembolic prophylaxis with unfractionated heparin or low–molecular-weight heparin during the peri- and postoperative periods.[130] The American Society of Clinical Oncology (ASCO) has published evidence-based clinical practice guidelines which include the recommendation for prophylaxis starting before surgery and continuing for at least 7 to 10 days following surgery. Extended prophylaxis for up to 4 weeks following surgery should be given to patients undergoing major abdominal and pelvic surgery.[131]

As the incidence of CRC increases with age, many patients have cardiovascular or respiratory conditions requiring medical clearance before surgery. While technical advances have made CRC operations safer, optimal outcomes require special effort to ensure that the patient's overall health is optimal at the time of surgery. Many CRC patients have other comorbid conditions such as diabetes, hypertension, and coronary artery disease requiring medical evaluation before undergoing surgery. Comorbidities can impact decision-making and affect short- and long-term outcomes. Patient clinical and performance status should be optimized to reduce the risk of perioperative complications. Fertility options should be discussed with all individuals of child-bearing potential.

Patients who may require a stoma should be seen before surgery by an enterostomal therapist. Adequate marking of the site improves outcomes for patients requiring a stoma. Preoperative teaching shortens the time patients require to become proficient managing the stoma, and reduces hospital stay.[132]

The Enhanced Recovery After Surgery (ERAS) protocols were introduced in open colorectal surgery in the 1990s, with the aim of speeding patient recovery, improving patient outcomes and satisfaction, shortening hospitalization, and reducing healthcare costs.[133] ERAS protocols span the entire perioperative period, and attempt to minimize surgical stress and postoperative ileus through patient education, preoperative hydration and carbohydrate loading, goal-directed intraoperative fluid management, narcotic sparing for intraoperative and postoperative pain control, and early mobilization and oral feeding in the postoperative period. A number of prospective trials have indicated that the

implementation of ERAS protocols reduces length of hospital stay, compared to conventional recovery in patients undergoing open or minimally invasive surgery for CRC.[134,135] A recent systematic review and a meta-analysis confirmed that ERAS protocols resulted in a shorter length of stay and a reduction in overall complications, with no difference in mortality and surgical complications.[136,137] Similar results have recently been reported from an international registry.[138]

Principles of Surgical Treatment

The goal for any curative-intent surgery is to remove the tumor-bearing segment of the bowel with adequate margins, along with en bloc excision of the mesentery containing the feeding vessels and regional lymph nodes. The location of the primary tumor determines lymphatic drainage and dictates the extent of the resection. Lymphatic capillaries are primarily located in the submucosal and subserosal layers of the bowel wall. The lymphatic flow in the colon is primarily circumferential, with longitudinal spread along the bowel wall thought to be less than 1 cm in each direction. Therefore, a 5-cm margin of normal bowel on either side of the primary tumor is considered sufficient to avoid anastomotic recurrence. The length of the terminal ileum resected in patients with right colon cancer does not influence the risk of anastomotic recurrence. In the rectum, where the longitudinal lymphatic flow is primarily upward, cancer cells rarely spread distally along the bowel wall farther than 1 cm from the macroscopic distal end of the tumor. Consequently, a 2-cm margin of normal bowel distal to the tumor, or even less in patients treated with neoadjuvant therapy, is considered appropriate to an oncologically safe resection.[139]

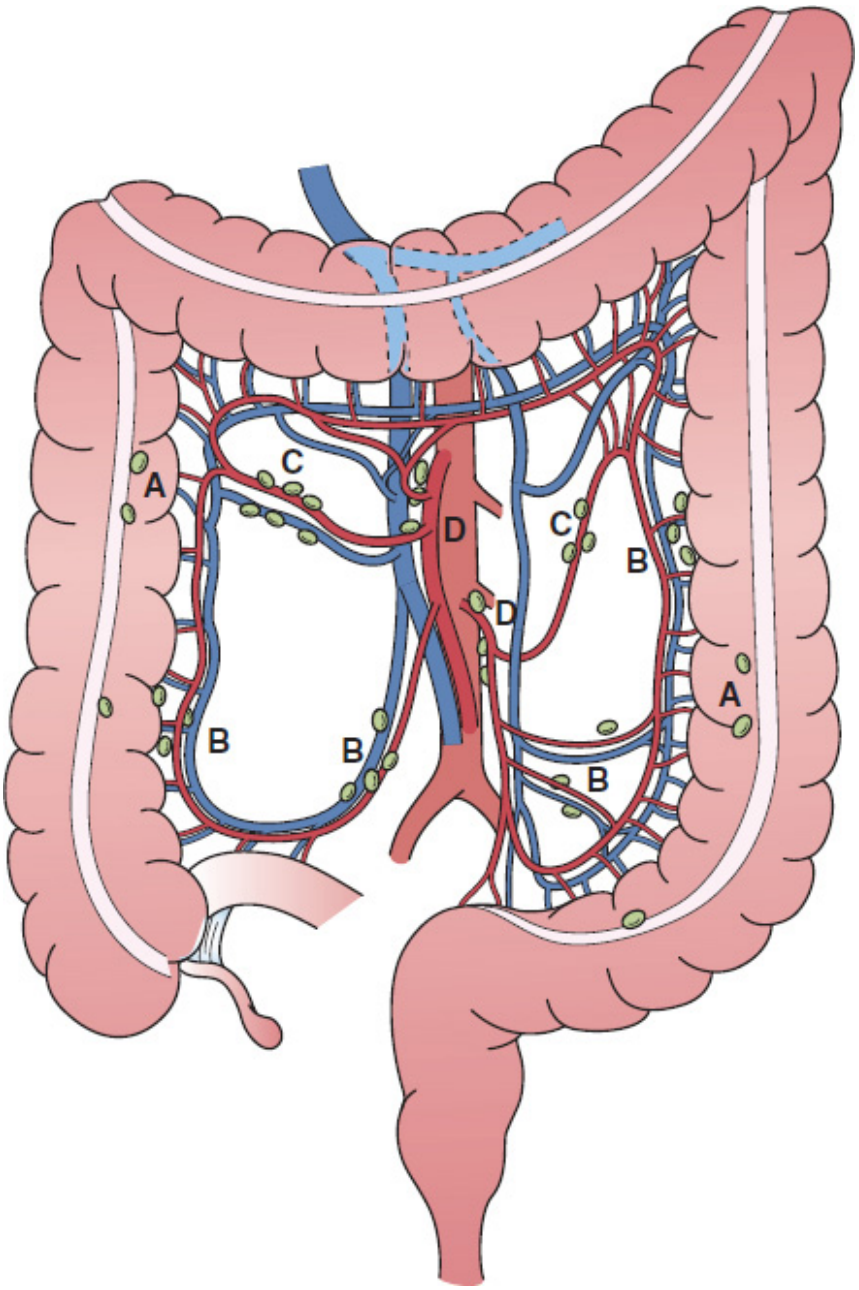

Figure 68.7 Anatomy of the colon. ***A***, Epicolic lymph nodes. ***B***, Paracolic lymph nodes. ***C***, Intermediate lymph nodes. ***D***, Apical-central lymph nodes.

The lymphatic channels in the bowel wall drain to the regional nodes, which are classified in different groups according to their proximity to the bowel and its blood supply (**Fig. 68.7**). The "epicolic" nodes are located in the bowel wall under the peritoneum, usually close to the epiploic appendices. The "paracolic" lymph nodes are located along the marginal vessels. Next, the "intermediate" nodes are positioned in the middle of the mesentery. Finally, the

"central" or "apical" lymph nodes are located close to the root of the mesentery, near the origin of the named vessels. While CRC generally spreads sequentially from the paracolic to the central or apical lymph nodes, nodal metastases skipping one of the groups are common.[140]

The extent of the mesenteric resection is determined by the need to remove all the lymph nodes draining the corresponding segment of bowel, including the central lymph nodes located at the origin of the named feeding blood vessels. As most tumors are located between two named vascular pedicles, both of these should be resected at their origin. When suspected of being involved by tumor, the central nodes should be marked on the specimen, as they have negative prognostic information. Other lymph nodes located away from the feeding vessels and suspected of tumor involvement during surgery, should be removed and analyzed, because in some patients the lymphatic drainage does not follow an orderly pattern.[141,142] If residual metastatic lymph nodes remain after sampling, the resection should be considered incomplete.

While achieving safe oncologic margins and adequate lymphadenectomy are the main considerations when performing a surgical resection for CRC, ensuring an adequate blood supply to the bowel ends, and maintaining tension-free anastomosis, are also important in order to avoid anastomotic complications.

Locally advanced tumors attached to other organs should be removed en bloc with contiguously involved structures. As it is impossible to distinguish clinically or radiographically between inflammatory adhesions and tumor infiltration, it is preferable to perform an en bloc resection of any organ attached to the primary tumor, rather than spilling cancer cells by separating structures infiltrated by tumor. Intraoperative tumor perforation has negative prognostic implications. It is important to report the completeness of the resection (R0, R1, or R2), combining clinical and pathologic information, to determine risk of locoregional recurrence and long-term prognosis.

The concept of the no-touch technique, with initial control of the vascular supply before manipulation of the tumor to avoid releasing cancer cells into the blood stream, has not been shown to be associated with improved outcomes.[143] However, early vascular control with medial-to-lateral dissection of the mesentery, before mobilization of the colon, is the preferred approach during minimally invasive colorectal surgery, because it helps identify all vascular and retroperitoneal structures.

Proper surgical technique is crucial in achieving optimal results in CRC patients. The removal of the rectum along with its mesorectal envelope, using sharp dissection along normal anatomical planes—an operation called total mesorectal excision, or TME—is associated with a reduced risk of local tumor recurrence.[144,145] Conversely, application of the same surgical principles to colon cancer, including the removal of all the lymph node-bearing mesentery to the origin of the named blood vessels—an operation called complete mesocolic excision or CME——has not been universally adopted due to conflicting evidence of the association of CME with improved survival and concern for higher complication rates in CME.[146–148] Published studies on CME are difficult to evaluate and compare because of inconsistent definitions, unclear description of the extent of dissection, and absence of randomization.[149] Often, the radicality of resection is self-reported by the surgeons. Confirmation of correct extent of resection should be validated by pathologists.[150] Prospective clinical trials should provide more conclusive evidence to the efficacy of CME.

TREATMENT OF LOCALIZED COLON CANCER

Malignant Colonic Polyps

The identification of a focus of invasive carcinoma in a polyp removed by snare excision during colonoscopy represents a surgical dilemma. These types of polyps are often referred to as “malignant polyps,” to distinguish them from lesions that are almost exclusively invasive adenocarcinoma with exophytic or polypoid morphology. Malignant polyps are now encountered more often because tumors are diagnosed at an earlier stage, as a result of screening programs. Although there are some lymphatic channels in the lamina propria, tumors superficial to the muscularis mucosa (also known as intramucosal carcinoma, carcinoma in situ, or Tis) are considered to carry no risk of lymph node metastasis. When the malignant cells penetrate beyond the muscularis mucosa they can access the lymphatic channels of the submucosa and metastasize to the regional lymph nodes. This risk of nodal metastasis depends on the morphology of the polyp, the depth of the invasive component, the presence of unfavorable histologic features (grade 3 or 4, lymphovascular invasion, perineural invasion) and the margin of resection.[151] Imaging studies are usually of no help in these patients, except to exclude distant metastases

(which are uncommon). In pedunculated polyps with focus of invasive cancer located in the head, neck, or stalk of the polyp, with favorable histologic features, resected with negative margins, the risk of nodal metastasis is small (**Fig. 68.8**). In these circumstances additional surgery is considered unnecessary, as the risk of surgery may outweigh the risk of residual tumor in the bowel wall or nodal metastasis. On the other hand, patients with pedunculated polyps with focus of invasive adenocarcinoma reaching the base of the polyp, sessile polyps with focus of invasive adenocarcinoma, the presence of adenocarcinoma at the resection margin, and malignant polyps with unfavorable histologic features, are at risk of regional nodal metastasis, and should be offered surgical resection.[152,153] Other factors such as the location of the polyp in the colon or rectum, the patient's comorbidities and performance status, and the patient's desires, should be taken into consideration.[154] Therefore, a final decision should only be made after full review of the pathology reports, and disclosure to the patient of the risks and benefits of each approach.

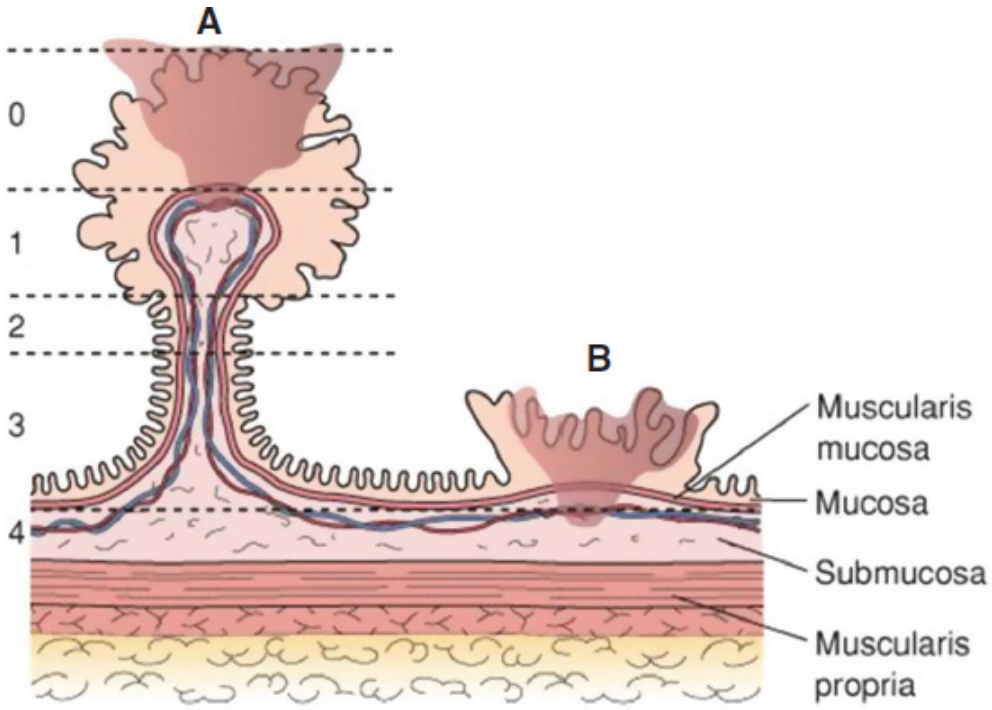

Figure 68.8 Malignant polyp. Haggitt levels of invasion. Level 0, Noninvasive, severe dysplasia; Level 1, Invading through muscularis mucosa but limited to the head of pedunculated polyp; Level 2, Invading the neck of pedunculated polyp; Level 3, Invading the stalk of pedunculated polyp; Level 4, Invading into submucosa of the bowel wall below the stalk of a pedunculated polyp and all sessile polyps.

Surgery for Localized Colon Cancer

Patients with biopsy-proven adenocarcinoma of the colon without evidence of distant metastasis, and without contraindications to major surgery, should be treated with surgical resection. The extent of a colon cancer resection is dictated by the location of the primary tumor. Tumors in the cecum and ascending colon require a right hemicolectomy that implies division of the ileocolic, right colic (if present), and the right branch of the middle colic vessels (**Fig. 68.9**). The portion of the omentum attached to the removed segment of colon should be resected en bloc with the colon and mesentery. Tumors located at the hepatic flexure and in the right side of the transverse colon require an extended right colectomy that, in addition to the ileocolic and right colic vessels, requires division of the middle colic vessels at their origin (**Fig. 68.9**). Tumors in the mid portion of the transverse colon can be treated with an extended right colectomy, or a transverse colectomy. A transverse colectomy involves division of the middle colic vessels only, but often requires mobilization of both the hepatic and splenic flexure to ensure a tension-free anastomosis (**Fig. 68.9**). Tumors located in the distal transverse colon, splenic flexure, and proximal descending colon can be treated with a left hemicolectomy, which requires division of the left branch of the middle colic and left colic artery at its branch point from the inferior mesenteric artery (**Fig. 68.9**). Locally advanced tumors located in the transverse colon can metastasize to the regional lymph nodes located along the greater omentum and gastroepiploic arcades, leading some surgeons to recommend removal of the omentum with the gastroepiploic arcade. In these patients, an omentectomy with division of the gastroepiploic vessels at their origin may be necessary for complete nodal control.[155] However, the benefit of such an extended lymphadenectomy is debated. Sigmoid tumors require sigmoid colectomy, which includes the superior rectal artery and its takeoff from the inferior mesenteric artery (**Fig. 68.9**).

Patients with synchronous tumors, which occur in up to 5.3% of patients with CRC, should be investigated for hereditary CRC syndromes or other predisposing conditions. Patients with sporadic synchronous cancers can be treated with separate resections, or an extended resection incorporating both lesions, depending on the location of the primaries.[156] When performing a segmental resection, it is important to preserve the blood supply to the intermediate segment of colon in order to avoid ischemia, which can lead to

perioperative complications. Synchronous tumors in patients with HNPCC, or other risk factors such as inflammatory bowel disease, are indications for a subtotal or total colectomy.

A number of well-conducted prospective trials have proved that laparoscopic colectomy for cancer is associated with short-term benefits and equivalent long-term oncologic outcomes, compared with the traditional open surgical approach. Patients treated laparoscopically have less postoperative pain, earlier return of bowel function, shorter hospital stay, and a decreased rate of complications. However, laparoscopic surgery is technically challenging and has a long learning curve. Laparoscopy may be particularly difficult in patients with multiple adhesions from previous surgery, in obese patients, and in patients with locally advanced disease. Late conversion from laparoscopic to open surgery (also known as reactive conversion) is associated with higher complication rates compared to open surgery, while early or preemptive conversion is associated with complication rates similar to open surgery.[157]

Laparoscopic colectomy is typically performed using a number of ports, usually 3 to 5, and a specimen extraction site. A single port laparoscopic approach that uses a small incision to insert all instruments and extract the specimen, increases the technical difficulty without reducing complications or expediting recovery compared to conventional laparoscopic surgery.[158]

The introduction of robotic platforms, which enhance the visualization and dexterity of the surgeon, has added a new dimension to minimally invasive colon cancer surgery. The evidence accumulated so far indicates that robotic colon resection is associated with lower conversion rates, similar complication rates, and higher costs, compared to conventional laparoscopic colon resection.[159]

Postoperative Adjuvant Therapy for Localized Colon Cancer

Many patients with what appears to be localized colon cancer at the time of diagnosis develop recurrence after a curative-intent surgery. These recurrences are attributed to micrometastases that are already present, but clinically undetectable, at the time of diagnosis. Postoperative adjuvant chemotherapy aims to improve survival by eradicating micrometastatic disease. Numerous chemotherapeutic agents are now considered for adjuvant therapy, mostly based

on their efficacy as observed in the setting of metastatic colon cancer. However, the mainstays of adjuvant therapy following resection of localized colon cancer remain fluoropyrimidines (5-fluorouracil [5-FU] and capecitabine) and oxaliplatin.

5-FU, a member of the family of antimetabolites, is a pyrimidine analog that works by irreversible inhibition of thymidylate synthase (TS), the rate-limiting enzyme in pyrimidine nucleotide synthesis, and by incorporation of its metabolites into RNA and DNA. 5-FU can only be delivered intravenously and is commonly administered with leucovorin, a reduced folate that is thought to stabilize fluorouracil's interaction with the enzyme TS. Capecitabine is an oral prodrug of fluorouracil that is absorbed intact through the gastrointestinal mucosa and undergoes enzymatic conversion to fluorouracil. Response rates to fluoropyrimidine, as first-line therapy alone for metastatic CRC, are only around 10% to 20%. Neutropenia, stomatitis, and diarrhea are the most common side effects of 5-FU. The toxicity profile for capecitabine is similar to 5-FU, with hand-foot syndrome being more frequent. Oxaliplatin produces cytotoxic effects by forming both inter- and intrastrand cross links leading to disruption of DNA replication and apoptosis. As a single agent, oxaliplatin has limited effect in CRC; but in combination it enhances the cytotoxic effect of fluoropyrimidines, possibly through downregulation of TS. The most relevant side effect of oxaliplatin is a progressive and often irreversible peripheral neuropathy. Other chemotherapy agents commonly used in patients with metastatic CRC have not shown proven benefit in the adjuvant setting.

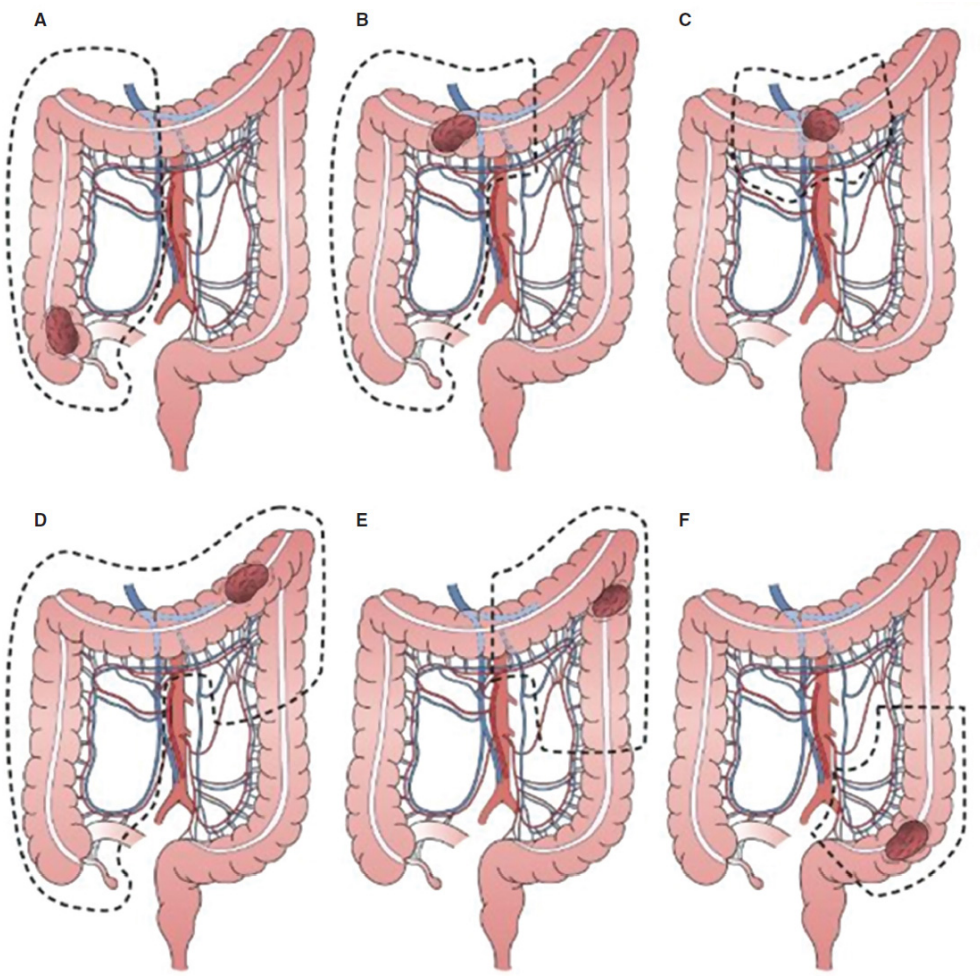

Figure 68.9 Segmental colonic resections. **A:** Right colectomy. **B:** Extended right colectomy to transverse colon. **C:** Transversectomy. **D:** Right colectomy extended to splenic flexure. **E:** Left colectomy. **F:** Sigmoidectomy.

The use of adjuvant therapy for stage III colon cancer was first shown to provide measurable benefit in the National Cancer Institute (NCI) Cooperative Intergroup trial INT-0035. Patients who received 5-FU and levamisole for 1 year after surgical resection had a 33% risk reduction in death or recurrence, compared to those who underwent surgery alone.[160,161] Since then, we have come to recognize that levamisole is overall an inactive agent; therapeutic combinations have evolved and have been tested rigorously.[162] A number of multi-institutional prospective, randomized trials have demonstrated a survival advantage with postoperative chemotherapy in selected patients after curative-intent surgery, compared to surgery alone. Pooled analyses of these trials have reported an approximately 30% reduction in recurrence, and 26% improvement in survival, in patients with stage III colon cancers treated with 6 months of

postoperative fluoropyrimidine-based chemotherapy.[163,164] More recently, the landmark MOSAIC (Multicenter International Study of oxaliplatin, fluorouracil, and leucovorin in the Adjuvant Treatment of Colon Cancer) trial, which randomized 2,246 stage II/III colon cancer patients to 5-FU/leucovorin with or without oxaliplatin, reported an additional 20% reduction in recurrence and 5% improvement in 5-year disease-free survival (73.3% vs. 67.4%; $p = 0.003$) in patients treated with 5-FU/leucovorin plus oxaliplatin, compared to 5-FU/leucovorin alone.[165,166] Based on these results, the current recommendation for patients with stage III colon cancer following curative-intent surgery consists of 6 months of 5-FU/leucovorin and oxaliplatin (FOLFOX), or capecitabine and oxaliplatin (CAPEOX).

Recently, the largest investigation into adjuvant therapy for stage III colon cancer was conducted in the scope of the International Duration Evaluation of Adjuvant Chemotherapy (IDEA) collaboration; it included six different prospective trials conducted in different countries, and randomized patients after curative resection to either 6 months, or 3 months of postoperative fluoropyrimidine- and oxaliplatin-based adjuvant chemotherapy. An expert panel interpretation of the results recommends 6 months of postoperative adjuvant chemotherapy for patients at high risk of recurrence (T4 or N2). For low-risk patients (T1–3/N1), 3 or 6 months of adjuvant chemotherapy is considered equivalent. Based on these results, a shared decision-making approach between the patient and the provider is recommended when deciding duration of adjuvant chemotherapy in patients with resected stage III colon cancer, taking into consideration the patient's comorbidities and performance status, the completeness of the surgical resection, the number of lymph node retrieved, and the histopathologic characteristics of the tumor.[167]

Several studies have proven that the addition of irinotecan—a topoisomerase I inhibitor that is effective in metastatic CRC—to standard fluoropyrimidines is not superior to fluorouracil/leucovorin combinations alone in stage III colon cancers.[168] Similarly, bevacizumab (anti–VEGF-A) and cetuximab (anti-EGFR), two biologic agents that have shown efficacy in metastatic disease, do not improve survival, compared to FOLFOX alone.[169–171] Therefore, at the present time irinotecan, bevacizumab, and cetuximab are not recommended in the adjuvant treatment of nonmetastatic CRC.

The use of adjuvant chemotherapy after curative resection for stage II CRC has been controversial for more than a decade. Three prospective, randomized trials have addressed the subject using 5-FU–based regimens, all of them

failing to show a clear benefit of adjuvant treatment over observation alone.[161,172,173] The addition of oxaliplatin to the adjuvant regimen does not seem to improve the results of pyrimidine-based regimens for stage II. Most of the evidence for adjuvant treatment in stage II CRC comes from pooled analyses, in which stage II and III CRC patients, undergoing different chemotherapy regimens and controls, are analyzed. The most influential study, including 37 trials and 11 meta-analyses, found a significant improvement in DFS for 5% to 10%, favoring adjuvant chemotherapy; nevertheless, no difference in OS was observed.[174] Therefore, postoperative adjuvant chemotherapy is still not routinely recommended after curative resection for stage II CRC. However, there is evidence that some node-negative patients at high risk for recurrence may benefit from postoperative adjuvant chemotherapy. Determining which patients are at high risk has most commonly included consideration of features such as tumor perforation, T4 category tumors, poorly differentiated histology, lymphovascular or perineural invasion, and patients with fewer than 12 nodes in the surgical specimen (who are considered inadequately staged).[175] At the present time, the use of adjuvant therapy for stage II disease ought to be weighed carefully by a multidisciplinary team, with adequate counseling of the patient. As mentioned earlier, some predictive nomograms may help stratify risk in patients with stage II disease, enabling us to more effectively select those more likely to benefit from adjuvant therapy; however, these tools have not been widely incorporated into clinical practice.

The search for molecular prognosticators aimed at stratifying stage II patients according to the risk of relapse, is an active area of research. MMR deficiency has been associated with an improved prognosis, but a decreased benefit from fluoropyrimidine-based adjuvant therapies, in patients with stage II disease.[31] Because of this, MMR/MSI testing is recommended for patients with stage II disease. Current guidelines recommend no use of single-agent fluoropyrimidine treatment for patients with stage II tumors exhibiting MSI or MMR deficiency. The discovery that ICIs are effective in MMRd CRC has revolutionized the treatment of locally recurrent and metastatic MMRd CRC.[176,177] Immune checkpoint blockade is currently not recommended in nonmetastatic MMRd CRC, but clinical trials are investigating the efficacy of ICI in nonmetastatic dMMR/MSI CRC.[178] The multigene molecular signatures discussed previously were developed, in large part, to stratify risk in patients with stage II CRC, and to identify those most likely to benefit from adjuvant chemotherapy.[56–58] While

initial results are promising, there is insufficient evidence to recommend their use in selecting adjuvant therapy for patients with stage II CRC.

TREATMENT OF LOCALIZED RECTAL CANCER

The treatment of rectal cancer presents different challenges, but also different opportunities, compared to colon cancer. Given the location of the rectum within the narrow bony pelvis surrounded by the urogenital organs, large blood vessels, and autonomic nerves, and its proximity to the anal sphincters, rectal cancer surgery is technically challenging, potentially associated with perioperative complications, and often followed by loss of urinary, sexual, and bowel function that permanently impairs quality of life. In addition, rectal cancer has been associated with a higher rate of local recurrence after curative-intent surgery, compared to colon cancer. But the extraperitoneal location of most of the rectum and its proximity to the anal orifice make it accessible to explorations (DRE, endorectal ultrasound [ERUS]) and interventions (external-beam radiation therapy, brachytherapy, and local excision [LE]) not currently available for colon cancer.

The selection of the best treatment option for each rectal cancer patient is a complex process and requires consideration of the clinical tumor stage, location of the tumor within the rectum, the impact of treatment upon anorectal and genitourinary function, and the consequences for the patient in terms of prognosis and quality of life. Some rectal cancers can be treated with LE. Others require a TME, with or without sphincter preservation. Finally, many rectal cancer patients require chemotherapy and radiation to reduce the risk of local recurrence and distant metastasis.

Anatomy of the Rectum

The rectum represents the distal portion of the large bowel, extending from the rectosigmoid junction—the area where the tenia coli (characteristic of the sigmoid colon) splay and become the longitudinal muscular layer of the rectum—to the anorectal ring, a palpable anatomical landmark that corresponds to the imprint of the puborectalis muscle on the bowel wall. The anal canal extends from the anorectal ring to the anal verge, the palpable groove between the distal edge of the internal sphincter and the subcutaneous portion of the external sphincter (**Fig. 68.10**). For practical purposes and standardization, the rectum is

defined in terms of distance in centimeters from the anal verge. The distance of a tumor from the anal verge is best measured using a rigid proctoscope, which allows the simultaneous visualization of the anal verge and the centimeter marks on the outside of the scope. In European countries, tumors with the distal edge located within the last 15 cm of the large bowel are considered rectal cancers; in the United States, the limit is 12 cm. The location of tumor in relation to the peritoneal reflection and the sacral promontory, and its distance from the anal verge, can also be determined by MRI, particularly in sagittal views.

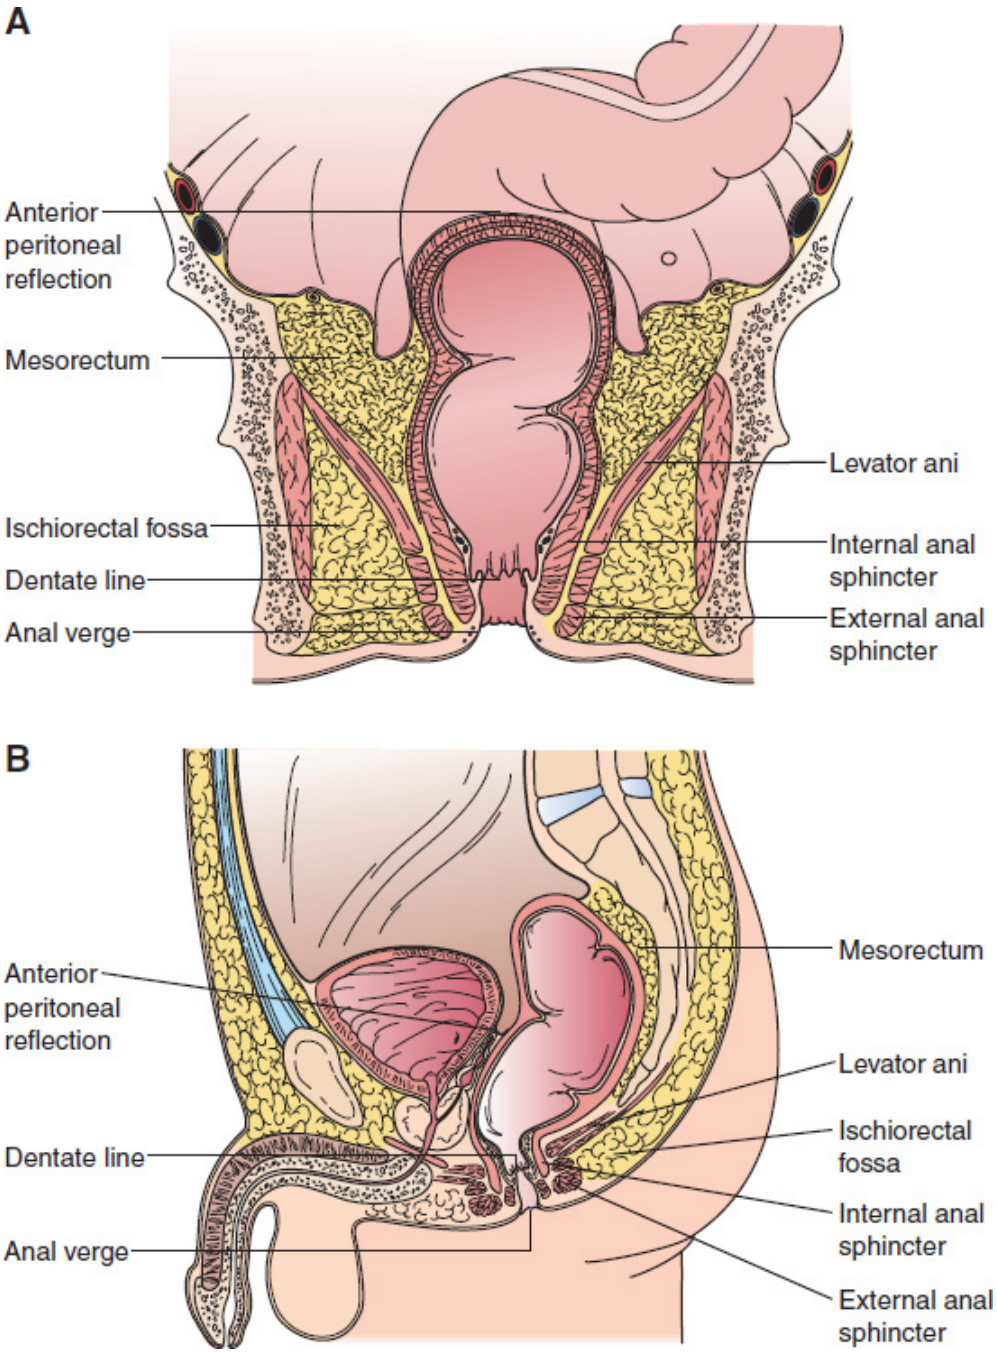

Figure 68.10 Anatomy of the rectum. **A:** Coronal pelvis. **B:** Sagittal pelvis.

The mesorectum is the visceral mesentery of the rectum containing the terminal branches of the superior rectal vessels and the rectum's lymphatic drainage. The upper portion of the rectum, located above the anterior peritoneal reflection, is covered with peritoneum in the front and on both sides. In this upper portion of the rectum, the mesorectum which is a continuation of the mesentery of the sigmoid colon, covers the rectum only posteriorly and is

attached to the concavity of the sacrum. Below the peritoneal reflection the rectum is completely extraperitoneal and fully surrounded by the mesorectum. The mesorectum is covered by a thin, glistening membrane called the mesorectal fascia (MRF). Posteriorly, the mesorectum is separated from the presacral fascia by an avascular plane of loose areolar tissue that is the natural plane of dissection during a radical proctectomy. Anteriorly, the mesorectum is separated from the urogenital organs by a remnant of the fusion of two layers of the embryologic peritoneal cul-de-sac known as Denonvilliers fascia——an important anatomical landmark in rectal cancer surgery. Below the peritoneal reflection, the lateral rectal ligaments or "lateral stalks" connect the mesorectum to the pelvic sidewall. The mesorectum tapers off distally as the rectum funnels toward the anorectal ring, where the longitudinal layer of the muscularis propria becomes the internal anal sphincter.

The blood supply of the rectum comes primarily from the superior rectal artery, which is the terminal branch of the inferior mesenteric artery after it gives off the left colic artery. The superior rectal vein has a parallel course to its homonymous artery, and joins the left colic vein to form the inferior mesenteric vein draining into the splenic vein. The lower portion of the rectum and the anal canal also receive blood supply from the internal iliac vessels through the middle rectal artery, an inconsistent branch of the inferior vesical artery. The inferior rectal artery is a branch of the pudendal artery. The middle and inferior rectal vessels anastomose with the upper rectal vessels, supplying enough blood to the entire rectum. As in other locations, the middle and inferior rectal veins follow the course of the homonymous arteries, draining into systemic circulation through the internal iliac veins.

The anatomy of the autonomic pelvic nerve system is very important when operating in the rectum, because of its proximity to the plane of dissection during different parts of the operation. Damage to these nerves can result in urinary and/or sexual dysfunction. The hypogastric plexus, located in front of the aorta, contains predominantly preganglionic sympathetic fibers originating from the lumbar sympathetic trunk. The fibers of the hypogastric plexus converge at the level of the aortic bifurcation into well-defined hypogastric nerves, which course laterally and anteriorly over the internal iliac vessels toward the lateral pelvic sidewall. There they join the splanchnic pelvic nerves, containing primarily postganglionic parasympathetic fibers from the anterior rami of S2, S3, and S4, to form the pelvic plexus. Branches of the pelvic plexus provide innervation to the distal ureter, the vas deferens, the

seminal vesicles, urinary bladder, and prostate. Branches of the pelvic plexus also provide innervation to the distal rectum, passing through the lateral stalks. Finally, distal to the lateral stalks, the distal pelvic plexus forms the urogenital neurovascular bundles that pass close to the posterolateral aspect of the seminal vesicles or the vagina, extending toward the apex of the prostate and the neck of the bladder.

Clinical Staging of Rectal Cancer

The preoperative evaluation of the rectal cancer patient follows the same principles as that of the colon cancer patient, but the wider spectrum of therapeutic options for rectal cancer patients requires accurate information about the location and stage of the tumor. The clinical stage is important in making treatment decisions, such as the intent of the treatment (palliative or curative), the need for neoadjuvant therapy, or even the extent of the surgery (LE vs. TME).

Patients with rectal cancer should undergo a complete colonoscopy because synchronous polyps are present in up to 30% of patients, and synchronous cancers in up to 5.3% of patients. They also require a CT scan of the chest, abdomen, and pelvis to exclude distant metastasis, which is present in 20% of patients at the time of diagnosis.

The preoperative locoregional staging of rectal cancer follows the clinical TNM system, based on depth of tumor penetration in the rectal wall and the presence of regional lymph nodes. However, the preoperative assessment of rectal cancer goes beyond determination of clinical tumor stage; it includes the distance of tumor from the anal verge, its relationship to the sphincter complex and the levator muscles, the proximity of tumor to the MRF, and the presence of extramural venous invasion (EMVI). This information is essential in planning treatment and surgery. Gross morphologic features such as size, morphology, and ulceration have been associated with prognosis. However, when stratified by stage, these characteristics have not appeared to contribute independently to oncologic outcomes, and therefore they are not incorporated into treatment decisions.

DRE and proctoscopy provide the surgeon with the first direct impression of the tumor. Tumor mobility on DRE provides a gross estimation of the tumor depth of invasion. There is a four-category clinical classification of rectal tumors, based on mobility on DRE, which supposedly corresponds to the four T

categories of the TNM system. However, the correlation between the clinical and pathologic T classifications is not very accurate, and varies significantly with the experience of the examiner. In general, DRE is able to distinguish between mobile tumors, most likely limited to the bowel wall, and tethered or fixed tumors, likely penetrating beyond the bowel wall. However, DRE fails to identify more than 50% of pathologically proven involved nodes. Finally, only very distal tumors are within reach of the examining finger. Therefore, pretreatment clinical staging requires imaging studies including ERUS, high-quality rectal MRI, as well as CT scan of the chest, abdomen, and pelvis with intravenous contrast.

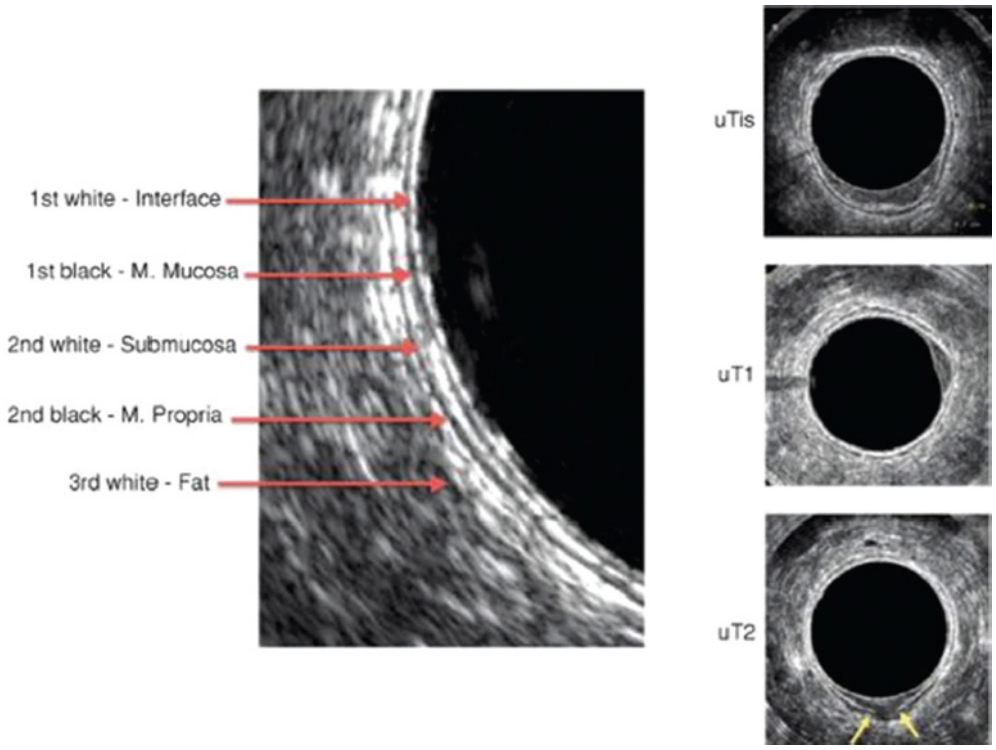

Figure 68.11 Endorectal ultrasound in rectal cancer staging. The sonographic five-layer structure of the rectal wall consists of three hyperechoic layers (interface, submucosa, perirectal fat and serosa) separated by two hypoechoic layers (muscularis mucosa and muscularis propria). Lesions are T staged as uT0/uTis when the mass is within the hypoechoic M. mucosa layer. Tumors staged as uT1 are invading the hyperechoic submucosal layer. Lesions with a distinct break of the submucosal layer and invasion into the hypoechoic muscularis propria layer are staged as uT2 (*yellow arrows*).

Ultrasound with an endorectal rotating probe is the imaging modality that best depicts the different layers of the bowel wall, and is most useful for staging early rectal cancer (**Fig. 68.11**).[179] But ERUS has a relatively short

focal range, and cannot depict important anatomical structures such as the MRF. CT scans provide accurate images of the rectum, adjacent pelvic structures, and even the MRF, but have lower tissue resolution compared to MRI. A CT scan of the chest, abdomen, and pelvis should be performed in every rectal cancer patient to exclude distant metastases. MRI with a surface phased-array coil has become the preferred imaging modality for locoregional staging of rectal cancer. Using various sequences and multiple planes, MRI provides high-tissue resolution and excellent anatomical depiction of the rectum, the mesorectum, the MRF, the levator muscles, and other pelvic structures, relative to tumor location (**Fig. 68.12**).[180] The addition of new contrast agents and advanced functional sequences such as diffusion-weighted imaging (DWI) and dynamic contrast enhancement (DCE) permit the quantification of tumor biologic processes such as microcirculation, vascular permeability, and tissue cellularity. DWI images in particular are useful for assessment of rectal cancer response to neoadjuvant therapy.[181,182]

Tumor distance from the MRF—the CRM when performing TME surgery—has prognostic implications for local recurrence and patient survival, and has become one of the most important parameters in the preoperative evaluation of rectal cancer patients.[47] MRI is the most accurate imaging modality in determining the distance of the tumor to the MRF, and predicting CRM involvement. The MERCURY trial, a prospective observational study assessing the accuracy of MRI in predicting a curative resection in rectal cancer, reported 92% specificity in predicting a negative CRM.[183] Other important tumor features accurately assessed by MRI, and associated with patient outcomes, are extramural spread, EMVI, involvement of the peritoneal reflection, and distance of tumor from the levator muscle and sphincter complex.[184,185] Using information on these parameters for patients registered to the MERCURY trial, clinicians are able to stratify rectal cancer patients with good prognosis (e.g., clear CRM, no evidence of EMVI, T2 or T3 <5 mm and not involving the intersphincteric plane) with a 3% LR rate and an 85% 5-year DFS after treatment with surgery alone.[186] In European and Scandinavian countries, the information gained from imaging, rather than clinical TNM staging, is used to determine treatment in patients with rectal cancer.[187]

Tumor response to neoadjuvant therapy has prognostic value, 4 and restaging after neoadjuvant therapy is becoming increasingly important in reassessing treatment options and planning the surgical procedure. Some patients with a clinical complete response, a subjective assessment that no

viable tumor remains based on DRE, endoscopy with or without biopsy, and MRI, are now offered alternatives to rectal resection, such as "watch and wait," in the context of clinical trials.[188–190] In the investigation of the accuracies of DRE, endoscopy, and MRI in predicting complete response, endoscopy is the most accurate.[191] This is true despite the fact that MRI can provide both morphologic and functional information regarding the tumor that can be seen in T2-weighted and diffusion-weighted sequences, respectively. When all three modalities (DRE, endoscopy, and MRI) are consistent with absence of residual tumor, the accuracy of predicting complete response can be as high as 98%. Clinical and radiologic modalities underestimate response to neoadjuvant treatment. DRE underestimates response in 78% of patients, relative to response in pathologic specimens.[192] Nearly three-quarters of patients with pCR have a residual mucosal abnormality that would have led to their being categorized as having had an incomplete clinical response.[193] Of patients for whom DRE, endoscopy, and MRI all indicate the possible presence of residual tumor, 15% still experience a complete response.[191]

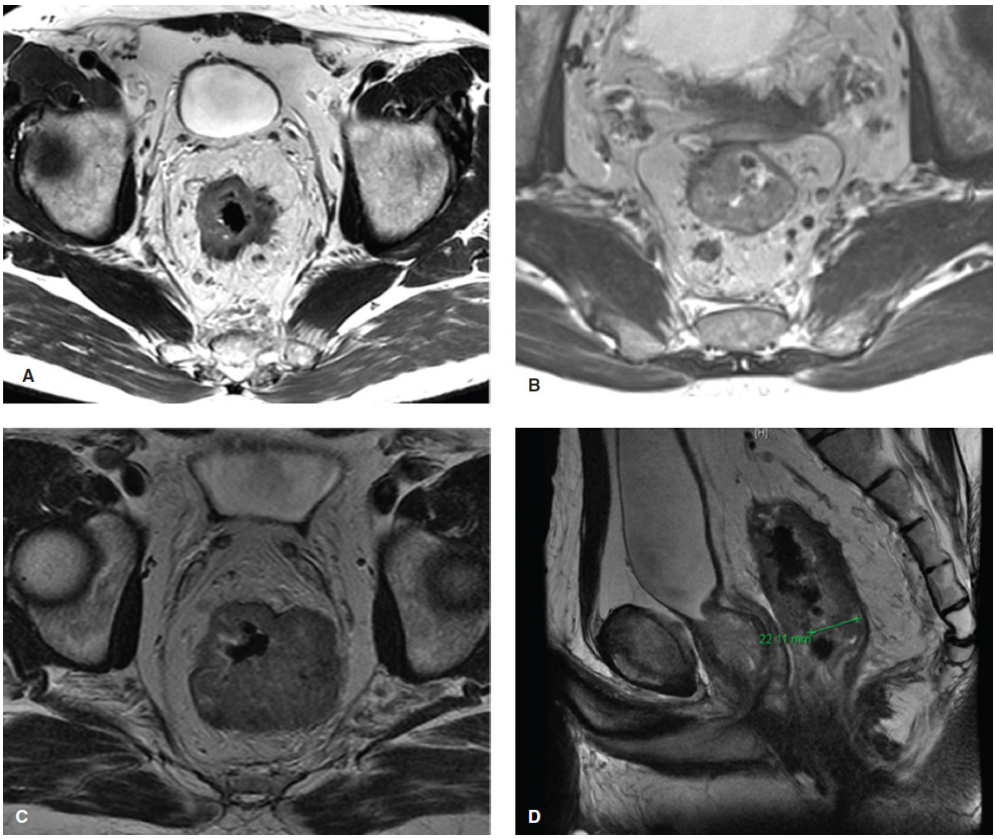

Figure 68.12 Magnetic resonance imaging in rectal cancer staging. Routine use of rectal MRI in the context of a multidisciplinary assessment of rectal cancer has been used to plan neoadjuvant therapy and surgery, and has been shown to reduce the incidence of positive circumferential margins. **A:** Rectal tumor with mesorectal lymph nodes suspicious for metastatic disease. **B:** Locally advanced rectal cancer threatening the mesorectum anteriorly. **C:** Rectal cancer invading the mesorectum in left lateral position. **D:** Sagittal view of a bulky locally advanced rectal cancer.

Local Excision for Early-Stage Rectal Cancer

Selected patients with stage I rectal cancer, those with tumors localized to the bowel wall (T1 or T2) and without involvement of the mesorectal nodes (N0), can be hypothetically cured with an LE of the portion of the rectal wall containing the tumor. This operation spares most of the mortality, morbidity, and bowel, urinary and sexual dysfunction associated with TME. However, the success of LE requires meticulous patient selection. With LE, the mesorectum is not inspected for pathologic nodal staging. Therefore, LE should only be offered to patients with a low risk of nodal metastasis. The selection criteria for LE include: tumor size smaller than 3 cm, involving less than 30% of the circumference of the rectum, mobile on DRE, localized to the submucosa on

ERUS, without evidence of metastatic lymph nodes on ERUS and CT or MRI, and no high-risk histologic features (i.e., grade 3 or 4, lymphovascular or perineural invasion) as noted in consensus guidelines.

In the past, only tumors located in the distal rectum could be treated with LE using conventional transanal techniques. Therefore, LE was only recommended for tumors located within 8 cm from the anal verge. With the use of endoscopic instrumentation and large operating proctoscopes (TEM, Richard Wolf Medical Instruments Corp., Vernon Hills, IL; TEO, Karl Storz Corp., El Segundo, CA) or single-port devices (TAMIS, Trans-Anal Minimally Invasive Surgery), LE can now be easily performed for tumors located in the mid and upper rectum. However, the benefit of LE is more significant for very distal tumors that otherwise would require a low anastomosis or a permanent stoma. The real benefit of LE for tumors located in the upper rectum is a matter of debate.

Independent of the approach, a full-thickness excision of the portion of the bowel wall involved by tumor, with a 1-cm negative margin is required to avoid local recurrence. The final decision regarding the suitability of LE is made after the pathologic evaluation of the surgical specimen. If the resection margins are positive, depth of invasion is beyond the submucosa (T stage ≥2), or the histology reveals high-risk features (grade 3 or 4, lymphovascular or perineural invasion), the patient should be offered immediate salvage TME.

Even in patients with tumors meeting all selection criteria, LE is associated with a higher rate of LR compared to TME. The recurrence rates for T1 tumors treated with LE have been described as up to 23%.[195–197] While some patients who develop LR after a failed LE are candidates for salvage TME, only half of these patients are ultimately cured of their tumors. Recurrences after LE generally present as more advanced tumors, often requiring extended pelvic dissection.[198,199] The oncologic outcome for these patients is worse than those treated originally with TME; this reinforces the importance of patient selection for this strategy.

A recent systematic review of one small randomized trial and 12 observational studies, including a total of 2,855 patients with T1N0M0 rectal cancer treated by LE (TAE/TEM-TEO) versus TME, showed that LE was associated with lower perioperative mortality (relative risk 0.31, 95% CI 0.14–0.71), major postoperative complications (relative risk 0.20, 95% CI 0.10–0.41), and need for a permanent stoma (relative risk 0.17, 95% 0.09–0.30). The LR rate was higher for patients treated with LE, and overall survival significantly lower, compared to patients treated with TME. The relative risk of

dying after LE was 1.46 (95% CI 1.19–1.77), which corresponds to 72 more deaths per 1,000 patients at 5 years. Meta-regression showed that the difference in overall survival observed between groups could be explained by the higher use of LE for tumors located in the lower third of the rectum, which is associated with worse prognosis. Survival was similar between groups when only tumors located in the distal rectum were included in the analysis.[200]

A number of studies have compared the outcomes of different techniques—conventional transanal excision, TEMS, TEO, and TAMIS—for LE of rectal cancer, with most comparisons limited to conventional TAE and TEMS. A recent meta-analysis of 6 retrospective case series including 927 procedures, reported that TEMS was associated with less specimen fragmentation, less positive resection margins, and lower LR rates. No difference was observed in complication rate.[201]

In summary, the literature suggests that LE may be an alternative to TME for patients with small, distal T1N0 rectal cancers, without high-risk histologic features, that would otherwise require a CAA or an APE. Transanal endoscopic techniques may be superior to conventional transanal excision. Patients considering LE should be informed about the potential gains in improved quality of life, but also about the higher risk of LR and the need for salvage surgery.

Patients with T2N0 tumors are not candidates for treatment by LE alone, independent of tumor histologic features. The rate of LR for these patients when treated with LE alone ranges from 13% to 47%, significantly higher compared to similar stage tumors treated with TME. Five-year overall survival is also significantly lower for patients with T2N0 tumors treated with LE (65% to 67.6%) compared to TME (76.7% to 81%).[202] A recent survey of the NCDB found that patients with T2N0 tumors treated with LE alone had a higher hazard ratio for death compared to similar patients treated with TME (1.535, 95% CI 1.283–1.835).[203] Similar results have been reported in an independent cohort from the SEER database.[204] Based on this evidence, LE alone cannot be recommended as an alternative to RS for patients with T2N0 tumor treated with curative intent.

Radiation therapy has been used to reduce the rate of LR in patients with T2N0 rectal cancer treated with LE. A number of retrospective case series have reported 15% to 21% LR rates and 66% to 76.1% 5-year survival rates with LE followed by radiation or chemoradiation for T2N0 tumors.[205–207] The CALGB 8984 trial investigated the role of LE followed by 5-FU–based

adjuvant chemoradiation for patients with T2N0 cancers, reporting a 66% (95% CI, 51% to 84%) overall survival and 64% (95% CI, 51% to 80%) DFS.[208] The trial compared the survival curves of patients with similar stage tumors treated with TME, concluding that LE and postoperative chemoradiation may be an alternative for patients with T2N0 tumors. However, 32% of the patients initially accrued for this trial were ultimately excluded from analysis due to tumor size, inaccurate staging, surgical specimen fragmentation, high-grade histologic features, or involved resection margins. Therefore, the conclusion is applicable only for properly staged early rectal cancers penetrating only into the muscularis propria (pT2), with full-thickness excision negative resection margins, and no high-risk histologic features.

The results of several retrospective studies have suggested that chemoradiation before LE reduces the risk of recurrence to rates similar to those observed in similar stage patients treated with TME alone.[209,210] However, these studies are limited by small sample size, variable clinical staging criteria and imaging modalities, and the use of different CRT regimens. A retrospective study using the SEER database showed that patients who had undergone neoadjuvant CRT and LE had equivalent oncologic outcomes compared to patients who had a radical resection/TME.[204] One prospective trial found that patients with ERUS-staged T2N0 rectal cancer treated with neoadjuvant CRT had similar recurrence and survival rates when randomized to LE or TME. More than one in four patients in the TME arm required a permanent colostomy, and a similar number required a temporary ileostomy.[211] Two single-arm prospective studies have shown that CRT followed by LE for early-stage distal rectal cancers is associated with local recurrence and disease-free survival rate equivalent to similar tumors treated with TME.[212,213] However, this treatment approach is associated with bowel dysfunction and impairment in quality of life, particularly in patients with very distal tumors.[212,214] The GRECCAR-2 trial randomized patients with T2 or T3 distal rectal cancer that responded to CRT to either LE or TME. Local recurrence rates, disease-free survival, and fecal incontinence were similar for patients treated in both treatment arms.[215] In summary, the standard treatment of T2N0 rectal cancer is TME. Neoadjuvant CRT followed by LE may be an alternative for patients with very distal T2N0 tumors interested in organ preservation, who otherwise would require a permanent colostomy.

LE and other forms of local therapy, such as endocavitary radiation, brachytherapy, or electrofulguration, have been used for palliation in patients

who have more advanced tumors or are unfit for a major surgical procedure.

Transabdominal Resection for Rectal Cancer

Patient preparation for rectal cancer surgery is similar to that for colon cancer surgery. Stoma marking is particularly important in these patients, as many will require a temporary or permanent stoma. In addition to discussing fertility options with all individuals of child-bearing potential, female patients receiving neoadjuvant radiation who are interested in preserving fertility should consult their gynecologist regarding the possibility of ovarian transposition. Mechanical bowel preparation, antibiotic and thromboembolic prophylaxis are similar to those described for colon cancer patients. Many surgeons recommend a rectal washout immediately before surgery to eliminate exfoliated cancer cells that could potentially implant in the anastomosis and cause LR. In fact, a recent meta-analysis with 5,012 patients found that this practice is associated with a lower incidence of LR.[216] On the operative table, the patient should be placed in lithotomy with the legs in stirrups to provide the surgeon with simultaneous access to the abdomen and perineum. It is important to avoid pressure on the bony prominences, which might cause peroneal nerve compression. Patients requiring prolonged Trendelenburg position during surgery are at risk of compartment syndrome, in particular obese patients and those with peripheral vascular disease. These patients require monitoring of the peripheral pulses, and position changes, to prevent compartment ischemia.
