This work is provided “as is,” and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals’ examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

Los Angeles, California

Preface

The editors are pleased to present the seventh edition of *Mulholland and Greenfield's Surgery: Scientific Principles & Practice*. The field of surgery has changed fundamentally in the years since the first edition of this text. Growth in the knowledge base of clinical surgery continues exponentially. Surgical practice has been transformed through scientific advancements and the introduction of new technology. The accelerating pace of scientific progress demands rapid adoption of new ideas into surgical therapy and a commitment to lifelong learning. Accordingly, the new edition of *Mulholland and Greenfield's Surgery* seeks to integrate new scientific knowledge with evolving changes in surgical care.

The seventh edition brings many changes and updates. First, there is a change in editorial leadership. Dr. Michael Mulholland, who has been integral to the success of this text since its inception, has stepped down. It is my great honor to be selected by our publisher to succeed Dr. Mulholland as the editor in chief. To recognize Dr. Mulholland's contributions, we have added his name to the title of the book to be recognized with Dr. Greenfield.

Second, the composition of the editorial team has also changed. Drs. Keith Lillemoe and Gerard Doherty have also stepped down after making great contributions to their sections during their long tenure as editors. We are grateful for their service and excited to build on their work as a new editorial team. Drs. Hasan Alam, Tim Pawlik, and Gilbert Upchurch, have agreed to continue to serve on the editorial team; and I am excited to add Dr. Mary Hawn and Dr. Julie Ann Sosa to our team of editors. The expertise, energy, and vision of this great team of editors has invigorated this edition.

With new leadership and editorial team, we have made many changes to the style, content, and authors. We have kept the vision of the text by integrating science and practice, but have shortened the book by eliminating some chapters that can be accessed elsewhere and are less relevant to current practice. We also instructed authors to shorten chapters and consolidate information into easy to read tables, rather than long blocks of text. This edition has many new authors and represents perhaps the greatest turnover in authorship since the book was launched.

On behalf of the editorial team, we hope that you find the seventh edition of *Mulholland and Greenfield's Surgery: Scientific Principles & Practice* to be an important part of your surgical library. We have carefully curated the content to serve your lifelong education goals and, ultimately, to improve the care of your patients.

Justin B. Dimick, MD, MPH

Contents

Contributors
Preface

Part One Scientific Principles

1 Lifelong Learning
Laura Mazer, Rebecca M. Minter, and Gurjit Sandhu

2 Substrate Metabolism in Surgery
Carrie Sims

3 Surgical Nutrition and Metabolism
Melissa H. Coleman and Deborah M. Stein

4 The Pathogenesis of Obesity and Metabolic Disease
Robert W. O'Rourke

5 Wound Healing
Katherine A. Gallagher

6 Hemostasis
Andrea T. Obi and Peter K. Henke

7 Inflammation
Matthew R. Rosengart, Matthew D. Neal, and Timothy R. Billiar

8 Surgical Infections
Lena M. Napolitano

9 Shock
Joseph Cuschieri

10 Critical Care
William C. Chiu and Samuel A. Tisherman

11 Fluids, Electrolytes, and Acid–Base Balance
Bellal Joseph and Michael F. Ditillo

12 Burns: Medical, Surgical, Critical Care and Reconstruction of the Burn Patient
Naveen F. Sangji, Stewart C. Wang, and Benjamin Levi

13 Anesthesiology and Pain Management
Paul Picton, Sachin Kheterpal, and Michael R. Mathis

14 Preoperative Risk Assessment
Pauline K. Park

15 Measuring the Quality of Surgical Care: Surgeons, Hospitals and Systems
Andrew M. Ibrahim and Justin B. Dimick

16 Improving Surgical Quality
Kristan L. Staudenmayer

17 Global Surgery
Tiffany E. Chao, Jahnavi K. Srinivasan, and Sherry M. Wren

18 Patient Safety
Kiran Gupta and Elizabeth C. Wick

Part Two Surgical Practice

SECTION A: TRAUMA

19 Trauma and Trauma Care: General Considerations
John W. Scott and Hasan B. Alam

20 Prehospital and New Advances in Resuscitation
Jason L. Sperry and Christine M. Leeper

21 Head Injuries
Jacob R. Joseph, Krishna Rajajee, and Krishnan ("Raghu") Raghavendran

22 Injury and Violence Prevention: A Public Health Approach
Joseph V. Sakran and Nicole Lunardi

23 Neck Injuries
Brandon R. Bruns and Thomas M. Scalea

24 Thoracic Trauma
Jill Streams and Marc de Moya

25 Abdominal Trauma
Kenji Inaba, Elizabeth R. Benjamin, and Demetrios Demetriades

26 Genitourinary Trauma
Bradley A. Rittenhouse and Martin Schreiber

27 Vascular Trauma
Kendal M. Endicott, Shahab Toursavadkohi, and Todd E. Rasmussen

28 The Principles of Orthopedic Surgery for Trauma
Raymond Malcolm Smith

29 Pediatric Trauma
Peter T. Masiakos, Cornelia L. Griggs, and Danielle B. Cameron

30 Geriatric Trauma
Tatiana C. P. Cardenas, Marc D. Trust, and Carlos V. R. Brown

31 Trauma in Pregnancy
Dirk C. Johnson and Kimberly A. Davis

32 Postinjury Management
Audrey C. Pendleton and Paula Ferrada

33 Environmental Injuries
J. Patrick Walker and Gregory J. Jurkovich

SECTION B: TRANSPLANTATION

34 Clinical Transplant Immunology
Seth A. Waits, Amit K. Mathur, and Satish N. Nadig

35 Organ Retrieval and Preservation
Mary T. Killackey

36 Kidney Transplantation
Jayme E. Locke and Peter G. Stock

37 Hepatic Transplantation
Benjamin Samstein and Christopher J. Sonnenday

38 Cardiac Transplantation
Ahmet Kilic and Robert S. D. Higgins

39 Lung Transplantation
Errol L. Bush

40 Pancreas and Islet Transplantation
Randall S. Sung

SECTION C: HEAD AND NECK

41 Head and Neck

Kelly Michele Malloy

SECTION D: ESOPHAGUS

42 Esophageal Anatomy and Physiology and Gastroesophageal Reflux Disease
Yulia Zak, Micaela Esquivel, and Mary T. Hawn

43 Esophageal Tumors and Injury
Natalie S. Lui, Mark F. Berry, Yulia Zak, and Leah M. Backhus

SECTION E: STOMACH AND DUODENUM

44 Gastric Anatomy and Physiology
Michael W. Mulholland

45 Gastroduodenal Ulceration
Michael W. Mulholland

46 Management of Obesity
Dana A. Telem and Robert W. O'Rourke

47 Gastric Neoplasms
Andrew P. Loehrer and Sandra L. Wong

SECTION F: SMALL INTESTINE

48 Anatomy and Physiology of the Small Intestine
Joslin Cheverie, Jared S. Matson, and Sonia L. Ramamoorthy

49 Ileus and Bowel Obstruction
David I. Soybel and Amanda B. Cooper

50 Crohn Disease

Anuradha R. Bhama and Scott R. Steele

51 Small Intestinal Neoplasms
James W. Fleshman Jr and Steven G. Leeds

SECTION G: PANCREAS

52 Pancreas Anatomy and Physiology
Teviah E. Sachs and Jennifer F. Tseng

53 Acute Pancreatitis
Elizabeth Pando Rau, Rogier Voermans, Casper van Eijck, Hjalmar van Santvoort, and Marc Besselink for the Dutch Pancreatitis Study Group

54 Chronic Pancreatitis
Katherine A. Morgan

55 Neoplasms of Exocrine Pancreas
Motaz Qadan and Cristina R. Ferrone

56 Neoplasms of the Endocrine Pancreas
Jordan M. Cloyd and George A. Poultsides

SECTION H: HEPATOBILIARY AND PORTAL VENOUS SYSTEM

57 Hepatobiliary Anatomy
Alice C. Wei

58 Hepatic Infection and Acute Liver Failure
Ola Ahmed and Maria B. Majella Doyle

59 Cirrhosis and Portal Hypertension
Russell N. Wesson and Andrew M. Cameron

60 Hepatic Neoplasms

Shishir K. Maithel

61 Calculous Biliary Disease
Salila S. Hashmi and Elijah Dixon

62 Biliary Injury, Strictures, and Sclerosing Cholangitis
Rory L. Smoot and Sean P. Cleary

63 Biliary Neoplasms
Kaitlyn J. Kelly, Yuman Fong, and Sharon Weber

SECTION I: COLON AND RECTUM

64 Anatomy and Physiology of the Colon, Rectum, and Anus
Elise H. Lawson and Elizabeth C. Wick

65 Gastrointestinal Bleeding
Richard H. Turnage and Benjamin L. Davis

66 Ulcerative Colitis
Aaron J. Dawes and Arden M. Morris

67 Colonic Polyps and Polyposis Syndromes
Emily Steinhagen and Neil Hyman

68 Colorectal Cancer
Julio Garcia-Aguilar and Emmanouil P. Pappou

69 Diverticular Disease
Lillias H. Maguire

70 Anorectal Disorders
Amy L. Halverson and Vitaliy Y. Poylin

71 Appendiceal Diseases
Arden M. Morris

SECTION J: HERNIA AND SPLEEN

72 Abdominal Wall Hernias
Benjamin K. Poulose, Jeremy A. Warren, and Robert J. Fitzgibbons Jr

73 The Spleen
Oliver A. Varban and Anne P. Ehlers

SECTION K: SURGICAL ENDOCRINOLOGY

74 Breast Disease
Thanh U. Barbie and Julie A. Margenthaler

75 The Thyroid Gland
Sarah B. Fisher and Elizabeth G. Grubbs

76 Parathyroid Glands
Gerard M. Doherty

77 Adrenal Gland
Hadiza S. Kazaure and Sanziana A. Roman

78 Pituitary Surgery
Benjamin I. Rapoport, Georgiana A. Dobri, and Theodore H. Schwartz

SECTION L: LUNG

79 Lung Neoplasms
Robert E. Merritt

80 Nonneoplastic Thoracic Disease
Rishindra M. Reddy

SECTION M: VASCULAR DISEASE

81 Congenital Heart Disease
Vikram Sood and Jennifer C. Romano

82 Valvular Heart Disease
Daniel J. P. Burns, Per Wierup, and A. Marc Gillinov

83 Mechanical Circulatory Support
Eric I. Jeng

84 Pericardium
Jules Lin

85 Vascular Diagnostics: The Noninvasive Vascular Laboratory
Gregory L. Moneta

86 Vascular Infection
Courtney E. Morgan and John E. Rectenwald

87 Cerebrovascular Disease
Omar Al-Nouri and Mahmoud B. Malas

88 Upper Extremity Arterial Disease
Heron E. Rodriguez and Courtney Furlough

89 Renal and Splanchnic Vascular Disease
Dawn M. Coleman, John E. Rectenwald, and Gilbert R. Upchurch Jr

90 Aortoiliac Occlusive Disease
Loay S. Kabbani, Mitchell R. Weaver, and Alexander D. Shepard

91 Peripheral Arterial Disease
Bryan A. Ehlert and William P. Robinson III

92 Lower Extremity Amputation
Matthew J. Sideman, Kevin E. Taubman, and Bradley D. Beasley

93 Thoracic and Thoracoabdominal Aorta: Aneurysm and Dissection
George J. Arnaoutakis and Eric Y. Pruitt

94 Abdominal Aortic Aneurysms
Dean J. Arnaoutakis, Gilbert R. Upchurch Jr, and Thomas S. Huber

95 Lower Extremity Aneurysms
Katherine E. Hawkins and Amy B. Reed

96 Venous Disease
Andrea T. Obi, Katherin E. Leckie, Michael C. Dalsing, and Thomas W. Wakefield

SECTION N: PEDIATRIC SURGERY

97 Fetal, Pediatric, and Neonatal Physiology
Chinwendu Onwubiko, Aaron R. Jensen, and Hanmin Lee

98 Fetal Intervention
Diana L. Farmer and Tippi MacKenzie

99 Pediatric Head and Neck
Nikolaus E. Wolter and Reza Rahbar

100 Pediatric Chest
Robert E. Cilley and Mary Catherine Santos

101 Pediatric Abdomen
Andrea Hayes-Jordan and Michael Phillips

102 Pediatric Genitourinary System
Natalia V. Leva and Hillary Copp

103 Childhood Tumors
Erika A. Newman

104 The Pregnant Patient
Eugene S. Kim and Michael J. Zobel

SECTION O: SKIN AND SOFT TISSUE

105 Cutaneous Malignancies
Lesly A. Dossett, Amod A. Sarnaik, Allison B. Durham, and Vernon K. Sondak

106 Sarcomas of Soft Tissue and Bone
Chandrajit P. Raut and Sandra L. Wong

107 Plastic and Reconstructive Surgery
Anthony P. Tufaro, Christian El Amm, E. Gene Deune, Michele A. Manahan, and Sachin M. Shridharani

Index

List of Algorithms

Algorithm 8.1 Empiric antimicrobial treatment of extrabiliary cIAIs, community acquired versus health care associated

Algorithm 8.2 Biliary infections and algorithm for diagnosis and management

Algorithm 8.3 Step-up approach to management of necrotizing infected pancreatitis

Algorithm 9.1 Neurohormonal response to hypovolemia

Algorithm 9.2 Shock resuscitation algorithm

Algorithm 11.1 Hyponatremia

Algorithm 11.2 Acute hyperkalemia

Algorithm 11.3 Guidelines for the treatment of diabetic ketoacidosis

Algorithm 12.1 Protocol for frostbite injury

Algorithm 13.1 Decision aid for preoperative cardiac evaluation prior to noncardiac surgery. This decision tree for preoperative evaluation takes into account not only the patient's physical status but also the severity of the surgical procedure

Algorithm 13.2 Algorithm for managing a patient on chronic buprenorphine therapy

Algorithm 14.1 Stepwise approach to perioperative cardiac assessment for CAD

Algorithm 14.2 Proposed algorithm for antiplatelet management in patients with PCI and noncardiac surgery

Algorithm 14.3A–B Physiologic evaluation prior to lung resection

Algorithm 14.4 Proposed algorithm for preoperative evaluation of patients with liver disease

Algorithm 19.1 2011 Guidelines for the field triage of the injured patients

Algorithm 26.1 Evaluation of renal trauma

Algorithm 26.2 Evaluation of ureteral injury

Algorithm 28.1 The Denver Protocol for management of major pelvic fractures

Algorithm 29.1A–B PECARN rules to identify children at very low risk of clinically important TBI. CT algorithm for children younger than 2 years (**A**) and for those aged 2 years and older (**B**) with GCS scores of 14–15 after head trauma

Algorithm 29.2A–B Algorithm generated by the Brain Trauma Foundation Committee for the first edition of the *Guidelines for the Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents* for first-tier therapies (**A**) and second-tier therapies (**B**)

Algorithm 29.3 New ATOMAC guidelines for management of pediatric solid organ injury

Algorithm 41.1 Workup of a neck mass in an adult patient

Algorithm 42.1 24-Hour esophageal pH monitoring

Algorithm 43.1 Evaluation and management of esophageal leiomyoma

Algorithm 43.2 Evaluation and management of esophageal perforation

Algorithm 43.3 Evaluation and management of acute caustic ingestion

Algorithm 45.1 Treatment of bleeding duodenal ulceration

Algorithm 46.1 Algorithm for management of abdominal pain months or years after Roux-en-Y reconstruction

Algorithm 47.1 Diagnosis and management of gastric cancer

Algorithm 49.1 Approach to recognition and management of early postlaparotomy obstruction of the small intestine

Algorithm 49.2 Algorithm for management of malignant obstruction

Algorithm 50.1 Management of small-bowel disease in Crohn disease

Algorithm 50.2 Management of colitis in Crohn disease

Algorithm 50.3 Crohn disease with anal complaints

Algorithm 50.4 Management of anal skin tags and hemorrhoids in Crohn disease

Algorithm 50.5 Management of anal fistula in Crohn disease

Algorithm 50.6 Management of anal fissure in Crohn disease

Algorithm 51.1 Management of patients with advanced neuroendocrine tumors (NETs) of the gastrointestinal tract

Algorithm 51.2 Management of patients with small bowel adenocarcinomas. The treatment strategy depends on disease stage and involves en bloc resection for locoregional disease and systemic chemotherapy for metastatic disease. All current recommendations are based on case series, retrospective reviews, or nonrandomized prospective trials because of an absence of any randomized data

Algorithm 51.3A–B Treatment algorithms for patients with (**A**) advanced/metastatic GIST and (**B**) resectable GIST

Algorithm 54.1 Algorithm for operative decision-making in chronic pancreatitis

Algorithm 55.1 International consensus guidelines for the management of IPMNs

Algorithm 62.1 Bile duct injury

Algorithm 68.1 Approach to rectal cancer according to clinical staging

Algorithm 68.2 Approach to locally advanced rectal cancer based on a three-tier risk stratification system ("the good, the bad, and the ugly")

Algorithm 68.3 Stage IV rectal cancer treatment algorithm

Algorithm 72.1 Management of initial inguinal hernia

Algorithm 72.2 Management of recurrent inguinal hernia

Algorithm 72.3 Management of groin pain after herniorraphy

Algorithm 72.4 Management of incisional hernia

Algorithm 74.1 Diagnosis and management of the patient with a clinically benign breast mass. The use of imaging studies varies according to age because breast carcinoma is infrequent in women younger than 35 years old

Algorithm 74.2 Diagnosis and management of the patient with a clinically indeterminate or suspicious solid breast mass. In this circumstance, imaging studies are insufficient to exclude malignancy, and tissue sampling is required

Algorithm 74.3 Diagnosis and management of the patient with a cystic lesion. Bloody fluid on aspiration, failure of the mass to resolve completely, and prompt refilling of the same cyst are indications for surgical biopsy

Algorithm 77.1 Diagnosis and management of the incidental adrenal mass

Algorithm 77.2 Diagnosis of hypercortisolism

Algorithm 77.3 Diagnosis and management of hyperaldosteronism

Algorithm 78.1 Treatment algorithm for acromegaly

Algorithm 78.2 Treatment algorithm for Cushing disease

Algorithm 80.1 Algorithm for management of lung abscess

Algorithm 80.2 Hemoptysis management

Algorithm 80.3 LVRS candidate workup

Algorithm 80.4 Algorithm to treat pneumothorax

Algorithm 80.5 Algorithm for management of tracheal masses

Algorithm 83.1 Current algorithm for assessing patients with advanced heart failure for heart transplantation and mechanical circulatory support. Transplant status is initially assessed to determine appropriate indication for MCS use; BTT versus DT

Algorithm 84.1 The algorithm outlines the initial approach to a patient with a large pericardial effusion

Algorithm 90.1 Patient with symptomatic aortoiliac occlusive disease

Algorithm 95.1 Management of femoral pseudoaneurysm

Algorithm 96.1 Treatment of chronic venous insufficiency

1

Lifelong Learning

Laura Mazer, Rebecca M. Minter, and Gurjit Sandhu

Key Points

1. Surgery is an ever-evolving field, and residency programs must provide trainees with the skills necessary to continuously evaluate and integrate new knowledge.
2. Many high performing students arrive in advanced training programs without explicit understanding of the *process* of learning.
3. Self-regulated learners are metacognitively, motivationally, and behaviorally active participants in the learning process: they set learning goals; they perceive themselves as capable of learning; and they structure their environment to optimize learning.
4. Lifelong learning depends on teaching students how to *self-regulate* their learning.
5. A number of evidence-based tools exist to help trainees explicitly identify and develop self-regulatory processes, including assessment tools, self-regulated reading strategies, and coaching.

"We can say that he learned rapidly because his first training was in how to learn. And the first lesson of all was the basic trust that he could learn. It is shocking to find how many people do not believe they can learn, and how many more believe learning to be difficult."

—Frank Herbert

1 THE IMPORTANCE OF LIFELONG LEARNING

Today more than ever, surgical practice is evolving quickly. Beyond any specific curricular objective, medical education needs to focus on creating lifelong learners: Physicians who will continue to acquire, retain, and integrate new knowledge from the first day of medical school through the last day of their careers. The Accreditation Council for Graduate Medical Education (ACGME) draws a clear and explicit connection between professionalism, safe patient care, and lifelong learning: "The ACGME Core Competencies aim to spur a lifelong-learning pattern for physicians and continuous improvement for medical schools."[1] Similarly, the Global Commission on Education for Health Professionals asks medical schools to create graduates "educated to mobilize knowledge and to engage in critical reasoning and ethical conduct."[2]

In a field that is changing faster than ever, how can surgical educators create this kind of lifelong learner and how can surgical trainees develop the skills necessary to become intentional, independent, and self-directed scholars? This is especially important because there is evidence that students frequently arrive in graduate education without these requisite skills. A 2009 study asked veterinary students to identify the factors considered most important in their learning. Overwhelmingly, they cited the quality of the instruction, workload, and curriculum, but almost never their own effort or study skills.[3] Learning is considered something that happens *to the learner*, rather than something the learner can control. This feeling is reinforced by a primary and secondary educational system that decouples effort from reward.[4] Similarly, undergraduate students asked to explain the reason for academic failures mostly describe either inadequate instruction, or an innate lack of ability—both things that are out of their control, rather than attributing failure to a volitional process or effort.[5] Overall, many students—even very high performers—come to professional education lacking essential self-regulation skills.[5] Even those students who have been very academically successful may have only a subconscious understanding of the traits leading

to that success. Understandably, medical training focuses on knowledge, technical skills, and professionalism: 2 the *end products* of learning. To create lifelong learners who can continue to expand their knowledge and skills beyond the confines of a training program, dedicated attention is needed to the metacognitive traits that enable the *process* of learning.

WHAT IS SELF-REGULATED LEARNING?

Self-regulated learning refers to a constellation of skills, traits, and habits that promote and sustain learning. It is the *volitional process* by which learners transform mental abilities into academic skills.[5] The volitional component explains why a very talented trainee can fail to achieve what a motivated but less gifted student can accomplish. The ability to self-regulate is consistently the strongest independent predictor of educational and workplace success, outperforming IQ, parental education level, or economic status.[5–7] In surgical training, these character traits, like self-control, discipline, perseverance, and determination, are a major predictor of successful completion of residency.[8,9]

Self-regulated learning is a total engagement activity, regardless of whether the learner is sitting in a class, reading a textbook, or learning in the workplace. Such learners are "metacognitively, motivationally, and behaviorally active participants in their own learning process."[10]

1. 3 **Metacognitively active learners** plan, organize, self-instruct, self-monitor, and self-evaluate. Crucially, such learners have the ability to set their own goals, and can determine when and if those goals are being met.
2. **Motivationally active learners** perceive themselves as competent, self-efficacious, and autonomous. Originating from Albert Bandura's work in clinical psychology, there is a strong correlation between perceived self-efficacy and performance.[11] When trainees are estimating their ability to perform a future task, they base the evaluation on past performance. An estimation of high ability exerts a strong positive effect on goal setting, effort, and persistence. It then becomes a virtuous cycle: perceived self-efficacy improves effort, effort improves performance, and good performance positively reinforces the sense of efficacy. In short: they think they can, so they do. Of note, this does not imply that learners will benefit

from an inflated sense of their own abilities. Studies of medical students on the wards show that inaccurate self-assessment results in worse performance.[12] It is *earned* self-efficacy and the ability to accurately self-evaluate—neither under- nor overestimating one's abilities—that is the key to self-regulation.

3. **Behaviorally active learners** select, structure, and create environments that optimize learning.

4 Because self-regulated learning takes place over time, several theorists have developed a three-stage model of the process. In this model, learners progress through a cycle of planning or forethought, through performance of the task, and then into a self-reflection or evaluation phase (**Fig. 1.1**).[5,13] Sitzmann et al. performed a meta-analysis of the theories of self-regulation in multiple fields, and developed a heuristic framework of the elements of self-regulatory learning as they fall into those three components.[6] In the planning phase, learners chose a *regulatory agent*—the specific goal to be achieved. The goal is accomplished by utilizing *regulatory mechanisms*—a broad list of skills and traits including learning strategies, persistence, help-seeking, emotion control, and more. Finally, *regulatory appraisals* allow the learner to self-evaluate and reassess self-efficacy. This stage is crucial for determining if the goal is achieved, and for connecting success or failure to their legitimate cause. Attributing failure to an innate lack of ability or an external process beyond the learner's control, usually results in a loss of motivation and reduced effort. A learner who emphasizes the success or failure of the regulatory mechanisms they employed toward the chosen goal is much more likely to continue learning. Some specific regulatory mechanisms are described in **Table 1.1**.[6,14] Three processes salient to self-regulatory learning—use of assessment tools, coaching, reading strategies—are explored in further detail.

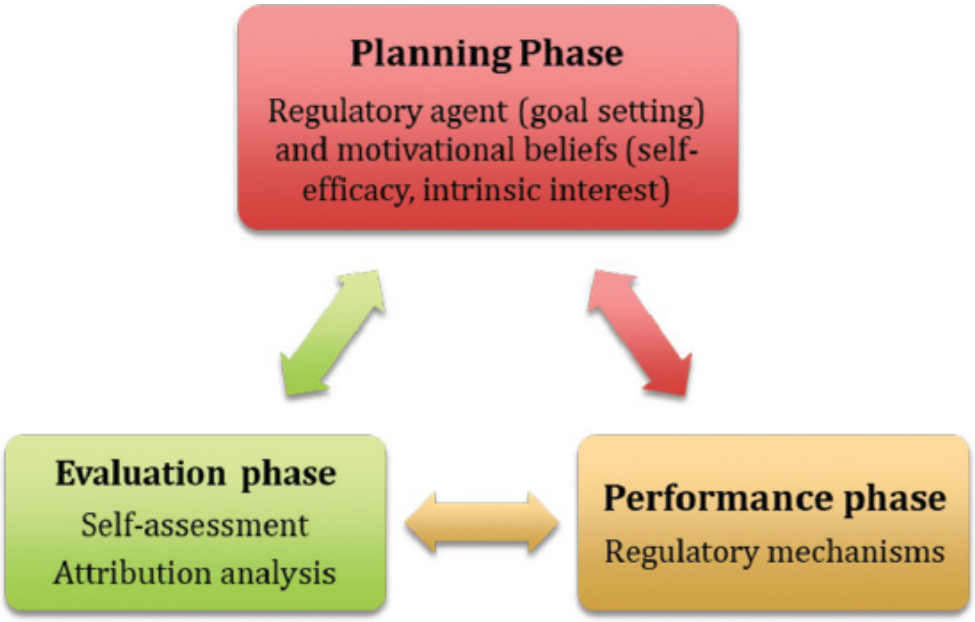

Figure 1.1 Model of self-regulated learning. The cycle of self-regulated learning, beginning with a planning, or forethought, phase where learners set a regulatory agent (learning goal), and decide on the amount of time and other resources to dedicate to the task. This continues through the performance phase, where regulatory mechanisms are employed, and is reinforced by an ongoing process of self-assessment. (Adapted in part from Zimmerman BJ. Becoming a self-regulated learner: an overview. *Theor Pract* 2002;41:64–70; Schraw G. Promoting general metacognitive awareness. *Instr Sci* 1998;26:113–125.)

Table 1.1 Personal and Social–Environmental Factors Contributing to Self-Regulated Learning

Personal Factors	
Goal setting	Standards trainees aim to achieve during training
Planning	Setting task-specific goals and deciding on strategies to achieve them
Monitoring	Paying attention to one's performance and understanding
Learning strategies	Techniques employed to integrate components of the material with existing knowledge
Persistence	Continuing to allocate effort and attention in the face of boredom or failure
Help seeking	Asking for help when one has difficulty understanding the material
Motivation	Willingness to engage in learning, desire to learn
Emotion control	Keeping anxiety, stress, or fear at bay while learning
Effort	Amount of time trainees' devote to learning
Attributions	Trainee beliefs about the causes of outcomes, e.g., attributing failure to external forces vs. one's own effort and work
Self-efficacy	Belief in one's ability to achieve goals or succeed in training
Social–Environmental Factors	
Cultural norms	Higher group standards encourage individuals to set higher personal goals
Role modeling	Positive role modeling of self-regulated

	behavior, including goal setting, help seeking, and attribution
Feedback	Feedback that stresses self-improvement and achievement toward the goal, emphasizing personal agency
Prepared environment	An environment that is optimized for educational goals as much as possible within the demands of the workplace

5 FOSTERING SELF-REGULATED LEARNING: ASSESSMENT TOOLS

The first step toward developing self-regulated learners is to explicitly value the *process* of learning, not just the end results. This requires a shift from evaluating students based on ability or achievements, toward focusing on how they activate and sustain learning processes.[10] Many learners have never consciously thought about the nature of learning; indeed, many educators do not think about how students learn, and these skills are rarely explicitly taught or evaluated.[4] One tool that can help both learners and educators is a structured self-assessment of regulatory behaviors. This type of assessment can provide a model for the evaluation stage of learning, helping trainees to identify potential areas for improvement in regulatory mechanisms. Additionally, a self-assessment can allow learner evaluations to reflect more than just current ability level or achievement, rewarding the traits known to predict long-term success. This can help improve perceived self-efficacy and autonomy, and empower the trainee to take control of their own learning process. Finally, the assessments serve as an indicator of learners who need help developing metacognitive skills, and can be the basis of early interventions and support systems.

Table 1.2 Sample Items from the Metacognitive Awareness Inventory (MAI)

Statement	Category[a]
I consider several alternatives to a problem before I answer	M
I try to use strategies that have worked in the past	PK
I learn best when I know something about the topic	CK
I pace myself while learning in order to have enough time	P
I understand my intellectual strengths and weaknesses	DK
I think about what I really need to learn before I begin a task	P
I know how well I did once I finish a test	E
I slow down when I encounter important information	IMS
I summarize what I've learned after I finish	E
I change strategies when I fail to understand	DS
I find myself pausing regularly to check my comprehension	M
I can motivate myself to learn when I need to	CK

[a]The MAI asks learners to rate their agreement with 52 items classified by either type of knowledge (declarative knowledge [DK], procedural knowledge [PK], or conditional knowledge [CK]) or type of metacognitive process (planning [P], information management strategies [IMS], monitoring [M], debugging strategies [DS], and evaluation [E]).

There are several available self-assessment tools for measuring metacognitive skills. In general, these scales ask learners to rate their agreement with statements like "I try to relate unfamiliar problems with

previous situations or problems solved,"[15] or "I ask myself periodically if I am meeting my goals."[16] The statements provide both an assessment and a model of self-regulated behaviors. A sample of the Metacognitive Awareness Inventory, developed by Schraw and Dennison in 1994, is seen in **Table 1.2**.[16] These assessments of learning skills are different than a self-assessment of technical skills or knowledge base, for example, asking a resident to rate their performance in the operating room. An operative performance self-assessment can identify strengths and weaknesses, and help the learner align performance expectations with external standards: the end products of learning. The self-regulation assessments help the learner identify aspects of the learning *process* that can be improved, providing tools that will help them succeed in any future learning goal.

FOSTERING SELF-REGULATED LEARNING: COACHING

Self-regulatory behaviors stress individual (and independent) identification of learning goals, strengths, and challenges. Putting aside the hurdle of an objective assessment of your own abilities, trainees face the additional difficulty of "not knowing what they don't know." As residents progress through the stages of learning, they may not have enough knowledge to evaluate their own strengths and challenges. In this setting, coaching can be a powerful tool that creates access to both the content and the process of learning.

While all of medical education can be defined as helping the trainee to expand upon knowledge, skills, and attitudes, coaching has a distinctive focus on empowering the coachee to become their own agent of change.[17] In other words, coaching is a tool for creating the skills of self-regulation. The Wisconsin Surgical Coaching Framework has been proposed as a systematic approach to surgical coaching interventions, and mirrors the essential elements of self-regulation: (1) Setting goals (metacognitively active learners), (2) encouraging and motivating (creating motivationally active learners), and (3) developing and guiding (behaviorally active).[17,18]

Lifelong learning can be set in motion during training, but requires a consistent and career-long effort to retain. Coaching can occur at any stage, and is as effective for practicing surgeons as it is for residents.[19–21] Video-based coaching in particular has been utilized in a variety of graduate and continuing medical education spheres. In this model, a surgeon or resident works with a trained colleague to evaluate their performance and identify areas for improvement.[22] By adding the wisdom and accountability of a supportive coach, participants improve both the development and the application of self-regulatory mechanisms.

FOSTERING SELF-REGULATED LEARNING: SELF-REGULATED READING

One of the primary means of acquiring knowledge independently remains the written word: journal articles, textbooks, even blog posts. The surgical textbook remains the mainstay of education for most students, residents, and fellows, yet many learners struggle to retain and integrate knowledge from reading. There are numerous strategies to improve reading comprehension, efficiency, and retention, and applying such a strategy ensures that trainees can continue to learn long after leaving the formal educational system.

Reflective writing: For learners who are reading an assigned chapter, comprehension questions can serve as both a knowledge test and a prompt to deepen the level of understanding.[4] The goal of such questions is to provide readers with a framework with which to evaluate similar readings in the future. These reflection exercises also model the process of *attentive reading* and *integration of knowledge*. Sample questions include the following: What was the most important point from this chapter? What was the most confusing point, and why? How will this chapter change your practice? Can you apply anything in this chapter to a patient you've seen recently?

Recall self-testing: There are multiple proposed methods by which readers can create their own reflective exercises, to improve independent reading comprehension and retention. One of the most popular methods for textbook reading is the SQ3R (**Table 1.3**).[4] In this method, students progress

through the stages of survey → question → read → recall → and review. First, they survey the chapter, paying attention to the headings, subheadings, tables, and any highlighted terms. This survey helps the reader assign a purpose or goal for the reading by developing questions to answer for each heading or subheading. The chapter is then read, with an eye toward answering the self-assigned questions. Next, the reader performs a verbal or written recall exercise, jotting down the essential points. Finally, the recall is reviewed against the text to check for omissions or mistakes. While this method has been criticized for being time-intensive, it is also ten times more effective for long-term retention compared with re-reading the material multiple times.[4,23] A modification of the SQ3R has also been proposed for journal articles, where the survey stage involves reading the abstract, and the questioning stage is a list of standardized questions, such as "what was the rationale for conducting the study?" and "what type of research methodology was used?"[24]

Table 1.3 SQ3R Method of Textbook Reading: Survey, Question, Read, Recall, Review

S	Q	3 R
1. Survey Skim the text first, paying attention to headings, subheadings, and any bold or highlighted words	**2. Question** Assign a purpose or goal to the reading by developing questions to answer from the headings and subheadings	**3. Read** Read the chapter with the goal of answering the self-assigned questions **4. Recall** Put away the book, and either verbally or in writing jot down the key points from memory **5. Review** Check your recall against the text, looking for omissions or mistakes

THE CHALLENGE OF SELF-REGULATED LEARNING DURING SURGICAL TRAINING

Self-regulated learning is both particularly vital and uniquely challenging in clinical education. The majority of training occurs on the wards, in the clinic, or in the operating room, rather than the organized and controllable environment of the classroom. In this context, trainees cannot focus entirely on their own learning goals, and they have much less ability to control their environment.[25] Even students who have developed good self-regulation skills in the academic setting may struggle to apply them in the world of clinical medicine. Surgical educators must acknowledge this challenge, and help

trainees develop self-regulation skills that can meet the demands of a chaotic setting and busy schedule.

The first strategy for surgical educators is to optimize those elements of training that are amenable to control. This includes providing strategies to increase the effectiveness of independent study, like using the SQ3R method described above for textbook reading, or integrating coaching behaviors into routine clinical interactions. This also includes training outside the wards, in simulation centers. Simulation-based curricula designed around principles of self-regulated learning, where each trainee is provided with materials and allowed to progress at their own pace, have led to increased long-term skill acquisition when compared with instructor-led sessions.[26] Similarly, providing clear learning plans, level-specific milestones, and dedicated feedback can help trainees integrate self-regulated learning into the activities of clinical care.

In the operating room and on the wards, the cultural norms of the training program are essential for encouraging or discouraging self-regulated behavior (**Table 1.1**).[14] Attending physicians can role model specific behaviors: for example, help seeking in the operating room, or openly discussing their own errors or mistakes to model self-reflection and attribution. In morbidity and mortality conferences, a culture of blame will teach residents to avoid self-reflection; a just culture of honest inquiry will encourage trainees to seek out a more genuine self-assessment and attribution of responsibility.

Ultimately, the goal of surgical training is to produce surgeons who can treat the problems of today, and help solve the problems of tomorrow. Surgery is not static, and surgeons cannot afford to be static either. Our field continues to change and grow, and we cannot expect residents to graduate with a mastery of every problem they will face in their career. For residents to be truly capable of independent practice, more than any specific surgical skill, they must have the ability to continually seek out new information, continually revising, reviewing, and questioning their knowledge base. By explicitly valuing and encouraging the elements of self-regulated learning, training programs can create surgeons who are prepared for the problems of today, and can face the challenges of tomorrow.

Substrate Metabolism in Surgery

Carrie Sims

Key Points

1. Despite wide fluctuations in dietary carbohydrate intake, blood glucose levels are tightly regulated through the balance of glycogenesis, glycogenolysis, and gluconeogenesis.
2. The hepatic Cori cycle is highly efficient at converting serum lactate, a byproduct of anaerobic metabolism, into pyruvate. As such, even patients with advanced liver disease do not exhibit elevated lactate levels at baseline although the rate at which lactate is cleared does correlate with liver function.
3. The pentose phosphate pathway (PPP) is an anabolic pathway that uses excess glucose to generate 5-carbon sugars known as pentoses, ribose-5-phosphate, a necessary component of nucleotides and nucleic acids, and NADPH, a critical bioreductive agent needed to detoxify intracellular reactive oxygen species.
4. Fat is a highly energetic fuel source with triglycerides yielding more than twice the energy per unit mass when compared to proteins or carbohydrates. The glycerol backbone undergoes glycolysis, whereas the fatty acid undergoes beta oxidation in the mitochondria to generate acetyl CoA molecules.
5. Excessive lipolysis during periods of starvation or with uncontrolled diabetes leads to an overall abundance of acetyl CoA and the creation of ketone bodies that can be sued for fuel.
6. Increased dietary intake of cholesterol suppresses endogenous synthesis by inhibiting the rate-limiting enzyme, 3-hydroxy-3-methylglutaryl CoA (HMG-CoA) reductase. This key enzyme can also be pharmacologically inhibited by statins which act as competitive antagonists and effectively lower plasma cholesterol by blocking cholesterol synthesis.
7. Essential amino acids include histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Arginine is conditionally essential amino depending on the developmental stage of the individual. All other amino acids are synthesized by the Krebs cycle or PPP.

8 The Krebs cycle includes a series of mitochondrial enzymes that transform acetyl CoA into water, carbon dioxide, or reducing equivalents (NADH and $FADH_2$) that drive the electron transport chain.

9 Biotransformation of potentially toxic, often hydrophobic compounds, into hydrophilic and excretable compounds occurs mainly in the liver by cytochromes P-450, the uridine diphosphate (UDP)-glucuronyl transferases, the glutathione (GSH)-transferases, and the sulfotransferases.

Substrate metabolism predominantly refers to the cellular fate of dietary carbohydrate, fat, and protein as they undergo a series of chemical reactions. Although admittedly intricate, all surgeons should be familiar with the biochemistry by which nutrients are converted to energy. This chapter will provide an overview of these biochemical pathways and delineate how cellular metabolism is impacted by surgical stress, critical illness, and trauma.

CARBOHYDRATE METABOLISM

Despite wide fluctuations in dietary carbohydrate intake, blood glucose levels are tightly regulated. Carbohydrates are initially broken down by salivary and pancreatic amylase. Additional enzymes secreted by the intestinal villi further facilitate absorption by converting sucrose into glucose and fructose, maltose into two glucose molecules, and lactose into galactose and glucose. After facilitated diffusion (fructose) or active transport (galactose and glucose), absorbed sugars are then transported to the liver via the portal system where galactose and fructose 1 are converted to glucose. The liver can store up to 100 g of glucose a day by converting it into glycogen (i.e., glycogenesis). It can also release glucose into the circulation by breaking down glycogen (i.e., glycogenolysis) or by creating new glucose from metabolic substrates (i.e., gluconeogenesis). Whether glucose is stored as glycogen or exported back into the systemic circulation is under tight

neurohormonal control. In times of ample glucose, insulin stimulates glycogenesis and glycolysis. In contrast, in times of fasting, glucagon stimulates glycogenolysis and gluconeogenesis.[1] Catecholamines can also influence the availability of glucose with epinephrine inhibiting glycogenesis and promoting glycogenolysis.[2]

Glycogenesis and Glycogenolysis

The first step in glycogen storage is the creation of glucose-6-phosphate (G6P) from glucose and G6P is then converted to glucose-1-phosphate followed by the creation of uridine diphosphate (UDP)-glucose. Glycogen synthase then anchors UDP-glucose to growing glycogen chains, creating a final molecule that can reach 107 daltons. Because complete oxidation of one molecule of G6P generates 37 molecules of ATP, and its creation only uses one molecule of ATP, the overall efficiency of glucose storage as glycogen is a remarkable 97%.

The release of glucose from glycogen, or glycogenolysis, however does not occur by simple reversal of glycogenesis. Following a series of cyclic AMP and kinase-mediated activations, each molecule of glucose on the glycogen chain is eventually released by glycogen phosphorylase which leads to the formation of G6P (**Fig. 2.1**). The conversion of G6P to glucose is catalyzed by glucose-6-phosphatase, an enzyme that exists only in hepatocytes, kidney, and intestinal epithelial cells. As such, once glucose is absorbed it is directly utilized by the majority of cells and not re-released into circulation.

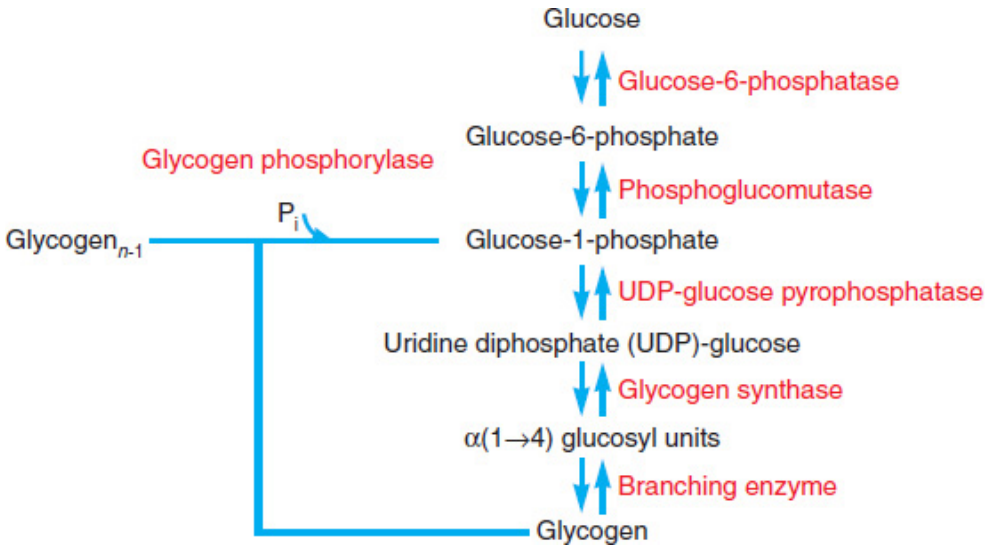

Figure 2.1 The chemical reactions of glycogenesis and glycogenolysis. Glucose-6-phosphatase allows hepatic glucose to be transported out of the hepatocyte for use in other tissues. Glucose-6-phosphate plays a central role in carbohydrate metabolism.

Glycolysis

Glycolysis is an oxygen-independent pathway by which glucose is converted to pyruvate in the cytoplasm. Although the process requires 10 enzymatic reactions, 3 are rate limiting and include hexokinase (or glucokinase in the liver), phosphofructokinase, and pyruvate kinase. As a result, a number of metabolic intermediates can either enter the glycolytic pathway at these various steps or they can exit to join other metabolic pathways depending on the needs of the organism (**Fig. 2.2**). During times of glucose excess, hepatic glycolysis can generate energy in the form of ATP, but the oxidation of ketoacids is a preferred energy source in liver. Overall, glycolysis results in the following biochemical equation:

$$\text{Glucose} + 2\ NAD^+ + 2\ ADP + 2P_i = 2\ \text{Pyruvate} + 2\ NADH + 2\ H^+ + 2\ ATP$$

While energetically favorable, this equation is not perpetual and cytosolic NAD^+ must be rejuvenated for this reaction to continue. In the absence of oxygen, NAD^+ is recovered when NADH is used to convert pyruvate to lactate in a process known as lactic acid fermentation. Because lactate levels

are proportional to ongoing tissue oxygen deficits, serum values can be used to gauge the degree of tissue perfusion during shock and the success of resuscitative therapies.[3]

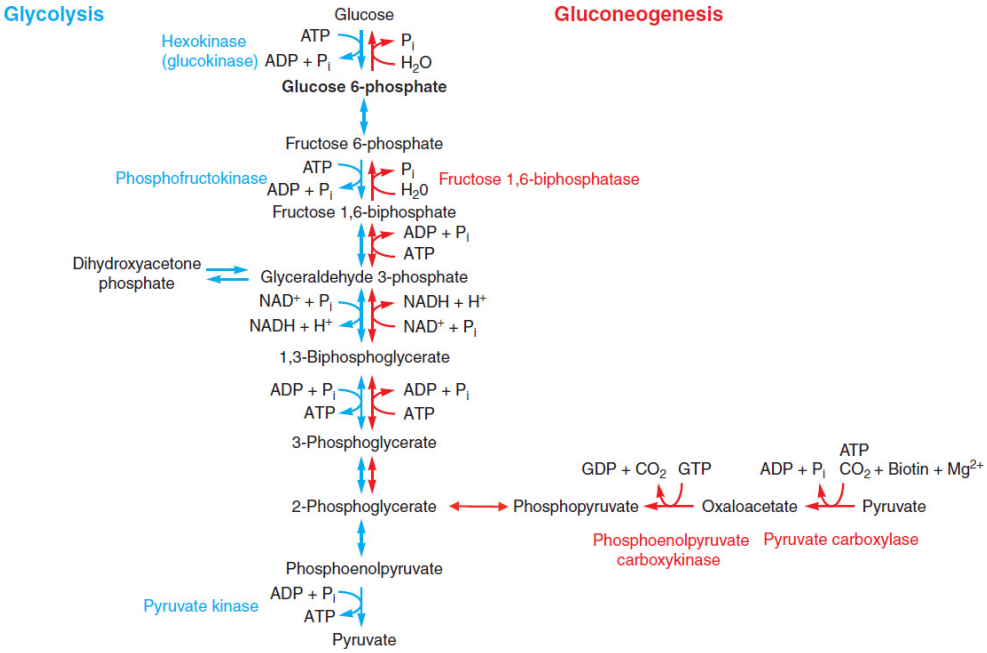

Figure 2.2 The glycolytic and gluconeogenesis pathways. Phosphofructokinase is the key regulatory enzyme in this glycolytic pathway. The irreversible nature of the glycolytic pathway means that a different sequence of biosyntheses is required for glucose production, or gluconeogenesis. In mammals, glucose can only be synthesized from cytosolic pyruvate. All the enzymes in *red* catalyze irreversible reactions.

In the presence of oxygen, however, NAD+ is recouped when electrons from NADH are "shuttled" across the impermeable inner mitochondrial membrane using the malate–aspartate or the glycerol phosphate shuttles. Simultaneously, pyruvate is transformed into acetyl CoA, CO_2 and NADH + H^+ within the mitochondria. Acetyl CoA then enters the Krebs cycle where additional intramitochondrial NADH is created (**Fig. 2.3**). In a process known as oxidative phosphorylation, electrons from intramitochondrial NADH (or $FADH_2$) are transferred through the electron transport chain and ultimately transferred to oxygen to form water. The energy released during this process creates a hydrogen ion gradient across the inner mitochondrial membrane that drives the formation of 2.5 ATP for every NADH oxidized.

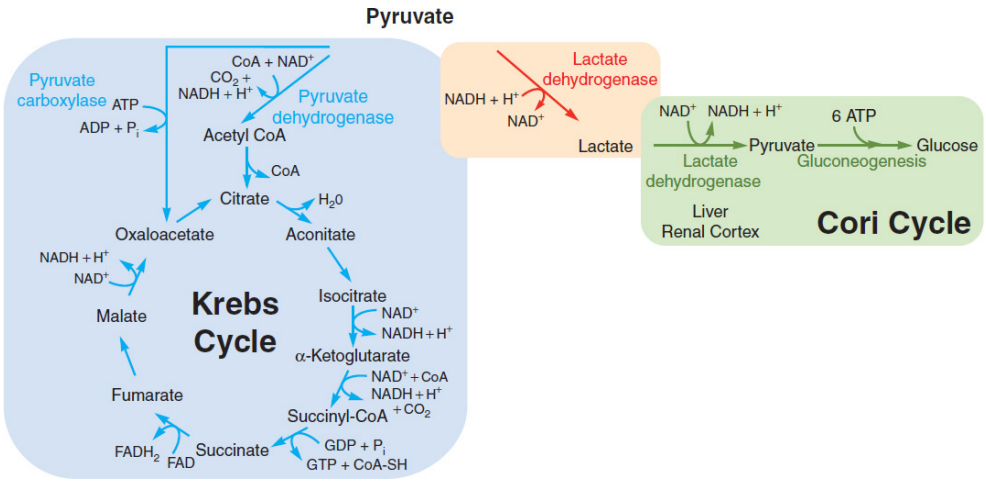

Figure 2.3 Pyruvate plays a key role in cellular metabolism. During hypoxic conditions (*red* box), pyruvate undergoes lactic acid fermentation. The Cori cycle (*green* box) is an elegant mechanism for the liver to convert systemic lactate into new glucose. In the presence of oxygen (*blue* box), pyruvate is converted to Acetyl CoA, or oxaloacetate, and enters the Krebs cycle to produce NADH and $FADH_2$ which will then drive the generation of ATP through oxidative phosphorylation.

The Cori Cycle

Under normal conditions, large quantities of lactate are made from active skeletal muscles and erythrocytes. Lactate can also be made during seizures, in the setting of shock, and in patients 2 with large wounds or burns. Thankfully, in the presence of oxygen, the liver is exceptionally efficient at converting lactate to pyruvate through the Cori cycle (**Fig. 2.3**). As such, even patients with cirrhosis do not exhibit elevated lactate levels at baseline although the rate at which a lactate load is cleared does correlate with liver function.[4] The kidneys also play a key role in lactate clearance with up to 20% to 30% of serum loads being metabolized and/or actively excreted. Thus, significant renal dysfunction will impair lactate clearance.

Gluconeogenesis

Glucose is absolutely required for cellular function and levels are tightly regulated in order to prevent brain dysfunction, coma, and death. When blood glucose levels fall, glucagon is secreted by the pancreas and there is a concomitant decrease in insulin secretion. Glucagon stimulates both

glycogenolysis (see above) as well as gluconeogenesis. Although the majority of gluconeogenesis occurs in the liver, the kidney becomes a key site in diabetics, during critical illness and with prolonged fasting.[5]

Gluconeogenesis creates new glucose from a variety of sources that primarily enter via the creation of pyruvate or oxaloacetate. Gluconeogenic precursors include glucogenic amino acids from the metabolism of proteins, glycerol and odd-chain fatty acids from the breakdown of lipids, and pyruvate and lactate from the glycolysis of carbohydrates. In humans, however, over 90% of new glucose is derived from lactate, glycerol, alanine and glutamine.

Gluconeogenesis is not a simple reversal of the glycolytic pathway and requires four separate, functionally irreversible enzymatic reactions to convert pyruvate into glucose (**Fig. 2.2**). Gluconeogenesis begins in the mitochondria where pyruvate carboxylase converts pyruvate into oxaloacetate. This reaction is stimulated by high levels of acetyl CoA and inhibited by high levels of ADP and glucose. Oxaloacetate is then reduced to malate using NADH and exported out of the mitochondria where it is reoxidized to oxaloacetate in the cytosol. Oxaloacetate is irreversibly transformed into phosphoenolpyruvate by phosphoenolpyruvate carboxykinase. The next reactions are the same as glycolysis but in reverse. Fructose-1,6-bisphosphatase, however, converts fructose-1,6-biphosphate into fructose-6-phosphate which is subsequently converted to glucose-6-phosphate. Glucose-6-phosphate can either feed into other metabolic pathways (e.g., pentose phosphate pathway [PPP]) or it can be hydrolyzed by glucose-6-phosphatase in the endoplasmic reticulum to produce free glucose that can easily diffuse out of the cell.

Pentose Phosphate Pathway

3 The PPP is an anabolic pathway that uses excess glucose to generate NADPH, 5-carbon sugars known as pentoses, and ribose-5-phosphate, a necessary component of nucleotides and nucleic acids (**Fig. 2.4**). These cytosolic reactions take place in two distinct phases. The first is an oxidative phase in which NADPH is generated utilizing the energy released when glucose-6-phosphate is converted to ribulose 5-phophate by the rate-limiting enzyme glucose-6-phosphate dehydrogenase (G6PD). NADPH is an essential

bioreductive molecule that is required for fatty acid, cholesterol, and steroid biosynthesis. It also plays a key role in preventing oxidative stress by generating reduced glutathione, a major scavenger of reactive oxygen species. NADPH is particularly important in maintaining red blood cell integrity because these cells lack mitochondria. As such, these cells have no alternative means of generating reducing power and no other way of mitigating oxidative damage. Indeed, patient with G6PD deficiency are at increased risk of hemolysis when exposed to fava beans, infections, aspirin, and other medications that increase oxidative stress and promote the formation of methemoglobin. In contrast, neutrophils and macrophages use NADPH to generate bacteria-killing superoxide radicals. Thus, patients with G6PD are also at increased risk of severe infections and sepsis.[6]

The second phase of the PPP is a series of nonoxidative reactions that converts ribulose 5-phophate into ribose 5-phosphate in order to synthesize RNA, DNA, ATP, NAD, FAD, or coenzyme A. Intermediates of the glycolytic pathway can enter and exit the PPP at various points with 5-phophate and other three-, four-, five-, six-, and seven-carbon sugars undergoing a series of nonoxidative interconversions (**Fig. 2.4**). Thus, the nonoxidative branch of the PPP can not only replenish the metabolites of the oxidative branch, it can regulate the flux of glycolysis or gluconeogenesis.

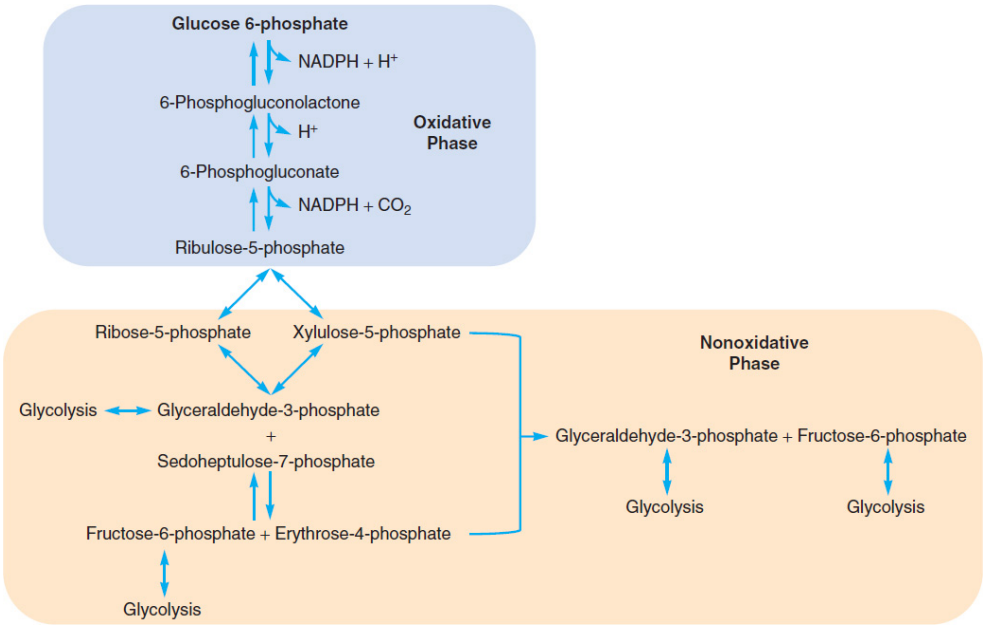

Figure 2.4 The Pentose Phosphate Pathway is divided into an oxidative phase (*blue* box) and a nonoxidative phase (*orange* box). One of the major purposes of this pathway is to generate reduced nicotinamide adenine dinucleotide, which can serve as an electron donor and allow the liver to perform reductive biosynthesis. Glucose-6-phosphate plays a central role and can be generated either through glycolysis or gluconeogenesis.

LIPID METABOLISM

Although fats are digested to a minimal degree by lingual and gastric lipases, the majority of lipid digestion occurs in the small intestine. When chyme reaches the duodenum, it stimulates the release of cholecystokinin (CCK) from the intestinal epithelial cells. CCK causes the gallbladder to contract releasing bile salts and stimulates the secretion of pancreatic lipase. Once emulsified by bile salts, pancreatic lipase breaks down each triglyceride into two free fatty acids (FFAs) and a monoglyceride. Short- and medium-chain FFAs (less than 10 to 12 carbons) are relatively water soluble and diffuse directly into the enterocyte where they enter the portal venous system. In contrast, long-chain fatty acids are hydrophobic and require encapsulation by micelles, or tiny spheres of bile salts and lecithin that create a hydrophobic core and hydrophilic exterior. The hydrophilic surface of the micelle enhances close contact with the enterocyte such that simple diffusion of the

fatty acid can then occur. Micelles also aid in the absorption cholesterol and fat soluable vitamins.

Given their relative hydrophobicity, triglycerides in circulation are carried by various lipoproteins of different densities and compositions. Once absorbed, FFAs and monoglycerides recombine within the enterocyte into triglycerides. Triglycerides are then packaged with phospholipids, cholesterol, and proteins into chylomicrons, a lipoprotein that enters the lymphatic circulation via exocytosis. After leaving the lymphatic system and entering the systemic circulation via the thoracic duct, chylomicrons can either go to the liver to be processed or they can be stored in adipocytes for later use. Once absorbed by the liver, triglycerides can either be converted into energy via lipolysis or they can be combined with proteins in the Golgi apparatus, processed in the endoplasmic reticulum, and exported to extrahepatic tissues as very–low-density lipoproteins (VLDLs). Low-density lipoproteins (LDLs) are subsequently formed when triglycerides are removed from VLDL by lipoprotein lipase thereby creating a smaller, denser, and more cholesterol-rich molecule. LDLs provide cholesterol to cells and may be oxidized in the vascular wall leading to atherosclerosis. In contrast, high-density lipoproteins (HDLs) are the smallest, most dense lipoprotein with the highest protein-to-lipid ratio. HDLs transport lipids out of tissues like the vasculature, decrease macrophage accumulation, and are associated with decreased atherosclerosis.[7]

Just like chylomicrons, VLDLs, HDLs, and LDLs have a nonpolar lipid core with a surface of phospholipids, cholesterol, and apolipoproteins. Different types apolipoproteins provide not only structure, but also serve as ligands, enzymatic cofactors, or inhibitors. For example, the apolipoprotein C-II serves as a cofactor for lipoprotein lipase and whereas the both apoliprotein B-100 and E serve as ligands for the LDL receptor.

Finally, fatty acids mobilized from adipocytes or liberated from plasma triglycerides can be “free” in the circulation. These FFAs are bound to serum albumin and can be taken up by target tissues such as the heart, skeletal muscle, and liver. FFAs are the main source of fuel during fasting or when glucose is not available. However, increased concentrations of FFAs correlate with higher rates of obesity and are associated with development of insulin resistance.[8]

Lipolysis

4 Fat is a highly energetic fuel source with triglycerides yielding more than twice the energy per unit mass when compared to proteins or carbohydrates. Lipolysis, or the hydrolysis of fat for energy, begins by breaking down each triglyceride molecule into one glycerol and three fatty acids. The glycerol enters glycolysis as dihydroxyacetone phosphate whereas the fatty acids undergo beta oxidation in the mitochondria. In order to cross the mitochondrial membrane, fatty acids in the cytosol must first be converted to fatty acyl CoA which then combines with carnitine via the rate-limiting enzyme carnitine palmitoyltransferase-1. Once in the mitochondrial matrix, the fatty acyl carnitine molecules are converted back to fatty acyl CoA. Beta oxidation occurs by cleaving two carbons from the fatty acyl CoA molecule in a four-step reaction to create acetyl CoA. This process continues until all the carbons of the fatty acyl CoA molecule are converted to acetyl CoA, or propionyl CoA in the case of odd-numbered fatty acids. Acetyl CoA can then take one of the following routes: (a) enter the Krebs cycle and be degraded to carbon dioxide, (b) enter the Krebs cycle and be converted to citrate for fatty acid synthesis, or (c) be converted into 3-hydroxy-3-methylglutaryl CoA (HMG-CoA), a precursor of cholesterol and ketone bodies (**Fig. 2.5**).[9]

Ketogenesis and Ketone Oxidation

5 Excessive lipolysis can result in the production of ketone bodies. During periods of starvation or with uncontrolled diabetes where there is insufficient insulin to utilize serum glucose, hepatic oxidation of fatty acids leads to an overall abundance of acetyl CoA. The excess acetyl CoA overwhelms the Krebs cycle and is subsequently diverted to create ketone bodies as an alternative fuel source. In the mitochondria, ketogenesis begins with two acetyl CoA–forming acetoacetyl CoA which is then transformed into hydroxymethylglutaryl CoA (HMG-CoA). HMG-CoA is then converted to the ketone body, acetoacetate. Although the majority of acetoacetate is reduced to beta-hydroxybutyrate, a small amount is converted to acetone. When ketones are produced faster than they can be used, the overall percentage of serum acetone increases. Acetone is removed by exhalation which gives the breath a fruity odor.

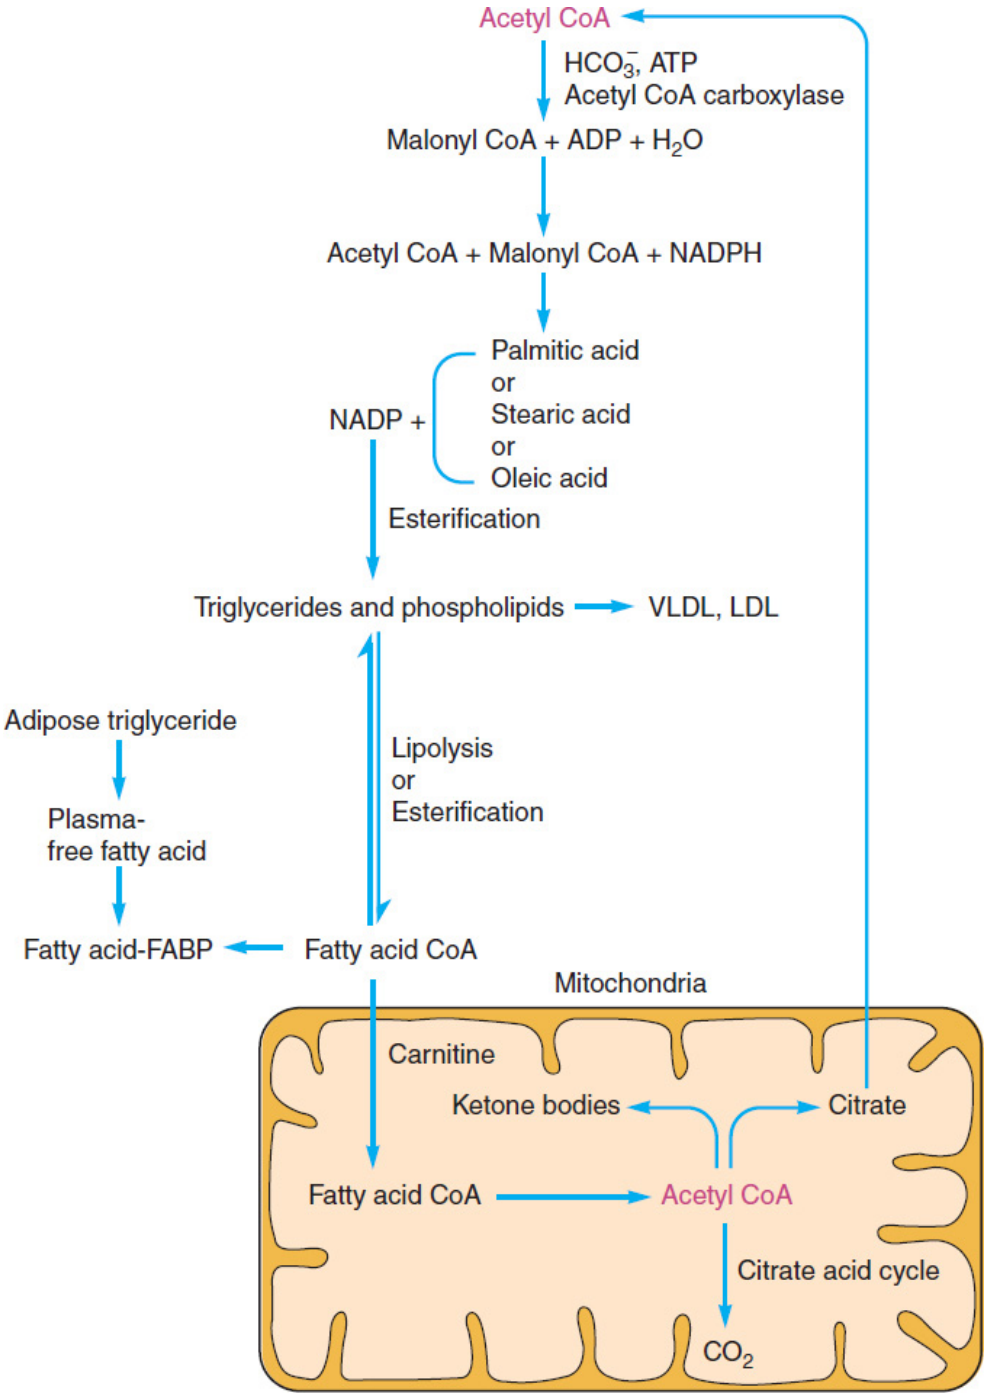

Figure 2.5 Diagram of hepatic fatty acid metabolism. Both dietary and newly synthesized fatty acids are esterified and subsequently degraded in the mitochondria for energy, first as reducing equivalents, then adenosine triphosphate via the electron transport chain. Acetyl CoA, in *red*, plays a central role in lipid metabolism.

Both acetoacetate and beta-hydroxybutyrate can pass easily through membranes and serve as key energy sources during fasting. This is particularly true for the brain which cannot directly metabolize fatty acids. Interestingly, although the liver produces ketone bodies, it lacks succinyl CoA transferase, the enzyme needed to use ketones for energy.

Lipogenesis

The intake of surplus glucose can stimulate lipogenesis, or the creation of triglycerides stored as fat in adipocytes and hepatocytes. In the cytoplasm, excess acetyl CoA is converted to malonyl CoA by acetyl CoA carboxylase in a rate-limiting step stimulated by insulin. Malonyl CoA, in turn, inhibits the mitochondrial uptake of fatty acid CoA in favor of triglyceride synthesis and serves as the building block for the creation of larger fatty acids. Fatty acids are then esterified to glycerol in the endoplasmic reticulum to create triglycerides, which can either be transported to extrahepatic tissues via VLDLs or stored in hepatocytes. Hepatic storage of triglyceride or fatty infiltration of the liver can be significant, leading to the development of nonalcoholic steatohepatitis (NASH). In many developed countries, NASH is the most common cause of liver disease and is rapidly becoming the number one indication for liver transplantation.[10]

Cholesterol Metabolism

Cholesterol is an important regulator of membrane fluidity and is a substrate for bile acid and steroid hormone synthesis. Most plasma cholesterol is esterified with oleic or palmitic acid. Cholesterol can be ingested or it can be created de novo 6 from its precursor, acetyl CoA. Increased dietary intake of cholesterol suppresses endogenous synthesis by inhibiting the rate-limiting enzyme, HMG-CoA reductase. This key enzyme can also be pharmacologically inhibited by statins which act as competitive antagonists and effectively lower plasma cholesterol by blocking cholesterol synthesis.[11] Perhaps more importantly, decreased levels of hepatic cholesterol stimulate the expression of LDL receptors on the liver leading to increased removal and metabolism of serum LDL lipoproteins.

Phospholipids

Phospholipid formation is controlled by the overall rate of fat metabolism and by the availability of choline and inositol. Phospholipids are amphiphilic and are essential for reducing surface tension between membranes and surrounding fluids. As such, the main role of phospholipids is to form plasma and organelle membranes. Although most cells in the body are capable of some phospholipid synthesis, the liver produces 90%. The three major classes of phospholipids synthesized by the liver are lecithins, cephalins, and sphingomyelins. Phosphatidylcholine, one of the lecithins, is the major biliary phospholipid and promotes the secretion of free cholesterol into bile. Thromboplastin, one of the cephalins, is needed to initiate the clotting cascade. The sphingomyelins are necessary for the formation of the myelin nerve sheath.

PROTEIN METABOLISM

Much of the body is made of protein and its metabolism includes both anabolism, or the synthesis of amino acids and proteins, and catabolism, or the breakdown of proteins. Although proteins can be synthesized from amino acids, humans cannot create nine amino acids which must come from 7 the diet. These "essential" amino acids include histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Arginine is a conditionally essential amino acid and depends on the developmental stage of the individual. For example, preterm infants are unable to synthesize arginine. The remaining 11 amino acids can be generated from intermediates of the Krebs cycle and the PPP (**Table 2.1**).

Protein metabolism begins with digestion in the stomach where hydrochloric acid denatures the proteins and pepsin breaks them into smaller polypeptides and amino acids. Once in the duodenum, pancreatic enzymes including trypsin, chymotrypsin, and elastase are activated by enterokinase in order to digest proteins into individual amino acids. Amino acids are subsequently absorbed using sodium–amino acid transporters. Free amino acids can then be used to make proteins. Although all tissues can make proteins, the liver is particularly prolific and can generate up to 50 g/d.

Hepatic protein synthesis includes albumin, fibrinogen, apolipoproteins, purines, heme proteins, and hormones. Of the total hepatic protein synthesized, 75% is destined for export. Unfortunately, excess amino acids cannot be stored for later use and must be converted to glucose or triglycerides. Excess amino acids can also be degraded resulting in nitrogenous waste that is cleared by the urea cycle (see below).

CLASSIFICATION

Table 2.1 Amino Acids Required by Adult Humans

Nutritionally Essential	Nutritionally Nonessential	
	Amino Acid	Precursor
Arginine	Alanine	Pyruvate
Histidine	Asparagine	Oxaloacetate
Isoleucine	Aspartate	Oxaloacetate
Leucine	Cysteine	Methionine
Lysine	Glutamate	α-Ketoglutarate
Methionine	Glutamine	α-Ketoglutarate
Phenylalanine	Glycine	3-Phosphoglycerate
Threonine	Hydroxyproline	α-Ketoglutarate
Tryptophan	Hydroxylysine	Lysine
Valine	Proline Serine Tyrosine	α-Ketoglutarate 3-Phosphoglycerate Phenylalanine

Proteins can also be catabolized, or broken down, into amino acids. Protein degradation occurs primarily by one of two routes. Proteins can be internalized into lysosomes via receptor-mediated endocytosis. The lysosomal enzymes do not require ATP and are nonselective in their

activities. A second pathway involves the covalent attachment of ubiquitin targeting proteins for destruction. This pathway is ATP dependent and generally is used for proteins with shorter half-lives. Liberated amino acids can then be used for new protein synthesis or they can be broken down into their carbon skeleton and amino groups by a transamination reaction. The carbon components are then converted to glucose, triglycerides, or Krebs cycle intermediates whereas the amino group is transferred to pyruvate, oxaloacetate, or α-Ketoglutarate converting it to alanine, aspartate, or glutamate respectively (**Fig. 2.6**).

THE UREA CYCLE

When amino acids are broken down for energy, the amino group is transferred to α-Ketoglutarate to form glutamate. Glutamate is then converted back to α-Ketoglutarate by glutamate dehydrogenase in reaction that generates both NADH and ammonium, a toxic metabolite. Ammonia is eliminated in the urea cycle, also known as the ornithine cycle. In the liver and kidney, ammonia combines with CO_2 in a series of five reactions of to create water and urea. The overall equation of the urea cycle is: $NH_3 + CO_2$ + aspartate + 3ATP + $2H_2O$ -> urea + fumarate + 2ADP + $2P_i$ + AMP + PP_i. The urea is then excreted in the urine.

CELLULAR ENERGY GENERATION

Overview

The fundamental mechanism by which mammalian cells generate energy is the aerobic conversion of sugars and fatty acids 8 into ATP. Stage I, glycolysis, occurs in the cytosol, and converts glucose into two molecules of pyruvate (see above). Cytosolic fatty acids are also converted to fatty acyl CoA. Pyruvate and fatty acyl CoA are then transported to the mitochondrial matrix where they are converted to acetyl CoA, a key metabolic intermediate, and in the process generates NADH, $FADH_2$, and CO_2. In stage II, mitochondrial acetyl CoA enters the Krebs cycle further generating NADH,

$FADH_2$, additional CO_2, and GTP. In stage III, oxygen is reduced to water via the electron transport chain using previously generated molecules of NADH and $FADH_2$ as electron donors. The electron transport chain causes hydrogen ions to move from the mitochondrial matrix to the intermembrane space generating a proton motive force. Lastly, in stage IV, ATP synthase uses energy generated by the proton motive force to generate large amounts of ATP.[12]

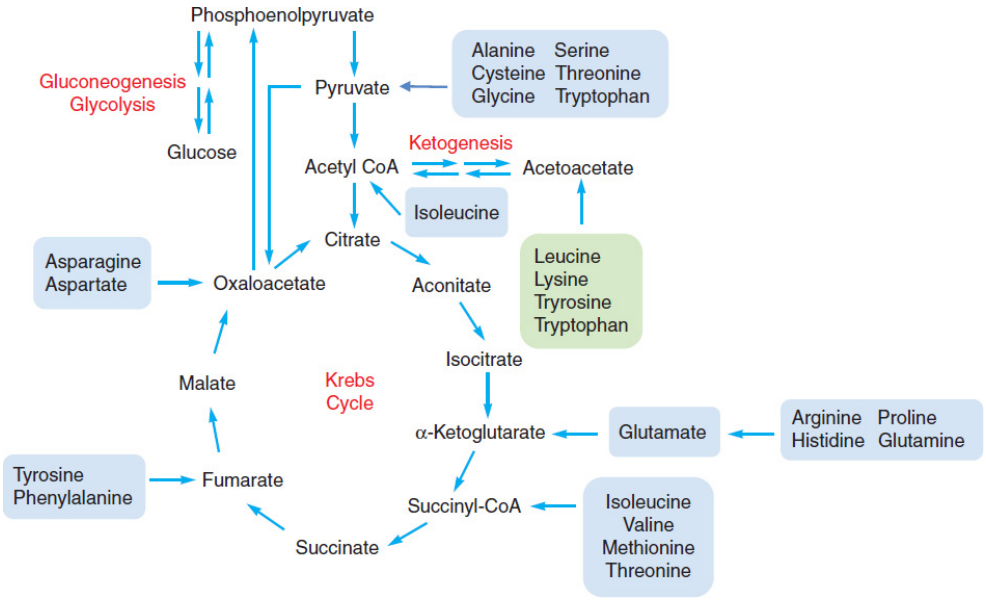

Figure 2.6 Amino acid degradation. Some amino acids such as glutamate can undergo direct deamination to their corresponding ketoacid (α-ketoglutarate). However, most amino acids undergo an initial transamination where the amino group is transferred to α-ketoglutarate, yielding glutamate and a ketoacid. The resulting glutamate is then deaminated to α-ketoglutarate and the ketoacids are converted to Krebs cycle metabolites. Some amino acids are glucogenic (*blue* boxes), while others are ketogenic (*green* boxes) and yield acetoacetyl CoA, and thus, ketone bodies. Note that some amino acids can be either glucogenic or ketogenic.

Stage II: The Krebs Cycle—Integration of Metabolic Pathways and Oxidation of Acetyl CoA

The Krebs cycle not only acts as a common pathway for the oxidation of carbohydrate, lipid, and protein, it also provides substrates for

gluconeogenesis, lipogenesis, and amino acid metabolism depending on the energy needs. As such, the metabolism of sugars, fats, and proteins changes can change rapidly based on conditions ranging from fed to fasting to starvation. Three key metabolites, G6P, pyruvate, and acetyl CoA orchestrate the fine balance between catabolism and anabolism (**Fig. 2.3**).

G6P can be stored as glycogen or converted into glucose, pyruvate, or ribose-5-phosphate (a nucleotide precursor). Pyruvate can be converted into lactate, alanine (and other amino acids), and acetyl CoA, or it can enter the Kreb cycle after conversion to oxaloacetate. Acetyl CoA that does not proceed through the whole Krebs cycle can be converted to HMG-CoA (a cholesterol and ketone body precursor depending on cellular location) or citrate for fatty acid and triglyceride synthesis. In humans, acetyl CoA cannot be converted into pyruvate due to the irreversible reaction of pyruvate dehydrogenase.

Probably the most important Krebs cycle function is to oxidize acetyl CoA into CO_2. The Krebs cycle is a series of enzymatic reactions that occur in the mitochondrial matrix and inner membrane. Here, acetyl CoA combines with oxaloacetate to form citrate. Through a series of subsequent enzymatic reactions involving both dehydrogenases and decarboxylases, each revolution of the Krebs cycle, generates three molecules of the reduced coenzyme NADH, one molecule of the reduced coenzyme $FADH_2$, and one molecule of GTP. The reduced coenzymes NADH and $FADH_2$ are charged with high-energy electrons that subsequently drive the electron transport chain (stage III) to generate a hydrogen ion gradient. Each molecule of NADH yields three molecules of ATP, and each molecule of $FADH_2$ generates two molecules of ATP. One molecule of ATP is created at the substrate level when succinyl CoA is converted to succinate; thus, a total of 12 molecules of ATP are generated per molecule of acetyl CoA.

Stages III and IV: Oxidative Phosphorylation

Oxidative phosphorylation uses the energy from NADH and $FADH_2$ to generate ATP. Electrons donated from NADH and $FADH_2$ are transferred down the proteins of the electron transport chain in a series of redox

reactions that ultimately create water from O_2. Electrons from NADH are transferred through complex I (NADH-CoQ reductase) to coenzyme Q (CoQ) whereas those from $FADH_2$ enter the electron transport chain via complex II (succinate-Q dehydrogenase). Complex II is also part of the Krebs cycle and the transfer of electrons from $FADH_2$ to CoQ is coupled with the oxidation of succinate to fumarate. Electrons then travel from CoQ to complex III (Q-cytochrome c oxoreductase) and finally to complex IV (cytochrome c oxidase). At complex IV, oxygen accepts the electron and is reduced to water. This final reaction releases half of all the energy in aerobic respiration. The energy transferred during the flow of electrons through the electron transport chain is used to pump protons across the mitochondrial inner membrane. This generates potential energy by creating both a pH gradient and a voltage gradient known as the proton motive force. ATP synthase uses the proton motive force to drive the conversion of ADP to ATP in a phosphorylation reaction. **Figure 2.7** is an admittedly simplified explication of a complex process.

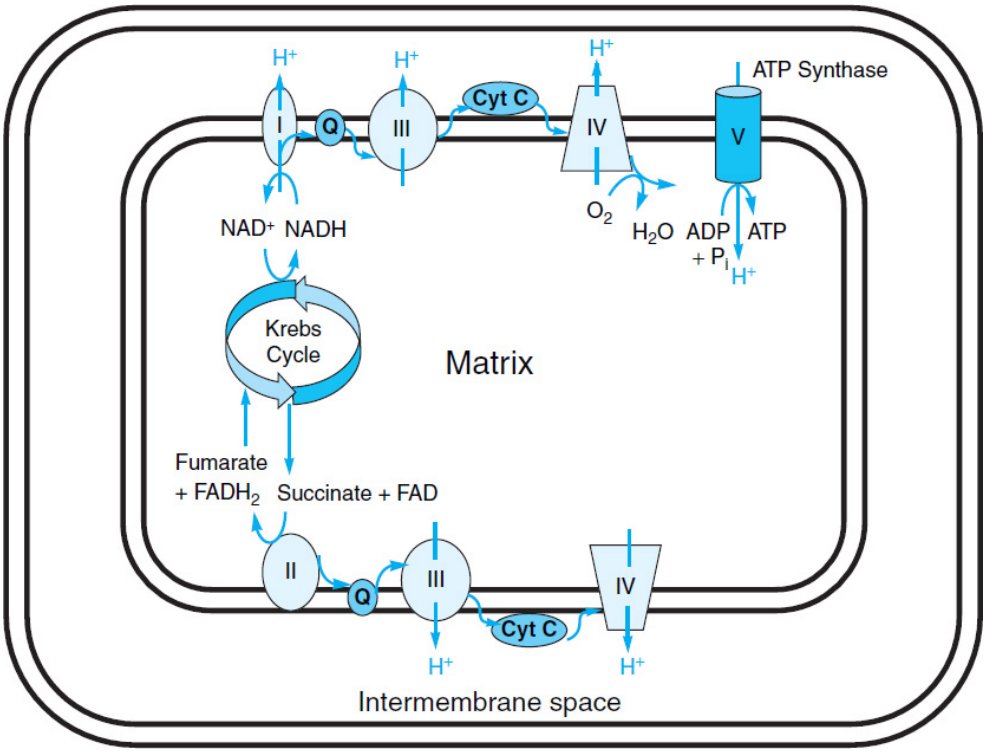

Figure 2.7 The electron transport chain. Electrons are donated from NADH and flow through complex I to complex III via the lipid-soluble molecule Coenzyme Q. From complex III, the electrons are transported through the intermembrane space by cytochrome *c* to complex IV. For every two electrons that flow from NADH to O_2, 10 protons are pumped to the intermembranous space creating a proton motive force. Electrons can also be donated during the conversion of succinate to fumarate via $FADH_2$. Electrons then flow from complex II from to complex III as previously described. For every two electrons that flow from $FADH_2$ and succinate to O_2, six protons are pumped to the intermembranous space. Complex V, or ATP synthase, then uses the proton motive force to drive the creation of ATP.

BIOTRANSFORMATION

Biotransformation is defined as the intracellular metabolism of endogenous organic compounds (e.g., heme proteins and steroid hormones) and exogenous compounds (e.g., drugs and environmental compounds). Most biotransformation occurs in the liver, which contains enzyme systems that can expose functional groups, such as hydroxyl ions (phase I reactions), or alter the size and solubility of a wide variety of organic and inorganic compounds by conjugation with small polar molecules (phase II reactions).[13] A general

strategy is to convert hydrophobic, potentially toxic compounds into hydrophilic conjugates that can then be excreted into bile or urine.

Biotransformation of compounds mainly occurs by the cytochromes P-450, the uridine diphosphate-glucuronyl (UDP-glucuronyl) transferases, the GSH S-transferases, and the sulfotransferases. 9 Biotransforming enzymes are not distributed uniformly within the cells of the hepatic lobule. This heterogeneity may account for the ability of some drugs to cause damage preferentially in zone 3 hepatocytes which are closest to the central venule.

Cytochromes P-450

The cytochromes P-450 are named for their ability to absorb light maximally at 450 nm in the presence of carbon monoxide. These enzymes are bound to the endoplasmic reticulum and collectively catalyze reactions by using NADPH and oxygen. P-450 isozymes catalyze a number of reactions including oxidation, hydroxylation, sulfoxide formation, oxidative deamination, dealkylation, and dehalogenation. Such reactions allow further phase II conjugation with polar groups such as glucuronate, GSH, and sulfate. The cytochromes P-450 can also create potentially toxic metabolites. Drugs such as acetaminophen, isoniazid, halothane, and phenothiazines can be converted into reactive forms that cause cellular injury and death. These cytochromes also are responsible for the formation of free radicals that can directly injure cells or act as haptens in the generation of an autoimmune response. In fact, cytochromes P-450s modify several of the most potent aromatic carcinogens.

Uridine Diphosphate-Glucuronyl Transferases

Glucuronidation is the conjugation of UDP-glucuronic acid to a wide variety of molecules by either ester (acyl) or ether linkages. The transferases catalyzing these reactions reside in the endoplasmic reticulum. Many common compounds are metabolized in this way, including bilirubin, testosterone, aspirin, indomethacin, acetaminophen, chloramphenicol, and oxazepam. Clinically significant loss of activity can occur with acute ethanol

exposure or acetaminophen overdose, when formation of UDP-glucuronic acid from UDP-glucose is outstripped by use. Some acyl linkages lead to the generation of electrophilic centers that can react with other proteins. The covalent linkage of conjugated bilirubin to albumin is believed to occur by this mechanism.

Glutathione S-transferases

The GSH transferases are more selective and GSH conjugation occurs only with compounds that have electrophilic and potentially reactive centers. The role of GSH conjugation is demonstrated by acetaminophen. In metabolism of this drug, cytochromes P-450 create an electrophilic center that reacts with protein thiol groups or GSH. The presence of GSH S-transferase allows the preferential detoxification of acetaminophen rather than its potentially injurious binding to thiol groups. A class of GSH S-transferases, known as *ligandins,* appears to facilitate the uptake and intracellular transport of bilirubin, heme, and bile acids from plasma to liver. In addition to the detoxification of potential toxins, GSH is a substrate for GSH peroxidase, an enzyme important in the metabolism of hydrogen peroxide.

Sulfotransferases

The sulfotransferases catalyze the transfer of sulfate groups from 3′-phosphoadenosine-5′-phosphosulfate (PAPS) to compounds such as thyroxine, bile acids, isoproterenol, methyldopa, and acetaminophen. They are located primarily in the cytosol. Although many P-450 derivatives can be further conjugated by either the sulfotransferases or the glucuronyl transferases, the limited ability of the liver to synthesize PAPS makes glucuronidation the predominant mechanism.

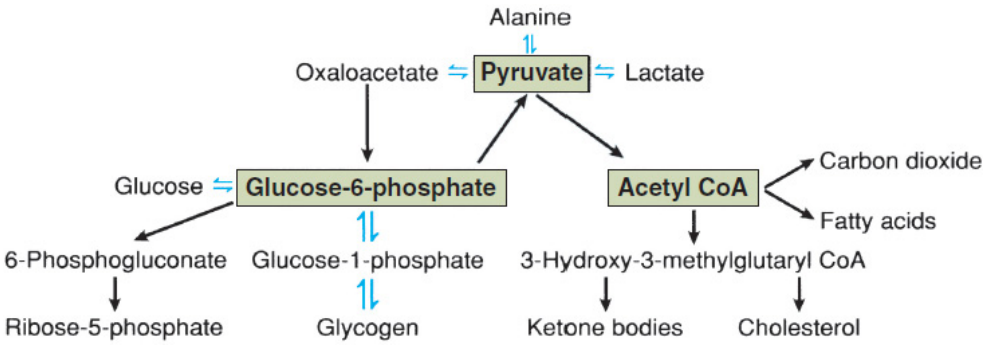

Figure 2.8 Summation of the key regulatory molecules used by the liver during diverse metabolic functions. Essentially, any compound found in the body can be synthesized in the liver from glucose-6-phosphate, acetyl coenzyme A, or pyruvate. As a consequence of the inability of mammalian liver to convert acetyl coenzyme A to pyruvate, fats cannot be converted to carbohydrates.

SUMMARY

Although the fundamentals of intermediary metabolism have been known for years, knowledge of how these details impact health and disease is continuously growing. A summary of the key regulatory molecules and their interconnected metabolic pathways can be found in **Figure 2.8**. A working understanding of the fundamental biochemical reactions by which substrates are metabolized is important for all surgical disciplines. Advanced knowledge of the genetics, cellular biology, bioenergetics, and molecular biology is being exploited to support and perhaps enhance general and specialized cellular function, combat disease, and improve health.

Surgical Nutrition and Metabolism

Melissa H. Coleman and Deborah M. Stein

Key Points

1. In the absence of indirect calorimetry, critically ill patients should be provided nutritional support targeting 25 to 30 kcal/kg/day.
2. Assessment of nutritional status is key in the perioperative period. Malnutrition is associated with worse outcomes after injury or surgery.
3. There is no single laboratory biomarker that accurately reflects a patient's nutritional status.
4. While adequate caloric intake is necessary to maintain weight and promote health, overprovision of calories can lead to overfeeding and obesity.
5. A strong relation between protein depletion and postoperative complications has been demonstrated in nonseptic, nonimmunocompromised patients undergoing elective major gastrointestinal (GI) surgery.
6. Preoperative optimization with nutritional support may be indicated in patients who are malnourished or at high risk of delayed initiation of postoperative nutritional support.
7. Critically ill patients should receive early enteral nutrition within 48 hours of admission to the intensive care unit. Nutritional support should prioritize the provision of adequate protein.
8. Enteral nutrition is preferable to parenteral nutrition in the presence of a functioning GI tract. Recent studies of parenteral nutrition versus enteral nutrition have not demonstrated increased mortality with parenteral nutrition. Parenteral nutrition should be utilized when enteral nutrition cannot be administered.
9. The maintenance of an intact brush border and intercellular tight junctions prevents the movement of toxic substances into the intestinal circulation and minimizes bacterial translocation. These functions may be affected in critical illness. Enteral nutrition helps restore them.

10 Routine glutamine supplementation is not supported during critical illness.

11 Routine monitoring of gastric residual volumes is not recommended. Postpyloric feeding can be used for patients at high risk of regurgitation or for patients with gastric feeding intolerance.

12 In the setting of sepsis, the BMR increases. Total energy requirements need to be assessed, increasing energy requirements by 20% to 30% for mild or moderate infection and approximately 50% above basal levels in severe infection.

INTRODUCTION

Surgery has a significant impact on the body, causing the release of stress hormones and is associated with a considerable inflammatory response. Nutritional support is needed to prevent and treat the catabolic state induced by surgery. Patients undergoing gastrointestinal (GI) procedures with evidence of malnutrition at baseline are more likely to suffer postoperative morbidity and mortality and require longer hospital stays than their well-nourished counterparts.[1–3] It has been shown that poor nutritional status can detrimentally affect postoperative outcomes, and in a consensus review of Enhanced Recovery After Surgery (ERAS), it was recommended that patients receive carbohydrate loading 24 hours preoperatively and nutritional supplements, from the day of surgery, until oral intake is achieved.[4]

In addition to patients undergoing elective surgery, severe injury and critical illness are associated with a hypermetabolic state that can increase energy expenditure dramatically and complicate the resuscitation and recovery of the critically ill or severe injury victim. Nutritional support is an integral part of the caring of the critically ill surgical patient, and the Society of Critical Care Medicine (SCCM) and the American Society for Parenteral and Enteral Nutrition (ASPEN) have made recommendations toward providing early, aggressive nutritional support that enables patients to preserve their immune function, maintain lean body mass, and minimize metabolic complications.[5] This chapter addresses the areas of nutritional

assessment and management of the surgical patient, reviewing key metabolic principles and providing an overview of pertinent literature.

BASIC METABOLIC PRINCIPLES

Body Composition

Total body mass is composed of aqueous and nonaqueous components, with the former constituting approximately 55% to 60% of total body mass (total body water, TBW). Mineralized bone and adipose tissue make up the majority of the nonaqueous component. The relationship between total body mass and TBW is relatively constant for an individual and typically reflects the amount of body fat. Solid organs and muscle contain a higher proportion of water than bone and fat; therefore, young lean males have a higher proportion of their total body mass as water than obese or elderly individuals. Obesity, older age, and female gender shift the body composition to a greater fat mass (**Fig. 3.1**).[6]

The aqueous portion is divided into three functional fluid compartments: plasma (5% of body weight), interstitial or extracellular fluid (ECF; 15% of body weight), and intracellular fluid (ICF; 40% of body weight) (**Fig. 3.2**). In a typical 70-kg male, there are approximately 3.5 L of plasma, 10.5 L of interstitial fluid, and 28 L of intracellular volume while the remainder 28 kg represents the nonaqueous portion. Of the aforementioned, the body cell mass constitutes the metabolic engine of the body, while the extracellular component forms the supporting "scaffolding" for the body cell mass.

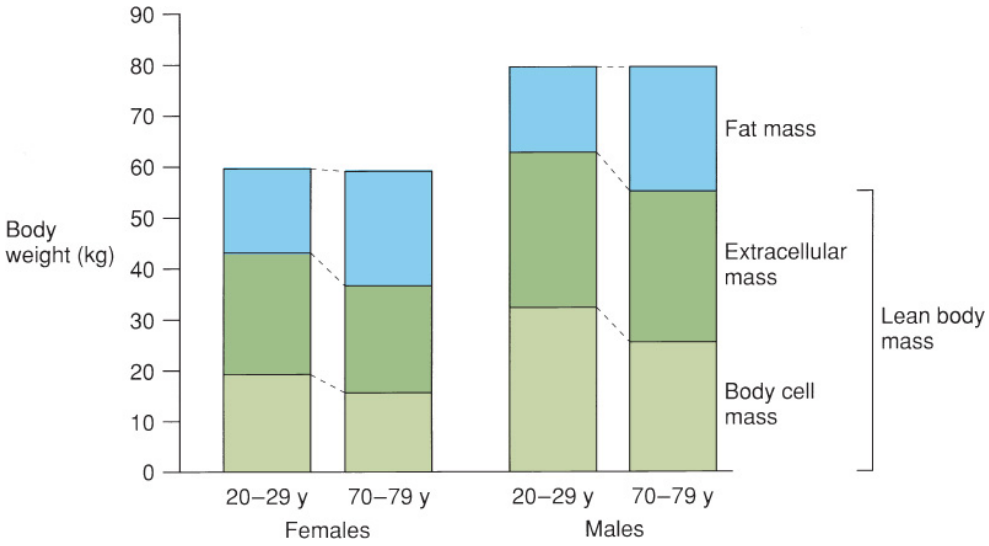

Figure 3.1 Body composition as a function of gender and age. (Data from Cohn SH, Vartsky D, Yasumura S, et al. Compartmental body composition based on total-body nitrogen, potassium, and calcium. *Am J Physiol-Endocrinol Metab* 1980;239(6):E524–E530.)

ENERGY AND SUBSTRATE METABOLISM

Measuring Energy Expenditure

In healthy individuals, total energy expenditure (TEE) reflects the activity of the fat-free mass (FFM) which primarily comprises organ systems that are highly metabolic, including the brain, heart, liver, and kidneys.[7] More specifically, TEE is the combination of basal metabolic rate (BMR), physical activity, and thermogenesis secondary to nutritional intake. The measurement of energy expenditure poses a challenge in the critically ill or surgical patient as this is a dynamic process that changes over the course of the disease process and is often not accurately measured by predictive equations. TEE can be measured by direct calorimetry which measures the total amount of heat produced by metabolic processes.[8] However, direct calorimetry is expensive and not widely available. In contrast, indirect calorimetry is a more feasible option.

Indirect Calorimetry

The gold standard for measuring resting energy expenditure and determining caloric need is indirect calorimetry. This method, based on thermodynamic principles, calculates heat produced through the measurement of oxygen consumed and carbon dioxide exhaled. Measurement by indirect calorimetry can be improved with proper patient selection. Patients should have stable hemodynamics and temperature, no chest tubes, and a fraction of inspired oxygen of <0.6 and should not be receiving nitric oxide.[9]

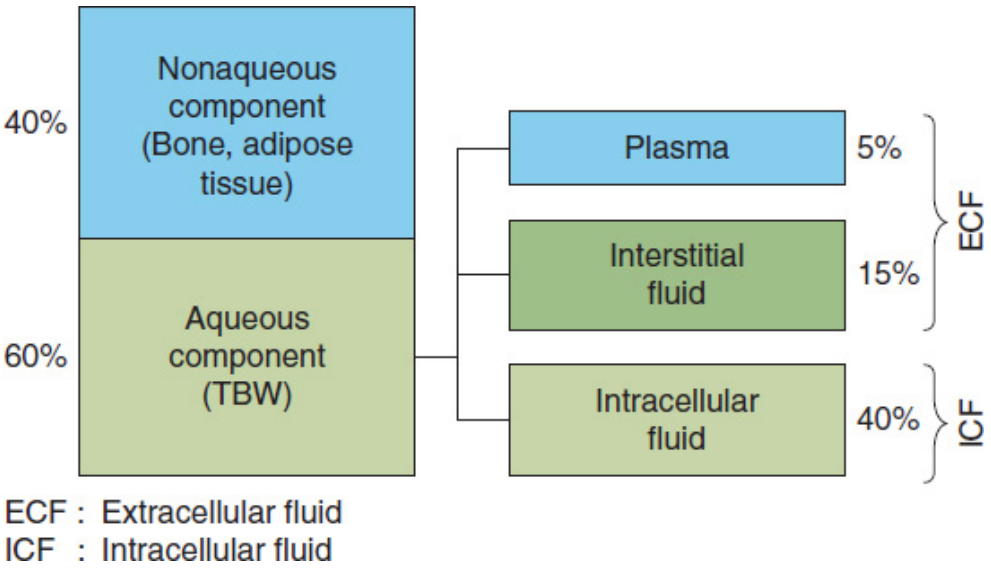

Figure 3.2 Aqueous and nonaqueous body composition.

Predictive Equations for Energy Expenditure

In most cases, energy expenditure is not measured, but estimated, on the basis of all metabolic activities that occur within the FFM. There are >200 predictive equations that have been developed for calculating energy expenditure that generally take into account body weight, height, age, and gender. When applied to critically ill or surgical patients, several equations will incorporate a stress factor to account for the increased metabolic state associated with illness or surgery. Several equations that predict basal energy expenditure, and hence daily caloric requirements, have been developed from the aforementioned variables, with the Harris–Benedict equation being among the most widely used (**Table 3.1**).[10]

Once the BMR has been calculated, minor adjustments based on exercise frequency and intensity can be made for estimation of the daily caloric requirement for an adult to maintain current weight.[10]

The Mifflin–St. Jeor equation appears to be even more accurate in estimating BMR in healthy individuals[11]:

$$\text{Men} \quad \text{BMR} = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) + 5$$

$$\text{Women} \quad \text{BMR} = (10 \times \text{weight in kg}) + (6.25 \times \text{height in cm}) - (5 \times \text{age in years}) - 161$$

1 For critically ill, or patients with highly inflammatory conditions, the estimated BMR is adjusted upward. Not surprisingly, basal energy requirements increase significantly with an active inflammatory response but minimally after elective surgery. The largest increases in energy expenditure are seen in patients with severe polytrauma or major burns.[12] Based on expert consensus from SCCM and ASPEN, in the absence of indirect calorimetry, either a predictive equation should be used or critical ill patients should receive 25 to 30 kcal/kg/day.[5]

Predicting Caloric Need for Underweight and Obese Patients

Indirect calorimetry is also the gold standard for estimating caloric needs in obese patients. When this is not available or not feasible, for critically ill obese patients, the Penn State University 2010 predictive equation is recommended with the Mifflin–St. Jeor equation as an alternative if the Penn State University (PSU) equation cannot be used.[13] However, in general, predictive equations are less accurate for estimating the caloric needs of underweight and obese patients.[5] Based on expert consensus, in the absence of indirect calorimetry, patients with body mass index (BMI) 30 to 50 should receive 11 to 14 kcal/kg (actual body weight)/day and patients with BMI > 50 should receive 22 to 25 kcal/kg (actual body weight)/day.[5] For patients with a BMI of 30 to 40, 2.0 g/kg (ideal body weight)/day of protein should be provided and patients with a BMI ≥ 40 should be provided 2.5 g/kg (ideal body weight)/day of protein.[5]

Table 3.1 The Harris–Benedict Equation and Adjustment Using the Harris–Benedict Principle

Men	BMR = 88.362 + (13.397 × weight in kg) + (4.799 × height in cm) − (5.677 × age in years)
Women	BMR = 447.593 + (9.247 × weight in kg) + (3.098 × height in cm) − (4.330 × age in years)
Little to no exercise	Daily kilocalories needed = BMR × 1.2
Light exercise (1–3 d/wk)	Daily kilocalories needed = BMR × 1.375
Moderate exercise (3–5 d/wk)	Daily kilocalories needed = BMR × 1.55
Heavy exercise (6–7 d/wk)	Daily kilocalories needed = BMR × 1.725
Very heavy exercise (twice per day, extra heavy workouts)	Daily kilocalories needed = BMR × 1.9

Adapted from Roza AM, Shizgal HM. The Harris Benedict equation reevaluated: resting energy requirements and the body cell mass. *Am J Clin Nutr* 1984;40(1):168–182.

Body Fuels

Human metabolism is organized in such a way that fuel consumption occurs in a hierarchical way when more than one energy source is present, with excess stored for the postprandial or fasting period. In the postprandial state, the body contains fuel reserves that it can also mobilize in an orderly fashion, as fasting is prolonged. The same fuel reserves are accessed during stress metabolism, although in a less orderly fashion (**Table 3.2**).

Calorically dense fat is by far the largest energy repository, providing 9 kcal/g when mobilized and oxidized. The ability of the body to store fat is essentially limitless. Protein comprises the next largest energy store in the

human body, yet amino acids when oxidized yield 4 kcal/g. Unlike fat, protein plays both structural and functional roles in the body; thus, in severe protein loss, major functional consequences can be expected. In malnutrition, proteolysis frees up amino acids to be used for gluconeogenesis to produce glucose, which, in turn, can be used as fuel. Carbohydrate reserves are minimal and exist in the form of glucose or glycogen in the liver. These can be depleted quickly, typically within 12 hours, unless replenished through nutrition. Carbohydrates, like protein, also yield approximately 4 kcal/g when mobilized for energy production (**Table 3.3**).

Carbohydrates

Carbohydrates are the most commonly used fuel by the human body, providing frequently >45% to 60% of daily energy requirements. Each gram of carbohydrate that is administered enterally yields approximately 4 kcal when broken down, whereas intravenously administered carbohydrates (such as dextrose-containing solutions) provide slightly less (approximately 3.4 kcal/g).

Table 3.2 Fuel Reserves of a Healthy, 70-kg Adult Male

Energy Source	kg	kcal Value
Fat	14	125,000
Protein		
Skeletal muscle	6	24,000
Other	6	24,000
Glycogen		
Muscle	0.15	600
Liver	0.075	300
Free glucose	0.02	80

The basic unit of carbohydrate metabolism in humans is glucose, and nearly all dietary carbohydrates are converted to glucose for energy production. Digestion of carbohydrates begins as proximally as the oral

cavity with food ingestion, where salivary amylase breaks down polysaccharides into smaller oligo- and disaccharides. This process continues in the duodenum and proximal jejunum with the pancreatic amylase. Oligosaccharidases that are present in the brush border of the proximal small bowel further hydrolyze oligosaccharides into di- or monosaccharides, most commonly glucose, to be absorbed by the gut mucosa. Once glucose reaches the bloodstream, it stimulates secretion of insulin from the endocrine pancreas (beta cells), which has major anabolic effects and stimulates protein synthesis, inhibits lipolysis, and upregulates glycogen production. Conversely, during stress, pancreatic glucagon exerts opposite effects: It promotes breakdown of glycogen, but also fat and protein, to be used as additional energy sources during a time when energy requirements are maximal. Deficiencies in carbohydrate digestion are rare in surgical patients, even in patients in whom the pancreatic exocrine function is significantly decreased. Patients with pre-existing celiac or Whipple disease may, however, have limited capacity to absorb carbohydrates.

The human central nervous system and circulating blood cells require glucose constantly for their energy requirements. In periods of extended fasting, after the liver has used up its stores of glycogen, the human body breaks down protein and uses the resulting amino acids to generate glucose, and even converts fat into ketones that can partly substitute glucose as an energy source. When glucose is reinstated through nutrition, these metabolic adaptations are completely reversed. During stress, gluconeogenesis and glycogen breakdown are accelerated and ketone production is minimized, leading to an abundance of glucose for use as the human body mounts an inflammatory response.

Table 3.3 Energy Value of Various Energy Sources

Energy Source	Energy Value
Fat	9 kcal/g
Carbohydrates (enteral)	4 kcal/g
Carbohydrates (intravenous)	3.4 kcal/g
Protein	4 kcal/g

Lipids

Lipids are the second most commonly used fuel for energy by the human body, accounting for 35% to 45% of daily caloric intake. Each gram of fat yields approximately 9 kcal of energy when oxidized. When lipids enter the proximal small bowel, cholecystokinin and secretin are released, which make the gallbladder contract and release bile into the duodenum. Bile salts contained in bile are necessary for lipid absorption, especially the long-chain fatty acids that are found in a typical Western diet, which occurs mostly in the distal ileum. Surgical resection of the distal ileum may lead to depletion of the bile salt pool and fat malabsorption.

Lipids are most commonly classified by the length of their contained hydrocarbon chains. Short-chain fatty acids typically refer to lipids containing two- to five-carbon length chains and are a product of dietary fiber fermentation in the colon by the intestinal flora. They are absorbed by, and are the preferred fuel for, the colonocytes. Medium-chain fatty acids (six- to nine-carbon length chains) are also not typically found in the human diet but are commonly used in numerous enteral nutrition formulas, as they are easier to digest, compared to longer-chain triglycerides. They are water soluble and hence require no emulsification or micelle formation for transport. Lipase is not required. The medium-chain triglycerides are absorbed directly into the portal circulation. Unlike the short- and medium-chain fatty acids, which can be produced from other dietary substrates, two long-chain fatty acids (more than nine-carbon length chains), linoleic and linolenic acids, are essential for human nutrition. These are not water soluble and require bile salts for emulsification as stated earlier, lipase for digestion, and micelle/chylomicron formation for transport. They gain access to the bloodstream via the lymphatic system (thoracic duct). Insufficient intake of these essential fats can lead to fatty acid deficiency, which can be prevented with provision of at least 3% to 4% of the daily calories as linoleic and linolenic acids. These two fatty acids are also a precursor of eicosanoids, significant mediators of the inflammatory response. On a cellular level, lipoprotein lipase is necessary for intake and carnitine for transport from the cytosol into the mitochondria for oxidation. Long-chain triglycerides are the main form of energy storage in the human body, given the numerous high-energy bonds they contain.

Protein

Protein is different from carbohydrate and lipids in that it contains nitrogen that neither fatty acids nor glucose does. It is also a key structural component, and there are no inactive protein stores. Essentially, all proteins are either functional or structural in the human body.

Proteins are polypeptides, containing numerous amino acids as their building blocks, and yield 4 kcal/g when used for energy production. Dietary protein is broken down into amino acids and smaller peptides by gastric pepsin and pancreatic proteases, the latter activated by enterokinase in the duodenum. These amino acids and oligopeptides get absorbed mostly in the proximal GI tract and travel to the liver, where they are recycled to synthesize new protein. In a healthy, 70-kg weighing adult male, >300 g of proteins are recycled daily. The branched-chain amino acids (BCAAs; leucine, isoleucine, and valine) are transported to muscle unaltered, while other amino acids are distributed to the intra- and extracellular pool for protein synthesis as needed. Excess amino acids are usually converted to glycogen or free fatty acids.

In addition to the dietary protein, intracellular proteins are continuously recycled and the resulting free nitrogen is excreted, mostly through urine. Most of the urine nitrogen is in the form of urea (85%), with smaller amounts excreted as creatinine and ammonia. Urinary nitrogen decreases significantly with protein-free diets (decreased intake) but increases during stress (greater turnover).

Amino acid metabolism generates ammonia, a highly toxic compound, which is converted into urea (nontoxic) in the liver. Glutamine and alanine serve as ammonia-transporting vehicles in a nontoxic form from the metabolically active peripheral tissues to the viscera. There, ammonia is resynthesized and either excreted (by the kidneys, where it also acts as a buffering system) or detoxified to urea (liver). Diseases that affect the functional capacity of either the kidneys or the liver can lead to significant ammonia build up in the body, with potentially toxic consequences to the central nervous system.

Provision of protein recommended for patients is dependent on clinical condition and comorbidities. SCCM and ASPEN recommend that critically

ill patients receive 1.2 to 2.0 g/kg of protein per day, with burn patients and polytrauma patients having higher protein needs.[5]

Vitamins

Vitamins A, D, E, and K are fat soluble and are absorbed in the small bowel in association with long-chain fatty acids. From there, they are transported to the liver (vitamins A and K) or the skin and subcutaneous tissue (vitamins D and E) for storage. Fat-soluble vitamins are required for normal immune function and play a significant role in wound healing. Daily vitamin A intake in patients on chronic corticosteroid regimens may counteract most of steroid-mediated adverse effects of wound healing.

Unlike vitamins A, D, E, and K, vitamins B_1 (thiamin), B_2, B_6, and B_{12}, along with vitamin C, niacin, folate, biotin, and pantothenic acid are water soluble and are absorbed in the proximal small bowel. From there, they are transferred to the liver with the portal circulation for use or storage. Water-soluble vitamins are required for normal amino and nucleic acid metabolism.

Deficiencies of vitamins B_1 (thiamin), B_9 (folate), and B_{12} can be associated with surgical procedures. Thiamin is an essential vitamin associated with carbohydrate metabolism and gluconeogenesis. Thiamin deficiency is commonly caused by alcoholism but may also be due to malabsorption (e.g., after Roux-en-Y gastric bypass), decreased nutritional intake (e.g., GI surgery, vomiting, intestinal obstruction), excessive losses (associated with loop diuretics and dialysis), and increased metabolism due to surgery or illness.[14] The central nervous system is affected by thiamine deficiency as seen in Wernicke encephalopathy, Wernicke–Korsakoff syndrome, and beriberi. Wernicke encephalopathy involves the triad of mental status changes, nystagmus, and ataxia. Wernicke encephalopathy may progress to Wernicke–Korsakoff syndrome, which is characterized by memory impairment. Beriberi involves muscular weakness and neuropathy.

Folate plays a role in protein metabolism and in the form of folic acid is often used to fortify numerous foods. Alcoholism and decreased nutritional intake are risk factors for folate deficiency. Folate deficiency may lead to anemia, weakness, and mouth sores. Additionally, folate supplementation is important for pregnant women to prevent neural tube defects in the setting of increased demand for embryonic DNA synthesis.

Electrolytes and Trace Elements

Electrolytes are important components of both the intra- and extracellular compartments, where they play a major role in maintaining electrical and osmotic balance across the body's plasma membranes. Such electrolytes include sodium (Na^+), potassium (K^+), calcium (Ca^{2+}), magnesium (Mg^{2+}), and chloride (Cl^-). Sodium is the main extracellular electrolyte and is important in maintaining volume homeostasis and in blood pressure control. Conversely, potassium is one of the key intracellular cations. The role of electrolytes is diverse and includes functions as varied as the conduction of electric signals, cotransport of larger molecules against their concentration gradient, muscular contraction, and participation in numerous essential biochemical reactions.

Trace elements play an important role in numerous metabolic, immunologic, and healing functions, and eight minerals have been identified as "essential." These include iron, iodine, zinc, chromium, copper, selenium, manganese, and molybdenum.

Iron is an integral component of the heme core in hemoglobin and of the mitochondrial cytochrome complex. Subtle impairments in central nervous, musculoskeletal, and immune system functions can be identified in patients with iron deficiency before microcytic anemia becomes clinically evident. Impaired cerebral, muscular, and immunologic functions can occur in patients with iron deficiency before anemia becomes clinically evident. Particular attention has to be paid to pregnant and lactating females, in whom iron requirements are even greater than the rest of the population.

Iodine is a key component of the thyroid hormonal system. Deficiencies are rare in the Western world, due to widespread use of iodinated salt. However, chronically malnourished patients can develop significant iodine deficiency, which can typically manifest clinically as diffuse goiter and hypothyroidism.

Zinc deficiency can manifest with skin discoloration and perioral rash, neuritis, hair loss, and alterations in taste and smell. Chromium deficiency presents as impaired glucose tolerance during prolonged fasting and is fairly common with total parenteral nutrition (TPN). Copper deficiency presents with microcytic anemia, typically unresponsive to iron, abnormal skin keratinization, and, in its most severe cases, pancytopenia. Selenium

deficiency, which can similarly be identified in cases of prolonged TPN administration, manifests as neuromuscular dysfunction or cardiac conduction defects, which in the most severe cases can lead to heart failure. Manganese deficiency can be identified as the underlying cause in a syndrome presenting as unintentional weight loss, hair color changes, and hypolipidemia. Molybdenum deficiency is associated with hypomethioninemia and hypouricemia, resulting in nausea and vomiting, tachycardia, and nonfocal central nervous system dysfunction (**Table 3.4**).

NUTRITIONAL ASSESSMENT

2 An accurate nutritional assessment is critical to identifying patients in need of nutritional support and determining the degree of nutritional support needed. Metabolism is altered to varying degrees by stress, namely, surgical injury, critical illness, infection, and physical trauma. In most cases, these alterations are short lived and reversible in a previously well-nourished individual, even if fasting is superimposed during acute illness. However, pre-existing malnutrition, even if mild, and prolonged poststressor fasting, intentional or not, can adversely affect healing, recovery, and overall outcomes after injury or surgery.[15] Factors such as weight loss and low preoperative albumin have been associated with poor outcomes after abdominal surgery.[16]

Subjective Global Assessment

Subjective global assessment (SGA) of a patient's nutritional status is commonly utilized to assess the presence and degree of malnutrition in surgical patients. It is one of the few clinical methods that has been validated as a reproducible method assessing a patient's nutritional status and has been consistently associated with clinical outcomes.[17] The SGA incorporates components of a patient's history, including weight loss, changes in nutritional intake, functional capacity, GI symptoms, and metabolic demand associated with underlying disease. Additionally, this assessment includes a focused physical examination to assess for edema, muscle wasting, and loss of subcutaneous fat.

Patients are classified as having (A) no evidence of malnutrition, (B) moderate or indeterminate malnutrition, and (C) severe malnutrition. Patients in this last category typically present with a recent history of unintentional weight loss and signs of tissue wasting (temporal and/or extremity most commonly). While the SGA can provide coarse information about the severity of malnutrition, it rarely yields clues pertaining to the underlying etiology (starvation vs. inflammation).

Table 3.4 Summary of the Daily Requirements of Vitamins, Electrolytes, and Trace Elements in a Per Os Diet by Healthy Adults

Vitamins	
Retinol (vitamin A)	1,000 µg
Thiamine (vitamin B_1)	1.4 mg
Riboflavin (vitamin B_2)	1.7 mg
Pyridoxine (vitamin B_6)	2.2 mg
Ascorbic acid (vitamin C)	60 mg
Niacin	20 mg
Folate	200 µg
Biotin	150 µg
Pantothenic acid	4–7 mg
Retinol (vitamin A)	1 mg
Vitamin D	5 µg
Vitamin E	10 mg
Vitamin K	75–150 mg
Electrolytes	
Sodium	90–150 mEq
Potassium	60–90 mEq
Calcium	1,300 mg
Magnesium	350 mg
Phosphorus	800 mg
Trace Elements	
Iron	10 mg
Iodine	150 µg
Zinc	15 mg
Chromium	5–200 µg
Copper	2–3 mg
Selenium	100 µg
Manganese	2.5–5 mg
Molybdenum	100–500 µg

Similar methods of assessing overall nutritional status encompassing dietary history, baseline health, and anthropometric and laboratory measurements have been described and used in certain patient subpopulations. These include the mini nutritional assessment, the malnutrition universal screening tool, the instant nutritional assessment, the geriatric nutritional risk index, among others. The SGA may be of limited use for critically ill patients and as such ASPEN and SCCM recommend the use of nutritional risk screening (NRS 2002) or NUTrition Risk in the Critically ill (NUTRIC score).[5]

NRS 2002 was developed to identify hospital patients who are at risk for malnutrition or are undernourished. This screening assesses weight loss, BMI, food intake, disease severity, and age.[18] The NUTRIC score is calculated based on age, Acute Physiology and Chronic Health Evaluation II (APACHE II) and Sequential Organ Failure Assessment (SOFA) scores, number of comorbidities, days between hospital and intensive care unit (ICU) admission, and IL-6 if available.[19] High NUTRIC scores have been associated with worse clinical outcomes and long hospital and ICU lengths of stay.[20]

Anthropometric Measurements and Nutritional Indices

Anthropometric measurements have been used extensively to provide information regarding lean body mass, total fat stores, and overall nutritional health. Body composition studies aid in determining TBW, fat, and nitrogen. These anthropometric measurements can be easily performed at the bedside or an ambulatory setting and may include an individual's height and weight (which allow calculation of the BMI), triceps skinfold, midhumeral circumference, and other body part summations. The BMI is widely used as a measure of overnutrition (a BMI of 25 to 29.9 suggests overweight status, whereas a BMI > 30 defines obesity). The BMI is calculated from an individual's height and weight using the following formula:

$$\text{BMI} = \text{weight (kg)}/\text{height (m)}^2 = 703 * \text{weight (lb)}/\text{height (in)}^2$$

More advanced techniques and measurements include x-ray absorptiometry that allows a more accurate assessment of total fat and lean body mass. With the exception of the BMI, most anthropometric

measurements are operator dependent, and skill and experience are important in order to obtain accurate studies.

Nutritional indices provide a means of risk stratifying and objectively comparing individuals, as well as to guide nutritional support. The BMI is one of the most commonly utilized nutritional indices. It provides information on normal, overweight, or obese status. It also provides information on the degree of protein–calorie malnutrition in underweight individuals.

Serum Protein Levels

3 An ideal biochemical marker of malnutrition would be one that is highly sensitive and specific to nutrition intake. Although a single laboratory biomarker that could effectively describe a patient's nutritional status is lacking, numerous freely circulating serum transport proteins have been used. The most commonly utilized ones are albumin, prealbumin, transferrin, and retinol-binding protein (RBP), each with its own advantages and disadvantages. Many nutrition-unrelated parameters, most commonly inflammation, dilution secondary to large-volume resuscitation, and chronic liver failure, affect the levels of these serum markers. Although it is customary for markers of inflammation, usually the C-reactive protein, to be measured with the aforementioned biomarkers (commonly prealbumin), limited data exist to support this practice.[5,21,22]

Albumin

Albumin is a serum protein synthesized in the liver with a long half-life (approximately 20 days) and a relatively large total pool size. Only 5% of total body albumin is produced daily. Its main function is to carry molecules in the bloodstream and to help maintain intravascular oncotic pressure. Due to its large pool, long half-life, and relative slow turnover, it has been used as an indirect marker of protein intake, hepatic synthetic ability, and chronic nutritional status. Unfortunately, it is a negative acute-phase reactant, decreasing during the acute-phase response, and numerous nutrition-unrelated factors may affect its levels in either direction (**Tables 3.3** to **3.5**). Albumin is neither a sensitive nor specific marker for malnutrition, as patients with even severe starvation can have normal levels.[23–26] In critical care, hypoalbuminemia more commonly reflects illness acuity, especially during the acute phase, due to its function as a negative acute-phase reactant, its

redistribution to the interstitial space, and dilution secondary to large-volume resuscitation.[27]

Prealbumin

Prealbumin, also known as transthyretin or transthyretin-bound prealbumin, similar to albumin, is a visceral protein synthesized in its majority by the liver and to a smaller extent by the choroid plexus in the central nervous system. Its name prealbumin was originally given because it ran faster than albumin on electrophoretic gels. Its main function is to transport thyroxin (T4) and retinol (vitamin A) in the bloodstream. As a visceral protein, it is a small part of the total body protein pool, which includes serum and intracellular proteins. Consequently, it is similarly affected by many of the same factors that affect serum albumin concentrations. The main advantage of prealbumin over albumin is its shorter half-life (2 to 3 days), which makes it more sensitive and rapidly adaptable to acute, short-lived changes in nutrient intake. Like albumin, prealbumin is a negative-phase reactant, with values decreasing during the acute inflammatory response. Therefore, rising prealbumin levels may reflect improvement in nutritional status or resolution of the inflammatory condition. Prealbumin is commonly measured along C-reactive protein, and low levels of the former accompanied by high levels of the latter are commonly seen in inflammatory conditions, as opposed to malnutrition. While this practice is not well validated, a better use for prealbumin as a marker of overall nutritional status is to monitor trends.[28]

Table 3.5 Serum Proteins Used in Nutritional Status Assessment

Marker	Reference Range	Half-Life	Elevated in	Decreased in
Albumin	3–5 g/dL	14–20 d	Dehydration, marasmus, blood transfusions, and exogenous albumin administration	Aggressive resuscitation, ascites, eclampsia, liver failure, inflammatory states, nephrotic syndrome, protein-losing states, burns, trauma/postoperative states, kwashiorkor, cancer, collagen diseases, corticosteroid use, chronic bed rest, zinc deficiency, and pregnancy
Prealbumin	18–45 mg/dL	2–3 d	End-stage renal failure, corticosteroid use, and oral contraceptives	Postoperative states, hepatitis, liver failure, inflammatory states, dialysis, hyperthyroidism, pregnancy, and severe hyperglycemia
Retinol-binding protein	4–6 mg/dL	12 hrs	End-stage renal failure, diabetes, obesity, vitamin A overdose, corticosteroid use, and oral contraceptives	Postoperative states, hepatitis, liver failure, inflammatory states, and vitamin A deficiency
Transferrin	200–250 mg/dL	8–10 d	Iron deficiency, dehydration, pregnancy (third trimester), oral contraceptives, estrogens, chronic anemia, hepatitis, liver failure, hypoxia, and end-stage renal failure	Pernicious anemia, anemia of chronic disease, folate-deficiency anemia, aggressive resuscitation, chronic infectious states, iron overload, acute catabolic states, uremia, nephrotic syndrome, liver failure, kwashiorkor, old age, zinc deficiency, corticosteroids, and cancer

Adapted from Parrish CR. Serum proteins as markers of nutrition: what are we treating? *Practical Gastroenterology* 2006;43(10):48–64.

Retinol-Binding Protein

The majority of RBP is present in the bloodstream in the form of retinol-circulating complex that includes prealbumin, retinol (vitamin A), and RBP. It is catabolized in the kidneys, and its levels may be elevated in end-stage renal failure. RBP is dependent on vitamin A and zinc, as low levels of these conutrients inhibit mobilization of RBP in the liver.[29] To some extent, measuring the RBP provides the same information as measuring prealbumin. RBP is less commonly used as a marker of nutrition, as it has a short half-life (approximately 12 hours), levels are affected by renal failure, and the measurement assay is more costly.[28]

Transferrin

Transferrin has also been identified and used as a nutrition biomarker. It has a half-life between that of albumin and prealbumin (8 to 10 days) and fairly small total body pool size. However, because it plays a key role in iron transport, its levels are affected by iron status. Iron deficiency may lead to increased levels secondary to greater iron absorption. Under these

circumstances, it may be a better marker of total iron-binding capacity, rather than malnutrition.

Nitrogen Balance

Nitrogen balance is another marker for overall nutritional status. It is an indicator of whether protein intake and catabolism are in balance, and along with trends in prealbumin levels, it is a commonly employed method to assess progress in patients on nutritional support. Nitrogen balance is calculated from the amount of nitrogen entering minus the amount leaving the human body over a 24-hour period. Nitrogen intake is estimated from total protein intake divided by 6.25 (the average nitrogen content of human protein is approximately 16%). The main route of nitrogen excretion is the urine (≥90%). Nitrogen is also lost through the skin and stool, but this loss is usually small (<2 g/day), difficult to measure, and therefore typically accounted for with a constant of 2 in the nitrogen balance equation. Total urinary nitrogen (TUN) is ideally measured but is frequently substituted by urine urea nitrogen (UUN), because it is easier to estimate. In the latter case, an additional 2 to 3 g is typically added to the output side of the nitrogen balance equation to account for the unmeasured losses. The nitrogen balance equations are as follows:

Nitrogen balance (g/day) = Protein intake/6.25 - (TUN + 2)
Nitrogen balance (g/day) = Protein intake/6.25 - (UUN + 2 + 3)

A nitrogen balance of −2 to +2 g/day indicates nitrogen equilibrium and typically represents the goal in medically indicated nutritional support. More negative balances are managed with increases in protein intake, while more positive values typically reflect anabolism in recovering patients, or simply errors in measurement in the acutely ill (a positive nitrogen balance implies anabolism, but bedridden patients with active inflammation are not anabolic). Achievement of a positive balance has been associated with improved outcomes in certain critically ill patients.[12] Limitations of the nitrogen balance assessment include false-negative results in overfed patients; long time for the equation to reequilibrate after adjustments in nutritional support; and renal insufficiency and upper GI bleeding may

invalidate results (due to incomplete excretion of urea nitrogen and due to excess urea nitrogen production, respectively).

OVERFEEDING AND MALNUTRITION

Overfeeding

4 While adequate caloric intake is necessary to maintain weight and promote health, overprovision of calories can lead to overfeeding and obesity. Excess calories, especially as carbohydrates, can lead to increased CO_2 production (which may prolong ventilatory weaning), hyperglycemia (which can contribute to immunosuppression and increase the risk for infectious complications), lipogenesis (indicated by a respiratory quotient [RQ] > 1), and hepatic steatosis (which can interfere with normal liver function). Additionally, excessive nutritional support may lead to mineral or vitamin poisoning and severe electrolyte imbalances, with hypophosphatemia being the most common. To avoid overfeeding, specifically in critically ill patients with numerous active medical conditions, indirect calorimetry may be indicated to accurately estimate energy expenditure during the various stages of disease.

Malnutrition

Starvation

During short periods of fasting, insulin levels drop and glucagon levels rise in the plasma, while glycogen is being broken down in the liver to release glucose. Liver glycogen stores are typically depleted within 24 hours of fasting. After carbohydrate stores are used up, caloric needs are met by protein and fat degradation. During starvation, downregulated insulin results in net muscle wasting, as protein is broken down to release amino acids. These amino acids—most commonly alanine and glutamine—are used for gluconeogenesis in the liver. The resulting glucose is used primarily by the central nervous system and the hemopoietic system that rely heavily on glucose metabolism for their energy requirements. Hepatic gluconeogenesis

itself also requires energy, which is typically supplied by the free fatty acid oxidation. The drop in circulating insulin levels, along with the concomitant rise in plasma glucagon, activates hormone-sensitive lipase in fatty tissue that hydrolyzes triglycerides to release free fatty acids, which in turn help generate energy for the aforementioned gluconeogenesis. Both gluconeogenesis and fatty acid oxidation require the permissive effect of cortisol and thyroxin.

During starvation, the human body attempts to recycle energy sources to the greatest extent possible. Lactate produced by the white blood cells or the muscles during anaerobic metabolism is recycled back to glucose in the liver, through the Cori cycle. BCAAs, unlike glutamine and alanine, which are taken up by the liver, are secreted by the gland in order to provide skeletal and cardiac muscles an energy substrate. Once BCAAs are oxidized for energy, their residual amino groups are utilized to recycle alanine and glutamine, which, in turn, return to the liver to allow further gluconeogenesis. However efficient this conservation of energy and substrates may seem, gluconeogenesis from amino acids in the liver results in a significant loss of lean body mass, which may reach fatal levels after approximately 4 weeks. The brain adapts to prolonged starvation after about 7 to 10 days (chronic starvation) to use ketones derived from fat as its primary energy source. At this stage, the BMR decreases by as much as 30%, and all functions requiring significant amounts of energy expenditure slow down, including voluntary muscle activity and cardiac function.

Table 3.6 Metabolic Differences between the Response to Simple Starvation and Stress

	Simple Starvation	Stress/Inflammation
Basal metabolic rate	–	++
Presence of mediators	–	+++
Major fuel oxidized	Fat	Mixed
Ketone body production	+++	±
Hepatic ureagenesis	+	+++
Negative nitrogen balance	+	+++
Gluconeogenesis	+	+++
Muscle proteolysis	+	+++
Hepatic protein synthesis	+	+++

Starvation versus Inflammation as the Cause of Malnutrition

Both starvation and the systemic inflammatory response result in lean body mass loss, which should indicate nutritional support.[1–3] However, the two processes have key dissimilarities that differentiate one from the other. On the one hand, starvation leads to progressive loss of both lean mass and body fat, preservation of serum protein levels, and reversal of the metabolic response with feeding. The most common causes of starvation in the surgical patient are functional and include nausea and emesis, ileus, dysphagia, and malabsorption. On the other hand, during a significant inflammatory response, the BMR increases significantly (both anabolism and catabolism) and becomes relatively insensitive to feeding, and levels of acute-phase proteins change. Inflammation may additionally worsen malnutrition by interfering with caloric intake acutely (anorexia of acute illness) or in the

chronic state (cancer cachexia). The key differences between the metabolic response to simple starvation and injury are summarized in **Table 3.6**.

Substrate Metabolism Changes during Stress

5 During the neuroendocrine response to stress, metabolism of commonly used nutritional substrates undergoes significant changes.

Altered Carbohydrate Metabolism

Hyperglycemia occurs commonly after injury, and its intensity generally reflects the severity of the stressor. During the ebb phase, insulin levels are low and glucose production is only minimally elevated. During the flow phase, hepatic gluconeogenesis occurs at a faster pace from peripheral tissue–released precursors and hyperglycemia persists, while insulin levels are normal or elevated. This phenomenon suggests relative insulin resistance.

Altered Protein Metabolism

After a major injury, nitrogen losses increase. These correlate to the extent of trauma and the injury victim's pre-existing nutritional status. In patients not receiving nutrition, protein breakdown exceeds synthesis and negative balance results. Providing exogenous calories is important to maintain a neutral nitrogen balance.[30] Skeletal muscle is the chief source of the nitrogen lost in urine following extensive injury, and it appears that amino acid release from muscle is heavily skewed toward glucogenetic precursors (alanine and glutamine), even though these comprise less than 5% of muscle total protein.

In addition to skeletal muscle, the kidneys and the GI tract release alanine, which may be used for glucogenetic purposes, even though the majority enters metabolic pathways that favor the production of urea and ammonia to be excreted from the body.

Altered Lipid Metabolism

To support the increased metabolic rates after injury or elective surgery, triglycerides are released from adipose tissue for energy production. Glucose administration minimally affects this lipolysis, which appears to be

a result of continuous neuroendocrine stimulation. Although mobilization and oxidation of free fatty acids are accelerated in injured subjects, ketone synthesis is minimal and occurs independently of protein catabolism. When severely injured patients remain unfed, their fat and protein stores become depleted rapidly, and the resultant malnutrition increases their susceptibility to infectious complications, multiple-organ system failure, sepsis, and ultimately death.

Stressor-Dependent Adjustments to the Metabolic Response

Response to Elective Surgery and Accidental Injury

One of the earliest consequences of major surgery is the rise in levels of circulating cortisol in response to a sudden release of adrenocorticotropic hormone (ACTH) from the anterior pituitary gland. This cortisol remains elevated for 24 to 48 hours after operation. Cortisol has generalized effects on tissue catabolism and mobilizes amino acids from skeletal muscle that provide substrates for wound healing and serve as precursors for the hepatic synthesis of acute-phase proteins or new glucose, as delineated earlier (**Fig. 3.3**). Associated with the activation of the adrenal cortex is stimulation of the adrenal medulla through the sympathetic nervous system, with release of epinephrine and norepinephrine. These circulating neurotransmitters play an important role not only in increasing vascular tone, which may be lessened from circulating cytokines, but also in promoting amino acid release from skeletal muscle, lipolysis in adipose tissue, and gluconeogenesis in the liver.

The neuroendocrine response to surgical trauma can also modify the various mechanisms that regulate salt and water excretion. Alterations in serum osmolarity and body fluid tonicity due to anesthesia, operative stress, and fluid resuscitation stimulate antidiuretic hormone (ADH) and aldosterone secretion. ADH and aldosterone promote water and sodium reabsorption in the renal tubules, respectively. Thus, weight gain from salt and water retention is not uncommon after major surgery. Edema occurs to a varying extent in all surgical wounds secondary to local cytokine release that

increases vascular permeability, and this local water accumulation is proportional to tissue trauma. This extravasated fluid eventually returns to the circulation as the postoperative inflammatory response subsides and diuresis commences, typically 2 to 3 days after surgery.

Glucagon from the endocrine pancreas is also released at greater rates postoperatively, while insulin levels decrease. This response appears to be associated with the increased sympathetic activity that typically follows surgical trauma. The rise in glucagon and the corresponding fall in insulin act as potent signals accelerating hepatic glucose synthesis.

This postoperative catabolic period, which may be worsened by inadequate caloric intake, has been termed the “adrenergic–corticoid phase,” which generally lasts 1 to 3 days, and is followed by the “adrenergic–corticoid withdrawal phase,” which may last an additional 1 to 3 days. An anabolic phase ensues, which can occur at a variable time during a surgical patient’s convalescence. In general, in the absence of significant postoperative complications, this stage starts 3 to 6 days after major abdominal surgery, usually when the bowel function returns and an oral diet is initiated. This phase is characterized by positive nitrogen balance and weight gain. Protein is synthesized at an increased rate, and return of lean body mass and muscular strength ensues.

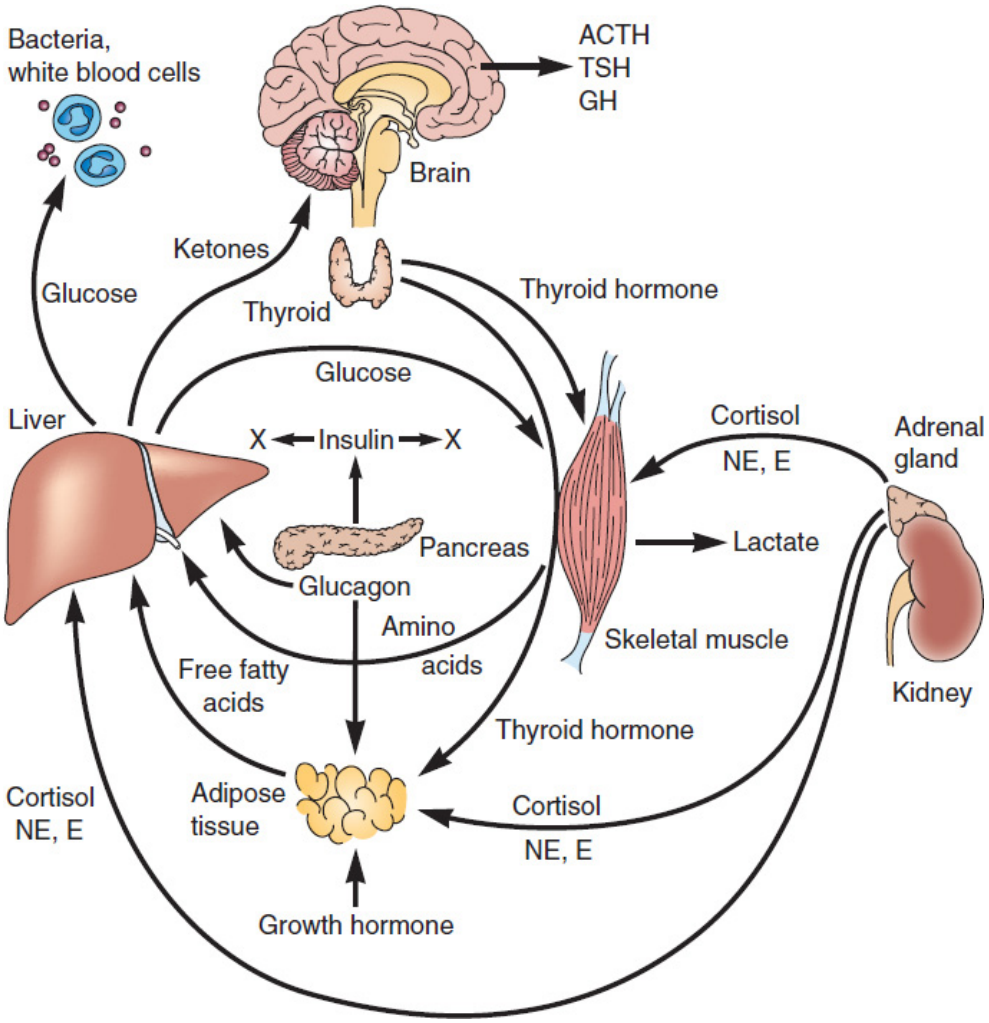

Figure 3.3 During sepsis, metabolism shifts to greater glucose synthesis and utilization, likely mirroring the greater metabolic needs of the pathogens and the mobilized host white blood cells.

Whether the body is injured within the carefully monitored confines of the operating room or accidentally, the response to tissue trauma is similar, although key differences exist. In accidental injury, tissue damage is uncontrolled and happens in a contaminated environment. The associated volume loss can be substantial and life-threatening. Pain and the sympathetic nervous system overexcitation are heightened and uncontrolled. As a consequence, the magnitude of the physiologic response to major accidental injury is considerable. In contrast, the elective tissue trauma inflicted occurs in a planned and monitored setting, and the team caring after the surgical patient perioperatively ensures appropriate resuscitation designed to attenuate such changes. Hydration during and after surgery is common, and

the latter typically happens in a clean field. At the same time, the anesthesiologist provides medications to minimize anxiety and fear to minimize the sympathetic nervous system response. Appropriately selected pharmacologic agents are used to minimize undesirable cardiovascular responses, and analgesic techniques are employed to minimize postoperative pain. As a result, the physiologic responses to elective surgery are generally of lesser magnitude than those following major accidental injury and are typically tolerated better (**Table 3.7**).

Metabolic Adaptations to Sepsis

The metabolic changes following invasive infection are not dissimilar to those seen after elective surgery and accidental trauma, although they are typically less predictable. Severe infection is characterized by fever, hypermetabolism, diminished protein economy, altered glucose dynamics, and accelerated lipolysis, much like the injured patient. Anorexia that commonly follows systemic infection is an added factor contributing to the loss of lean body mass.

Table 3.7 Differences between Elective Surgery and Accidental Injury

Insult	Elective Surgery	Accidental Injury
Tissue damage	Minimal and controlled, usually occurring in a clean environment; tissues are dissected with care along anatomic planes and reapproximated	Can be substantial; tissues torn in contaminated field. Debridement often necessary
Hypotension	Uncommon. Pre- and intraoperative hydration employed and volume status carefully monitored intraoperatively	May occur with significant blood loss and lead to shock. Fluid resuscitation often delayed
Pain, fear, and anxiety	Typically attenuated with perioperative analgesics and anxiolytics	Generally present in the first hours after trauma
Infectious complications	Relatively rare. Procedures take place in a sterile field, and preoperative administration of antibiotics is commonplace	More common due to contamination and tissue devitalization
Overall stress response	Controlled and of lesser magnitude. Starvation better tolerated	Controlled and proportional to the magnitude of the injury. Malnutrition poorly tolerated

Hypermetabolism and increased oxygen consumption are additional traits, with the latter reaching peak levels that may be 50% to 60% higher than baseline in severe sepsis. A portion of this metabolic acceleration can be attributed to the escalation in enzymatic reaction rates associated with fever. It is estimated that the BMR rises by 10% to 13% for every 1°C rise in central temperature. Glucose metabolism is increased to much greater levels in systemically infected subjects than in trauma victims. As an example, burn patients synthesize glucose at a rate approximately 50% above normal. If superinfection ensues, hepatic glucose production doubles, and it appears that the additional glucose requirements correlate with the bacterial burden and white blood cell activation (**Fig. 3.3**).

Increased proteolysis and nitrogen excretion leading to negative nitrogen balance typically occur following invasive infection, in a pattern that is similar to that described for injury. Visceral amino acid uptake is accelerated during sepsis, and this is matched by faster amino acid efflux from skeletal muscle. In infected burn patients, splanchnic amino acid uptake is amplified >50% above rates in uninfected burn victims with comparable injuries. These amino acids serve either as glucose precursors or as building blocks for acute-phase protein synthesis.

Fat is another major fuel utilized for energy in infected patients. Increased fat catabolism is particularly profound in patients during periods of inadequate nutritional support or relative starvation. Lipolysis is accelerated, among other reasons, by a heightened sympathetic activity, and serum triglyceride levels reflect the balance between synthesis in the liver and storage in the peripheral adipose tissue. Marked hypertriglyceridemia has been associated with certain gram-negative infections, but frequently triglyceride concentrations are normal or low, indicating enhanced utilization and clearance by other organs. Infected patients cannot convert fatty acids to ketones as efficiently in the liver, and do not adapt to starvation, as well as their fasted, unstressed counterparts. It is postulated that the low ketone state of infection is a consequence of the hyperinsulinemia, which in turn follows insulin resistance in high-degree catabolic states.

Trace elements and electrolytes (zinc, iron, potassium, magnesium, and inorganic phosphate) typically follow alterations in nitrogen balance. Although the iron-binding capacity of transferrin typically remains unchanged in early infection, free iron cannot be found in the plasma of patients with

severe pyrogenic infections. Similar changes are seen in zinc levels. These decreases cannot be totally accounted for by total body losses; rather, an accumulation of these elements appears to occur in the liver through not yet elucidated mechanisms. Unlike iron and zinc, serum copper levels generally rise, seemingly due to greater ceruloplasmin synthesis in the liver.

Metabolic Response to Cancer and Acquired Immunodeficiency Syndrome

Patients with cancer and acquired immunodeficiency syndrome (AIDS) have similar metabolic states, characterized by chronic malnutrition, typically a result of anorexia and treatment side effects, and prolonged low-grade inflammatory changes. Cancers of the aerodigestive tract interfere with taste, swallowing, and/or digestion, precluding adequate caloric and/or protein intake. Supplementation with zinc and B vitamins may help taste-related symptoms, and soft mechanical diets may allow greater caloric intake in patients with swallowing difficulties or proximal GI tract malignancies. The aggressive management of nausea and vomiting may also afford greater interest in food.[31]

Cancer- and AIDS-related cachexia is seen in the later stages of disseminated disease and represents a chronic catabolic state due to unrelenting inflammation that is difficult to reverse, even with adequate caloric and protein supplementation. Proinflammatory cytokines (TNF, IL-1, and IL-6) are constantly released in response to the tumor or an infectious source in AIDS, respectively, and lead to a chronic state of muscle wasting and fat loss. The cachexia of cancer and AIDS is difficult to manage, as removing the inflammatory stimulus can prove elusive. However, mitigation of the chronic, low-grade inflammatory response may be useful and so can aggressive nutritional supplementation and appetite stimulants.

Age and Gender

Certain patterns in the metabolic response to surgical pathology that occur with aging can be attributed to alterations in body composition. Although weight remains roughly stable, fat mass tends to increase with age while lean body mass tends to decline. The loss of strength that accompanies immobility, starvation, and acute surgical illness may have significant

consequences. Although the increased energy requirements after elective surgery occur essentially independent of age, the capacity of muscle to serve as a source of amino acids may be limited during acute surgical illness in the elderly and muscle strength may rapidly become inadequate for respiratory function.

In addition to a smaller muscle mass, older age is commonly associated with a greater prevalence of cardiovascular and pulmonary diseases. Relatively decreased arterial compliance, lower baroreceptor sensitivity, and a blunted response to the catecholamine surge may impair the cardiovascular homeostatic response during acute surgical illness. Thus, tissue oxygenation may not be able to meet the heightened demand.

Gender, in addition to age, may affect the body's ability to adapt to surgical stress. Observed differences in the metabolic response between men and women in general reflect differences in body composition. Lean body mass, as a proportion of total body weight, is lower in women than in men. This difference is thought to account for the lower net loss of nitrogen after major elective abdominal surgery in women. Women, in general, have approximately half the skeletal muscle mass of men of the same age. Therefore, young muscular men experience the greatest nitrogen losses during acute surgical illness, as opposed to elderly, sedentary women.[6]

NUTRITIONAL SUPPORT

Nutritional Support in Elective Surgery

With any patient undergoing an elective surgical procedure, consideration of perioperative nutrition is important. Malnutrition and underfeeding are risk factors for perioperative complications.[32–34] **Table 3.8** highlights the key aspects of perioperative care per the European Society for Clinical Nutrition and Metabolism (ESPEN). Patients undergoing major elective surgical procedures, particularly for cancers, should undergo nutritional screening as they are being prepared for surgery.[32]

Table 3.8 Key Aspects of Perioperative Care

- Integration of nutrition into the overall management of the patient
- Avoidance of long periods of preoperative fasting
- Reestablishment of oral feeding as early as possible after surgery
- Start of nutritional therapy early, as soon as a nutritional risk becomes apparent
- Metabolic control, e.g., of blood glucose
- Reduction of factors that exacerbate stress-related catabolism or impair gastrointestinal function
- Minimized time on paralytic agents for ventilator management in the postoperative period
- Early mobilization to facilitate protein synthesis and muscle function

From Weimann A, Braga M, Carli F, et al. ESPEN guideline: clinical nutrition in surgery. *Clin Nutr* 2017;36(3):623–650.

Most patients undergoing elective operations are adequately nourished and are typically only fasted for a few hours prior to surgery. The previous dictum that all patients must be made "NPO after midnight" is no longer recommended, and most patients can safely be fed clear liquids up to 2 hours prior to general anesthesia.[35] Preoperative intake of carbohydrate-based liquids ("CHO-loading") may impact postoperative insulin resistance and has been shown to be associated with overall reduction in length of hospital stay.[32] Early oral intake after most elective procedures is favored and may be associated with a reduction in the risk of postoperative ileus in some patients.[36] There are numerous studies that have demonstrated that it is safe to resume oral diet or enteral feedings early after GI surgery.[37,38] Early enteral nutrition within 24 hours should be initiated in all patients undergoing major head and neck or intestinal procedures for cancer.[32] ERAS has become standard of care in many countries and across numerous surgical disciplines. Most ERAS programs include components of nutritional assessment and reestablishment of early enteral nutrition postoperatively.[39]

6 Preoperative malnutrition is a clear risk factor for complications following elective surgery. There are a number of definitions and diagnostic criteria that can be applied, but proposed criteria are BMI < 18.5 kg/m^2 or a combined metric of weight loss >10% or >5% over 3 months and reduced

BMI or a low fat-free mass index (FFMI).[40] In patients who are determined to be malnourished preoperatively and in those patients at high risk of delayed postoperative nutrition initiation, nutritional support preoperatively may be indicated.[32] If the patient is malnourished preoperatively, or it is anticipated that the patient will be unable to take oral diet for more than 5 days postoperatively, nutrition should be instituted.[32] If a patient is unable to meet >50% of their nutritional needs for more than 7 days postoperatively, nutritional support is also recommended. As a general rule, enteral nutrition is preferred over parenteral nutrition. However, if adequate nutrition cannot be maintained by the enteral route, parenteral nutrition should be initiated after 7 days of enteral intolerance.[5]

Standard high-protein feeding formulas are adequate for most surgical patients. The choice of product and volume of feeding are based on the results of nutrition assessments. The majority of tube feeding formulas are rich in water-soluble dietary fiber, which is considered standard in the nutritional care of the surgical patient. Specific adjustments can be undertaken if special considerations (e.g., cardiac failure, renal failure, diabetes, etc.) are needed. In patients who present for elective surgery and who meet criteria for malnutrition, preoperative addition of balanced macronutrient and high-protein supplementation could be useful. This preoperative support should be initiated as soon as possible, even though it is estimated that the minimum time required to derive any benefit from this support is in the range of 2 to 4 weeks.[41]

Nutritional Support in Critical Care

While resuscitation, bleeding control, and preservation of the vital body functions, such as maintenance of gas exchange and supporting of adequate cardiac output, remain immediate priorities for survival in any critically ill surgical patient, it is increasingly recognized that nutritional support is an integral part of the metabolic care of the critically ill, and aggressive pursuit of target energy requirements is associated with optimal wound healing, recovery, and rehabilitation (**Fig. 3.4**). Critically ill patients who are typically quite catabolic often have anorexia that can be adaptive or maladaptive and may be unable to be fed by mouth volitionally for extended periods. Severe malnutrition can complicate the hospital course and

adversely affect outcomes. Numerous studies have demonstrated the association between energy deficit in critical illness and longer ICU stays, greater incidence of infectious complications, and even mortality.[5,42–44] The management of the nutritional support in critically ill patients is largely guided by the ESPEN guideline on clinical nutrition in the ICU[45] and the Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient from SCCM and ASPEN.[5] **Table 3.9** summarizes the recommendations for nutritional support in critically ill patients from SCCM and ASPEN.

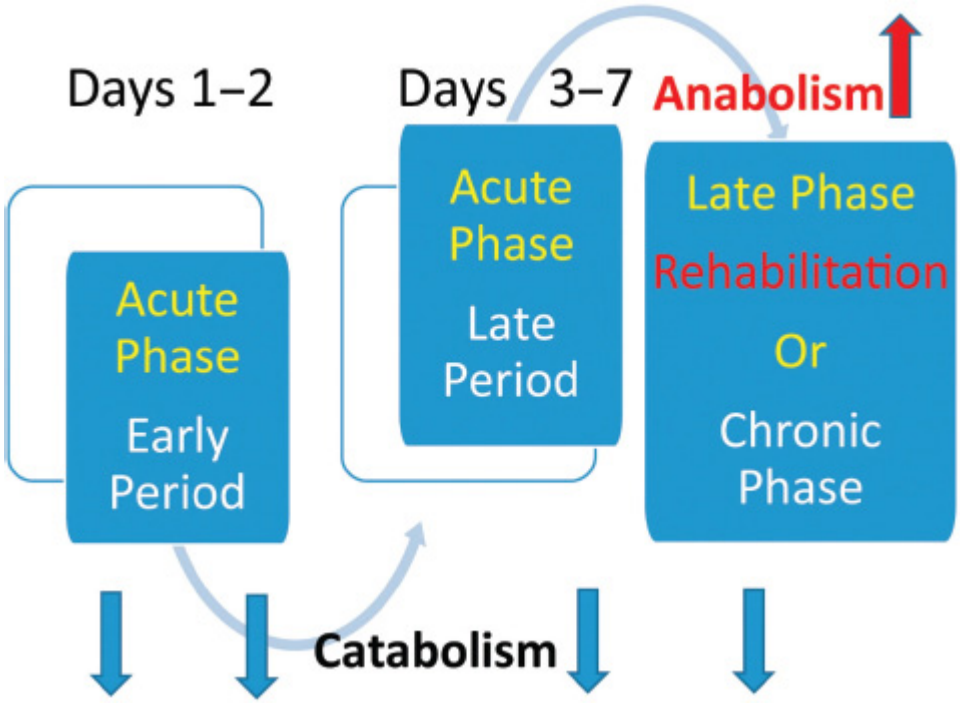

Figure 3.4 Description of the acute and late phases following infection/stress/injury. After injury, the acute phase is composed of an early period and a late period. Then the post–acute phase can be progressing to convalescence and rehabilitation or chronicity and prolonged inflammatory and catabolic syndrome (PICS). (From Martindale RG, McClave SA, Vanek VW, et al. Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine and American Society for Parenteral and Enteral Nutrition: executive summary. *Crit Care Med* 2009;37:1757–1761.)

Table 3.9 Bundle Statements from the Society of Critical Care Medicine and American Society for Parenteral and Enteral Nutrition's Guidelines for the Provision and Assessment of Nutrition Support Therapy in the Adult Critically Ill Patient

- Assess patients on admission to the intensive care unit (ICU) for nutrition risk and calculate both energy and protein requirements to determine goals of nutrition therapy.
- Initiate enteral nutrition (EN) within 24–48 hrs following the onset of critical illness and admission to the ICU, and increase to goals over the first week of ICU stay.
- Take steps as needed to reduce risk of aspiration or improve tolerance to gastric feeding (use prokinetic agent, continuous infusion, chlorhexidine mouthwash, elevate the head of bed, and divert level of feeding in the gastrointestinal tract).
- Implement enteral feeding protocols with institutionspecific strategies to promote delivery of EN.
- Do not use gastric residual volumes as part of routine care to monitor ICU patients receiving EN.
- Start parenteral nutrition early when EN is not feasible or sufficient in highrisk or poorly nourished patients.

From McClave SA, Taylor BE, Martindale RG, et al. Guidelines for the provision and assessment of nutrition support therapy in the adult critically ill patient: Society of Critical Care Medicine (SCCM) and American Society for Parenteral and Enteral Nutrition (A.S.P.E.N.). *JPEN J Parenter Enteral Nutr* 2016;40(2):159–211.

Upon admission to the ICU, some assessment of nutritional risk should be performed. There are several validated tools, including the NUTRIC and NRS 2002, both of which evaluate nutritional status and disease severity. When available, indirect calorimetry is a useful adjunct to the evaluation of nutritional needs.[46,47] The finding that enteral nutrients exert a trophic effect on the cellular integrity and function of the gut mucosa has provided the rationale for initiating enteral feedings early in the 7 course of critical illness. In fact, evidence from multiple studies appears to support that critically ill patients who were fed earlier had better overall outcomes than those who did not.[48] Current recommendations are that critically ill patients receive enteral nutrition within 48 hours of ICU admission.[5,45] Despite early

enthusiasm for postpyloric feeds, it is now recognized that most patients can be fed safely into the stomach. If gastric feeding intolerance exists, prokinetic agents can be tried. If that fails, it is recommended to convert to postpyloric feeding via a nasojejunal tube.[45] Routine monitoring of gastric residual volumes is no longer recommended.[5] Interruptions in enteral feeding should be minimized to prevent inadequate nutrient delivery.

There is a great deal of controversy and disparate literature on the best quantity and quality of nutritional support. Current recommendations are that a comprehensive approach toward nutrition that considers the route, timing, and content of nutrition provided. The appropriate calorie intake to be provided to critically ill patients via enteral nutrition remains unclear. One metaanalysis of randomized controlled trials that compared the effect of initial underfeeding and full feeding in acutely critically ill patients demonstrated no significant difference in overall mortality between the underfeeding and fullfeeding groups. However, a subgroup analysis of the underfeeding subgroup that was feed more than one-third of the caloric requirements indicated that mortality was significantly lower in this group. There were no differences in the secondary outcomes evaluated.[49] A recent multicenter, double-blind, randomized trial evaluating energy-dense versus routine enteral nutrition failed to demonstrate a mortality benefit with the use of an energy-dense formulation.[50] There is also increasing recognition that provision of adequate protein is more important than goal calories via a carbohydrate substrate.[51] Current recommendations are to provide 1.2 to 2.0 g/kg of actual body weight per day of protein.[5] Requirements may be even higher in patients with burns or polytrauma. One noncontroversial issue is the avoidance of overfeeding. It should be a goal of all to avoid the provision of excessive amounts of nutrients by any route in the early phase of critical illness.

Another frequently asked question is whether it is safe to enterally feed patients who are requiring hemodynamic support with vasopressors. One randomized trial comparing enteral to parenteral nutrition in patients requiring vasoactives did not demonstrate reduction in mortality or the risk of secondary infections but an increased risk of GI complications in enterally fed patients, including intestinal ischemia.[52]

8 For years, parenteral nutrition was considered far inferior to enteral nutrition. Recently, this notion has been challenged with the recognition that

mortality in patients provided with parenteral nutrition was not different from mortality in those fed enterally.[53] However, infectious complications may be higher as was ICU length of stay in one study. This difference did not occur when the calories administered by parenteral and enteral routes were similar, suggesting that overfeeding may be responsible for the infectious complications of parenteral nutrition. Focusing specifically on patients after GI surgery, one meta-analysis confirmed the beneficial effects of enteral nutrition for a lower rate of infectious complications, anastomotic leaks, and shorter hospital length of stay[54] while another demonstrated shorter time to return of bowel function and shorter hospital length of stay[55] without mortality benefits. A recent multicenter, randomized trial found no difference in mortality, infectious complications, or hospital length of stay between the two groups.[56]

Both the ESPEN and ASPEN/SCCM guidelines strongly endorse the use of enteral over parenteral nutrition when possible.[5,45,57] In patients who are severely malnourished and cannot tolerate enteral nutrition, preoperative parenteral nutrition has been associated with fewer noninfectious complications than in patients who were not provided with nutritional supplementation.[58] In critically ill patients, if parenteral nutrition is to be used, the timing of when to initiate it is controversial. Current recommendations are for patients at high nutritional risk to have parenteral nutrition initiated as soon as possible.[5] For patients at low nutritional risk, current recommendations are to wait 7 days before starting parenteral nutrition if they are unable to take oral or enteral nutrition. The rationale on the delay in parenteral nutrition administration is based on complications associated with its use, such as infections, hyperglycemia, hypertriglyceridemia, and liver function abnormalities.[59–62] In certain select cases, “dual feeding” with parenteral and enteral nutrition may be warranted.[63–65]

Parenteral Nutrition Considerations

One significant downside of parenteral nutrition is the concern of disuse of gut enterocytes, which may exacerbate intestinal microflora translocation from the gut lumen to the mesenteric lymph circulation, worsening total bacterial load and stress, as well as cause a loss of gut mucosal immunity.

Evidence suggests that parenteral nutrition may accentuate stress and predispose to gut-derived infectious complications, and even multiple-organ failure,[66,67] but is associated with fewer GI complications.[53,56] Due to the high osmolarity of its content, parenteral nutrition must be delivered centrally to minimize the risk of venous sclerosis. Patients on parenteral nutrition therapy should be monitored regularly by measuring blood sugar, serum electrolytes, and liver function tests, as abnormalities in these laboratories are common. Parenteral nutrition–related complications can be broadly categorized into those that are access-related, metabolic, and infectious. A list of these complications is summarized in **Table 3.10**.

Hyperglycemia

Hyperglycemia is common in surgical patients. Hyperglycemia is a well-recognized side effect of parenteral nutrition. Current guidelines recommend a target blood glucose range of 140 or 150 to 180 mg/dL.[68] Most hyperglycemia can generally be controlled with subcutaneous or intravenous insulin administration if mild or moderate. Insulin can be added to parenteral nutrition once the daily insulin requirements have been calculated. It has been shown that stressed individuals can maximally oxidize up to 4 to 5 mg of glucose/kg/min. For a 70-kg man, this is equal to approximately 400 to 500 g/day (1,600 to 2,000 kcal/day). Therefore, it is common for patients to receive up to two-thirds of their daily caloric needs in carbohydrate form through parenteral nutrition. Excess glucose can result in hyperglycemia and glycosuria and can be converted to fat and deposited in the liver. Glycosuria, with its osmotic load, can lead to osmotic diuresis, which can be misinterpreted as a sign of adequate resuscitation status or transition to recovery phase, while the patient may actually be clinically worsening.

Provision of Fat

Fat is an important fuel for the critically ill, as stressed patients preferentially utilize endogenous fat as an energy source. Fat oxidation is only minimally affected by carbohydrate administration during stress, unlike traditional starvation, and glucose infusion above certain levels may lead to hepatic steatosis. Lipids are commonly added to parenteral nutrition formulations to help meet the caloric requirements, to provide the essential

fatty acids, and to minimize complications associated with the infusion of large amounts of carbohydrate-containing fluids. Inclusion of lipids in parenteral nutrition provides the essential linoleic acid, inhibits lipogenesis from carbohydrates, and helps lower the RQ, which may benefit patients with CO_2 retention. Lipid emulsions for parenteral nutrition solutions are mostly 18-carbon soy-based omega-6 fats containing primarily long-chain fatty acids. These formulations with a high omega-6 polyunsaturated fatty acid content (linoleic acid in particular) have been associated with an increase in complications.[69] Newer nutritional methods of modifying the catabolic response to injury and infection propose the use of omega-3 fatty acids, which may decrease eicosanoid synthesis and thereby diminishing the vasoconstriction, platelet aggregation, and immunosuppression that may occur when soy-based omega-6 derivatives are given. Studies suggest that n-3 fatty acids may be of benefit to the critically ill patient.[70]

Table 3.10 TPN-Related Complications

Complication	Etiology
Access-Related	
Pneumothorax	Air accumulation between the pleural leaflets from puncture/laceration
Carotid/Subclavian arterial injury	Accidental puncture of the adjacent arterial structure
Catheter malposition and arrhythmias	Tip of catheter may find its way into an unintended venous structure or the right atrium, causing arrhythmogenesis
Venous thrombosis	Thrombus formation in a major vein, due to alterations in blood flow and the presence of a foreign body
Metabolic	
Hyperglycemia	Excessive carbohydrate administration, glucose intolerance, or combination of the two
Hypoglycemia	Sudden cessation of TPN, while insulin stimulation has not subsided
CO_2 retention	Carbohydrate calories in excess of energy requirements
Azotemia	Excessive protein administration with inadequate calories
Essential fatty acid deficiency	Inadequate essential fatty acid administration
Hypertriglyceridemia	Rapid fat infusion or decreased fat clearance
Hypophosphatemia and hypokalemia	Sudden full-strength nutritional restitution in a starved patient (refeeding syndrome)
Any electrolyte abnormality	
Hemorrhagic diathesis	

	Excess or inadequate electrolyte supplementation Vitamin K deficiency
Infectious	
Septicemia Skin site cellulitis Pneumonia, other systemic infectious	Catheter tip becomes colonized with bacteria and continuously seeds bloodstream Skin flora enters the subdermal/subcutaneous space High n-6 fatty acid content adversely affects immune function

Electrolytes

The amounts of the various electrolytes provided to patients receiving parenteral nutrition vary, depending on volume status and preexisting electrolyte abnormalities. Careful monitoring of serum electrolyte levels is critical, especially during the acute phase of disease or in severely malnourished individuals, because as metabolism switches to the anabolic phase, potassium and phosphate can move rapidly into the intracellular compartment, leading to potentially fatal electrolyte abnormalities from refeeding syndrome.[71] Vitamin and trace mineral levels, although not as life-threatening, should be monitored as well. The composition of a standard parenteral nutrition solution is shown in **Table 3.11**.

Table 3.11 Composition of a Standard Total Parenteral Nutrition Formulation

Volume		
10% Amino acid solution		500 mL
50% Dextrose solution		500 mL
Fat emulsion		—
Electrolytes + vitamins + minerals		~50 mL
Total volume		~1,050 mL
Composition		
Amino acids		50 g
Dextrose		250 g
Total N		50/6.25 = 8 g
Dextrose kcal		250 g × 3.4 kcal/g = 840 kcal
mOsm/L		~2,000
	Usual Concentration	**Range of Concentrations**
Electrolytes to Total Parenteral Nutrition Solutions		
	60	0–150
	40	0–80
Sodium (mEq/L)	50	50–150
Potassium (mEq/L)	50	0–150
Acetate (mEq/L)	15	0–30
Chloride (mEq/L)	4.5	0–20
Phosphate (mEq/L)	5	5–15
Calcium (mEq/L)[a]		
Magnesium (mEq/L)		

[a]Generally added as calcium gluconate or calcium chloride: one ampule of calcium gluconate = 1 g of calcium = 4.5 mEq.

Enteral Nutrition Considerations

Enteral nutrition is generally safer and less expensive than parenteral nutrition, and numerous studies have demonstrated superiority of enteral nutrition compared to parenteral nutrition as discussed earlier and extensively in guidelines.[5,45,57] The GI tract can be used for administration of complex nutrients that cannot be provided as readily intravenously, such as polypeptides and fiber. Gut processing of many of these nutrients stimulates hepatic protein synthesis, while intravenous administration 9 bypasses the portal circulation altogether. In addition to the systemic benefits of enteral nutrition, enteral feedings afford significant local benefits on the gut mucosa itself. Enterocytes are being fed directly, and the absorptive surface of the mucosa is stimulated and maintained. Luminal nutrients, such as glutamine and short-chain fatty acids, are used as fuel by small bowel enterocytes and colonocytes, respectively.[72] The trophic effects of luminal nutrition are well documented, even if small amounts of enteral feedings are provided; evidence suggests that earlier enteral nutrition is preferable.[73,74] An additional immunologic benefit of enteral nutrition is that complex polypeptides and long-chain fatty acids stimulate the production of gut-derived immunoglobulin A, which is important in maintaining the mucosal immunity barrier. Luminal nutrients also help maintain a normal pH and flora, thus diminishing the risk of opportunistic bacterial overgrowth in the bowel.

In addition to the physiologic, metabolic, and immunologic benefits of enteral nutrition, safety and cost benefits exist. Enteral feedings are considered safer than parenteral nutrition as there is a less risk of hyperglycemia, which may be the reason why parenteral nutrition–nourished patients were at a greater risk for infectious complications. With the advent of aggressive hyperglycemia management, this risk may be eliminated and may partially explain the differences seen in older studies of parenteral versus enteral nutrition. Additionally, there are obvious cost benefits, as tube feedings are in general cheaper than parenteral nutrition formulations.

Gastrointestinal Function

Although enteral nutrition is generally the preferred method for nutritional support in malnourished patients or patients at risk for developing malnutrition, an intact and well-functioning GI tract is required. Postoperative ileus is frequent, reflects functional immobility of the GI tract,

and is typically proportional to the amount of manipulation the bowel sustained during the surgical intervention. Contraindications to enteral feedings are usually relative or temporary and include short, obstructed, or perforated bowel, a GI tract in discontinuity, protracted vomiting, fistulas, or active GI ischemia. ESPEN and the European Society of Intensive Care Medicine endorse contraindications to enteral nutrition and suggest withholding enteral nutrition in critically ill patients with uncontrolled shock, uncontrolled hypoxemia and acidosis, uncontrolled upper GI bleeding, gastric aspirate >500 mL/6 hr, bowel ischemia, bowel obstruction, abdominal compartment syndrome, and high-output fistula without distal feeding access.[45,75] The ASPEN/SCCM recommendations are similar.[5]

Complications of Enteral Nutrition

Despite the numerous benefits of enteral nutrition, it is not completely free of complications. These can be categorized into access-related, functional, and metabolic and are summarized in **Table 3.12**. In general, these can be avoided with meticulous care while inserting and maintaining feeding tubes, considering using nasal bridles,[76] ensuring head-of-bed elevation to minimize risk of aspiration, using motility agents when gastric motility is suboptimal, closely monitoring patients' metabolic profile and adjusting content, or adding bulking agents if osmotic diarrhea develops.

Enteral Feeding Formulations

Enteral feedings are generally categorized into intact or polymeric, hydrolyzed or monomeric, or modular. With the intact or polymeric formulations, protein, carbohydrate, and lipid molecules exist in an unaltered form. Hydrolyzed or monomeric formulations contain predigested proteins, simple sugars, and medium-chain triglycerides. Modular feeds typically contain one type of fuel, carbohydrate, lipids, or fat, and can be combined to address each patient's specific needs. Despite previous enthusiasm for specialty feeds for a variety of disease states, current recommendations are for standard polymeric enteral feeding formulas for medical patients. Postoperative surgical patients and patients with traumatic brain injury may benefit from immunomodulating enteral formulations, although the quality of

evidence is low.[5] Some of the most commonly used enteric feeding formulas and their metabolic characteristics are shown in **Table 3.13**.

Macro- and Micronutrient Selection

Protein

An additional topic of debate is whether selection of specific macro- and micronutrients included in nutritional formulas, be it enteral or parenteral, can afford specific benefits to patients receiving them, depending on the underlying pathology. Gluconeogenesis from amino acids (glutamine and alanine) released from muscle protein breakdown cannot be fully suppressed with exogenous glucose and insulin administration, due to the complex hormonal stress response the human body elicits during critical illness, which results in relative insulin resistance. It was postulated, therefore, that exogenous amino acid and oligopeptide infusion would help minimize lean body mass erosion.[77] Therefore, the optimal protein to total energy ratio in critical illness was previously unknown. More recent studies in critical ill populations suggest that provision of protein is more closely linked to outcome than provision of total energy in the forms of carbohydrates and fats.[5] In addition, the dose of protein required by critically ill patients appears to be higher than previously thought. At least two studies have demonstrated better outcomes when high-protein targets were met.[78,79]

Table 3.12 Enteral Nutrition–Related Complications

Complication	Etiology
Access-Related	
Feeding tube malposition, clogging, and accidental removal	The feeding tube can be misplaced in the tracheobronchial tree; it can become clogged with dense tube feedings or inadequately crushed medications or be accidentally removed
Oro/nasogastric or enteral tube perforation of the proximal gastrointestinal tract or tracheobronchial tree	Accidental puncture of the wall of the structure the feeding tube in placed into
Pressure ulcers at skin entry site and sinusitis	A foreign body is continuously pressing against healthy skin and increases risk of bacterial colonization of the nasal passages
Functional	
Nausea, vomiting, and abdominal distension	Usually due to delayed gastric emptying
Diarrhea	Usually polyfactorial, but high protein content and high osmolarity of enteral feedings are the most common culprits
Metabolic	
Electrolyte abnormalities	When enteral nutrition content is inadequate to cover daily needs. Hyperosmolarity may be a consequence when calorically dense enteral feedings are administered
Volume overload	From excess sodium and water loading, typically in patients with preexisting heart failure
Hyperglycemia	

	Less common than in patients receiving TPN but may manifest in patients with diabetes or impaired glucose tolerance or can herald sepsis

Glutamine

10 Glutamine is the most abundant nonessential amino acid and in humans, it is predominantly released with skeletal muscle proteolysis. It is one of the key precursors for hepatic gluconeogenesis at times of stress, and low glutamine levels have been associated with poor outcomes in critical illness, as it is an important nutrient necessary for the function of immune cells, enterocytes, and hepatocytes. It has been postulated that low glutamine levels are a consequence of muscle wasting, and a meta-analysis of early randomized controlled trials suggested that glutamine supplementation may help decrease infectious complications, hospital length of stay, and even mortality.[80] However, this finding has not been replicated in newer, higher-quality studies, and, in fact, it appears that aggressive glutamine supplementation may increase risk of death in patients with organ failure.[81–83] These findings do not support glutamine supplementation routinely. Its supplementation may be beneficial when depletion is severe or when the intestinal mucosa is damaged by chemo- and/or radiation therapy.[84] Similarly, arginine supplementation may be associated with a lower infectious risk and shorter hospital length of stay; however, no currently available evidence supports its use during critical illness.[85]

Table 3.13 Commonly Used Enteral Nutrition Formulations

Product Name	Calories (per mL)	Protein (g/L)	Carbohydrates (g/L)	Fat (g/L)	Fiber (g/L)	Osmolality (mOsm/L)	Special Features
Tube Feeding Formulations							
Osmolite 1 Cal	1.06	44	144	35	0	300	Isotonic
Jevity 1.2 Cal	1.2	56	169	39	18	450	High protein with fiber
Jevity 1.5 Cal	1.5	64	50	50	22	525	Concentrated calories with fiber
Promote with Fiber	1	63	138	28	14	380	Very high protein with fiber
Nepro with Carb Steady	1.8	81	161	96	13	745	Renal formula

Fatty Acids

The omega-3 fatty acids, which are found in fish oil preparations, have been shown to have anti-inflammatory effects as opposed to omega-6 fatty acids, found in soybean oil, which appear to be proinflammatory.[86] Some initial studies suggested that administration of high omega-3 to omega-6 fatty acid ratio formulas may benefit critically ill patients.[87,88] However, more recent, higher-quality studies have failed to show a beneficial effect of omega-3 fatty acid preparations in either enteral or parenteral nutrition formulations.[89,90] Currently, the lack of high-quality evidence precludes any recommendation on the use of specific lipids in critically ill patients.

Micronutrients

Micronutrients—electrolytes, vitamins, and trace elements—are administered in critical illness to prevent deficiencies and associated complications. With repletion of micronutrient stores after starvation, refeeding syndrome can occur. Refeeding syndrome is associated with the reintroduction of feeding after a period of caloric deprivation and is characterized by hypophosphatemia. This can be life-threatening and present with lactic acidosis, cardiac arrhythmias, worsening respiratory failure, and even heart failure. Therefore, routine administration of physiologic doses of micronutrients during critical illness is warranted. Provision of therapeutic doses of trace elements (selenium, copper, zinc, and iron) and vitamins (E, C, and beta-carotene) with antioxidant activity has also been proposed[91]; however, a recent randomized controlled trial failed to demonstrate a benefit.[82] Selenium supplementation may also be beneficial in subjects with selenium deficiency, and the potential benefit is supported by a recent meta-analysis.[92]

Nutritional Access

Parenteral Nutrition Access

Parenteral solutions are administered through a central venous catheter, generally inserted in the subclavian or internal jugular vein, or through peripherally inserted central catheters (PICCs) that are typically inserted via veins of the antecubital fossa with the tip in the atriocaval junction. Current

recommendations are to choose the smallest device possible and always "reserve" one lumen to be dedicated to the parenteral nutrition administration.[57] Peripheral parenteral nutrition (PPN) can be infused through peripheral venous cannulas. Peripheral intravenous feedings may be used for infusion of protein, lipid, and lower concentration dextrose solutions. PPN is limited in caloric delivery, due to the large volumes it would require to meet daily demands, but it avoids central venous cannulation, which has considerable complications. It can be considered for short-term parenteral nutrition, for example, in the case of postoperative patients with ileus expected to resolve in a few days.

Enteral Nutrition Access

11 In the acute phase of surgical illness, enteral feedings are often administered through oral or nasal enteric feeding tubes. The tip of the tubes can either reside in the stomach—gastric—or the duodenum or proximal jejunum—"postpyloric." The stomach is easily accessed with a soft flexible feeding tube. Intragastric feedings provide several advantages compared to more distal GI tract feedings, as the stomach has the capacity and reservoir for bolus feedings. Feeding into the stomach stimulates the biliary and pancreatic axis, with trophic benefits for the entire small bowel. Finally, gastric secretions exert a dilutional effect on tube feeding osmolarity, reducing the risk of diarrhea. An important risk of intragastric feedings is regurgitation of gastric contents, with possible aspiration into the tracheobronchial tree. This risk is highest in patients with altered mental status or who are on neuromuscular blockade. Routine monitoring of gastric residual volumes is currently not recommended, as it has not been shown to be associated with a reduction in aspiration events.[93]

First-line therapy for patients with gastric feeding intolerance is the provision of prokinetic agents.[5] Placement of the feeding tube through the pylorus reduces the risk of regurgitation and is advisable in patients with gastric feeding intolerance that does not resolve with prokinetic agents.[5,94,95] Nasoduodenal/nasojejunal tubes are smaller in caliber and therefore more comfortable for patients; however, they are more prone to clogging. Patients who repeatedly remove their catheters may be candidates for feeding tube

bridles. Placement of nasogastric or nasoduodenal tubes should always be confirmed radiographically prior to initiation of feedings.

Patients with chronically impaired mental status, an inadequate swallowing mechanism, or dysphagia and those with oropharyngeal or proximal GI tract pathology may be candidates for longer-term transabdominal GI access. This access is traditionally provided through temporary Stamm gastrostomies, in which a small laparotomy incision is made, and the gastric lumen in the midportion of the gastric body is accessed, while a transabdominal large-bore feeding tube is secured in place with concentric purse string sutures. This procedure is more frequently performed with a minimally invasive laparoscopic approach now. Percutaneous endoscopic gastrostomy (PEG) tubes can be inserted and provide access for gastric feedings, without the need for laparotomy, general anesthesia, and even a trip to the operating room, as they can be performed at the bedside under endoscopic guidance. Using monitored anesthesia care, a gastroscope is advanced transorally into the stomach and helps transilluminate the anterior gastric wall through the abdominal wall. A small abdominal incision is made over the area of maximal transillumination, ideally over the midportion of the gastric body, and through an angiocatheter, a wire is advanced into the gastric lumen, which is snared and pulled back out of the mouth with the gastroscope. The wire is looped around the PEG tube and pulled through the abdominal wall in an antegrade fashion, until only the head of the feeding tube remains in the stomach, with the rest of it being extracorporeal. The inner part of the PEG tube is confirmed to be in correct position and the feeding tube is secured in place. This technique may be difficult in obese patients, whose abdominal walls can be hard to transilluminate. Fluoroscopic approaches can also be used.

Feeding jejunostomies can be considered following any major abdominal procedure if the need for prolonged enteral nutrition is anticipated and there is preference to feed the small bowel. A loop of proximal small bowel, typically 20 to 40 cm distal to the ligament of Treitz, is elevated and secured against the abdominal wall fascia of the left upper or lower quadrant and is accessed transabdominally with a feeding tube. The tube can be covered for a short distance with bowel serosa, called a Witzel jejunostomy. Feeding jejunostomies are standardly placed via a laparoscopic approach.[96] Dual-lumen transgastric jejunal feeding tubes have the lower morbidity of a

gastrostomy as compared to a jejunostomy with the benefit of small bowel feeding, as well as the passage of jejunostomy tubes through percutaneously placed gastrostomy tubes.

NUTRITIONAL CONSIDERATIONS IN SPECIAL POPULATIONS

Sepsis and Septic Shock

12 In the setting of severe inflammation and fever such as that occurs with sepsis, the BMR increases. Total energy requirements need to be assessed, increasing energy requirements by 20% to 30% for mild or moderate infection and approximately 50% above basal levels in severe infection. Many of the recommendations about nutritional support in the setting of sepsis have been previously discussed. Based on expert consensus, the ASPEN/SCCM guidelines suggest that critically ill patients receive enteral nutrition 24 to 48 hours as soon as the patient is hemodynamically stable.[5] Initiation of enteral nutrition while the patient is still in shock may aggravate impaired splanchnic perfusion.[97] The NUTRIREA-2 study demonstrated an increase in GI complications when patients on vasoactive agents were fed enterally early in the course of septic shock.[52] Provision of goal calories does not need to be achieved, but provision of goal protein has demonstrated benefit.[78] Supplemental parenteral nutrition or parenteral nutrition alone is not recommended early in the course of sepsis and septic shock but should be instituted if enteral nutrition is not feasible for a prolonged period.[45] Immunomodulating formulas should not be routinely used.

Acute Respiratory Failure

A condition commonly complicating surgical patients is respiratory failure with the need for prolonged mechanical ventilation. The main concern in mechanically ventilated patients is adequate gas exchange, which includes oxygen and CO_2 transport across the capillary–alveolar membrane. Not uncommonly the indication for ventilatory support is pulmonary infection, which along with a postoperative status, contributes to the overall

hypermetabolism. Hypermetabolism is accompanied by increased oxygen consumption, which drives CO_2 production, as more substrate must be oxidized to support the greater energy requirements. While nutrition commonly takes lower priority in ventilated patients, in whom all efforts are directed toward managing the underlying etiology for the respiratory insufficiency, consideration should be given to the content of the nutritional support, as they may facilitate or prolong weaning, especially in those with chronic CO_2 retention. Despite early enthusiasm for enteral formulations that were high in fat and low in carbohydrate to decrease CO_2 production, this strategy only results in lower CO_2 production in patients who are being overfed.[98] Fluid restriction with energy-dense enteral feeds may be appropriate in patients with fluid overload.[5]

Acute Renal Failure

Renal failure affects the body's ability to clear the by-products of protein metabolism but does not change the catabolic rate or the protein requirements. Therefore, a careful balance needs to be achieved between the need for protein and to limit uremia. When acute surgical stress is superimposed, consideration for potentially earlier or more aggressive renal support should be given so that the body is not restricted of protein, which is critical during the hypermetabolic phase of acute disease. Based on expert consensus, patients with acute renal failure should be placed on a standard enteral formulation, energy (25 to 30 kcal/kg/day) provision, with standard recommendations for protein (1.2 to 2 g/kg actual body weight per day).[5] Only if significant electrolyte abnormalities develop, a specialty formulation designed for renal failure should be utilized. In patients on renal replacement therapy, patients should receive increased protein, up to a maximum of 2.5 g/kg/day. Protein should not be restricted in patients with acute renal failure as a means to avoid or delay initiating renal replacement therapy.[5]

Acute Liver Failure

Patients with liver disease are often chronically malnourished. These individuals are protein depleted, yet tolerate protein poorly, due to their

likelihood to become encephalopathic with high nitrogen intake. Due to liver damage and portosystemic shunting, these patients can develop derangements in circulating levels of amino acids. The plasma aromatic to branched chain amino acid ratio is increased, favoring the transport of aromatic amino acids across the blood–brain barrier. These amino acids are precursors of neurotransmitters that can worsen encephalopathy and lethargy. Therefore, historically, protein restriction was used to help reduce hepatic encephalopathy. This strategy may worsen nutritional status, decrease lean muscle mass, and ironically lead to decreased ammonia elimination. Therefore, protein should not be restricted as a management strategy aimed at reducing hepatic encephalopathy.[99,100] Using solutions enriched in BCAAs and deficient in aromatic amino acids in liver failure patients has failed to show benefit in patients being treated with lactulose and luminal-acting antibiotics.[5]

Complications of Gastrointestinal Surgery

After GI surgery, whether elective or emergent, complications such as anastomotic leaks and enteroatmospheric or enterocutaneous fistulae can complicate nutritional management. In critically ill patients with surgical complications after abdominal or esophageal surgery who are unable to eat orally, enteral nutrition, rather than parenteral nutrition, should be utilized unless the patient is in discontinuity, has obstruction of the GI tract, or has abdominal compartment syndrome.[45] GI cutaneous or GI atmospheric fistulas with high output (commonly defined as having output >400 mL/24 hr) represent a classic indication for long-term parenteral nutrition. Oral intake in patients with such fistulas typically results in greater output, especially in fistulas involving the proximal GI tract, which can lead to dehydration and significant metabolic disturbances and adversely affect the ability of the fistula to heal. In the case of an unrepaired anastomotic leak or fistula, a feeding access distal to the defect should be the goal to allow for enteral nutrition.[45] If distal feeding access is not achieved, parenteral nutrition is appropriate. Parenteral nutrition has been shown to increase spontaneous rate of closure of enterocutaneous fistulas by improving overall nutritional status in the host or improving perioperative outcomes in those requiring surgical therapy. Somatostatin and analogs have been used to aid with fistulous output

and spontaneous closure with varying results. In patients who are treated via a damage control laparotomy approach or who have an open abdomen, early enteral nutrition is recommended[5] as long as there is intestinal continuity. Additional protein supplementation may be appropriate due to the high protein loss of the exudate.[101–103]

Burns

Burn victims often suffer from prolonged ileus, which encumbers enteral nutritional support. Even if the bowel is usable and patients are not on mechanical ventilation, they are frequently unable to consume adequate calories, due to anorexia of severe injury and extreme catabolism. Based on expert consensus, early (within 4 to 6 hours of injury if possible) enteral nutrition should be administered to all burn patients to meet estimated energy needs. Parenteral nutrition should only be reserved for those patients for whom enteral nutrition is not feasible or not tolerated. Enteral nutrition has been associated with fewer infections and improved survival when compared with parenteral nutrition.[104] Patients with burns should also be provided protein in the range of 1.5 to 2 g/kg/day.[5] Indirect calorimetry is recommended to assess energy needs in burn patients with routine repeated measures.

Acute Pancreatitis

Mild pancreatitis is defined by the absence of organ failure and local complications, while moderate to severe acute pancreatitis is defined by transient organ failure.[105] Differentiating patients with severe acute pancreatitis from those with mild severity helps identify those patients who will require early provision of nutrition therapy. ASPEN/SCCM recommends that the initial nutrition assessment in acute pancreatitis evaluate disease severity to guide nutritional therapy and that frequent reevaluation is performed.[5] Patients with moderate to severe acute pancreatitis should have a nasal or oral enteric tube placed and enteral nutrition with a standard polymeric formulation initiated at a low rate and advanced to goal as fluid volume resuscitation is completed.[5] This is based on studies that have demonstrated benefit from early enteral nutrition.[106–110] Parenteral nutrition

should be avoided when possible, but if the patient is unable to be fed enterally, parenteral nutrition should be instituted 7 days after the onset of the critical illness.[74] Probiotics may be beneficial in patients with acute pancreatitis, based on a meta-analysis from 2010.[111]

Trauma

Trauma patients have a high risk of developing septic complications and multiple-organ failure. Early enteral nutrition has been shown to reduce septic complications[112,113] and reduce the rate of organ failure when initiated within 24 hours.[114] Both ASPEN/SCCM and ESPEN recommend early enteral feeding with a high protein polymeric formulation in the immediate posttrauma period once the patient is hemodynamically stable.[5,45] Immunomodulating formulae may be considered in severely injured patients.[5] For patients with traumatic brain injury, early feeding is associated with decreased infection rates and better outcomes.[115]

Solid Organ Transplant

Malnutrition is a major factor influencing outcome after transplantation. Candidates for solid organ transplantation should have regular assessment of their nutritional status, and if meet criteria for malnutrition, oral nutritional supplements or even *tube feeding* is advised.[32] *Since there is* often a long preoperative waiting period, there is time to try to replete patients nutritionally. In addition to malnutrition, obesity remains a significant metabolic risk factor for the outcome of patients undergoing organ transplantation.[116] Despite some suggestion of benefit of immunomodulating formulas in the literature,[117] a consistent benefit has not been demonstrated. After solid organ transplantation, early intake, either orally or via a feeding tube, within 24 hours is recommended. *No strong recommendations are made for the use of probiotics, parenteral nutrition, or omega-3 fatty acid provision. Long-term nutritional monitoring and counseling are recommended.*[32]

Bariatric Surgery

Bariatric patients pose a special challenge, as they are at an increased risk for several macro- (usually protein) and micronutrient deficiencies (most commonly vitamins D and B_{12}, calcium, iron, folic acid, zinc, and selenium).[118–120] Nutritional support of the obese or post–weight loss surgery patient is particularly complex because of the balance needed between minimizing overfeeding and avoiding the hypercatabolic state. There is widespread consensus that early oral nutrition after bariatric surgery is appropriate.[121,122] Clinical practice guidelines recommend a preoperative assessment including screening for malnutrition and deficiency in vitamins and trace elements.[123] Early postoperative enteral nutrition is advocated and supplementation with protein in order to meet daily requirements of 60 g of protein per day.[32] Standard oral supplements should be avoided in bariatric patients as they can cause dumping syndrome. Postoperative nutritional follow-up by a dedicated team is essential to monitor weight loss and prevent deficiencies of micronutrients. ERAS principles have been applied and appear to be beneficial in bariatric surgery.[124] In case of a major complication requiring reoperation, recommendations are no different from those for patients undergoing any major *abdominal surgery*. Despite the excessive fat stores, critically ill postoperative bariatric patients should receive early and timely nutrition, as protein–calorie malnutrition does occur. Consideration for indirect calorimetry, which allows accurate estimation of the caloric requirements, is appropriate, and early involvement of a nutritionist is essential.

Geriatrics

Attention to appropriate nutritional support of the geriatric or frail patient is of paramount importance, both in the perioperative stage and in the ICU, given the multiple physiologic alterations seen in both frailty and older age. These alterations include greater ratio of fat to muscle mass, decreased cardiac and pulmonary reserves, poor dentition, polypharmacy, and a high incidence of malnutrition. Malnutrition rates may be as high as 85% in nursing home residents.[125,126] Compared to younger cohorts, elderly patients are more likely to have comorbid disease processes affecting their general nutritional status, including diabetes, cancers, cardiac, pulmonary, and renal

insufficiency. Given that a certain degree of lean body mass loss is to be expected in this demographic, a higher protein intake (>1.5 g/kg/day) should be the goal preoperatively in the elderly undergoing elective surgery or early in the recovery phase after emergency procedure or acute surgical illness.[127,128]

Obesity

Overweight and obese patients have become more prevalent in ICUs as the prevalence of obesity increases in the general population. As a general rule, an isocaloric high-protein diet can be administered to obese patients, preferentially guided by indirect calorimetry measurements and urinary nitrogen losses. It is still unclear whether overweight and obese critically ill patients have a higher nitrogen loss than patients with a normal BMI when adjusted for actual lean body mass. Other metabolic derangements are common such as decreased glucose tolerance, altered lipid metabolism, lack of micronutrients, and decreased gut motility.[129] Recommendations for early enteral nutrition apply similarly to overweight and obese patients as to other critically ill and postoperative patients.[45] High-protein hypocaloric feeding should be implemented to preserve lean muscle mass whenever feasible.[5]

The Pathogenesis of Obesity and Metabolic Disease

Robert W. O'Rourke

Key Points

1. Obesity is a polygenic phenomenon, and up to 70% of the propensity to obesity is due to genetic influences.
2. Epigenetics and environment interact with genetics to produce the obesity phenotype.
3. Control of food intake via satiety and hunger is a dominant mechanism of body weight regulation, but other processes contribute, including but not limited to metabolic rate, adipocyte physiology, and the microbiome; alterations in these processes are linked to the development of obesity.
4. The hypothalamic feeding center (HFC) is a dominant central control site of energy homeostasis, with multiple afferent inputs and diverse efferent outputs to all organ systems.
5. Bariatric surgery regulates body weight via multiple mechanisms that are qualitatively different from responses to nonsurgical weight loss.
6. Nutrient excess is a key early trigger in the development of cell stress that underlies the pathogenesis of metabolic disease.
7. Adipose tissue acts as a critical nutrient "buffer" to protect other tissues from nutrient excess; as adipose buffering capacity is overwhelmed, nutrient excess overflows to all tissues, inducing metabolic disease.
8. Hepatic steatosis and peripheral and central insulin resistance are dominant features of metabolic disease, but metabolic disease encompasses all organ systems with pleiotropic pathology.

GENETICS OF OBESITY

Metabolic Thrift, Genetics, and Epigenetics

The *thrifty gene hypothesis*, proposed by geneticist Neel, posits that humans are predisposed to a *thrifty metabolism* by genes selected over eons of

evolution in environments characterized by food scarcity.[1] These genes were adaptive in our ancient past but lead to a blossoming of obesity in our modern *obesogenic environment*. While competing theories exist, such as predation release and genetic drift, Neel's hypothesis remains the basis of a modern understanding of obesity as a genetic phenomenon. *Quantitative analysis of twin studies,* in which phenotypic traits of thousands of twin pairs are analyzed using statistical methods based on Mendelian principles, consistently demonstrate that approximately 70% of the tendency 1 to obesity is due to genetics.[2] *Genome-wide association studies* (GWAS), which involve sequencing thousands of genomes and correlating single-nucleotide polymorphisms (SNPs) with phenotypic traits and disease states, permit study of genetics at the nucleotide level. GWAS studies have identified thrifty genes that Neel postulated decades earlier. Many obesity SNPs lie within genes associated with body weight regulation. Others lie in genes not clearly related to energy balance, but instead regulate neural and limb development, DNA repair, and other cellular functions, testament to the fact that the processes that regulate energy homeostasis overlap with all aspects of physiology. Emerging data demonstrate that the effect size of each individual SNP's contribution to the obesity phenotype is small, on the order of 1% to 3%, and that potentially hundreds of SNPs contribute to obesity. Obesity, like many chronic diseases, is a complex polygenic phenomenon. GWAS studies have so far identified over 50 SNPs that correlate with human obesity.[3]

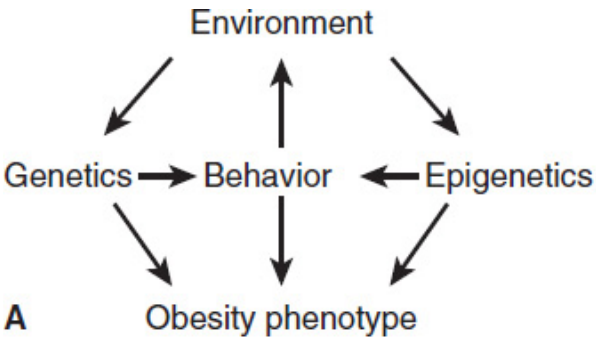
The *thrifty phenotype hypothesis* was proposed by Hales and Barker in 1992 to explain the observation that infants born to malnourished mothers are at increased risk of adult obesity and metabolic disease compared to offspring born of the same mothers during well-nourished pregnancies.[4] The fetus was presumed to be responding to instability in environmental food resources by adjusting its phenotype toward a thrifty metabolism, a phenomenon termed *fetal programming*. A similar response was subsequently observed in fetuses born of obese and diabetic mothers.[5] Excess or scarcity of nutrients may be interpreted similarly by the fetus as signs of unstable food resources, explaining the similar effect of maternal under- and overnutrition on offspring metabolic phenotype. Subsequent research demonstrated that these effects are mediated by *epigenetic* mechanisms, covalent modification of the genome independent of changes in

Watson–Crick base-pair sequence, 2 including but not limited to DNA methylation, glycosylation, and histone modification, changes that persist for one or more generations. Epigenetic modification of the genome is widespread, occurs primarily during fetal development but extends into adulthood, and regulates normal developmental processes as well as pathologic responses. Epigenetics allows the fetus to respond in utero to environmental cues delivered by changes in maternal homeostasis, the so-called "weather forecast" model.[6] Epigenetic modifications in response to fetal under- and overnutrition have been demonstrated in animals and humans, play an important role in disease pathogenesis, and suggest that intervention must occur early, prior to birth, to prevent adult obesity and metabolic disease.

Human Metabolic Diversity and Environment

The multiple thrifty SNPs in the human genome impart genetic heterogeneity that underlies the intrinsic variability of human body habitus and metabolism, with a wide range of body types from lean to obese, gynecoid and android obesity phenotypes, variability in age of onset, triggers, and severity of obesity, response weight loss interventions, as well as differences in satiety and hunger thresholds, metabolic rates, and multiple specific metabolic functions. *Metabolic diversity* has allowed humans to adapt to a wide range of habitats. Multiple examples exist of human subpopulations whose genetic heritages are adaptive in their native environments, but maladaptive in a modern obesogenic environment. Polynesians, for example, manifest a marked genetic propensity to obesity and insulin resistance, traits that provided a selective advantage in the ancient South Pacific environment, but which impart a high risk for obesity and metabolic disease in our modern environment. Similar human subpopulations metabolically adapted to specific niche environments but at high risk for metabolic disease in industrialized society include Inuit Eskimos, Aboriginal Australians, and Pima Indians (**Fig. 4.1**). Environment plays a critical role in the obesity phenotype. Modern environmental contributors include an excess of processed food and a structured *built environment* that discourages physical activity. Modern processed food is not only calorie dense but also highly palatable, stimulating central nervous system reward centers and

hunger/satiety circuits not designed for chronic stimulation, thus reinforcing overeating. Physical activity is markedly decreased in our modern environment. Paleolithic humans were estimated to have consumed 30% more calories than modern humans but engaged in significantly higher levels of physical activity.[7] Other factors also contribute, including disruption in Circadian rhythms, home temperature stability, and assortative mating patterns. An evolving field of environmental engineering has arisen to address these issues.



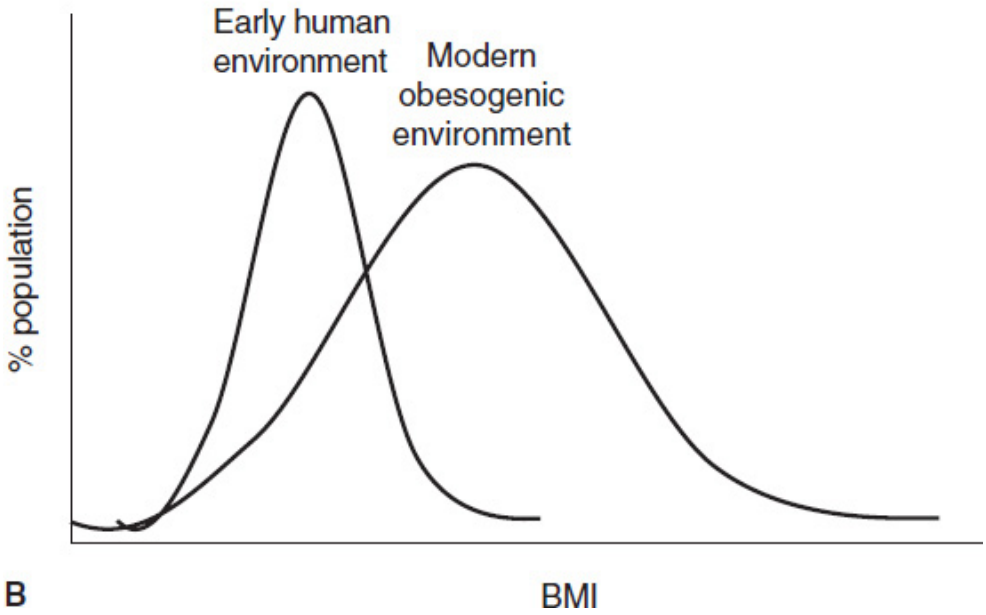


Figure 4.1 Interactions between environment and genetics dictate phenotype. **A:** Environment alters genetics over millennia, while the effects of environment on epigenetics take place over generations. In the case of humans, genetics dictates our behavior which in turn has led us to create an obesogenic environment, creating a vicious cycle that exacerbates the obesity epidemic. **B:** The obesity phenotype blossoms in a modern obesogenic environment, with the population BMI curve broadening and shifting rightward, with an increase in median BMI. The increase in median BMI is relatively modest, but a substantially larger percentage of people populate overweight and obese BMI ranges. Of note, the schematic graphs shown are similar to those that describe the shift in U.S. population BMI NHANES data from the late 1970s to the early 2000s.

3 PHYSIOLOGY OF OBESITY

The Adipostat

A dominant determinant of systemic metabolic homeostasis is the quantity of existent adipose tissue stores, the adequacy of which is determined by the hypothalamic feeding center (HFC). The HFC receives multiple afferent neural and hormonal inputs from all organ systems, including adipose tissue, and orchestrates a range of responses via efferent outputs that monitor and maintain adipose tissue stores, regulate all aspects of metabolism, and which together comprise the *adipostat*, the sum total of all processes that defend body weight. The amount of adipose tissue "deemed" adequate by the HFC varies among individuals and is dictated by multiple poorly understood thrifty genes which collectively determine the *adipostat set-point*. The hypothalamus of a lean person "considers" a lower amount of adipose tissue to be adequate, while the hypothalamus of an obese person requires higher levels of adipose tissue stores. Weight loss alerts the HFC to deviation from the adipostat set-point and triggers robust compensatory responses that restore adipose tissue mass to baseline levels, including increased hunger, decreased satiety, and decreased metabolic rate. HFC-mediated metabolic responses are characterized by tight regulation; deviation outside the range of these responses for more than limited periods of time is not possible based on conscious choice, explaining the high failure rate of diet-induced weight loss, and the lack of efficacy of liposuction for weight loss, as reduction in adipose tissue mass activates compensatory mechanisms that restore adipose tissue mass to set-point levels. Bariatric surgery–induced weight loss is an exception to this rule, inducing poorly understood paradoxical responses that bypass the adipostat. Multiple physiologic mechanisms comprise the adipostat and regulate body weight. Most important in humans are the collective satiety and hunger systems that regulate food intake. Also important are mechanisms that control metabolic rate, adipocyte physiology, and the microbiome.

Satiety and Hunger

Regulation of food intake is the dominant mechanism by which humans control body weight. Food intake is controlled by a family of proteins that regulate satiety and hunger primarily by acting on receptors within the hypothalamus. These diverse proteins are secreted by multiple organ

systems, including but not limited to adipose tissue, the gut, the liver, and skeletal muscle.

The Ob mouse, a mutant strain described in 1950, manifests an obese phenotype along with immune, endocrine, and reproductive abnormalities. The Ob mouse harbors an inactivating point mutation in the *leptin* gene (Gr *leptos*, thin). Leptin is a 16-kD satiety hormone secreted by adipose tissue in response to a meal that binds receptors in the HFC and induces satiety. Leptin mediates communication between adipose tissue, gut, and brain that signals the status of adipose tissue stores, which in turn dictates food intake. As such, leptin is a paradigmatic mediator of the adipostat and an example of the complex interorgan communication that underlies its function (**Fig. 4.2**). Soon after cloning of the leptin gene in 1994,[8] rare humans with leptin mutations were identified with an Ob phenotype that was reversed with administration of exogenous recombinant leptin. Similar therapy was ineffective in common human obesity, which is not due to a single leptin mutation, but rather is polygenic and characterized by hypothalamic resistance to leptin satiety effects. Nonetheless, the discovery of leptin led to an explosion of research, and over the ensuing decade multiple satiety and hunger proteins were described.

The control of feeding behavior and nutrient intake is a 4 highly regulated process centered in the hypothalamus, which integrates information regarding nutritional status, environment, and energy expenditure via central and peripheral orexigenic and anorexigenic signals. Peripheral messengers include signals from adipose tissue (*adipokines*), including leptin and adiponectin, *cytokines*, such as TNF-α and IL-6, and *gut peptides*. Among this diverse latter class of mediators, ghrelin is a dominant orexigen. Ghrelin is expressed primarily by oxyntic glands in the fundus of the stomach, but is also produced in the hypothalamus. Encoded by five exons, preproghrelin undergoes endoproteolytic processing and posttranslational modification to yield des-acyl ghrelin and acyl ghrelin. Acyl ghrelin, the active form, regulates feeding, metabolic activity, and insulin secretion. The ghrelin receptor is a member of the G protein–coupled receptor family and is widely distributed in central and peripheral tissues, including the pituitary gland, hypothalamus, pancreas, stomach, and intestine. In humans, plasma acyl-ghrelin levels increase with fasting and decrease after feeding, and intravenous administration of ghrelin induces hunger and stimulates oral

intake. Ghrelin secretion is increased by weight loss and caloric restriction, and depressed in obese subjects. Ghrelin antibodies and ghrelin receptor antagonists are under study as therapeutic agents.

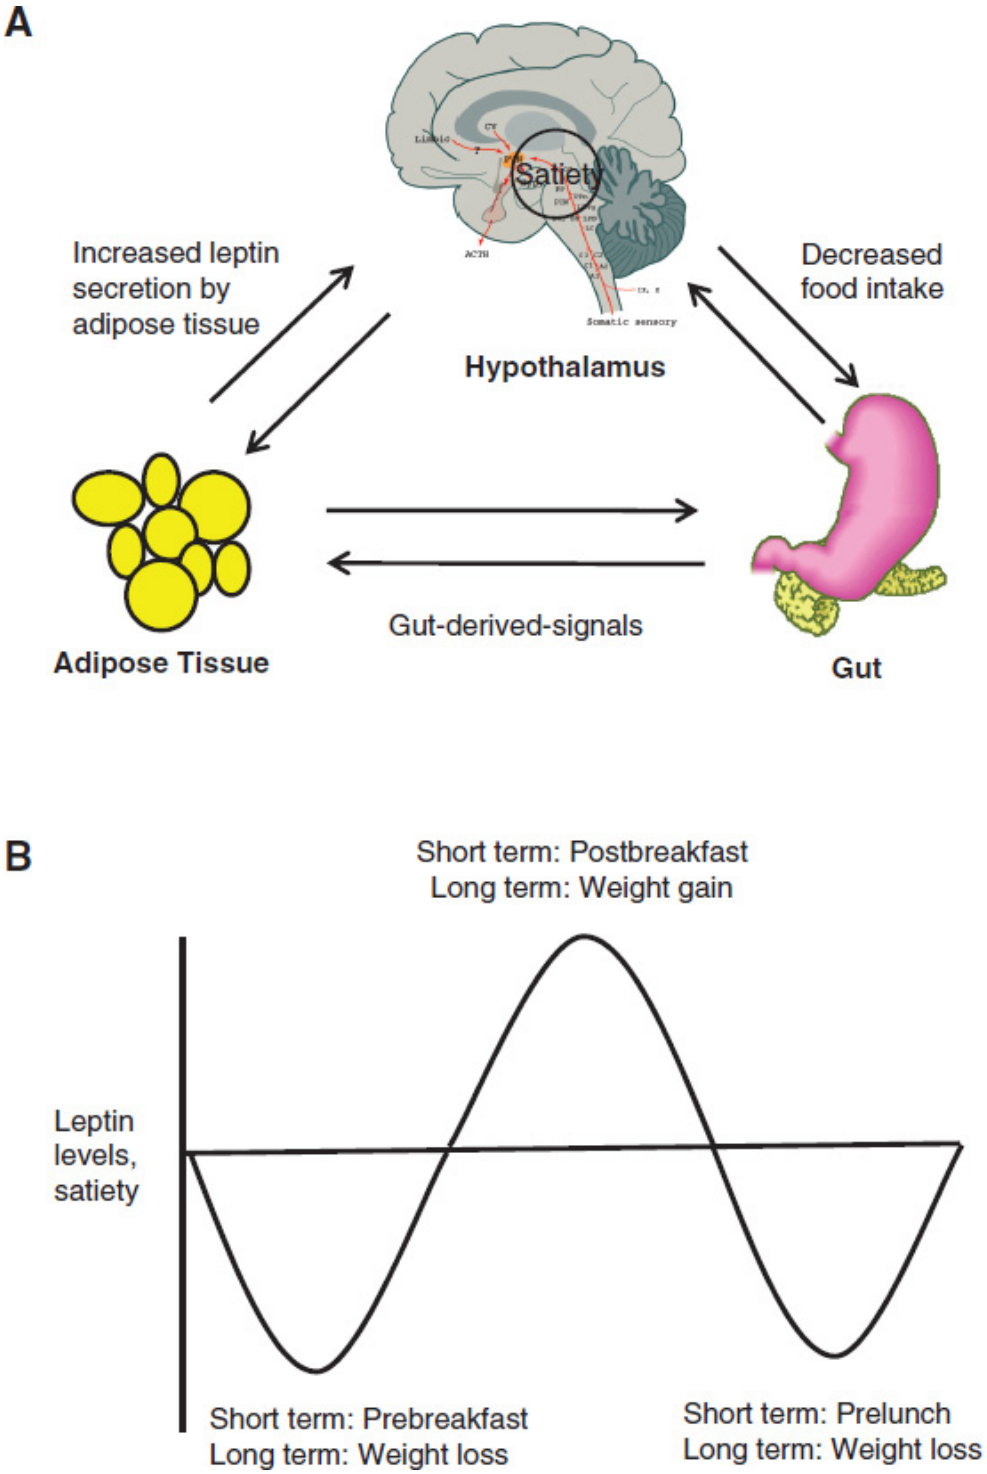

Figure 4.2 Leptin mediates communication between adipose tissue, gut, and brain. **A:** Signals from the gastrointestinal tract triggered by a meal circulate to adipose tissue and induce adipocyte leptin secretion. Leptin circulates to the hypothalamus, where it binds receptors in the arcuate nucleus to induce satiety, leading to decreased food intake. Leptin is one of many signals that mediate bidirectional communication between gut, adipose tissue, and brain. Other organ systems are

also involved, including immune and reproductive systems and the liver. **B:** Leptin regulates allostatic control of short-term and long-term food intake. Postprandial leptin secretion induces satiety for a period of hours, after which leptin levels and satiety wane, prompting food intake. Similarly, leptin, along with other mediators of food intake, controls long-term weight regulation: diet-induced weight loss leads to decreased adipose tissue mass, reducing peak postprandial leptin levels, leading to decreased postprandial satiety and increased food intake at each subsequent meal until adipose tissue mass is restored to set-point levels. In this manner, leptin functions as a component of the adipostat. This allostatic control provides an explanation for rebound weight gain after diet-induced weight loss.

The arcuate nucleus of the hypothalamus is a crucial site for the integration of fasting and feeding signals. Two types of neurons, with opposing actions on feeding behavior, have been identified in the arcuate nucleus. Neurons that express proopiomelanocortin (POMC) and cocaine and amphetamine-related transcript (CART) suppress food intake, reduce body weight, and increase energy expenditure. In contrast, neurons producing neuropeptide Y and agouti gene–related transcript (AgRP) are orexigenic. These cells act to stimulate food intake and reduce energy expenditure. Ghrelin, as well as leptin and multiple other gut peptides, adipokines, and cytokines, directly mediates the activities of these two types of neurons (**Fig. 4.3**).

Other adipokines that regulate satiety include adiponectin, visfatin, apelin, and lipocalin; gut peptides with diverse effects on food intake and metabolism include glucose-dependent insulinotropic peptide (GIP), glucagon-like peptide-1 (GLP-1), nesfatin-1, oxyntomodulin, pancreatic polypeptide, cholecystokinin, amylin, glucagon, somatostatin, cholecystokinin, and insulin. Cytokines, including TNF-α and IL-6, in addition to immunoregulatory functions, also play important roles in the control of food intake. TNF-α, for example, mediates anorexigenic responses in the context of cachexia and inflammatory states. Virtually all adipokines, gut hormones, and cytokines have multiple overlapping functions that include regulation of satiety and hunger, immune function, glucose homeostasis, lipid metabolism, and endocrine and reproductive function (**Fig. 4.4**). This functional diversity speaks to the intimate association of energy homeostasis with all aspects of physiology.

Genetic polymorphisms in the melanocortin 4 receptor gene, which regulates satiety and hunger responses and the HFC set-point, are implicated in 5% of cases of human obesity. Similar polymorphisms associated with

obesity exist with the genes encoding leptin and its receptor, ghrelin, neuropeptide Y, adiponectin, GLP-1, and other genes associated with the control of satiety and hunger. These observations demonstrate that variability in the genes that regulate food intake contribute to the development of human obesity.

Metabolic Rate

In obese subjects who lose weight with diet, total energy expenditure is decreased up to 20% beyond that expected by loss of fat and fat-free mass alone, and is accompanied by a corresponding decrease in voluntary physical activity.[9] Compensatory decreases in energy expenditure counteract caloric restriction and contribute to adipostat responses that resist declines in adipose tissue mass. Studies of overfeeding and weight gain in obese subjects demonstrate converse changes with a compensatory increase in total energy expenditure. Importantly, overfeeding studies in twin cohorts demonstrate a significant genetic component to variability in energy expenditure responses to overfeeding, suggesting that variability in metabolic rate responses to weight loss contributes to the development of obesity in those at risk.[2] Differences in sympathetic nervous system activity contribute to variability in metabolic rate. Obese humans demonstrate decreased sympathetic nervous system activity, and higher levels of sympathetic nervous system activity predict successful diet-induced weight loss. Differences in endocrine responses also contribute, with obese humans manifesting differences in thyroid hormone and catecholamine balance associated with decreased metabolic rates. At the cellular level, differences in energy utilization and thermogenesis play an important role. Skeletal muscle energy utilization efficiency is increased in humans who achieve successful weight loss and decreased in those who gain weight. Furthermore, obese humans manifest decreased skeletal muscle nonexercise-induced thermogenesis and diet-induced thermogenesis,[10] suggesting that fundamental differences in cellular energy homeostasis contribute to obesity. The mechanisms underlying these variable cellular responses are not fully defined, but differences in uncoupling protein (UCP) function are implicated. UCP proteins uncouple oxidative phosphorylation from electron transport in mitochondria, creating a proton leak that generates heat rather than ATP. The

role of UCPs in the pathogenesis of obesity is an important area of active research. UCP function is highly variable and genetically determined in mice, and polymorphisms in UCP genes correlate with obesity and metabolic disease in humans, supporting a role for genetic variability in UCP function in obesity pathogenesis. Transgenic mice overexpressing UCP-1 under control of the adipose tissue–specific AP2 promoter are resistant to obesity, suggesting the potential for therapy for obesity based on manipulation of cellular thermogenesis and metabolic rate.

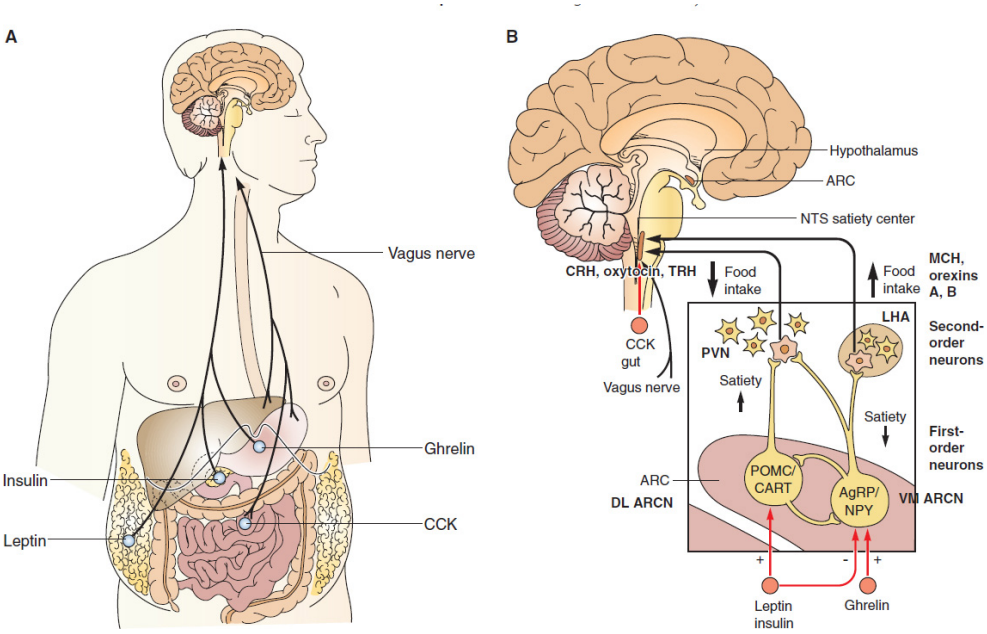

Figure 4.3 A simplified schematic of the hypothalamic feeding center and its primary afferent signals: Multiple hormones secreted by the gastrointestinal tract and adipose tissue act as afferent signals that regulate the arcuate nucleus (ARCN) within the hypothalamic feeding center function. These signals impact on first-order ARCN neurons, which in turn communicate with second-order paraventricular nucleus (PVN) and lateral hypothalamic area (LHA) neurons to coordinate behavioral and metabolic output. PVN signaling is primarily anorexigenic and catabolic, and is enhanced by leptin and insulin, while LHA signaling is primarily orexigenic and anabolic and inhibited by leptin and insulin. Higher-order anorexigenic PVN outputs include corticotropin-releasing hormone (CRH), oxytocin, and thyrotropin-releasing hormone (TRH); higher-order orexigenic LHA outputs include melanin-concentrating hormone (MCH) and orexins. **A** and **B**: Both pathways negatively regulate the other. Other peripheral and central mediators stimulate first- and second-order neurons as well, including ghrelin, CCK, GLP-1, serotonin, endogenous cannabinoids, and norepinephrine.

Adipocyte Physiology

Adipocytes arise from mesenchyme-derived *adipocyte stem cells* (ASCs), also termed *preadipocytes*. ASCs are pluripotent, and depending on the stage of differentiation, may give rise to adipocytes, fibroblast, myocytes, and other cell types. Multiple ASC subpopulations give rise to adipocytes of variable phenotypes, including white, brown, and beige. Evidence suggests that hematopoietic precursor cells may also give rise to adipocytes. Until recently it was thought that ASC proliferation did not occur in postnatal humans, and that adipocyte hypertrophy was the primary mechanism of increased adipose tissue mass in obesity. Recent data suggest that both hyperplasia and hypertrophy contribute to evolving obesity, with hyperplasia predominating during childhood and hypertrophy predominating during adulthood. These data derive in part from ingenious methods studying incorporation of C14 into adipocyte DNA in individuals born before and after mid-20th century nuclear bomb testing, which raised environmental C14 levels.[11] Data over the last decade demonstrate that ASC from obese humans demonstrate increased hyperplastic and hypertrophic capacities, contributing to progressive obesity.[12] Epigenetic programming of ASC during fetal development may account for differences in adipocyte function between obese and lean subjects. Defining regulatory mechanisms of ASC is an active area of research and will lead to methods to manipulate adipocyte biology.

The Microbiome

The microbiome plays an important role in energy homeostasis. Animals raised in germ-free environments manifest increased food intake, decreased body weight, and do not develop obesity and insulin resistance when fed a high-fat diet, demonstrating that gut microbiota contribute to nutrient digestion. Gut microbiota ferment non–host-digestible polysaccharides into monosaccharides and short-chain fatty acids that are absorbed by host enterocytes and colonocytes. Products of microbiota fermentation act not only as nutrients, but also regulate host metabolism: short-chain fatty acids induce satiety, mediated in part by increased secretion of GLP-1 and peptide YY and decreased secretion of ghrelin. Separate data demonstrate interactions between microbiota and adipose tissue, liver, skeletal muscle,

and central nervous system. These effects are mediated by short-chain fatty acids, activation of Toll-like receptors on host cells via lipopolysaccharide and other bacterial products, regulation of host systemic and cellular metabolism, and other diverse mechanisms.

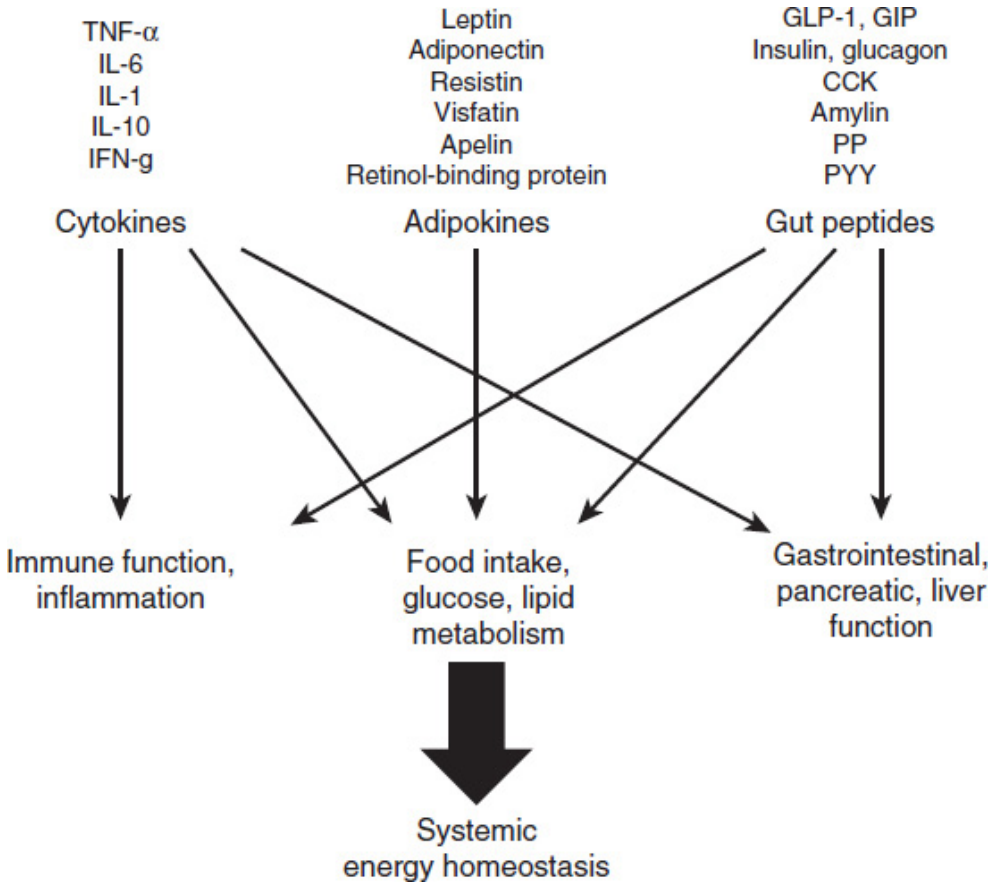

Figure 4.4 Primary peptide mediators of energy homeostasis: Cytokines, adipokines, and gut peptides regulate diverse aspects of metabolism to control global energy homeostasis. Each of these proteins has dominant functions within its primary family, but also demonstrates cross-regulatory functions in other domains. In addition, mediators participate in crosstalk at the level of cellular receptors and downstream intracellular signaling mediators. Shown are only partial lists of peptides and the physiologic functions they control.

Alterations in the microbiome contribute to obesity and metabolic disease. Germ-free mice, when colonized with stool from obese mice, gain more weight than mice colonized with stool from lean mice, demonstrating an obesity-specific microbiome. The ratio of gut Firmicutes/Bacteroidetes species is increased in obese mice and humans. Ongoing research has begun to identify specific subspecies within these broad categories of bacteria that

are altered in obesity and metabolic disease to provide a high-resolution picture of the microbiome in obesity. For example, obesity in mice and humans is associated with an increase in gram-negative gut bacteria, with a concomitant increase in lipopolysaccharide absorption from the gut, which has been postulated to contribute to obesity-associated inflammation and insulin resistance. The tools used to evaluate the microbiome are rapidly evolving. Sequencing of the microbial genome using ribosomal 16S is well established, while evolving technologies include shotgun sequencing of the metagenome and functional assays involving transfer of human microbiota in the form of stool into germ-free animals to study in vivo effects. Manipulation of the microbiome holds therapeutic promise. Prebiotic (nondigestible bacterial nutrients), probiotic (specific bacterial subspecies thought to confer systemic benefits), and tailored antibiotic therapies are areas of active research.

Bariatric Surgery and Weight Physiology

Bariatric surgery regulates body weight physiology via mechanisms that are qualitatively different than those observed in diet-induced weight loss. While restriction of caloric intake and nutrient malabsorption in the past were presumed mechanisms of surgery-induced weight loss, mounting evidence suggests otherwise. For example, little data exists to support that smaller gastric pouches or sleeves are associated achieve greater weight loss; in fact, larger sleeve diameters and antral pouches are associated with greater weight loss in response 5 to sleeve gastrectomy.[13] Other features of restriction are similarly counterintuitive: for example, weight loss after gastric bypass and sleeve gastrectomy is associated with increased gastric emptying rates compared to native anatomy. These observations suggest a complex relationship between weight regulation, metabolism, and gut anatomy and motility. Indeed, bariatric surgery somehow “sidesteps” normal compensatory responses that defend body weight in response to nonsurgical weight loss. For example, satiety is increased, hunger decreased, and metabolic rate increased after bariatric surgery, the opposite of diet-induced weight loss responses. Surgery also induces unique metabolic effects; diabetes often improves within days or weeks of gastric bypass, before substantial weight loss, the result of changes in gut hormone secretion

secondary to altered intestinal anatomy. Decades ago, it was observed that an oral glucose load elicits a greater insulin response than an intravenous glucose load, leading to postulation of the existence of *incretins*, gut hormones secreted in response to a meal that regulate systemic glucose metabolism. Subsequent research led to the discovery of GIP and GLP-1, incretins secreted by duodenal K-cells and ileal L-cells, respectively, in response to nutrient delivery to the small intestine. Incretins have diverse effects on glucose homeostasis, potentiating central insulin secretion and peripheral insulin sensitivity. Anatomic effects of gastric bypass, including diversion of the alimentary stream from the duodenum and proximal jejunum (the *foregut hypothesis*), and increased caloric delivery to the distal jejunum and ileum (the *hindgut hypothesis*), alter secretion of gut hormones and contribute to improvement in glucose homeostasis. While debate persists regarding the magnitude of these effects on diabetes remission after gastric bypass, an understanding of incretin physiology has led to the development of GLP-1 agonists as pharmacologic therapy for diabetes.

Gut anatomic derangements mediate additional metabolic changes. Gastric bypass and sleeve gastrectomy reduce secretion of the orexigenic hormone ghrelin from the gastric fundus, which may reduce hunger after surgery. Gastric bypass and sleeve gastrectomy are associated with increased secretion of peptide YY and oxyntomodulin, gut hormones secreted by L-cells in response to a meal that induce satiety, inhibit gut motility, and are central mediators of the "ileal brake" mechanism. Roux-en-Y anatomy alters bile acid metabolism, increasing serum levels of conjugated bile acids with beneficial effects on glucose and lipid metabolism. Bariatric surgery disrupts vagal and enteroenteric innervation of the gut and alters central nervous system satiety responses. Finally, bariatric surgery is associated with alterations in gut microbiota that contribute to weight loss and resolution of metabolic disease.

Summary

Satiety and hunger, metabolic rate, adipocyte physiology, and the microbiome are a few of many processes that regulate metabolism and are dysregulated in obesity. Differences in lipid and glucose metabolism, immune function, central and peripheral nervous system function, and multiple other processes

contribute to the wide variability of the obesity phenotype and metabolic diversity in humans, driven by genetic polymorphisms that were selected over eons of evolution. The question is often posed, should obesity should be considered a disease? Rather, obesity is better thought of as a maladaptive response to an environment that is radically different than that in which our species evolved. The obesity phenotype remains relatively underexpressed in environments of food scarcity, in which obesogenic genes acted to defend adipose tissue stores and enhance survival, but blossoms in our modern environment. An understanding of these intimate genetic–environment interactions will lead to novel therapy for obesity based on manipulation of environment and genetics. Elucidation of the physiologic mechanisms of weight regulation will similarly lead to next-generation therapy. Bariatric surgery provides a unique opportunity in this regard, as surgery-induced weight loss does not trigger adipostat-mediated defense of body weight in the same way as diet-induced weight loss. An emerging field of *metabolic surgery* is exploring operations designed to mimic metabolic effects of bariatric surgery (e.g., ileal transposition, foregut exclusion) in lean diabetic humans with promising results. As mechanisms underlying surgery-induced weight loss are deciphered, pharmacologic interventions developed through "reverse engineering" of bariatric surgery will emerge.

PATHOPHYSIOLOGY OF METABOLIC DISEASE

Obesity and Metabolic Disease

Obesity is associated with a range of pathology involving every organ system collectively referred to as metabolic disease. While underlying mechanisms are multiple, the root cause of metabolic disease is a failure of adipose tissue nutrient buffering capacity, leading to overflow of nutrients, metabolites, cytokines, and adipokines from adipose tissue to other tissues. The clinical effects of overflow differ depending on the target tissue, but the fundamental cellular responses to nutrient excess common to all tissues, adipose included, involve mechanisms by which cells control nutrient flux and respond to

nutrient excess. These cellular responses underlie the pathophysiology of metabolic disease.

6 Nutrient Excess

Energy homeostasis is the dominant overriding goal of all biologic systems. Metabolism (Gr. *metabole*, change) may be defined as the sum total of all chemical reactions and physiologic processes that regulate cellular and systemic energy homeostasis. At the cellular level, metabolic processes are fundamental to all metazoan life and are highly conserved across phyla; examples include the citric acid cycle and mitochondrial respiration, which utilize multiple enzymes, the structure and function of which are conserved from yeast to humans. At the systemic level, metabolic processes are central to maintaining homeostasis and interface with virtually every organ system and every physiologic process. The basic substrates of metabolism are macronutrients, fatty acids, amino acids, and carbohydrates, and their metabolites, along with micronutrients that catalyze reactions that synthesize and degrade macronutrients and higher-order macromolecules. Cellular nutrient flux provides substrate for synthesis of macromolecules via anabolic metabolic processes, which are in turn degraded via catabolic metabolic processes. Maintaining the balance between anabolism and catabolism at cellular and systemic levels is of critical importance. Cancer, for example, may be viewed as a metabolic imbalance that favors cellular anabolism over catabolism. Cachexia, in contrast, may be considered as a metabolic disorder that favors systemic catabolism over anabolism. The nutrient flux with which cells are constantly faced determines the balance between anabolism and catabolism and dictates organism-wide energy homeostasis. Nutrients are, much like oxygen, high energy-capacity molecules, capable of participating in energy-intensive, potentially damaging reactions. Fatty acid metabolites such as ceramides and diacylglycerols, and glucose metabolites including advanced glycation end products and glucosamines, trigger inflammation, oxidative stress, and insulin resistance. Cellular physiology has therefore evolved processes designed to control exposure, flux, and sequestration of these high-energy molecules. These cellular processes were selected by evolution to manage *transient* nutrient excess, but are not well adapted to *chronic* nutrient excess. Maladaptive cellular responses to chronic nutrient

excess underlie the pathogenesis of metabolic disease and occur in all cells, explaining the involvement of virtually every organ system in metabolic disease. These processes include fundamental cellular stress responses: *endoplasmic reticulum (ER) stress*, *oxidative stress*, and *inflammation*.

Cellular Responses to Nutrient Excess

The ER is a complex organelle present in all eukaryotic cells that orchestrates synthesis and intracellular transport of macromolecules. The rough ER, studded with ribosomes, is responsible for protein synthesis, while the smooth ER is responsible for lipid and carbohydrate synthesis. The ER receives a constant influx of nutrients, which it sequesters and directs toward macromolecule synthesis or degradation, carefully metering cellular nutrient exposure. In this capacity, the ER acts as a nutrient sensor, responding to changes in nutrient flux by balancing cellular anabolism and catabolism. The ER also responds to other cell stressors, including hypoxia, toxins, disturbances in electrolyte balance, and a host of other stimuli that alter cell homeostasis. Excess cellular nutrient flux, like other forms of stress, leads to a series of stepwise ER responses collectively referred to as the *ER stress response*. The initial ER stress response to modest increases in nutrient flux induces increased expression of *chaperone proteins* involved in macromolecule synthesis to accommodate increased anabolism of excess nutrients. If nutrient excess persists beyond cellular processing capacity, the ER stress response progresses to activate the *unfolded protein response,* which downregulates global protein expression. If nutrient excess persists beyond the capacity of the ER to maintain proper protein synthesis, then the unfolded protein response progresses to induce cell *apoptosis*. The unfolded protein response thus protects cells from modest increases in nutrient flux and induces cell death in the face of extreme nutrient excess.

Macromolecule synthesis generates reactive oxygen species (ROS) (e.g., superoxides, oxygen/hydroxyl free radicals, hydrogen peroxide) which, like nutrients, are highly energetic molecules capable of damaging cells. Cells have evolved multiple mechanisms to sequester ROS which together comprise the *oxidative stress response*, including antioxidant enzymes such as superoxide dismutase, glutathione peroxidase, and catalase, scavenging molecules such as ascorbic acid, urate, and divalent ions, and the thioredoxin

and glutaredoxin systems. The ER and mitochondria are primary cellular sites of control of oxidative stress. When nutrient flux, macromolecule synthesis, and ROS production exceed cellular antioxidant capacity, cells activate oxidative stress responses, which increase expression of antioxidant proteins, sequester ROS, and increase mitochondrial uncoupling, transiently reducing cellular ROS production. Oxidative stress responses overlap with ER stress responses, and if oxidative stress persists, the unfolded protein response is activated and leads to apoptosis.

Increased nutrient flux generates an *inflammatory response* designed to scavenge debris and byproducts from increased cell turnover that results from ER and oxidative stress responses. Testament to the close relationship between metabolism and inflammation, inflammatory and metabolic mediators demonstrate functional overlap. For example, TNF-α and leptin, in addition to their dominant functions in regulating inflammation and satiety, respectively, each play important reciprocal roles in regulating body weight and inflammation.[14,15] All satiety and hunger factors and inflammatory cytokines manifest dual immunoregulatory and energy homeostasis functions. In addition, molecular byproducts of metabolism trigger inflammation. Free fatty acids are ligands for Toll-like receptors, while advanced glycation end products trigger receptors of advanced glycation end products' pathways which activate innate immune effector cells, establishing a molecular link between metabolism and inflammation. Obesity is associated with a state of chronic systemic inflammation that plays a central role in the pathogenesis of metabolic disease. Serum cytokine levels are increased in obese animals and humans, and adipose tissue manifests a pan-leukocyte infiltrate, findings that directly correlate with the magnitude of obesity and severity of metabolic disease.

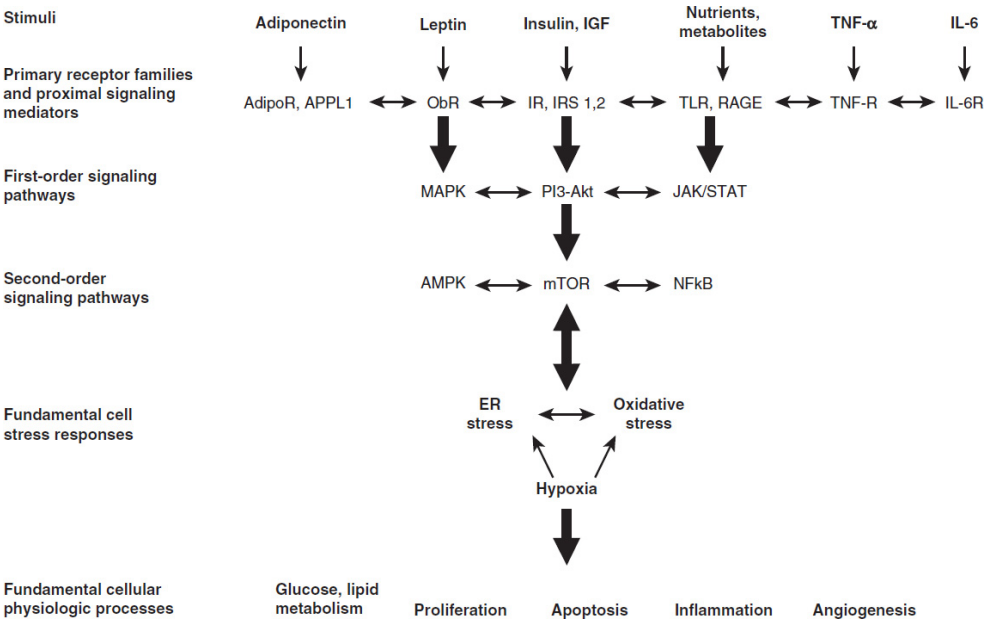

Figure 4.5 Highly simplified schematic of major cell signaling pathways that regulate energy homeostasis and cell stress responses: Primary stimuli for all cells include adipokines, insulin, IGF-1, nutrients and metabolites including free fatty acids, and their derivatives such as ceramide (which activate Toll-like receptors, TLR), glucose, fructose, and advanced glycation end products (which activate receptors for advanced glycation end products, RAGE), and cytokines. Primary intracellular signaling nexi include mitogen-activated protein kinases (MAPK), PI3-Akt, JAK/STAT signaling mediators, AMP-activated protein kinase (AMPK), mammalian target of rapamycin (mTOR), and NFkB, all of which are linked to ER stress and oxidative stress responses. These pathways engage in highly redundant crosstalk via cross-reactivity of intracellular signaling mediators and induction of gene transcription, and conspire to integrate multiple stimuli to regulate fundamental aspects of cell metabolism, survival, and death in response to nutrient availability and cell stressors such as hypoxia.

Increased ER stress, oxidative stress, and inflammation have been demonstrated in obese rodents and humans. An important aspect of cellular stress responses is that each potentiates the others via overlap in fundamental cell signaling pathways including PI3-Akt, MAPK, AMPK, mTOR, JAK-STAT, and NFκB. These signaling pathways are triggered by multiple stimuli that are dysregulated in obesity, including adipokines, cytokines, growth factors, and nutrients and metabolites, all of which participate in crosstalk, establishing a vicious cycle that perpetuates cell stress in the face of chronic nutrient excess (**Fig. 4.5**). These processes are common to all cells and affect all tissues in late-stage obesity, explaining the diverse manifestations of

systemic metabolic disease. But it is within adipose tissue that these processes are initiated and metabolic disease originates.

Adipose Tissue Failure

Adipocytes are exquisitely well designed to manage high levels of nutrients. Hypertrophy is an early response of adipocytes to chronic elevations in nutrient flux in early overweight and obesity. Free fatty acids are absorbed by adipocytes through pinocytosis mediated by fatty acid–binding proteins, as well as synthesized from glucose and glutamine via de novo lipogenesis, and stored in lipid droplets via a highly regulated process mediated by perilipin proteins. Virtually all cells are capable of storing lipid to some degree, but adipocytes have an extremely high capacity for lipid storage and hypertrophy. Adipocytes are one of only a few cell types that can enlarge to diameters greater than 100 microns, the diffusion distance of oxygen. Adipocyte diameter in humans correlates directly with the magnitude of obesity and the severity of metabolic disease; adipocytes in lean subjects are virtually all less than 100 microns in diameter, while those in obese subjects are greater than 100 microns, in some cases exceeding 200 microns.[16] Progressive adipocyte hypertrophy establishes a state of cellular hypoxia within adipose tissue that has been verified in obese mice and humans. Decreased adipose tissue capillary density and blood flow in obesity exacerbates hypoxia. This hypoxic state has broad effects on adipocyte metabolism, inducing insulin resistance, ER stress, oxidative stress, and inflammation, and inhibiting lipogenesis. Manipulation of hypoxic responses in adipocytes holds therapeutic promise. For example, targeting hypoxia-inducible factor-1α, a dominant cellular hypoxia response protein, ameliorates murine metabolic disease.[17]

Inflammation is a dominant feature of adipose tissue dysfunction in obesity, and is directly linked to insulin resistance and dysregulation of lipid metabolism at local (adipose tissue) and systemic levels. Hypoxia induces adipocyte apoptosis and necrosis which in turn recruits an inflammatory response designed to scavenge dead and dying adipocytes. Adipose tissue macrophages (ATMs) are a central component of this response. ATMs in obesity are altered in phenotype, shifting from a scavenging "M2" phenotype to an inflammatory diabetogenic "M1" phenotype.[18] ATMs are a dominant

source of inflammatory cytokines, including TNF-α, IL-6, and IL-1, all of which induce insulin resistance and aberrations in glucose and lipid metabolism in adipocytes via multiple mechanisms. Supporting a central role for ATMs in metabolic disease, obese mice transgenically engineered to lack macrophage homing molecules in adipose tissue do not develop macrophage infiltrates and are protected from diabetes. Agents that interfere with macrophage homing to adipose tissue in humans show promise as treatment for diabetes. Finally, adipose tissue inflammation involves more than macrophages, and is associated with a pan-leukocyte infiltrate that includes T cells, B cells, NK cells, NKT cells, and eosinophils. Therapy targeting these cell subpopulations is an area of active research.

As inflammation persists, adipose tissue undergoes fibrotic remodeling, with increased expression of matrix metalloproteases and collagens and increased extracellular matrix turnover. Adipose tissue fibrosis limits adipocyte hypertrophic and lipid storage capacity, accelerating adipocyte stress. Obese collagen VI knockout mice demonstrate increased adipocyte hypertrophic capacity due to decreased fibrosis and are protected from systemic metabolic disease.[19] These observations speak to a critically important role of the adipose tissue extracellular matrix in regulating adipocyte nutrient buffering capacity.

Adipose Tissue Overflow

7 As obesity progresses, adipose tissue buffering capacity is overwhelmed and cell stress responses, initially confined to adipose tissue, overflow into circulation and cause systemic metabolic disease (**Fig. 4.6**). Patients with rare congenital and acquired lipodystrophy syndromes characterized by a paucity of adipose tissue suffer from metabolic disease, including insulin resistance, hyperlipidemia, and hepatic steatosis, demonstrating that an absence of adipose tissue is as detrimental as its excess. In lipodystrophy and in obesity, adipose tissue nutrient buffering capacity is overwhelmed, and nutrients overflow to other tissues not well adapted to manage nutrient excess, inducing systemic metabolic disease.

Adipocytes reside in multiple discrete anatomic depots as well as within every organ and every tissue. Adipose tissue is more than simply a storage depot for lipid; only half the cells in adipose tissue are adipocytes, the

remainder comprising the so-called stromovascular cell fraction, which consists of immune leukocytes, fibroblasts, endothelial cells, ASCs, and other cell types. Adipose tissue is highly innervated with sympathetic and parasympathetic afferent and efferent fibers, and has important immunoregulatory and endocrine functions. Adipose tissue participates in robust communication with the central nervous system and all peripheral organs, orchestrating responses to alterations in nutrient availability, systemic health and metabolism, ambient temperature, and a host of other stimuli. Adipose tissue is a central regulator of systemic energy homeostasis.

Hibernating bears accumulate large amounts of adipose tissue without developing inflammation or other cellular stress responses, while in some humans, excess subcutaneous adipose tissue appears to protect against metabolic disease. These examples demonstrate that adipose tissue phenotype is as important as quantity with respect to systemic metabolic state. Adipose tissue may be broadly divided into white and brown phenotypes. White adipose tissue comprises the majority of adipose tissue in humans, is strongly associated with metabolic disease, increases with increasing obesity, and is a primary storage site for lipid. Brown adipose tissue, in contrast, comprises a minority of total adipose tissue in humans, has beneficial effects on metabolism, decreases with increasing obesity and age, and manifests lower lipid storage capacity. Brown adipocytes engage in higher levels of fatty acid oxidation and thermogenesis via expression of mitochondrial UCPs. White adipose tissue derives from mesodermal stem cells that migrate to sites of canonical depots in humans in early embryonic development and proliferate to form-defined depots in late fetal and early neonatal periods. White adipose tissue depots include visceral and subcutaneous, which may be further subdivided into omental, retroperitoneal, and mesenteric visceral adipose tissue compartments, and deep and superficial subcutaneous adipose tissue compartments, each with distinct functional characteristics. Brown adipose tissue develops in rodents during gestation from precursor cells that also give rise to myocytes and form-defined brown adipose tissue depots prior to birth. Brown adipose tissue in humans is less well understood; while most voluminous in the neonatal period, positron emission tomography scanning demonstrates cervical, supraclavicular, mediastinal, paraspinous, and perirenal brown adipose tissue depots in adult humans as well.[20] Recent data suggest that the

dichotomy between white adipose tissue and brown adipose tissue is overly simplistic, and that adipocyte phenotype spans a spectrum. An intermediate phenotype, termed *"brite"* (brown-in-white) or "*beige adipocytes,*" are found in white adipose tissue depots in rodents and humans. These cells manifest brown adipocyte functions, and are induced to proliferate by cold stress and β-adrenergic stimuli, suggesting phenotypic plasticity. Pharmacologic "browning" of adipocyte phenotype is an important area of research with preclinical and clinical trials in progress.

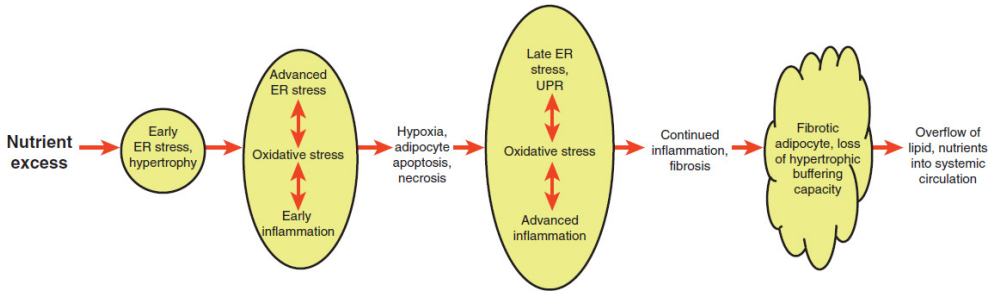

Figure 4.6 Nutrient excess and cell stress in adipocytes: Nutrient excess is an early signal that induces ER stress and hypertrophy in adipocytes. ER stress is tightly linked to oxidative stress and inflammation, and each of these processes induces and potentiates the others. As hypertrophy progresses, adipocyte diameter expands beyond the diffusion distance of oxygen, leading to cellular hypoxia, which exacerbates cell stress responses, leading to adipocyte apoptosis and necrosis via the unfolded protein response and other advanced cell stress responses. Adipocyte apoptosis and necrosis triggers recruitment of an advanced inflammatory response designed to scavenge dead and dying adipocytes. This inflammatory response is associated with fibrotic tissue remodeling which limits adipocyte hypertrophic and lipid buffering capacity of surviving adipocytes, leading to overflow of lipids, nutrients, metabolites, and inflammatory products from adipose tissue into the systemic circulation.

Adipose tissue is anatomically heterogeneous. Human obesity may be broadly classified into android and gynecoid phenotypes, defined by excess visceral and subcutaneous adipose tissue, respectively, with the former strongly associated with metabolic disease, while the latter is less strongly associated with metabolic disease, and in some studies has been shown to be protective. Surgical lipectomy of visceral adipose tissue but not subcutaneous adipose tissue ameliorates murine diabetes.[21] Similar studies of visceral omentectomy in humans demonstrate conflicting results, likely due to more complex human adipose tissue depot anatomy, but excess visceral adipose tissue as measured by waist circumference and imaging techniques

nonetheless correlates strongly with metabolic disease. The reasons for the disproportionate effect of visceral adipose tissue on metabolic disease are unclear. While the abdominal location of visceral adipose tissue plays a role, intrinsic differences between visceral and subcutaneous adipose tissues also exist, as visceral adipose tissue manifests higher levels of inflammation, lipolysis, β-adrenergic receptor expression, steroid sensitivity, insulin resistance, and adipocyte proliferation and differentiation relative to subcutaneous adipose tissue.

SYSTEMIC METABOLIC DISEASE

8 Mediators of Metabolic Disease

In addition to its distinct functional phenotype, visceral adipose tissue contributes disproportionately to metabolic disease via direct anatomic communication with the liver via the portal venous system. *Portal overflow* of free fatty acids, excess nutrients and metabolites, and hormones and cytokines from visceral adipose tissue to the liver is an early step in the progression to systemic disease. As obesity progresses, *peripheral overflow* extends beyond the liver to involve all tissues, including skeletal muscle, pancreas, vasculature, kidneys, lungs, and the central nervous system; inflammation and ER stress occur in the hypothalamus, and mediate reciprocal effects on adipose tissue and other organ systems via aberrations in CNS efferent outputs that exacerbate obesity and metabolic disease. In essence, adipose tissue dysfunction "metastasizes," inducing cell stress responses in all tissues that underlie the pathogenesis of metabolic disease (**Fig. 4.7**).

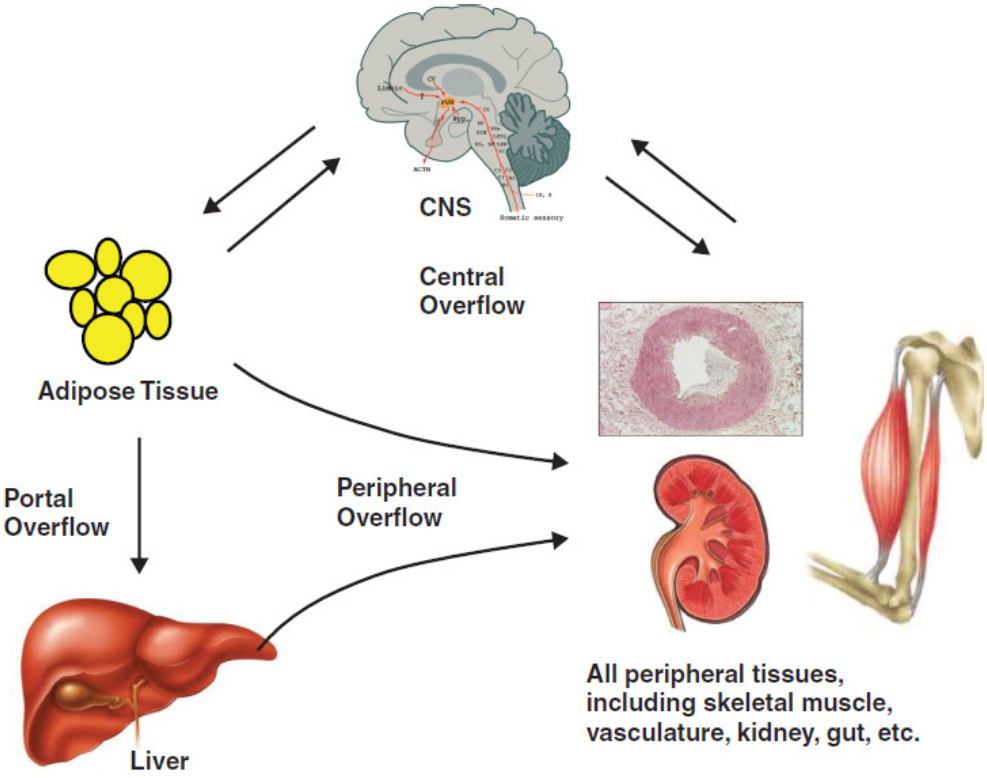

Figure 4.7 Adipose tissue overflow, interorgan communication, and systemic metabolic disease: As adipose tissue buffering capacity is overwhelmed, lipids, nutrients, cytokines, and adipokines overflow into the systemic circulation and cause systemic metabolic disease via the same cellular effects that initially unfold in adipocytes. Early overflow occurs via the portal system, which drains visceral adipose tissue venous effluent into the liver, which becomes the first site of systemic metabolic disease and an important secondary site of nutrient buffering via the development of hepatic steatosis. Overflow progresses to involve all peripheral tissues, inducing cell stress and disease in all organ systems. Overflow involves the central nervous system as well, as inflammation and cell stress have been documented in the hypothalamus in obesity, which in turn is thought to disturb peripheral metabolic function via alterations in CNS efferent signaling.

Nutrients and metabolites are central mediators of the systemic effects of adipose tissue overflow. Free fatty acids mediate systemic *lipotoxicity*, acting as ligands for Toll-like receptors and other immunostimulatory and cell stress–inducing receptor families. Lipid metabolites induce cellular insulin resistance, ER stress, and apoptosis. Metabolic products of glucose and fructose, including advanced glycation end products and glucosamines, mediate similar effects. Cytokines and adipokines overflow from adipose tissue as well. TNF-α, a dominant inflammatory cytokine expressed by adipose tissue macrophages, exerts proinflammatory and diabetogenic

effects. Leptin also promotes inflammation and regulates cellular glucose homeostasis. Expression of adiponectin, which attenuates inflammation and has beneficial effects of cellular metabolism, is decreased in obesity, as adipose tissue's cytokine and adipokine balance shifts toward a proinflammatory milieu. Metabolites, adipokines, and cytokines establish in multiple tissues the same cellular stress responses that initially unfold in adipose tissue, including ER stress, oxidative stress, and inflammation. Within target tissues, as in adipose tissue, these processes potentiate one another and exacerbate cell stress, leading to systemic metabolic disease.

Portal Overflow and Liver Disease

The liver is one of the first organs to be affected by adipose tissue failure, as portal overflow induces hepatic steatosis, the result of an imbalance in delivery and export of hepatocyte lipid. Sources of hepatic lipid include fats absorbed from the diet and delivered from the gut as chylomicrons, lipids synthesized by hepatocytes via de novo lipogenesis, and free fatty acids delivered from visceral and subcutaneous adipose tissues. Free fatty acids from adipose tissue constitute over 60% of lipid delivery to the liver.[22] Lipids are exported from the liver primarily in the form of very low–density lipoproteins (VLDL). Abnormalities in each of these aspects of hepatic lipid delivery and efflux have been identified in obese animals and humans. As lipid storage capacity is reached, hepatocytes experience ER, oxidative, and inflammatory stresses, causing steatohepatitis, a histologic entity characterized by Mallory bodies, hepatocyte ballooning and an inflammatory infiltrate consisting of macrophages (Kupffer cells) and other leukocytes. As in adipose tissue, TNF-α plays a central role in the hepatic inflammation; neutralization of TNF-α ameliorates steatohepatitis in mice and is under study as therapy in humans.[23,24] Interleukin-6 and other inflammatory cytokines have also been implicated in steatohepatitis. Steatosis is present in over 90% of patients with BMI >40, up to 30% of whom will develop steatohepatitis; 10% to 30% of patients with steatohepatitis will develop cirrhosis. Ethnic and genetic predispositions to steatohepatitis exist, with Asians and Hispanics at higher risk than Caucasians or Blacks. Weight loss reverses steatosis and halts progression of steatohepatitis.

Diabetes

Insulin resistance is a central metabolic response of all cells to stress, but it begins in adipose tissue. Free fatty acids are central mediators of cellular insulin resistance. Insulin regulates not only glucose homeostasis in adipocytes, but also lipid metabolism, inhibiting lipolysis and free fatty acid release. Early nutrient excess, with resultant ER and oxidative stress, induces insulin resistance in adipocytes, impairing adipocyte glucose uptake, attenuating insulin's inhibitory effects on lipolysis, and increasing free fatty acid release by adipocytes. Free fatty acids in turn activate Toll-like receptors on adipose tissue inflammatory cells, inducing inflammatory cytokine expression, including TNF-α. TNF-α induces insulin resistance by regulating expression and phosphorylation of genes involved in glucose homeostasis, including insulin receptor, insulin receptor substrates, the cell signaling nexus protein Akt, and glucose transporter molecules. TNF-α also promotes lipolysis, exacerbating insulin resistance and free fatty acid release by adipocytes. While other mediators contribute, TNF-α provides a cogent example of the vicious cycle in adipose tissue that contributes to worsening insulin resistance.

As adipose tissue lipid buffering capacity is overwhelmed, free fatty acids overflow into the systemic circulation, resulting in lipotoxicity, which underlies the pathogenesis of insulin resistance in peripheral tissues. Skeletal muscle, responsible for 70% of systemic glucose disposal, is a dominant site of systemic insulin resistance. Lipotoxicity triggers ER stress, oxidative, stress, and inflammation in skeletal muscle myocytes, contributing to insulin resistance via mechanisms described above. Skeletal muscle, like adipose tissue, becomes inflamed, with increased levels of macrophages and diabetogenic inflammatory cytokines. Circulating free fatty acids also have important metabolic effects on the liver and skeletal muscle. As lipid delivery to skeletal muscle and liver increases, energy production shifts from glucose utilization to fatty acid oxidation. Increased free fatty acid beta-oxidation leads to increased hepatic gluconeogenesis and reduced skeletal muscle glucose utilization, exacerbating hyperglycemia. The initial response of pancreatic beta cells to peripheral insulin resistance and hyperglycemia is a compensatory increase in insulin secretion, leading to hyperinsulinemia, a pathognomonic feature of early type 2 diabetes. As disease progresses,

lipotoxicity and cell stress responses induce pancreatic beta cell exhaustion, leading to decreased insulin secretion, and insulin resistance progresses to frank diabetes. Like obesity itself, genetics plays an important role in type 2 diabetes: Asian, Black, and Hispanic ethnicities are associated with increased risk and multiple diabetes-associated SNPs have been identified. Worldwide incidence is rapidly increasing; diabetes represents a dominant emerging health crisis.

Cancer

The incidences of almost all types of cancer increase in a dose-dependent manner with increasing BMI, with risk ratios range from 2 to greater than 6 depending on cancer type and BMI.[25] At the cellular level, energy homeostasis involves fundamental processes central to carcinogenesis, and signaling pathways activated by chronic overnutrition promote cell proliferation. Epidemiologic data suggest that long-term metformin use is associated with decreased cancer incidence, suggesting the potential for metabolism-based cancer therapy. Chronic inflammation, characteristic of obesity and a risk factor for cancer, activates NFκB and other signaling pathways that potentiate cell proliferation, increase production of ROS that may contribute to oncogenic mutation, and induce expression of inflammatory cytokines that act as cell mitogens. Overnutrition in obesity predisposes to a state of chronic anabolism and is associated with increased expression of multiple growth factors, including insulin, insulin-like growth factor-1, and leptin. Chronic inflammation on a background of chronic anabolism creates an ideal milieu for carcinogenesis. Steroids represent another putative molecular link between obesity and cancer. Steroid metabolism is aberrant in obesity and adipose tissue is a source of estrogen which may promote estrogen-responsive cancers. Finally, peritumor adipocytes have been implicated in carcinogenesis. In addition, adipocyte precursors home from adipose tissue depots to tumors and provide growth factors and energy substrates that promote tumor growth. The mechanisms by which obesity causes cancer are multiple, and as details are elucidated, metabolism-based therapy for cancer will emerge.

CONCLUSION

Obesity is associated with an increased risk of cardiovascular disease, including hypertension, atherosclerosis, and hyperlipidemia, the result of cell stress responses that afflict vascular tissue. Immune diseases including allergy, atopy, and autoimmune diseases, are increased in the obese, due in part to alterations in immune and inflammatory function. While mechanical stress due to excess weight are contributing factors to sleep apnea, osteoarthritis, and gastroesophageal reflux disease, fundamental cell stress mechanisms also contribute, as inflammation has been implicated in these diseases as well. The pan-systemic nature of metabolic disease provides opportunity for developing therapy that will simultaneously treat multiple obesity-related pathologies.

Wound Healing

Katherine A. Gallagher

Key Points

1. Wound healing is a complex process that involves four major phases: hemostasis, inflammation, proliferation and remodeling.
2. Innate immune cells play a major role in the inflammatory phase of healing.
3. Macrophages are critical for the transition from the inflammatory to the proliferative phase.
4. Multiple factors can adversely impact healing including advanced age, poor nutrition, obesity, DM, steriods/chemotherapy.

The role of disease states including diabetes and cancer-related treatments including radiation, chemotherapy and steroids negatively influence wound repair. Hence, a thorough understanding of the pathways/processes involved in both normal and pathologic healing is essential. Thus, a fundamental understanding of the wound healing cascade is essential to surgical practice. Besides the controlled injury that occurs in elective surgery, all invasive surgical procedures cause soft tissue trauma regardless of the circumstances. All aspects of surgical care from patient selection, surgical instruments and technique, and postoperative management are needed to optimize tissue

healing and avoid complications. In addition to surgical procedures, there is the growing problem of people suffering from chronic wounds, particularly in diabetes is on the rise. Nonhealing wounds affect about 10 million people in the United States, with persons 65 years and older accounting for the majority of these events. The development of new data regarding the normal and pathologic wound healing responses both at the cellular levels and the biologic markers associated with healing will help develop new therapeutic strategies.

PHASES OF WOUND HEALING

1 Wound healing is a dynamic process that occurs in a programmed series of four phases: hemostasis, inflammation, proliferation, and remodeling.[1] These steps occur in a linear fashion under normal, nondiseased conditions. The timing of these four phases of wound repair is illustrated in Figures 5.1 and **5.2** and the major cell types involved are shown in **Figure 5.3**.

Hemostasis

The hemostasis phase begins almost instantaneously after injury. The tissue response is mediated by: (1) blood leaking into the wound, (2) proteins stored in the ECM, and (3) locally resident surviving cells following injury.

Following injury, hemostasis occurs and is characterized by the recruitment of platelets and circulating coagulant factors to the wound site to initiate clotting.[2] Concurrent with platelet recruitment, injured cells release damage signaling factors, which activate resident macrophages,[3–6] as well as damage associated molecular patterns (DAMPs).[7] Together, these stimulate recruitment of polymorphonuclear neutrophils (PMNs) from the vasculature to defend against pathogens.[3,5,7] As platelets aggregate to the exposed collagen bed, they secrete cytokines and growth factors such as platelet-derived growth factor, that promote clotting and serve to further recruit PMNs.[8] Once PMNs begin to migrate to the wound, this initiates the inflammation stage.

The plasma membrane of each platelet contains specific receptors for collagen known as the glycoprotein Ia/IIa complex. When plasma membrane

receptors come into contact with collagen of the ECM (type I) and the basement membrane of the vascular endothelium (type IV), platelets bind and anchor to the site. Simultaneously, platelet activation occurs and the platelet changes from a rounded amorphous shape to a flattened configuration and discharges the contents stored cytoplasmic granules in an event known as the platelet release reaction. These bioactive factors serve a dual purpose in hemostasis and wound healing. Platelet anchoring is strengthened by von Willebrand factor (vWF) released by damaged endothelium and activated platelets. Platelet binding is also characterized by rapid vascular restriction and the formulation of a stable fibrin clot. Platelets are the main cellular players of the first phase. Platelet-derived functions that achieve hemostasis include: adhesion, aggregation, and formation of a procoagulant surface that facilitates the generation of thrombin and results in a fibrin plug. In addition, platelets express and release substances that promote tissue repair and influence future processes such as angiogenesis, inflammation, and the immune response. They contain large secreted pools of biologically active proteins, including platelet-derived growth factor (PDGF), transforming growth factor-β (TGF-β), and vascular endothelial growth factor (VEGF) as well as cytokines. The therapeutic use of platelets in a fibrin clot has a positive influence in clinical situations requiring rapid healing, dental implant surgery, orthopedic surgery, muscle and tendon repair, skin ulcers, hole repair in eye surgery and cardiac surgery are situations where the use of autologous platelets accelerates healing.

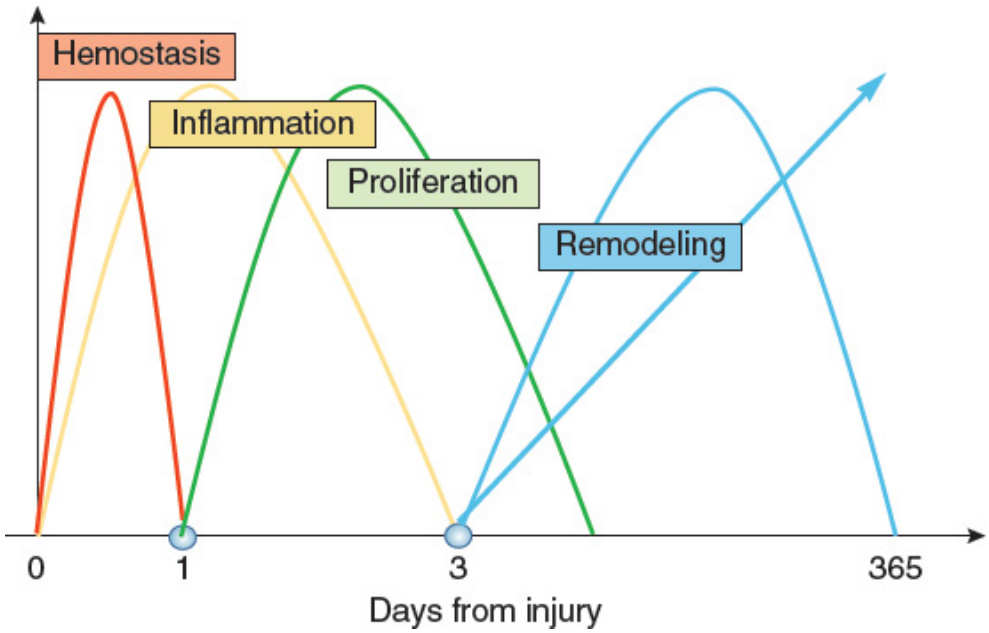

Figure 5.1 Four phases of wound healing: plotted against "Time" on the x-axis, the four phases shown in different colors occur sequentially, and overlap. Overall the total time period for completion is 1 year.

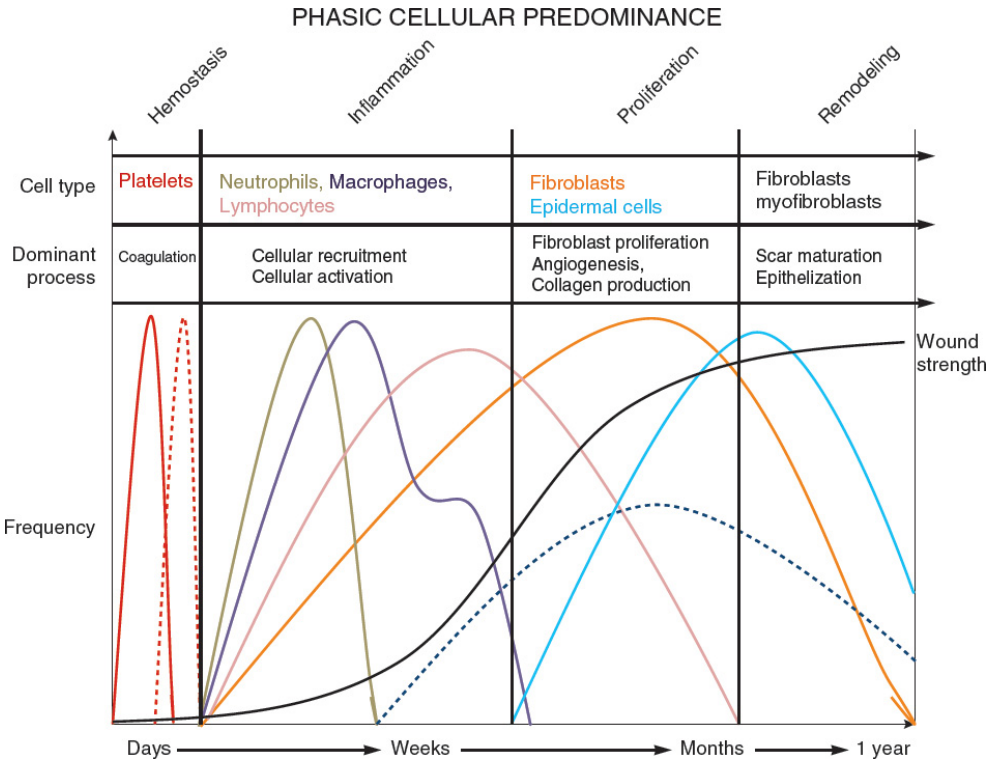

Figure 5.2 The dominant cells, physiologic process as well as the temporal distribution of the four phases of wound healing.

The growing platelet plug inside the vessel is stabilized by fibrin polymerized from circulating fibrinogen. The vascular response is mediated by local factors modulated by the systemic control of sympathetic nervous system. Vasoconstriction, mediated by catecholamines and prostaglandins (thromboxane and PGF 2a), normally is limited to the time required to achieve hemostasis. Vasodilation and alteration in capillary permeability soon follow mediated by histamine, prostaglandins (PGE2 and PGI2), VEGF released from resident interstitial mast cells and damaged endothelium. This causes increased blood flow and controlled delivery of fluid, leukocytes, macrophages, and relevant plasma proteins to the wound environment which facilitates the inflammatory phase. Platelets release two factors with particular importance for would healing: PDGF and TGF-β which in turn stimulate chemotaxis and proliferation of inflammatory cells.

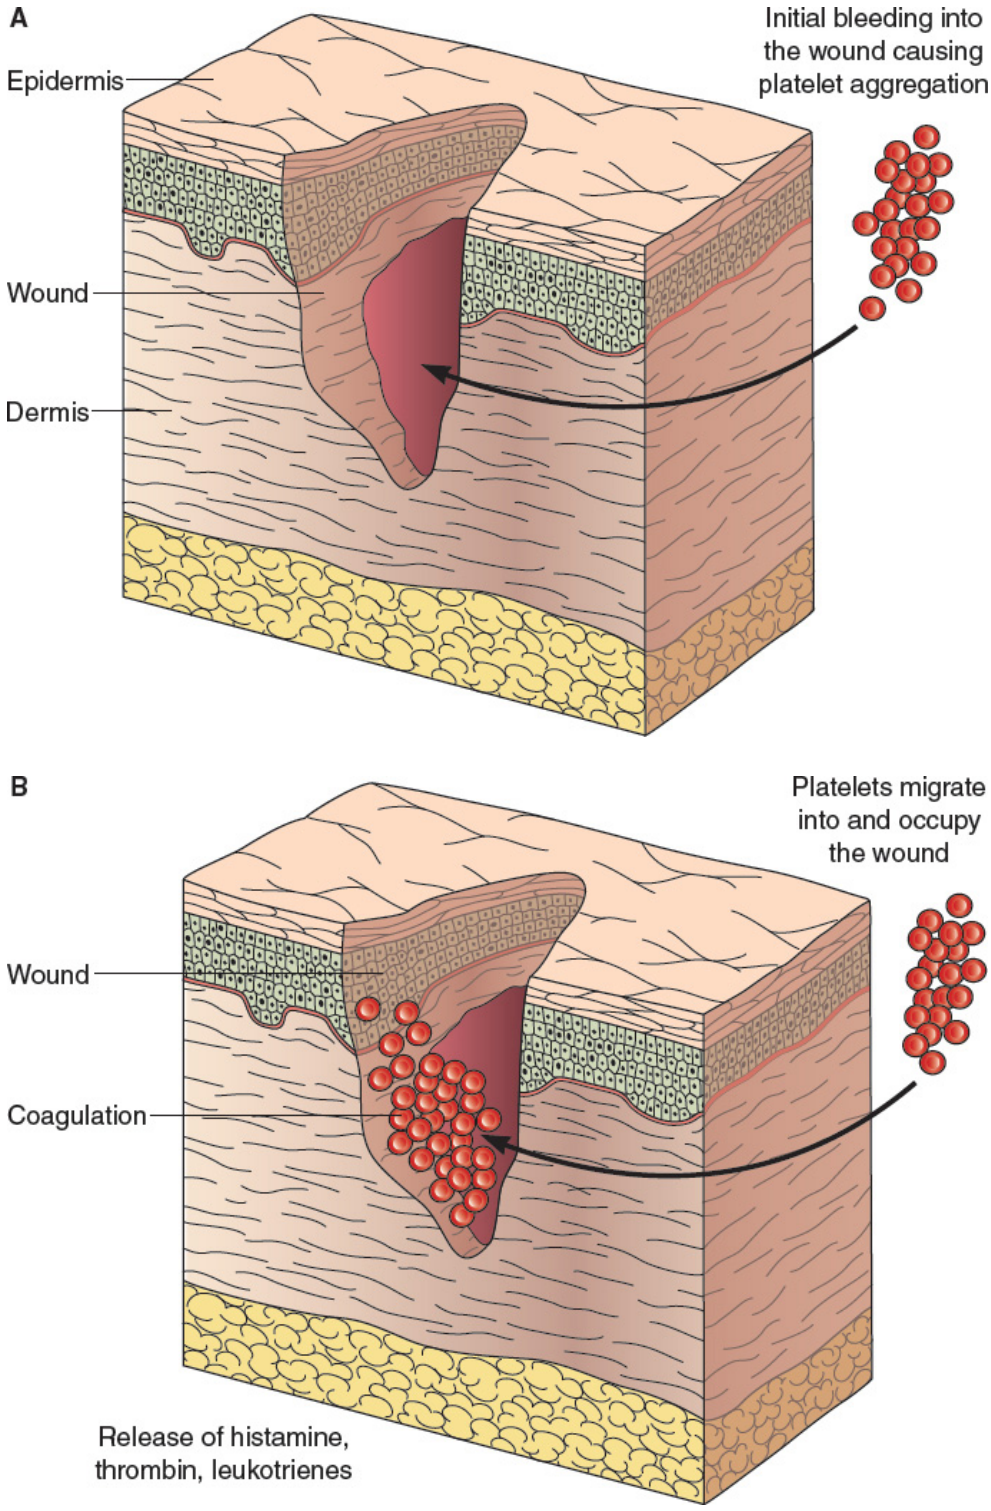

Figure 5.3 **A**: Diagrammatic wound healing model. Platelets, the first cells to arrive at the wound are critical to create a clot and establish hemostasis. **B**: Phase 1—Hemostasis.

Inflammatory Phase

The second phase of healing involves inflammation (acute then chronic) that begins following the hemostasis phase. 2 The cells involved in this phase are mainly immune cells, as shown in **Figure 5.4**. Neutrophils (PMNs) dominate during the early part of the inflammation phase; however, their presence is short lived as they start to wane after 24 to 48 hours.[9] 3 PMNs set the stage for the appearance of macrophages, the most important cellular mediator of the inflammatory phase of wound healing (**Fig. 5.5**). Neutrophils release chemokines that are responsible for recruiting circulating monocytes from the peripheral blood to the wound site. Recruited monocytes that differentiate into macrophages and dendritic cells, along with F4/80+ resident tissue macrophages, carry out the critical steps of the inflammatory phase of wound healing.[10,11] However, the specific roles of recruited monocytes/macrophages, dendritic cells, and tissue macrophages in wound healing are unclear.[12] Wound macrophages initially display a "classical" activation state, indicated by expression of proinflammatory cytokines such as IL-12, IL-1β, IL-6, TNF-α, and iNOS. Proinflammatory, or M1-like, macrophages work to clear debris and recruit additional inflammatory cells. As the inflammatory phase progresses, macrophages phagocytose apoptotic cells in the wound and chemokines are released (e.g., CXCL12), promoting the transition from a proinflammatory state to one promoting tissue repair and remodeling.[13,14] This occurs as the predominant macrophage phenotype in the wound transitions to an "alternatively activated" state, or M2-like, secreting anti-inflammatory cytokines such as IL-4, IL-10, IL-13, and TGF-β.[10,15] In vivo, macrophages exist along a spectrum and the distinct phenotypes seen in vitro (e.g., M1, M2) are rarely seen.[10,16,17]

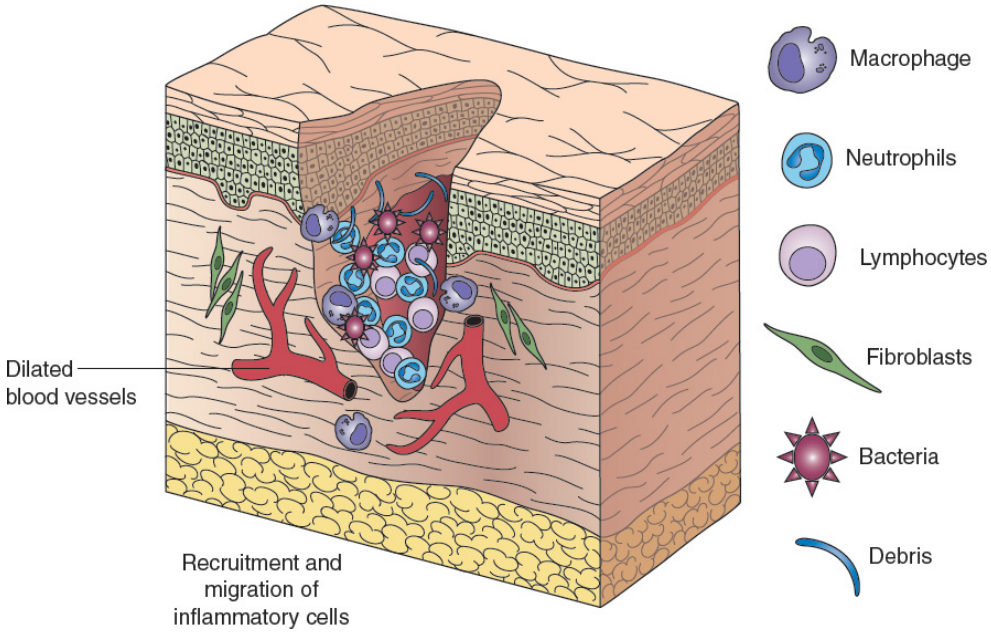

Figure 5.4 Phase 2—Inflammation.

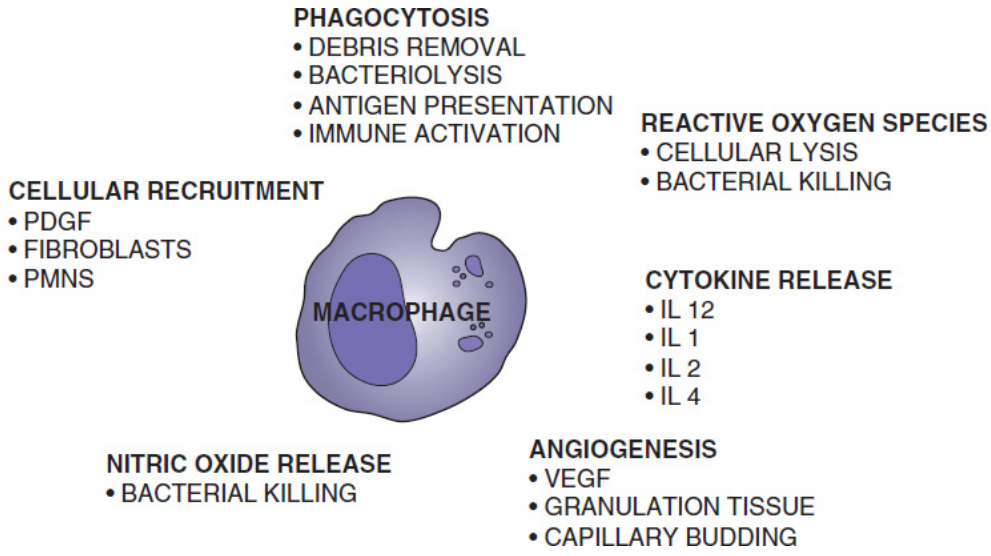

Figure 5.5 Macrophage functions.

The mechanisms underlying monocyte-macrophage phenotype plasticity in vivo are complex, but are under intense investigation. An early step in this transition of monocyte-macrophages from the proinflammatory to the anti-inflammatory phenotype, and thus the initiation of tissue repair, is the ingestion of apoptotic PMNs and other immune cells by monocyte-macrophages. Apoptotic neutrophils have been found to secrete a variety of signaling molecules, such as lysophosphatidylcholine, which attract

monocyte-macrophages via the chemotaxis receptor G2A, causing subsequent engulfment of these cells.[18] As wound healing progresses, monocyte-macrophages show increased expression of MerTK, a cell-surface tyrosine kinase involved in phagocytosis of apoptotic cells; these $MerTK^{+}Ly6C^{lo}$ monocyte-macrophages demonstrate the ability to produce VEGF and TGF-β.[19] Indeed, it appears that phagocytosis of these apoptotic cells triggers the release of these growth factors and augments other tissue repair processes. In one study, Voll et al.[20] demonstrated that coculture of LPS-activated monocyte-macrophages with apoptotic lymphocytes inhibited monocyte-macrophage expression of proinflammatory mediators such as TNF-α and increased release of anti-inflammatory cytokines. These findings were replicated in a subsequent study where human peripheral blood monocytes failed to upregulate expression of proinflammatory mediators IL-1β, IL-8, and TNF-α, but demonstrated increased TGF-β expression in monocyte-macrophages that engulfed apoptotic PMNs compared with naive monocyte-macrophages.[21]

In addition to the cellular and molecular mechanisms underlying monocyte-macrophage plasticity, the maturing field of epigenetics has become a new focus in the investigation of monocyte-macrophage–mediated inflammation (**Fig. 5.6**). A number of epigenetic alterations have been associated with MΦ polarization.[22,23] Histone deacetylases (HDACs) are a group of epigenetic regulators associated with influencing monocyte-macrophage phenotype via alterations in chromatin conformation. For example, HDAC3 has been found to promote proinflammatory and inhibit anti-inflammatory monocyte-macrophage polarization.[24–26] In Mullican et al.,[25] mice lacking HDAC3 in monocyte-macrophages displayed a gene expression profile recapitulating in vitro M2 activation. Furthermore, a chromatin immunoprecipitation assay revealed localization of HDAC3 to a subset of sites bound by PU.1, a major determinant of the monocyte-macrophage epigenome.[27,28]

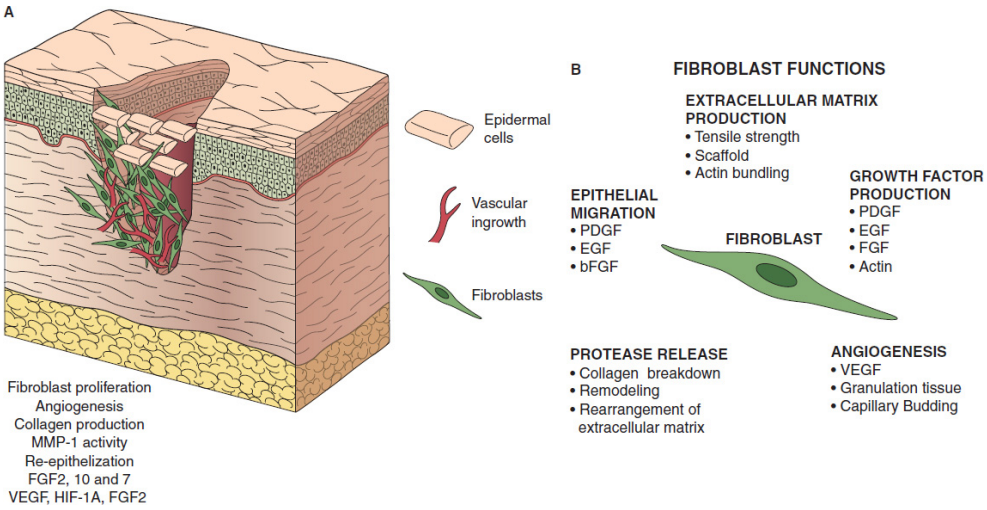

Figure 5.6 **A**: Phase 3—Proliferation. Vast array of cells are recruited into the wound bed and carry out diverse functions including proliferation and deposition of ECM. **B**: Fibroblast functions.

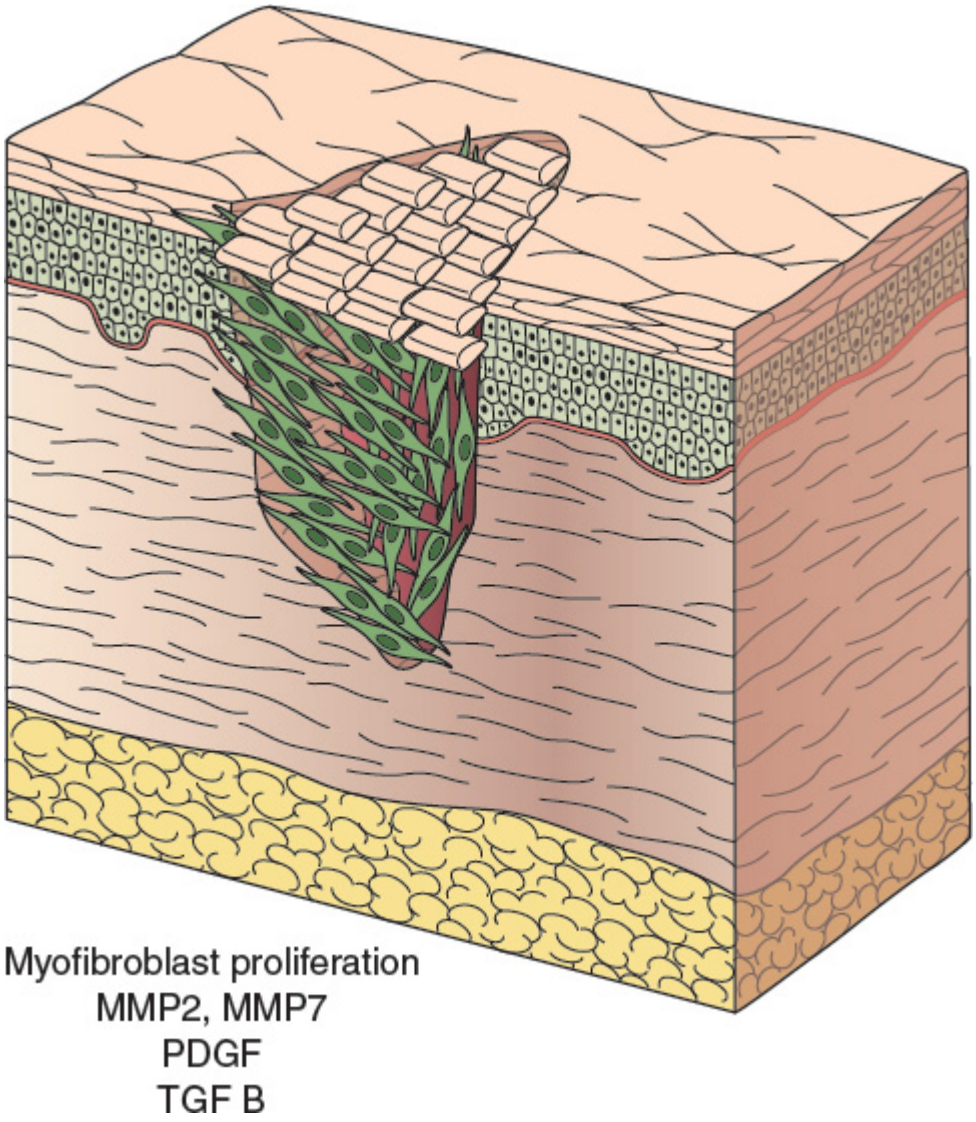

Figure 5.7 Phase 4—Remodeling and maturation.

Epigenetic enzymes also play a role in monocyte-macrophage phenotype skewing in type 2 diabetes (T2D) and metabolic syndrome. Hyperlipidemia has been shown to induce DNA methylation and repress anti-inflammatory cytokines; similarly, a genome-wide analysis for promoter methylation in MΦs revealed hypomethylation of M1 genes and hypermethylation of M2 reparative genes.[29] DNA methyltransferase 3b has been found to promote M1 activation in obese mice by DNA methylation of peroxisome proliferator-activated receptor γ1 promoter. Furthermore, knockdown of DNA methyltransferase 3b enhances M2 activation and suppresses the M1 response.[30]

Given the role of epigenetic factors in the systemic inflammatory milieu of type 2 diabetes (T2D) and metabolic syndrome, attention has recently turned to epigenetic alterations present within diabetic wounds (**Fig. 5.7**). Alterations in histone methylation have been linked to impairments in diabetic wound healing. As mentioned previously, pathologic expression of IL-1β contributes to impaired wound healing.[31] In a study by Kimball et al.,[10] monocyte-macrophages isolated from wounds of a diet-induced obese mouse model of T2D expressed increased IL-1β after stimulation with LPS, and chromatin immunoprecipitation analysis revealed increased histone H3 lysine (H3K) 4 (H3K4; activation mark) and decreased H3K27 (repressive mark) methylation, suggesting an epigenetic mechanism underlying IL-1β expression. Another epigenetic event that strongly influences healing is decreased global methylation through a reduction of (H3K27) trimethylation.[32] Gallagher et al.[33] discovered that, in diet-induced obese mice, the IL-12 promoter exhibited increased demethylation of the repressive H3K27me3 mark in bone marrow progenitor cells, circulating blood monocytes and tissue monocyte-macrophages. This allowed increased expression of proinflammatory IL-12. Further, the histone demethylase enzyme JMJD3 was decreased at the IL-12 gene, suggesting that these monocyte-macrophages were epigenetically preprogrammed toward a proinflammatory phenotype, ultimately negatively impacting wound healing.[33]

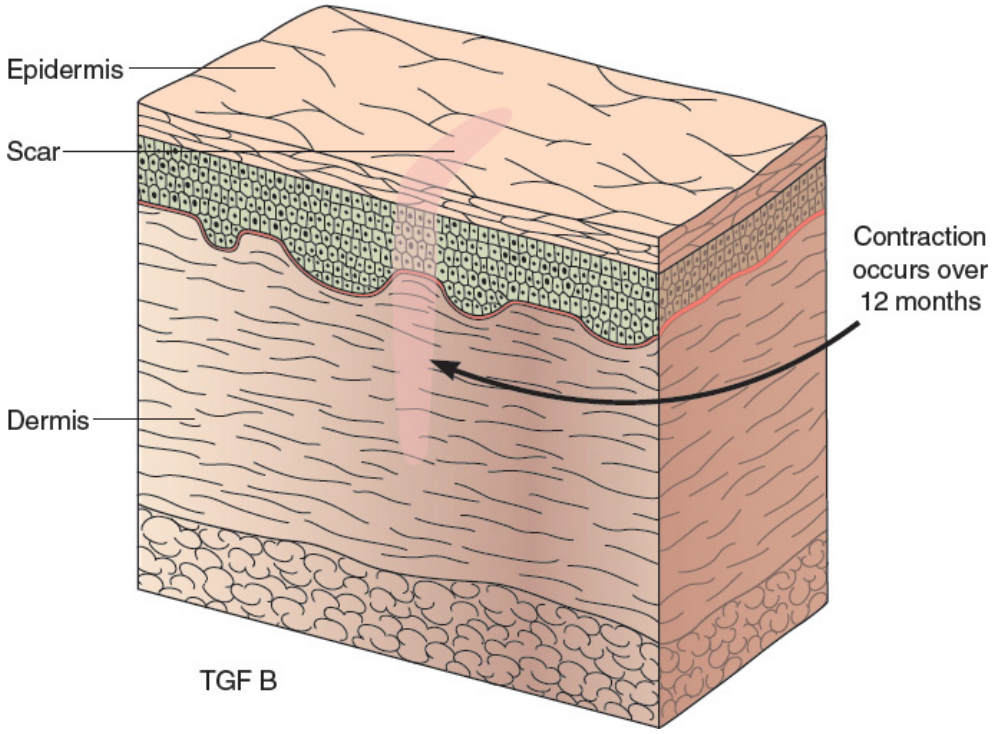

Figure 5.8 Contraction of scar—This process occurs over the course of 1 year.

MicroRNAs regulate gene expression and interact with epigenetic enzymes through a complicated feedback network. It has recently been demonstrated that hyperglycemia leads to changes in the microRNA signature in wound healing, and they have been found to play a role in the dysregulated inflammation of diabetic wounds.[34–36] For example, miR-125b epigenetically enhances monocyte-macrophage activation by increasing the responsiveness to IFN-γ and concurrently inhibits the reparative phenotype by targeting the M2 transcription factor IRF4.[37] Thus, although this field of study is in its relative infancy, there is great potential for continued exploration of the epigenetic mechanisms in inflammatory disease and diabetic wound healing.

Proliferation Phase

The subsequent proliferation phase is characterized by the recruitment and activation of keratinocytes and fibroblasts. During this phase, growth factors stimulate keratinocytes to re-epithelialize the wound.[15] During this time, the provisional matrix established by platelets during hemostasis is replaced by granulation tissue. Fibroblasts secrete proteinases and matrix

metalloproteases (MMPs) to degrade the provisional matrix while simultaneously secreting collagen and other extracellular matrix (ECM) proteins into the granulation tissue.[38]

The defining characteristic of the proliferative phase of healing is ECM production, as shown in **Figure 5.8**. The provisional ECM is a protein scaffold that stabilizes wound edges and provides a framework for migration of PMNs, macrophages, fibroblasts, and other cells into the wound from surrounding tissues. As the inflammatory phase slows the proliferative phase begins and becomes dominant, fibroblasts replace macrophages as the most numerous cell type. Like macrophages, fibroblasts are multifunctional. They are responsible for new tissue formation, collagen production and the laying down of the ECM (**Fig. 5.9**). Angiogenesis occurs simultaneously as new capillaries form and blood vessels penetrate the provisional matrix sprouting from vessels of the surrounding uninjured tissues. Vasculogenesis a process dictated by endothelial progenitor cells (EPCs) from bone marrow, that form de novo blood vessels. The processes that actually coordinate formation of ECM and new tissue with angiogenesis are not well defined. Signaling pathways that stimulate new tissue formation involve the role of low oxygen tension that increases the expression "hypoxia-induced factor" (HIF) by vascular endothelial cells. SDF-1α has been shown to be a key chemokine that promotes vasculogenesis.[39]

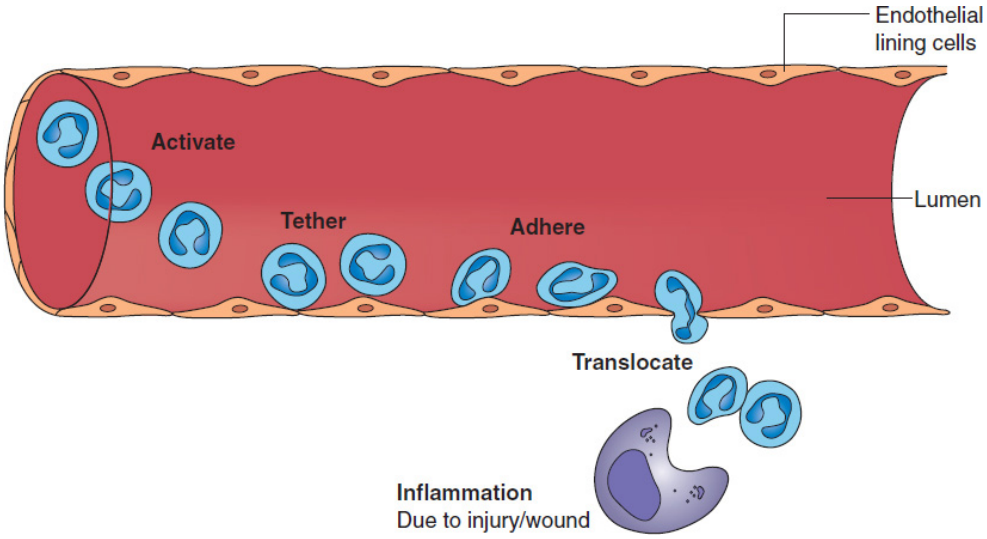

Figure 5.9 The biochemical factors that elicit migration of cells from intravascular compartment into the wound site.

As the proliferative phase progresses the predominant cell in the wound site is the fibroblast. This multifunctional cell of mesenchymal origin mainly produces and deposits the new matrix for structural integrity at the level of the wound bed. The ECM is primarily collagen. At least 23 individual types of collagen have been identified—type I is present mostly in scar tissues.[40] Fibroblasts produce collagen via their attachment to the cables of the provisional fibrin matrix.[41] During this process, there is an important step involving hydroxylation of proline and lysine residues.[42] The collagen molecule transforms itself into the classical triple helical structure and thereafter its nascent chains are modified through glycosylation[43]; this procollagen molecule is released into the extracellular space.[44] The hydroxyproline in collagen gives the molecule its stable helical conformation,[45] whereas fully hydroxylated collagen has higher stability, unhydroxylated forms are fragile, similar to collagen produced under anaerobic disease conditions or vitamin C–deficient states (scurvy), where in the collagen undergoes denaturation easily and can break.

Finally, collagen released into the extracellular space undergoes further processing by cleavage of the procollagen N- and C-terminal peptides. Cross-linking steps give collagen its strength and stability over time.[46]

Remodeling Phase

The final phase of wound healing is the remodeling phase and begins once granulation tissue is present. Here, fibroblasts differentiate into contractile myofibroblasts that contract the wound and the collagen III deposited in the ECM during the proliferation phase is exchanged for collagen I which has a higher tensile strength.[47] Once healed, the site is mechanically functional but many structural components, for example, hair follicles, may not recover and the healed site has, at maximum, ~70% of the original tensile strength.[15]

The remodeling phase is characterized by continued synthesis and degradation of the ECM components trying to establish a new equilibrium—and the formation of an organized scar (**Fig. 5.10**). Collagen degradation occurs[48] via the action of specific collagenases that are secreted by various cells; fibroblasts, neutrophils, and macrophages each of which can cleave the collagen molecule at differing specific locations on all three chains, and break it down to characteristic three-quarter and one-quarter pieces. These

collagen fragments undergo further denaturation and digestion by other proteases. Several molecules including TGF-β play a major role in the remodeling phase.

CLINICAL CONSIDERATIONS

Multiple clinical pathologies can impair wound healing as illustrated in **Figure 5.9**.

Chronic versus Acute Wounds

Wounds heal within a reasonable time of 4 to 6 weeks. Those 4 that do not are termed chronic. As shown in **Table 5.1**, a variety of factors and disease conditions impair wound healing and result in chronic nonhealing wounds. Reasons that lead to chronicity instead of normal healing, are complex—but the salient points are detailed below. The most important concept is a persistent proinflammatory condition that paradoxically leads to increased degradation of matrix proteins, and an unstable wound that is recalcitrant to healing.

Advanced Age and Gender

Many clinical and animal studies at the cellular and molecular level have examined age-related changes and delays in wound healing. It is commonly recognized that, in healthy older adults, the effect of aging causes a temporal delay in wound healing, but not an actual impairment in terms of the quality of healing.[49] Delay wound healing in the aged is associated with an altered inflammatory response, such as delayed T-cell infiltration into the wound area with alterations in chemokine production and reduced macrophage-phagocytic capacity.[50] Overall, there are global differences in wound healing between young and aged individuals.

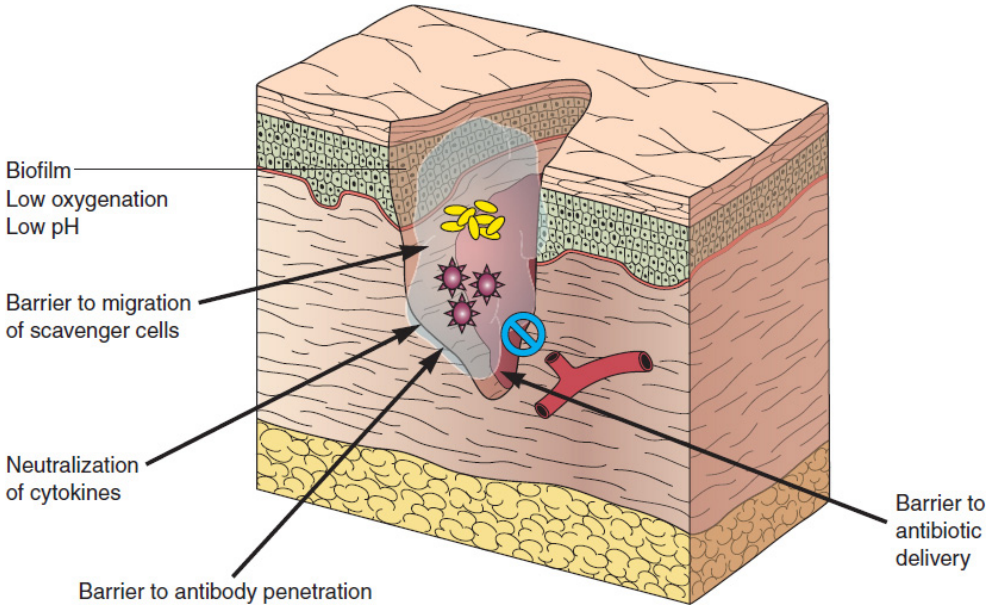

Figure 5.10 Effects of biofilm on wound healing.

Sex hormones play a role in age-related wound healing deficits. Compared with aged females, aged males have been shown to have delayed healing of acute wounds. A partial explanation for this is that the female estrogens (estrone and 17β-estradiol), male androgens (testosterone and 5α-dihydrotestosterone, DHT), and their steroid precursor dehydroepiandrosterone (DHEA), appear to have significant effects on the wound healing process.[51] It was recently found that the differences in gene expression between elderly male and young human wounds are almost exclusively estrogen regulated.[52] Estrogen effects wound healing by regulating a variety of genes associated with regeneration, matrix production, protease inhibition, epidermal function, and genes primarily associated with inflammation.[53] Studies indicate that estrogen can improve the age-related impairment in healing in both men and women, while androgens regulate cutaneous wound healing negatively.

Several treatments to reduce the age-related impairment of healing have been studied. Interestingly, exercise has been reported to improve cutaneous wound healing in older adults as well as aged mice, and the improvement is associated with decreased levels of proinflammatory cytokines in the wound tissue. Improved healing response may also be due to an exercise-induced anti-inflammatory response in the wound.[54]

Table 5.1 Cellular and Biologic Events That Frame the Normal Wound Healing Process

Phase	Cellular and Biophysiologic Events
Hemostasis	Vascular constriction Platelet aggregation, degranulation, and fibrin formation (thrombus)
Inflammation	Neutrophil infiltration Monocyte infiltration and differentiation to macrophage Lymphocyte infiltration
Proliferation	1. Re-epithelialization 2. Angiogenesis 3. Collagen synthesis 4. ECM formation
Remodeling	1. Collagen remodeling 2. Vascular maturation and regression

ECM, extracellular matrix.

Nutrition

Malnutrition or specific nutrient deficiencies can have a profound impact on wound healing after trauma and surgery. Patients with nonhealing wounds and experiencing nutrition deficiency often require special nutrients, energy, carbohydrates, proteins, fat, vitamins, and mineral metabolism all can affect the healing process.[55]

Glutamine is the most abundant amino acid in plasma and is a major source of metabolic energy for rapidly proliferating cells such as fibroblasts, lymphocytes, epithelial cells and macrophages, glutamine improves nitrogen balance and diminishes immunosuppression and plays a critical role in stimulating the early inflammatory phase of wound healing. Major surgery, trauma, and sepsis require supplementation of glutamine. Oral glutamine

supplementation has been shown to improve wound breaking strength and to increase levels of mature collagen.[56]

Lipids are used as nutritional support for surgical or critically ill patients to help meet energy demands and provide essential building blocks for wound healing and tissue repair. Polyunsaturated fatty acids (UFAs), consist mainly of two families, n-6 (omega-6 found in soybean oil) and n-3 (omega-3 found in fish oil). Although fish oil has been widely touted, effects of omega-3 fatty acids on wound healing are not conclusive. They have been reported to affect proinflammatory cytokine production, cell metabolism, gene expression, and angiogenesis in wound sites.[57]

Vitamins, Micronutrients, and Trace Elements

Vitamins C (L-ascorbic acid), A (retinol), and E (tocopherol) show potent antioxidant and anti-inflammatory effects. Vitamin C had many roles in wound healing and a deficiency in this vitamin has multiple effects on tissue repair. Vitamin C deficiencies result in impaired healing and have been linked to decreased collagen synthesis and fibroblast proliferation, decreased angiogenesis, and increased capillary fragility. Also, vitamin C deficiency leads to impaired immune response increased susceptibility to wound infection. Similarly, vitamin A deficiency leads to impaired wound healing. The biologic properties of vitamin A include antioxidant activity, increased fibroblast, proliferation, modulation of the cellular differentiation and proliferation, increased collagen and hyaluronate synthesis, and decreased MMP-mediated ECM degradation.[1]

Obesity

The prevalence of obesity continues to increase among adults, children, and adolescents in the United States, with more than 30% of adults and 15% of children and adolescents classified as obese in a recent study. Obesity is well known to increase the risk of many diseases and health conditions, which include coronary heart disease, type 2 diabetes, cancer, hypertension, dyslipidemia, stroke, sleep apnea, respiratory problems, and impaired wound healing. Obese individuals frequently face wound complications, including skin wound infection, dehiscence, hematoma and seroma formation, pressure ulcers, and venous ulcers.[58] An increased frequency of wound

complications has been reported for obese individuals undergoing both bariatric and nonbariatric operations.[59] In particular, a higher rate of surgical site infection occurs in obese patients.

The function of adipose tissue used to be considered as primary caloric storage. However, more recent findings have documented that adipose tissue secretes a large variety of bioactive substances that are collectively named adipokines. Both adipocytes as well as resident macrophages in adipose tissue are known to produce bioactive molecules including cytokines, chemokines and hormone-like factors such as leptin, adiponectin, and resistin. Adipokines have a profound impact on the immune and inflammatory response.[60] The negative influence of adipokines on the systemic immune response seems likely to influence the healing process, although direct proof for this is lacking. Impaired peripheral blood mononuclear cell function, decreased lymphocyte proliferation, and altered peripheral cytokine levels have been reported in obesity. Importantly, many of the obesity-related changes in peripheral immune function are improved by weight loss.[61]

Diabetes Mellitus

Over 30 million people over the age of 18 in the United States have diabetes mellitus.[62] Additionally, another 86 million live with "pre-diabetes," a condition that can progress to type 2 diabetes (T2D).[62] The overall prevalence of diabetes continues to increase, thereby contributing to increasingly high healthcare costs.[62] Diabetes-related healthcare expenditure was 548 billion USD in 2013, accounting for 11% of the total adult healthcare cost, and is projected to exceed 627 billion USD by 2035.[63] Further, it is estimated that approximately 7 million people go undiagnosed thus delaying disease treatment and management.[62] Nonhealing wounds that result in lower limb amputation, are among the most common complications associated with diabetes and account for more than 200 billion USD annually in healthcare costs and loss of productivity.[64] Importantly, amputation is associated with high mortality rates of 16.7% at 12 months and over 50% at 5 years, rates that are worse than many cancers.[65]

Impaired wound healing in diabetes is the result of a combination of factors that promote inflammation and disrupt epithelialization and wound closure. Although this process is complex, it has been shown that neutrophils

and macrophages recruited to the site of the wound are critical components of the healing process.[66–68] During the normal healing process, macrophages are initially proinflammatory and then transition to an anti-inflammatory phenotype where they promote tissue repair and transition to the next phase of healing.[67,69,70] In diabetic wounds, however, this macrophage transition is altered, causing them to remain in a proinflammatory state and prevent wound resolution.[11,33,71,72] The factors driving the macrophage transition are not fully understood but recent evidence suggests that epigenetics plays a role in regulating macrophage function in both normal and diabetic wound healing.[33,73–76] These processes include DNA methylation of CpG islands, and methylation of histone tails.

Additionally, re-epithelialization is delayed in diabetic wounds due to impaired keratinocyte and fibroblast function brought on by hyperglycemia and accumulation of advanced glycation end-products (AGEs)[77–80] and epigenetic regulation has also been implicated in these processes.[81–83]

The etiology of nonhealing diabetic foot ulcerations is multifactorial due to a combination of peripheral neuropathy, peripheral artery disease, and altered immune function.[84] These factors work together to predispose the diabetic patient to ulceration and infection. Despite the cause of the wound, it is failure of the wound to heal that is responsible for considerable morbidity and mortality associated with diabetes. Neuropathic edema makes the diabetic foot susceptible to ulceration and infection[85] and ischemia resulting from occlusive arterial disease reduces blood flow,[86] both contributing to delayed healing in the diabetic wound. Additionally, recruitment of EPCs is impaired in diabetes due to reduced nitric oxide (NO) production which, ultimately, results in impaired angiogenesis.[39] However, the most direct effects on wound healing come from functional alterations in cells activated by the immune response, including platelets, macrophages, neutrophils, endothelial cells, fibroblasts, and keratinocytes; all contributing to a failure to progress through the normal phases of wound healing.

Platelets

Platelets are key constituents of hemostasis and are responsible for some of the earliest events in response to injury, initially forming a platelet plug. As healing progresses, however, the clot must be degraded in order for re-epithelialization to occur. Sustained high glucose and insulin resistance

causes platelets to release high levels of fibrinogen and plasminogen activator inhibitor 1 (PAI-1) making them more adherent to the vascular endothelium and more likely to aggregate.[87,88] Additionally, under diabetic conditions, platelets have been shown to be less responsive to NO released from the vascular endothelium which normally reduces aggregation at the vessel wall.[89] Exacerbating this, defects in insulin signaling cause the vascular endothelium to produce less NO.[90,91] Thus, platelet dysfunction in diabetes contributes to development of microvascular disease that is well established in diabetic patients. Hence, in the setting of wound healing, the platelet phenotype induced by diabetes hinders wound healing by reducing coagulation during hemostasis.

Neutrophils

Neutrophils are important components during the inflammatory phase of wound healing, working to clear pathogens. However, sustained recruitment and activation of neutrophils are associated with chronic, nonhealing wounds.[92–94] Elevated levels of neutrophil-derived proteases are believed to contribute to persistent inflammation and delayed wound healing.[92,93] In addition to proteases, neutrophils release extracellular traps (NETs) composed of decondensed chromatin lined with cytotoxic proteins to kill microbes.[94] It has been shown that the protein responsible for NET formation, peptidyl deiminase 4 (PAD4), is elevated in neutrophils from diabetic mice and humans making them more susceptible to NETosis and potentially contributing to persistent inflammation and tissue damage in diabetes.[94]

Monocytes/Macrophages

Monocytes are recruited to the wound site very early during the inflammatory phase where they differentiate into macrophages and dendritic cells. Despite the lack of clarity regarding the in vivo definition of these cells, there is substantial evidence that infiltrating monocytes/macrophages are critical for establishing the initial inflammatory phase as well as promoting the transition from a proinflammatory to anti-inflammatory environment.[33,67,69] In diabetic wounds this transition does not occur and macrophages remain in a persistent inflammatory state where they promote the destruction of the surrounding tissue both directly and indirectly by recruiting other proinflammatory

immune cells.[33,95,96] It has been recently reported that Ly6C^{Hi} monocytes/macrophages, which have been shown to promote inflammation, normally transition to Ly6C^{Lo}, which are more regenerative; however, in diabetic wounds, a second wave of Ly6C^{Hi} macrophages are recruited during the reparative phase and fail to transition to the anti-inflammatory Ly6C^{Lo} cells contributing to a sustained proinflammatory environment.[10] Furthermore, it has been shown that hyperglycemia and formation of AGEs impede the phagocytic capacity of macrophages ability to clear apoptotic neutrophils thereby promoting a sustained proinflammatory state.[97,98] Since the transition from a pro- to anti-inflammatory state is partly stimulated by neutrophil clearance, this results in a higher number of proinflammatory macrophages present in the wound. Additionally, studies have shown that monocyte-macrophage infiltration is sustained in diabetic mouse models due to alterations in expression of P-selectin and macrophage chemoattractant protein 1 (MCP-1).[95]

Endothelial Cells

Endothelial cells line the luminal surface of blood vessels and are responsible for regulating vasoconstriction and dilation by expression of vasoactive factors such as endothelial nitric oxide synthase (eNOS).[99] Reduced eNOS expression is associated with peripheral neuropathy and peripheral artery disease and contributes to decreased peripheral blood flow which, in turn, slows wound healing.[100] Additionally, EPCs are required for neovascularization of the wound and eNOS stimulates mobilization of EPCs from the bone marrow[39,101]; thus the observed decrease in eNOS also contributes to impaired local angiogenesis during diabetes.

Keratinocytes and Fibroblasts

The late phase of wound healing is carried out by keratinocytes and fibroblasts. In nonhealing diabetic wounds, a variety of alterations in keratinocyte function contribute to diminished epithelialization including defective keratinocyte migration and proliferation,[102,103] gap junction abnormalities,[104] chronic inflammation and infection,[95,105] reduced angiogenesis,[39,101] oxidative stress,[105] and abnormal expression of MMPs.[82,106,107] The mechanisms associated with these processes have been reviewed elsewhere.[108–110]

Alterations in fibroblast function also contribute to dysfunctional epithelialization and delayed healing in diabetic wounds. These are primarily involved with decreased proliferation, increased apoptosis, and impaired migration to the wound site.[79,80,111] Alterations in both keratinocytes and fibroblasts can be induced directly by hyperglycemia and AGE formation.[77,78,81,112,113] Moreover, crosstalk between the two cell types is important for re-epithelialization and is dependent on a delicate balance between proinflammatory and anti-inflammatory cytokine expression in the wound.[114]

In summary the impaired healing that occurs in individuals with diabetes, involves hypoxia, dysfunction in fibroblasts and epidermal cells, impaired angiogenesis and neovascularization, high levels of MMP, damage from reactive oxygen species and advanced glycation end products, decreased host immune resistance and neuropathy.

MEDICATIONS AND DIETARY SUPPLEMENTS

Glucocorticoid Steroids

Systemic glucocorticoids, which are frequently used as anti-inflammatory agents, are well known to inhibit wound repair via global anti-inflammatory effects and suppression of cellular wound responses, including fibroblast proliferation and collagen synthesis. Systemic steroids cause wounds to heal with incomplete granulation tissue and reduced wound contraction.[115] Glucocorticoids also inhibit production of HIF-1, a key transcriptional factor in healing wounds.[116] Beyond effects on repair itself, systemic corticosteroids may increase the risk of wound infection. While systemic corticosteroids inhibit wound repair, topical application produces quite different effects. Topical low-dosage corticosteroid treatment of chronic wounds has been found to accelerate wound healing, reduce pain and exudate, and suppress hypergranulation tissue formation in 79% of cases. While these positive effects are striking, careful monitoring is necessary to avoid a potential increased risk of infection with prolonged use.[117]

Peripheral Vascular Disease

Total disease prevalence based on objective testing has been evaluated in several epidemiologic studies and is in the range of 3% to 10%, increasing to 15% to 20% in persons over 70 years.[118] Peripheral vascular disease (PVD) is an independent risk factor for subsequent ulceration and limb loss in diabetes. It is present in 50% of patients with diabetic foot ulcer (DFU), a proportion that may be increasing. Those with DFU and peripheral arterial disease (PAD) are less likely to heal and more likely to require amputation compared to patients without PAD. It is therefore essential that PVD is identified in all patients with diabetes.

Patients with PVD commonly suffer from chronic toe and foot sores, cramping leg muscles when walking or numbness, weakness or heaviness in the muscles. Other chronic PVD symptoms include:

- Numbness in the extremities
- Weakness and atrophy of calf muscles
- A feeling of coldness in legs or feet
- Changes in the color of the feet: feet will turn pale when elevated and turn dusky red when in the dependent position
- Hair loss over the dorsum of the feet, thickening toenails
- Painful ulcers and/or gangrene in tissue, typically in the toes

Traditional wound care algorithms include aggressive detection of PAD and treatment with revascularization for all patients with PVD and lower extremity wounds—in order to prevent limb amputation. This is covered in data in other chapters.

Cigarette Smoking

It is well known that smoking increases the risk of heart and vascular disease, stroke, chronic lung disease, and many kinds of cancers. Similarly, the negative effects of smoking on wound healing outcomes have been known for a long time.[119] Postoperatively, patients who smoke show a delay in wound healing and an increase in a variety of complications such as infection, wound rupture, anastomotic leakage, wound and flap necrosis, epidermolysis, and a decrease in the tensile strength of wounds.[120]

Most studies have focused on the effects of nicotine, carbon monoxide, and hydrogen cyanide from smoke. Nicotine interferes with oxygen supply by inducing tissue ischemia, since nicotine can cause decreased tissue blood

flow via vasoconstrictive effects.[121] Nicotine stimulates sympathetic nervous activity, resulting in the release of epinephrine, which causes peripheral vasoconstriction and decreased tissue blood perfusion. Nicotine also increases blood viscosity caused by decreasing fibrinolytic activity and augmentation of platelet adhesiveness. In addition to the effects of nicotine, carbon monoxide in cigarette smoke also causes tissue hypoxia. Carbon monoxide binds to hemoglobin with an affinity 200 times greater than that of oxygen, resulting in a decreased fraction of oxygenated hemoglobin in the bloodstream. Hydrogen cyanide, another well-studied component of cigarette smoke, impairs cellular oxygen metabolism, leading to compromised oxygen consumption in the tissues. Beyond these direct tissue effects, smoking increases the individual's risk for atherosclerosis and chronic obstructive pulmonary disease, two conditions that might also lower tissue oxygen tension.[66,122]

Chemotherapy and Radiation

Chemotherapy Drugs

Most chemotherapeutic drugs are designed to inhibit cellular metabolism, rapid cell division, and angiogenesis and thus inhibit many of the pathways that are critical to appropriate wound repair. These medications inhibit DNA, RNA, or protein synthesis, resulting in decreased fibroplasia and neovascularization of wounds.[123] Chemotherapeutic drugs delay cell migration into the wound, decrease early wound matrix formation, lower collagen production, impair proliferation of fibroblasts, and inhibit contraction of wounds.[115] In addition, these agents weaken the immune functions of the patients, and thereby impede the inflammatory phase of healing and increase the risk of wound infection. Chemotherapy induces neutropenia, anemia, and thrombocytopenia, thus leaving wounds vulnerable to infection, causing less oxygen delivery to the wound, and also making patients vulnerable to excessive bleeding at the wound site.

Radiation

Radiation is one of the most commonly used therapies for the treatment of multiple types of human cancer.

Hemostasis

Andrea T. Obi and Peter K. Henke

Key Points

1. During the time that thrombin forms, natural anticoagulant mechanisms oppose further thrombin formation and help to localize thrombin activity to areas of vascular injury. Just as thrombin generation is key to coagulation, antithrombin is the central anticoagulant protein.
2. The endothelial cell acts as a nonthrombogenic surface, and inflammation tips the balance to procoagulant state.
3. Thrombosis and inflammation are closely linked, and may perpetuate each other. Leukocytes and chemokines are involved with normal DVT resolution. These essential inflammatory mechanisms may drive vein wall injury.
4. Both acquired and inherited factors contribute to pathologic thrombosis; often occurring together.
5. Factor VIII and IX deficiency states are involved in hemophilia A and B and von Willebrand disease.

BASIC CONSIDERATIONS

Coagulation is an essential homeostatic mechanism for survival, and involves tightly controlled processes to maintain vascular integrity, including thrombosis localization, amplification, and neutralization. These coordinated steps occur at the vessel, cellular, and subcellular levels. Thrombosis, directly or indirectly, is the underlying leading cause of death in the world, and is an essential part of surgery.

Platelets form the initial hemostatic plug after vascular injury, and are locally activated and aggregation induced (**Fig. 6.1**). Platelet aggregation is mediated by receptors that are part of the mammalian integrin family. This family includes the β_1 family, mediating platelet

interaction with cells, collagen, fibronectin, and laminin; the β_2 family, present on leukocytes mediating interactions between leukocytes and other cells important in inflammation; and the β_3 family (cytoadhesion), including the megakaryocyte-specific glycoprotein (Gp) IIb/IIIa receptor and the vitronectin (Vn) receptor present on platelets and other cells.[1] Platelet aggregation is mediated by GpIIb/IIIa, which binds fibrinogen, von Willebrand factor (vWF), fibronectin, Vn, and thrombospondin to activated platelets. These high-density receptors are hidden on inactivated platelets and become exposed on the surface of activated platelets.

Two platelet activation routes are thought to occur physiologically.[2] Without direct vessel damage, platelet activation may occur via tissue factor (TF) deencryption and activation by protein disulfide isomerase (PDI), with factor VIIa generation and activation of platelets. Alternatively, subendothelial collagen may directly bind to GpVI and vWF, leading to platelet capture and activation. Of note, PDI inhibition can directly block experimental thrombus formation.[3]

Once stimulated, activated platelets contract, with externalization of negatively charged procoagulant phospholipids, including phosphatidylserine and phosphatidylinositol (termed platelet factor 3). This allows the coagulation proteins to assemble on the surface membrane of platelets, accelerating the coagulation reaction.[4] During platelet activation, granules release calcium and serotonin, and membranes are exposed that are rich in receptors for factors Va and VIIIa,[5,6] as well as fibrinogen, vWF, and ADP, a potent activator of other platelets. vWF is responsible for platelet adhesion through binding to GpIb,[7] whereas fibrinogen forms bridges between activated platelets by binding to GpIIb/IIIa on adjacent stimulated platelets.[8] Platelets also release polyphosphates that activate factor XII and the intrinsic pathway.[9]

While long thought to be a bystander in venous thrombosis (VT) as compared to the arterial system, the role of the platelet is now thought to play a critical role, as well as direct later inflammatory cell actions.[10,11] First, recent clinical trials suggest antiplatelet therapy may reduce recurrent VTE.[12] Second, in stasis and nonstasis experimental murine VT, genetic deletion of vWF was associated with significantly reduced VT size and not restored with recombinant factor rVIII.[13] Intravital microscopy also showed direct association of leukocytes and platelets in a growing acute thrombus. Consistently, platelets via $GpIb_2$, may promote VT by colocalizing leukocytes and coagulation factors at the site of injury or stasis in the vein.[14]

Once the platelet plug has formed, the stage is set for coagulation protein assembly (**Fig. 6.2**). Initiating agents for coagulation include subendothelial collagen and TF, usually from vascular injury.[1,2] There is also growing evidence that blood-borne TF associated with leukocytes, or circulating in soluble form, is also involved with venous thrombogenesis.[15,16] Leukocyte adhesion to platelets may trigger leukocyte activation, causing recruitment of blood-borne TF onto the surface of leukocytes associated with thrombus, or recruitment of TF-positive leukocytes onto the growing thrombus.[17] TF, both blood-borne and local, activates the extrinsic pathway of coagulation by complexing with activated factor VII (VIIa), activating factors IX and X to factors IXa and Xa.[16,18] Factor Xa, activated factor V (Va), ionized calcium, and factor II (prothrombin) form on the platelet phospholipid surface

to initiate the prothrombinase complex, which catalyzes the formation of thrombin faster than can be achieved with factor Xa alone.

Thrombin is central to coagulation and acts to cleave fibrinopeptide A (FPA) from the α chain of fibrinogen and fibrinopeptide B (FPB) from the β chain. This leads to the release of fibrinopeptides and the formation of new fibrin monomers, which then cross-link, resulting in fibrin polymerization. Thrombin also activates factor XIII, which catalyzes the cross-linking of fibrin to make the clot firm, activates platelets, and activates factors V and VIII, two nonenzymatic cofactors, to Va and VIIIa. This is important because only activated factors Va and VIIIa are involved in coagulation. Factor XIIIa also cross-links other plasma proteins, such as fibronectin and α_2-antitrypsin, resulting in their incorporation into clot.

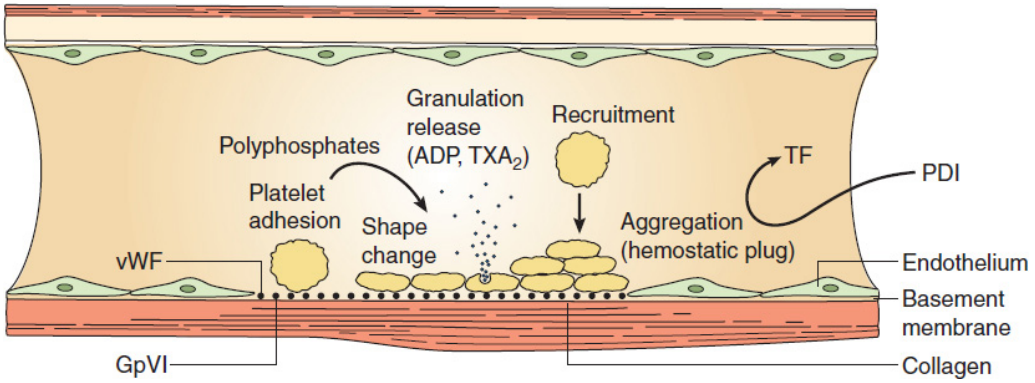

Figure 6.1 Primary hemostasis is achieved initially with a platelet aggregation as illustrated. Note that platelet adhesion, shape change, granule release, followed by recruitment and the hemostatic plug at the area of subendothelial collagen (binds to GpVI) exposure are the initial events for thrombus formation. Platelets can also be activated by PDI with deencryption of TF.

The intrinsic pathway of blood coagulation requires activation of factor XI to XIa. This may occur by both the contact activation system through activation of factor XII, plasma prekallikrein, and high–molecular-weight kininogen and, more important, through thrombin with negatively charged surfaces.[19] Factor XIa activates factor XI autocatalytically and also catalyzes the conversion of factor IX to IXa. After activation, factor VIIIa dissociates from vWF and assembles with factors IXa and X. Factor IXa, factor X, ionized calcium, and thrombin-activated factor VIII (VIIIa) then assemble on the platelet surface in a complex called the *Xase complex* to catalyze the activation of factor X to Xa. Factor Xa then shunts into the prothrombinase complex for further amplification of thrombin formation.

The importance of a mechanism of factor XI activation independent of the contact activation system is apparent because patients deficient in those factors of the contact activation system, including factor XI, have abnormal prolongation in bleeding, whereas patients deficient in factor XII, prekallikrein, and high–molecular-weight kininogen do not.[20] The contact activation system is the most important coagulation process involved in extracorporeal bypass circuits, including cardiopulmonary bypass and extracorporeal membrane oxygenation.

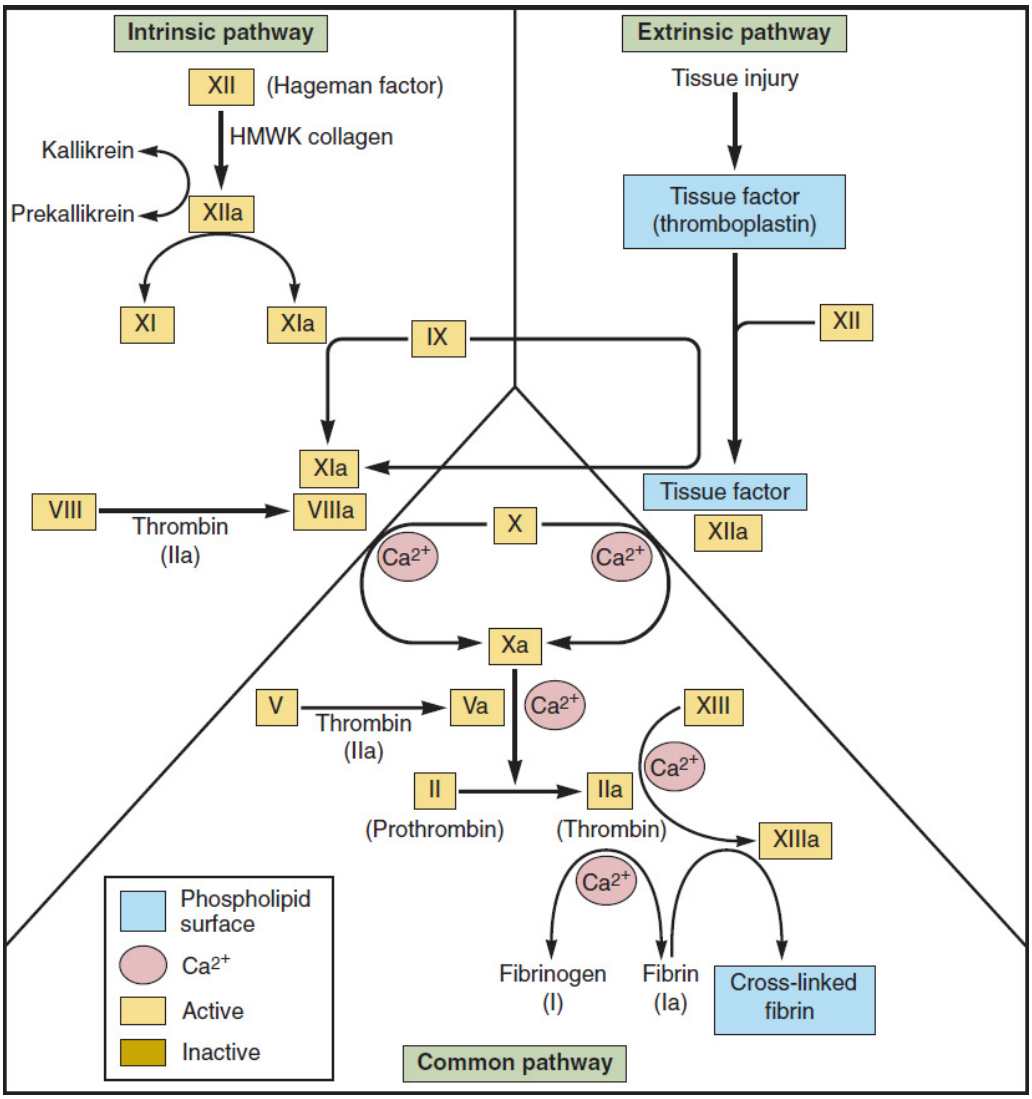

Figure 6.2 The classical pathway showing the interface between the intrinsic pathway, extrinsic pathway, and the common pathway is illustrated with the ultimate production of thrombin. This catalyzes fibrin from fibrinogen, and then cross-links the fibrin to form a stable clot.

NATURAL ANTICOAGULANT MECHANISMS

1 At the same time that thrombin forms, natural anticoagulant mechanisms oppose further thrombin formation and help to localize thrombin activity to areas of vascular injury.[2] Just as thrombin generation is key to coagulation, antithrombin (AT) is the central anticoagulant protein (**Fig. 6.3**). This glycoprotein of 70-kD molecular weight binds to thrombin, preventing the removal of FPA and FPB from fibrinogen, prevents the activation of factors V and VIII, and inhibits the activation and aggregation of platelets. In addition, AT directly inhibits factors IXa, Xa, and XIa.

A second natural anticoagulant is activated protein C (APC), which inactivates factors Va and VIIIa, thus reducing the Xase and prothrombinase complex acceleration of the rate of

thrombin formation. In the circulation, protein C is activated on endothelial cell surfaces by thrombin complexed with one of its receptors, thrombomodulin (TM).[21–23] The formation of this thrombin–TM complex accelerates the activation of protein C compared with thrombin alone. Thrombin, at the same time, by binding to TM, loses its platelet-activating activity as well as its enzymatic activity for fibrinogen and factor V. Protein S is a cofactor for APC.

Another innate anticoagulant is tissue factor pathway inhibitor (TFPI). The protein binds to TF–VIIa complex, inhibiting the activation of factor X to Xa and the formation of the prothrombinase complex.[24] A fourth natural anticoagulant is heparin cofactor II.[25] Its concentration in plasma is estimated to be significantly less than that of AT, and its action is implicated primarily in the regulation of thrombin formation in extravascular tissues. Finally, thrombin is inactivated when it becomes incorporated into the clot.

FIBRINOLYSIS

In addition to natural anticoagulants such as proteins C and S, physiologic clot formation is balanced by a contained process of clot lysis, which prevents thrombus formation from proceeding outside of the injured area (**Fig. 6.4**). The central fibrinolytic enzyme is plasmin, a serine protease generated by the proteolytic cleavage of the proenzyme, plasminogen. Its main substrates include fibrin, fibrinogen, and other coagulation factors. Plasminogen, tissue plasminogen activator (tPA), and α_2-antiplasmin (α_2-AP) become incorporated into the fibrin clot as it forms. Plasminogen activators are serine proteases that activate plasminogen, by cleavage of a single arginine–valine peptide bond, to the enzyme plasmin. Plasminogen activation provides localized proteolytic activity.[26] The major endogenous plasminogen activators include tPA and urokinase, and intrinsic factors, such as factor XII, prekallikrein, and high–molecular-weight kininogen. These later factors of the contact system are more important in clot lysis than thrombus formation. These enzymes may also liberate bradykinin from high–molecular-weight kininogen, resulting in an increase in vascular permeability, prostacyclin (PGI_2) liberation, and tPA secretion. Finally, APC has been found to proteolytically inactivate the inhibitor to tPA, thus promoting tPA activity and fibrinolysis.[27] Thrombin promotes tPA release from endothelial cells as well as the production of plasminogen activator inhibitor (PAI-1) from endothelial cells.[28,29]

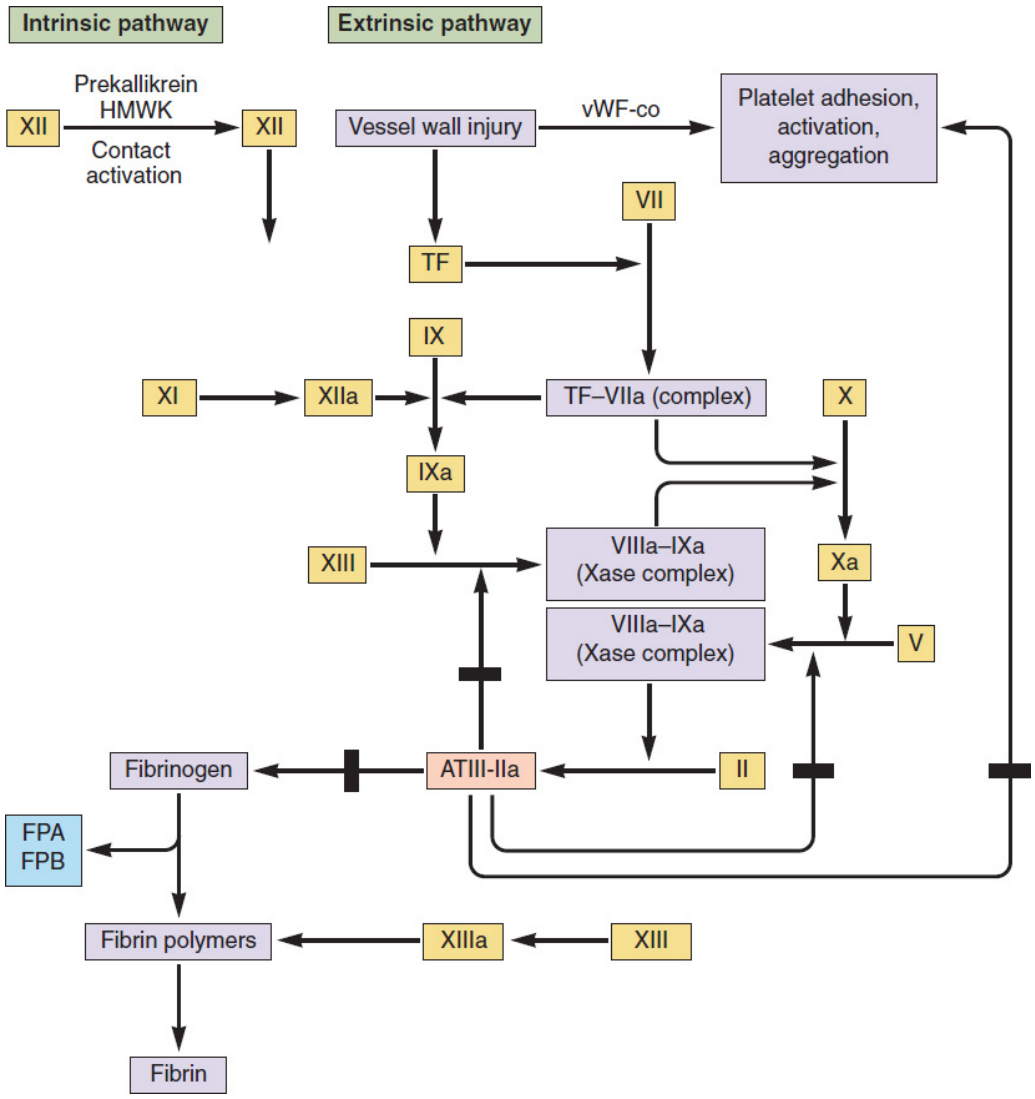

Figure 6.3 Antithrombin is a primary anticoagulant. Note antithrombin complexes with IIa to inhibit fibrin polymerization, as well as factor Xa, and inactivates factors Va and VIIIa.

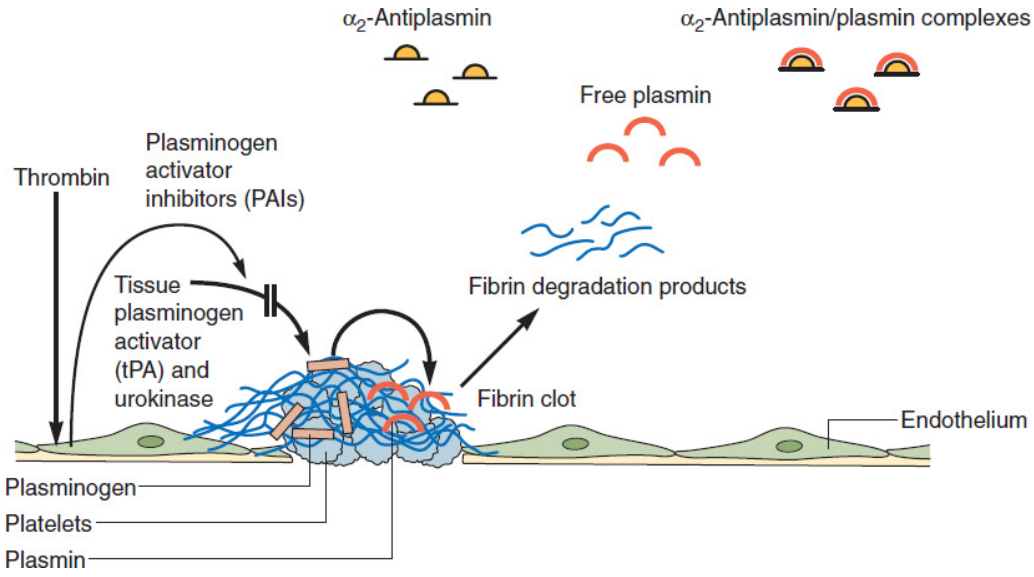

Figure 6.4 Hemostasis with thrombus production is a tight and intricate process that is locally confined. Balancing thrombus production are tissue plasmin activator and urokinase plasminogen activator which activate plasmin and cause thrombolysis. These are balanced by plasminogen activator inhibitor-1 and α_2-antiplasmin. Free plasmin is complexed rapidly. Fibrin degradation products, such as D-dimer, are produced.

Fibrin, when digested by plasmin, yields one molecule of fragment E and two molecules of fragment D. In physiologic clot formation, fragment D is released in dimeric form (D-dimer),[20] and is a marker for fibrinolysis of formed clot. An elevated D-dimer level after treatment of DVT is one biomarker that has been found to accurately predict an ongoing risk of recurrent VTE.[30,31]

Two primary inhibitors of plasmin are important. First, α_2-AP is released by endothelial cells and complexes with plasmin. In physiologic fibrinolysis, α_2-AP is bound to fibrin and excess plasmin is readily inactivated. In plasma, PAI-1 is the primary inhibitor of plasminogen activators.[32] It is secreted in an active form from liver and endothelial cells and stabilized by binding to Vn. PAI-1 levels are elevated by hyperlipidemia, and PAI-1 elevation appears to synergize with factor V Leiden genetic abnormalities.[33]

In summary, coagulation is an ongoing process of thrombus formation, inhibition of thrombus formation, and thrombus dissolution. The central mediators are TF, platelets, thrombin, and plasmin. Abnormalities in coagulation occur when one process—thrombus formation, thrombus inhibition, or fibrinolysis—overcomes the others and dominates the delicate balance.

ENDOTHELIUM AND HEMOSTASIS

2 Through its ability to express procoagulant and anticoagulant factors, vasoconstrictors and vasodilators, as well as key cell adhesion molecules and cytokines, the endothelial cell is a key regulator of hemostasis (**Fig. 6.5**).[34] The vascular endothelium maintains a vasodilatory

and local fibrinolytic state in which coagulation, platelet adhesion and activation, and leukocyte activation are suppressed.

Vasodilatory endothelial products include adenosine, nitric oxide (NO), and PGI_2. A nonthrombogenic endothelial surface is maintained by four main mechanisms, including endothelial production of TM and subsequent activation of protein C, endothelial expression of surface heparan and dermatan sulfate, constitutive expression of TFPI by endothelium (which is markedly accelerated in response to heparin), and local production of tPA and urokinase plasminogen activator (uPA).[34,35] Finally, the elaboration of NO and interleukin (IL)-10 by the endothelium inhibits leukocyte adhesion and activation.

During states of endothelial disturbances such as injury, a prothrombotic and proinflammatory state of vasoconstriction is driven by the endothelial surface. Endothelial release of platelet-activating factor (PAF) and endothelin-1 promotes vasoconstriction.[35] Endothelial cells increase production of vWF, TF, PAI-1, and factor V to augment thrombosis with exposure to prothrombotic stimuli. Finally, in response to endothelial injury, endothelial cells are activated, resulting in increased surface expression of cell adhesion molecules, promoting leukocyte adhesion and activation.

THROMBOSIS, INFLAMMATION, AND RESOLUTION

After VT, an acute to chronic inflammatory response occurs in the vein wall and thrombus progressing from thrombus amplification, to organization, and vein recanalization (often at the expense of vein wall fibrosis and vein valvular damage). Initially, there is an increase in neutrophils (PMN) in the vein wall followed by monocytes/macrophages. Cytokines, chemokines, and inflammatory factors (e.g., tumor necrosis factor [TNF]) facilitate inflammation. The ultimate response of the vein wall depends on proinflammatory and anti-inflammatory mediator balance at the interface between the leukocyte, activated platelet, and endothelium.[36]

Cell Adhesion Molecules

Selectins (P- and E-selectins, sP-sel, sE-sel) have been found to be intimately involved in thrombosis (**Fig. 6.6**).[37] P selectin is the first upregulated glycoprotein on activated platelets (α granules) and endothelial cells (Weibel–Palade bodies). They mediate the adhesion of leukocytes, platelets, and even cancer cells in inflammation and thrombosis. sP-sel is released from activated platelets and endothelial cells and levels rise significantly during pathologic conditions.[38–40] The P-selectin receptor is P-selectin glycoprotein ligand-1 (PSGL-1). P-selectin: PSGL-1 interactions trigger the release of procoagulant microparticles (MPs) that support fibrin formation, thrombus growth, and increase monocyte TF expression.

sP-sel has been studied as a biomarker for DVT,[38,41–43] and combining sP-sel with Wells score (clinical pretest probability of DVT) establishes the diagnosis of DVT. An sP-sel (≥90 ng/mL) combined with Wells score (≥2) showed a better PPV (91%) than D-dimer (≥500 ng/mL) combined with Wells score (≥2), which was 69%.[44] E-selectin, upregulated after P-

selectin, is an important regulator of thrombus formation and fibrin content in a mouse VT model.[45,46] Endotoxin-induced TF-mediated coagulation is enhanced in humans carrying the *S128R* E-selectin allele,[47] and patients homozygous for the *S128R* E-selectin allele have an increased risk for VTE recurrence.[48] E-selectin has been shown to be efficient at raising the affinity and avidity of two (CD18) integrins which support neutrophil trafficking to sites of acute inflammation and recruit platelets and red blood cells.[49]

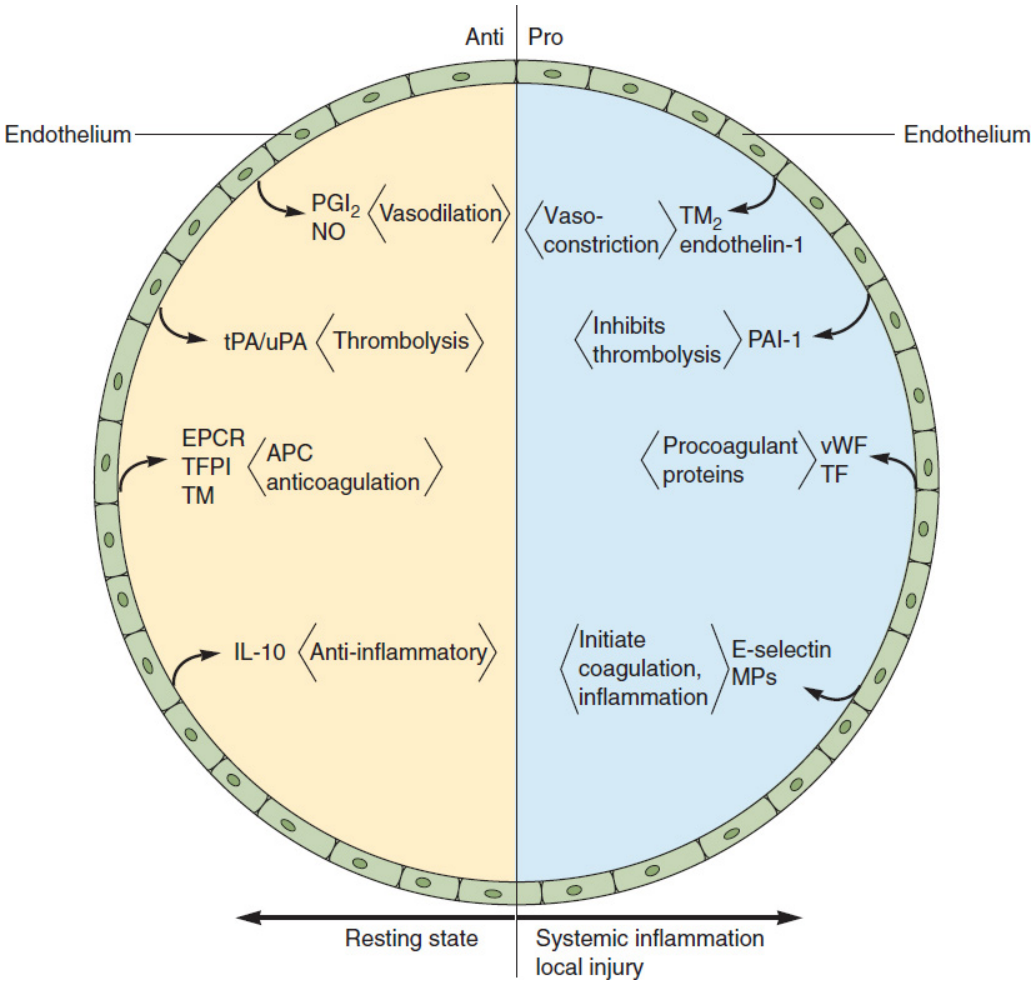

Figure 6.5 The endothelium is a primary interface allowing both anticoagulant functions in the resting state, with prostacyclin, NO, plasminogen activators, and thrombomodulin. Procoagulant proteins are expressed on activated endothelium including selectins, von Willebrand factor, TF, as well as PAI-1.

Other factors of importance to venous thrombogenesis include vWF, a factor that stabilizes procoagulant factor VIII to promote the initiation and formation of stable thrombus at the site of vascular inflammation and TF. Using a ferric chloride model of vein wall injury, it has been shown that occlusive thrombus formation is dependent on vWF.[50] TF activity is increased in cells treated with chemotherapy and in circulating MPs. Patients with cancer have elevated MPs, suggesting a role for TF in the pathogensis of cancer-associated DVT.[51] In addition, cancer patients with VTE were found to have elevated levels of MP TF compared to cancer patients without VTE.[52,53]

Leukocytes and Thrombosis

Inflammatory cells are important to the process of thrombus recanalization and organization (**Fig. 6.7**).[54,55] Thrombus resolution resembles wound healing, and involves profibrotic growth factors, collagen deposition, matrix metalloproteinase (MMP) expression, and activation.[56,57] As the thrombus resolves, a number of proinflammatory factors are released into the local environment, including interleukin-1 beta (IL-1β) and tumor necrosis factor-alpha (TNF-α).[58] The cellular sources of these different mediators are probably leukocytes and smooth muscle–like cells within the resolving thrombus and adjacent vein wall. The fact that leukocytes invade the thrombus in a specific sequence suggests their importance in the normal thrombus resolution.[59]

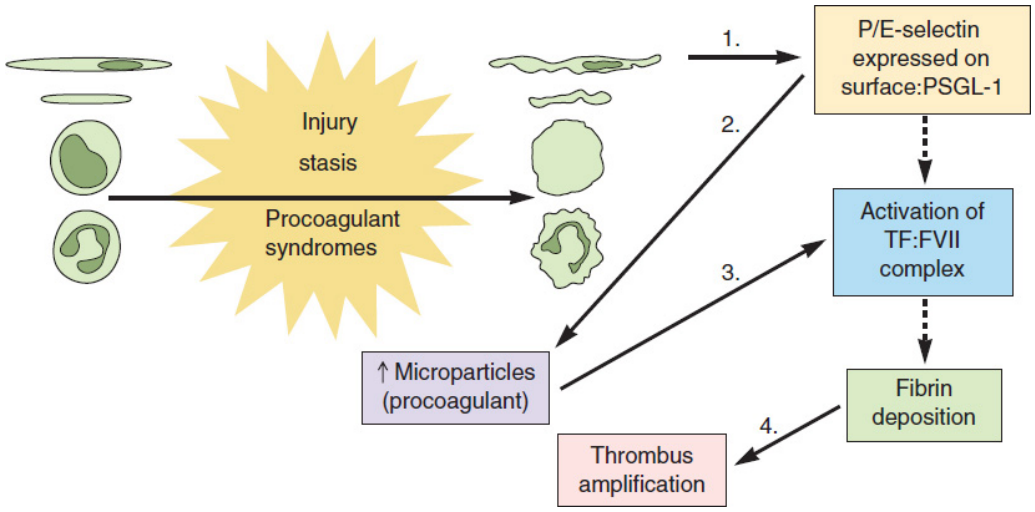

Figure 6.6 The interaction between stasis injury and procoagulant syndromes is represented by Virchow triad. Endothelial and vascular injuries cause leukocytes and platelets to express P- and E-selectins and the PSGL-1 receptor. Microparticles are released which express TF. This stimulates the coagulation pathway, fibrin production, and thrombus amplification.

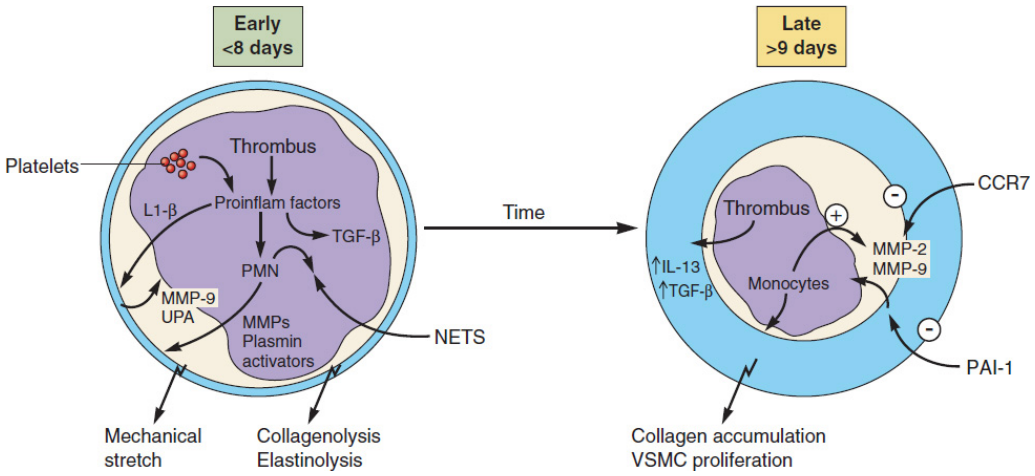

Figure 6.7 The proposed resolution mechanism involves both early thrombolysis with a large distending clot and then, over time, a fibrotic thrombus that resembles scar tissue as produced. Note proinflammatory factors, as well as neutrophils (releasing NETs), platelets, and MMP are present early with subsequent vein wall injury related to collagenolysis and elastinolysis. Later, vascular smooth muscle cell proliferation appears to occur, with thrombus resolution with increased profibrotic growth factor such as IL-13 and TGF-β. This promotes collagen accumulation. Both PAI-1 and CCR7 are protective against fibrosis.

The first cell type in the thrombus is the PMN. Although 3 PMNs may cause vein wall injury, they are essential for early thrombus resolution by promoting both fibrinolysis and collagenolysis.[60,61] It is likely the timing of PMN influx and the amount of perithrombus blood flow that tip PMN activities towards thrombosis or thrombolysis. In a rat model of stasis VT, neutropenia was associated with larger thrombi at 2 and 7 days, and was correlated with increased thrombus fibrosis and significantly lower thrombus levels of both uPA and MMP-9.[60] Conversely, in a nonstasis VT model, PMNs promote thrombosis.[14] Through processes that also involve the initial activation of leukocytes and platelets, PMNs form neutrophil extracellular traps (NETs), which are extracellular fragments of DNA containing histones and antimicrobial proteins.[14,62] The NETs provide a scaffold for thrombus formation, are proinflammatory, and are prothrombotic.[63]

In order to investigate if plasma DNA is a surrogate for NETs in patients with DVT, and to determine correlations with other biomarkers of DVT studied in our laboratory, patients presenting to our diagnostic vascular laboratory were investigated.[64] Patients were divided into positive for DVT by ultrasound, leg pain but negative for DVT by ultrasound, and control volunteers. Circulating DNA was significantly elevated in DVT patients, compared with controls. Of interest was a significant positive correlation of circulating DNA with C-reactive protein, D-dimer, vWF, and the Wells score (all $p < 0.01$).

The monocyte/macrophage is likely the most important cell for later DVT resolution.[58] Monocyte influx into the thrombus peaks at day 8 after thrombogenesis, and correlates with elevated MCP-1 levels, which has been associated with DVT resolution.[65] Targeted deletion of CC receptor-2 (CCR-2 KO) in the mouse model of stasis thrombosis was associated with late impairment of thrombus resolution, probably via impaired MMP-2 and MMP-9

activities.[66] Indeed, precedent exists in humans that the monocytic activation state may predict long-term DVT resolution.[67]

Thrombi have been found to contain increasing amounts of both tPA and uPA activities as they resolve, and this activity is expressed by invading monocytes.[68,69] In a recent study, mice genetically deleted for uPA had impaired thrombus resolution with reduced monocyte infiltration at the margins of the thrombus, with few neovascular channels present.[70] Mice gene deleted for tPA, however, were not similarly affected, suggesting that uPA, not tPA, is responsible for this activity.

The local venous environment is by definition hypoxic. A major angiogenic growth factor is hypoxia-inducible factor-1 alpha (HIF-1α). Experimental data in a stasis model of VT suggest that thrombosis stimulates increased vein wall HIF-1α, and that by exogenous stimulation of HIF-1α expression, thrombus recanalization was increased and associated with accelerated VT resolution.[71] Thus, thrombus resolution is in part dependent on neovascularization. The effect of mechanical stretch, such as by a VT, may also stimulate HIF-1α as well as MMP-2 and MMP-9, both leading to reduced vein contractility.[72]

Recent data linking inflammation to fibrosis demonstrate that inhibition of the inflammatory response can decrease vein wall fibrosis. In a rat model of stasis DVT, treated with either low–molecular-weight heparin (LMWH) or an oral inhibitor to P-selectin 2 days after establishment of thrombosis, inhibition of P-selectin significantly decreased vein wall injury (independent of thrombus size).[73] The mechanism accounting for this protective effect is not yet known, but probably does not involve leukocyte blockade, because no differences in influx of monocytes into the vein wall were observed.

Loss of venous endothelium likely also contributes to the vein wall fibrosis, as well as the predisposition to recurrent thrombosis. An experimental model of DVT showed lower expression of homeostatic endothelial genes such as NO and TM than in controls, which correlated with loss of vWF positive cell luminal staining.[74] Other investigators have found that prolonged venous stasis is associated with decreased plasminogen activators, probably related to loss of endothelium, as well as early vein wall dysfunction.[75,76]

Associated with the early biomechanical injury from DVT is an elevation of profibrotic mediators, including transforming growth factor-beta (TGF-β), interleukin-13 (IL-13), IL-6, and monocyte chemotactic protein-1 (MCP-1).[73,77,78] These mediators are present within the vein wall and thrombus and may drive the fibrotic response. Although exogenous MCP-1 may hasten DVT resolution, it promotes organ fibrosis in vivo. The profibrotic growth factor TGF-β is also present in the thrombus and is activated with normal thrombolysis.[79] TGF-β may be a key mechanism promoting vein wall fibrosis.[80]

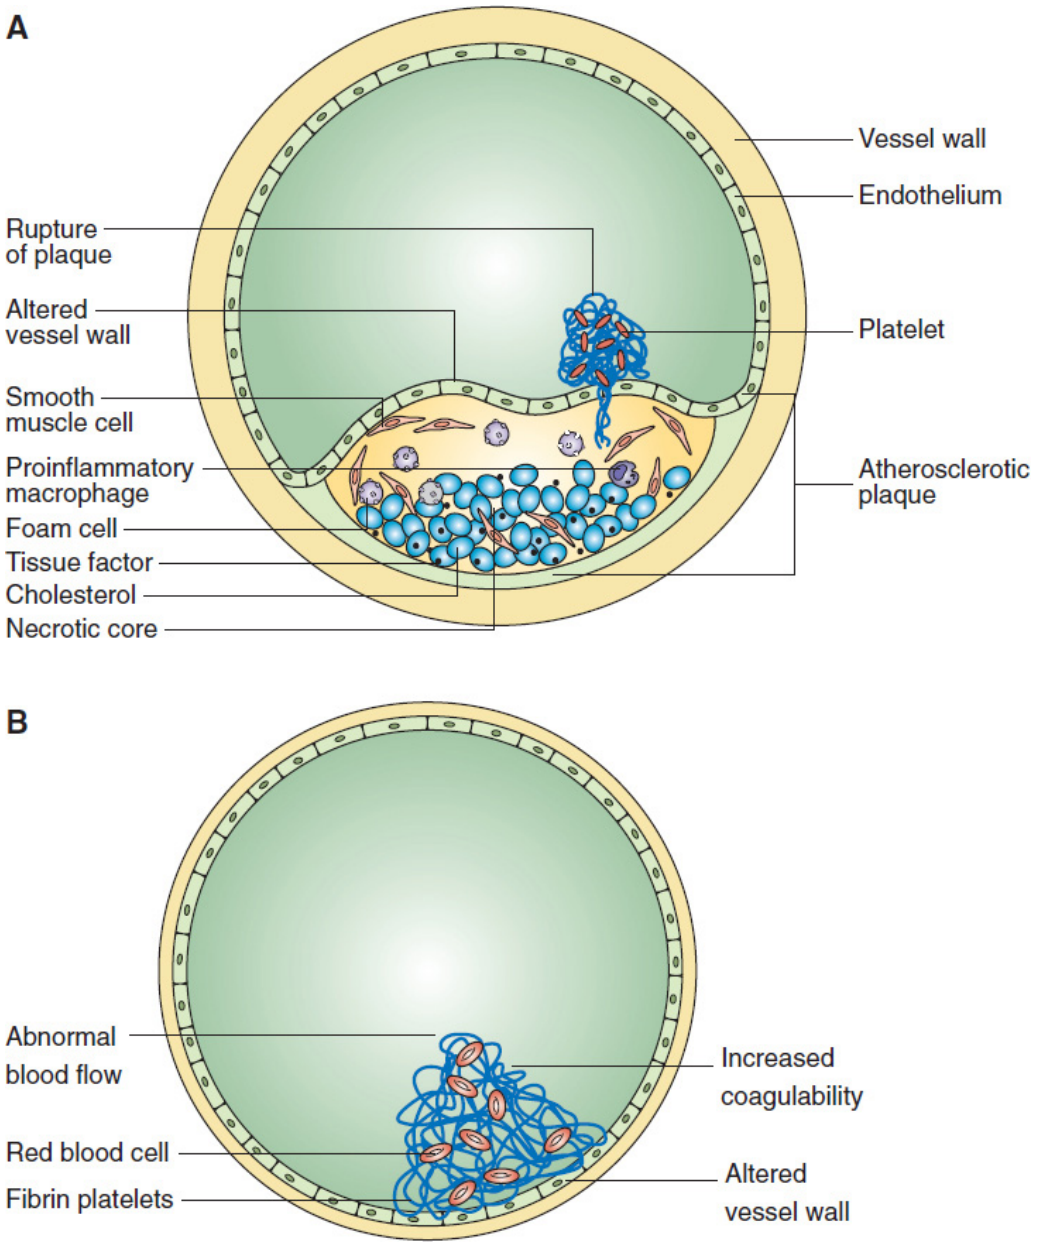

Figure 6.8 Depicted in **A** is the typical atherosclerotic thrombotic nidus, which includes rupture of a plaque, composed of smooth muscle, foam cells, and leukocytes. Platelets are the primary intermediary in arterial thrombosis, as well as TF. In figure **B**, increased coagulability, as well as vessel wall changes with procoagulant TF expression, promotes thrombosis.

Late fibrosis has been observed in our mouse model of DVT, which demonstrated a significant increase in vein wall collagen after stasis thrombogenesis.[77,81–83] Based on experimental studies, elastinolysis and collagenolysis seem to occur early, as measured by an increase in vein wall stiffness, persisting through 14 days, and are accompanied by elevated MMP-2 and MMP-9 activities.[77,81] Correlating with this increase in fibrosis is altered procollagen I and III gene expression, as well as an increase in MMP-2 and MMP-9 gene expression and activity. Genetic deletion of MMP-2 or MMP-2/9 is associated with

decreased midterm vein wall fibrosis, possibly by modulating vein wall elastin/collagen metabolism as well as monocyte influx.[56,57] It has been demonstrated that decreasing inflammation with a selectin inhibitor or with neutralizing IL-6 can also decrease vein wall fibrosis.[45,73,78] Moreover, the thrombus size itself does not drive the vein wall injury response; rather, the mechanism of thrombosis seems more important.[77,84] Lastly, PAI-1 overexpression is associated with decreased vein wall fibrosis, in part by decreased MMP-2/9 activity.[82]

ARTERIAL VERSUS VENOUS THROMBOSIS

Thrombosis in the arterial system occurs somewhat differently than in the venous system (**Fig. 6.8**). The elements required for the initiation of DVT were described by Virchow as stasis, endothelial injury, and hypercoagulability of the blood. In the arterial circulation, endothelial vascular injury (whether acute or chronic) is key to thrombosis. This is most clearly demonstrated by the typical atherosclerotic plaque. In advanced lesions, the lipid core of the plaque is rich in inflammatory cells, cholesterol crystals, and TF (generated by activated macrophages within the plaque).[85] Plaque ulceration exposes highly thrombogenic lipid to the bloodstream, activating coagulation, platelet aggregation, and leading to the deposition of clot.[86] Platelet deposition occurs at the apex of stenosis, the point of maximal shear force. The blood flow velocity itself regulates how quickly both thrombi form and dissolve.[87]

A platelet-rich thrombus is observed in arterial thrombus, while in contrast, venous blood stasis and changes in its composition (leading to hypercoagulability) incite the formation of thrombus from local procoagulant events, including small endothelial disruptions at venous confluences, saccules, and valve pockets.[11] Hypercoagulable states have classically been highly associated with VTE, but do play a role in cardiovascular disease as well.[88,89] Moreover, HMG-CoA reductase inhibitors (statin) not only decrease atherothrombotic events, but also incident VTE,[90] suggesting some common pathogenic pathways.

PROCOAGULANT STATES

Acquired Procoagulant States

Most thrombotic clinical episodes have an identifiable cause, although environment risks and genetic predispositions to thrombosis may account for many of the VTEs that manifest clinically.[11] Risk factors for arterial thrombosis are primarily related to atherosclerosis, and are detailed elsewhere.

Table 6.1 Acquired Hypercoagulable States

Risk	Relative Risk of VTE
Malignancy	++++
Trauma	++
Indwelling catheters	+
Surgery	++++
Pregnancy	+
HRT/OC	+
Lupus anticoagulant	+++
Obesity	+
Postoperative infection	++++
IBD	+++
Prolonged immobility	++

HRT, hormone replacement therapy; IBD, inflammatory bowel disease; OC, oral contraceptive; +, low risk; ++, moderate risk; +++, high risk; ++++, very high risk.

The most common risk factors for VTE are prior DVT, malignancy, immobility, intravenous catheters, increased age, major 4 surgery, trauma, infections such as pneumonia and urinary tract infection, and certain chemotherapies (**Table 6.1**).[91–93] Certain medications such as oral contraceptives and hormonal replacement therapies also increase the risk of VTE.

Of primary importance to surgeons is how best to estimate perioperative VTE risk, and apply appropriate prophylaxis. This can be done with a screening form, such as that devised by Caprini et al.[94] and Pannucci et al.[95] Essentially, this is a focused assessment of VTE risks related to current illnesses and history that may not be fully covered in the routine history and physical. The recommendations are also well detailed in the routinely updated American College of Chest Physicians VTE evidence-based guidelines.[96,97] The higher the risk, the more intensive the prophylaxis is. For example, an outpatient hernia patient may require no prophylaxis outside of early ambulation, whereas a hip replacement in an obese patient would be best treated with anticoagulation as well as sequential compression devices for the lower extremities. However, all patients should be assessed for VTE risk.

Malignancy

Cancer represents an independent risk factor for the development of VTE, with a sixfold increased risk in cancer patients. Importantly, cancer patients undergoing surgical procedures have twice the risk of development of postoperative DVT.[98] Highest rates of VTE are seen in

pancreas, stomach, and lung cancer. The malignancy itself activates a procoagulant phenotype by expression of TF by malignant cells, release of TF-bearing MPs, and increased activation of NETs—the downstream effects of which have been outlined above.[99]

Despite considerable evidence supporting the use of prophylactic anticoagulation in cancer patients, many do not receive optimal pharmacoprophylaxis for DVT while inpatient.[100] An extended duration of therapy—28 days—was found to be associated with a decreased incidence of DVT at the end of the study period; consequently, current guidelines recommend extended thromboprophylaxis in cancer patients after an operative intervention.[97]

Inflammatory Bowel Disease

Since the first half of the last century, a link between inflammatory bowel disease (IBD) and VTE has been recognized. While there does appear some correlation between thrombosis and the inflammatory nature of the disease, the link between the inflammatory and coagulation cascades does not tell the whole story. There are several possible mechanisms for this increased tendency toward thromboembolic events under active investigation, including spontaneous platelet activation through the CD40–CD40L pathway.[101]

A recent retrospective cohort study of the National Surgical Quality Improvement Program database demonstrated that the presence of IBD is an independent risk factor for postoperative VTE with an odds ratio of 2.[102] Interestingly, there appears to be an increased tendency to form clot in unusual locations, such as cerebral and hepatic veins. Currently, guidelines recommend only standard pharmacologic thromboprophylaxis for patients with IBD.

Trauma

As with other acquired prothrombotic states, the systemic inflammatory milieu is associated with VTE in trauma patients. Activation of inflammatory pathways through TNF-α with increased circulating TF and procoagulant MP induces a prothrombotic state.[103] Incidence of VTE in trauma patients is around 2%, and this may be higher in patients with other risk factors, such as old age, obesity, and prolonged immobility after bone fractures.[104,105] LMWH with application of pneumatic compression devices has been shown to be the preferred thromboprophylaxis in trauma patients, and this is reflected in anticoagulation guidelines.[96] However, optimal dosing regimens are not well defined.

Lupus Anticoagulant/Antiphospholipid Syndrome (Antiphospholipid Antibody)

Antiphospholipid antibody syndrome is a particularly virulent hypercoagulable state that results in both arterial thrombosis and VTE. For the diagnosis of antiphospholipid syndrome, both clinical and laboratory criteria are necessary (**Tables 6.2** and **6.3**). The prolongation in the aPTT is strictly a laboratory phenomenon. The dilute Russell viper venom time confirms the presence of a lupus anticoagulant. There is imperfect agreement between diagnostic tests for this abnormality. Approximately 80% of patients with a prolonged aPTT will have a

positive antiphospholipid antibody, but only 10% to 50% of patients with a positive antiphospholipid antibody will have a prolonged aPTT.[106]

Table 6.2 Diagnostic Criteria for Antiphospholipid Antibody Syndrome

Clinical Criteria (must have ≥1)	1. ≥1 clinical episode of, objectively confirmed, arterial, venous, or small vessel thrombosis. 2. Pregnancy morbidity: ≥1 unexplained fetal death at ≥10-wk EGA; ≥1 premature birth (≤34th wk of gestation) due to eclampsia, severe preeclampsia, or placental insufficiency; ≥3 unexplained consecutive spontaneous abortions at <10-wk EGA.[107]
Laboratory Criteria (must have ≥1)	1. LA (+) ≥2 occasions, at least 12 wks apart, according to ISTH guidelines (prolonged PL-based clotting assay, lack of correction with 1:1 mix, and correction with excess PL). 2. ACLA and/or anti-β_2 glycoprotein-I antibody (medium or high immunoglobulin G [IgG] and/or IgM isotype titer ≥2 occasions, at least 12 wks apart using standardized ELISA assays).

Hypercoagulability Testing

Clinical signs of possible thrombophilia include thrombosis at a young age (<40), unprovoked thrombosis, recurrent thrombosis, thrombosis at unusual locations such as the mesentery, CNS venous sinus, and portal vein, a family history of thrombosis, particularly unprovoked, severe, and in those <50 years of age.[126] Testing for hereditary defects in patients with thrombosis with no family history has pros and cons. On the pro side, testing may improve understanding of pathogenesis of thrombosis, identify and counsel affected family members, and obviate expensive diagnostic testing (e.g., CT scans) looking for a malignancy. On the con side, testing may identify patients with defects whose management would change, with the potential for overaggressive management, insurance implications for the patient arise, and the rather costly testing.

In order to determine the efficacy of hypercoagulable testing, a multicenter international observational registry on clinical characteristics, treatment patterns, and outcome in consecutive patients with symptomatic, objectively confirmed acute VTE was done. In this study, 22,847 patients were enrolled and 4,503 tested for thrombophilia. Of the total patient

population, 8.4% had factor V Leiden, 6.8% had PTG20210A, and 3% had activated protein C resistance (APC-R). The authors concluded that for the low incidence and in accordance with the recommendations made by other authors and international bodies, "the undertaking of thrombophilia testing on patients with a first episode of VTE is not advisable."[127]

A hypercoagulable screen should include routine coagulation tests such as the aPTT and platelet count, AT activity and antigen assay, protein C antigen and activity levels, protein S antigen level, and mixing studies to identify a lupus anticoagulant (if indicated); APC-R assay and factor V Leiden gene analysis; prothrombin G20210A genetic analysis; homocysteine level; an antiphospholipid antibody screen that includes anticardiolipin antibody; fibrinogen level; FVIII, FIX, and FXI levels and a functional plasminogen assay.

Inherited Procoagulant States

Defects with High Risk for Thrombosis

Inherited procoagulant states at high risk for thrombosis consist of antithrombin III (AT) deficiency, protein C deficiency, and protein S deficiency (**Table 6.3**). AT is a serine protease inhibitor (SERPIN) of thrombin, kallikrein, and factors Xa, IXa, VIIa, XIIa, and XIa. It is synthesized in the liver and has a half-life of 2.8 days. Protein C and its cofactor protein S are both vitamin K–dependent factors synthesized in the liver with half-lives of 4 to 6 hours and 12 to 14 hours, respectively. The majority of cases of protein C or protein S deficiency are inherited as autosomal dominant. Protein deficiency is divided into a type I deficiency (quantitative) and a type II deficiency (qualitative). Patients heterozygous for protein C deficiency usually have antigenic protein C levels less than 60% of normal.[128,129] Protein S is a cofactor to protein C in inactivating FVa and FVIIIa, and is regulated by complement C4b-binding protein.

Table 6.3 Severity and Frequency of VTE due to Hypercoagulable States

	Frequency (%) VTE	Thrombotic Phenotype	Diagnostic and Therapeutic Considerations
High Risk for Thrombosis			
▪ AT deficiency	0.5–3	Venous >> arterial ▪ May have thrombosis at unusual sites. ▪ Inherited cases become apparent by age 50 yrs.[108] ▪ Homozygous patients die in utero. ▪ Can be acquired from liver or kidney disease, sepsis, DIC, or malnutrition.[109]	Suspect in patients who cannot be adequately anticoagulated on heparin. Anticoagulation with direct thrombin inhibitors is recommended; alternatively, may administer FFP with heparin. Lifelong anticoagulation recommended following the first VTE.
▪ Protein C deficiency	3	Venous >> arterial ▪ Patients often present between ages 15 and 30 with VTE.[110] ▪ Homozygous patients die at birth from purpura fulminans. ▪ Can be acquired from liver failure, DIC, and nephrotic syndrome.	If asymptomatic heterozygote carriers, aggressive thromboprophylaxis is recommended in the perioperative period. Lifelong anticoagulation is recommended following first episode of thrombosis. Patients are at particular risk of warfarin-induced skin necrosis and must undergo bridging anticoagulation with heparin, LMWH, or direct thrombin inhibitor.[111]
▪ Protein S deficiency	3–6	Venous >> arterial ▪ Cofactor to protein C;	If asymptomatic heterozygote carriers, aggressive

		deficiency results in clinical state identical to protein C deficiency. ▪ Acquired deficiency can occur in liver disease, nephrotic syndrome, OCP use, pregnancy, and during breastfeeding.[112]	thromboprophylaxis is recommended in the perioperative period. Lifelong anticoagulation is recommended following the first episode of thrombosis. Patients are at particular risk of warfarin-induced skin necrosis and must undergo bridging anticoagulation with heparin, LMWH, or direct thrombin inhibitor.[111]
▪ Antiphospholipid antibody syndrome	3–5	Venous > arterial ▪ Associated with thrombosis, fetal loss, stroke, MI, visceral infarction, extremity gangrene, and graft thrombosis. ▪ May be induced by medications, cancer, and certain infections.[113]	Treatment is with warfarin followed by heparin; direct oral anticoagulants are associated with higher thrombosis risk.[113,114] For recurrent fetal loss, LMWH is recommended. Anti-Xa levels should be used to monitor LMWH/heparin levels.
Lower Risk for Thrombosis			
▪ Factor V Leiden (FVL)	20–60	Venous >> arterial Combined defects with protein C or S deficiency or prothrombin G20210A increase thrombotic risk.[115,116]	Diagnosis is made with a clot-based functional assay and genetic analysis to determine hetero- vs. homozygosity. Long-term anticoagulation is not necessary after first episode of thrombosis in a heterozygote, but

			is recommended after recurrent thrombosis.[117]
▪ Hyper-homocysteinemia	10	Arterial ~ venous ▪ Can be acquired via smoking, coffee consumption, diabetes, cancer, hypothyroidism, and low dietary levels of folate and vitamins B_6 or B_{12}. ▪ Common medications that increase levels: metformin, methotrexate, theophylline, levodopa, and anticonvulsants.[118]	Diagnosis is made via fasting homocysteine levels or after a methionine oral loading regimen. Treatment is through/by folate supplementation. Anticoagulation choice and duration should not be influenced by diagnosis of hyperhomocysteinemia.
▪ PT G20210A	4–6	Venous >> arterial ▪ Thrombosis risk is increased in combination with FVL and pregnancy. ▪ Most prevalent in Caucasians.[119]	Long-term anticoagulation is recommended for patients with recurrent thrombosis or when diagnosed in conjunction with FVL.[120]
▪ Dysfibrinogenemia	1–3	Venous > arterial Common presentations include VTE and digit ischemia.[121]	Standard anticoagulation according to guidelines.[122,123]
▪ Dysplasminogenemia	<1	Arterial ~ venous	Standard anticoagulation according to guidelines.[122,123]
▪ Elevated factors VIII, IX, and XI	1	Venous > arterial Thrombosis risk is dose responsive,	Diagnosis is with activity assays; however, factor VIII carrier is vWF

	for example, factor VIII:C above the 90th percentile is associated with fivefold increased risk of VTE.[124] Acquired and environmental factors precipitate VTE.[125]	which is an acute phase reactant and must be accounted for, usually by measuring ESR or CRP. Standard anticoagulation according to guidelines.[123]

AT, antithrombin; HITTS, heparin-induced thrombocytopenia and thrombosis syndrome; PAI-1, plasminogen activator inhibitor-1; VTE, venous thromboembolism.

Defects with Lower Risk for Thrombosis

Resistance to APC (Factor V Leiden)

Resistance to APC has been reported to be present in 20% to 60% of cases of idiopathic VTE and is the most common underlying abnormality associated with VTE. This disorder is present in 1% to 2% of the general population.[130–132] As a result of the substitution of a single amino acid, glutamine for arginine, at position 506 in the protein for factor V, caused by a nucleotide substitution of guanine for adenine at 1,691 in factor V gene, hypercoagulability is conferred by resistance to inactivation of factor Va by APC.[110,133,134] Factor V Leiden accounts for 90% of APC-R (**Table 6.3**).

Prothrombin G20210A Polymorphism

Prothrombin (factor II), a vitamin K–dependent factor synthesized in the liver, becomes thrombin when activated. A genetic polymorphism in the distal 3′ untranslated region of the gene for prothrombin, a transition from guanine to adenine at the 20210 nucleotide of the prothrombin gene, has been described in patients with VTE.[135] This results in a normal prothrombin but at increased levels.[120,136,137] This polymorphism confers an increased risk for VTE by 2.8-fold, is associated with 4% to 6% of patients with VTE, and is the second most common cause for hypercoagulability in Caucasians (**Table 6.3**).[117,119,138–140]

Hyperhomocysteinemia

Hyperhomocysteinemia has been a known risk factor for atherosclerosis and vascular disease for more than 25 years, though a direct cause and effect relationship has not been established.[141,142] However, a recent meta-analysis suggests the risk of VTE to be 2.5-fold with elevated homocysteine levels.[143] Two enzyme deficiencies, N^5,N^{10}-methylenetetrahydrofolate reductase (MTHFR) or cystathionine β synthase, are responsible for elevated homocysteine levels.[144] Although mutations in these enzymes are not infrequent, the common polymorphism in MTHFR alone is not a factor in either the elevation of plasma homocysteine or thrombosis (**Table 6.3**).[145]

Other Disorders Associated with Thrombosis

Defective Fibrinolysis/Dysfibrinogenemia/Lipoprotein(a)

Abnormal plasminogens (dysplasminogenemias), although rare (<1%), have been described in cases of spontaneous arterial thrombosis or VTE (**Table 6.3**).[146] Both type I quantitative and type II qualitative deficiency states have been described. Numerous molecular defects have been classified. Defective thrombin binding or resistance to plasmin-mediated breakdown has been described.[147] Although not clearly documented, defects in plasminogen activators, tPA or uPA, may incite thrombotic events.[148] Elevated PAI-1 has been associated with DVT and myocardial infarction.[146]

Lipoprotein(a), associated with LDL, has both atherogenic and prothrombotic properties.[149–151] It prevents plasminogen from binding to cells or fibrin and inhibits fibrinolysis.[152] Elevated levels of lipoprotein(a) have been associated with VTE in childhood; it is a weak thrombotic risk factor in adults (**Table 6.3**).[153–155]

Abnormal Platelet Aggregation

It has been recognized for some time that there are patients who have thrombosis and may have hyperactive/hyperresponsive platelets but this entity is poorly defined. Diabetes mellitus, which is known to be associated with hyperactive platelets and hyperlipidemic states, may be a contributing factor. Hyperactive platelets have been noted during graft thrombosis in peripheral vascular reconstructions.[156] Although platelet aggregation assays may be helpful in making the diagnosis, these assays are not commonly performed or standardized and, thus, the incidence and importance of platelets to thrombosis are not well known. Bleeding time measurements are not specific, and not recommended for making this diagnosis. This condition has been called “sticky platelet syndrome” and both arterial and venous events have been reported.[157]

Standard anticoagulant treatment is recommended for this condition. Aspirin and the thienopyridine derivatives such as clopidogrel may be useful, but their utility is unknown.[158]

Elevated Procoagulant Factors: VIII, IX, and XI

Elevated prothrombotic factors have only recently been associated with primary and recurrent VTE (**Table 6.3**).[117,159]

Disseminated Intravascular Coagulation

DIC is a primary form of acute thrombosis. Causes of DIC include sepsis, trauma, pancreatitis, obstetric complications such as abruptio placentae or amniotic embolism, transplant rejection, malignant tumors, certain snake bites, hematologic malignancies, and hepatic failure. Coagulation in DIC is activated by the release of TF into the circulation causing unregulated activation of the coagulation cascade, leading to massive thrombin production and fibrin generation. Fibrinolysis then becomes activated as well, leading to bleeding in the later, hemorrhagic stages of the syndrome because of the consumption of clotting factors, depletion of fibrinogen, and unchecked plasmin activity. The diagnosis of DIC is a clinical one, which requires consideration of the gestalt of the patient. Laboratory values in DIC reveal a downtrend in platelet count—even within the normal range,

decreased fibrinogen level, prolonged PT, and concomitant elevation in fibrin split products and the presence of a positive D-dimer test. The treatment of DIC requires treatment of the underlying condition. The need for platelet or plasma transfusion is based on the presence of hemorrhage, rather than on particular laboratory values.[160]

BLEEDING DISORDERS

Although the surgeon deals more often with procoagulant states than bleeding disorders, it is important to recognize these disorders when they occur.

Coagulation Factor Deficiency

Coagulation factor deficiency states are important causes of 5 bleeding and the most common are factor VIII and IX deficiency states, termed hemophilia A and B, and type I von Willebrand disease (vWD).

Hemophilia A is inherited as a sex-linked recessive deficiency of factor VIII, with fewer cases secondary to spontaneous mutation. The incidence of this abnormality is approximately 1 in 5,000 births.[161] Clinical findings range from bleeding into joints and muscles, epistaxis, hematuria, and bleeding after minor trauma, to prolonged postoperative bleeding, retroperitoneal bleeding, and intramural bowel hemorrhage. Laboratory screening tests usually reveal a prolongation of the aPTT along with decreased factor VIII levels; other test results are normal. The minimum level of factor VIII required for hemostasis is 30%, and spontaneous bleeding is uncommon with factor VIII levels greater than 5% to 10% of normal. Levels less than 2% constitute severe, 2% to 5% moderate, and greater than 5% mild deficiency.[162] Although the half-life of factor VIII is 2.9 days in normal subjects, the half-life of factor VIII concentrates is only 9 to 18 hours.[161] Levels between 80% and 100% of normal should be attained for surgical bleeding or life-threatening hemorrhage. Acquired deficiency has been reported to occur with the development of antibodies to factor VIII after therapy. Inhibitor antibodies develop in approximately 10% to 15% of patients with hemophilia A, although the incidence of antibody formation may be much higher in previously untreated patients and in those with severe hemophilia A.

Recombinant factor VIII preparation has been developed and tested in children and infants. Despite the development of low levels of inhibitors in 20% of children at a mean 9 days after first administration, these inhibitors either disappeared or remained at low levels.[163]

Factor IX deficiency (Christmas factor), known as hemophilia B, is transmitted as an X-linked recessive trait. It may also be acquired because of enhanced factor IX clearance in states such as the nephrotic syndrome, abnormal protein production in vitamin K deficiency, and acquired specific inhibitors to factor IX in various autoimmune diseases, such as SLE. It is clinically indistinguishable from hemophilia A, and laboratory screening tests reveal a prolonged aPTT, with other test results normal, although a greater proportion of patients have only mild or moderate deficiency.[164] Severe deficiency (approximately 30% of cases)

is defined as a level of activity less than 4% of normal, whereas moderate deficiency is reported with activity levels between 20% and 40%.[162] Treatment consists of plasma or factor IX concentrates and vitamin K. It has been recommended that levels greater than 30% be achieved for hemostasis.

vWF causes platelet adhesion to collagen, initiating platelet plug formation. It also forms a complex with factor VIII in the blood. Produced in endothelial cells and megakaryocytes (compared with the liver for factor VIII), it has a circulating half-life of 6 to 20 hours. vWD, a deficiency of vWF, is the most common of the inherited coagulation disorder. A number of different subtypes have been identified for its deficiency state, and the syndrome is transmitted as both autosomal dominant (heterozygous) and autosomal recessive (homozygous) forms. Variants include types I and III (quantitative decreases in normal-appearing vWF) and type II (qualitative abnormalities in structure and function of vWF).[165] vWF deficiency is probably as common as hemophilia A, although the true incidence may surpass what is generally appreciated because many mild cases probably remain undiagnosed.

The classic syndrome is caused by a reduction of factor VIII activity (although not as great as in hemophilia A) and vWF (vWF–factor VIII complex). Clinical manifestations include easy bruisability, mild to moderate epistaxis, gingival bleeding, menorrhagia, rare joint or muscle bleeding, prolonged bleeding following surgery, and subcutaneous bleeding. Spontaneous bleeding is not as common as in hemophilia A.

Abnormal laboratory tests include a prolonged bleeding time; a decreased level of factor VIII activity; decreased immunoreactive levels of the vWF; and abnormal platelet aggregation response to ristocetin. The most reliable source of vWF is cryoprecipitate, although many concentrates of factor VIII have vWF present and show promise. Desmopressin acetate (DDAVP) is available for the treatment of mild cases of type I vWD and types 2a and 2b; serum levels of 25% to 50% are needed for hemostasis. In other type II states and type III vWD, factor VIII concentrates are necessary. Recombinant factor VIII/vWF concentrates that avoid the infectious risks of transfusion are available.

Rare Factor Deficiencies

Other specific factor deficiencies are much less common and receive only a brief mention here. These include factors II, XI, V, VII, and X. These can be measured by serum assays, although this is not routinely available in many hospitals. The treatments are primarily FFP concentrates to give back the clotting factors.

Deficiencies of fibrinogen can also lead to bleeding disorders. This is the only factor deficiency state in which the TCT is prolonged. It is generally believed that a fibrinogen level of 100 mg/mL should be achieved to stop bleeding related to fibrinogen abnormalities. Fibrinogen deficiency may also occur from consumption during DIC and from primary fibrinolytic states.

Platelet Disorders

Platelet disorders are another important cause of bleeding. Inherited defects of platelet receptors include defects of GpIIb/IIIa (Glanzmann thrombasthenia), characterized by impaired platelet binding to vWF, fibrinogen, and fibronectin. In patients with defects in GpIb (Bernard–Soulier syndrome), the absolute number of platelets is decreased, the platelets are larger, and platelet aggregation and adhesion are abnormal. Acquired deficits occur in uremia; both GpIb and GpIIb/IIIa receptors are defective, resulting in impaired adhesion and aggregation. Acquired deficits also occur in patients who previously received platelet transfusions and then acquired immune-mediated antiplatelet antibodies.

Abnormalities in Fibrinolysis

Abnormalities in fibrinolysis may play a role in abnormal bleeding disorders. Genetic or acquired deficiencies in α_2-AP may be associated with bleeding, whereas deficiencies in factor XIII (fibrin-stabilizing factor) may lead to highly lysable clot. α_2-AP deficiency is treated with ε-aminocaproic acid or tranexamic acid. Homozygous patients with factor XIII deficiency and less than 1% of normal plasma activity often show bleeding from the umbilical cord at birth, bleeding after trauma or surgery, and delayed bleeding 24 to 36 hours later. Screening test results include a shortened euglobulin lysis time. A specific assay for factor XIII activity exists. Treatment consists of FFP, cryoprecipitate, and factor XIII concentrates.

Inflammation

Matthew R. Rosengart, Matthew D. Neal, and Timothy R. Billiar

Key Points

1 Innate immunity, arm of the immune system poised in advance of any prior stimulus, provides the initial defense against invading pathogens. Subsequent more targeted reinforcement is provided by the adaptive immune system, which possesses extensive capacity to learn and tailor the response to repeated exposures and thereby manifests an exquisite specificity for subsequent exposure to individual microbes. Both are comprised of cellular and humoral components.

2 Implicit with the capacity for pathogen elimination is the potential for destruction of host tissues. Numerous regulatory mechanisms provide temporal and spatial control of the inflammatory processes, including programmed cell death (i.e., apoptosis).

3 Damage-associated molecular patterns (DAMPs) are the endogenous equivalent of PAMPs, represent danger signals or "alarmins," and share many characteristics similar to cytokines. These are released following nonprogrammed cell death, such as necrosis, or secreted as mediators by cells and regulate the inflammatory response.

4 The T_H1 inflammatory response (i.e., cell-mediated immunity or delayed-type hypersensitivity) is induced by IL-12 derived from phagocytes, provides one major arm of the adaptive immune response; it is mediated by $CD4^+$ and $CD8^+$ lymphocytes, innate lymphocytes type 1 (IL-C1) and macrophages, which regulate production of opsonizing and complement fixing antibodies and are effectors of phagocyte-dependent responses.

5 The principal stimulus for T_H2 differentiation is IL-4, which is derived from T cells, mast cells, and basophils. As the cellular effectors of humoral immunity, T_H2 responses are another major arm of the adaptive immune response mediated by T_H2 $CD4^+$ cells, IL-C2, B cells, plasma cells, and antibodies.

6 Over 60 randomized-controlled clinical trials have been conducted to assess the efficacy of modulating injurious inflammation, in particular systemic cytokine concentrations, in reducing mortality

from either trauma or sepsis. The only "biologic" adopted by the medical community as a potential therapeutic is the combination of corticosteroids and fludrocortisone in the management of sepsis.

7 T_H17 effecters are upregulated by IL-6 and IL-23 and can drive proinflammatory or tissue protective responses driven by the release of the cytokine IL-17A/F. Sources of this cytokine include T_H17 cells and IL-C3.

8 The complement system is integral to both innate and adaptive immunity and has the capacity to independently eliminate organisms and facilitate host defense by marking foreign particles for phagocytosis through opsonization. Complement activation products can also drive inflammation (i.e., C3a and C5a).

9 Additional systems, including the vascular (i.e., vasodilatation, adhesion receptors, kinin cascade), neuroendocrine (i.e., ACTH, AVP, CRH), and coagulation cascades integrate with the immune system and share similar mediators and their receptors as to orchestrate an intense, coordinated response to any injurious/septic insult.

10 Our immune system differentiates pathogens and damaged cells from self, using evolutionarily ancient sets of recognition molecules called pattern recognition receptors (PRRs), which bind conserved molecular structures found in large groups of pathogens, termed pathogen-associated molecular patterns (PAMPs), an example being the toll-like receptors (TLRs).

Our intimate understanding and appreciation for the complexity of the integrated mechanisms collectively called "inflammation" has exponentially evolved since Celsus in 1c AD first described the four cardinal signs and symptoms: "rubor et tumor cum calor et dolore," redness and swelling with heat and pain.[1–3] Centuries lapsed until John Hunter postulated that inflammation provides a survival mechanism to preserve the host. Ironically, he commented that an exuberant inflammatory response could be deleterious.

This is all too true, as the pathologic sequelae of excessive inflammation (i.e., ARDS, MODS) are encountered ever more frequently as technology affords survival of the initial insult.[1–3] The 19th century witnessed milestone contributions to our understanding of this process, as Rudolph Virchow detailed the cellular pathology of inflammation, Julius Cohnheim provided microscopic details of the acute phases of inflammation (vasodilatation, edema formation, and leukocyte emigration), and Elie Metchnikoff described the events of phagocytosis.[1,4,5] The integration of these new data created a novel paradigm of cellular and humoral concepts of inflammation, both of which were deemed critical in host defense against foreign pathogens.

In the 20th century, technologic advancements in molecular biology and biochemistry facilitated more detailed investigation and enabled the rapid expansion of knowledge of the many interwoven facets of inflammation. Evidence began to accumulate that the ramifications of these processes extended beyond the regional confines of the inciting insult. Many humoral mediators, in addition to local effects, influenced distant targets as well, such as the liver and neurohormonal centers. Recently we have come to appreciate that the immune system, endocrine system, and nervous system comprise a singular collaborative network sharing similar mediators and their cognate receptors. Such an integrative view, introduced by J. Edwin Blalock, when combined with Hans Selye's concept of stress, led to the contemporary understanding of sickness behavior, defined by Robert Dantzer as a highly organized strategy of the organism to fight infections and to respond to other environmental stressors. Hence, what originated nearly 2 millennia ago as a simple concept founded upon a constellation of signs and symptoms now is considered an intense, coordinated interplay of the nervous, vascular, endocrine, and immune systems to any injurious insult. It is the culmination of millions of years of evolution, and without it, life would be an arduous, painful, and brief existence, at best.

INNATE VERSUS ADAPTIVE IMMUNITY

1 Innate immunity, a system comprised of both cellular and humoral components, "stands" in anticipation of and prepared to respond to any stimulus and provides our initial security against invading microbes.[6]

Evolutionarily conserved across phyla, it notably provides the primary defense mechanism for invertebrates, as well. The response is typically uniform and consistent with each successive infection, though recent data suggest that like the adaptive arm, it too can "learn," or rather, "be trained."[7,8] Subsequent reinforcement is provided by the more specific and targeted efforts of the adaptive immune system, which mounts responses of increased magnitude and defensive capabilities with each successive insult.[6] This exquisite specificity for individual microbes, the capacity to "learn," "remember," and modify subsequent responses to repeated exposures, has provided the impetus for the name; though as aforementioned, the term "innate immune memory" has been adopted by the scientific community.[8]

CELLULAR COMPONENTS

Neutrophils

Neutrophils are integral to both innate and humoral immunity, providing the initial defense against invading viral, bacterial, and parasitic pathogens. This vital contribution is highlighted by the fact that 55% to 60% of hematopoietic output is the production of neutrophils.[9] On exiting the marrow, neutrophils circulate for approximately 7 to 10 hours and then emigrate into the tissues where they reside for an additional 1 to 2 days (**Table 7.1**).[10,11] Upon sensing minute concentration gradients of microbial products and inflammatory mediators, they rapidly accumulate to the site of infection to ingest and dispose of a wide array of pathogens with their vast microbicidal armamentarium. This pathogenicity, however, carries with it an implicit capacity for host injury and accordingly, neutrophil function must be tightly regulated.

Recruitment

Neutrophil recruitment, conceptually, is a sequence of events progressing from (1) initial adhesion to activated endothelium, to (2) subsequent extravasation and emigration toward the inflammatory focus, to (3) the ultimate elimination of foreign microorganisms through phagocytosis, the

generation of reactive oxygen species (ROS), and the release of antimicrobial substances.[6]

After injury or microbial invasion, hyperemia as a consequence of local and regional vasodilation facilitates the delivery of leukocytes to the focus of injury. Extravasation of plasma creates edema, and in combination with the release of vasoactive substances leads to hemoconcentration, which promotes the peripheral margination of leukocytes.[12,13] Circulating neutrophils transiently interact with the endothelial cell surface molecules during a process called "rolling" that involves a series of loose and reversible attachments between the neutrophil and endothelium (**Fig. 7.1**). These interactions are prerequisite to subsequent tighter cell–cell interactions, mediated by the family of selectin receptors, which bind with their counterligands, the sialyl Lewis family and other fucosylated and sulfated structures. E-selectin and P-selectin are present on endothelium and L-selectin is found on leukocytes.[6]

In response to a variety of inflammatory mediators (thrombin, histamine, complement fragments, oxygen species, lipopolysaccharide [LPS], and cytokines such as IL-1, TNFα and IFNγ), the endothelium expresses P- and E-selectin, which binds to the cell surface glycoprotein P-selectin glycoprotein ligand 1 (PSGL-1) or sialyl Lewis of neutrophils. Endothelial cells also translocate ligands for neutrophil L-selectin and release mediators like platelet-activating factor (PAF) and IL-8. Cytokines such as TNFα, granulocyte-macrophage colony-stimulating factor (GM-CSF), and G-CSF increase the affinity of leukocyte L-selectin for its counterreceptor. In addition to mechanical anchorage, these selectins induce signal transduction pathways that influence subsequent cell function. P-selectin facilitates neutrophil degranulation and superoxide production, and cross-linking L-selectin primes the neutrophil for increased superoxide production.[14–16]

After rolling, L-selectin is rapidly shed in preparation for leukocyte diapedesis and emigration into the interstitium (**Fig. 7.1**). The receptors mediating this process are members of the β_2-integrin family: leukocyte function antigen 1 (LFA-1, CD11a/CD18) and Mac-1 (CD11b/CD18); the expression of which is enhanced by prior selectin binding. Both integrin receptors engage the intercellular adhesion molecules ICAM-1 and ICAM-2; yet, each provides additional important functions. Leukocyte emigration is

primarily an LFA-1-dependent process, as mice deficient in this receptor exhibit reduced neutrophil attachment to ICAM-1 and endothelial cells. By contrast, mice lacking Mac-1 demonstrate impaired degranulation, superoxide production, and phagocytosis. Mac-1 also binds fibrinogen, heparin, and factor X and is implicated in neutrophil phagocytosis-induced apoptosis, a process essential for resolution of the inflammatory process (*vida infra*). The very late antigen 4 (VLA-4) binds vascular cellular adhesion molecule 1 (VCAM-1) and may provide an additional mechanism for tight adhesion. In addition to providing mechanical anchorage, these receptors interact with the cytoskeleton and other structural proteins and signaling cascades and are thought to represent a *biochemical* link between the external environment and intracellular signal transduction cascades that induce a cellular phenotype more appropriate for the inflammatory environment (**Fig. 7.2**).[17–19]

Table 7.1 Leukocyte Subsets

Cell	Neutrophil	Monocyte	Lymphocyte	Eosinophil	Basophil
Size (μm)	13	16–20	9–16	12–16	15
Differential (%)	40–75	2–6	20–45	1–6	<1
Life span	6 h to 7 d	1 d to years	Months to years	8 to 12 d	1 year
Activators	G-CSF, IL-8	M-CSF, GM-CSF, IFNγ, TNFα	IL-2, IL-12 (T_H1), IL-4 (T_H2)	G-CSF, IL-5	G-CSF, IL-3

(G, M)-CSF (granulocyte, monocyte) colony-stimulating factor; IL, interleukin; T_H, helper T cell; TNF, tumor necrosis factor.
Modified from Burkitt G, Young B, Heath JW, eds. *Wheater's Functional Histology: A Text and Colour Atlas*. 3rd ed. Edinburgh, New York: Churchill Livingstone; 1993.

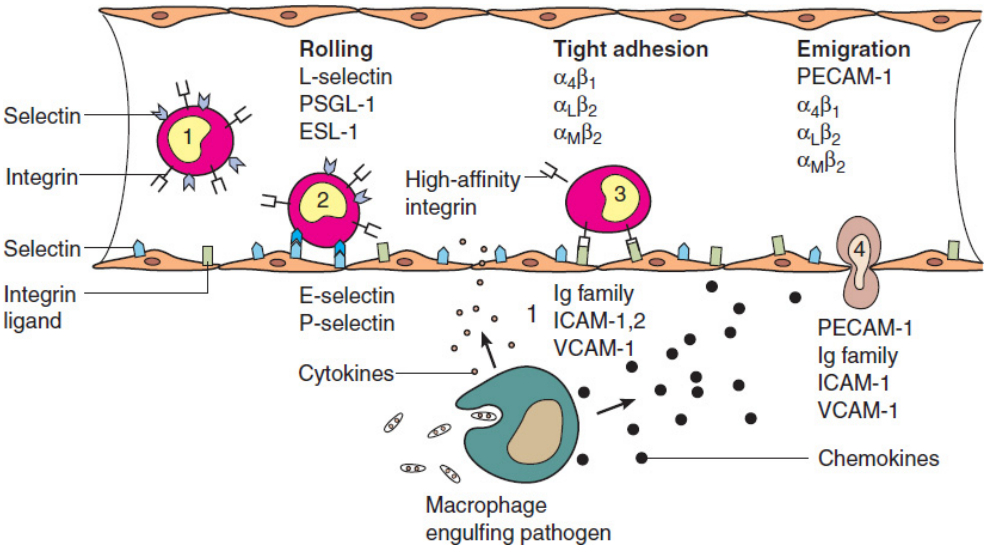

Figure 7.1 Leukocyte recruitment. **1.** Circulating leukocytes express integrins in a low-affinity conformation. **2.** Exposure to activated endothelium leads to rolling, which is mediated by L-selectin and P-selectin on the neutrophil and E-selectin on endothelium. **3.** Leukocyte exposure to cytokines released by macrophages phagocytosing pathogens induces a high-affinity integrin conformation integrins. Tight leukocyte-endothelial adhesion involves integrin engagement with counterligand expressed on the endothelium. **4.** Subsequent exposure to chemokines leads to diapedesis, which is further mediated by the family of β_1 and β_2 integrins. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia, PA: Saunders, 2003.)

Now tightly adhered, neutrophils must diapedese between endothelial cells and across the basement membrane on their trek toward the focus of inflammation. Platelet/endothelial cell adhesion molecule 1 (PECAM-1) and integrin-associated protein are integral to transmigration (**Fig. 7.1**).[17,18,20,21] PECAM-1 is concentrated along the intercellular junctions of endothelial cells, and both leukocyte and endothelial PECAM-1 appear to be essential for neutrophil and monocyte diapedesis. Other candidate receptors include the β_1 integrins, or VLAs, which possess affinity for many constituents of the extracellular matrix, including laminin, fibronectin, and collagens, the β_3 family of integrins including the glycoprotein (gp) IIβIIIα and the vitronectin receptor.[6] Further "directions" for migration to the focus of inflammation are delivered by the concentration gradients of chemotactic factors; examples include, complement C5a, IL-8, LTB_4, and the bacterial product fMLP.[22–24]

The clinical significance of even minor derangements in any aspect of this process is evident in the disease leukocyte adhesion deficiency, characterized by complete absence of CD18, and therefore all β_2 integrins. Patients usually succumb to recurrent skin and mucosal infections within the initial 10 years of life.[6]

Phagocytosis

Upon initial encounter with a foreign pathogen the neutrophil readies the "machinery" for microbial elimination. Phagocytosis is facilitated by opsonization, a process in which microbes are bound by immune globulins and complement and by subsequent binding to their cognate cell surface receptors, FcγRs and Mac-1, are rendered more accessible to the neutrophil.[25–27] Neutrophils constitutively express low-affinity immune globulin receptors FcγRII and FcγRIII and can be induced to express high-affinity FcγRI by incubation with IFNγ or cross-linking β_2 integrins.[9,28] Complement-dependent phagocytosis is mediated by interactions between the leukocyte Mac-1 receptor and the complement opsonin iC3b.

Once engaged, FcγRs are phosphorylated on tyrosine residues within an immunoreceptor tyrosine activation motif (ITAM) by the Src-family kinases.[28] These phosphorylated sites serve as docking regions for a variety of proteins, in particular Syk. The importance of Syk is underscored by the observation that mice deficient in Syk are incapable of ingesting IgG-opsonized particles. A series of enzymes are subsequently activated including phosphoinositol 3-kinase, phospholipase C, and protein kinase C. Ultimately, the actin cytoskeleton undergoes rearrangement and the local plasmalemma is remodeled as the phagosome is formed and physically excluded from the external environment.[6,28]

This immature phagosome undergoes a series of maturation steps, whereby it acquires the machinery necessary for the killing and disposal of internalized microorganisms. Alterations in cytosolic calcium concentration induce the fusion of secretory vesicles and granules containing the microbicidal armamentarium with the immature phagosome.[28] Proteins effected by calcium concentration and that may govern phagosomal maturation include synaptogamins, actin, calmodulin, and the Src family of kinases.[28] The SNARE (soluble N-ethylmaleimide-sensitive-fusion-protein

attachment protein receptor) proteins are thought to assist in fusion by engaging cognate receptors on the target membrane and approximating the two membranes. Antibodies to the SNARE 5 syntaxin 6 and SNAP-23 inhibited exocytosis of azurophilic and specific granules, respectively.[28]

Neutrophil Granules and Secretory Vesicles

Neutrophils exhibit an oxygen-dependent "respiratory burst" pathway that generates toxic oxygen derivatives and an oxygen-independent pathway that utilizes toxic proteinases.[29] These two microbicidal arms are compartmentalized into four distinct granules or vesicles (**Table 7.2**).[30] They are mobilized in a hierarchical fashion in response to gradual elevations in the intracellular calcium level.[31] They also contain adhesion molecules and important inflammatory mediators that help further orchestrate the involvement of other cells.

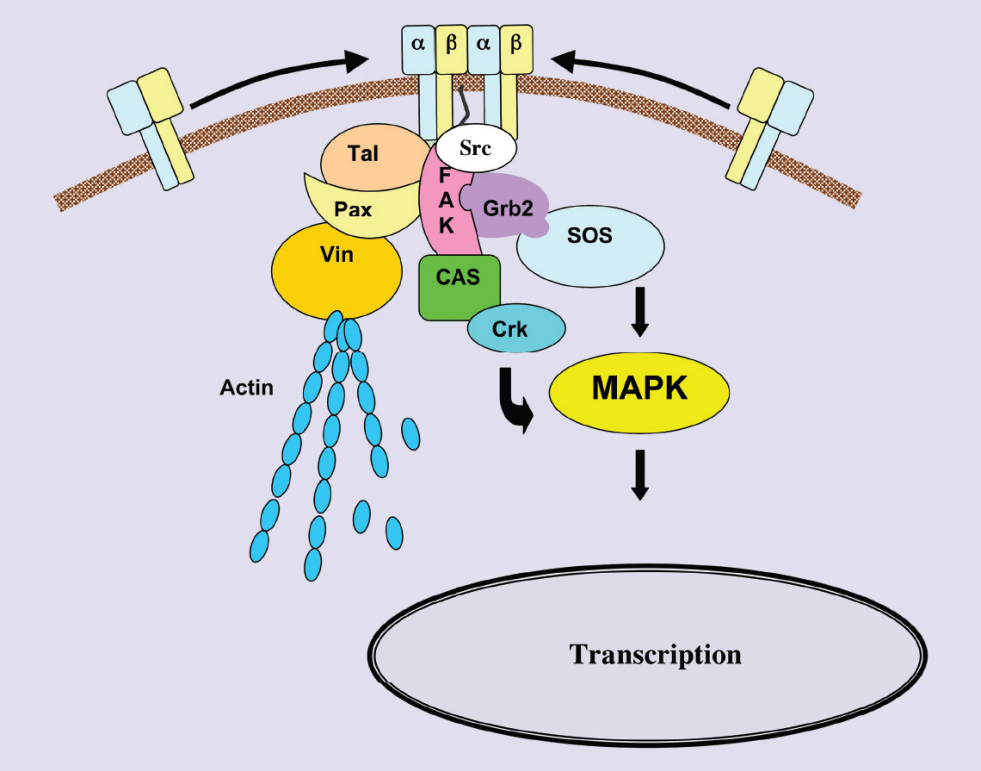

Figure 7.2 Integrin signaling. Integrins comprise a large family of cell surface receptors that are composed of two subunits, α and β, and are activated by dimerization. The cytoplasmic tails are devoid of enzymatic activity, and hence, signal transduction is effected by adaptor proteins that connect the receptor to the cytoskeleton, cytoplasmic kinases, and transmembrane growth factor receptors. As integrins bind the extracellular matrix they become clustered and associated with the cytoskeletal proteins talin, paxilin, and vinculin and signaling complexes. Actin stress fibers form, which increase integrin clustering. Ultimately, focal adhesion kinase (FAK) is recruited via interactions with talin and paxillin or with the β-integrin subunit. Subsequent autophosphorlyation on tyrosine 397 provides a binding site for the Src homology 2 (SH2) domain of Src. The Src kinase phosphorylates a number of focal adhesion components including paxillin and tensin and pl30CAS, a docking protein that recruits Crk, which can subsequently activate proximal elements in the JNK cascade of the MAPK family. FAK may also be phosphorylated by Src on tyrosine 925, creating a binding site for the complex of the adaptor Grb2 and Ras guanosine 5'-triphosphate exchange factor mSOS. These interactions also lead to activation of MAPK cascades, and ultimately the induction of a variety of genes. (Redrawn from Giancotti F, Ruoslahti E. Integrin signaling. *Science* 1999:1028–1032.)

Primary, or azurophil (affinity for the dye azure A) granules (**Table 7.2**). Myeloperoxidase (MPO) within these granules generates hypochlorous acid (HOCl) from products generated by NADPH oxidase; this is what imparts the characteristic greenish color of pus.[13,31] Other major constituents include

(1) α-defensins, cytotoxic proteins that scaffold into transmembrane pores within the microbial cell wall and perturb the maintenance of vital transmembrane gradients, and (2) bactericidal/permeability-increasing protein (BPI), which binds to gram-negative organisms and induces rearrangement of membrane lipids and inhibits growth.[31–34] Elastase cleaves constituents of the extracellular matrix, including proteoglycans, collagen (types I, III, IV), and fibronectin and, of course, elastin.[35] Azurocidin is chemotactic for monocytes and stimulates LPS-induced release of IL-6 and TNFα from monocytes.[6,31]

Specific granules are rich in antimicrobial substances that are released extracellularly (**Table 7.2**).[30] Lactoferrin, by sequestering iron, inhibits bacterial growth and can bind bacterial cell membranes and induce irreversible membrane damage and lysis.[31] Phospholipase A_2 (PLA_2) degrades bacterial membrane phospholipids. Lysozyme, present in all granules, is a cationic antimicrobial peptide that cleaves peptidoglycan polymers of bacterial cell walls. Gelatinase and collagenase are other extracellular matrix degrading enzymes.[31] These granules also possess receptors for a variety of extracellular matrix proteins and cell surface ligands (i.e., β_2-integrin Mac-1) that strengthen neutrophil adherence to the endothelium. In addition to the mechanical function of cellular anchorage, engagement of these receptors with their respective counterligands induces phenotypic alterations such as degranulation and enhanced ROS production.[6,31]

Table 7.2 Neutrophil Granules and Secretory Vesicles

Azurophil Granules	Specific Granules	Gelatinase Granules	Secretory Vesicles	
Myeloperoxidase (MPO)	Lysozyme	Gelatinase	Plasma proteins	M
Lysozyme	Phospholipase A_2	Lysozyme		E
Cathepsins	Gelatinase	β_2-microglobulin		M
Elastase	Collagenase	Acetyltransferase		B
Proteinase 3	Lactoferrin			R
Azurocidin	TNF			A
BPI	β_2-microglobulin			N
Defensins	Histaminase			E
iNOS	Heparinase			
α1-antitrypsin	uPA			
α-mannosidase				
Sialidase				
Acid mucopolysaccharide				
β-glycerophosphatase				
Elastase				
CD63	Mac-1	Mac-1	Mac-1	C
CD68	SNAP proteins	SNAP proteins	SNAP proteins	Y
	CD15	Cytochrome b558	Cytochrome b558	T
	CD66	fMLP R	CR1	O
	CD67	DAG-deacylating enzyme	CD14	S
	Cytochrome b558	uPA R	CD45	O
	Fibronectin R		fMLP R	L
	Laminin R		uPA R	
	Vitronectin R		C1q R	
	Thrombospondin R			
	fMLP R			
	uPA R			

BPI, bactericidal/permeability-increasing protein; CD, cluster of differentiation; CR1, complement component C3b; fMLP, N-formylmethionine-leucyl-phenylalanine; iNOS, inducible nitric oxide synthase; R, receptor; uPA, urokinase-type plasminogen activator.
Modified from Faurschou M, Borregaard N. Neutrophil granules and secretory vesicles in inflammation. *Microbes Infect* 2003:1317–1327.

Gelatinase granules contain matrix metalloproteases, zymogens that upon proteolytic activation degrade the interstitial matrix including collagens, fibronectin, proteoglycans, and laminin; this may facilitate neutrophil extravasation and migration (**Table 7.2**). They too are a source of cell surface adhesion molecules.[6,31,34]

Secretory vesicles are dense with the β_2 integrins LFA and Mac-1, the complement receptor (CR1), the LPS receptor CD14, and the FcγRIII. Through fusion with the plasmalemma, the cell surface is enriched with these receptors, which facilitates firm neutrophil-endothelial engagement, leukocyte recruitment, and the capacity to respond to a variety of stimuli.[6,31] Not surprisingly, because of the essential nature of leukocyte recruitment, secretory vesicles possess the lowest threshold for release and are released

earliest, followed by gelatinase, specific, and azurophil granules (**Table 7.2**).[31]

Oxidative Burst and Oxidant Metabolites

The generation of toxic oxygen metabolites and ROS is the cardinal characteristic of the neutrophil, though is also a defensive quality of the monocyte/macrophage. Their essential antimicrobial properties are equally destructive to host tissues and implicated in the pathophysiology of many inflammatory disorders (**Table 7.3**). Thus, a delicate balance must be maintained between ensuring elimination of the offending pathogen and minimizing host damage.

A free radical is any species possessing one or more unpaired electrons. They are categorized under the broader term ROS or reactive nitrogen species (RNS), which encompasses all molecules capable of radical formation. Despite a very brief existence (10^{-11} to 10^{-6} seconds) extensive damage may occur through the induction of free radical chain reactions. Species underlying both physiologic and pathophysiologic inflammation include the following: the superoxide anion ($O_2^{\bullet -}$), the hydroxyl radical (•OH), hydrogen peroxide (H_2O_2), the singlet oxygen, and the reactive nitrogen intermediates nitric oxide (NO), and peroxynitrite ($ONOO^-$) (**Table 7.3**). Counterintuitive to their role in microbial killing and tissue injury, recent data also support as an intracellular signal.[36] In the context of signal transduction, ROS modulate the immune response by activating neighboring inflammatory cells and inducing cytokine secretion.[37,38]

Numerous regulatory mechanisms provide temporal and spatial control of the ROS production. The NADPH oxidase complex itself exists in a disassembled state, and only upon cell activation and the need for ROS production, are the subunits approximated to enable enzymatic function.[39] In addition, high plasma and tissue concentrations of proteinase inhibitors provide continuous surveillance and systemic control. However, such regulation is incomplete as evidenced by such diseases as rheumatoid arthritis, chronic obstructive pulmonary disease, and autoimmune vasculitis, which are the consequence of damage due to neutrophil-derived products.[39]

NADPH oxidase is a heteromeric complex composed of six subunits: flavocytochrome b558, the electron-transporting apparatus comprised of

gp91(phox) and p22(phox); the cytosolic complex p40(phox), p47(phox) and p67(phox); and the oxidase factor rac-2 (**Fig. 7.3**).[39] Microorganisms or high concentrations of chemoattractants bind to cell surface receptors and initiate oxidase activation, heralded by phosphorylation of p47(phox). Cytochrome b558 (gp91 and p22), which exists within the plasmalemma and the membranes of specific granules and secretory vesicles, is recruited by phagocytosis and granule fusion. Phosphorylation of p47(phox) induces a conformation change that enables its incorporation within the membrane, where it facilitates the translocation of rac2 and p67(phox) and stabilizes the association of this cytosolic complex with cytochrome b558, thereby rendering the complex functional.[39]

Table 7.3 Major ROS and Their Metabolism

ROS Molecule	Main Sources	Enzymatic Defense Systems	Products
Superoxide ($O_2^{\bullet -}$)	Leakage from electron transport chain Activated phagocytes Xanthine oxidase Flavoenzymes	Superoxide dismutase Superoxide reductase	$H_2O_2 + O_2$ H_2O_2
Hydrogen peroxide (H_2O_2)	From $O_2^{\bullet -}$ via superoxide dismutase NADPH oxidase Glucose oxidase Xanthine oxidase	Glutathione peroxidase Catalase Peroxiredoxins	$H_2O + GSSG$ $H_2O + O_2$ H_2O
Hydroxyl radical ($O_2^{\bullet -}$)	From $O_2^{\bullet -}$ and H_2O_2 via transition metals		
Nitric oxide (NO)	Nitric oxide synthases	Glutathione/TrxR	GSNO

NADPH, nicotinamide adenine dinucleotide phosphate; ROS, reactive oxygen species; TrxR, thioredoxin.

Modified from Nordberg J, Arner E. Reactive oxygen species, antioxidants, and the mammalian thioredoxin system. *Free Radic Biol Med* 2001:1287–1312.

At the redox center of the oxidase an electron is transferred from NADPH to oxygen, thereby generating superoxide.[40]

$$O_2 + e^- = O_2^{\bullet -}$$

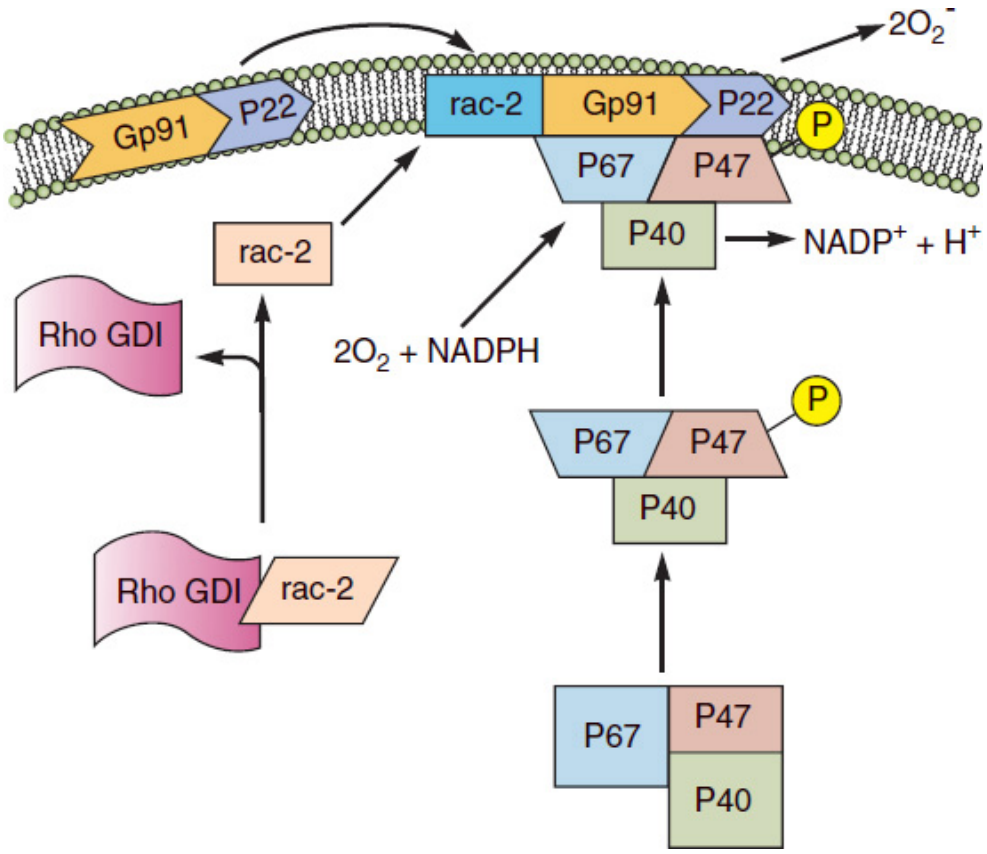

Figure 7.3 NADPH oxidase assembly. In the resting neutrophil, the cytochrome subunits gp91 and p22 are tightly bound in the membrane. P47(phox), p67(phox) and rac-s complex are in the cytosol. On activation, GDI releases rac-2, and p47(phox) becomes phosphorylated. This causes translocation of rac-2, p47(phox), and p67(phox) to the membrane and complex formation with the cytochrome components, thereby completing the assembly of the active oxidase. (Redrawn from Burg ND, Pillinger MH. *Clin Immunol* 2001;1:7–17.)

Other mechanisms of superoxide production include uncoupling of xanthine dehydrogenase system, uncoupling of mitochondrial and ER electron transport chains, and nonenzymatic reactions such as autooxidation of hemoglobin.[41,42]

Superoxide is relatively weak and of low bactericidal potency. However, its membrane permeability and role as a reactant in reactions yielding highly toxic products confers upon it a high potential for cellular and tissue

damage.[40] Superoxide can spontaneously or enzymatically (superoxide dismutase) dismutate into hydrogen peroxide.[39,40]

$$2H^+ + 2O_2\cdot^- \Leftrightarrow H_2O_2 + O_2$$

It can also be converted to the more potent hydroxyl radical through the metal-catalyzed Haber-Weiss reaction[39,40]

$$H_2O_2 + O_2\cdot^- + Fe^{3+} \Leftrightarrow O_2 + OH^- + \cdot OH + Fe^{2+}$$

or through the Fenton equation[39,40]

$$H_2O_2 + Fe^{2+} \Leftrightarrow Fe^{3+} + OH^- + \cdot OH + Hb\text{-}Fe^{2+} + H_2O_2 \Leftrightarrow Hb\text{-}Fe^{3+} + OH^- + \cdot OH$$

Under physiologic conditions, lactoferrin found in neutrophil-specific granules provides the iron catalyst for the Haber-Weiss reaction. In the Fenton reaction, superoxide or other reducing agents such as lactate or ascorbate donate electrons to generate the ferrous ions required to react with hydrogen peroxide to produce the hydroxyl radical.[39,40,43]

The hydroxyl anion is highly reactive and induces DNA strand breaks and base hydroxylations leading to ATP depletion and gene mutations. It can attack lipid side chains of membrane phospholipids to form hydrogen peroxide and lipid hydroperoxides in a process called lipid peroxidation. These products disrupt membrane function, serve as substrates for the production of cytotoxic aldehydes, and can uncouple calcium-ATPase thereby increasing cytosolic calcium concentration, which too is toxic. Recent data support a mechanism by which oxidation of critical sulfhydryl residues on the ryanodine receptors induces an “open” configuration and a leak of intracellular ER calcium into the cytosol.[44] This elevation of cytosolic calcium can activate calcium-dependent proteases and phospholipases that propagate cellular damage.[43]

Superoxide reacts with NO to produce peroxynitrite ($ONOO^-$) and hydroxyl radical.[40,45]

$$NO^\bullet + O_2\bullet^- \Leftrightarrow ONOO^- + H^+ \Leftrightarrow ONOOH \Leftrightarrow \bullet OH + NO_2\bullet$$

The hemoprotein MPO yields the potently bactericidal HOCl from the reactants chloride and H_2O_2. HOCl oxidizes amino acids, nucleotides, and hemoproteins, can activate neutrophil collagenases and permit unabated elastase injury by inhibiting α1-antitrypsin, and contribute to hydroxyl radical and singlet oxygen production.[37,43,46] Though short-lived, subsequent reactions with secondary amines generate secondary chloramines, which are equally toxic but much more stable. These metabolites can oxidize similar cellular components. They can combine with halide anions to generate toxic free halides or with taurine chloramines that induces MAC complement formation.[37,43,46]

In light of the central role of MPO during inflammation and pathogen elimination, it is surprising that MPO deficiency is common and relatively benign. Though MPO-deficient neutrophils show early depressed bacterial killing, bactericidal function normalizes within 60 minutes.[47] It is hypothesized that though bacterial killing is impaired, postphagocytosis oxidase-dependent neutrophil apoptosis is normal, resulting in appropriate regulation of the inflammatory response.[47]

Singlet oxygen, a highly reactive and extremely short-lived species, is formed by an input of energy to O_2 that reverses the spin direction of one of the outermost unpaired electrons away from a parallel spin. It is produced during reactions of the MPO-H_2O_2-halide system and is a potential product of superoxide dismutation and the Haber-Weiss reaction. It is highly electrophilic, reacting with compounds containing electron-rich double bonds and may react with membrane lipids to produce peroxides.[43]

The highly destructive potential of ROS, for both host, as well as, pathogen obligates continuous tight spatial and temporal regulation. The oxidase complex itself exists spatially disaggregated; only upon cellular activation are its constituents assembled and enzymatic function restored (**Fig. 7.3**).[39,47] As elegant and intricate as are the mechanisms by which ROS production is controlled, so too are the mechanisms by which these products are removed when no longer needed. Superoxide is eliminated by spontaneous and enzymatic (superoxide dismutase) dismutation to H_2O_2 (**Fig. 7.4**). H_2O_2 is subsequently reduced to oxygen and water by catalase.[40,43] In the extracellular environment, this function is performed by GSH peroxidase, a selenium-dependent enzyme that reduces H_2O while

oxidizing reduced GSH to its oxidized form. N-acetylcysteine (NAC) is a reducing agent that restores GSH and is used in the treatment of acetaminophen toxicity. More contemporary preclinical data support therapeutic utility in a variety of related inflammatory disease states. A systematic review concluded that NAC exhibits an ameliorative effect against obesity-related comorbidities, in part, by attenuating abnormal proinflammation and limiting oxidative damage.[48] Similar conclusions were reported of the protective effects of NAC against diabetes-associated cardiovascular complications by reducing oxidative stress.[49] NAC has also been shown to reduce hepatocellular injury in an animal model of warm liver ischemia/reperfusion.[36] Similarly purported mechanisms are invoked to support its prophylactic use in reducing contrast-induced nephropathy in patients undergoing iodinated contrast imaging procedures; however, equipoise persists in actual clinical efficacy.[50–52] Mechanisms of preventing hydroxyl radical-induced tissue damage include the binding of transition metal ions by albumin, ceruloplasmin, haptoglobulin, lactoferrin, and transferrin.[37,40,43] Taurine, an endogenous amino acid, is a scavenger for HOCl. It, in combination with its derivative taurolidine, is being investigated as an agent to reduce perioperative inflammation.[53] Other antioxidants that may assist in controlling the reaction include vitamins E (tocopherol) and C. Vitamin C has many antioxidant properties, including the ability to regenerate α-tocopherol. It can prevent activation of neutrophil-derived collagenase and is a powerful scavenger of HOCl, superoxide, singlet oxygen, and hydroxyl radicals. However, clinically, the recent CITRIS-ALI randomized trial of patients with sepsis and severe acute respiratory failure did not observe significant improvements in organ dysfunction scores or alterations in markers of inflammation and vascular injury in the cohort administered a 96-hour infusion of vitamin C compared with placebo.[54] Carotenoids have long double bonds to attract and sequester free radicals. Uric acid is a powerful scavenger of water-soluble radicals such as HOCl and singlet oxygen. It can also bind copper and iron ions to suppress hydroxyl radical formation. Stress proteins or heat-shock proteins (HSPs) are induced by oxygen radicals and ischemia and may play a role in defense. Furthermore, heme oxygenase-1 (HO-1) catalyzes the cleavage of heme to biliverdin, which is subsequently converted to bilirubin, an efficient free radical scavenger.[37,40,43]

All of the aforementioned participants of the NADPH oxidase are vital for health, as evidenced by those who suffer from chronic granulomatous disease (CGD).[39,47] These patients have deficient superoxide production and experience ineffective inflammatory reactions to infection. They commonly suffer from repeated bacterial infections (pneumonia, cutaneous abscesses and hepatic and perihepatic abscess, and osteomyelitis) by organisms that are catalase positive (*Staphylococcus aureus*). Organisms that produce large amounts of peroxide are less of a threat as the neutrophils can utilize bacterial peroxide to produce toxic metabolites. The use of prophylactic antibiotics and IFNγ has reduced the frequency of serious infections in this patient population.[39,47]

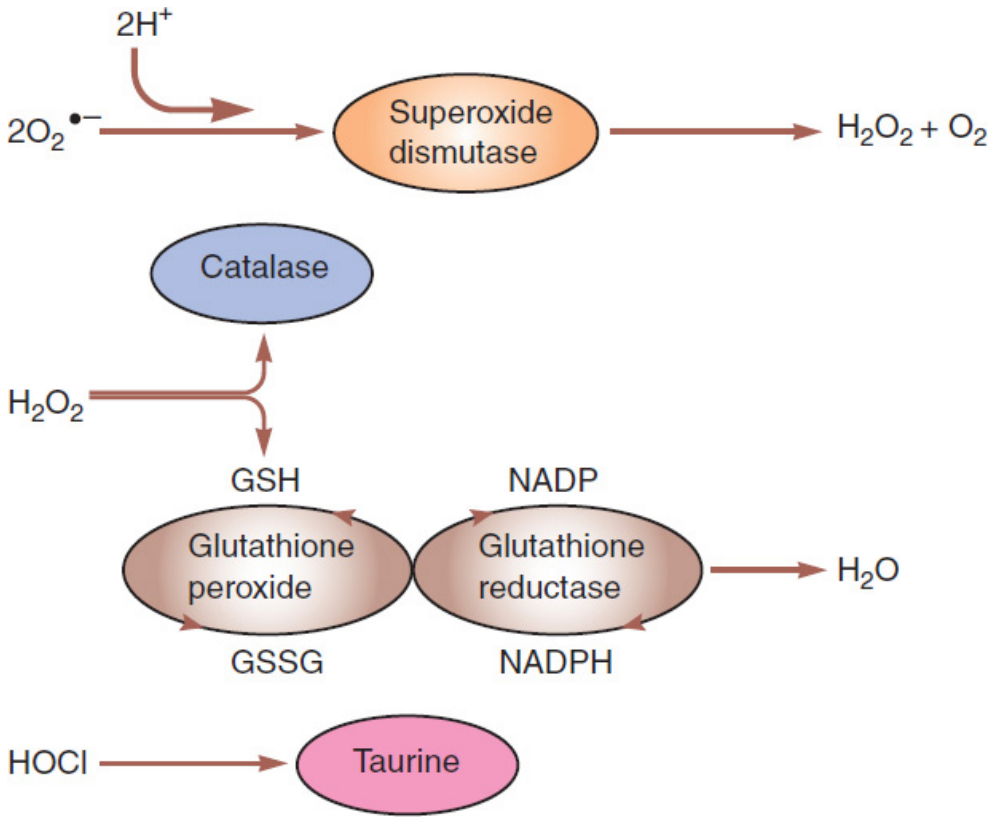

Figure 7.4 Scavengers of ROS. (Redrawn from Klebanoff SJ. In: Gallin JI, Snyderman R, eds. *Inflammation: Basic Principles and Clinical Correlates*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999:723.)

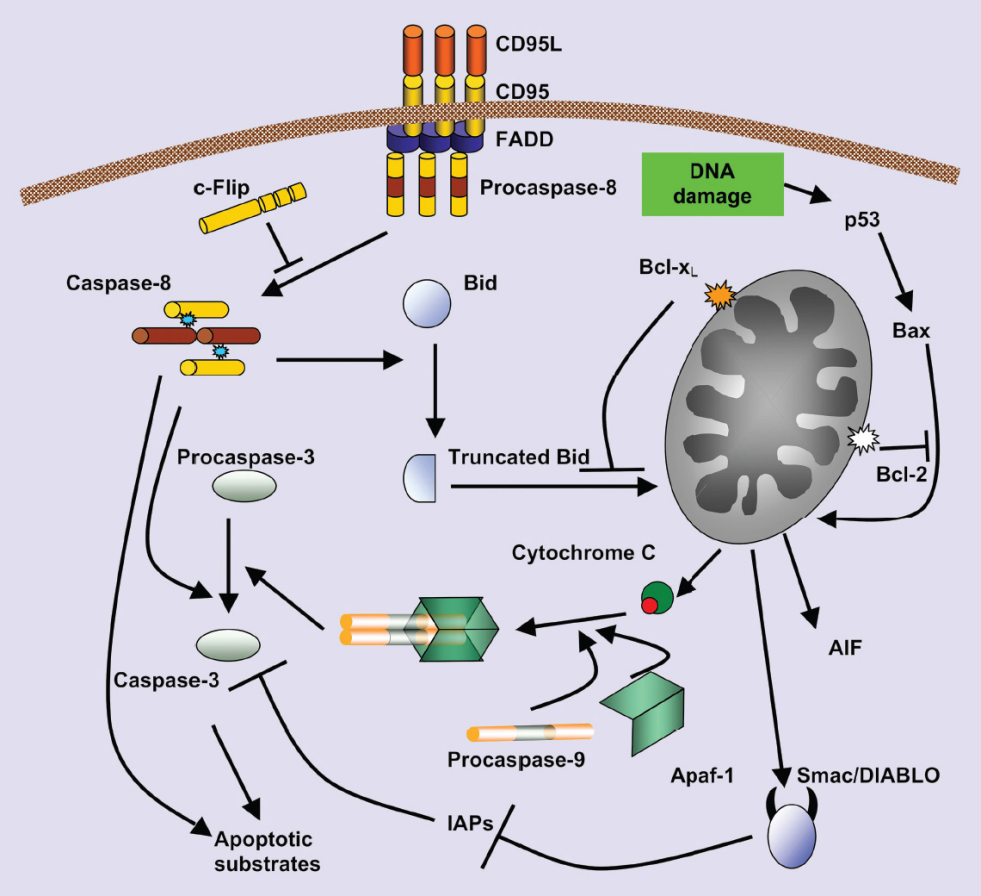

Figure 7.5 Apoptosis. Apoptosis is an integral component in the regulatory mechanisms that limit and resolve inflammation. Unlike cell necrosis, which is characterized by loss of membrane integrity, cellular edema and lysis, and release of intracellular products that incite an inflammatory reaction, apoptosis is a physiologic process of programmed cell death, characterized by DNA fragmentation and plasma membrane blebbing, with the compartmentalization of cytoplasmic and membrane particles into apoptotic bodies consisting of cytoplasmic and membrane fragments. Cytoplasmic contents are not released and consequently, an inflammatory response is not induced. Neutrophils are programmed to undergo apoptosis constitutively, and the signal transduction pathways culminating in apoptosis are activated early in acute inflammation. Subsequent neutrophil apoptotic particles are phagocytosed by resident macrophages. This is the preferred mechanisms for clearing neutrophils from inflammatory foci, and has also been implicated in the clearance of eosinophils, monocytes, and lymphocytes.

Apoptosis plays a prominent role in the immune system. Most developing T cells undergo apoptosis during the selection process in the thymus. Termination of the cellular immune response also involves cytokine-induced apoptosis. Apoptosis can be used by lymphocytes as a means of effecting death in other cells. CTLs kill target cells by inducing apoptosis via a Fas-induced pathway and a perforin- and granzyme-mediated pathway. Increased apoptosis has been observed in lymphoid tissues of patients dying of sepsis, suggesting that excessive lymphocyte apoptosis may contribute to fatal sepsis.

Inducers of apoptosis include oxidant stress, radiation, viral infection, trauma, and cytokines. Many of the pathologic agents that induce apoptosis at low concentrations can cause necrosis at higher concentrations. Apoptogenic stimuli activate the apoptotic pathway through both receptor-dependent and independent pathways. The sphingomyelin breakdown product, ceramide, is implicated as a transducer of apoptosis. DNA damage secondary to radiation or oxygen radical formation results in the accumulation of the tumor suppressor gene p53. p53 promotes non–receptor-mediated modulation of apoptosis.

Receptor-mediated pathways involve the "death receptors" that belong to the TNF receptor superfamily. Ligands shown to induce apoptosis include FasL, TNF, TNF-related apoptosis-inducing ligand (TRAIL), nerve growth factor, and CD40L. The best-characterized death receptors are Fas bound by FasL and TNFRI bound by TNF and lymphotoxin a. Although primarily produced by macrophages, TNF is expressed on many cell types, whereas FasL is restricted to the surfaces of CTL, macrophages, and neutrophils. TNF and FasL also differ in that FasL directly activates a cell death pathway, whereas TNF does so indirectly and concurrently stimulates pathways that inhibit apoptosis. Independent and divergent proinflammatory signaling pathways by TNF lead to the induction of NFKB, an inhibitor of apoptosis. The mechanism by which several cytokines, including IL-1, IL-6, and GM-CSF, inhibit apoptosis is through induction of NFKB and apoptosis is one of many factors that ultimately determine the cell's fate.

Ligation of death receptors recruits "death domain" containing adaptor proteins that interact with the receptor's intracellular death domain. This interaction initiates the enzyme cascade responsible for apoptosis effector mechanisms, the caspases. All signaling pathways converge on the activation of cysteine proteases related to IL-1/3 converting enzyme called caspases. Caspases propagate apoptotic signaling by cleaving/activating other caspases, and eventually execute terminal events in apoptosis by cleaving specific target proteins. Caspases 8 and 10 activate apoptosis signaling by linking Fas-associated death domain protein (FADD) with the caspase cascades. Caspases 3 and 7 are the executor molecules in the nucleus that cleave death substrates, including nuclear structural proteins, protein kinases, and proteins involved in cell cycle regulation or DNA fragmentation. Cytochrome C release from mitochondria is a key component in the activation of caspases. Cytochrome C release, and therefore apoptosis, is inhibited by Bcl-2, the primary death protection protein that belongs to the Bel family of pro- and antiapoptotic proteins involved in the regulation of apoptosis. CD95L binds CD95, induces receptor clustering and the formation of a death-inducing signaling complex. This complex recruits, through the adaptor molecule Fas-associated death domain (FADD) protein, procaspase-8, resulting in caspase-8 activation; this event can be blocked by the caspase homologue c-FLIP. These diverse response pathways converge on mitochondria, often through the activation of a proapoptotic member of the Bcl-2 family. Unlike Bcl-2, which is primarily membrane-associated, Bax, Bad, Bim, and Bid, can shuttle between the cytosol and organelles. Proapoptotic signals redirect these proteins to the mitochondria. Proapoptotic and antiapoptotic Bcl-2 family members converge on the mitochondrium to compete to regulate cytochrome c exit. If the proapoptotic camp wins, an array of molecules is released from the mitochondrial compartment. Principal among these is cytochrome c, which associates with Apaf-1 and then procaspase-9 to form the apoptosome. The death receptor and mitochondrial

pathways converge at the level of caspase-3 activation. Caspase-3 activity is antagonized by the ZAP proteins, which themselves are antagonized by the Smac/DIABLO protein, integration between the death receptor and mitochondrial pathways is provided by Bid, a proapoptotic Bcl-2 family member. Caspase-8–mediated cleavage of Bid greatly increases its prodeath activity, and results in its translocation to mitochondria, where it promotes cytochrome c exit. (Redrawn from Hengartner MO. The biochemistry of apoptosis. *Nature* 2000;407:770–776.)

Neutrophil Extracellular Traps (NETs) and NETosis

The antimicrobial weapons possessed by neutrophils to fulfill the task of pathogen elimination are vast. To this arsenal another distinct "weapon" has been described: NETs. NETosis is a process in which neutrophils extrude a lattice of chromatin and histones; it is postulated that this functions to entrap invading pathogens, which are then killed. The characteristic feature is the presence of neutrophil nuclear DNA in the extracellular space. Attached to this DNA backbone is an array of microbicidal agents that are typically compartmentalized inside the azurophilic, specific and gelatinase granules: neutrophil elastase (NE), cathepsin G, and MPO. Distinct from apoptosis, the process does lead to cell death, though clearly contributes to pathogen control. It is conserved in various vertebrates, insects, and even plants. Several microorganisms exhibit mechanisms of resistance to NETs, which may be additional evidence highlighting the importance of this process.

Pathogens (i.e., bacteria, fungi, viruses, and protozoa) and their subcellular components, such as LPS, M1 protein, and fMLP induce NET formation. Similarly, sterile insults, inflammatory stimuli (e.g., PAF, IL-8, TNFα, HMGB1, NO), and chemical compounds (PMA, ionomycin) all can stimulate NETosis. The process begins with engagement of the aforementioned stimuli with TLRs, Fc receptors, cytokine, and CRs located on the neutrophil cell surface. Subsequent calcium release stimulates PKC activity and assembly of functional NADPH oxidase, leading to ROS and NO production. ROS are requisite for NET formation, as antioxidant scavengers (e.g., N-acetylcysteine) attenuate the process. Interestingly, individuals with CGD, a disease characterized by insufficient ROS production, inefficiently produce NETs. The chromatin undergoes decondensation followed by mixing of nuclear and cytoplasmic components with granulate antimicrobial contents. Plasma membrane rupture ensues with the release of chromatin decorated with granular proteins into the extracellular space.[55–57]

NETs are able to trap almost all pathogens, including those too large to be phagocytosed. Indeed, it is proposed that trapping by NETs is one of the most important functions that limits microbial spread. The antimicrobial functions of NETs are mediated by the microbicidal compounds accompanying the chromatin: NE, MPO, histones, cathepsin G, proteinase 3, lactoferrin, calprotectin, and antimicrobial peptides such as defensive or the cationic LL37. However, the histones H1, H2A, H2B, H3, and H4 themselves also possess powerful antimicrobial and proinflammatory effects.

As fundamental as NETosis is for microbial defense, recent data suggest that excessive NETosis or ineffective NET clearance may underlie several pathologic conditions or syndromes characterized by excessive inflammation, including autoimmunity, cancer, and thrombosis.[55–57] Furthermore, methods of dissolving NETs (e.g., DNAase) may offer therapeutic utility.

During acute lung injury (ALI) a high concentration of stimulating factors promotes NETosis and the release of neutrophilelastase, LL-37, and ROS, which may exacerbate injury. Cystic fibrosis is characterized by peribronchial neutrophil infiltration and an inflammatory response that includes both upper and lower airways. Studies show that neutrophil cytotoxins, NETs and high concentrations of extracellular DNA are thought to underlie the high mucus viscosity and are associated with increased mucus clogging and lung injury in cystic fibrosis.[55–57] Degrading DETS appears to help manage CT airway disease.[58]

Several autoimmune diseases are also characterized by perturbed NETosis, and more than 70% of NET components are potent autoantigens, and the neutrophils from patients with various autoimmune diseases appear more prone to NETose.[55–57] NETs have been identified in rheumatoid arthritis, systemic lupus erythematosus (SLE) and antineutrophil cytoplasmic antibodies (ANCA)-associated vascularitis, psoriasis, and gout. In fact, an imbalance between NETosis and NET degradation may be a causal mechanism of autoimmune diseases themselves.[59,60] Small vessel vasculitis is characterized by ANCA reactive against PR3 and MPO. Externalization of IL-17 in the extracellular traps of neutrophils and mast cells is now thought to be central to the pathogenesis of psoriasis. In SLE, an imbalance between NET formation and clearance may underlie the systemic tissue damage that

occurs. In fact, decreased NET degradation correlates with renal disease. NETs may also activate complement, thereby amplifying the disease.

NETs may also serve as a link between inflammation and thrombosis. NETs are also rich in bioactive molecules that promote thrombosis and induction of NETosis is one mechanism by which antiphospholipid antibodies may cause thrombotic events in patients with antiphospholipid syndrome.[61] They can provide a stimulus and scaffold for thrombus formation by promoting platelet and RBC adhesion and by concentrating effector proteins and coagulation factors. Activated endothelium produces compounds that, upon contact with neutrophils, stimulate NETosis, which in turn, promotes endothelial damage.[55–57]

Regulation of Neutrophil Activity

In addition to the previously described mechanisms for controlling the inflammatory response of neutrophils, there is substantial evidence supporting the role of apoptosis in halting and 2 resolving neutrophil-derived inflammation (**Fig. 7.5**).[62] Within 90 minutes of phagocytosis, over 250 genes are induced, of which more than 30 encode proteins integral to at least three distinct apoptotic pathways.[62] These observations suggest that the mechanism-inducing apoptosis is initiated quite proximal in the inflammatory cascade, in fact, just subsequent to phagocytosis. The timely execution of a controlled cell death program in human PMNs is essential for preventing damage to healthy tissues and for the resolution of infection. Furthermore, evidence suggests that the phenotype of other immune cells, including monocytes and macrophages, is altered after encountering and phagocytosing apoptotic neutrophils. Thus, apoptotic neutrophil particles may function to downregulate the inflammatory function of neighboring cells. In some circumstances of infection or trauma, neutrophil apoptosis may be delayed, which might contribute to prolonged or a failure to resolve inflammation.

The inflammatory capacity of neutrophils is also transcriptionally regulated. Genes encoding proinflammatory mediators or signal transduction molecules such as receptors for IL-8, IL-10, IL-13 are downregulated early after activation and decrease rapidly after the initiation of apoptosis.[62] In addition, regulating oxidative stress and ROS achieve high priority as the genes involved in glutathione and thioredoxin metabolism and heme

catabolism are upregulated as is the production of reduced glutathione.[62] Hence, activation-induced apoptosis in neutrophils stimulates self-directed regulation, an event that likely facilitates removal of neutrophils by macrophages. As aforementioned, removal of apoptotic neutrophils by activated macrophages also appears to serve a role in modifying their function and halting the inflammatory response.

Mononuclear Phagocytes

Monocytes circulate for about 1 to 2 days, whereafter, they constitutively hone to a particular tissue (i.e., lung, peritoneum) to differentiate into macrophages possessing a phenotype specific to the resident tissue (dendritic cells [DCs] of the skin, Kupffer cells of the liver) (**Table 7.1**).[6,63,64] Resident macrophages are typically found at interfaces with blood (liver and spleen) and with lymph, where they can readily detect, ingest, and destroy invading organisms.[43] Mononuclear cells function as antigen presenting cells in T cell-mediated adaptive immune responses, presenting antigen in the appropriate context to effector T cells. They provide services integral to both innate and adaptive immune responses. Evidence also supports their role in providing an "alarm" both locally and systemically through the release of intracellular proteins (i.e., HMGB1, IL-1α) expressing damage-associated molecular patterns 3 (DAMPs) that can function as a danger signal (*vida infra*). Like neutrophils, circulating monocytes are generated through myelopoiesis in the bone marrow. At steady state these monocytes are characterized by cell surface markers. In humans $CD14^+$ monocytes are described as proinflammatory and rapidly egress into tissues under inflammatory conditions to become macrophages. $CD16^+$ monocytes are referred to as patrolling monocytes and remain in the circulation where they "patrol" and repair damaged endothelial cells. Under systemic stress as seen after trauma or sepsis, emergency myelopoiesis or demand adaptive myelopoiesis is induced and massive numbers of primed neutrophils and monocytes are released into the circulation.

Recruitment

Monocytes are recruited and emigrate to foci of inflammation utilizing similar mechanisms of adhesion and diapedesis as described for neutrophils (**Fig. 7.1**). PAF, C5a, the CC chemokines (i.e., MCP family members), RANTES, and MIP-1α, are potent monocyte-macrophage chemotaxins.[65,66] The selectin family of adhesion receptors mediates the initial tethering of monocytes to endothelial cells.[22] Firm adhesion to the endothelium involves the interactions β_1 and β_2 integrins on monocytes with the endothelial adhesion molecules ICAM-1 and VCAM-1.[22]

Phagocytosis

Phagocytosis involves the IgG receptor (FcγR) and the receptor for the complement factor C3b. Terminal sugar patterns on microbial surfaces also allow recognition by macrophages for nonspecific phagocytosis through the mannose lectin pathway.[26] However, phagosomal maturation differs from that which occurs in the neutrophil. Monocytes and macrophages have an endocytic pathway targeting the phagosome to a lysosome.[28] After endocytosis of a receptor–ligand complex, the contents of a vesicle are targeted to an early endosome; the ligand and receptor dissociate, and the receptor is then recycled to the cell surface.[28] This early endosome undergoes a series of maturation steps in which it is acidified (pH 5.5–6.0). This acidification is requisite for optimal protease and hydrolase activity involved in pathogen killing. It may also be integral for phagosome maturation as titrating the acidity inhibits phagosome-lysosome fusion.[28] Ultimately, the endosome fuses with a lysosome, which is characterized by its extreme acidity (pH <5.0) and elevated concentration of proteases.[28] Lysosomes are the terminal destination of phagocytosed material targeted for degradation.

After fusion, MPO released into phagosomes can react with hydrogen and halides to yield toxic hypohalous acids, superoxide anion, hydrogen peroxide, and hydroxyl radical (**Table 7.3**). Macrophages may also use peroxidase generated by adjacent neutrophils, eosinophils, and monocytes and acquired through endocytosis to generate these ROS. In addition to supporting the inflammatory response, macrophages also play an important immunoregulatory role in inflammation by scavenging apoptotic neutrophils at sites of inflammation.[43]

Activation

IFNγ derived primarily from T cells and innate lymphocytes (i.e., natural killer cells) is the primary activator of macrophages and yields what has been entitled "M1" macrophages; these are generalized as "inflammatory macrophages" and produce proinflammatory cytokines, phagocytose microbes, and initiate the immune microbicidal response. They also produce NO and ROS.[6,64,67] Optimal M1 macrophage activation requires both interferon IFNγ and a sensitizing agent (T_H1 4 activation), both of which can be provided by activated T lymphocytes. CD40 ligand on T cells can bind CD40 on macrophages to sensitize the cell. Alternatively, membrane-associated TNFα or lymphotoxin from lymphocytes can activate macrophage TNFα synthesis and thereby sensitize the macrophage to IFNγ.[43] IL-10 promotes monocyte maturation and macrophage differentiation.[68] Other activators include GM-CSF, TNFα, IL-1, and LPS.

Activated monocytes and M1 macrophages can produce approximately 100 different products, including GM-CSF, M-CSF, G-CSF, IL-1, TNFα, G-CSF, and NO.[43,69] Mononuclear phagocytes are important sources of chemoattractants such as IL-8, PAF, and leukotriene B_4 (LTB_4) that recruit neutrophils and other leukocytes. Their release of HMGB1 and other damage-associated molecular patterns (DAMP) molecules serves an endogenous "danger" signals to other immune cells in the local environment (**Table 7.4**). These bind to various pattern recognition receptors (PRRs) to alter cell function. However, systemic release of HMGB1 may also be causally related to mortality in such inflammatory states as sepsis and trauma.[70,71] The respiratory burst and subsequent production of toxic ROS mirrors that of neutrophils.

Alternatively, 5 exposure to IL-4, IL-10 or IL-13 (T_H2 activation) induces M2 macrophages. They produce low levels of proinflammatory cytokines, typically are not involved in antigen presentation or NO production. Through the high expression of arginase, M2 elaborate either polyamines to induce proliferation or proline to induce collagen production, and thus, are associated with wound healing and tissue repair. Recent metabolism studies have shown that alterations in the metabolic profile of macrophages shape their activation state and function; specifically, the plasticity of phenotype is postulated, in part, to be dictated by use or disuse

of oxidative metabolism. M1 macrophage metabolism is characterized by aerobic glycolysis, fatty acid synthesis and a curtailment in the tricarboxylic acid (TCA) cycle. Alternatively, the metabolic signature of M2 macrophages is characterized by fatty acid oxidation and a predominant use of oxidative metabolism for ATP generation. The teleologic purposes of these metabolic differences are likely many and varied, though include the use of metabolites in signal transduction, autocrine modulation of activation state, epigenetic modifications, and antimicobicidal properties.[72] This dichotomous characterization, though helpful, has come under scrutiny for its oversimplification of what is a more likely a spectrum of macrophage phenotypes. More advanced molecular techniques (e.g., single-cell RNA seq) suggest that in response to septic or sterile insult, several distinct monocyte/macrophage populations emerge, each with a distinct genomic signature and likely, function.

Table 7.4 Monocyte/Macrophage Products

Product	Functions
Enzymes	
Lysozyme	Antimicrobial
Urokinase	Plasminogen activation and fibrinolysis
Collagenase	Connective tissue degradation
ACE	Vasopressor
Cytokines	
IL-1	Multiple
TNFα	Multiple
Interferon α/β	Antiviral, immune modulation
IL-6	Acute-phase response
IL-10	Anti-inflammatory
IL-12, IL-18	Stimulate IFN γ production
IL-8	Neutrophil chemoattraction
FGF	Fibroblast growth
GM-CSF	Granulocyte, macrophage differentiation
MIP-1 α/β	Chemoattractant
MCP-1	Monocyte recruitment
RANTES	Monocyte/T_H cell recruitment
Complement proteins	Opsonization, complement activation
Coagulation Factors	Coagulation
Adhesion, matrix molecules Fibronectin, proteoglycan	Localization, migration
Transport proteins	
Transferring	Iron transport
B_{12}-binding protein	Vitamin transport
Bioactive lipids	
Cyclooxygenase	Inflammation
Lipooxygenase	Inflammation

PAF	Platelet activation
Reactive oxygen intermediates Superoxide, hydrogen peroxide Oxygen singlet	Antimicrobial
Reactive nitrogen intermediates NO, nitrates, nitrites	Antimicrobial
Defensins	Antibacterial

ACE, angiotensin-converting enzyme; FGF, fibroblast growth factor; GM-CSF, granulocyte/macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MCP, membrane cofactor protein; MIP, macrophage inflammatory protein; NK, natural killer; PAF, platelet activating factor; RANTES, regulated on activation, normally T-cell expressed and secreted; TNF, tumor necrosis factor.

Modified from Gordon S. Development and distribution of mononuclear phagocytes: relevance to inflammation. In: Gallin Jl, Snyderman R, eds. *Inflammation: Basic Principles and Clinical Correlates*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.

Antigen Presentation

T cells recognize only those antigens associated with surface MHC molecules. MHC class I molecules are expressed on all nucleated cells, whereas MHC class II molecules are restricted to antigen-presenting cells (APC). After phagocytosing pathogen, mononuclear cells process and display antigen to T cells, and in doing so, initiate the development of the adaptive response (i.e., antibody formation). There is evidence that the HSP receptor CD91 may also participate in this process (*vide infra*). This processed antigen is presented on the APC cell surface in the context of major histocompatibility complex (MHC) molecules that are specifically recognized by T-cell receptors (TCRs) and essential for T-cell activation. $CD4^+$ T cells, or helper T cells (T_H), recognize antigen coexpressed with MCH class II molecules and induce B cell differentiation into either memory or antigen-specific antibody-producing plasma cells. These T_H cells can also induce macrophage production of NO, ROS, and other inflammatory mediators. $CD8^+$ cytotoxic T lymphocytes (CTLs) recognize antigen in the context of MHC class I molecules and induce target cell lysis; they destroy host cells infected with intracellular pathogens or cells of malignant potential.[73] Activated mononuclear phagocytes release IL-12, a potent

stimulus for T_H cells and the production of inflammatory cytokines, and elaborate IL-15 the function of which mirrors that of IL-2.[74,75]

The three professional APC are DCs, macrophages, and B cells. DCs are a specialized APC, which process and present antigen to naïve T cells. Monocytes stimulated with GM-CSF, IL-4, or IL-13 differentiate toward DCs. Maturation of the DCs requires TNFα or LPS stimulation.[43] Epidermal Langerhans cells, after encountering antigen, migrate through the lymphoid organs and differentiate into mature DC. DCs are particularly effective at presenting viral antigen. They present antigen in the context of both MHC I and MHC II, and thereby induce both a T_H1 and T_H2 response, respectively. DCs can also present antigens derived from apoptotic cells in the context of MHC I.[76–78] Antigen presentation through MHC I activates $CD8^+$ lymphocytes to become cytotoxic.

Macrophages present antigenic peptides from ingested pathogens that persist in the phagosomes. These peptides, usually of bacterial origin, are expressed in conjunction with MHC II molecules. B cells, by contrast, bind specific soluble molecules (insect toxins, venom, and allergens) via immunoglobulin. This is endocytosed, processed, and presented on surface MHC II.[43,78–80]

Lymphocytes

B, T, and NK cells comprise this lineage of inflammatory cells (**Table 7.1**). B and T cells are central to the adaptive immune response, whereas NK cells lack antigen specificity and primarily function during innate immune response. NK cells are the first line of defense against many viral infections. The loss of surface expression of MHC class I molecules as occurs with virus-infected cells serves as a target for NK cells.[43,81] Alternatively, NK cells bind cell-bound antibody and participate in antibody-dependent cell cytotoxicity. Cells targeted by either mechanism are induced to undergo cell death.

B Lymphocytes

B cells, though of bone marrow origin, attain full maturation within extramedullary sites such as lymph nodes, the spleen, and the mucosal lymph

nodules of tonsils and Peyer patches. With activation, B cells differentiate into antibody-producing plasma cells, which through the elaboration of antibody, aid the neutralization of viruses and bacterial toxins, and facilitate opsonization for phagocytosis and complement activation.[6] Activation requires antigen binding to cell surface receptors and stimulation by T_H cell–derived cytokines; they do not need the assistance of APCs. Polyclonal B-cell activation can occur in a T-cell–independent mechanism if the antigen has a large repeating polymeric sequence.[43,82]

T Lymphocytes

Development of T lymphocytes begins within the marrow and is completed in the thymus. The final population profile is determined by apoptotic processes of both positive and negative selection.[83] Any protein or antigen of *host* origin is presented by APCs, and thymocytes reactive to these self-proteins are deleted.[84] Alternatively, expansion of cell lines recognizing foreign, or rather non–self antigen, occurs through positive selection. IL-7 provides the stimulation for proliferation and differentiation of developing T cells. Ultimately, two lines of mature cells, $CD4^+$ and $CD8^+$, will develop.[85]

Lymphocytes, the smallest of the leukocytes, constitute approximately 20% of circulating leukocytes.[6] Most circulating lymphocytes are T cells, and 60% of those are $CD4^+$, a marker of a T_H phenotype. The other 40% are $CD8^+$, called cytotoxic T cells, T_C. The normal ratio of $CD4^+/CD8^+$ is 2:1.[6] Lymphocytes continuously recirculate through lymph nodes, spleen, lymphatics, lymph nodules, and blood, providing continuous surveillance. Encounter with a particular antigen initiates activation toward an effector T cell. Activation of a T cell requires binding to its specific antigen plus a costimulatory signal provided by the interaction between costimulatory molecules on the APC and their cognate receptors on the T cell.[43]

Naïve T cells circulate continuously between blood and lymphoid organs, making contact with many APCs and the epitopes of the antigens they express.[86] Initially, lymphocytes enter the cortical region of lymph nodes by migrating across the high endothelial venules, a process mediated by the Selectin family of receptors. L-selectin, which is found constitutively on all lymphocytes, binds sialyl Lewis carbohydrate on the endothelium.[43] For example, L-selectin on lymphocytes binds GlyCAM-1 on the high endothelial

venules in lymph nodes. In mucosal tissues, L-selectin and endothelial MAdCAM-1 guide emigration. Migration across the endothelium requires integrins, in particular LFA-1 and its interaction with ICAM-1 and ICAM-2 on endothelial cells.[87] Most lymphocytes are carried back to the blood by the efferent lymphatics. If a T lymphocyte recognizes its specific antigen on the surface of an APC, it remains for several days, then returns to the blood as an armed effector T cell.[43]

Adhesion molecules mediate many of the transient interactions between T cells and APCs that are required for the T cell to sample each antigen it encounters. Lymphocyte LFA-1 can bind the APC in a loose, reversible fashion by any of the ICAM molecules on APCs. If a match between T cell and antigen is found, conformational changes in LFA-1 greatly increase its affinity for ICAM-1 and ICAM-2 to stabilize the interaction. The T cell can then proliferate and differentiate into an effector cell. Effector T cells lose surface expression of L-selectin and no longer circulate through lymphoid tissue. Instead they express VLA-4, an integrin, which binds vascular endothelium at sites of infection, and the cell is retained at the focus. Effector T cells have increased LFA-1 and CD2 adhesion molecule expression that facilitate tight binding to target cell.[88,89] Though a predominant purpose of integrins is cellular adhesion and the mechanical processes of cell recruitment, intracellularly they interact extensively with a variety of signal transduction pathways (e.g., mitogen-activated protein kinases [MAPKs]). Signals induced by and specific to components of the extracellular milieau to which the integrins are exposed (e.g., microbe, fibronectin) cultimate in changes to the cell phenotype, rendering it better suited for the "current" environmental conditions (i.e., microbe vs. sterile injury).

Antigen binding in the appropriate context provides the signal for clonal expansion and differentiation of T cells into effector and memory lymphocytes. The appropriate contact is comprised of antigen complexed with MHC class II molecules on APCs, costimulators, and cytokines produced by the APCs and by the T cells themselves. This first encounter of naïve T cells with antigen is the primary immune response, which serves to induce the formation of effector and memory T cells. These activated T cells hone to peripheral tissues where, upon reexposure to their specific antigen, they activate macrophages to eliminate phagocytosed microbes and induce B-cell differentiation and antigen-specific antibody secretion. The $CD8^+$ CTLs

kill infected host cells and tumor cells that display class I MHC associated antigen. Naïve T cells require activation by DCs, whereas effector T cells can respond to antigens presented by a wider variety of APCs, such as macrophages and B lymphocytes. Not surprisingly, differentiated effector and memory T cells possess lower thresholds for costimulation and require lower antigen concentration for activation than naïve T cells.

In general, antigen presented on MHC II molecules is the prototypical stimulus for $CD4^+$ T-cell activation and the subsequent production of a variety of cytokine mediators, including IL-2, which stimulate further expansion and activation. However, the circumstances under which this activation occurs may dictate disparate paths of differentiation, producing T-cell subsets with distinct cytokine profiles and effector functions. These differing phenotypes have been utilized to characterize two distinct subsets: T_H1 and T_H2.[74,75,90] IL-12 derived from phagocytes infected with intracellular pathogen provides the necessary signal for T_H1 differentiation.[43] IL-12 also stimulates production of IFNγ, the principal macrophage activator, by NK cells and $CD4^+$ lymphocytes. Interferons stimulate T_H1 development by augmenting phagocytic IL-12 production and by maintaining IL-12 receptor expression on $CD4^+$ T cells. The principal effector action of T_H1 cells is the activation of macrophages through the production of IFNγ, GM-CSF, TNFα, CD40L, and FasL.[43,74,75,90] They regulate production of opsonizing and complement fixing antibodies and are effectors of phagocyte-dependent responses. This inflammatory response, also referred to as cell-mediated immunity or delayed-type hypersensitivity, provides one major arm of the adaptive immune response; it is mediated by $CD4^+$ and $CD8^+$ lymphocytes and macrophages.

The principal stimulus for T_H2 differentiation is IL-4, which is derived from T cells, mast cells, and basophils.[74,75,90] These cells are the cellular effectors of humoral immunity and provide the other major arm of the adaptive immune response, which is mediated by T_H2 $CD4^+$ cells, B cells, plasma cells, and antibodies. They produce IL-4, IL-5, and CD40L, thereby inducing B-cell activation and antibody production, and a host of other proinflammatory and anti-inflammatory cytokines.[43] Activation of mast cells and eosinophils by extracellular pathogens is associated with activation of

T_H2 cells. T_H2 cells quell the inflammatory response by inhibiting macrophage functions and T_H1 responses. They are considered the anti-inflammatory arm of cell-mediated inflammation. Helper T cells that express both T_H1 and T_H2 patterns of cytokine expression have been called T_H0 cells, and further studies will certainly discern other subsets of T cells.[6,90]

T-cell activation, differentiation, and expansion are orchestrated by the T cell itself. The responding T cell, in an autocrine fashion, serves as both source and target of a variety of mediators stimulating growth. The principal autocrine growth factor is IL-2, which is induced by signaling regulated by the phosphatase calcineurin (*vida infra*).[91] IL-15 stimulates the proliferation of $CD8^+$ T cells, especially memory cells of the $CD8^+$ subset. After antigen exposure, the numbers of T cells specific for that antigen may increase to about 1 in 10 for $CD8^+$ and 1 in 1,000 to 10,000 for $CD4^+$ cells.[6]

After activation, some proliferating T cells will differentiate into effector cells that eliminate antigens and activate other immune cells. Mature $CD4^+$ cells induce the activation of mononuclear phagocytes and B cells. $CD8^+$ cells differentiate into CTL that recognize viral and other intracellular pathogen antigens that are presented in the context of MHC class I molecules and induce target cell death by releasing the cytotoxins perforin and granzymes from cytoplasmic granules. Granzymes are serine proteases that trigger DNA fragmentation and apoptosis. Perforin stimulates cell membrane pore formation that facilitates granzyme entrance into cells. Apoptosis can also be induced by the binding of Fas ligand on CTL to fas on the target cell. CTLs also release the cytokines IFNγ, TNFα, and CC chemokines. IFNγ and certain CC chemokines have antiviral properties, and both are potent activators of macrophage function. IL-2 produced by CTL and local helper $CD4^+$ lymphocytes expands the CTL, and IL-12 released by APC stimulates CTL activity. As with $CD4^+$ cells, early evidence suggests that the population $CD8^+$ may be divided into T_C1 and T_C2 cells based on their cytokine profiles and effector functions.[43,73–75]

Other T cells will mature into long-lived functionally quiescent memory cells. Upon antigen reexposure, a cell surface rich in adhesion molecules (i.e., integrins, CD44) facilitates rapid and efficient migration to peripheral sites of infection.[6] These cells accumulate over time and in the adult human comprise more than half of the circulating T cells.

Mere antigen exposure is insufficient for activation of naïve T cells. Proliferation and differentiation require costimulatory signals provided by molecules on APCs. The best characterized costimulator pathway involves the T-cell surface molecule CD28 and its counterligands B7-1 and B7-2 expressed on activated APCs.[6,43] CD28 delivers signals that enhance T-cell survival, by increasing expression of the anti-apoptotic protein Bcl-X, the production of cytokines such as IL-2 and the IL-2 receptor, and the differentiation of immature T cells. In vitro, purified populations of $CD4^+$ cells challenged with antigen by APCs that express B7, proliferate and secrete cytokines. This does not occur if B7 is absent. The costimulatory signal must come from the same APC that provides the initial signal. DCs are the most potent APC because they express both classes of MHC molecules and the B7 molecules, whereas macrophages and B cells must be activated to express the costimulatory molecules. This expression of costimulators is regulated so as to ensure that T-cell activation is temporally and spatially appropriate. For instance, during T-cell activation, engagement of CD40 ligand with CD40 induces upregulation of B7 costimulators on the APCs. In addition, it increases the secretion of cytokines such as IL-12 that promote T-cell differentiation, and cytokines are secreted that promote T-cell differentiation and activation. A protein CTLA-4, expressed on activated T cells, is homologous to CD28 and binds B7-1 and B7-2. Unlike CD28, CTLA-4 functions to terminate T-cell responses and plays a role in self-tolerance.

The differentiation of naïve $CD8^+$ T cells to CTL requires a stronger costimulatory signal. This can be provided by either DCs, as they have the greatest intrinsic costimulatory activity, or by a $CD4^+$ helper T lymphocyte. Naïve helper T cells attached to the same APC as the $CD8^+$ T cell can be activated to elaborate IL-2. Attached effector T helper cells stimulate the APC to express more costimulatory molecules. In the case of virulent viruses, cytotoxicity can substitute for CD28 costimulation, and so the typical costimulatory signal is not required for activation. For less virulent viruses, costimulation is necessary for CTL induction.[43,92] The absence of costimulation results in an unresponsive, or anergic T cell. This step has been shown to be mediated by the serine/threonine kinase calcium/calmodulin-dependent protein kinase (CaMK) II (see below).[93] Anergic T cells do not produce IL-2 and therefore cannot proliferate and

differentiate into effector cells even when presented with antigen at a later time.[43]

The affinity of most TCRs for peptide-MHC complexes is low, with dissociation constants on the order of 10^{-5} to 10^{-7} and an estimated TCR–antigen interaction of less than 10 seconds. Furthermore, on any APC fewer than 1,000 of the 10^5 available MHC molecules are likely to be displaying any one peptide at any particular time. Therefore, one APC can engage a small fraction of the 10^4 to 10^5 antigen receptors on a single T cell.[6] Activation of an individual T cell may require multiple sequential engagements of that cell's antigen receptors by peptide–MHC complexes on APCs. With engagement, there is clustering of membrane receptors, tyrosine phosphorylation of several proteins, and recruitment and activation of adaptor proteins.

TCRs are devoid of enzymatic activity and must utilize other proteins to effect signal transduction.[6] After TCR-MHC engagement, several membrane surface proteins and intracellular signaling proteins are rapidly recruited: TCR complex, CD4 or CD8, receptors for costimulators such as CD28, and enzymes and adaptor proteins.[6] After TCR clustering, activated tyrosine kinases associated with and phosphorylate tyrosine residues on CD3 and TCR (**Fig. 7.6**). These phosphorylation sites provide docking sites for other tyrosine and protein kinases, such as Lck, a Src family tyrosine kinase, and ZAP-70, a tyrosine kinase. These kinases become activated with phosphorylation. Activated ZAP-70 phosphorylates several adaptor proteins that subsequently induce a variety of signal transduction cascades. Adaptor proteins contain structural domains that bind other proteins and thereby facilitate the correct spatial orientation that is required for signal transduction. The ras pathway is also activated, which is an early step in the activation of the MAPKs that can activate a variety of transcription factors. Ras is a member of a family of guanine nucleotide-binding proteins (GDP/GTP) that are involved in diverse activation responses in different cell types. This pathway is an amplification process by which few upstream kinases lead to the activation of several downstream kinases. Ultimate activation of the terminal extracellular–regulated kinase (ERK 1/2) leads to the phosphorylation of the protein ELK, which stimulates the transcription of fos, a component of the activation protein 1 (AP-1) transcription factor (**Table 7.5**). Concomitantly, c-Jun N-terminal kinase (JNK) is activated,

which phosphorylates c-Jun, the second component of AP-1. The third member of the MAPK family, p38, is also activated. The activities of the MAPKs are terminated by specific protein tyrosine/threonine phosphatases that are regulated by the MAPKs themselves. Hence, the entire system is self-regulated by a negative feedback system.[6] From a clinical therapeutic standpoint, the anti-inflammatory properties of statins is postulated to be mediated, in part, by inhibition of GTPase isoprenylation and the secondary pathways they regulate in inducing immune cell activation.[94] A variety of clinical trials have been and are being conducted to determine the efficacy of statin therapy, or avoiding statin withdrawal, to mitigate inflammation, particularly in the context of cardiovascular disease.[95–99]

Activation of TCR also leads to the induction of phospholipase C (PLC), in particular PLCγ1 (**Fig. 7.6**). Phosphorylated PLCγ1 catalyzes the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PIP_2) into inositol 1,4,5-triphosphate (IP_3) and diacylglycerol (DAG), and activates enzymes that generate additional active transcription factors. IP_3 increases cytosolic calcium that leads to a large influx of both intracellular and extracellular calcium with subsequent activation of calcium- and calmodulin-dependent proteins. Calcineurin, a calcium/calmodulin-dependent phosphatase is integral to T-cell activation via modulation of the activation of the transcription factors NFATs and NFκB (**Table 7.5**).[4,19] These transcription factors are essential for the induction of cytokine transcription, in particular IL-2 production. However, in the absence of costimulation, activation of the CaMK II opposes the actions of calcineurin as described above and produces an anergic cell.[93] DAG activates protein kinase C, which activates additional transcription factors. Three transcription factors that are activated in T cells and appear critical for most T-cell responses are NFATs, AP-1, and NFκB (**Table 7.5**). Regulation of those kinases operant in T-cell signaling involves protein tyrosine phosphatases. Through dephosphorylation they modulate TCR signaling. Two phosphatases induced with TCR clustering are SHP-1 and SHP-2.

The role of PKC and calcium signaling in T-cell function is made evident by studies in which pharmacologic activation of PKC and/or elevation of intracellular calcium concentration stimulates T-cell cytokine secretion and proliferation.[6] Similarly, elevating mononuclear phagocyte cytosolic calcium

concentration augments a proinflammatory phenotype, characterized by elevated cytokine production with exposure to LPS. These biologic pathways are clinically relevant. Derangements in calcium homeostasis and hypocalcemia are nearly universal in patients suffering from a variety of critical illness: trauma, burns, septic shock. Translationally oriented studies underscore the prevalence of derangements in calcium homeostasis, and moreover, that pharmacologic calcium supplementation to treat hypocalcemia is associated with heightened inflammation and more severe organ dysfunction.[100]

Table 7.5 Transcription Factors

Transcription Factor	Stimuli	Effector Genes
AP-1	TNF, IL-1, UV light, H_2O_2, LPS, stress, ROS, hypoxia	TNF, IL-1, IL-2, IL-5, IFN-γ, ICAM-1, E-selectin, GM-CSF, MMPs, COX-2
NFκB	TNF-IL-1, UV light, H_2O_2, LPS, ROS	IL-1, IL-2, IL-6, IL-8, IL-12, TNF, E-selecting, VCAM-1, ICAM-1, MIP-1, MCP-1, RANTES, iNOS, eotaxin, PLA_2, G-CSF, GM-CSF, IFN-β
STAT	IFNs, CSFs, GFs, IL-1 to IL-15	FOS, E-selectin, Myc, ICAM-1, Fc γRI
NFAT	TCR, BCR, FcεR, FcγR, histamine and thrombin receptors	IL-2, IL-3, IL-4, IL-5, IL-8, IL-13, TNF, GM-CSF, IFN-γ, CD40L, FASL

AP, activator protein; CSF, colony-stimulating factor; COX, cyclooxygenase; GF, growth factor; ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; iNOS, inducible nitric oxide synthase; LPS, lipopolysaccharide; MMP, matrix metalloproteinase; MPO, myeloperoxidase; NF AT, nuclear factor of activated T cells; NFkB, nuclear factor kappa-B; PLA_2, phospholipase A_2; ROS, reactive oxygen species; STAT, signal transducer and activator or transcription; TNF, tumor necrosis factor; UV, ultraviolet; VCAM, vascular cell adhesion molecule.

Modified from Gallin JI, Snyderman R, eds. *Inflammation: Basic Principles and Clinical Correlates*. 3rd ed. Philadelphia, PA: Lippincott Williams & Wilkins; 1999.

A third mechanism of T-cell activation involves lipid antigens, such as cell wall protein from intracellular bacteria. These antigens bind CD1, an MHC-related cell surfacemolecule that presents these antigens to certain subtypes of T cells. A superantigen is an unprocessed bacterial or retroviral product that binds the MHC molecule and the TCR outside the usual antigen-

binding sites. This engagement leads to a polyclonal and nonspecific stimulation of a large proportion of the T-cell population. An overwhelming activation of all arms of the immune system ensues and underlies much of the pathophysiology of toxic shock syndrome (TSS). Intravenous gamma globulin (IVIG), by binding this antigen, is thought to be of therapeutic benefit.

Several important regulatory molecules in cell-mediated immunity are expressed on the cell surface of lymphocytes, including T-cell immunoglobulin- and mucin-domain containing molecule-3 (TIM-3), lymphocyte activation gene 3 protein (LAG3), and programmed death-1 (PD-1). These "checkpoint inhibitors" are responsible for maintaining immune balance through the inhibition of an aggressive immune response, though they have also been associated with immune, particularly lymphocyte, exhaustion. TIM-3 is a transmembrane protein expressed on $CD4^+$ and $CD8^+$ T cells and limits the duration and magnitude of T-cell responses. However, the upregulation of TIM-3 is associated with the proliferation, apoptosis, and functional failure of lymphocytes; it has been found in several malignancies and portends a poorer prognosis. LAG-3 is a member of the immunoglobulin superfamily, is expressed on activated $CD4^+$, $CD8^+$, and NK cells, and functions as a negative regulator of T-cell homeostasis. It has been shown to be expressed on tumor infiltrating lymphocytes (TILs) and correlates with functionally exhausted T cells and inferior cancer outcomes. PD-1 is a type 1 transmembrane receptor that belongs to the immunoglobulin superfamily. It was originally identified as a coinhibitory molecule on T cells; interactions with its ligands PD-L1 and PD-L2 activate downstream signals and suppress T-cell activation. It has also been identified on DCs, macrophages and some nonhematopoietic cells, such as the endothelium and astrocytes. PD-1 maintains tolerance and preventing autoimmunity, however, it is also associated with lymphocyte exhaustion and in the context of cancer biology, has been shown to correlate with worse tumor biology and clinical outcome. Importantly blocking these molecules, notably PD-1, has been shown to revert the functional impairment of exhausted T cells. This appreciation has led to an explosive development of a wide variety of small molecular inhibitors and monoclonal blocking antibodies that now support immunotherapies for the treatment of severe sepsis and several cancers: including renal cell carcinoma, head and neck squamous cell carcinoma, cervical, uterine and breast cancer; and a variety of lymphomas.[101]

Eosinophils

Eosinophils are marrow-derived granulocytes that share some properties of neutrophils, act in conjunction with basophils and mast cells as primary effectors in allergen inflammation and are involved in the eradication of helminthic infections (**Table 7.1**). Upon exiting the marrow, their intravascular half-life is but a few hours, whereafter they enter the mucosa of the lung, gastrointestinal, and genitourinary tracts.[43,102] IL-3, GM-CSF, and IL-5 promote eosinophil differentiation, the induction of effector functions, and survival, the last by inhibiting apoptosis.[102] Emigrating through inflamed endothelium they release inflammatory mediators and toxic agents from cytoplasmic granules. They generate superoxide anion and hydrogen peroxide, though less efficiently than neutrophils. They express IgE receptors and stimulate histamine release from basophils and mast cells through major basic protein (MBP). They can also regulate basophil and mast cell function by releasing enzymes that inactivate histamine and slow-reacting substance of anaphylaxis (SRS-a).

Recruitment and Activation

Eosinophils are recruited primarily to sites of parasitic infection and allergen challenge. Mast cells and macrophages responding to either secrete mediators (IL-5, PAF, LTB-4) that upregulate expression of endothelial adhesion molecules. Eosinophils themselves are more responsive to CC chemokines (MIP-1α, RANTES, and MCP-3) and the cytokines produced with T_H2 activation. Engagement of eosinophil β_1 integrin VLA_4 with VCAM-1 and fibronectin on the endothelium initiates the process of emigration. IL-4 can activate both the binding and the upregulation of endothelial cell VCAM-1. Diapedesis and tissue infiltration also involve members of the β_2-integrin family (Mac-1 and LFA) similar to that which mediates neutrophil recruitment.[43,103]

Eosinophils are activated by IL-3, GM-CSF, IL-5, PAF, CC chemokines, and C3a and C5a of complement. IL-5 is a potent activating agent and enhances the ability of eosinophils to release granule contents on FcR cross-linking. A positive feedback cycle ultimately is established, in which

recruited eosinophils produce cytokines and chemokines that recruit more eosinophils and other leukocytes.

Granules

Eosinophils possess a compartmentalized armamentarium of toxic substances that assist in the elimination of organisms, in particular helminths. Their specific granules contain GM-CSF and MBP, the latter of which is cytotoxic to parasites and normal cells. Further, it functions as a stimulus for histamine release from mast cells and basophils.[104] The granule matrix contains eosinophil peroxidase (EPO), eosinophil-derived neurotoxin, lysosomal enzymes, catalase, TNFα, TGFβ, and eosinophilic cationic proteins that stimulate formation of transmembrane pores to increase target cellular permeability.[105] EPO is released extracellularly on target cell surfaces where it generates hydrogen peroxide and hydrogen halides. Approximately 30% of oxygen consumed by stimulated eosinophils is utilized in the formation of halogenating species. Thiocyanate may be the major halide for the EPO–H_2O_2 system.[106] If ingested by a neighboring phagocyte, EPO can combine with H_2O_2 and halides to form hypohalous acids. EPO also stimulates neutrophil aggregation and adhesion to endothelial cells. Although they express Fc receptors for IgG, IgA, and IgE, they are relatively insensitive to activation by antigen-mediated cross-linking of these receptors. However, they can kill microorganisms by antibody-dependent cell-mediated cytotoxicity (ADCC).[6,43]

The primary targets of eosinophils are extracellular parasites. The size of these pathogens prohibits phagocytosis, and their integument is relatively resistant to the microbicidal products of neutrophils and macrophages; however, they can be killed by MBP, which is released after cross-linking of Fc-bound IgE coating the parasite. The T_H2 response to parasitic invasion produces IL-4, IL-5, and IL-13. IL-4 stimulates the production of specific IgE antibodies, which opsonize helminths. IL-5 activates eosinophils, which bind to the IgE-coated helminthes via Fc receptors. Activated eosinophils then release their granule contents and generate ROS and hypohalous acids. EPO also stimulates neutrophil aggregation and adhesion to endothelial cells. The sparse uncompartmental granules contain Charcot–Leyden crystals and have lysophospholipase activity. Finally, eosinophils produce and release lipid

mediators such as PAF, prostaglandins, and leukotrienes, which probably contribute to the process of allergic diseases.[6,107,108]

Basophils and Mast Cells

Basophils and mast cells are central to the development of allergic inflammation and produce cytokines, lipid mediators, vasoactive amines, and proteases that can also participate in nonallergic inflammatory responses (**Table 7.1**). Both cells share a common progenitor cell, which diverges early during differentiation. The primary growth factors for basophil development are IL-3 and GM-CSF, whereas stem cell factor is the primary stimulus for mast cell maturation.[109] Although basophils and mast cells are distinct cell types, they are often grouped together because of their similarity of their granule content, the stimuli inducing activation, and in their effector functions.[43]

Mature basophils constitute only 0.5% to 1% of the circulating leukocytes. Mast cells are primarily tissue-fixed residents of connective tissue. Engagement of IgE-bound antigen with the high-affinity IgE antibody receptor, FcεR, provides the primary stimulus for basophil and mast cell activation and degranulation. In addition, diverse agents such as contrast media, opiates, anaphylatoxins, chemokines, and neuropeptides may serve as activators. Basophils and mast cells elaborate both preformed, as well as, newly synthesized inflammatory mediators. The main basophil proteoglycan is chondroitin sulfate A, whereas mast cells contain heparin, chondroitin sulfate, and chondroitin sulfate E and also store neutral proteases.[110] The lipid mediators LTB_4, LTC_4, and PGD_2 are synthesized de novo in response to stimulation. The leukotrienes are powerful vasoconstrictors, bronchoconstrictors, and chemoattractants for neutrophils and eosinophils. PGD_2 inhibits platelet aggregation and is chemotactic for neutrophils. Both basophils and mast cells synthesize and secrete histamine. Histamine, or 2-(4-imidazolyl)-ethylamine, is formed by the carboxylation of histidine. It is stored in preformed granules at acid pH as a complex with proteins and proteoglycans. Mast cells carry greater quantities of histamine than do basophils. The classic vasoactive properties of arteriolar dilatation, increased vascular permeability, and bronchoconstriction are mediated by

the H_1 receptors. H_2 receptors are involved in modulation of the immune response and stimulating gastric output and mucus secretion. H_3 receptors participate in neuroconduction.[43,110,111]

Platelets

Though classically considered in the context of hemostasis, studies confirm that platelets are also integral to normal and pathologic inflammation and link the processes of hemostasis, inflammation, and tissue repair. They are activated in a variety of sterile inflammatory conditions, such as trauma,[112,113] idiopathic pulmonary fibrosis,[114] thromboembolic disease,[115] diabetes,[116] cardiovascular disease,[117] sickle cell disease,[118] and autoimmune disease[119] such as rheumatoid arthritis, and inflammatory bowel disease, a testimony to their role in inflammation.[120] They also have been shown to be critical regulators of early immune response in sepsis, with multiple effects on platelet function regulated by pathogens.[121–123] Upon activation, they release factors that enhance vascular permeability, chemokines, microbicidal proteins, and mitogens for endothelial cells, smooth muscle cells, and fibroblasts. They assist leukocytes in promoting the inflammatory reaction and killing microbes by providing an adhesive surface to facilitate emigration, by stimulating adhered leukocytes, and by further modulating chemokine synthesis (**Table 7.6**).[120,124]

Humans possess about 150 to 400 × 10^9 platelets per liter of blood.[120] Thrombopoiesis is regulated by thrombopoietin (TPO) as well as a variety of other mediators (IL-3, IL-4, IL-6, IL-7, and IL-11). In fact, human IL-11 is in clinical use to stimulate thrombopoiesis in patients undergoing chemotherapy.[125] After release from the marrow, platelets circulate with a half-life of approximately 12 days. Interferon α is inhibitory for megakaryocyte growth, and the elevated levels induced with some viral and inflammatory conditions may explain the relative thrombocytopenia observed in these conditions.[120,126] However, thrombocytopenia is exceptionally common in critical illness with complex and multifactorial etiologies.[127]

Table 7.6 Platelet-Derived Mediators
Chemoattractants C5a 12-HETE
PAF α-Granule proteins

Recruitment and Activation

Platelets are activated by and aggregate in response to thrombin or activated endothelium. Clot formation triggers the release of vasoactive agents (PGE_2, PGI_2, $PGF_{2\alpha}$, and PDGF) and inflammatory mediators. Serotonin, PGE_2, and PAF increase vascular permeability. The adhesion molecule PECAM-1 and the β_3 integrins mediate platelet plug formation, endothelial cell adhesion, and leukocyte emigration. The integrin IIb/IIIa and P-selectin facilitate platelet interactions with other inflammatory cells, with P-selectin serving as a critical ligand for leukocytes with recognition by PSGL-1. The α granules are rich in membrane-bound P-selectin; upon fusion with the cell surface membrane they enhance the cell surface density of this receptor. On stimulation, both receptors are expressed on the platelet surface in an activated state. IIb/IIIa binds various adhesive proteins containing the RGD sequence (i.e., fibrinogen), which serve as a mechanical link to other platelets, leukocytes, and the endothelium. Possibly the immobilization of activated P-selectin–expressing platelets on the vessel wall may biochemically and functionally promote the adhesion of neutrophils to endothelial cells.[120,126]

Platelets are a primary source of chemoattractants for neutrophils. Neutral proteinases released from stimulated platelets cleave complement factor C5, liberating the chemoattractant C5a. PDGF binds strongly to the extracellular matrix, providing a long-acting source of chemoattractant. Platelet factor 4 (PF4) is a cationic protein that penetrates the vascular wall and is a chemoattractant. Activated platelets also bind monocytes via P-selectin and PSGL-1 and induce the expression and secretion of monocyte chemotactic protein-1 (MCP-1) and IL-8. Thrombospondin released from activated platelets mediates monocyte binding to platelets. Together these substances promote leukocyte margination, activation, and recruitment to the sites of injury, and the chemoattractant effect of platelets for neutrophils has been linked to subsequent neutrophil activation and NET production.[43]

Granules

The vasoactive substances and inflammatory mediators of platelets are either stored in cytoplasmic granules or synthesized de novo. A platelet contains about 35 α *granules* and 5 *dense bodies*. The dense granules contain adenosine diphosphate (ADP), adenosine triphosphate (ATP), serotonin, and

calcium that are required during the earlier stages of inflammation. ADP is the principal platelet agonist during platelet aggregation and augments the oxidative burst of neutrophils. Serotonin increases vascular permeability and enhances the superoxide production by macrophages.[120]

The more abundant α granules contain fibrinogen, RANTES, MIP-1α, thrombospondin, P-selectin, PF4, PDGF, TGFβ, β-thromboglobulin, high–molecular-weight kininogen (HMWK), high mobility group box 1 (HMGB1), and many other biologically active proteins. PF4 and β-thromboglobulin initiate leukocyte recruitment and activation. PF4 induces neutrophil adherence to unstimulated endothelium and the release of secondary granules. It inhibits monocyte apoptosis and promotes macrophage differentiation. PF4 can also stimulate histamine release from basophils. RANTES is deposited on the endothelium and recruits monocytes from the circulation. PAF induces platelet aggregation, increases vascular permeability, enhances phagocyte-free radical formation, and the adhesion of platelets to neutrophils. HMGB1 is a critical regulator of platelet activation and aggregation, and direct release of HMGB1 by platelets has been shown to regulate neutrophil function and NET production in trauma, autoimmune disorders, and sepsis. Platelet activation appears to occur in allergic asthma and may precede the delayed accumulation of eosinophils in the lung after allergen exposure. The α granules also carry several important growth factors, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and TGFβ. VEGF promotes extravasation and aids recruitment of leukocytes. PDGF is chemotactic for neutrophils and monocytes. TGFβ is chemotactic for and activates neutrophils and monocytes early during inflammation, but displays immunosuppressive effects during later stages of inflammation.[120]

Platelets are an important source of eicosanoids, including thromboxane, prostaglandins $F_{2\alpha}$ and E_2. $PGF_{2\alpha}$ causes vasoconstriction, whereas PGE_2 vasodilates and modulates pain.[128,129] Thromboxane synthetase in platelets is responsible for the production of TXA_2, a potent vasoconstrictor that also increases vascular permeability and stimulates platelet aggregation. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit platelet function by inhibiting TXA_2 production. As this effect is irreversible, new platelets must be produced (7 to 10 days) to restore normal clot formation. In emergent circumstances (management of intracranial hemorrhage) platelet

administration is requiredoften utilized, however, the ability of transfused platelets to “reverse” the effects of antiplatelet agents is controversial, with a recent meta-analysis demonstrating no improvement in mortality in patients who received platelet transfusion in the setting of traumatic brain injuries with a history of prehospital antiplatelet agent use. As most means of platelet function testing (aggregation, adhesion, activation) required laborious or sophisticated testing means, there is a substantial limitation inherent in the lack of rapid platelet functional assays. Light transmission aggregometry-based testing has been developed to detect aspirin and P2Y12 inhibition in a point-of-care fashion, which has been validated in cardiovascular disease, particularly for the monitoring of aspirin resistance. These point-of-care devices are used in other acute care settings, although often without validation, to monitor platelet function and response to transfusion. Recently, an aspirin response test has been developed that assists in guiding therapy and targeting transfusion to those with functional evidence of platelet inhibition. It has also assisted in monitoring the response to transfusion.

Platelets participate in transcellular lipoxygenase metabolism (LO), which refers to the production of eicosanoids through interactions with neighboring inflammatory cells. Endothelial cells utilize platelet-derived endoperoxides to synthesize PGI_2. Platelets interact with neutrophils in several pathways, providing a direct link between thrombosis and inflammation, including the direct stimulation of NET production referenced above. 12-HETE released from activated platelets can be used by unstimulated neutrophils to produce the chemoattractant 12,20-HETE. 12-HETE and 5-HETE from activated platelets and neutrophils, respectively, can combine in either cell type to form 5,12 diHETE, an anti-inflammatory compound, which diverts production away from the proinflammatory leukotrienes. 12-LO from platelets and LTA_4 formed by neutrophils can produce the intermediate 5(6)-epoxytetraene. This intermediate produces lipoxins A_4 and B_4 that have primarily counterinflammatory functions.[43,124,128,130]

In addition to modulating inflammation platelets possess some direct microbicidal activity. Platelets are activated and degranulate when exposed to certain bacteria. Electron microscopic studies have shown that activated platelets internalize bacteria and viruses. The α granules contain antibacterial proteins called thrombocidins (TC) in humans that support the

killing of adherent bacteria. The two antibacterial proteins isolated from human platelets (TC-1, TC-2) are bactericidal for *Escherichia coli* and *S. aureus*.[120] Additionally, platelets are able to engulf bacteria independently, including *S. aureus*, demonstrating a direct role in microbial interaction and clearance.[131]

Myeloid-Derived Suppressor Cells

Myeloid-derived suppressor cells first came to attention a decade ago as a heterogeneous population of myeloid cells with potent immune-regulatory activity generated in the context of a variety of disease states. They are now appreciated as universal regulators of immune function in many pathologic conditions. They represent a pathologic state of activation of monocytes and relatively immature neutrophils, possessing a distinct set of genomic and biochemical features, the most salient of which is their ability to inhibit T-cell function and thereby contribute to the pathogenesis of various diseases from cancer to obesity.[132]

Under physiologic conditions in response to infection or injury, GM-CSF drives myelopoiesis, and G-CSF and M-CSF induce the differentiation of granulocytes and macrophages. However, in pathologic statues characterized by unresolved inflammation (e.g., cancer), low level production of these factors persists and favors the development of MDSCs. The first group of signals is driven by factors produced by tumors or tissue stroma in response to chronic infection and inflammation: GM-CSF, G-CSF, M-CSF, S-SCF, and VEGF. The transcriptional factors/regulators STAT3, STAT5, IRF8, C/EBP-β and NOTCH are active during this stage. The second group of signals includes inflammatory cytokines and DAMPs: IFNγ, IL-1β, IL-4, IL-6, IL-13, TNF, and HMGB1, which signal via NF-κB, STAT1, and STAT6.

The distinguishing feature of MDSCs is immune suppression. M-MDSCs are more suppressive than granulocyte MDSCs. MDSCs have an immature phenotype and morphology; relatively weak phagocytic activity; increased background levels of ROS and NO, and high expression of arginase, PGE_2 and a number of anti-inflammatory cytokines. This persistent and aberrant state of activation fails to eliminate the threat, but rather, inhibits adaptive

immunity. In the context of cancer, this supports tumor progression and metastasis.

Early oncology studies reported a positive correlation of MDSC numbers in the peripheral blood with cancer stage and tumor burden. In a meta-analysis, elevated numbers of MDSCs in the circulation proved to be an independent indicator of poor outcomes in subjects with solid tumors and shorter progression-free interval and/or overall survival in subjects. More recent studies suggest a value in prognosticating response to chemotherapy; the frequency of M-MDSCs is negatively correlated with response.

A similar pathologic role for MDSCs has been characterized in several types of infection. Studies have shown that bacteria can induce or modulate MDSCs. During *S. aureus* infection, M-MDSC and PMN-MDSCs suppress T-cell function, thereby exacerbating the infection. An expansion of PMN-MDSCs and M-MDSC has been reported to occur in tuberculosis, fungi, gram-positive or gram-negative pathogens, and chronic HCV infection. These can be but are not always associated with disease persistence and adverse outcome.

MDSC populations have also been characterized in autoimmune diseases, including SLE and rheumatoid arthritis, obesity, wherein it may contribute to the increased risk of infectious disease, and pregnancy, a state characterized by maternal–fetal tolerance.

NONCELLULAR COMPONENTS

Cytokines

Cytokines are soluble protein mediators secreted by the cells of the innate and adaptive immunity in response to microbes and other antigens, including intra- and extracellular proteins, and mediate many of the functions of these cells (**Table 7.7**). They mediate and modulate the host response to both pathogen-associated molecular patterns (PAMPs) on bacteria, viruses, fungi, and parasites and damage-associated molecular patterns (DAMPs) released during trauma, burns, allograft rejection, ischemia/reperfusion injury, and autoimmune disease. They govern lymphocyte differentiation during adaptive immunity and activate effector cells of both arms of inflammation to

eliminate microbes. Cytokines play important roles in tumor biology and angiogenesis. Though essential for a normal immune response, excessive cytokine release underlies a variety of pathophysiologic inflammatory states such as acute respiratory distress syndrome (ARDS) and multiple organ dysfunction syndrome (MODS).[133–136] So essential is their function to health and disease that modulating cytokine biology nearly comprises an entire domain of drug development, and they been targeted in several preclinical and clinical trials.

Cytokine secretion is brief, and as they typically are not stored preformed, necessitates transcription and de novo synthesis, which is also transient as the messenger RNA is unstable. Their functions are pleiotropic and redundant, which has been interpreted to represent a teleologic safety mechanism. However, such protective characteristics greatly limit the therapeutic utility of either cytokine administration or blockade. In fact, 6 over 60 randomized-controlled clinical trials have been conducted to assess the efficacy of modulating inflammation, on reducing mortality in a variety of contexts: trauma, sepsis. The majority have involved manipulating systemic cytokine concentrations. Only one valid biologic, activated protein C, was briefly FDA approved for use; it was subsequently removed from the market due to a lack of benefit.[137] Corticosteroids have regained favor by the medical community for the treatment of severe sepsis and septic shock. The recent APROCCHSS (Activated Protein C and Corticosteroids for Human Septic Shock) trial confirmed earlier studies demonstrating that a 7-day course of the corticosteroid hydrocortisone in combination with the mineralocorticoid fludrocortisone reduced 28-day mortality: relative risk 0.88 (95% confidence interval, 0.78 to 0.99).[138] A updated meta-analysis similarly concluded that in critically ill patients with sepsis, corticosteroids probably result in a small reduction in mortality.[139] However, the exact mechanism conferring such benefit remains to be identified and may not be immunomodulatory in nature.

Cytokines often influence the synthesis and actions of other cytokines, such as IL-1–induced T-cell IL-2 production; this interaction may be synergistic (additive or multiplicative) or antagonistic. They may function in an autocrine, paracrine, or even endocrine function, although the inability to correlate plasma cytokine concentrations with the extent of tissue damage

suggests that they are designed for local rather than systemic inflammation.[6,43,133]

Cytokine actions are mediated by specific membrane receptors on target cells to which they bind with high affinity (Kd α 10^{-10} to 10^{-12}). Hence, only minute quantities are necessary to elicit a response. Such efficiency is accompanied by a narrow therapeutic index and potential for unwanted global effects (i.e., MODS) with even small systemic concentrations. The receptors and the cells expressing them are regulated by external stimuli, which provide some degree of specificity to the response, even though the cytokines themselves are not antigen specific. Receptor binding alters cellular gene transcription (induction or suppression) that may result in proliferation, differentiation, and the acquisition of new or suppression/enhancement of pre-existing functions.[6]

All cytokine receptors consist of at least one transmembrane protein with an extracellular portion for ligand binding and an intracellular domain mediating signal transduction. Current receptor classification is based on structural homologies among the extracellular cytokine binding domains. Type I cytokine receptors contain a domain with two conserved pairs of cysteine residues and a membrane proximal sequence of tryptophan-serine-X-tryptophan-serine, where X is any amino acid (WSXWS). Type II resemble type I receptors, however the WSXWS motif is absent. The Ig superfamily consists of receptors with extracellular Ig domains. TNF receptors belong to a family of receptors with conserved cysteine-rich extracellular domains. Finally seven-transmembrane α-helical receptors mediate the functions of cytokines called chemokines through GTP-binding (G) proteins.[6]

Translating ligand engagement to the signaling events that alter cellular phenotype involves a variety of signaling cascades dependent upon the structure of the cytoplasmic tail of the particular receptor (**Table 7.7**). This is another method by which to classify cytokine receptors. These individual signaling cascades will be discussed in the context of the various cytokines and respective receptors employing them.

Table 7.7 Cytokines

Cytokine	Receptor	Signal Transduction	Cellular Source	Targets	Effects	
TNFα	TNF R	TRAFS Death domains	Mo/Mϕ, MC, Ba, Eo, NK, B, T, fibroblast, Epithelia	Endothelium PMN Many cells	↑ inflammation, coagulation, adhesion molecules ↑activation ↑ apoptosis ↑ fever, APP, catabolism	INNATE/EARLY CYTOKINES

Early Cytokines/Innate Immunity

TNFα

TNFα is the principal initiating mediator of the inflammatory response to gram-negative bacteria and other infectious pathogens. It is an important early mediator of inflammation and is essential for the normal initiation, maintenance, and repair of tissue injury. However, aberrant production may

underlie the pathologic sequelae of many inflammatory and infectious states (i.e., MODS, rheumatoid arthritis, Crohn disease). Mononuclear phagocytes are the principal source of TNFα, usually in response to the potent prototypical stimulus lipopolysaccharide of gram-negative organisms.[140,141] TNFα production may be augmented by concomitant stimulation with IFNγ, IL-4, and IL-10, whereas, corticosteroids are suppressive.[142] Secondary sources include mast cells, NK cells, and T and B lymphocytes. Other stimuli inducing production and release include complement C5a, GM-CSF, hypoxia, IL-1, NO, ROS, and TNFα itself.[43]

TNFα is expressed on the cell membrane as a bioactive protein and is cleaved into its soluble form by a specific TNFα-converting enzyme. There are two distinct TNF receptors present on virtually all cell types (**Fig. 7.7**).[143] Ligand binding to TNF-RII leads to recruitment of TNF receptor-associated factors (TRAFs) that ultimately activate the transcription factors NFκB and AP-1, and thereby influence gene expression and cellular phenotype.[6] Alternatively, binding to TNF-RI activates caspases and triggers apoptosis, in addition to signaling transcription factors. The manner by which either a proinflammatory or apoptotic path is chosen is unknown, although the net effect of TNFα binding is probably the culmination of differential adaptor protein expression and downstream signal transduction cascades. TNF-RI appears to be more important in host defense as knockout TNF-RI mice show a greater degree of impairment in host defense than mice lacking TNF-RII.[6]

Shedding of extracellular domains of the two TNFα receptors by metalloproteinases, can further alter the biologic activity of TNFα by decreasing the number of cell-signaling sites on target tissues and increasing the amount of circulating inhibitors. Unlike other members of the TNF family that are primarily involved in regulation of cell proliferation, TNFα has both proinflammatory and apoptosis-inducing properties.[133,144]

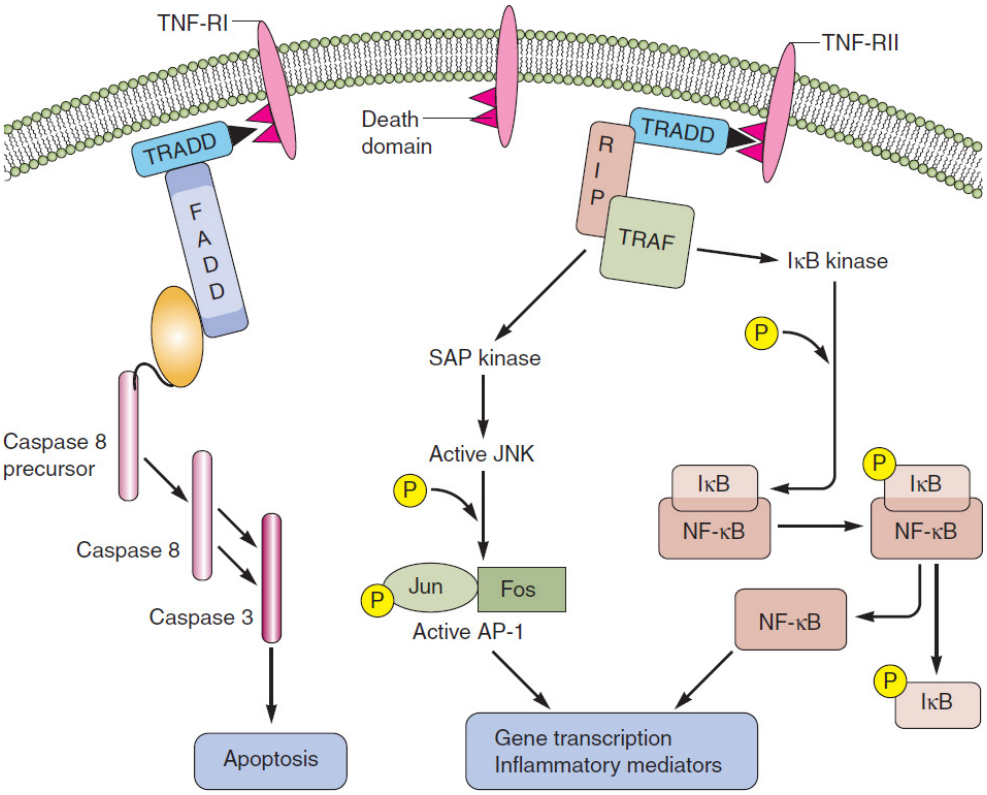

Figure 7.7 TNF receptor–signaling pathway. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia, PA: Saunders, 2003.)

The principal function of TNFα is to recruit neutrophils and monocytes to foci of infections and to activate these cells to eradicate microbes. TNFα activates the endothelium to upregulate the expression of the adhesion molecules E- and P-selectin, ICAM-1, PECAM-1, and VCAM-1. It potently stimulates these cells and macrophages to secret chemokines (IL-8, MIP-1α, and Gro-α) that enhance the affinity of leukocyte integrins for their ligands and induce leukocyte chemotaxis and recruitment.[145] TNFα also can induce HMGB1 release by activated macrophages, which generates a forward feedback mechanism, as HMGB1, by signaling through RAGE (*vida infra*), also induces TNFα release.[146,147] TNFα by stimulating the release of tissue factor, PAF, von Willebrand factor, and thromboplastin generates a state of hypercoagulability. By inhibiting tissue-type plasminogen activator and thrombomodulin, it suppresses fibrinolysis, decreases protein C and S activation, and increases thrombin formation. However, TNFα also induces the release of a variety of anticoagulants (prostacyclin), fibrinolytics

(urokinase-type plaminogen activator), and vasodilators (NO, PGE_2), which may offset or balance the tendency toward procoagulation. Most likely, the ultimate effect of TNFα depends on the location and quantity in which it is produced and the vascular bed with which it interacts.[6,133]

Though clearly vital for host defense and microbial elimination, in severe infections, exuberant production and aberrant release of TNFα, wherein it possess endocrine function, can cause a plethora of pathologic sequelae. These systemic effects include fever by stimulating the production of PGE_2 by the hypothalamus (hence the name endogenous pyrogen), acute-phase protein production by the liver, cachexia, inhibition of myocardial contractility and vascular tonus, and intravascular thrombosis due to loss of normal anticoagulant properties of the endothelium and the production of tissue factor. TNFα is central to the pathogenesis of severe sepsis and septic shock, and either state can be reproduced by the exogenous administration of TNFα.[148,149] The organ dysfunction characteristic of these states may result from the hypercoagulability and subsequent tissue ischemia induced by this cytokine. Antagonists of TNFα can prevent mortality in experimental models, however several clinical trials with anti-TNFα antibodies or with soluble TNFα receptors in sepsis have been to no avail.[6,148] Greater clinical efficacy with anti-TNFα therapy has been achieved in treating the more chronic inflammatory diseases of rheumatoid arthritis, psoriasis, and Crohn disease.[150,151]

Soluble TNF receptors formed by proteolytic processing of both types of receptors bind and neutralize TNFα and serve as an endogenous regulator of cytokine activity.[43] TNFα also directly induces the expression and release of TNFα inhibitors, including IL-10, corticosteroids, and prostanoids, which in a negative feedback loop suppresses TNFα production and processing.[133] Hence, TNFα serves as its own regulator.

Interleukin 1

Interleukin 1 possesses similar functions to TNFα in mediating a proinflammatory host response to insult; it is frequently released concomitantly with TNFα (**Table 7.7**).[152] The major source of IL-1 is the mononuclear phagocyte. Synthesis and release are induced by LPS, cytokines such (TNFα, IL-2, TGF-β, all the interferons), antigen–antibody complexes,

C5, and hypoxia.[133] IL-1 is also produced by neutrophils, B cells, helper T cells, epithelial cells, fibroblast, renal mesangial cells, and endothelial cells. There are two forms of IL-1: IL-1α and IL-1β. Both forms are active, bind to the same receptors and mediate the same effects. Most IL-1 found in circulation is IL-1β.[6]

The two IL-1 receptors (IL-1R) are members of the Ig superfamily. IL-1RI is universally expressed and transduces the majority of IL-1 responses.[153,154] IL-1RII expression is restricted to B cells, but may be induced on other cells. There is little evidence that this latter receptor serves any function, and in fact, may serve as a decoy.[155] The cytoplasmic portion of IL-1RI is homologous to a domain of toll-like receptors (TLRs), which mediate the cellular responses to endotoxin (**Fig. 7.8**). Engagement of IL-1 with IL-1RI induces the activation of the IL-1 receptor-associated kinase (IRAK) and the subsequent induction of the transcription factors NFκB and AP-1.[6,154]

The functions of IL-1 mirror those of TNFα, and synergy between the two cytokines is evident.[152] IL-1 activates endothelial cells to increase cell surface expression of adhesion molecules and the production of prostaglandins, PAF, and a variety of colony-stimulating factors (CSFs). In doing so, it facilitates the recruitment and activation of appropriate leukocyte populations for specific localized immune responses. IL-1 also induces a procoagulant state by suppressing fibrinolysis through enhanced plasminogen activator inhibitor-1 and decreased tissue-type plasminogen activator activity. It increases thrombosis by stimulating tissue factor-like procoagulant and thromboplastin production and suppressing thrombomodulin release. It induces the synthesis of PAF, a potent vasoconstrictor and stimulus for platelet and leukocyte activation. However, similar to TNFα, it also stimulates the production of prostacyclin and urokinase-type plasminogen activator, which promotes an antithrombotic state.[156] At larger concentrations, its effects become systemic causing fever, the synthesis of acute-phase proteins, cachexia, myalgia, somnolence, and hypotension. It stimulates arachidonic acid and prostaglandin metabolism, and the release of pituitary stress hormones. It stimulates collagenase release and is a potent mitogen for neutrophils. Though similar in effect to TNFα, probably by activating similar signaling cascades and transcription factors, IL-1 does not induce apoptosis. Even at high concentrations IL-1 does not cause the physiologic derangements of septic shock.[43,152]

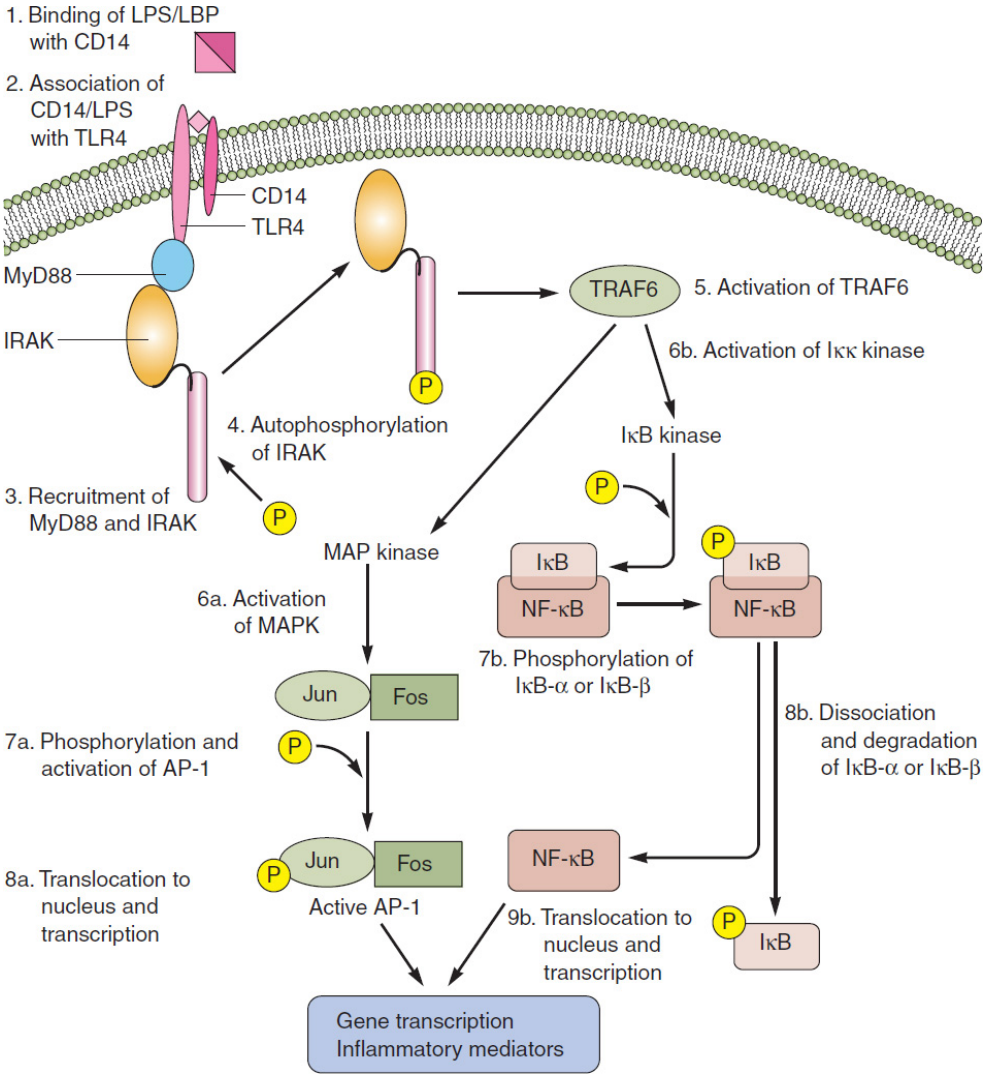

Figure 7.8 Toll-like receptor (TLR)-signaling pathway. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia, PA: Saunders, 2003.)

Mononuclear cells produce the natural inhibitor of IL-1, IL-1Ra. This IL-1 structural homologue is an inactive competitive inhibitor and may function as an endogenous regulator of IL-1. As occurred with immunomodulatory agents of TNFα, early attempts to inhibit IL-1 were shown not been of clinical benefit in human trials of sepsis.[43] However, greater awareness of the heterogeneity of sepsis as a disease, supported posthoc analyses and additional clinical trials that have yielded more encouraging results. A reanalysis of a phase III trial of a human IL-1 receptor antagonist (i.e., anakinra) for severe sepsis focused on a subgroup of patients experiencing what is termed macrophage activation syndrome, a fulminant cytokine storm

characterized by fever, disseminated intravascular coagulation, hepatobiliary dysfunction, cytopenias, and hyperferritenemia. In this subgroup, anakinra was associated with improved 28-day survival.[157] Similar "positive" results were obtained in a separate study of IL-1Ra stratified by plasma IL-1 concentration; benefit was observed with IL-1Ra in the cohort with elevated plasma IL-1 concentrations.[158]

Chemokines

This large family of cytokines primarily orchestrates leukocyte chemotaxis, hence the name (**Table 7.7**).[159–164] Those bound on the endothelial surface induce leukocyte integrins to express a high-affinity state for their ligands, which is critical for tight leukocyte adherence and subsequent migration into the extravascular space. However, they also assist in orchestrating the migration of immune cells into lymphoid organs. Unlike other chemoattractants, members of this family possess a degree of cellular specificity, influencing the recruitment of discrete subsets of leukocytes. They mediate their effects both directly, as well as indirectly through the induction of other mediators such as histamine and ROS. Though some chemokines, in particular those regulating cell traffic through tissues, are constitutively produced (MIP-3β and RANTES), most necessitate cellular stimulation for synthesis and release, in particular, those involved in inflammatory reactions. They are typically produced by macrophages, leukocytes, endothelial cells, fibroblasts, and many other cell types stimulated by LPS, phagocytosis, and inflammatory cytokines such as IL-1, TNFα, IL-6, and IFNγ.[43]

Chemokines can be classified into four families based on the number and location of N-terminal cysteine residues.[164] The two major families are the CC chemokines, in which the cysteine residues are adjacent, and the CXC chemokines, in which one amino acid is interposed between these cysteine residues. This amino acid sequence appears to account for the disparate influence, either promotion or inhibition, on neutrophil chemotaxis. The three amino acids that immediately precede the first cysteine are critical in defining receptor binding and neutrophil activation.[165,166] This area has been designated the ELR motif. The other two chemokine families are represented by lymphotactin (C chemokine) and fractalkine (CX3C chemokine).[43]

Chemokine receptors are seven transmembrane receptors that signal by G proteins and the formation of the second messengers, IP_3 and DAG (**Fig. 7.6**). Currently 7 CXC chemokine receptors, 10 CC, and 1 receptor each for the last 2 subfamilies have been identified and defined. The pattern of cellular expression of the receptors determines the specificity of the cellular response to binding.[6,164,166]

CXC chemokines primarily govern the chemoattraction and activation of neutrophils, and to a lesser degree, lymphocytes, in particular T cells. At least 17 different chemokines have been identified. They are clustered on chromosome 4 and demonstrate 20 to 50% homology at the amino acid level. IL-8 is the prototypical CXC chemokine.[136] It is produced by an array of immune and nonimmune cells including monocytes, alveolar macrophages, neutrophils, keratinocytes, mesangial cells, epithelial cells, fibroblasts, and endothelial cells. TNFα and IL-1 are key molecules for inducing IL-8. It is chemotactic for all granulocytes and influences nearly every aspect of neutrophil function. IL-8 stimulates neutrophil degranulation, phagocytosis, transendothelial migration and shedding of L-selectin, upregulation of β_2 integrins, and augments superoxide production. It is also a potent angiogenic factor and binds to both the CXCR1 and CXCR2, receptors that also engage the chemokines GCP-2, GRO-α, and ENA-78. ENA-78 is a potent neutrophil chemotaxin produced by the endothelium in response to TNFα or IL-1, neutrophils, or monocytes. Studies have demonstrated that ELR-containing CXC chemokines are angiogenic, whereas those lacking this motif are angiostatic.[43,133,165–167]

The interferon-influenced chemokines, IP-10 (CXCL10) and Mig (CXCL9) do not target neutrophils, and the ELR motif is absent. They induce IFNγ production and may play a more prominent role in mediating the inflammatory response to viral infections and autoimmune disorders. Mig is chemotactic for TILs, activated T cells, and monocytes and promotes CTL activity. IP-10 is chemotactic for monocytes, T cells, and NK cells and augments T-cell adhesion. Both chemokines bind the CXCR3 receptor found on IL-2–activated T cells. IFNγ attenuates the expression of both IL-8 and ENA-78, and hence may serve as an important mechanism to the control and regulate inflammation.[43,133] Stromal cell–derived factor-1 (SDF-1/CXCL12) is the only known ligand for the CXCR4 receptor and in the presence of IL-7

stimulates proliferation of pre–B-cell clones and growth of bone marrow B progenitor cells. The receptor has gained much interest since it was identified as a coreceptor for HIV-1. Platelet factor 4 and neutrophil-activating protein-2 are CXC chemokines of platelet origin. PL-4 has angiostatic properties and inhibits the growth of various cancer cell lines in a manner that appears to be related to its angiostatic properties. It binds heparin with high affinity to stimulate coagulation.[43]

There are at least 27 distinct members of *CC* chemokines, whose function is to recruit monocytes, granulocytes, T cells, NK cells, and DCs. Regulated on Activation, Normal T-cell Expressed and Secreted (RANTES) is produced by stimulated T cells, platelets, and endothelial cells and is constitutively produced in resting T cells, which implies a homeostatic function. MIP-1α and β are produced by activated T cells and are chemotactic for neutrophils, monocytes, eosinophils, basophils, and T lymphocytes. They are also mitogenic for hematopoietic progenitor cells and upregulate TNFα, IL-1, and IL-6. The membrane cofactor protein (MCP) family of chemokines influences the recruitment of monocytes and T cells. Their influence upon the function of these target cells is dictated by the cell's specific profile of receptor expression. MCP-1 (also known as CCL2) is produced by nonlymphocytic cells (endothelial cells, epithelial cells, fibroblasts, smooth muscle cells, macrophages, and mast cells). CCL2 is critical for the mobilization of inflammatory ($LY6C^{hi}$) monocytes from the bone marrow and their recruitment to peripheral tissues and sites of inflammation.[168,169] Binding to CCR1 enhances chemotaxis, whereas activation of CCR2 increases the release of intracellular substances such as histamine and leukotrienes from basophils.[43]

Lymphotactin is the only member of the *C* chemokine family and is produced by $CD8^+$ lymphocytes, thymocytes, and NK cells, and, to a lesser degree, by DCs and activated mast cells. It selectively recruits lymphoid cells.[43]

Fractalkine is the sole *CX3C* chemokine and is produced by the endothelium. In its membrane-bound form it may act as a solid-phase adhesion molecule, but upon cleavage serves as a soluble chemoattractant for lymphoid cells and monocytes.[43]

Interleukin 12 (NK Cell Stimulatory Factor, Cytotoxic Lymphocyte Maturation Factor)

IL-12 is integral in the innate immune response (**Table 7.7**). It is produced early during innate immune reactions and is critical for initiating a sequence of responses involving macrophages, NK cells, and T lymphocytes that results in the eradication of intracellular microbes. It stimulates subsequent adaptive responses that confer further host protection against these pathogens. Hence, it is an important link between innate and adaptive immune responses. IL-12 is primarily derived from activated mononuclear phagocytes and DCs, and most importantly stimulates IFNγ from T cells and NK cells. There are two pathways leading to IL-12 production: (1) T-cell dependent and (2) T-cell independent pathway. During innate immunity, LPS, infection by intracellular bacteria, and viral infections may induce IL-12 production. In addition interactions between CD40 ligand and CD40 on activated lymphocytes and APC, respectively, induce the release of APC IL-12.[170,171] Thus, IL-12 is produced during the induction of and the effector phases of cell-mediated immune response when APCs present antigens to T cells.[6,43]

The IL-12 receptor is a heterodimer composed of β_1 and β_2 subunits, the latter of which is involved in signaling, although both are required for engaging ligand. The receptor signals through the JAK/STAT pathway (**Fig. 7.9**).[6] This signal transduction pathway is employed by numerous cytokines including interferons, IL-6, IL-12, IL-2, IL-7, IL-9, IL-4, and IL-10. A characteristic of this cytokine is the generation of a positive amplification loop, which heightens the inflammatory response. Expression of the IL-12 receptor is induced by IFNγ. Activated NK cells and T_H1 cells produce IFNγ that potentiates macrophage IL-12 production. IL-12 stimulates further production of IFNγ by NK cells and T lymphocytes, which continues to fuel the reaction in a positive feedback mechanism. Ultimately, IFNγ activates macrophages to kill and degrade phagocytosed microbes. IL-12 potentiates bacterial LPS-induced macrophage TNFα production. IL-12 antagonists reduce mortality in experimental models of LPS-induced septic shock; however, there is no evidence of their efficacy in human clinical trials.[6]

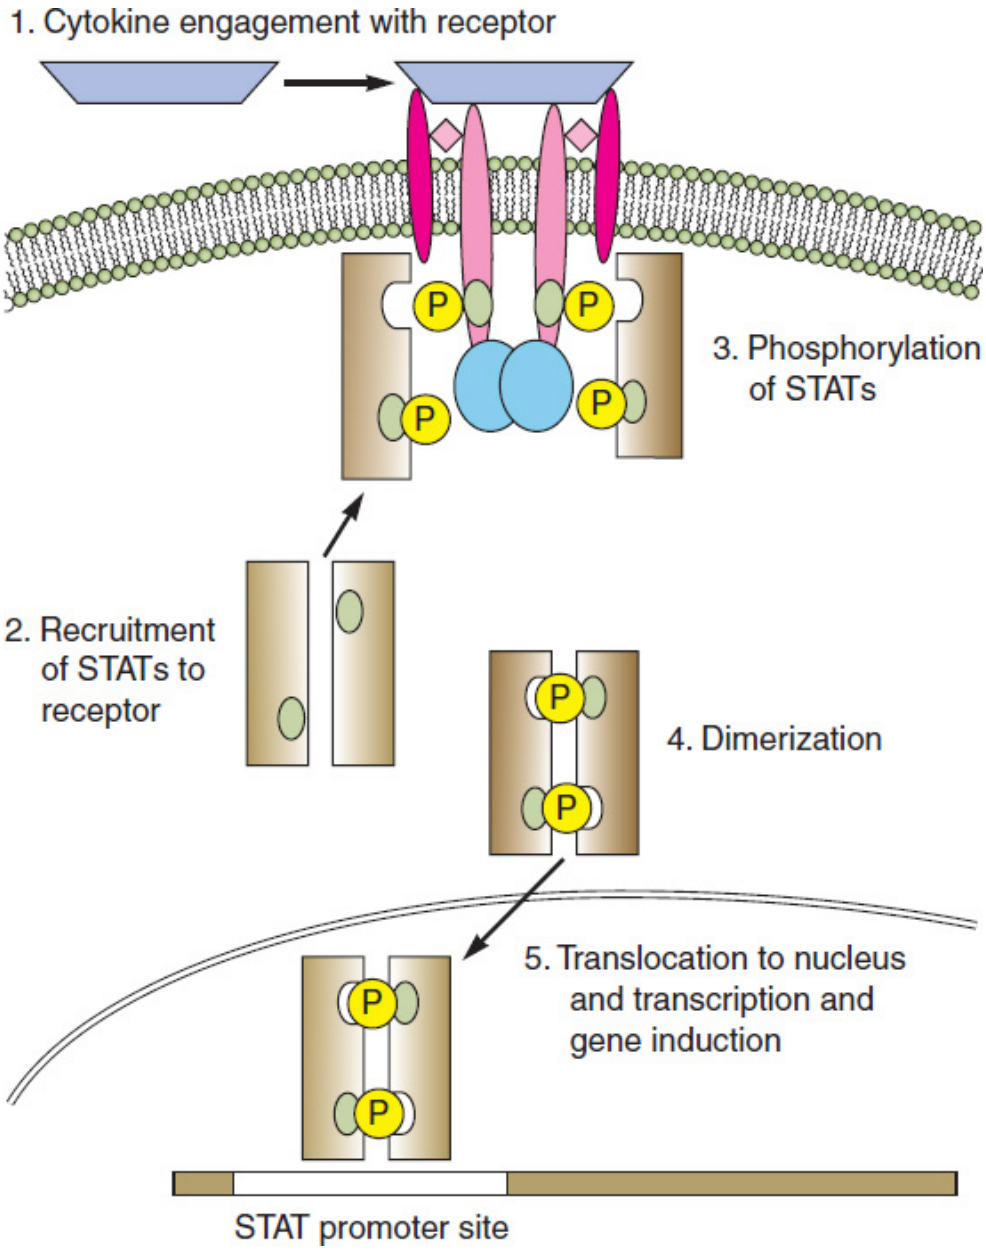

Figure 7.9 JAK/STAT-signaling pathway. JAK (Janus Kinase) components are associated in an inactive form with the cytopasmic portion of cytokine receptors. Cytokine binding leads to receptor aggregation. Adjacent JAK proteins become activated and phosphorylate each other and tyrosine residues. Through the Src homology domain, STAT proteins bind phosphotyrosine residues on the cytoplasmic portion of cytokine receptors. Bound STAT proteins are phosphorylated by bound JAK proteins and subsequently dissociate. Phosphorylated STAT proteins dimerize and then move to the nucleus where they induce transcription by binding to STAT-binding regions within the promoter. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia, PA: Saunders, 2003.)

$CD4^+$ helper T lymphocytes, under the influence of IL-12, differentiate into T_H1 cells, which subsequently activate phagocytes in cell-mediated immunity. IL-12 enhances the cytolytic functions of activated NK cells and $CD8^+$ CTLs, and suppresses T_H2 cell differentiation and effector activity. The inhibition of T_H2 and IL-4 activity confers antiallergic properties to IL-12. IL-12 knockout mice demonstrate diminished IFNγ production and defective T_H1 cell development and cell-mediated immunity against intracellular organisms.[6,43]

Recent data support the potential for anti–IL-12 therapy in the long-term management of rheumatoid arthritis and Crohn's disease. The CERTIFI trial evaluated ustekinumab, a monoclonal antibody to the p40 subunit of IL-12 and IL-23, in adults with moderate-to-severe Crohn disease that were resistant to anti-TNF treatment. They observed that the cohort allocated to ustekinumab had an increased rate of response to induction; for those who responded, maintenance therapy with ustekinumab resulted in significantly increased rates of clinical remission. Similarly, the more recent UNITI-IM-UNITY Study Group showed that among patients with moderately to severely active Crohn's disease, a significantly higher response was observed in those receiving ustekinumab, and subcutaneous administration maintained remission in patient who had a clinical response to induction therapy.[172]

Interleukin 6

IL-6 regulates the acute-phase response to inflammation, characterized by altered thermoregulation (i.e., fever), perturbation in nitrogen balance (i.e., cachexia and catabolism), and the generation of the acute-phase reactants of innate immunity by the liver (**Tables 7.7** and **7.8**).[133,173] It functions in both innate and adaptive immunity to enable the host to recover. Despite in vitro data demonstrating that a variety of cells can produce IL-6, the most prominent in vivo sources of IL-6 are monocytes and macrophages stimulated with LPS or IL-1 or fibroblasts and endothelial cells stimulated with TNFα.[174] Steroids inhibit the induction of IL-6. The receptor for IL-6 consists of cytokine-binding protein and a signal-transducing subunit, which belong to the type I cytokine receptor family. It signals through the JAK-STAT pathway (**Fig. 7.9**).[6]

In conjunction with IL-1 and TNFα, IL-6 regulates the systemic manifestations of the acute-phase response.[173] It potentiates the immune response by inducing B-cell differentiation and activating T cells. It interacts with TNFα to enhance T-cell proliferation and promotes neutrophil activation and accumulation. In adaptive immunity, IL-6 stimulates the growth of B lymphocytes that have differentiated into antibody-producing plasma cells. IL-6 antagonizes LPS-induced TNFα production and TNFα-induced IL-1 production.[175,176]

The SIRROUND-T was a multinational, randomized, double-blind, placebo-controlled, parallel-group phase 3 study that tested the efficacy and safety of sirukumab, a human monoclonal antibody that selectively binds to IL-6 with high affinity, in patients with active rheumatoid arthritis refractory to anti-TNF therapy.[177] In patients who received sirukumab, showed significantly improved signs and symptoms of the disease compared to placebo. The proportions of patients who achieved an American College of Rheumatology criteria (ACR2) was 40% with sirukumab and 24% with placebo control ($p < 0.001$).

Table 7.8 Acute-Phase Proteins

Acute-Phase Protein	Function	
C-reactive protein	Opsonin	**I**

High Mobility Group Box 1 Protein (HMGB1)

HMGB1 was initially identified as an architectural chromatin-binding factor that bends DNA and directs protein assembly on specific DNA targets. It is abundant, ubiquitous, and evolutionarily conserved, as evident by the 99%

amino acid homology between rat and human proteins.[70] Thirty years after its original discovery, Tracey and colleagues demonstrated that HMGB1 acts as a late mediator of mortality in murine endotoxemia and sepsis. HMGB1 appeared 8 hours poststimulation and plateaued at 16 to 32 hours, very distinct from the acute rise and fall of early mediators (TNFα, IL-1β) of severe sepsis and septic shock.[70] Recent studies show that systemic concentrations are elevated in those patients who die of sepsis.[178]

HMGB1 is the prototypical damage-associated molecular pattern (DAMP). When cells die by necrosis (i.e., nonprogrammed cell death), HMGB1 is released into the extracellular medium. In contrast, apoptotic cells modify their chromatin so that HMGB1 irreversibly binds, and thus is not release.[179,180] However, HMGB1 is also released by activated cells of many types, via an active process that necessitates shuttling the protein from nucleus to cytoplasm; this event does not require further synthesis.[179–181] Acetylation of HMGB1 appears essential for release, however acetylation of histones as occurs during apoptosis, strengthens its interaction with chromatin and inhibits release.[179,180] Recent studies have shown that nucleocytoplasmic shuttling of HMGB1 involves serine phosphorylation by CaMKIV that enables it to be translocated to the cytoplasm by 14-3-3 and CRM1 chaperones.[182,183] Subsequent release of cytoplasmic HMGB1 appears to involve active secretion through a secretory lysosomal pathway.[179,181] The liver is a major source of circulating HMGB1 in sepsis.[184]

HMGB1 has many of the intercellular signaling activities characteristic of cytokines and therefore is often classified as a proinflammatory cytokine and potent regulator of the inflammatory response. In light of the fact that it is released by immune and nonimmune cells responding to bacterial challenge or by injured cells, it may mediate inflammation consequent to sepsis or trauma. After release, signaling is thought to occur by binding to RAGE with subsequent activation of p21ras, MEK, the MAPK kinases, and NFκB.[146,185] This receptor is expressed on mononuclear phagocytes, vascular smooth muscle cells and neurons. Blocking studies of antibodies to RAGE failed to completely prevent cellular activation suggesting the presence of an alternate receptor. Recent studies suggest that both TLR2 and TLR4 may mediate HMGB1-induced activation of NFκB in macrophages and neutrophils. This observation is very important as it demonstrates that a receptor classically

considered specific for microbial danger signals may interact with an endogenous molecule.[70,146,185] Binding to TLRs results in inflammatory signaling while binding to RAGE results in HMGB1 uptake. Here HMGB1 carries PAMPs such as LPS and DNA into cells where these can activated intracellular PRRs.

In a series of elegant studies, anti-HMGB1 antibodies conferred a dose-dependent protection in animal models of endotoxemia, even when the first dose of anti-HMGB1 antibodies was delayed for 2 hours.[71] This occurred without changes in TNFα, IL-1β, or MIP-2 concentrations. Even more striking are the in vivo CLP models, in which anti-HMGB1 administration up to 24 hours after CLP significantly increased survival, 72% versus 28%.[71] This wider therapeutic window may enable the development of inhibitors of HMGB1 for treat of sepsis.[146,186–188] These observations have stimulated the search for other inhibitors of HMGB1. Ethyl pyruvate a nontoxic food additive, dose-dependently inhibits HMGB1 release, and confers significant protection against the lethality of sepsis, even when the first dose is administered 24 hours after the onset of sepsis. In addition, it inhibits the translocation of NFκB and p38 MAPK signaling.[146,186,189,190] However, few clinical trials have been conducted, and those that have do not suggest clinical benefit.[191]

HMGB1 is also elevated during hemorrhage shock.[192] In a clinical case, serum HMGB1 levels increased significantly within 24 hours of hemorrhagic shock and returned toward basal levels as the clinical condition improved.[193] HMGB1 also appears to mediate cell damage and death in other noninfectious insults. In a model of warm liver ischemia reperfusion, HMGB1 inhibition attenuates hepatocellular injury.[36] Interestingly, this protection, as well as reduced systemic concentrations of HMGB1, was also afforded by inhibiting CaMK.[36]

High levels of HMGB1 have also been found in other conditions of sterile inflammation such as rheumatoid arthritis.[194–196] In human arthritis, overexpression of HMGB1 at the site of joint inflammation may be detected in the synovial fluid of rheumatoid arthritis patients.[195,196] HMGB1 may in fact amplify the effect of local cytokines as suggested by its ability to stimulate macrophages derived from synovial fluid of rheumatoid arthritis patients to release TNFα, IL-1β, and IL-6.[194,197] Hence, HMGB1 may serve as a signal of danger from endogenous threats or perturbations.

Interleukin 15

IL-15 is produced by various cells in response to LPS and other stimuli, though the principal cellular source is mononuclear phagocytes (**Table 7.7**). It is structurally homologous to IL-2, as is its receptor and the IL-2R. IL-15 stimulates the proliferation of NK cells similar to the manner by which IL-2 functions later in the adaptive immune response. It also acts as a T-cell growth and survival factor especially for long-lived memory $CD8^+$ T cells.[6]

Interleukin 17

7 IL-17 is an inflammatory cytokine involved in host defense, tissue repair, the pathogenesis of inflammatory disease and cancer progression. The IL-17a gene was initially identified in T cells, and subsequent studies have characterized a distinct family of IL-17 members: IL-17B–IL-17F.[198]

IL-17A and IL-17F signal through the IL-17RA and IL-17RC receptor subunits to mediate qualitatively similar but quantitatively distinct signals, with the following graded signaling potency: IL-17A > IL-17A–IL-17F > IL-17F. Whereas IL-17RA is ubiquitously expressed, the more restricted expression of IL-17RC limits IL-17 signaling mostly to nonhematopoietic epithelial and mesenchymal cells. Subsequent to receptor binding, IL-17 signaling induces inflammatory gene expression via the transcription factor NF-κB and the activation of MAPK pathways.[198]

IL-17's main effect is to regulate innate immunity. IL-17 induces neutrophils, by indirectly stimulating the release of G-CSF, CCL2, and the CXC chemokines from nonhematopoietic cells. IL-17 deficiency is nearly always associated with reduced activation of neutrophils. IL-17 contributes to the response to extracellular bacteria and intracellular pathogens such as *Mycobacterium tuberculosis*. Patients with mutations of IL-17RA genes experience a mucocutaneous infection with *Candida albicans* and *S. aureus*. This also provides a causal between the early loss of T_H17 cells during HIV infection and elevated incidence of opportunistic fungal infections.[198]

While regulated IL-17 activity supports a physiologic response to infection and tissue injury, chronic IL-17 activity is pathogenic and promotes cancer and autoimmunity. IL-17 has been shown to promote tumorigenesis and tumor progression. However, the observation of its role in autoimmunity has inspired intense interest in the IL-17 family of cytokines for potential

therapeutic use. Mouse models of arthritis show that T_H17 rather than T_H1 cells are dominant instigators of autoimmunity. Accordingly, blockade or deletion of IL-17 and IL-23 in mice reduced disease signs. This has rapidly "come to the bedside." The biologic ustekinumab has been approved for use, and its success has spurred development of more specific therapies directed against IL-17–IL-17R and IL-23. The efficacy of the biologics secukinumab and ixekizumab, which are monoclonal antibodies to IL-17, in psoriasis is particularly striking. These drugs also work in psoriatic arthritis and ankylosing spondylitis and in a subgroup with rheumatoid arthritis. In preclinical settings, blockade of IL-17 also ameliorates pathologies triggered by environmental challenges in models of asthma and COPD.

Interleukin 18

IL-18 is structurally homologous to IL-1 and utilizes a similar IRAK-signaling pathway (**Table 7.7**). Macrophages responding to microbial challenge or exposure to LPS are the principal source. Its primary function is to stimulate the production of IFNγ by NK cells and T cells, and in synergizing with IL-12, augments cell-mediated immunity. Knockout mice lacking IL-18 are deficient in IFNγ production, and concomitant IL-12 deficiency eliminates all IFNγ production and any T_H1 response.[6]

Interferons (Type I)

Type I interferons possess potent antiviral and antitumor properties (**Table 7.7**). It is from this ability to "interfere" with viral infection that the name is derived. They are subcategorized into α and β interferons. Mononuclear phagocytes are the major source of interferon α, whereas many cell types produce interferon β. The most potent stimulus inducing the synthesis and release of either is viral infection, particularly double-stranded RNA produced during viral replication. Other inducers include IL-1, TNFα, LPS, and antigen-activated T cells. Both groups bind to the same cell surface receptor and induce similar responses by signaling through the JAK/STAT pathway (**Fig. 7.9**).

These cytokines provide the first line of defense against viral infection and promote cell-mediated immunity against intracellular pathogen. They are secreted from virally infected cells to protect neighboring uninfected ones by

inducing the synthesis of a number of enzymes that interfere with viral RNA or DNA transcription and viral replication. Through enhanced expression of class I MHC molecules, the type 1 interferons facilitate recognition of class I–associated viral antigens on infected cells by CTLs and increase the efficiency of CTL-mediated killing. Type I interferon stimulates the development of T_H1 cells by promoting these cells to express IL-12 receptor. They can also stimulate B-cell development, proliferation, and immunoglobulin heavy chain switching from IgM to IgG.[199–201] Knockout mice lacking the receptor for these cytokines are susceptible to viral infections. Interferons are currently in clinical use for hepatitis B and C infection, multiple sclerosis, CML, and Kaposi sarcoma.[199–201]

Interleukin 10 (Cytokine Synthesis Inhibiting Factor)

IL-10 inhibits activated macrophages and APC and functions in a counterregulatory mechanism to suppress innate immune reactions (**Table 7.7**). It is produced mainly by macrophages, and hence functions by negative feedback. T lymphocytes, particularly the T_H2 subset, B cells, and some other nonlymphoid cells produce IL-10, in response to a variety of stimuli including LPS, TNFα, IL-2, IL-4, and IL-13.

IL-10 binds to a type II (interferon) receptor. Though the manner by which it effects curtailment of the inflammatory response is unknown, its presence inhibits NKκB activation and the generation of inflammatory mediators. Thus, it may inhibit, in some manner, the activation of signal transduction cascades and gene activation in proinflammatory pathways.[6,202]

IL-10 terminates many of the functions of activated macrophages and participates in reestablishing homeostasis as the infection resolves. It downregulates proinflammatory cytokine (TNFα, IL-1, IL-6, and IL-8) production, suppresses the production of IL-12 and inhibits IFNγ production and the innate and cell-mediated immune responses.[6,74,133] It represses the expression of costimulators and class II MHC molecules on APC, thereby terminating T-cell activation and inhibiting cell-mediated immunity.[6] In neutrophils it inhibits cytokine release, superoxide generation, migration, and even survival.[203] In combination with IL-4 it inhibits IFNγ release and IL-12 production to limit differentiation and function of T_H1 cells, favoring a T_H2 profile.[74]

IL-10 knockout mice develop inflammatory bowel disease, which is hypothesized to result from unregulated macrophage reaction to enteric microbes.[204] In observational studies of ARDS or MODS, serum IL-10 levels were often elevated, and those patients with the highest systemic concentrations died.[202] It is unclear whether this is actually a pathologic response, or merely a marker of disease severity. Contemporary belief is that IL-10 is not a mediator of immunosuppression, but rather, important for immunoregulation.

Late Cytokines/Adaptive Immunity

Interleukin 2 (T-Cell Growth Factor)

Interleukin 2 stimulates the growth and proliferation of T lymphocytes and is responsible for T-cell clonal expansion after antigen recognition (**Table 7.7**).[205] IL-2 is produced by $CD4^+$, and to a lesser extent $CD8^+$ T cells. The receptor is heterotrimeric, consisting of three noncovalently associated proteins, α, β, and γ. The α and β chains are involved in cytokine binding, and the β and γ chains mediate signal transduction.[6] Antigen recognition enhances the expression of functional IL-2 receptors, which confers a degree of specificity, as those T cells recognizing antigen are preferentially induced to proliferate in response to IL-2. Though, the α chain appears on T-cell activation and binds IL-2, signal generation necessitates the β and γ chains. Cells expressing the complete α, β, and γ complex bind IL-2 with higher affinity (Kd of 10^{-11} M), and growth stimulation of such cells occurs at a low IL-2 concentration.[6] Upon antigen receptor-mediated T-cell activation, IL-2R α is rapidly upregulated, which reduces the concentration of IL-2 needed to stimulate growth. Therefore, antigen-stimulated T cells are more responsive to IL-2 than naïve T cells. This receptor signals through numerous signal transduction pathways including the JAK/STAT, PI 3 kinase, and MAP kinase pathways (**Figs. 7.6** and **7.9**).

IL-2 functions in an autocrine and paracrine fashion to induce the proliferation of the antigen-specific cells. After exposure to IL-1, there is a rise in cyclins and activation of cyclin-dependent kinases that stimulates the progression of the cell cycle from the G1 to the S phase. A reduction in p27, an inhibitor of cyclin–kinase complexes, facilitates this progression, and the

induction of Bcl-2, an antiapoptotic protein, facilitates survival. It also stimulates the production of other cytokines such as IFNγ and IL-4.[6]

IL-2 promotes the proliferation and differentiation of many immune cells. NK cells are stimulated to grow and transform into lymphocyte-activated killer (LAK) cells. In combination with IFNγ and IL-12, IL-2 can trigger a positive feedback cycle of NK activation. IL-2 stimulates B-cell growth and antibody synthesis. Repeated activation of $CD4^+$ T cells in the presence of IL-2 sensitizes these cells to apoptosis by fas-fas-ligand. IL-2 may also stimulate the development of regulatory T cells, and IL-2 knockout mice develop autoimmunity. Knockout mice lacking the γ chain develop X-linked severe combined immunodeficiency syndrome. This is probably due to an inability of immature T cells to respond to IL-7.

Our understanding of these mechanisms has enabled the development of several immunomodulatory drugs. Daclizumab (anti-Tac) is a humanized monoclonal antibody that binds, thereby inhibiting, the α subunit of the IL-2 receptor of T cells. Both the DECIDE and SELECT trials provide compelling data supporting the clinical utility of IL-2 receptor inhibition in the management of multiple sclerosis. The Ruxolitinib (JAK1 inhibitor) is an orally available biochemical inhibitor of JAK1/2 that has been approved for us in the treatment of myeloproliferative disorders and is currently under investigation for chronic graft versus host disease. Tofacitinib (JAK3 inhibitor) has been approved to treat adults with moderately and severely active rheumatoid arthritis who have had an inadequate response to methotrexate. It is also used to treat psoriatic arthritis, ankylosing spondylitis, and ulcerative colitis. IL-2 has been used in the management of cancer, in particular renal cell carcinoma, and investigation continues to determine clinical applications.[206–209]

Interleukin 4

IL-4 is the major stimulus for the production of IgE antibodies and for the development of T_H2 cells from naïve $CD4^+$ T cells (**Table 7.7**). The principal cellular sources are $CD4^+$ T cells, mast cells, and basophils. The IL-4 receptor belongs to the type I cytokine receptor family and signals through the JAK/STAT pathway (**Fig. 7.9**).[210] IgE is integral in orchestrating the defense against parasitic infections. It stimulates IgE production and mast

cell/eosinophil-mediated reactions and induces B-cell Ig heavy chain class switching to the IgE isotype. However, IL-4 also serves a counterregulatory role by inducing T_H2 cell differentiation and growth. IL-4 antagonizes the macrophage-activating effects of IFNγ and thus inhibits cell-mediated immunity.

Interleukin 5

IL-5 is produced by T_H2 cells, IL-C2, and activated mast cells and activates eosinophils (**Table 7.7**). It signals through the type I cytokine receptor and the JAK/STAT pathway (**Fig. 7.9**). IL-5 is an inducer of eosinophil growth, differentiation, and activation, and also participates the eradication of helminthic infection. IL-5 also stimulates the proliferation of B cells and the production of IgA antibodies.[6]

Interleukin 13

IL-13 is produced by T_H2 cells and some epithelial cells and is structurally homologous and functionally similar to IL-4 (**Table 7.7**). The receptor is found mainly on nonlymphoid cells and can be activated by either IL-13 or IL-4. IL-13 downregulates the expression of Fcγ on monocytes and macrophages, thereby decreasing antibody-dependent cellular cytotoxicity. It increases 15S-HETE and lipoxin A_4, both of which antagonize proinflammatory leukotrienes. However, they can increase the expression of MHC class II and costimulatory molecules on monocytes, and thereby serve an immunostimulatory function. The major action is to inhibit the activation of macrophages, drive macrophages toward M2, and to antagonize IFNγ.[211]

Interferon γ (IFNγ)

IFNγ is produced by NK cells, T_H1 cells, and $CD8^+$ cells and as the principal stimulus for macrophage activation, provides necessary functions during both innate and adaptive immune responses (**Table 7.7**). It modulates cellular differentiation, cytotoxicity, cytokine production, cellular adhesion, and oxidative metabolism. During innate immunity, NK cells secrete IFNγ upon exposure to pathogen or stimulation by IL-12. $CD8^+$ T cells and the T_H1 subset of $CD4^+$ T cells produce it in response to MHC-bound peptide antigen

with a costimulatory signal. The IFNγ receptor is composed of two homologous proteins belonging to the type II cytokine receptor family and functions through the JAK/STAT pathway (**Fig. 7.9**).[6]

The antiviral and antitumor properties of IFNγ are redundant with those of type I interferons. In concert with TNFα and IL-12 it forms one arm of a positive feedback loop fueling the activation of both NK cells and macrophages. Stimulated macrophages activate NK cells by releasing TNFα and IL-12. These NK cells produce IFNγ, which further stimulates macrophages to secrete more TNFα and IL-12.[212,213]

IFNγ induces the genes encoding the enzymatic machinery required for generating ROS generation and provides the principle stimulus for macrophages to kill phagocytosed microbes. It regulates the expression of MHC class I and class II molecules and costimulators of APC, and induces the transcription of enzymes regulating antigen processing.[212,213]

IFNγ synergizes with TNFα to activate the endothelium and upregulate adhesion molecule expression; in doing so it facilitates lymphocyte recruitment and leukocyte recruitment. Interferon promotes the differentiation of naïve $CD4^+$ cells into T_H1 cells and inhibits the proliferation of T_H2 cells, in part, by inducing IL-12, the major T_H1-inducing cytokine, from activated mononuclear phagocytes. It promotes B-cell switching to certain IgG subclasses, notably IgG2a, and inhibits the switching to IL-4–dependent isotypes such as IgE and IgG1. These IgG subclasses bind the Fcγ receptors on phagocytes and activate complement, thereby promoting phagocytosis of opsonized microbes. It activates PMNs and stimulates the cytolytic activity of NK cells. The net effect is to promote macrophage-rich inflammatory reactions while inhibiting IgE-dependent eosinophil-rich reactions. IL-10, by suppressing macrophage release of TNFα and IL-12, negatively regulates IFNγ production.

IFNγ also demonstrates counterregulatory properties. It selectively inhibits LPS-induced expression of CXC chemokines. It upregulates macrophage production of IP-10, MIG, and ELR-negative chemokines that inhibit neutrophil chemotaxis and activation and decreases macrophage release of ELR-positive CXC chemokines (e.g., IL-8), which are chemotactic for neutrophils.[6]

Transforming Growth Factor β (TGFβ)

TGFβ is a homodimer synthesized and secreted by activated T cells, macrophages, and many other cells (**Table 7.7**). It is primarily immunosuppressive and inhibits the proliferation and activation of lymphocytes and other leukocytes. It promotes wound healing by increasing extracellular matrix protein synthesis and stimulating mononuclear cell and fibroblast influx.[214–216] Though the family consists of three closely related isoforms, most cells utilize TGFβ. Its effects are mediated through two high-affinity TGF receptors (types I and II) that signal through a serine/threonine kinase domain that phosphorylates transcription factors called SMADS.[6]

TGFβ inhibits the proliferation and differentiation of T cells and the activation of macrophages. It favors differentiation of $CD4^+$ cells to the T_H2 subset and inhibits MHC class II surface expression. By suppressing the expression of MHC class II antigen, it abrogates the adaptive immune response. Macrophages demonstrate diminished ROS production and TNFα and NO release. It directly counteracts the influence of proinflammatory cytokines on PMNs and endothelial cells, and in combination with IL-4, IL-13, and IL-10 can antagonize the production or effects of these proinflammatory mediators. Knockout mice, deficient in TGFβ develop uncontrolled inflammatory lesions.[6,43]

Cytokines that Stimulate Hematopoiesis

Cytokines are necessary for normal hematopoiesis. Several of the cytokines stimulated during both innate and adaptive immune responses are mitogenic for and induce differentiation of bone marrow progenitor cells. CSFs are cytokines made by activated T cells, macrophages, endothelial cells, and bone marrow stromal cells that stimulate increased production of inflammatory leukocytes by bone marrow progenitors. Receptors for granulocyte-macrophage colony-stimulating factor (GM-CSF) and G-CSF are of the class I family of cytokine receptors. GM-CSF is expressed by T and B cells, macrophages, mast cells, fibroblasts, and endothelium in response to stimuli such as IL-1, IL-2, LPS, and TNFα. It stimulates neutrophils, monocytes, macrophages, and DCs and is a powerful inducer of hematopoiesis. It enhances cytokine release, degranulation, and phagocytosis

of opsonized particles in neutrophils. In monocytes and macrophages, it enhances cytotoxicity and cytokine release. It promotes the activity of APCs and the maturation of bone marrow cells into DCs and monocytes.[217] G-CSF is produced by macrophages, endothelial cells, fibroblasts, and bone marrow stromal cells. It functions as an endocrine hormone to mobilize neutrophils and induces subsequent leukocyte proliferation and maturation. In 1991, the FDA approved the use of G-CSF for use in patients with neutropenia.[218,219]

Stem cell factor or c-Kit ligand is synthesized by marrow stromal cells and binds to a cell surface tyrosine kinase receptor on pluripotent stem cells that is the protein product of the cellular proto-oncogene c-kit. Its effects appear to be permissive, as it is corequisite for stem cell responsiveness to other CSFs, yet in isolation does not stimulate colony formation. It may also play a role in sustaining the viability and proliferative capacity of immature T cells in the thymus.[6]

IL-3 is a product of $CD4^+$ T cells that promotes the differentiation of immature marrow progenitors into all known mature cell types. It also promotes the growth and development of mast cells. Surprisingly, despite these important functions, murine knockouts do not manifest noticeable impairment of hematopoiesis.[6]

IL-7 is secreted by bone marrow stromal cells and promotes the growth and survival of immature precursors committed to the B and T lymphocyte lineages. Knockout mice, deficient in IL-7 or its receptor, are lymphopenic and possess diminished populations of B and T cells.[6]

The Complement System

8 The complement system is integral to both innate and adaptive immunity. It has the capacity to independently eliminate organisms and to facilitate host defense by marking foreign particles for phagocytosis through opsonization. Many pathophysiologic inflammatory diseases, immune complex diseases, ischemia/reperfusion injury, and ARDS are considered consequences of excessive or unregulated induction of this system.[220–223]

The system consists of 3 pathways comprised of approximately 30 serum and cell surface proteins that interact with one another and with other molecules of the immune system in a highly coordinated fashion. These cascades involve the sequential proteolytic activation of zymogens to

generate enzymes with proteolytic activity. This mechanism for activation amplifies the response because each individual enzyme activated can cleave numerous zymogens in the next step and generate multiple activated enzyme molecules. Ultimately, the products of complement activation adhere to microbial cell surfaces or to antibody-bound microbes and other antigens to directly or indirectly eliminate these pathogens. Temporal and spatial regulation to the focus of infection is ensured both by the transience of activation of these enzymes in the absence of microbes or antigens and by several circulating proteins that provide surveillance.[220,222]

The complement cascade is divided into three distinct pathways: (1) the classical pathway (humoral immunity), which is activated by antibody bound to antigen, (2) the alternative pathway (innate immunity) in which complement is activated by components of microbial cell surfaces, and (3) the mannose/lectin pathway (innate immunity), which is activated by a plasma lectin that binds to mannose residues on microbes. Despite differences in which the cascade is activated, all three complement pathways ultimately result in the cleavage of C3 and share the same late cascade.[220,222]

The alternative pathway functions in the absence of antibody and is phylogenetically the oldest pathway (**Fig. 7.10**). Bacteria, viruses, fungi, and parasites all function as stimuli. Initial activation begins with the cleavage of C3 and the stable attachment of its product C3b to the microbial surface. Bound C3b finds factor B, which is subsequently cleaved by a plasma serine protease called factor D to generate Bb. The C3bBb complex is called the alternative pathway C3 convertase and functions to cleave more C3. In doing so the convertase serves as an amplification step in both the classical and alternative pathways. Properdin prolongs the half-life of C3 convertase by delaying the release of Bb from C3bBb. C3b is the recognition component of the alternate pathway and is responsible for the opsonization of bacteria. C3a in conjunction with C5a and C4a induces acute inflammation by activating mast cells and neutrophils. These inflammatory mediators play a significant role in increasing blood vessel permeability, vasodilatation, edema formation, neutrophil adhesion and activation, chemotaxis, and the release of toxic oxygen species and lysosomal enzymes from phagocytic cells. The binding of another C3b to this complex generates the alternative pathway C5 convertase, C3bBb3b.[6,220,222]

Activation of the alternative pathway is restricted to the cell surface of microbes, as mammalian cells possess several regulatory proteins to rapidly degrade any C3bBb. Excessive amplification is regulated by factors H and factor I. H accelerates the decay and delays the formation of C3bBb. It also acts as a cofactor for I to degrade C3 into iC3b, which is unable to bind B to generate C3 convertase. Decay acceleration factor (DAF) hinders C3 convertase assembly and mediates its dissociation in all three pathways. Also, the protein properdin, which stabilizes this alternative pathway C3 convertase, has a higher affinity for microbial than mammalian cell surfaces.[6,220,222]

The classical pathway is the primary mediator of adaptive humoral immunity and is initiated by binding of the complement protein C1 to IgG or IgM molecules engaged with antigen (**Fig. 7.10**). Other substances such as lipid A in endotoxin and mitochondrial membranes may activate this pathway independent of antigen–antibody complexes in vitro.[220,224]

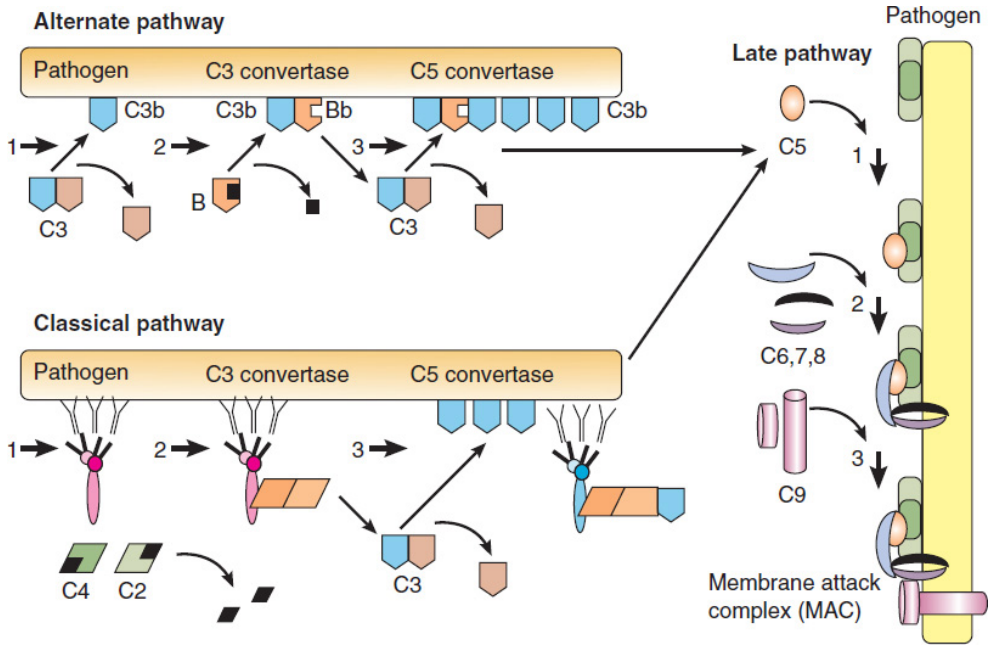

Figure 7.10 Complement pathways. Alternate pathway: 1. C3 is cleaved to C3b. 2. C3b binds and cleaves B to Bb to form C3 convertase (C3bBb). 3. Another C3b binds C3 convertase to form C5 convertase (C3bBbC3b). Classical pathway: 1. C1 binds immunoglobulin. 2. C1 binds and cleaves C4 and C2 to C4b and C2a to form C3 convertase (C4b2a). 3. C4b2a binds another C3b to generate C5 convertase (C4b2aC3b). Late pathway: 1. C5 converatse cleaves C5 to form C5b, which integrates into the plasmallema. 2. C6–8 are recruited, forming the C5b-8 complex. 3. C5b-8 recruits numerous C9 subunits, which form a pore in the pathogen cell wall. (Redrawn from Abbas AK, Lichtman AH. *Cellular and Molecular Immunology*. Philadelphia, PA: Saunders, 2003.)

C1 is a calcium-dependent trimeric protein consisting of C1q, which recognizes and binds the Fc region of the immunoglobulin, and C1r and C1s, which are proteases. C1q engages the Fc portion of the immunoglobulin μ and γ heavy chains. Each Fc region has a single C1q binding site, yet for activation, each C1q molecule must bind to two Ig heavy chains. Hence, multiple antibodies must be approximated for activation, which restricts activation to foci of immunoglobin engagement. IgM exists as a pentamer enabling it to bind to two C1q molecules, and hence it is more efficient at complement activation.[6,220,224]

Interaction between C1q and the immunoglobin Fc region induces a conformational change in C1q that activates C1r, which subsequently cleaves and activates C1s. C1s cleaves C4 to generate C4b and C4a. The C4a anaphylatoxin possesses properties similar to those described for C3a. C4b

localizes to immune complexes on the cell surface. C2, after complexing with C4b, is cleaved by C1s, thereby generating the classical C3 convertase C4b2a complex, which has the ability to cleave C3. The C3b generated can bind Bb, producing more C3 convertase and amplifying the signal. The key early steps of the alternative and classical pathways are analogous: C3 and factor B of the alternative pathway are homologous to C4 and C2 in the classical pathway. C3b can also combine with the classical C3 convertase to generate C4b2a3b, the classical C5 convertase.[6]

Numerous regulatory mechanisms exist to restrict activation to sites of inflammation. Excessive classical C3 convertase activity is prevented by the rapid decay of C2a from the complex, which renders the complex unstable. C1 inhibitor covalently binds C1s, reducing the half-life of activated C1 to only 13 seconds. C4-binding protein enhances spontaneous dissociation of C4b2a and also acts as a cofactor for C3b/C4b inactivator, which degrades C4b.[43]

The mannose-binding lectin (MBL) pathway is activated by microbial polysaccharides bound to circulating lectins; MBL serves as the recognition unit of the MBL pathway. This pathway recognizes polysaccharides with high mannose content and other oligosaccharides with characteristic linkages found exclusively on pathogens and not on normal host components. Binding is calcium-dependent and results in the activation of MBL-associated serine proteases (MASP-1 and MASP-2). Activated MASP-2 cleaves and activates C4 and C2 in the same fashion as the classical complement pathway. Subsequent steps of complement activation of the MBL pathway mirror those of the classical complement pathway.[220,225,226]

The C5 convertases generated during either the classical or alternative pathway initiate a cascade of events that culminates in the formation of the cytocidal membrane attack complex (MAC). Specifically, C5 convertase cleaves C5, yielding C5a and C5b. C6 and C7 bind to generate the C5b67 complex. This hydrophobic moiety penetrates deeply into the lipid bilayer as a high-affinity receptor for C8. Binding of C8 forms the complex C5b–8 that recruits numerous C9 subunits, which polymerize to form pores in the plasma membrane of bacteria. The pores structurally resemble the membrane pores formed by perforin, the cytolytic granule protein found in CTLs and NK cells. Their diameter may span 100 angstroms, which prevents the maintenance of vital ionic gradients, induces osmotic lysis, and ultimately the

death of target cells or pathogens. Patients with deficiencies in the terminal components of C5, C6, C7, and C8 are susceptible to meningococcal and gonococcal infections.[6,227] By contrast, recent studies suggest that aberrant induction of the complement system, specifically C5a, plays an integral role in inducing paralysis of the innate immunity and the development of ARDS and MODS.

The effects of complement are in part mediated through several CRs. Opsonization and phagocytosis are important mechanisms for pathogen destruction, and phagocytic cells express receptors for complement factor C3 components. Complement receptor type 1 (CR1), the C3b receptor for C3b and C4b, mediates engagement of and facilitates phagocytosis of complement bound microbes and the clearance of immune complexes from the circulation. It is expressed on a variety of cells including RBC, neutrophils, monocytes, eosinophils, and T and B cells. RBCs facilitate elimination by transporting these opsonized particles to the liver and spleen where the immune complexes are removed by phagocytes. CR2 stimulates humoral immune response by enhancing B-cell activation by antigen and by promoting the trapping of antigen–antibody complexes in germinal centers. In humans, this receptor is the receptor for EBV. CR3 and CR4 are β_2 integrins that bind the iC3b-processed fragment of C3 and promote macrophage and neutrophil phagocytosis of iC3b-opsonized antigen.[6,43]

This entire cascade is under strict regulation to ensure that activation is restricted to sites of inflammation and infection. This regulation is needed as low-level activation is always occurring, and if not quelled, would certainly damage normal tissues. Even when locally activated, byproducts may damage nearby cells and tissues. Several circulating proteins function to do this. C1r and C1s are inhibited by C1 inhibitor, a serine protease inhibitor that mimics C1r and C1s. C1 inhibitor targets activated C1qrs, and after attachment, C1r–C1s dissociate and activation of classical complement ceases. This inhibition prevents the accumulation of active C1r–C1s, thereby limiting the duration during which active C1r–C1s can initiate the cascade.[6] C1 inhibitor also inhibits other circulating inflammatory serine proteases including kallikrein and factor XII, both of which can activate the formation of bradykinin.[6] Hereditary angioneurotic edema is an inherited deficiency of

C1 inhibitor and manifests as acute intermittent edema of the skin and mucosa causing abdominal pain, vomiting, diarrhea, and airway obstruction.

MCP, CR1, and decay-accelerating factor (DAF) are regulatory proteins that bind to C3b and C4b deposited on cell surfaces and competitively inhibit the binding of other components of the C3 and C5 convertases, such as Bb and C2a, and thereby block further progression of the cascade. These proteins are only produced by mammalian cells. Deficiency of an enzyme required to form the linkages necessary to express DAF underlies paroxysmal nocturnal hemoglobinuria, a disease characterized by recurrent intravascular hemolysis due to unregulated complement activation on the surface of erythrocytes. Cell-associated C3b is proteolytically degraded by a plasma serine protease called factor I which is active only in the presence of regulatory proteins such as MCP, factor H, C4BP, and CR1. MAC formation is inhibited by CD59, a membrane protein that incorporates itself into growing MACS and inhibits the incorporation of C9. It is not present in microbes. The function of these regulatory proteins may be overcome by increasing amounts of complement activation.[6]

Several disease states are considered either the consequence of or propagated by aberrant complement activation, and thus, considerable interest exists in understanding methods of modulating this cascade and thereby restoring complement homeostasis. Paroxysmal nocturnal hemoglobinuria is a rare acquired disorder characterized by chronic complement-mediated intravascular hemolysis. Eculizumab is a humanized monoclonal antibody that binds to the terminal complement component C5, inhibiting the cleavage of C5 by C5 convertase into C5a. Similarly, Ravulizumab is a new complement C5 inhibitor that through high-affinity binding to C5 inhibits C5a and C5b formation. Both have demonstrable efficacy in preventing immune activation and hemolysis and treating paroxysmal nocturnal hemoglobinuria.[228,229] They are also used in the treatment of hemolytic uremic syndrome. Other studies are in progress to test the ramifications of targeting the complement pathway in age-related macular degeneration, aquaporin-4–positive neuromyelitis optic spectrum disorder, and Guillain–Barré syndrome.[230–233]

9 Lipid Mediators

Eicosanoids

Eicosanoids are 20-carbon lipid inflammatory mediators that are derived from membrane arachidonic acid and are involved in numerous homeostatic processes and inflammation. These lipid mediators are not stored in tissues but are synthesized de novo within seconds in response to a variety of stimuli, including mechanical trauma, specific cytokines, growth factors, and other mediators (**Fig. 7.11**). Although most cells are capable of producing eicosanoids, neutrophils and macrophages are the predominant sources. They are rapidly degraded in the circulation, which limits their role primarily to that of autocrine and paracrine mediators of local inflammatory changes.[234–236]

The liberation of the precursor molecule, arachidonic acid, is the major rate-limiting step. The family of PLA_2, in particular type IV cytosolic PLA_2, is responsible for eicosanoid production; cells lacking type IV PLA_2 are devoid of eicosanoid synthesis.[237] Many PLA_2 are transcriptionally regulated by IL-1 and TNFα, whereas others are regulated by the MAP kinase pathway and by calcium-dependent translocation to membranes. Once formed, arachidonic acid metabolism proceeds along one of two pathways.[234–236]

Cyclooxygenase Pathway (Prostaglandins)

Cyclooxygenase catalyzes the initial step of a series of reactions that converts arachidonic acid to prostanoids (**Fig. 7.11**). There are two isoforms, COX1 and COX2; the former is constitutively expressed, whereas COX2 is inducible. COX2 is considered more important during inflammatory processes such as fever, hyperalgesia, and edema formation. Either enzyme catalyzes the conversion of arachidonic acid to the endoperoxidase PGG_2, which is subsequently converted to PGH_2. PGH_2 serves as the precursor to numerous specific prostaglandins. All of these products possess very short half-lives and are rapidly inactivated.[237,238]

Prostaglandins mediate their effects through G protein signaling (**Table 7.9**). Prostacyclin (PGI_2) is produced by the endothelium as a potent vasodilator and inhibitor of platelet aggregation and adhesion; these characteristics enhance tissue perfusion. PGI_2 inhibits neutrophil chemotaxis and activation and interacts synergistically with PGE_2 to increase vascular

permeability through the bradykinin pathway. PGE_2 is the predominant anti-inflammatory prostaglandin and is produced by nearly all inflammatory cells. It is produced in response to IL-1 and mediates the hypothalamic fever response and synergizes with bradykinin and histamine to mediate pain. It is a bronchodilator, inhibits both IL-1 production and T-cell responsiveness to IL-1, and at low concentrations suppresses TNFα production. It also inhibits neutrophil chemotaxis and activation and T_H1 lymphocyte proliferation.[237,238] There is some suggestion from animal studies that PGE_2, PGE_1, and PGI_2 may be beneficial in response to sepsis through their endogenous counterregulatory properties. Administration of each of these has been shown to improve survival in several animal models of hypovolemic and traumatic shock, though clinical trials have failed to identify benefit.[238] PGD_2 is a potent bronchoconstrictor that inhibits neutrophil chemotaxis and activation. TXA_2, PGG_2, and PGH_2 oppose the actions of prostacyclin by promoting platelet aggregation and inducing bronchoconstriction. TXA2 produced by platelets and macrophages is a powerful vasoconstrictor that induces neutrophil accumulation and increases vascular permeability.[234–236,239] There is substantial evidence that TXA_2 plays a significant role in early acute-phase organ injury.[238]

Lipoxygenase Pathway (Leukotrienes and Lipoxins)

Leukotrienes and lipoxins are leukocyte-derived molecules synthesized by the oxidation of arachidonic acid by 3 lipoxygenase (LO) enzymes: 5-LO, 12-LO, and 15-LO (**Fig. 7.11**). 5-LO associates with the perinuclear membrane protein 5-LO–activating protein (FLAP) to catalyze the formation of 5-hydroperoxyeicosatetraenoic acid (5-HPETE). 5-HPETE is subsequently converted to LTA_4 by the combined efforts of a dehydrase and 5-LO. LTA_4 serves as the precursor for either LTB_4 or LTC_4. LTC_4 can in turn be successively hydrolyzed to the dipeptide derivative LTD_4 and the LTE_4. Additional LO activity results in the production of 12-HPETE, 12-HETE, and 15-HPETE. These compounds exhibit biologic activity, although they are not as potent as the leukotrienes or prostaglandins. The leukotrienes are inactivated by oxidation followed by dehydration.[235–237,239,240]

The major lipoxygenase product of neutrophils is LTB_4, though macrophages may also synthesize this compound. This compound is potently chemotactic for both neutrophils and eosinophils. By upregulating endothelial cell surface adhesion molecules, it promotes leukocyte recruitment. It increases vascular permeability, either directly or through interaction with neutrophils and endothelial cells. LTB_4 has also been shown to induce hyperalgesia.[130,237]

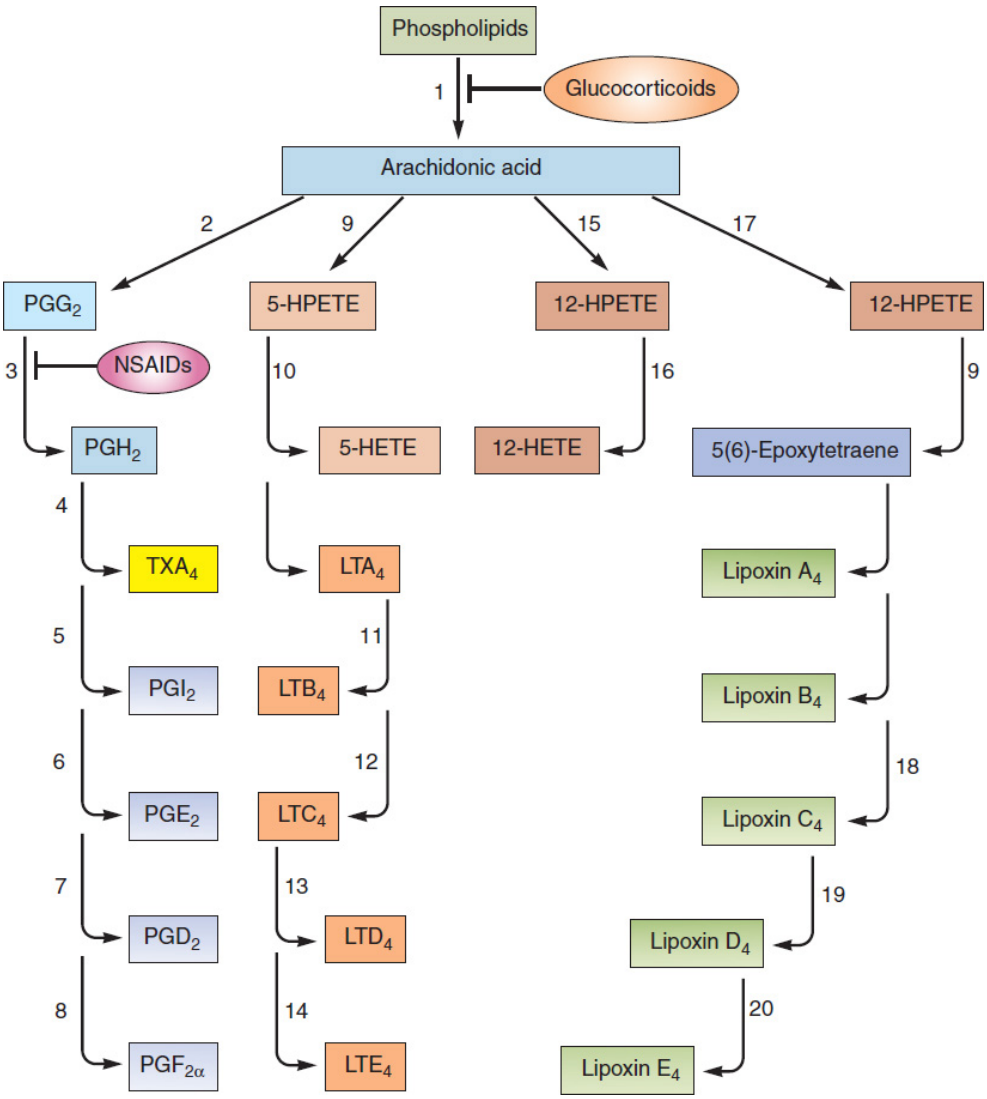

Figure 7.11 Eicosanoid production. 1. Phospholipases; 2. Cyclooxygenase; 3. Hydroperoxidase; 4. Thromboxane synthetase; 5. Prostacyclin synthetase; 6. E-isomerase; 7. D-isomerase; 8. F-reductase; 9. 5-Lipoxygenase; 10. Glutathione peroxidase; 11. Hydrolase; 12. Glutathione S-transferase; 13. γ-Glutamyl transpeptidase; 14. Cysteinyl glycinase; 15. 12-Lipoxygenase; 16. Peroxidase; 17. 15-Lipoxygenase; 18. GSH-cis-11-trans lipoxin A_4; 19. α-Glutamyl transferase; 20. Dipeptidase.

LTC_4, LTD_4, and LTE_4 comprise the family of slow-reacting substances of anaphylaxis (SRSA), compounds synthesized by mast cells during anaphylactic reactions. LTC_4 is the major eicosanoid product of eosinophils and the only mast cell-derived product of LO. These three leukotrienes are potent vasoconstrictors and the most powerful bronchoconstrictors in

humans, being three orders of magnitude more potent than histamine. They also increase vascular permeability and are vasodilatory in skin.[47,237]

Lipoxins are biosynthesized by several routes in a tissue-specific manner. Current evidence implicates the eosinophil. A 5(6)-epoxytetraene intermediate can be formed by 5-LO activity on 15-HPETE. This reaction, when carried out in blood vessels, requires the interaction of platelets and neutrophils. On mucosal surfaces, 12-LO and 5-LO activity on LTA_4 can result in formation of this lipoxin intermediate through leukocyte–epithelial interactions. The 5(6)-epoxytetraene intermediate is then converted to lipoxin A_4, lipoxin B_4, or lipoxin C_4, the last of which serves as the precursor for lipoxins D_4 and E_4.[128,241,242]

Though many of the functions of lipoxins have yet to be elucidated, they appear to counterregulate the actions of leukotrienes. They inhibit leukotriene production by downregulating 5-LO as 15-LO is upregulated. The anti-inflammatory cytokines IL-4 and IL-13 further contribute to suppression of inflammatory responses by enhancing 15-LO activity. In addition to inhibiting synthesis, lipoxins inhibit the actions of LTB_4 and LTD_4. Lipoxins A_4 and B_4 are potent vasoactive compounds. Lipoxins influence smooth muscle and vascular tonus by increasing NO and prostacyclin production, increasing arachidonate release, and reversing endothelin-induced vasoconstriction. Counterinflammatory functions of lipoxin A_4 include inhibition of leukotrienes, fMLP, and other chemoattractants. Lipoxin A_4 also downregulates LTB_4-mediated delayed-type hypersensitivity reactions.[128,241–243]

Table 7.9 Prostanoid Effects

	PGG_2	PGH_2	PGI_2	PGE_2	TXA_2
Chemotaxis	↑	↑	↓	↓	↑
Bronchial resistance	↑	↑	↓	↓	↑
Platelet aggregation	↑	↑	↓	↓	↑
Systemic vascular resistance			↓	↓	↑
Pulmonary vascular resistance	↑	↑	↓	↓	↑

A large number of anti-inflammatory drugs, many of which are in clinical use, act by interfering with eicosanoid synthesis. The anti-inflammatory properties of corticosteroids are mediated at least in part by the inhibition of PLA_2 through the induction of lipocortin. They have been shown to selectively inhibit COX2 activation without affecting COX1. NSAIDs block the synthesis of both prostaglandins and thromboxanes by inhibiting COX activity. In contrast to the other NSAIDs, aspirin inhibits COX in an irreversible manner, and restoration of platelet function necessitates the administration of platelets. Aspirin, by either acetylating COX2 or by inducing the oxidation of arachidonic acid by cytochrome p450 or 5-LO, has been shown to stimulate the formation of 15R-HETE in endothelial or epithelial cells. These 15-epilipoxins exhibit higher potency in suppressing inflammation because of their prolonged half-lives. A potential complication of NSAID use and COX inhibition is the shunting of arachidonate through the 5-LO pathway and subsequent greater production of proinflamamtory leukotrienes (asthma). Such consequences minimize any benefit achieved from reducing other eicosanoid levels. In addition, NSAIDs act systematically in a nonselective manner, so that inhibition of prostaglandin synthesis can result in dangerous side effects in locations where prostaglandins normally exert cytoprotective effects (stomach).[238,242,244]

Platelet-Activating Factor (PAF)

PAF is a heterogeneous mixture of 1-0-alkyl-2-acetyl-sn-glycero-3-phosphocholines that plays a prominent role in both physiologic and pathologic inflammatory states. It does not exist preformed but is rapidly produced by activated cells. Synthesis involves either the remodeling of membrane phospholipids by PLA_2, usually more important under inflammatory conditions, or by de novo synthesis as occurs in resting cells. De novo synthesis is regulated by substrate availability and involves a constitutively active enzyme that produces PAF in small basal amounts.[245] The membrane phospholipid precursor is present in high amounts in neutrophils. Other cells that can synthesize PAF include platelets, basophils, monocytes, eosinophils, mast cells, and vascular endothelial cells. Similar to eicosanoid production, the synthesis of PAF is initiated by calcium-dependent activation of PLA_2, which yields 1-0-alkyl-sn-

glycerophosphocholine (lyso-PAF); subsequent acetylation generates PAF. PAF may be released from the cell, or it may be converted back to lyso-PAF by an acetylhydrolase and to the precursor ether-phosphatidylcholine.[245]

The actions of PAF are mediated by G-protein activation. As the name implies, PAF induces platelet aggregation and degranulation; yet also possesses many other critical functions for inflammation. Its vasoactive properties include vasodilation and increased permeability, and it is an equally potent bronchoconstrictor. PAF enhances arachidonic acid metabolism, leading to increased leukocyte motility, degranulation, and free radical formation. PAF plays an integral role in promoting activation and adherence of inflammatory cells to the endothelium.[246] During the early inflammatory response, activated endothelial cells synthesize and express PAF on the cell surface. Leukocytes tethered by selectins to the endothelium are activated by endothelial PAF, which results in the induction of tight integrin-dependent adhesion and subsequent emigration and chemotaxis toward the inflammatory focus. Acyl-PAF, the major acetylated lipid from mast cells, basophils, and endothelial cells, is a less potent derivative of PAF that likely plays a similar role in the regulation of neutrophil recruitment. PAF also promotes platelet and neutrophil aggregation, thereby contributing to the prothrombotic state of acute inflammation. In circumstances of persistent pathologic stimuli, PAF may be liberated systemically, thereby causing the sequelae of an excessive inflammatory response. As a mediator of sepsis, PAF augments endotoxin-induced hypotension and neutrophil and platelet accumulation in the lungs. There is evidence that the NO-induced hypotension in experimental models of endotoxemia is mediated by PAF.[247] PAF infusion leads to a shock state that is similar to septic shock in that there is tissue hypoperfusion despite adequate fluid resuscitation. In animal studies, PAF has been shown to contribute many manifestations of sepsis including coronary vasoconstriction, reduced cardiac contractility, reduced preload, peripheral vasodilation, pulmonary vasoconstriction, increased microvascular permeability, gastrointestinal hemorrhage, and thrombocytopenia.[238] Two prospective randomized, placebo-controlled trials of PAF inhibition in sepsis have suggested a benefit.[238]

PAF acetylhydrolase, an enzyme regulated by dexamethasone, estrogen, and PAF itself, is the enzyme responsible for degradation of PAF.

Kinins

Kinins (i.e., bradykinin and lysyl bradykinin) are small vasoactive peptides generated during the inflammatory response (**Fig. 7.12**). Three sources and mechanisms of kinin formation occur during inflammation: (1) plasma proteins; (2) tissue proteins; (3) cellular proteinases.[248–251]

Production of Bradykinin

Biosynthesis commences with the activation of Hageman factor (HF), or factor XII of the coagulation cascade (**Fig. 7.12**). HF is activated by exposure to anionic surfaces such as the basement membrane of injured endothelium, heparin, or lipid A of endotoxin. It can also be proteolytically cleaved and activated by kallikrein. Prekallikrein circulates complexed with HMWK, a nonenzymatic protein. Kininogen enhances the binding of prekallikrein to negatively charged surfaces. Activated HF converts prekallikrein to kallikrein, which in turn activates more HF in a positive feedback cycle. HFf, a cleavage product of activated HF, is also capable of activating prekallikrein. Kallikrein in plasma, tissues, and secretions specifically cleaves HMWK to release the nonapeptide bradykinin. In addition to bradykinin production, kallikrein participates in the activation of plasminogen and C1q of the complement system; yet another link between inflammation and the coagulation system. The only major plasma inhibitor of activated HF is C1 inhibitor. The primary inhibitors of kallikrein in plasma are C1 inhibitor and α_1 macroglobulin.[43,248]

Kinin Production in Tissue

Lysyl-bradykinin (kallidin) is the cleavage product of either HMWK or low–molecular-weight kininogen (LMWK) by tissue kallikreins, which are proteins distinct from their plasma counterparts. LMWK is present in higher concentrations intracellularly compared with HMWK. Whereas both HMWK and LMWK can be converted to lysyl-bradykinin by tissue kallikrein, only HMWK is cleaved by plasma kallikrein. Kallidin itself can be converted to bradykinin by a plasma aminopeptidase. Both kallidin and bradykinin use the same receptors and perform similar functions, but kallidin is approximately 85% as potent as bradykinin. Tissue kallikrein is synthesized from a

preproenzyme and is converted intracellularly to tissue prokallikrein by enzymes that are not yet well characterized. The secreted prokallikrein is then converted to tissue kallikrein extracellularly by plasmin or plasma kallikrein. The only significant inhibitor of tissue kallikreins is α_1-proteinase inhibitor.[43,248]

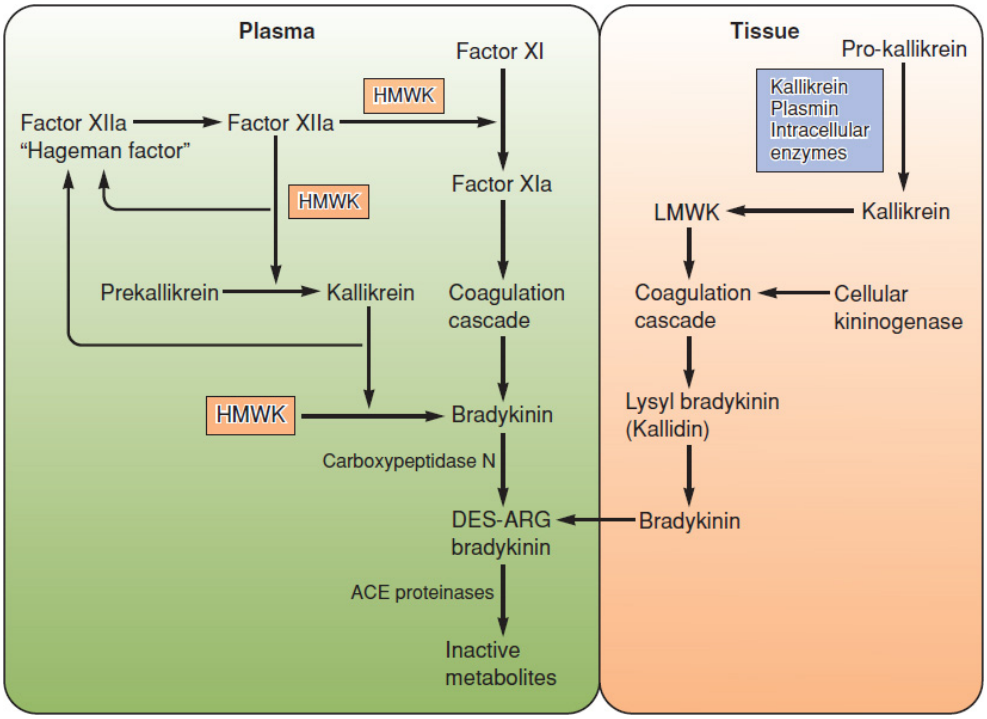

Figure 7.12 Kinin pathway. (Modified from Proud D, Kaplan AP. Kinin formation: mechanisms and role in inflammatory disorders. *Annu Rev Immun* 1988;6:49.)

Cellular Kininogenase Activity

Neutrophils, mast cells, and basophils are sources of kininogenase activity. Neutrophils produce leukokinins by way of cathepsin D. Their role in inflammation is unclear. Bradykinin is metabolized sequentially to the partially active eight-amino acid peptide, des-Arg-bradykinin, by carboxypeptidase N, and then to inactive five-amino acid and three-amino acid fragments by the angiotensin-converting enzyme (ACE). ACE is the predominant enzyme to inactivate bradykinin in the pulmonary vasculature. Arginine released as a byproduct of the carboxypeptidase N reaction may contribute further to the modulation of inflammation by acting as a substrate for the formation of NO.[43,248,252]

There are three kinin receptors, of which two are well characterized.[248,250] B1 receptors are expressed primarily on the vasculature under pathologic conditions such as tissue injury. They bind des-Arg-bradykinin and des-Arg-kallidin and mediate the hypotension characteristic of sepsis and pain.[248,253] Both B1 and the more widely distributed B2 receptors are G-protein–coupled receptors. Activation of B2 receptors stimulates IP and phospholipase C (PLC), resulting in the accumulation of the second messengers IP_3, DAG, and calcium. The B2 receptors are more important in mediating the effects of inflammatory kinins, such as bradykinin and lysyl-bradykinin. These kinins induce arteriolar dilatation and mediate pain. Similar to histamine, bradykinin increases the gaps between postcapillary venule endothelial cells leading to increase in vascular permeability. It is a potent constrictor of bronchial, uterine, and gastrointestinal smooth muscle, and the coronary and pulmonary vasculature.[250] Activation of endothelial B2 receptors stimulates production of NO to further enhance vasodilatation. Kinins have been implicated in mediating the antihypertensive and cardioprotective effects of ACE inhibitors.[254] ACE, in addition to catalyzing the formation of angiotensin II from angiotensin I, promotes the hydrolysis of bradykinin to inactive metabolites. In addition, bradykinin can modulate platelet function by stimulating endothelial cell secretion of PGI_2 and thromboxane through activation of PLA_2.[248]

Hereditary angioedema (HA) is an autosomal dominant disorder caused by a deficiency of C1 esterase inhibitor, which has a regulatory role in the classic complement pathway and in coagulation, fibrinolytic, and kallikrein–kinin cascades. The disease is characterized by recurrent attacks of angioedema of the skin, larynx, and gastrointestinal tract. Reduced activity of C1 esterase inhibitor results in an elevated plasma level of bradykinin, which has now been shown to be a key mediator of HA. The idiopathic angioedema due to ACE inhibitor therapy is hypothesized to involve a similar mechanism of elevated bradykinin concentration. Icatibant, a new bradykinin-recpetor antagonist was tested in a two-blind, randomized, multicenter trial (For Angioedema Subcutaneous Treatment—FAST 1 and 2 trials) in patients with HA presenting with cutaneous or abdominal attacks.[255] In FAST-2, the median time to first improvement of symptoms was

significantly shorter with icatibant compared to tranexamic acid: 2.0 versus 12.0 hours ($p < 0.001$).

Neuropeptides

Neuropeptides may provide a neuroendocrine link between psychological stress and inflammatory diseases such as psoriasis and inflammatory bowel disease. Like cytokines, their actions are pleiotropic and redundant. Neuropeptides execute their inflammatory and immunomodulatory effect by binding to specific G-protein–coupled receptors on the surfaces of target cells, and the resultant effect may be proinflammatory, anti-inflammatory, or both. For example, substance P mediates the hypothalamic fever response to PGE_2 induced by IL-1 and TNFα, whereas adrenocorticotropic hormone (ACTH), arginine vasopressin (AVP), and α-melanocyte–stimulating hormone (α-MSH) suppress it. The pituitary peptides prolactin, corticotropin-releasing hormone (CRH), and AVP have been shown to augment immune responses by enhancing T_H1 activity.[43,256,257]

Tachykinins are important proinflammatory neuropeptides that mediate pain and vasodilatation and promote the classic inflammatory signs of erythema and edema. Substance P stimulates monocyte and neutrophil influx and neutrophil phagocytosis. Its inflammatory effects appear to be mediated by the proinflammatory cytokines TNFα and IL-1 from mast cells, monocytes, macrophages, bone marrow, and endothelial cells. During allergic inflammation, substance P stimulates histamine release from mast cells. As an effector of immune function, substance P promotes T-cell proliferation and antibody production. Substance P released locally by nerve terminals is important in mediating the perception of pain.[43,248]

CRH induces the release of IL-1, IL-6, and superoxide anion from macrophages and negatively regulates its own proinflammatory effects through cortisol release. Cortisol downregulates production of proinflammatory cytokines such as IL-1, TNFα, and IL-2, metalloproteinases, and iNOS, and through this negative feedback loop, inhibits the production of CRH, ACTH, and AVP. AVP, growth hormone, and prolactin are other important proinflammatory neuropeptides.[43,256,257]

Vasoactive intestinal peptide (VIP) and its homologues display both proinflammatory and anti-inflammatory effects. VIP is widely distributed throughout the central and peripheral nervous systems and serves as a chemoattractant for macrophages, neutrophils, and T cells, and may play an important role in granulomatous reactions. VIP stimulates the release of histamine and IL-5 and is a potent vasodilator. It inhibits IL-6, TNFα, and IL-12 release and iNOS expression in activated macrophages. VIP has also been shown to stimulate the production of the anti-inflammatory cytokine IL-10 by macrophages and to inhibit T lymphocyte proliferation and the production IL-2 and IFNγ.[258]

Somatostatin and α-MSH are primarily anti-inflammatory in action. Somatostatin, which colocalizes with substance P in sensory nerves, inhibits IgE formation and NK cell activity, whereas α-MSH inhibits leukocyte chemotaxis, IFNγ production, and downregulates T_H1 activity. ACTH, calcitonin, and β endorphin are other neuropeptides with predominantly anti-inflammatory properties.[43]

Calcitonin gene-related peptide (CGRP) is an immunomodulator that inhibits the activity of T cells and macrophages, in part through the induction of IL-10. It also is an inhibitor of antigen presentation. CGRP promotes vasodilatation and neutrophil influx, and synergizes with bradykinin and histamine to promote edema formation.

Nitric Oxide (NO)

Endogenous NO was first discovered in 1987, and NO was the first gaseous molecule shown to be synthesized for the purpose of cell signaling.[259] NO is a weakly reactive radical that diffuses short distances from cell to cell independent of membrane channels or receptors. Its half-life is short because of its rapid inactivation by hemoglobin and other endogenous substances; thus, it functions primarily in a paracrine and autocrine fashion. The enzyme NO synthase (NOS) catalyzes the formation of NO and citrulline from the substrates L-arginine and oxygen.[67,260–262] NOS contains prosthetic groups for flavin-adenine dinucleotide, flavin mononucleotide, tetrahydrobiopterin, iron protoporphyrin IX, and zinc. Three isoforms of NOS have been identified. The calcium-dependent constitutive isoforms, neuronal NOS (nNOS) and endothelial NOS (eNOS), generate the small amounts of NO necessary for those processes maintaining physiologic homeostasis, such as neurotransmission and endothelial regulation of vascular tone. The expression of inducible NOS (iNOS), however, requires stimulation and produces larger, sustained amounts of NO that possess both cytoprotective and cytotoxic properties. This distinction is not absolute, as certain cell populations express low basal levels of iNOS, and constitutive NOS transcripts can be enhanced by certain stimuli such as shear stress and hypoxia.[67,260–262]

Many of the physiologic effects of NO are mediated by the activation of soluble guanylate cyclase. Increased levels of intracellular cyclic guanosine monophosphate trigger a reduction in calcium concentration and promote vascular smooth muscle relaxation and the inhibition of platelet aggregation and adhesion. The cellular response to NO also likely involves multiple signal transduction mechanisms, including the MAPK pathway.

Inflammation secondary to endotoxemia, hemorrhagic shock, and ischemia/reperfusion are associated with increased NO production by iNOS. First described in macrophages, iNOS can be expressed in essentially any cell type in response to immunologic stimuli. Unlike nNOS and eNOS, iNOS does not depend on elevations in intracellular calcium levels for its activity.[67,260–262] Important inducers of iNOS upregulation include LPS, IL-1, TNFα, and IFNγ. Expression is primarily transcriptionally regulated,

although stabilization of iNOS mRNA also appears to play a role. IFNγ stabilizes iNOS mRNA, whereas TGFβ can destabilize it. Transcription of the iNOS gene is controlled by NFκB, IFNγ-responsive element, and TNF-responsive element. Induction of iNOS can be inhibited by glucocorticoids, thrombin, macrophage deactivation factor, PDGF, IL-4, IL-8, IL-10, and IL-13.[67,260–262] Dexamethasone may inhibit iNOS induction by impairing the DNA-binding capacity of NFκB and by increasing levels of IκB.[263,264]

The endothelial dysfunction and vascular hyporeactivity that characterizes septic shock is consequential, in part, to iNOS production of NO.[265] NO has been shown to be the effective mediator of the negative myocardial inotropy of TNFα, IL-6, and IL-2 and the TNFα-induced vasodilatation in the systemic and microcirculations.[266] NO may indirectly increase prostaglandin production by increasing the catalytic activity of cyclooxygenase and decrease leukotriene production by inhibiting 5-lipoxygenase.[267] NO plays an autoregulatory role in the T_H1 subset of T_H cells by limiting their own proliferation.[268]

NO can mediate tissue injury in inflammation by modulating organ perfusion, mediating interactions with neutrophils, contributing to proinflammatory signaling, and by regulating apoptosis.[269] Whereas eNOS primarily regulates perfusion during homeostasis, both eNOS and iNOS modulate organ flow in pathophysiologic states. Basal NO production from eNOS prevents the adherence of neutrophils to the endothelium and inhibits chemotaxis under physiologic conditions. Animal studies have demonstrated that pharmacologic inhibition of iNOS or genetic deletion of iNOS attenuates neutrophil accumulation in organs after ischemia/reperfusion injury.[270] Conversely, similar experiments in endotoxemia implicate an antiadhesive role for iNOS, suggesting that the effect of induced NO on neutrophil accumulation is insult specific.[269] Activated neutrophils can be stimulated by fMLP, PAF, LTB_4 to produce NO. NO produced by neutrophils at sites of inflammation can combine with superoxide to form peroxynitrite as another means of effecting toxicity.[43,271]

The reaction of NO with superoxide is the only reaction that outcompetes the reaction of superoxide with superoxide dismutase. Small amounts of peroxynitrite are produced under basal conditions from constitutively produced NO and superoxide from mitochondria and other cellular sources.

However, endogenous antioxidants such as GSH, vitamins E and C, and superoxide dismutase likely limit its toxicity. A low concentration of peroxynitrite has been shown to inhibit neutrophil adhesion. Higher concentrations of peroxynitrite can initiate a wide range of toxic oxidative reactions through a peroxynitrous acid intermediate. These include the initiation of tyrosine nitration, lipid peroxidation, and direct inhibition of mitochondrial respiratory enzymes. The balance between superoxide and NO determines the reactivity of peroxynitrite; excess NO reduces the oxidation elicited by peroxynitrite. In addition, peroxynitrite may contribute to cytotoxicity by a more indirect pathway. Peroxynitrite-induced single strand breaks in DNA activate the nuclear enzyme poly (ADP-ribose) synthetase, leading eventually to irreversible energy depletion of the cells and necrotic-type cell death.[43,45]

iNOS plays a key role in host defense, with NO or peroxynitrite-exhibiting potent antimicrobial activity against a number of pathogens including viruses, fungi, and bacteria. Although microbicidal susceptibility to NO-mediated killing can vary considerably between species, essential roles have been identified in tuberculosis and bacterial peritonitis.[272] Induced NO has been shown to be essential for the upregulation of the inflammatory response in hemorrhage shock and other inflammatory processes. NO produced by iNOS leads to the activation of NFκB.[273] This is followed by the induction of proinflammatory cytokines and increased leukocyte recruitment and activation.

NO possesses both pro- and antiapoptotic effects depending upon the circumstances. NO derived from eNOS may inhibit apoptosis.[274] Proapoptotic effects appear to be associated with pathophysiologic conditions in which iNOS is upregulated. Low concentrations of peroxynitrite have also been shown to induce apoptosis, whereas higher concentrations promote cell necrosis in vitro. The role of NO-mediated apoptosis in the regulation of the inflammatory response is yet to be more clearly defined.

NO, typically delivered by inhalation, has been subjected to intense investigation for clinical efficacy in a variety of diseases: pulmonary embolism, ARDS, and sick cell pain crisis.[275–277] It has even been added to the cardiopulmonary bypass circuit to provide myocardial protection during cardiac surgery.[278] No study, however, provides definitive data to support

clinical efficacy, and thus, NO as a therapeutic has not been widely incorporated into clinical care.

In summary, NO mediates tissue injury both directly through the formation of peroxynitrite, as well as, indirectly through the amplification of the inflammatory process. Like many mediators, NO has dual regulatory functions, and it is therefore difficult to characterize NO as distinctly pro- or anti-inflammatory. In general, basal levels of NO produced by constitutive NOS may confer anti-inflammatory effects, whereas induced NO may tend to promote the upregulation of the inflammatory response. It is likely that an optimal level of NO is necessary in host defense; too little NO may be as harmful as too much.

Heme Oxygenase (HO)

HO catalyzes the breakdown of heme to iron, biliverdin, and carbon monoxide (CO).[279] Three isoforms of HO have been identified. HO-2 is constitutively expressed in many tissues, whereas HO-3 expression appears to be limited to the brain. HO-1 is not expressed constitutively in most tissues, but is rapidly upregulated by both heme and nonheme cellular stresses, including hypoxia, redox stress, and inflammation. Additionally, NO is a potent inducer of HO-1. HO-1 has profound antiapoptotic and anti-inflammatory effects. These cytoprotective effects have been attributed to the individual catalytic products of heme metabolism. Biliverdin is converted to bilirubin by biliverdin reductase, and bilirubin has been demonstrated to act as a potent intracellular antioxidant. CO alone can mimic many of the actions of HO-1 and has been shown to protect in models of sepsis, hemorrhagic shock, and ischemia/reperfusion when administered as an inhaled gas. The mechanism of action of CO has both similarities and dissimilarities with NO, and is an area of active investigation.[279]

Hydrogen Sulfide

Hydrogen sulfide (H_2S) is a colorless, flammable gas, with the typically malodor of putrid eggs. It is highly lipophilic and freely penetrates the cell wall, which greatly facilitates its biologic activity.[280] Recent evidence

highlights the widespread distribution of H_2S in the plasma, brain, and other tissues. H_2S is formed in mammalian cells largely by the activity of two pyridoxal phosphate-dependent enzymes, cystathione γ lyase (CSE) and cystathionine β synthetase (CBS) that utilize cysteine and homocysteine to form H_2S.[281] Large amounts of these enzymes occur in the brain (CBS), liver (CSE), kidney (CSE), and blood vessels (CSE). Interestingly, lipopolysaccharide exposure induces the expression of CSE, suggesting that H_2S may regulate inflammation.[280] Both pro- and anti-inflammatory actions have been described. H_2S levels and CSE expression are increased in animal models of endotoxemia, sepsis, and hemorrhagic shock.[280,282,283] It has been shown to increase leukocyte attachment and rolling in jejunal blood vessels and to increase ICAM-1 expression.[284] In human monocytes, H_2S donors induce the formation of proinflammatory cytokines and chemokines via an NFκB mechanism.[285] Inhibitors of CSE reduce the inflammation in these animal models of sepsis and hemorrhage. By contrast, H_2S decreases LPS-induced upregulation of NFκB in RAW 264.7 macrophages, and H_2S-releasing derivatives of diclofenac exhibit greater anti-inflammatory activity in endotoxic shock.[280,281,286]

RECOGNITION AND ACTIVATION PROCESSES

Exogenous and Endogenous Danger Recognition

Multicellular organisms have evolved an essential mechanism of surveillance, defense, and repair of injured cells. Implicit with this system is the ability to differentiate pathogens and damaged cells from self. The initial response is orchestrated by the evolutionarily ancient and more universal innate immune system, which employs monoclonal sets of recognition molecules called PRRs.[287,288] PRRs bind conserved molecular structures found in large groups of pathogens, termed PAMPs. PAMPs are a diverse set of microbial molecules, which share a number of different recognizable

biochemical features that alert the organism to intruding pathogens.[287–289] These PAMPs are recognized by cells of innate and acquired immunity, primarily through the toll-like PRRs. Activation induces several signaling pathways, most notably NFκB.[287,289] Consequent to this activation, an immune response is triggered to destroy the pathogen and/or pathogen-infected cells, and an adaptive response is initiated to select pathogen-specific T cells and antibodies for future occasions.

However, pathogens are not the only causative agents of tissue and cell damage. Cells, and thus tissues, can be injured by various noxious insults: heat, cold, chemicals, radiation, ischemia, or direct mechanical injuries. Evolution has enabled us to deal with these damages, which though not caused by pathogens, still necessitate repair. It is becoming apparent that specific receptors exist by which to recognize extrinsic threats (i.e., pathogen) and intrinsic altered self (cytokines, oxidized mitochondrial DNA, HSPs, and uric acid).[289]

Damage-Associated Molecular Patterns (DAMPs)

DAMPs, the endogenous equivalent of PAMPs, represent danger signals or "alarmins" and share many characteristics similar to cytokines.[289] DAMPs may be released following nonprogrammed cell death, such as necrosis, and under such circumstances tend to elicit inflammation. By contrast, programmed cell death (i.e., apoptosis) incorporates mechanisms such as acetylation, to minimize the release of these mediators and any subsequent inflammatory response. Cells of the immune system also can be induced to secrete these mediators.[289] This secretion may occur by specialized secretion systems or by the classical ER-Golgi secretion pathway.[289] Under these circumstances, DAMPs may facilitate the inflammatory response by aiding the recruitment of innate immune cells, most notably DC. In doing so, they indirectly orchestrate the subsequent adaptive immune response and facilitate tissue repair.[289] The prototypical alarmin, HMGB1, has already been discussed.

S100 Proteins

The family of S100 proteins incorporates over 20 related calcium-binding proteins.[289] S100A8 and S100A9 form heterocomplexes in the cytosol of granulocytes, monocytes, and macrophages, whereas S100A12 exists as homodimers in the cytoplasm of granulocytes. S100 proteins are actively secreted at sites of inflammation via a nonclassical pathway. The receptors mediating their effects are still being defined, though it appears that S100A12 and S100B interact with RAGE, whereas S100A8/9 may interact with TLR receptors. S100 proteins have been shown to induce increased vascular permeability and a prothrombotic effect. Recent studies implicate S100 proteins in the pathogenesis of autoimmune arthritis and psoriasis.[289]

Uric Acid

Uric acid is released after cellular injury, and upon exposure to the extracellular environment, precipitates to form monosodium urate (MSU).[289] Uric acid stimulates dendritic maturation and, when coinjected with antigen in vivo, significantly enhances the generation of responses from $CD8^+$ T cells.[289] It has significant proinflammatory properties that are best evidenced in the disease gout, in which uric acid accumulates in tissues and induces inflammation-dependent arthritis. MSU crystals engage the inflammasome, resulting in the production of IL-1β and IL-18.[289] Macrophages from mice deficient in IL-1R or in various components of the inflammasome, such as caspase-1, ASC, and NALP3 are defective in MSU-induced cytokine secretion and have reduced inflammation.[289] Extracellular uric acid is eliminated by uricase.[289]

Mitochondrial DAMPs (MTDs)

The concept of circulating mitochondrial DAMPs, in particular mitochondrial DNA, as an etiology of inflammatory responses was definitively established over a decade ago, when investigators observed that mitochondrial DAMPs (MTDs) were released in consequence to tissue and injury. By signaling through innate immune pathways identical to those activated in sepsis MTDs could recapitulate a “sepsis-like” state.[290] Since then an explosive amount of investigation has defined a role for MTDs in the pathologic sequelae of additional diseases: tumor microenvironment, inflammation and biology; cardiac complications postcardiopulmonary

bypass surgery; liver inflammation and oxidative stress; and chronic neuroinflammation.[291–293] Subsequent studies have identified pattern recognize receptors, notably TLR 9, as the cognate receptor. Studies are underway to determine the clinical ramifications of scavenging circulating mitochondrial DNA as a potential therapeutic for systemic inflammation and multiple organ dysfunction.[294]

Receptors for Danger Recognition

10 Innate immunity is not antigen specific, but rather programmed to respond to groups of evolutionarily conserved macromolecules that represent "patterns of danger" and signal a potential threat to the host. PRRs identify these pathogen-associated molecular patterns (PAMPs) and include the TLRs and NOD-like receptors. Recent studies highlight the promiscuity of these PRRs in also recognizing and mediating DAMP-dependent signaling. In fact, multiple positive feedback loops between DAMPs and PAMPs and their overlapping receptors may represent the molecular basis for the observation that infections, as well as, nonspecific stress factors, can trigger flares of autoimmune diseases (i.e., rheumatic).[195] Additional, novel receptors have subsequently been identified and designated PRRs, including RAGE.[288,289]

CD14

The prototypical receptor identifying external infectious threat (i.e., gram-negative infection) is CD14. CD14 was identified as the LPS receptor when transfection of CD14-negative CHO cells with CD14 conferred responsiveness to LPS.[295] Its critical role in LPS recognition is underscored by the LPS-hyporesponsive phenotype of CD14-deficient mice. It has been identified on cells of the myeloid lineage, B cells, liver parenchymal cells, and fibroblasts. Differential expression is observed; ranging from high levels on peritoneal and pleural macrophages to lower levels on Kupffer cells, alveolar macrophages, monocytes, and PMN. Expression may be modified; human PMNs express low levels of CD14 that is upregulated by TNFα, G-CSF, GM-CSF, and fMLP. Prototypically, CD14 binds LPS bound to LPS-binding protein (LBP) in combination with MD-2 and presents it to TLR4.[295] MD-2 is required for cellular responsiveness to LPS, as demonstrated by

both transfection studies and an analysis of a CHO cell line with mutated MD-2 gene. Most of the available evidence indicates that a complex of TLR4/MD-2/CD14 directly binds LPS.[295] CD14 is also important in TLR2 signaling, whereby it presents bacterial products other than LPS.

Toll-Like Receptors (TLRs)

CD14 is a glycosylphosphatidylinositol-linked receptor devoid of any transmembrane domain. This, in combination with the identification of a soluble form of CD14, necessitated identifying the manner by which LPS induced activation.[296] In 1996, the toll protein in Drosophila was shown to be necessary for an effective immune response to the fungus *Aspergillus fumigatus*.[287] In 1998, Poltorak et al. discovered that the *lps* gene in LPS-hyporesponsive C3H/HEJ mice encoded a murine member of the TLR family. These data provided the initial evidence that mammalian TLRs function as PRRs.[297] Subsequent studies have confirmed that TLR4 is the "LPS receptor" and that it is essential for the defense against gram-negative microorganisms.[295]

Thirteen mammalian TLR receptors have been characterized in humans and mice. Each recognizes a specific set of conserved microbial molecules, and as a family, they can detect most microbes.[295] Interestingly, the subcellular localization of different TLRs correlates to some extent with the molecular patterns of their ligands and their function.[298] TLR1, TLR2, and TLR4 are located on the cell surface and are recruited to phagosomes after activation by their respective ligands. They are the receptors mediating the response to exogenous insults including bacterial infection and trauma. By contrast, TLR3, TLR7, and TLR9, all of which are involved in the recognition of nucleic-acid like structures (i.e., viral DNA), are expressed intracellularly.[287,299]

TLR4 is required for the innate response to gram-negative organisms and LPS, though other TLR, such as TLR2, can also recognize and mediate this response.[288] TLR4 has been shown to trigger the response to additional ligands, including lipoteichoic acid (LTA) and peptidoglycans from gram-positive bacteria and the fusion protein of the respiratory syncytial virus.[300] Polymorphisms in the receptor confer variability in function. Individuals with the D299G polymorphism in TLR4 demonstrate increased risk of gram-

negative infections, and other studies have linked this with an increased incidence of SIRS.[301] In addition, this polymorphism has been associated with alterations in the susceptibility to other inflammatory and potentially infectious processes (carotid artery atherosclerosis, coronary artery disease).[301] HSP60 of Chlamydial origin has been found in atherosclerotic plaques and can bind TLR4. Perhaps recognition of HSP60 by human TLR4 might exacerbate the inflammatory component of atherosclerosis, whereas people with the D299G polymorphism might be at least partly protected from this exacerbation.[301] TLR4 has been well characterized as a PRR for DAMPs, including HSPs (HSP60, HSP70, gp96), hyaluronate, heparan sulfate, and other matrix proteins. Because of its ability to recognize endogenous proteins, TLR4 is implicated in a variety of diseases, including arthritis and atherosclerosis.[195,299] Eritoran is a synthetic lipid A antagonist that blocks lipopolysaccharide from binding at the cell surface MD2-TLR4 receptor. Despite TLR4 possessing such a fundamental vantage point in immune signaling, the randomized, double-blind, placebo-controlled multinational phase 3 trial ACCESS did not observe a benefit in the treatment of patients with severe sepsis.[302]

TLR2 recognizes lipoproteins derived from the cell wall of bacteria such as *Treponema pallidum* and *Mycoplasma fermentas*, LTA from gram-positive bacteria (i.e., *Streptococcal* sp.), lipopeptides, LPS and lipid A.[288,299,300] It also can recognize a host of DAMPs, including the HSPs, fibronectin, fibrinogen, heparan sulfate, and hyaluronate. Recent data suggest that TLR2 forms heterodimers with other TLR, including TLR1 or TLR6 to recognize these DAMPs. A likely consequence of this cooperation is an increased repertoire of ligand specificities. The R753Q polymorphism in the TLR2 is associated with decreased response to these bacteria and may increase susceptibility to staphylococcal infections or tuberculosis.[299,301]

Additional TLRs involved in inflammation include TLR9, which recognizes unmethylated CpG motifs present in bacterial DNA; most of the host mammalian genome is methylated. TLR9–ligand engagement occurs intracellularly, in either endosomes or lysosomes, presumably following bacterial lysis. Data support that TLR9 recognizes host DNA released by dead or dying cells and may participate in autoimmune diseases such as SLE.[287] Immunotherapy with a TLR9 vaccine consisting of AMB a 1, a ragweed-pollen antigen, conjugated to a phosphorothioate

oligodeoxyribonucleotide immuostimulatory sequence of DNA appeared to offer long-term clinical efficacy in the treatment of ragweed allergic rhinitis.[303] TLR7 is of particular relevance for respiratory allergies. TLR7 polymorphisms have been strongly linked with susceptibility to asthma and other atopic disorders.[304] TLR7 agonists effectively prevent T_H2-mediated airway disease in animal models. A recent randomized, double-blind, placebo-controlled trial concluded that a novel selective TLR7 agonist (GSK2245035) reduced allergic reactivity to nasal challenge in a cohort of patients with allergic rhinitis.[304] Similar observations were reported in studies of TLR8 and TLR9 agonists.[305,306] TLR5 recognizes flagellin of bacterial flagella.[307] TLR3 recognizes double-stranded RNA of both viral and endogenous sources. Because of the later characteristic, TLR3 has been implicated in autoimmune arthritis. A recent trial tested the efficacy of TLR3 receptor blockade with CNTO3157, an inhibitory monoclonal antibody, in rhinovirus-induced experimental asthma exacerbations in healthy subjects and patients with mild-to-moderate stable asthma. The investigators concluded that CNTO3157 is ineffective in attenuating the effect on lung function, asthma control, and symptoms in patients.[308]

TLRs induce signal transduction via their cytoplasmic toll-interleukin-1 receptor (TIR) domains that promotes the subsequent expression of a variety of host defense genes. These include inflammatory cytokines and chemokines, antimicrobial peptides, costimulatory molecules, MHC molecules, and other effectors. A considerable portion of the functional response is mediated by activating intracellular signaling pathways that culminate in the induction of the transcription factor NFκB. Specifically, the CD14/MD-2/TLR4 complex, upon engagement with LPS-LBP recruits the adaptor protein MyD88, which engages the serine/threonine kinase IRAK. IRAK undergoes autophosphorylation and recruits TRAF6. Ultimately, activated IκK phosphorylates and targets for degradation the NFκB inhibitor IκB, which enables the nuclear translocation of NFκB and transcription of inflammatory genes. AP-1 and members of the MAPK transduction cascade are also activated by this mechanism. This pathway is critical to the production of IL-12, TNFα, and IL-6. All TLRs signal through this conserved signaling cascade, and for some MyD88 (TLRs 2, 6, 9) is their sole receptor-proximal

adaptor. For instance, MyD88 is essential for clearance of *S. aureus* a gram-positive bacteria, which signal through TLRs 2, 6, 9.[287,288,300]

Subsequent studies utilizing MyD88-deficient mice suggested that alternate TLR pathways existed. These mice, in response to many TLR ligands, including peptidoglycan and unmethylated CpG motifs, did not activate NFκB or MAPK. Surprisingly, however, LPS could still activate NFκB and MAPK, though in a delayed fashion. Subsequently, a MyD88-independent pathway has been characterized that is utilized by TLR4 and utilizes a distinct adaptor protein called TIR domain-containing adaptor protein TIRAP or Mal. A dominant negative mutant of TIRAP specifically impairs TLR4- and TLR2- but not IL-1R or TLR9-induced NFκB, indicating a specificity of TIRAP for the TLR4 pathway. A third TIR-containing adaptor molecule, TIR-domain containing adaptor inducing IFN-β (TRIF) also appears to mediate a MyD88-independent pathway.[287,288,300]

Most of this research has occurred in the realm of sepsis and provided insight into the manner by which organisms identify infectious threats and activate the inflammatory pathway to preserve the host. However, several circumstances of sterile inflammation suggest a role of the TLRs in mediating inflammation in response to endogenous danger signals (uric acid, mitochondrial DNA, HMGB1).[295] Hepatocellular injury consequent to ischemia/reperfusion (I/R) has been shown to be dependent on TLR4.[36]

RAGE

RAGE is an immunoglobulin superfamily molecule that belongs to the multiligand receptors that recognize families of ligands rather than a single polypeptide.[135,289,309,310] It has a single transmembrane spanning domain and a highly charged cytoplasmic tail that though lacking known signaling motifs, is critical for cellular activation. Though RAGE knockout mice are viable and fertile, they display a wide range of defects. Most of these defects are subtler than expected, leading to the suggestion that other receptors with overlapping function might exist. Signaling appears to necessitate clustering into a particular orientation, which facilitates binding of cytosolic-signaling complexes.[135,309] Its ligands include products of nonenzymatic glycosidation (e.g., advanced glycation endproducts or AGEs), the amyloid-β precursor protein, the S100/calgranulin family of proinflammatory cytokine-like

mediators, and the high mobility group 1 DNA-binding proteins (HMGB-1). Its expression is upregulated at sites of diverse pathologies including atherosclerosis and Alzheimer disease. In fact, RAGE-mediated cellular stimulation is thought to increase expression of the receptor itself, thereby generating a positive feedback mechanism and perpetuating the proinflammatory state.[135,309,310]

Recent studies demonstrate the activation of multiple signal transduction cascades subsequent to ligand binding, including the family of MAPKs (p38, ERK 1/2, and JNK) and the rho GTPases (cdc42 and rac).[310] Like TLRs and IL-1R, RAGE engagement leads to NFκB activation, suggesting that both receptor usage and signaling pathways evoke similar responses when cells are activated by PAMPs and DAMPs. It is currently hypothesized that RAGE–ligand interaction induces a new heightened basal state of activation. With a superimposed stimulus, cellular perturbation is magnified. Rather than returning to homeostasis, cellular signal transduction mechanisms favor augmented dysfunction.[135,309]

Studies have implicated RAGE to be an important receptor during various acute and chronic inflammatory processes, including tumor biology. RAGE expression and function directly correlated with tumor growth in RAGE-transfected C6 glioma cells. In a murine tumor model, mice treated with soluble RAGE, which functions as a decoy, exhibited a reduction in lung metastases, cellular invasion, and expression of matrix metalloproteinases.[310]

RAGE has also been identified as a receptor for S100A12, a member of the S100/calgranulin family of proinflammatory mediators. Endothelial cells cultured with S100A12 displayed RAGE-dependent expression of VCAM-1 and tissue factor. Mononuclear phagocytes displayed S100A12-RAGE chemotaxis, expression of tissue factor, and elaborated IL-1 and TNFα. In vivo studies of delayed-type hypersensitivity demonstrated reduced inflammatory response when mice were treated with anti-RAGE F(ab')2, anti-S100 F(ab')2, or soluble RAGE. Treated animals also displayed reduced NFκB activation and IL-1 and TNFα expression.[310]

The angiopathy of diabetes is thought to be consequent to inflammatory processes generated by elevated glucose concentrations. Hyperglycemia has been demonstrated to activate numerous signaling cascades. One process that might mediate these effects is through the nonenzymatic formation of

advanced glycation endproducts AGEs.[135,309,310] AGE–RAGE interactions on endothelium lead to the expression of procoagulant tissue factor and VCAM-1 and macrophages released tissue factor. Animals treated with soluble RAGE showed decreases in atherosclerotic lesion area and number and a marked reduction in lesion complexity. Also, treated animals had reduced expression of adhesion molecules, tissue factor, MCP-1, and matrix metalloproteinases.[135,309,310]

CD91

The immunologic properties of HSPs were discovered by their ability to elicit antitumor immunity. It was later discovered that this antigenic specificity was determined by the peptides they chaperoned. APCs can bind and internalize HSP–peptide complexes derived from virus-infected cells or tumors and represent them on major histocompatibility MHC class I molecules. In addition, APC engagement of HSP–peptide complexes induces maturation, the expression of costimulatory molecules, and the induction and release of cytokines (TNFα, IL-1, IL-12, IL-6, GM-CSF, MIP-1, RANTES, and NO).[311,312]

CD91 had been identified as a receptor for the serum protein α_2 macroglobulin, a natural protease inhibitor that like HSPs is found across many species. In fact, α_2 macroglobulin is the evolutionary precursor of the C3 complement component. By binding pathogen proteases utilized during invasion and shuttling them for endocytosis, α_2 macroglobulin hinders pathogen invasion.[311,313]

However, such a method of host defense would be ineffective for intracellular pathogens that gain access by alternative means, such as mimicking host proteins and developing ligands for host receptors. Hence, another method of signaling danger is necessary. It is currently thought that upon cell death, HSPs contained within the cell transfer information regarding the infected intracellular environment to CD91. This large cell surface receptor, complexed with the HSPs, is internalized and delivers antigen to the classical MHC class I pathway. The MHCs bind and present them to $CD8^+$ T cells. On recognizing nonself, T cells are induced to proliferate and mediate killing. This mechanism could be generalized to

implicate CD91 and HSP interactions in the recognition of all cellular stress that culminates in injury and death.[313]

CD91 was first identified by Binder et al. as the receptor for gp96 and then by Basu as a common receptor for other HSPs (HSP70, HSP90, and calreticulin).[314,315] This large multidomain 600-kD protein possesses multiple binding sites for at least 32 ligands. The binding of this receptor to many members of the HSP family has been corroborated by several independent functional and structural studies.[313]

Several in vivo studies suggest a physiologic relevance for HSP–CD91 interaction. Mice immunized with tumor-derived gp96–peptide complexes reject a subsequent tumor challenge. If CD91 antiserum is mixed with the HSP–peptide inoculum, the mice fail to reject the tumors. Srivastava et al. noted that blocking of CD91 completely inhibits the phenomenon of re-presentation of peptides that are carried or chaperoned by HSPs, suggesting that not only is CD91 a receptor for HSPs, but it may also be the sole receptor involved in antigen representing.[312,315]

HSPs have been shown to chaperone antigenic peptides (tumor, viral, minor histocompatibility antigens) from all cellular compartments. The family of HSPs thus appears to be a universal mechanism for antigen capture, and they permit a high-efficiency antigen uptake through a receptor-mediated mechanism.

Evidence that HSP–peptide–CD91 interactions serve to signal cellular stress is beginning to culminate. Basu et al. demonstrate that HSP70, HSP90, gp96, and calreticulin are released from cells as a result of necrotic cell death, but not apoptotic cell death.[314] Similarly, Melcher reported that tumor cells undergoing necrotic death are highly immunogenic as compared to those undergoing apoptotic death.[316] Actual necrosis may be unnecessary as stressed cells and cancer cells have been reported to express cell surface HSP molecules, which may activate APCs. Li et al. observed that physical contact of tumor cells artificially engineered to express cell surface HSPs with immature DCs elicits a powerful maturation of DCs.[317]

Other HSP Receptors

CD40 was reported as a receptor for HSP70 when anti-CD40 antibodies were observed to inhibit macrophage chemokine secretion in response to

mycobacterial HSP70. Subsequently, Becker noted the association of recombinant GST-tagged CD40 with murine HSP70.[318,319] They further demonstrated enhanced binding after the APCs were stimulated with LPS. As LPS induces expression of a number of cell surface molecules, the authors concluded that CD40 mediates recognition and binding of HSP70.[320]

CD36 has been implicated as a receptor for gp96. Transfection of CD36 into CD36-negative cells has been shown to enhance gp96 binding. In addition, $CD36^{-/-}$ macrophages have a 52% reduction in gp96 binding compared with wild-type controls, suggesting that some role for CD36 as an HSP receptor.[320]

LOX-1, a member of the same scavenger superfamily as CD91 and CD36 has been postulated to be an additional receptor for endocytic uptake of HSP70 and chaperoned peptides by human DCs. Anti–LOX-1 antibodies and LOX-1 ligand-acetylated albumin competed with HSP70 for binding to DCs.[156]

Both TLRs and CD14 have been implicated as receptors for HSPs, such as HSP70.[321] HSP70 stimulates macrophage IL-12p40 production that is partially abrogated by inhibiting downstream TlR-signaling cascades. In addition, human HSP60–activated NFκB and TNFα production by 293 T cells transfected with either TLR-2 or TLR-4 and MD-2.[322] HSP60 also activated JNK kinase and IKK kinase signaling and TNFα production by macrophages, an effect that was partially eliminated by knocking out MyD88 or TRAF6. Similar functional studies have proposed that CD14 might serve as an HSP70 receptor in APCs. All of these studies heavily suggest a role of TLRs or CD14 in HSP binding, although several investigators call into question the potential for contamination with LPS to be mediating much of these effects.[320]

AUTOPHAGY

Autophagy is an ancient cytoplasmic homeostatic process governing cellular biomass quantity, quality, and distribution through the recycling of cytoplasmic proteins and organelles to support vital functions during periods of stress (i.e., starvation).[323,324] It literally originates from the Greek words *auto* meaning "self" and *phagein* meaning "to eat." Fundamental for

embryologic development and survival, it integrates extensively with apoptosis and may itself function as a form of programmed (type II) cell death.[324–326] Hence, it is not surprising that it is preserved in all eukaryotic organisms, from yeast to humans.

Macroautophagy is coordinated by specialized autophagy-related proteins (ATGs) that sequester large protein aggregates, dysfunctional organelles, and even microorganisms and target them for lysosomal degradation. In the setting of nutrient deprivation, the mechanisms orchestrating this dynamic process involve the main growth rheostat mammalian target of rapamycin (mTOR) and adenosine monophosphate (AMP) kinase, a sensor of cellular energy status.[324,327–332] Prototypically, AMP kinase, sensing-reduced cellular energy (i.e., elevated AMP) inhibits mTOR, a negative regulator of autophagy, thereby inducing autophagy.[327,332–334]

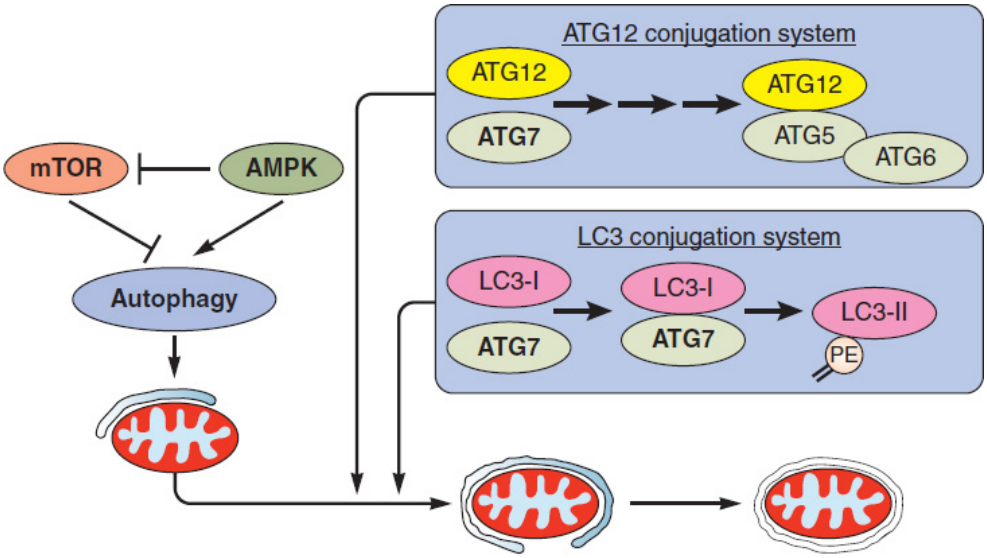

Figure 7.13 Autophagy/mitophagy. Autophagy is inhibited by the metabolic growth rheostat mTOR that inhibits autophagy when ATP and nutrients are plentiful. Sepsis and metabolic stress lead to inhibition of mTOR and initiation of the isolation membrane. Atg12-ATG5-Atg16L and LC3-II localize to the phagophore to capture selected targets for degradation. Upon completion of autophagosome formation, the Atg12-Atg5-Atg16L complex dissociates while LC3-II remains on it. The autophagosome ultimately fuses with the lysosome to form an autolysosome, where its contents are degraded.

Autophagy is initiated by complex formation of ULK1 and ULK2, the class III phosphatidylinositol-3-phosphate kinase VPS34, and ATG14-like protein, ATG14L. This initiates the ATG conjugation cascade in which ATG5 and

ATG12 complex with ATG16L1 to form an isolation membrane around the target (**Fig. 7.13**). The complex facilitates the addition of a phosphatidylethanolamine group to LC3-1 to form LC3-II. LC3-II together with other factors leads to elongation and closure of the autophagosome, which is then targeted for fusion with the lysosome, forming the autolysosome (**Fig. 7.13**).

Though the quintessential function of autophagy is to digest and recycle portions of the cytoplasm during starvation, it has recently been described as an important effector arm of immune cells responding to exogenous (i.e., PAMP: LPS)[335,336] and endogenous (DAMP: HMGB1) stimuli.[323,333,336–340] It is proposed that competition with microorganisms for nutrients, and thus nutrient deprivation, may have served as a sign of invading organisms and thereby supported the emergence of eukaryotic autophagic mechanisms of pathogen elimination. However, a host of other PAMPs and DAMPs and mediators may induce autophagy. In Mϕ, LPS induces autophagy through mechanisms dependent on TLR4, TRIF, RIP1, and p38 MAPK.[335,341] Cytosolic pathogens, such as viruses, can induce autophagy, or rather xenophagy. DAMPs, such as DNA, ATP, and HMGB1 may also induce autophagy, the later through RAGE. The induction of autophagy by the inflammatory cytokine IL-1β is critical for control of *M. tuberculosis*. Similarly, TNFα stimulates autophagy in restricting intracellular bacteria. By contrast, T_H2 cytokines such as IL-4 and IL-13 and NO inhibit autophagy.

During innate immunity, autophagy has been shown to be important in the elimination of intracellular microbes, through LC3-associated phagocytosis and xenophagy. This latter process of selectively degrading intracellular pathogens, involves sequestosome 1-like receptors (SLRs) that recognize molecular motifs on invading pathogens. These SLRs help to clear microorganisms that gain entry to the cytoplasm if they escape the defenses that are controlled by conventional PRRs. Microbial polymers, such as DNA, that are present in the cytoplasm might function as autophagy-inducing PAMPs, as in the case of *M. tuberculosis* infections. The critical importance of autophagy to cell survival is also supported by the defenses several microbes (Listeria, Shigella, Legionella) exhibit to combat the autophagy machinery.

Autophagy can assist PRRs by delivering cytosolic PAMPs to endosomal TLRs (i.e., TLR7) and stimulate their activity.[342–344] Nucleic acid receptors called RIG (retinoic acid inducible gene)-I–like receptors (RLRs) recognize viral RNA, and induce the production of type I IFN to thwart viral invasion. The interaction between TLRs and autophagy may also serve to augment antigen presentation by DCs.

Autophagy limits the activation of the inflammasome, a cytoplasmic complex that responds to PAMPs and DAMPs by inducing the proteolytic processing and secretion of IL-1β and IL-18. It does so by clearing the cytoplasm of debris, such as damaged or depolarized mitochondria that can function as endogenous agonists. Inhibition of autophagy leads to the release of the products, such as mitochondrial DNA and ROS.[342–344] Autophagy also affects the secretion of pro- and anti-inflammatory mediators. In senescent cells, it regulates the secretion of IL-6 and IL-8. It reduces immunoglobulin secretion from plasma cells, and thus, may be important in negatively regulating antibody production.

During adaptive immunity, autophagy contributes to MHC class II presentation. Classically this is described in the context of presenting cytoplasmic antigen (e.g., virus or self-antigen) to endosomal receptors, such as TLR7 (*supra vide*). Thus, autophagy is implicated in autoimmune disorders, such as autoimmune colitis and Crohn disease. The link between autophagy and inflammatory diseases has also been reported. Polymorphisms in ATG16L1 and IRGM are linked to Crohn disease. IRGM polymorphisms may be a risk factor for SLE, and rheumatoid arthritis has been associated with variations in the ATG5 gene. In summary, autophagy influences adaptive immune responses through its effects of antigen presentation, naïve T-cell repertoire selection, T-cell homeostasis, and T_H cell polarization.[342–344]

Interestingly, nonimmune cells, such as hepatocytes and renal tubular cells also exhibit TLR signaling and respond to the stress of sepsis or lipopolysaccharide by inducing autophagy.[36,338,345–348] Studies suggest that these mechanisms are similarly induced in vivo in the early response to sepsis, and regulate bronchoalveolar cytokine/chemokine production and neutrophil accumulation. Others have shown that sepsis induces similar AMPK- and mTOR-dependent mechanisms of autophagy in the Mφ, kidney, and liver.[341,345,349–351] This mechanism may be critically important for cell

survival, as it has been shown that augmenting mTOR- or AMPK-dependent autophagy during CLP sepsis attenuates mitochondrial injury and reduces AKI (**Fig. 7.7**).[348] In summary, recent data support a fundamental role of autophagy in nearly every arm of immunity as an antimicrobial effector of TLRs.[326,338,339,341,342]

In the field of cancer biology, autophagy has been shown to be one potential mechanism by which cancers establish treatment resistance to chemotherapy. This paradigm has been well characterized in pancreatic cancer, in which transcriptional control of autophagy–lysosome drives pancreatic cancer metabolism and is critical for tumor growth and progression.[352,353] Early studies of hydroxychloroquine, which nonselectively inhibits autophagy by decreasing autophagosome–lysosome fusion, suggested benefit in enhancing the sensitivity of tumors to systemic chemotherapy.[354,355] However, a recent phase 2 randomized clinical trials comparing gemcitabine and nab-paclitaxel with or without hydroxychloroquine in patients with advanced pancreatic cancer failed to observe a prolongation in 1-year all-cause survival.[356]

Mitophagy, autophagy directed at the removal of damaged mitochondria, is considered of particular importance in protecting against organ injury, such as acute kidney injury (AKI).[357] At least two mechanisms are involved in the sequestration and elimination of defective mitochondria: Atg7 and PINK1/Parkin. Atg7 is an autophagy protein that is required for the initiation of ubiquitin-like conjugation pathways of autophagy. During erythroid maturation, Atg7 serves a nonredundant role in mitochondrial clearance through canonical autophagosomal pathways.[358,359] Alternatively, PINK1 accumulation at the outer mitochondrial membrane of dysfunctional mitochondria selectively recruits Parkin, which in turn promotes their selective degradation by mitophagy.[360–363] Conditions that induce mitochondrial dysfunction and depolarization strongly induce this pathway, which is important for cell survival.[364] Indeed, endogenous Parkin production and exogenous Parkin overexpression have been found cytoprotective in different conditions of stress, including sepsis. Not surprising, due to the potential for release of cytochrome C and ROS, it is vital that a cell possess a programmatic mechanism for the elimination of defective mitochondria.

THE STRESS RESPONSE

The stress response is the cellular reaction to any perturbation or disruption in equilibrium and serves to restore homeostasis. Inducers of the stress response include physical stresses (burns, radiation, trauma), chemical agents and mediators (toxin, heavy metals, cytokines, ROS), infectious agents (bacteria, viruses, parasites), and allergens. It is often referred to as the heat-shock response after the identification in the 1960s of the HSPs, a group of genes expressed after exposure to heat.[365] However, subsequent investigations delineated additional cellular proteins that are expressed in response to a wide variety of insults. Clinically, expression of HSP has been observed under conditions in which oxygen delivery is compromised, as in hemorrhage or ischemia.[366]

Activation of the stress response is characterized by both morphologic and metabolic cellular alterations. Morphologic alterations include the accumulation of unprocessed forms of mRNA in the nucleolus, and increased numbers of actin microfilaments in the cytoplasm. Changes in cellular metabolism include a rapid reduction in intracellular ATP levels, most likely correlated with alterations in the integrity of mitochondria. The stress response is characterized by transient downregulation of most cellular products and by the upregulation of stress proteins.[367] It is the induction of stress proteins that confers the primary adaptive and protective effects of the stress response.

After expression of stress genes, cells become resistant to subsequent stresses. Members of the stress protein family include HO (*supra vida*); the multiple-drug resistance (MDR) gene product P-glycoprotein; ubiquitin, involved in targeting proteins for degradation; scavengers such as superoxide dismutase, ferritin, and metallothioneins; and the glycolytic enzymes enolase and glyceraldehyde 3-phosphate dehydrogenase. The most extensively characterized are the HSPs.[43]

HSPs are molecular chaperones that may either be constitutively expressed or induced upon cellular stress.[368] Classification is based upon their molecular mass and degree of homology. The most extensively studied is the HSP70 family, members of which possess a mean molecular mass of 70 Kd and greater than 70% homology. Members of the HSP70 family bind ATP and are induced under conditions of energy depletion and stress. HSP70

is integral in cellular adaptation to and survival during environmental stresses. Both HSP72 and HSP73 are present in the cytosol and nucleus. The former is constitutively expressed, whereas, expression of HSP72 is exclusively induced. In most studies HSP72 is used as a marker of HSP induction.[43,366,369,370]

The HSP60 family members are also referred to as chaperones. The glucose-regulated protein group of HSP is induced with glucose starvation, inhibitors of N-glycosylation, and calcium ionophores. The decrease in glucose content may affect the pool of sugar donors during protein glycosylation. The low–molecular-weight HSP (molecular masses of 20 to 30 Kd) may be important regulatory components of the actin-based cytoskeleton.[366]

HSP regulation of transcription occurs through the activation of heat-shock elements in the gene promoters. Two heat-shock transcriptional factors (HSFs) have been identified, HSF1 and HSF2. HSF1 activates transcription of the HSP72 gene in response to heat, heavy metals, and other inducers of the stress response. With stimulation, unbound HSF1 oligomerizes, translocates to the nucleus, and binds to the HSP promoter to activate the transcription of the gene. HSF2 is not activated by the classic inducers of heat-shock genes, but may be important in controlling the activities of HSP gene expression in the normal or unstressed cell.[43,366,369,370]

HSP can play multiple roles in modulating the inflammatory response. A number of conditions such as rheumatoid arthritis, ARDS, and asthma have been shown to benefit experimentally from increased HSP expression.[365–367,370] Functions of HSP include enhancement of immune responses, thermotolerance, regulation of apoptosis, hemostasis, and cytoprotection against ROS and other inflammatory mediators. HSP–CD91 interaction is integral to the processing and representation of antigen by APCs. HSP may shift the balance between T_H1 and T_H2 toward an increase in more anti-inflammatory T_H2 cells. ROS, including H_2O_2, hydroxyl radical, and peroxynitrite, activate HSP synthesis. In the presence of iron, ROS also induce the oxidation-specific stress proteins HO and ferritin, which afford protection against oxidative stress by binding iron and preventing it from participating in the Fenton reaction. Mechanisms of HSP-mediated cytoprotection from the toxic effects of ROS include the maintenance of

cellular GSH levels (HSP27) and mitochondrial protection (HSP70). Hence, ROS induce a cytoprotective response that counteracts their own toxicity. Other inflammatory mediators such as NO have also been shown to induce expression of HSP.[43]

HSP may participate in intracellular signaling pathways that modulate the production or function of inflammatory mediators. For example, HSP90 has been shown to facilitate signaling that leads to NO formation by eNOS.[371] HSP70 has been reported to prevent apoptosis, which may promote propagation rather than resolution of inflammation. In addition, the body's immune response to bacterial and parasitic stress proteins likely protects the host from infection. The bacterial homologue of HSP60, GroEL, is a major target of the mammalian humoral response to bacterial infections. Many activators of HSF1 are potent inhibitors of the proinflammatory transcription factor NFκB. Aspirin and other NSAIDs activate HSF while inhibiting NFκB. Therefore, the anti-inflammatory effects associated with the stress response might be related more to the inhibition of NFκB activation.[366,372]

The Acute-Phase Response

The acute-phase response consequent to trauma or cellular injury is characterized by alterations in hepatic metabolism; activation of the central nervous system, leading to fever and adaptive behaviors; altered hematopoiesis; activation of complement and the fibrinolytic and coagulation cascades; and the release of neuropeptides, kinins, and hormones. It is a rapid, nonspecific response that accompanies both acute and chronic inflammatory disorders. Many of the processes induced during the acute-phase response are mediated by cytokines. IL-6, IL-1, and TNFα play particularly central roles.[373,374] Though considered a defense mechanism promoting host survival, aberrant or unregulated production of many of these inflammatory mediators can be lethal.

Acute-Phase Proteins

An acute-phase protein is defined as a protein whose concentration increases by at least 25% during inflammation (**Table 7.8**).[374,375] These changes are primarily due to altered hepatic synthesis and typically occur within

approximately 6 hours of the inciting stimulus. The function is to restore homeostasis: hemostatic functions (fibrinogen), microbicidal and phagocytic functions (complement components, C-reactive protein [CRP]), antithrombotic properties (plasminogen, protein S), antioxidant properties (haptoglobin), and antiproteolytic actions (α_2 macroglobulin, α_1 protease, α_1 chymotrypsin). The negative acute-phase proteins albumin, prealbumin, transferrin, and retinol-binding protein decrease by at least 25%. Levels of the negative acute-phase proteins albumin and transferrin drop almost immediately after operation and remain depressed for several days. The rapid initial loss of these proteins is likely due to increased vascular permeability and loss to the extravascular space. The magnitude of the response is proportional to the severity of the stress. Whereas trauma and burns lead to significant increases in acute-phase reactants, exercise and psychiatric illness induce more moderate responses.

The two major acute-phase proteins in humans are CRP and serum amyloid A (SAA). CRP, named because of its reaction with pneumococcal C-polysaccharide, displays both proinflammatory and anti-inflammatory effects. It has been shown to activate complement, recognize foreign pathogens, bind phagocytic cells, and enhance activation of tissue factor, the main initiator of coagulation. CRP can also inhibit superoxide production by neutrophils and inhibit neutrophil adhesion by decreasing surface expression of L-selectin. Changes in plasma or serum CRP, although nonspecific, may reflect the magnitude of an inflammatory process, and may aid the differentiation of inflammatory from noninflammatory conditions. Measurement of CRP is more precise than the erythrocyte sedimentation rate (ESR); the latter largely depends on plasma fibrinogen levels and is influenced by a variety of other, unrelated factors in the circulation. SAA may promote chemotaxis and adhesion of phagocytes during inflammation.[43]

C1 inhibitor is of special interest as an acute-phase protein because of its effects outside of the complement cascade. This antiprotease inhibits the activity of HF, limiting kinin production and factor XI production. Thus, enhanced expression of a complement inhibitor protein during acute inflammation may also influence coagulation, fibrinolysis, and kinin pathways.

Systemic Manifestations of the Acute-Phase Response

Systemic manifestations include neuroendocrine changes, shifts in the hematologic profile, and metabolic and chemical alterations. The classic neuroendocrine manifestation is fever. IL-1, IL-6, and TNFα mediate the fever response by resetting the hypothalamic temperature setpoint through the synthesis of PGE_2. The secretion of neuropeptides, such as CRH and AVP, and of hormones, such as glucagon, insulin, thyroxin, and aldosterone, is also characteristic of the acute-phase response. CRH and AVP are released by the hypothalamus and increase ACTH and cortisol levels. The rise in plasma cortisol levels occurs rapidly and may function to inhibit the fever response and cytokine gene expression, thereby serving a potential negative regulatory function in the acute-phase response. Glucocorticoids also stimulate macrocortin synthesis, which by inhibiting synthesis of PLA_2, limits the availability of arachidonic acid for prostaglandin synthesis. Glucocorticoids increase the rate of synthesis of certain acute-phase proteins involved in connective tissue repair and clotting, as well as antioxidants and antiproteinases. They also may function to counteract the hypoglycemic response to insulin overproduction during infection or stress.

Other alterations include a prominent leukocytosis, thrombocytosis, and the "anemia of chronic disease." Metabolic changes include altered lipid metabolism and negative nitrogen balance. Changes in the chemical and enzymatic profile include increased hepatic production of metallothionein, iNOS, HO, manganese superoxide dismutase, and glutathione (GSH). Plasma levels of zinc and iron are noted to drop, whereas copper levels increase slightly. This persists for the duration of inflammation and is likely due to sequestration induced by IL-6, glucocorticoids, and catecholamines. Low levels of iron and zinc may confer protective antimicrobial effects because they are essential micronutrients for microbial growth.[43]

Mediators of the Acute-Phase Response

Bacterial products such as LPS are probably the most potent activators of tissue macrophages, the initiators of the acute-phase response. LPS, through its interactions with LBP, CD14, and TLRs, induces macrophage synthesis of ROS, including NO; lipid derivatives (e.g., PGE_2, thromboxane A_2, and

PAF); and acute-phase cytokines (e.g., TNFα, IL-6). Additional mediators inducing the synthesis of acute-phase cytokines in the absence of bacterial infection include free radicals, prostaglandins, and the release of DAMPs from injured tissues.[43] Indeed the response to the sterile insult of trauma mirrors much of what is observed during severe sepsis, a similarity that may be the consequence of substantial overlap in signaling mechanisms, such as TLR4.

Acute-phase cytokines can be proinflammatory (IL-1, TNFα, IFNγ, IL-8) or anti-inflammatory (IL-10, IL-4, IL-13, TNFβ). However, it is IL-6 and IL-6-type cytokines that are most critical in the acute-phase response. IL-6 is the major inducer of acute-phase proteins synthesis and, together with IL-1 and TNFα, is responsible for the systemic features classically associated with the acute-phase response (fever, anorexia, leukocytosis, and hormonal changes).[43]

In addition to the aforementioned cytokines, IFNγ is a potent inducer of complement components. The anti-inflammatory cytokine TGFβ stimulates synthesis of antiproteases, urokinase, and negative acute-phase proteins. IL-4 is inhibitory to some acute-phase proteins. Growth factors, including hepatocyte growth factor and TGFβ are also able to modulate the synthesis of acute-phase proteins. Glucocorticoids augment the response to cytokines, and insulin attenuates the cytokine-induced rise in acute-phase proteins.[43]

Effects of the cytokines are influence by cytokine receptors, receptor antagonists, and hormones. IL-1RA competes with IL-1 and attenuates the acute-phase response in vivo. Soluble receptors for IL-1 and TNFα act as antagonists. In contrast, soluble receptors for IL-6 act as agonists.

Regulation of Acute-Phase Cytokines and Proteins

Several major families of transcription factors participate in the upregulation of acute-phase cytokines and proteins, the most important being NF-IL-6, AP-1, and NFκB.[376] NF-IL-6 participates in the expression of the cytokines IL-1, TNFα, IL-6, and IL-8. Activation through the NFκB is probably the predominant pathway. The triggering of IL-6 in monocytes in vitro by IFNγ involves a change in the amount of the phosphorylated transcription factor Sp1, together with the induction and activation of IFN-regulatory factor.

All known acute-phase proteins are regulated primarily at the transcriptional level. Activation of TNFα and IL-1 receptors triggers signaling pathways that activate transcription factors AP-1 and NFκB. Many type I acute-phase proteins genes contain response elements for NFκB, NF-IL-6, and AP-1. Acute-phase protein responses to IL-6 are mediated through the JAK-STAT signal transduction pathway. In addition, both IL-1 and IL-6 signal transduction mechanisms activate the MAPK pathway that activates transcription factors NF-IL-6, linking the IL-1 and IL-6 pathways.

Reperfusion Injury

Prolonged tissue ischemia produces irreversible injury and cell death. Timely restoration of perfusion may salvage some tissue, though paradoxically can induce injury as well. Reperfusion injury is the damage caused by the restoration of blood flow in previously ischemic tissue (i.e., myocardial ischemia, transplantation, vascular surgery). Injury is the direct consequence of activation of the inflammatory response, especially complement activation and neutrophil recruitment. Components of the complement cascade promote tissue damage through the generation of anaphylatoxins and by the formation of the MAC. Invading neutrophils injure tissue through the generation of ROS and the release of proteolytic enzymes. Recent evidence points to TLR4 as a sensor of tissue stress, the signal of which is probably through release of DAMPs from ischemic cells.[36]

Alterations in the microvascular endothelium are central to the pathophysiologic process of reperfusion injury. Early loss of constitutive NO production facilitates neutrophil adherence, the upregulation of cell adhesion molecules such as P-selectin, and inhibits vasorelaxation and perfusion.[377] Low oxygen tension induces the conversion of xanthine dehydrogenase to xanthine oxidase. Reperfusion and reoxygenation yield the formation of superoxide anion and H_2O_2 and induce oxidant injury. Neutrophils and other cellular effectors are progressively recruited and activated, releasing ROS, cytokines, and NO, further contributing to increased vascular permeability and tissue injury. PAF released by neutrophils activates circulating platelets and promotes vascular plugging. Platelets also release factors that enhance platelet–neutrophil adhesion. Both cell types also release vasoconstricting

agents that can further exacerbate no-reflow. Capillary plugging by neutrophils and platelets can impair local blood flow and cause the "no-reflow phenomenon."[43]

Neutrophils mediate direct toxicity to the surrounding tissue through the elaboration of ROS and granule contents. Peroxynitrite formed by the reaction of NO and superoxide can contribute directly to tissue injury during reperfusion. Neutrophil granule proteases such as elastase, collagenase, and gelatinase alter the vascular permeability and are highly destructive to local tissue. The significance of the neutrophil in mediating these effects are apparent in neutrophil depletion studies demonstrating attenuated tissue injury when compared to subjects with normal numbers of neutrophils.[378] Animal studies using blocking monoclonal antibodies to selectins and β_2 integrins show improved organ function ischemia/reperfusion.[379]

The mechanism by which complement is activated with reperfusion is not completely understood. Ischemia may alter the cell's plasma membrane or through the exposure of basement membrane or subcellular organelle components, creating a complement-activating surface. Alternatively, binding of natural antibody may lead to induction of these cascades.[223] Complement activation has been shown to occur in the setting of therapeutic thrombolysis. The generation of plasmin-dependent fibrinolytic agents and plasmin after tissue plasminogen activator administration has been associated with complement activation.[380]

Anaphylatoxins are important effectors of complement-mediated injury. They alter vascular permeability, induce smooth muscle cell contraction, and stimulate the release of histamine from mast cells and basophils. C3a and C5a are potent chemoattractants especially for neutrophils. C5 can be activated by an abundance of oxygen free radicals. The subsequent generation of the MAC perturbs the maintenance of vital ion gradients, induces cell lysis, and facilitates neutrophil recruitment. In addition it can induce the expression of numerous inflammatory mediators, including cytokines (TNFα, IL-1, IL-8), ROS, prostaglandins, leukotrienes, and cell surface adhesion molecules.[381]

Systemic Inflammatory Response Syndrome

The inability of host defenses to control a localized inflammatory process or an unchecked inflammatory response can result in SIRS, defined as the presence of any two of the following physiologic parameters: (1) a temperature greater than 38°C or less than 36°C; (2) leukocytosis (>12,000), leukopenia (<4,000), of more than 10% bands; (3) pulse greater than 90 beats per minute; (4) tachypnea (respiratory rate greater than 20 or $PaCO_2$ <32 mm Hg).[382] Infection underlies a significant minority of cases, as only a third of patients with SIRS will have a documented infection and meet the criteria for sepsis. In one prospective study, 26% of patients with SIRS developed sepsis and 7% died.[383] In fact, SIRS is so nonspecific insofar as facilitating diagnosis that it has been removed as a criterion in the new definitions of sepsis (Sepsis-3).[384]

SIRS may be initiated by infectious or noninfectious causes, such as trauma, autoimmune reactions, or pancreatitis. Gram-negative organisms, rich in LPS, induce a potent inflammatory response mediated through the CD14/TLR4/MyD88 pathway previously described and account for the majority of infectious SIRS cases. Gram-positive organisms can generate a similarly impressive degree of inflammation either through TLR2 or alternative mechanisms. Streptococcal superantigen may induce a global and nonspecific activation of T cells that culminates in massive systemic elaboration of cytokines and cardiovascular collapse termed TSS. Trauma, either through tissue injury (HMGB1-RAGE, HSP-CD91) or the ischemia/reperfusion consequent to hemorrhage can culminate in inflammatory pathophysiology indistinguishable from that accompanying these other inflammatory states. As the growing evidence continues to support the promiscuity of TLR and other signaling pathways, we are replacing the former concept distinct receptor-signaling mechanisms for each stimulus with one that emphasizes the similarities, overlap, and integration. Though there are clearly mechanisms by which host distinguishes normal self from endogenous (trauma) and exogenous (infection) dangers, there is considerable overlap, and all stimuli appear to converge upon similar signaling mechanisms in attaining the goal of preserving the host.

The development of SIRS has been described as progressing through stages: Stage I—local cytokine production recruits inflammatory cells to the injured site; Stage II—an acute-phase response is initiated and small

quantities of cytokines are released into the circulation to enhance the local response; and Stage III—homeostasis cannot be reestablished.[385] Enhanced levels of CRP, the major acute-phase protein in humans, occur in SIRS/sepsis, and clinical resolution is preceded by a drop in CRP levels.

The elaboration of proinflammatory cytokines (IL-1, TNFα, and IL-6) is central to the pathogenesis of SIRS regardless of the initiating stimulus. Their release triggers increased expression of adhesion molecules, leukocyte recruitment, and the production of secondary proinflammatory mediators, such as chemokines. Endotoxin is one of the most powerful triggers of SIRS. LPS activates the complement and coagulation cascades, induces endothelial cell activation, and increases TNFα and IL-1 synthesis, and the late release of HMGB1. Noninfectious tissue injury (i.e., sterile), perhaps through the release of DAMPs such as mitochondrial DNA, may too induce a similar inflammatory response. LPS, TNFα, and IL-1 also induce increased production of NO by iNOS. PGI_2 and arachidonic acid, together with NO contribute to decreased systemic vascular resistance and hypotension. Autocrine and paracrine NO production also results in myocardial depression. Increased vascular permeability promotes extravasation of fluid and edema formation. Activated endothelial cells express tissue factor, PECAM, and TXA_2, which promote a procoagulant local environment that predisposes to microthrombi formation. Adherent leukocytes further exacerbate organ injury by mechanically impeding microvascular blood flow and by damaging the endothelial cells and surrounding connective tissue. The results are end-organ hypoperfusion, inadequate oxygen delivery, initiation of anaerobic metabolism, and organ failure. The metabolic and nutritional sequelae of this activated cytokine milieu include fever, catabolism, cachexia, and altered fat, glucose, and trace mineral metabolism.

SIRS is counteracted by the concomitant induction of an anti-inflammatory response termed the compensatory anti-inflammatory response syndrome (CARS).[385] Many of the proinflammatory mediators that participate in SIRS modulate the immune function of lymphocytes and mononuclear cells. Proinflammatory mediators can inhibit their own synthesis or enhance the synthesis of natural antagonists by negative feedback mechanisms. Thus, at any given time, the clinical manifestation is SIRS, CARS, or an intermediate, mixed inflammatory response syndrome. The spectrum of features that

characterizes these syndromes has been termed CHAOS (cardiovascular shock, homeostasis, apoptosis, organ dysfunction, and immune suppression). Studies employing a variety of specific anticytokine agents have failed to observe an improvement in the outcome of patients with SIRS or sepsis.

Chronic Inflammation

There are no clear boundaries between an acute and a chronic inflammatory response. In general, if the source of an acute inflammatory process is incompletely eliminated, a state of chronic inflammation eventually ensues. Chronicity is usually not characterized by the signs classically associated with acute responses, such as swelling, heat, or redness. Pain is minimal if not absent. Microscopically, a mononuclear cell infiltrate predominates (lymphocytes, monocytes, plasma cells) with proliferation of fibroblasts and vascular elements.

Many agents can create a state of chronic inflammation, including persistent infectious agents, remnants of dead organisms, foreign bodies, and metabolic byproducts. Ultimately, chronicity of inflammation is a result of the immune response to a persistent antigen. Furthermore, a chronic inflammatory response can develop in the absence of a preceding acute response, such as infections with agents of low toxicity such as mycobacterium and treponema. $CD4^+$ T cells and macrophages are the primary cellular orchestrators of chronic inflammatory response.[386] T_H1 cell-mediated immune responses are protective against most microbes and usually result in the elimination of the pathogen. If the microbe persists, the ongoing T_H1 response results in inflammatory tissue injury. Cytokines and growth factors released by T lymphocytes and macrophages stimulate proliferative responses. Neutrophils and eosinophils contribute to the release of proteolytic enzymes and oxygen derivatives. Eosinophilia occurs with chronic parasitic infections and hypersensitivity conditions. Fibroblasts are actively recruited by chemoattractants such as fibrin, collagens, and cytokines. Local IL-1 stimulates fibroblast proliferation and collagen production. Irreversible tissue damage can occur through the replacement of normal parenchyma with fibrous connective tissue. Fibroblasts can release metalloproteinases that degrade normal tissue, further contributing to tissue

destruction. Mast cells are elevated in chronic conditions and may play a part in cell-mediated immune responses. Inflammatory cyst formation may occur as a result of epithelial hyperplasia.

Surgical Infections

Lena M. Napolitano

Key Points

1. Surgical infections include intra-abdominal infections (appendicitis, cholecystitis/cholangitis, diverticulitis, colitis including *Clostridium difficile* colitis, pancreatitis, and peritonitis), soft tissue infections (necrotizing and nonnecrotizing), surgical site infections (SSIs), and hospital-acquired infections that occur in surgical patients (pneumonia, central line–associated bloodstream infections [CLABSI], and catheter-associated urinary tract infections [CAUTI]).
2. Early appropriate empiric broad-spectrum antimicrobial therapy, to cover all potential causative pathogens, is an important adjunct to source control in the treatment of surgical infections. Inappropriate antimicrobial therapy is associated with increased mortality.
3. Any of these surgical infections can result in sepsis or septic shock.
4. A key concept in surgical infections is "*source control,*" defined as any physical intervention to remove or eliminate a focus of invasive infection (drainage, debridement, and device removal) and to restore optimal anatomic function.
5. Pathogen identification and appropriate deescalation of antimicrobial therapy are of paramount importance in treatment of surgical infections, as increasing prevalence of multidrug-resistant pathogens has been identified in both abdominal and skin surgical infections.
6. Complicated intra-abdominal infection (cIAI) extends beyond the hollow viscus of origin into the peritoneal space and is associated with either abscess formation or peritonitis.
7. Recommendations for specific antimicrobial therapy for cIAI are based on whether the infection is "community acquired" or "health care associated."
8. In patients with intra-abdominal infections who have undergone an adequate source control procedure, fixed-duration antibiotic therapy for 4 days is noninferior to longer duration antimicrobial therapy until resolution of physiologic abnormalities, with no difference in SSI, recurrent intra-abdominal infection, or death.

9 The two surgical procedures indicated for *C. difficile* colitis treatment include the following: (1) total abdominal colectomy (for peritonitis, colonic perforation, ischemia, necrosis, toxic megacolon with impending perforation, septic shock with organ failure) and (2) diverting loop ileostomy and intraoperative colonic lavage for toxin reduction. The second option is associated with colonic preservation.

10 The initial treatment of infected pancreatic necrosis is percutaneous catheter or endoscopic (transgastric/transduodenal) drainage with additional drain placement as required.

11 Lack of clinical improvement of necrotizing infected pancreatitis with initial percutaneous drainage warrants consideration of minimally invasive techniques for pancreatic necrosectomy including video-assisted retroperitoneal debridement, minimally invasive retroperitoneal pancreatectomy, or transluminal direct endoscopic necrosectomy.

12 Acute bacterial skin and skin structure infections are defined as bacterial infection of the skin with a lesion size area of at least 75 cm^2 (lesion size measured by the area of redness, edema, or induration), including cellulitis, wound infection, and abscess.

13 Early operative debridement is the major determinant of outcome in necrotizing soft tissue infections. Delayed definitive debridement remains the single most important risk factor for death.

INTRODUCTION

1 Surgical infections include intra-abdominal infections (appendicitis, cholecystitis, diverticulitis, colitis, and pancreatitis), soft tissue infections (necrotizing and nonnecrotizing), surgical site infections (SSIs), and hospital-acquired infections that occur in surgical patients (pneumonia, central line–associated bloodstream infections [CLABSIs], and catheter-associated urinary tract infections [CAUTIs]).[1] Appropriate therapy of surgical

infections to optimize patient outcomes includes four steps: (1) early diagnosis, (2) early initiation of appropriate empiric broad-spectrum antimicrobial therapy, (3) adequate source control (surgical or interventional radiology), and (4) pathogen identification and appropriate deescalation of antimicrobial therapy (**Table 8.1**).

The initial management of all surgical infections should include the initiation of early empiric antimicrobial therapy to cover all potential possible pathogens, since early and appropriate empiric antibiotic therapy improves patient outcomes (**Table 8.2**).[2] The choice of early empiric antimicrobial therapy is guided by the specific site of infection, the common pathogens associated with that infection, and by local and regional antibiograms. The goal of antimicrobial therapy is to achieve antibiotic levels at the site of the infection that exceed the minimum inhibitory concentration of the microbial pathogens present.

Table 8.1 Appropriate Therapy of Surgical Infections

1. Early diagnosis of surgical infection
2. Early initiation of appropriate empiric broad-spectrum antimicrobial therapy
3. Adequate source control
4. Pathogen identification and appropriate deescalation of antimicrobial therapy

Early Use of Appropriate Broad-Spectrum Antimicrobial Therapy

2 Early use of appropriate broad-spectrum antimicrobial therapy is an important adjunct to appropriate surgical management of surgical infections. Numerous studies have confirmed that inappropriate empiric antibiotics (i.e., antibiotics that do not cover the causative pathogens) are associated with increased mortality.[3] In patients who manifest sepsis or septic shock, every hour delay of antimicrobial therapy is 3 associated with increased mortality.[4] The Surviving Sepsis Guidelines recommendations are listed in **Table 8.3**.

Source Control

4 Source control is defined as any physical intervention to remove or eliminate a focus of invasive infection (drainage, debridement, and device removal) and to restore optimal anatomic function.[5] In surgical infections, antimicrobial agents are used in conjunction with adequate source control of the initial infection. Adequate source control can be accomplished by either surgical or percutaneous interventional radiologic techniques. A number of factors have been identified that predict failure of source control for intra-abdominal infections (**Table 8.4**).

Pathogen Identification

5 Pathogen identification is extremely important, in part related to increased prevalence of multidrug-resistant pathogens that are associated with surgical infections. Whenever possible, high-quality specimens should be obtained from source control procedures for Gram stain and culture in order to identify causative pathogens and determine antimicrobial susceptibility of the bacterial isolates identified. This will enable appropriate deescalation of antimicrobial therapy from broad-spectrum therapy to directed potential single antimicrobial agent therapy.

Table 8.2 Spectrum of Activity of Specific Antimicrobials for Specific Pathogens

Antibiotic	Gram Negative	Gram Positive	Resistant Gram Negative	Resistant Gram Positive	Anaerobe	Pseudomonas
Beta-lactam/beta-lactamase inhibitor	+	+	#	0	+	#
First-generation cephalosporins	0	+	0	0	0	0
Second-generation cephalosporins	#	#	0	0	0	0
Third-generation cephalosporins	+	+	#	0	0	#
Fourth-generation cephalosporins	+	+	#	0	0	#
Fifth-generation cephalosporins	0	+	0	+	0	0
Tigecycline	+	+	+	+	+	0
Glycopeptides	0	+	0	+	0	0
Carbapenems	+	+	#	0	+	#
Quinolones	+	+	0	0	#	#

0, no activity; +, activity; #, activity, but varies by product within class.

Table 8.3 Antimicrobial Therapy, Surviving Sepsis Guidelines 2016

1. Recommend administration of intravenous antimicrobials be initiated as soon as possible after recognition and within 1 hr for both sepsis and septic shock (strong recommendation, moderate quality of evidence)
2. Recommend empiric broad-spectrum therapy with one or more antimicrobials for patients presenting with sepsis or septic shock to cover all likely pathogens (including bacterial and/or fungal or viral) (strong recommendation, moderate quality of evidence)
3. Recommend that empiric antimicrobial therapy be narrowed once pathogen identification and sensitivities are established and/or adequate clinical improvement is noted (Best Practice Statement)
4. Suggest empiric combination therapy (using at least two antibiotics of different antimicrobial classes) aimed at the most likely bacterial pathogens for the initial management of septic shock (weak recommendation, low quality of evidence)
5. Recommend daily assessment for deescalation of antimicrobial therapy in patients with sepsis and septic shock (Best Practice Statement)

Adapted from Rhodes A, Evans LE, Alhazzani W, et al. Surviving sepsis campaign: International Guidelines for Management of Sepsis and Septic Shock: 2016. *Crit Care Med* 2017;45(3):486–552.

Table 8.4 Clinical Factors Predicting Failure of "Source Control" for Intra-Abdominal Infection
Delay in the initial intervention (>24 hrs)
High severity of illness (APACHE [Acute Physiology and Chronic Health Evaluation] II score ≥15)
Advanced age
Comorbidity and degree of organ dysfunction
Low albumin level
Poor nutritional status
Degree of peritoneal involvement or diffuse peritonitis
Inability to achieve adequate drainage or debridement
Presence of malignancy

INTRA-ABDOMINAL INFECTIONS

Classification

6 Complicated intra-abdominal infection (cIAI) extends beyond the hollow viscus of origin into the peritoneal space and is associated with either abscess formation or peritonitis. "Uncomplicated" intra-abdominal infection involves intramural inflammation of the gastrointestinal tract and has a substantial probability of progressing to cIAI if not adequately treated.

Diagnosis

Patients with cIAI present with abdominal pain and gastrointestinal symptoms. A comprehensive abdominal physical examination must be performed in these patients. If peritonitis is present, evaluation for emergent laparotomy without diagnostic studies is considered. If peritonitis is not present, recent evidence-based guidelines recommend that computed

tomography (CT) scan of the abdomen and pelvis is the diagnostic imaging modality of choice to evaluate for cIAI and its source.[6,7]

Treatment

7 Early appropriate empiric systemic antimicrobial therapy to cover all potential causative pathogens and early source control are the mainstays of treatment of cIAIs. In order to select appropriate empiric antimicrobial agents for use, cIAIs are further classified as "community-acquired" or "health care-associated."

Community-Acquired Complicated Intra-Abdominal Infection

For patients who have "community-acquired" cIAI, determination of whether the disease is "mild/moderate (appendicitis, mild diverticulitis)" or "severe (fecal peritonitis, perforated diverticulitis)" facilitates appropriate antimicrobial treatment (**Table 8.5**). Patients with "severe" community-acquired cIAI should have antibiotics that cover *Pseudomonas* and *Enterococcus* pathogens, and both single-agent and combination-agent regimens are available for use. A number of antimicrobials are no longer recommended for use in community-acquired cIAI:

- Ampicillin/sulbactam is not recommended because of high resistance of *Escherichia coli* to this agent (B-II).
- Cefotetan and clindamycin are not recommended for use because of increasing resistance of the *Bacteroides fragilis* group to these agents (B-II).
- Because of the availability of less toxic agents demonstrated to be of at least equal efficacy, aminoglycosides are not recommended for routine use in community-acquired cIAI in adults (B-II).

Health Care–Associated Complicated Intra-Abdominal Infection

For patients with "health care–associated" cIAI, separate evidence-based guideline recommendations for empiric antimicrobial treatment are provided (**Algorithm 8.1**). Specific antimicrobials are recommended based on

whether the patient and/or institution have high risk for infection with multidrug-resistant pathogens. Quinolone-resistant *E. coli* have become common in many communities, and quinolones should not be used unless hospital antibiograms confirm greater than 90% susceptibility of *E. coli* to quinolones. In patients with health care–associated cIAI, carbapenems are an excellent single-agent regimen for empiric treatment.

Table 8.5 Empiric Antimicrobial Treatment of Extrabiliary cIAIs, Community Acquired

	Community-Acquired Infections in Adults	
	Mild to Moderate	**Severe**
Single agent	▪ Cefoxitin ▪ Ertapenem ▪ Moxifloxacin ▪ Tigecycline ▪ Ticarcillin/clavulanic acid	▪ Imipenem/cilastatin ▪ Meropenem ▪ Doripenem ▪ Piperacillin/tazobactam
Combination regimen	▪ Cefazolin,[a] cefuroxime, ceftriaxone, cefotaxime, ciprofloxacin, or levofloxacin, each in combination with metronidazole	▪ Cefepime, ceftazidime, ciprofloxacin, or levofloxacin, each in combination with metronidazole

- Ampicillin/sulbactam is not recommended because of high resistance of *Escherichia coli* to this agent (B-II).
- Cefotetan and clindamycin are not recommended for use because of increasing resistance of the *Bacteroides fragilis* group to these agents (B-II).
- Because of the availability of less toxic agents demonstrated to be of at least equal efficacy, aminoglycosides are not recommended for routine use in community-acquired IAI in adults (B-II).

[a]Caution—local antibiograms should direct use of this agent.

Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Surg Infect (Larchmt)* 2010;11(1):79–109.)

Duration of Antibiotics for Complicated Intra-Abdominal Infection

Duration of antibiotics for treatment of cIAI has long been [8] controversial. A recent important randomized controlled trial examined the efficacy of short-course (4 days) antimicrobial therapy in patients with intra-abdominal infections who had undergone an adequate source control procedure. Fixed-duration antibiotic therapy for 4 days was noninferior to longer duration antimicrobial therapy until resolution of physiologic abnormalities, with no difference in the composite endpoints of SSI, recurrent intra-abdominal infection, or death.[8]

SPECIFIC INTRA-ABDOMINAL INFECTIONS

Appendicitis

Appendicitis is common with over 300,000 hospital discharges in the United States per year. Although appendectomy provides definitive source control for the treatment of acute nonperforated appendicitis, intravenous (IV) antibiotics should be administered preoperatively with a dose repeated intraoperatively if the surgery is prolonged, a number of controversies in diagnosis and management of appendicitis persist.[9]

Antibiotics versus Appendectomy

In patients with uncomplicated appendicitis (nonperforated, no abscess, or phlegmon), appendectomy is definitive source control. But a number of recent randomized trials have confirmed that acute nonperforated appendicitis can be treated successfully with antibiotics alone. A meta-analysis of six studies with 1,201 patients reported that in patients treated with antibiotics alone, 7 ± 4% failed to respond and required appendectomy, and acute appendicitis recurred in 14 ± 11%. A normal appendix was found in 7.3 ± 5.1% of patients at appendectomy. Complications were considerably less likely to occur with antibiotic treatment than with appendectomy. Major surgical complications included enterocutaneous fistula and reoperation.[10]

A Cochrane meta-analysis of five trials with 901 patients reported that 73.4% of patients who were treated with antibiotics and 97.4% of patients who underwent appendectomy were cured within 2 weeks without major complications (including recurrence) within 1 year.[11] Another meta-analysis included only four trials and reported that efficacy was significantly higher for surgery but rates of perforated appendicitis were not different, and complication rates were significantly higher for surgery.[12] The most recent meta-analysis included 11 trials with 2751 patients and concluded for both uncomplicated and complicated adult acute appendicitis, nonoperative management with antibiotics was associated with significantly fewer complications and a shorter length of stay but a lower effective rate and higher relapse rate.[13]

The APPAC trial enrolled 530 patients in Finland with uncomplicated appendicitis confirmed by CT scan and randomized to early appendectomy

or antibiotic treatment (ertapenem for 3 days, then oral levofloxacin and metronidazole for 7 days) with 1-year follow-up. In the antibiotic group, 70 patients (27.3%) underwent appendectomy within 1 year of initial presentation for appendicitis. Antibiotic treatment did not meet the prespecified criterion for noninferiority compared with appendectomy. But it was notable that 72.7% of patients with uncomplicated appendicitis treated with antibiotics alone did not require subsequent appendectomy.[14,15] In the 5-year follow-up, 39.1% of patients who were randomized to antibiotics underwent appendectomy.[16] In the 7-year follow-up, long-term quality of life was similar, but patients who received antibiotics and later underwent appendectomy were less satisfied than patients with successful antibiotics or appendectomy.[17]

The trials published to date were primarily from European countries, used antibiotics not available in the United States and had minimal use of laparoscopic appendectomy or CT scan for diagnostic imaging.[18] Further high-quality randomized trials are therefore needed to determine which patients are most likely to benefit from antibiotic therapy alone. The Comparison of Outcomes of Antibiotic Drugs and Appendectomy (CODA) trial[19] just completed enrollment in the United States (n = 1552 randomized with parallel observation cohort over 4 years), and aims to compare patient-reported and clinical outcomes in patients randomized to antibiotics (10-day course) or appendectomy. Although appendectomy remains the standard treatment for acute appendicitis, antibiotic treatment alone may be used as an alternative treatment in patients with contraindication to surgery (or where surgery is high risk).

Laparoscopic versus Open Appendectomy

Appendectomy can be performed by laparoscopic or open approach. A large retrospective review (2005–2008) of laparoscopic versus open appendectomy using the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP) reported that 76.4% were performed laparoscopically and 23.6% performed open. Open appendectomy was associated with increased morbidity, SSI, and mortality.[20]

A Cochrane review of 67 trials was updated in 2010 and reported that laparoscopic appendectomy was associated with lower SSI rates but higher

intra-abdominal abscess rate. Laparoscopic approach was associated with shorter hospital length of stay, faster return to normal activity, and decreased postoperative pain. This review concluded that laparoscopic appendectomy should be considered the preferred approach where surgical expertise and equipment are available.[21]

Time to Appendectomy and Perforation Risk

It has long been thought that appendiceal luminal obstruction leads to appendiceal perforation without timely surgical intervention. This belief led to attempts to decrease time from presentation and diagnosis of acute appendicitis to operating room start time. With the advent of early appropriate empiric systemic antimicrobial therapy, this fundamental concept is no longer true. As discussed previously, in patients with uncomplicated appendicitis, antibiotic treatment alone does not lead to appendiceal perforation. Furthermore, using data from the Washington State Surgical Care and Outcomes Assessment Program (SCOAP) with 9,048 adult patients who underwent appendectomy, there was no association between appendiceal perforation and in-hospital time prior to surgery. This study confirmed that appendiceal perforation is most commonly a prehospital occurrence, and timing of surgery should be determined based on all factors relevant to the surgeon and patient.[22]

Abscess or Phlegmon Management

In patients with periappendiceal abscess or phlegmon, current evidence (mainly retrospective studies) supports nonoperative management with IV transitioned to oral antibiotics and percutaneous drainage if possible. A meta-analysis of 19 retrospective studies from 1969 to 2005 reported that nonsurgical treatment failed in only 7.6% of patients and immediate appendectomy was associated with higher morbidity. Similar findings were confirmed in a more recent review.[23] Routine interval appendectomy is not recommended since the risk of recurrence is low (7.4%). But either colonoscopy or repeat CT imaging is recommended due to the risk of a malignant disease (1.2%) or important benign disease (0.7%) identified during follow-up.[24]

Interval Appendectomy after Initial Nonoperative Management

A large retrospective cohort study reported that 3% of patients were initially treated with nonoperative management. Of these, 15% had an interval appendectomy and the remaining 85% did not. Of the 864 patients who did not undergo interval appendectomy, only 39 patients (5%) had recurrence of appendicitis after a median follow-up of 4 years.[25] Routine interval appendectomy after initial successful nonoperative treatment is therefore not justified based on the evidence to date. In a meta-analysis including 2,771 patients initially treated nonoperatively for appendiceal phlegmon or abscess, 31 patients were found to have a malignant diagnosis and a lower rate of inflammatory bowel disease. Peri-Appendicitis Acuta Randomized Clinical Trial[26] patients either to interval appendectomy or MRI after initial successful nonoperative treatment of periappendiceal abscess, and all patients underwent colonoscopy. An interim analysis of 60 patients confirmed a high rate of neoplasm (17%) with all inpatients with age >40 years, and the trial was prematurely terminated. These data highlight the need for follow-up with either CT scan or colonoscopy after successful nonoperative management.[24] Although a retrospective study in pediatric appendicitis reported a 2.8-fold higher rate of recurrent appendicitis in patients with an appendicolith, this study is limited by small sample size (n = 96) and a higher overall rate of recurrent appendicitis than all other published studies.[27] See also chapter on Appendiceal Diseases.

Biliary Infections

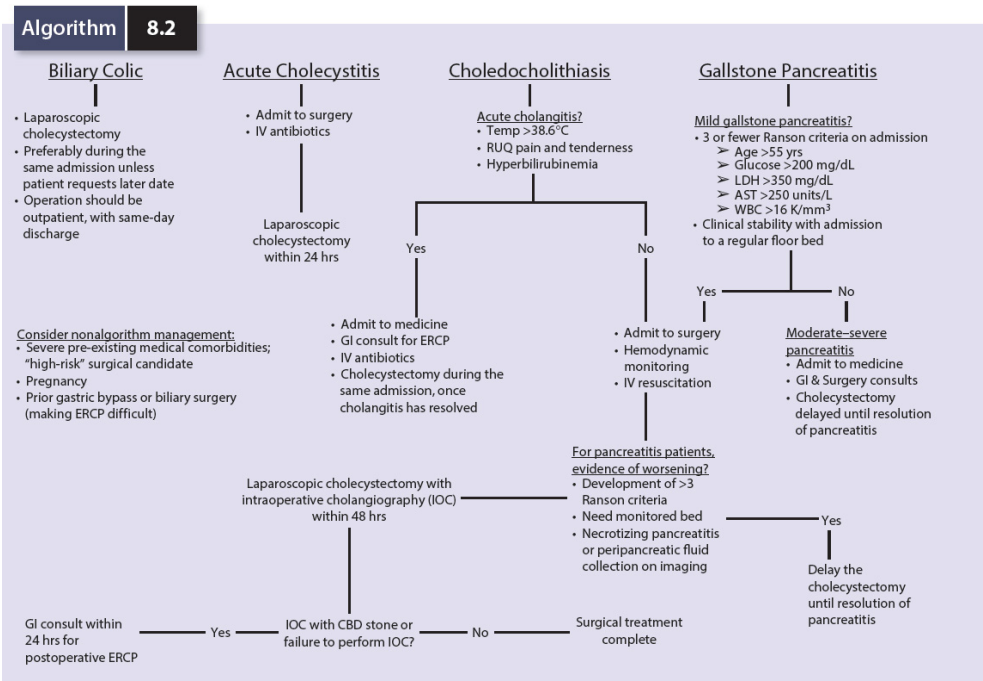
Biliary infections include acute cholecystitis which may be calculous or acalculous, may include choledocholithiasis or not, and cholangitis.[28] Acute cholecystitis and ascending cholangitis are primary inflammations of the gallbladder and bile ducts, respectively, which are caused by infection and possible biliary obstruction.

Acute Cholecystitis

Acute cholecystitis is inflammation of the gallbladder resulting from obstruction of the cystic duct and subsequent bacterial invasion and

overgrowth. Cholelithiasis is the cause of cystic duct obstruction in more than 90% of cases of acute cholecystitis in the United States. Acalculous cholecystitis is more common in critically ill patients and the pathophysiology is transmural ischemia. Acalculous cholecystitis carries higher morbidity and mortality rates than calculous cholecystitis.

The diagnosis of acute cholecystitis is made based on the common constellation of right upper quadrant tenderness, leukocytosis, and fever. Initial diagnostic imaging is right upper quadrant ultrasound to evaluate for gallstones, gallbladder wall thickening, and pericholecystic inflammation (sensitivity 88% to 94%, specificity 78% to 80%). If ultrasound is inconclusive or is discordant with the clinical evaluation, then cholescintigraphy (99mTc-hepatobiliary iminodiacetic acid, HIDA scan) is recommended, and nonvisualization of the gallbladder confirms acute cholecystitis with sensitivity of 96% and specificity of 90% (**Algorithm 8.2**).[29,30] Contrast-enhanced CT scan imaging is recommended for diagnosis of emphysematous cholecystitis or complications such as pericholecystic abscess, perforation, and peritonitis. The Tokyo Guidelines classify severity grading for acute cholecystitis into Grade I (mild), II (moderate) and III (severe) based on clinical, laboratory, and imaging criteria, with higher severity grades associated with worse outcomes, prolonged hospital length of stay, and conversions to open surgery (**Table 8.6**). Treatment recommendations are then based on severity classification and coexistent comorbidities and ASA classification.[31]



Algorithm 8.2 Biliary infections and algorithm for diagnosis and management. (From Demehri FR, Alam HB. Evidence-based management of common gallstone-related emergencies. *J Intensive Care Med* 2016;31(1):3–13.)

Early systemic antimicrobial treatment is indicated for acute cholecystitis to cover the causative pathogens, including aerobic, enteric, gram-negative bacilli (i.e., *E. coli*, Klebsiella, Enterobacter, and Proteus), and aerobic gram-positive organisms (i.e., Enterococcus and Streptococcus). Anaerobes are uncommon, identified in approximately 15% of isolates. Clostridial organisms can be identified in cases of emphysematous cholecystitis confirmed by identification of gas in the gallbladder wall.

Cholangitis

Cholangitis signs/symptoms include jaundice, fever, right upper quadrant tenderness, hyperbilirubinemia, and leukocytosis. Ultrasound confirms common bile duct dilation (>7 mm). Acute cholangitis has long been diagnosed on the basis of clinical signs of Charcot triad (jaundice, fever, right upper quadrant abdominal pain), which provides highly specific diagnostic criteria, but very low sensitivity (about 26%).

Appropriate evidence-based recommendations for diagnosis and treatment from the Tokyo Guidelines are provided in **Tables 8.7** and **8.8**. For treatment recommendations, urgent biliary drainage (<24 hours) is indicated in severe

cholangitis or when (1) obstructive biliary stones are associated with moderate acute cholangitis OR (2) mild acute cholangitis is not responding to IV antibiotics and fluid resuscitation.

For patients with biliary infections, specific evidence-based guideline recommendations for antimicrobial treatment are classified into four patient populations (**Table 8.9**). For patients undergoing cholecystectomy for acute cholecystitis with complete source control (i.e., complete cholecystectomy), antimicrobial therapy should be discontinued within 24 hours of the operation unless there is evidence of infection outside the wall of the gallbladder. For patients with gallbladder perforation or pericholecystic abscess, antimicrobial treatment should be continued until signs and symptoms of infection are resolved (normal WBC count, no fever, abdominal findings resolved).[32] For acute cholangitis, antimicrobial therapy should be continued for 4 to 7 days after source control is obtained. See also chapter on Calculous Biliary Disease.

Diverticulitis

Diverticulitis is a common intra-abdominal infection. Its pathophysiology is associated with altered gut motility, increased luminal pressure, and an altered colonic microenvironment.

Uncomplicated diverticulitis is treated with systemic antibiotics and usually resolves. Antimicrobial treatment of diverticulitis is the same as for cIAI which is reviewed above. In a cohort study of 2,366 patients hospitalized in the Kaiser Permanente system and followed for 8.9 years, only 13.3% had a first recurrence and 3.9% had a second recurrence.[33] Antibiotic therapy alone is associated with a very high success rate for complicated acute diverticulitis with abscess size <4 cm diameter,[34,35] and percutaneous drainage of abscesses >4 cm successfully resolve in 80% of patients with a low complication and reintervention rate.

Table 8.6 Severity Grading for Acute Cholecystitis: Tokyo Guidelines 2018

Severity of Acute Cholecystitis		Treatment
Mild (Grade I)	Does not meet the criteria of "Grade II" or "Grade III" acute cholecystitis Also defined as acute cholecystitis in a healthy patient with no organ dysfunction and mild inflammatory changes in the gallbladder, making cholecystectomy a safe and low-risk operative procedure	Early laparoscopic cholecystectomy if the patient meets the criteria of CCI ≤5 and ASA-PS ≤2
Moderate (Grade II)	Acute cholecystitis associated with any one of the following conditions: ▪ Elevated WBC count (>18,000/mm^3) ▪ Palpable tender mass in the right upper abdominal quadrant ▪ Duration of complaints >72 hrs ▪ Marked local inflammation (gangrenous cholecystitis, pericholecystic abscess, hepatic abscess, biliary	Early laparoscopic cholecystectomy by experienced surgeons if the patient meets the criteria of CCI ≤5 and ASA-PS ≤2 If not, after medical treatment and/or gallbladder drainage, laparoscopic cholecystectomy would be indicated

	peritonitis, emphysematous cholecystitis)	
Severe (Grade III)	Acute cholecystitis associated with dysfunction of any one of the following organs/systems: ▪ Cardiovascular dysfunction (hypotension requiring vasopressors) ▪ Neurologic dysfunction (decreased level of consciousness) ▪ Respiratory dysfunction (PaO_2/FiO_2 ratio <300) ▪ Renal dysfunction (oliguria, serum creatinine >2 mg/dL) ▪ Hepatic dysfunction (elevated PT/INR >1.5) ▪ Hematologic dysfunction (platelet count <100,000/mm^3)	Lap-C is indicated with strict criteria: favorable organ system failure, and negative predictive factors, with CCI ≤3 and ASA-PS ≤2 and who are being treated at an advanced center (where experienced surgeons practice) If the patient is not considered suitable for early surgery, early/urgent biliary drainage is recommended followed by delayed Lap-C once the patient's overall condition has improved.

CCI, Charlson comorbidity index; ASA-PS, American Society of Anesthesiologists physical status classification system.

Adapted from Yokoe M, Hata J, Takada T, et al. Tokyo Guidelines 2018: diagnostic criteria and severity grading of acute cholecystitis (with videos). *J Hepatobiliary Pancreat Sci* 2018;25:41–54; Okamoto K, Suzuki K, Takada T, et al. Tokyo Guidelines 2018: flowchart for the management of acute cholecystitis. *J Hepatobiliary Pancreat Sci* 2018;25:55–72.

Surgery for acute diverticulitis is indicated for patients who present with peritonitis and/or sepsis or who do not improve with medical management and/or percutaneous drainage of associated abscess/infection. Although less than 25% of patients will develop generalized peritonitis after colonic perforation, it is severe with high mortality. Surgical options include simple colostomy formation in the setting of profound inflammation (rarely performed), traditional sigmoid resection with colostomy (Hartmann procedure), and sigmoid resection with a primary colocolonic or colorectal anastomosis with or without a diverting loop ileostomy. Laparoscopic surgery is preferred to open surgery when possible.[36]

Table 8.7 Diagnosis of Cholangitis: Tokyo Guidelines 2018

Systemic inflammation	▪ Fever and/or shaking chills ▪ Laboratory data: evidence of inflammatory response (WBC, CRP, etc.)
Cholestasis	▪ Jaundice (total bilirubin ≥2 mg/dL) ▪ Laboratory data: abnormal liver function tests (ALP, GGT, AST, and ALT)
Imaging	▪ Biliary dilatation ▪ Evidence of the etiology on imaging (stricture, stone, stent, etc.)
Diagnosis of cholangitis	Suspected: presence of 1 item in A + 1 item in either B or C Definite: presence of 1 item in A, 1 item in B, and 1 item in C

ALP, alkaline phosphatase; ALT, alanine transaminase; AST, aspartate aminotransferase/aspartate transaminase; CRP, C-reactive protein; GGT, γ-glutamyl transferase; WBC, white blood cell.

Adapted from Kiriyama S, Kozaka K, Takada T, et al. Tokyo Guidelines 2018: Diagnostic criteria and severity grading of acute cholangitis (with videos). *J Hepatobiliary Pancreat Sci* 2018;25:17–30.

Since recurrence after recovery from an uncomplicated episode of diverticulitis is rare and two or more recurrences are not associated with increased risk of complications, elective colectomy following two episodes of diverticulitis is no longer recommended. Decisions regarding surgical intervention and colectomy must therefore be based on individual potential risks and benefits of colon resection.[37]

For patients who require surgical intervention, the specific treatment that is associated with the best outcome is controversial. Hinchey proposed a practical clinical classification of diverticulitis based on the severity of peritoneal contamination (**Fig. 8.1**) identified at operation.[38] The modified Hinchey classification includes Hinchey Ia (confined pericolic inflammation–phlegmon) and Ib (confined pericolic abscess) and considers classification based on radiologic imaging with CT scan as well. The majority of Hinchey Ib–II cases can be successfully managed nonoperatively. Furthermore, the majority of patients with Hinchey I–II disease who are successfully managed without surgery are unlikely to experience any further acute diverticulitis and therefore, surgery should not be routinely offered to avoid future episodes. A personalized patient-specific approach for elective surgery should be used.

Increasing Hinchey classification is associated with increased mortality. The mortality for patients with Hinchey III is reported as 6% but increases greatly to 35% for fecal peritonitis (Hinchey IV). A systematic review comparing surgical treatments for Hinchey III or IV colonic diverticulitis confirmed that primary resection with anastomosis has a significant advantage with lower mortality compared to Hartmann procedure. Furthermore, laparoscopic peritoneal lavage with subsequent surgical resection, if indicated, had lower surgical morbidity and hospital length of stay compared to the primary resection and anastomosis group.[39] The 2019 EAES/SAGES Diverticulitis Guidelines recommend "Lavage may be considered in selected Hinchey III patients by surgeons with appropriate expertise and the ability to closely watch for and manage complications. The lower stoma rate should be weighed against the higher risk of complications and re-intervention." See also chapter on Diverticular Disease.

Table 8.8 Treatment of Acute Cholangitis by Severity Classification: Tokyo Guidelines 2018 Criteria

Severity of Acute Cholangitis	
Mild (grade I)	Does not meet the criteria of "severe" or "moderate" acute cholangitis at time of initial diagnosis
Moderate (grade II)	Acute cholangitis associated with any two of the following conditions: ▪ Abnormal WBC (>12,000, <4,000/mm^3) ▪ High fever (≥39°C) ▪ Age ≥75 years old ▪ Hyperbilirubinemia (total bilirubin ≥5 mg/dL) ▪ Hypoalbuminemia (<lower limit of normal × 0.7)
Severe (grade III)	Acute cholangitis associated with the onset of dysfunction in at least one of the following organs/systems: ▪ Cardiovascular dysfunction (hypotension requiring vasopressors) ▪ Neurologic dysfunction (disturbance of consciousness) ▪ Respiratory dysfunction (PaO_2/FiO_2 ratio <300) ▪ Renal dysfunction (oliguria, serum creatinine >2 mg/dL) ▪ Hepatic dysfunction (elevated PT/INR >1.5) ▪ Hematologic dysfunction (platelet count <100,000/mm^3)
Assessment of Urgency of Draining **Urgent** biliary drainage (<24 hrs) is indicated when:	

a. severe (grade III) acute cholangitis is present.
b. obstructive biliary stones are associated with severe or moderate acute cholangitis.
c. mild acute cholangitis is not responding to IV antibiotics and fluid resuscitation.

Early (but not urgent) ERCP (<72 hrs) is recommended for patients with mild acute cholangitis who respond to medical therapy.

ERCP, endoscopic retrograde cholangiopancreatography; PT/INR, prothrombin time and international normalized ratio.

Tokyo Guidelines 2018: diagnostic criteria and severity grading of acute cholangitis (with videos). *J Hepatobiliary Pancreat Sci* 2018;25:17–30; Miura F, Okamoto K, Takada T, et al. Tokyo Guidelines 2018: initial management of acute biliary infection and flowchart for acute cholangitis. *J Hepatobiliary Pancreat Sci* 2018;25:31–40.

Table 8.9 Antimicrobials for Treatment of Biliary Infections

Community-acquired acute cholecystitis of mild to moderate severity ▪ Cefazolin ▪ Cefuroxime ▪ Ceftriaxone
Community-acquired acute cholecystitis of severe physiologic disturbance, advanced age, or immunocompromised state ▪ Imipenem/cilastatin ▪ Meropenem ▪ Doripenem ▪ Piperacillin/tazobactam ▪ Ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole
Acute cholangitis following bilioenteric anastomosis of any severity ▪ Imipenem/cilastatin ▪ Meropenem ▪ Doripenem ▪ Piperacillin/tazobactam ▪ Ciprofloxacin, levofloxacin, or cefepime each in combination with metronidazole
Health care–associated biliary infection of any severity ▪ Imipenem/cilastatin ▪ Meropenem ▪ Doripenem ▪ Piperacillin/tazobactam ▪ Ciprofloxacin, levofloxacin, or cefepime, each in combination with metronidazole ▪ Vancomycin added to each regimen

Adapted from Solomkin JS, Mazuski JE, Bradley JS, et al. Diagnosis and management of complicated intra-abdominal infection in adults and children: guidelines by the Surgical Infection Society and the Infectious Diseases Society of America. *Surg Infect (Larchmt)* 2010;11(1):79–109.

Clostridium Difficile Colitis

The incidence and severity of *Clostridium difficile* infection (CDI) has increased, particularly in surgical patients who have been exposed to prior antimicrobial therapy. There has been a substantial change in the management of CDI related to the emergence of the NAP1/BI/027 strain which is associated with higher toxin production and more severe forms of disease. CDI may be associated with mild to moderate diarrhea or colonic ileus and obstipation to severe colitis.[40,41]

Early diagnosis of CDI is imperative. Recommended testing includes two steps, using a glutamine dehydrogenase assay for the Clostridium difficile antigen, followed by enzyme immunoassay toxin testing. Polymerase chain reaction (PCR) confirmatory testing is used if the antigen is positive and toxin is negative.[42] Radiologic testing is helpful, and CT may show colonic mucosal edema (thumbprinting or target sign), ascites, inflammation, and fat stranding and the "accordion sign" which indicates alternating edematous colonic haustra separated by transverse mucosal ridges filled with enteral contrast.

Initial management of CDI is cessation of all antibiotics if possible. The 2017 Update[43] to the 2010 SHEA/IDSA Guidelines have evidence-based recommendations for CDI based on severity of disease (**Fig. 8.2**).[44] Vancomycin or Fidaxomicin are now first-line therapy, and enteral metronidazole is no longer recommended except if the other agents are not available. Fidaxomicin (a macrocyclic antibiotic with a narrow antimicrobial spectrum against *C. difficile*, staphylococci, and enterococci) may also be considered for recurrent CDI or where risk of recurrence is high. A multicenter, multinational randomized trial confirmed decreased recurrence rates compared to oral Vancomycin, and is U.S. Food and Drug Administration (FDA) approved with a recommended treatment dose of 200 mg PO BID.[45] A monoclonal antibody against toxin B (bezlotoxumab) was safe and effective for prevention of recurrent CDI and may be a good therapeutic option for severe CDI as well.[46] Fecal microbiota transplantation is associated with symptom resolution and may be effective in recurrent CDI, but has no role in primary CDI treatment.

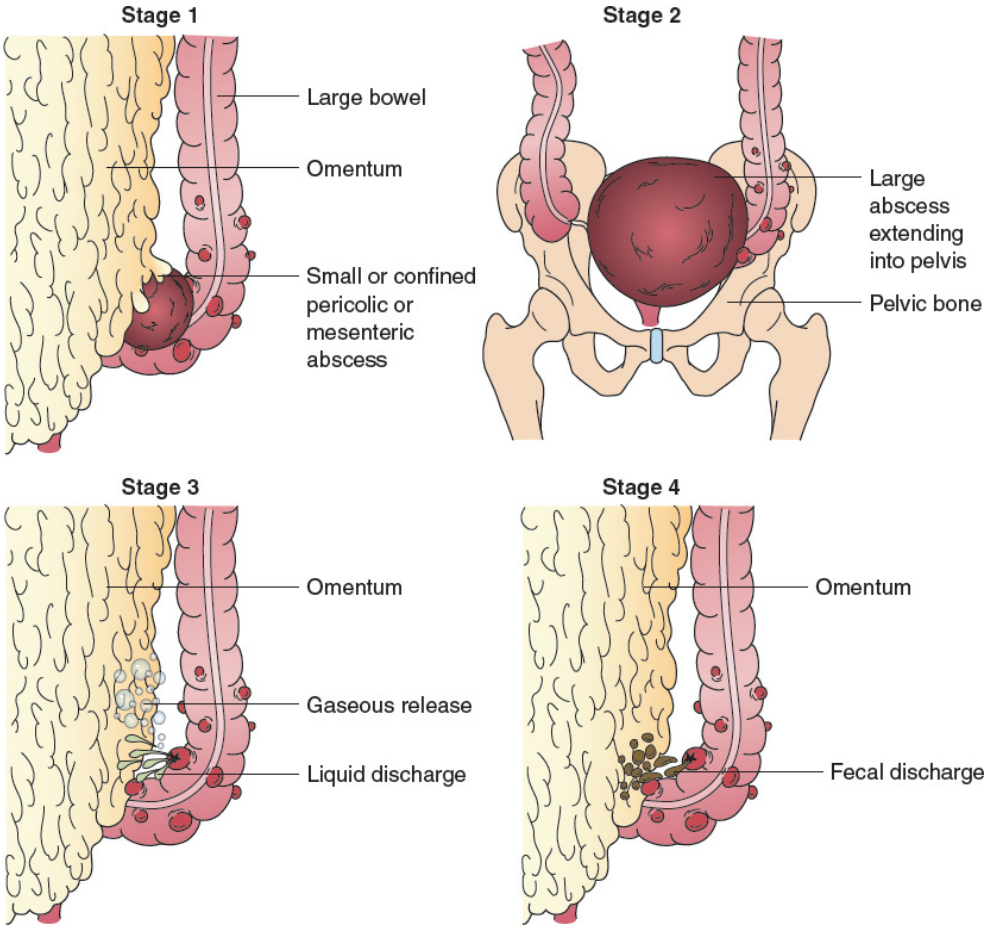


Figure 8.1 Hinchey classification scheme. Patients with stage 1 disease have small, confined, pericolic, or mesenteric abscesses, whereas those with stage 2 disease have larger abscesses, often confined to the pelvis. Stage 3 disease, or perforated diverticulitis, is present when a peridiverticular abscess has ruptured and caused purulent peritonitis. Rupture of an uninflamed and unobstructed diverticulum into the free peritoneal cavity with fetal contamination, the so-called free rupture, signifies stage 4 disease and carries the highest risk of an adverse outcome.

CDI may warrant surgical intervention. Surgical consultation should occur very early in the course of disease in patients with severe and complicated CDI. The indications for surgical management of CDI patients are not clearly defined, but severe disease, worsening clinical condition despite appropriate treatment, and peritonitis or shock states are all potential indications. 9 The two surgical procedures indicated for CDI treatment include (1) total abdominal colectomy (for peritonitis, colonic perforation, ischemia, necrosis, toxic megacolon with impending perforation, septic shock with organ failure) and (2) diverting loop ileostomy and intraoperative colonic lavage for toxin reduction while preserving the colon (**Fig. 8.3**). This new

treatment strategy resulted in reduced mortality compared with the historical population who had undergone total abdominal colectomy (19% vs. 50%), and preservation of the colon was achieved in 93% of patients.[47] A retrospective multicenter study compared total colectomy versus loop ileostomy for CDI treatment and reported that loop ileostomy was associated with decreased mortality.[48] No randomized studies have been published to date comparing these two options.

Pancreatitis

A new classification of acute pancreatitis has been implemented and is based on local disease (whether pancreatic necrosis is present or not, whether it is sterile or infected) and systemic determinants (whether organ failure is present or not, whether it is transient or persistent) of severity (**Table 8.10**). Early management requires goal-directed fluid resuscitation (with avoidance of overresuscitation and abdominal compartment syndrome), assessment of severity of pancreatitis, diagnostic CT imaging to assess for necrotizing pancreatitis, consideration of endoscopic retrograde cholangiopancreatography (ERCP) for biliary pancreatitis, and early enteral nutrition support. Antibiotic prophylaxis for severe acute or necrotizing pancreatitis is not recommended.[49]

Necrotizing pancreatitis is high risk for progression to necrotizing *infected* pancreatitis. Therapeutic antibiotics are required for treatment of documented infected pancreatic necrosis. Causative pathogens include gram-negative microbes and an increase in gram-positive organisms has been reported.[50] Therefore broad-spectrum IV antimicrobials are recommended.

10 The initial treatment of infected pancreatic necrosis is percutaneous catheter or endoscopic (transgastric/transduodenal) drainage with a second drain placement as required. The "step-up" approach consisted of percutaneous drainage followed, if necessary, by minimally invasive retroperitoneal necrosectomy. The minimally invasive step-up approach, as compared with open necrosectomy, reduced the rate of the primary composite endpoint (12% vs. 50%, including major complications [new-onset multiple organ failure or multiple systemic complications, perforation of a visceral organ or enterocutaneous fistula, or bleeding] or death), but the mortality rate did not differ significantly between groups (19% vs. 16%).[51,52]

The long-term follow-up of patients in the PANTER trial confirmed the step-up approach for necrotizing pancreatitis to be superior to open necrosectomy, without increased risk of reinterventions.[53]

11 Lack of clinical improvement after these initial procedures warrants consideration of minimally invasive techniques for pancreatic necrosectomy including video-assisted retroperitoneal debridement (VARD), minimally invasive retroperitoneal pancreatic necrosectomy (MIRP), or transluminal direct endoscopic necrosectomy (DEN).[54] VARD and MIRP use the tract created by percutaneous drainage catheters as a guide for placement of a laparoscope into the retroperitoneum so that debridement and lavage can be performed under direct visualization. Open necrosectomy is associated with substantial morbidity, but to date no randomized trial has documented superiority of either minimally invasive or open surgical technique. Additional trials are underway to address this (**Algorithm 8.3**). See also chapter on Acute Pancreatitis.

Clinical Definition	Supportive Clinical Data	Recommended Treatment[a]	Strength of Recommendation/ Quality of Evidence
Initial episode, non-severe	Leukocytosis with a white blood cell count of ≤15000 cells/mL and a serum creatinine level <1.5 mg/dL	▪ VAN 125 mg given 4 times daily for 10 days, OR ▪ FDX 200 mg given twice daily for 10 days ▪ Alternate if above agents are unavailable: metronidazole, 500 mg 3 times per day by mouth for 10 days	Strong/High Strong/High Weak/High
Initial episode, severe[b]	Leukocytosis with a white blood cell count of ≥15000 cells/mL or a serum creatinine level >1.5 mg/dL	▪ VAN, 125 mg 4 times per day by mouth for 10 days, OR ▪ FDX 200 mg given twice daily for 10 days	Strong/High Strong/High
Initial episode, fulminant	Hypotension or shock, ileus, megacolon	▪ VAN, 500 mg 4 times per day by mouth or by nasogastric tube. If ileus, consider adding rectal instillation of VAN. Intravenously administered metronidazole (500 mg every 8 hours) should be administered together with oral or rectal VAN, particularly if ileus is present.	Strong/Moderate (oral VAN); Weak/Low (rectal VAN); Strong/Moderate (intravenous metronidazole)
First recurrence	…	▪ VAN 125 mg given 4 times daily for 10 days if metronidazole was used for the initial episode, OR ▪ Use a prolonged tapered and pulsed VAN regimen if a standard regimen was used for the initial episode (e.g., 125 mg 4 times per day for 10–14 days, 2 times per day for a week, once per day for a week, and then every 2 or 3 days for 2–8 weeks), OR ▪ FDX 200 mg given twice daily for 10 days if VAN was used for the initial episode	Weak/Low Weak/Low Weak/Moderate
Second or subsequent recurrence	…	▪ VAN in a tapered and pulsed regimen, OR ▪ VAN, 125 mg 4 times per day by mouth for 10 days followed by rifaximin 400 mg 3 times daily for 20 days, OR ▪ FDX 200 mg given twice daily for 10 days, OR ▪ Fecal microbiota transplantation[c]	Weak/Low Weak/Low Weak/Low Strong/Moderate

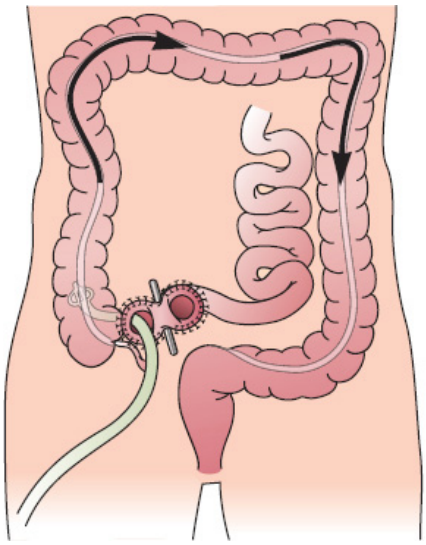
Abbreviations: FDX, fidaxomicin; VAN, vancomycin.
[a]All randomized trials have compared 10-day treatment courses, but some patients (particularly those treated with metronidazole) may have delayed response to treatment and clinicians should consider extending treatment duration to 14 days in those circumstances.
[b]The criteria proposed for defining severe or fulminant *Clostridium difficile* infection (CDI) are based on expert opinion. These may need to be reviewed in the future upon publication of prospectively validated severity scores for patients with CDI.
[c]The opinion of the panel is that appropriate antibiotic treatments for at least 2 recurrences (i.e., 3 CDI episodes) should be tried prior to offering fecal microbiota transplantation.

Figure 8.2 Treatment of initial episode of *Clostridium difficile* infection.

SKIN AND SOFT TISSUE INFECTIONS

Skin and soft tissue infections (SSTIs) span a broad spectrum of clinical entities from limited cellulitis to rapidly progressive necrotizing fasciitis, which may be associated with septic shock or toxic shock syndrome and associated organ failure.[55,56] These SSTIs may result in critical illness and require management in the intensive care unit (ICU).[57,58] Methicillin-resistant *Staphylococcus aureus* (MRSA) has emerged as the most common identifiable cause of severe SSTIs, therefore initiation of empiric anti-MRSA antimicrobials is warranted in all cases of severe SSTIs. In addition, appropriate critical care management, including fluid resuscitation, organ support, and nutritional support are necessary components of treatment of severe SSTIs.

The complex interplay of environment, host, and pathogen is important to consider when evaluating SSTIs and planning therapy. The key to a successful outcome in caring for patients with severe SSTIs is (1) early diagnosis and differentiation of necrotizing versus nonnecrotizing SSTI, (2) early initiation of appropriate empiric broad-spectrum antimicrobial therapy with consideration of risk factors for specific pathogens, (3) "source control," that is, early aggressive surgical intervention for drainage of abscesses and debridement of necrotizing soft tissue infections (NSTIs), and (4) pathogen identification and appropriate deescalation of antimicrobial therapy.



1. Creation of diverting loop ileostomy.
2. Intraoperative antegrade colonic lavage with 8 L of warmed PEG3350/electrolyte solution via ileostomy.
3. Postoperative antegrade colonic enemas with vancomycin (500 mg in 500 mL x 10 days) via ileostomy.

Figure 8.3 Diverting loop ileostomy with antegrade colonic irrigation for CDI.

Before surgery is started:

1. Place the patient in lithotomy position with easy access to rectum.
2. Place a fluid collection bag (commonly used by urology) under the patient's rectum for drainage collection.
3. Place a rectal drainage tube (large Malecot catheter, large Foley catheter, #9 or #10 endotracheal tube, or other large catheter).
4. Have 8 L of warmed polyethylene glycol 3350/electrolyte solution (GoLYTELY; Braintree Laboratories) available in OR for intraoperative colonic irrigation, and dulcolax suppository.

Intraoperatively:

1. Ensure that the colon is viable and without perforation.
2. Create a loop ileostomy (laparoscopic or open).
3. Place a 24-Fr Malecot catheter into the efferent limb of the ileostomy and advance into the right colon through the ileocecal valve. Secure to skin with sutures.
4. Infuse 8 L of warmed polyethylene glycol 3350/electrolyte solution (GoLytely; Braintree Laboratories) into the 24-Fr Malecot catheter via the efferent limb of the ileostomy.
5. Once colonic lavage is completed, perform rectal examination to empty rectum, place dulcolax suppository in rectum to encourage colonic emptying.
6. Instill antegrade colonic enema with vancomycin (500 mg in 500 mL) via ileostomy efferent limb, continue postoperatively.

(Adapted from Neal MD, Alverdy JC, Hall DE, et al. Diverting loop ileostomy and colonic lavage: an alternative to total abdominal colectomy for the treatment of severe, complicated Clostridium difficile associated disease. *Ann Surg* 2011;254:423–427; discussion 427–429.)

Table 8.10 New International Classification of Acute Pancreatitis: Determinants of Severity of Acute Pancreatitis by the 2011 World Congress of the International Association of Pancreatology

Mild AP	No evidence of necrosis or organ failure		
Moderate AP	Evidence of sterile necrosis or transient organ failure		
Severe AP	Evidence of infected necrosis or persistent organ failure		
Critical AP	Evidence of infected necrosis and persistent organ failure		
Local Determinant: Peri/Pancreatic Necrosis	**Systemic Determinant: Organ Failure**		
Nonviable tissue located in the pancreas alone, or in the pancreas and peripancreatic tissues, or in peripancreatic tissues alone. It can be solid or semisolid (partially liquefied) and is without a radiologically defined wall	Defined for three organ systems on the basis of the worst measurement over a 24-hr period In patients without pre-existing organ dysfunction, defined as either SOFA score of 2 or more in the assessed organ system are: ▪ Cardiovascular: need for inotropic agent ▪ Renal: ≥171 μmol/L (≥2 mg/dL) ▪ Respiratory: PaO_2 ≤30 mm Hg (≤40 kPa)		
Sterile necrosis	No proven infection in necrosis	Transient organ failure	Evidence of organ failure in the same organ system for

			less than 48 hrs
Infected necrosis	At least one is present: 1. Gas bubbles within peri/pancreatic necrosis on CT 2. Positive culture by image-guided fine-needle aspiration 3. Positive culture obtained during the first drainage and/or necrosectomy	Persistent organ failure	Evidence of organ failure in the same organ system for 48 hrs or more

SOFA, sepsis-related organ failure assessment; CT, computed tomography.

Classification of Skin and Soft Tissue Infections

The FDA previously classified SSTIs into two broad categories for the purpose of clinical trials evaluating new antimicrobials for the treatment of SSTIs: **uncomplicated** and **complicated** (Table 8.11). **Uncomplicated** SSTIs include superficial infections such as cellulitis, simple abscesses, impetigo, and furuncles. These infections can be treated by antibiotics and/or surgical incision for drainage of abscess alone. In contrast, **complicated** SSTIs include deep soft tissue infections that require significant surgical intervention such as infected ulcers, infected burns, and major abscesses, and these patients also have significant underlying comorbidities, that is, disease states which complicate (and usually delay) response to treatment. Complicated SSTIs are a significant clinical problem, in part related to the increasing resistance of infecting bacteria to current antibiotic therapies.

Uncomplicated Skin and Soft Tissue Infections

Uncomplicated SSTIs are associated with ***low*** risk for life- or limb-threatening infection. These patients can be treated with empiric antibiotic therapy according to likely pathogen and local resistance patterns.

Table 8.11 Comparison of Old and New Classification of SSTIs by FDA

- Uncomplicated
  - Superficial infections, such as:
    - simple abscesses
    - impetiginous lesions
    - furuncles
    - cellulitis
  - Can be treated by antibiotics or surgical incision alone
- Complicated
  - Deep soft tissue, such as:
    - infected ulcers
    - infected burns
    - major abscesses
  - Significant underlying disease state which complicates response to treatment
  - Requires significant surgical intervention and antimicrobials

New FDA Definition (October 2013):

ABSSSI defined as bacterial infection of the skin with a lesion size area of at least 75 cm^2 (lesion size measured by the area of redness, edema, or induration), including the following:

- **Cellulitis/erysipelas:** A diffuse skin infection characterized by spreading areas of redness, edema, and/or induration
- **Wound infection:** An infection characterized by purulent drainage from a wound with surrounding redness, edema, and/or induration
- **Major cutaneous abscess:** An infection characterized by a collection of pus within the dermis or deeper that is accompanied by redness, edema, and/or induration

From https://www.fda.gov/regulatory-information/search-fda-guidance-documents/acute-bacterial-skin-and-skin-structure-infections-developing-drugs-treatment. Accessed September 24, 2020.

Complicated Skin and Soft Tissue Infections

Complicated SSTIs are associated with ***high*** risk for life- or limb-threatening infection. In these patients, it is of paramount importance to initiate appropriate and adequate broad-spectrum initial empiric antimicrobial therapy with coverage for MRSA, and to consider the need for surgical intervention for abscess drainage or debridement.

Patients with complicated SSTIs require hospitalization for treatment. Specific circumstances that warrant hospitalization include the presence of tissue necrosis, sepsis, severe pain, altered mental status, immunocompromised state, and organ failure (respiratory, renal, hepatic). SSTIs can lead to serious potentially life-threatening local and systemic complications. The infections can progress rapidly, and early recognition and proper medical and surgical management is cornerstone of therapy.

12 In October 2013, the FDA changed the SSTI terminology and issued final guidance for the treatment of acute bacterial skin and skin structure infections (ABSSSI).[59] This guidance defined ABSSSI as cellulitis, erysipelas, wound infection, and major cutaneous abscess. An ABSSSI is defined as a bacterial infection of the skin with a lesion size area of at least 75 cm^2 (lesion size measured by the area of redness, edema, or induration). The minimum area of involvement of 75 cm^2 is chosen to select patients with acute bacterial skin infections for which a reliable control drug treatment effect can be estimated for the conduct of new antimicrobial treatment trials. While the FDA generally requires two phase III trials to support approval of drugs to treat ABSSSI, this guidance stated that a single phase III study that is supported by additional independent evidence may suffice.

Patients with the following infection types can be enrolled in ABSSSI clinical trials:

- **Cellulitis/erysipelas:** A diffuse skin infection characterized by spreading areas of redness, edema, and/or induration.
- **Wound infection:** An infection characterized by purulent drainage from a wound with surrounding redness, edema, and/or induration.
- **Major cutaneous abscess:** An infection characterized by a collection of pus within the dermis or deeper that is accompanied by redness, edema, and/or induration.

Unfortunately, this new guidance does not address less serious skin infections, such as impetigo and minor cutaneous abscess, or more serious

infections needing more complex treatment regimens, such as infections resulting from animal or human bites, NSTIs, diabetic foot infection, decubitus ulcer infection, myonecrosis, osteomyelitis, and ecthyma gangrenosum.

Early Diagnosis and Differentiation of Necrotizing versus Nonnecrotizing SSTI

Another classification for SSTIs that is commonly used is the differentiation of **NSTIs** from **nonnecrotizing infections**. This differentiation is critical since necrotizing infections warrant prompt aggressive surgical debridement. Clinical clues to the diagnosis of NSTIs are listed in **Table 8.3**. The differentiation of necrotizing infections from nonnecrotizing infections is critical to achieving adequate surgical therapy.[60] A clear approach to these infections must allow rapid identification and treatment of NSTIs because they are limb threatening and life threatening.

When "hard clinical signs" (bullae, crepitus, gas on x-ray, hypotension with SBP <90 mm Hg, or skin necrosis) of NSTI are present, establishing the diagnosis of NSTI is not difficult. However, hard signs of NSTIs are often absent on presentation, thus potentially delaying diagnosis and surgical intervention. Studies have documented that less than 50% of patients with a definitive diagnosis of NSTI presented with "hard clinical signs" of NSTI.[61] Admission of white blood cell count >15,400 × 10^9/L and/or serum sodium <135 mEq/L was documented to help differentiate NSTI from non-NSTI and aided in early diagnosis.[62,63] The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) score is also helpful as a laboratory aid in distinguishing necrotizing from nonnecrotizing SSTIs (see NSTI section below). In retrospective studies, CT scan has been shown to have a negative predictive value of 100% and a positive predictive value of 76% in diagnosing NSTI.[64]

If there is any question regarding the possible diagnosis of an NSTI, it is imperative to proceed with surgical intervention and to be certain that the surgical incision is continued down to the fascial and muscle level to make a definitive diagnosis.

Early Initiation of Appropriate Empiric Broad-Spectrum Antimicrobial Therapy with Anti-MRSA Coverage and Consideration of Risk Factors for Specific Pathogens

Antimicrobial therapy is an essential element in the management of severe SSTIs. As in all serious life-threatening infections, it is important to initiate **early** and **appropriate** empiric antimicrobial therapy. It is well established that prompt appropriate treatment of hospitalized infections reduces mortality.[2] Similar findings were reported in studies of patients with ventilator-associated pneumonia[65] and sepsis.[66] A study of ICU patients found that the higher mortality rate associated with inappropriate initial therapy is still observed when antibiotics are switched from an inappropriate to an appropriate treatment.[67]

Furthermore, appropriate and timely antibiotic therapy improves treatment outcomes for SSTIs caused by MRSA.[68] In a study of 492 patients with community-onset MRSA SSTIs, 95% of episodes treated with an active antibiotic within 48 hours were treated successfully, compared with an 87% rate of successful treatment in patients who did not receive an active antibiotic. In logistic regression analysis, failure to initiate active antimicrobial therapy within 48 hours of presentation was the only independent predictor of treatment failure. Similarly, in a study of patients admitted to the hospital with MRSA sterile-site infection, multivariate analysis found inappropriate antimicrobial treatment to be an independent risk factor for hospital mortality.[69]

An empiric treatment algorithm for SSTI directed against community-associated MRSA (CA-MRSA) in the emergency department that promotes both the use of antibiotics likely active against CA-MRSA and early incision and drainage of abscesses was examined. Clinical failure occurred in only 3% of cases treated according to the algorithm, compared with 62% of those not treated according to the algorithm. Furthermore, among cases that underwent immediate incision and drainage, initial treatment with antibiotics active in vitro against the MRSA isolate was associated with a decreased clinical failure rate when compared to those treated with inactive antibiotics (0% vs. 67%).[70]

Empiric antibiotic therapy should be initiated in **all** patients with SSTIs. IV broad-spectrum antimicrobial therapy should be initiated when an infection is severe or progresses rapidly, when there are signs of systemic illness, when the patient has comorbidities or is immunosuppressed, for very old or young patients, when an abscess cannot be completely drained, and when the infection does not respond to incision and drainage.[71]

Timely initiation of antimicrobial therapy is also important in the treatment of severe SSTIs, particularly if associated with septic shock. In a study of 2,731 adult patients with septic shock, a strong relationship between the delay in effective antimicrobial initiation and in-hospital mortality was noted.[4] Administration of an antimicrobial effective for isolated or suspected pathogens within the first hour of documented hypotension was associated with a survival rate of 79.9%. Each hour of delay in antimicrobial administration over the ensuing 6 hours was associated with an average decrease in survival of 7.6%. By the second hour after onset of persistent/recurrent hypotension, in-hospital mortality rate was significantly increased relative to receiving therapy within the first hour. In multivariate analysis (including Acute Physiology and Chronic Health Evaluation II score and therapeutic variables), time to initiation of effective antimicrobial therapy was the single strongest predictor of outcome. Interestingly, only 50% of septic shock patients received effective antimicrobial therapy within 6 hours of documented hypotension.

Necrotizing Soft Tissue Infections

NSTIs are aggressive soft tissue infections that cause widespread necrosis, and can include necrotizing cellulitis, fasciitis, and myositis/myonecrosis.[72,73] Establishing the diagnosis of NSTI can be the main challenge in treating patients with NSTI, and knowledge of all available tools is key for early and accurate diagnosis.[74] There have been a number of recent advances in the definition, pathogenesis, diagnostic criteria, and treatment of NSTIs.[75,76]

Patients with NSTIs require prompt aggressive surgical debridement, appropriate IV antibiotics, and intensive support. Despite aggressive treatment, their mortality and morbidity rates remain high, with some series reporting mortality rates of 25% to 35%.[77] A high index of suspicion should

be used in conjunction with laboratory and imaging studies to establish the diagnosis as rapidly as possible. Successful treatment requires early, aggressive surgical debridement of all necrotic tissue, appropriate broad-spectrum systemic antibiotic therapy, and supportive care (fluid resuscitation, organ and critical care support) to maintain oxygenation and tissue perfusion. Delayed definitive debridement remains the single most important risk factor for death. Early operative debridement is the major determinant of outcome in NSTIs.

A recent single-institution series of 166 patients documented that the overall mortality rate was 17% and limb loss occurred in 26% of patients with extremity involvement.[78] Independent predictors of mortality included white blood cell count greater than 30,000 × $10^3/\mu L$, creatinine level greater than 2 mg/dL, and heart disease at hospital admission. Independent predictors of limb loss included heart disease and shock (systolic blood pressure <90 mm Hg) at hospital admission. Clostridial infection was an independent predictor for both limb loss and mortality and was highly associated with IV drug use and a high rate of leukocytosis on hospital admission.

A 30-day postoperative mortality risk calculator for NSTI was developed using the NSQIP which identified seven independent variables that correlated with mortality: age older than 60 years, functional status, requiring dialysis, American Society of Anesthesiologists (ASA) class 4 or higher, emergent surgery, septic shock, and low platelet count. The receiver operating characteristic area was 0.85, which indicated a strong predictive model that can aid physicians in the decision-making process.[79]

13 Early operative debridement is the major determinant of outcome in NSTIs. However, early recognition of NSTIs is difficult clinically. A novel diagnostic scoring system for distinguishing NSTIs from other severe soft tissue infections based on laboratory tests routinely performed for the evaluation of severe SSTIs is called the LRINEC score (**Table 8.12**).[80] The LRINEC score was initially developed in a retrospective observational study including 145 patients with necrotizing fasciitis and 309 patients with severe cellulitis or abscesses admitted to the two tertiary care hospitals. The cutoff value for the LRINEC score was 6 points with a positive predictive value of 92% and negative predictive value of 96%. The LRINEC score is a robust score capable of detecting clinically early cases of necrotizing

fasciitis. The variables used are routinely measured to assess severe soft tissue infections. Patients with a LRINEC score of ≥6 should be carefully evaluated for the presence of necrotizing fasciitis.

Table 8.12 The Laboratory Risk Indicator for Necrotizing Fasciitis (LRINEC) Score

Variable, Units	Score
C-reactive protein, mg/L	
<150	0
≥150	4
Total white cell count, per mm^3	
<15	0
15–25	1
>25	2
Hemoglobin, g/dL	
>13.5	0
11–13.5	1
<11	2
Sodium, mmol/L	
≥135	0
≤135	2
Creatinine, μmol/L	
≤141	0
>141	2
Glucose, mmol/L	
≤10	0
>10	1

The maximum score is 13; a score ≥6 should raise the suspicion of necrotizing fasciitis and a score of ≥8 is strongly predictive of this disease.

Since the initial development of the LRINEC score, a number of other cohort studies have validated its utility in the diagnosis of NSTIs. A

multicenter study in 229 patients with NSTIs from 2002 to 2005 reported an overall mortality rate of 16% and amputation rate of 26%. This study also documented that a LRINEC score ≥6 was associated with a higher rate of both mortality and amputation.[81]

Diagnostic Imaging in Necrotizing Soft Tissue Infections

NSTIs necessitate prompt aggressive surgical debridement for satisfactory treatment in addition to antimicrobial therapy. Because of the rapidly progressive and potentially fatal outcome of this condition, if imaging cannot be performed expeditiously, delaying treatment is not justified. Plain film findings may reveal extensive soft tissue gas. CT examination can reveal asymmetric thickening of deep fascia in association with gas, and associated abscesses may also be present. MR imaging can also assist in the diagnosis of NSTIs.[82] MR imaging has been documented to effectively differentiate between necrotizing and nonnecrotizing infections of the lower extremity and other areas of the body, but should not delay prompt surgical intervention in NSTIs management.[83–85]

Microbiology of Necrotizing Soft Tissue Infections

Necrotizing fasciitis and myonecrosis are typically caused by infection with *group A streptococcus (GAS)*, *Clostridium perfringens*, or, most commonly, aerobic and anaerobic organisms as part of a polymicrobial infection that may include *S. aureus*. In case series, CA-MRSA has recently been described as a predominantly monomicrobial cause of necrotizing fasciitis.[86,87] A retrospective review of patients presenting with necrotizing fasciitis indicated that MRSA was the most common pathogen, accounting for one-third of the organisms isolated.[88]

NSTIs have been classified into two types, either polymicrobial (**type I**) or monomicrobial (**type II**). Polymicrobial infections are more common, due to both aerobic and anaerobic organisms, and commonly occur in the trunk and perineum. NSTIs that are monomicrobial in origin commonly occur in the limbs and are typically caused by infection with GAS, *C. perfringens,* or *S. aureus*. NSTIs are categorized into these two specific types based on the microbiologic etiology of the infection, and this classification does impact on

the specific antimicrobial agents required for treatment of these NSTIs. Increasingly, MRSA has been identified as the causative microbe in NSTIs, but a separate category for this NSTI does not currently exist.[89–93] Given this finding, anti-MRSA empiric antimicrobial therapy should be initiated in all patients with NSTIs and pathogen-directed antimicrobial therapy should be considered once tissue culture results are available.

Uncommon microbiologic causes of NSTIs and primary sepsis include *Vibrio* and *Aeromonas* species, virulent gram-negative bacteria, and members of the Vibrionaceae family that thrive in aquatic environments.[94] These NSTIs are likely to occur in patients with hepatic disease, diabetes, and immunocompromised conditions.[95] These organisms are found in warm sea waters and are often present in raw oysters, shellfish, and other seafood. The diagnosis of vibrio NSTIs should be suspected when a patient has the appropriate clinical findings and a history of contact with seawater or raw seafood.[96] Early fasciotomy and culture-directed antimicrobial therapy should be aggressively performed in those patients with hypotensive shock, leukopenia, severe hypoalbuminemia, and underlying chronic illness, especially a combination of hepatic dysfunction and diabetes mellitus. The rates of amputation and mortality are very high in these patients, and early definitive management is of paramount importance.[97–99] A study of 125 patients identified that a LRINEC score of 2 or greater and the presence of hemorrhagic bullous/blistering lesions in patients with *Vibrio vulnificus* SSTI are associated with a 12-fold increased risk for the presence of NSTI and necrotizing fasciitis.[100]

Pyomyositis

Myositis is a rare infection that may lead to serious and potentially life-threatening local and systemic complications.[101] The infection can progress rapidly, and early recognition and proper medical and surgical management is therefore the cornerstone of therapy. With the increasing prevalence of community-associated MRSA as a pathogen in severe SSTIs, pyomyositis is more common than in past years.[102,103] Myositis often occurs in muscle sites that have been compromised by injury, ischemia, malignancy, or surgery. The predominant pathogens are *S. aureus,* GAS, gram-negative aerobic and

facultative bacilli, and the indigenous aerobic and anaerobic cutaneous and mucous membranes local microflora.

CT scan imaging is a rapid and sensitive diagnostic test and commonly demonstrates diffuse enlargement of the involved muscle and may demonstrate the presence of fluid or gas collections within the muscle suggesting the presence of abscesses. MRI is more sensitive in showing early inflammatory changes prior to development of abscesses in myositis.[104] Emergency surgical exploration is warranted in order to define the nature of the infective process which is accomplished by direct examination of the involved muscles. Surgical intervention is required to perform appropriate abscess drainage and debridement and also to evaluate for necrotizing myositis. Fasciotomies and extremity amputation are sometimes necessary.

SURGICAL SITE INFECTIONS

Epidemiology

SSI is the leading nosocomial infection among surgical patients and the second most common nosocomial infection overall. In the United States, greater than 40 million inpatient and outpatient surgical procedures are performed each year and 2% to 5% are complicated by SSIs. SSIs result in increased length of stay (7 days) and additional cost ($400 to $2,600 per infection; total $130 to $845 million per year).[58,105–107] Among the four health care–associated infections (pneumonia, SSI, urinary tract infection, and bloodstream infection), SSIs are the second most common health care–associated infection, accounting for 17% of all health care–associated infections among hospitalized patients. A similar rate was obtained from the National Healthcare Safety Network (NHSN) hospitals reporting data in 2006–2008 (15,862 SSI following 830,748 operative procedures, with an overall rate of nearly 2%).[108]

Definitions

SSIs are defined in three specific categories by the Centers for Disease Control and Prevention (CDC), including superficial incisional SSI, deep

incisional SSI, and organ/space SSI (**Fig. 8.4**, Table 8.13), dependent on the depth of the infection at the surgical incision site. In addition, the SSI must occur within 30 days after the operative procedure if no implant is left in place or within 1 year if implant is in place and the infection appears to be related to the operative procedure. More specific criteria regarding these definitions are available in the CDC Guideline for Prevention of Surgical Site Infection.[109]

Risk Factors for Surgical Site Infection

SSI risk is strongly associated with wound classification, with low risk for SSI in *clean* and *clean–contaminated* wound classes, and high risk for SSI in *contaminated* and *dirty–infected* wound classes. Three independent variables have been shown to be associated with SSI risk, initially developed by the National Nosocomial Infections Surveillance System (NNIS). The NHSN was established in 2005 to integrate and supersede three legacy surveillance systems at the CDC: the NNIS system, the Dialysis Surveillance Network (DSN), and the National Surveillance System for Healthcare Workers (NaSH). Similar to the NNIS system, NHSN facilities voluntarily report their health care–associated infection surveillance data for aggregation into a single national database.

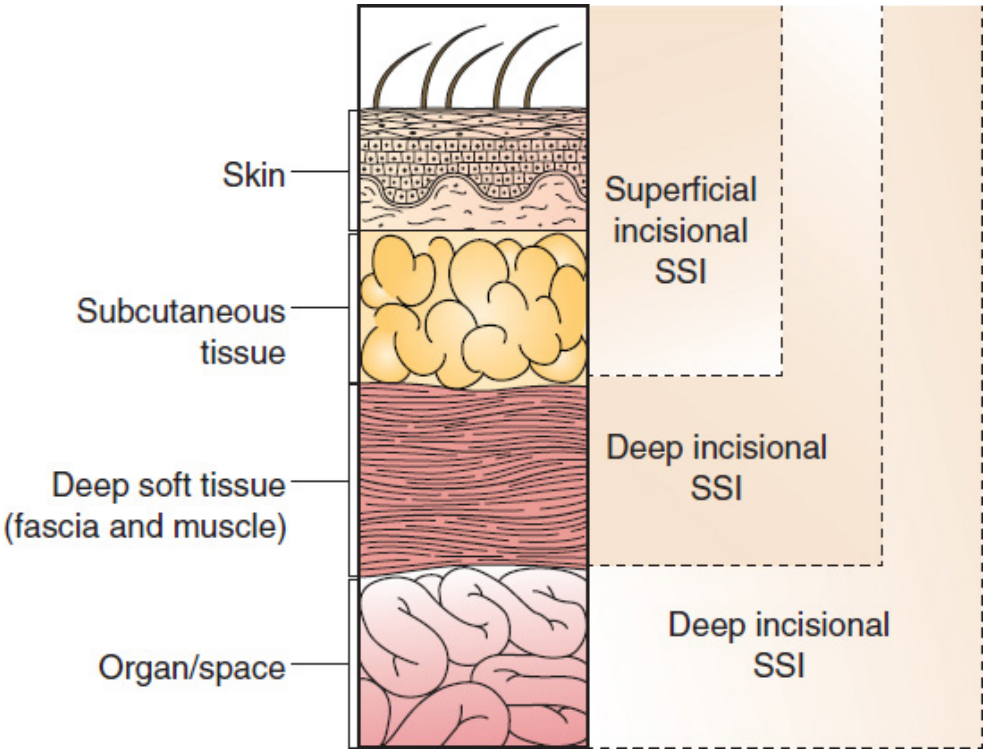

Figure 8.4 Surgical site infection (SSI) definitions by CDC.
Cross-section of the abdominal depicted.
Superficial incisional SSI involves only the skin and subcutaneous tissue layer of the incision.
Deep incisional SSI involves deep soft tissues (e.g., fascia and muscle layers) of the incision.
Organ/Space SSI involves any part of the body, excluding the skin incision, fascia or muscle layers, that is opened or manipulated during the operative procedure (e.g., intra-abdominal abscess or thoracic empyema).

Table 8.13 CDC/NHSN Classification of Surgical Site Infections (SSIs)

Type of SSI	Definition
Superficial incisional	Infection occurs within 30 days after the operative procedure and involves only skin and subcutaneous tissue of the incision and patient has at least one of the following: a. Purulent drainage from the superficial incision b. Organisms isolated from an aseptically obtained culture of fluid or tissue from the superficial incision c. At least one of the following signs or symptoms of infection: pain or tenderness, localized swelling, redness, or heat, and superficial incision is deliberately opened by surgeon and is culture positive or not cultured. A culture-negative finding does not meet this criterion d. Diagnosis of superficial incisional SSI by the surgeon or attending physician
Deep incisional	Infection occurs within 30 days after the operative procedure if no implant[a] is left in place or within 1 yr if implant is in place and the infection appears to be related to the operative procedure and involves deep soft tissues (e.g., fascial and muscle

	layers) of the incision, and patient has at least one of the following: a. Purulent drainage from the deep incision but not from the organ/space component of the surgical site b. A deep incision spontaneously dehisces or is deliberately opened by a surgeon and is culture positive or not cultured when the patient has at least one of the following signs or symptoms: fever (38°C), or localized pain or tenderness. A culture-negative finding does not meet this criterion c. An abscess or other evidence of infection involving the deep incision is found on direct examination, during reoperation, or by histopathologic or radiologic examination d. Diagnosis of a deep incisional SSI by a surgeon or attending physician

[a]Implant: A nonhuman-derived object, material, or tissue (e.g., prosthetic heart valve, nonhuman vascular graft, mechanical heart, or hip prosthesis) that is permanently placed in a patient during an operative procedure and is not routinely manipulated for diagnostic or therapeutic purposes.

From Horan TC, Andrus M, Dudeck MA. CDC/NHSN surveillance definition of health care-associated infection and criteria for specific types of infections in the acute care setting. *Am J Infect Control* 2008;36:309–332.

The NHSN SSI Risk Index includes an ASA score greater than 2, classification of wound as contaminated or dirty, and prolonged duration of operation.[110,111] Although the risk of infection increases within the wound

classification, it has been shown to be also dependent within each wound class on the NNIS classification.

Basic SSI Risk Index

The index used in NHSN assigns surgical patients into categories based on the presence of three major risk factors:

1. Operation lasting more than the duration cut point hours, where the duration cut point is the approximate 75th percentile of the duration of surgery in minutes for the operative procedure
2. Contaminated (class 3) or dirty/infected (class 4) wound class
3. ASA classification of 3, 4, or 5

The patient's SSI risk category is simply the number of these factors present at the time of the operation.

The laparoscopic surgical approach is associated with decreased SSI incidence, and a modified risk index (category 1 when procedure was performed with a laparoscope) has been created to address this approach.

Additional patient-specific risk factors for SSI have also been identified that are not included in this risk index, including the presence of anemia, blood transfusion intraoperatively, and colonization with resistant pathogens.[111,112] This SSI Risk Index warrants reevaluation for the future, particularly with regard to resistant pathogens and other patient-specific risk factors that are not modifiable prior to surgical intervention. It is of paramount importance to include an SSI risk assessment in all future clinical trials where SSI is a primary outcome measure.

Surgical Site Infection Prevention

Preventive measures for SSI include antimicrobial prophylaxis, sterilization methods, proper ventilation of operating rooms, use of barriers, no shaving, clipping if hair removal is required, proper surgical skin preparation and surgical techniques, maintenance of normothermia, glycemic control, and the provision of supplemental oxygen.[107] The National Surgical Infection Prevention (SIP) project was initiated as the first component of the Surgical Care Improvement Project (SCIP). Initiated in 2003, the SCIP partnership

sought to substantially reduce surgical mortality and morbidity through collaborative efforts.

Despite evidence of effectiveness of preoperative antimicrobials for SSI prevention and the publication of guidelines for antimicrobial prophylaxis, it was recognized that use was often suboptimal. As part of the SIP initiative, three SIP performance measures were developed:

- SIP-1: **Antibiotic timing:** Proportion of patients in whom IV antimicrobial prophylaxis is initiated within 1 hour before incision.
- SIP-2: **Antibiotic selection:** Proportion of patients are given prophylactic antimicrobials consistent with published guidelines.
- SIP-3: **Antibiotic discontinuation within 24 hours:** Proportion of patients whose antimicrobial prophylaxis is discontinued within 24 hours after surgery.

Numerous studies document that antimicrobial prophylaxis for SSI is most effective when provided 30 to 60 minutes prior to the initial surgical incision, allowing adequate blood and tissue concentrations at the time of skin incision. Risk of SSI increases when antimicrobial prophylaxis is given too early (more than 2 hours prior to skin incision) or too late (after skin incision). In a recent study of 4,472 patients, SSI risk increased incrementally as the interval of time between antibiotic infusion and the surgical incision increased. These data from a large multicenter collaborative study confirmed lower SSI risk when surgical antimicrobial prophylaxis with cephalosporins and other antibiotics with short infusion times were given within 30 minutes prior to surgical incision.[113]

In addition, the correct antimicrobial must be administered to cover the potential causative pathogens, dependent on the surgical procedure performed. The SCIP pocket card (**Table 8.14**) provides a list of the recommended preoperative antimicrobials for specific surgical procedures. The recent publication of the "Clinical practice guidelines for antimicrobial prophylaxis in surgery" by the American Society of Health-System Pharmacists, Infectious Diseases Society of America, Surgical Infection Society, and Society for Healthcare Epidemiology of America provides evidence-based national recommendations.[114]

Table 8.14 Recommended Preoperative Antimicrobials for Specific Surgical Procedures

Prophylactic Antibiotic Regimen Selection for Surgery	Prophylactic Antibiotic Regimen Selection for Surgery
Surgical procedure: CABG, other cardiac or vascular	**Surgical procedure: hip/knee arthroplasty**
Approved antibiotics Cefazolin, cefuroxime, or vancomycin[a] If β-lactam allergy: vancomycin[b] or clindamycin[b]	**Approved antibiotics** Cefazolin or cefuroxime or vancomycin[a] If β-lactam allergy: vancomycin[b] or clindamycin[b]
Surgical procedure: hysterectomy	**Surgical procedure: colon**
Approved antibiotics Cefotetan, cefazolin, cefoxitin, cefuroxime, or ampicillin/sulbactam If β-lactam allergy: clindamycin + aminoglycoside, or clindamycin + quinolone, or clindamycin + aztreonam OR metronidazole + aminoglycoside, or metronidazole + quinolone	**Approved antibiotics** Cefotetan, cefoxitin, ampicillin/sulbactam, or [c]ertapenem OR cefazolin or cefuroxime + metronidazole If β-lactam allergy: clindamycin + aminoglycoside, or clindamycin + quinolone, or clindamycin + aztreonam OR metronidazole with aminoglycoside, or metronidazole + quinolone
Surgical procedure: special considerations	**Surgical procedure: special considerations**

[a]Vancomycin is acceptable with a physician/APN/PA/pharmacist documented justification for its use (see data element *Vancomycin*).

[b]For cardiac, orthopedic, and vascular surgery, if the patient is allergic to β-lactam antibiotics, vancomycin or clindamycin is an acceptable substitute.

[c]A single dose of ertapenem is recommended for colon procedures.

The first report of the National SIP Project baseline results from a systematic random sample of 34,133 Medicare inpatients undergoing surgery in U.S. hospitals in 2001 documented that only 55.7% of patients received a dose of parenteral antimicrobial prophylaxis within 1 hour before surgical incision. Antimicrobial agents consistent with published guidelines were administered to 92.6% of patients and antimicrobial prophylaxis was discontinued within 24 hours of surgery end time for only 40.7% of patients. Interestingly, only 28% of these surgical patients had compliance with all three of these performance measures.[115]

We have truly made remarkable progress in the United States with appropriate perioperative antimicrobial prophylaxis since that initial published report. Compliance with SIP-1 measure (antibiotics within 60 minutes prior to incision) increased from 55.7% to 91.6%; compliance with SIP-2 measure (guideline antibiotics) increased from 92.6% to 95.8%; and compliance with SIP-3 (antibiotics discontinued) increased from 40.7% to 87.7%.

Additional Strategies for Surgical Site Infection Prevention

Surgical Hand Antisepsis

Surgical hand antisepsis, to destroy bacteria, is routinely carried out before undertaking invasive procedures. A recent review of 10 trials confirmed that alcohol rubs used in preparation for surgery by the surgical team are as effective as aqueous scrubbing in SSI prevention. There is no evidence to suggest that any particular alcohol rub is better than another. Evidence from four studies suggests that chlorhexidine gluconate–based aqueous scrubs are more effective than povidone iodine–based aqueous scrubs in terms of the numbers of bacterial colony–forming units on the hands.[116]

Chlorhexidine as Skin Surgical Site Preparation

Preoperative skin antisepsis of the surgical site is performed to reduce the risk of SSI by removal of skin microorganisms. A review of six randomized controlled trials identified significant heterogeneity and the trial results could not be pooled. There was no evidence of a benefit in four trials associated with the use of iodophor-impregnated drapes.[117] More recent studies have documented that chlorhexidine provided superior skin decontamination compared to povidone-iodine.[118–121] The most recent Cochrane systematic review found evidence that preoperative skin preparation with 0.5% chlorhexidine in alcohol was associated with lower SSI rates following clean surgery than alcohol-based povidone-iodine paint.[122]

Appropriate Hair Removal

The preparation of the surgical site has traditionally included the routine removal of body hair, however, some studies have suggested that this is deleterious. A Cochrane systematic review of 11 randomized clinical trials, and 3 trials (n = 3,193) comparing shaving with clipping, found that there were statistically more SSIs with shaving than clipping. If it is necessary to remove hair, clipping results in fewer SSIs than shaving using a razor.[123]

Normothermia Maintenance during Surgery

Perioperative hypothermia is common and adversely affects clinical outcomes. The primary beneficial effects of warming are mediated through increased blood flow and oxygen tension at the tissue level. Hypothermia may facilitate SSI in two ways. First, sufficient intraoperative hypothermia triggers thermoregulatory vasoconstriction. Second, considerable evidence indicates that mild core hypothermia directly impairs immune function including T-cell–mediated antibody production and nonspecific oxidative bacterial killing by neutrophils. Randomized controlled trials have documented that perioperative warming is associated with a significant reduction in SSI and this simple SSI preventive strategy should be implemented in all surgical patients.[124–126]

Normoglycemia Maintenance during Surgery

Perioperative hyperglycemia has been associated with increased SSIs and previous recommendations have been to treat glucose levels above 200

mg/dL. Recent studies have questioned the optimal glycemic control regimen to prevent SSIs. A recent Cochrane Database systematic review included five randomized controlled clinical trials with a total of 773 patients randomized. Due to heterogeneity in patient populations, perioperative period, glycemic target, route of insulin administration, and definitions of outcome measures, combination of the results of the five trials into a meta-analysis was not appropriate. The authors concluded that there is insufficient evidence to support strict glycemic control in the intra- and postoperative period among surgical patients for the prevention of SSIs.[127] A Cochrane review of 12 trials that randomized diabetic patients to intensive or conventional glycemic control perioperatively concluded that no significant differences were identified in patients with diabetes mellitus. However, post hoc analysis indicated that intensive glycemic control was associated with greater incidence of hypoglycemia episodes.[128]

There are no randomized trials evaluating immediate preoperative glycemic control in any setting or intra/postoperative glycemic control in non-ICU patients. High-quality evidence for strict glycemic control in the intra- and/or postoperative period among surgical ICU patients, cardiac and noncardiac, to reduce SSIs, independent of other potential benefits, is also lacking. Further large, adequately powered, well-designed randomized trials are necessary to identify the ideal target for perioperative glycemic control in patients at high risk for SSIs. Future trials should report all nosocomial infections as well as SSIs. Given the heterogeneity seen in the included trials, it would appear that trials should be targeted at very specific populations and attempts to draw broader conclusions should not be made. At present, we should strive at least to maintain blood glucose <200 mg/dL in the perioperative period in our surgical patients.

Supplemental Oxygen in Perioperative Period

Several randomized controlled trials have been conducted to assess the benefit of perioperative supplemental oxygen in SSI reduction, yet meta-analyses have arrived at different conclusions.[129–131] On careful review, a number of problems with the conduct of these trials are noted: (1) SSI definition was not consistent with CDC definitions; (2) the interval for assessment of SSI was variable, ranging from 15 to 30 days; (3) SSI was

captured retrospectively in some studies and was not always a primary outcome measure; (4) no assessment of the patient's individual risk factors for SSI was performed; (5) no control of perioperative antibiotic prophylaxis timing or selection was performed; and (6) there was variable provision of high FiO_2 supplemental oxygen in each of the studies.[132]

The first institutional priority should be to universally implement all the evidence-based practices that reduce SSIs. The "SSI Bundle" from the Institute for Healthcare Improvement includes (1) appropriate use of antibiotics, (2) appropriate hair removal, (3) perioperative glucose control, and (4) perioperative normothermia.[133] The additional provision of increased inspired oxygen concentrations should be considered as an additional quality improvement measure, particularly in institutions with high SSI rates. A collaborative of 44 hospitals implemented the SSI preventive strategies discussed above and documented a significant reduction in the SSI rate, from 2.3% to 1.7%, representing a 27% reduction from the first to the last 3 months of the 1-year project.[134] Finally, prospective SSI surveillance, including postdischarge surveillance, should be instituted to obtain accurate information regarding institutional SSI rates.[135]

Surgical Site Infection and Colorectal Surgery

Surgical care bundles have been documented to be effective in reducing SSIs in patients undergoing colorectal surgery and therefore should be implemented.[136] Surgeons have held a long-standing belief that mechanical bowel preparation is an efficient strategy to reduce SSI and anastomotic leak rates following elective colorectal surgery. Recent systematic reviews have found that there is no statistically significant evidence that patients benefit from mechanical bowel preparation either in SSI or anastomotic leak rates.[137] In contrast, the use of nonabsorbable enteral antimicrobials covering aerobic and anaerobic colonic bacteria, in addition to IV preoperative antibiotics, is associated with a significant reduction in SSI by at least 75%.[138–140]

Treatment of Surgical Site Infection

Once superficial or deep incisional SSI is diagnosed, "pathogen identification" is of paramount importance. In years past, the surgical incision was opened and dressing changes were initiated with no culture of the surgical site obtained. In today's era of multidrug-resistant pathogens, a Gram stain and culture of the surgical site should always be obtained in order to determine the optimal antimicrobial therapy that is required for SSI treatment.

SSI treatment includes four strategies for successful treatment: (1) early empiric antimicrobial therapy; (2) decision-making regarding whether the surgical site should be opened; (3) pathogen identification; and (4) deescalation of antimicrobial therapy once culture results are available.

For organ/space SSI, "source control" and "pathogen identification" are both high priorities in order to achieve successful treatment. In the case of intra-abdominal abscess, source control can be provided by either interventional radiology percutaneous drainage or open surgical drainage of the abscess. Abscess fluid should be sent for Gram stain and culture, and empiric antimicrobial treatment should be deescalated once culture results are available.

Current Challenges in Surgical Site Infection

There are a number of growing challenges in SSI, including resistant pathogens, our increasingly elderly population, more patients with chronic diseases or immunocompromised states undergoing surgery, and increasing patients undergoing surgery for solid organ transplantation and placement of prosthetic devices. MRSA was reported to be the most common cause of SSI in vascular surgery patients (n = 772 over a 2-year period) in 2004.[141,142] MRSA has emerged as the leading cause of postoperative infection in vascular surgery patients, and is associated with substantial morbidity, increased hospital length of stay, and higher incidences of amputation and graft removal.

Comparison of the causative pathogens for SSI in U.S. hospitals documents that *S. aureus* increased from 22.5% (1986–2003) to 30% (2006–2007), with MRSA now the leading causative pathogen, comprising 49.2%

of all isolates.[142,143] In a study of 8,302 patients readmitted to U.S. hospitals with culture-confirmed SSI from 2003 to 2007, it was noted that the proportion of infections due to MRSA significantly increased from 16.1% to 20.6% and was associated with higher mortality rates, longer length of stay, and higher hospital costs.[144] Based on this important finding, some have strongly advocated for active screening for nasal carriage of MRSA prior to elective surgery with modification of antimicrobials for SSI prevention based on those results.[145–147] Eradication of MRSA before surgery appears to lower SSI rates due to MRSA and is recommended.[148,149] In contrast, a prospective interventional cohort study that employed a universal rapid MRSA admission screening strategy among 21,754 surgical patients at a Swiss teaching hospital reported that nosocomial MRSA infection, including SSI, did not decrease, but relatively low rates of MRSA infection were present at the start of this study.[150]

An "MRSA bundle" has been developed including five components:

1. MRSA nasal screening of patients upon admission, transfer, and discharge using PCR
2. Contact isolation of positive patients
3. Standardized hand hygiene
4. Cultural transformation campaign with staff and leadership engagement through positive deviance
5. Ongoing monitoring of process and outcome measures

Implementation of the MRSA bundle was associated with a significant decrease in MRSA transmission from 5.8 to 3.0 per 1,000 bed-days, significant reduction in MRSA nosocomial infections (2.0 to 1.0 per 1,000 bed-days), and a significant decrease in overall SSIs, with a 65% reduction in orthopedic MRSA SSIs and a 1% decrease in cardiac MRSA SSIs.[151]

The advent of CA-MRSA[152,153] has also significantly impacted SSI. Recent studies document that CA-MRSA is replacing traditional health care–associated or nosocomial MRSA strains in SSI among inpatients.[154] A report from a large community hospital in St. Louis, MO, examined the rates of SSI due to *S. aureus* in a total of 122,040 surgical procedures in an earlier period (2003–2006) versus later period (2006–2007). MRSA was identified as the SSI pathogen in 40% of all inpatients in both time periods. Interestingly, the percentage of clindamycin-susceptible MRSA

(distinguishing CA-MRSA) as an SSI causative pathogen for inpatients rose from 9% in the early period to 19% in the later period. This increase in the rate of CA-MRSA SSI was observed only among inpatients, not among ambulatory patients. Similarly, CA-MRSA has emerged as a leading cause of health care–associated infections among patients with prosthetic joint SSIs.[155]

The use of perioperative intranasal mupirocin for SSI prevention, particularly in patients with MRSA nasal colonization, remains controversial. Reviews of multiple clinical trials documented that no reduction in SSI was seen in general surgery or cardiac surgery patients; however, in nongeneral surgery patients, the use of mupirocin was associated with a reduction in SSI.[148,149,156]

Shock

Joseph Cuschieri

Key Points

1. Shock is the clinical syndrome that results from inadequate tissue perfusion.
2. Shock can be caused by hypovolemic, cardiogenic, extracardiac obstructive, and distributive conditions.
3. Hypovolemic shock due to ongoing fluid, blood, and/or plasma loss leads to progressive cardiovascular deterioration, ultimate hypotension, oliguria, confusion, irreversible cell injury, and death.
4. Cardiogenic shock results in decreased tissue perfusion due to intrinsic cardiac pump failure.
5. Extracardiac obstructive shock attenuates cardiac pump function due to external compression of inflow and outflow (tamponade, tension pneumothorax, etc.).
6. Septic and traumatic shock, forms of distributive shock, are systemic inflammatory responses to infection or tissue injury with cellular breakdown, producing severe hypotension requiring massive volume resuscitation and high risk of multiple organ failure and death.
7. Complications of an episode of shock include ischemia–reperfusion injury from oxidant stress; potential secondary immunosuppression with enhanced nosocomial infection risk; hypothermia and coagulopathy; and multiple organ failure syndrome, including abdominal compartment syndrome (ACS).
8. Treatment of shock requires goal-directed volume resuscitation with treatment of the underlying etiology and careful monitoring of adequacy of end-organ perfusion to avoid under- and overresuscitation.

INTRODUCTION

The current accepted concept of shock was first described in 1929 by Cannon[1] as inadequate blood flow that results 1 in cellular hypoxia.

Persistence of cellular hypoxia results in dysfunction at both cellular and organ levels. Although shock can result from a number of etiologies, it was Blalock who first described the four major causes: hematogenic, neurogenic, cardiogenic, and vasogenic.[2,3] In fact, Blalock was the first to recognize the third-space fluid loss that follows shock resuscitation that is greater than the quantity of initial blood loss.[4] As a result, therapy began to focus not only on restoring intravascular volume but also on replacing fluid lost to the interstitium with a balanced salt solution. Investigators then became increasingly intrigued by the fact that, at some point, shock becomes irreversible and is no longer responsive to further volume resuscitation. As stated nearly a century ago by Wiggers, "at a certain stage adequate circulation cannot be restored by merely filling the system, as one does an automobile radiator."[5] Other "unknown" factors sustain the shock state, blood pressure cannot be restored, improvements are only transient, and death occurs shortly thereafter due to progressive organ dysfunction.

The current concept of shock has led to a reclassification into four distinct groups—hypovolemic, cardiogenic, extracardiac obstructive, and distributive—that may occur independent of each other, or more characteristically synergistic with each other.[6] Early recognition and prompt treatment are essential to modern treatment. If delayed, uncorrected critical oxygen delivery deficits occur that lead to irreversible shock. However, it is believed that future therapies will move beyond simple recognition, fluid resuscitation, and cardiovascular support. Thus, investigators are increasingly looking to gain an understanding of the chain of events that occur, which lead to organ damage and irreversibility. This chapter describes these events, discusses the therapeutic approaches utilized in current management, and offers a brief perspective on what may lie ahead in the future.

EVALUATION OF SHOCK

It is critically important to the patient's ultimate outcome that recognition and treatment of shock occur before decompensation. The clinical assessment must be guided by the knowledge that the severity of symptoms and signs of shock vary between patients and the type of shock present. The patient is

evaluated based on clinical appearance, hemodynamic measurements, physiologic responses, and biochemical analyses.

Early during various shock states, vasoconstriction frequently causes the skin to be cool leading to poor capillary refill. However, this must be contrasted to shock states induced by either neurogenic or septic states in which vasodilation is present causing the skin to be warm, with good capillary refill. Common to the various shock states is the presence of hyperventilation, a compensatory response due to progressive metabolic acidosis. As shock progresses, decreased cerebral blood flow and increased catecholamine stimulation may lead to anxiety and restlessness. With continued shock, lethargy may result. True coma, however, seldom results due to shock alone, unless complete cardiovascular collapse occurs or severe hypoxia develops.[7]

The initial hemodynamic assessment should include evaluation of the rate and character of the pulse; the blood pressure; and, in some cases, the central venous pressure (CVP), invasive or noninvasive cardiac assessment, and pulse pressure variation (PPV).[8] Tachycardia is a normal response to volume loss but also to pain, anxiety, and fear, all of which are commonly present. Assessment of the pulse may be helpful in determining the proper diagnosis. Because of the body's ability to compensate for hypovolemia, changes in blood pressure do not occur reliably until nearly 30% of blood volume has been lost. However, the pulse pressure usually narrows, even in compensated shock, because of the effects of vasoconstriction on the diastolic blood pressure. Importantly, the CVP does not reflect true blood volume, but the state of the venous tone. Although changes in CVP in response to treatment or from continuing hemorrhage may be more revealing than a solitary measurement, this remains debatable. Pulmonary artery catheters (PACs) are no longer routinely placed secondary to misuse or overuse in the past with associated morbidity and mortality.[9] As a result, invasive monitoring using PPV, and noninvasive measures such as echocardiography have become more commonly used to assess volume status and cardiac function.[10]

An indirect but extremely valuable measure of perfusion and volume status is urine output. A urinary catheter should be inserted in every patient being evaluated for shock. Hourly urine output should be 0.5 to 1 mL/kg for adult patients, at least 1 mL/kg for most pediatric patients, and 1 to 2 mL/kg for

patients younger than 2 years of age. Lack of adequate urine output in the setting of previous normal kidney function should cause the provider to be highly concerned about the continued presence of inadequate perfusion and cellular hypoxia.

Although the physical examination is important in the identification of shock, used alone it can fail to diagnose compensated shock. As a result, biochemical markers are used as a means to identify shock in its early stages. Biochemical analysis of shock is based on the shift from aerobic to anaerobic metabolism in underperfused tissues. This shift is marked by the production of lactate that can be measured in the circulation. Resuscitation of shock results in a decrease in serum lactate levels, and the time required to normalize serum lactate levels appears to be an important prognostic factor for survival.[11–15]

Another biochemical marker useful in the resuscitation of shock is the base deficit. This is defined as the amount of a fixed base (or acid) that must be added to an aliquot of blood to restore the pH to 7.40. Base deficit values have been categorized as normal (2 to −2), mild (−3 to −5), moderate (−6 to −9), and severe (>−10). Changes in base deficit toward normal with volume infusion can be used to judge the efficacy of resuscitation.[16–18] Base deficit has been shown to be superior to pH values in assessing the normalization of acidosis after shock resuscitation, and the time required for normalization of base deficit has perhaps even greater prognostic significance than that of lactate.[16,19] Furthermore, severe abnormalities in base deficit are associated with development of chronic critical illness (CCI), and thus early identification and correction may lead to improvement in the development of CCI.

The biochemical changes associated with the hypoperfusion of shock occur even with compensation. Because of the potential difficulties in diagnosing compensated shock, an arterial and/or venous blood gas analysis including base deficit and lactate should be obtained for every patient suspected of being in shock. Additionally, any patient with a lactate of ≥4 mmol/L or base deficit of ≥6 mEq/L should be considered to be in shock until proven otherwise.[17,20,21]

Additionally markers that can be used to determine the degree of shock include central and mixed venous oxygen saturation. Although the etiology of the shock state cannot be determined based on these measurements, they do

provide a global assessment of perfusion. Improvement in these values toward normal indicates reversal of hypoperfusion, and thus may be used to guide the resuscitation ("endpoints of resuscitation").[22–24]

TYPES OF SHOCK

Although several different classifications for shock have been described, the most widely accepted classification of shock was proposed by Weil and Shubin in 1971.[6] This classification divides the shock syndrome into four distinct categories (**Table 9.1**). 2 Despite this separation, however, there is considerable overlap between the categories, with some patients presenting with more than one factor at the same time. Given this overlap, it is helpful to evaluate the hemodynamic pattern in order to elucidate the etiology and appropriately manage the patient (**Table 9.2**).

3 Hypovolemic Shock

Hypovolemic shock is the form of shock most commonly encountered in surgical practice (**Table 9.2**). The essential feature is a reduction in intravascular volume to a level that prevents the heart from being able to pump sufficient blood to vital organ systems. Substantial blood (>20% circulating volume) or plasma (via soft tissue, enteric sequestration, gastrointestinal, urinary, or other insensible losses) losses are required to produce this syndrome.

The signs and symptoms of shock vary with both the severity and duration of fluid loss. A review of the Advanced Trauma Life Support classification system of the American College of Surgeons is useful to comprehend the manifestations and physiologic changes associated with hemorrhagic shock in adults.[22] Blood volume is estimated at 7% of ideal body weight, or approximately 4,900 mL in a 70-kg patient (**Table 9.3**).

Class I: Mild hemorrhage, up to 15% of total blood volume. This condition is exemplified by voluntary blood donation. In the supine position, there are no measurable changes in heart or respiratory rates, blood pressure, or pulse pressure. Capillary refill is normal. This degree of hemorrhage

requires little or no treatment, and blood volume is restored within 24 hours by transcapillary refill and the other compensatory methods.

Class II: Loss of 15% to 30% of blood volume (800 to 1,500 mL). Clinical symptoms include tachycardia and tachypnea. The systolic blood pressure may be only slightly decreased, especially in the supine position, but the pulse pressure is narrowed (because of the diastolic increase from adrenergic discharge). Urine output is reduced only slightly (20 to 30 mL/hr). Mental status changes (e.g., anxiety) are frequently present. Capillary refill is usually delayed. Patients with class II hemorrhage usually can be resuscitated with crystalloid solutions, but some may require blood transfusion.

Class III: Loss of 30% to 40% of blood volume (up to 2,000 mL). Patients with class III hemorrhage present with inadequate perfusion that is obvious; marked tachycardia and tachypnea; cool, clammy extremities with significantly delayed capillary refill; hypotension; and significant changes in mental status (e.g., confusion, combativeness). Class III hemorrhage represents the smallest volume of blood loss that consistently produces a decrease in systolic blood pressure. The resuscitation of these patients requires blood transfusion in addition to administration of crystalloids.

Class IV: Loss of more than 40% of blood volume (more than 2,000 mL), representing life-threatening hemorrhage. Symptoms include marked tachycardia, a significantly depressed systolic blood pressure, and narrowed pulse pressure or unobtainable diastolic pressure. The mental status is depressed and the skin is cold and pale. Urine output is negligible. These patients require immediate transfusion for resuscitation and frequently require immediate surgical or other (e.g., angiographic embolization) intervention.

In practice, individual susceptibility to blood loss varies greatly and is affected by age, pregnancy, pre-existing disease, prescription and nonprescription medications (e.g., beta-blockers), adequacy of compensatory mechanisms, and other factors that are poorly characterized. Presence of these factors should lead the provider to consider early use of invasive monitoring as an adjunct to appropriate fluid resuscitation.

Table 9.1 Classification System and Causes of Shock

Classification	Etiology	Cause
Hypovolemic	Hemorrhagic	Trauma Gastrointestinal
	Nonhemorrhagic	Absolute fluid loss (renal, gastrointestinal) Redistributive or "third spacing"
Cardiogenic	Myocardial	Ischemia Infarction Contusion Cardiomyopathy Myocarditis Pharmacologic/toxic (beta-blockers, calcium channel blockers, tricyclic antidepressants, anthracycline)
	Valve failure	Metabolic (hypophosphatemia, hypocalcemia, acidosis) Infection Injury Ruptured papillary muscle Stenosis Ischemia Pharmacologic/toxic Metabolic
	Arrhythmias	
Extracardiac Obstructive	Extrinsic compression	Mediastinal tumors
	Increased intrathoracic pressure	Tension pneumothorax

	Intrinsic vascular flow obstruction	Positive-pressure ventilation Pulmonary embolism Air embolism Tumors (myxoma) Proximal aortic dissection Aortic coarctation Acute pulmonary hypertension Tamponade Pericarditis
Distributive	SIRS related	Trauma Sepsis Pancreatitis Burns Drugs
	Anaphylactic/anaphylactoid	Venoms
	Neurogenic	Spinal cord injury Vasodilators
	Toxic/pharmacologic	Benzodiazepines
	Endocrine	Adrenal insufficiency Thyroid Myxedema

SIRS, systemic inflammatory response syndrome.

Hypovolemia due to plasma losses may also lead to hypovolemic shock. The clinical findings of hemorrhagic shock are typically present, but significant differences do exist. Hemoconcentration, elevated blood urea nitrogen (BUN) and creatinine, and hypernatremia are typical of acute plasma and/or free water losses and are not necessarily present in other forms of shock. Appropriate evaluation of preload and urine output should be followed, with specific considerations for unique electrolyte abnormalities associated with specific plasma and fluid losses (e.g., gastric vs. colonic losses).

Cardiogenic Shock

Cardiogenic shock occurs as a result of decreased cardiac output (CO) despite adequate intravascular volume with resulting tissue hypoperfusion. It is caused by a primary problem with the cardiac muscle, electrical conduction system, or valves. The most common cause is anterior wall myocardial infarction, although in surgical patients it may be precipitated by pulmonary embolus, myocardial contusion, or pulmonary hypertension.[25]

Table 9.2 Hemodynamic Patterns in Shock

Type	CO	SVR	PAOP	CVP	SvO_2
Hypovolemic	↓	↑	↓	↓	↓
Cardiogenic					
Left ventricular MI	↓	↑	↑	N, ↑	↓

CO, cardiac output; CVP, central venous pressure; MI, myocardial infarction; N, normal; PAOP, pulmonary artery occlusion pressure; SvO_2, mixed venous oxygen saturation; SVR, systemic vascular resistance.

Distinguishing cardiogenic shock from other shock etiologies is occasionally difficult. It is not uncommon to see combined cardiogenic and hypovolemic shock in the elderly patient, with one often being the precipitating event for the other. The hallmarks of the hemodynamic and neuroendocrine response to systemic hypoperfusion from other causes are also typical of cardiogenic shock. Eliciting a history of pre-existing cardiac disease, and physical findings such as pulmonary rales, cardiac murmurs, an S3 gallop, and jugular venous distention may be helpful. An electrocardiogram may detect significant ischemia or other pathology. A chest radiograph may reveal bilateral pulmonary infiltrates typical of

cardiogenic edema, and cardio-specific serum tests (troponin I and creatine phosphokinase [CPK]) may indicate myocardial damage.

Manifestations of cardiogenic shock develop as a consequence of failure of peripheral perfusion, the associated adrenergic response, and the inability of the heart to accommodate blood returning from the lungs and the periphery. In the absence of sepsis or tissue injury, however, there is not usually an associated increase in the metabolic needs of the peripheral tissues. Sympathetic-mediated constriction of the peripheral vasculature attempts to maintain central blood pressure and perfusion of cerebral and coronary circulations. The clinical findings of cardiogenic shock may thus be similar to those of hypovolemic shock because both involve induction of the adrenosympathetic response.

Diminished or ineffective contractile activity of the right or left side of the heart allows blood to accumulate in the respective venous circulations. Shock from an acute left ventricular myocardial infarct occurs when more than 40% of the left ventricle is involved and may be present in approximately 20% of Q-wave infarcts.[25] Shock from an acute right ventricular myocardial infarct, on the other hand, is rare and only occurs in approximately 10% of all inferior wall infarcts.[23] Not only does the diagnosis of each infarct vary, but also the treatment and support vary significantly.

In any patient in shock, especially in those with compromised cardiac function, consideration should be given to the institution of mechanical ventilation. The work of breathing can be considerable, especially for the patient in a state of agitation or distress. Oxygen needs are decreased through intubation and mechanical ventilation. In this manner, the patient can be comfortably sedated with a secure airway; the work of breathing is undertaken by the ventilator, and gas exchange can be optimized. If there is a tenuous balance between myocardial oxygen needs and availability, the balance can thus be shifted in the patient's favor.

Table 9.3 Classification of Hemorrhagic Shock

	Class I	Class II	Class III	Class IV
Blood Loss (mL)	Up to 750	750–1,500	1,500–2,000	>2,000
Blood Loss (%)	Up to 15	15–30	30–40	40
Heart Rate	<100	>100	>120	>140
Blood Pressure	Normal	Normal	Decreased	Decreased
Pulse Pressure	Normal	Decreased	Decreased	Decreased
Respiratory Rate	14–20	20–30	30–40	>35
Urine Output (mL/hr)	>30	20–30	5–15	Minimal
Mental Status	Normal	Mildly anxious	Anxious and confused	Confused and lethargic
Fluid Replacement	Crystalloid	Crystalloid	Crystalloid and blood	Crystalloid and blood

Like other forms of shock, cardiogenic shock tends to be self-perpetuating. Myocardial perfusion depends on the pressure gradient between the coronary artery and the left ventricle and the duration of diastole. Both are compromised by the hypotension and tachycardia that characterizes this condition. High-volume fluid resuscitation, sometimes necessary for treatment of other forms of shock, is poorly tolerated and likely to be detrimental to an individual with cardiogenic shock.

Extracardiac Obstructive Shock

4 A subset of patients with perceived evidence of cardiogenic shock do not have intrinsic cardiac disease but have pump failure due to extrinsic compression that limits diastolic filling and CO. Cardiac tamponade, tension pneumothorax, diaphragmatic herniation of abdominal viscera, mediastinal hematoma, massive pulmonary embolism, and, occasionally, positive-pressure mechanical ventilation may all precipitate shock by exerting constricting pressure on the myocardium. The key to diagnosis and appropriate therapy is the physical examination, supplemented by use of appropriate diagnostic modalities.

Distributive Shock

Distributive shock occurs in a state of inappropriate oxygen utilization associated with the systemic inflammatory response syndrome (SIRS). Classically, SIRS is triggered by sepsis, but SIRS is associated with other immune processes including trauma, pancreatitis, and other types of tissue injuries. However, other types of distributive disturbances can occur unrelated to inflammation that may be directly due to loss of vascular tone from spinal cord injury, endocrine dysfunction, or anaphylaxis.

Septic Shock

5 Septic shock is defined as sepsis that is associated with hypotension, despite adequate fluid resuscitation.[26] It occurs when bacterial products interact with cells of the immune system, leading to elaboration of mediators that cause circulatory disturbances and direct and indirect cell damage leading to the clinical manifestations of shock.[27] Hemodynamic changes are defined as early (warm or hyperdynamic) or late (cold or hypodynamic). These stages are primarily characterized by the degree of ventricular contractility and peripheral vasomotor impairment present, but can be misclassified if not appropriately evaluated. Early septic shock is distinguished by peripheral vasodilation, flushed and warm extremities, and a compensatory elevation in CO. Although an increase in venous capacitance diminishes venous return to the heart, CO is maintained via tachycardia and the decrease in afterload due to systemic vasodilation.

Late septic shock is characterized by impaired myocardial contractility due to local and systemic release of cardiac depressants, worsening peripheral perfusion, vasoconstriction, extremity mottling, oliguria, and hypotension. Peripheral oxygen utilization may be severely impaired by bacterial toxins, such as lipopolysaccharide (LPS) and the inflammatory products of the host's own immune response, resulting in metabolic dysfunction and acidosis despite a high systemic oxygen delivery. This inappropriate oxygen utilization and systemic shunting lead not only to confusion regarding the adequacy of resuscitation but also to progressive cell death. Together, both systemic hypoperfusion and the altered tissue metabolism create a vicious cycle that propagates the inflammatory response

initiated in reaction to the initial infectious challenge leading to progressive cellular injury.

Due to both volume deficits and cardiovascular dysfunction, persistent perfusion deficits are common and contribute significantly to multiple organ failure and mortality. In fact, the fluid volume required for treatment may exceed that required for treatment of other forms of shock due to persistent microvascular endothelial capillary leak. As a result of this profound leak, interstitial and total body fluid balances become extreme, leading to the potential development of marked hypoxia and the abdominal compartment syndrome (ACS).

Although appropriate early resuscitation and cardiovascular support are essential to the treatment of septic shock, as important are early infection source control and appropriate administration of antimicrobials. In fact, numerous investigators have demonstrated that even a few hours delay in initiation of antimicrobial therapy is associated with a significant increase in mortality.[28]

Traumatic Shock

The major contributor to shock after injury is hypovolemia due to hemorrhage. Even when hemorrhage ceases or is controlled, patients can continue to suffer loss of plasma volume into the interstitium of injured tissues and develop progressive hypovolemic shock. In addition, tissue injury evokes a broader pathophysiologic immunoinflammatory response and a potentially more devastating degree of shock than that produced by hypovolemia alone.

The degree to which direct tissue injury and an inflammatory response participate in the development and progression of traumatic shock distinguishes it from purely hypovolemic shock. Thus, traumatic shock results from direct tissue or bony injury, resulting in not only hypovolemia caused by fluid and blood loss but also an immunologic and neuroendocrine response to tissue destruction and devitalization. This combined insult complicates what might otherwise be straightforward hemorrhagic shock by inducing a systemic response that utilizes many of the inflammatory mediators present in septic shock.[28] These mediators propagate and intensify the effects of the

initial hypovolemia and make subsequent multiple organ failure far more likely than occurs with hypovolemic shock alone.

Although this condition can lead to increased fluid requirements, common problems associated with this condition such as rhabdomyolysis should be aggressively evaluated and treated with optimal resuscitation.[24] In addition, common patient characteristics are known to alter traumatic shock resuscitation, in particular, morbid obesity that can result in delayed correction of metabolic acidosis and increased risk for organ dysfunction.[29]

Thus, initial management of the seriously injured requires the assurance of an airway, breathing, and circulation; later management requires appropriate volume resuscitation and control of ongoing losses. Control of hemorrhage is a major concern and demands priority over attention to other injuries. After resuscitation and control of volume losses, efforts become necessary to minimize the potentially lethal postshock sequelae, including acute respiratory distress syndrome (ARDS), multiple organ dysfunction syndrome (MODS), and CCI.

Neurogenic Shock

Neurogenic shock is defined as failure of the nervous system to provide effective peripheral vascular resistance, resulting in inadequate end-organ perfusion. Warm, flushed, flaccid extremities; paraplegia; confusion; oliguria; and hypotension are the classic clinical findings. Injury to the proximal spinal cord, with interruption of the autonomic sympathetic vasomotor pathways, disrupts basal vasoconstrictor tone to peripheral veins and arterioles. Profound vasodilation of all microvascular beds below the level of cord injury diminishes venous return to the heart, reduces CO, and precipitates hypotension. Injuries at or above the fourth thoracic vertebrae may disrupt sympathetic enervation to the heart, resulting in significant bradycardia and severe decompensation.

Similar to the initial therapy for shock resulting from hypovolemia, treatment of the relative hypovolemia due to vasodilation of neurogenic shock requires intravenous volume resuscitation. Restoration of the pathologically expanded intravascular space improves preload and CO and may reverse hypotension. However, maintenance of adequate hemodynamics often requires vasopressor support in an effort to avoid the administration of

excessive fluids. Monitoring cardiac preload should be considered to determine adequate (but not excessive) filling volume, as loss of vasomotor capacity within the pulmonary circulation predisposes these patients to pulmonary edema. As spinal cord injury is often associated with other traumatic injuries, the diagnosis of isolated neurogenic shock must be a process of exclusion.

Physiologic Response to Hypovolemia

Common to each shock state is usually an initial decrease in circulating intravascular volume. This reduction is due directly to fluid loss or secondarily to fluid redistribution. This reduction in circulating fluid volume initiates both a rapid and sustained compensatory response. Within minutes, a rapid compensatory response occurs primarily due to adrenergic output. Sustained responses, in contrast, occur slower and result in intravascular fluid reabsorption and renal conservation of water and electrolytes (**Algorithm 9.1**).

Acute Response

Hypovolemia results in the initial secretion of epinephrine and norepinephrine from the adrenal gland due to decreased afferent impulses from arterial baroreceptors. Catecholamine release is acute and limited to the first 24 hours following the onset of hypovolemia. This results in vasoconstriction, tachycardia, and increased myocardial contractility. Adrenergic-induced vasoconstriction of the systemic capacitance of small veins and venules shifts blood back to the central venous circulation, thus increasing right-sided filling pressures. Left-sided filling and pressure are augmented by pulmonary vasoconstriction. Concomitantly, vasoconstriction occurs in the skin, kidneys, and viscera, effectively shunting blood to the heart and brain. Adrenergic-induced vasoconstriction increases cardiac filling and causes increased contractility and reflex tachycardia, all of which combine to increase stroke volume (SV) and CO.

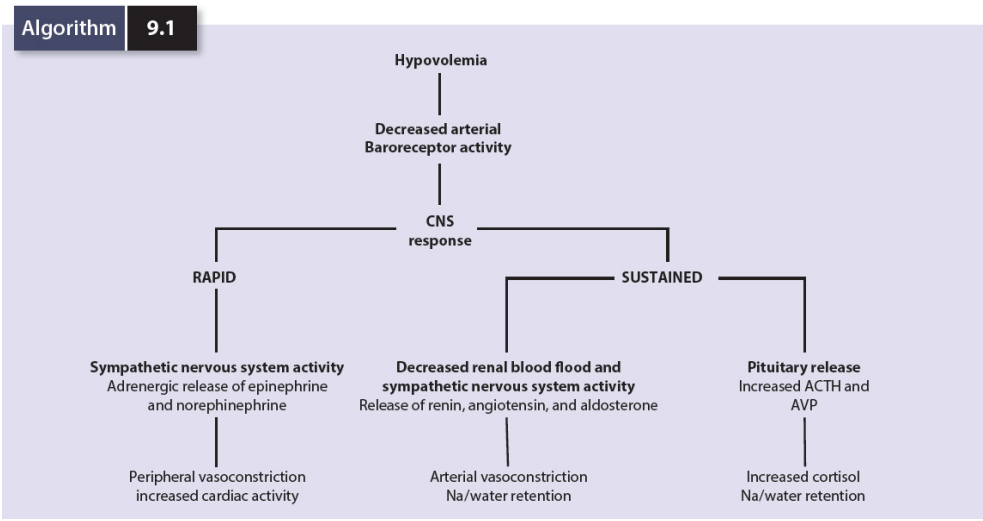
Adrenergic-mediated vasoconstriction affects arterioles, pre- and postcapillary sphincters, and small veins and venules. Due to this specific vasoconstriction, decreased hydrostatic pressure distal to the precapillary

sphincter occurs that leads to reabsorption of interstitial fluid (water, sodium [Na^+], and chloride [Cl^-]) into the vascular space. This functions to restore circulating blood volume and is known as transcapillary refill.[30]

Sustained Response

Sustained compensatory responses include the release of vasoactive hormones and fluid shifts from the interstitium and the intracellular space to the intravascular compartment. Decreased renal blood flow, increased adrenergic activity, and compositional changes in tubular fluid lead to the secretion of renin from the juxtaglomerular complex. Renin results in increased formation and release of angiotensin I by the liver. Circulating angiotensin I is rapidly converted to angiotensin II by the lungs and is the most potent known arterial and arteriolar vasoconstrictor. Angiotensin II also stimulates the release of pituitary ACTH. Increased circulating levels of both angiotensin II and ACTH result in increased secretion of aldosterone. As a result, reabsorption of Na^+ in the distal renal tubules in exchange for potassium (K^+) and hydrogen ions occurs.

Additionally, due to hypovolemia and increased serum osmolarity, reduced stimulation of arterial baroreceptors occurs, leading to the release of arginine vasopressin (AVP) This hormone not only functions as a potent vasoconstrictor but also causes increased reabsorption of water by increasing water permeability and passive Na^+ transport in the distal renal tubule. The overall net effect of aldosterone and AVP is to decrease glomerular filtration and increase salt and water tubular reabsorption in an effort to replace circulating intravascular volume deficits.



Algorithm 9.1 Neurohormonal response to hypovolemia. CNS, central nervous system; ACTH, adrenocorticotropic hormone; AVP, arginine vasopressin.

Finally, the increased release of the stress hormones (epinephrine, ACTH, cortisol, and glucagon) leads to glycogenolysis, lipolysis, and protein catabolism, causing a negative nitrogen balance and high extracellular concentration of glucose due to decreased insulin release and resistance. This leads to increased glucose utilization by insulin-independent tissues such as the brain and heart. In addition to glucose, products of anaerobic metabolism from hypoperfused cells accumulate in the extracellular compartment, inducing hyperosmolarity. This extracellular hyperosmolarity draws water from the intracellular space, increasing interstitial osmotic pressure, which in turn drives water, Na^+, and Cl^- across the capillary endothelium into the vascular space.

ORGAN-SPECIFIC COMPENSATORY RESPONSES TO SHOCK

Cardiac and Microvascular Response

Cardiovascular physiology is profoundly affected by shock. Reduced SV is caused by an absolute or relative loss of preload. Intrinsic neuroendocrine and renal compensatory responses, along with additional intravenous fluid, are needed to increase ventricular end-diastolic volume. Restoration of

adequate preload alone is often sufficient to return CO to levels required to overcome peripheral perfusion deficits. However, some cases are complicated by acquired myocardial contractility derangements. Contractile function under these conditions is less a function of preload and more related to intrinsic myocardial dysfunction.

A defining characteristic of shock is compromise of microvascular perfusion. Far from being a passive conduit, the microvasculature actively participates in the response to shock. Arteriolar vessels are innervated by sympathetic nerves, as are small veins and venules. The vasoconstriction of hypovolemic shock and the vasodilation of septic and neurogenic shock are a result of these autonomic responses. The majority of the circulating blood volume resides in the venous system, and normal physiologic compensation mechanisms rely on this venous blood pool as an autotransfusion reservoir. Collapse of underperfused veins passively propels blood toward the heart, while α-adrenergic venoconstriction actively mobilizes the venous pool. Profound peripheral vasoconstriction via α-adrenergic, vasopressin, angiotensin II, and endothelin-1 stimulation of arteriolar and precapillary smooth muscle sphincters selectively diminishes perfusion to dermal, renal, muscle, and, significantly, splanchnic vascular beds to preserve perfusion of critical central organs, primarily the central nervous system (CNS) and myocardium.[31]

The capillary endothelial monolayer maintains a semipermeable barrier between the intra- and extraluminal spaces and is compromised by shock.[43] Circulating inflammatory mediators and byproducts of infection (LPS, thrombin, tumor necrosis factor alpha [TNF-α], interleukin [IL]-1, nitric oxide, and endothelin-1) generated in response to traumatic or septic shock have been shown to induce and sustain endothelial capillary leak. Although the exact mechanisms of endothelial monolayer dysfunction are unclear, the only available therapies to reverse microvascular decompensation are timely restoration of peripheral perfusion, rapid elimination of infectious and necrotic tissue, and pharmacologic and mechanical support of cardiopulmonary function.[32,33]

Neuroendocrine Response

The neuroendocrine reaction to shock consists of involuntary responses by the hypothalamus, autonomic nervous system, and secretory endocrine glands and is directed toward restoration of tissue perfusion and a redirected utilization of metabolic substrates. The autonomic response is initially triggered by hypoxia, hypotension, or hypovolemia detected by aortic and carotid baroreceptors and chemoreceptors (**Algorithm 9.2**). Subsequently, sympathetic vasoconstriction of specific vascular beds, induced by direct synaptic release of norepinephrine, results in redistribution of circulating blood volume from tissue of low metabolic activity to more metabolically demanding organs. CO, diminished by loss of preload, is augmented by inhibition of cardiac vagal activity and a resulting reflex tachycardia.

Circulating epinephrine and norepinephrine alter several aspects of glucose utilization, availability, and metabolism. The hyperglycemia of stress results from catecholamine-induced glycogenolysis, gluconeogenesis, and decreased pancreatic insulin release. Simultaneously, hypothalamic stimulation of the anterior pituitary induces release of ACTH, which in turn prompts cortisol and aldosterone release by the adrenal cortex. Elevated serum cortisol contributes to postinjury hyperglycemia by increasing gluconeogenesis, enhancing lipolysis, and diminishing peripheral utilization of glucose and amino acids. The pancreatic response is characterized by a decrease in insulin release and an increase in glucagon secretion, which further stimulates hepatic gluconeogenesis. The combined actions of catecholamines, cortisol, and glucagon are synergistic and create a shock-related hyperglycemia that is often refractory to insulin treatment.

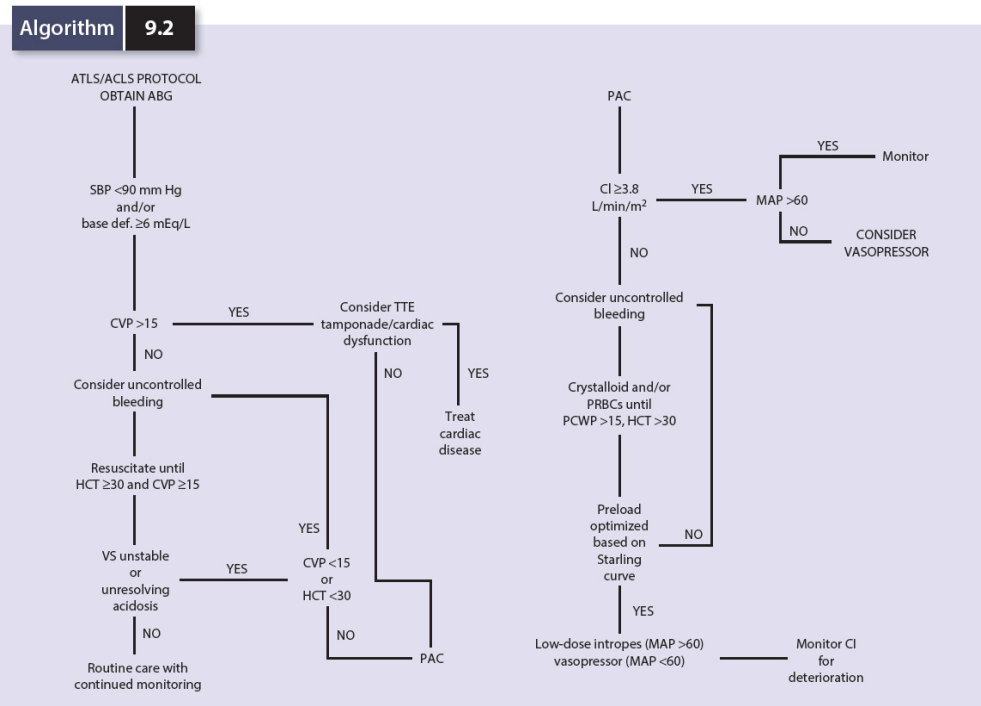
Renal juxtaglomerular secretion of renin in response to adrenergic stimulation and renal hypoperfusion triggers the formation of angiotensin I in the liver, which is subsequently converted to angiotensin II by the lungs. Angiotensin II, a potent vasoconstrictor, augments shock-induced catecholamine-mediated peripheral and splanchnic vasoconstriction and stimulates aldosterone release from the adrenal cortex. Renal tubular reabsorption of sodium in response to elevated circulating aldosterone creates highly concentrated, low-volume urine. Vasopressin secretion by the posterior pituitary similarly contributes to compensatory restoration and maintenance of intravascular volume by promoting water reabsorption by the renal distal tubules and by causing peripheral and splanchnic

vasoconstriction. A major result is a prolonged severe hypoperfusion of the splanchnic vascular bed, further augmenting the deleterious host response.

Immunoinflammatory Response

Many shock-inducing events, particularly those associated with septic or traumatic shock, simultaneously trigger a massive systemic inflammatory response. Although inflammatory mediators (TNF-α, ILs, chemokines, etc.) play an integral role in the recovery of local tissue to trauma and infection, an uncontrolled systemic inflammatory response contributes to organ failure. Immunologically active cells involved in the systemic inflammatory response include nucleated blood cells (monocytes, polymorphonuclear leukocytes [PMNs]) and platelets, microvascular endothelial cells, and tissue macrophages. These cells generate and secrete scores of signal-amplifying inflammatory mediators ranging in complexity from individual molecules (nitric oxide) to large multisubunit, extensively modified proteins (TNF-α, IL-1, etc.). Even transient systemic elevation of any of these mediators has profound physiologic consequences.

Local tissue destruction, microbial contamination, and infection similarly activate the coagulation cascade and induce platelet aggregation and release of numerous platelet-, endothelial-, and clot-derived vasoactive mediators. Persistent, profound, and recurring microvascular hypoperfusion of the splanchnic and other organs likewise causes local tissue ischemia, parenchymal cell injury, microvascular coagulation, activation of inflammatory cells, and release of inflammatory mediators. Circulating monocyte, lymphocyte, and PMN adherence to activated endothelium results in extraluminal transmigration of these inflammatory cells into tissues remote from the area of injury. This hyperdynamic immunologic response, with continued generation of proinflammatory mediators, is responsible for the progression of MODS.[34–37]



Algorithm 9.2 Shock resuscitation algorithm. ATLS, advanced trauma life support; ACLS, advanced cardiac life support; SBP, systolic blood pressure; CVP, central venous pressure; HCT, hematocrit; VS, vital signs; TTE, transthoracic echocardiography; PAC, pulmonary artery catheter; CI, cardiac index; MAP, mean arterial pressure.

Regulation of the systemic inflammatory response has been an active area of shock research for several decades. Elimination of particular inflammatory mediators from the systemic circulation, or inhibition of particular cell–cell interactions in experimental animal systems, has been shown to improve outcomes after shock resuscitation.[38–42] However, to date, all efforts to regulate this response have proven ineffective or even harmful.

Pulmonary Response

The lung is the organ system most sensitive to systemic insult and injury and is frequently the first organ to fail in the progression to MODS. ARDS represents a high-mortality form of pulmonary insufficiency that is often precipitated by sepsis or traumatic shock. It is triggered and perpetuated by the numerous inflammatory mediators created in the hypoperfused microvasculature elsewhere in the body.[38–43]

Renal Response

Direct sympathetic-induced renal vasoconstriction increases afferent arteriole resistance in response to shock. This effect is reinforced by elevated circulating angiotensin II and catecholamines. The resulting decrease in renal blood flow and glomerular filtration rate (GFR), along with elevated circulating aldosterone and vasopressin and anti-diuretic hormone (ADH), produce oliguria and prerenal azotemia. Acute tubular necrosis (ATN) may result from prolonged decreases in renal cortical blood flow, as well as from toxins generated during sepsis. Oliguric renal failure, like the pulmonary insufficiency of ARDS, is a common component of MODS.

Distinguishing low urine output due to oliguric renal failure from the oliguria of decreased renal perfusion pressure can be aided by analyzing urine sodium and osmolality. Renal hypoperfusion usually results in urine sodium of less than 20 mEq/L with an osmolality of greater than 400 mOsm/kg, whereas acute tubular injury impairs sodium reabsorption and is associated with a low urinary osmolality. A fractional excretion of sodium of less than 1% may also help determine whether the cause is renal or prerenal.

Hepatic Response

Ischemic injury to liver is not apparent early during shock. However, the liver plays an important role in the regulation of shock and subsequent tissue injury through both the release of acute-phase reactants and lack of clearance of potential toxic agents. As shock continues, hepatic necrosis occurs, leading to the release of aspartate aminotransferase and alanine aminotransferase. Continued shock results in attenuated synthesis of coagulation factors, albumin and prealbumin. Although progressive ischemia can occur, leading to complete loss of glycogen stores and marked hypoglycemia, this condition is rare without pre-existing liver disease, significant direct liver injury, or hepatic artery occlusion.

Genetic Regulation of the Response to Shock

Individuals vary considerably in their susceptibility to shock and in their ability to recover from its consequences. Unique host-specific responses have been identified as important determinants of the outcome of sepsis and septic shock. Genetic predispositions in an individual's immunoinflammatory response may dictate whether infection is adequately or inadequately countered. These differences in response may be partially explained by single-nucleotide polymorphisms (SNPs) in the genetic sequences for various inflammatory mediators. These subtle nucleotide variations may affect the transcription or translation of associated genes or the secretion or function of the corresponding proteins.

The recognition that genetic background may regulate the response to severe sepsis and septic shock has led to the identification of an array of genetic markers associated with enhanced risk of septic mortality. These SNPs are in genes encoding proteins involved in pathogen recognition (Toll-like receptors 2, 4, and 5; CD14; and mannose-binding lectin), cytokine expression (TNF-α, IL-1, IL-6, and IL-10), and several other genes involved in mediating and controlling the innate immune response and the inflammatory cascade.[44,45]

Investigation into genetic polymorphisms should provide important insights into the pathophysiology of shock. SNP identification leading to early diagnosis of individuals at risk of developing or dying from the complications of shock may allow therapies to become more preemptive and effectively targeted.

LOSS OF COMPENSATORY RESPONSES TO SHOCK

If shock is prolonged, the arteriolar and precapillary sphincters become refractory and relax, while the postcapillary sphincter remains in spasm. Therefore, the capillary hydrostatic pressure increases, and Na^+, Cl^-, and water are moved into the interstitium, leading to depletion of intravascular volume.

Cellular membrane function is also impaired with prolonged shock. The normal negative membrane potential approaches neutrality, leading to

increased permeability and interstitial flooding by K^+. This is caused, at least in part, by a decrease in the normal function of the adenosine triphosphate–dependent Na^+–K^+ membrane pump that is a result of cellular hypoxia. The loss of the membrane potential difference leads to cellular swelling due to an intracellular influx of Na^+ and fluid.

In addition to these cellular effects, severe and prolonged shock results in the development of progressive organ dysfunction. Although the mechanisms responsible are incompletely understood, it appears that the vital organs, in particular the lung early on, are limited in their ability to protect themselves during shock. As a result, direct endothelial injury occurs, resulting in leakage of various inflammatory mediators, which in turn results in accumulation of interstitial fluid and subsequent reduction in nutrient and gaseous diffusion. This condition, along with progressive microcirculatory thrombosis, is responsible for the late organ dysfunction characteristic of uncompensated shock.

COMPLICATIONS OF SHOCK

Ischemia–Reperfusion Injury

Inadequate microvasculature flow results in activation of leukocytes and converts local endothelial cells to a proinflammatory, prothrombotic phenotype. On reperfusion, the reintroduction of oxygen prompts these cells to generate superoxide anion, hydroxyl radicals, and hydrogen peroxide, further injuring local tissue. Microvascular endothelial adherence, monolayer transmigration, and local oxidative burst by activated neutrophils, along with the profound loss of endothelial monolayer integrity (i.e., microvascular capillary leak), contribute to massive interstitial edema after reperfusion. Although all tissues are sensitive to varying degrees, ischemia–reperfusion injury appears to be most detrimental to the pulmonary vasculature and the splanchnic circulations. Pulmonary interstitial edema and alveolar fluid accumulation are associated with the development of ARDS, whereas extensive visceral edema may contribute to development of ACS and mesenteric ischemia.

Multiple Organ Dysfunction Syndrome and CCI

6 The development of MODS is complex, but appears to depend on changes in the splanchnic and pulmonary microcirculations. These vascular beds appear to be major sites of the activation and subsequent immunoinflammatory mediator production. As splanchnic microcirculatory flow decreases in response to homeostatic vasoconstrictive responses during hypovolemia, excessive and prolonged hypoperfusion of the gut results in extensive microvascular injury and subsequent activation of endothelium, neutrophils, and macrophages. In addition, mucosal barrier disruption permits translocation of bacteria and bacterial toxins to circulate and reach the large tissue-fixed macrophage population in the liver. Extensive activation of the Kupffer cells in the liver results in the release of inflammatory mediators that cause distant organ injury through the systemic activation of other immune cells.

Not only is a proinflammatory innate phase present, but there is also a concurrent anti-inflammatory adaptive phase that is evolutionarily designed to counter the locally generated hyperimmune response and check systemic spread of proinflammatory mediators. If the concurrent anti-inflammatory response syndrome results in excessive immunosuppression, it may contribute to susceptibility to primary and secondary infections that can further perpetuate organ failure.[46] These variable inflammatory responses can lead to the development of MODS, and associated chronic dysfunction termed CCI.

Abdominal Compartment Syndrome

ACS is a highly morbid complication of reperfusion injury to the splanchnic viscera. This syndrome appears to be increasingly prominent due to aggressive resuscitation techniques that enable salvage of profoundly hypotensive and hypovolemic patients. Splanchnic ischemia and reperfusion result in extensive visceral capillary leak and interstitial edema of the bowel. Excessive volume resuscitation during this phase leads to grossly edematous viscera within the closed space of the abdomen, which dramatically

increases intra-abdominal pressure, and compromises intra-abdominal organ function, increases renovascular resistance, limits diaphragmatic excursion, and may decrease CO and elevate intracranial pressure. The clinical hallmarks of ACS are a distended and tense abdomen, diminished tidal volume, pulmonary edema, decreased CO, oliguria, and elevated urinary bladder pressure. Presence of all or a major part of this syndrome should prompt consideration of an urgent operative laparotomy to decompress the abdomen and treat by leaving the abdomen open.

Hypothermia

Hypothermia (core temperature <35°C) is common during severe shock, as the energy-dependent homeostatic processes (such as maintaining body temperature) are impaired. This reduction in oxygen delivery directly contributes to progressive hypothermia if uncorrected due to loss of ATP generation and heat production. Furthermore, prehospital and postadmission exposure can exacerbate hypothermia through conductive, convective, and evaporative heat loss, which should all be minimized. In addition, the administration of room temperature intravenous fluids and of cold-stored blood also contributes to hypothermia.[47] Hypothermia increases fluid requirements and independently increases acute mortality rates.[48] As the core temperature decreases, the rate of oxygen consumption also decreases, to approximately 50% of normal at 28°C. A leftward shift in the oxyhemoglobin dissociation curve also occurs with hypothermia but is partially compensated by the acidosis. CNS effects progress from confusion and loss of manual dexterity to obtundation and frank coma as the core temperature decreases from 35° to 26.5°C. The heart rate decreases to approximately half of baseline at 28°C, with a concomitant decrease in CO. All cardiac electrical conduction intervals are prolonged, consistent with the changes in heart rate, and both atrioventricular dissociation and refractory ventricular fibrillation occur at 28°C. Other potential physiologic effects include ileus and pancreatitis (from cold enzyme activation) at temperatures lower than 35°C.

Compensatory responses to hypothermia include increased excretion of catecholamines, resulting in doubling of the basal metabolic rate, and increased production of thyroid hormones, further increasing the basal metabolic rate to five times baseline. Shivering can increase heat production

as well, but it represents a significant energy expenditure and has been shown to be inhibited during episodes of hypotension or hypoxemia.[49] Compensatory responses to hypothermia are lost at temperatures below 30°C or 31°C, and a state of complete poikilothermy is reached.

The treatment for hypothermia is to primarily to treat the underlying cause of shock. However, in situations of severe hypothermia, reversal of shock may need to be accompanied by passive and active rewarming. The core temperature should be obtained on admission of patients in shock. Patients whose core temperatures are 33° to 35°C can be treated with passive rewarming, warm blankets, and hot packs. Patients with core temperatures lower than 33°C require active rewarming. If the patient is unconscious, airway control should first be obtained. Because severe hypothermia causes vasoconstriction, noninvasive blood pressure measurements may not be feasible or accurate, and an arterial line should be placed for monitoring and blood gas sampling. The inspired gas through the ventilator should be heated to 41°C and fully saturated with water vapor to increase heat conductance in the lung. The intravenous fluids should also be warmed. Commercially available rapid infusion systems with countercurrent heating elements should be used. For extreme hypothermia, continuous mechanical arteriovenous rewarming either by cardiac bypass or extracoporial membrane oxygenation can be performed for both circulatory support and rewarming. Recently developed microtechnology permits core rewarming by percutaneous placement of countercurrent warming coils directly in the inferior vena cava (IVC). Finally, other warming methods include lavage of heated saline through nasogastric and thoracostomy tubes as well as peritoneal lavage, but are not as effective.

Coagulopathy

Coagulopathy is a frequent problem complicating shock, especially in those patients who have received large volumes of crystalloid solution and blood for resuscitation. Although this problem is incompletely understood, it is clear that coagulation defects during shock are multifactorial. The presence of shock, the fluid volume required for resuscitation, the presence of hypothermia, and pre-existing diseases all influence the likelihood and severity of coagulopathy.[50]

A major factor in coagulopathy is usually due to the dilutional thrombocytopenia that occurs after massive volume resuscitation. Although bleeding times can be prolonged with platelet counts less than 100,000 cells/mL, platelet counts of 50,000 cells/mL or greater are usually adequate for surgical hemostasis. Dilutional thrombocytopenia becomes more likely with infusions of more than one blood volume. Each unit of platelets administered increases the platelet count by 10,000 to 15,000 cells/mL. Control of surgically remediable hemorrhage is prudent before platelet transfusion to prevent the loss of the transfused platelets.

Dilution of other coagulation factors also plays a role in development of coagulopathy. Factors V and VIII are the most labile in banked blood, but levels of less than 10% of normal for factors VII, X, XI, XII, and XIII are all associated with abnormalities in hemostasis, as demonstrated by prolonged partial thromboplastin time and prothrombin time. Fresh-frozen plasma can be administered as a source of all the soluble coagulation factors. The administration of cryoprecipitate may be necessary as a concentrated source of factor VIII and fibrinogen, particularly if adequate hemostasis is not obtained with the use of fresh-frozen plasma. Recent support has emerged to suggest the addition of tranexamic acid (TXA) for patients suffering from exsanguinating hemorrhage.[51] TXA prevents fibrinolysis, and thus results in more rapid control of hemorrhage. The benefits are primarily seen in the subset of patients with severe hemorrhagic shock, when TXA is given within the first 3 hours. Although TXA theoretically could be associated with thrombotic complications including pulmonary embolism, myocardial infarction, and stroke, data so far has does not show this association. Other agents continue to show promise in rapidly reversing anticoagulants including the use of prothrombin concentrates.[52,53]

Finally, evidence has suggested that coagulopathy and hemorrhage can be minimized following massive blood loss if early aggressive use of fresh-frozen plasma is administered. Coagulopathy is present after massive injury, even before blood component therapy is begun. Both civilian and military experience with a 1:1 ratio of packed red blood cells to fresh-frozen plasma has been associated with reduced mortality.[54–57] However, this practice has been associated with an increase in the development of ARDS and organ dysfunction due to poorly defined mechanisms.[58] Thus, generalization of this

data to all patients with hemorrhage other than the massively injured should be performed with caution as demonstrated in the PROPRR study.[59]

TREATMENT

Fluid Therapy

Early investigators of hemorrhagic shock noted that decreased CVP and a reduction in total body oxygen delivery (DO_2) were key early findings. If the decrease in oxygen delivery was severe or prolonged, a reduction in total body oxygen consumption ensued. After adequate fluid resuscitation, oxygen delivery and consumption increased above the baseline value for several hours, as if the body was paying back an "oxygen debt." Failure of the patient to achieve this hyperdynamic response to resuscitation was almost always fatal. Because early death from shock appeared to be explained by the dynamics of oxygen delivery and utilization, therapy focused on restoring hemodynamics and oxygen transport with fluid and inotropes.

The provision of additional fluid beyond the amount of blood loss was associated with improved survival in both clinical and experimental studies of hemorrhagic shock, leading to widespread acceptance of aggressive fluid infusion. However, some researchers have recently described a significant increase in mortality associated with crystalloid overresuscitation and have postulated that excessive fluid administration increases the clinical risk of ARDS, MODS, increased intracranial pressure, and ACS.[60–62] Because massive volumes of fluid are only provided to patients with severe shock, it is unclear if it is the excessive fluid or the associated underlying shock that increases the risk of ARDS, organ failure, or death after massive fluid resuscitation.[63]

A minimum of two large-bore (14- to 16-gauge) intravenous catheters should be established in adults. Isotonic fluid is then infused at the same time as blood is obtained for arterial blood gas analysis, screening, and typing. Fluid can be infused up to 200 mL/min through a 14-gauge catheter and up to 220 mL/min through a 7-French catheter. A fluid challenge of 10 to 25 mL/kg is administered to the hypotensive patient and the response assessed. However, patients with a shock state consistent with hypovolemia due to

hemorrhage should undergo early blood and blood product resuscitation rather than crystalloid infusion, and early activation of a massive transfusion protocol instituted. Sustained hypotension despite active blood product resuscitation in this patient population should warrant early surgical intervention for control. In patients that are in shock due to nonhemorrhage etiologies, the initial crystalloid therapeutic challenge is an effective trial in determining the amount of pre-existing or continuing volume loss. If the blood pressure returns to normal and is stabilized, the volume loss was relatively small, and the only treatment required may be infusion of isotonic fluid. If the increase in blood pressure is transient after fluid bolus, then hemorrhage or continued fluid losses should be considered. If hypotension persists, and no evidence of hemorrhage is found, carefully assessment of other etiologies of shock should then be investigated including septic, neurogenic, and cardiac with the potential need for vasopressor support.

Crystalloids

Balanced salt solutions are the most commonly used resuscitative fluids, and their use to restore extracellular volume significantly decreases the transfusion requirement after mild–moderate hemorrhagic shock. Lactated Ringer solution is isotonic, readily available, and inexpensive. It rapidly replaces the depleted interstitial fluid compartment and does not aggravate any pre-existing electrolyte abnormalities. Previous investigations have shown that administration of lactated Ringer solution does not lead to aggravation of the lactic acidosis that is present in shock.[64] In fact, animal models have demonstrated that the use of blood plus lactated Ringer solution results in a more rapid return to normal lactate and pH than dose-shed blood alone. As volume and perfusion are restored, lactate is mobilized and metabolized to bicarbonate in a single pass through the liver. In fact, mild metabolic alkalosis may occur 1 or 2 days after large-volume resuscitations with lactated Ringer solution. Normal saline solution is also effective for resuscitation of hypovolemic patients. Concerns about inducing hypernatremic, hyperchloremic metabolic acidosis with massive resuscitation volumes should be evaluated.

Colloids

Colloids have the theoretic advantages of increasing the colloid oncotic pressure and requiring smaller volumes for resuscitation than crystalloids.[65] Colloids commonly used for volume expansion in hypovolemia include albumin, dextran 70, dextran 40, and hydroxyethyl starch. Although each has unique individual characteristics, currently there is little justification for the routine addition of colloids to balanced salt solutions for volume replacement during shock. In fact routine use of colloid such as hydroxyethyl starch may be associated with increased risk of mortality without any benefit.[66]

Albumin solutions have been used during resuscitation to increase colloid oncotic pressure and, hypothetically, to protect the lung from interstitial edema; however, there is a relatively rapid flux of albumin across the pulmonary capillary membranes and relatively rapid clearance through the pulmonary lymphatics. In fact, colloid albumin infusion has been demonstrated to prolong the resuscitation phase and delay postresuscitation diuresis. Additionally, albumin may serve to depress circulating immunoglobulin levels and suppress albumin synthesis.

Dextran 40 and dextran 70 are polysaccharides with molecular weights of 40 and 70 kD, respectively. Dextran 40 (10%) is hyperoncotic and initially exerts a volume-expanding effect. However, because of its lower molecular weight, it is more rapidly excreted. Thus, dextran 40 is commonly used in cases of peripheral vascular disease and hyperviscosity syndromes. Dextran 70, conversely, is provided as a 6% solution and does not exert a hyperoncotic effect. The volume expansion is somewhat greater than the amount infused, and because of its large molecular size the effect is maintained for up to 48 hours. The dextran preparations, however, cause decreased platelet adhesiveness and decreased factor VIII activity. They also carry an incidence of allergic reaction of up to 5% and anaphylaxis of 0.6%.[65,67]

Hydroxyethyl starch is an amylopectin with volume-expanding effects for approximately 36 hours. It has side effects similar to those of dextran, but with less frequency. The incidence of anaphylaxis is 0.006%. A new hydroxyethyl starch, pentastarch, has a lower molecular weight and fewer hydroxyethyl groups than hydroxyethyl starch. Pentastarch has a shorter duration of action (2.5 hours) and has been reported to have even fewer side effects.[67,68]

The controversy regarding use of crystalloids versus colloids in resuscitation has not been fully resolved. Both types of solutions can restore circulating volume. The effects of the solutions on pulmonary function are at issue and are summarized as follows: (a) the use of crystalloid solutions decreases plasma oncotic pressure, thereby leading to lung edema at lower microvascular pressures; and (b) colloids given in the face of pulmonary injury can extravasate, promoting edema because of the reduced plasma interstitial oncotic gradient. In fact, a previous meta-analysis of colloid versus crystalloid resuscitation after hemorrhagic shock demonstrated a higher mortality rate among the colloid-resuscitated patients, partly because of pulmonary complications.[69] Therefore, since colloid infusion has not demonstrated a significant benefit over crystalloid resuscitation alone, it is not currently recommended in the management of hypovolemic shock.[70,71]

Resuscitative Strategy

7 Aggressive fluid resuscitation is clearly a lifesaving modality and a key strategy in the treatment of shock and prevention of secondary consequences (**Algorithm 9.2**). However, resuscitation is not a substitute for early hemorrhage control, and indiscriminate fluid loading causes problematic edema in the lungs, gut, brain, and other organs. The amount of fluid used for resuscitation should be titrated to carefully selected hemodynamic and oxygen transport endpoints.

Permissive Hypotension

Elevation of systemic arterial pressure in patients with disruption of the arterial system or major solid organ injury, especially after penetrating trauma, may cause acceleration of hemorrhage, disrupt natural clotting mechanisms, and cause dilution of clotting factors. Laboratory and clinical evidence support judicious use of intravenous fluids until hemorrhage is controlled by surgery, angiography, or direct pressure for penetrating trauma.[72] Fluid resuscitation for patients with multisystem blunt trauma, especially with concomitant traumatic brain injury, represents a more complicated decision process, as maintaining cerebral perfusion pressure is a competing priority. Avoidance of both excessive fluid administration and

prolonged hypoperfusion is best achieved in all patients not by maintenance of a marginal blood pressure, but by rapid surgical or angiographic intervention to control bleeding.

Transfusion

Anemia prompts clinical concerns because it may signify blood loss or hematologic disease, but it rarely causes tissue ischemia. The hemoglobin level that causes concern should depend on the adequacy of other mechanisms involved in oxygen delivery such as arterial oxygen saturation and CO, the specific clinical situation, and the organ systems most at risk, balanced against the risk of transfusion. Clinical evidence suggests that hemoglobin values above 7 mg/dL are adequate in most patients, including the critically ill, but this has not been explored during shock. In one prospective randomized trial in critically ill patients, it was clearly demonstrated that a reduction in complications and improvement in survival were noted when lower hemoglobin values were accepted.[73] However, this study excluded patients with hypovolemia, acute coronary syndrome, and sepsis. Although the role of transfusion during shock remains problematic, it appears in patients without shock these thresholds of transfusion are even acceptable for elderly patients with significant cardiac disease.[74]

Given this limitation, currently it is held that most patients with class I or II shock can be resuscitated with balanced salt solutions alone. Patients who lose more than 25% to 30% of total blood volume require blood for resuscitation, as do patients with persistent evidence of inadequate end-organ perfusion.[20] The decision about the extent of blood cross-match prior to being transfused is determined in part by the urgency of the situation. Blood that has been fully typed and cross-matched carries the least risk of transfusion reactions, but it also takes the most time to obtain. Other transfusion options include the use of type O or type-specific blood (**Table 9.4**).

Type O Blood

Type O (universal donor) blood is immediately available without a cross-match. Because type O blood contains no AB cellular antigens,

administration of packed red blood cells is relatively safe in patients with any blood type. Males should be transfused type O Rh-positive blood, while prepubescent females and females of childbearing age should be given type O Rh-negative blood to avoid sensitization that would complicate future pregnancies. The administration of more than four units of type O blood to a non–O-blood-type patient, however, theoretically can result in an admixture of blood type. A pretransfusion blood specimen should be sent to the blood bank when the patient is admitted, and type-specific blood should be transfused as soon as it is available.

Type-Specific Blood

Type-specific blood is available from most blood banks within 5 to 10 minutes of receipt of the blood specimen, while the patient is being resuscitated with balanced salt solutions. Although not cross-matched, this blood can be administered safely, as demonstrated in both military and civilian experiences.[75]

Autotransfusion

Autotransfusion involves collection of the shed blood and its reinfusion through a filter back into the patient. Autotransfusion can be as simple as aspiration of the blood into a citrate-containing collection chamber, followed by reinfusion through a 40-mm filter. A more elaborate system, the Haemonetics autotransfuser (Haemonetics Corp., Braintree, MA), centrifuges the collected blood and delivers washed, packed red blood cells for reinfusion. The advantages of autotransfusion include transfusion with warm, compatible blood without delays and with no risk of transmission of hepatitis, human immunodeficiency virus, or other blood-borne pathogens.

Autotransfused blood can produce disseminated intravascular coagulation and activation of fibrinolysis. In addition, collection of blood from the peritoneal cavity after hollow viscus injury, even with cell washing, may lead to bacterial contamination of the autotransfused blood.[76] Successful autotransfusion of contaminated blood has been demonstrated, but blood obtained from enteric-contaminated cavities probably should not be used, except perhaps in extreme circumstances.[77] Despite the potential benefits, investigators have found that the autotransfuser was used in only 26% of the

trauma patients for whom it was prepared.[78] Currently, no evidence exists that autotransfusion improves outcome compared to exclusive homologous blood transfusions in trauma patients.

Endpoints of Resuscitation

Endpoints of resuscitation can be categorized as either global or regional indicators of perfusion. Blood pressure and pulse are global measures and are relatively poor determinants of the adequacy of tissue oxygenation. They must also be interpreted in the context of patient age and pre-existing medical conditions. Tachycardia is a component of SIRS and does not always resolve with increased preload. Arterial pressure is maintained by myriad compensatory mechanisms, even in the face of a significant volume deficit, and interpretation is complicated by highly variable baseline pressures, age, and pre-existing medical conditions.

Base deficit and serum lactate are also global indicators of perfusion and may help in the detection of patients who are in otherwise compensated shock. Acidosis arising from regional tissues may not be apparent in peripheral blood samples, as is frequently the case in patients with intestinal ischemia, in whom systemic acidosis is a late finding. An elevated base deficit and lactate can be caused by electrolyte abnormalities, accelerated glycolysis or pyruvate production, and/or decreased clearance by the liver. They may also reflect dysfunction caused by a period of hypoperfusion that has already resolved and that does not need further treatment. A positive response toward correction, however, is indicative of appropriate resuscitation.

Table 9.4 Comparison of Blood Availability

Blood	Typing	Antibody Screen	Cross-Match	Time
Type O	No	No	No	Immediate
Type Specific	Yes	No	No	<10 min
Type and Screen	Yes	Yes	Yes	20–30 min
Type and Cross-Match	Yes	Yes	Yes	45–60 min

A PAC has obvious appeal as a monitor because ensuring adequate 8 oxygen delivery is paramount in the treatment of shock (**Algorithm 9.2**). A progressive decline in systemic oxygen delivery (DO_2) results in an increase in the oxygen extraction ratio, evident as a reduction in pulmonary mixed venous oxygen saturation. When DO_2 is reduced below the level needed to maintain normal tissue metabolic activity, anaerobic metabolism occurs. This is evident as a decrease in total body oxygen consumption (VO_2). Adequate resuscitation requires eliminating any pathologic decrease in VO_2 by restoring oxygen delivery to an adequate level. In clinical practice, however, there is no precise level of VO_2 that can be used as an endpoint, as tissue oxygen needs vary according to the patient's condition, level of sedation, body temperature, and other factors, and are affected by endogenous and exogenously administered catecholamines.

Oxygen consumption may be especially difficult to interpret in patients with late-stage sepsis because acquired defects in mitochondrial respiration may prevent utilization of oxygen, resulting in decreased consumption and progressive acidosis despite normal or high DO_2.

The adequacy of resuscitation can also be assessed by measurement of end-organ function and perfusion, in addition to global measures. Blood flow to the most vital organs (brain and heart) is preserved during shock at the expense of flow to the skin, muscles, gut, and, ultimately, kidneys. Detection of ischemia in less vital organs could theoretically identify patients in compensated shock who have otherwise normal global indicators.

Low urine output (<0.5 to 1.0 mL/kg/hr) is an indicator of inadequate end-organ perfusion, but inappropriate urine output may initially be maintained by peripheral venoconstriction and maintenance of CO due to tachycardia. The use of gastric tonometry to measure intramucosal pH has highlighted the uneven recovery from shock by visceral organs. Persistent visceral hypoperfusion, as demonstrated by intramucosal acidosis despite correction to normal hemodynamics, is associated with organ failure and poor outcomes. Unfortunately, direct measurement of visceral hypoperfusion, as well as hypoperfusion in other regional vascular beds, requires use of technically challenging, labor-intensive devices that often produce variable unreliable results and has not yet had widespread application. Presently, the goal of therapy is to restore tissue perfusion, both global and regional as

measured by organ function, and to normalize cellular metabolism while avoiding excessive use of fluids and inotropes.

Recently, several biomarkers, in addition to base deficit and lactate, have demonstrated potential promise. Among the most promising is procalcitonin for the early recognition of sepsis. However, in addition to being significantly elevated during sepsis, procalcitonin has recently been demonstrated, similar to lactate and base deficit, to be prognostic of outcome from hypovolemia based on rate of clearance.[79] Thus, this biomarker along with potential others may lead to early recognition and treatment of shock.

MONITORS

Central Venous Pressure

CVP has been used as a surrogate for venous return to the right heart and extended to represent preload. Preload is often diminished in the setting of shock and must be optimized in order to maintain adequate oxygen delivery. The venous system serves a capacitance function containing roughly two-thirds of our circulating blood volume. It is a compliant system that, in a healthy state, functions to maintain adequate venous return to the heart over a variable total blood volume. In states of shock, this capacitance function may be overcome by too low a circulating volume—as in the setting of hypovolemic or hemorrhagic shock—or by dysregulation—as in the setting of neurogenic or septic shock. CVP may be measured directly via an appropriately positioned central venous catheter. The catheter tip should ideally be positioned at the cavoatrial junction—roughly 2 cm caudal to the carina on chest x-ray.[80] Intravenous fluids are administered to achieve adequate preload. Despite challenges for the ability for CVP to determine preload, CVP still remains used clinically.[81] In the surviving sepsis campaign, CVP is pushed to a goal of 8 to 12 mm Hg, which is thought to optimize preload.[20] This, however, has been called into question in recent years with several investigators suggesting that there is no survival benefit to achieving such high CVPs.[20] It has certainly been demonstrated that CVP is not a perfect measure of venous return to the right heart or cardiac preload as there are several intrinsic cardiopulmonary factors that influence both CVP

and CO. The role of CVP may be most useful at its extremes and when used within the context of the patients' clinical situations. A CVP <5 mm Hg in the setting of a young, otherwise healthy trauma patient with ongoing hemorrhage is likely consistent with hypovolemic shock and warrants volume resuscitation. Alternatively, a CVP of 15 mm Hg in an elderly patient with known congestive heart failure does not alone provide adequate information as to a patient's volume status nor should it guide resuscitation. As such, CVP is one measure that can help to guide shock resuscitation when evaluated in the proper context.

Pulmonary Artery Catheter

Hemodynamic monitoring utilizing a flow-directed PAC was a standard in the treatment of shock for decades, and was considered to be essential for the optimal management of certain forms of shock. However, as a result of a multicenter study that reported that use of a PAC was associated with increased mortality, the indications for PAC use have been questioned.[82,83] Clinicians may not always interpret PAC data appropriately. In a multicenter study of physicians' knowledge and interpretation of PAC data, nearly half (47%) were unable to appropriately determine the wedge pressure from a clear tracing, and a similar percentage (44%) could not identify the determinants of oxygen delivery.[83] Studies have demonstrated improved outcome when patients are managed in ICUs staffed by specialists in critical care, despite their more frequent use of PACs.[84]

An additional consideration regarding the controversy over the utility of PACs is that currently used endpoints for PAC-guided resuscitation may be inappropriate. For example, efforts to augment systemic oxygen delivery have not demonstrated any benefits and, in fact, harm may be caused by this approach, whereas treatments used to alter the variables ascertained with the catheter may themselves cause harm (fluid overload, excessive inotropes, blood transfusions). Finally, PACs are associated with specific complications, including the risk of central venous catheter insertion, endocarditis, and pulmonary artery injury, which may outweigh any potential benefits. As the safety and utility of the PAC have not yet been evaluated with prospective clinical trials in specific shock states, its usefulness in the management of shock remains to be determined.

Minimally Invasive CO Monitors

Newer versions of invasive cardiac monitoring have been developed, including the LiDCO (Cambridge, United Kingdom), PiCCO (PULSION medical system, Munich, Germany), and FlowTrac (Edwards Lifesciences, Irvine, United States) devices. Common to each is the need for an arterial line that is used to determine CO and PPV.

The LiDCO device combines pulse contour analysis with lithium dilution to determine SV. In combination with lithium chloride dilution, CO can be calculated and continuously measured following calibration. This device has been studied against PAC, and demonstrated to have good correlation.

The PiCCO device is a pulse counter device that requires a central line in addition to arterial cannulation. The device combines pulse contour analysis with transpulmonary thermodilution CO to determine hemodynamic parameters. This device is more invasive than LiDCO given the additional need for central venous access. Although this device has demonstrated to be reliable under most instances, sustained hemodynamic instability has resulted in significant errors in comparison to PAC.

The FlowTrac device is a pulse contour device that only requires an arterial line. Unlike the other devices, it does not need external calibration and relies on a linear relationship between pulse pressure and SV to determine hemodynamic parameters. Similar to the LiDCO device, this device has demonstrated good correlation to PAC under a number of different conditions. The only noted problem is during periods of severe vasoconstriction of the radial artery at which time CO is poorly determined. However, this problem most likely occurs with other devices that rely on the radial artery for analysis.

Arterial Wave Contour Analysis

Analysis of the arterial wave contour in a mechanically ventilated patient has been shown to be a marker of fluid responsiveness. This is a dynamic measurement, and as such, provides more information than static measures such as CVP or PCWP. Inspiration during positive-pressure ventilation increases intrathoracic pressure and decreases venous return to the right heart. This, in turn, leads to a decrease in left ventricular preload, a lower

SV, and a decreased CO. This effect is more pronounced in the hypovolemic patient, and calculation of PPV has been consistently shown to predict fluid responsiveness in critically ill patients. PPV is a measure of percent change in the pulse pressure over the respiratory cycle, with a PPV greater than 12.5% being consistent with fluid responsiveness.[81] Arterial wave contour analysis relies on patients having a sinus rhythm, no spontaneous respiratory function, and a tidal volume of at least 8 mL/kg. Interpretation of PPV and other arterial wave contour measurements should be cautioned outside of these parameters.

Bedside Ultrasound and Echocardiography

Improved ultrasound technology—better image quality and improved portability—over the past several years has led to its frequent use in the emergency department and intensive care settings. Ultrasound offers the benefits of being noninvasive, real time, accurate, and reproducible. A focused cardiac ultrasound can provide information on both left and right ventricular function as well as volume status. Additionally, a pericardial effusion is easily identified and may be leading to tamponade physiology. Valvular disease is much more difficult to identify and may require a formal transthoracic or transesophageal echo.[85]

In addition to assessment of cardiac function, ultrasound has demonstrated use in assessment of volume status and fluid responsiveness in shock states. Measurement of the superior vena cava (SVC), IVC, and left ventricular stroke area (LVSA) have proved helpful in guiding resuscitation. Measurement of the SVC and LVSA are performed via transesophageal echocardiography, which limits their routine use in patient management. However, SVC and LVSA variation over the respiratory cycle has been demonstrated to be predictive of fluid responsiveness.[86,87] Measurement of the IVC is performed using bedside ultrasound. The IVC is identified just caudal to the diaphragm, and an anterior–posterior dimension is recorded at the end of expiration. In the setting of trauma and shock, an IVC diameter of <1 cm is consistent with a transient responder and correlates with fluid responsiveness.[88,89] The use of ultrasound in critical care settings is growing and will continue to do so as technology and provider experience improves.

PHARMACEUTICAL SUPPORT

Therapeutic adjustments of preload and afterload form the basis of treatment strategies in all forms of shock. Optimal volume resuscitation should always precede measures to augment the contractile function of the heart. Inotropic augmentation of CO may, therefore, be required when restoration of venous preload fails to provide sufficient CO to satisfy tissue oxygen demands. The effect of inotropic agents depends on the specific adrenergic receptor affinity, chronotropic effects, and demands placed on myocardial oxygen consumption of the individual agents (**Table 9.5**). Vasodilators reduce demands on the myocardium and augment cardiac function via reduction in systemic vascular resistance (SVR) or afterload or by dilating the venous system and reducing cardiac preload. Afterload reduction may preserve SV in the face of a failing myocardium, whereas venodilation reduces pulmonary capillary wedge pressure and pressure-driven pulmonary edema. Agents that increase afterload may be needed when blood pressure falls below the autoregulatory range of the coronary, cerebral, and renal vascular beds.

Inotropes and Vasopressors

Dopamine

Dopamine is an endogenous sympathetic amine that is a biosynthetic precursor of epinephrine and functions as a central and peripheral neurotransmitter. The effects of dopamine vary from individual to individual, and are altered with increasing doses. The highest-affinity receptors are occupied at low-serum concentrations (infusions <2 to 3 μg/kg/min) and consist of dopaminergic receptors in the renal and splanchnic beds that serve to augment regional blood flow, increase urine output, and cause natriuresis. However, multiple studies, including prospective randomized trials, have failed to demonstrate that low-dose dopamine prevents acute renal failure or decreases the need for dialysis in critically ill patients. At modest concentrations (3 to 5 μg/kg/min), dopamine occupies cardiac β_1-adrenergic receptors and increases myocardial contractility and heart rate. Higher doses (>5 μg/kg/min) cause an increase in heart rate and blood pressure. α-Adrenergic receptors are stimulated at higher-dose ranges (>10 μg/kg/min),

resulting in elevation of blood pressure and peripheral vascular resistance. Dopamine is, therefore, an effective agent for increasing blood pressure in hypotensive patients after appropriate fluid resuscitation. Because the relationship among a specific dose, receptor affinity, and clinical effect is unique to each patient, individual titration is required to achieve the desired effect.

Dobutamine

Dobutamine, a synthetic catecholamine, has a predominant affinity for β-adrenergic receptors. At clinically relevant doses (5 to 20 μg/kg/min), dobutamine enhances myocardial contractility with mild to moderate changes in heart rate. It also induces peripheral vasodilation, which limits its utility in patients with hypotension. It is an appropriate agent when CO augmentation, not blood pressure support, is required and when a drop in peripheral resistance and preload is clinically tolerable or beneficial. Treatment of cardiogenic shock following myocardial infarction or cardiac dysfunction following shock and reperfusion typically requires support of myocardial contractility and reduction of peripheral resistance, which makes dobutamine an excellent choice in this setting.

Epinephrine

Epinephrine, the endogenous adrenal catecholamine, is released physiologically in response to stress. It has a broad spectrum of systemic actions, including significant cardiovascular effects. When epinephrine is administered as a pharmacologic agent (0.01 to 0.05 μg/kg/min), β_1-adrenergic effects predominate, causing increased SV, heart rate, and contractility, along with modest β_2-receptor stimulation. At higher infusion rates, α-adrenergic receptors are stimulated, which overcome β_2-mediated peripheral vasodilation, resulting in an increase in blood pressure and SVR. Renal and splanchnic vasoconstriction, cardiac dysrhythmias, and increased myocardial oxygen demands limit the prolonged use of high-dose epinephrine. Transient increases in serum lactate have also been noted, possibly due to impaired regional blood flow. Epinephrine should be considered as a potential short-term agent for use in patients with impaired cardiac function not responsive to other agents such as dobutamine.

Table 9.5 Pharmacodynamics of Inotropic/Vasoconstrictor Agents

		Sites of Action				Hemodynamic Response			
Drug	Metabolism	Heart β_1	Heart β_2	Vessels α	Vessels β_2	Renal Perfusion	CO	SVR	BP
Isoproterenol 1 mg/250 mL 1–2 µg/min initially	Renal	+++	+++	0	+++	+/–		–	+/–
Dobutamine 250 mg/250 mL 3 µg/kg/min initially	Hepatic	+++	0/+	0/+	0/+			–	0/+
Dopamine 200 mg/250 mL 2–5 µg/kg/min low dose 20–50 µg/kg/min high dose	Hepatic	+++	+	0	Low dose High dose		Low dose High dose	0/+	
Epinephrine 2 mg/250 mL 2 µg/min initially	Renal	+++	+++	+++	++	–		–	
Norepinephrine 4 mg/250 mL 4 µg/min initially	Renal	++	++	+++	0	–	+/–		
Phenylephrine	Renal	0	0	+++	0	–	–		

α (alpha), vasoconstrict peripheral arterioles; β_1 (beta-1) myocardial inotropy, chronotropy, enhance atrioventricular conduction; β_2 (beta-2) chronotropy, vasodilate mesenteric/skeletal bed, bronchodilation; dopaminergic, vasodilate mesenteric/renal bed. BP, blood pressure; CO, cardiac output; SVR, systemic vascular resistance.

Norepinephrine

Norepinephrine, the sympathetic neurotransmitter, also has concentration-dependent cardiovascular effects. It should be considered as a drug with predominantly α-constrictor effects and less pronounced β-stimulation and is, therefore, appropriate for use in patients who remain hypotensive despite dopamine administration or as a dopamine alternative. Combined α- and β-stimulation typically results in an increase in afterload and renal glomerular perfusion pressure, with preservation of CO. Despite the potential for renal vasoconstriction, as a result of its effects on mean arterial pressure, norepinephrine is associated with an increase in urine output and creatinine clearance in hypotensive, and particularly septic, patients. A primary concern is to ensure adequate volume resuscitation prior to utilization due to risk of severe tissue damage from excessive vasoconstriction on the hypovolemic patient.

Isoproterenol

Isoproterenol is a synthetic catecholamine with potent β-adrenergic effects. From a cardiovascular standpoint, both cardiac and peripheral effects are significant. Stimulation of cardiac β_1-receptors prompts an increase in contractility, heart rate, and conduction velocity. The chronotropic response, however, may predominate. These activities, in conjunction with peripheral vasodilation, generate significant increases in CO and pulse pressure. Isoproterenol greatly increases myocardial oxygen demand and limits coronary filling due to tachycardia. As a result, indications for isoproterenol are limited to patients with hemodynamically significant bradyarrhythmias while preparations are made for electrical pacing.

Phenylephrine

Phenylephrine is a pure α-agonist and is an effective agent for increasing peripheral vascular resistance and arterial blood pressure. Although it has no direct effect on the myocardium, the increase in afterload increases left ventricular work and oxygen demand and may cause a decrease in SV and CO. It is often used as a first-line agent in patients with neurogenic shock, but its use is otherwise generally restricted to patients who remain hypotensive when the dosage of agents such as dopamine or norepinephrine cannot be increased due to excessive tachycardia.

Vasopressin

Vasopressin acts directly on V_1 receptors in vascular smooth muscle to cause vasoconstriction and increases the reactivity of vascular smooth muscle to catecholamines. Release of endogenous vasopressin is a normal physiologic response to shock. After septic or prolonged hemorrhagic shock, circulating vasopressin levels are decreased, possibly due to depletion of hypophyseal secretory stores. This relative deficiency may play a role in causing refractory hypotension. Vasopressin has minimal effects on normotensive patients, but in patients with septic shock, it is effective in increasing SVR and mean arterial pressure. Vasopressin does not have inotropic properties but has potent splanchnic and coronary vasoconstrictors. It has been associated with decreased CO due to myocardial ischemia and increased afterload and may worsen metabolic acidosis in patients in shock by causing splanchnic ischemia. As a result, early use of vasopressin at only physiologic

concentrations to minimize associated other pressor use may be indicated in the event that other pressor agents are unable to achieve optimal perfusion.[90]

Amrinone and Milrinone

Amrinone and milrinone are noncatecholamine inotropes with cardiovascular effects similar to dobutamine, but with minimal chronotropic activity. As steroid-like phosphodiesterase antagonists, they increase smooth muscle cyclic adenosine monophosphate (cAMP) and alter calcium metabolism. Cardiac contractility, SV, heart rate, and CO are increased, while a concomitant reduction in afterload offsets cardiac workload. The increase in cardiac performance with minimal demands on myocardial oxygen consumption offers some utility in the treatment of cardiogenic shock or as a potential alternative to dobutamine infusion. Both agents have a relatively long half-life of nearly 3 hours and should therefore be used with caution in patients at risk of developing hypotension, a major risk in the critically ill patient.

Vasodilators

Vasodilators are used as a means to augment cardiac function through optimization of preload and afterload, both of which reduce demands on the myocardium. The failing ventricle responds to afterload reduction with significant increases in SV. The reason for this is that the compromised myocardium is working past the plateau and on the down slope of the Starling curve. As a result, afterload reduction with vasodilator agents may allow CO to increase, resulting in improved oxygen delivery.

Nitroprusside

Nitroprusside is a balanced but potent arterial and venous smooth muscle vasodilator. It causes a reduction in afterload that increases CO and has a less prominent venodilatory effect that reduces pulmonary venous pressure and preload. Hypotension may limit its use, particularly in the presence of contractility deficits or inadequate preload. Infusions (>3 μg/kg/min) continued for greater than 48 hours require monitoring of serum thiocyanate levels and arterial pH to detect complications of cyanide toxicity.

Nitroglycerin

Nitroglycerin is primarily a venous smooth muscle vasodilator, with less significant arterial vasodilation effects than nitroprusside. Thus, although nitroprusside predominantly decreases afterload, nitroglycerin predominantly increases venous capacitance. It is an effective treatment for acute myocardial ischemia because it reduces excessive preload and ventricular end-diastolic pressure, thereby diminishing myocardial oxygen demand.

Miscellaneous Therapeutics

Corticosteroids

In septic shock, ACTH resistance may diminish the normal cortisol response. Also, peripheral tissue resistance to corticosteroids may develop through proinflammatory-induced downregulation of normal corticosteroid receptors. Utilizing low or physiologic doses (<300 mg/day) of hydrocortisone for a longer duration (>5 days) of treatment have demonstrated a beneficial impact on mortality, particularly in septic patients.[91] Currently, routine use of ACTH stimulation tests is not advocated since they provide little more than prognostic information.[92] Given that hypoadrenal shock complicates various shock states, routine use by some experts is considered appropriate. However, this should only be based on patients who have achieved adequate intravascular volume but remain in shock despite high vasopressor administration. Thus use of corticosteroids at only physiologic doses with immediate tapering once hemodynamics have improved should be used with caution.[93]

Metabolites and Electrolytes

Severe shock is frequently associated with hypocalcemia. Severe hypocalcemia that causes cardiac dysfunction or electrical instability should be rapidly treated. Calcium chloride rapidly corrects calcium deficits, whereas calcium gluconate must be degraded in the liver to release calcium ion, resulting in slower correction of deficits but less risk of tissue reaction. In the absence of evidence of cardiac dysfunction, attempts to restore plasma calcium to normal during shock are not warranted. Ischemia results in

decreased cell membrane ATP and failure of the membrane calcium pump. Thus, reduced serum calcium levels during severe shock are probably due to movement of ionized calcium into the cells. Increased cytosolic calcium causes release of lysosomal enzymes and activation of phospholipases, protein kinases, and proteases that cause membrane damage and cytoskeletal destruction. Administration of exogenous calcium may merely worsen this uncontrolled intracellular calcium influx, whereas effective resuscitation will usually restore circulating calcium levels to normal.

Many shock resuscitation protocols emphasize correction of metabolic acidosis with fluids and inotropes until the pH begins to normalize. When interpreting an acid–base disorder, the presence of an anion gap is supportive evidence of lactic acidosis. However, a non–anion gap acidosis with worsening base deficit frequently occurs when normal saline is administered in large volumes. Efforts to correct a non–anion gap acidosis with additional fluids that may no longer be needed will only increase the risk of fluid overload.

Future Therapies

When initiating therapy for shock, the clinician does not know whether therapy has been started early, when salvage is still possible, or late, after irreversible changes have occurred within the cell and death is inevitable. Failure to respond to fluids, inotropes, and vasopressors with restoration of normal oxygen consumption and aerobic metabolism probably represents a defect in cellular and subcellular function in critical organ systems. There are many active areas of investigation that reflect the progression of our understanding of shock that have been outlined in this chapter and that have begun to move the field beyond the basics of fluid resuscitation and hemodynamic monitoring.

Efforts to control ischemia–reperfusion injury include controlled reperfusion with carbon monoxide or other compounds to reduce oxidative stress. Induced hypothermia may interrupt generation of harmful byproducts of ischemia and enable restoration of circulation and repair of structural injuries in a cellular environment where hypoxia is no longer critical. Additional biomarkers, such as procalcitonin, may allow earlier diagnosis and treatment of sepsis and shock.[79] New biosensors using near-infrared light

may enable transcutaneous identification of critical limitations of blood flow and enable clinicians to more accurately target areas of regional hypoperfusion.[94] A search for agents that optimize circulation in the microvascular system by preventing activation of the endothelium may enable resuscitative efforts to restore oxygen to cells as needed to maintain normal respiration and provide critical nutrients.[94] Ultimately, further understanding of functional genomics may enable clinicians to target transcription and translational events triggered by shock and thus alter outcome.

Critical Care

William C. Chiu and Samuel A. Tisherman

Key Points

1 In 1957 Peter Safar from the Baltimore City Hospital Department of Anesthesiology (later from the University of Pittsburgh School of Medicine) first reported on his new technique of mouth-to-mouth respiration using an artificial airway, leading to the development of cardiopulmonary resuscitation (CPR). In 1958, the first "Intensive Care Unit" (ICU) was established at the Baltimore City Hospital, to provide optimal medical and nursing care to all critically ill patients.

2 A recent systematic review and practice management guideline evaluated the use of focused echocardiography (ECHO) and pulse waveform analysis in patients with shock. The results were variable regarding the benefits of either modality in predicting fluid responsiveness, reduction in organ failure or complications, or mortality. However, the recommendations were that, in appropriate subpopulations and with adequate training in the technology, ECHO and pulse waveform analysis protocols can be associated with favorable outcomes.

3 In the recent Berlin definition of acute respiratory distress syndrome (ARDS), the ARDS spectrum is classified by the PaO_2/FiO_2 (P/F) ratio as mild (201 to 300), moderate (101 to 200), or severe ($\leq$100). Conventional ventilatory strategies incorporate a low-stretch philosophy. Evidence-based adjunctive strategies include prone positioning, airway pressure release ventilation, inhaled prostacyclins, and extracorporeal support.

4 Venous thromboembolism (VTE) is a significant problem in surgical ICU patients and chemical prophylaxis has been demonstrated to beneficially impact outcome. Low–molecular-weight heparin (LMWH) is more efficacious than unfractionated heparin in those at the highest risk in this population, if the risk of bleeding can be mitigated. Since LMWH is primarily eliminated by the kidneys, LMWH should be avoided in those with renal dysfunction. Increasing the prophylactic dose of LMWH may be appropriate in morbidly obese patients. Laboratory monitoring of anti-Xa activity should be considered when using LMWH in patients with renal impairment or obesity.

5 A conservative transfusion trigger (7 g/dL hemoglobin) may be appropriate in most surgical ICU patients, including those with gastrointestinal bleeding, neurotrauma, cardiac disease, and sepsis.

6 ICU patients should undergo routine assessment and adequate support of their nutritional status to preserve lean body mass, maintain immune

function, and avert metabolic complications. Enteral nutrition is strongly preferred over parenteral nutrition. There is little evidence for benefit of specialized formulas, either for immunonutrition or for specific organ failure support. Prophylaxis against stress-related mucosal disease is indicated for patients who will require mechanical ventilation for more than 48 hours or have a coagulopathy. Either proton pump inhibitors or histamine-2 antagonists can be used.

7 Acute kidney injury (AKI) is a common complication in the ICU and is associated with worse outcomes. Rapid restoration of normal hemodynamics and treatment of sepsis, as well as avoidance of nephrotoxic agents, are the best preventative measures. Both continuous and intermittent dialysis play an important role with severe AKI.

8 Successful management of sepsis requires rapid identification, appropriate cultures, early antibiotics, fluid resuscitation, and hemodynamic support with goals of normalizing perfusion. Catheter-associated infections are often preventable with proper maintenance and removal as soon as possible.

9 Delirium is common in critically ill patients and is associated with increased length of stay, increased post-intensive care syndrome, and, possibly, mortality. The causes are multifactorial. Trying to maintain normal day/night cycles can help. There are no drugs that directly improve delirium. Pharmacologic therapy is mainly useful for managing patients with hyperactive delirium with the main goal of preventing harm. Drugs that can aggravate the delirium, such as anticholinergics or benzodiazepines, should be avoided.

INTRODUCTION

The history of intensive care dates back to the 1854 Crimean War with Florence Nightingale, the founder of professional nursing.[1] Nightingale was known to have separated the most severely injured soldiers into close proximity to the nursing station to provide more intensive care. During the 1952 poliomyelitis epidemic in Denmark, Bjorn Ibsen advanced the concept of artificial respiration outside the operating room in a special department at the University of Copenhagen.[2] The majority of severe polio patients treated with the standard iron lung negative pressure respirator tanks were still dying. The new strategy employed was that patients with paralysis and respiratory failure underwent tracheotomy and manual

intermittent positive pressure ventilation performed by medical students at bedside in six-hour shifts.

1 In 1957 Peter Safar from the Baltimore City Hospital Department of Anesthesiology (later from the University of Pittsburgh School of Medicine) first reported on his new technique of mouth-to-mouth respiration using an artificial airway, leading to the development of cardiopulmonary resuscitation (CPR).[3] In 1958, the first "Intensive Care Unit" (ICU) was established at the Baltimore City Hospital, to provide optimal medical and nursing care to all critically ill patients.[4] This ICU maintained early emphasis on airway, ventilation, and resuscitation. Also in 1958, cardiologists Max Harry Weil and Herbert Shubin created the Shock Ward at the Los Angeles County General Hospital of the University of Southern California. This unit had early emphasis on acute circulatory failure and hemodynamics, employing new continuous monitoring techniques and physiologic measurements to manage patients with life-threatening critical illness. This evolving concept of multidisciplinary patient care with medicine, anesthesiology, surgery, nursing, and various collaborators would come to be known as the modern day ICU.[5]

Surgical ICUs and their patients share many features with those in medical ICUs. Patients admitted to the ICU make up a large proportion of hospital cost and resources, estimated to be roughly 1% of gross domestic product. More importantly, both surgical and medical ICUs continue to find themselves understaffed. The supply of critical care practitioners is inadequate and the demand is extensive, largely from aging patients with complex comorbidities undergoing complicated procedures. There are approximately 3,000 Board-certified surgical intensivists with less than 200 completing training annually, most of whom do not practice critical care exclusively. In the United States, these surgical intensivists serve largely in surgical specialty units of academic medical centers that account for approximately 10% to 15% of the nearly 6,500 ICUs with roughly 100,000 beds and 5 million admissions annually. The largest growing demographic in hospitals and ICUs is the group over 65 years of age, now accounting for over half of all admissions.[6]

HEMODYNAMIC MONITORING

Oxygen Transport

The transport of oxygen to the microcirculation and tissues is mediated by four general parameters: (1) arterial oxygen content (CaO_2), (2) the rate of oxygen delivery (DO_2) to tissues, (3) the rate of oxygen uptake from tissues, and (4) the fraction of oxygen in blood that is extracted by tissues. Oxygen delivery, the rate at

which oxygen is transported to the microcirculation, is the product of cardiac output and CaO_2 and is normally about 1,000 mL/min. Oxygen delivery falls in instances of cardiac failure, hypovolemia, anemia, but less so due to poor oxygenation. Oxygen consumption (VO_2), the rate at which oxygen is removed from the blood by the microcirculation, is the product of cardiac output and the arteriovenous O_2 difference and is normally 250 mL/min in an average adult. The oxygen extraction (OE) ratio or the ratio of VO_2 to DO_2 is normally about 25%. The myocardium has the body's highest extraction ratio at approximately 75%. Oxygen consumption remains constant over a wide range of DO_2 by changes in OE. For example, in situations of decreased DO_2 such as hemorrhagic or cardiogenic shock, VO_2 can be maintained by increasing extraction ratio. This mechanism may be altered in critically ill patients who show marked increases in VO_2 under the influence of stress hormones and catecholamines.

To evaluate the balance between systemic DO_2 and VO_2, the oxygen saturation of hemoglobin in mixed venous blood can be assessed. Mixed venous blood is obtained from the pulmonary artery using a pulmonary artery catheter (PAC) and reflects the final destination of circulating blood from all tissue beds prior to reoxygenation in the lung. Mixed venous oxygen saturation (SvO_2) may be used as a measure of tissue oxygenation, and is expressed as $1 - VO_2/DO_2$, with normal values of 60% to 80% that can be continuously displayed with an oximetric PAC. Reductions in SvO_2 reflect a mismatch between DO_2 and VO_2, commonly from a reduction in DO_2 and/or an elevation in VO_2 (**Table 10.1**).

More recently, central venous blood obtained from a central venous catheter in the superior vena cava (SVC) has been a more practical source for measurement of venous saturation. The normal values of central venous oxygen saturation ($ScvO_2$) are 65% to 85%, slightly shifted up compared to SvO_2. While large studies have revealed discordant results demonstrating the utility of monitoring $ScvO_2$, for common practice we recommend that $ScvO_2$ may be used as a helpful adjunct, but not as the only endpoint of resuscitation.

Volume Assessment

Assessment of volume status and cardiac function in the critically ill patient is evolving. Traditional static measures of volume assessment using central venous catheters and PACs are being replaced in many settings by dynamic or functional measures afforded by technologies such as pulse waveform analysis and focused

echocardiogram (ECHO). Similarly, indirect measurement of cardiac function by PACs is being succeeded by pulse waveform analysis and systolic and diastolic evaluation of left and right global and regional function using ECHO.

Table 10.1 Normal Hemodynamic Parameters

Parameter	Equation	Normal Range	Units
Oxygen delivery	$DO_2 = CO \times CaO_2 \times 10$	950–1,150	mL/min
Arterial oxygen content	$CaO_2 = SaO_2 \times 0.0138 \times Hgb + 0.003 \times PaO_2$	17–20	mL/dL
Oxygen consumption	$VO_2 = CO \times (CaO_2 - CvO_2) \times 10$	200–250	mL/min
Oxygen extraction ratio	$OE = VO_2/DO_2 \times 100$	22–30	%
Mixed venous oxygen saturation	$SvO_2 = (1 - VO_2/DO_2) \times 100$	60–80	%
Cardiac output	$CO = HR \times SV/1000$	4–8	L/min
Stroke volume	$SV = CO/HR \times 1000$	60–100	mL/beat
Stroke volume variation	$SVV = (SV_{max} - SV_{min})/SV_{mean} \times 100$	10–15	%

DO_2, oxygen delivery; CO, cardiac output; CaO_2, arterial oxygen content; SaO_2, oxygen saturation; PaO_2, partial pressure of oxygen in arterial blood; VO_2, oxygen consumption; CvO_2, central venous oxygen content; OE, oxygen extraction; SvO_2, mixed venous oxygen saturation; HR, heart rate; SV, stroke volume; SVV, stroke volume variation.

2 A recent systematic review and practice management guideline evaluated the use of ECHO and pulse waveform analysis in patients with shock. The results were

variable regarding the benefits of either modality in predicting fluid responsiveness, reduction in organ failure or complications, or mortality. However, the recommendations were that in appropriate subpopulations, and with adequate training in the technology, ECHO and pulse waveform analysis protocols can be associated with favorable outcomes.[7]

Fluid Responsiveness

The concept of volume status using static measures has evolved to "volume responsiveness" using dynamic or functional measures to assess whether a fluid bolus will improve the stroke volume (SV) and cardiac performance of a critically ill patient. Static measures such as central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) can give inferential data of cardiac filling pressures at a single time-point, which then extrapolates to cardiac preload (end-diastolic volume) and volume status of the patient. However, these pressures can be altered depending on cardiopulmonary physiology, do not always correlate with Frank–Starling principles, and give no indication of whether the patient will respond to a bolus of infused fluid.

Measurements of CVP and PAOP are made at end-expiration when the pleural pressure is closest to atmospheric pressure. Normal venous waveform components include the "a" wave (corresponding to right atrial contraction), the "c" wave (tricuspid valve closure and isovolumic right ventricular contraction), and the "v" wave (ventricular ejection driving venous filling of the atrium) (**Fig. 10.1**). Clinically, the high point of the "a" wave is the atrial pressure at maximum contraction, where atrial pressure is greater than ventricular diastolic pressure. Here, the right atrium is contracted and the tricuspid valve is open, which is synonymous with right ventricular end-diastolic pressure, making the ventricle, atrium, and vena cava interconnected.

The use of CVP to guide resuscitation has not been demonstrated to be beneficial in many large clinical series. A large meta-analysis revealed a very poor relationship between CVP and blood volume.[8] Additionally, several large recent trials of sepsis resuscitation demonstrated that resuscitation targeted to CVP endpoints did not improve outcome.[9,10]

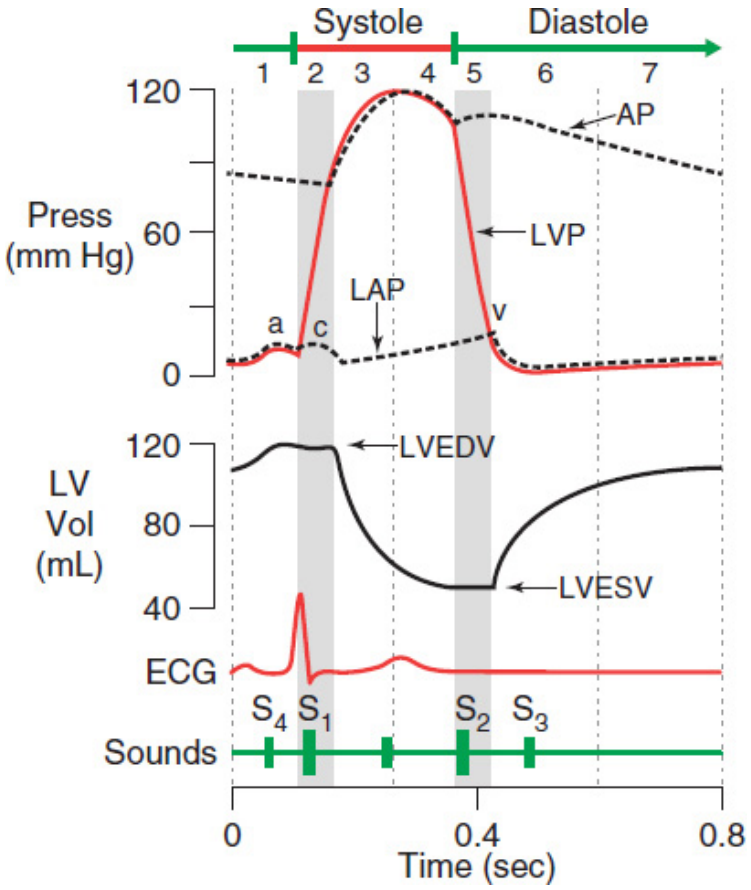

Figure 10.1 Normal venous waveform with ECG (a, c, and v waves).

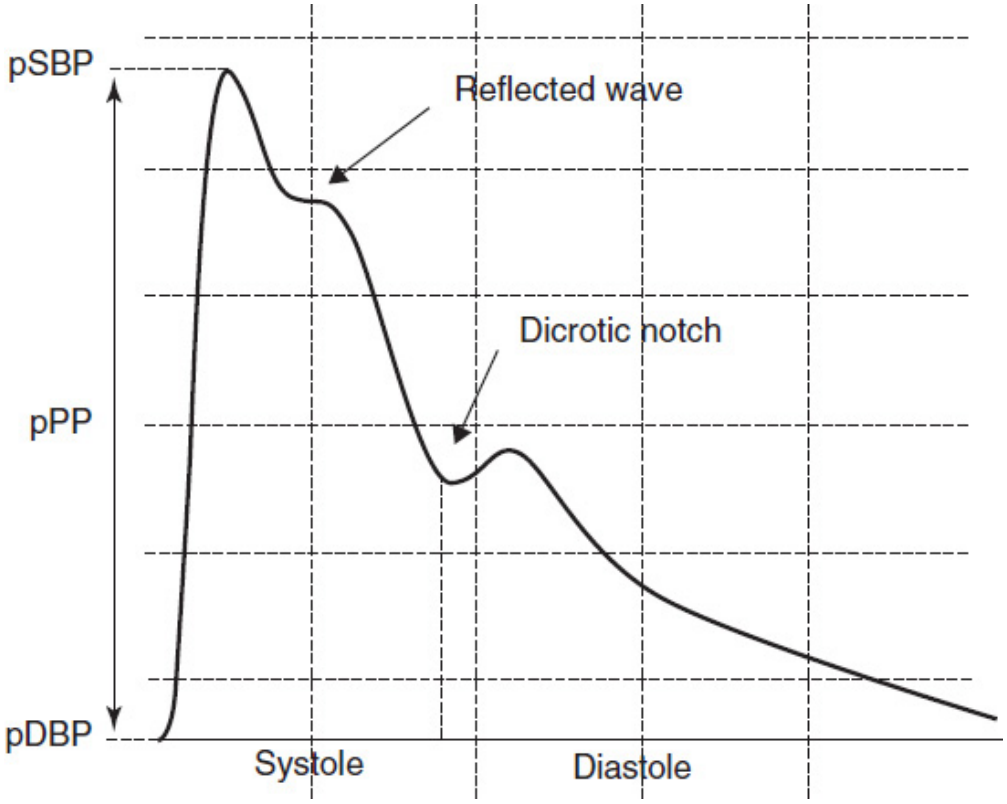

Figure 10.2 Arterial pressure waveform. Area under systole curve is used to calculate stroke volume. pSBP, peripheral systolic blood pressure; pPP, peripheral pulse pressure; pDBP, peripheral diastolic blood pressure.

PAC-based volume assessment employs the principle that a single column of fluid forms from the pulmonary artery to the left ventricle during diastole. For a given left ventricular end-diastolic pressure (LVEDP) and compliance, left ventricular end-diastolic volume (LVEDV) can be estimated. Based on the Frank–Starling principle, the force of ventricular contraction is proportional to muscle stretch and LVEDV. As PAOP estimates LVEDV for a given cardiac output, preload may be determined. Numerous physiologic changes may alter the relationship between PAOP and LVEDV, including pulmonary veno-occlusive disease, pulmonary hypertension, ARDS, increased intrathoracic pressure, valvular disease, and altered cardiac compliance. Finally, large clinical trials have failed to demonstrate a benefit to outcome for those resuscitated to a PAOP endpoint.[11]

Dynamic and functional assessment of volume responsiveness includes those on both the arterial and venous side of the heart. Normally, the inspiratory increase in pleural pressure during positive pressure breathing reduces right ventricular preload and stroke volume, manifested on the arterial side within a few beats. Left ventricular SV diminution is maximal during expiration. These normal physiologic

changes during the mechanically supported respiratory cycle are augmented with hypovolemia that is volume responsive.

Pulse waveform analysis is minimally invasive and uses a proprietary algorithm analysis of the arterial pressure waveform. The area under the curve corresponding to systole (i.e., before the dicrotic notch) is used to calculate SV (**Fig. 10.2**). Computer calculation is made of the maximal and minimal amplitude of the curve. In general, a stroke volume variation (SVV) of greater than 13% to 15% reflects volume responsiveness, whereas values below this threshold imply that the patient is beyond the upper inflection point of the Frank–Starling curve and will not benefit from further volume loading. There are instances where it is possible to misinterpret these values. For example, high vasopressor burden or lack of arterial compliance may alter blood flow and arterial wave morphology. However, clinical applications of SVV as a volume assessment tool have been promising.[12]

ECHO can provide arterial and venous volume assessment with both static and dynamic values. Many static measures can be rendered functional by performing measurements both before and after a passive leg raise, a maneuver that replicates volume loading. Passive leg raising measurements may be the only accurate methodology to approximate fluid responsiveness in spontaneously breathing patients. In these patients, a breath results in an increase in SV and systolic pressure. Static values include measurement of the diameter of the inferior vena cava (IVC) on the long axis view, or, in some series, the SVC or internal jugular vein (IJV) on the venous side or calculation of the velocity time integral (VTI) on the arterial side. Collapsibility of the IVC (or SVC/IJV) of at least 15% and as much as 50% during respiration predicts fluid responsiveness.[13] Right-sided heart failure may alter the size relationships of the central veins, thus providing an underestimate of fluid responsiveness using venous measurements.

In summary, ECHO, SVV, and passive leg raise are complementary tools to predict fluid responsiveness. Each technique has its own benefits and drawbacks, but in combination, depending upon local expertise, they can provide a multi-faceted approach. Repeated measures during resuscitation can allow the provider to further fine tune fluid management.

Cardiac Function

Assessment of cardiac function is best understood by recollection of the cardiac pressure–volume curve depicting the cardiac cycle (**Fig. 10.3**). Starting at the top right at “A,” the aortic valve opens and blood is ejected into the outflow tract. At “B” systole ends as the aortic valve closes. A period of isovolumic relaxation occurs and ventricular pressure falls until the mitral valve opens at “C,” the start of

diastole. Diastole ends as the mitral valve closes at “D” and then there is a period of isovolumic contraction with both valves closed until the cycle repeats. Note that the distance across the box represents SV, the amount of blood ejected per heartbeat, which is expressed in mL and determined by preload, afterload, and contractility. The product of SV and heart rate is CO. Ejection fraction (EF), a more valid estimate of cardiac function, is the proportion of preload or EDV ejected per beat or SV/EDV.

PACs determine cardiac output by thermodilution. The thermodilution technique measures temperature changes sensed by a thermistor at the distal end of the catheter after a cold saline injection is performed through the proximal port. Based on the modified Stewart–Hamilton equation, which constructs a plot of temperature change against time, measurements of cardiac output can be obtained. The thermodilution technique assumes that complete mixing of the blood occurs, that there is constant blood flow in the heart, and that there is no loss in concentration of the indicator between the point of injection and the distal balloon tip. Pulse contour analysis can also be used to measure stroke volume and cardiac output. Using PAC thermodilution as the gold standard, accuracy is acceptable.

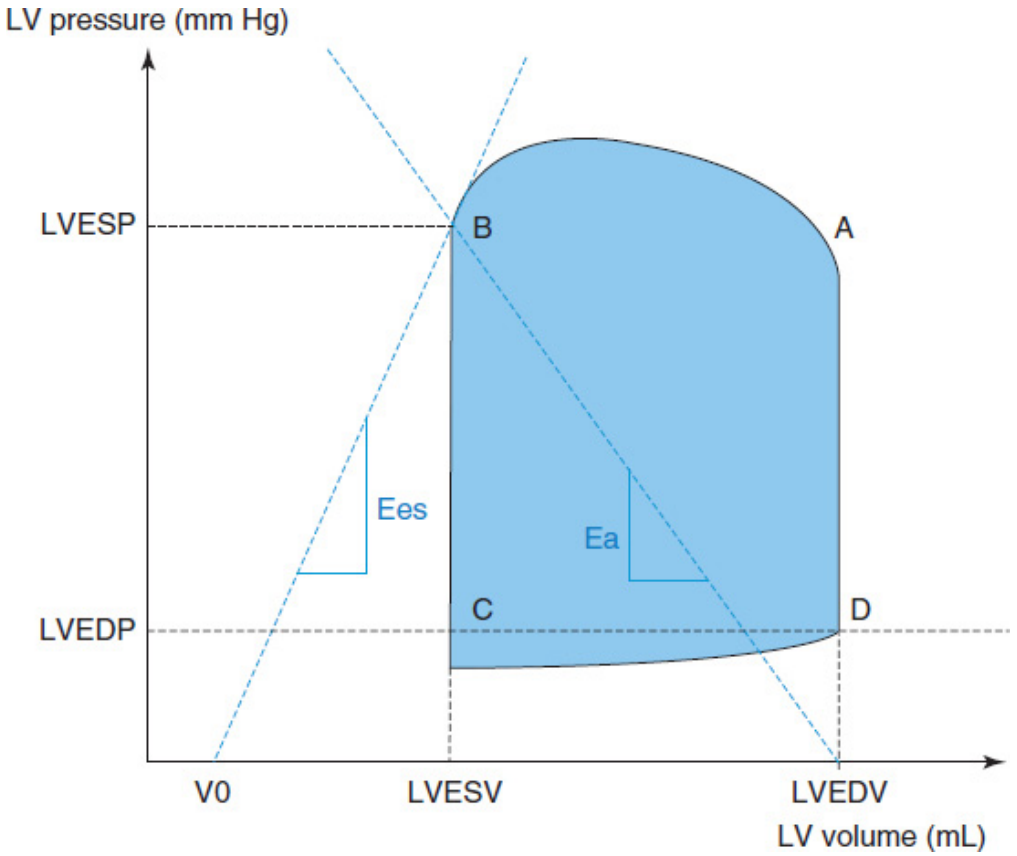

Figure 10.3 Left ventricular pressure–volume curve. Ees, LV elastance; Ea, arterial elastance; ESV, end-systolic volume; EDV, end-diastolic volume; ESP, end-systolic pressure; EDP, end-diastolic pressure; LV, left ventricle. *A:* aortic valve opens; *B:* aortic valve closes; *C:* mitral valve opens; *D:* mitral valve closes.

ECHO does not suffer from many of the shortcomings of CVP, PAC, or arterial line assessment of cardiac function, such as static measurement and requiring an invasive catheter. ECHO can determine left and right ventricular function, assess wall motion abnormalities, valve defects, pericardial fluid, and provide real-time information on effectiveness of inotropic and vasopressor therapy. ECHO can provide information about heart function in a qualitative or quantitative fashion, can be used to assess left and right heart morphology, dynamics, and size, can determine the difference in EF and SV, and can perform quantitative estimates of pulmonary artery and right ventricular pressure. Shock states may be due to impaired EF or contractility, or due to diminished volume status and SV.

ECHO can also discern right heart dysfunction, common in surgical ICU patients, by examining size, morphology and function of the right ventricle. Underfilling of the left heart, typically treated by volume loading, requires attention to inotropic support in the case of right heart failure. Finally, unique to ECHO is the ability to assess for diastolic dysfunction as occurs with diastolic heart failure, sepsis, tamponade, and

increased pleural pressure (as with pneumothorax, abdominal compartment syndrome, and massive pleural effusions). ECHO can be readily repeated as frequently as needed based upon the clinical situation.[14]

CARDIAC ARREST AND DYSRHYTHMIAS

Dysrhythmias are common in both cardiac and noncardiac surgical ICU patients. The most life-threatening dysrhythmias can be treated by following current American Heart Association Advanced Cardiac Life Support (ACLS) guidelines.[15] For patients who become pulseless in the ICU, rapid restoration of the circulation employing basic life support (BLS) is vital. The most important features of the current BLS guidelines include the recognition that CPR, when indicated, be delivered by pushing hard and fast with complete recoil at a rate of at least 100 compressions/min to a depth of 2 inches in adults. CPR providers should deliver no more than 2 minutes of chest compressions each (or five cycles of compressions) until a personnel switch is made. In adults, if 2 providers are present, the ratio of 30 compressions to 2 breaths is maintained until respirations can be controlled by intubation and controlled ventilation.

The rapid use of a defibrillator is key to improving postarrest survival. Cardiac arrest from a rhythm other than ventricular fibrillation, such as from bradycardia progressing to asystole or pulseless electrical activity (PEA), portends a poor prognosis, often as the result of acidosis or profound hypoxia incidental to sepsis and multiple organ failure. Another important feature of the current BLS and ACLS guidelines that may impact surgical ICU patients is the recognition of the need for postcardiac arrest care. This certainly includes fluid resuscitation and administration of vasopressors and inotropes as needed. However, there may also be a need to interrogate via coronary angiography and treat for acute coronary syndrome if anticoagulation can be tolerated and for consideration of postarrest targeted temperature management (goal of 33° to 36°C for 24 hours) to preserve neurologic function. Although targeted temperature management protocols were established to address out of hospital cardiac arrest with coma, there has been increasing use of the modality for hospitalized patients as well. Current guidelines also address new technology with biphasic electrical sources that deliver shocks for dysrhythmias with a pulse and defibrillation in those with ventricular fibrillation. Another important component of the recommendations is the use of end-tidal CO_2 monitoring to ensure adequacy of CPR quality.

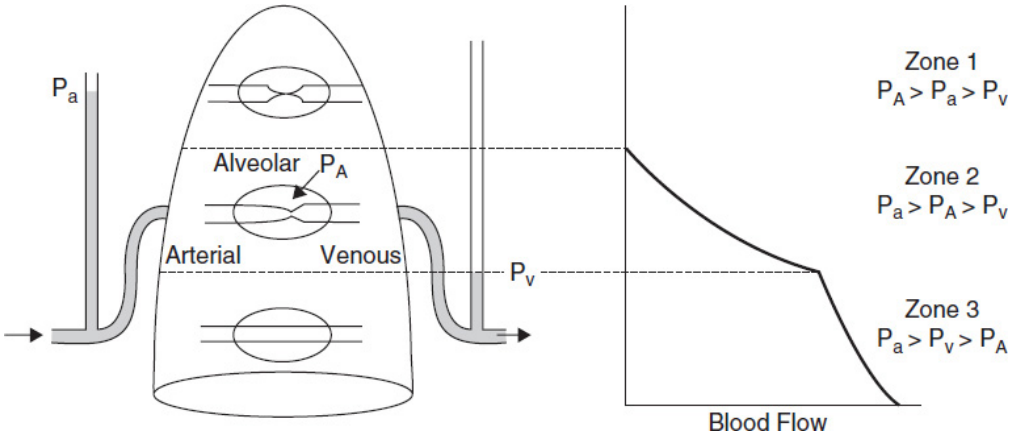

Figure 10.4 West lung zones. **Zone 1:** Not observed in healthy lung. Alveolar pressure exceeds pulmonary blood vessel pressure leading to alveolar dead space. **Zone 2:** Located approximately 3 cm above heart. Pulmonary vessel pressure exceeds alveolar pressure in a pulsatile fashion and allows pulmonary blood flow and alveolar distention. **Zone 3:** Majority of healthy lungs with continuous blood flow and oxygenation. P_A, Alveolar Pressure; P_a, arterial pressure; P_V, venous pressure.

Three dysrhythmias produce pulselessness: ventricular fibrillation, PEA, and asystole. Only ventricular fibrillation is responsive to defibrillation which is with 120 to 200 J using a biphasic device as per manufacturer's recommendations. PEA and asystole are treated by administration of epinephrine (1 mg every 3 to 5 minutes) and/or vasopressin (40 U one-time dose). Pulseless ventricular tachycardia is treated like ventricular fibrillation with additional shocks given after five cycles of CPR (2 minutes). In addition, epinephrine and vasopressin are administered as CPR continues. Continued pulseless ventricular tachycardia and fibrillation can be treated with amiodarone (300 mg with a second dose of 150 mg if refractory) or lidocaine (1.0 to 1.5 mg/kg).

PULMONARY GAS EXCHANGE

Oxygenation

Normal lung function and gas exchange require patent alveoli and pulmonary capillaries. Once red blood cells become saturated with oxygen, additional oxygen dissolves into the plasma and the measured partial pressure of oxygen (PO_2) is 100 mm Hg with an oxygen saturation (SaO_2) of 100%. Since a small portion of oxygenated blood is diverted away from the pulmonary circulation (via bronchial vessels), a normal PaO_2 is 90 mm Hg with 98% saturation. Insufficient blood oxygenation is termed hypoxemia. This is to be differentiated from hypoxia, which is

abnormally low oxygen content in a tissue or organ. The alveolar to arterial (A-a) oxygen gradient is a common measure of oxygenation ("A" denotes alveolar and "a" denotes arterial oxygenation).

Perturbations causing hypoxia and hypoxemia may be the result of ventilation/perfusion (V/Q) mismatch, impaired diffusion, or shunt. Hypoventilation, a result of neuromuscular dysfunction and impaired diffusion (occurring with pulmonary edema or interstitial lung disease) can be treated effectively by exogenous administration of oxygen. The A-a gradient is normal in hypoxemia due to pure hypoventilation and increased in V/Q mismatch. V/Q mismatch, the most frequent cause of hypoxemia in the ICU, occurs with decreased airflow to the alveoli in relation to the amount of pulmonary capillary blood flow. In the normal lung, there is V/Q mismatch because perfusion and ventilation are heterogeneous. Both ventilation and perfusion are greater in the bases than in the apices. However, the difference between apical and basilar ventilation is less than the difference between apical and basilar perfusion. Therefore, the V/Q ratio is higher in the apices than in the bases. In the diseased lung, V/Q mismatch increases because heterogeneity of both ventilation and perfusion worsen resulting in hypoxemia. Common causes of hypoxemia due to V/Q mismatch include obstructive lung diseases, pulmonary vascular diseases, and interstitial diseases. Shunting occurs when there is adequate ventilation of the alveoli but decreased pulmonary capillary blood flow. Hypoxia due to shunting with venous admixture as with severely depressed cardiac output or anemia cannot be overcome by administration of oxygen (**Fig. 10.4**).

Ventilation

Ventilation refers to the exchange of air from the lungs and alveoli. The rate at which alveolar ventilation occurs determines the amount of carbon dioxide (CO_2) excretion, a readily diffusible substance. The amount of CO_2 produced and requiring elimination is related to the respiratory quotient (RQ). RQ is the ratio of CO_2 produced to O_2 consumed and is normally 0.8, depending on the diet. Chemoreceptors in the medulla are responsive to pH changes and when patients become acidemic they hyperventilate to decrease $PaCO_2$ to maintain normal pH. End-tidal CO_2 may be lower than $PaCO_2$ if substantial lung is ventilated but not perfused (dead space).

VENTILATOR MODES

One of the initial steps in evaluating a patient with respiratory failure is to confirm a patent and protected airway. The ICU team must determine if the patient has an acute issue causing the respiratory failure that can be treated without mechanical ventilation. Through the use of physical examination, bedside ultrasound and radiography, the ICU team may diagnose a pneumothorax or acute pulmonary edema that can be treated without intubation. If the patient has acute respiratory failure without an easily treatable process, intubation and mechanical ventilation may be safest. When setting up the mechanical ventilator there are several options and modalities from which to select.

Mechanical ventilation may improve oxygenation and ventilation by attempting to improve V/Q mismatch and decreasing the amount of shunt. Current recommendations are for low tidal volume (Vt) settings of 6 to 8 mL/kg for the prevention of barotrauma in surgical ICU patients.[16] Respiratory rate (RR) is typically set at 12 to 16 breaths/min. RR is altered to achieve an optimal $PaCO_2$ or end-tidal CO_2. Positive end-expiratory pressure (PEEP) is applied to prevent significant alveolar collapse (atelectotrauma) during expiration and is particularly important in low lung volume ventilation strategies. PEEP is typically started at 5 cm H_2O but can be titrated up to improve oxygenation. The initial setting for patients with respiratory failure is an FiO_2 of 1.0. After initial check of ABG or O_2 saturation the FiO_2 is weaned down to maintain a minimal PaO_2 of >60 mm Hg and O_2 saturation of >90% with goals of FiO_2 <0.4 to prevent O_2 toxicity.

Pulmonary Mechanics

Pulmonary mechanics can be displayed graphically and include scalars and loops. Scalars are plots against time—either flow, pressure, or volume. Several loops are helpful clinically and include the pressure–volume and flow–volume loops. Each graphic can be important in demonstrating a physiologic abnormality. The flow–time scalar is helpful for identifying air trapping or auto-PEEP (**Fig. 10.5**). This can result in barotrauma or hemodynamic instability. Measures to decrease auto-PEEP include decreasing tidal volume, respiratory rate, inspiratory time, or increasing flow rate. The pressure–time scalar allows the practitioner to view and calculate compliance (**Fig. 10.6**). Elevations in peak airway pressure may occur as a result of bronchospasm, mucus plugging, a pneumothorax or kinked endotracheal tube or a sharp decrease may represent an airway leak or disconnection. The volume–time scalar allows one to identify an airway leak as well (**Fig. 10.7**).

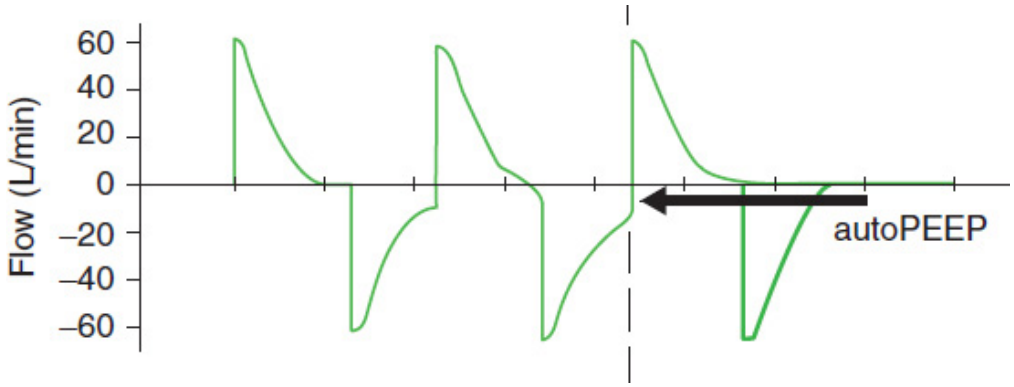

Figure 10.5 Flow–time scalar showing autoPEEP.

Ventilators often display all three scalars simultaneously. A spontaneously breathing patient is identified by the negative deflection in the pressure–time scalar at breath initiation (**Fig. 10.8**). Distinct ventilator modes have unique methods of cycling, triggering, and limitations of breaths. In volume-controlled ventilation, breaths are volume-cycled, time-triggered, and flow-limited (**Fig. 10.9**). In pressure-controlled ventilation, breaths are time-cycled, time-triggered, and pressure-limited. Note the distinct difference in the flow and pressure-time scalars compared to CMV (**Fig. 10.10**). Pressure supported breaths are flow-cycled, patient-triggered, and pressure-limited (**Fig. 10.11**). Pressure- and volume-controlled ventilation can be set in an assist control (AC) mode or synchronized intermittent mandatory ventilation (SIMV) mode. With either mode, the patient receives a minimum number of breaths delivered per minute whether with pressure or volume. In the AC mode, if the patient triggers additional breaths, the full pressure or volume is delivered, whereas these breaths are unassisted in the SIMV mode. Patients who are critically ill may require AC for full support but these patients may be weaned to a PSV mode to prevent respiratory muscle atrophy.[17]

ACUTE RESPIRATORY FAILURE

Diagnosis

3 Past consensus definitions of acute respiratory distress syndrome (ARDS) and acute lung injury (ALI) categorized them by acute onset hypoxemia, bilateral infiltrates on chest radiography, and absence of cardiac etiology.[18] ALI and ARDS were differentiated by the degree of hypoxia, with ALI typified by a ratio of PaO_2/FiO_2 (P/F) $\leq$ 300 and ARDS with P/F $\leq$ 200. The newer Berlin definition makes an attempt at describing timing of ARDS relative to a known insult. Most importantly, ALI is now part of the ARDS spectrum that is classified as mild,

moderate, or severe if the PaO_2/FiO_2 ratio is between 200 and 300, between 100 and 200, and less than 100, respectively (**Table 10.2**).[19] Also, patients must be on at least 5 cm H_2O PEEP. Further, this gradation of disease is consistent with therapy, wherein less acute patients might be successfully treated with noninvasive ventilation, moderately ill patients with higher PEEP and possibly neuromuscular blockade, and severely ill patients possibly requiring prone positioning therapy and extracorporeal support.

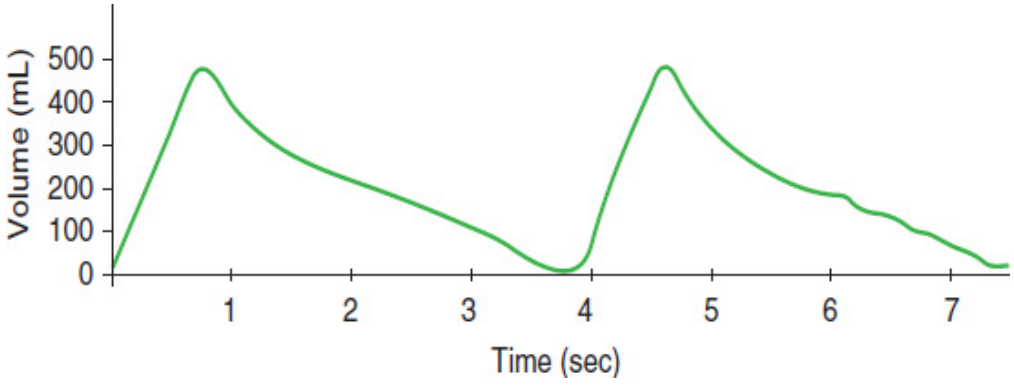

Figure 10.7 Volume–time scalar.

Ventilator Management

Conventional Modes

The standard of care of volume-controlled ventilation with low tidal volume was set forth as a result of an early study from the NIH ARDS Network. Patients ventilated at 6 mL/kg had better outcome than those who received 12 mL/kg. Thus, the standard of care for ventilating ARDS patients became the use of low tidal volumes, or low stretch therapy to diminish the incidence of ventilator-associated barotrauma.[20]

Adjunctive Therapies

High PEEP

Ideally, to prevent atelectasis and avoid overdistension, PEEP is titrated to the safe window between the lower and upper inflection points of the pressure–volume curve (**Fig. 10.12**). The precise PEEP level to optimize outcome from ARDS, particularly in the face of low stretch ventilation, has been the subject of several trials. The Assessment of Low Tidal Volume and Elevated End-Expiratory Pressure to Obviate Lung Injury (ALVEOLI) trial did not demonstrate a benefit to adding high PEEP to those ventilated with lower tidal volumes.[21] Two other trials (LOVS and EXPRESS) reached similar conclusions.[22,23] A systematic review and meta-analysis showed no statistically significant difference in hospital mortality overall but worse mortality in those with severe established ARDS treated with high PEEP.[24]

Table 10.2 ARDS: Comparison of AECC and Berlin Definitions

PaO_2/FiO_2 (P/F)	AECC Definition (Old)	Berlin Definition (New)
201–300	ALI	Mild ARDS
101–200	ARDS	Moderate ARDS
≤100		Severe ARDS

ARDS, acute respiratory distress syndrome; AECC, American-European Consensus Conference; PaO_2, partial pressure of oxygen in arterial blood; FiO_2, fraction of inspired oxygen; ALI, acute lung injury.

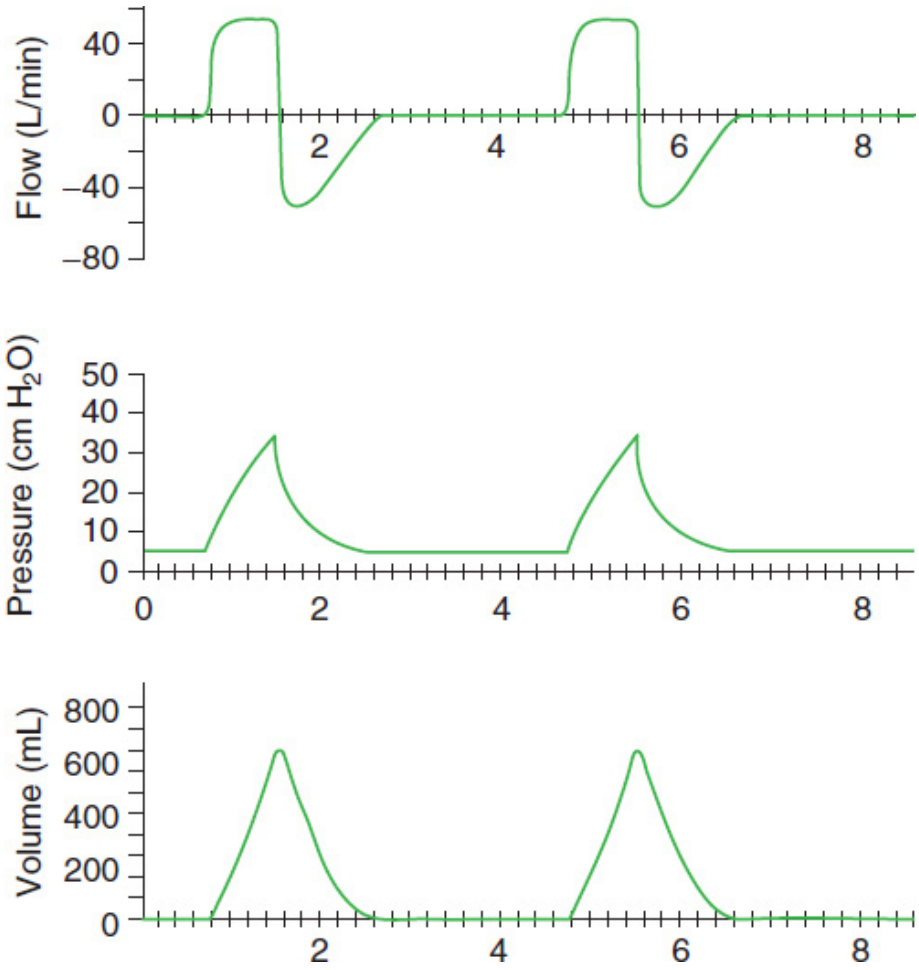

Figure 10.9 Controlled mandatory ventilation. Breaths are volume-cycled, time-triggered, and flow-limited.

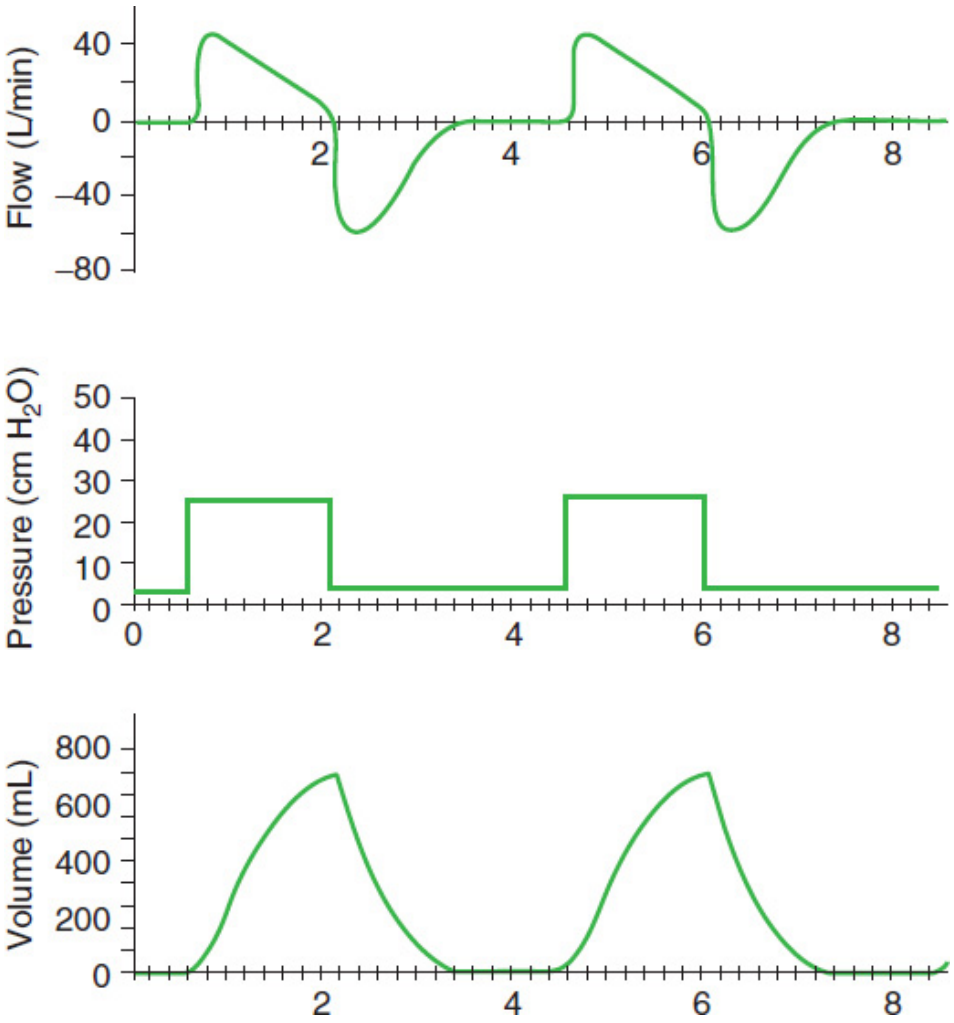

Figure 10.10 Pressure controlled ventilation: Breaths are time-cycled, time-triggered, and pressure-limited.

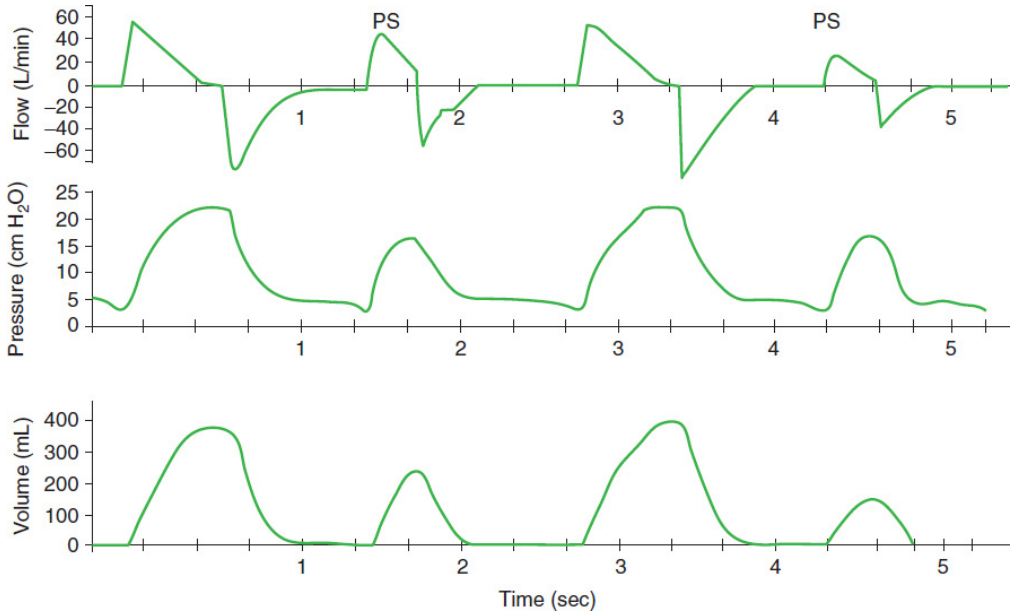

Figure 10.11 Pressure support (PS). Breaths are flow-cycled, patient-triggered, and pressure-limited. Pressure support breaths are second and fourth breaths.

High-Frequency Ventilation

These modes include high-frequency jet and oscillatory ventilation. Both utilize ultrafast subtidal ventilation and can be employed for rescue or treatment of bronchopleural fistulae. In general, heavy sedation and/or paralysis are required. The ventilator decouples oxygenation and ventilation such that unique settings are used to manipulate either one. The ventilatory circuit is heavy and cumbersome in this mode and secretion clearance is problematic. Importantly, two large trials failed to show improvement in ARDS patients, with one demonstrating an increased mortality in the high-frequency group.[25,26]

Airway Pressure Release Ventilation (APRV)

APRV takes advantage of spontaneous breathing with CPAP and an ultra-brief timed pressure release, generating a very high inspiratory to expiratory (I:E ratio). The extremely short phase time of pressure release maintains intrinsic PEEP to prevent atelectasis. There are increasing studies in the literature that demonstrate that APRV is at least equivalent to low stretch ventilation in terms of safety and outcome.[27,28] As APRV may be better tolerated than low tidal volume ventilation, some would say this provides an advantage. There is also some suggestion that routine use of APRV may decrease the incidence of, and mortality from ARDS.[29]

Inhaled Nitric Oxide and Prostacyclin

Inhaled nitric oxide (iNO) relaxes smooth muscle for selective vasodilation of the pulmonary vasculature without systemic effect. It improves oxygenation and lowers

pulmonary artery pressures. Five of the early meta-analyses showed improved oxygenation without a mortality benefit, with three of them demonstrating increased renal failure.[30] A more recent meta-analysis failed to show a mortality advantage for iNO use for ARDS.[31] Inhaled prostacyclins such as epoprostenol can also lower pulmonary artery pressures and improve oxygenation. A 2010 Cochrane review demonstrated no safety or outcome differences between iNO and epoprostenol. Although neither agent improves mortality, it seems reasonable to employ prostacyclin in ARDS patients with concomitant pulmonary hypertension.[32]

Positional Therapy

Prone positioning therapy can be used in conjunction with many other therapies previously described. It can be accomplished on a conventional ICU bed or one specially equipped to provide this therapy. Either way, extreme caution must be taken to avoid tube and line dislodgement and development of pressure-related skin complications. The ideal amount of time to keep a patient in the prone position is of debate. A recent large multicenter study in ICU patients demonstrated a significant improvement in mortality in ARDS patients treated with prone positioning therapy. This multicenter, prospective, randomized, controlled trial was from the French Proning Severe ARDS Patients (PROSEVA) study investigators.[33] They concluded that in patients with ARDS and severe hypoxemia, early application of prolonged (16-hours) prone-positioning sessions significantly decreased mortality. Similarly, a systematic review and meta-analysis reinforced the mortality benefit of nearly 25% by prone positioning therapy for ARDS.[34]

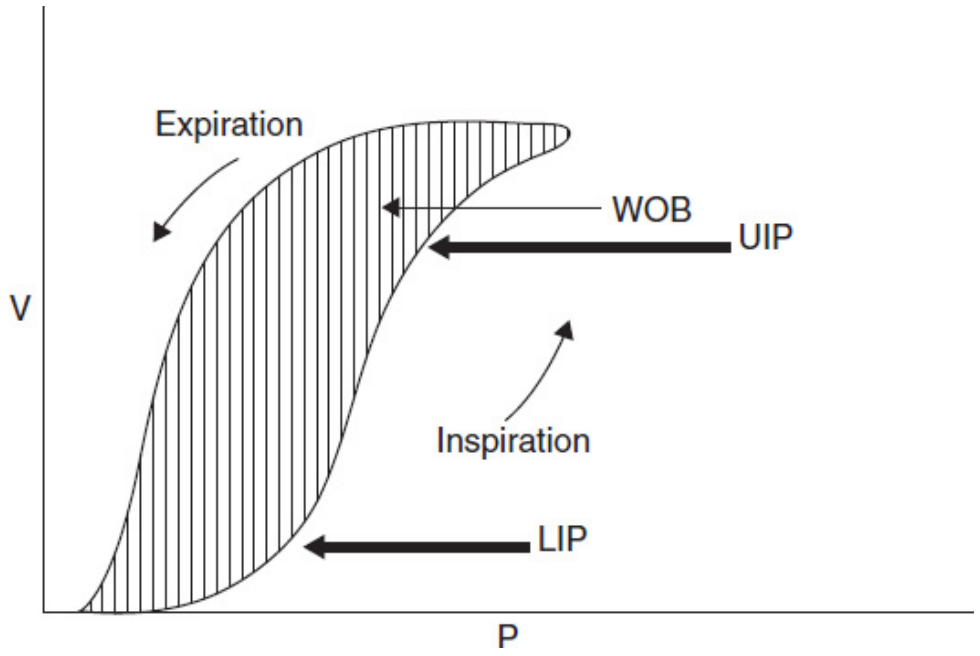

Figure 10.12 Pressure–volume curve with added PEEP. V, volume; P, pressure; LIP, lower inflection point; UIP, upper inflection point. Ideal PEEP is set between LIP and UIP.

Fluid Management

In ARDS, fluid management strategies should maintain the concept of providing sufficient circulating volume, but avoiding excessive extravascular lung water. A large trial conducted by the ARDSnet group Fluid and Catheter Treatment Trial (FACTT) demonstrated that ARDS patients have better outcome if managed with a conservative fluid strategy.[11] These findings must be reconciled with extensive data supporting improved outcome in septic patients who received more robust fluid resuscitation.[35,36] Another controversial topic concerns the utility and timing of diuretics in ARDS patients. Diuretics may improve lung compliance, oxygenation, and possibly ventilator duration, but there is little evidence for a survival benefit.

Rescue Therapies

Extracorporeal Support

Extracorporeal membrane oxygenation (ECMO) was thought to provide a beneficial effect to those patients in the European Conventional Ventilation versus ECMO for Severe Adult Respiratory Failure (CESAR) trial.[37] However, it was apparent on further analysis that patients with severe ARDS benefit most from transfer to a center that had ECMO capabilities, whether or not the therapy was actually used. Data from recent viral pneumonia epidemics are similarly confusing. Regardless of the effect on mortality, it is apparent that ECMO may be thought of as a rescue effort to improve oxygenation. Current technology involving smaller access catheters, more

portable oxygenators and venovenous deployment has made ECMO far less morbid than initial experience with it decades ago with prior mortality rates in excess of 50%.

Ventilator-Associated Events

Ventilator-associated pneumonia (VAP) is the most common life-threatening healthcare-associated infection.[38] VAP is associated with increased ICU and hospital length of stay and costs, and may often be preventable. Nonetheless, it can be extraordinarily difficult to define, particularly in injured patients who may be febrile and have pulmonary infiltrates for reasons other than pneumonia. Further, if attempts are made to diagnose the entity predominantly by microbiologic criteria (using bronchoalveolar lavage to culture $>10^4$ organisms), then the incidence of VAP may be overstated. Thus, the CDC has worked with various critical care societies to define the surveillance definition of ventilator-associated events (VAE) which are publicly reportable and include probable and possible VAP, which are not reportable. Briefly, VAE require patients to have a baseline period of more than 2 calendar days on the ventilator followed by a sustained decrement in oxygenation. Note there are no longer radiographic criteria for VAE or VAP. An infection-related VAE requires a change in temperature or white blood cell count and the initiation of a new antibiotic that is continued for 4 days. The differentiation between possible and probable VAP involves positive cultures as previously prescribed.[39]

Liberation from Ventilation

It is now apparent that the need for ventilation can be approached in a more bimodal, on–off approach, rather than the concept of sequential "weaning" of ventilator support. Thus, current practice is to complete daily spontaneous breathing trials (SBTs) to assess patients' readiness for liberation from ventilation. Of course, these trials should not be conducted in patients with hypoxia or hemodynamic instability. SBTs may be accomplished using CPAP with or without low PSV (<10 mm Hg), the latter to enable ventilatory monitoring of work of breathing and respiratory effort. If patients develop tachypnea, tachycardia, hypoxia, hypercapnia, and/or use accessory muscles during the SBT they are not ready to be extubated. Typically, the parameter that predicts extubation success most accurately is the rapid shallow breathing index (RSBI) or the respiratory frequency divided by the tidal volume with a level of less than 105 most predictive of success.[40]

Further, the requirement for airway support, as might be expected in those with burns, head injury, or anasarca must be considered separately from the requirement

for ventilatory support. Checking for a cuff leak, although conceptually of benefit in identifying patients with airway edema, may not be an accurate metric of those with a stable airway. Trials in the medical literature suggest that a short course of steroids may benefit some to diminish airway edema; these have not been replicated in surgical patients.[41] Finally, some patients, such as those with COPD, may benefit from extubation to noninvasive modes of ventilation such as bilevel positive airway pressure (BiPaP) or CPAP. Additionally, the use of high-flow nasal cannula oxygen, typically delivered at 40 L/min or greater may prevent reintubation.[42]

VENOUS THROMBOEMBOLISM PROPHYLAXIS

The surgical ICU patient is a particular target for venous thromboembolism (VTE) prophylaxis and has unique features rendering prophylaxis more challenging than it may be in a ward patient. VTE is a common cause of preventable morbidity and mortality in critical care patients. A large amount of VTE complications occur following surgery and injury.[43,44] Further, the risk of bleeding in the multitraumatized, immobile, and/or postoperative patient may be heightened in the ICU patient. Finally, safe administration of a chemoprophylactic agent must take into account drug metabolism that may be altered with renal or hepatic failure seen in ICU patients.

Incidence

The risk for developing asymptomatic lower extremity deep venous thrombosis (DVT) depends on the assessment of general risk factors and the type of surgical patient. The incidence can vary from less than 10% (in mobile patients undergoing brief, minor surgery) to over 80% (in those with spinal cord injury or elderly hip fracture patients) in the absence of prophylaxis. However, the true incidence may be unknown. It has become clear that upper extremity DVT is more common than previously appreciated and may result in pulmonary embolism at a higher rate than thought in the past,[45] thus dramatically affecting VTE rates. The incidence of fatal pulmonary embolism in surgical patients ranges from less than 1% in most undergoing elective general surgery to as high as 5% to 8% in those receiving operations for hip fractures.[46]

Risk Factor Scoring

Surgical ICU patients are at increased risk of VTE via Virchow's triad of stasis, vessel wall injury, and hypercoagulability. Acquired risk factors in the surgical critical care patients are a consequence of surgery, trauma, immobilization, obesity, malignancy, advanced age, and invasive monitoring devices. The American College of Chest Physicians (ACCP) 2012 guidelines[47] stratify surgical patients into four risk categories: very low, low, moderate, and high. The most widely used tool to assist in classification is the Caprini score (**Tables 10.3A** and **B**).[48]

Approaches to Prevention of VTE

Screening

One prevention strategy involves the early detection of subclinical venous thrombosis by regular screening tests. These tests include Duplex ultrasonography scans and laboratory assays such as evaluation of D-dimer. As most ICU patients will fall into moderate and high-risk categories for VTE (in whom D-dimer assays are universally elevated), there is virtually no role for utilizing D-dimer acquisition for diagnostic purposes. Further, the safety of early administration of chemoprophylactics is now being proven in even the highest-risk patients (e.g., neurotrauma).[49]

Mechanical Devices

Mechanical devices for thromboprophylaxis include graduated compression stockings and intermittent pneumatic compression devices. The use of mechanical devices alone, without chemical prophylaxis, is only considered for surgical ICU patients at the lowest risk for VTE, or for those patients with a contraindication to a chemoprophylaxis agent. Intermittent compression devices may afford additional protection from VTE in those in high-risk groups if used in concert with chemical agents.[50]

Chemical

UFH and LMWH

4 Few studies have performed a direct comparison of these agents for VTE prophylaxis in surgical ICU patients. A study of injured patients completed by Geerts and published in 1996 demonstrated that use of LMWH resulted in a significantly lower incidence of VTE (31% vs. 44%).[51] This likely drove the 2009 ACCP recommendation that moderate- and high-risk ICU patients should preferentially receive LMWH for prophylaxis. However, in the interim, Dr. Geerts and colleagues

performed a multicenter, RCT (PROTECT) that did not demonstrate a difference in the development of DVT or proximal DVT in those who received LMWH in the form of dalteparin compared to those administered twice-daily UFH.[52] There was no difference in bleeding rate, but a higher incidence of PE was noted in the UFH patients. This study, undoubtedly, drove the 2012 ACCP recommendation that UFH or LMWH can be used interchangeably.[47] However, it is vital to mention that the authors excluded injured, orthopedic, and neurosurgical patients from this study. Geerts himself provides guidelines suggesting that ICU patients at high risk for VTE including injured and major surgery patients should receive LMWH preferentially (**Table 10.4**). UFH should be reserved for moderate-risk ICU patients. High-risk patients at risk for bleeding should receive mechanical prophylaxis until the risk for bleeding is abrogated, and then LMWH should be initiated.[53] Literature suggests that this may be substantially earlier than we might have thought in the past.[54]

Since LMWH is primarily eliminated by the kidneys, LMWH should be avoided in those with renal dysfunction. Increasing the prophylactic dose of LMWH may be appropriate in morbid obesity (body mass index ≥ 40 kg/m^2). Laboratory monitoring of anti-activated factor X (anti-Xa) activity should be considered when using LMWH in patients with renal impairment or obesity.[55]

Factor Xa Inhibitors

Fondaparinux is a synthetic injectable indirect factor Xa inhibitor and has been studied extensively in the orthopedic and general surgery populations. In both these populations, it may be more efficacious than LMWH without an increase in bleeding risk.[47] How this extrapolates to the ICU population is unknown; however, it may be helpful in those with heparin-induced thrombocytopenia.

Table 10.3A Caprini Risk Assessment for Venous Thromboembolism (VTE) in Surgical Patients

1 Point	2 Points	3 Points	5 Points
41–60 yrs old	61–74 yrs old	>75 yrs old	Hip, pelvis, or leg fracture
BMI >25 kg/m^2	Arthroscopic surgery	PMH of VTE	Elective arthroplasty
Minor surgery	Major open surgery	FH of VTE	Stroke (<1 mo)
Swollen legs	Laparoscopic surgery	Factor V Leiden	Spinal cord injury (<1 mo)
Varicose veins	Malignancy	Prothrombin 20210 A	
Pregnancy/Postpartum	Bed rest >72 hrs	Lupus anticoagulant	
PMH of spontaneous abortion	Immobilizing cast	Anticardiolipin antibodies	
Oral contraceptives/hormone therapy	Central venous access	Elevated serum homocysteine	
Pneumonia (<1 mo)		HIT	
Sepsis (<1 mo)		Other thrombophilia	
Abnormal pulmonary function			
Acute MI			
CHF (<1 mo)			
PMH of inflammatory bowel disease			
Medicine patient on bed rest			

BMI, body mass index; PMH, past medical history; MI, myocardial infarction; CHF, congestive heart failure; FH, family history; HIT, heparin-induced thrombocytopenia.

There is even less experience using oral direct factor Xa inhibitors (rivaroxaban and apixaban) and direct thrombin II inhibitors (dabigatran) in the ICU. These agents may be less than helpful because of a long half-life. Nonetheless, we should appreciate that all three agents had a lower rate of significant bleeding such as intracranial hemorrhage in outpatients who were being treated for atrial fibrillation. Rivaroxaban is metabolized renally and apixaban both hepatically and renally. Due to similar concerns of time and ability to reverse, the use of warfarin may be limited in the ICU.

Table 10.3B Caprini VTE Percentage Risk Based on Score

Risk	Score	Estimated VTE Percentage Risk without Prophylaxis
Very low	0	<0.5%
Low	1–2	1.5%
Moderate	3–4	3%
High	>5	6%

TRANSFUSION

5 Transfusion of packed red blood cells to promote oxygen delivery is common in surgical ICU patients (**Table 10.5**). Nearly 85% of those who remain in the SICU after a week and over 40% overall will be transfused, many of whom are not actively bleeding.[56] It was common practice a decade or so ago to prescribe a transfusion for ICU patients whose hemoglobin levels fell below 10 g/dL with at least two units being administered. However, packed red blood cell transfusion may not dramatically improve oxygen delivery, particularly in situations where the oxygen dissociation curve has been shifted to the left, as with decreased 2,3-diphosphoglycerate concentrations (**Table 10.6**). In addition, in many patient populations, transfusion of packed red blood cells has been associated with increased infections and organ failure. The Transfusion Requirements in Critical

Care (TRICC) trial published in 1999 provided data to question the universal practice of red blood cell transfusion.[57] This multi-institutional trial of patients in Canadian ICUs was designed as a noninferiority trial comparing a restrictive transfusion strategy, aimed at maintaining a hemoglobin level greater than 7 to 9 g/dL, to a liberal one, targeting a level of 10 to 12. Hebert and colleagues demonstrated no difference in mortality between the groups. Although patients with significant cardiac history were excluded a priori, nearly 300 were studied, and there was no outcome difference in this group either.[58]

Table 10.4 VTE Prophylaxis in the ICU

ICU Patient Population	Thromboprophylaxis
Moderate VTE risk	(LMWH [40 mg QD] or LDUH [5,000 units TID]) + IPC
High VTE risk	LMWH (40 mg QD) + IPC
Trauma	LMWH (30 mg BID) + IPC
High bleeding risk	IPC until bleeding risk decreases
Renal impairment	LDUH (5,000 units TID) + IPC
Morbid obesity	LMWH increased dose + anti-Xa monitoring

VTE, venous thromboembolism; ICU, intensive care unit; LMWH, low–molecular-weight heparin; QD, daily; LDUH, low-dose unfractionated heparin; TID, thrice daily; IPC, intermittent pneumatic compression; BID, twice daily; anti-Xa, anti-activated factor X.

Table 10.5 Indications for RBC Transfusion in the General Critically Ill Patient

- RBC transfusion is indicated for patients with evidence of hemorrhagic shock.
- RBC transfusion may be indicated for patients with evidence of acute hemorrhage and hemodynamic instability.
- A "restrictive" strategy (transfuse when Hb <7 g/dL) is as effective as a "liberal" strategy (transfuse when Hb <10 g/dL) in critically ill patients with hemodynamically stable anemia, except possibly in patients with acute myocardial ischemia.
- The use of only Hb level as a "trigger" for transfusion should be avoided.
- In the absence of acute hemorrhage, RBC transfusion should be given as single units.
- RBC transfusion should not be considered as an absolute method to improve tissue oxygen consumption.

Adapted from Napolitano LM, Kurek S, Luchette FA, et al. American College of Critical Care Medicine of the Society of Critical Care Medicine and the Eastern Association for the Surgery of Trauma Practice Management Workgroup. Clinical practice guideline: Red blood cell transfusion in adult trauma and critical care. *Crit Care Med* 2009;37(12):3124–3157.

Despite widespread dissemination of this landmark article, transfusion practice did not rapidly change in many surgical ICUs, and there is still a minority viewpoint that older, cardiac, actively bleeding, neurosurgical, and septic patients should be excluded from restrictive transfusion practices. However, subsequent studies have further questioned this dogma. A large propensity matched study analyzed the effect of transfusion on ICU patients who were not actively bleeding. It revealed that nontransfused patients (including those with a significant cardiac history) had a lower hospital mortality and incidence of infection and acute kidney injury (AKI).[59] The RELIEVE trial was a multicenter randomized controlled trial of ventilated ICU patients over the age of 55, including one-third with ischemic cardiac disease. Those in the restrictive group received almost a quarter fewer transfusions and had over a 30% lower mortality rate.[60] A meta-analysis of the effect of blood transfusion during myocardial infarction noted that the therapy was associated with a relative risk of 2.91 for mortality and 2.04 for a subsequent MI with a number to treat of 8.[61] Further, a British propensity-matched study of cardiac surgery patients revealed odds ratios of 3.8 and 3.5, respectively, for infection and ischemia after transfusion and ratios of 6.69 and 1.32, respectively, for 30-day and 1-year mortality in transfused patients.[62]

Table 10.6 Factors Altering the Oxygen Dissociation Curve

Left Shift	Right Shift
Decreased temperature	Increased temperature
Decreased 2,3-DPG	Increased 2,3-DPG
Increased pH	Decreased pH
High altitude, carbon monoxide	

Oxygen dissociation curve describes how our blood carries and releases oxygen. Right shift represents a decreased affinity for oxygen by hemoglobin favoring to the ability to release oxygen to tissues in need. Left shift represents increased affinity by hemoglobin for oxygen.

2,3-DPG, 2,3-diphosphoglycerate.

This risk of transfusion in cardiac surgery patients is apparent even with administration of small-volume (i.e., one or two units of packed red blood cells) transfusions.[63] A large, randomized controlled trial of cardiac surgery patients over the age of 18 undergoing a bypass or valve replacement revealed no change in 30-day all-cause mortality or morbidity utilizing a transfusion trigger of 8 versus 10 g/dL of hemoglobin.[64] Further, a large single center study randomized those with severe acute upper gastrointestinal bleeding—almost 75% variceal—to a transfusion target of 7 versus 9 g/dL of hemoglobin. Nearly half of those in the restrictive group did not receive a transfusion and the mean time to endoscopy was 6 hours. This study reinforced the findings of a previous observation study that a liberal transfusion target in active upper gastrointestinal bleeding doubled the risk of rebleeding and increased mortality by 28%, presumably by promoting "popping the clot."[65] In a randomized clinical trial of patients with traumatic brain injury, a hemoglobin target of 10 compared to 7 g/dL was associated with no improvement in neurologic outcome at 6 months but a higher incidence of adverse events including thromboembolism.[66]

METABOLISM AND NUTRITION

Critically ill patients are at significant risk for developing severe malnutrition because the stress response to critical illness, surgery, and/or trauma significantly increases metabolic demands. The result is worse outcomes, including inability to wean from mechanical ventilation, inability to heal wounds (surgical or hospital acquired pressure injuries), and increased risk of nosocomial infections.

Starvation in a noncritically ill person leads to rapid depletion of hepatic glycogen stores as the brain and cellular components of blood require glucose. Once glycogen stores are depleted, gluconeogenesis from protein breakdown and, later, fat oxidation is required. Adaptation to more prolonged starvation includes shifting neuronal metabolism to free fatty acids, ketones, and glycerol, as well as a decrease in overall metabolic demands. These adaptations are quite limited in critically ill patients. Stress hormones, including cortisol and catecholamines, further drive protein catabolism.

Severely ill patients may develop the Persistent Inflammation, Immunosuppression, and Catabolism Syndrome (PICS), a combination of the Systemic Inflammatory Response Syndrome (SIRS) and the Compensatory Anti-Inflammatory Response Syndrome (CARS). These patients remained chronically critically ill. There is no specific test for this syndrome or any specific treatment. It seems logical; however, that providing aggressive nutritional support in addition to organ system support is the best approach.[67] The overall goals for nutritional support include preservation of lean body mass, wound healing, and immune function.[68]

Table 10.7 NUTRIC Score Table

Variable	Range	Points
Age (years)	<50	0
	50–<75	1
	≥75	2
APACHE II	<15	0
	15–<20	1
	20–28	2
	≥28	3
SOFA	<6	0
	6–<10	1
	≥10	2
Number of comorbidities	0–1	0
	≥2	1
Days from hospital to ICU admission	0–<1	0
	≥1	1
IL-6	0–<400	0
	≥400	1

APACHE, Acute Physiologic Assessment and Chronic Health Evaluation; SOFA, Sequential Organ Failure Assessment; ICU, intensive care unit; IL, interleukin.

Metabolic Requirements and Assessment

6 Assessment of nutritional status and risk for severe malnutrition begins with a careful history and physical examination. Key information includes diet, recent weight loss, the severity of critical illness, and the nature of any surgical procedures or trauma. Various scoring systems for nutritional risk have been developed. One commonly used score is the NUTRIC score (**Table 10.7**), which takes into account age, illness severity using the Acute Physiologic and Chronic Health Evaluation (APACHE), Sequential Organ Failure Assessment (SOFA), comorbidities, days in the hospital prior to ICU admission, and interleukin-6 level (if available).[69]

Because of the severely catabolic state of critically ill patients, meeting protein requirements are critical. Though it's possible to measure nitrogen balance by comparing nitrogen input via nutritional support with urinary urea nitrogen in 24 hours, this is cumbersome and does not clearly improve outcomes. Generally,

providing 1.2 to 2.5 g/kg/d of protein is sufficient.[68] The highest requirements are for patients with major surgical procedures, multitrauma, and burns. Measurement of serum proteins, such as prealbumin, transferrin, and retinol-binding protein, may demonstrate trends in nutritional status, but the utility is questionable, particularly since these proteins are acute phase reactants.

Meeting patients' caloric requirements is also important for improving outcomes, though hypocaloric feeding within the first several days of ICU admission does not seem to be harmful. Several equations, including Harris–Benedict and the Mifflin St. Jeor, have been used to calculate resting energy expenditure (REE). These equations take into account height, weight, age, and gender.

Indirect calorimetry, by measuring oxygen consumption (VO_2) and carbon dioxide production (VCO_2) and calculating the respiratory quotient ($RQ = VCO_2/VO_2$), can also be used, but the measurement is complicated. Intubated patients must be on a steady FiO_2 that is ≤80% and PEEP of ≤10 torr, without a cuff leak. REE is then calculated using the Weir formula ($1.44 \times [3.94\ VO_2 + 1.11\ VCO_2]$).[70] Like nitrogen balance, indirect calorimetry does not clearly impact outcomes.

In general, critically ill patients should receive 25 to 30 kcal/kg/d.[68] It's worth considering that hypothermia, coma, stable quadriplegia, barbiturates, sedatives, anesthesia, and muscle relaxants can decrease metabolic needs, while fever, sepsis, stress, shivering, and seizures can increase the needs.

The best way to estimate energy requirements in obese patients is unclear. A high-protein, hypocaloric strategy is favored in order to reduce fat mass, improve insulin sensitivity, and preserve lean body mass. One suggestion is to utilize 11 to 14 kcal/kg actual body weight per day in patients with body mass index (BMI) of 30 to 50 and 22 to 25 kcal/kg ideal body weight per day for patients with BMI >50. Obese patients should receive 2.0 to 2.5 g/kg ideal body weight per day of protein.

Nutritional Support

Macronutrients include carbohydrates, fat, and protein. Carbohydrates provide 3.4 kcal/g and have the highest RQ of 1.0. While a higher RQ from administration of a large amount of carbohydrates, compared to fats, may mildly increase the need for CO_2 removal via the lungs, the bigger issue can be overfeeding as overfeeding leads to increased glycogenesis and lipogenesis, which have an RQ higher than 1. Thus, overfeeding may impact the ability to wean a patient from mechanical ventilation.

Fat provides 9.0 kcal/g with an RQ of 0.7. Free fatty acid deficiency can cause anemia, thrombocytopenia, respiratory distress, and rash, but this deficiency is easily prevented. Fatty acids exist in two varieties, omega-3 and omega-6. Omega-3

fatty acids are derived from linolenic acid, found in fatty fish such as salmon, and are less pathogenic than omega-6 fatty acids derived from linoleic acid. It has been difficult, however, to demonstrate a benefit of using formulas such as SMOF (soybean oil, medium chain triglycerides, olive oil, and fish oil) designed to decrease the SIRS response to critical illness and trauma.[71]

Protein delivers 4.0 kcal/g with an RQ of 0.8. Essential amino acids cannot be synthesized endogenously and must be provided in the diet.

Current nutritional formulas contain sufficient trace elements and vitamins to make deficiency of these micronutrients in ICU patients extremely rare. These formulas generally include vitamin K, which is worth keeping in mind if anticoagulation using vitamin K antagonists is anticipated.

Routes of Nutritional Support

Enteral nutrition is preferred over parenteral nutrition as it preserves the gut mucosa and is associated with fewer complications and costs. Standard formulas have a calorie density of 1 kcal/mL. More concentrated formulas may provide more nutrition with less fluid volume. Standard enteral formulas are polymeric. For patients who have malabsorption with resultant diarrhea and/or fail to tolerate standard formulas, use of an elemental diet, which includes the basic building blocks of the energy substrates, for example, proteins as free amino acids, fats as medium chain triglycerides, and carbohydrates as oligosaccharides, may be beneficial. Formulas with high osmolarity may also cause diarrhea with tube feeds. Decreasing the osmolarity or adding bulking agents can help.

There are several complications related to enteral nutrition in the ICU. The most significant of which is aspiration. The risk for aspiration can be decreased by maintaining head-of-bed elevation at 30 to 45 degrees or greater. Though monitoring gastric residuals has been standard, the benefit of such monitoring has been questioned, at least in patients who have not undergone abdominal procedures. In general, there is no difference in aspiration risk between gastric versus postpyloric feedings.[72] When patients don't tolerate gastric feedings, use of prokinetic agents or placement of a postpyloric feeding tube may help.

Placement of transnasal feeding tubes can result in intrapulmonary or even transpulmonary placement. Having a dedicated team with a protocol for tube placement can minimize these risks.[73] Surgically placed tubes in the stomach or jejunum can become dislodged, leading to intra-abdominal leak and peritonitis.

For patients who have an artificial airway in place and may need to undergo multiple, nonabdominal operations, continuing tube feedings up to, and possibly during, the operation is safe.

When provision of enteral nutrition is not possible, parenteral nutrition may be indicated. Parenteral nutrition requires the insertion of a central line, adding risks for mechanical complications and infection. Some complications related to parenteral nutrition, such as cholestasis, can be decreased by the provision of at least a small amount of enteral feedings to maintain the trophic effects of gut hormones on the liver and prevent biliary stasis.

Timing of Nutritional Support

Nutritional support should be initiated within 24 to 48 hours of ICU admission following adequate resuscitation. Initiating enteral nutrition while the patient remains in shock can lead to bowel ischemia. On the other hand, patients who are relatively stable on low doses of vasoactive agents may tolerate feedings quite well. Having an open abdomen is not an absolute contraindication to enteral feedings, depending upon the status of the bowel.[74] The use of prone positioning for the management of the ARDS is also not an absolute contraindication.[75]

Enteral feeding does not need to immediately provide full nutritional support. Ideally, nutritional goals should be met within 5 to 7 days. If it is anticipated that the patient will not be able to tolerate enteral feedings for at least seven days, parenteral nutrition may be indicated. In addition, if the patient already has evidence of severe malnutrition at the time of admission, there may be benefit in earlier parenteral nutritional support.[68]

Patients often don't actually receive the amount of enteral nutritional support that is ordered. Tube feedings get held for many reasons, including procedures, baths, and ventilator weaning trials. One approach to make up for this decrease in support has focused on volume-based feeding. If the patient falls behind, the nurse can increase the feeding rate for a period of time to make up for the difference. Another approach to achieving feeding goals quickly is to start with a semi-elemental feeding formula that is readily absorbed, combined with the volume-based feeding approach and liberal use of prokinetic medications.[76]

Organ Specific Nutritional Support

A variety of formulas have been developed to potentially improve outcomes of specific organ dysfunction. Recognizing that a higher RQ is associated with increased CO_2 production, enteral formulas have been developed that are high in fat and low in carbohydrates. Use of such formulas has not improved weaning from mechanical ventilation or improved survival. Formulas with large quantities of antioxidants have also been tested in patients with the ALI without success.

For patients with AKI, the goals have been to decrease fluid volume, potassium load, and urea production. Provision of formulas high in essential amino acids to decrease urea has not decreased the need for dialysis. In general, minimizing protein intake to decrease urea production is counterproductive because these patients are so catabolic.

For patients with hepatic dysfunction, aromatic amino acids can cross the blood–brain barrier and worsen encephalopathy. Formulas that are high in branched chain amino acids but low in aromatic amino acids do not seem to have benefit, however.

In patients with acute pancreatitis, enteral nutrition, if tolerated, may decrease length of stay, improve resolution of SIRS, and decrease infection rate.[77] Enteral nutrition does not stimulate exocrine pancreatic secretion as much as was once thought. Parenteral nutrition should be reserved for patients who clearly do not tolerate enteral feedings.

Immunonutrition

A number of additives to nutritional formulas could improve immune function and thereby decrease the risk for infection and, perhaps, mortality. Immune modulating formulas containing arginine, glutamine, nucleotides, and omega-3 fatty acids did seem to improve some aspects of immune function, but did not clearly improve outcomes.[78] It seems that there may be marginal benefit for these formulas in patients who have undergone major surgery or trauma, but not in nonsurgical patients. Glutamine, which can be used as a substrate for gut metabolism could improve gut barrier function and thereby decrease translocation and infection, also lacks clear benefit.

Stress-Related Mucosal Disease

Endoscopic evidence of upper gastrointestinal bleeding from stress-related mucosal disease (SRMD) is common, even shortly after admission, in high-acuity ICU patients. The pathophysiology is thought due to be impaired mucosal protection, mostly related to blood flow, and not acid hypersecretion or *Helicobacter pylori* infection. Overt bleeding, that is, coffee ground upper intestinal aspirates or hemoccult-positive stool, is not uncommon in the ICU. Clinically significant bleeding resulting in the need for a blood transfusion and/or hemodynamic instability is much less common, with or without pharmacologic prophylaxis. The strongest risk factors for SRMD in the ICU are the need for more than 48 hours of mechanical ventilation and the presence of coagulopathy. It seems prudent that pharmacologic prophylaxis of SRMD be limited to those with one of these two risk factors. There

may, however, be a role to avoid pharmacologic agents even in the highest-risk patients, particularly if they are being enterally fed.[79] If pharmacologic prophylaxis is prescribed, proton pump inhibitors may be equivalent to histamine-2 receptor antagonists in terms of risk for gastrointestinal bleeding, mortality, prolonged length of stay, pneumonia, or *Clostridium difficile* colitis.[80]

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) complicates at least 5% and as many as 30% of all surgical ICU admissions with a mortality of over 50%, though it's not clear how much the AKI contributes to mortality or is more of a marker of illness severity.

Etiology

The causes of AKI are typically divided into prerenal, intrinsic renal, and postrenal. Prerenal causes relate to renal blood flow and may include hypovolemia, shock, and low cardiac output. Heart failure can also impair renal function by significantly increasing the pressure in renal veins and, thereby, impeding renal blood flow. Sometimes, the renal dysfunction, as manifest by low urine output, is the first sign of an underlying problem. Initially, the kidney is able to maintain perfusion by selectively dilating the afferent arteriole and vasoconstricting the efferent arteriole of the juxtaglomerular apparatus. As hypotension persists and the renin–angiotensin system is activated, systemic vasoconstriction occurs and cortical hypoperfusion occurs.

Renal parenchymal causes of AKI are the most common. Differentiating prerenal from renal AKI is not always obvious. Serum and urinary studies can help (**Table 10.8**). Postrenal causes can be detected with ultrasound or CT of the kidneys. More extensive testing is usually unnecessary, but may be needed in unusual cases.[81]

Table 10.8 Workup for Acute Kidney Injury

Diagnostic Study	Prerenal	Acute Tubular Necrosis
Urinalysis	Normal	Casts and epithelial cells
Serum BUN:creatinine	20:1	Normal
Urine osmolality	>500 mOsm/kg	<350–450 mOsm/kg
FENa	<1%	>2%

BUN, blood urea nitrogen; FENa, fractional excretion of sodium.

The most common cause of intrinsic renal AKI is acute tubular necrosis (ATN), though other causes, such as acute interstitial nephritis can occur. ATN is often caused by ischemia (initially a prerenal cause) or nephrotoxic agents. Medications that may cause ATN include aminoglycosides, cephalosporins, amphotericin, and cisplatin. Iodinated contrast-induced nephropathy is uncommon and, in fact, its existence has been debated.[82] Age, pre-existing kidney disease, diabetes, and vascular disease have been touted as risk factors. If iodinated contrast is clearly necessary, the best approach to prevention is administration of intravenous fluids before contrast administration. N-acetyl cysteine, bicarbonate, and prophylactic dialysis, before or after the contrast load, are not beneficial. Though gadolinium does not seem to be as directly toxic to the kidneys as iodinated contrast, it may cause nephrogenic systemic fibrosis in patients with pre-existing renal dysfunction. It, too, should be used with caution in patients with renal dysfunction.

Large amounts of pigments, such as myoglobin or hemoglobin, can cause AKI. Hemoglobin pigment rarely causes ATN in surgical ICU patients, except perhaps after a severe transfusion reaction. Myoglobinuria as a consequence of rhabdomyolysis is far more common, particularly after severe trauma, compartment syndrome, electrical burns, seizures, or coma with prolonged immobilization.[83] Myoglobinuria should be suspected in patients with dark urine and a positive urine dipstick without red cells on microscopy. Patients with a serum myoglobin level exceeding 10,000 ng/mL or a creatinine phosophokinase (CPK) greater than 20,000 IU/L are at risk for pigment nephropathy. Myoglobin is both a potent vasoconstrictor and a direct tubular toxin when converted to ferrihemate in an acid environment. However, alkalinization of the urine (with administration of sodium bicarbonate) has not been proven to be more effective than volume administration and forced diuresis to achieve a urine output of 2 mL/kg/hr. There is also no evidence that early initiation of dialysis improves outcomes, even if myoglobin levels decrease. Controlling the source of rhabdomyolysis is also critical.

Table 10.9 Acute Kidney Injury Severity Scores

Stage	RIFLE	AKIN	KDIGO	Urine output
1	Risk = SCr ↑ ≥1.5 or GFR ↓ >25% × baseline	SCr ↑ ≥0.3 mg/dL or 1.5–2 × baseline	SCr ↑ ≥0.3 mg/dL or 1.5–1.9 × baseline	<0.5 mL/kg/hr for 6–12 hrs
2	Injury = SCr ↑ ≥2 or GFR ↓ >50% × baseline	SCr ↑ 2–3 × baseline	SCr ↑ 2.0–2.9 × baseline	<0.5 mL/kg/hr for >12 hrs
3	Failure = SCr ↑ ≥3 or GFR ↓ >75% × baseline, or SCr >4 mg/dL with an acute ↑ >0.5 mg/dL	SCr ↑ >3 × baseline, or SCr ≥4.0 mg/dL with an acute ↑ >0.5 mg/dL, or on RRT	SCr ↑ ≥3 × baseline or SCr ≥4.0 mg/dL or initiation of RRT	<0.3 mL/kg/hr for ≥24 hrs or anuria for ≥12 hrs
4	Loss = Complete loss of kidney function >4 wks			
5	ESRD >3 mo			

RIFLE, risk, injury, failure, loss, end-stage renal disease (ESRD); AKIN, Acute Kidney Injury Network; KDIGO, Kidney Disease Improving Global Outcomes; SCr, serum creatinine; GFR, glomerular filtration rate; RRT, renal replacement therapy.

The best approaches to prevention of AKI include early resuscitation to restore renal blood flow, which should include appropriate volume expansion, vasopressors and inotropes, and avoidance of nephrotoxic agents.[84] There is little evidence that colloids are better than crystalloids. Hydroxyethyl starch preparations should be avoided, however, as they are nephrotoxic through tubular obstruction. There is no role for the use of low-dose dopamine or fenoldopam for protection against AKI or improvement of diuresis.

Postrenal AKI is caused by obstruction, usually from urinary retention, rarely from bilateral ureteral obstruction or unilateral ureteral obstruction in a patient with one functioning kidney. Evaluation may include placement of a urinary catheter, if one is not already present and patent, and renal ultrasound.

Severity

There has been interest in developing markers for early development of AKI with the thought that earlier detection could lead to earlier intervention and improved outcomes. Markers involved in cell cycle arrest during the early phase of renal cell injury include insulin-like growth factor–binding protein 7 (IGFBP7) and tissue inhibitor of metalloproteinases 2 (TIMP-2). The NephroCheck point of care device can measure these markers. Neutrophil gelatinase–associated lipocalin (NGAL) is also produced after ischemic or toxic insults to the kidney. So far, however, measurement of these markers has not led to improved outcomes in terms of need for renal replacement therapy (RRT) or mortality.[85]

Several grading systems for AKI are based upon serum creatinine and urine output (**Table 10.9**). These include the Risk to Injury to Failure to Loss to End-stage kidney disease (RIFLE), as defined by the Acute Dialysis Quality Initiative (ADQI), Acute

Kidney Injury Network (AKIN) criteria, and Kidney Disease Improving Global Outcomes (KDIGO) work group criteria.[86,87] None of these systems are better or worse than the others at predicting outcome from AKI.

Treatment of Acute Kidney Injury

7 The most important issues in the management of patients with AKI are: (1) Minimizing any further injury to the kidney through adequate resuscitation and avoidance of nephrotoxic agents. (2) Adjusting the dosing regimens for medications that are excreted by the kidneys. Consultation with a critical care pharmacist can be invaluable. (3) Management of the physiologic effects of AKI, including electrolyte disturbances, acid–base disorders, and hypervolemia. Hyperkalemia is the most immediately life-threatening electrolyte disturbance. The absolute level of potassium may not be as important as the presence of changes on electrocardiography, such as peaked T waves or prolonged QRS. Depending upon severity, medical management can include the administration of calcium to stabilize the myocardium, administration of insulin and glucose, bicarbonate, and/or an inhaled beta-agonist to drive potassium intra-cellularly, or administration of polystyrene sulfonates to bind potassium in the gastrointestinal tract. Ultimately, dialysis (RRT) may be needed.

RRT is often required for patients who develop severe AKI.[88] The urgent indications for RRT include severe, refractory acidosis (e.g., pH <7.1 without respiratory acidosis), electrolyte abnormalities (particularly hyperkalemia), intoxication with agents that can be dialyzed, hypervolemia, and uremia, as manifested by pericarditis or encephalopathy. The latter can be difficult to separate from other causes of altered mental status in the ICU. Platelet dysfunction is also associated with AKI, particularly in face of a BUN in excess of 100 mg/dL. The administration of desmopressin (DDAVP) or analogues help temporarily.

Timing of RRT has remained controversial. Though some studies have suggested benefit from early initiation, others have suggested that waiting for a clear indication as outlined above is reasonable.[89]

Once a decision is made to initiate RRT, the next question is whether or not to utilize intermittent hemodialysis (IHD) or continuous RRT (CRRT). In general, the latter is preferred in patients with hemodynamic instability, but the benefit of this approach is unclear. Studies of using high-flux CRRT or specialized adsorbers to remove cytokines or endotoxin have not demonstrated benefit.[90]

LIVER DYSFUNCTION

In addition to acute liver failure (ALF), complications of chronic liver disease that may result in ICU admission include variceal hemorrhage, encephalopathy, spontaneous bacterial peritonitis, and hepatorenal syndrome. In addition, liver disease, as a comorbid condition, can have a significant impact upon patients who present with other disease processes.

Variceal Bleeding

The management of a patient with potential variceal bleeding should proceed like that for any other patient with an upper GI bleed. If necessary, the patient may need to be intubated to prevent aspiration. At the same time, fluid resuscitation, including transfusion of packed red blood cells, should be initiated. To minimize the effect of acid on the varices and potentially treat concomitant peptic ulcer disease, high-dose proton pump inhibitor therapy should be started. Administration of octreotide, a synthetic analogue of somatostatin, can decrease portal pressure and decrease bleeding. Vasopressin also reduces portal pressure but may cause myocardial ischemia and is less specific than octreotide.

Definitive control of hemorrhage usually requires endoscopic intervention, either with banding or sclerotherapy.[91] Complications include perforation, ulceration, and delayed stricture. In the face of massive, uncontrolled bleeding, balloon tamponade, using the Sengstaken–Blakemore or Minnesota tube, can temporarily control hemorrhage to allow time for adequate resuscitation. Complications of balloon tamponade include aspiration and esophageal ischemia or perforation. If other interventions fail, a portosystemic shunt, such as the transjugular intrahepatic portal-systemic shunt (TIPS) or surgical shunt, can be performed to reduce the pressure in the varices.

Patients with variceal bleeding are also at risk for worsening encephalopathy or infection, particularly spontaneous bacterial peritonitis (SBP). Prophylactic antibiotics are often administered.

The effects of liver disease on the clotting system are complex.[92] Not only are key coagulation factors synthesized in the liver, but so are anticoagulant proteins, such as protein C and protein S. Patients may have an elevated international normalized ratio but are actually hypercoagulable. Monitoring thromboelastography may be the best way to understand the patient's coagulation status and, thereby, titrate the use of fresh frozen plasma or cryoprecipitate. Patients with liver disease are also often thrombocytopenic. Platelet transfusions may be indicated.

Hepatic Encephalopathy

Hepatic encephalopathy may be precipitated by gastrointestinal hemorrhage or infection.[93] The diagnosis may be difficult because of other causes of an altered mental status such as hypoglycemia, hypoxemia, uremia, and medications. Hepatic encephalopathy results from increased blood ammonia and aromatic amino acid levels from nitrogenous substances within the gut lumen resulting in increased stimulation of γ-aminobutyric acid (GABA) receptors. Ammonia levels, however, do not correlate well with the severity of encephalopathy. In addition to controlling precipitating factors, management includes pharmacologically reducing the production and/or absorption of ammonia from the gut. The mainstay of therapy is lactulose, which acts to acidify the colon, trapping nonabsorbable ammonium in the gut lumen and causing diarrhea, eliminating nitrogen from the body. Reduction of urease-producing gut flora with antibiotics, such as neomycin or rifaximin, may also help relieve severe encephalopathy.

Ascites and Spontaneous Bacterial Peritonitis

Severe ascites may result in respiratory distress and, rarely, the development of abdominal compartment syndrome. Paracentesis is a temporizing measure for refractory ascites. SBP can occur in any patient with ascites. Common clinical manifestations include fever, abdominal pain and unexplained encephalopathy. Paracentesis is the appropriate diagnostic test for SBP. Finding greater than 250 neutrophils/mL suggests SBP, with or without a positive culture. Treatment is based on the organism sensitivity if the culture is positive, but empiric therapy with fluoroquinolones or third-generation cephalosporins is reasonable.

Hepatorenal Syndrome

Portal hypertension can lead to splanchnic vasodilation and reduced renal blood flow leading to decreased effective circulatory volume and activation of the renin–angiotensin system leading to worsening renal function, the hepatorenal syndrome.[94] Infection or bleeding can cause a rapid decline in renal function. Medical management focuses on improving renal blood flow with midodrine as a vasoconstrictor and octreotide to inhibit vasodilation. Patients with severe hepatorenal syndrome may require RRT, but the most definitive therapy is liver transplantation.

Liver Failure

Liver transplantation is the most effective treatment for chronic liver failure. The prognostic model for end-stage liver disease (MELD) score predicts liver-related mortality based on a formula involving the serum creatinine, serum bilirubin, and INR. The MELD score is used to allocate donor livers to the most appropriate patient.

ALF in patients with previously normal liver function or previously compensated liver disease is defined by a rapid decline in liver synthetic function combined with encephalopathy not attributable to another cause.[95] Supportive management focuses on respiratory failure, hypotension, coagulopathy, gastrointestinal bleeding, renal failure, sepsis, and encephalopathy. As the primary cause of death in ALF is cerebral edema, aggressive management of elevated ICP, whether or not invasive intracranial pressure monitoring is employed, is indicated. In rare circumstances, extracorporeal liver support systems, such as Molecular Adsorbent Recirculating System,[96] can bridge patients to recovery or transplantation.

ENDOCRINE ISSUES

Glucose Control

Hyperglycemia is common in critically ill patients due to elevated cortisol, growth hormone, and catecholamine levels, leading to increased hepatic gluconeogenesis and insulin resistance, and, ultimately, poor clinical outcomes.[97] Complications of hyperglycemia include an increased risk of infection and worse outcomes in patients with acute neurologic disorders such as stroke or traumatic brain injury. Though intensive insulin therapy, maintaining glucose levels of 80 to 110 mg/dL, demonstrated benefit in medical or cardiac surgery patients, subsequent studies did not demonstrate the same benefit, perhaps because of an increased rate of hypoglycemia. There is also evidence that glucose variability, in addition to absolute values, is associated with worse outcomes. Current guidelines recommend moderate blood glucose control of 144 to 180 mg/dL for critically ill patients to avoid both marked hyperglycemia and iatrogenic hypoglycemia.

Adrenal Insufficiency

The presence or absence of adrenal insufficiency in critically ill patients has been controversial for years. Absolute adrenal insufficiency is extremely rare, but relative adrenal insufficiency, also known as critical illness-related corticosteroid insufficiency, manifested by hypotension and fever (and rarely with electrolyte

abnormalities), may be more common in ICU patients and may be associated with worse outcomes.[98]

In the ICU, however, patients may have total levels of cortisol that are normal, but they may not respond appropriately to the stress of critical illness and lack the typical diurnal variation of cortisol seen in normal volunteers. In the past, relative adrenal insufficiency was defined by a cortisol level of less than 11 to 25 mcg/dL and/or failure to raise the level by more than 9 mcg/dL after stimulation by high-dose (250 mcg) ACTH. However, there is much debate as to what cortisol level is appropriate in septic shock, what constitutes an adequate response to ACTH stimulation and what dose of ACTH should be used. Current consensus is that ACTH stimulation tests are not helpful for determining which patients may benefit from steroid administration. Steroid administration in septic shock has undergone several randomized trials. One large, multicenter trial of hydrocortisone compared to placebo did not demonstrate benefit.[99] In contrast, two studies that included fludrocortisone in addition to hydrocortisone did demonstrate a mortality benefit.[100,101] The current Surviving Sepsis Campaign guidelines recommend adding hydrocortisone at a dose of 200 mg/d for patients with refractory shock despite adequate fluid resuscitation and vasopressors without doing any ACTH stimulation tests.[102] The steroids can be rapidly tapered off when the pressor requirement resolves.

Another controversial question regarding adrenal insufficiency is the potential effect of the induction agent etomidate, which is a reversible inhibitor of 11-beta-hydroxylase, and thus may cause transient adrenal insufficiency. Etomidate is frequently utilized for intubations in critically ill patients because it has little directly detrimental hemodynamic effects. Studies have not definitively demonstrated worse outcome between patients intubated using etomidate versus other induction agents such as ketamine.[103]

Critically ill patients who were on therapeutic steroids prior to their current illness are at risk for developing true adrenal insufficiency if the steroids are abruptly stopped or the relative dosing decreased. The stress dose of steroids currently recommended for refractory septic shock may actually be less than the equivalent baseline dose of steroid prior to admission.

Thyroid Abnormalities

New onset of clinically important thyroid abnormalities in ICU patients is extremely rare. Nonthyroidal illness, previously called euthyroid sick syndrome, seems to be more of a laboratory finding marked by high reverse T_3 levels and total T_3, normal

or low free T_4 and thyroid-stimulating hormone levels. The actual clinical significance is questionable. No treatment is required.

True hypothyroidism in the ICU is very rare. Consequently, there is little utility in testing thyroid function in chronically critically ill patients without a specific indication. Although the half-life of commonly administered thyroid medications is long, it is possible that critically ill patients with pre-existing hypothyroidism could develop severe hypothyroidism without supplementation in the ICU. Patients with severe hypothyroidism develop hypothermia, bradycardia, and obtundation with low serum sodium and glucose levels. The treatment includes supportive care and administration of thyroxine and hydrocortisone.

Thyroid storm can occur in patients with Graves disease or toxic nodular goiters who become stressed by infection, pregnancy, trauma, or surgery.[104] Supportive management includes monitoring hemodynamics and arrhythmias, cooling, and hydration. Beta-adrenergic antagonists, for example, propranolol, can ameliorate many of the physiologic effects of thyroid storm. Propylthiouracil (PTU) or methimazole is administered to inhibit the release of T_4. PTU also blocks the conversion of T_4 to T_3. Thereafter, iodine as saturated solution of potassium iodide (SSKI) or Lugol solution is given after PTU or methimazole have been administered to inhibit T_4 release. Glucocorticoids may also be indicated.

INFECTIOUS DISEASE ISSUES

Sepsis is the primary cause of death from infection, especially if not recognized and treated promptly. Sepsis-induced organ dysfunction may be occult; unrecognized infection should be considered as the cause of new-onset organ dysfunction. In addition, specific infections may result in local organ dysfunction, for example, acute respiratory failure from pneumonia.

The working definition of sepsis has evolved over the years. The most recent, Sepsis-3, definition states that sepsis is a life-threatening organ dysfunction caused by a dysregulated host response to infection.[105] In other words, it's the patient's immune response to the infection that leads to the organ failure. Operationally, a patient can be diagnosed with sepsis in the presence of a suspected infection and either an increase by at least 2 in the SOFA score or at least 2 of 3 quick SOFA criteria (respiratory rate of ≥22/min, altered mentation, systolic blood pressure ≤100 mm Hg). Septic shock is defined as vasopressor requirement to maintain mean arterial pressure (MAP) of at least 65 mm Hg and serum lactate level >2 mmol/L in the absence of hypovolemia.

Sepsis Guidelines

8 The management of patients with sepsis and septic shock has continued to evolve over the years. The comprehensive Surviving Sepsis Campaign (SSC) guidelines for management cover resuscitation, antibiotic coverage and source control, as well as many aspects of organ-specific supportive care.[102] The initial resuscitation of the patient with sepsis focuses on rapid restoration of normal hemodynamics and normalization of lactate level, termed early goal directed therapy. When compared to standard care in 2001, this approach significantly improved mortality.[106] More recent studies of relatively similar hemodynamic goals did not demonstrate significant differences in outcome.[9,10,107] It's worth pointing out, however, that the current control groups did as well as the treatment group in the original study, suggesting that the current standard of care already achieves early goal directed therapy, though specific goals continue to evolve.[108,109]

The SSC guideline for initial fluid resuscitation includes the administration of 30 mL/kg intravenous crystalloid in every patient who is hypotensive or has a lactate of at least 4 mmol/L. Additional fluids should be given as needed. There is no indication for the use of albumin unless the patient requires substantial crystalloids. Starches should not be administered. There is no indication for blood transfusion unless the patient's hemoglobin is <7 g/dL. The goal MAP is 65 mm Hg. If this is not achieved with the initial fluid bolus, initiation of a vasopressor, for example, norepinephrine, is indicated. Second-line agents include vasopressin and epinephrine. Dobutamine or epinephrine is also helpful if myocardial dysfunction is identified. The response to these interventions should be reassessed by lactate levels, $ScvO_2$, ECHO, passive leg raising, and/or focused physical examination.

If hemodynamic stability is not restored with adequate fluid resuscitation and vasopressor therapy, intravenous hydrocortisone at a dose of 200 mg/d delivered by bolus dosing or continuous infusion should be considered. The hydrocortisone can be tapered off once the patient is off vasoactive agents. There is no indication for performing the ACTH stimulation test.

Administration of antimicrobials should be initiated as soon as possible, with a goal of within 1 hour after recognition of sepsis or septic shock. Appropriate cultures should be obtained prior to starting antimicrobial therapy as long as doing so does not delay the start of antimicrobials. The initial empiric regimen should have activity against all likely pathogens. This regimen should be deescalated as soon as possible once cultures and sensitivities are known. The duration of antimicrobial therapy should generally be 7 to 10 days. Longer courses are appropriate in patients who have a slow clinical response, undrainable foci of infection, bacteremia with *S. aureus*, some fungal and viral infections, or immunologic deficiencies. Procalcitonin

levels may be utilized to shorten the course of antimicrobials or discontinue antimicrobials when there is limited evidence of sepsis.

For patients with surgical infections that require drainage, debridement, device removal, or definitive control (e.g., resection), a target of source control within 6 to 12 hours is sufficient in most cases. Adequate hemodynamic resuscitation is important prior to the administration of a general anesthetic.

The SSC has encouraged the use of bundles of care (**Table 10.10**). Within the first 3 hours of sepsis recognition, one should measure a lactate level, obtain blood cultures prior to administration of antibiotics, administer broad-spectrum antibiotics (though now this should be within 1 hour), and administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L in all patients, regardless of previous heart or renal failure. Earlier completion of this bundle, particularly the early antibiotics, can improve survival.[110] Within 6 hours, one should initiate vasopressors if hypotensive after a fluid bolus, reassess volume status and tissue perfusion, and reassess lactate level. Lactate may not be the best endpoint for resuscitation. Mixed venous O_2 saturation may be useful. Repeated assessment of capillary refill in a standardized fashion may be just as good.[111]

Table 10.10 Sepsis Bundles

To Be Completed within 3 hrs	To Be Completed within 6 hrs
Measure lactate level	Apply vasopressors for hypotension after that does not respond to initial fluid resuscitation
Obtain blood cultures	Reassess volume status and tissue perfusion
Administer broad spectrum antibiotics	Remeasure lactate if initial lactate elevated
Administer 30 mL/kg crystalloid for hypotension or lactate ≥4 mmol/L	

Hospital Acquired Infections

Central line-associated blood stream infections (CLABSI) can be an important cause of morbidity, resource utilization, and even attributable mortality in ICU patients.[112] The Center for Disease Control defines a CLABSI as a positive blood culture in a patient who has a central line in place within 2 calendar days of the culture and no

identifiable secondary sources of bacteremia. Typically, the management includes appropriate antimicrobial therapy and removal of the line. If more clinical proof is needed because of the potential risks and challenges related to catheter removal, quantitative blood cultures or differential time to positivity can be compared between paired cultures drawn from the line and peripherally. Blood drawn from an infected line should have a higher quantity of organisms that should also become positive more quickly than blood drawn peripherally.

Preventative measures, including use of an antimicrobial coated catheter (minocycline/rifampin or chlorhexidine/silver sulfadiazine), maximal sterile barrier precautions (handwashing, sterile gloves, large drape, sterile gown, mask, and cap) during insertion, use of a chlorhexidine-impregnated dressings, meticulous care of the insertion site, and rapid removal of catheters that are no longer needed, have significantly decreased the rate of CLABSI. The best site for line placement has been debated for years. Though it has been thought that subclavian has the least risk for infection, there may be reasons for choosing a separate site because of the risk for pneumothorax or venous stricture in a patient who may require long-term dialysis access. The internal jugular or femoral sites may be reasonable choices.

Catheter-associated urinary tract infections (CAUTI) are a common cause of bacteremia, leading to significant morbidity, but rarely mortality, in ICU patients. Maintenance of sterility during insertion and careful attention to care of the catheter following insertion are helpful. The most important strategy is assessing the need for the catheter on a daily basis and removing it when appropriate.

NEUROLOGIC ISSUES

Analgesia and Sedation

Surgical patients who require intensive care need appropriate levels of analgesia. Pain management in the ICU can be challenging because patients may not be able to describe or quantify their pain. Numerical pain scales or visual analog scales are commonly used, but these require subjective input from the patient. Behavioral scales, which assess the patient's pain based upon behaviors, may be more objective. Narcotics are frequently prescribed, either enterally or intravenously. The minimum dose of narcotic to achieve an acceptable level of pain should be utilized. Dosing should balance analgesia with the potential for mental status changes, respiratory depression, hypotension, prolonged need for mechanical ventilation, and constipation. Nonnarcotic alternatives, such as acetaminophen, no-steroidal anti-

inflammatories, regional blocks, lidocaine patches, and environmental modifications, should be utilized as much as possible.

Sedation is often used for patients on mechanical ventilation. As with analgesics, the minimum dose required to achieve the desired effect should be utilized. Short-acting agents, such as propofol or dexmedetomidine, are used as a continuous infusion. There are a number of sedation scales available. Regardless of which one is used, the goal is usually to have a calm, but responsive patient. Daily interruption or at least titration of the infusion is an important way to prevent over sedation. Deeper levels of sedation may be required in some circumstances, such as difficulty with ventilation requiring high airway pressures, intracranial hypertension, or an open abdomen.

Delirium

9 Delirium, defined as a state of altered or fluctuating mental status and inattention, plus disordered thinking or altered level of consciousness, is very common in critically ill patients. Delirium may be further classified as hypoactive (lethargic) or hyperactive (agitated). Common causes for delirium include patient factors (e.g., alcoholism, endocrine disorders), acute illness (e.g., sepsis [sometimes occult], stroke, head trauma), complications of acute illnesses (e.g., hypoxemia, hypoglycemia, hypovolemia, electrolyte abnormalities), and iatrogenic factors (e.g., medications). Lack of sleep and loss of the usual day/night cycles contribute substantially to delirium. Trying to maintain normal day/night cycles by keeping the patient active during the day and turning off lights, minimizing disturbance at night, and assisting sleep with mild medication, such as melatonin, can help.

The workup for a patient with delirium should focus on ruling out reversible causes. Any focal findings should be evaluated with a CT of the head. Without focal findings, a CT scan is likely to be unrevealing, but may still be indicated. If the patient remains unarousable, an electroencephalogram should be considered for ruling out nonconvulsive status epilepticus before assuming the issue is hypoactive delirium.

Management is mostly supportive. There are no drugs that directly improve delirium. Pharmacologic therapy is mainly useful for managing patients with hyperactive delirium with the main goals of preventing harm, for example, from an unplanned extubation, and promoting sleep.[113] Drugs that can aggravate the delirium, such as anticholinergics or benzodiazepines, should be avoided. Antipsychotics, such as haloperidol, which can be administered intravenously, are helpful in the acute situation. For ongoing issues, the atypical antipsychotics, such as risperidone, olanzapine, and quetiapine, can be very effective. The risk of arrhythmias related to

prolonged QTc with these agents seems to be small, but still worth monitoring. Dexmedetomidine infusion is also very effective in the acute situation, but its use may be limited by bradycardia, hypotension, or cost.

Delirium is associated with increased length of stay and, possibly, mortality. In addition, delirium can increase the risk for development of the postintensive care syndrome, which may include impairments of memory and concentration, judgment, and even posttraumatic stress disorder.[114]

ORGANIZATIONAL STRUCTURE OF CRITICAL CARE

Though critical care can be provided anywhere, the ICU provides an environment that allows close monitoring and care by experienced physicians, nurses, respiratory therapists, pharmacists, and other ancillary staff. Current ICUs have the following common features: (1) a designated geographical space, (2) specialized monitoring and therapeutic capabilities, (3) resources to provide continuous care, and (4) appropriate staffing. ICU nurse to patient ratios vary from 1:3 to 2:1 depending on patient acuity and therapeutic needs that may be addressed with a scoring system such as the therapeutic intervention severity score (TISS). Dedicated pharmacists, dieticians, physical therapists, and advanced practice providers improve process of care compliance and patient outcomes. Diagnostic and therapeutic capabilities may include invasive and minimally invasive cardiac monitoring, basic and rescue modes of ventilation and adjuncts, extracorporeal circulatory support, dialysis and hepatic support, and neurologic monitoring.

There is controversy, particularly in adult surgical ICUs, as to how superspecialized they should be (e.g., trauma, visceral transplant, cardiac surgery, noncardiac thoracic surgery, neuro). Practically, this is an issue of institutional volume and expertise as there is little data to support superspecialization in surgical units. Some of these decisions are based around the use of specific technology, such as intra-aortic balloon pumps or ECMO in a cardiac surgery ICU or intracranial pressure monitoring in a neuro ICU.

Traditionally there are two types of ICU organizational structures: open and closed formats. In an open ICU, the patients are admitted under the supervision and care of the primary medical or surgical team, which is responsible for decision-making, order entry, and communication with the staff and family. They have the option of consulting other services, perhaps including an intensivist service. This team also continues to care for patients in other areas of the hospital, providing

continuity, but decreasing their focus on care of the most acutely ill and injured in the ICU.

Within a closed ICU, the patient's care is transferred to an intensivist whose only responsibility is to take care of patients within the ICU. Of course, hybrid models exist. Some units have a mandatory intensivist consult. In some units, both the surgical team and the critical care team can write orders or share other responsibilities.

A multidisciplinary team led by an intensivist can function in either closed or open structures. A high-intensity staffing model (with an intensivist-led team or mandatory intensivist consultation) can improve adherence to national guidelines, shorten ICU stay, decrease costs and improve outcomes.[115] A ratio of one intensivist to a maximum of 14 patients should be maintained to ensure timely completion of rounds, staff satisfaction, and provision of high-quality patient care and education of trainees.[116] Extending this model to 24/7 attending intensivist coverage does not seem to improve outcomes, at least in large academic medical centers.[117] There may be a benefit in units with a lower-intensity staffing model during the day. Good communication between members of the healthcare team and patients/families, processes for performance improvement, development of protocols, and institutional support are critical for good outcomes.[118]

The role of telemedicine in the ICU environment continues to evolve. Clinicians, including physicians and advanced practice providers, have developed the skills necessary to be able to closely monitor critically-ill patients from a distance and work closely with the healthcare providers at the patient's bedside. The technology for compliance with the Health Insurance Portability and Accountability Act continues to improve. Also, the requirements for third-party pay or reimbursement have been defined. Use of telemedicine has been associated with decreased mortality, length of stay, patient safety, and, possible fewer malpractice claims.[119] The responses from trainees working with the telemedicine intensivist have generally been positive.

Table 10.11 Organ Failure Scores

Multiple Organ Dysfunction Syndrome Score

Organ System	0	1	2	3	4
Respiratory (PO_2/FiO_2)	>300	226–300	151–225	76–150	<75
Renal (Serum Creatinine) [μmol/L]	<100	101–200	201–350	351–500	>500
Hepatic (Serum Bilirubin) [μmol/L]	≤20	21–60	61–120	121–240	>240
Cardiovascular (Pressure Adjusted Heart Rate) (HRxCVP/MAP)	≤10	10.1–15	15.1–20	20.1–30	>30
Hematologic (Platelet) [$mL \times 10^3$]	>120	81–120	51–80	21–50	≤20
Neurologic (Glasgow Coma Scale)	15	13–14	10–12	7–9	≤6

Sequential Organ Failure Assessment Score

Organ System	0	1	2	3	4
Respiratory (PO_2/FiO_2)	>400	400–300	299–200	200–100 + mechanical ventilation	<100 + mechanical ventilation
Renal (Serum Creatinine) [mg/dL]	<1.2	≥1.2–≤2	≥2–≤3.5	≥3.5–≤5	≥5 or Dialysis
Hepatic (Serum Bilirubin) [mg/dL]	<1.2	≥1.2–≤2	≥2–≤6	≥6–≤12	≥12
Cardiovascular (MAP or vasopressor required)	≥70	<70	dopamine ≤5 μg/kg/min or dobutamine (any dose)	dopamine ≤5 μg/kg/min OR epinephrine ≤0.1 μg/kg/min norepinephrine ≤0.1 μg/kg/min	dopamine >15 μg/kg/min OR epinephrine >0.1 μg/kg/min norepinephrine >0.1 μg/kg/min
Hematologic (Platelet) [$mL \times 10^3$]	>150	100–150	50–99	49–20	≤20
Neurologic (Glasgow Coma Scale)	15	13–14	10–12	6–9	<5

Denver

Organ System	0	1	2	3	4
Respiratory (PO_2/FiO_2) [mm Hg]	>250	250–175	175–100	<100	
Renal (Serum Creatinine) [mg/dL]	<1.6	≥1.6–≤2.1	≥2.11–≤4.2	>4.2	
Hepatic (Serum Bilirubin) [mg/dL]	<2	≥2–≤4	>4–≤8	>8	
Cardiovascular (inotrope required)	None	1 inotrope, small dose	1 inotrope, moderate dose, or >1 inotrope, small dose	1 inotrope, large dose, or >2 inotropes, moderate dose	

Evidence-Based Care

National and international organizations have developed numerous evidence-based guidelines for various aspects of ICU care. Good examples of comprehensive guidelines are those developed by the SSC, discussed above. Recommended bundles of care that accompany guidelines provide actionable items that can be addressed routinely during patient care. Such guidelines and bundles lend themselves to the development of multidisciplinary, multi-professional, institutional protocols and clinical practice guidelines. The electronic health record can often help with order sets or electronic prompts to improve compliance. The use of a daily goals checklist in the ICU enables practitioners to ensure that important components of care are addressed. Discussing the goals assures that all members of the critical care team understand the game plan.[120]

The ABCDEF bundle developed by the ICU Liberation ABCDEF Initiative includes ***A***ssess, prevent, and manage pain; ***B***oth spontaneous awakening and breathing trials; ***C***hoice of Analgesia and Sedation; ***D***elirium assess, prevent, and manage; ***E***arly Mobility and Exercise; ***F***amily engagement/empowerment. Implementation of this bundle is associated with decreased mortality, mechanical ventilation use, coma, delirium, need for restraints, and ICU readmissions, and improved post-ICU discharge disposition.[121]

Severity of Illness

Several ICU scoring systems have been developed to provide a framework to describe patients' severity of illness for the routine evaluation of ICU performance and quality improvement initiatives. They have been designed more for evaluation of an ICU cohort and less for prognostication in an individual case. The most robust prognostication systems compare observed and risk-adjusted hospital mortality for critically ill patient groups derived from analysis of large data sets, based mainly on early physiologic derangements. Other systems have been developed to quantify organ dysfunction in a longitudinal fashion.

The most frequently used severity of illness scores in an adult ICU used to prognosticate hospital mortality are Acute Physiology and Chronic Health Evaluation (APACHE), the Mortality Probability Model (MPM), and the Simplified Acute Physiology Score (SAPS) with higher scores portending increased hospital mortality. Some versions of these systems can be calculated manually, while others require inputting data into a proprietary software program, which can be embedded in the electronic health record.[122] The ideal scoring system should be valid, reliable, calibrated, discriminating, and simple. The future of ICU prognostication may well

involve interpretation of "big data" that relies less on traditional data acquisition and storage and more on linear or logistic regression modeling.

Several organ failure scores for initial and/or serial assessments exist as well for use in clinical trials or quality assessment (**Table 10.11**). The Sequential Organ Failure Assessment and Marshall Multiple Organ Dysfunction Score consider variables in six categories (respiratory, cardiovascular, hematologic, central nervous system, renal, and hepatic). The Denver score excludes the hematologic and neurologic components.[123]

Fluids, Electrolytes, and Acid–Base Balance

Bellal Joseph and Michael F. Ditillo

Key Points

1 The human body is conceptualized as being composed of two primary fluid compartments: extracellular fluid (ECF) and intracellular fluid (ICF). The two compartments are separated by cellular membranes.

2 The ECF can be further divided into smaller compartments: transcellular fluid, plasma, interstitial fluid, and bone/connective tissue fluid. Blood is a composite compartment containing both ECF (plasma) and ICF (red cell volume).

3 Sodium and potassium are the dominant cations of the ECF and ICF, respectively.

4 Extracellular tonicity is under tight regulation by osmoreceptors found in the hypothalamus. As sodium accounts for the majority of ECF tonicity, these receptors function essentially as ECF monitors.

5 Effective circulating volume is sensed by volume receptors (capacitance vessels, atria, hepatic, and central nervous system [CNS]) and pressure receptors (aortic arch, carotid, and intrarenal) that alter sodium and water balance mediated by renin–angiotensin, aldosterone, atrial natriuretic peptide (ANP), dopamine, and renal prostaglandins.

6 Water losses are composed of both sensible (i.e., measurable) losses via urine, stool, and sweat and insensible (i.e., immeasurable) via evaporative loss from the skin, respiratory tract, or open abdomen.

7 Goals of fluid therapy are to normalize body fluid compartment volumes and electrolyte concentrations. This can be achieved with crystalloid (preferable) or colloid infusion to correct deficits and/or match ongoing and expected losses.

8 The major electrolytes (Na^+, K^+, Ca^{2+}, Mg^{2+}, Cl^-, HCO_3^-, and HPO_4^{2-}) should be monitored and replaced, when possible, with respect to the pathophysiology of various disease states.

9 Acid–base balance is carefully buffered within very narrow limits. Acid–base disturbances are frequently mixed, involving combined

respiratory and metabolic derangements.

INTRODUCTION

In this chapter, the normal physiologic mechanisms of fluid and electrolyte homeostasis, inclusive of acid–base physiology, are reviewed. This will be the starting point for a discussion of fluid and electrolyte pathophysiology and the management of specific clinical situations. With a thorough understanding of disease- and injury-related alterations from normal fluid volume and electrolyte physiology, one can effectively care for all surgical and critically ill patients.

BODY FLUIDS

Total Body Water and Body Fluid Compartments

Total body water (TBW) is defined as the total amount of water contained within the body. The relationship between TBW and body weight varies according to the percentage of body fat.[1] The average TBW in adult men is 60% of total body weight and 55% in adult women. In infants, water makes up approximately 75% to 80% of body weight. This figure decreases to approximately 65% by 1 year of age and continues to decrease slowly throughout life, primarily related to decreases in lean body mass and an increase in adipose tissue.[1]

1 TBW is principally distributed into the intracellular and extracellular compartments which are in dynamic equilibrium (**Table 11.1**). ICF makes up approximately two-thirds of the TBW, and the remaining one-third is composed of ECF.[2]

2 The ECF compartment is subdivided into the interstitial and intravascular spaces. Interstitial water volume can be calculated as ECF–intravascular space volume and constitutes approximately 25% of TBW. The

intravascular space accounts for 25% of the ECF and contains the plasma volume, which is approximately 8% of the TBW.

Composition of Body Fluids

3 Sodium and potassium are the dominant cations in the body. As mentioned above, sodium is restricted primarily to the ECF. Sodium content in an average adult is approximately 60 mEq/kg. Approximately 25% is confined to bone and is nonexchangeable. Of the exchangeable fraction, approximately 85% is in the ECF. Potassium, calcium, and magnesium make up the remainder, smaller fraction, of the cations present in the ECF (**Table 11.2**).

In the ICF, potassium is the dominant cation. Total body potassium is normally approximately 42 mEq/kg, and most of this potassium is intracellular and freely exchangeable.

The Gibbs–Donnan equilibrium describes the relationship between charged particles in a solution that are unevenly distributed across a semipermeable membrane.[4] This special type of equilibrium exists between the ICF and ECF because of the high concentration of protein and nondiffusible phosphates in the cell. ECF cations are in electrochemical balance with chloride, bicarbonate, phosphate, and sulfate anions, although chloride is the major contributor to this balance. In addition, anionic proteins contribute to ion balance in plasma but not in interstitial fluid, which is essentially an ultrafiltrate of plasma that normally contains little protein. As a result, the content of both cations and anions in interstitial fluid is slightly higher than in plasma (**Table 11.2**).

Table 11.1 Body Fluid Compartments

	Body Weight (%)	Total Body Water (%)
Total	60	100
Intracellular	40	67
Extracellular	20	33
Intravascular	5	8
Interstitial	15	25
Transcellular	2	4

Interstitial fluid, in comparison, contains little protein. These impermeable intracellular negative charges tend to favor diffusion of permeable anions into the ECF. The concentration of protein is higher on the blood side of the capillary than on the interstitial fluid side. Thus, the concentrations of diffusible ions are not necessarily equal across these membranes because of the presence of these complex anions.

Osmotic Activity of Body Fluids

The concentration of solutes in the fluid compartments depends on the osmotic activity generated by the ion species contained in each compartment. When two solutions are separated by a semipermeable membrane, water moves across the membrane to equalize the concentration of osmotically active particles to which the membrane is impermeable. The maintenance of osmotic equilibrium across a semipermeable membrane is based primarily on the number of solute particles rather than on the molar concentration of the solution on each side of the membrane due to the flow of water.

The unit of measurement of osmotically active particles is the osmole (Osm) or milliosmole (mOsm) rather than the conventional units of solute concentration such as milliequivalents per liter (mEq/L). In solution, osmolarity (mOsm/L) and osmolality (mOsm/kg water) define the osmotic activity of particles. When 1 mol of NaCl dissociates in water to Na^+ and

Cl^-, it produces 2 Osm. The measured osmolality of a solution may not equal the calculated osmolality if the ions do not totally dissociate.

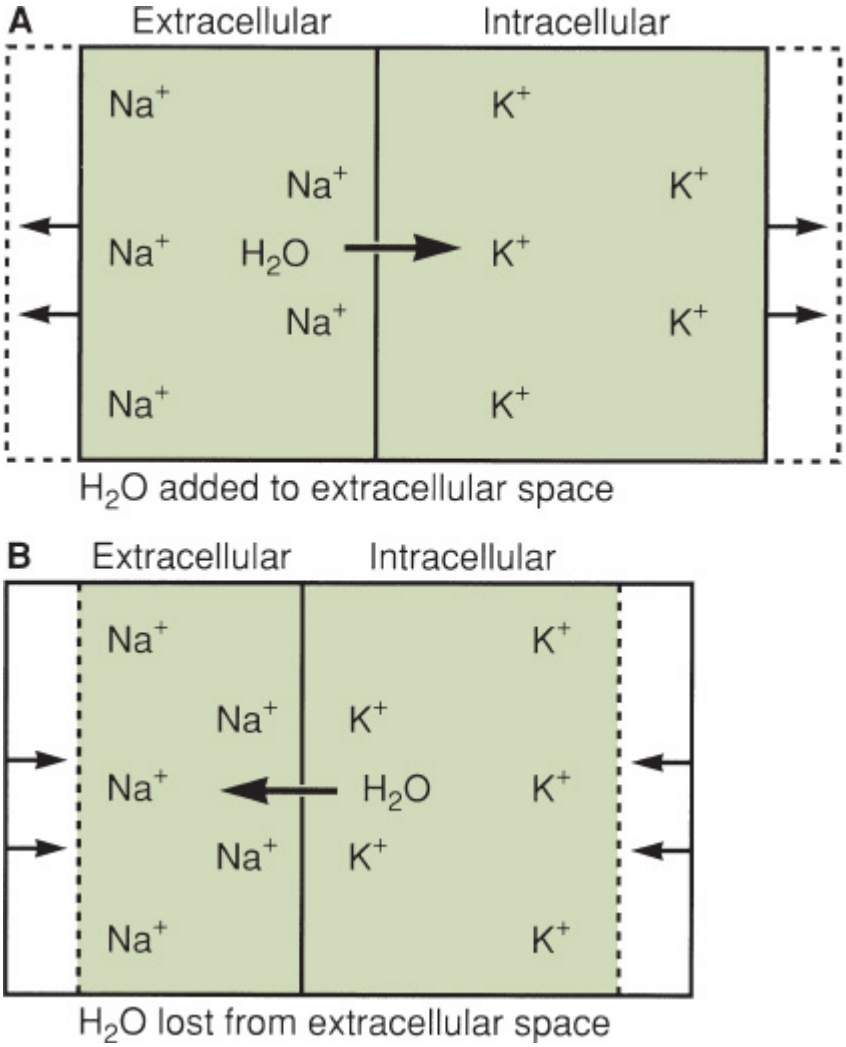

Figure 11.1 **A:** The equilibration of water from the extracellular to the intracellular space after the addition of free water to the extracellular fluid compartment. Osmolality transiently decreases in the extracellular compartment, causing water to move across the cell membranes into the intracellular space. **B:** Similar shifts after free water loss from the extracellular compartment. Water moves from the intracellular space to the extracellular space in response to the osmolal gradient that is established.

Cells are bounded by a semipermeable membrane. Adding free water to the fluid surrounding a cell causes water to move across the cell membrane to equalize the osmolality differential between the intracellular and extracellular compartments. On a larger scale, adding free water to the ECF

of the body causes an immediate expansion of the extracellular space, followed by a redistribution of water into the intracellular compartment (**Fig. 11.1A**). Conversely, loss of free water from the extracellular space ultimately leads to a shift of water from the intracellular to the extracellular space (**Fig. 11.1B**).

Table 11.2 Electrolyte Concentrations of Intracellular and Extracellular Fluid Compartments

	Extracellular Fluid (mEq/L)		
	Plasma	**Interstitial**	**Intracellular Fluid (mEq/L)**
Cations			
Na^+	140	146	12
K^+	4	4	150

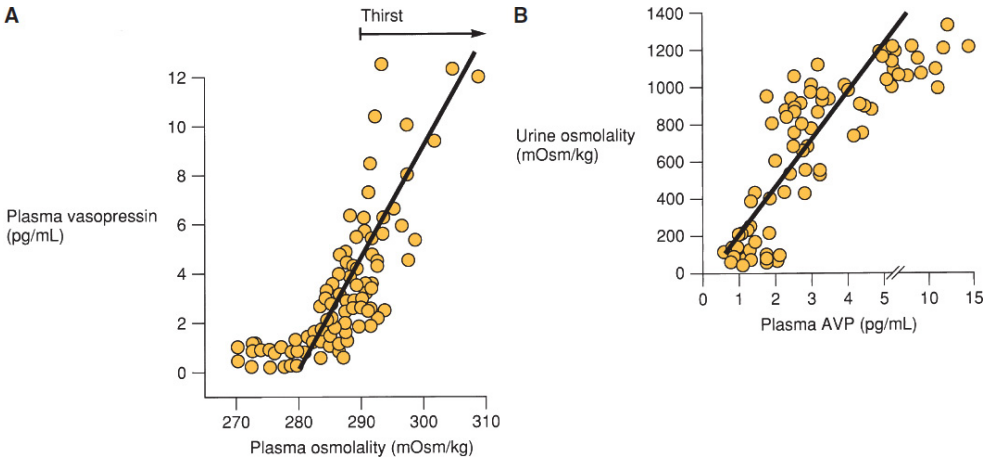

Figure 11.2 The relation of plasma antidiuretic hormone (arginine vasopressin [AVP]) secretion to plasma (**A**) and urine (**B**) osmolality in healthy adults in varying states of water balance. (Reproduced with permission from Robertson GL, Berl T. Water metabolism. In: Brenner BM, Rector FC Jr, eds. *The Kidney*. Philadelphia, PA: WB Saunders; 1986:392.)

Colloid Oncotic Pressure (Colloid Osmotic Pressure)

Plasma proteins are confined primarily to the intravascular space and contribute to the osmotic pressure developed between the plasma and the interstitial fluid. Normal plasma protein levels of 7 g/dL contribute approximately 0.8 mOsm/L.

Osmoregulation

Osmolality of body fluids stays fairly constant at approximately 4 285 to 295 mOsm/L as the result of tightly regulated water balance. Osmoreceptor cells in the paraventricular and supraoptic nuclei of the hypothalamus exert central control over the thirst mechanism and antidiuretic hormone (ADH) secretion from the posterior pituitary.[5] In the presence of excess free water, ECF osmolality falls toward 280 mOsm/kg H_2O, thirst is inhibited, and ADH levels decline. In the absence of ADH, the permeability of renal collecting tubules to water is decreased, causing free water reabsorption to decrease and excretion to increase. Urine osmolality (U_{osm}) can decline to 50 mOsm/kg H_2O (**Fig. 11.2**). As excess free water is eliminated, P_{osm} begins to

rise. Conversely, free water depletion causes an increase in P_{osm}. As P_{osm} approaches 295 mOsm/kg H_2O, thirst is stimulated as is ADH secretion. As ADH levels rise to approximately 5 pg/mL, the renal collecting tubules become maximally permeable to water. Water is reabsorbed from the collecting ducts in response to the concentration gradient developed in the renal medullary interstitium. Thus, the final concentration of urine depends on both the permeability of the collecting ducts (controlled by ADH secretion) and the concentration of the medullary interstitium.[5] Maximal U_{osm} may approach 1,200 mOsm/kg H_2O. The net effect of these mechanisms is to promptly return high or low P_{osm} to normal. The high sensitivity of the osmoreceptors and the responsiveness of the ADH feedback system ensure that even small changes in P_{osm} result in marked alterations in urine concentration. This relation can be expressed as follows:

$$\text{Urine osmolality} = 95 \times \text{Plasma osmolality}$$

Thus, a 1-mOsm change in P_{osm} results in a 95-fold change in U_{osm}.

Angiotensin II and neural input from medullary baroreceptors can also influence ADH secretion and thirst, thus tying water balance to hemodynamic alterations. Relatively small changes in pressure have little effect on ADH secretion, but large decreases in pressure can cause tremendous increases in ADH release. Therefore, ADH release as a response to changes in serum osmolality is regulated by a very sensitive system (only small changes in serum osmolality outside its normal range lead to dramatic changes in ADH release), while the nonosmotic release of ADH occurs in the setting of profound hypotension for the purposes of preserving volume homeostasis with the subsequent effect of water retention regardless of serum osmolality (**Fig. 11.3**).

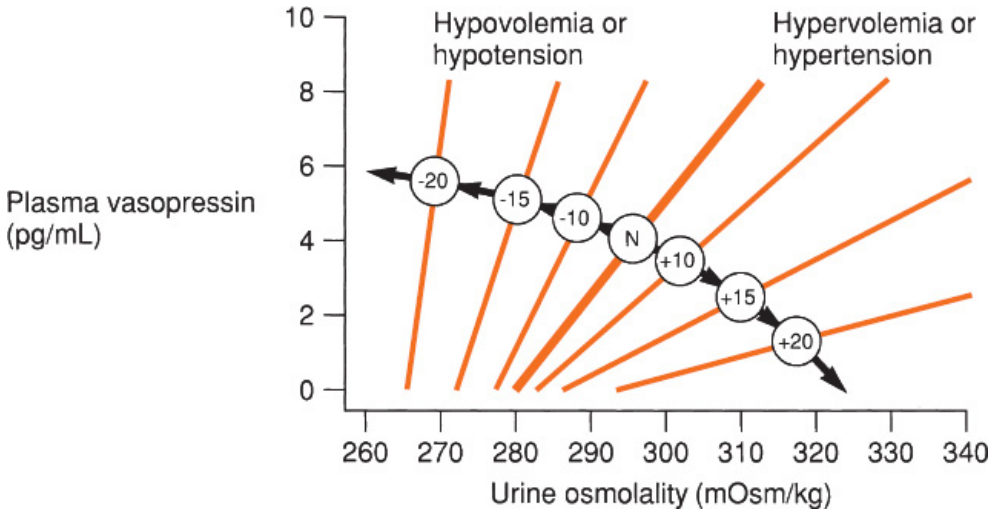

Figure 11.3 Effect of acute changes in blood volume or pressure on the osmoregulation of antidiuretic hormone (ADH; vasopressin). The heavy oblique line in the center represents the relation between plasma ADH and osmolality under normovolemic, normotensive conditions. The lines to the left and right show the shift in the relation when blood volume or blood pressure is acutely decreased or increased by the percentage indicated in the circles. (Reproduced with permission from Robertson GL. Physiology of ADH secretion. *Kidney Int* 1987;32(Suppl 21):520.)

Tonicity of Body Fluids

Tonicity refers to the effect of the particles on cell volume. (NB: O*smolality* defines the concentration of osmotically active particles in solution.) Permeable solutes can freely cross cell membranes, whereas impermeable solutes cannot. Although permeable solutes contribute to the osmolality of a solution, they have no effect on tonicity because they contribute neither to oncotic gradients across cell membranes nor to alterations in cell volume. Sodium is an example of an impermeable solute that affects both osmolality and tonicity. Urea and ethanol are permeable solutes that contribute to osmolality but have little effect on tonicity because they distribute equally across membranes.

Both impermeable and permeable solutes can contribute to *hyperosmolar* and *hypoosmolar* states. However, hypoosmolar states are always accompanied by hypotonicity, whereas hyperosmolar states are not always associated with hypertonicity. There may be marked hyperosmolality without hypertonicity with elevation of blood urea nitrogen (BUN) levels because urea is a freely permeable molecule. In contrast, elevated levels of plasma

glucose in diabetic patients are associated with hyperosmolarity and associated hypertonicity. Insulin increases the transport of glucose across cell membranes, rendering these osmoles *ineffective* and reducing hypertonicity. Plasma hyperglycemia is associated with the movement of intracellular water to the extracellular space. This causes expansion of ECF and plasma volume and a consequent decrease in the concentration of plasma sodium. The osmotic diuresis caused by the elevated glucose level tends to normalize the serum sodium if adequate hydration is maintained.

Plasma osmolality (P_{osm}) is an excellent measure of total body osmolality. Osmolality differentials between fluid compartments are only transient because fluid shifts maintain isosmotic conditions. Sodium is the predominant extracellular cation; thus, estimates of P_{osm} can be made by simply doubling the serum sodium concentration (serum $[Na^+]$):

$$P_{osm}\ (mOsm/L) = 2 \times \text{serum } [Na^+]$$

Because glucose and BUN may make significant contributions to P_{osm} in certain disease states, this formula is modified for glucose and for BUN:

$$P_{osm}\ (mOsm/L) = 2 \times \text{Serum } [Na^+] - \text{Glucose}/18 - \text{BUN}/2.8$$

Discrepancies of greater than 15 mOsm/L between calculated P_{osm} and P_{osm} measured in the clinical laboratory may be the result of the presence of other osmotically active particles, such as mannitol, ethanol, or ethylene glycol, or of a reduced fraction of plasma water secondary to high levels of myeloma proteins or hypertriglyceridemia.

FLUID BALANCE

Sodium Concentration and Water Balance

Abnormalities in serum sodium are usually indicative of abnormal TBW content. This is due to sodium being the primary extracellular cation. As potassium is the predominant intracellular cation, the serum $[Na^+]$

approximates the sum of the exchangeable total body sodium (Na^+_e) and total body exchangeable potassium (K^+_e) divided by TBW:

$$\text{Serum } [Na^+] = (Na^+_e + K^+_e)/\text{TBW}$$

Because the sum of total body solute content ($Na^+_e + K^+_e$) remains relatively stable over time, changes in TBW content is, therefore, inversely proportional to changes in the serum $[Na^+]$ (**Fig. 11.4**).

Volume Control

5 Changes in volume (i.e., hypovolemic/nonosmotic stimuli) are detected by both osmoreceptors and baroreceptors.[3] The osmoreceptors are responsible for the day-to-day fine-tuning of volume by responding to changes in tonicity, whereas the baroreceptors contribute relatively little to the control of fluid balance under normal conditions. As mentioned previously, large changes in circulating volume (10% to 20% blood volume loss) can modify the osmoregulation of ADH leading to nonosmotic stimulation of ADH release. Cardiac atrial baroreceptors control volume by means of sympathetic and parasympathetic neural mechanisms, whereas ANP released by atrial myocytes in response to atrial wall distention may influence sodium-linked volume control by inhibition of renal sodium reabsorption.[6–8]

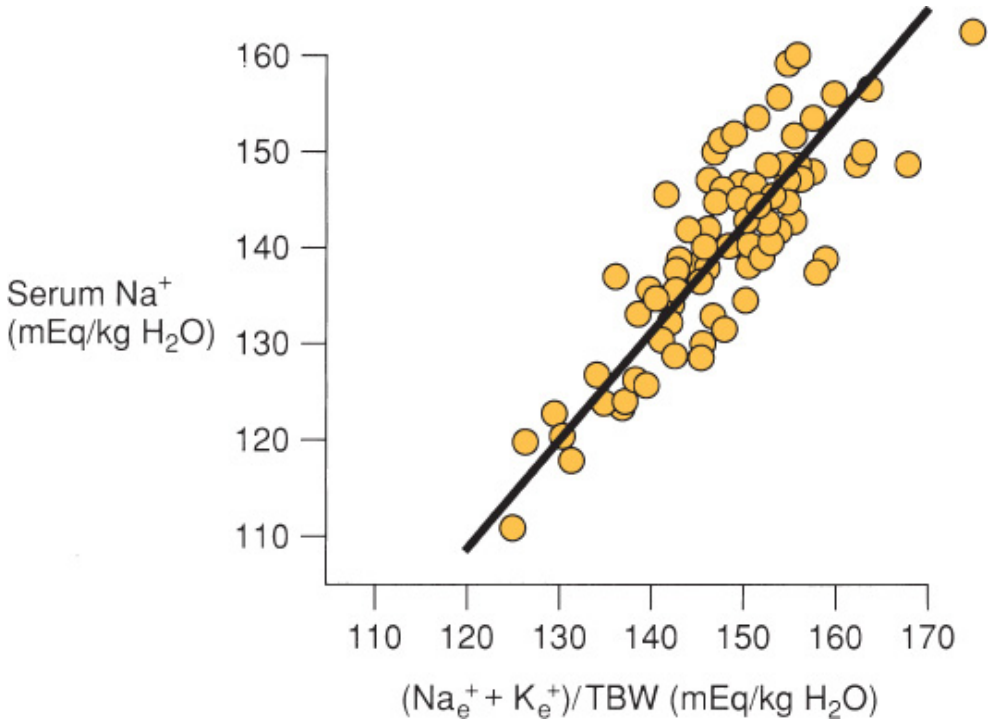

Figure 11.4 Relation between serum [Na^+] and the ratio of ($Na^+_e + K^+_e$) to total body water (TBW). (Reproduced with permission from Edelman IS, Liebman J, O'Meara MP, et al. Interrelationships between serum sodium concentration, serum osmolarity and total exchangeable sodium, total exchangeable potassium and total body water. *J Clin Invest* 1958;37:1236–1256.)

Osmoreceptors

Specialized cells in the anterolateral region of the hypothalamus that respond to changes in extracellular tonicity are known as *osmoreceptors*. It is believed that the activity of ion channels in the cell membrane, aquaporins, and changes in cell volume contribute to the function of these receptors. Osmoreceptors can respond to changes in tonicity as small as a few percent. For example, these cells shrink response to increase in plasma tonicity triggering the release of ADH and/or the sensation of thirst.

Baroreceptor Modulation of Volume Control

Effective circulating volume describes that portion of the extracellular volume that perfuses the organs of the body and is sensed by baroreceptors. The effective circulating volume normally corresponds to the intravascular volume.

Changes in the effective circulating volume are sensed by volume receptors in the intrathoracic capacitance vessels and atria, pressure receptors of the aortic arch and carotid arteries, intrarenal baroreceptors, and hepatic and cerebrospinal volume receptors.[8] These stretch receptors respond to changes in pressure and circulating volume and, through a complex system of neural and hormonal actions, alter sodium and water balance in the kidneys. Hormonal effects are mediated by the renin–angiotensin system, aldosterone, ANP, dopamine, and renal prostaglandins.

Hormonal Mediators of Volume Control

Renin–Angiotensin System

Renin is a proteolytic enzyme that is released from the juxtaglomerular cells of afferent arterioles in the kidney in response to several stimuli. These include changes in arterial pressure, changes in sodium chloride delivery to the macula densa of the distal convoluted tubule, increases in β-adrenergic activity, and increases in cellular cyclic adenosine monophosphate.

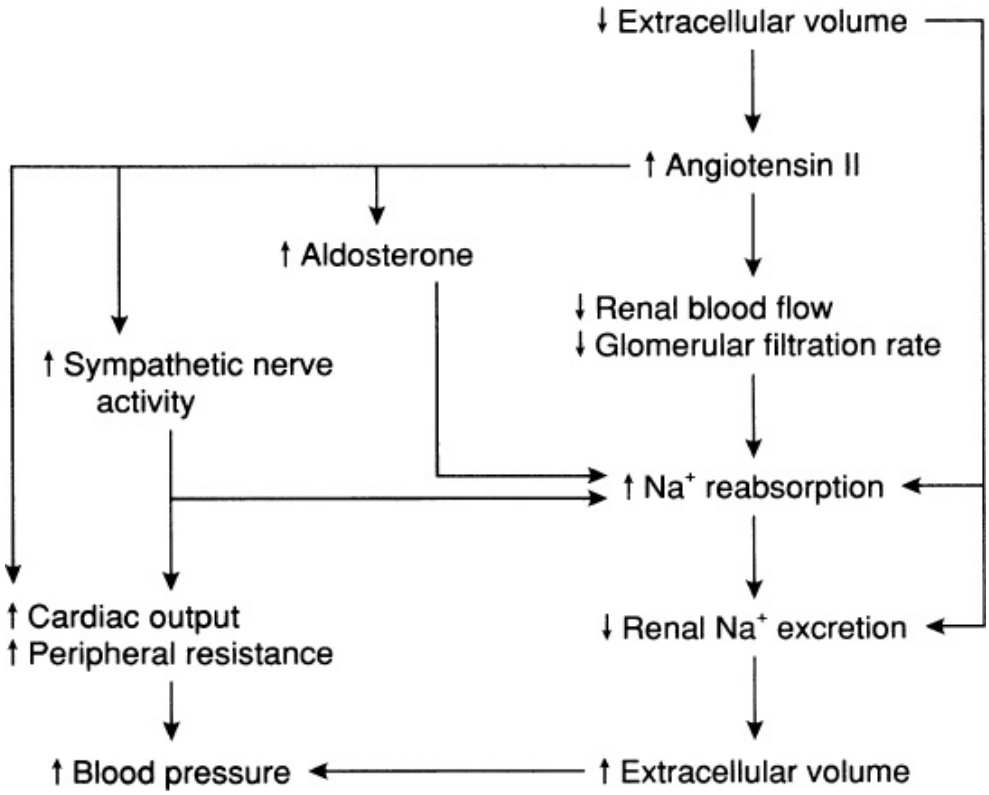

Figure 11.5 Multiple effects of increased angiotensin II release in response to the stimulus of decreased extracellular volume.

Renin cleaves angiotensin I from circulating angiotensinogen, produced by the liver. Angiotensin I is cleaved to the octapeptide angiotensin II by angiotensin-converting enzyme (ACE), which is produced by pulmonary vascular endothelial cells. The multiplicity of actions of angiotensin II is depicted in **Figure 11.5**.

Aldosterone

Aldosterone is a mineralocorticoid produced in the *zona glomerulosa* of the adrenal cortex. Aldosterone increases renal tubular reabsorption of sodium. Aldosterone acts directly on the distal tubule cells by modifying gene expression and stabilizing the epithelial Na^+ channel in the open state and by increasing the number of channels in the apical membrane of these cells.[5] By increasing protein production in these tubular cells, aldosterone induces an influx of sodium, which causes an increase in cellular Na^+-K^+-adenosine triphosphatase activity. The net result is increased sodium reabsorption and the obligate loss of potassium via the renal outer medullary potassium (ROMK) channel. Although the primary regulator of aldosterone secretion is angiotensin II, aldosterone release is also stimulated by increased potassium levels, adrenocorticotropic hormone, endothelins, and prostaglandins.[9]

Atrial and Renal Natriuretic Peptides

ANP is synthesized and released by atrial myocytes in response to atrial wall distention.[7,8] There is evidence that ANP has a direct inhibitory effect on renal sodium reabsorption. Although pharmacologic doses of ANP can cause changes in both renal blood flow and glomerular filtration rate (GFR), physiologic levels do not appear to have any major effect on these parameters. Other active fragments of the ANP prohormone have been found to have natriuretic activity. The best described is urodilatin, also known as *renal natriuretic* peptide.

Renal Prostaglandins

Renal prostaglandins (PG) appear to play a role in volume control, although under normal physiologic conditions, this role may be minimal.

PGE_2 and PGI_2 appear to be the predominant prostaglandins produced in the kidney. PGE_2 increases sodium excretion in the absence of changes in GFR. PGI_2 is a vasodilator, and its effects on renal vascular resistance

increase both renal blood flow and GFR. PGI_2 production is augmented by increases in angiotensin, catecholamines, and sympathetic tone. The administration of nonsteroidal anti-inflammatory agents, which inhibit cyclooxygenase, to patients with conditions known to cause renal dysfunction (e.g., cirrhosis) can precipitate renal failure, presumably because of loss of the protective effects of the renal prostaglandins.

Endothelins

Endothelins are peptide vasoconstrictors that are involved in volume and pressure regulation.[9] Endothelin is produced and released by endothelial and other cells to act on adjacent smooth muscle cells. In addition to increasing peripheral resistance, endothelin infusion has a direct inotropic effect on the myocardium.

Endothelin increases ANP secretion, activates ACE, and inhibits renin release by the juxtaglomerular apparatus. At low doses, endothelin-1 produces natriuresis and diuresis. Endothelin also modulates the biosynthesis of aldosterone, thereby inhibiting water reabsorption through aldosterone-controlled mechanisms. Vasopressin-mediated water reabsorption is also inhibited.[10]

Nitric Oxide

Nitric oxide is a short-lived free radical produced from L-arginine by nitric oxide synthases.[10] Nitric oxide is produced in renal smooth muscle cells, mesangial cells, tubules, and endothelial cells and participates in the regulation of renal hemodynamics and renal handling of water and electrolytes. Nitric oxide contributes to tubuloglomerular feedback, which modulates the delivery and reabsorption of sodium and chloride in the renal tubules. Nitric oxide also regulates renin release by the juxtaglomerular apparatus and mediates the effects of angiotensin on tubular reabsorption.[10]

Normal Water and Electrolyte Exchange

Surgical patients are prone to fluid and electrolyte abnormalities. It is important to recognize that disease states, trauma, and stress-related abnormalities—especially those caused by a surgical procedure—alter many of the body's fundamental homeostatic mechanisms. It is therefore important

to understand normal fluid and electrolyte balance to avoid additional iatrogenic perturbations of these mechanisms.

NORMAL WATER EXCHANGE

6 Water losses are both sensible (measurable) and insensible (unmeasurable). Measurable losses include urinary and intestinal. **Table 11.3** summarizes the normal sensible and insensible losses encountered in a 24-hour period. The volumes of these losses may vary considerably especially in disease states. Under normal conditions, the minimal amount of water needed to excrete normal metabolic waste products is approximately 300 to 500 mL/day.

Table 11.3 Water Losses in a 60- to 80-kg Man

	Average Daily Volume (mL)	Minimal Daily Volume (mL)
Sensible losses		
Urinary	800–1,500	300
Intestinal	0–250	0
Sweat	0	0
Insensible losses		
Lungs and skin	600–900	600–900

Adapted from Shires GT, Canizaro PC. Fluid and electrolyte management of the surgical patient. In: Sabiston DC, ed. *Textbook of Surgery*. Philadelphia, PA: WB Saunders; 1986:77, with permission.

The GI tract has a net secretory action down to the level of the jejunum. After that, the resorptive capacity of the remainder of the small and large bowel acts to keep further water loss to a minimum. Fecal water loss is usually trivial: ~150 mL/day. In disease conditions like bowel obstruction, severe diarrhea, and enterocutaneous fistulas, GI losses of water and electrolytes can be significant causing secondary pathophysiologic conditions.

Sweating and diaphoresis are active processes involving the secretion of a hypotonic mixture of electrolytes and water.

These aforementioned conditions are distinct from the immeasurable, evaporative loss of water from the skin under normal conditions (**Table 11.3**). Evaporative skin losses are increased with an increase in body surface area (especially infants and small children), patient temperature, and the relative humidity of the environment. Overall, normal insensible water losses average approximately 8 to 12 mL/kg/day. Insensible water loss increases 10% for each degree of body temperature above 37.2°C (99°F). Patients who are on respirators or who breathe air that is 100% humidified have no respiratory losses and may gain free water.

FLUID AND ELECTROLYTE THERAPY

Parenteral Solutions

Crystalloids

7 The most widely used parenteral solutions are composed most commonly of sodium and chloride. They are collectively referred to as *crystalloids* (based on the solid, room temperature form of the primary ingredient sodium chloride). Crystalloids are inexpensive and highly effective for fluid maintenance and rapid volume replacement. They also have excellent safety profiles.[11–15] The most commonly used crystalloid solutions available for parenteral administration are found in **Table 11.4**. Selection of the appropriate fluid requires assessment of the patient's maintenance fluid needs, existing fluid deficits, and anticipated ongoing fluid losses.

Isotonic saline (0.9% sodium chloride or *normal saline*) contains 154 mEq of both sodium and chloride. Although this solution can be useful in patients with hyponatremia or hypochloremia, the excess of both sodium and chloride can lead to acid–base disturbances. For example, infusion of large volumes of 0.9% saline can lead to a hyperchloremic metabolic acidosis.

Table 11.4 Electrolyte Content of Commonly Used Intravenous Crystalloid Solutions

	Electrolyte (mEq/L)					
Solution	Na^+	K^+	Ca^{2+}	Mg^{2+}	Cl^-	...
0.9% NaCl	154	—	—	—	154	—
0.45% NaCl	77	—	—	—	77	—
0.33% NaCl	56	—	—	—	56	—
0.2% NaCl	34	—	—	—	34	—
Lactated Ringer	130	4	4	—	109	28
3.0% NaCl	513	—	—	—	513	—
5.0% NaCl	855	—	—	—	855	—

Lactated Ringer solution is a buffered solution composed of the conjugate-base lactate. The solution has a lower sodium and chloride content (130 mEq/L) and adds a very small amount of potassium and calcium (4 mEq/L each). It is ideal for the replacement of acute fluid losses where serum electrolyte concentrations are initially normal. Normal renal function usually ensures that any extra free water from this solution is excreted. Hyponatremia can occur with extended use of lactated Ringer solution. Furthermore, the presence of potassium in lactated Ringer solution has been a concern when used in patients with acute kidney injury, although more recent data have suggested that normal saline (with no potassium in solution) may actually be more likely to cause hyperkalemia in this population due to metabolic acidosis-induced cellular shifts of potassium from the cell. Although the lactate anion in lactated Ringer solution is metabolized to bicarbonate in the liver, this does not appear to contribute to acidosis in normal hepatic function.[16] Studies suggest that the usage of chloride-restrictive intravenous fluids such as lactated Ringer solution was associated with a significant

decrease in the incidence of acute kidney injury and the need for renal replacement therapy.[17]

For maintenance fluid therapy especially prior to an operation with *nil per os* status or following correction of any existing deficits, less concentrated saline solutions are more appropriate to replace ongoing fluid losses (e.g., nasogastric tube losses). The specific crystalloid selected is best determined by calculated requirements. These fluids are hypoosmotic and hypotonic with respect to plasma. In theory, rapid infusion of very hypotonic solutions can result in red blood cell lysis. For this reason, 5% dextrose (50 g of dextrose per liter) has traditionally been added to these solutions to increase tonicity. The addition of dextrose is beneficial in pediatric patients who are unable to adequately control glucose homeostasis due to immature livers. A 5% dextrose solution represents 200 kcal/L of solution.

Hypertonic saline solutions (HTSs) (3% NaCl, 5% NaCl, 7.5% and 23% NaCl) are used as resuscitation fluids or for sodium delivery.[16,18,19] HTS appears to increase intravascular volume more quickly than isotonic solutions. It is believed that the osmotic gradient produced redistributes fluids leading to plasma volume expansion (up to fourfold). This, in turn, may decrease the total resuscitation volume requirement. When HTS is used for resuscitation of patients with severe sepsis, it has been shown to result in improvements in oxygen transport, cardiac output, and pulmonary capillary wedge pressure.[16]

The osmotic effect of HTS may benefit patients with acute severe brain injury.[19] By reducing the water content of the brain, HTS can help to control intracerebral pressure. In addition, HTS has immunomodulatory effects, which are well documented.[20] HTS reduces the systemic inflammatory response syndrome and may attenuate multiple organ dysfunction syndrome. HTSs are not without adverse effects, however. Patients are at risk for electrolyte abnormalities such as hypernatremia, hyperchloremia, and consequent metabolic acidosis.

Colloids

Colloids are composed of large molecules (e.g., albumin) that have a greater tendency to stay in the intravascular space. Their effectiveness at enhancing the plasma volume relative to crystalloid fluids is debatable. Colloid

solutions offer the potential benefits of promoting fluid retention in the intravascular space and reducing excess interstitial fluid (edema). Colloids are typically confined to the intravascular space resulting in transient plasma volume expansion. However, abnormal capillary membrane permeability (sepsis, hemorrhagic shock) allows the extravasation of colloids into the interstitial space worsening edema tissue oxygenation.[21,22] The CRISTAL trial (crystalloids vs. colloids) found no overall difference in survival when comparing crystalloids administration to colloids infusion.[23]

Albumin

Albumin is the primary protein in plasma responsible for oncotic pressure. Exogenous human albumin is derived from human plasma. It is available in a 5% (50 g/L) and a 25% solution (250 g/L) in isotonic saline. These act by increasing plasma oncotic pressures and theoretically slowing or even reversing movement of water into the interstitial space. Albumin has an approximate intravascular half-life of 4 hours in conditions of normal physiologic capillary permeability.

Hetastarch

Hydroxyethyl starches (HES) are synthetic colloids derived from hydrolyzed amylopectin. HES is slightly more effective than 5% albumin as a colloid—it has a higher colloid oncotic pressure than 5% albumin.

Hetastarch has been used as a resuscitative solution with variable results. Coagulopathy and bleeding complications have been widely reported.[24–26] HES administration prompted a prospective study, with results published in 2012.[27,28] The results of these trials prompted the FDA, the Pharmacovigilance Risk Assessment Committee, the European equivalent of the FDA, to suspend marketing authorization of all HES products and issued warnings to its use.[29,30] The Surviving Sepsis Campaign recommends against HES administration in septic patients.[31]

Dextrans

Dextrans are glucose polymers. Their use involves risks of anaphylaxis, hyperglycemia, renal dysfunction and failure, coagulopathy, and increased

thrombosis. The use of dextran solutions is no longer favored given a higher relative risk of mortality compared to HESs.[32]

Gelatins

Gelatin solutions produced from bovine collagen are effective as plasma volume expanders. These are currently only available outside the United States and were used in similar clinical settings to HES, with similar clinical results.[33] Adverse effects include: renal impairment, allergic reactions, and anaphylaxis.[34]

Artificial Oxygen Carriers

Non–red blood cell hemoglobin-based oxygen-carrying solutions (e.g., PolyHeme, Northfield Laboratories, Inc.)[35] are made from polymerized human hemoglobin. PolyHeme's originally was used in military trauma situations with massive blood loss when fresh whole blood is not readily available. On May 9, 2009, Northfield Laboratories, Inc. shut down operations after it failed to secure a biologic license application for PolyHeme from the FDA.

GOALS OF FLUID AND ELECTROLYTE THERAPY

Maintenance Fluid Therapy

Maintenance fluid volume requirements can be calculated based on body weight (**Table 11.5**). A 10-kg child requires 100 mL/kg/day or 1,000 mL/day. A 70-kg man requires 1,000 mL/day for the first 10 kg (100 mL/kg × 10 kg), plus 500 mL/day for the second 10 kg (50 mL/kg × 10 kg), plus 1,000 mL/day for the last 50 kg (20 mL/kg × 50 kg), for a total daily water requirement of 2,500 mL/day. In patients who may be intolerant of hypervolemia (i.e., cardiac disease, elderly patients), the requirement per kilogram over 20 kg is decreased to 15 mL/kg/day.

Maintenance Electrolyte Therapy

One to 2 mEq/kg/day of sodium is required, with any administered excess managed by urinary sodium excretion. Potassium requirements are approximately 0.5 to 1 mEq/kg/day. If sodium is replaced at 2 mEq/kg/day and potassium is replaced at 1 mEq/kg/day, a 70-kg patient requires 2,500 mL of water containing 140 mEq of sodium and 70 mEq of potassium. Each liter of parenteral solution would contain 56 mEq of sodium and 28 mEq of potassium. The solution that best fits this patient's daily maintenance requirements is 0.33% saline solution (56 mEq/L Na^+). Potassium chloride can be added to each liter of solution (20 to 30 mEq/L), with appropriate adjustments for the patient's electrolyte and renal functional status.

Table 11.5 Calculation of Maintenance Fluid Requirements

Body Weight	Fluid Requirement[a]	
For 0–10 kg	Give 100 mL/kg/day	A
For the next 10–20 kg	Give an additional 50 mL/kg/day	B
For weight >20 kg[b]	Give 20 mL/kg/day	C

[a]Maintenance fluid requirements = A + B + C.

[b]For elderly patients or patients with cardiac disease, this amount should be reduced to 15 mL/kg/day.

Additional Electrolyte Therapy

Short-term maintenance therapy generally does not require addition of calcium, phosphate, or magnesium. In patients with acute and/or chronic disorders, patients who experience significant volume shifts, or patients who require long-term parenteral fluid therapy, these electrolytes should be measured and corrected by the most practical, physiologically natural route. In general, the enteral route is preferred given normal physiology. If the enteral route is unavailable, these additional electrolytes are administered in parenteral nutrition solutions along with trace elements, vitamins, and appropriate caloric sources. Corrections and allotment must be made for disease states that may alter the need or absence of electrolytes (e.g., potassium in renal failure patients) in replacement solutions.

CORRECTION OF VOLUME ABNORMALITIES

Volume Deficits

Hypovolemia is common among surgical and trauma patients due to direct blood loss or other fluids. Large volumes of fluid can be sequestered in extravascular spaces (third-space losses) because of inflammation, sepsis, or shock-related endothelial injury and increased endothelial permeability.[36] Examples of disorders that cause third-space losses include bowel obstruction with edema of the bowel wall and transudation of fluid into the bowel lumen, pancreatitis (especially with retroperitoneal fluid extravasation) and extensive tissue destruction in trauma. With the resolution of the pathologic condition and normalization of microvascular permeability, these fluid losses abate. Sequestered extravascular fluid returns—albeit at variable rates—to the intravascular space.

Volume deficits can manifest either acutely or over time. Chronic volume deficits may manifest with decreased skin turgor, sunken eyes, oliguria, weight loss, hypothermia, tachycardia, and orthostatic hypotension. In addition, serum BUN and creatinine values may be elevated, with a high BUN/creatinine ratio (above 15:1). The absolute hematocrit level has been shown to be a poor predictor of intravascular volume status.

Acute volume losses usually manifest by an increase in heart rate and eventually hypotension and decreased urine output. Fluid resuscitation for hypovolemia is initiated with an isotonic solution (normal saline, lactated Ringer solution). Urine flow in critically ill patients is monitored with an indwelling Foley catheter with a goal of at least 0.5 mL/kg/hr output. In addition, a thorough history and physical examination will help determine the origins of the volume deficits, specifically addressing underlying causes and resultant losses.

Volume Excess

Volume excess may occur with significant resuscitative fluid, blood product administration, or excessive parenteral volume administration. Volume overload will occur if adjustments to fluid therapy are not made as the clinical status of the patient changes. Possible manifestations of volume

overload are weight gain, truncal and peripheral edema, and pulmonary congestion. Intravascular volume excess is treated by a combination of volume restriction and diuresis.

REPLACEMENT OF ONGOING FLUID LOSSES

Ongoing losses from stomas, fistulae, open body compartments (e.g., abdomen, chest) and all tubes (e.g., nasogastric) and drains—are recorded during the course of care. Once the net "ins and outs" have been calculated, any existing volume deficits should be replaced with fluid replacement. The electrolyte content of these fluids can be estimated or measured and used to guide the choice of replacement fluid type (**Table 11.6**).

Intraoperative Fluid Therapy

Fluid losses during operative procedures result from evaporative losses in open wounds, blood loss, and extravascular, third-space sequestration. Relative operative blood loss can frequently be measured. Evaporative losses as well as shifts of intravascular fluid to the extravascular space are difficult to measure but should be anticipated. Intraoperative replacement with crystalloid solutions is usually accomplished at rates of 500 to 1,000 mL/hr as this is roughly equivalent to the hourly insensible loss rate during open celiotomy cases. The choice of intraoperative fluid is dependent on many factors. Administration of buffered solutions (e.g., Ringer lactate solution) is as efficacious and safe as nonbuffered, saline-based fluids and may prevent postoperative hyperchloremic metabolic acidosis. Close monitoring of blood pressure, blood loss, urine output, and invasive monitoring techniques aids the surgeon and anesthesiologist in gauging fluid shifts and potential problems associated with intraoperative volume depletion.

Table 11.6 Electrolyte Concentrations in Gastrointestinal Secretions

	Electrolyte (mEq/L)					
Secretion	Na^+	K^+	Cl^-	...	H^+	Rate (mL/day)
Salivary	50	20	40	30	—	100–1,000
Gastric						
Basal	100	10	140	—	30	1,000
Stimulated	30	10	140	—	100	4,200
Bile	140	5	100	—	—	500–1,000
Pancreatic	140	5	75	—	—	1,000
Duodenum	140	5	80	—	—	100–2,000
Ileum	140	5	70	—	—	100–2,000
Colon	60	70	15	—	—	—

Postoperative Fluid Therapy and Monitoring

Routine monitoring of intraoperative and postoperative fluid status consists of serial vital signs (e.g., blood pressure and heart rate), measurements of all tubes, lines, and drains (e.g., urine output) and inclusive of all intravenous and enteral drips. The net gains (all inputs) minus the losses allow daily and length-of-stay volume assessments to be made. Daily weight should also be recorded and compared to the patient's starting or "dry" weight prior to their surgery, if possible. In the postsurgical patient, rapid fluctuations in weight are generally related to changes in TBW. In the absence of any extenuating circumstances (e.g., renal dialysis, kidney transplantation), adequate fluid is usually given to maintain a urine output of greater than 0.5 mL/kg/hr in adult patients.

Urine specific gravity can also be measured and serves as an indicator of both volume status and renal ability to concentrate and dilute the urine. A urine specific gravity of greater than 1.010 to 1.012 indicates that the urine is being concentrated (relative to plasma), and a urine specific gravity of less than 1.010 indicates that dilute urine is being produced.

Renal failure in the postoperative period may be accompanied by low urine volume (oliguric renal failure, <0.5 mL/kg/hr, or <500 mL/day). Additionally, normal or high urine volumes (nonoliguric or high-output renal failure) may also indicate renal dysfunction. Measuring the fractional excretion of sodium compared to creatinine (i.e., FeNa) can help delineate the potential etiology of renal dysfunction by discerning prerenal states (FeNa usually <1%) from acute tubular necrosis (FeNa usually >2%).

$$FeNa = (Urine_{Na})(Serum_{Creat})/(Urine_{Creat})(Serum_{Na})$$

Central venous pressures (CVPs) have also been extensively used to gauge fluid status and responsiveness. Normal CVP may range from 5 to 12 mm Hg. Higher pressures usually indicate volume overload or cardiac failure, whereas pressures below this range indicate intravascular volume depletion. However, the use of CVP measurements alone has been shown to be highly variable and inaccurate in assessing intravascular volume and venous return.

More recently, assessments of fluid status, responsiveness, and overall tissue perfusion are being accomplished by the use of (1) bedside echocardiography (e.g., transthoracic) to measure function through ventricular filling and ejection, (2) ultrasound of the vena caval diameter, and (3) peripheral arterial pulse-volume variability calculations. The latter measures the stroke volume variability (SVV) during the ventilatory cycle via a peripherally placed arterial line. SVV is the calculated percentage of the difference between the maximal and minimal stroke volumes (SVs) divided by the mean SV. This is usually calculated over a time period between 20 and 30 seconds.[37] Use of the SVV has been shown to be a reliable indicator of fluid responsiveness.

The efficacy of these techniques may be altered in abnormal right and/or left ventricular compliance, increased intrathoracic pressure (via elevated levels of positive end expiratory pressure and intraabdominal pressure), valvular heart disease (e.g., mitral stenosis) and cardiac dysrhythmias (e.g.,

atrial fibrillation). In order to solve any serious questions of volume status, the gold standard technique remains pulmonary artery catheterization in the critically ill patient.

Table 11.7 Electrolyte Concentrations in Plasma and Intracellular Compartments

	Normal Ranges	
Solute (mEq/L)	**Plasma**	**Intracellular**
Na^+	135–145	10–15
K^+	3.5–5.0	120–150
Ca^{++}	2.5 (8.5–10.5 mg/dL)	$0.0001–10^{-7}$
Mg^{++}	1.3–1.9	7
Cl^-	98–110	3–20
HCO_3	22–28	10–15
pH	7.37–7.43	7.0–7.2
Osmolarity	280–290	280–290

ELECTROLYTES

8 An electrolyte is defined as a substance that ionizes when dissolved in an appropriate solvent, the most common example being water.

In order to maintain homeostasis, the human body has a complex yet stable arrangement of electrolytes in different concentrations in the intracellular and extracellular environments (**Table 11.7**). In clinical practice, only measurements of serum values (extracellular space excluding the interstitial space) are performed and used to infer disruptions of homeostasis, which cause organ damage. For instance, with hyperkalemia, the serum concentration itself does not directly cause injury. It initiates depolarization

leading to impairment of cardiac conduction resulting in an end pathway of ventricular fibrillation or asystole.

Given that serum derangements can only be discovered if lab evaluation or symptoms are present, it is important to try to anticipate potentially life-threatening electrolyte abnormalities. This is especially important in surgical patients in whom the loss of electrolyte-rich GI fluids occurs and can cause predictable serum derangements (**Table 11.8**).

Table 11.8 Electrolyte Concentrations in Gastrointestinal Secretions

Secretion	Na^+	K^+	Cl^-	H^+	Rate (mL/day)
Salivary	50	20	40	—	100–1,000
Gastric					
Basal	100	10	140	30	1,000
Stimulated	30	10	140	100	4,200
Bile	140	5	100	—	500–1,000
Pancreatic	140	5	75	—	1,000
Duodenum	140	5	80	—	100–2,000
Ileum	140	5	70	—	100–2,000
Colon	60	70	15	—	—

Where Sodium Goes, Water Follows

There is a distinct correlation between sodium and fluid status. This relationship can help establish both the etiology and treatment of various derangements. For example, when thinking about hyponatremia, it is clinically important to assess the patient's volume status as well as check laboratory studies. These include serum sodium, serum osmolality, and urine electrolytes. Other values such as serum glucose, serum protein, and serum

lipids may also help to differentiate hyponatremia from pseudohyponatremia.[38,39]

Pseudohyponatremia

Marked elevations in serum lipid or protein result in a reduction in the fraction of serum that is water/sodium and thus causes a "dilutional" hyponatremia. Examples include hyperlipidemia, hyperproteinemia (e.g., multiple myeloma), hyperglycemia, and mannitol administration. In the case of hyperglycemia, the serum sodium concentration should fall 1.6 mEq/L for every 100 mg/dL rise in serum glucose concentration.

Hyponatremia

The most common pathophysiology is retention of water, which most commonly stems from oral intake or iatrogenic use of intravenous hypotonic fluids. The kidney has an enormous ability to dilute urine, however, in most surgical/trauma patients who experience hyponatremia, there is an inability to suppress ADH, as it is normally elevated during a stress response. In this case, the sodium rarely falls below 130 mEq/L because the hyponatremia itself, as well as volume expansion, decreases the effects of ADH on the renal collecting tubules.

In significant cases (i.e., serum sodium <130 mEq/L) it is helpful to take a more systematic approach. This entails assessing serum and urine osmolality as well as urine sodium (**Algorithm 11.1**).

Symptoms of hyponatremia occur in multiple organ systems including the CNS, GI, and musculoskeletal (**Table 11.9**). In acute hyponatremia, symptoms often start when serum sodium is less than 130 mEq/L; whereas in chronic hyponatremia symptoms typically do not occur until serum sodium is less than 120 mEq/L.

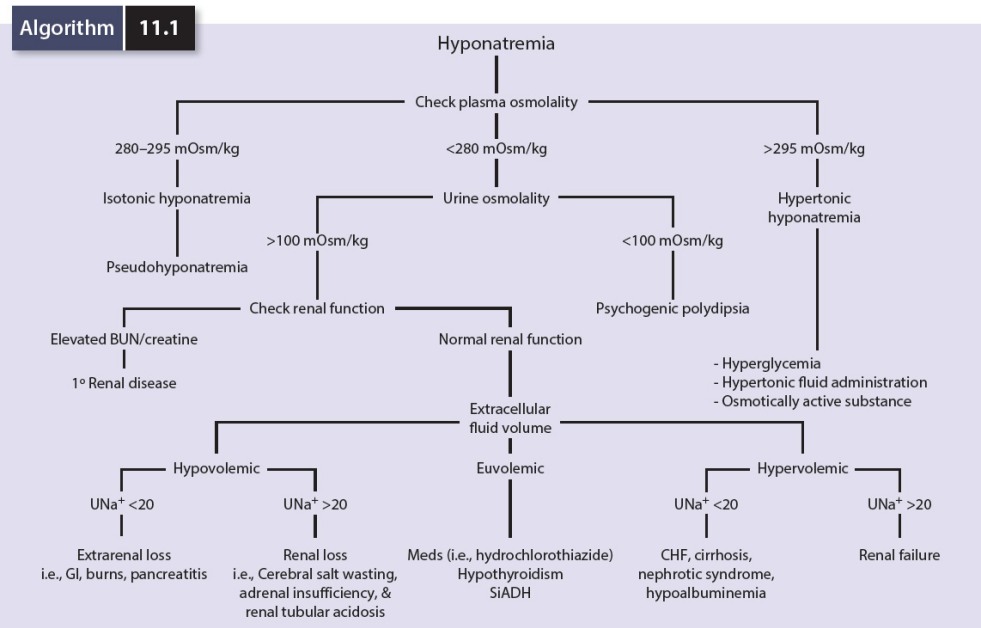
Treatment

Treatment depends on the patient's volume status. Hypovolemic patients are treated by rehydration with isotonic saline, with caution not to correct serum sodium faster than 0.5 mEq/L/hr and less than 10 mEq/L over 24 hours. If correction is faster than this rate the patient may develop *central pontine myelinolysis*. This can lead to "locked in" syndrome, which consists of

quadriplegia, dysarthria, and dysphagia. In order to best prevent this rare, yet highly morbid complication, use of the following calculation is recommended:

Table 11.9 Causes of Hypernatremia

Volume Status	Cause
Low	Free water loss Insensible—skin, respiratory Gastrointestinal loss Excessive hyperosmotic peritoneal dialysis Renal: diuretics, diabetes insipidus, nonoliguric renal failure
Normal	Same as "Low" volume status but with improper correction
High	Free water loss Increased mineralocorticoids—hyperaldosteronism, hypercortisolism Iatrogenic Excessive sodium administration



Algorithm 11.1 Hyponatremia.

$$Na^+ \text{ required (in mEq)} = (\text{Desired } Na^+ - \text{Actual } Na^+) \times \text{TBW}$$

$$\text{TBW} = 0.6 \times \text{Weight (kg)}$$

Rapid correction with 3% or higher-concentration solutions should be avoided unless significant CNS symptoms such as coma or seizures are present and should be done using the calculation above to prevent overcorrection. A reasonable initial dose in an emergent situation would be 100 mL of 3% saline given as a bolus; this can be repeated in 10-minute intervals with definite need for follow-up laboratory evaluation to prevent overly rapid correction.

Cerebral Salt Wasting and Syndrome of Inappropriate Antidiuretic Hormone

Cerebral salt wasting (CSW) and syndrome of inappropriate antidiuretic hormone (SIADH) are both seen in the setting of CNS disease, which is especially pertinent to trauma patients. CSW is much rarer and typically occurs within the first 10 days of CNS insult/injury. The pathophysiology is likely related to impaired sodium reabsorption leading to volume depletion, followed by increased ADH release causing hyponatremia from water retention. Laboratory findings are nearly identical among CSW and SIADH.

Both have elevated urine osmolality compared to serum. However, CSW is associated with ECF depletion and thus hypotension and/or elevated hematocrit, whereas SIADH patients are often net positive in fluid balance. Given the volume status associated with CSW the treatment is usually isotonic fluids which will suppress the release of ADH. On the contrary if isotonic fluid is given for SIADH it can actually worsen the hyponatremia. Other options to treat CSW include salt tablets and if needed fludrocortisone.

The initial treatment for SIADH is often fluid restriction of <800 mL/day. For more significant cases the use of oral salt tablets or 3% hypertonic saline is recommended. Finally, vasopressin receptor antagonists such as Conivaptan (IV) and Tolvaptan (PO) can be used; however, these do carry risks such as hepatotoxicity and can rapidly overcorrect serum sodium levels. Furthermore, they are fairly expensive in the United States and hence should only be used in select cases.[38,40]

Hypernatremia

Although a less common problem in surgical patients, hypernatremia has a variety of etiologies which, like hyponatremia can be categorized based on the patient's volume status (**Table 11.9**). The most common scenario is excessive free water loss associated with hypovolemia.

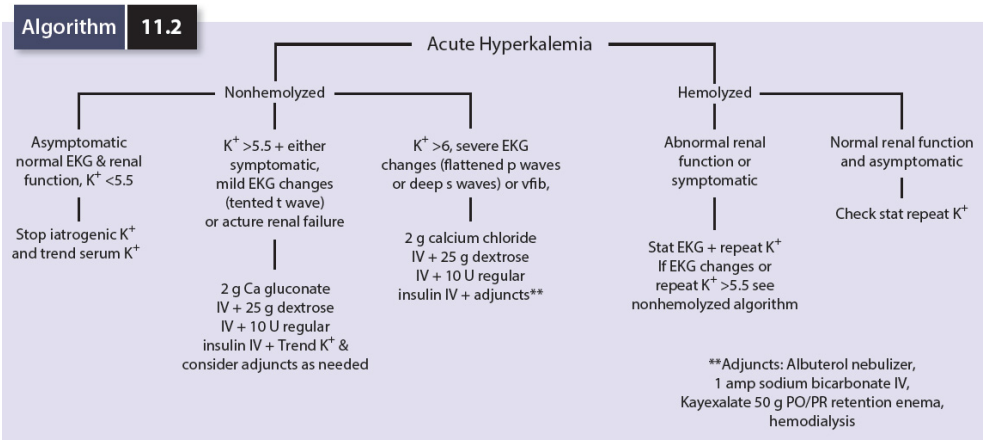
Symptoms of hypernatremia typically do not develop until serum sodium exceeds 160 mEq/L or serum osmolality is higher than 320 to 330 mOsm/kg. Acute hypernatremia can cause symptoms at lower levels than chronic hypernatremia. The majority of symptoms experienced are CNS related with early signs being irritability, restlessness, and spasms. Later symptoms include ataxia and seizures.

The treatment of hypernatremia, like hyponatremia should not occur too rapidly, otherwise complications can ensue. A rate >0.7 mEq/L is considered dangerous as it can lead to cerebral edema and brainstem herniation. The most judicious way to correct hypernatremia involves calculating the free water deficit to obtain a desired sodium level.

$$\text{Water requirement} = (\text{Desired change in } Na^+ \times \text{TBW})/\text{Desired } Na^+$$

$$\text{TBW} = 0.6 \times \text{Weight (kg)}$$

A caveat to this equation is that it does not take into account ongoing free water losses such as urinary or GI loss. Further calculations can be done to quantify urine losses if this is a major concern.



Algorithm 11.2 Acute hyperkalemia.

Potassium

Potassium is the most abundant intracellular cation with a normal intracellular concentration of 150 mEq/L as opposed to an extracellular level ranging from 3.5 to 5 mEq/L. This large gradient produces a strong membrane potential especially in cardiac, skeletal, and smooth muscles. The overall potassium balance is determined by potassium intake and renal/extrarenal excretion. Renal excretion accounts for 90% of excreted potassium. Thus, renal failure leads to hyperkalemia. Humoral factors such as aldosterone, vasopressin, and β-agonists stimulate renal excretion of potassium. Intracellular shifting is another strong causative agent for extracellular potassium change. For instance, insulin and alkalosis both cause K^+ to shift intracellular, one for glycolysis, the other in exchange for H^+ as a buffer. Conversely, acidosis causes K^+ to shift extracellular in exchange for H^+, again to buffer serum pH.

Hyperkalemia

Renal insufficiency is the leading cause of hyperkalemia in surgical patients. Potassium-rich intravenous fluids, especially blood transfusions can also lead to hyperkalemia. Disease processes associated with cellular injury such

as crush injuries, reperfusion syndrome, tumor lysis syndrome, and burns are all potential causes of hyperkalemia. Additionally, medications such as succinylcholine and ACE inhibitors can worsen existing hyperkalemia.

Regardless of the etiology, the common pathway for clinical manifestations is dysfunctional membrane depolarization, the most lethal scenario effecting cardiac membrane depolarization. On an electrocardiogram (EKG) this can be seen in the mildest form with peaked T waves, in a more severe state with flattened P waves, prolongation of the QRS, or deep S waves. The final pathway can yield ventricular fibrillation with or without cardiac arrest.

The initial medication of choice for hyperkalemia is intravenous calcium for membrane stabilization, which lasts approximately 30 to 60 minutes. Subsequent therapy can include insulin coadministered with dextrose, β_2-agonist, and sodium bicarbonate, which are designed to shift extracellular potassium into the intracellular space. Resin-binding agents such as Kayexalate act to decrease potassium absorption and thus are more important in the management of chronic hyperkalemia.[41,42] Loop diuretics can assist by promoting renal potassium excretion, but should only be used if the patient is not hypovolemic. A last resort in situations of complete renal failure or critical levels of potassium is hemodialysis. The treatment utilized depends upon the laboratory value, but more importantly the clinical scenario and EKG findings (**Algorithm 11.2**).

Hypokalemia

Similar to hyperkalemia, manifestations of hypokalemia result from the disturbance in the gradient between intracellular and extracellular potassium. The reference level of 3.5 mEq/L is often cited as the lowermost level of normal serum potassium. Below this level minor disturbances including intestinal ileus, premature ventricular complexes, and nonfatal arrhythmias can occur. Severe cardiac and muscle manifestations often do not occur until levels fall below 2.5 mEq/L. Findings at this dangerous level include significant muscle weakness and major EKG changes. Possible changes include prolonged QT, flattened T waves, ST depression, prominent U waves, and most dangerously ventricular arrhythmias.

Initial treatment consideration must include elucidation of possible etiologies (**Table 11.10**); certain etiologies are especially important, as without correction of the underlying cause, the hypokalemia itself may not be correctable. Examples of this include hypomagnesemia, acute alkalosis, hyperaldosteronism, and mucus secreting villous adenoma. The mainstay of initial treatment for hypokalemia is enteral or intravenous potassium replacement. If the patient is symptomatic, then the replacement or at least a portion of it should be given intravenously to achieve a more rapid effect. Limiting the rate of intravenous potassium infusion is necessary to prevent caustic injury to veins. Maximal recommended rates include 10 to 20 mEq/hr via a peripheral IV or up to 40 mEq/hr via central access.

Table 11.10 Causes of Hypokalemia

Major Causes of Hypokalemia
Vomiting/diarrhea
Diuretics (i.e., loop diuretic)
Catecholamines (endogenous or exogenous)
Renal tubular acidosis
Refeeding syndrome
Insulin
Hypomagnesemia
Acute alkalosis

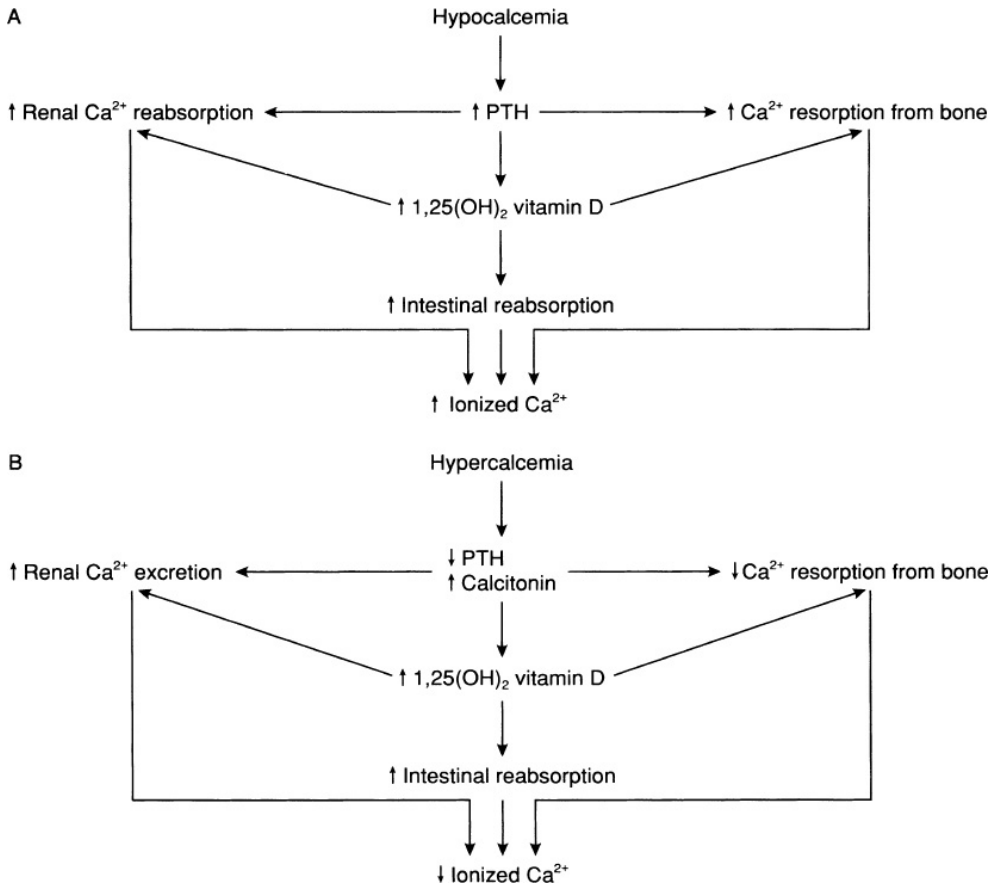


Figure 11.6 Effects of hypocalcemia (**A**) and hypercalcemia (**B**) on the mediators of calcium homeostasis. PTH, parathyroid hormone.

Calcium

Calcium (Ca^{2+}) is essential for human life. Calcium participates in numerous processes including cardiac membrane depolarization, muscle contraction, enzymatic reactions, coagulation, and formation of bone/teeth. Approximately 99% of total body calcium is located in bone. Ionized calcium, which makes up approximately 45% of total calcium, is responsible for most of the physiologic actions of calcium in the body. Normal serum concentration of ionized calcium is approximately 4.5 mg/dL and this level is tightly regulated. Both pH and plasma protein level can affect the proportion of calcium in the ionized state. A change in albumin concentration of 1 g/dL changes protein-bound calcium by 0.8 mg/dL in the same direction. The fundamentals of the regulation of calcium homeostasis are depicted in **Figures 11.6** and **11.7**.

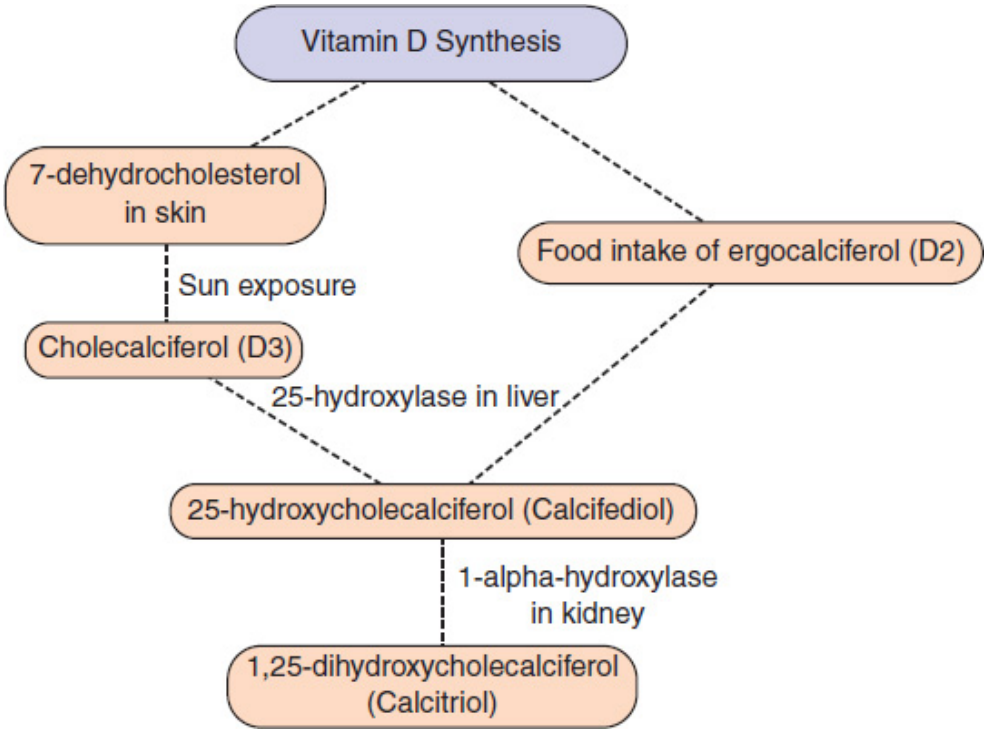

Figure 11.7 Vitamin D synthesis.

Hypercalcemia

The most common causes of hypercalcemia are hyperparathyroidism and malignancy (**Table 11.11**).[43,44]

Primary hyperparathyroidism occurs when one or more parathyroid glands inappropriately produce increased amounts of PTH. Parathyroid adenomas are responsible for ~85% of cases. Chief cell hyperplasia accounts for an additional 15% of cases, while parathyroid cancer is the cause in less than 1% of cases of primary hyperparathyroidism.

Table 11.11 Other Causes of Hypercalcemia

PTH mediated	Lithium Familial hypocalciuric hypercalcemia (FHH)
Cancer	PTHrp-mediated breast, lung, renal cancer Bone metastases Multiple myeloma
Calcitriol mediated	End-stage renal disease Sarcoid/granulomatous Lymphoma (ectopic 1,25 vit D) Milk alkali syndrome Exogenous vitamin D
Other causes	Vitamin A toxicity Thyrotoxicosis Paget disease Adrenal insufficiency Medications (i.e., Thiazide)

Table 11.12 Differential Diagnosis of Hypercalcemia

Cause	Ca^+	Phos	PTH	24-h UCa
Primary PTH	Increased	Decreased	Elevated/normal	Elevated
Secondary PTH	Low or normal (can be high w/ prolonged disease)	High	Elevated	N/A
FHH	Increased	Normal	Elevated/normal	Decreased
PTHrp mediated	Increased	Decreased	Decreased	Elevated
Tertiary PTH	Increased	Decreased	Very Elevated	Elevated

PTHrp, parathyroid hormone-related peptide; UCa, urine Ca^+.

Secondary hyperparathyroidism occurs when there is elevated PTH due to another organ system, namely renal failure. This occurs because of poor

renal excretion of phosphate and decreased intestinal absorption of calcium secondary to impaired renal hydroxylation of vitamin D.

Tertiary hyperparathyroidism is parathyroid hyperplasia with autonomous PTH production. Most commonly, patients who had renal failure with secondary hyperplasia then undergo renal transplant and still have hypercalcemia. This occurs in up to 30% of patients with prerenal transplantation hyperparathyroidism (**Table 11.12**).

Regardless of cause, hypercalcemia has characteristic clinical manifestations that affect various organ systems. Classically taught as "stones, moans, and psychiatric undertones," meaning renal, abdominal/GI, and neuropsychiatric manifestations (**Table 11.13**). The earliest symptoms are usually neuromuscular and mild GI symptoms. Cardiac and renal complications typically occur later in disease progression.

Treatment

Serum calcium concentration >14 mg/dL requires prompt treatment. If combined with hyperphosphatemia, this situation is even more concerning due to the potential for metastatic calcification. Initial treatment should include aggressive hydration with 0.9% normal saline with 20 mEq/L potassium with a goal of hydration to promote a urine output greater than 200 mL/hr. Once the patient is adequately hydrated a trial of furosemide can be performed as long as a positive fluid balance is maintained, and potassium and magnesium are adequately replaced. Other adjuncts include calcitonin (especially for inhibition of bone resorption), bisphosphonates (especially to treat malignancy), and in patients with renal failure the use of low-calcium dialysate. Patients with hematologic malignancies and granulomatous disease can be considered for treatment with steroids. Lastly, for those with hyperparathyroidism, parathyroidectomy of some form is clearly indicated, with operation type dependent upon whether the etiology is adenoma or hyperplasia. In medically refractory secondary or tertiary hyperparathyroidism, total parathyroidectomy with parathyroid autotransplantation or sub-total parathyroidectomy should be considered.[46]

Table 11.13 Signs and Symptoms of Hypercalcemia	
Constitution symptoms	Weakness, fatigue, anorexia
CNS	Drowsiness, lethargy, altered mental status, stupor, coma
Cardiac	Short QT interval
Renal	Nephrolithiasis, polyuria, renal failure, nephrogenic diabetes insipidus, nephrocalcinosis
GI	Constipation, abdominal pain, pancreatitis
Ophthalmologic	Calcium deposits in cornea

Hypocalcemia

There are many causes of hypocalcemia (**Table 11.14**). Other factors can affect the serum calcium level as mentioned previously, namely pH and albumin. In critically ill patients the incidence of hypocalcemia can be up to 85%. From a surgical perspective the most common causes are postsurgical, including hungry bone syndrome and loss of calcium from circulation.

Postsurgical hypocalcemia can occur in any neck surgery, although the incidence is higher with parathyroidectomy. In non-neck surgery hypocalcemia can occur because of hypoalbuminemia; this does not affect ionized calcium levels. Other postsurgical causes of hypocalcemia include atrophy of the remaining parathyroid glands (i.e., after removal of a large parathyroid adenoma), venous congestion, devascularization or *hungry bone syndrome*. Transient hypoparathyroidism is seen in up to 20% of thyroid cancer surgery; this is permanent in 1% or less of cases.

Table 11.14 Causes of Hypocalcemia	
Low PTH (hypoparathyroidism)	Postsurgical (thyroidectomy, parathyroidectomy, radical neck dissection, hungry bone syndrome) Autoimmune Infiltration of the parathyroid gland (granulomatous, iron overload, metastases) Radiation-induced destruction parathyroid glands HIV infection
High PTH (secondary hyperparathyroidism in response to hypocalcemia)	Vitamin D deficiency Pseudohypoparathyroidism Hypomagnesemia Renal disease Loss of calcium in circulation (i.e., hyperphosphatemia, tumor lysis, acute pancreatitis, osteoblastic metastases, acute respiratory alkalosis, sepsis)
Drugs	Bisphosphonate, calcitonin, phenytoin, foscarnet, calcium chelators

Other surgery-related etiologies include pancreatitis, small bowel fistula, renal failure, massive transfusion of blood, and severe hypomagnesemia. Pancreatitis-induced hypocalcemia occurs due to calcium precipitation in peripancreatic tissue. Small bowel fistula can lead to hypocalcemia by loss of calcium-rich effluent and vitamin D deficiency from malnutrition. Renal failure hypocalcemia is due to deficiency in 1,25-dihydroxyvitamin D and hyperphosphatemia. Massive transfusion hypocalcemia does not affect total

calcium but decreases ionized calcium as a result of citrate binding to ionized calcium.

Symptoms typically do not occur until calcium levels are below 8 mg/dL. Chronic symptoms include cataracts, dental changes, and extrapyramidal disorders. Symptoms of acute hypocalcemia are tetany, papilledema, and seizures. Tetany is defined as repetitive discharges after a single stimulus. Tetany usually does not occur until ionized calcium is less than 4.3 mg/dL or serum total calcium is less than 7.0 mg/dL. Alkalosis also plays a strong role in the development of tetany, even beyond its association with hypocalcemia, as tetany is rarely seen in renal failure patients despite low calcium levels. This is likely due to the protective effect of concurrent metabolic acidosis. The earliest symptoms of hypocalcemia are perioral and acral paresthesias. Motor symptoms such as *Trousseau sign* (induction of carpopedal spasm by inflation of sphygmomanometer above systolic pressure for 3 minutes) and *Chvostek sign* (tap facial nerve and ipsilateral facial muscles twitch) occur later. Of note, Chvostek sign is seen in up to 10% of normal patients. The last findings to occur are cardiac, in the form of ST segment prolongation (**Table 11.15**).[45]

Asymptomatic hypocalcemia needs no treatment as it is most commonly attributed to hypoalbuminemia with normal ionized calcium. Symptomatic hypocalcemia is best treated with intravenous infusion of calcium gluconate or calcium chloride. Calcium chloride is faster acting as it does not require hepatic metabolism to dissociate into an active form, hence is usually the drug of choice if severely symptomatic. A study during the anhepatic stage of liver transplantation found equally rapid increase in calcium after administration of calcium chloride and gluconate.[46] Calcium chloride carries a higher risk of irritation of veins and tissue damage should extravasation occur; hence calcium gluconate should be the drug of choice except in emergent situations. In order to minimize caustic damage to veins, any form of calcium should be administered at a rate not to exceed 1.5 mEq/min. If prolonged calcium replacement is needed it is recommended to check vitamin D levels and replace any deficiency with calcitriol, in addition to giving an oral form of calcium such as calcium carbonate, calcium citrate, or calcium lactate.

Table 11.15 Clinical Manifestations of Hypocalcemia	
Acute	Neuromuscular Paresthesia (initially perioral) Seizures Tetany (i.e., Trousseau/Chvostek sign) Pulmonary Laryngospasm, bronchospasm Cardiac Prolonged QT, hypotension, heart failure, arrhythmias Ocular Papilledema
Chronic	Abnormal dentition Extrapyramidal signs Ectopic calcification Subcapsular cataracts

Magnesium

Half of the total body magnesium is confined to bone. Most of the remaining magnesium is intracellular, with less than 1% of total body magnesium found extracellular. Magnesium is primarily absorbed in the small intestine and is influenced by 1,25-dihydroxyvitamin D3. The other source of magnesium is bone.

Hypermagnesemia

Outside of renal failure, hypermagnesemia is rare, as the kidneys have a strong ability to excrete large amounts of magnesium. Instances do occur with severe burns, crush injuries, or other causes of rhabdomyolysis but usually in the setting of renal insufficiency. Symptoms of hypermagnesemia include loss of deep tendon reflexes at levels greater than 8 mg/dL. Once levels are greater than 12 mg/dL paralysis can occur. Cardiac arrest can occur if levels exceed 18 mg/dL. The mainstay of treatment is intravenous calcium to

antagonize the effect of magnesium, volume expansion or loop diuretic depending on volume status, correction of acid–base disturbances and if needed, hemodialysis.

Hypomagnesemia

Kidneys are also able to conserve magnesium quite well with about 40% reabsorption in the proximal tubule. Most instances of hypomagnesemia occur with chronic malnutrition, prolonged intravenous fluid replacement without magnesium, and loop diuretics. Other causes include pancreatitis and diabetic ketoacidosis (DKA). Magnesium functions as a cofactor for many neuromuscular functions, thus deficiency can lead to muscle fasciculation or tetany. The treatment depends on the severity, which includes taking into account symptoms and magnesium level. For instance, if serum magnesium level is less than 1 mEq/L or if the patient is hemodynamically unstable or is in a torsade de pointes arrhythmia then immediate infusion of intravenous magnesium sulfate is indicated. The maximum recommended rate would be 150 mg/min excluding the above emergent situations where it can be given as IV push or over 5 minutes for torsade de pointes. If the patient has chronic or mild hypomagnesemia, oral doses of magnesium should be used, with options including magnesium oxide, magnesium chloride, and magnesium hydroxide (milk of magnesia) depending on side-effect profiles. It should be noted that doses greater than 80 mEq/day can become cathartic.

ACID–BASE

An acid is defined as a chemical that can donate a hydrogen ion (H^+), for example, HCl and H_2CO_3. A base is a chemical that can accept an H^+, for example, OH^- and HCO_3^-. Bases are commonly anions, but neutral substances can also function as bases (e.g., ammonia and creatinine). Some chemicals do not fit the classic definition of an acid, although they retain acidic properties when dissociated in water. For example, when $CaCl_2$ is dissolved in water, the Ca^{2+} accepts OH^- to form $Ca(OH)_2$.

The concentration of hydrogen ions [H^+] determines the acidity of a solution. The pH is the negative logarithm of [H^+] expressed in moles per

liter (mol/L). The concentration of H^+ in biologic systems is in the range of nanomoles (10^{-9} mol) per liter (nmol/L). The degree to which an acid dissociates determines its strength.

The *Henderson–Hasselbalch* equation describes pH as a measure of acidity in a biologic system.

$$pH = pK_a + \log_{10} ([A^-]/[HA])$$

pK_a = Negative log of the acid dissociation constant

A^- = Conjugate base

HA = Acid–base pair

Table 11.16 HCO_3^- and PCO_2 Derangements in Primary and Secondary Acid–Base Disturbances

		Primary		Secondary	
Disorder	pH	HCO_3^-	PCO_2	HCO_3^-	PCO_2
Metabolic acidosis	↓	↓			↓
Metabolic alkalosis	↑	↑			↑
Respiratory acidosis	↓		↑	↑	
Respiratory alkalosis	↑		↓	↓	

Buffer Systems

Buffers are chemicals in solution that tend to minimize changes in pH that would otherwise occur after the addition of acid or alkali. For instance, if a strong base is added to a weak acid, the base is neutralized:

$$NaOH - H_2CO_3 \rightarrow NaHCO_3 + H_2O$$

One type of buffer is a mixture of a weak acid and its salt. The presence of such buffer systems in the body is crucial in minimizing changes in pH, which can be deleterious to cell function.

The principal intracellular buffers are organic phosphates, bicarbonate, and peptides. In addition, hemoglobin functions as a significant buffer in red blood cells. The major extracellular buffer is bicarbonate. An approximation of the total body buffer capacity is 15 mEq/kg. More than half of the total body alkaline buffer content is located outside the ECF and may in large part reside in bone.[50] The buffer pair carbonic acid/bicarbonate (H_2CO_3/HCO_3^-) is the primary buffer system of the body.

From a chemical point of view, the ideal buffer should have a pKa that allows normal physiologic pH. The H_2CO_3/HCO_3^- buffer system has a pKa of only 6.1, which is not the normal body pH. That said, this buffer system is efficient because of the presence of large amounts of bicarbonate, the conversion of its acid H_2CO_3 to CO_2 that is rapidly excreted through the lungs, and an inexhaustible supply of CO_2 from metabolism.

Acid–Base Disturbances

9 There are four primary acid–base disturbances, each of which are related to changes in either $[HCO_3^-]$ or PCO_2. These are categorized as metabolic and/or respiratory (**Table 11.16**). A metabolic acidosis is a decrease in pH as a result of a relative decrease in $[HCO_3^-]$, whereas a metabolic alkalosis is an increase in pH caused by a relative increase in $[HCO_3^-]$. A respiratory acidosis is a decrease in pH secondary to a relative increase in PCO_2, and a respiratory alkalosis is an increase in pH caused by a relative decrease in PCO_2. In each of these disorders, compensatory changes occur to minimize changes in the relative ratio of $[HCO_3^-]$ to PCO_2 and thereby blunt the effect of the primary disturbance on pH (**Table 11.17**).[47,48]

Metabolic Acidosis

Anion Gap

The difference in the measured serum cations and anions yields the anion gap. This can be utilized to identify the etiology of a metabolic acidosis. The most common equation used in practice is as follows:

$$\text{Anion gap} = [Na^+] - ([Cl^-] + [HCO_3])$$

The normal value of serum anion gap is approximately 3 to 10; however, each laboratory should establish its own normal. If one includes potassium in the equation then the normal value should be increased by about 4 mEq/L. The differential for an elevated anion gap acidosis includes: lactic acidosis, salicylate poisoning, acute or chronic kidney disease, chronic acetaminophen ingestion, ketoacidosis (i.e., diabetic), and acute or chronic kidney disease. A common mnemonic used to address etiologies is the acronym: MUDPILES: methanol, uremia, diabetic ketoacidosis, propylene glycol, isoniazid, lactic acidosis, ethylene glycol, and salicylates.

Mechanisms of Metabolic Acidosis

Four mechanisms result in a decrease in extracellular bicarbonate concentration and metabolic acidosis:

1. Dilutional acidosis. Rapid infusion of an alkali-free solution results in dilution of the bicarbonate concentration.
2. Increased acid generation (e.g., lactic acidosis, ketoacidosis, salicylate poisoning).
3. Diminished renal acid excretion (e.g., renal failure or type I renal tubular acidosis [RTA]).
4. Decreased body bicarbonate content (e.g., severe diarrhea, fistula, type II RTA).

Table 11.17 Compensatory Mechanisms

Disorder	Compensation	Time
Metabolic acidosis	PCO_2 = serum HCO_3^- + 15 PCO_2 = 1.5 × serum HCO_3^- + 8 ± 2	12–24 h
Metabolic alkalosis	0.7 mm Hg PCO_2 per 1 mEq/L HCO_3^-	12–24 h
Acute respiratory alkalosis	2 mEq/L HCO_3^- per 10 mm Hg PCO_2	<3 days
Chronic respiratory alkalosis	4–5 mEq/L HCO_3^- per 10 mm Hg PCO_2	3–5 days
Acute respiratory acidosis	1 mEq/L HCO_3^- per 10 mm Hg PCO_2	<3 days
Chronic respiratory acidosis	~4 mEq/L HCO_3^- per 10 mm Hg PCO_2	3–5 days

The most common example of a dilutional acidosis is large resuscitation with normal saline, which causes a hyperchloremic acidosis. Clinically significant metabolic acidosis in surgical patients is most commonly related to net loss of bicarbonate. One means of classification would be renal acidosis versus extrarenal acidosis. Renal acidosis is not as readily compensated because the kidney's ability to regulate acid/base is compromised. Extrarenal acidosis can be further subdivided into increased acid production (e.g., lactic acidosis in shock) or increase bicarbonate loss (e.g., fistula).

Nonrenal Loss of Bicarbonate

Diarrhea, intestinal or pancreatic fistulas, and burns can cause metabolic acidosis secondary to loss of bicarbonate. Urinary diversion with segments of GI tract (ureterosigmoidostomy and ureteroileostomy) can result in loss of bicarbonate with reabsorption of NH_4Cl from the urine. The potential for fistulas to result in metabolic acidosis depends on the concentration of bicarbonate in the fluid and the rate of external drainage. For instance, metabolic acidosis is less common with biliary fistulas than pancreatic fistulas.

Ketoacidosis

Ketoacids are produced from the beta oxidation of fatty acids with subsequent formation of acetoacetate and β-hydroxybutyrate. During prolonged starvation, production of ketoacid increases to modest levels. In DKA, the ketoacid production is excessive because of insulin deficiency, which drives ketoacid production. The resulting osmotic glucose diuresis causes increased renal excretion of sodium, potassium, and water. Despite total body potassium depletion, serum potassium concentration is often increased in DKA secondary to metabolic acidosis, renal insufficiency, insulin deficiency, and hyperosmolality. These pathophysiologic changes result in the typical clinical presentation, which includes dehydration, polyuria, polydipsia, hyperglycemia, hyperventilation, and metabolic acidosis with an increased anion gap.

Lactic Acidosis

Lactic acid is one of the most common causes of metabolic acidosis.[49] Lactic acidosis commonly occurs in patients with sepsis[50] and hemorrhagic shock.[51] Its levels have been shown be highly predictive of outcomes in shock states.[51] In the setting of hypoxia, the cellular dependence on anaerobic metabolic pathways increases generating lactic acid. This process is directly correlated with the total oxygen debt, degree of hypoperfusion, and the severity of shock.[49] Lactic acidosis must be addressed by optimizing tissue perfusion with volume resuscitation. Upon restoring adequate perfusion, the lactic acid is rapidly metabolized by the liver and cleared from circulation normalizing the serum pH level.

Renal Acidosis

The most common renal-associated acidosis in surgical patients is that of acute or chronic renal failure. One of the kidney's many important functions is to excrete acid. When GFR decreases so does the ability to excrete acid, thus causing a metabolic acidosis.

The impaired ability of the kidney to excrete acid may be secondary to a decrease in the number of functioning nephrons and is termed RTA. Type I (distal) RTA is most commonly caused by autoimmune diseases (e.g., Sjögren disease or rheumatoid arthritis) and hypercalciuria in adults. Distal RTA leads to impaired distal acidification.

Type II (proximal) RTA is caused by a reduction in proximal bicarbonate reabsorption—the most common cause in adults being monoclonal gammopathies or medications such as carbonic anhydrase inhibitors.

Clinical Features of Acute Metabolic Acidosis

The major cardiovascular effects of acute metabolic acidosis are peripheral arteriolar dilatation, decreased cardiac contractility, and central venous constriction. These can lead to cardiovascular collapse and pulmonary edema. In addition, metabolic acidosis can increase oxygen delivery by shifting the oxygen–hemoglobin dissociation curve to the right.

Renal Compensation

The kidney is extremely sensitive to changes in serum bicarbonate concentration and responds by increasing net acid excretion primarily in the form of ammonia excretion. Maximal renal compensation requires 2 to 4 days. In addition, the maximal amount of ammonia excreted during acidosis depends on factors such as glutamine delivery, GFR, and the type of anion that accompanies the acid.

Respiratory Compensation

A decrease in blood pH causes an immediate stimulus to hyperventilate. Although effective in promptly raising blood pH, early ventilatory compensation is only partial. Full respiratory compensation can occur in 12 to 24 hours. The magnitude of the decrease in PCO_2 in response to a given

degree of metabolic acidosis can be used to determine whether the metabolic acidosis is complicated by coexisting respiratory acidosis or respiratory alkalosis. There are multiple equations that can describe this relationship:

$$\text{Arterial } PCO_2 = \text{Serum } HCO_3^- + 15$$

$$\text{Arterial } PCO_2 = 1.5 \times \text{Serum } HCO_3^- + 8 \pm 2 \text{ (Winter equation)}$$

The PCO_2 can fall no lower than 8 to 12 mm Hg in response to a severe metabolic acidosis and this compensation can only be maintained for a limited period due to respiratory muscle fatigue.

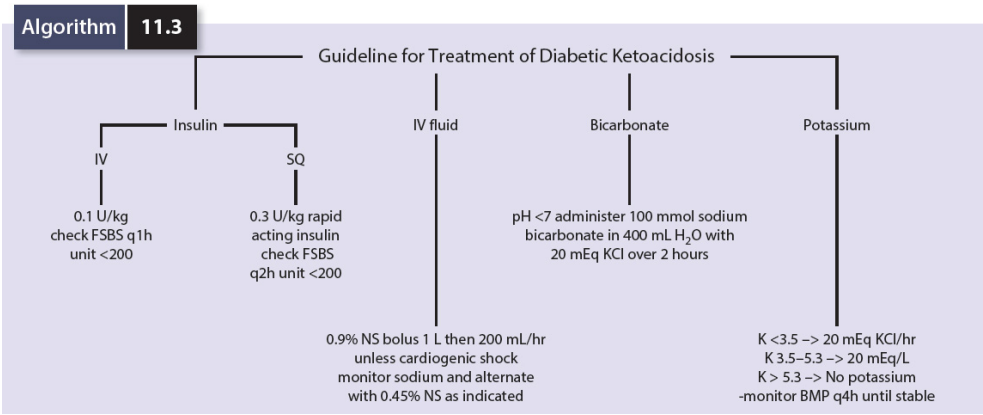
Treatment of Acute Metabolic Acidosis

Volume resuscitation alone may be enough to correct this acidosis. Attempts to correct acidosis with exogenous bicarbonate without addressing inadequate tissue perfusion will be unsuccessful. Furthermore, exogenous administration of bicarbonate may cause a superimposed respiratory alkalosis and a deleterious left shift of the oxygen–hemoglobin dissociation curve, by not allowing reversal of 2,3-diphosphoglycerate depletion, hence resulting in tissue hypoxia (**Algorithm 11.3**).

Metabolic Alkalosis

Sustained metabolic alkalosis occurs only if extracellular bicarbonate concentration is increased and renal excretion of excess bicarbonate is inhibited. Extracellular bicarbonate concentration increases can occur through several mechanisms. In surgical patients, loss of HCl is a frequent cause of metabolic alkalosis, most commonly due to vomiting or nasogastric drainage in the presence of gastric outlet obstruction. External loss of gastric acid results in a net gain in bicarbonate (generated by equimolar gastric secretion of HCl), which causes alkalosis. Although the kidney can excrete excess bicarbonate, this must be accompanied by excretion of sodium. Renal excretion of sodium is limited in the presence of the volume depletion that occurs with external losses of gastric secretion. As volume depletion progresses, sodium is conserved in exchange for hydrogen, and urine will

become acidic, even in the presence of severe metabolic alkalosis. This phenomenon is referred to as *paradoxical aciduria.*



Algorithm 11.3 Guidelines for the treatment of diabetic ketoacidosis.

Increased extracellular bicarbonate concentration can occur with administration of either bicarbonate or precursors of bicarbonate, such as lactate, citrate, or calcium carbonate, or as a result of increased renal production of bicarbonate. Conditions in which acid excretion exceeds endogenous acid production and in which the renal threshold for bicarbonate reabsorption is increased can result in metabolic alkalosis. Such conditions include moderate potassium depletion, excess mineralocorticoids, and high PCO_2.

Hypokalemia and cellular exchange of potassium for hydrogen can also lead to metabolic alkalosis. Hypokalemia results in enhanced proximal tubular bicarbonate reabsorption and distal tubular acid excretion. When potassium leaves the cell, it is exchanged for either sodium or hydrogen to maintain electrical neutrality. Loss of potassium from the body then results in a net gain in bicarbonate in the ECF.

Maintenance of elevated extracellular bicarbonate concentration can occur by a number of mechanisms. Volume contraction leads to decrease in renal blood flow and GFR thus reducing the filtered load of bicarbonate. This, in addition to increased proximal tubular reabsorption of bicarbonate, maintains high extracellular concentrations of bicarbonate. High PCO_2 causes an increase in renal threshold for bicarbonate secondary to decreased intracellular pH of the renal tubular cell. The net result is increased bicarbonate reabsorption.

Diuretics can cause or exacerbate metabolic alkalosis by both causing rapid contraction of intravascular volume and increasing renal excretion of acid. Chloride deficiency is another common factor that maintains an alkalotic state. In some instances of metabolic alkalosis, urinary excretion of chloride is markedly reduced. Reversal of metabolic alkalosis in these cases can be readily achieved by administration of chloride-containing solutions. Metabolic alkalosis can be categorically divided into chloride-responsive and chloride-resistant types.

Clinical Features

Clinical signs of metabolic alkalosis may not be prominent because the condition usually develops slowly. If acute, CNS manifestations of confusion, obtundation, stupor, and coma may be present as well as tetany or neuromuscular irritability.

Respiratory Compensation

Respiratory compensation for metabolic alkalosis should raise the PCO_2 by 0.7 mm Hg for every 1 mEq/L elevation in serum HCO_3^-. Typically the arterial PCO_2 does not go above 55 mm Hg. Among the four major acid–base disorders, this compensatory mechanism is the least effective.

Treatment

Correction of the underlying cause is the mainstay of treatment in this disorder. In general, correction of potassium depletion and volume depletion corrects the metabolic alkalosis. Renal excretion of bicarbonate cannot occur in the face of persistent volume depletion. Volume depletion should be corrected with chloride-containing solutions. In patients without intravascular volume deficits, renal excretion of bicarbonate can be enhanced by administration of the diuretic, carbonic anhydrase inhibitor acetazolamide. In extremely rare circumstances where renal excretion of bicarbonate cannot be increased because of underlying renal insufficiency or if the metabolic alkalosis is severe, acid may be administered to titrate in opposition the excess extracellular bicarbonate. Acids that can be used include ammonium chloride, arginine hydrochloride, lysine hydrochloride, or

dilute hydrochloric acid (0.1N). Partial correction of the alkalosis is the initial goal and a specialist should be involved prior to instituting this care. In the face of frank renal failure, dialysis may be necessary to remove excess bicarbonate.

Respiratory Alkalosis

Respiratory alkalosis is defined as increased extracellular pH secondary to decreased PCO_2 with hyperventilation. Hyperventilation and the ensuing fall in PCO_2 may be secondary to hypoxia, reflex stimulation from decreased pulmonary compliance, drugs, mechanical ventilation, or other causes.

Hypoxia stimulates ventilation through peripheral chemoreceptors in the carotid and aortic bodies. Decrease in arterial partial pressure of oxygen (pO_2), rather than in oxygen content, is the main stimulus. Acute drops in arterial pO_2 result in sustained hyperventilation only when the PCO_2 decreases below 60 mm Hg. Although hyperventilation occurs with even slight degrees of hypoxia, the resulting increase in brain pH suppresses the stimulus for hyperventilation unless severe hypoxia is present. In contrast, chronic hypoxia results in hyperventilation even with mildly decreased PCO_2 because brain pH is lowered by metabolic compensation. The two most common causes of hypoxia resulting in respiratory alkalosis are pulmonary disease and exposure to high altitudes.

Clinical Features

Chronic respiratory alkalosis is usually asymptomatic because compensatory mechanisms are successful in maintaining pH close to normal. Acute respiratory alkalosis may cause sensations of breathlessness, dizziness, and nervousness and can result in circumoral and extremity paresthesias, altered levels of consciousness, and tetany. These signs are related to decreased cerebral blood flow secondary to the decreased PCO_2 and decreased ionized calcium concentration secondary to the increased blood pH.

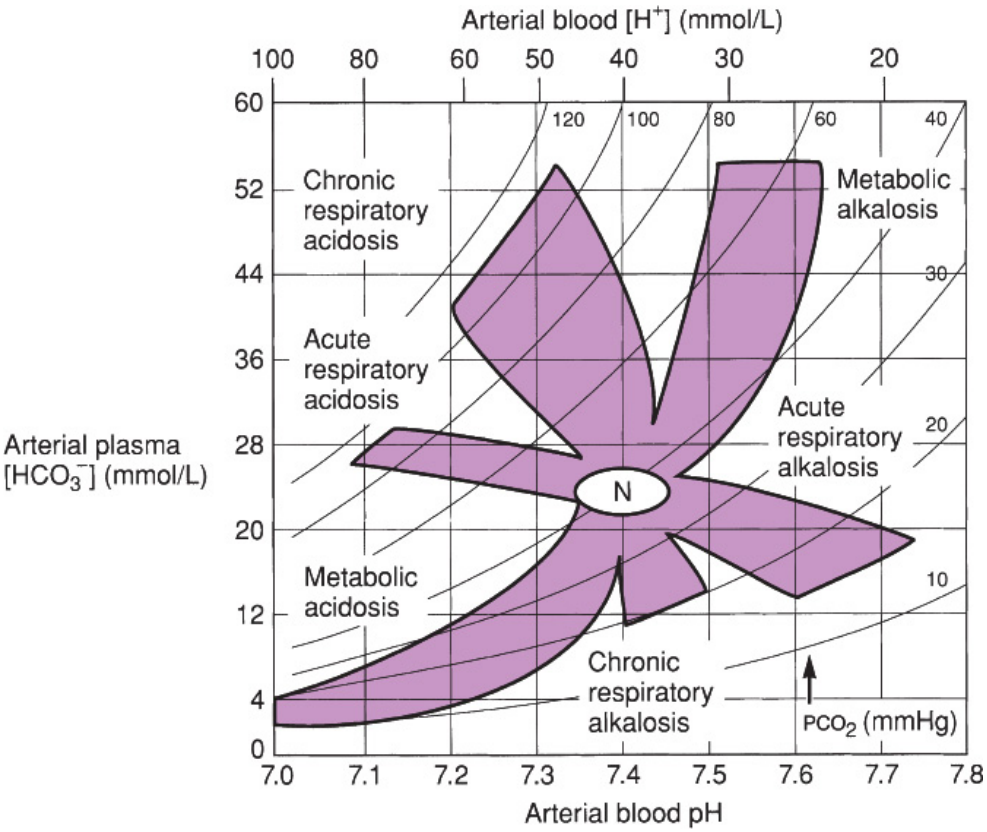


Figure 11.8 Acid–base nomogram. Shown are the 95% confidence limits of the normal respiratory and metabolic compensations for primary acid–base disturbances. (Reproduced with permission from Cogan MG, Rector FC Jr. Acid–base disturbances. In: Brenner BM, Rector FC Jr, eds. *The Kidney*. Philadelphia, PA: WB Saunders; 1986:473.)

Compensatory Mechanisms

Tissue buffering is the initial response to a decrease in PCO_2. Red blood cells provide one-third of the buffering. Consumption of bicarbonate results from cellular liberation of H^+. The magnitude of tissue buffering is weak compared with renal compensation. This is accomplished not by increasing bicarbonate excretion but by decreasing net acid excretion, namely ammonia. Acute compensation is not as strong as chronic compensation, which takes at least 3 days to occur.

Acute compensation: Decrease serum HCO_3^- by 2 mEq/L per 10 mm Hg reduction in PCO_2

Chronic compensation: Decrease serum HCO_3^- by 4 to 5 mEq/L per 10 mm Hg reduction in PCO_2

Treatment

The underlying stimulus for the hyperventilation should be addressed. The cause of hypoxemia should be determined and corrected. In acute symptomatic respiratory alkalosis, rebreathing or breathing 5% CO_2 temporarily relieves symptoms. If the condition is secondary to mechanical ventilation, decreasing tidal volume or respiratory rate should result in resolution of respiratory alkalosis.

Respiratory Acidosis

Respiratory acidosis is defined by a decrease in extracellular pH from a primary increase in PCO_2, due to inadequate ventilation. Causes of hypoventilation include CNS depression, impaired pulmonary mechanics, airway obstruction, and chronic obstructive pulmonary disease (COPD). In addition, inappropriate ventilator settings may result in respiratory acidosis in patients on mechanical ventilation.

Clinical Features

The magnitude of clinical manifestations depends on the chronicity and rate of development of respiratory acidosis. Acute increases result in cerebral acidosis, manifested by drowsiness, restlessness, and tremor, as well as stupor or coma in more severe cases. Cerebral vasodilation occurs in response to acidosis, resulting in increased cerebral blood flow. This may, in turn, result in increased intracranial blood pressure, headache, and papilledema. Systemic acidosis results in peripheral vasodilatation, depressed cardiac contractility, and insensitivity to catecholamines.

Compensatory Mechanisms

Increased pCO_2 results in increased H_2CO_3, which dissociates into H^+ and HCO_3^-. Cellular exchange of Na^+ and K^+ for H^+ allows the reaction to continue in this direction with increased extracellular bicarbonate. This tissue buffering is accomplished within minutes. Persistently elevated PCO_2 also stimulates increased renal acid excretion, primarily the chloride salt of

ammonia, and results in increased renal generation of HCO_3^-. Full renal compensation occurs over 3 to 5 days.

Acute compensation: 1 mEq/L HCO_3^- per 10 mm Hg PCO_2

Chronic compensation: ~4 mEq/L for every 10 mm Hg PCO_2

Treatment

Treatment should be directed to the underlying cause of hypoventilation. Endotracheal intubation to achieve adequate ventilation is paramount to the treatment of acute respiratory acidosis of any cause. In select cases of respiratory acidosis, namely patients with COPD, noninvasive positive pressure ventilation (i.e., CPAP/BiPAP) has proven effective. However, patients must be able to protect their airway and have no major concern for aspiration (i.e., not appropriate in the setting of a bowel obstruction). Furthermore, there must be close follow-up to ensure the acidosis is resolving.

The treatment of chronic, compensated respiratory acidosis may be complicated by the accompanying hypoxemia. In chronic hypercapnia, the central chemoreceptors may be insensitive, and the accompanying hypoxemia may supply the main respiratory drive through stimulation of peripheral chemoreceptors. In such patients, complete correction of the hypoxemia may further suppress respiration and worsen the respiratory acidosis. In addition, PCO_2 should not be normalized rapidly. Equilibration of cerebral bicarbonate concentration lags behind systemic changes. Thus, even if PCO_2 is normal, cellular and cerebral metabolic alkalosis may develop.

Mixed Acid–Base Disorders

Combinations of two or more of the four primary acid–base disorders may occur and should be suspected when blood pH approaches normal despite abnormal PCO_2 and [HCO_3^-], or when compensatory changes appear to be either excessive or inadequate (**Fig. 11.8**).

Burns: Medical, Surgical, Critical Care and Reconstruction of the Burn Patient

Naveen F. Sangji, Stewart C. Wang, and Benjamin Levi

Key Points

1. Most chemical injuries should be treated with dilution of the chemical rather than neutralization.
2. Frostbite outcomes are improved if patients with threatened extremities are treated with tPA within 24 hours of injury.
3. Resuscitation is of crucial importance for burn patient outcome and physicians must be aware when to begin resuscitation (>20% total body surface area [TBSA]) and to monitor the patient response to avoid overresuscitation.
4. Early excision and grafting within 72 hours of the injury remains a pillar of burn care.
5. Order of burn coverage can affect patient outcome and can help prevent the patient from needing a tracheostomy.
6. New technologies have a role to play in scar rehabilitation, improving quality and pain associated with these scars.

INTRODUCTION

Burn injuries represent a major source of trauma, subsequent scarring and debilitation throughout the world. Improved worker safety programs, fire prevention efforts, and fire detection systems have significantly decreased the prevalence of major burn injuries. Burn survival has also been impacted by improvements in surgical critical care in areas such as lung protective ventilation, blood glucose control, and antibiotic stewardship. Overall, survival after burn injuries remains high, leading to a need for improved reconstructive treatment options for burn survivors.

EPIDEMIOLOGY

According to the Centers for Disease Control and Prevention (CDC), approximately 489,000 people received medical treatment for burns in the

United States in 2017.[1] Overall, more than 67% of reported cases had burn sizes <10% total body surface area (TBSA).[2] Men account for 67% and women account for 33% of reported injuries. Men make up the majority of burns in every age group except for those aged >80 years. Of those injured, 59% are Caucasian, 21% are African American, and 11% are Hispanic. The cause of these burn injuries vary with 41% from fire or flame burns, 35% from scald burns, 10% from contact burns, and 7% from electrical and chemical burns. Approximately 13% of these injuries are work related. The majority of all burn injuries happen at home. In 2018, there were 40,000 hospital admissions and 3,655 deaths from fire and smoke inhalation.[3] Of the patients who died, 74% of the deaths resulted from home fires, an increase of 3% from 2017. An estimated 13% of deaths were due to highway vehicle fires.

As in other trauma populations, children are affected to a greater degree. Children under 16 years of age comprise 26% of total burns, and adults 20 to 59 years make up 55% of burns. Older adults >60 years represent 15% of cases, but 37% of deaths from burns. Fire/flame is the most common etiology of injury for adults, whereas children under the age of 5 years typically suffer from scald burns caused by spilling of hot liquids. With improved surgical critical care and understanding of burn injury physiology, over 96% of burn patients survive.

Children

Burns are the fifth leading cause of unintentional nonfatal injury in infants and the third leading cause of fatal injury for newborns to children 9 years of age. Scald burns caused by hot liquids are the most common cause of pediatric burns and occur most often in the home.[2,4,5] The number of burns decreases from age 9 until adolescence and increases again after the age of 15, presumably due to greater exposure to hazards, experimentation, risk-taking, and employment.[6] Intentional burns account for around 10% of all cases of child abuse.[7] Scalds from hot bath immersion are the most frequent cause of these cases. Other common etiologies of intentional burns include contact with heated objects including cigarettes, irons, and heated kitchen utensils.

Adults

Flame burns are the most common cause of burns in adults and the elderly. Cigarette ignition of upholstered furniture or bedding account for 47% of fires and alcohol appears to be a significant contributor.[8]

Older Adults

The burn-related mortality rate increases greatly for adults aged 60 years or older. The mortality rate for a burn >20% TBSA is 15% for adults 60 years and older.[2] Individuals over the age of 65 comprise 12% of all burn unit admissions. The average age of those admitted is 76 ± 7 years.[9] The most frequent cause of burns that led to death in elderly women is clothing ignition during cooking.[10] Elderly burn patients treated for scald burns had relatively small burns (<13% of TBSA) but high mortality rates (30%).[11–13] Overall, burns are the fourth leading cause of mortality among the elderly population. Those aged 80 years and older have an overall mortality rate of 20% from burn injury. The mortality rate for a burn >20% TBSA is >60% for those aged 80 or older.

Race and Ethnicity

Differences exist in the susceptibility to burns by race and ethnicity. Burns are the leading cause of injury-related death in Black children between the ages of 1 and 9 and the rates are 2.7 times higher than in White, Hispanic, and Asian/Pacific Islander children.[14] In the pediatric population, for children under the age of 16 who sustain burns, non-White children exceed white children in each age group.[2] Likewise, in adults, the rate of burns in Black Americans aged 35 to 39 years was 221 per 100,000 Blacks, which is remarkably higher than the 135 per 100,000 Whites with burns in the same age group. The emergency room visit rate for burns from 1993 to 2004 in the United States was 62% greater among Black Americans (340 per 100,000 Black Americans) than White Americans (210 per 100,000 White Americans).[15] The age-adjusted death rate from burns of all causes in the United States in 2018 was highest in Blacks (1.6 per 100,000) and lowest in

Asians (0.3 per 100,000), with Native Americans (1.1 per 100,000), and Whites (1.1 per 100,000) falling in between this range.[6]

Socioeconomic Status

Socioeconomic status (SES) factors such as low household income, crowded household living conditions, and unemployment also increase the risk of burns. Children in the lowest SES groups requiring hospitalization for treatment in U.S. burn centers is twice the proportion of all children in the general population.[3] Furthermore, the incidence of house fires was eight times greater in low-income families compared to high incomes.[16] The higher incidence of house fires has been attributed to the frequent absence of functioning smoke detectors.[16]

ETIOLOGY

Numerous modalities, including fire or flame, scalds, contact, electrical conduction, and chemicals can produce burns. Between 2008 and 2017, 41% of burns were produced by fire or flame, 35% by scald, 10% by contact, and 7% by electricity and chemicals.[2]

Burns are caused by contact of heat, cold, or chemicals with the cutaneous surface of the skin. The depth of the burn injury is proportional to the temperature and duration of exposure. Burn depth is also dependent on the body region due to differences in skin thickness and blood flow.

Scald burns are most commonly caused by water in the community. Once the water temperature exceeds 156°F, only 1 second is needed for a full-thickness burn injury. The difference in contact time underlines the importance of making sure that hot water heaters are set at a low enough temperature to minimize childhood bath and shower scald injuries (120°F). It takes 3 minutes for a burn to occur from 120°F whereas it takes only 1 second for a burn to occur from 156°F water.

Though water scalds do not always cause full-thickness injury due to the variation in temperature, grease burns almost uniformly cause a deep partial- or full-thickness burn. Grease is usually 400°F and thus even minimal exposure will cause significant thermal injury. Tar and asphalt also exceed

400° to 500°F making them a high burn injury risk for industrial workers. Water and grease injury sites should be cleansed with aqueous solutions. Tar, however, requires a petroleum-based solution to remove it from the burn wound.

Flame Burns

Thermal injuries, caused by fire or flames, are the most common burn etiology reported over the past decade.[2] These injuries usually occur as a result of flammable liquids, motor vehicle crashes, cooking fires, or if bedding/clothes ignite. Flame injuries are associated with the highest risk of death and complications compared to all other burn etiologies. When evaluating thermal injuries, it is important to consider the possibility of smoke inhalation as its presence significantly impacts the morbidity and mortality of patients with flame burns. Inhalation injury occurs in 17% of patients with flame burns. The presence of smoke inhalation in burn patients is associated with an overall mortality rate of 24%, compared to the mortality rate of 4% in those patients without smoke inhalation.

Contact Injuries

Contact burns occur as the result of direct contact with hot surfaces and material, most frequently glass, metal, or plastic. The depth of the injury depends on the heat of the material and the length of contact. Frequent sites of injury include the palms of the hands as people, especially toddlers, will often fall with outstretched hands. Other commonly seen contact injuries are due to hot metal devices such as space heaters, curling irons, motorcycle exhaust systems, and vaping devices.

Electrical Burns

Electrical injuries occur more frequently in adults than children, since most result from occupational exposure. Patients who have high-voltage electrical injuries, defined as greater than 1,000 V, are at elevated risk of spine fracture injury due to tetany and require complete immobilization until vertebral injury is ruled out. Providers must also evaluate patients with high-voltage

injuries for cardiac damage. Direct muscle injury from current flow may cause gross myoglobinuria, requiring more aggressive fluid resuscitation.[17] Patients with gross myoglobinuria often require fasciotomy of affected limbs and a severe electrical injury often requires monitoring in the intensive care unit. Bone has the highest conductance and electricity flows along the skeleton causing significant muscle necrosis adjacent to the bone. TBSA involved is not necessarily associated with prognosis and it does not quantify damage to deep tissues in electrical injuries.

Thermal injuries occur as electricity can generate temperatures over 100°C. Electroporation occurs as electrical force drives water into lipid membrane causing cell rupture. Tissue resistance in decreasing order includes bone, fat, tendon, skin, muscle, vessel, and nerve. Bone heats to a high temperature and burns surrounding structures such as muscle, leading to muscle swelling and compartment syndrome which are common in high-voltage electrical injuries.

Electrical exposure can cause significant injuries to other organ systems. Arrhythmias are common at the scene (any voltage) or in the hospital (high voltage ≥1,000). Heart rhythm should be monitored continuously for at least 24 hours if cardiac injury is suspected at the scene or if a high-voltage injury has occurred. Ventricular fibrillation and asystole are the most common and advanced cardiac life support should be instituted immediately. Coronary artery spasm and myocardial injury and infarction have also been described. A normal cardiac rhythm on admission, however, means dysrhythmia is unlikely and thus 24-hour monitoring is not needed.[18] Additionally, injury to solid organs, acute bowel perforation, and gallstones after myoglobinuria have been described. Myoglobinuria from other causes require increased fluid administration; however, burn resuscitation usually provides adequate fluid. Given that electrical injury only patients often do not exceed 20% TBSA, fluid for high-voltage injuries should be given to maintain urine output of 75 to 100 cc/hr. Cataracts are also a long-term adverse effect of electrical injury necessitating an ophthalmology evaluation and follow-up.

When taking the patient to the operating room for debridement and grafting of electrical injuries, the physician should perform serial debridements and allow the tissue to completely declare itself which takes longer than a typical flame scald or flame burn. These injuries will often evolve with progressive muscle necrosis over time, thus early grafting (within the first week) often

fails to fully close the burn wound. These injuries have similarities to crush injuries and thus multiple trips to the operating room for debridement should not be viewed as a failure.

1 Chemical Burns

General Approach to Chemical Burn Treatment

Health care providers should use personal protective equipment—always considering that the chemicals are still present and must be neutralized or temporized. With few exceptions (see below), all chemical burns should be copiously irrigated with water. Water dilutes but does not neutralize the chemical and cools the injured area. Neutralization of the chemical is generally contraindicated because neutralization may induce a hyperthermic reaction leading to further thermal injuries. Water irrigation, however, is contraindicated or ineffective following exposure to elemental sodium, potassium, and lithium (precipitates an explosion). Dry lime should be brushed off, not irrigated. Phenol is water insoluble and should be wiped from the skin with polyethylene glycol–soaked sponges.

Types of Chemical Burns

Alkali causes liquefaction necrosis and protein denaturation and is found in oven and drain-cleaning products, fertilizers, and industrial cleaners. Alkali injuries extend deeper into tissues following exposure and are especially disruptive to eyes. **Acids** cause damage to tissue via coagulation necrosis and protein precipitation. Acid burns tend to be self-limited secondary to pain as the patient will quickly react to the offending agent. **Organic compounds (**phenol and petroleum**)** cause damage due to fat-solvent action (cell membrane–solvent action) and systematic absorption with toxic effects on the liver and kidneys. These agents also can cause significant erythema in the surrounding areas that can be mistaken for cellulitis.

Specific Types of Chemical Burns

Hydrofluoric acid is a potent and corrosive acid used for rust removal, glass etching, and to clean semiconductors. It is a weak acid but the fluoride ion is

toxic as it leaches calcium from cells. Hydrofluoric acid causes severe pain and local necrosis and should be treated with copious water irrigation. The fluoride ion is neutralized with topical calcium gel (one ampule of calcium gluconate in 100-g lubricating jelly). If symptoms persist, intra-arterial calcium infusion (10-mL calcium gluconate diluted in 80 mL of saline, infused over 4 hours) and/or subeschar injection of dilute (10%) calcium gluconate solution should be administered. Fluoride ion binds free serum calcium and thus it is crucial to make sure to check the serum calcium and replace with IV calcium as needed.

Phenol is commonly used in disinfectants and chemical solvents; it is an acidic alcohol with poor water solubility. Phenol causes protein disruption and denaturation resulting in coagulation necrosis. Systemically, phenol can cause cardiac arrhythmias and liver toxicity. Thus patients should have cardiac and liver function monitored. Additional adverse effects include renal injury and demyelination. Given phenol's anesthetic effect, pain is not a reliable indicator of injury. Treatment is copious water irrigation and cleansing with 30% polyethylene glycol or ethyl alcohol.

Tar is used in the paving and roofing industry and can be heated to 260°C (~500°F) prior to application. Tar causes thermal injury and then solidifies as it cools, often becoming enmeshed with hair and skin. Patients with tar injuries should be cooled with copious water irrigation to stop the burning process. Tar removers promote micelle formation to break the tar–skin bond. Sterile surfactant mixture (De-Solv-it or Shur-Clens) allows tar to be wiped away quickly. Wet dressings using polysorbate (Tween 80) or Neomycin cream for 6 hours prior to tar removal can also be effective.

White phosphorus is used to manufacture military explosives, fireworks, and methamphetamine. Obvious particles should be brushed off. Skin should be irrigated with a 1% to 3% copper sulfate solution. Copper sulfate stains the particles black for identification. Copper sulfate will also prevent ignition when particles are submerged in water. After copper sulfate irrigation, the exposed area should be placed in a water bath and the white phosphorous removed.

Anhydrous ammonia is an alkali used in fertilizer. Skin exposure is treated with irrigation and local wound care. Exposure is associated with rapid airway edema, pulmonary edema, and pneumonia. It is important to consider early intubation for airway protection in these cases.

Methamphetamine injuries have been on the rise. In addition to these compounds being highly flammable, exposure to methamphetamines causes tachycardia (greater than expected with a similar sized burn), hyperthermia, agitation, and paranoia. Any suspicion of chemical injury to the globe should be treated with prolonged irrigation with Morgan lenses. Eyelids may need to be forced open due to edema or spasm. Utilize topical ophthalmic analgesic and consult an ophthalmologist.

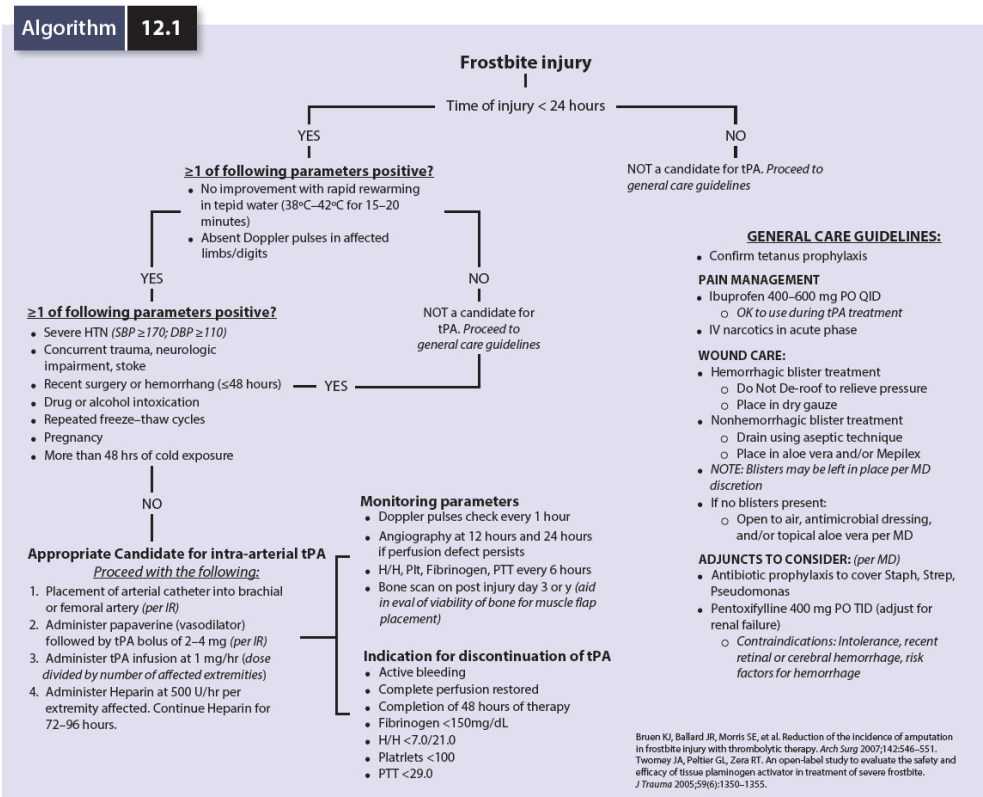
2 Frostbite

Frostbite injuries frequently result in severe ischemic damage of distal extremities. Frostbite classification is similar to that of burn injury (**Table 12.1**).

Historically, frostbite patients have been managed expectantly with long periods of observation followed by amputation of devitalized tissue. Recent advances with interventional radiology, thrombolytic therapy, and nuclear medicine have changed the treatment paradigm and protocol for these patients (**Algorithm 12.1**). Current treatment paradigms for patients with frostbite include rapid rewarming of affected area in 104° to 108°F water bath, not radiant heat as well as ibuprofen 400 mg, elevation of the limb, tetanus prophylaxis, and appropriate referral. If the patient has severe frostbite within the last 24 hours, the patient should be transferred to a center with interventional radiology expertise. Once they arrive, these patients should receive an arterial line (usually brachial or femoral) and intra-arterial tPA which treats the microvascular thrombosis.[19] Additionally, patients might benefit from nitroglycerin to treat the vasospasm. Patient should return to the interventional radiology suite after 12 hours to evaluate progress and potentially treat again. In general, tPA is stopped after 48 hours. After 5 to 7 days, a nuclear bone scan can help assess the extent of deeper tissue necrosis as the more superficial tissue will often appear worse than the actual extent of the injury.[20]

Table 12.1 Classification of Frostbite Injury

Degree	Depth	Clinical Characteristics
First	Very superficial	Central area of pallor; anesthesia of the skin surrounded by edema
Second	Superficial; no tissue loss	Large blisters containing clear fluid surrounded by edema and erythema. The blisters may form an eschar, but this later sloughs off, revealing healthy granulation tissue
Third	Deeper; tissue loss	Smaller blisters, hemorrhagic, more proximal. The skin forms a black eschar in one to several weeks
Fourth	Extends to muscle and bone	Mummification in 4–10 days



Algorithm 12.1 Protocol for frostbite injury.

PHYSIOLOGY OF BURNS

Burn Shock

Most patients with large burn or inhalation injuries will meet criteria for systemic inflammatory response syndrome (SIRS). Burn shock does not equate to septic shock in the acute setting as true sepsis from a burn injury with subsequent infection usually does not occur until after the first 48 to 72 hours.

Burn shock is unique in the degree of vascular permeability coupled with increased hydrostatic pressure.[21] This increased permeability is thought to result from the release of histamine from mast cells in burned skin following burn injury.[22] Histamine interferes with the venous tight junctions and thereby allows efflux of fluid and proteins causing intravascular hypovolemia despite total-volume hypervolemia.

Platelet activation products such as eicosanoids and serotonin also act to increase pulmonary vascular resistance and amplification of the vasoconstrictive effects of norepinephrine and angiotensin II.[23] In addition to the increased vascular leak, platelet-activating factor in addition to clotting factor dysregulation creates a hypercoagulable state with bleeding that resembles disseminated intravascular coagulation. This coagulation disorder is further amplified if patients become hypothermic during their resuscitation.[24] Thus, patient temperature monitoring and maintenance is crucial during resuscitation.

Changes in cardiac output are also seen in burn patients acutely as patients often have an increase in heart rate and systemic vascular resistance but hypovolemia. Though not defined as "cardiogenic shock," cardiac function is altered due to inflammatory mediators.[25–27] With appropriate burn resuscitation, cardiac output should return to normal levels within 24 to 72 hours.

Metabolic Response to Burn Injury

A physiologic response unique to burn injury is the extent of hypermetabolism. This hypermetabolism is characterized by increased body temperature, glycolysis, gluconeogenesis, proteolysis, lipolysis, and prolonged substrate cycling.[28,29] The degree of the hypermetabolic response is proportional to the size of burn injury and appears to plateau at 70% TBSA. Overall the basal level of glucose is elevated despite a high insulin state which can complicate outcomes and exacerbate muscle catabolism.

Lipolysis also occurs at a rate that is higher than normal due to abnormal substrate cycling. This results in an accumulation of triglycerides causing steatosis. Recent work to combat this peripheral lipolysis has had some success using propranolol.[30]

Proteolysis is increased in burn patients compared to nonburn patients. This is due to a combination of increased muscle breakdown and increased plasma protein production by the liver.

Catecholamines are also significantly elevated following a burn injury and are thought to play a role in the hypermetabolic response. Burn injuries also cause alterations in diurnal glucocorticoid levels leading to persistent hypercortisolemia.

There are three ways to influence hypermetabolism: nutrition, medication, and surgery as discussed in subsequent sections in the chapter.

Immunologic Response to Burn Injury

The immune system in burn patients demonstrates significant dysregulation that may explain their increased risk of infection. Serum levels of IgA, IgG, and IgM are decreased indicating decreased B-cell function. T-cell function or cell-mediated immunity is also impaired that is why prolonged homograft and xenograft take is seen. Interleukin 2 (IL-2) production is also decreased whereas IL-10 is increased. Similar to other types of nonthermal trauma, burn patients also have elevated tumor necrosis factor alpha and IL-6. With regard to the innate immune system, polymorphonuclear neutrophils have impaired chemotaxis as well as decreased oxygen consumption and impaired bactericidal capabilities.

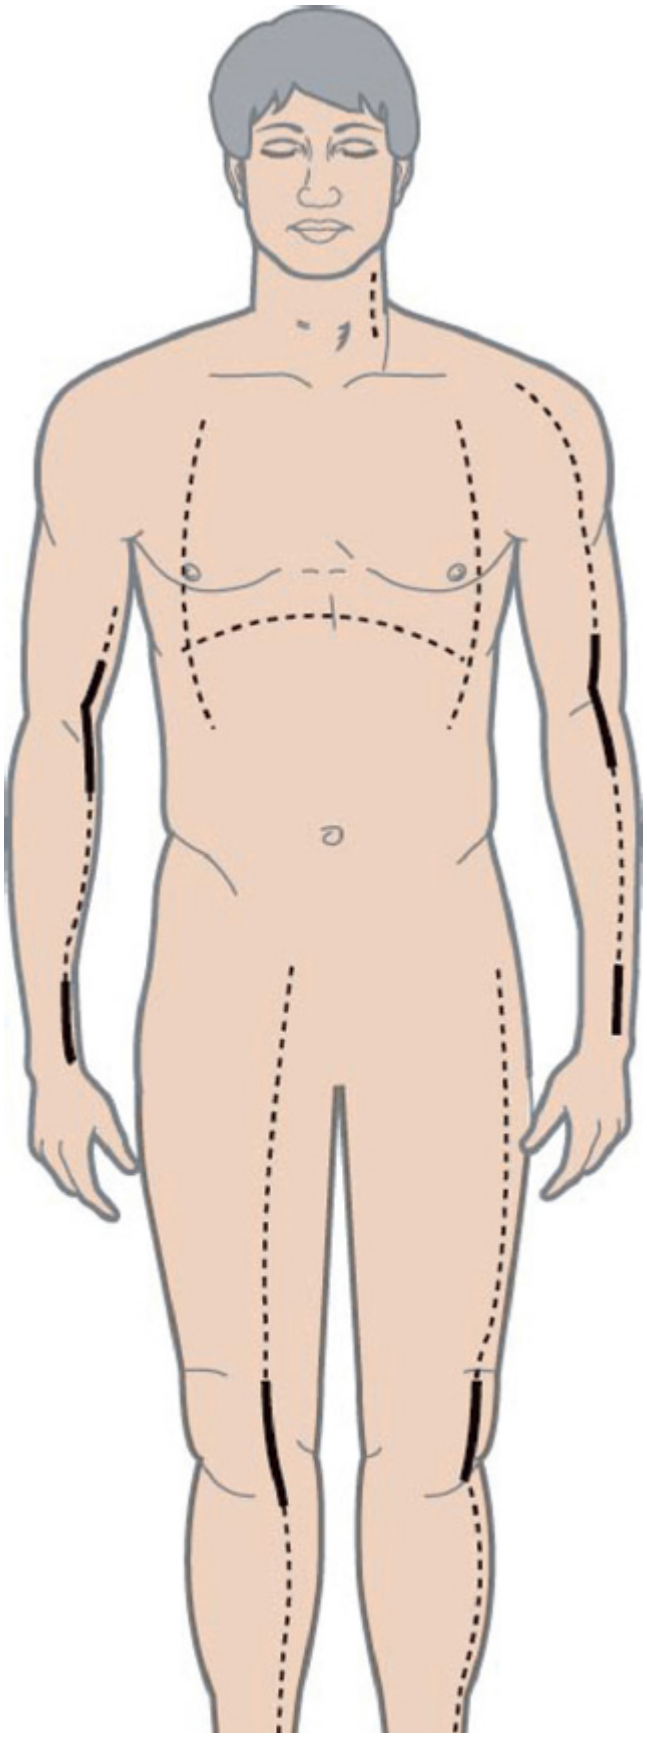
EMERGENCY CARE

The initial care in the field and emergency room is similar to that of any trauma patient. The airway should be stabilized, IV access should be obtained, concomitant life-threatening injuries should be ruled out, and escharotomies should be performed if there are any circumferential areas of full-thickness injury. Escharotomies should be placed on the lateral aspects of the extremities avoiding the sites of potential nerve and large vessel injury (**Fig. 12.1**). Escharotomies should be extended across the chest if there is full-thickness injuries and if difficulty ventilating arises. Abdominal escharotomies can also help with ventilation. Guidelines from the American College of Surgeons Advanced Trauma Life Support and the American Burn Association Advanced Burn Life Support programs have standardized the care of trauma patients and have improved overall patient outcomes. A complete history and physical examination should be performed with specific focus placed on the cause and timing of the injury, risk of smoke inhalation injury, concomitant injuries, and treatments including intravenous fluids received prior to patient arrival. The primary goal is to stabilize the patient, ensure standard injury assessment, and transfer to a burn center if

necessary. The American Burn Association (ABA) has published criteria to follow regarding when to transfer a patient to a verified burn center that is listed in **Table 12.2**.[31]

Table 12.2 American Burn Association Burn Center Referral Criteria

1. Over 10% total body surface area (TBSA) partial- or full-thickness burns
2. Burns that involve difficult anatomic sites such as the face, hands, feet, genitalia, perineum, or major joints
3. Full-thickness burns in any age group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in patients with pre-existing medical conditions that could complicate management, prolong recovery, or affect mortality
8. Any patient with burns and concomitant trauma. If, however, the coincident trauma is of greater risk to mortality, the patient should be stabilized prior to transfer. Physician's judgment will be necessary and should be in concert with the regional medical control plan and triage protocols
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or rehabilitative intervention



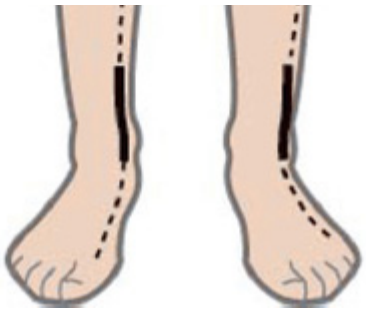


Figure 12.1 Incision lines for escharotomies. In general incisions should be kept on the lateral aspect of extremities to avoid damage to neurovascular structures.

Airway Assessment

Primary survey assessment should begin with evaluation of the airway. Inhalation injuries occur in approximately 10% of all burn patients, but are notably present in 70% of those who eventually die of their burn injury.[32] Thus, it is important to specifically note such findings as soon as the patient presents. Risk for inhalation injury can be first assessed by the history. In general, patients burned outside (not in an enclosed space) very rarely suffer inhalational injuries. If, however, the patient was in a burning home or a burning building, one's suspicions should be raised. Close physical examination should note facial burns, changes in voice, shortness of breath, singed nasal vibrissae, carbonaceous sputum, and intraoral swelling. If these findings are present and the patient appears to be in distress, oral intubation should be performed immediately by an experienced airway physician. In addition to a laryngoscope, the trauma team should have a video laryngoscope available and a surgeon present in case a surgical airway is required. If the patient is not in extremis and the level of inhalation injury is unknown, nasoendoscopy or bronchoscopy should be performed to directly visualize the airway and vocal cords. If significant swelling exists and the patient is expected to receive a large-volume intravenous fluid resuscitation, the airway should be immediately secured. If a patient is transferred with an endotracheal tube that the accepting physician feels is no longer needed, a spontaneous breathing trial should be performed followed by direct laryngoscopy to assess for cord swelling and assessment for a cuff leak should be performed before removing the endotracheal tube.

Oxygenation in a burned patient may be altered by carbon monoxide (CO) poisoning. Physical examination findings include red lips and altered mental status. Formal diagnosis should be based on history and evidence of carbon monoxide levels in the blood. Carbon monoxide binding is assessed by measuring the level of carboxyhemoglobin in a peripheral arterial blood gas sample. Symptoms of CO poisoning typically begin with headaches at levels around 10%, while CO in the blood becomes lethal at around 50% to 70%. The half-life of CO is normally 4 hours when breathing room air, however its half-life is shortened considerably with administration of supplemental oxygen. Treatment with 100% oxygen (FiO_2 100%) reduces the half-life of CO to 30 to 90 minutes. Hyperbaric oxygen treatment can reduce the half-life of CO to 15 to 23 minutes. However, if the patient has additional burn injuries or is unstable, the patient should not be placed in a hyperbaric chamber. Also, the time needed to transfer patients to hyperbaric facilities and the subsequent difficulty of resuscitating a critically ill patient in a closed chamber make hyperbaric oxygen an impractical option. Therefore, prompt and aggressive evaluation and maintenance of the airway is the most important initial step in management of a burn patient.

3 Fluid Resuscitation

It is important to have large-bore IV access with 16G or 18G peripheral IVs. Intravenous access catheters should preferentially be placed in nonburned areas of skin although this is not always possible. If the patient is going to require invasive hemodynamic monitoring, a central line should be placed under sterile conditions. Peripherally inserted central catheter (PICC) lines can be used in burn patients, however, their infection rate remains high. If a central line is used, this does not need to be changed out at a certain time point but rather should be monitored daily for signs of infection. Minimally invasive monitoring of cardiac output is helpful. Though several technologies exist including esophageal Dopplers, arterial waveform monitors, and thermodilution modalities, the trend of these values are more useful than the absolute value. Burn injury and soft tissue edema make noninvasive blood pressure measurement difficult and inaccurate, hence arterial line placement is frequently necessary.

The Parkland or Consensus Formula is most commonly used to estimate fluid requirements for the first 24 hours and should be used to guide initial fluid infusion rates. This is a start point and should not be construed as a dogmatic prescription of the total fluid volume to be given during the first day after injury. It is extremely important to note the original time of the injury is what is used in the calculation, not the time of initial presentation to care providers. Only partial- and full-thickness burns are totaled to calculate burned TBSA.

Consensus formula: First 24-hour requirement = 2–4 cc × %TBSA × weight (kg)

Half of this fluid volume is planned to be administered in the first 8 hours after burn injury and the second half is administered over the next 16 hours. For example, if a 70-kg patient with 20% TBSA burn sustained at 10 AM presents 2 hours later, the crystalloid fluid to be administered in the first 8 hours is calculated using the following formula: [(4 cc × 20% × 70kg)/2]/6 hours. Lactated Ringer's crystalloid solution is recommended as the first choice fluid to avoid complications associated with metabolic acidosis when using normal saline or abnormal fluid shifts with colloid fluids.[33] Currently the data do not support hypertonic saline, dextran, or albumin during the first 24 hours of resuscitation in standard clinical situations.[34,35] Studies, however, have suggested that limited albumin usage may play a role in reducing the rate of abdominal compartment syndrome when the patient requires substantially more fluid administration than estimated by the Parkland Formula (>1.5 times).[36–38] Additionally, D5LR is commonly used for maintenance fluids in children under 1 year of age to avoid hypoglycemia. After 24 hours, there are data to suggest that providing albumin reduces fluid requirement.

Once resuscitation is initiated, the patient's vital signs and urine output should be closely monitored and laboratory studies should be drawn frequently, since proper fluid resuscitation should be guided by overall clinical response and the trend of vital signs as well as several laboratory values (**Table 12.3**). Intravenous fluid infusion rate should be increased or decreased based on the response of the patient on an hourly basis with fluid administration titrated to maintain urine output goals of 0.5 to 1 mL/kg/hr in

adults and 1 to 1.5 mL/kg/hr in children. Blood pressure and heart rate should also be monitored, however, burn patients are often tachycardic regardless of the degree of resuscitation. Though the urine output is considered a "gold standard," it often lags behind and thus it may be necessary to increase fluid administration to compensate for increased urine output on occasion. In addition, close monitoring of the patient's laboratory parameters are necessary to determine the trend in organ perfusion (**Table 12.3**). Although any one of these values alone does not provide a sensitive marker of the patient status, trending these values during resuscitation can help direct resuscitation adjustments if the current fluid rate is causing a positive trend.

In the second 24 hours, all patients should receive crystalloid fluids that are sufficient to maintain urine output and parameters of perfusion including lactate, pulse volume variation, and cardiac output. This will often be at a maintenance rate plus adjustment for losses of fluid into the burn wound. Nutritional support should be started enterally within 24 hours. After 24 to 36 hours, fluids can be decreased by one-third as long as the patient continues to make adequate urine, and cut again for hours 36 to 48. Colloid can be given after initial crystalloid resuscitation (5% albumin at 0.3 to 0.5 mL/kg per %TBSA over 24 hours).

After 48 hours, fluids should be given to maintain urine output at 0.5 to 1 mL/kg body weight per hour. Insensible losses and hyperthermia are associated with hyperdynamic state and increased fluid requirements. Daily patient weights can be helpful to determine insensible fluid loss or retention.

Pediatric fluid resuscitation does have some differences with regard to fluid management. Due to the limited reserve in children under 20 kg, an additional glucose-based maintenance fluid is recommended based upon patient using D5-containing solutions. Additionally, their fluid requirements may be as high as 6 mL/kg per TBSA and their urine output should be 1.0 to 1.5 mL/kg/hr.[39] Since burn resuscitation should be considered in the setting of a 10% TBSA in children, transfer to a burn center is recommended.

Pulmonary status is also an indicator of fluid status but in a delayed fashion. Complications such as pulmonary edema result from fluid overload and necessitate daily evaluation of oxygen requirements and ventilator settings.

Difficult to Resuscitate Patients

If the fluid resuscitation required during the first 24 hours is 1.5 times greater than initially estimated or >6 cc/kg/hr, the physician should reassess the clinical picture. If estimates predict these high levels of fluid will be given, clinicians should consider changing the crystalloid to colloid. Additionally, continuous renal replacement therapy (CRRT) should be considered for cases where excessive fluid is estimated and the patient has kidney injury.[40] Giving excessive crystalloid fluids and failure to use appropriate early resuscitation adjuncts is associated with significantly worse outcomes. Physicians often will give additional fluid due to low urine output not realizing that the kidney, like other organs during burn shock often lag behind the clinical picture. Specific complications associated with excessive resuscitation include compartment syndrome of both the extremities and the

abdomen. Signs of abdominal compartment syndrome include abdominal distention, decreased urine output, elevated ventilator pressures, and desaturations. Surgeons should have a low threshold to assess for this devastating complication in any patient requiring resuscitation above the Parkland formula. Diagnosis can be made both by observing clinical signs as well as by assessment of bladder pressure transduced through a Foley catheter. Pressures over 20 mm Hg are considered abnormal and pressures greater than 25 mm Hg with evidence of organ failure indicate the urgent need for intervention. Strategies to intervene should begin with decreasing the rate of fluid administration. If the patient has full-thickness burns on the abdomen or torso, escharotomies should be performed. The bed should be reclined and a chemical paralytic can be given to relax the musculature. If elevated bladder pressures remain despite these maneuvers, a decompressive laparotomy is often required. Some surgeons will attempt decompression with a suprapubic peritoneal drainage catheter; however, the morbidity of these procedures is significant in burn patients. Therefore, attempts should be made to minimize fluid overload with early vigilant monitoring of fluid administration.

When patients are difficult to resuscitate, additional monitoring devices can be used including monitors of cardiac output and cardiac index. Examples include esophageal Doppler, bedside echo, and a formal transthoracic echo. Serial echo examinations after providing a fluid bolus allow monitoring of cardiac filling, IVC variation, and wall motion changes.[41,42]

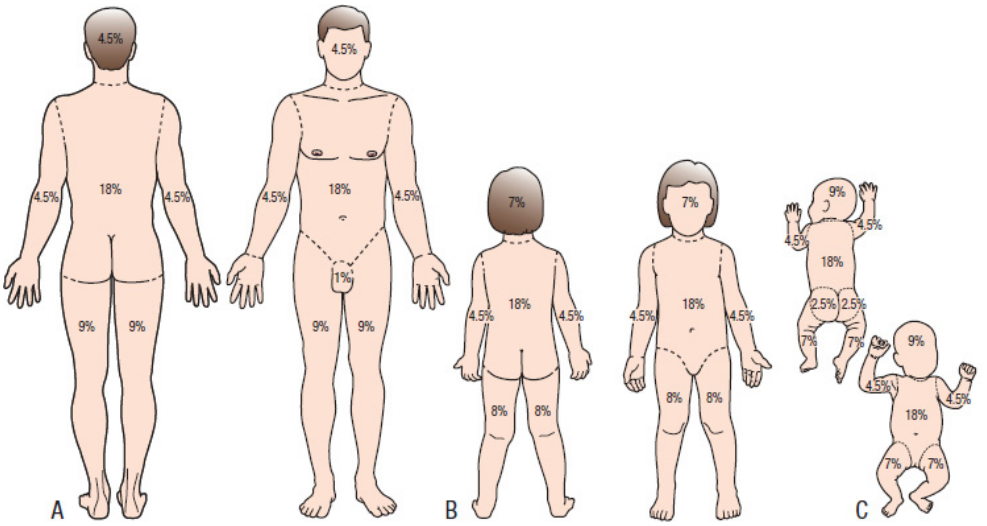
4 BURN SEVERITY

For full- and partial-thickness burns, identifying the extent of the burn injury is crucial. TBSA is useful to guide fluid resuscitation administration and defines the overall prognosis. Only partial- and full-thickness burns are totaled to calculate TBSA.

If small areas in various distributions are affected, it may be easier to use the patient as a ruler with one palm size (patient's) representing 1% TBSA. Another useful guide is the rule of 9s, where the adult body is partitioned into several areas that each constitutes 9% of the TBSA (**Fig. 12.2**). In children

and infants, the body surface area of the lower extremities constitutes a lower percentage while the head is higher. Careful estimation of TBSA is essential for proper early management of burn patients, as patients who have burns of more than 20% TBSA commonly require resuscitation.

Acute burn injuries require prompt intervention and serial examinations. On initial evaluation, it is important to recognize and treat constrictive circumferential burns that can lead to tissue ischemia and subsequent necrosis by limiting perfusion to the distal tissues.[32] All blisters and nonviable tissue must be debrided upon presentation. After the initial debridement, dressing changes are initiated while the patient is stabilized from a systemic standpoint. If patients suffer from full-thickness or deep partial-thickness injuries, debridement and grafting within 72 hours should be the standard of care.



rule of nines: (A) adult; (B) child; (C) infant

Figure 12.2 Rule of 9s used to estimate percent burns in adults and kids.

CRITICAL CARE OF THE BURN PATIENT

Hemodynamic Monitoring

Ideally, a critical care physician caring for a burn patient would be able to assess real-time responses to fluid administration through accurate cardiac output readings. Unfortunately, no such noninvasive devices to directly

assess cardiac output exist and those invasive devices that estimate cardiac output lack definitive studies supporting their use. Some centers use a pulse-induced contour cardiac output (PiCCO) device which provides a cardiac output based on temperature changes and use of the Fick equation; however, this requires a femoral arterial line and a large-bore internal jugular (IJ) or SVC catheter which introduces potential for complications. Some surgeons will use pulse volume variation (>25% being abnormal), however, this too lacks accuracy. Though goal-directed therapies with a pulmonary artery catheter, esophageal Doppler, TEE, or CVP monitor have demonstrated promising results in some critical care populations, their use in burn patients have been mixed.[43,44] Frequently, the output of monitors such as pulmonary artery catheters or CVP monitors fail to reflect the actual resuscitation of the patient.[46,47]

Ventilator Strategies

Treatment for Inhalational Injury

If inhalation injury is suspected, the patient should undergo urgent airway assessment and be placed on supplemental oxygen. Inhalation injury has three components that must be considered: (1) upper airway thermal injury which can cause swelling and obstruction, (2) carbon monoxide poisoning, and (3) lower airway chemical injury from toxic agents found in smoke. Upper airway thermal injury is treated by intubation of the airway and carbon monoxide poisoning is treated by 100% oxygen administration. Lower airway injury is diagnosed by evidence of soot or mucosal irritation on bronchoscopy. Airway mucosal injury from chemical pneumonitis leads to increased secretions while compromising the patient's ability to clear those secretions. This leads to increased risk of mucus plugging. Airway mucosal sloughing can also result in bleeding and clot formation that further obstruct airways. The use of aerosolized heparin, albuterol, and Mucomyst (HAM) following smoke inhalation to promote airway clearance is advocated in some centers, however, larger studies are needed to validate these treatments.[41,42,47–49]

Early endotracheal intubation and mechanical ventilator support is important in patients with inhalation injury or in large TBSA burns expected

to receive large-volume resuscitation. Ventilator management should follow ARDSnet protocol recommendations.[50,51] Recruitment maneuvers may be needed to improve oxygenation and/or ventilation. Permissive hypercapnia is preferred over large tidal volumes to avoid lung barotrauma. Limited studies have shown a potential role for high-frequency percussive ventilation in burn patients.[52]

Pulmonary infection in burn patients occurs in 30% to 50% of patients. Patients with three of the following five clinical criteria should be assessed for pneumonia with culture samples and placed on empiric antibiotic therapy: purulent sputum production, fever, elevated WBC, infiltrate on chest radiograph, and increasing supplemental oxygen requirements. If the patient has pneumonia and been in the hospital for over 48 hours, they should be treated for hospital-acquired pneumonia. Sputum or a bronchoalveolar lavage sample should be sent for aerobic, anaerobic, and quantitative cultures. Empiric antibiotics including coverage of Pseudomonas species and MRSA should be started until culture results become available.

Ventilator-Associated Pneumonia

Staphylococcus aureus and Streptococcus are common causes of early ventilator-associated pneumonia (VAP). *Pseudomonas aeruginosa* is the most common cause of late VAP. Normal diagnosis of pneumonia (fever, purulent sputum, or leukocytosis) is not helpful in burn patients since almost all patients are febrile, tachypneic, and have elevated white blood cell counts. The best diagnostic test is bronchoscopy-obtained bronchial alveolar lavage sample with quantification of the bacteria. Quantity of $>10^3$ CFU is considered positive for bronchoscopic specimen. ABA recommendations for length of VAP treatment are 8 days of antibiotic therapy for antibiotic-sensitive organisms and 15 days of therapy for multidrug-resistant organisms.[53] Consideration should be given to antifungal therapy (fluconazole [Diflucan]) if the patient does not respond to prolonged broad-spectrum antibiotics.

Electrolyte Abnormalities and Acute Renal Failure

The immediate effects of burn injury on kidney function are secondary to hypovolemia and circulating inflammatory mediators. The diuresis phase occurs at 48 to 72 hours after "third-space" fluid is reabsorbed. Hyponatremia is often seen due to large-volume resuscitation with hypotonic IV fluids and will usually self-correct. Open burn wounds or the use of topical silver nitrate can also cause hyponatremia. Renal hypoperfusion exacerbates hyponatremia by decreasing glomerular filtration. Hypernatremia may also occur due to insensible and evaporative water losses. Hypophosphatemia can result from dilution or refeeding syndrome. Hypocalcemia can result from use of silver nitrate.

Acute Kidney Injury

Risk factors include sepsis, large TBSA burns, organ failure, and antibiotic administration. Renal function is compromised by hypoperfusion, pharmacologic nephrotoxic insult, and sepsis which are all common following major burn injury. Physiologically there is a decrease in renal perfusion, glomerular filtration rate, and renal blood flow. Patients present with oliguria and decreased creatinine clearance. Early renal failure often results from hypovolemia-induced ischemic injury. However, overresuscitation can also compromise renal perfusion by causing abdominal compartment syndrome. Late renal failure occurs after fifth postburn day and is frequently caused by sepsis or nephrotoxic antibiotics. Continuous renal replacement therapy and pharmacologic treatments such as dopamine have not definitively been shown to improve outcomes. The initial care of acute renal failure patients should focus on reversing underlying causes and correcting any fluid and electrolyte imbalances.

Metabolic Response and Nutrition

The metabolism rate is significantly greater in burn patients than in other critically ill patients and leads to accelerated lean body mass wasting. Positive nitrogen balance is key to prevent skeletal muscle breakdown and highlights the importance of early nutritional support. The general composition of enteral feeding should include at least 60% calories from carbohydrates not exceeding 1,600 kcal/day, 12% to 15% from lipids and

essential fatty acids, and 20% to 25% from protein. Failure to meet large energy and protein requirements can impair wound healing and alter end-organ function. Even though adequate nutrition is crucial, overfeeding must be avoided. A randomized, double-blind, prospective study demonstrated that aggressive high-calorie feeding with enteral and parenteral nutrition was associated with increased mortality.[54] The daily caloric requirements can be calculated using the Curreri formula: [(25 kcal)(body weight (kg)] + [(40)(%TBSA burn)] 1 to 2 g/kg/day of protein for synthetic needs of the patient. Burn patients should receive less percentage of calorie requirements from fat than other ICU patients. The liver in a burn patient has less VLDL causing hepatic triglyceride elevation. Increased fat leads to increased complications including fatty liver, infection, hyperlipidemia, hypoxia, and mortality. Decreased gastrointestinal absorption and increased urinary losses can also lead to deficiencies in vitamin C, E, and zinc, iron, and selenium. Burn patients, like a subset of trauma and gastrointestinal surgery patients have been shown to benefit from glutamine supplementation.

Acute response to thermal injury is biphasic with the hypodynamic shock state at 24 to 72 hours and hyperdynamic catabolic state beginning on the fifth postburn day. Patients have supraphysiologic cardiac output, elevated body temperature, supranormal oxygen consumption, supranormal glucose consumption and altered glucose metabolism, increased and CO_2 production and accelerated tissue catabolism. This response is thought to be caused by excessive release of catabolic hormones including catecholamines, glucagon, and cortisol. There is a shift from anabolic–catabolic homeostasis to hypercatabolic state requiring increased substrates for energy including skeletal muscle which is broken down to maintain sufficient glucose amino acids. The resting metabolic rate is directly related to the severity of burn injury and a persistent hypermetabolic state is unsustainable. This hypermetabolism can be reduced by promptly treating sepsis as well as performing early excision and grafting of burn wounds. Recent studies have shown efficacy of a nonselective beta blocker such as propranolol which inhibits the effect of catecholamines and slows muscle catabolism. Herndon et al. demonstrated that propranolol in acute burns in the pediatric population improved net muscle synthesis and increased lean body mass.[55] Additionally, current standard of care includes providing pharmacologic agents such as

oxandrolone (testosterone analog given 0.1 mg/kg q12hr). Oxandrolone improves muscle synthetic activity, increases expression of muscle anabolic genes, and increases net muscle protein synthesis improving lean body mass composition and has been shown to reduce weight loss, improve donor-site wound healing and decreased hospital stay. Patients with burn injuries greater than 30% should receive oxandrolone for 6 months as the hypermetabolic state has been shown to persist following major burn injury. Despite being well tolerated, patients on oxandrolone should have their liver function tests monitored weekly. Human growth hormone and insulin-like growth factor have also been investigated but results have been indeterminate.

Glucose Control

Burn injury results in an increase in hepatic gluconeogenesis and impaired insulin-mediated glucose transport into skeletal and cardiac muscles and adipose tissue. Hypermetabolism seen in burn injury also leads to hyperglycemia and insulin resistance and thus glucose should be monitored in large burn injury patients. Currently, the data do not support strict glucose control (<110 mg/dL) but moderate blood glucose control is recommended (<180 mg/dL) and may decrease infectious complications.[56]

WOUND MANAGEMENT

There are a variety of burn wound dressing materials. Patient factors such as burn wound depth, condition, location of the burn, and comfort during dressing changes dictate the choice utilized.[33] Although the indications for systemic antibiotic therapy have not been clearly defined within the literature, use of antimicrobial dressings is recommended. Silver sulfadiazine (Silvadene) is a silver-containing cream that has broad-spectrum coverage against both gram-negative and gram-positive bacteria. Silvadene is commonly used on the skin of both partial- and full-thickness burn injuries. Its use is contraindicated in patients with sulfa allergies and over wounds near the eyes.[57] A self-limited leukopenia is commonly seen during the initial days of Silvadene treatment, but its use can be continued as leukocyte counts recover quickly without intervention. Mafenide acetate

(Sulfamylon) is an analogous agent that is used over cartilaginous areas such as the nose or ear due to increased tissue penetration compared to other dressing materials. Since topical Sulfamylon cream can be used without secondary dressing, it can be used for open burn wound therapy and regular examination of the burn wound surface. Both the cream and a 5% solution of Sulfamylon are equally effective.[58] Sulfamylon cream is useful for ear burns when there is risk of cartilage exposure. Sulfamylon may cause increased pain in the burn wound. In addition to the cream, Sulfamylon soaks can also be used for burn and postoperative dressings. Patients receiving large surface area Sulfamylon dressings should be monitored for complications such as hyperchloremic metabolic acidosis that can occur due to its mechanism of action as a carbonic anhydrase inhibitor.

Silver nitrate can also be used by soaking dressings in a 0.5% to 1.0% concentration solution and applied three to four times a day. These dressings offer several advantages over Sulfamylon soaks as they cover fungus in addition to bacteria and it is more cost effective. However, the use of silver nitrate in burn patients remains slightly controversial as nitrates are toxic to tissues and wound healing may be delayed by its use. The nitrates impair reepithelization and this effect is partially offset the benefits of silver in these compounds.[59] Furthermore, it can cause leaching of cations causing hyponatremia.

Bacitracin and Xeroform are additional examples of antimicrobial type dressing regimens and can be used after the first dressing takedown. While both can be used anywhere on the body, bacitracin is commonly used for facial burns. If grafts are placed in an area with surrounding cellulitis, soaks can be used during the first few days when the compressive dressing is still needed.

For patients who are at lower risk of infection based on the appearance of burn wounds, dressings may be changed with less frequency to achieve a balance between pain control and the need for wound coverage. Acticoat is one such option that is mainly used in partial-thickness burn injuries. This dressing consists of silver-impregnated sheets that have antimicrobial properties and can be changed less frequently, reducing pain and cost.[60] The nanocrystalline particles in Acticoat are able to reduce wound infection and promote wound healing compared to older silver products, including silver nitrate.[61] When using Acticoat, it is important to remember to moisten it with

water and not normal saline as sodium can inactivate the silver. There are other commercial products in addition to Acticoat that utilize the principle of nanocrystalline dressings. These dressings can be stuck on with mild adhesive (Mepilex), or wrapped or placed on like a glove (Silveron).

While dressing changes are sometimes used to optimize a wound before and after operative interventions, dressings also have the potential to completely heal a wound without the need for surgical intervention depending on the overall appearance of the burn and patient as a whole. Thus, a proper wound care team must not only include a critical care physician and surgeon, but it must also include a specialized wound care nurse to appropriately address this central modality of care for any burn patient.

Donor sites can be the most painful area for the patient and thus consistent donor-site care should be provided. Like other wounds, these wounds heal in a moist environment and though dry Xeroform can be used, this can be extremely painful for the patient. We prefer an adherent dressing that maintains wound moisture in addition to having an antimicrobial silver such as Mepilex.

OPERATIVE INTERVENTIONS

Excision and Grafting

After initial stabilization of the patient, which generally takes 24 to 48 hours, surgical intervention should occur as soon as possible since there are no benefits to delaying surgery when it is clear that a burn wound is of sufficient depth that it will not heal on its own.[62,63] Early excision of devitalized tissue appears to reduce the local and system effects of mediators released from burned tissue, thus reducing the progressive pathophysiologic derangements. It also removes dead skin which can serve as a nidus for wound infection. Tangential excision with a sharp blade on a guarded device removes necrotic tissue while preserving as much of the underlying viable tissue as possible. For large burn wounds, debridement should occur within 2 to 4 days of the initial injury. If there are insufficient donor sites to autograft all of the burn wounds, the debrided wound should be covered temporarily with allograft.[64]

Alternatively, the burn can be completely excised within the first several days after injury, and a temporary skin substitute can be used to close the wound remaining after available autologous skin has been harvested and grafted (**Fig. 12.3**). Sequential debridement and grafting is the backbone of burn care in those suffering from large TBSA burns. The use of allograft also allows the surgeon to assess the depth of the injury and the adequacy of their excision. If the homograft has good take, then it is likely an autograft will also take.

Figure 12.3 Full-thickness friction burn staged with Integra to allow for full declaration of the wound prior to grafting.

Figure 12.4 Grafting back of donor site with 4:1 split-thickness skin graft. (**Top**) Intraop placement of graft back. (**Bottom**) 4 weeks postop from graft back.

During tangential excision, tissue is debrided until healthy, bleeding tissue is reached. Grafting exists in many forms and decisions on coverage material and thickness of graft must be made in a strategic fashion to optimize functional and aesthetic outcomes. The gold standard is to use the patient's own tissue or autograft for reconstruction.

After a decision regarding the use of allograft versus autograft has been made, attention is turned to the size and thickness of the skin graft. Commonly, split-thickness skin grafts (STSGs) composed of the epidermis and a thin layer of dermis are utilized to minimize donor-site morbidity and optimize graft take. When delayed donor-site wound healing is expected such as in elderly patients and patients on chronic immunosuppressives, backgrafting back the donor site with 4:1 meshed grafts can accelerate healing (**Fig. 12.4**).

Thin grafts are more likely to succeed than thick grafts as it is easier to adhere and neovascularization to occur. There are certain areas, however, where split-thickness grafts should not be used since they cause greater secondary contracture and less color match over time as compared to full-thickness grafts. Areas of function, such as the hands and feet, lose a remarkable amount of utility if afflicted by scar contracture and may benefit from full-thickness grafts.[65] If split-thickness skin is used on the feet and hands, the grafts should be harvested on the thick side and meshing should be avoided if possible (**Fig. 12.5**). Similarly, aesthetically important areas, such as the face, are also more amenable to full-thickness skin grafting to optimize color match and minimize contracture over such areas.[66] If the cheeks or periorbital regions are involved, full-thickness skin grafts (FTSGs) should be placed prior to the development of ectropion which can be extremely difficult to treat. The abdomen can offer a site for large full-thickness harvest using an abdominoplasty incision (**Fig. 12.6**). Full-thickness grafts, nonetheless, are limited by increased donor-site morbidity due to the need to obtain both the epidermis and dermis from a region and also require closing the tissues primarily to avoid additional wounds. There is also more difficulty with successful and complete healing of the graft given that a more robust blood supply within the wound bed is necessary to optimize take of this thicker piece of tissue. Both full- and split-thickness grafts can be meshed to increase the surface area that may be covered. Meshing also allows for fluid egress, which minimizes the risk of fluid accumulation beneath the graft, a common cause of skin graft failure. Meshing should not be performed, however, over cosmetically sensitive areas given that the meshed pattern will be quite apparent even after complete healing has been achieved. Both types of skin grafts should be bolstered once placed to minimize shear, improve contact, and allow for imbibition and inosculation. **Table 12.4** summarizes the key steps involved in a burn excision.

Figure 12.5 Sheet grafting of full-thickness hand burns. In general meshed grafts should be avoided on the hands and across important joints to avoid scar contracture. (**Left**) Preop photo. (**Middle**) Intraop photo. (**Right**) 1-month postop photo.

Figure 12.6 Use of full-thickness skin graft to prevent facial ectropion. Full-thickness graft harvested from the abdomen. (**Left column**) Intraop photos. (**Middle figures**) Intraop donor-site photos. (**Right column**) Postop 2-week photo.

When burn injuries lead to large regions of exposed tendons, especially in the distal one-third of the lower extremity, free tissue transfer is often

required (**Fig. 12.7**). It is necessary to ensure that all dead tissue is debrided prior to coverage with a free flap to mitigate infection and flap failure. Additionally, if the patient is elderly or has vascular insufficiency, a preoperative CT angiogram should be obtained.

In larger burn wounds, patients may not have an adequate surface area available for donor sites. In such cases, allograft can be used instead for initial coverage. This homograft will serve as a temporary coverage and its take will ensure that the initial excision was performed at the correct depth. Allografts will eventually be rejected as the body recognizes the newly engrafted skin as foreign material after 10 to 13 days. The process is initiated by the placement of the allografts, which is associated with an inflammatory process, leading to the activation of the innate immune response. Donor dendritic cells migrate from the graft to the recipient's secondary lymphoid organs where they present donor antigens and elicit an adaptive immune response. This response results in activated effector T cells from the donor leaving the secondary lymphoid organs and infiltrating the graft where they mediate the rejection of the allograft.[67]

Additionally, if insufficient autograft exists even after temporary allograft, the surgeon should consider use of cultured epidermal autografts. Cultured epidermal autografts utilize the ability to grow keratinocytes in vitro to generate cohesive sheets of stratified epithelium, which maintains the characteristics of authentic epidermis. This technique was developed by Rheinwald and Green in 1975.[68] A 3- to 4-cm^2 sample is taken usually from the axilla or pubic area at the same time as initial debridement, and epidermal cells are isolated from the small skin biopsy and plated onto a layer of feeder cells that act as a supporting "feeder layer."[69] The feeder layer supports optimal clonal expansion of proliferative epithelial cells and promotes keratinocyte growth. Under optimal growth conditions, keratinocytes initiate growing colonies and after 3 to 4 weeks, the cultured epidermal autograft sheets are 8 to 10 cells thick.[70] These constructs require advanced planning as it takes at least 3 to 4 weeks to develop. Additionally, risks and benefits should be discussed with the family and patient as there is a high percentage of graft loss due to fragility. Furthermore, case reports of squamous cell cancer developing from cultured epidermal autograft sites do exist.

A newer technology known as the RECELL Autologous Cell Harvesting Device (or RECELL) is a point-of-care preparation and application of a suspension of noncultured, disaggregated, autologous skin cells. A 1 cm^2 of donor-site skin can be used to treat up to 80 cm^2 of excised burn.[71] It is used with widely meshed STSG (e.g., 6:1). Small trials have demonstrated noninferiority to STSG for small surface areas of mixed depth burn, however, the data are still lacking on effectiveness measures for this technology to be widely adopted.

Table 12.4 Pre- and Intraoperative Steps for a Burn Excision and Grafting Procedure

1. Preoperatively, it is helpful to correct hematologic and metabolic derangements given potential for large amount of blood loss.
2. The preoperative time-out should include a discussion of expected blood loss, the blood products available, and the transfusion triggers for the case.
3. In any burn over 20%, a preoperative blood type and crossmatch should be performed and PRBCs should be available in the operating room, and given appropriately, to avoid intraoperative acute blood loss anemia.
4. Arterial lines as well as large-bore IVs and often a central line should be in place before beginning the operation.
5. Techniques to decrease intraoperative blood loss include:
    a. The use of tourniquets on the extremities
    b. Use of topical spray thrombin and epinephrine-soaked Telfa pads placed immediately after excision followed by wrapping with Kerlix gauze soaked in a 1:1,000,000 epinephrine in saline solution
    c. In regions where circumferential wrapping cannot be performed, this epinephrine solution can be used as an injectable solution to perform dermatoclysis with an 18G spinal needle on the end of a 60 cc syringe or injection device
    d. This epinephrine injection solution is also used as a preharvest tumescent solution for donor sites, helping to create a flat surface on which to run the dermatome as well as decrease postharvest blood loss
    e. If working on an extremity, a good strategy is to start proximally and perform the excision followed by inflation of the tourniquet. Subsequently, the distal excision can be performed under tourniquet control
6. After achieving a healthy and well-vascularized wound bed, proceed with allografting or autografting.
7. If autografting is carried out, grafts can be excised in thicknesses ranging from 0.010 to 0.018 in. We typically use 0.012 in for standard grafts.
    a. Thinner grafts lead to faster donor-site healing, hence are helpful if there is a need to reharvest donor sites, or if the patient has thin skin

due to increased age or chronic immunosuppression.
   b. Thinner grafts increase the likelihood of skin graft take and decrease the risk of superficial epidermolysis of the graft, however, result in greater secondary contracture.
8. Grafts are meshed in 1:1 or 1:1.5 ratio to allow fluid egress.
9. Backgrafting: If backgrafting of the donor site is needed, the same area of graft harvested should be harvested next to the donor site then meshed 4:1 and placed over the entire donor site (**Fig 12.4**).

5 Order of Coverage

The first operations performed in large burn patients can often set the stage for if and how quickly a patient will recover. The first priority should be to excise all eschar and achieve coverage with autograft if available or with allograft if not available. In patients with large TBSA burns, it is crucial to get the back excised and covered first as delay of this step will make it difficult to have a patient stable enough to tolerate a prone position. Additional strategies to improve coverage of the back include the use of autograft meshed 3:1 covered with allograft meshed 2:1 and a secure bolster placed over top. This minimizes sheer and loss of the autograft. This early coverage of the back and avoidance of prone positioning may also mitigate the need to perform an early tracheostomy which in all other critical care patients has not proved beneficial. Once the posterior areas of the patient are excised and covered, then attention can be turned to the anterior regions and the extremities.

Extremity Treatment

Though the hands and feet are important to excise and cover early, these areas require the use of sheet or 1:1 meshed grafts. These areas should not delay the coverage of large areas such as the back which can use widely meshed grafts. More important, for the digits, is the use of early K-wire fixation in the intrinsic plus position in deep burns to the fingers. K-wires should be placed in the fingers to keep them in the intrinsic plus position: MC flexed at 70 to 90 degrees, wrist 20 to 30 degrees, IP joints in full

extension, and thumb kept abducted and slightly opposed. This will help prevent severe joint flexion contractures which can lead to the loss of digits if straightened in a delayed fashion.

Skin Alternatives

Integra is a newer alternative for temporary coverage and creation of a neodermis in a wound after debridement. Composed of bovine collagen and silicone film, this construct is designed to mimic the epidermis and dermis of the missing tissue.[64,72] Its structure allows for the growth of healthy granulation tissue into a wound bed to optimize the wound niche to promote greater and healthier take of the skin graft that will eventually be placed over the site of injury. This is especially important over areas of function, such as the hand, which has the potential for significant debilitation if scar or graft contracture occurs over the traumatized site. Integra is also important for areas that do not have enough viable or vascularized tissue to support a skin graft. Integra, however, often fails in burn patients due to infection and requires constant soaks with Sulfamylon. Additionally, clinicians should examine the Integra frequently and remove any areas of silicone under which there is concern for infection.

Porcine xenografts are an alternative to dressing changes alone in superficial partial-thickness burn wounds. In wounds that are likely to heal by themselves taking the patient to the operating room, performing a good debridement under anesthetic, and placement of xenograft to the burn wound can be beneficial (**Fig. 12.8**). The xenograft can minimize pain, improve wound healing, and deescalate the complexity of dressing changes. This benefit may be maximal in children or patients with tolerance to narcotic pain medications due to excessive pharmacologic supplementation before becoming injured.

PAIN CONTROL

Acute Pain

Burn injuries are among the most painful traumatic injuries sustained given their extensive nature. Thermal injury to the overlying epidermis leads to exposed nerve endings which are sensitive to stimulation. Thus, superficial partial-thickness burn injuries often cause the most pain to the patient. Deeper partial-thickness and full-thickness injuries may not cause as much pain to palpation; however, these regions are still painful due to the inflammatory response. Given the multifactorial nature of burn pain, elimination of pain in burn patients is not possible. Outcomes are often improved if a dedicated physician with expertise in pain management is part of the burn team. When establishing a pain regimen, the physician should focus on treating acute as well as chronic pain. A successful regimen often includes the use of short- to intermediate-acting narcotics to treat the acute pain as well as a long-acting narcotic such as methadone for the chronic pain.[73] Some patients will also benefit from gabapentin (Neurontin) to alleviate neurologic pain. Additional studies are underway to investigate the use of quetiapine (Seroquel) for patients with a large anxiety component associated with their pain. Balancing of narcotic dosing over time is essential to preserve their acute pain relief effect and to avoid situations in which tolerance renders all available agents and doses ineffective.

Chronic Pain and Substance Abuse

The burn patient population that is admitted with underlying substance abuse and alcohol dependency are a particular challenge for the burn team to successfully treat with regard to pain relief. In such circumstances, the team should have high vigilance for symptoms of drug or alcohol withdrawal. New studies are investigating prophylactic treatment with barbiturates to prevent alcohol withdrawal rather than currently used strategies which are largely reactionary and treat withdrawal after symptoms occur. Again the involvement of psychiatrist or pain specialist in the prescription of these drugs is beneficial. Methadone can also serve as helpful adjunct for patients with chronic pain at doses of 5 to 10 mg BID–TID given its decreased addictive potential to other narcotics.

INFECTIONS

Wound Infections

Burn wound sepsis is a severe sequelae of burn injuries caused by colonization of the damaged skin and soft tissues with infectious bacteria or fungi. The most common organisms are *Staphylococcus aureus, Streptococcus pneumoniae,* and *Pseudomonas aeruginosa*. Despite the morbidity of this complication, its incidence has decreased dramatically with the use of early excision and grafting and appropriate topical antibiotics therapy. If a burn wound infection is suspected, wound dressings should be taken down and a quantitative culture should be obtained. A bacterial count of greater than or equal to 10^5 colony-forming units bacteria/gram of tissue is considered a significant infection, though the data from which this number was derived dates back to the 1960s. General critical care infection protocols should be followed with burn wound debridement if the patient does not yet have skin grafts placed. If adequate excision was performed and the patient already has skin grafts placed, then antibiotic soaks or cream dressing changes and IV antibiotics will often help combat infection. Repeat quantitative cultures should be obtained every 3 to 4 days when treating a burn would infection to gauge progress and allow for escalation or deescalation of treatment.

(**Top, right** and **bottom, left**) Placement of xenograft over burn using interrupted absorbable sutures. (**Bottom, right**) 1-month postop from xenograft placement.

Vascular Catheter–Related Infections

All central venous catheters should be placed using sterile technique and antibiotic impregnated catheters as these have proven efficacious in the general critical care population.[74] Additionally, central venous catheters should be placed in nonburned areas if possible. Routine changing of catheter after a specific time period has not been shown to improve outcomes. However, close attention should be paid to catheters in place for over 7 days, especially in burn areas if the patient is febrile and has signs of systemic infection. If a catheter-related infection is suspected, two peripheral blood cultures should be drawn. A culture specifically from the catheter does not improve diagnosis or outcomes. Despite the increased prevalence of the use of PICC lines, these lines have equal if not increased risk of infection than central venous lines.

Pneumonia

Along with the increased survival of burn patients comes the increased amount of time burn patients are on the mechanical ventilator. Increased incidence of pneumonia is seen with inhalation injuries and prolonged intubation and mechanical ventilation. As in other critical care populations, an emphasis should be placed on daily awakening and extubation/spontaneous breathing trials. Additionally, all patients on the ventilator should have their head of bed elevated greater than 30 degrees and daily chlorhexidine mouthwashes may be beneficial. If a pulmonary infection is suspected, a CXR should be performed and a quantitative culture specimen should be obtained from the bronchial tree. A quantitative result greater than 10^5 cfu/mL is considered positive and should be treated.

BURN RECONSTRUCTION

Optimizing Acute Treatment to Minimize the Need for Reconstruction

As in any plastic and reconstructive surgery case, meticulous planning and foresight is imperative. During the acute burn injury stages, emphasis should be placed on general coverage of burn wounds and large flaps and local tissue rearrangements should be delayed. However, if there is a high likelihood that the patient might need a flap or local tissue rearrangement in the future, the region of graft harvest should be carefully planned. For example, if a patient has a large neck burn or exposed lower extremity tendons or bone and an anterolateral thigh flap would help, then the thigh should be avoided as a donor site. Surgeons should consider the fact that a meshed skin graft will have an abnormal appearance once it heals as well as causing increased hypertrophic scarring. Donor sites should be harvested from inconspicuous locations in case a hypertrophic scar results. Other examples requiring acute reconstructive surgery include eyelid contracture with exposure keratitis and cervical contractures causing airway issues. Once acute grafts and donor sites have healed patients and physicians should focus on maximizing normal scar healing. Normal wound healing requires a balance in the hydration of the wound and water-based moisturizers should be encouraged. Silicone sheeting or other occlusive dressings can help in

early hydration of the wound.[75–77] Additionally, attempts should be made to minimize tension off of the scar with potential applications of new devices. Compression garments are also commonly used to decrease formation of hypertrophic scarring, though their efficacy is still debated.[78,79]

6 Hypertrophic Scarring

Thermal burn injures can cause tremendous morbidity, leaving the patient with not only cosmetic but also functional impairments. Hypertrophic scarring is a major complication after burn injury with a prevalence of 32% to 72%. Several risk factors have been identified that contribute to its development including the localization of the burn injury, burn depth, time to heal, and skin color.[80,81] While the precise mechanism by which hypertrophic scarring occurs remains unclear, strong and persistent expression of transforming growth factor beta (TGFβ), focal adhesion kinase-1 (FAK1), and its receptors have been associated with postburn hypertrophic scarring. Furthermore, a critical step in the healing process that is altered is the transition from granulation tissue into normal scarring. During this remodeling process, wound epithelization and scar collagen is formed but accompanied by a gradual decrease in cellularity due to apoptosis. However, early immature hypertrophic scars caused by burns are hypercellular and during the process of remodeling and maturing, fibroblast density do not resemble that of normal healing.[82] More specifically, apoptosis of myofibroblasts occur 12 days after injury in normal wound healing, but in hypertrophic scar tissue, the maximum apoptosis occurs much later at 19 to 30 months.[83] These events result in a significantly higher percentage of myofibroblast and the hypertrophy of the scar tissue following severe burn injuries.

One of the key pathologic factors that must be addressed in any hypertrophic scar is tension. A new concept of "scar rehabilitation" has emerged with the key idea being to improve the environment of the scar without actually excising the scar. The most important step in rehabilitating the scar is release of the tension. Rather than excising, the scar, this involves just releasing the area of greatest tension. Despite not removing any tissue, a large defect is often created once the tension is released. This defect can then be treated by adding new tissue such as an FTSG or a thick STSG.

Additional ways to relieve tension involve the use of tissue rearrangements such as a Z-plasty. A Z-plasty lengthens the scar at the expense of width alleviating tension along the central access of the hypertrophic scar. In general Z-plasty rearrangements are made with 60-degree angles to maximize tissue gain without causing excess tension on the donor-site closure. Alternative V-Y advancements are useful if there is healthy tissue surrounding the scar and can be advanced into the area of the contracture release. Both Z-plasties and V-Y advancements relieve the tension on the scar that help create the hypertrophic environment. By relieving this tension, the scars can heal in a more normal environment and often will do so without the raised erythematous characteristics initially present. The physiology of the Z-plasty is thought to result from improved collagen remodeling after relief of tension.[84,85] Z-plasties can be used to flatten a hypertrophic scar or elevate a depressed scar as long as the lateral limbs extend into normal tissue. The classic design of a Z-plasty has a central segment with limbs oriented at 60 degrees (although can be 30 to 90 degrees) with all three lines of equal length (**Fig. 12.9**). Widening the angle of the limbs increases percent gain in length along the central limb. Multiple Z-plasties can be designed in series to improve contracture release in large hypertrophic scars.

Although less well studied, postburn pruritus is another significant problem affecting almost 100% of pediatric and 87% adult patients and may persist for many years, resulting in a scratching/inflammation cycle leading to hypertrophic scarring. Treatment options are limited for postburn pruritus, commonly involving antihistamines and moisturization of the skin with only incomplete resolution of symptoms and thus significant deterioration in the quality of life.[86]

Current treatment strategies for hypertrophic scars include surgical manipulation, intralesional corticosteroid injections, cryotherapy, and laser therapy. Surgical manipulation to remove the excess skin remains the traditional treatment for hypertrophic scar. Recent studies investigating the role of fat grafting into scars have shown promise to further improve function and appearance.[87] Patients who have undergone fat transfer reported satisfactory results 6 months after the procedure, indicating considerable improvement in the features of the skin, skin texture, and thickness. Histologic examination demonstrated new collagen deposition, neovascularization, and dermal hyperplasia in regions treated with fat

grafting, which mimicked surrounding undamaged skin. Additionally, intralesional corticosteroids suppress the inflammatory process in wounds, diminish collagen synthesis, and enhance collagen degradation.[88] Conversely, cryotherapy induces vascular damage that leads to anoxia and ultimately tissue necrosis and has yielded marked improvement of hypertrophic scars.[89] However, its efficacy is limited to the management of small scars.

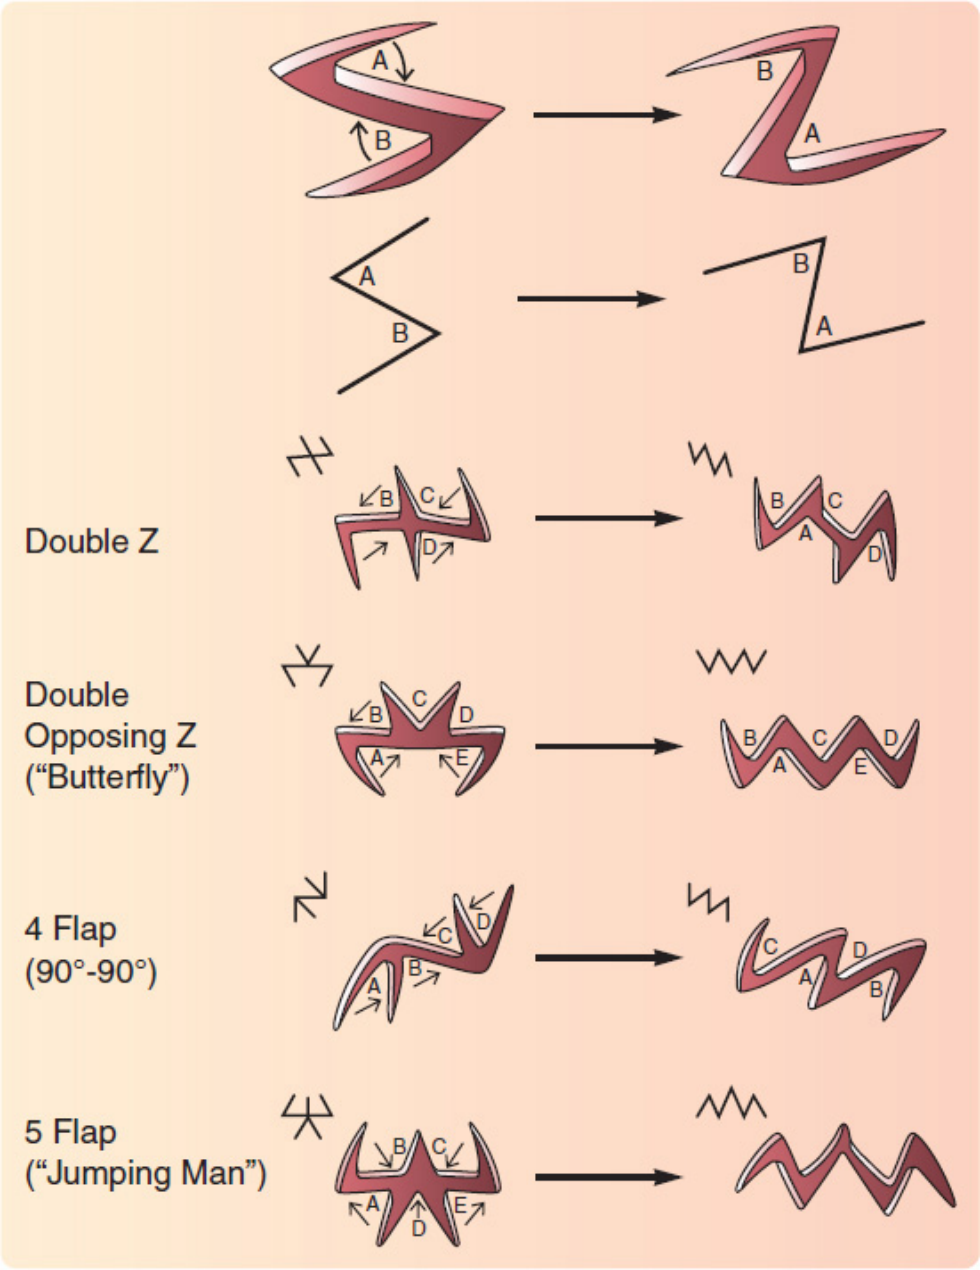

Figure 12.9 Z-plasty diagrams demonstrated tissue rearrangement used for hypertrophic burn scars.

Last, since the introduction of laser treatment in the mid-1980s, additional lasers with different wavelengths have been employed. Encouraging results have been obtained with the 585-nm wavelength pulsed dye laser (PDL), which has been recognized as an excellent therapeutic option for the treatment of younger hypertrophic scars.[90] PDL induces the dissociation of disulfide bonds in collagen fibers and leads to collagen fiber realignment, decreased fibroblast proliferation, and neocollagenesis. However, it is necessary for repeated treatments, generally between two and six treatments, for the optimal resolution. Shorter-pulse durations are generally more effective for scar improvement.[91] Unlike vascular malformations and hemangiomas, scars also tend to respond better to low or medium PDL fluences, about 4 to 7 J/cm^2, than to higher fluences.[92] Low, short-pulse duration PDL fluences induce local damage to the vascular endothelium followed by mural platelet thrombi, while high PDL fluences at longer-pulse durations tend to cause immediate intravascular coagulation with cessation of blood flow.[93] Side effects include erythema/purpura for 7 to 14 days, hyperpigmentation, and hypopigmentation. Though these lasers are effective in improving scar erythema, they do not have a substantial effect on the thickness or contour of hypertrophic scars. Controversy still exists about how much of this redness would subside if given adequate time compared to laser treatments.

Recently, research studies have demonstrated the benefit of fractional photothermolysis in the treatment of hypertrophic scarring. Though the exact mechanism is unknown, this concept uses a CO_2 laser (10,600 nm), which is an ablative laser that targets water in the underlying tissues. The laser creates columns of tissue destruction, which stimulates collagen production in adjacent uninjured columns of tissue. Only a portion of the epidermis and dermis is treated with columns of energy in order to create targeted areas of thermal damage (microthermal treatment zones, or MTZs). The untreated areas are a reservoir of collagen and promote tissue regrowth. Fractional lasers, as opposed to nonfractional lasers allow for greater penetration with decreased risk of scarring. This healing will take place outside of the acute inflammation period and thus allow for a more normal wound healing cascade than existed at the time of the initial excision and graft. The adjacent uninjured tissue allows for more rapid tissue regeneration from their follicles

and sweat glands. Ablative lasers have a greater potential depth of treatment compared to nonablative lasers (4.0 mm compared to 1.8 mm). Ablative lasers appear to be more effective for thicker scars and those associated with restriction. Overall, this creates a smoother appearance and allows meshed grafts to appear less obvious. Patients have described less tightness as well as decreased pruritus and improved overall appearance.[94–99]

Tissue Expansion

As a reconstructive technique, tissue expansion is versatile, reliable, and repeatable, and can be applied to many regions of the body. A tissue expander (TE) is an artificial filling device that is used to grow and expand local tissue to reconstruct an adjacent soft tissue defect. A silicone elastomer reservoir is placed beneath the donor tissue and slowly filled over time with saline, causing the overlying soft tissue envelope to stretch with a net increase in surface area per unit volume. Advantages to TE is that it allows the surgeon to reconstruct "like with like" using donor and recipient tissues that share similarities in color, thickness, texture, and hair-bearing patterns. Larger soft tissue defects that would usually require a local flap for reconstruction can be closed primarily using expanded local tissue, limiting donor-site morbidity. A robust angiogenic response is achieved histologically within the expanded local tissue resembling an incisional delay phenomenon. Predictable amounts of donor tissue can be gained through the expansion process. Disadvantages of tissue expansion include the need for multiple operations (at least two for placement and removal of the expander) and outpatient visits. Definitive reconstruction is delayed secondary to the expansion process. Specific complications related to the presence of foreign material can be as high as 30% (e.g., infection, exposure, or extrusion). This complication risk is even higher in the extremities and scalp.

Specific Anatomic Concerns

Neck contractures are the most common wound healing complication of burn injury. Functionally this can limit range of motion and oral competence. Surgical release of the scar contracture down to platysmal or subplatysmal

layer followed by coverage with large FTSG or thick STSG followed by aggressive range of motion 5 days after having patient in neck brace is an option for correction. If the contraction is severe, a free tissue transfer may be required after neck release. Postoperatively it is crucial to use compression garments for 6 to 18 months and neck bracing to keep neck extended to prevent contracture recurrence.

Ectropion is a common complication after periorbital burns. This deformity is caused by inadequate tissue therefore in addition to release the surgeon needs to replace tissue. If the ectropion is caused by an extrinsic contracture, scar release and provision of additional tissue are needed to prevent recurrence.

The axilla also represents a common area of contracture because it is difficult to maintain adequate positioning in the acute phase of burn wound healing. Anatomically the axilla can be divided into the anterior axillary fold, midaxillary line, and posterior axillary line. The shoulder should be kept 90 to 120 degrees abduction and 15 to 20 degrees flexion (60 to 80 degrees arm elevation). There are three grades of axillary contractures:

1A: Involves anterior axillary fold
1B: Involves posterior axillary fold
2: Involves both axillary folds
3: Involves both folds and axillary dome

Type 1 and 2 contractures can be treated with sequential release and thick STSGs or FTSGs. Type 3 contractures require local and distant flaps including parascapular and latissimus flaps. It is important to pay attention to where hair-bearing regions are transposed. Postoperative occupational therapy and splinting are necessary to prevent recurrence.

ASSOCIATED COMPLICATIONS OF BURN INJURIES

Muscle Catabolism and Wasting

Burn injury leads to significant changes in essential metabolic processes, which shift the physiologic homeostasis to a catabolic state, specifically resulting in the loss of lean body mass. The TBSA affected by the burn injury plays an important role, since reestablishing a functional skin barrier initially takes priority and requires a protein substrate, which is often provided by skeletal muscle.[100]

Muscle catabolism after burn injury is mediated by several factors including an increased energy requirement[101] and heightened inflammatory state involving the systemic release of stress hormones, catecholamines and glucocorticoids, which mediate the underlying metabolic derangements. Other factors include prolonged immobilization and the loss of a functional skin barrier, which leads to a disturbed thermoregulation requiring increased energy expenditure to maintain body temperature. The consequences can have devastating effects on the convalescence of the adult and especially pediatric burn patients, where an increased catabolic state can lead to delayed linear growth for up to 2 years after the injury.[102] The physiologic response of skeletal muscle to anabolic stimuli is altered in pediatric patients with amino acid infusion therapy failing to stimulate a net protein deposition in skeletal muscle of pediatric patients even 6 to 12 months post injury. This is most likely due to excessive protein breakdown.[103,104]

Some therapeutic approaches which have shown benefit in clinical trials include the blockage of beta-adrenergic receptors, resulting in attenuated catecholamine effect and improved net muscle protein balance.[105] Anabolic steroids, such as oxandrolone, and physical exercise have been shown to increase lean body mass in children who suffered from >40% TBSA burn injury.[106]

When the body is in a prolonged catabolic state due to the increase in caloric requirements, the patients must consume at least 2.5 to 3 g/kg/day of protein.[66] Nutritional shakes and high calorie foods are a necessity to optimize the conditions for wound healing. It is important to start nutrition as soon as possible, preferentially using the enteric route if possible.

Patients should also be referred to physical and occupational therapy. A therapeutic exercise program should be implemented to maintain normal range of motion, strength, and endurance. In order to counteract the catabolic effects of burn injuries, a program of active and active-assisted exercise is necessary. Depending on the severity of the burn and the patient's willingness

to tolerate the associated pain with exercise, passive range-of-motion exercises should be prescribed. In the event that full range of motion is not achievable, a program of stretching can be prescribed in its place. Furthermore, anesthesia can be used to assist these exercises, but should only be used in cases of patients who cannot tolerate the pain.

Range-of-motion exercises can also minimize skin contractures, as skin is a tissue that requires sustained mechanical stretch to facilitate lengthening of the underlying collagen and extracellular matrix compartments. Initial skin exercises should attempt to elongate the skin with repetitive low loads with differences in length. Following this initial precondition, a prolonged stretch is applied to maximize the skin laxity. Blanching is a clinical sign that capillary blood flow is impeded and is a good sign that the tissue has reached its maximum yield point. Strength exercise should follow as soon as the patient can tolerate it. Strength programs best suited for burn patients should include progressive resistive exercises. Fatigue and loss of endurance are major issues as a patient recovers. It is important to include endurance training and monitor cardiopulmonary response. Concurrently, patients should be encouraged to walk as ambulating patients have fewer lower extremity contractures, endurance problems, and venous thrombosis.

Heterotopic Ossification

Heterotopic ossification (HO) is the pathologic formation of bone in extraskeletal regions of soft tissue including muscle, joint spaces, and often encasing major nerves. This complication of burn injury causes significant pain, joint restriction, and contractures.[107] The incidence of HO is proportional to the severity of the injury with an increased incidence in severely burned patients. It may affect all areas of the body but is most frequently encountered in the elbow joint.[107,108] While the etiology of HO remains elusive, common risk factors that have been identified include upper extremity burns, large TBSA burns, young age, prolonged immobilization,[109] and a delay in time to wound closure.[110]

Early detection and diagnosis of heterotopic bone formation is critical in the clinical management of this complication, which oftentimes involves surgical resection. However, surgical intervention is associated with a high recurrence rate. Perioperative radiotherapy has been suggested as an adjunct

to surgical resection and has been shown to reduce the recurrence rate to some extent.[111]

Pharmacologic interventions have been shown to have some efficacy in limiting the severity of HO. Bisphosphonates and NSAIDs have been used for prophylaxis and treatment of HO with some success.[112,113] While there is no consensus on choice or timing of therapy, it has been proposed that bisphosphonates should be prescribed as soon as elevated alkaline phosphatase is noted or imaging studies establish the presence of HO. Other studies have shown that NSAIDs limit the severity of HO when delivered as a preventative therapy.

Majorlin Ulcer

Similar to chronic wounds from other etiologies, chronic untreated burn scars can lead to malignant degeneration. Squamous cell carcinoma is the most common type of malignancy observed, however, these malignancies are rare in an era of early excision and grafting. Malignancy requires wide excision with at least a 2-cm margin as well as sentinel lymph node biopsy. If the sentinel node is observed to be positive, a compete lymph node excision should be performed.

CLINICAL RESEARCH

Within the last decade, critical care, wound care treatment, and burn reconstruction research has advanced in both diagnosis and identification of efficacious therapies to improve the overall recovery process for burn victims.

Critical care research has focused on the delivery of appropriate resuscitation during the initial phase following the traumatic burn injury. Immediately following the trauma, burn patients experience severe shock due to concomitant inflammation leading to severe edema. Typical fluid resuscitation for burns has been crystalloid, though some centers use colloid as rescue therapy when patients exhibit increasing and greater than expected fluid requirements, known as “fluid creep.” A retrospective study assessing the use of crystalloid with colloid (5% albumin) supplementation in patients

with injury >20% TBSA demonstrated normalizing of resuscitation ratios (ratio of hourly intake in mL/kg/%TBSA/hr to hourly urine output in mL/kg/hr) with the addition of albumin.[38] Similar findings have also been reported in pediatric burn literature.[114] Our practice uses colloid supplementation after the first 24 hours in patients requiring higher than expected resuscitation to minimize fluid creep.

Transfusion strategy is also an area of investigation in burns, given that patients with major burns require large-volume transfusion during the acute treatment phase. The Transfusion Requirement in Burn Care Evaluation (TRIBE) trial compared a restrictive (hemoglobin goal 7 to 8 g/dL) versus a liberal (hemoglobin goal 10 to 11 g/dL) strategy for burns >20% TBSA.[115] The restrictive strategy halved blood product utilization. There was no difference in mortality, blood stream infection, or organ dysfunction with the restrictive strategy compared to the liberal strategy.

Autologous coverage burn excision sites in the setting of limited donor-site availability remains a challenge for large, full-thickness burns. As discussed in previous sections, cultured epithelial autografts have gained increased interest as an alternative for cutaneous coverage for patients with large burn wounds and small potential donor sites, however, there is yet a skin substitute to be developed that can function as well as an autograft. An active area of research is investigation of the effectiveness of new technologies such as RECELL. While small studies have demonstrated noninferiority to STSG for small burn wounds, the technology requires further investigation to prove effectiveness. There are currently trials ongoing to assess for the benefit of different wound dressings with RECELL technology, such as the BRACS trial, which is comparing silver dressings on mixed depth wounds with RECELL technology with and without Biobrane, a biosynthetic wound dressing.[116] Another trial is assessing the efficacy of negative pressure wound therapy in pediatric burns, the SONATA in C trial.[117] These studies will provide evidence-based guidelines for best practices in burn wound care.

BASIC SCIENCE AND TRANSLATIONAL SCIENCE RESEARCH

Basic science and translational science research in burn injuries have significantly advanced in the last 50 years and have focused on both understanding and treating the primary wound site as well as complications that arise from these traumatic burn injuries.

Wound healing can be described in three different stages: inflammation, proliferation, and remodeling phase. Hypertrophic scarring is an aberrant form of the normal wound healing process that does not extend beyond the original wound margins. Hypertrophic scar formation involves the constitutively active proliferative phase of wound healing, resulting in high vascularity and dense extracellular matrix deposition.[118] Histologic studies suggest that a robust inflammatory response, involving mast cells, macrophages, fibrocytes, and lymphocytes, may underlie the excessive fibrosis seen in hypertrophic scar formation.[119] The secretion of TGF-beta1, platelet-derived growth factors, and epidermal growth factor contribute to the inflammatory response and results in excessive inflammatory cell stimulation, fibroblast proliferation, adhesion, neovascularization, matrix production, and ultimately contraction.[120] As such, translational science research from the bench to the bedside focuses on new therapies targeted at quenching the inflammatory response, limiting fibrosis, and inhibiting angiogenesis to target the mediators of this scarring process.[121,122] Additional basic science research aimed at understanding the wound healing process and translational science research investigating new treatment options will continue to advance our understanding and treatment of burn-related injuries.

CONCLUSION

Burns are responsible for significant morbidity and mortality and are among the most complex and devastating of all traumatic injuries. Early proper diagnosis of burn depth and extent allows for the delivery of appropriate treatment ensures the best prognosis for burn patients. Early tangential excision and autografting remains the foundation of burn treatment. Diagnosis of secondary burn complications, such as joint contracture and heterotopic ossification, has advanced with new imaging tools. Nevertheless, the management of burn patients requires a team of physicians, nurses, critical care specialist, physical therapist, and counselor to provide optimal care to

patients and lessen the burden of the initial burn injury. Furthermore, novel clinical, basic science, and translational science research continues to improve our understanding of the pathophysiology of burn injuries. Elucidating the pathophysiology of both the primary wound and secondary complications will assist in the treatment during the critical period and following the initial trauma and prevent secondary burn complications.

Anesthesiology and Pain Management

Paul Picton, Sachin Kheterpal, and Michael R. Mathis

Key Points

1 Anesthetics are generalized depressants of consciousness, pain, cardiopulmonary function, motor function, and recall.

2 To prevent movement and to facilitate the surgical exposure, neuromuscular blocking agents are generally used. These drugs are competitive or noncompetitive inhibitors of the neurotransmitter acetylcholine at the neuromuscular junction.

3 Residual neuromuscular blockade is a common and underappreciated phenomenon that impacts postoperative adverse events such as hypoxemia, pneumonia, reintubation, and prolonged recovery room stay. Sugammadex, a novel medication capable of reversing deep neuromuscular blockade, may revolutionize perioperative care for high-risk patients.

4 Opioids produce profound analgesia and respiratory depression. They have no amnesic properties, minimal direct myocardial depressive effects, and no muscle-relaxant properties.

5 Propofol is a lipid-soluble substituted isopropyl phenol that produces a rapid induction of anesthesia followed by awakening in 4 to 8 minutes after a single bolus. However, as the duration and dose of the maintenance infusion is increased, the time to return of consciousness is also significantly increased.

6 Although neuraxial techniques (spinal and epidural) may decrease pulmonary complications, they are associated with hemodynamic instability and are contraindicated in patients with severe flow-dependent cardiovascular diseases.

7 Peripheral nerve blockade can be used in lieu of general anesthesia as a primary anesthetic for surgery, or in conjunction with general anesthesia to serve as a postoperative pain management technique. Use of long-acting local anesthetics or placement of an indwelling continuous catheter provides long-term (16 hours to several days) pain relief.

8 The concept of airway management should be focused on not just endotracheal intubation, but also mask ventilation. Until the airway

can be secured via intubation, the patient must be supported through mask ventilation. The key elements of an airway examination are an assessment of obesity, mouth opening, neck flexion and extension, Mallampati oropharyngeal classification, presence of beard, and mandibular protrusion ability.

9 Laryngeal mask airways offer an alternative to endotracheal intubation for general anesthesia airway management in selected patients and procedures.

10 More than 8% of patients undergoing major noncardiac inpatient surgery will experience postoperative myocardial ischemia, elevating their risk of 30-day mortality. For symptomatic patients, benefits must be weighed against risk of initiating preoperative beta-blockers, alpha-blockers, and aspirin.

11 The appropriate duration to defer elective surgery after coronary stenting remains controversial, but recent guidelines from the American College of Cardiology/American Heart Association recommend 6 months for drug-eluting stents and 30 days for bare-metal stents. The role for antiplatelet therapy remains a major question, but data suggest that cessation of recommended antiplatelet therapy in the perioperative period may have significant coronary thrombotic risks without major improvement in bleeding adverse events.

12 The three goals of the preoperative evaluation are (a) to develop an anesthetic plan that considers the patient's medical condition, the requirements of the surgical procedure, and the patient's preferences; (b) to ensure that the patient's chronic disease is under appropriate medical therapy before an elective procedure; and (c) to gain rapport with and the confidence of the patient, answer any questions, and allay fears.

13 Patients receiving chronic pain or opioid addiction therapy with buprenorphine (Subutex, Suboxone) can be particularly challenging to manage in the postoperative period and should be immediately referred to their primary care physician and an anesthesiologist to

create a pain management plan prior to the day of surgery. Buprenorphine is mixed opioid agonist/antagonist that tightly binds at the μ-receptor and has a long and varied half-life (24 to 60 hours). It can inhibit the analgesic benefits of traditional opioids in the postoperative period, resulting in uncontrolled pain, decreased patient satisfaction, and the potential for adverse events due to the need for very high doses of opioids.

14 As positive-pressure ventilation impedes venous return within a closed thorax, decreases in systolic pressure associated with a respiratory pattern can be detected. In patients with sinus rhythm with stable cardiac contractility, the degree of systolic pressure variation (SPV) is inversely related to the intravascular volume status of the patient. The normal range of SPV is 5 to 10 mm Hg. Other measures such as pulse pressure variation (PPV) use similar physiologic assumptions to assess volume status.

15 Enhanced recovery programs incorporating preoperative optimization, standardized surgical and anesthesia protocols, and goal-directed therapy may improve patient outcomes and reduce costs.

16 Postoperative acute pain management may require a multimodal approach that incorporates opioids, peripheral nerve blockade, and nonopioid analgesics. Chronic pain patients can be particularly difficult to manage and may require preoperative optimization by an anesthesiologist.

INTRODUCTION

The goal of anesthesia is to enable the safe conduct of otherwise noxious procedures with maintenance of physiologic homeostasis while optimizing procedural conditions. The state of general anesthesia is a combination of hypnosis, amnesia, analgesia, and muscle relaxation, achieved by the administration of single or multiple anesthetic agents via inhalational or

intravenous routes. Historically, anesthesia was achieved by inhaling anesthetic vapors that produced each of these conditions in proportion to the concentration achieved in the central nervous system. Anesthesia can also be achieved by using a balance of multiple pharmacologic agents, each targeted to produce a specific effect—hypnotic/sedatives, analgesics, and neuromuscular blocking agents. As the concentration of hypnotic/sedative and analgesic agents increases, cardiovascular and respiratory functions may be progressively blunted; titration of these agents is necessary to optimize conditions for the surgery while maintaining cardiovascular stability.

Despite serious potential complications surgical anesthesia is administered with a high degree of safety 30 to 40 million times a year in the United States. The high degree of safety may be attributed to the efforts of thousands of surgeons and anesthesiologists who have advanced the art and science of their field.[1] Although modern surgical techniques, regional or neuraxial blockade procedures, and systemic analgesics have made it possible to ameliorate perioperative pain, significant challenges in postoperative pain management remain. Pain is not only unpleasant, but also can provoke a stress response leading to significant adverse effects.

ANESTHETIC AGENTS AND THEIR PHYSIOLOGIC EFFECTS

Inhalation Agents

1 Inhalational anesthetics produce dose-dependent depression of consciousness, pain, cardiopulmonary function, motor function, and recall. Comparative potency of inhalation agents is expressed as the minimum alveolar concentration (MAC), an empirically derived number defined as the expired percent concentration required to prevent movement on painful stimulation (incision) in half of experimental subjects. There is significant patient-to-patient variability independent of underlying comorbidities. Compounding this variability are the effects of age, weight, pre-existing heart disease, liver disease, and co-administered medications. **Table 13.1** lists the commonly used inhalation agents, their MACs and side effects. In general, all agents cause hypotension by myocardial depression and vasodilation. There

is also a generalized depression of cerebral function and cerebral metabolic rate for oxygen, although cerebral blood flow may increase because of cerebrovascular dilatation and a loss of flow-metabolism coupling. Renal blood flow and glomerular filtration rate are reduced by 20% to 50%. The body's regulation of core body temperature is lost, resulting in a redistribution of heat from the core to the periphery; the cold environment of the operating room and open body cavities make anesthetized patients extremely vulnerable to hypothermia (core body temperature <36°C).

Intravenous Sedatives/Hypnotics

Several commonly used intravenous sedative/hypnotic medications can also be used, by intravenous infusion, in lieu of an inhalational anesthetic to achieve maintenance of anesthesia. Unlike inhalational agents, currently, there is no ability to measure the patient's expired or blood concentration of these intravenous agents. As a result, the infusion rate is titrated to effect by observing patient movement (if muscle relaxants are not used concurrently) and hemodynamic responses to procedural stimuli. The sedative/hypnotic intravenous agents do not possess clinically useful muscle relaxant or analgesic properties and must be combined with other agents to deliver a "balanced" anesthetic. The most commonly used intravenous agent for maintenance of anesthesia is propofol, a lipid-soluble substituted isopropyl phenol that produces hypnosis and sedation through interactions with γ-aminobutyric acid (GABA), the primary inhibitory neurotransmitter of the central nervous system. When administered as a continuous infusion, propofol can achieve minimal levels of sedation, deep sedation, or general anesthesia. Additional details regarding the use and side effects of propofol are discussed later. Other classic agents such as benzodiazepines can also be used as maintenance infusions, but do not enable the rapid return to consciousness that propofol offers. The highly specific α_2-receptor agonist, dexmedetomidine, may also be used as an intravenous sedative/hypnotic and also has analgesic effects and does not produce significant respiratory depression. In the perioperative setting, it is currently limited to use as an adjunct to propofol and inhalational anesthetics for general anesthesia or as a sole agent during procedural sedation.

Muscle Relaxants

2 To prevent movement and to facilitate surgical exposure, neuromuscular blocking agents are generally used. These drugs are competitive or noncompetitive inhibitors of the neurotransmitter acetylcholine at the neuromuscular junction. The only noncompetitive inhibitor used clinically is succinylcholine. This drug rapidly binds to the nicotinic receptors and produces depolarization at the neuromuscular junction, clinically manifesting as fine-muscle fasciculations occurring 30 to 60 seconds after injection. Succinylcholine cannot be reversed, but has a short duration of action (<10 minutes) because it is quickly hydrolyzed in the plasma by cholinesterase. Because of rapid onset and short duration of action, succinylcholine is classically used to facilitate endotracheal intubation when it must be accomplished quickly, or when quickly regaining neuromuscular function is beneficial.

All other clinically useful muscle relaxants compete with endogenous acetylcholine at the neuromuscular junction, are termed *competitive inhibitors* and do not cause depolarization (nondepolarizing). The block produced is in direct proportion to the concentration of the agent relative to the concentration of acetylcholine. If the concentration ratio is low enough, competitive relaxants can be reversed by agents that block acetylcholine metabolism, an anticholinesterase (e.g., neostigmine). The neuromuscular blocking agent is still present, but motor function returns when acetylcholine concentration is high enough to overwhelm the blocking agent. Anticholinesterases hence exhibit a ceiling effect. There are systemic consequences to increasing the plasma concentration of acetylcholine. Acetylcholine is the predominant neurotransmitter in the preganglionic sympathetic and parasympathetic nervous systems and in the postganglionic parasympathetic nervous system. To counter the undesirable effects of systemic acetylcholine an anticholinergic drug (atropine or glycopyrrolate) must be given with the anticholinesterase. The common neuromuscular blocking drugs and their doses, durations, and side effects are listed in **Table 13.2**; common regimens of reversal agents are shown in **Table 13.3**.

Table 13.1 Common Inhalation Agents: Minimum Alveolar Concentrations and Effects

Agent	Minimum Alveolar Concentration (%)	Strengths	Weaknesses
Nitrous oxide	105	Analgesia Rapid uptake and elimination Less cardiac or respiratory depression	Sympathetic stimulation Expansion of closed air spaces Interference with vitamin B_{12} metabolism Limitation of inspired oxygen fraction
Isoflurane	1.15	Good muscle relaxation Stable cardiac rate and rhythm Usability in neurosurgery	Airway irritant, may cause coughing
Desflurane	6	Rapid induction and emergence	Airway irritant, may cause coughing High vapor pressure (Boiling point 23.5°C) requiring special

			pressurized vaporizer High cost
Sevoflurane	1.71	Rapid induction and emergence Less pungent, does not cause airway irritation	Moderate cost

3 Postoperative residual neuromuscular blockade is recognized as a common problem after routine administration of nondepolarizing muscle relaxants. The evaluation of depth of muscle relaxation is a subjective process based upon empirical pharmacokinetics or visual inspection of a patient's peripheral nerve response to external electrical stimulation. During peripheral nerve stimulator monitoring, two electrode patches are placed on the patient's skin along the course of a peripheral nerve which innervates an observable muscle group. Commonly used monitoring locations include the ulnar nerve, ophthalmic branch of the facial nerve, or the posterior tibial nerve. Electrodes are connected to a hand-held device which delivers four short transcutaneous bursts of electricity, ranging from 10 to 100 mA every 0.5 seconds, hence the term "train-of-four monitoring." A clinician visually inspects the response to each electrical stimulation. In a patient without any pharmacologic neuromuscular blockade, the strength of the fourth muscle response (or "twitch") matches that of the first. In the face of complete pharmacologic competitive inhibition of neuromuscular transmission, no muscular twitches are observed at all. At varying levels of neuromuscular blockade in between, the fourth, third, or second twitch may be absent. Due to competitive blocking of the neuromuscular junction nicotinic receptor, each successive stimulation results in a weaker response because sequentially fewer receptors are available for stimulation. The ratio between the strength of the fourth twitch and the first twitch is known as the train-of-four ratio. During normal neuromuscular transmission, the ratio is 1. Historically, a ratio of 0.7 was considered adequate muscular strength for

extubation. However, more recent literature suggests that a ratio between 0.7 and 0.9 still exposes the patient to significant risks of atelectasis, hypoxemia, aspiration, pneumonia, and possibly reintubation. In routine practice, a clinician is incapable of assessing a concept as precise or nuanced as train-of-four ratio. As a result, the number of twitches observed is typically reported, that is, 0/4, 1/4, 2/4, 3/4, 4/4. A patient with 3/4 or 4/4 twitches is capable of responding to cholinesterase inhibitors and return to normal function. A patient with 0/4, 1/4, or 2/4 is unlikely to adequately respond to cholinesterase inhibitors. Data from multiple centers have demonstrated that a significant proportion of patients demonstrated residual neuromuscular blockade of <0.9 in the recovery room despite reversal.

Table 13.2 Common Neuromuscular Blocking Drugs and Reversal Agents

Muscle Relaxant	Intubating Dose (mg/kg)	Infusion Dose (mg/kg/min)	Strengths	Weaknesses
Depolarizing				
Succinylcholine	1.0	100[a]	Fastest onset (30–60 s) Short duration[b] (5–10 min)	Associated with malignant hyperthermia, dysrhythmias, bradycardia, and hyperkalemia, especially in patients with burns or neurologic injury
Nondepolarizing				
Cisatracurium	0.2	0.1	Spontaneous degradation, not affected by renal or liver disease	Moderate cost
Vecuronium	0.1	1	No cardiovascular effects	
Rocuronium	0.8	10	Fast onset, no cardiovascular effects	

[a]This should not be used for longer than 1 hr.
[b]Duration is dramatically increased in patients with abnormal plasma pseudocholinesterase.

Table 13.3 Drugs for Antagonizing Nondepolarizing Neuromuscular Blockade[a]

Dose	Time to Peak Effect (min)	Dose	Use with	Comments
Anticholinesterases				
Edrophonium	1–2	0.5–1.0 mg/kg	Atropine	Very fast onset, not commonly used
Neostigmine	3–5	0.04–0.07 mg/kg	Glycopyrrolate	Most commonly used
Pyridostigmine	10–12	0.2–0.3 mg/kg	—	Not used clinically for neuromuscular reversal
Selective Relaxant Binding Agents				
Sugammadex	2–3	2–16 mg/kg	—	Primarily used for reversal of rocuronium and vecuronium

[a]For reliable results in reversing the effects of nondepolarizing muscle relaxants, administration of anticholinesterases is delayed until spontaneous recovery permits three to four twitch responses to a train-of-four stimulus. For patients with more profound blockade, larger amounts of anticholinesterases may be required, but doses of neostigmine higher than 0.14 mg/kg are unlikely to produce additional improvement.
CNS, central nervous system.
Adapted from Watling SM, Dasta JF. Prolonged paralysis in intensive care unit patients after the use of neuromuscular blocking agents: a review of the literature. *Crit Care Med* 1994;22:884.

The use of subjective train-of-four monitors is inferior to objective acceleromyography, a calibrated device used to accurately establish the "true" train-of-four ratio. Although clinically effective at eliminating the limitations of subjective train-of-four monitoring, its use remains limited because of the time necessary for set up, and an under-appreciation of the frequency of residual neuromuscular blockade. It has been promoted by patient safety experts, and is beginning to demonstrate increased penetration.

Muscles in the body are not equally sensitive to muscle relaxants. The diaphragm is most resistant to neuromuscular blockade, whereas the neck and pharyngeal muscles that support the airway are most sensitive. It is therefore possible for an intubated patient to exhibit adequate spontaneous ventilation and produce a large negative inspiratory pressure and yet develop complete airway obstruction when extubated.

A novel class of compounds known as *selective relaxant binding agents*—currently comprised of only one FDA-approved drug, sugammadex—may serve to revolutionize the practice of neuromuscular blockade and its reversal. Such compounds are able to rapidly reverse the effects of profound levels of muscle relaxation (0/4 twitches) created by steroidal nondepolarizing muscle relaxant agents rocuronium and vecuronium. These agents physically bind free muscle relaxant molecules within a cyclodextrin ring structure and decrease the concentration of free muscle relaxant allowing acetylcholine to function normally at the neuromuscular junction.

The cyclodextrin–muscle relaxant combination is eliminated via the kidney. The drug rapidly (<3 minutes) reverses profound muscle relaxation[2] without cholinergic side effects offering considerable advantage over the traditional approach. Sugammadex cannot reverse neuromuscular blockade achieved with benzylisoquinolinium muscle relaxants (atracurium, cisatracurium) given incompatibility in chemical structures.

Opioids (Narcotics) and Other Intravenous Analgesics

Narcotics and synthetic analogues belong to the class of drugs called *opioids*. The most commonly used drugs in this family are morphine, fentanyl, and hydromorphone. Since the mid-1980s, a series of synthetic opioids have been developed with fentanyl as the prototype. More recently developed synthetics (sufentanil, alfentanil, and remifentanil) are more potent and 4 of varying duration (**Table 13.4**). Opioids produce profound analgesia and respiratory depression. They have no amnesic properties, minimal direct myocardial depressive effects, and no muscle-relaxant properties. Opioids can produce significant hemodynamic effects indirectly by releasing histamine or blunting the patient's sympathetic vascular tone. Acutely injured patients may be hypovolemic and in pain, with high sympathetic tone and peripheral vascular resistance and can, therefore, experience dramatic drops in systemic blood pressure with minimal doses of opioids. Because of the lack of direct myocardial depression and the absence of histamine release with the synthetic opioids, they are frequently used as the primary anesthetic in combination with an amnesic agent and a muscle relaxant in patients with significant myocardial dysfunction.

All opioids can be reversed with naloxone. The duration of action of naloxone can be shorter than that of the opioid, and patients must be observed carefully for renarcotization after they have been treated with naloxone. Naloxone treatment has been associated with acute pulmonary edema and myocardial ischemia and should not be used electively to reverse the effects of a narcotic.

Propofol

Propofol is a lipid-soluble substituted isopropyl phenol that produces a rapid induction of anesthesia in 30 seconds followed by awakening in 4 to 8 minutes after a single bolus. Intravenous propofol can effectively produce total anesthesia (for less stimulating procedures), including amnesia, some 5 analgesia, and some degree of muscle relaxation. As the duration and dose of the maintenance infusion is increased, the time to return to consciousness is also significantly increased. This context-sensitive half-life of propofol must be incorporated into expectations of a "quick wake-up." Propofol has direct antiemetic properties and is a valid alternative to inhalational anesthetics in patients who have demonstrated a history of prolonged, refractory postoperative nausea and vomiting. It has an important role in intensive care units when used as a continuous infusion sedative. However, prolonged infusions have been associated with a lethal metabolic derangement known as propofol infusion syndrome, characterized by a profound metabolic acidosis and cardiovascular compromise.[3] Due to dose-dependent direct myocardial depression and peripheral vasodilation, propofol can produce significant hypotension when IV induction doses are administered. It also produces significant pain on injection in peripheral veins. Propofol is insoluble in aqueous solution and therefore presented dissolved in a lipid emulsion that has the associated risk of bacterial contamination. Once a vial of propofol is opened, it is not recommended that it be used after 6 hours.

	Potency	Sedation Dose	Duration	Infusion Dose
Opioids				
Morphine	1	0.02–0.1 mg/kg IV	2–7 hrs	—
Fentanyl	100	0.5–1 mcg/kg IV	30–60 min	—
Sufentanil	1,000	Not recommended	—	—
Alfentanil	25	10–20 mg/kg IV	10–15 min	—
Remifentanil[a]	—	Not recommended	10 min	0.1–0.2 mg/kg/min
Other Analgesics and Anesthetics				
Propofol		0.1–0.5 mg/kg IV[b,c]		100–200 mcg/kg/min[b]
Ketamine		0.1–0.5 mg/kg IV[b] 1.0–2.0 mg/kg IM		1–2 mg/min (anesthetic dose) 500 mcg/kg (analgesic dose)
Dexmedetomidine		Not recommended		0.2–1.0 µg/kg/hr

[a]Will produce apnea.
[b]May produce apnea.
[c]Produces pain on injection that can be reduced by treatment with 20 mg of lidocaine IV.
IM, intramuscular; IV, intravenous.

Ketamine

Ketamine is a phencyclidine derivative that produces anesthesia characterized by dissociation between the thalamus and limbic systems. Induction of anesthesia is achieved within 60 seconds after IV injection of 1 to 2 mg/kg or within 2 to 4 minutes of intramuscular (IM) injection of 5 to 10 mg/kg. Patients appear to be in a cataleptic state in which their eyes remain open with a slow nystagmic gaze. The drug produces intense amnesia and analgesia but has been associated with unpleasant visual and auditory hallucinations that can progress to delirium. The incidence of these problems can be significantly reduced if benzodiazepines are co-administered. At low doses (0.1 to 0.2 mg/kg IV or 2 mg/kg IM), patients continue to spontaneously ventilate. At higher doses, ketamine acts as a respiratory depressant and produces complete apnea. Ketamine also has direct and indirect sympathetic nervous system stimulatory effects, which can be useful in hypovolemic patients or in patients likely to encounter bronchospasm. These effects are diminished or absent in patients who are catecholamine depleted. The

sympathetic stimulatory effect increases myocardial oxygen consumption and intracranial pressure, and ketamine is relatively contraindicated in patients with ischemic heart disease or space-occupying intracerebral lesions. Owing to its analgesic properties and relatively preserved ventilation, ketamine is frequently used as an IV analgesic during debridement procedures, at doses listed in **Table 13.4**. IM ketamine (1 to 2 mg/kg) is also very useful for sedating patients who are difficult to manage (e.g., combative or cognitively disabled patient), so IV access can be obtained. Ketamine's most frequent use is in subanesthetic doses as part of multimodal analgesic regimens hoping to minimize the use of opioids. For procedures requiring general anesthesia that may have significant postoperative opioid requirements, a preincision ketamine bolus dose with a low-dose intraoperative infusion may be associated with improved acute and chronic pain outcomes.[4]

Amnesics and Anxiolytics

Benzodiazepines are the primary class of agents used as amnesics and anxiolytics. The prototype drug, diazepam, has been mostly replaced by its water-soluble analog of shorter duration, midazolam. Lorazepam also belongs in this family of agents, but because it has a very long duration of action, it is not routinely used intraoperatively. Lorazepam has intensive care unit applications (**Table 13.5**). Benzodiazepines have no analgesic properties but can be used in combination with the short-acting opioid fentanyl to produce conscious sedation for minor procedures. Benzodiazepines can produce apnea and have synergistic adverse effects with narcotics. As with all anesthetics, benzodiazepines used as IV agents for sedation should be given in small incremental doses to achieve the desired effect. A reversal agent is also available for benzodiazepines (flumazenil). The recommended dosages of these drugs and the reversal agents appear in **Table 13.5**.

Local Anesthetics

Local anesthetics temporarily block nerve conduction by binding to neuronal sodium channels. As the concentration of the local anesthetic increases around the nerve, autonomic transmission will be blocked first, followed by sensory transmission, and then motor nerve transmission. These drugs can be

injected locally into tissue to produce a field block, around peripheral nerves to produce a specific dermatomal block, around nerve plexuses to produce a major conductive block, or into the subarachnoid or epidural space to produce extensive neuraxial blockade. All the methods have been used to assist in the provision of an alternative form of balanced anesthesia by supplementing analgesia and muscle relaxation.

Table 13.5 Anxiolytics and Amnesics (Benzodiazepines)

Name	Dose (mg)	Duration (hr)	Strengths	Weaknesses
Midazolam (Versed)	0.5–2 IV	0.5	Water soluble Short duration Good for sedation for short procedures	Acute respiratory depression
Diazepam (Valium)	5–10 IV	1	Intermediate duration	Irritation on IV injection Phlebitis Acute respiratory depression after IV overdose
Lorazepam (Ativan)	2–4 IV	6–8	Long duration	—
Benzodiazepine Reversal				
Flumazenil (Romazicon)	0.2 IV (0.2 mg repeated every 2–10 min until reversal is achieved) Maximum dose 1 mg	45–90 min	—	May produce seizures, panic, arrhythmias

IV, intravenous.

Adverse consequences associated with the use of local anesthetics fall into three categories: acute central nervous system toxicity due to excessive plasma concentration, hemodynamic and respiratory consequences due to excessive conduction block of the sympathetic or motor nerves, and allergic reactions. Whenever a local anesthetic is injected, there can be inadvertent intravascular injection or an overdose of the drug because of rapid uptake from the tissues. Overdose can produce seizures, as well as cardiovascular collapse from ensuing arrhythmias. Agents differ in duration of action (**Table 13.6**) which may be prolonged by the addition of epinephrine to the administered drug. Epinephrine works, for this purpose, by local vasoconstriction and hence delays the distribution of local anesthetic from tissues to the blood stream; it is not recommended for any anatomic site that may be subject to ischemia such as penis and digits.

When local anesthetics are administered for a spinal or epidural block, they produce a progressive blockade of the sympathetic nervous system,

which produces systemic vasodilation. Sympathetic nerves travel along the thoracolumbar region with the first four thoracic branches, including the cardiac sympathetic accelerators. A sympathetic blockade of this entire region produces a characteristic profound systemic vasodilatation and bradycardia. This condition is referred to as *total sympathectomy.* Affected patients are bradycardic, hypotensive, unconscious, and usually apneic. This disastrous situation is easily remedied if treated quickly with a vasopressor (phenylephrine or ephedrine) and atropine or small doses of epinephrine (increments of 10 μg for an adult). If not treated promptly, the situation proceeds to cardiac arrest. The required doses of epinephrine are higher than in a usual cardiac arrest because of the total sympathectomy.[5] Because the level of sympathetic block is two to six dermatomal levels higher than the sensory block, it is often 6 difficult to obtain a high spinal sensory level without approaching a total sympathectomy. For this reason, spinal or epidural techniques can present a prohibitively high risk in patients with severe flow-dependent cardiovascular disease.

Table 13.6 Local Anesthetics

	Maximum Single Dose (mg/kg)	Duration (hr)	Comments
Amides			
Lidocaine	4.5	1[a]	Fast onset
Ropivacaine	3	4–12[a]	Less cardiac toxicity than bupivacaine
Bupivacaine	3	4–12[a]	Exaggerated cardiotoxicity with IV injection Slow onset Long duration
Esters[b]			
2-Chloroprocaine	12	0.5–1[a]	Fast onset Lowest toxicity, rapid metabolism
Tetracaine	3	0.5–1	Slow onset

[a]Addition of 100 µg of epinephrine (0.1 mL of 1:1,000) lowers the toxicity and increases the duration of the local anesthetic.

[b]Metabolism to para-aminobenzoic acid may cause allergic reactions.

IV, intravenous.

Local anesthetics are chemically divided into two groups: esters and amides. The esters (2-chloroprocaine and tetracaine) produce metabolites that are related to *p*-aminobenzoic acid and have been associated with allergic reactions. Amides (e.g., lidocaine and bupivacaine) are rarely associated with allergic reactions. If an allergic reaction does occur, it is

most likely due to the preservative (methylparaben) used in multidose vials of lidocaine.

NEURAXIAL BLOCKADE

The two primary neuraxial techniques, a "single-shot" spinal and continuous epidural catheter, can be used for lower extremity and lower abdominal procedures. In the case of a spinal anesthetic—also known as a subarachnoid block—the intrathecal sac surrounding the cauda equina at vertebral interspace L2–L3 or below is located using a sterile, small-caliber needle (25 gauge typically). Once cerebrospinal fluid is observed in the hub of a needle, 1 to 3 mL of preservative-free local anesthetic (typically bupivacaine or lidocaine) is injected into the intrathecal space. The needle is then completely withdrawn. Blockade of sensory, motor, and sympathetic nerves occurs at the nerve roots. The spread of local anesthetic within the subarachnoid space is primarily determined by three factors: (a) the vertebral interspace accessed, (b) the density of the local anesthetic in relation to the density of cerebrospinal fluid (a concept known as *baricity*), and (c) the position of the patient during injection and immediately thereafter. In order to eliminate the risk of needle puncture of the spinal cord, subarachnoid blocks are only performed below L2–L3 in adults and L3–L4 in children. The local anesthetic solution may be combined with vasoconstrictors such as epinephrine or opioids such as fentanyl or morphine in order to increase the density or duration of the sensory blockade. Surgical anesthesia ranging from 1 to 2 hours can be achieved using a subarachnoid block. Because of concerns regarding permanent nerve damage, intrathecal catheters are typically not used.[6,7]

In the case of epidural techniques, the nerve roots are blocked outside the thecal sac in a potential space between the ligamentum flavum and dura mater. This space is accessed sterilely using a 19-gauge introducer needle and a loss of resistance technique. Once the space is identified, a 21-gauge catheter is inserted into the space via the introducer needle and the needle is removed leaving the catheter in place and redosing is therefore possible. Dilute local anesthetics combined with vasoconstrictors or opioids are the mainstay of epidural therapy. Epidural neuraxial techniques can be used for

surgical anesthesia, as an adjunct to general anesthesia, or for postoperative pain relief. Epidural catheters can be placed in the thoracic or lumbar regions because the intrathecal sac is not being accessed; associated dermatomal spread and analgesia is observed. Epidural techniques often fail to result in a dense sacral nerve root blockade making it a suboptimal choice for surgical anesthesia below the knee.

PERIPHERAL NERVE BLOCKADE

Peripheral nerve blockade (PNB) has been used for surgical anesthesia of the extremities since the days of intravenous regional anesthesia described by Bier in 1908. Upper extremity, lower extremity, and visceral peripheral nerves are targets. 7 Much like neuraxial blockade, PNB can be used to achieve intraoperative surgical anesthesia, intraoperative analgesia as an adjunct to general anesthesia, or for postoperative analgesia. Use of long-acting local anesthetics or placement of an indwelling continuous catheter provides long-term (16 hours to several days) pain relief. A specific preoperative planning discussion to match the planned surgical procedure to a feasible dermatomal distribution of blockade is essential. Even when blockade of a dermatomal distribution specific to a surgical procedure is feasible, a PNB may be contraindicated if a neurologic examination performed at or near the surgical site in the early postoperative period is necessary.

Because of the limited distribution of sympathetic blockade, PNB has a much smaller hemodynamic effect than general or neuraxial anesthesia. In addition, if general or neuraxial anesthesia can be supplemented by a PNB, the residual unwanted side effects of these anesthetics can be limited. However, PNB is not without side effects; the impact of phrenic nerve motor blockade associated with specific upper extremity blocks (common with interscalene and rare with supraclavicular) may have significant consequences for patients with underlying pulmonary disease.

Most anesthesiologists employ real-time ultrasound guidance of needle under direct visualization for the placement of PNB. Vascular structures and nerves are visualized in relation to a PNB needle in order to decrease the likelihood of intravascular or intraneural injection, increase the likelihood of

an efficacious block, and minimize the dose of local anesthetic required to achieve an efficacious block. Despite direct visualization using ultrasound, PNB in adults are typically performed in the awake state to minimize the risk of intraneural injection, which may be detected via patient complaint of significant pain upon injection. PNB can be extremely difficult or contraindicated in patients with challenging body habitus, local superficial infection, significant coagulopathy, or implants near the area to be visualized or injected.

While PNB targets named major peripheral nerves resulting in both motor and sensory blockade sufficient for surgical anesthesia, field blocks target small cutaneous sensory nerve fibers, used more commonly to achieve moderate sensory blockade for postoperative analgesia. These blocks typically do not achieve sensory blockade sufficient for surgical anesthesia and must be augmented by general anesthesia or deep sedation. Procedures such as transversus abdominis plane (TAP), adductor canal, intercostal nerve, and local infiltration enable postoperative analgesia.

SEDATION ANALGESIA FOR MINOR SURGICAL PROCEDURES

Sedation occurs on a continuum from minimal sedation (responds normally to verbal stimuli) to general anesthesia (unarousable). "Deep sedation" describes a drug-induced depression of consciousness from which a patient cannot easily be aroused but maintains the ability to respond purposefully to repeated or painful stimuli; since inadvertent progression to general anesthesia is a risk, providers are held to similar standards to those who provide anesthesia services by federal code. The term "monitored anesthesia care" (MAC) does not describe a level of sedation but is rather a specific anesthesia service in which an anesthesiologist participates. There are a variety of minor surgical procedures that can be accomplished safely and comfortably with anesthesia provided by infiltration of local anesthetics (most commonly 1% lidocaine or 0.25% bupivacaine) and minimal sedation/anxiolysis provided by IV agents. All IV benzodiazepines, narcotics, and other IV anesthetics produce apnea with substantial patient-to-

patient variation; small incremental doses are recommended to achieve a safe sedated state. Inadequate infiltration of local anesthetic cannot be compensated by increased doses of IV sedatives. Because of the potentially serious consequences of an apneic episode, The Joint Commission has required that all patients receiving sedation for minor surgical or medical procedures undergo the following as a minimum standard[8]:

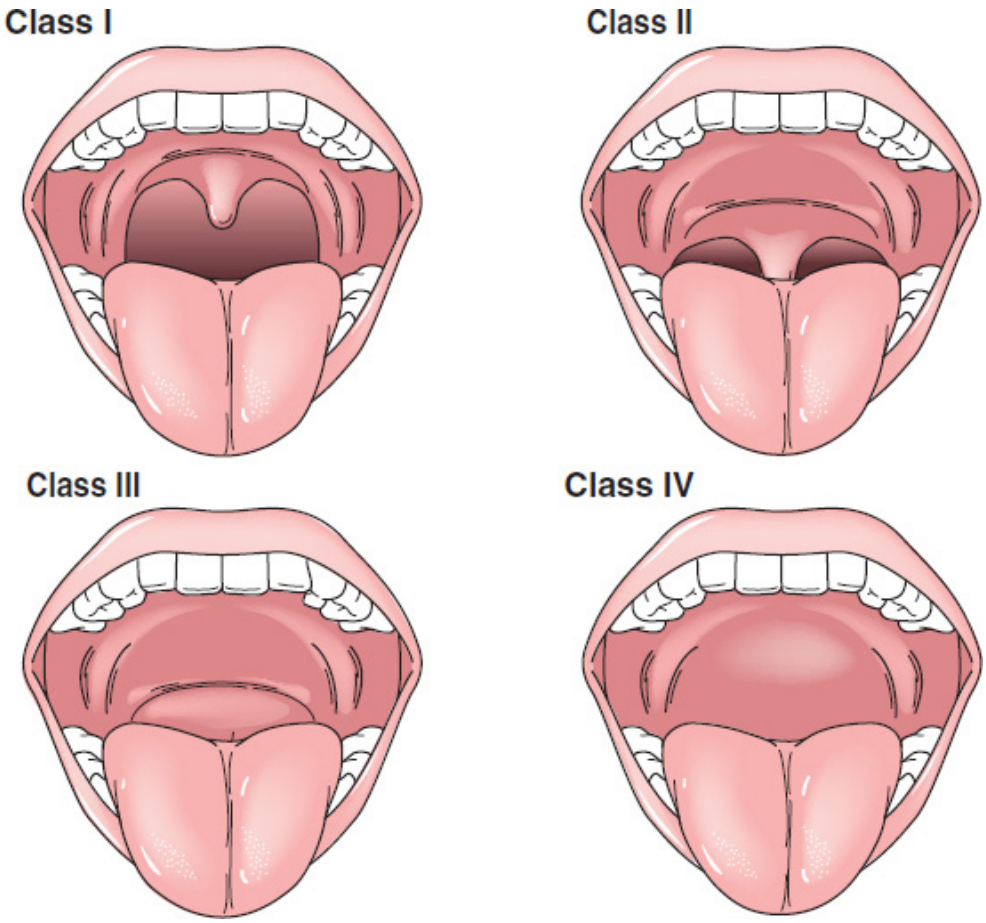

Figure 13.1 Classification of the patient's upper airway based on the size of the tongue and the pharyngeal structures visible on mouth opening. Class I, soft palate and anterior/posterior tonsillar pillars, and uvula visible; Class II, tonsillar pillars and part of uvula hidden by base of tongue; Class III, soft and hard palate visible; Class IV, soft palate not visible, only hard palate visible. (Redrawn from Stoelting RK, Miller RD. *Basics of Anesthesia*. 5th ed. New York: Churchill Livingston; 2007:146.)

1. A preprocedure evaluation including an airway examination (**Fig. 13.1**)
2. Appropriate monitoring: pulse oximetry as a minimum

3. Documentation of the patient's vital signs and arterial saturation as well as the dose and timing of sedatives provided during the procedure
4. Documentation of a recovery period and a return to a safe recovered state

The preprocedure evaluation should include current medications, coexisting disease, and a brief physical examination including an evaluation of the airway. The most common drug used to provide sedation is midazolam. This is a fast-onset, relatively short-acting benzodiazepine that can be easily titrated to produce a sedated yet cooperative arousable state. It is usually given to adults in incremental doses of 1 mg (0.01 mg/kg in children). Narcotics such as fentanyl even in small doses act synergistically with benzodiazepines to cause a more sedated state with a much higher incidence of apnea. To assess the effect of the drug, a validated sedation scale can be of value. The scale used at the University of Michigan is presented in **Table 13.7**.[9]

AIRWAY EVALUATION FOR THE NONANESTHESIOLOGIST

An essential skill for all clinicians is the assessment of a patient's airway to determine how difficult it may be to obtain control of the airway if a patient requires 8 ventilatory support. The concept of airway management should be focused on not just endotracheal intubation, but also mask ventilation. Until the airway can be secured via intubation, the patient must be supported through mask ventilation.[10] Supraglottic airway devices (laryngeal mask airways) are of additional consideration, used for both intraoperative airway management as well as a rescue technique for failed mask ventilation or failed intubation. Limitations to supraglottic airway devices, however, include a relative lack of protection from aspiration, as well as a limited ability to provide adequate positive-pressure ventilation in patients prone to airway obstruction 9 (e.g., morbidly obese, sleep apnea). The key elements of an airway examination are an assessment of obesity, mouth opening, neck flexion and extension, Mallampati oropharyngeal classification, presence of beard, and mandibular protrusion ability (**Table 13.8**).[11] There is no perfect combination of clinical tests to predict difficult intubation. However, the

presence of abnormalities in three or more of the aforementioned elements increases the likelihood of a difficult mask ventilation and/or difficult intubation by more than eight-fold.[11] In patients with multiple (three or more) airway abnormalities, the presence of a beard is an easily corrected characteristic. Assessment of oropharyngeal classification is performed by having patients open their mouth and maximally protrude the tongue without phonation. This Mallampati oropharyngeal assessment can be classified depending on whether the uvula can be completely seen (class 1), only partly seen (class 2), or not seen, with the hard and soft palate visible (class 3), or only the hard palate visible (class 4) (**Fig. 13.1**).[12]

Table 13.7 Sedation Scale

Sedation Scale	Description
0	Awake and alert
1	Minimally sedated: tired/sleepy, appropriate response to verbal conversation and/or sound
2	Moderately sedated: somnolent/sleeping, easily aroused with light tactile stimulation or a simple verbal command
3	Deeply sedated: deep sleep, arousable only with significant repeated physical stimulation
4	Unarousable

Table 13.8 Standard Airway Examination for Nonanesthesiologists

Exam Element	Concerning Findings
Body mass index (kg/m^2)	Body mass index ≥31
Mouth opening	Interincisor or intergingival distance <3 cm
Mallampati classification	Class III or IV (see **Fig. 13.1**)
Mandibular protrusion	Inability to protrude lower incisors to meet or extend past upper incisors
Neck anatomy	Radiation changes, or thick obese neck
Cervical spine mobility	Limited extension or possibly unstable cervical spine
Beard	Presence of full beard

RISKS ASSOCIATED WITH ANESTHESIA

With the advent of newer agents and monitoring techniques, it is estimated that the mortality rate directly attributable to anesthesia has decreased from about 1 in 10,000 patients in the 1950s to as low as 1 in 200,000 or less for healthy patients today.[13] When patients are placed in a condition in which they cannot breathe, there is always the possibility of a technical or judgmental error resulting in hypoxia and brain damage or death. It has been estimated that between 50% and 75% of anesthetic-caused deaths are due to human error and are preventable.

Efforts to improve outcome can be approached at three levels: (a) reduction of the incidence of rare but catastrophic anesthetic-related problems, (b) improvement of the care and experience of every patient undergoing anesthesia and surgery, and (c) improvement of the preparation and management of patients with pre-existing medical conditions that have

higher morbidity and mortality rates. Historically, the most common problems associated with adverse outcomes were related to the airway and included inadequate ventilation, unrecognized esophageal intubation, unrecognized extubation, and unrecognized disconnection from the ventilator. The incidence of these problems has been significantly reduced by including capnometry and pulse oximetry in addition to other noninvasive monitors, although a cause-and-effect relation has been difficult to prove. Standardized anesthesia machine checklists, anesthesiology training, pain management programs, and improved understanding of pre-existing comorbidities have also had positive impact.

Cardiovascular Diseases

Hypertension

Hypertension is the most common pre-existing medical disease in patients presenting for surgery and is a major risk factor for renal, cerebrovascular, peripheral vascular, and coronary artery diseases, as well as congestive heart failure (CHF). It is particularly associated with lipid disorders, diabetes, and obesity. It is these associated comorbidities that are most likely to lead to morbidity and mortality in the perioperative period. Hypertensive patients should be treated medically to render them normotensive before elective surgery. In general, antihypertension medications should be continued throughout the perioperative period. However, patients treated with angiotensin receptor blockers (ARBs), such as valsartan, candesartan, losartan, or angiotensin-converting enzyme inhibitors (ACE-Is), such as lisinopril, captopril, or ramipril, who are exposed to general anesthesia, are at risk for developing profound, refractory intraoperative hypotension. This ACE-I/ARB hypotension has been treated successfully with terlipressin, vasopressin, and methylene blue.[14–16] Most medical centers recommend withholding ACE-Is/ARBs the morning of surgery.[17,18] Patients on concomitant diuretic therapy are at greatest risk for intraoperative hypotension requiring treatment.[19,20]

The incidence of hypotension and myocardial ischemia intraoperatively is higher in untreated hypertensive patients than in adequately treated hypertensive patients if the preoperative diastolic pressure is 110 mm Hg or

higher.[21] Inadequately treated hypertensive patients undergoing carotid endarterectomies have an increased incidence of neurologic deficits, and those with a history of prior myocardial infarctions have an increased incidence of reinfarction. Patients commonly have an elevated blood pressure on admission to the hospital. Hypertensive patients can have exaggerated responses to painful stimuli and have a higher incidence of perioperative ischemia.

Coronary Artery Disease

Coronary artery disease or its risk factors are present in about 30% of patients who undergo major surgery each year.[22] It is the leading cause of death in the United States and continues to be a major cause of postoperative morbidity and mortality.[23] The goal of the preoperative cardiac evaluation is to identify patients who are at increased risk of perioperative cardiac morbidity and ensure that their chronic conditions are optimized. Although perioperative cardiac events are the leading cause of death following anesthesia and surgery, it has been difficult to define patient characteristics that accurately predict a high risk of adverse outcome.[24] It has been even more difficult to modify that risk effectively.[25] Preoperative CHF is clearly a significant risk factor, as is recent myocardial infarction or unstable angina (**Table 13.9**). Diabetes mellitus (DM), atherosclerotic vascular disease, and hypertension also appear to confer risk, although less than with CHF or unstable angina. Perioperative risk in patients with valvular heart disease varies with the severity of the disease as represented by CHF, pulmonary hypertension, and dysrhythmias. Dysrhythmias are also a concern in the presence of coronary artery disease. Age and stable angina remain controversial as predictors of perioperative risk, with equal numbers of supporting and refuting studies. The value of revascularization remains controversial as well. The ability to climb two flights of stairs without stopping or experiencing symptoms of angina or shortness of breath is considered a good practical test of cardiac reserve. Unfortunately, many patients with ischemic heart disease have concomitant pulmonary disease or other medical problems that limit their activity. A history of myocardial infarction is important information. Large retrospective studies have found that the incidence of reinfarction is related to the time elapsed since the

previous myocardial infarction.[26–28] The incidence of reinfarction appears to stabilize at about 6% (50-fold higher than patient without myocardial infarction) after 6 months. The highest rate of reinfarction occurs in the 0- to 3-month period. Mortality from reinfarction, for patients undergoing noncardiac surgery (**Table 13.10**), has been reported to be between 20% and 50% and usually occurs within the first 48 hours after surgery.

Table 13.9 Clinical Predictors of Increased Perioperative Cardiovascular Risk (Myocardial Infarction, Heart Failure, Death)

Major
Unstable coronary syndromes
Acute or recent MI[a] with evidence of important ischemic risk by clinical symptoms or noninvasive study
Unstable or severe[b] angina (Canadian class III or IV)[c]
Decompensated heart failure
Significant arrhythmias
High-grade atrioventricular block
Symptomatic ventricular arrhythmias in the presence of underlying heart disease
Supraventricular arrhythmias with uncontrolled ventricular rate
Severe valvular disease
Intermediate
Mild angina pectoris (Canadian class I or II)
Previous MI by history or pathologic Q waves
Compensated or prior heart failure
Diabetes mellitus (particularly insulin dependent)
Renal insufficiency
Minor
Advanced age
Abnormal ECG (left ventricular hypertrophy, left bundle-branch block, ST–T abnormalities)
Rhythm other than sinus (e.g., atrial fibrillation)
Low functional capacity (e.g., inability to climb one flight of stairs with a bag of groceries)
History of stroke
Uncontrolled systemic hypertension

[a]The American College of Cardiology National Database Library defines recent MI as >7 d but ≤1 mo (30 d); acute MI is within 7 d.

[b]May include "stable" angina in patients who are unusually sedentary.

[c]From Campeau L. Grading of angina pectoris. *Circulation* 1976;54:522.

ECG, electrocardiogram; MI, myocardial infarction.

Table 13.10 Cardiac Risk Stratification for Noncardiac Surgical Procedures

High (reported cardiac risk often >5%)[a]
Emergent major operations, particularly in the elderly
Aortic and other major vascular surgery
Peripheral vascular surgery
Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss
Intermediate (reported cardiac risk generally <5%)
Carotid endarterectomy
Head and neck surgery
Intraperitoneal and intrathoracic surgery
Orthopedic surgery
Prostate surgery
Low[b] **(reported cardiac risk generally <1%)**
Endoscopic procedures
Superficial procedures
Cataract surgery
Breast surgery

[a]Combined incidence of cardiac death and nonfatal myocardial infarction.

[b]Do not generally require further preoperative cardiac testing.

Perioperative cardiac adverse event risk reduction has undergone significant changes over the past decade. Despite 10 these efforts, a large, international prospective study across 15,000 patients demonstrated that more than 8% of patients undergoing major inpatient surgery still experience postoperative myocardial ischemia.[29] These patients have significantly increased 30-day mortality, even though only 15% of perioperative ischemic episodes included typical cardiac symptoms. Previous retrospective studies demonstrating value to coronary revascularization spurred aggressive preoperative coronary artery disease identification and management. However, recent data have questioned the value of coronary revascularization among asymptomatic patients in not only the perioperative

period, but also in the general medical population.[30,31] The most recent American College of Cardiology (ACC)/American Heart Association (AHA) guidelines reserve preoperative coronary revascularization for patients demonstrating asymptomatic left main coronary artery disease, three-vessel disease, reduced ejection fraction, unstable angina, or acute myocardial infarction.[32] Furthermore, large retrospective and prospective studies have demonstrated that perioperative beta-blockade also bears significant risks that must be weighed against possible benefits.[33,34] As a result, the most recent ACC/AHA guidelines reserve the commencement of beta-blocker therapy for only high-risk patients that would warrant blockade independent of the surgical procedure.[32] Patients already on beta-blocker therapy should continue throughout the perioperative period.[32] The widespread use of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors, commonly known as statins, for cardiovascular disease and hyperlipidemia has introduced another medication into the surgical preoperative evaluation. Although prospective data establishing the value of instituting preoperative statin therapy are limited, there is general consensus that these medications should not be withdrawn.[35] A large randomized controlled trial evaluating the benefit of other promising agents—clonidine and aspirin—as perioperative optimization standards failed to demonstrate benefit.[36,37]

All patients in high-risk groups or with a history of ischemic heart disease must be evaluated and properly treated before elective surgery. All elective surgery should be delayed for 6 months after myocardial infarction. If this is not feasible, invasive monitoring should be considered in the perioperative period and intensive postoperative observation should continue for at least 48 hours. The intrusiveness of the surgical procedure also plays a part in the overall risk and need for preoperative workup of heart disease. The AHA has produced and updated an algorithm for the recommended preoperative workup (**Algorithm 13.1**).[32]

Percutaneous Coronary Intervention with Stenting

An increasing number of patients present for surgery following percutaneous coronary interventions via stenting (with or without drug-eluting coating). In-stent thrombosis is a feared complication with profound morbidity and mortality. Given the known proinflammatory and prothrombotic physiologic

state induced by acute illness, surgery, and anesthesia, coronary stents may be at elevated risk for thrombosis during the perioperative period. The risk of perioperative in-stent thrombosis is increased if noncardiac surgery is performed soon after percutaneous coronary 11 intervention.[38,39] The appropriate duration to defer elective surgery after coronary stenting remains controversial, but recent ACC/AHA guidelines recommend 6 months for drug-eluting stents and 30 days for bare-metal stents.[32] Data suggest that cessation of recommended antiplatelet therapy in the perioperative period may have significant coronary thrombotic risks without major reduction in bleeding.[38,39] The decision to stop antiplatelet therapy prior to recommended guidelines should be limited to specific procedures that demand a nearly bloodless surgical field or in procedures involving closed spaces incapable of tolerating minor bleeding (intracranial, minimally invasive spine surgery). The continuation of aspirin therapy throughout the perioperative period in patients with coronary artery stents should be the standard of care.[32]

Congestive Heart Failure

CHF has been described as the single most important factor predicting postoperative cardiac morbidity[40]; patients are less tolerant of the fluid shifts associated with surgery and the myocardial depression associated with the anesthetic. All elective procedures should be deferred until heart failure is medically optimized. If surgery cannot be deferred, aggressive management to enhance cardiac output is warranted. In contrast to isolated ischemic heart disease, CHF is more easily diagnosed by history, physical examination, and basic preoperative laboratory workup, electrocardiography (ECG), chest radiography, and echocardiography.

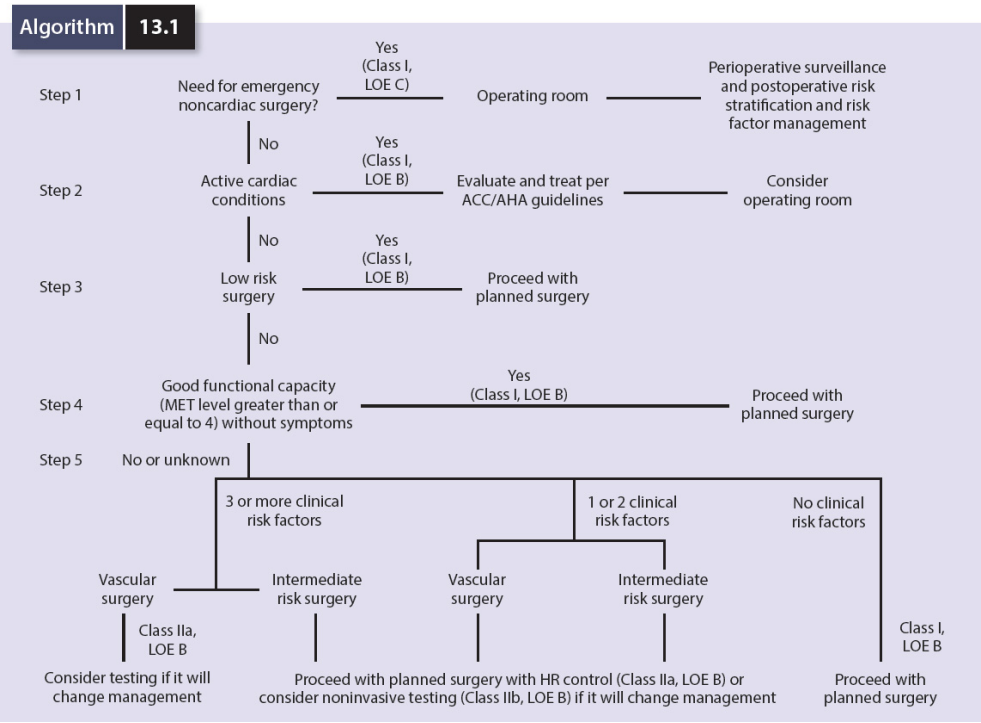
Pulmonary Disease

Recent data demonstrate that although cardiac complications have been the focus of surveillance and prevention, pulmonary and infectious complications may warrant similar attention.[41]

Pulmonary disease is classically divided into acute and chronic restrictive and obstructive disease. Restrictive disease is defined by processes that

reduce lung volumes; obstructive disease is characterized by reduced flow rates.

Obstructive diseases are present in patients with forced expiratory volume in 1 second (FEV_1)/forced vital capacity (FVC) ratios of less than 50%. Obstructive pulmonary disease can be either chronic or acute (asthma). Any reversible component of obstruction should be reversed before surgery. Patients are maintained on bronchodilator medications, and those with chronic secretions are appropriately hydrated and receive physiotherapy to mobilize secretions. Reactive bronchospasm can complicate anesthetic induction and the emergence; severe bronchospasm is a life-threatening. Administration of potent local (albuterol) and systemic (epinephrine) bronchodilators in a timely fashion is essential.



Algorithm 13.1 Decision aid for preoperative cardiac evaluation prior to noncardiac surgery. This decision tree for preoperative evaluation takes into account not only the patient's physical status but also the severity of the surgical procedure. ACC, American College of Cardiology; AHA, American Heart Association; LOE, level of evidence.

Regional or neuraxial techniques which allow airway manipulation to be avoided have particular advantage. However, for sensory and motor levels

of T6 and above, patients lose significant accessory motor function that can decrease expiratory reserve volume and the ability to cough and clear secretions. Any intubated patient with severe respiratory disease should be extubated with caution only when they meet adequate extubation criteria relative to preoperative test data. Patients undergoing upper abdominal surgery are at particular risk. Both vital capacity and functional residual capacity are reduced, reaching lowest levels in the first 24 hours postoperatively. Therapy should be directed toward restoring functional residual capacity to preoperative levels. Because of the potential adverse effects of systemic narcotics on respiratory drive, the use of epidural narcotics and local anesthetics for postoperative pain control is very popular. These techniques allow the patients to be extubated earlier and, in patients with intrathoracic and upper abdominal surgery; help restore pulmonary function toward baseline.[42]

Obesity

Obesity is defined as a body mass index (BMI) greater than or equal to 30 kg/m^2. The pathophysiologic changes associated with morbid obesity (BMI $\geq$40 kg/m^2) affect the respiratory, cardiovascular, and gastrointestinal systems. Patients develop external restrictive lung disease that reduces functional residual capacity and is exacerbated by supine positioning. Increased airway pressures required to maintain adequate ventilation in obese patients predispose this patient group to barotrauma, furthering their risk of pulmonary complications. Obese patients frequently desaturate at night and have a high incidence of sleep apnea. Because of increased blood volume and frequent desaturations, obese patients can develop pulmonary hypertension and right-sided heart failure. Obese individuals have a high incidence of coronary artery disease. Because of size alone, they have increased cardiovascular demands with limited cardiac reserve and exercise tolerance. Obese patients have a high incidence of hiatal hernia and gastroesophageal reflux, increasing the risk for aspiration on induction and emergence from anesthesia. Venous access, positioning and blood pressure measurement are often difficult.

The combined problems of aspiration risk, rapid desaturation caused by reduced functional residual capacity and increased oxygen demand, and

technical difficulties associated with intubation due to anatomic fat deposits make intubation a high-risk procedure. Awake intubation can be useful or necessitated. Patients should receive prophylactic administration of H_2-receptor antagonists and a nonparticulate antacid to improve the pH of gastric contents. To prevent aspiration on emergence, obese patients should be extubated when fully awake, preferably in the sitting position. Epidural analgesics for postoperative pain management allow earlier extubation and ambulation of these patients.[43]

Diabetes Mellitus

The incidence of DM is rising, particularly, type 2 DM in the elderly. This is a systemic disorder that has particular relevance for the anesthesiologist and surgeon because of its effect on the vascular, renal, nervous, and immune systems. Patients with DM should be investigated for the presence of concomitant coronary artery disease, peripheral vascular occlusive disease, renal failure, and autonomic and peripheral neuropathy. Problems with cardiovascular instability, fluid balance, and aspiration due to gastroparesis should be expected. In addition, these patients are more prone to infection and have problems with temperature control. The management of the diabetic state is important and complicated. Hypoglycemia during anesthesia is a feared complication because of challenges in prompt diagnosis. Oral hypoglycemic agents such as glipizide should be stopped prior to surgery and hyperglycemia treated with short-acting intravenous or subcutaneous insulin during the perioperative period. Insulin-dependent diabetics for same-day admission or outpatient surgery should take one-half of their usual morning dose of long-acting insulin. Additional insulin is directed according to frequent (every 1 to 2 hours) blood sugar monitoring. Although there are compelling data associating perioperative hyperglycemia with adverse postoperative events, there are no randomized controlled trials demonstrating improved outcomes with aggressive intraoperative hyperglycemia management.[44] Furthermore, complications from hypoglycemia are arguably greater than those from hyperglycemia, and are more likely as insulin therapy becomes more aggressive during the perioperative period.

Renal Insufficiency and Failure

Because the kidneys play a vital role in metabolic, synthetic, and fluid homeostasis, renal failure is associated with many effects on the cardiovascular, pulmonary, hematologic, gastrointestinal, and immune systems. Pre-existing renal insufficiency is a known risk factor for postoperative myocardial infarction and renal failure.[45,46] Optimizing fluid and metabolic status of a patient in end-stage renal disease is of vital importance. Elective surgery should be delayed until such optimization is performed. In emergent situations, the urgent need for hemodialysis should be considered to avoid life-threatening electrolyte and fluid derangements. Nearly 15% of patients undergoing general surgery procedures experience postoperative acute kidney injury, as defined by a 0.3 mg/dL increase in serum creatinine within seven postoperative days.[47] Risk factors for postoperative acute kidney injury in patients undergoing general surgery are listed in **Table 13.11** and should be considered during the patient consent.

Table 13.11 Predictors of Postoperative Acute Kidney Injury after General Surgery Procedures

Age ≥56 yrs
Male sex
Emergency surgery
Intraperitoneal procedures
Preoperative renal insufficiency (serum creatinine >1.2 mg/dL)
Ascites
Active congestive heart failure
Diabetes mellitus requiring oral hypoglycemic or insulin therapy
Hypertension requiring chronic medication

Obstructive Sleep Apnea

With increasing obesity prevalence, obstructive sleep apnea (OSA) is emerging as a major comorbidity that has impact on postoperative outcomes and costs.[48] The physiologic changes on the upper airway, lungs, pulmonary circulation, heart, and brain are extensive and challenge immediate perioperative and postoperative management.[49] These patients are prone to airway collapse at induction and emergence, hypoxemia, delayed emergence, respiratory depression, and cardiovascular collapse.[50] Preliminary data demonstrate increased sensitivity to the effects of opiates as well.[51] Observational data demonstrate a relationship between OSA treatment and a reduction in postoperative complications.[52,53] The standard protocol for all preoperative evaluations should be the use of a locally accepted OSA screening tool (STOP-BANG questionnaire, Perioperative Sleep Apnea Prediction score, etc.) and ensuring postoperative access to continuous positive airway pressure therapy for patients currently prescribed such therapy as outpatients. Some undiagnosed or noncompliant patients may require initiation of therapy in the immediate postoperative period and the perioperative resources to fulfill clinical urgency are essential.

Risks Associated with Regional Techniques in Patients Being Treated with Anticoagulants

As the indications for anticoagulant therapy have increased, ranging from drug-eluting stents to atrial fibrillation and venous thromboembolism prophylaxis, the number of patients and types of anticoagulant therapy has continued to increase. In particular, low–molecular-weight heparin (LMWH) and oral direct factor Xa inhibitors are often part of a patient's pre- or postoperative therapy plan. The use of neuraxial or PNB in patients with preoperative anticoagulation requires careful planning and assessment of the risks and benefits of specific anesthetic techniques and withdrawal of anticoagulant therapy. LMWH raises specific concerns of epidural hematoma formation when neuraxial techniques are used. The American Society of Regional Anesthesia has published specific guidelines for central conduction block (spinal and epidural anesthesia) to try to minimize the incidence of this

devastating complication[54]: In general, LMWH therapy requires coordination of neuraxial administration at least 12 hours after the last dose. Coumadin, clopidogrel, and ticlopidine should be held for at least 5, 7, and 10 days prior to neuraxial techniques, respectively. The absence of any reversal agents or reliable diagnostic testing for oral direct Xa inhibitors requires a conservative approach of withdrawal of therapy and no data currently exist to establish a specific threshold. Data regarding risks for PNB are even more scarce and local protocols should be established and followed.

PREOPERATIVE EVALUATION

12 The three goals of the preoperative evaluation are (a) to develop an anesthetic plan that considers the patient's medical condition, the requirements of the surgical procedure, and the patient's preferences; (b) to ensure that any chronic disease is under appropriate control; and (c) to establish rapport answer questions, and allay fears.

Optimization of a patient's medical conditions (**Table 13.12**) is best performed by the primary care physician, with medical specialty consultation, if necessary. The following questions must be answered when evaluating a patient undergoing an elective surgical procedure: What must be included in the preoperative evaluation? Who should be involved in this process? When and where are all the steps in this process to be conducted? How should all the information be coordinated so that it is available to the appropriate personnel at the appropriate time? If the procedure is deemed a surgical emergency, the anesthesiologist is responsible for assessing the patient quickly, developing the appropriate anesthetic plan, and proceeding to the operating room as soon as possible. During such scenario, the anesthesiologist is not obligated to seek medical consultation to evaluate chronic medical problems.

Table 13.12 Hospital Mortality Rates in Relation to Age, Preoperative Disease, and Surgery

Preoperative Disease and Surgery	Age (yr) <50[a]	Age (yr) 50–69[a]	Age (yr) >70[a]
Chronic heart failure	0.1%/0.5%	0.4%/2%	0.8%/4%
Renal failure	0.2%/1%	0.9%/2%	2%/9%
Abdominal surgery	0.3%/2%	1%/6%	3%/12%
Chronic heart failure and renal failure	0.7%/3%	3%/13%	6%/24%
Chronic heart failure and abdominal surgery	0.9%/4%	4%/17%	7%/30%
Renal failure and abdominal surgery	2%/8%	2%/32%	16%/50%
Chronic heart failure, renal failure, and abdominal surgery	6%/26%	22%/60%	37%/76%

[a]Figures are for elective surgery (first number) and emergency surgery (second number).

From Pedersen T, Eliasen K, Henriksen E. A prospective study of mortality associated with anesthesia and surgery: risk indicators of mortality in hospitals. *Acta Anaesthesiol Scand* 1990;34:176, with permission.

The following steps must be completed before moving the patient into the operating room:

1. A comorbidity-focused history and physical examination
2. Appropriate laboratory studies and medical consultations
3. An anesthesiologist's preoperative evaluation with assignment of an American Society of Anesthesiologists (ASA) physical status
4. Discussion with the patient of the options and risks
5. Development and communication of the anesthetic plan to the patient and surgeon
6. Acute optimization of any pertinent medical conditions

The history and physical examination have repeatedly been shown to be the most valuable parts of the preoperative assessment. The anesthesiologist must review previous anesthetic problems experienced by the patient or blood relatives, the patient's exercise tolerance, and additional details regarding general medical conditions. This evaluation not only determines the laboratory tests that may be required but also allows for the assignment of ASA physical status (PS) (**Table 13.13**). The classification serves as a general measure of the patient's state of well-being, taking into account all problems the patient brings to the operating room, including systemic disturbances caused by the surgical illness. Although studies of anesthetic mortality show a correlation with the PS classification, this categorization does not describe the risk directly. The risk of any operation is determined not only by patient-related factors but also by procedure-specific ones. For patients with complex medical problems, it is frequently helpful to supplement the surgical history and physical examination with a recent assessment by the patient's primary physician in order to assess the patient's long-term health trajectory. There are no data demonstrating the value of routine preoperative medical consultation.[55]

Table 13.13 Physical Status Classification of the American Society of Anesthesiologists

Physical Status Classification	Description
PS-1	A normal, healthy patient
PS-2	A patient with mild systemic disease that results in no functional limitation *Examples:* Hypertension, diabetes mellitus, chronic bronchitis, morbid obesity, extremes of age
PS-3	A patient with severe systemic disease that results in functional limitation *Examples:* Poorly controlled hypertension, diabetes mellitus with vascular complications, angina pectoris, prior myocardial infarction, pulmonary disease that limits activity
PS-4	A patient with severe systemic disease that is a constant threat to life *Examples:* Congestive heart failure, unstable angina pectoris, advanced pulmonary, renal, or hepatic dysfunction
PS-5	A moribund patient who is not expected to survive without the operation *Examples:* Ruptured abdominal aneurysm, pulmonary embolus, head injury with increased intracranial pressure
PS-6	A declared brain-dead patient whose organs are being removed

	for donor purposes
Emergency operation (E)	Any patient in whom an emergency operation is required *Example:* An otherwise healthy 30-year-old woman who requires dilation and curettage for moderate but persistent vaginal bleeding (PS-1E)

Table 13.14 Simplified Strategy for Preoperative Testing

Estimated Energy Requirements for Various Activities

1 MET ↓ 4 METs	Can you take care of yourself? Eat, dress, or use the toilet? Walk indoors around the house? Walk a block or two on level ground at 2 to 3 mph or 3.2 to 4.8 km/hr? Do light work around the house like dusting or washing dishes?	4 METs ↓>10 METs	Climb a flight of stairs or walk up a hill? Walk on level ground at 4 mph or 6.4 km/hr? Run a short distance? Do heavy work around the house like scrubbing floors or lifting or moving heavy furniture? Participate in moderate recreational activities like golf, bowling, dancing, doubles tennis, or throwing a baseball or football? Participate in strenuous sports like swimming, singles tennis, football, basketball, or skiing?

MET, metabolic equivalent; mph, miles per hour.

The value of preoperative laboratory studies has undergone substantial reevaluation since the mid-1980s. The current thinking is that a laboratory test should not be ordered unless a change in the surgical or anesthetic plan is anticipated. The only preoperative screening test required at the University of Michigan, for instance, is an ECG within a year of the planned surgical procedure for men older than 50 years and women older than 60 years of age. For procedures with significant anticipated blood loss, a type and cross match is ordered, and a preoperative hematocrit is also required. All other tests should have an indication based on history and physical examination. A simple strategy to evaluate physical robustness is presented in **Table 13.14**. Electronic patient questionnaires have also been developed, allowing the appropriate laboratories to be selected based on the patient's response to questions.[56]

Discussions of the options of anesthetic techniques and anesthetic risks are best performed by the anesthesiologist who will provide the anesthetic. However, because of the logistical problems of scheduling, most institutions have developed preoperative anesthesia clinics to allow for a more efficient and timely patient assessment, to facilitate planning, and to avoid unnecessary same-day case cancellations.

The patient's medication regimen must be reviewed to ensure that appropriate medications are continued or discontinued in the days and hours leading up to an elective procedure. In general, diuretics and ACE-I/ARB's should not be taken the day of surgery. Several important classes of medications should be continued as per the patient's normal regimen: chronic pain therapy (including opioids), beta-blockers, statins, and proton pump inhibitors. The decision regarding anticoagulant therapy is complex and must consider the indication for therapy, the likelihood and impact of surgical bleeding, and the risk of perioperative thrombosis. Insulin and oral 13 hypoglycemic agents should be continued at a reduced dose. Patients receiving chronic pain or opioid addiction therapy with buprenorphine (Subutex, Suboxone) can be particularly challenging to manage in the postoperative period. Buprenorphine, a mixed opioid agonist/antagonist, tightly binds at the μ receptor and has a long and varied half-life (24 to 60 hours). Patients who continue treatment risk impaired analgesic benefits of traditional opioids and the potential for adverse events due to the need for very high doses of opioids,[57] while those that discontinue treatment risk

addiction relapse. A management protocol used at the University of Michigan is demonstrated in **Algorithm 13.2**.

The potential of a difficult intubation is of fundamental concern as should be evaluated as previously discussed (**Fig. 13.1** and **Table 13.8**). The requirement of an awake fiberoptic technique, takes planning and can cause delay without prior warning.

MONITORING THE SURGICAL PATIENT

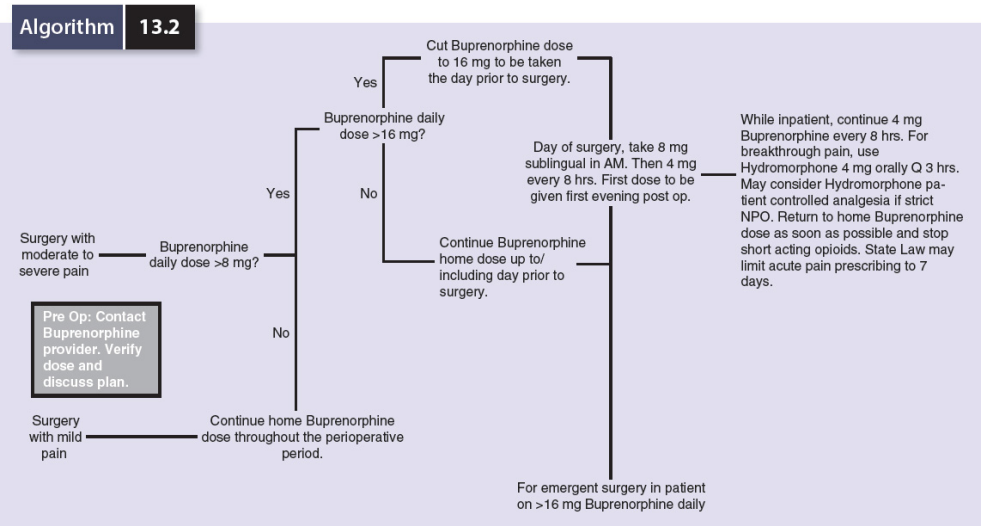
The routine use of an array of electronic monitors to provide continuous surveillance of physiologic status is well established. Because the art and science of anesthesiology involves titrating pharmacologic agents to produce desired physiologic effects, there must be a measured parameter to which drug dosages are titrated. Depending on the severity of pre-existing disease and the extent of the surgical procedure, invasive techniques can be used to provide comprehensive continuous data to guide the titration of fluid therapy and cardiovascular agents.

Monitors of Oxygenation

Pulse oximetry is perhaps the most significant advance in patient monitoring to date. This device continuously, noninvasively, and inexpensively provides arterial hemoglobin saturation (SaO_2) and peripheral pulse by measuring light absorption in a manner similar to that of a laboratory cooximeter. A laboratory cooximeter shines light through a cuvette filled with a blood sample. Each hemoglobin species absorbs light in direct proportion to its concentration (Beer–Lambert law). A cooximeter requires one wavelength of light for each hemoglobin species to be measured, that is, one wavelength for oxyhemoglobin and one for reduced hemoglobin. To measure other hemoglobins, such as carboxyhemoglobin or methemoglobin, the device requires four wavelengths of light.

The traditional pulse oximeter uses two wavelengths of light, one red and one infrared that shine through a tissue bed, usually a finger. Opposite the light sources is a photodiode that measures the transmitted light intensity. A large proportion of the light absorbed as it passes through the tissues is not

associated with arterial blood but with other components of the tissue, such as skin, muscle, bone, and venous blood. Therefore, the device analyzes only the pulsatile component of absorption and assumes that anything that pulses within the tissue bed is arterial blood, hence the name *pulse oximeter.* Actually, the pulse oximeter measures the ratio of the pulsatile component of red light absorbed to the pulsatile component of the infrared light absorbed. This ratio changes with SaO_2. The exact relation between this ratio and SaO_2 has been empirically determined from volunteer studies and is programmed into the electronics of the oximeter. If any artifacts occur in a pulsatile nature, they may be erroneously integrated into the equation, causing erroneous SaO_2 estimates.



Algorithm 13.2 Algorithm for managing a patient on chronic buprenorphine therapy. APS, acute pain service; ICU, intensive care unit; PCA, patient-controlled anesthesia; NSAIDs, nonsteroidal anti-inflammatory drugs.

Several things should be remembered when interpreting a pulse oximeter's output: (1) The device measures SaO_2 and not arterial oxygen tension (PaO_2). (2) The PaO_2 must drop below 80 mm Hg before any significant change in SaO_2 occurs. (3) As the PaO_2 drops below 60 mm Hg, the SaO_2 rapidly falls as the inflection point of the sigmoidal oxyhemoglobin dissociation curve is approached. (4) The pulse oximeter measures saturation and not arterial content or oxygen delivery to tissues.

Traditional pulse oximeters use only two wavelengths of light, and therefore, cannot detect the presence of carboxyhemoglobin or methemoglobin. Pulse oximeters that incorporate additional wavelengths of light and are capable of detecting carboxyhemoglobin and methemoglobin have been developed but are not widely used clinically.[58]

Ventilation Monitors

By definition, a patient is appropriately ventilated when arterial carbon dioxide tension ($PaCO_2$) is 40 mm Hg. Measuring the respiratory rate can document only the presence of ventilation, not its adequacy. Capnography, or end-tidal CO_2 monitoring, is the visual display of the CO_2 concentration at the airway. To understand the utility of capnography, one must understand dead-space (DS) components and how they affect CO_2 removal from the body.[59] DS is defined as the portion of the tidal volume (V_T) that does not participate in gas exchange.

$$V_T = DS + V_A$$

The alveolar volume (V_A) is the volume of the inspired gas that reaches well-perfused alveoli. The remainder of the V_T, which equals the DS, can be divided into three subcomponents: apparatus dead space (DS_{ap}), anatomic dead space (DS_{an}), and alveolar dead space (DS_{al}). At the end of inspiration, the respiratory apparatus (e.g., endotracheal tube) is filled with inspired gas that should not contain CO_2. Similarly, all the anatomic airways (trachea, bronchi, and all conducting airways down to the alveoli) should be filled with inspired gas and should therefore contain no CO_2. In this model, there are two types of alveoli: those that are well perfused and those that are not perfused. The alveolar gas should completely equilibrate with the arterial blood and contain CO_2 at the same tension as the arterial blood; ideally, $PaCO_2$ should equal 40 mm Hg. As the patient expires, the CO_2 detected at the patient's mouth first reflects the DS_{ap} gas having no CO_2 followed by the DS_{an} gas, again with no CO_2 and finally the alveolar gases, containing both DS and well-perfused alveolar gas. When mixed alveolar gas reaches the

airway, it produces a rapid rise in the CO_2 concentration to a level somewhere between the concentration in the alveolar gas (40 mm Hg) and the DS_{al} (0 mm Hg), depending on each component's proportion of volume. For example, if half of the alveoli are DS_{al} and $PaCO_2$ equals 40 mm Hg, then the plateau value of the capnogram should be 20 mm Hg, implying that half of the alveoli are not being perfused. With inspiration, the CO_2 value again drops to 0 until another expiration, and a square wave appears again as the alveolar gas is detected at the mouth. With each breath, there should be a square wave, the height of which approaches the $PaCO_2$ value as the amount of the DS_{al} gas approaches 0.

In a healthy young adult, there is no significant DS_{al} gas, and the end-tidal CO_2 value equals the $PaCO_2$. Therefore, the difference between these values indicates the proportion of DS_{al} in the patient. The presence of a capnogram itself implies that there is metabolism (the production of CO_2), circulation (blood flow to the lungs), and ventilation (respiratory rate and an intact ventilator circuit).

Providing this information on a breath-to-breath basis, the continuous capnogram is extremely useful in many critical situations. It can be used as a surveillance monitor of both the respiratory circuit and the cardiovascular system. Any acute decrease in cardiac output will decrease blood flow to the lungs and increase the DS_{al}, causing an acute drop in end-tidal CO_2. The only acute catastrophic cardiopulmonary problem that will not be detected by the capnometer is arterial desaturation. Therefore, the combination of the capnometer and the pulse oximeter creates a dynamic beat-to-beat and breath-to-breath surveillance of metabolism, circulation, ventilation, and oxygenation.

Circulation Monitors

Hemodynamic stability can be monitored by a variety of methods, the most basic of which is systemic arterial blood pressure. Intermittent, noninvasive measurement of systemic blood pressure with an oscillometric blood pressure cuff is the standard in the operating room, and its accuracy equals that of clinical measurements by auscultation. Blood pressure cuffs can be

cycled as quickly as once per minute, but when used for an extended duration, they should be cycled no more than once every 3 to 5 minutes. When tighter control or observation is required in patients with significant comorbidities or large swings in hemodynamics due to surgical circumstances, invasive arterial monitoring is recommended. Pressure measurements provided by invasive and noninvasive techniques, usually coincide closely. A continuous invasive arterial tracing can also be used to assess the adequacy of fluid resuscitation by following the systolic pressure variation (SPV) with positive-pressure ventilation. 14 As positive-pressure ventilation impedes venous return within a closed thorax, decreases in systolic pressure associated with a respiratory pattern can be detected. In patients with sinus rhythm with stable cardiac contractility, the degree of SPV is inversely related to the intravascular volume status of the patient. The normal range of SPV is 5 to 10 mm Hg. A systolic pressure decrease of greater than 10 mm Hg during positive-pressure ventilation implies inadequate preload and the need for more aggressive fluid resuscitation.

In this context, central venous access may be reserved for patients and procedures with the potential for large, rapid volume resuscitation requirements or expected need for potent vasoactive medication. Transesophageal echocardiography (TEE) is now commonly used to quickly assess systolic and diastolic function as well as valvular dysfunction. Increasing familiarity in the use of TEE by noncardiac anesthesiologists may result in the pulmonary artery catheter being reserved for very specific patients demonstrating the need for pulmonary artery pressure monitoring or continuous cardiac output trending.

Finally, a wave of noninvasive continuous cardiac output monitors has gained the attention of surgeons and anesthesiologists alike. These monitors, promising the realization of goal-directed therapy, use indirect means to assess the missing aspect of blood pressure-focused hemodynamic management—stroke volume. Thoracic electrical bioimpedance, pulse wave transit time, peripheral pulse contour analysis, volume clamp, and other methods of estimating stroke volume have been in existence for decades, but have seen a recent rise in interest as variation in intraoperative fluid management may impact surgical outcomes. However, conflicting studies in real-world critically ill patients have failed to establish an outcome benefit.[60] Despite the absence of compelling clinical data, many enhanced

recovery protocols have begun including some type of noninvasive cardiac output monitoring to guide fluid therapy.[61] It is unclear whether these monitoring devices offer superior guidance to sound clinical judgment administered by a vigilant anesthesiologist.

"Awareness" and Level of Consciousness Monitors

When delivering a general anesthetic, one of the major imperatives is to achieve and maintain a loss of consciousness. Normally, this is achieved through careful observation of vital signs (heart rate, blood pressure), physical examination signs (movement in a patient without neuromuscular blockade), and delivery of inhalational or intravenous agents at doses consistent with a loss of consciousness. However, this "science" is inexact and must account for patient age, comorbidities, chronic medications, surgical stimulus, and patient-to-patient variability. As a result, patients may rarely experience "awareness under anesthesia"—a state characterized not only by consciousness but also by recall of intraoperative events. The lay press and public have increased their scrutiny of this perioperative event.

First, appropriate expectations and effective communication of the anesthetic are required. Literature has demonstrated that patients undergoing regional anesthesia are as likely to report unpleasant "awareness" as patients undergoing a general anesthetic.[62] This is despite the reality that loss of consciousness is only a goal of general anesthesia.

Second, several level of consciousness monitors have been developed in hopes of providing the anesthesiologist with additional objective data to guide their assessment and actions. The current generation of monitors generally uses electroencephalographic (EEG) analysis to provide the clinician with an assessment of the relative "depth" of anesthesia achieved. Several commercially available monitors such as the bispectral index (BIS) from Aspect Medical Systems and Entropy from General Electric Healthcare are in common clinical use. Data evaluating the value of these EEG-based monitors in reducing awareness are conflicting.[63,64] As a result, the ASA has not adopted awareness monitors as a standard of care and leaves the decision to use such monitoring technology to each provider, patient, and

situation.[65] The largest, trials have failed to demonstrate a measurable reduction in awareness.[66,67]

COMMON PROBLEMS IN THE POSTOPERATIVE PERIOD

Postanesthesia care units are required in any setting where surgical procedures are conducted. The increased scope of surgery and the invasive technology used to monitor sicker patients has increased the service at and training required to operate these facilities. In 2014, the ASA revised the Standards for Postanesthesia Care (**Table 13.15**).

The scoring systems used to assess the postoperative patient direct attention to the primary areas of concern. The postanesthesia recovery score is an attempt to evaluate postanesthesia patient status (**Table 13.16**).[68] This basic information should be incorporated in a record that provides clear documentation of postoperative events. Documentation should also include details of postoperative outpatient care, with a note indicating postoperative telephone contact made to elucidate problems. Problems should receive appropriate follow-up, and written postoperative discharge instructions should be provided for the patient.

Almost ¼ of patients experience a complication within the postanesthesia care unit. Nausea, vomiting, and the need for airway support constitute 70% of these (**Fig. 13.2**).[69] The need to maintain airway support is by far the most common respiratory complication. The duration of the procedure, ASA classification and type of procedure appear to be important determinants. Hypothermia is also noteworthy, slowing drug metabolism, delaying recovery and is associated with prolonged postoperative postanesthesia care unit stay.

Among cardiovascular complications in the postoperative period, none is more important or more difficult to diagnose than myocardial ischemia. The association of perioperative myocardial ischemia with cardiac morbidity has been clearly documented.[26] Diagnosis is complicated by the fact that only 10% to 30% of patients suffering documented myocardial infarction have pain and that postoperative ECG T-wave changes are often nonspecific.[70]

Instead, one must seek secondary indications of ongoing ischemia or such as hypotension, arrhythmias, elevated filling pressures, or postoperative oliguria. Arrhythmias are common and are significant primarily because of the association with myocardial ischemia or hypoxemia.

Nausea and vomiting are rarely unifactorial and cause considerable discomfort. Opioids are responsible for stimulating the emesis center in a significant cohort of patients. These patients may provide a clear history of opioid sensitivity and anesthetic and analgesic regimens may be tailored to limit exposure. In general, however, there is little evidence to favor one anesthetic or anesthetic technique over another, although propofol appears to have an antiemetic effect. Nitrous oxide, often considered causative, does not appear to increase the incidence of nausea. It is not unusual for an antiemetic agent to be included preoperatively or as part of the anesthetic technique, especially in patients with a positive history or those deemed to be at risk, such as menstruating young women undergoing laparoscopy. Standard usage includes phenothiazines, butyrophenones, $5HT_3$ antagonists, and steroids. A multimodal approach that avoids redosing of a given medication class is most beneficial.[71] Despite decades of research, classic medications such as droperidol remain a mainstay of therapy. The FDA recently added a black-box warning to droperidol due to concerns of QT prolongation, but such concerns have not been validated when compared to other perioperative medications.[72,73]

Table 13.15 Standards for Postanesthesia Care

Standards		Criteria to be Fulfilled
Standard I[a]	All patients who have received general, regional, or monitored anesthesia care shall receive appropriate postanesthesia management.	1. A PACU or an area that provides equivalent postanesthesia care shall be available to receive patients after anesthesia care. All patients who receive anesthesia care shall be admitted to the PACU or its equivalent *except* by specific order of the anesthesiologist responsible for the patient's care. 2. The medical aspects of care in the PACU shall be governed by policies and procedures that have been reviewed and approved by the department of anesthesiology. 3. The design, equipment, and staffing of the PACU shall meet requirements of the facility's accrediting and licensing bodies.
Standard II	A patient transported to the PACU shall be accompanied by a member of the anesthesia care team who is knowledgeable about the	

	patient's condition. The patient shall be continually evaluated and treated during transport with monitoring and support appropriate to the patient's condition.	
Standard III	On arrival in the PACU, the patient shall be re-evaluated and a verbal report provided to the responsible PACU nurse by the member of the anesthesia care team who accompanies the patient.	1. The patient's status on arrival in the PACU shall be documented. 2. Information concerning the preoperative condition and the surgical/anesthetic course shall be transmitted to the PACU nurse. 3. The member of the anesthesia care team shall remain in the PACU until the PACU nurse accepts responsibility for the nursing care of the patient.
Standard IV	The patient's condition shall be evaluated continually in the PACU.	1. The patient shall be observed and monitored by the methods appropriate to the patient's medical condition. Particular attention shall be given to monitoring oxygenation, ventilation, circulation, and temperature. During recovery from all

anesthetics, a quantitative method of assessing oxygenation such as pulse oximetry shall be employed in the initial phase of recovery. This is not intended for application during the recovery of the obstetric patient in whom regional anesthesia was used for labor and vaginal delivery.

2. An accurate written report of the PACU period shall be maintained. Use of an appropriate PACU scoring system is encouraged for each patient on admission, at appropriate intervals prior to discharge, and at the time of discharge.
3. General medical supervision and coordination of patient care in the PACU should be the responsibility of an anesthesiologist.
4. There shall be a policy to ensure the availability in the facility of a physician capable of managing complications and providing

		cardiopulmonary resuscitation for patients in the PACU.
Standard V	A physician is responsible for discharging the patient from the PACU.	1. When discharge criteria are used, they must be approved by the department of anesthesiology and the medical staff. They may vary depending on whether the patient is discharged to a hospital room, to the ICU, to a short stay unit, or home. 2. In the absence of the physician responsible for the discharge, the PACU nurse shall determine that the patient meets the discharge criteria. The name of the physician accepting responsibility for discharge shall be noted on the record.

[a]For nursing care issues, refer to Standards of Postanesthesia Nursing Practice, published by the American Society of Postanesthesia Nurses.

ICU, intensive care unit; PACU, postanesthesia care unit.

Based on American Society of Anesthesiologists (ASA)'s *Standards for Postanesthesia Care.* A copy of the full text can be obtained from ASA, 1061 American Lane, Schaumburg, IL 60173. https://www.asahq.org/standards-and-guidelines/standards-for-postanesthesia-care.

Table 13.16 Postanesthesia Recovery Score

Parameter	Score[a]
Activity	
Voluntary movement of all limbs to command	2
Voluntary movement of two extremities to command	1
Unable to move	0
Respiration	
Breathes deeply and coughs	2
Dyspnea, hypoventilation	1
Apneic	0
Circulation	
Blood pressure equals 80% of preanesthetic level	2
Blood pressure equals 50%–80% of preanesthetic level	1
Blood pressure equals <50% of preanesthetic level	0
Consciousness	
Fully awake	2
Arousable	1
Unresponsive	0
Color	
Pink	2
Pale, blotchy	1
Cyanotic	0

[a]Patients should score at least 7 before discharge from the postanesthesia care unit.

The most common cause of delayed emergence is the residual effects of anesthesia. The differential diagnosis is best approached by ruling out physiologic, pharmacologic, and neurologic cases, in this order (**Table 13.17**). There should be little confusion about the implication of muscle relaxants because physical indications of ventilatory distress, combined with the readings of the blockade monitor are diagnostic. Where appropriate, opioids can be reversed using titrated doses of naloxone. Flumazenil can be used for reversal of benzodiazepines.

ENHANCED RECOVERY PROTOCOLS

15 With the increasing adoption of minimally invasive surgical techniques and a realization that postoperative complications may be impacted by intraoperative management, nearly every surgical subspecialty establish efforts towards enhanced recovery protocols. These comprehensive care management plans dictate the preoperative preparation, intraoperative management, surgical technique, and postoperative management. While a consistent decrease in length of stay, complications, and costs have been observed across the many trials assessed in many surgical specialties, there are very few consistent protocols.[74,75] The process of collaboration and standardization may be the most important element.

POSTOPERATIVE ACUTE PAIN MANAGEMENT

Postoperative pain is an inevitable consequence of surgery. Its severity is site dependent (**Table 13.18**), but the magnitude of the pain experienced by individual patients after similar surgical procedures is influenced by a multitude of factors. Variation in patient experience has been clearly demonstrated by several authors and is reflected in deficiencies in postoperative pain control.[76]

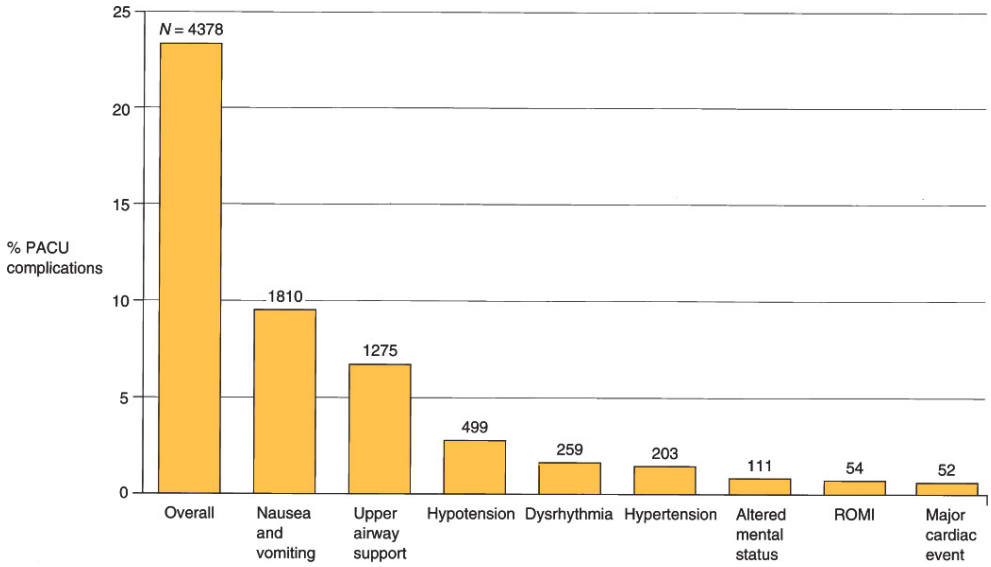


Figure 13.2 Major postanesthesia care unit complications by percentage of occurrence and number of patients experiencing each complication. Nausea and vomiting were the most frequently observed complications. ROMI, rule out myocardial infarction. (Reproduced with permission from Hines R, Barash PG, Watrous G, et al. Complications occurring in the postanesthesia care unit: a survey. *Anesth Analg* 1992;74:505.)

Seizure disorders

In 1965, the crucial role of nociceptive C fiber feedback behavior and its modulation by cells in the substantia gelatinosa of the dorsal horn was recognized.[77] Repetitive stimulation of these fibers by cellular mediators, such as kinins and catecholamines, promotes neural excitation, prolongs repetitive firing, and lowers the threshold to further excitation. As a result, C fibers do not show fatigue, and the stage is set for continuous pain. Counterirritation of large afferent activity has been shown empirically to have beneficial effects. The gate-control theory provides an explanation for the inhibition of C fiber–mediated pain. Serotonergic and enkephalinergic descending inhibitory pathways modulate activity in the dorsal horn before information is relayed to the somatosensory cortex through the spinothalamic tract. The common observation that pain is worse at night, when less sensory

information is processed, and that it decreases with daytime activity is an example of how this complex neural system functions.

Superficial somatic pain is well localized and has a protective function. Superficial somatic pain is readily treated by common analgesic techniques. Deep somatic pain may not be well localized; may have some protective function, as in joint immobilization; and is fairly responsive to a variety of analgesics. Visceral pain, served almost entirely by C fiber activity, is poorly localized, often referred, and difficult to treat. In major operations, all modes can be activated, compounding the clinical challenge of providing adequate pain management. These clinical observations direct the focus of postoperative pain management to the treatment of somatic pain by attacking the nociceptor and the subsequent transmission of the painful impulse by the nerve fiber. The use of nonsteroidal anti-inflammatory drugs with or without the injection of local anesthetics into the wound is very effective. If done preemptively at the time of surgery, this approach can significantly benefit the patient's postoperative experience. Examples of nerve blocks for various procedures are shown in **Figure 13.3**.

Including potent opioids in the treatment of deep pain, both somatic and visceral, has been routine. However, the responses to standard regimens have been notoriously unreliable, from inadequate pain relief to narcosis, with complications at both ends of the scale. It was not until the 1980s that variations in response were linked to variable serum concentrations of analgesic drugs. Interpatient variation in serum levels to any standard dose can be fivefold, and interpatient therapeutic concentrations can vary on a similar scale. When factored together, there is the potential for a 25-fold variation in patient response to a standard drug prescription. Each patient has an individual therapeutic window. The clinical implications are enormous.

Table 13.18 Percentage of Patients Who Require Analgesic Injections

Operation	No Analgesic Needed (%)	Three or More Analgesic Injections (%)
Minor chest wall	82	0
Inguinal hernia	52	0
Appendectomy	25	10
Lower abdominal surgery	18	40
Upper abdominal surgery	10	45–65

In 1968, investigators demonstrated the virtue of small IV doses given on demand. As a result, the patient experienced greater pain relief, yet used the same or less total narcotic (**Figure 13.4**). Although there was significant patient variation, the demand from any individual patient, though cyclic, was constant. Patient-controlled analgesia (PCA) and the technologic and administrative systems to provide it have developed to a point of some sophistication, requiring servicing and a support structure with its own set of problems (**Table 13.19**). PCA administration requires a receptive environment, education of all personnel, and adequate patient instruction. PCA has received widespread acceptance by patients, nursing staff, and physicians because it provides more prompt and painless analgesia that more closely matches the patient's need over time. PCA is as safe as conventional IM medication. Morphine is the most commonly used drug, and an example of orders is shown in **Table 13.20**.

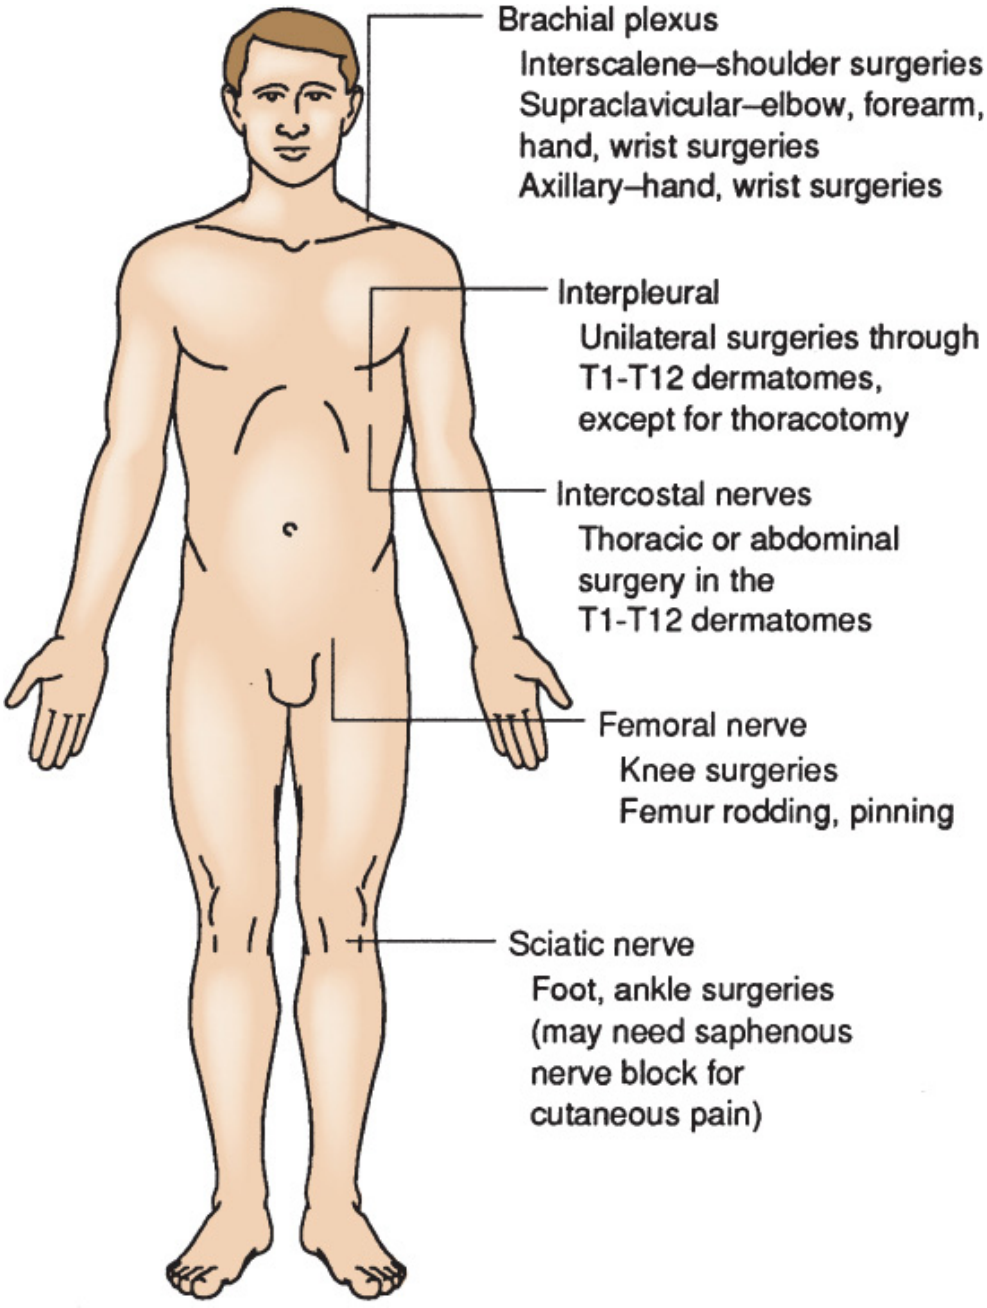

Figure 13.3 Surgical procedures in which peripheral nerve blockade can provide postoperative pain relief.

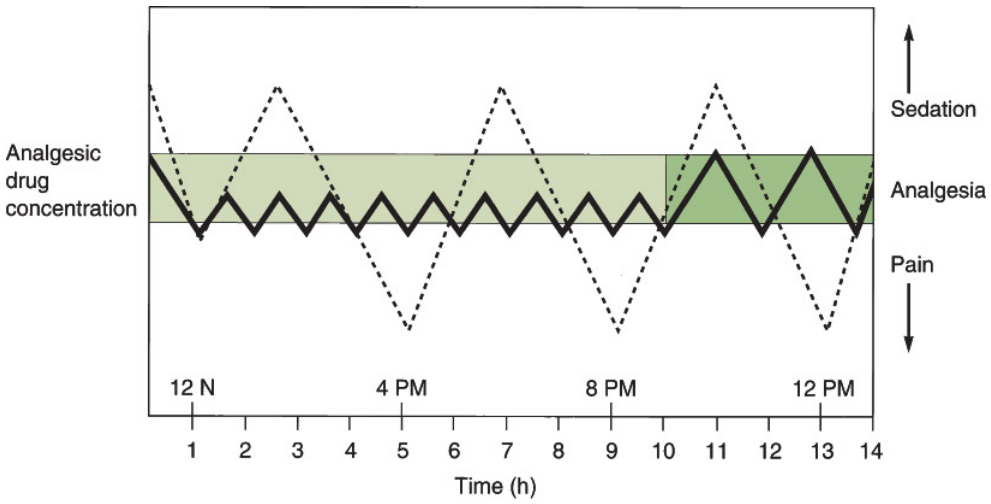

Figure 13.4 Theoretical relation among dosing interval, analgesic drug concentration, and clinical effects when comparing a patient-controlled analgesia system (*solid line*) to conventional intramuscular therapy (*dashed line*). (Reproduced with permission from White PF. Patient-controlled analgesia: a new approach to the management of postoperative pain. *Semin Anesth* 1985;4:261.)

Transdermal narcotic delivery is receiving attention and may become available for postoperative pain. The method is both practical and inexpensive and aims to maintain continuous delivery and constant blood levels. Fentanyl has been the drug of choice and has been well received by patients. The method appears to be safe, but there is a significant lag time between application and the attainment of therapeutic blood levels.

The discovery of endorphins in the 1970s and recognition of their importance in modulating pain at spinal sites led to the supposition that it would be possible to selectively apply opioids directly to receptors. This led to the development of epidural opiate analgesia, in which opioids are applied directly to the receptors at spinal sites. The goal of epidural analgesia is to obtain maximal analgesia while minimizing systemic side effects. For severe acute postoperative pain caused by major surgery, epidural analgesia has proved to be a superior modality for pain control. In high-risk cases, there is evidence that it has an overall beneficial effect on morbidity.[43]

Table 13.19 Problems That Can Occur during Patient-Controlled Analgesia (PCA) Therapy

Operator Errors
1. Misprogramming PCA device
2. Failure to clamp or unclamp tubing
3. Improperly loading syringe or cartridge
4. Inability to respond to safety alarms
5. Misplacing PCA pump key
Patient Errors
1. Failure to understand PCA therapy
2. Misunderstanding PCA pump device
3. Intentional analgesic abuse
Mechanical Errors
1. Failure to deliver on demand
2. Defective one-way valve at Y-connector
3. Faulty alarm system
4. Device malfunctions

The effective use of this sophisticated modality requires education and the establishment of protocols with rigorous attention to detail. The potential for respiratory depression demands adherence to monitoring standards. Morphine and fentanyl, often in combination with a dilute local anesthetic solution, are most often prescribed (**Table 13.21**).

A comprehensive postoperative pain management service demands resources and must use the physical and pharmacologic modalities available while recognizing the significant subjective component of any individual's pain. The ability to recognize the impact of acute pain or an underlying chronic pain disorder requires experience and the active involvement of nursing staff and surgeons is essential.

16 Postoperative acute pain management may require a multimodal approach that incorporates opioids, PNB, and nonopioid analgesics. Chronic pain patients can be particularly difficult to manage and may require preoperative optimization and opiate tapering. These patients require very

large doses of IV analgesics and need to be maintained orally. The best way to evaluate an appropriate starting dose is to convert the preoperative opioid regimen to an IV morphine equivalent, then add what would be required to treat the acute surgical pain. The use of nonopioid and nonpharmacologic treatments is essential in the management of acute postoperative pain in this patient population. PNB, aggressive use of acetaminophen and nonsteroidal anti-inflammatory agents, and novel agents such as dexmedetomidine may be necessary to minimize the adverse effects associated with uncontrolled postoperative pain. The relationship between the administration of opiates during the intraoperative and immediate postoperative phase of care with the "opiate crisis" remains to be fully determined.

Table 13.20 Example of Orders for Patient-Controlled Analgesia (PCA)

1. Patient is to be initiated on PCA with standard monitoring protocol		
2. Drug selection	Morphine 1 mg/mL	Hydromorphone 0.2 mg/mL
3. Loading initial dose (start PRN for pain) Maximum total loading dose	2–5 mg 10 mg	0.2–0.5 mg 1 mg
4. Pump setting PCA dose Lockout interval 4-hr limit	1–2 mg 6–10 min 30–45 mg	0.1–0.2 mg 6–10 min 4–5 mg

University of Michigan Hospitals online order form Acute Pain Service, Patient Controlled Analgesia Standard Orders.

Table 13.21 Opioid Protocols in Epidural Opiate Analgesia

	Morphine[a]	Fentanyl[b]
Length of onset	Longer (30–60 min)	Shorter (15–30 min)
Duration	Longer (6–24 hrs for single bolus)	Shorter (1–2 hrs for single bolus)
Cephalad spread and side effects	More prone	Less prone
Indication	Favored for lumbar administration after abdominal surgery	Favored for thoracic administration after chest surgery
Dose	Typically 3–5 mg, q6–8h	Typically 50–75 mg/hr (±dilute bupivacaine)

[a]Hydrophilic: slow in, slow out.

[b]Lipophilic: fast in, fast out.

ACKNOWLEDGMENTS

The authors would like to thank Kevin K. Tremper and Timothy W. Rutter for their contributions to earlier editions of this chapter.

Preoperative Risk Assessment

Pauline K. Park

Key Points

1 Preoperative risk assessment is critical to informing patients of the risk and benefits of surgical interventions.

2 The development of postoperative complications drives patient mortality and higher healthcare costs.

3 Consideration of patient-centered outcomes may appropriately determine that non-curative surgical intervention may be counter to the patient's true desires.

4 Interventions aimed at prevention and early recognition of complications may lower surgical risk.

5 National Surgical Quality Improvement Programs from the Veterans' Administration and the American College of Surgeons have examined large datasets in a data-driven approach to more finely characterize risk for outcomes of mortality and complications.

6 Identification of patients at risk permits quality assurance monitoring and offers the opportunity to improve care with individual and system level interventions.

7 Specific comorbidities affect both the conduct of surgery and the outcome in ways that can be anticipated and addressed.

INTRODUCTION

1 The goal of preoperative assessment is to evaluate an individual's risk for postoperative adverse events to balance against the benefits of proceeding with surgery. It forms the basis of the contract between the patient and the surgeon; by synthesizing clinically available data, we can stratify and attempt to modify risk to maximize benefit and prioritize patient-centered goals of care.

Early landmark work in cardiac preoperative evaluation by Goldman[1] demonstrated that high-risk surgical patients could be identified through careful assessment of clinical history, physical examination, and laboratory data. This has been extended by further observations in specific types of

surgery and in subgroups of patients with particular disease states. Patient-level analyses using "big data" approaches have informed development of targeted interventions aimed at reducing the risk of a given procedure for a given patient. Additional work in systems of care and patient safety has also reduced patient morbidity and mortality.[2,3] Thus, preoperative evaluation has evolved to include not only prediction of risk but also implementation of proactive interventions during the perioperative period at both the individual patient and system levels.[4] Inclusion of patient values and desired outcomes completes the course of informed decision making.

This chapter will review the relevance of risk determination, clinical aspects of preoperative evaluation, guidelines for specific disease-related conditions and future directions for prevention of complications and intervention should they occur. All of these should be considered in the context of selecting the best approach for each of our patients.

SURGICAL MORTALITY, COMPLICATIONS, AND PATIENT-CENTERED OUTCOMES

Mortality rates following surgery have continued to improve with innovations in surgical technique and advances in overall quality of medical care. Since the 1950s, large reductions in intraoperative mortality have been accomplished through initiatives championing safer operating room protocols, continuous monitoring, and error reduction. By incorporating high-reliability processes into operating room routines, the overall mortality risk attributable to a general anesthetic has been reduced from 25 to 50 per million in the 1970s and 1980s to 1 to 5 per million.[5]

From the surgical standpoint, population-based mortality varies sharply with the extent of the procedure and patient age.[6] Overall surgical mortality in an American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP®) sample from 2013 showed overall unadjusted 30-day mortality of 1.06%.[7] Substantial interhospital variation in outcomes exists and underscores the possibility for additional opportunities for improvement.

2 The search for further improvement in surgical mortality has focused on reducing the incidence of postoperative complications. The 10 most common perioperative complications seen in the Patient Safety in Surgery study included infectious, pulmonary, cardiac, renal, and venous thrombotic events (**Table 14.1**).[8] Surgical complications are strongly related to mortality,[9–11] with the ability to rescue from postoperative complications an important factor in determining eventual outcome.[12] Postoperative complications are associated with increased healthcare costs and resource utilization.[13] They are the most common reason for hospital readmission[14] and a substantial number of complications are identified after discharge (**Table 14.2**).[15]

3 The direct impact of postoperative complications on an *individual* patient's quality of life should be considered. A surgical admission may represent a turning point in the overall trajectory of a patient's life; in 2008, one-third of Medicare decedents underwent a surgical procedure during their last 12 months of life.[16] The preoperative discussion should address the patient's understanding of the potential impact of surgical care and include expected quality-of-life outcomes. It is important to integrate patient-centered goals of care into treatment recommendations; an operation that does not prolong meaningful quality of life may be counter to the patient's expectations of surgical care.

Table 14.1 Surgical Complications: Comparison of the 10 Most Frequent Perioperative Complications between Private Sector and VA Hospitals in **the Patient Safety in Surgery Study**

14 Private Sector Hospitals (n = 54,585)		128 VA Hospitals (n = 130,258)	
Perioperative Complication	**%**	**Perioperative Complication**	**%**
1. Superficial wound infection	3.6	1. Superficial wound infection	3.1
2. Failure to wean from ventilator for >48 hrs	2.9	2. Pneumonia	2.5

RISK STRATIFICATION

4 The goal of risk stratification is to identify patients at risk for adverse 5 outcomes and to target high-risk groups for potential interv 6 ention to reduce that risk. To date, the largest organized surgical efforts have evolved through the ACS NSQIP. In 1991, the Department of Veterans Affairs (VA) system implemented the NSQIP paradigm which collects demographic information, baseline physiologic status, medical comorbidities, laboratory values, and surgical operative characteristics to model the risk of postoperative morbidity and mortality (**Table 14.3A**,**B**). Ongoing system-level analysis evaluates and benchmarks performance between institutions using observed/expected (O/E) ratios for specified outcomes, and allows for linkage of outcomes to process and structure of care.[17] Ten years after the start of NSQIP data collection, the 30-day mortality of major surgery in the VA system decreased by 27% and the 30-day morbidity decreased by 45%.[17] Success in data-driven VA process improvement initiatives has led to validation and adoption in academic and community centers.[17]

Table 14.2 Common Reasons for Unplanned Surgical Readmissions

Surgical procedure–related infection, fever
GI complication, ileus, obstruction
Failure to thrive, dehydration, malnutrition
Pulmonary complications
Venous thromboembolism
Pain

Continued data collection and benchmarking have been sponsored by the American College of Surgeons (ACS) under the ACS NSQIP program. Reports have been utilized as catalysts for institutional-level change, with substantial improvements seen with targeted quality improvement efforts.[18] Following implementation, 66% of ACS NSQIP hospitals saw reduced

mortality and 82% saw reduction in complications. The annual benefit for a hospital enrolling in ACS NSQIP has been estimated at 250 to 500 fewer complications and 12 to 36 fewer deaths.[19] Observed improvements in outcomes appear to be sustained, with the magnitude of quality improvement increasing over time.[20] Of note, improvements in risk-adjusted outcomes at ACS NSQIP hospitals were not found to differ significantly from those concurrently seen in matched non-NSQIP hospitals, suggesting that while feedback and reporting may be critical to implementing process change, they are not by themselves required to drive improvement.[21,22]

Risk Calculators

Algorithm-based risk stratification based on large datasets is now available through the internet and on mobile devices. In 2011, a cardiac risk calculator based on NSQIP variables compared favorably to performance of the

Revised Cardiac Risk Index (RCRI).[23] In 2013, the ACS released an online decision support tool including a perioperative risk calculator built on the NSQIP database, now including data from 4.3 million operations (www.riskcalculator.facs.org). The calculator incorporates 21 variables from the original VA NSQIP data collection and has excellent predictive performance for mortality, morbidity, and six specific complications.[24] In 2019, the option to view geriatric outcomes was added for patients greater than 65 years of age. Potential criticisms of the model include dependence on American Society of Anesthesiology (ASA) Physical Status classification, imprecise definition of functional outcomes and lack of validation outside of an NSQIP cohort,[25] however the ability to rapidly provide individualized patient risk estimation is an important advance. **Figure 14.1A,B** demonstrates an example of risk determination for a patient undergoing elective colon surgery, entering specific clinical variables and reporting specific complications in an individualized fashion.

GENERAL CONCEPTS OF PREOPERATIVE EVALUATION

7 The setting for preoperative evaluation varies with the surgical procedure and with patient circumstances. Coordinated preoperative care at a dedicated facility has led to improved efficiency for outpatient elective surgery,[26] however rapid changes in telehealth practices begun during the COVID-19 pandemic[27] will likely shape practice in the future.

Patient education remains a key aspect of the initial preoperative visit. Preoperative teaching has been shown to improve patient satisfaction and increase cooperation with postoperative recommendations.[28] The wealth of information available on the internet has enabled patients to be better educated, stronger consumers and has empowered many to participate more actively in their care. Prior to the first office visit, many will have researched their disease process, surgical procedure as well as the scorecards of the hospital and surgeon. Forward-thinking surgeons can leverage this engagement to increase the value of the face-to-face

appointment by providing online teaching materials ahead of the actual office visit.

Initial evaluation includes a standard medical history and complete physical examination. The presence of allergies, current medications, chronic illnesses related and unrelated to the surgical condition, prior procedures as well as staging and acuity of disease all contribute to the risk and benefit determinations.

Routine preoperative laboratory testing is no longer recommended for low-risk surgery. The majority of preoperative laboratory tests are rarely indicated and are of limited value.[29] It has been demonstrated that, even when abnormal, preoperative testing often does not lead to change in perioperative management or adverse postoperative outcomes.[30] Despite this, preoperative testing continues to be overused in both low-risk[31] and hospital settings.[32]

Selective laboratory testing has potential value in certain elective cases, as well as in remote telemedicine evaluations[33] and as part of risk assessment in elderly patients.[34] In all cases, testing should be based on clinical likelihood of finding and acting on abnormal results. Adjunctive cardiopulmonary evaluation should be performed selectively (see Cardiovascular and Pulmonary sections).

Anesthesia

For otherwise healthy patients, selective, rather than routine, evaluation by an anesthesiologist is recommended. Use of a screening questionnaire identifying high-risk conditions (history of prior or familial anesthetic difficulty, difficult airway/limited neck motion, decreased exercise tolerance, stroke, thyroid cardiac, asthma, liver and renal disease) has been validated as a trigger for formal anesthesia consult.[35,36]

The ASA Physical Status classification (**Table 14.4**) addresses the overall physical status of the patient, exclusive of specific surgical considerations. Despite its relative imprecision and inconsistent application, ASA class remains strongly associated with other predictors of surgical outcomes[37] and continues as a standard adjunct during preoperative evaluation.

The choice of anesthetic approach (local, monitored anesthesia care/sedation, neuraxial, and general) varies based on the indicated

procedure as well as patient considerations, with general anesthesia carrying a higher risk for pulmonary complications.[38] General anesthesia–related reduction in FRC may persist for up to 2 weeks postoperatively, with endotracheal intubation, inhalational anesthetic, and neuromuscular blockade all potentially contributing to pulmonary dysfunction. Shorter-acting neuromuscular blocking agents may minimize periprocedural weakness and promote better recovery from general anesthesia.

Epidural anesthesia combined with general anesthesia can reduce intraoperative shunting and preemptively address postoperative pain.[39] Meta-analysis of 141 randomized controlled trials suggests that the use of neuraxial blockade (spinal or regional anesthesia) in surgery is associated with overall mortality reduction and decreased complications, notably the incidence of postoperative pneumonia and respiratory failure,[40] however it is not possible to ascertain if these findings were due to salutary effects of regional blockade or reduction in use of general anesthesia.[40]

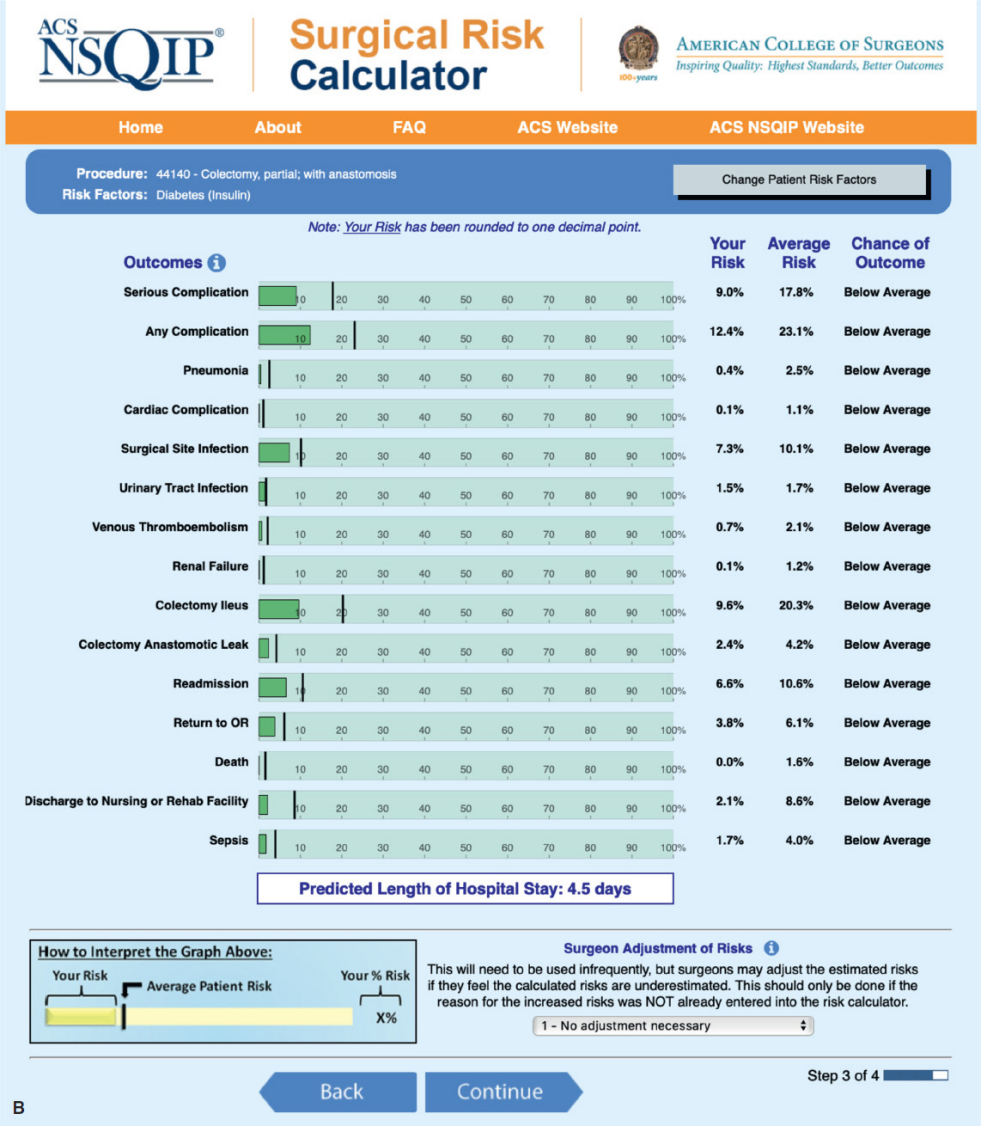

Figure 14.1 **A, B:** Risk stratification: ACS NSQIP risk calculator. (From www.riskcalculator.facs.org, American College of Surgeons.)

Surgical Procedure

Each surgical procedure carries its own set of specific risks. Procedures involving the thoracic or abdominal cavity, neurosurgery, head and neck, or vascular system carry higher risk[41] than those limited to the extremities or subcutaneous tissue. Procedural duration, often associated with complexity and extent of resection, is also associated with increased risk.[38] The extent of surgical exposure has also been correlated with physiologic impact with thoracotomy and upper abdominal incisions associated with most marked

changes in postoperative functional residual capacity. Minimally invasive approaches have, in general, been associated with lower hospital length of stay, earlier return to function, reduced postoperative pain and patient satisfaction. For vascular surgery, endovascular approaches reduce risk of pulmonary complications compared with open surgery.[42]

The urgency of the procedure affects risk assessment (**Table 14.5**).[25] **Emergency surgery** carries the additional challenges of life- or limb-threatening condition without the opportunity for medical optimization. The underlying processes are often catastrophic, with increased risk of infection, hemorrhage, and uncorrected physiologic derangement adding to the risk of postoperative complications[43] and mortality.[41] In ACS NSQIP, unadjusted 30-day mortality was 0.4% for elective procedures, 2.3% for urgent procedures, and 3.7% for emergency procedures.[7]

Table 14.4 American Society of Anesthesiologists (ASA) Physical Status Classification

ASA PS Classification	Definition	Adult Examples, Including, but not Limited to:
ASA I	A normal healthy patient	Healthy, nonsmoking, no or minimal alcohol use
ASA II	A patient with mild systemic disease	Mild diseases only without substantive functional limitations. Current smoker, social alcohol drinker, pregnancy, obesity (30 < BMI < 40), well-controlled DM/HTN, mild lung disease
ASA III	A patient with severe systemic disease	Substantive functional limitations; one or more moderate to severe diseases. Poorly controlled DM or HTN, COPD, morbid obesity (BMI ≥40), active hepatitis, alcohol dependence or abuse, implanted pacemaker, moderate reduction of ejection fraction, ESRD undergoing regularly scheduled dialysis, history (>3

		mo) of MI, CVA, TIA or CAD/stents
ASA IV	A patient with severe systemic disease that is a constant threat to life	Recent (<3 mo), MI, CVA, TIA or CAD/stents, ongoing cardiac ischemia or severe valve dysfunction, severe reduction of ejection fraction, shock, sepsis, DIC, ARD, or ESRD not undergoing regularly scheduled dialysis
ASA V	A moribund patient who is not expected to survive without the operation	Ruptured abdominal/thoracic aneurysm, massive trauma, intracranial bleed with mass effect, ischemic bowel in the face of significant cardiac pathology or multiple organ/system dysfunction
ASA VI	A declared brain-dead patient whose organs are being removed for donor purposes	

Adapted from the ASA Relative Value Guide®.

The addition of "E" denotes Emergency surgery: (An emergency is defined as existing when delay in treatment of the patient would lead to a significant increase in the threat to life or body part.)

These definitions appear in each annual edition of the ASA Relative Value Guide. There is no additional information that will help you further define these categories.

Last amended by the ASA House of Delegates on December 13, 2020 (original approval: October 15, 2014).

Disparities

Disparities in surgical outcomes persist based on racial and socioeconomic considerations.[44] The relative rates of postoperative complications, including respiratory failure, bleeding, infection, and physiologic, and metabolic derangements are generally increased for minority patients over Caucasian patients.[45] The causes are multifactorial and, likely chronic and acute healthcare resource availability, as well as patient-related factors, play a role. In a survey of the U.S. Nationwide Inpatient Sample involving over three million oncologic procedures performed between 1999 and 2009, African American, but not Hispanic patients had higher rates of vascular, wound, GI, and infectious complications when compared to white patients.[46] Variations in outcomes suggest that unexploited opportunities likely exist to reduce the existing disparities. Cultural and economic barriers to surgical care may not be readily visible to the surgeon and should be intentionally considered.

Age

Patients are living longer and with more substantial comorbidities. The world's population of people 60 years of age and older has doubled since 1980 and is forecast to reach two billion by 2050.[47] Demand for surgical services continues to increase faster than the rate of population growth; in 2006, surgery on elderly patients accounted for 35% of inpatient and 32% of outpatient surgical procedures.[48]

Table 14.5 Procedural Urgency

Category	Characteristics	Time Frame	Example
Emergency	Immediate threat to life or limb	Typically in <6 hrs	Acute traumatic hemorrhagic shock
Urgent	Threat to life or limb	6–24 hrs	Small bowel obstruction
Time-Sensitive	Sufficient time for evaluation and management changes which may significantly alter outcome	1–6 wks	Oncologic surgery
Elective	Condition permits delay	Up to a year	Aesthetic surgery

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;130(24):2215–2245.

Normal aging reduces the ability to maintain homeostatic response in the face of acute physiologic stress[49] such as surgery. In a series of over a million Medicare patients, operative mortality for patients 80 years of age and older was observed to be more than twice that for patients 65 to 69 years of age.[6] Compared with patients less than 60 years of age, the risk of postoperative pulmonary complication was doubled for patients between the ages of 60 and 69 and tripled for patients aged 70 to 79.[50] In addition, an initial infectious or pulmonary complication is associated with significantly higher-risk–adjusted failure-to-rescue rates in elderly patients when compared with younger patients.[51] Attending to both prevention and early

recognition of complications potentially will have the greatest impact on these outcomes in the elderly population.

Table 14.6 Preoperative Evaluation of the Geriatric Patient

Domain	Evaluation	Potential Intervention
Cognitive impairment and dementia	Cognitive screen: Mini-Cog, family interview	If screens positive, further evaluation by PCP, geriatrician, or mental health specialist
Decision-making capacity	The patient can: clearly indicate treatment choice understand relevant information acknowledge condition, treatment options, and likely outcomes engage in rational discussion about treatment options	If altered, discuss surrogacy for medical decision making
Depression	Depression screen: PHQ2	If screens positive, further evaluation by PCP, geriatrician, or mental health specialist
Risk for postoperative delirium	Risk assessment	In at-risk patients avoid benzodiazepines and antihistamines when appropriate
Alcohol and substance abuse	Modified CAGE questionnaire	If procedure can be delayed, consider referral to substance abuse specialist

		Perioperative daily MVI and thiamine
Cardiac evaluation	ACC/AHA algorithm (**Algorithm 14.1**)	If positive, consider strategies to reduce risk
Risk for pulmonary complications	NSQIP predictors (**Table 14.11**)	If positive, consider strategies to reduce risk
Functional status, mobility, and fall risk	Timed Up and Go test	If abnormal
Frailty scoring	Frailty score	If abnormal
Nutritional status	BMI <18.5 kg/m^3 Serum albumin 3.0 g/dL without renal or hepatic dysfunction Unintentional weight lost >10–15% in past 12 mo	If feasible, full nutritional assessment by dietician with perioperative nutritional planning
Medication management	Review medication list	Avoid polypharmacy
Counseling regarding: advance directive and surrogate decision making the patient's treatment goals the patient's expectations of surgery		

the patient's family and social support system		
Appropriate preoperative diagnostic testing	Selective preoperative testing	Normal laboratory values obtained up to 4 mo preoperatively can be used safely as long as nonsubstantial interval change in clinical status has occurred

Adapted from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg* 2012;215(4):453–466.

The ACS and American Geriatrics Society (AGS) have published a best practices guideline for the Optimal Preoperative Assessment of the Geriatric Surgical Patient.[48] The guidelines highlight 13 geriatric-specific domains to identify and address during the preoperative period (**Table 14.6**). Few of these domains are covered in detail during traditional preoperative surgical evaluation and further integration into routine practice is needed. In 2016, an additional best practices guideline for perioperative management was added.[52] Interdisciplinary, geriatric-focused preoperative and perioperative care has been demonstrated to decrease complications, shorten hospitalization, increase discharge home and reduce readmissions.[53]

While surgical risk increases with advancing age, chronologic age alone should not be considered a contraindication to surgery in otherwise healthy patients. The association of age with other factors such as decreased functional status, increased number of comorbidities, and more complex pharmacologic history[54] renders simple conclusions unfeasible. For example, in the RCRI model for cardiac mortality, other risk factors become more significant than age alone,[55] while in cases of advanced age, adding age to the RCRI model improves its utility for prediction.[56]

Medical Comorbidity

Hypertension, coronary artery disease, diabetes, and COPD are the most frequently seen comorbidities in patients over the age of 70.[54] More than 50% of these patients suffer from at least one infirmity and 30% suffer from two or more.[54] Adaptation to multiple chronic illnesses and treatments may combine to create altered physiologic response to surgery. For example, a patient with hypertension that is well controlled with diuretics and β-blockade may be chronically volume depleted and unable to mount cardiovascular response to further blood loss in surgery.

Obesity/Obstructive Sleep Apnea

The prevalence of adult obesity is increasing in the United States, with one-third of adults in 2009–2010 considered to be obese (body mass index [BMI] ≥30 kg/m^2).[57] Paradoxically, in nonbariatric general surgery, a J-shaped relationship of lower mortality has been reported in overweight and moderately obese patients.[58]

The American Society of Anesthesiologists updated guidelines for perioperative management of patients with obstructive sleep apnea in 2014.[59] In this report, the prevalence of sleep-disordered breathing was 9% in women and 24% in men. Patients often present without formal polysomnographic confirmation of the diagnosis. Increases in perioperative risk are noted to occur in proportion to the severity of sleep apnea.[60] Sleep apnea should be suspected in patients with history of apparent airway obstruction during sleep, BMI >35 kg/m^2, large neck circumference, craniofacial abnormalities, snoring, frequent arousals from sleep, and unexplained daytime somnolence or fatigue. A trial of preoperative continuous positive airway pressure (CPAP) may be attempted to improve nighttime airway obstruction, particularly if OSA is severe. Other potential interventions include the use of mandibular advancement devices, oral appliances and preoperative weight loss, however evidence was judged to be insufficient to make formal recommendations.

Intraoperative considerations include choice of anesthetic technique, airway management, patient positioning, and patient monitoring. For appropriate procedures, regional anesthesia may be preferred over general anesthesia and continuous monitoring should be employed because of the

potential for airway obstruction. Patients at risk for obstructive sleep apnea may have associated difficult airway and require special attention during induction and emergence from anesthesia. Sedation and neuromuscular blockade should be carefully monitored and fully reversed prior to extubation. Postoperative analgesia should be carefully titrated, using any appropriate modalities to minimize opioid requirements. Supine positioning should be avoided and upright, sitting, lateral or prone positioning may be considered. When not contraindicated by the surgical procedure, patients who use CPAP or noninvasive positive pressure ventilation (NIPPV) preoperatively should have these continued postoperatively. It is important to titrate support based on their usual home settings and patients may bring their home machines to use perioperatively. Continuous, rather than intermittent pulse oximetry, combined with direct observation, is recommended for as long as the patient remains at risk for postoperative respiratory depression.

Anemia

Anemia is independently associated with mortality in noncardiac surgery,[61] yet it is not clear that correction of anemia will alter mortality. Several randomized trials examining transfusion strategies in relatively stable patients failed to demonstrate mortality benefit with higher transfusion triggers in the ICU,[62] cardiac,[63] and orthopedic surgery[64] settings. At present, recommendations for perioperative transfusion are general, with consideration for higher thresholds given to patients who are symptomatic with chest pain, hypotension or fatigue, those with known cardiac ischemia or those receiving massive transfusion for hemorrhagic shock. Current evidence does not support aggressive preoperative transfusion in patients with sickle cell disease.[65] Systematic review of trials evaluating the use of human recombinant erythropoietin combined with iron supplementation in anemic patients prior to noncardiac surgery suggests that these agents successfully reduce the need for RBC transfusion and at higher doses, can increase preoperative hemoglobin, but mean number of units of PRBC transfused, risk of adverse events, hospital length of stay, or 30-day mortality are not clearly reduced.[66]

Preoperative Functional Status

The importance of preoperative functional status has been recognized for years. Self-reported exercise intolerance (to walking four blocks or two flights of steps) is independently associated with higher risk of perioperative cardiovascular, myocardial ischemia, and neurologic events after elective major noncardiac surgery.[67] The relationship is inversely related to the total number of blocks that could be walked or flights of stairs that could be climbed. Functional ability can be quantified in terms of metabolic equivalents (METs), with 1 MET defined as the amount of oxygen consumed while sitting at rest and equal to 3.5 mL O_2 uptake/kg/min.[68] Functional status can be categorized as excellent, >10 METs; good, 7 to 10 METs; moderate, 4 to 6 METs; and poor, <4 METs. Risk is increased if unable to perform at a level of 4 METs (**Table 14.7**).[25] The ACS recommends a four-question survey of activities of daily living (ADLs) as a screen to identify unsuspected functional compromise in geriatric patients (**Table 14.8A**).[69]

Systematic reviews of the ability to influence postoperative outcomes by improving preoperative physical status ("prehabilitation") are limited, but suggest that inspiratory muscle training, aerobic exercise, and/or resistance training may decrease postoperative complications following abdominal and cardiac surgery.[70,71]

Table 14.7 METs Equivalents

METs Level	Example
>10 METs	Strenuous sports (swimming, skiing, singles tennis)
>4 METs	Climbing flight of stairs Walking up a hill Walking 4 mph on level ground
<4 METs	Slow ballroom dancing Golfing with a cart Playing a musical instrument Walking at 2–3 mph
1 MET	Eating, dressing, toileting

Adapted from Fleisher LA, Fleischmann KE, Auerbach AD, et al. 2014 ACC/AHA guideline on perioperative cardiovascular evaluation and management of patients undergoing noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. *Circulation* 2014;130(24):2215–2245.

Table 14.8A Short Simple Screen for Functional Assessment

Ask the patient the following questions: 1. Can you get out of bed or chair yourself? 2. Can you dress and bathe yourself? 3. Can you make your own meals? 4. Can you do your own shopping?
If NO to any of these questions, more in-depth evaluation should be performed, including full screening of activities of daily living and instrumental activities of daily living.
Deficits should be documented and may prompt perioperative interventions (i.e., referral to occupational therapy and/or physical therapy) and proactive discharge planning.

Adapted from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg* 2012;215(4):453–466.

Frailty

Separate from comorbidity, elderly patients may suffer from frailty and sarcopenia.[72] In the Medicare population, additional mortality has been related to frailty[73] and the relationship has been documented in a broad population, including patients undergoing ambulatory general surgery,[74] gastric surgery,[75] gynecologic oncology,[76] and cardiac surgery,[77] as well as in patients requiring unplanned admission following elective ambulatory surgery.[78] CT-based morphomic quantitation of trunk muscle volume is associated with decreases in functional performance on ADLs and independent activities as measured by the Vulnerable Elder Survey[79] as well as poorer outcomes in liver transplantation[80] and aortic surgery.[81] An operational frailty score (**Table 14.8B**) has been validated in elderly surgical patients and is associated with higher incidence of postoperative adverse events, increased length of hospital stay, and higher likelihood of discharge to a skilled or assisted-living facility.[82]

Direction of Care

One of the most important discussions between a surgeon and patient is the understanding of the patient's desires regarding direction of care. There is little question of aggressive interventions for a healthy patient expecting rapid return to their preoperative level of function after elective surgery. Nevertheless, patients with severe underlying comorbidity or limited life expectancy should have the opportunity to direct overall goals of their care. Approaches that incorporate principles of geriatric and palliative care can be used to frame surgical care for these patients in the context of time-limited trials[83,84] or best case/worst case framework.[85] In this fashion, treatment decisions can be matched to the individual patient's overall priorities and goals.

Table 14.8B Frailty Scoring (Operational Definition)

Criteria	Definition
Shrinkage	Unintentional weight loss ≥10 lb past year
Weakness	Decreased grip strength
Exhaustion	Self-reported poor energy and endurance
Low physical activity	Low weekly energy expenditure
Slowness	Slow walking
The patient receives 1 point for each criterion met: 0–1 Not frail 2–3 Intermediate frail (prefrail) 4–5 Frail	

Adapted from Chow WB, Rosenthal RA, Merkow RP, et al. Optimal preoperative assessment of the geriatric surgical patient: a best practices guideline from the American College of Surgeons National Surgical Quality Improvement Program and the American Geriatrics Society. *J Am Coll Surg* 2012;215(4):453–466.

MEDICATION MANAGEMENT

Medication management in the perioperative period is subject to general guidelines of practice. The pharmacokinetics of drug administration, distribution, metabolism, and excretion may all be affected by surgery. Major GI procedures limit oral intake and may require alternate routes of administration. Patients receiving volume resuscitation may have increased drug volume of distribution. Fluctuations in hepatic and renal function and addition of multiple new medications may alter drug metabolism and excretion. New drug interactions may lead to increased toxicity; appropriate monitoring by drug levels may improve drug management.

A careful medication history includes prescription and nonprescription medications, nutritional and herbal supplements. Patients may be taking over-the-counter herbal supplements with substantial physiologic effects[86] but may not perceive these as being relevant to the conduct of their surgery. In one series, more than 70% of patients failed to disclose herbal medicine use during routine preoperative assessment.[87] Herbal supplements are presently not subject to FDA regulation; contents may vary substantially from manufacturer to manufacturer and frank adulteration has been documented.[88] Variations in supplement content may make a 7-day holding period prudent.[89]

In the absence of clear evidence-based guidelines for perioperative medication management, a general approach is to continue drugs that would cause withdrawal within the perioperative period, and to discontinue unnecessary drugs or those with potential for adverse events, restarting them as soon as the patient condition permits (**Table 14.9**).[89] Medications that are generally continued include β-blockers, clonidine, statins, and selective serotonin reuptake inhibitors (SSRIs). Medications that can be discontinued include diuretics, metformin and, possibly, angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs). Additional specific management of cardiac medications and dual antiplatelet therapy in the setting of cardiac stent placement is detailed in the Cardiovascular section.

Management of anticoagulation is of critical importance to surgeons and the indication for anticoagulation should be weighed against the risk of procedural bleeding. Agents should be held for the minimum interval felt safe after invasive procedure.

Patients on chronic long-acting anticoagulation who are undergoing elective operation generally can use preoperative bridging with unfractionated or low–molecular-weight heparin prior to surgery.[90] In the recent PAUSE trial, patients with atrial fibrillation who had direct oral anticoagulant interruption for elective surgery, a perioperative strategy without bridging or coagulation function testing was associated with low rates of major bleeding or thromboembolic complications.[91]

In the emergent setting, the American College of Chest Physicians (ACCP) has published guidelines covering reversal of vitamin K competitors based on urgency of procedure and risk of life-threatening hemorrhage.[92] Reversal of newer direct thrombin inhibitors is now feasible with targeted monoclonal antibodies. In addition, dabigatran may be removed with dialysis, however rivaroxaban and apixaban are highly protein bound and unlikely to be removed with this modality.

Table 14.9 Common Medications Which May Require Special Perioperative Management

Anticoagulants	▪ May require reversal in acute situations ▪ May bridge therapy with unfractionated or LMW heparin
Aspirin or dipyridamole	▪ In setting of PCI and prior drug-eluting stent, see **Algorithm 14.2** ▪ Withhold 7 d prior to surgery with increased bleeding risk ▪ May continue in select procedures
Thienopyridine P2Y12 inhibitors (i.e., clopidogrel, ticlopidine)	▪ In setting of PCI and prior drug-eluting stent, see **Algorithm 14.2** ▪ Withhold 7 d prior to surgery with increased bleeding risk
Glycoprotein IIb/IIIa inhibitors	▪ In setting of PCI and prior drug-eluting stent, see **Algorithm 14.2** ▪ Withhold at least 12 hrs prior to surgery, although antiplatelet effect may persist for longer
NSAIDs	▪ Withhold prior to surgery with risk of renal complications
β-Blockers	▪ Continue in patients already receiving drug, including day of surgery ▪ Do not begin new therapy in preoperative setting
Statins	▪ Continue in patients already receiving drug, including day of surgery ▪ Consider initiating in patients undergoing vascular surgery
Calcium channel blockers, nitrates, most antiarrhythmics	▪ Continue in patients already receiving drug, including day of surgery
Angiotensin-converting	▪ Risk of intraoperative hypotension and

enzyme inhibitors, angiotensin receptor blockers	renal risk, hold day of surgery
Diuretics	▪ Renal risk, potential for hyperkalemia with potassium sparing diuretics, hold day of surgery
Metformin	▪ Risk of lactic acidosis, withhold at least 2 d prior to surgery
Insulin	▪ Adjust dose prior to surgery
Lithium	▪ Potential prolongation of neuromuscular blockade, sedative action, cardiac arrhythmia ▪ Withhold at least 1 d prior to surgery
Monoamine oxidase inhibitors	▪ Potential anesthetic interactions ▪ Proceed with MAO-safe anesthetic or hold for 2 wks
Selective serotonin release inhibitors	▪ Potential bleeding complications ▪ Discontinue for 3 wks preoperatively in conjunction with psychiatry evaluation
Buprenorphine/naloxone	▪ Preoperative weaning in conjunction with the prescribing physician ▪ Postoperative pain management may require pain/addiction specialist consultation
HIV drugs	▪ Minimize interruptions in antiretroviral therapy ▪ Prophylaxis may vary based on immune status
Steroids, immunosuppressives	▪ Stress dose steroids indicated only if evidence of abnormal hypothalamic–pituitary–adrenal axis

	▪ May be advisable to discontinue or reduce dose in presence of active infection
Oral contraceptives, conjugated estrogen	▪ Increase hypercoagulable state ▪ Consider holding 4 wks prior to surgery; if not feasible, ensure adequate DVT prophylaxis
Over-the-counter herbal medications	▪ Consider holding 7 d prior to surgery

In large series, perioperative aspirin administration was associated with an increased risk of postoperative hemorrhage,[93] however a recent meta-analysis concluded that aspirin should not be stopped in the perioperative period unless bleeding risk outweighed thrombotic risk of holding the drug.[94]

Perioperative glucose control reduces mortality, hospital length of stay, and deep wound infections in cardiac surgery.[95] An adjusted dose of short-acting insulin is administered perioperatively, with intravenous insulin infusion intraoperatively if needed. The oral hypoglycemic, metformin, is associated with lactic acidosis and should be held prior to surgery.

Psychiatric medications should be managed based on concern for precipitating withdrawal. Abrupt withdrawal of SSRIs may lead to nausea, vomiting, lethargy, with symptoms seen more quickly in drugs with shorter half-life.[96] The use of SSRIs may increase the risk of bleeding, particularly when used in conjunction with nonsteroidal anti-inflammatory drugs (NSAIDs).[89] Benzodiazepines may be continued perioperatively. Older agents, including tricyclic antidepressants and monoamine oxidase inhibitors (MAOIs), may precipitate hypertensive crisis in conjunction with indirect sympathomimetics.

Patients receiving daily maintenance buprenorphine will not have sufficient surgical analgesia from usual postoperative opioid dosing regimens. Preoperative consultation with their prescriber and with the anesthesiology pain service is recommended prior to surgery. Alternative strategies, including the use of regional anesthesia, nonsteroidal and nonnarcotic regimens may facilitate postoperative management.

Immunosuppressant mediations may be reduced or discontinued prior to surgery, depending on the extent and the presence of associated infection, although a systematic review of immunomodulators in patients with inflammatory bowel disease has suggested no clear increased risk of total or infectious complications with azathioprine, cyclosporine, or infliximab.[97] Steroid use carries a dose-dependent relationship with increased risk of postoperative complications, both infectious and overall.[98] Meta-analysis of randomized controlled trials suggests that perioperative stress dose steroids are not required unless there is dysfunction of the hypothalamic–pituitary–adrenal axis.[99] Anti-VEGF inhibitors are associated with increased risk of GI perforation and delayed wound healing and their use is not recommended for 28 days before or after surgery or until surgical wounds are healed.

SPECIFIC ORGAN SYSTEM GUIDELINES

Cardiovascular

Prediction of cardiac adverse events following noncardiac surgery was pioneered in the 1970s[1] and risk stratification is most refined in this area.

Risk Stratification

The current RCRI (**Table 14.10**)[55] is based on risk of surgery, history of ischemic heart disease, history of congestive heart failure, history of cerebrovascular disease, preoperative insulin–requiring diabetes mellitus, and preoperative renal insufficiency and can be used to identify patients at higher risk for major cardiac complications (MI, pulmonary edema, ventricular fibrillation, primary cardiac arrest, complete heart block). The RCRI has been validated as a predictor of increased risk, and pooled estimates of external validation studies over the past 15 years show higher-risk estimates than the original RCRI.[100] Disappointingly, targeted interventions in high-risk groups have yet to show benefit in risk reduction. Active angina, recent myocardial infarction, signs of left ventricular dysfunction, such as dyspnea or worsening heart failure, syncope, significant arrhythmias, and severe valvular disease should also prompt further preoperative evaluation.

The American College of Cardiology (ACC) and the American Heart Association (AHA) issued joint recommendations for perioperative cardiovascular evaluation and management for noncardiac surgery in 2014.[25] The guideline covers preoperative evaluation, risk assessment, perioperative management, and postpercutaneous coronary intervention (PCI) recommendations. Outcomes are defined in terms of a composite major adverse cardiac event (MACE), which includes death or myocardial infarction (MI). Low-risk procedures are defined as carrying a predicted MACE risk of <1%, and elevated-risk procedures carrying a MACE risk of ≥1%.

Stable patients undergoing low-risk surgery and those with good exercise tolerance rarely need further cardiac evaluation. For those at higher risk, cardiology evaluation is recommended. In urgent or emergent situations where surgical intervention must proceed prior to any meaningful management changes, delay for cardiac evaluation will not be of benefit and care is focused on prompt recognition and treatment of any perioperative events. In this paradigm, decision making for higher-risk patients can be simplified to (1) initial determination if the procedure can be delayed to permit additional evaluation and management which could significantly alter the outcome and (2) further risk stratification and intervention if the patient condition permits. The overall ACC/AHA algorithm is reproduced in **Algorithm 14.1** and specific recommendations are summarized below.

Table 14.10 Revised Cardiac Risk Index

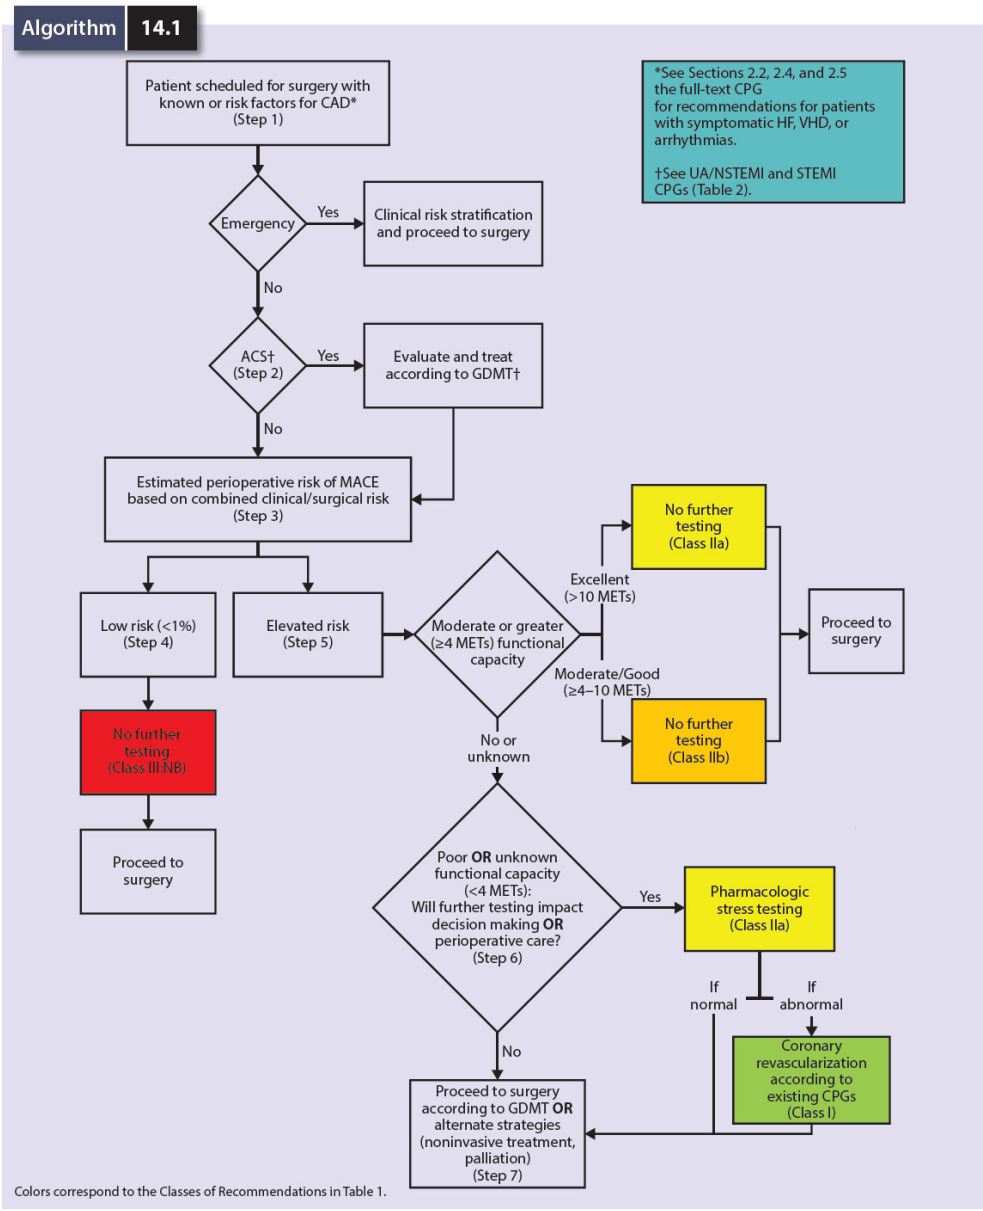
Revised Cardiac Risk Index Criteria	
High-Risk Surgery ▪ Intraperitoneal ▪ Intrathoracic ▪ Suprainguinal vascular	
History of Ischemic Heart Disease ▪ History of myocardial infarction ▪ History of or current angina ▪ Use of sublingual nitrate therapy ▪ History of positive exercise test ▪ Pathologic Q waves on electrocardiogram	
History of Congestive Heart Failure ▪ Pulmonary edema, bilateral rales, or S3 gallop ▪ Paroxysmal nocturnal dyspnea ▪ CXR showing pulmonary vascular redistribution	
History of Cerebrovascular Disease ▪ History of transient ischemic attack ▪ History of cerebrovascular accident	
Diabetes Mellitus Requiring Insulin Therapy Chronic renal insufficiency, defined as a baseline creatinine level of at least 2.0 mg/dL (177 μmol/L)	
Patient receives 1 point for any finding within the 6 major categories	
Points	**Risk of Major Cardiac Event (%)**
0	3.9
1	6.0
2	10.1
3–6	15.0

Adapted from Lee TH, Marcantonio ER, Mangione CM, et al. Derivation and prospective validation of a simple index for prediction of cardiac risk of major noncardiac surgery. *Circulation* 1999;100(10):1043–1049.

Pre-Existing Cardiac Disease

The presence of underlying coronary artery disease is associated with postoperative MACE following noncardiac surgery. Following an acute MI, the rate of subsequent postoperative ischemia and MI decreases as the time interval to surgery increases. The risk of perioperative stroke was also increased with surgery occurring within 6 months of MI.[101] In the absence of myocardial revascularization, noncardiac surgery should be delayed for 60 days or more after acute MI. Coronary artery bypass grafting (CABG) solely to reduce perioperative risk is not recommended and should be performed only if the procedure would otherwise be indicated.

The presence of heart failure is a strong predictor of perioperative cardiac morbidity and mortality. The stability of heart failure is likely to affect outcomes, with decompensated, symptomatic heart failure identified on physical examination carrying higher risk. Preservation of left ventricular ejection fraction is an independent predictor for patients undergoing elevated-risk surgery[102] and patients with an LVEF ≤29% were identified as having higher risk in vascular surgery.[103]



Algorithm 14.1 Stepwise approach to perioperative cardiac assessment for CAD. Abbreviations: ACS, acute coronary syndrome; GDMT, Guideline-directed medical therapy; MACE, major adverse cardiovascular events; METs, metabolic equivalents; CPGs, clinical practice guidelines. (Data from Fleisher LA, et al. *Circulation* 2014;130[24]:2215–2245.)

Patients with clinically suspected valvular heart disease should have review of echocardiography evaluation performed within 1 year prior to surgery or have repeat study if there has been a significant change in status or physical evaluation. Concomitant evaluation for ischemic disease should be

considered. If valvular intervention is clinically indicated, intervention prior to noncardiac surgery may reduce perioperative risk.[104]

Postoperative arrhythmias are common and are often triggered by the stress of surgery. Patients with heart block, implanted pacemakers, or automatic implantable cardioverter defibrillators (AICDs) are best served by effective communication between surgery, anesthesiology, and cardiology to optimize perioperative device management.

Although not included in most cardiac risk scoring, pulmonary hypertension is associated with increased complications[105] and patients may benefit from referral to a center with expertise for further evaluation. In a single institution study evaluating adult patients with pulmonary hypertension undergoing anesthesia, specific risk factors were identified as associated with short-term morbidity (history of pulmonary embolism, NYHA functional class ≥2, elevated-risk surgery, anesthesia >3 hours) and postoperative mortality (pulmonary embolism, right axis deviation on EKG, RV hypertrophy or RVSP:systolic blood pressure >0.66, intraoperative vasopressor and anesthesia when nitrous oxide was not used).[106]

Adult patients with congenital heart disease, when possible, should undergo preoperative evaluation in a regional center specializing in congenital cardiology.[107]

Preoperative Testing (Algorithm 14.1)

EKG should be considered for patients undergoing elevated-risk surgery. It should also be considered in patients with a history of CHD, significant arrhythmia, peripheral arterial disease, cerebrovascular disease or significant structural heart disease, unless they are undergoing low-risk surgery.

More extensive evaluation, including exercise stress testing, assessment of left ventricular function or coronary angiography is performed selectively after initial risk stratification and determination of exercise tolerance. Exercise stress testing is not recommended for patients undergoing low-risk surgery or patients able to tolerate >10 METs; patients with elevated RCRI risk, but able to tolerate >4 METs; and patients with elevated RCRI risk, unable to tolerate <4 METs, but for whom cardiac evaluation will not change management. In patients with elevated RCRI risk or unable to tolerate <4

METs in whom the opportunity exists to improve cardiac management, stress exercise testing can be useful.[25]

Management of Antiplatelet Therapy Following Percutaneous Coronary Intervention (Algorithm 14.2)

Recommendations following PCIs center not only on the cardiac risk, but also the risk of discontinuing dual antiplatelet therapy. Premature discontinuation of antiplatelet agents increases the risk for early and late stent thrombosis and this must be weighed against the relative risk of surgical bleeding. Dual antiplatelet therapy should not be interrupted for the initial 4 to 6 weeks after PCI. Elective surgery should be delayed at least 14 days after balloon angioplasty, 30 days after bare-metal stent implantation if antiplatelet agents are to be discontinued, and 365 days after drug-eluting stent (DES) implantation, if feasible. Elective surgery may considered earlier (180 days) following DES implantation if risk of surgical delay outweighs risk of stent thrombosis.

Management in all other situations should be determined by consensus of the surgeon, anesthesiologist, cardiologist, and patient. In patients undergoing emergent surgical procedures that mandate discontinuation of P2Y12 platelet receptor inhibitors, aspirin should be continued if possible and the P2Y12 platelet receptor inhibitor resumed as soon as possible following surgery.[25]

Other Cardiac Medication Management

Patients on chronic β-blockade should continue treatment during the perioperative period. Prior recommendations for initiating β-blockade in patients without cardiac risk factors have been removed after meta-analysis indicated increased mortality.[108] In patients with intermediate or high risk for myocardial ischemia, that is, three or more risk factors on RCRI, new initiation of β-blockers can be considered preoperatively but enough time should be allowed to assure stability before surgery. Statin therapy should be continued perioperatively and new initiation can be considered for vascular[109] or elevated-risk patients' clinical indications. α-2 Blockade with clonidine should not be administered for prevention of cardiac events.[110] Aspirin, while it has a role in acute coronary syndrome and following PCI, is not indicated solely for prevention of perioperative cardiac events.[93] No

benefit has been identified for perioperative nitroglycerine and routine use is not recommended.

Pulmonary

Pulmonary complications following surgery are among the most frequent and costly postoperative events and lead to similar increases in morbidity, mortality, and length of stay as cardiac complications.[38] In particular, the development of pulmonary complications in the elderly may predict long-term mortality after surgery.[111] Age-related diminution of pulmonary function is associated with postoperative complications[38] and increasing age is an independent risk factor for postoperative pulmonary complications.[50] Other factors associated with increased risk of postoperative pulmonary complications are summarized in **Table 14.11**.

Risk Stratification

The 2006 American College of Physicians guideline for preoperative pulmonary evaluation includes evaluation of patient-related, operative, and laboratory risk factors associated with increased risk of postoperative pulmonary complications.[50] Chronic lung disease was the most frequently identified risk factor; other patient-related factors include ASA class greater than II, increasing age, congestive heart failure, functional dependence, restrictive lung disease, and uncontrolled reactive airway disease. Operative risk factors include surgical site, duration, choice of anesthetic, emergency procedures, and low serum albumin. Other pulmonary risk stratification scales also identified elevated BUN, dyspnea at rest, or low levels of activity[112]; low preoperative arterial oxygen saturation, acute respiratory infection during the previous month, age, preoperative anemia, upper abdominal or intrathoracic surgery, surgical duration of at least 2 hours, emergency surgery[113]; and age, smoking status, airflow limitation, ASA class, hypoalbuminemia, emergency surgery, and nonlaparoscopic abdominal/cardiac and AAA repair[114] as risk factors for pulmonary complications. In Europe, the ARISCAT Score for pulmonary complications has been validated to predict three levels of postoperative pulmonary

complications, though performance differed between different regions (**Table 14.12**).[115]

Table 14.11 Risk for Pulmonary Complications in Noncardiac Surgery

Risk Assessment for Pulmonary Complications in Noncardiothoracic Surgery
Patient-Related Factors
Age >60
ASA class II, or greater
Chronic obstructive pulmonary disease
Functional dependence
Congestive heart failure
Dyspnea at rest or minimal exertion
Operative Factors
Prolonged surgery (>3 hrs)
Abdominal surgery
Thoracic surgery
Neurosurgery
Head and neck surgery
Vascular surgery
Emergency surgery
Use of general anesthesia
Laboratory Values
Serum albumin <3.5 g/dL
BUN >40 mg/dL

Modified from Qaseem A, Snow V, Fitterman N, et al. Risk assessment for and strategies to reduce perioperative pulmonary complications for patients undergoing noncardiothoracic surgery: a guideline from the American College of Physicians. *Ann Intern Med* 2006;144(8):575–580 and Khuri SF, Henderson WG, Daley J, et al. Successful implementation of the Department of Veterans Affairs' National Surgical Quality Improvement Program in the private sector: the Patient Safety in Surgery study. *Ann Surg* 2008;248(2):329–336.

Abbreviations: BMS, bare metal stent; DES, drug eluting stent; DAPT, dual antiplatelet therapy; ASA, aspirin; P2Y12, P2Y12 inhibitor; ASAP, as soon as possible. (Data from Fleisher LA, et al. *Circulation* 2014;130[24]:2215–2245.)

Preoperative Evaluation

Symptomatic dyspnea is a strong predictor of pulmonary complications and should be investigated further as it may signal underlying cardiopulmonary or neuromuscular dysfunction. Chronic cough or sputum production, particularly in the setting of chronic obstructive lung disease, cigarette smoking, or occupational exposures should trigger consideration of possible associated infection. Systemic diseases may have associated pulmonary compromise. A history of restrictive chest wall disease or neuromuscular disorders may signal impaired ventilatory reserve and may impart additional risk. Physical examination findings of abnormal auscultation, scoliosis, chest wall deformity, and accessory muscle use may denote decreased functional

capacity. While a history of asthma has not been confirmed to be independently associated with postoperative pulmonary complications, patients with poor control are at increased risk.[116]

≥45	High	42.1

[a]Either upper or lower (i.e., URI, bronchitis, pneumonia), with fever and antibiotic treatment.

Complications were defined as a composite including respiratory failure, respiratory infection, pleural effusion, atelectasis on chest x-ray, pneumothorax, bronchospasm treated with bronchodilators, and aspiration pneumonitis.

Adapted from Canet J, Gallart L, Gomar C, et al. Prediction of postoperative pulmonary complications in a population-based surgical cohort. *Anesthesiology* 2010;113(6):1338–1350.

An early international study of over 1,000 patients identified with perioperative SARS-CoV-2 infection showed high overall 30-day mortality (23.8%), with pulmonary complications occurring in half of the patients and implicated in over 80% of deaths.[117] Independent risk factors for mortality included male sex, age ≥70, malignancy, ASA 3 to 5, and major and emergency surgery. Pending further data, higher thresholds for surgical intervention were recommended, with nonoperative therapy or postponement of nonurgent procedures considered when feasible.

Routine chest radiography, pulmonary function tests, and arterial blood gases are not indicated for extrathoracic surgery,[50] but may be considered in evaluation for resectional and nonresectional thoracic surgery and in patients with symptoms and undiagnosed chronic lung disease. Dyspnea on exertion should be evaluated with pulmonary function tests and chest radiography. If a cardiac etiology is suspected by history or physical examination, echocardiography can be considered. Abnormal chest radiography suggesting diffuse parenchymal disease should be investigated further. Preoperative albumin and BUN are associated with increased complications and should be obtained as part of evaluation in patients with at least one other identified risk factor.[50] Identification of patient, operative, or laboratory risks should prompt further investigation.

Cigarette smoking is directly toxic to respiratory epithelium, is associated with chronic lung disease, and is associated with increased chance of major morbidity (surgical site infection, pneumonia, shock, unplanned intubation) and mortality.[118] Benefits of smoking cessation likely increase with increased interval between stopping and surgery. Meta-analyses suggest that the effects of cigarette smoking on the tissue microenvironment and inflammatory cellular functions may be reversed within 4 weeks[119] and that smokers who quit more than 4 weeks before surgery have lowered risk of perioperative respiratory and wound complications.[120] Reports of increased airway

reactivity during these initial weeks following smoking cessation raise concerns regarding proceeding with surgery during this period,[121,122] although more recent studies suggest no increase in complications for shorter intervals.[120,123] A general recommendation is that for maximum benefit, smoking should be discontinued 6 to 8 weeks preoperatively, but that stopping for any duration before surgery is beneficial.

Additionally, surgery may represent an opportunity for a teachable moment for the patient's health. In a longitudinal study, patients undergoing major surgery doubled the chance of quitting.[124] A recent Cochrane review suggested that brief and intensive interventions reduced perioperative smoking, and that more intensive structured smoking cessation interventions, including weekly preoperative counseling and nicotine replacement therapy, may be used to extend perioperative smoking cessation to long-term success.[125]

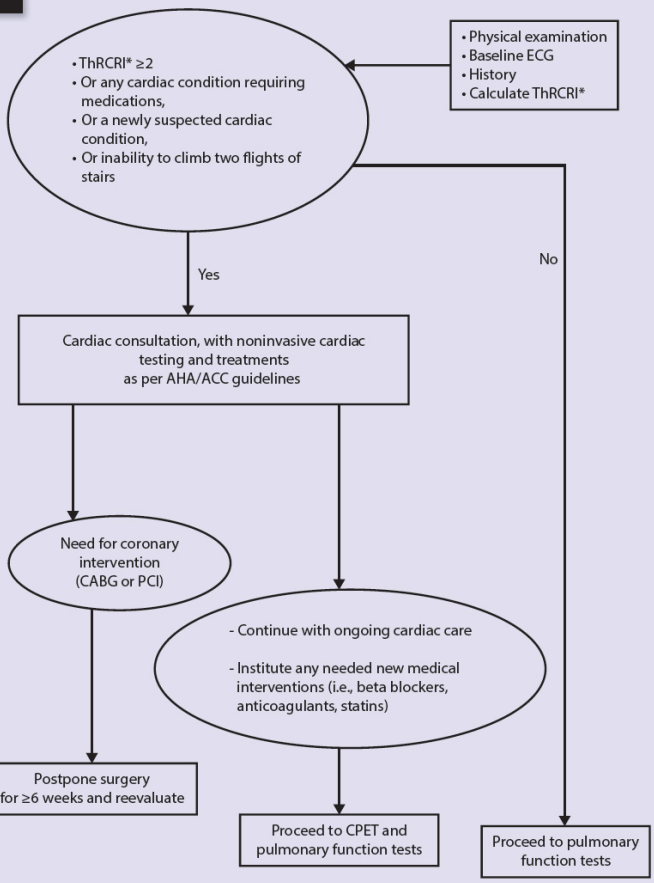
Pulmonary complications may be reduced by optimizing status of patients with pre-existing lung disease, lung expansion maneuvers, and smoking cessation. Patients with chronic lung disease should be optimized prior to elective surgery with longer-acting controller medications. Aerosolized β_2-adrenergic receptor agonists, inhaled anticholinergics, and inhaled and systemic corticosteroids may be used to improve pulmonary function.[50] Preoperative management of poorly controlled asthma includes eliminating wheezing, cough or dyspnea, and targeting peak expiratory flows >80% of predicted or the patient's personal best.[126] Elective surgery should be delayed for signs of acute infection, including increased secretions or change in character of sputum.

Lung expansion maneuvers reduce postoperative reductions in FRC by augmenting alveolar recruitment. Common modalities, including incentive spirometry, deep-breathing exercises, and CPAP, have been demonstrated to improve postoperative pulmonary outcomes.[50,127] Concentrating education during preoperative sessions may increase patient compliance and enhance improvements in high-risk patients.[128,129]

Preoperative Evaluation Prior to Lung Cancer Resection (Algorithm 14.3)

Considerations for patients undergoing surgical treatment of lung cancer balance the intent for curative resection with concern for residual function and long-term disability following surgery. As conditions promoting the development of lung cancer, that is, cigarette smoking and occupational exposures, are also associated with intrinsic reductions in pulmonary function, the guidelines rely on physiologic testing to estimate perioperative risk as well as the effect on postoperative lung function.

Algorithm 14.3A



*** ThRCRI (*Thoracic revised Cardiac Risk Index*)**

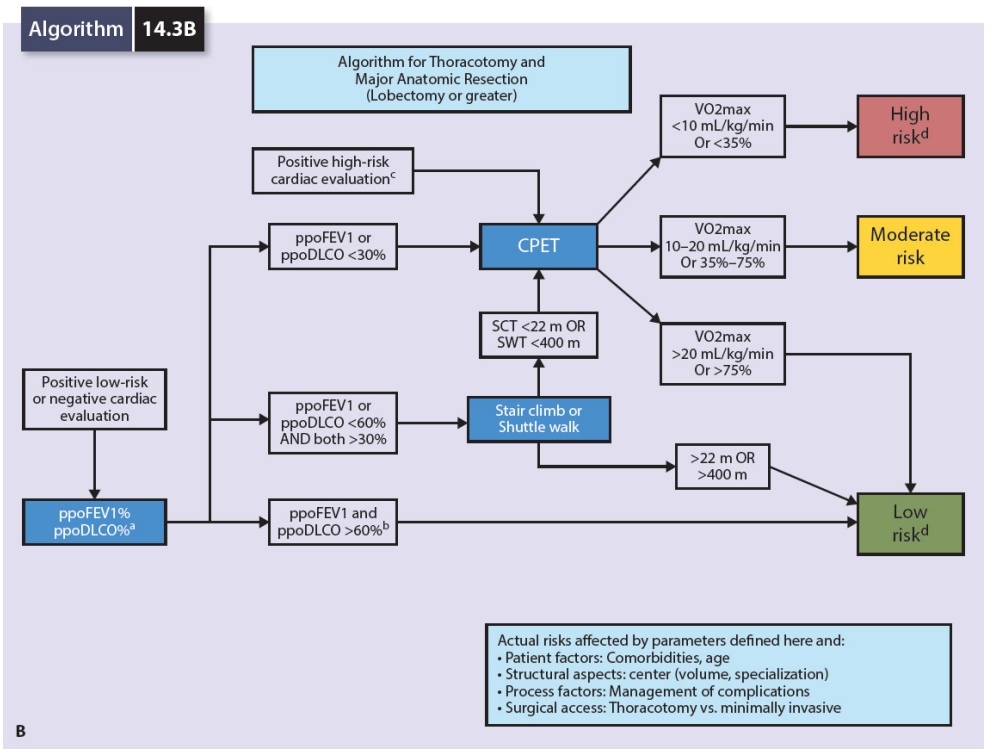
- Previous ischemic heart disease: 1.5 points
- Previous stroke or TIA: 1.5 points
- Creatinine >2 mg/dL: 1 point

A



Algorithm 14.3 **A**: Physiologic evaluation prior to lung resection. Abbreviations: ThRCRI, Thoracic revised Cardiac Risk Index; ACC, American College of Cardiology; AHA, American Heart Association; CABG, coronary artery bypass graft surgery; CPET, cardiopulmonary exercise test; PCI, percutaneous coronary intervention; TIA, transient ischemic attack. **B**: ppoFEV1 or ppoDLCO cutoff value of 60% predicted values has been chosen based on indirect evidences and expert consensus opinion. Definition of risk. Low risk: The expected risk of mortality is below 1%. Major anatomic resections can be safely performed in this group. Moderate risk: Morbidity and mortality rates may vary according to the values of split lung functions, exercise tolerance, and extent of resection. Risks and benefits of the operation should be thoroughly discussed with the patient. High risk: The risk of mortality after standard major anatomic resections may be higher than 10%. Considerable risk of severe cardiopulmonary morbidity and residual functional loss is expected. Patients should be counseled about alternative surgical (minor resections or minimally invasive surgery) or nonsurgical options. For pneumonectomy candidates, we suggest to use Q scan to calculate predicted postoperative values (ppo) of FEV1 or DLCO (ppo values = preoperative values × (1 − fraction of total perfusion for the resected lung), where the preoperative values are taken as the best measured postbronchodilator values. For lobectomy patients, segmental counting is indicated to calculate predicted postoperative values of FEV1 or DLCO (ppo values = preoperative values × (1 − y/z), where the preoperative values are taken as the best measured postbronchodilator value and the number of functional or unobstructed lung segments to be removed is y and the total number functional segments is z. Abbreviations: ppoDLCO, predicted postoperative diffusing capacity for carbon monoxide; ppoDLCO%, percent predicted postoperative diffusing capacity or carbon monoxide; ppoFEV1, predicted

postoperative FEV1; ppoFEV1%, percent predicted postoperative FEV1; SCT, stair climb test; SWT, shuttle walk test; VO_2 max, maximal oxygen consumption; mL/kg/min, milliliters per kilogram per minute; m, meters; CPET, cardiopulmonary exercise testing. (Adapted from Brunelli A, Kim AW, Berger KI, et al. Physiologic evaluation of the patient with lung cancer being considered for resectional surgery: diagnosis and management of lung cancer, 3rd ed: American College of Chest Physicians evidence-based clinical practice guidelines. *Chest* 2013;143[5 Suppl]:e166S–e190S.)

In 2013, the ACCP updated clinical practice guidelines for physiologic evaluation of the patient with lung cancer being considered for resectional surgery.[130] Multidisciplinary evaluation was stressed as essential for counseling, particularly in patients with borderline function. Age alone was felt to be insufficient grounds to deny lung resection surgery. Cardiology evaluation was recommended for patients with major factors for increased perioperative cardiac risk and a modified Thoracic revised cardiac risk index (ThRCRI) incorporating need for pneumonectomy, prior ischemic heart disease, stroke or TIA, and creatinine >2 mg/dL has been validated.[131] Measurement of preoperative FEV1 and diffusing capacity for carbon monoxide (D_{LCO}) and calculation of predicted postoperative values are recommended for patients undergoing lung resection surgery. Further evaluation with low technology exercise test (stair climb or shuttle walk test) or formal cardiopulmonary exercise testing with measurement of maximal oxygen consumption (VO_{2max}) is recommended based on the initial results. In patients with borderline assessments, counseling regarding nonstandard surgery and nonoperative treatment options is recommended.

Postoperative atrial fibrillation occurs in up to 19% of patients following lung cancer resection with incidence peaking on the second postoperative day.[132] Greater risk is present for men >55 years of age and in the presence of a resting heart rate >72 beats/min. Close attention should be paid to volume and electrolyte status.

Hepatic

Postoperative risk in liver disease is related to the severity of underlying liver disease and the extent of the surgical procedure.[133] Patients are living longer with chronic liver disease and they may present as relatively

asymptomatic with normal liver function tests even with substantial degree of hepatic dysfunction. In addition, occult chronic liver disease with silent cirrhosis may be present. Nonalcoholic steatohepatitis (NASH) affects 2% to 5% of Americans, primarily middle-aged, overweight, or obese patients. In a series of patients undergoing bariatric surgery, 6% were found to have unsuspected cirrhosis in the setting of fatty liver.[134]

The presence of cirrhosis is associated with high risk of complications and death; delayed hepatic decompensation can follow routine surgery. Intra-abdominal[135,136] and cardiac surgery[137] have been associated with high mortality rates in cirrhotics. In one series, patients with cirrhosis undergoing surgery had a 30-day mortality of 11.6% and an overall complication rate of 30%.[138] The most frequent complication was pneumonia, with other complications including bleeding, hepatic decompensation, sepsis, and renal failure. Formal hepatic resection in cirrhosis carries a high mortality rate which is elevated in patients with postresectional liver failure.[139] Umbilical hernia may be aggravated in the presence of uncontrolled ascites and nonoperative management may be warranted.

Table 14.13 Modified Child–Turcotte–Pugh Score

	Score		
	1 Point	2 Points	3 Points
Total serum bilirubin (μmol/dL)	<3.4	3.4–5.0	>5.0
Serum albumin (g/dL)	>3.5	2.8–3.5	<2.8
International normalized ratio	<1.7	1.7–2.2	>2.2
Ascites	None	Controlled with medication	Treatment refractory
Encephalopathy	None	Grade I–II or controlled with medication	Grade III–IV or treatment refractory

	Sum total points for each component:	
	Total Points	Surgical Mortality (%)
Class A	5–6	10
Class B	7–9	30
Class C	10–15	80

Adapted from Child CG, Turcotte JG. Surgery and portal hypertension. *Major Probl Clin Surg* 1964;1:1–85 and Pugh RN, Murray-Lyon IM, Dawson JL, et al. Transection of the oesophagus for bleeding oesophageal varices. *Br J Surg* 1973;60(8):646–649.

While the liver is usually protected from ischemia due to dual portal and systemic blood flow, in disease states, alterations in splanchnic and

autonomic vascular regulation increase vulnerability to hypoperfusion and ischemic injury. Avoidance of shock states is imperative for at-risk patients.

Patients with portal hypertension are at risk for bleeding from visceral and retroperitoneal varices; meticulous hemostasis is necessary and may prolong expected operative times. Perioperative management includes optimization of liver function, including management of portal hypertension, cholestasis and coagulopathy, and avoidance of further hepatic injury secondary to drugs, inhalation agents, hypoperfusion, and ischemia. Surgical procedures with anticipated right heart failure may worsen hepatic congestion and thus may be contraindicated. Peripheral shunting and vasodilation complicate management of acute volume shifts. β-blockade and octreotide may be of use in reducing splanchnic hypertension; the role of preoperative TIPS is unclear.

Risk Stratification

Overall surgical risk in cirrhotic patients appears to correlate with established scoring systems. Risk stratification extrapolates scoring based on studies in cirrhotic patients undergoing portal decompression (modified Child–Turcotte–Pugh [CTP]) score (**Table 14.13**)[140,141] and survival models for patients with end-stage liver disease (model for end-stage liver disease, MELD score, **Table 14.14**).[142–144] MELD and CTP scores both may correlate with postoperative mortality and are useful to guide preoperative counseling.[145–147] A calculator version of a modified MELD score incorporating age and ASA score is available at www.mayoclinc.org/meld/mayomodel9.html.

Historically, surgery in Child class A patients carries a mortality of 10%, Child class B, 30% and Child class C, 76% to 82%.[148,149] The rate of postoperative complications including liver failure, encephalopathy, bleeding infection, renal failure, hypoxia, and intractable ascites also increases with class. Poorer outcomes are associated with anemia, ascites, the presence of encephalopathy, hypoalbuminemia, hypoxia, malnutrition, concomitant infection, preoperative upper GI bleeding, intraoperative hypotension, associated renal failure or COPD, and emergency, cardiac, hepatic resection, or abdominal procedures.[133,138] In general, mortality rates for patients undergoing emergency surgery and patients with portal hypertension are higher.

Table 14.14 Model End-Stage Liver Disease Score (MELD) and Surgical Mortality

MELD score = $(9.57 \times \log_e[\text{creatinine mg/dL}]) + (3.78 \times \log_e[\text{bilirubin mg/dL}]) + (11.20 \times \log_e[\text{international normalized ratio}]) + 6.43$

Minimum laboratory value is 1.0 (for laboratory values <1.0, use value of 1.0)

Maximum creatinine is 4.0 (for creatinine >4.0, use value of 4.0)

If patient has had dialysis twice within the previous week, use value of 4.0

Round final score to nearest whole number

Maximum score is 40

MELD		Postoperative Mortality					
Score	(n)	7 d	30 d	90 d	1 yr	5 yrs	10 yrs

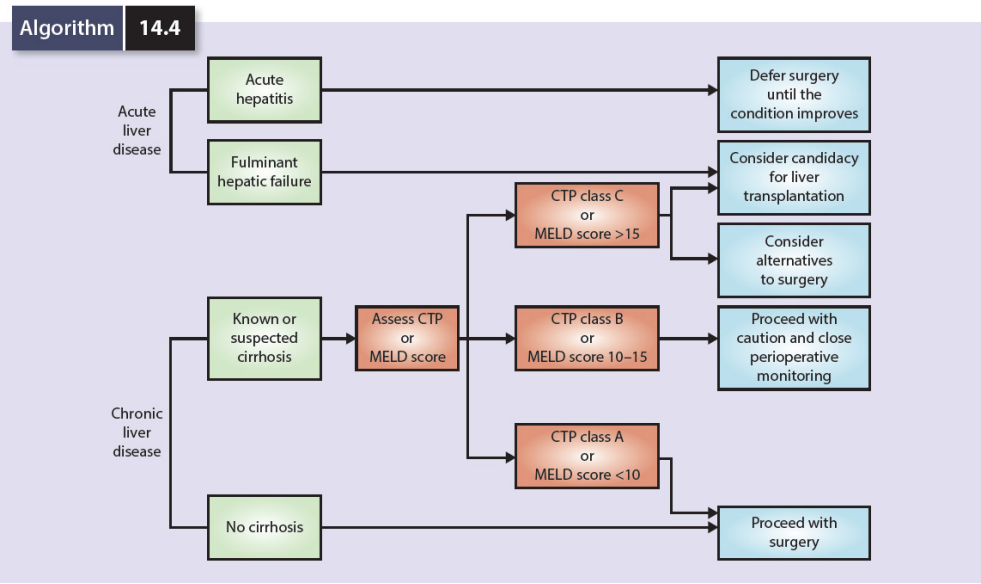
Adapted from Northup PG, Wanamaker RC, Lee VD, et al. Model for end-stage liver disease (MELD) predicts nontransplant surgical mortality in patients with cirrhosis. *Ann Surg* 2005;242(2):244–251 and Teh SH, Nagorney DM, Stevens SR, et al. Risk factors for mortality after surgery in patients with cirrhosis. *Gastroenterology* 2007;132(4):1261–1269.



Algorithm 14.4 Proposed algorithm for preoperative evaluation of patients with liver disease. (Adapted from Hanje AJ, Patel T. Preoperative evaluation of patients with liver disease. *Nat Clin Pract Gastroenterol Hepatol* 2007;4[5]:266–276.)

Preoperative Evaluation (Algorithm 14.4)

History and physical examination may reveal unsuspected liver disease. History of prior hepatitis, cirrhosis, hepatic decompensation, prior anesthetic toxicity, biliary disease, hereditary metabolic disorders, bleeding, or prior alcohol or substance abuse should be sought. Physical examination may reveal stigmata of portal hypertension including hepatomegaly, splenomegaly, ascites, abdominal wall varices, asterixis, and palmar erythema. Thrombocytopenia secondary to splenic sequestration may be an early sign of previously undiagnosed portal hypertension. If liver disease is suspected during routine preoperative evaluation, elective surgery should be deferred for further workup.[150]

Acute conditions for which elective surgery is contraindicated include acute liver failure, acute viral hepatitis, alcoholic hepatitis, liver disease with associated acute renal failure, cardiomyopathy, hypoxemia, or severe coagulopathy.[133] Hepatic recovery may occur following an initial insult and elective surgery should be deferred for a period of several weeks to optimize the patient's condition. For acute alcoholic hepatitis, abstinence from alcohol for 12 weeks before elective surgery has been recommended.

For patients with known chronic liver disease and cirrhosis, surgical morbidity and mortality correlates with the degree of hepatic dysfunction. Patients with compensated chronic liver disease generally tolerate most surgery well, however patients with decompensated cirrhosis may have substantial perioperative risk proportional to the degree of hepatic dysfunction. A suggested preoperative evaluation for hepatic disease is presented in **Algorithm 14.4**.[151] A preoperative checklist for patients with portal hypertension has been published.[152]

Patients with a history of alcohol abuse may undergo acute withdrawal immediately prior to or following surgery. Signs of autonomic instability, agitation, and delirium should be managed symptomatically with β-blockade, clonidine, and benzodiazepines. Protocolized symptom–triggered regimens are associated with lower total medication dose compared to standing regimens.[153] DT prophylaxis with round-the-clock medication is not indicated outside of high-risk cases or a history of prior DTs. Empiric thiamine, folate, and multivitamin replacement should be considered.

Renal

Renal dysfunction is frequent after surgery and there is increasing recognition that new renal failure manifested by even small, transient increases in serum creatinine during the postoperative period is associated with later mortality.[154] Small increases in creatinine, as little as 0.3 mg/kg, may increase risk.[155] In a noncardiac general surgical population, the incidence of postoperative renal failure may be as high as 1%.[156] Therefore, preoperative evaluation should be based not only on determining current status of chronic or acute renal disease, but also the potential for further deterioration.

Risk Stratification

The strongest risk factor for development of postoperative acute kidney injury is the presence of pre-existing chronic renal disease.[157] The development of postoperative renal failure is in turn strongly associated with increased mortality.[154,156,158] A single episode of AKI as defined by RIFLE criteria is associated with long-term mortality in proportion with the severity of injury. Preoperative risk scores have been developed, primarily in cardiac

surgery[159,160] populations and are based on baseline renal function, and the presence of associated medical comorbidity. In a large noncardiac surgery series,[161] anemia (hemoglobin <12.0 g/dL) and decrease in postoperative hemoglobin greater than 1.1 g/dL were associated with higher risk for renal failure. Using a large intraoperative dataset, risk factors for the development of acute kidney injury in noncardiac surgical patients were identified and used to model an Acute Kidney Injury Risk Index scoring system (**Table 14.15**).[156] Biomarker-based and physiologic time series data are being investigated for development of prediction models using machine learning computational approaches.[162]

Table 14.15 General Surgery Acute Kidney Injury Risk Index Classification System

	Derivation Cohort, *n* = 57,080			Validation Cohort, *n* = 18,872		
Preoperative Risk Class	Total Patients, *n*	AKI Incidence % (*n*)	Hazard Ratio (95% Confidence Interval)	Total Patients, *n*	AKI Incidence % (*n*)	Hazard Ratio (95% Confidence Interval)
Class I (0–2 risk factors)	31,500	0.2 (66)		10,301	0.2 (25)	
Class II (3 risk factors)	12,570	0.8 (104)	4.0 (2.0–5.4)	4,218	0.6 (32)	3.1 (1.0–5.3)
Class III (4 risk factors)	7,033	1.6 (144)	6.8 (0.0–11.5)	2,025	2.0 (53)	8.5 (5.3–13.7)
Class IV (5 risk factors)	3,015	3.3 (118)	10.1 (11.0–21.5)	1,244	3.6 (45)	15.4 (0.4–25.2)
Class V (6+ risk factors	1,450	8.0 (120)	40.3 (34.2–62.0)	484	9.5 (40)	40.2 (26.3–70.9)
	Patient receives 1 point for each risk factor:					
	Age ≥56 yrs					
	Male sex					
	Active congestive heart failure					
	Ascites					
	Hypertension					
	Emergency surgery					
	Intraperitoneal surgery					
	Renal insufficiency, preoperative serum creatinine >1.2 mg/dL					
	Diabetes mellitus, on oral or insulin therapy					

From Kheterpal S, Tremper KK, Heung M, et al. Development and validation of an acute kidney injury risk index for patients undergoing general surgery: results from a national data set. *Anesthesiology* 2009;110(3):505–515.

Preoperative Evaluation

The presence of underlying renal disease should be suspected based on history. Chronic renal disease in the adult population is not uncommon, with an estimated prevalence at 13%.[163] Common systemic conditions such as hypertension, diabetes mellitus, and arteriosclerosis may lead to end-organ damage. Renal impairment must be considered in the context of the presence of associated systemic disease. A history of prior renal injury should be sought.

Determination of renal function is based on the glomerular filtration rate (GFR), estimated by equations such as the Cockcroft–Gault equation.[164] As the GFR is reduced to <30% of baseline, electrolyte, volume, and red cell homeostasis are altered. Medication excretion will be decreased and drug dosing should be titrated by levels to minimize toxicity.

Prevention of Acute Kidney Injury

Strategies for prevention of postoperative renal failure include stabilization of homeostatic imbalances, maintenance of adequate renal perfusion, avoidance of intraoperative hypotension, and judicious use of nephrotoxic agents, including aminoglycosides, ACE inhibitors, intravenous contrast agents, and NSAIDs. In patients with known chronic renal disease, careful evaluation of electrolyte abnormalities, anemia, and intravascular volume should be performed.

The mainstay of prevention strategies is to assure adequate renal perfusion by avoiding hypotension from hypovolemia. Despite extensive clinical testing, no pharmacologic intervention has been found to successfully improve postoperative renal outcomes. Preoperative statin,[165] prophylactic or therapeutic acetylcysteine,[166] ANP,[167] insulin-like growth factor,[168] tight glycemic control, fenoldopam,[169] clonidine, and antiplatelet drugs[155] have all failed to show efficacy.

Renal replacement therapy is indicated emergently for correction of acidosis, symptomatic hyperkalemia, severe volume overload, or uremic pericarditis. Dialysis may be undertaken preoperatively to optimize volume and electrolyte status prior to surgery. Once GFR falls below 5 to 10 mL/min, hemodialysis is usually indicated for clearance. Continuous venovenous hemodialysis may permit volume removal in the hemodynamically unstable patient. Consideration should be given to the

location of temporary dialysis access; subclavian and upper extremity access should be avoided in patients who may eventually go on to require permanent dialysis access.

ADDITIONAL CONSIDERATIONS, FUTURE DIRECTIONS

Considerable progress has been made in refining preoperative risk assessment, however the majority of the risk factors identified to date have been nonmodifiable (i.e., age, need for emergent surgery, type of surgery required). As electronic health data collection becomes more prevalent and facile, new predictors of surgical risk that permit targeted interventions may be uncovered and present opportunities for study.

In the meantime, the preoperative visit should continue to function as an opportunity to initiate perioperative care for patients identified as high-risk. Process of care practices with broad proven benefit can be protocolized as part of routine presurgical orders. Studies evaluating early "prehabilitation" or "training for surgery" for patients with functional deficits are in progress. Advances in preoperative assessment combined with proactive preoperative and perioperative interventions will enable the best outcomes for surgical patients.

Measuring the Quality of Surgical Care: Surgeons, Hospitals and Systems

Andrew M. Ibrahim and Justin B. Dimick

Key Points

1. Quality measures fall into three categories: structure, process, and outcomes. Healthcare structure refers to fixed attributes of the system in which patients receive care. Process of care measures are the clinical details of care provided to patients. Outcome measures reflect the end result of care, from a clinical perspective or as judged by the patient.
2. No quality measure is perfect. Clinical leaders, patient advocates, payers, and policy makers will have to make decisions about when imperfect measures are good enough to act upon. A measure should be implemented only with the expectation that acting on it will result in net improvement in health quality.
3. It is important to ensure a good match between the performance measure and the primary goal of measurement. The right measure depends on whether the underlying goal is (a) quality improvement —raising the level of performance for all providers or (b) optimizing delivery—directing patients to providers and hospitals best aligned to their needs.
4. For quality improvement purposes, a good performance measure must be actionable. Measurable improvements in the given process should translate to clinically meaningful improvements in patient outcomes.
5. With optimizing delivery, a good measure will steer patients to the best providers without limiting access.
6. One of the biggest limitations of surgical quality measurement is the statistical "noise" from the small sample sizes at most hospitals. This problem makes it difficult to isolate the quality signal from the background statistical noise. Multiple statistical techniques (e.g., reliability adjustment), directly addresses this problem. This technique, based on hierarchical modeling, quantifies and subtracts statistical noise from the measurement process.
7. While the structure, process, and outcomes framework to evaluate surgical quality has traditionally focused on surgeons and hospitals,

an emerging area of study now includes healthcare systems. As hospitals have merged into larger networks they have an opportunity to optimize their accumulated assets to deliver high quality surgical care. Metrics in this growing space center around access (e.g., distance traveled, wait time for appointment), appropriate referral (e.g., centralizing high-risk operations), and resource stewardship (e.g., appropriate decentralization of ambulatory operations).

INTRODUCTION

With growing recognition that the quality of surgical care varies widely, good measures of performance are in high demand. Patients and their families need accurate information to help them choose the safest hospitals for surgery.[1] Employers and payers need reliable measures for their value-based purchasing programs.[2] Motivated in part by these external pressures, clinical leaders need better measures to guide their quality improvement efforts.[3]

Despite a broadening array of measures, there remains considerable uncertainty about which measures are most useful.[4,5] Current measures are remarkably heterogeneous, encompassing different elements of healthcare structure, process, and outcomes. With the proliferation of value-based purchasing which requires a global assessment of quality that has significant implications on reimbursement, growing attention has been placed on evaluating the performance measures themselves.[6] Although each of these measurement approaches has strengths, each is also associated with conceptual, methodologic, and/or practical problems (**Table 15.1**).

This chapter provides an overview of existing quality indicators followed by a review of the main strengths and limitations of each type of measure: structure, process, outcomes. For common limitations, the chapter outlines established statistical techniques now applied routinely in measuring surgical quality. The chapter then closes with how these measurement tools are moving from evaluating surgeons and hospitals toward the performance of across an entire healthcare system.

OVERVIEW OF CURRENT MEASURES

An ever-broadening array of performance measures has been developed for assessing surgical quality. Over the past few years, the National Quality Forum (NQF) has emerged as the leading organization endorsing quality measures. While the NQF is the central organization for evaluating candidate measures, many other organizations continue to create their own quality indicators. For example, the Centers for Medicare & Medicaid Services (CMS) Surgical Care Improvement Program (SCIP), which includes process measures related to prevention of surgical site infections, postoperative cardiac events, venous thromboembolism, and respiratory complications, are routinely collected and publicly reported on the Hospital Compare website for most U.S. hospitals. The Agency for Healthcare Research and Quality (AHRQ) has focused on quality measures that can be used with administrative data. For example, the AHRQ maintains and distributes state and national administrative data as part of their Healthcare Cost and Utilization Project (HCUP).

Table 15.1 Examples, Strengths, and Limitations of Different Approaches to Measuring Surgical Performance

	Examples	Strengths	Limitations
Structure	Hospital or surgeon volume Surgeon specialty training	Inexpensive and readily available Strong relationship to important outcomes	Not actionable for quality improvement Not good at discriminating individual provider performance
Process	Appropriate selection, timing, and duration of antibiotic prophylaxis Use of internal mammary artery for coronary artery bypass grafting	Actionable as targets for improvement Everybody can achieve 100% compliance	Most known processes relate to secondary outcomes High-leverage processes are unknown for most procedures
Outcome	Risk-adjusted mortality Risk-adjusted morbidity	Seen as the bottom line of patient care Buy-in from providers	Sample sizes too small at individual hospitals

Most recently, U.S. News and World Report announced that it will explore the new measures—structure, process, and outcomes—that apply not to just to surgeons or hospitals, but instead entire healthcare systems.[7] We will discuss possible candidates for system levels measures later in this chapter.

TRADITIONAL QUALITY MEASURES

1 Quality measures fall into three categories: structure, process, and outcomes.

Structure

Healthcare structure refers to fixed attributes of the system in which patients receive care. Many structural measures describe hospital-level attributes, such as the resources or staff coordination and organization (e.g., nurse-to-patient ratios, hospital teaching status). Other structural measures reflect attributes of individual physicians (e.g., subspecialty board certification, procedure volume).

Strengths

Structural measures of quality have several attractive features. First, they are strongly related to patient outcomes. For example, with esophagectomy and pancreatic resection, operative mortality rates at high-volume hospitals are often 10% lower, in absolute terms, than low-volume centers.[8,9] In some instances, structural measures such as procedure volume are more predictive of subsequent hospital performance than any known processes of care or even direct mortality measures.

Perhaps the most important advantage of structural variables is the ease with which they can be assessed. Many can be determined using readily available sources, such as administrative billing data. Although some structural measures require surveying hospitals or providers, such data are much less expensive to collect than measures requiring detailed patient-level information.

Limitations

Perhaps the greatest limitation of structural measures is that they are not readily actionable. For example, a small hospital cannot readily make itself a high-volume center. Thus, while selected structural measures may be useful for selective referral initiatives, they have limited value for quality improvement purposes. Structural measures are also limited in their ability to

discriminate the performance of individual providers. For example, in aggregate, high-volume hospitals have much lower mortality rates than lower-volume centers for pancreatic resection.[8,9] However, some individual high-volume hospitals may have high mortality rates, and some low-volume hospitals may have low mortality rates.[10] Although the true performance of individual hospitals is difficult to confirm empirically (for sample size reasons), this lack of discrimination is one reason structural measures are often viewed as "unfair" by many providers.

Process of Care

Process of care measures are the clinical details of care provided to patients. Although they historically have applied mostly to medical care, their popularity in surgery is growing rapidly. Perhaps the best example of the trend toward using process measures is the CMS's SCIP. As previously mentioned, this quality measurement initiative focuses exclusively on processes related to prevention of surgical site infections, postoperative cardiac events, venous thromboembolism, and respiratory complications.

Strengths

Since processes of care reflect the care actually delivered by physicians, they have face validity and enjoy greater buy-in from providers. They are also directly actionable and provide good substrate for quality improvement activities. Although risk adjustment may be important for outcomes, it is not required for many process measures. For example, the appropriate prophylaxis against postoperative venous thromboembolism is a widely used process measure. Since virtually all patients undergoing open abdominal surgery should be offered some form of prophylaxis, there is little need to collect detailed clinical data for risk adjustment.

Limitations

The biggest limitation of process measures is the lack of correlation between processes of care and important outcomes.[4] There is a growing body of empirical data showing very little correlation between processes of care and important outcomes.[11–13] Most data come from literature on medical

diagnoses, such as acute myocardial infarction. For example, The Joint Commission and CMS process measures for acute myocardial infarction explained only 6% of the observed variation in risk-adjusted mortality for acute myocardial infarction.[12]

Emerging evidence demonstrates a similar relationship for surgical process measures, especially for SCIP measures, with no measurable relationship between these widely collected process measures and important outcomes.[13]

There are several reasons why existing process measures explain very little of the variation in important surgical outcomes. First, most process measures currently used in surgery relate to secondary outcomes. While none would dismiss the value of prophylactic antibiotics in reducing risks of superficial wound infection, this process is not related to the most important adverse events of major surgery, including death.

Second, process measures in surgery often relate to complications that are very rare. For example, there is consensus that venous thromboembolism prophylaxis is necessary and important. The SCIP measures, endorsed by the NQF, include the use of appropriate venous thrombosis prophylaxis. However, pulmonary embolism is very uncommon, and improving adherence to these processes will, therefore, not avert many deaths. Until we understand which processes of care account for those adverse events leading to death and severe disability, process measures will have limited usefulness in surgical quality measurement.[4,11–14]

Outcomes

Outcome measures reflect the end result of care, from a clinical perspective or as judged by the patient. Although mortality is by far the most commonly used measure in surgery, other outcomes that could be used as quality indicators include complications, hospital readmission, and a variety of patient-centered measures of quality of life or satisfaction. For example, a recent evaluation of Medicare revealed a significant drop in hospital readmissions among surgical patients after payment incentives were announced. While some readmissions after surgery may in fact be good and represent high-quality care, the significant drop suggested there were also avoidable readmissions that were prevented.[15]

Strengths

There are at least two key advantages of outcome measures. First, outcome measures have obvious face validity, and thus are likely to get the greatest "buy-in" from hospitals and surgeons. Surgeon enthusiasm for adopting objective measurement of quality and joining quality collaboratives centered on outcomes clearly underline this point. Second, the act of simply measuring outcomes may lead to better performance—the so-called Hawthorne effect. For example, surgical morbidity and mortality rates in VA hospitals have fallen dramatically since implementation of systematic measurement two decades ago.[16] No doubt many surgical leaders at individual hospitals made specific organizational or process improvements after they began receiving feedback on their hospitals' performance. However, it is very unlikely that even a full inventory of these specific changes would explain such broad-based and substantial improvements in morbidity and mortality rates.

Limitations

Hospital- or surgeon-specific outcome measures are severely constrained by small sample sizes. For the large majority of surgical procedures, very few hospitals (or surgeons) have sufficient adverse events (numerators) and cases (denominators) for meaningful, procedure-specific measures of morbidity or mortality. For example, data from the Nationwide Inpatient Sample to study seven procedures for which mortality rates have been advocated as quality indicators by the AHRQ.[17] For six of the seven procedures, a very small proportion of U.S. hospitals had adequate caseloads to rule out a mortality rate twice the national average (**Fig. 15.1**). Although identifying poor-quality outliers is an important function of outcome measurement, focusing on this goal alone significantly underestimates problems with small sample sizes. Discriminating among individual hospitals with intermediate levels of performance is even more difficult.

Another significant limitation of outcome assessment is the expense of data collection. Reporting outcomes requires the costly collection of detailed clinical data for risk adjustment. For example, it costs over $100,000 annually for a private sector hospital to participate in the ACS-NSQIP. Because of the expense of data collection, the ACS-NSQIP currently collects data on only a sample of patients undergoing surgery at each hospital.

Although this sampling strategy decreases the cost of data collection, it exacerbates the problem of small sample size with individual procedures.

CHOOSING THE RIGHT MEASURE

2 No quality measure is perfect. Clinical leaders, patient advocates, payers, and policy makers will have to make decisions about when imperfect measures are good enough to act upon. A measure should be implemented only with the expectation that acting on it will result in net improvement in health quality. Thus, the direct benefits of implementing a particular measure cannot be outweighed by the indirect harms. Unfortunately, these benefits and harms are often difficult to measure and heavily influenced by the specific context and who—patients, payers, or providers—is doing the accounting. For this reason, there is no simple answer for where to "set the bar."

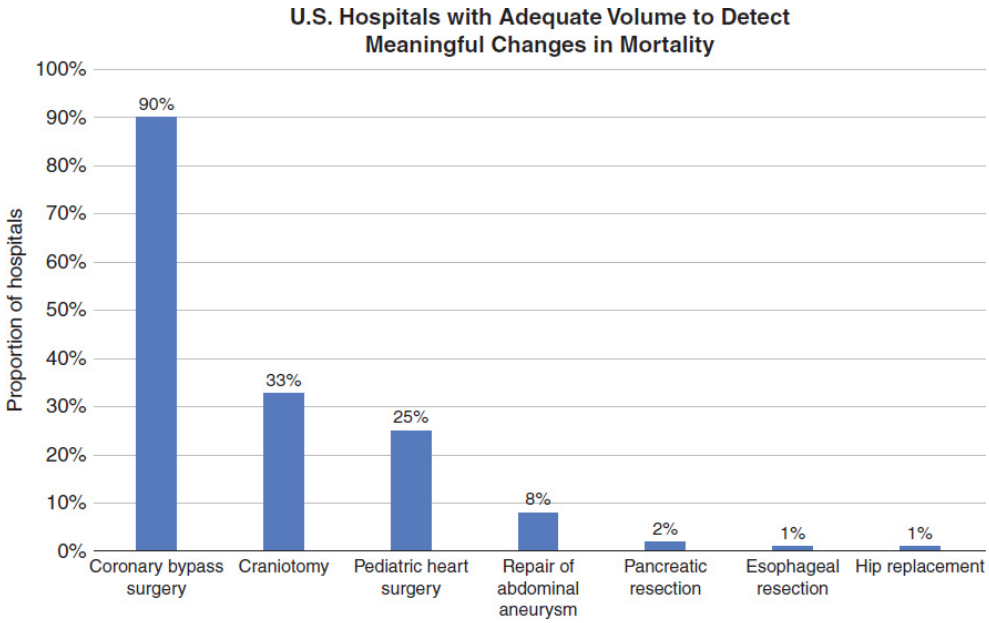

Figure 15.1 Big problems with small samples: the proportion of hospitals in the United States with sufficient caseloads (sample size) to reliably use mortality rates to measure quality.

3 It is important to ensure a good match between the performance measure and the primary goal of measurement. The right measure depends on whether the underlying goal is (a) quality improvement—raising the performance of all providers or (b) selective referral—directing patients to

higher-quality hospitals and/or providers. Although many pay-for-performance initiatives have both goals, one often predominates. For example, the ultimate objective of the CMS's pay-for-performance initiative with prophylactic antibiotics is improving quality at all hospitals (quality improvement). Conversely, the Leapfrog Group's efforts in surgery are primarily aimed at getting patients to hospitals likely to have the best outcomes (selective referral).

4 For quality improvement purposes, a good performance measure must be actionable. Measurable improvements in the given process should translate to clinically meaningful improvements in patient outcomes. Although quality improvement activities are rarely "harmful," their major downsides relate to their opportunity cost. Initiatives hinged on bad measures divert resources (e.g., time and focus of physicians and other staff) away from more productive activities.

5 With selective referral, a good measure will steer patients to better hospitals or physicians. As a basic litmus test, a measure based on prior performance should reliably identify providers likely to have superior performance now and in the future. At the same time, an ideal measure would not incentivize perverse behaviors (e.g., surgeons doing unnecessary procedures to meet a specific volume standard) or negatively affect other domains of quality (e.g., patient autonomy, access, and satisfaction).

Many believe that a good performance measure must discriminate performance at the individual level. From the provider perspective in particular, a "fair" measure must reliably reflect the performance of individual hospitals or physicians. Unfortunately, as described earlier, small caseloads (and sometimes case mix variation) conspire against this objective for most procedures. Patients, however, should value information that improves their odds of good outcomes on average. Many measures meet this latter interest while failing on the former (e.g., hospital volume standards). There may be no simple solution to resolving the basic tension implied by performance measures that are unfair to providers yet informative for patients. However, it underscores the importance of being clear about both the primary purpose (quality improvement or selective referral) and whose interests are receiving top priority (provider or patient).

IMPROVING OUR ABILITY TO MEASURE

Over the last two decades significant progress has been made in the science of quality measurement for surgical outcomes. One 6 of the biggest limitations of surgical quality measurement is the statistical "noise" from the small sample sizes at most hospitals. This problem makes it difficult to isolate the quality signal from the background statistical noise. In other words, it is often hard to know whether hospitals or surgeons have poor performance because they provide low-quality care or because they were unlucky. For obvious reasons, labeling surgeons and hospitals correctly is extremely important.

An emerging technique, reliability adjustment, directly addresses the problem of statistical noise.[18,19] This technique, based on hierarchical modeling, quantifies and subtracts statistical noise from the measurement process. Essentially, it "shrinks" providers' performance back toward average unless they deviate to such an extreme that it is safe to assume they are truly different. In this way, it gives providers the benefit of doubt. **Figure 15.2** shows the risk-adjusted mortality rates for pancreatic resection in Medicare patients before and after reliability adjustment. Prior to reliability adjustment, the mortality rates varied from 0% to 100%. After reliability adjustment, the mortality rates only vary from 2% to 22%, yielding a range of performance that is clinically more realistic. Reliability adjustment is gaining popularity outside surgery (e.g., ambulatory care) and is becoming widely recognized as a valid tool for improving the accuracy of quality measurement.[18–20]

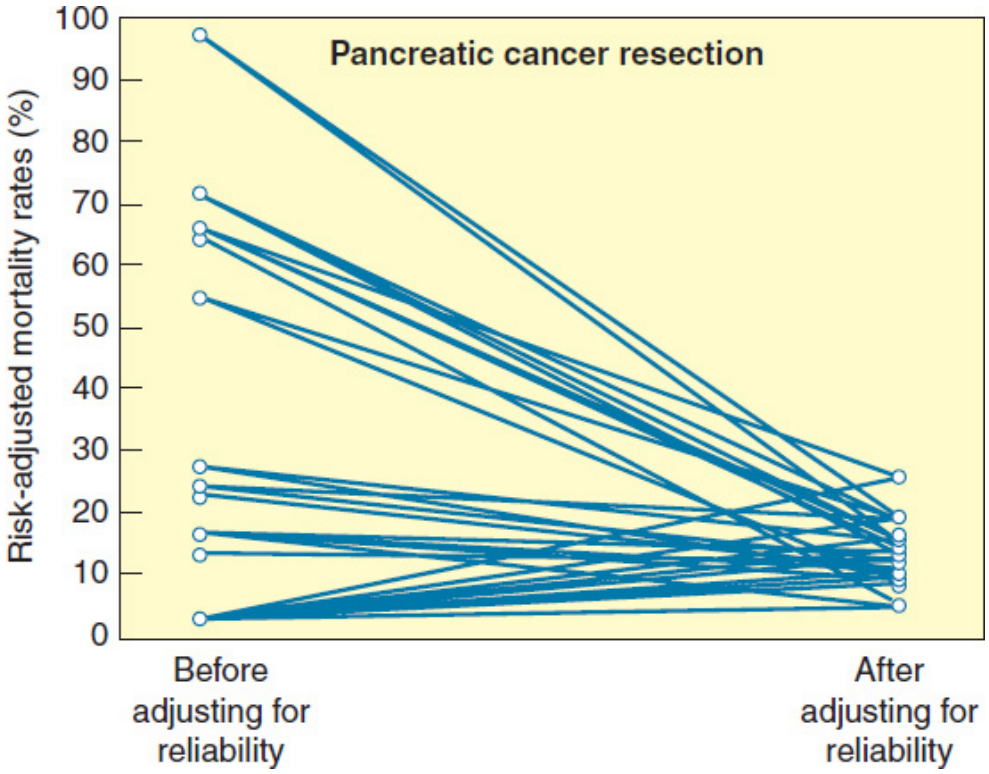

Figure 15.2 Variation in hospital mortality rates before and after adjusting for reliability. Twenty randomly sampled hospitals are shown. (Sourced from National Medicare Claims Data.)

EMERGING NEED TO MEASURE AND IMPROVE SURGICAL CARE ACROSS HEALTHCARE SYSTEMS

7 While previous measures of surgical quality have focused on individual surgeons and hospitals (as discussed above), increasing attention is now being focused on healthcare systems. Since passage of the Affordable Care Act in 2010, the rate of hospital mergers as doubled.[21] As a result, the majority of hospitals now belong to a larger system. The interest in measuring quality of surgical care at the systems level can be understood through a recent study of 16 healthcare systems. Together, these 16 systems comprise 87 hospitals. When measuring key quality measures after surgery at the hospital level (e.g., failure to reassure, complications), there is just as much variation within healthcare systems as there is across them.[22] In other

words, hospitals now belonging to the same system vary widely in their outcomes.

There are multiple reasons why measuring quality at the healthcare system level has appeal. First, doing so reflects the day-to-day reality of healthcare leadership who now assume responsibility for care delivery across multiple sites. Second, payers and policy makers have increasingly explored and adopted systems level metrics as a novel way to incentivize quality. Third, patients now increasingly recognize the trusted brand of a healthcare system and assume uniform quality across multiple sites of care. Taken together, systems level metrics reflect an optimism that the parts together can function at a higher quality than when they were alone by taking advantage of shared resources and expertise.

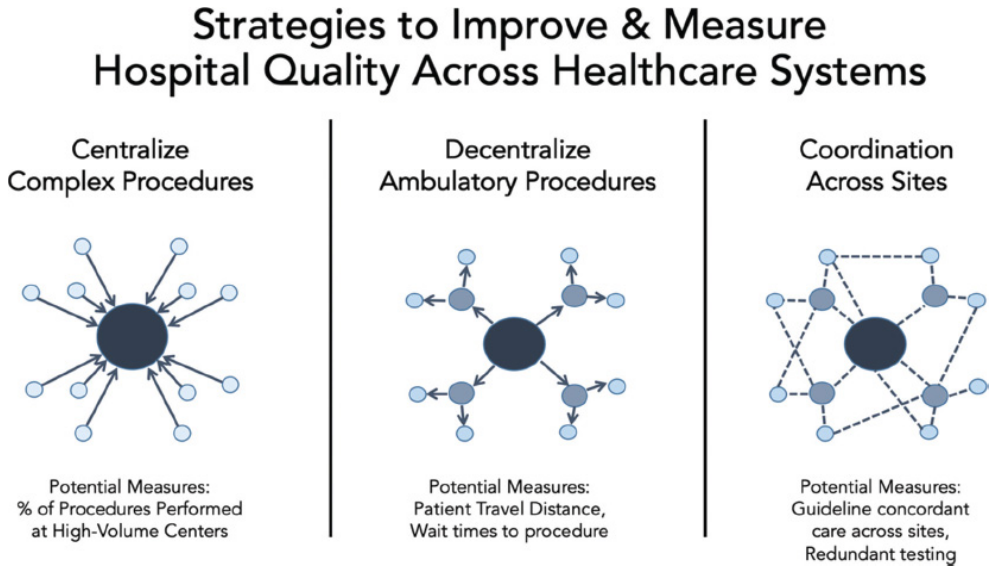

Figure 15.3 Measuring and improving systems delivery of surgical care.

At present, there are no widely agreed upon measures to evaluate surgical quality across healthcare systems. We propose three possible domains that build on previous quality measures and apply them toward measuring healthcare system (**Fig. 15.3**).

Centralize Complex Procedures. Multiple surgical procedures, particularly those are high risk, have known volume-outcome relationships. With the creation of new hospital networks, it has become fertile ground for in-network regionalization.[23] The percent of patients undergoing high-risk procedures at a high-volume center could be an important systems metric.

More importantly, the clinical outcomes (e.g., mortality) should also be measured.

Decentralize Ambulatory Procedures. With accumulated assets of a newly formed networks, hospital systems can be provided at multiple sites. For common procedures that are low risk, these can be performed at multiple sites that have lower overhead and are located closer to patients. In doing so, healthcare systems can improve access for patients and also decrease the cost of the procedure. Measures to assess this level of systems delivery could include patient travel time and procedure expenses.

Delivery Coordination. As patients will likely move across multiple sites within a healthcare system, there will need to be ways to measure how well their care is coordinated. Possible measures may include patient wait times or redundant tests and imaging.

When measuring quality, it is important to keep in mind the ultimate goal: improving the quality and efficiency of surgical care. Quality measures are only useful if they inform improvement efforts. Future refinements in measurement should therefore aim to meet the diverse needs of the improvement efforts of patients, payers, and providers. In this chapter, the three dominant approaches for improving surgical quality were discussed: selective referral, process compliance, and outcome measurement. These three policy approaches roughly mirror the three types of quality measures (structure, process, and outcomes), providing real-world examples of how various stakeholders weigh the pros and cons of quality indicators, and ultimately choose an assessment approach by matching the measure to the purpose.

Improving Surgical Quality

Kristan L. Staudenmayer

Key Points

1. The foundation for quality metrics in healthcare was established by Donabedian in 1966 when he proposed using the framework of structure, process, and outcome to evaluate quality.
2. There are strengths and limitations to all structure, process, and outcome metrics.
3. Balancing measures are important to ensure possible unintended consequences from quality improvement efforts are identified and addressed.
4. Current quality improvement efforts focus on peer review and and a focus on culture.
5. Payers and regulators are attempting to improve quality by shifting payment incentives from fee-for-service to value-based models.

INTRODUCTION

Efforts to improve quality have been increasing ever since the landmark publication by the Institute of Medicine in 2000, “To Err is Human,” raised

the alarm bells on the state of quality in healthcare in the United States.[1] The report estimated that 44,000 to 98,000 lives were lost in hospitals every year as a result of medical errors, and that costs from medical errors were estimated to be as high as $29 billion. Despite efforts to improve quality, issues remain and new dimensions to these issues have been identified. For example, it is well recognized that the burden of poor quality is not spread evenly across the United States, and disparities based on factors such as race and socioeconomic status exist. It is clear that quality needs to remain a priority focus for the U.S. healthcare system.

Ensuring the delivery of quality healthcare involves obtaining a good medical education, practicing evidence-based medicine, and having a strong grounding in biomedical ethics. Within surgery, quality improvement takes on additional dimensions. Surgery is, by its nature, invasive and involves technical components. Every point in the surgical planning and delivery process can impact the quality of care a patient receives. These characteristics have historically made surgeons highly attuned to the importance of and need for quality measurement and improvement. As a result, surgeons have often been in the lead with regard to quality improvement. For example, registry-based quality improvement programs hosted by surgical organizations such as the Society for Thoracic Surgeons and the American College of Surgeons are well-established efforts that have been shown to improve quality on a national scale.

Going forward, surgeons need to continue to lead quality improvement. To do so requires a solid understanding of necessary quality improvement components, which will be discussed in this chapter. The first concept addresses quality metrics. W. Edwards Deming, a leader in quality improvement, had said “if you can’t measure it, you can’t manage it.” It is easy to conceptualize how this could apply in other industries, such as automobile manufacturing. In medicine, it is more challenging but just as important. The second is an overview of strategies that are currently being used by providers to improve surgical quality. The third includes a summarization of current regulations and incentives by payers that are aimed at quality improvement.

QUALITY METRICS

1 The foundation for quality metrics in healthcare was established by Donabedian in 1966 when he proposed using the framework of structure, process, and outcome to evaluate quality.[2] There have been modifications to this framework since, but this construct continues to guide quality efforts today. For example, process metrics are endorsed by the National Quality Forum, structural metrics are used in surgical quality programs to verify and accredit centers of excellence, and outcome metrics are promoted by various organizations such as Medicare (**Table 16.1**).

The first category of metrics, structural metrics, consist of characteristics possessed by a hospital or a provider that are associated with desired outcomes. These metrics area attractive for quality improvement as they are relatively easy to measure. One of the most commonly recognized structural metrics is surgical volume. The volume–outcome relationship was recognized as early as 1979.[3] In 2002, Birkmeyer et al. confirmed the existence of a volume–outcome relationship for selected surgical procedures,[4] and others have validated these findings. The reasons for this relationship have been found to be wide ranging, including such factors as institutional experience with diseases and others such as technical skills. Other structural measures include closed intensive care units, nurse–patient ratios, Level 1 trauma center designation to name a few.

While structural metrics are conceptually appealing and relatively easy to measure, their usefulness in improving quality is less clear. For example, with regard to surgical volume, the relationship between volume and outcomes appears to be sensitive to many factors. For example, the relationship between volume and outcomes is not always linear and varies for different procedures. For abdominal aneurysm repair, there are diminishing returns in outcomes as the number of surgeries increases, whereas for cardiac valve replacement, there is a reliable linear association between volume and outcomes maintained across the range of volume.[5] There are also other factors that can modify the relationship between volumes and outcome, such as the surgeon's specialization.[5,6] In addition to the complex relationships between structural metrics and outcomes is the fact that structural metrics might have limited pragmatic usefulness. In the case of surgical volume, surgeons and hospitals do not necessarily have the ability to

change volume to the scale required to achieve quality for a selected procedure. In summary, while structural metrics such as volume–outcome metrics are attractive for their simplicity, using them is complicated by the fact that important quality-driving factors are overlooked and implementation of policy to change these factors can have negative unintended consequences.

Table 16.1 Process Metrics

	Process	Structure	Outcomes
Example	Checklists	Surgical Volume	30-Day Mortality
Pros	Easy to measure Based on known process–outcome relationships	Easy to measure Based on known structure–outcome relationships	Directly measures outcomes that are desired
Cons	Policies that employ these metrics not universally successful	Policies that employ these metrics not universally successful Might not reflect factors amenable to change	Hard to measure and analyze No single measures for all patients, conditions, or procedures

Another category of quality metrics consists of process measures. Process measures are similarly easy to measure but have the added benefit of helping to identify possible quality improvement solutions. One example of a process measure is the now-retired Surgical Care Improvement Project (SCIP), a collaborative between the Centers for Disease Control (CDC) and the Centers for Medicare and Medicaid Services (CMS) initiated in 2005. The purpose was to improve surgical quality by reducing surgical site infections. SCIP process measures included the timely delivery of appropriate

antibiotics and other factors known to be associated with infection (e.g., hyperglycemia, hypothermia). Encouraging compliance with these process metrics was attractive on many fronts. The recommendations had biologic plausibility, were evidence based, and compliance could be easily measured. However, process measures such as SCIP also have limitations. For example, compliance with the SCIP guidelines was found to not result in improved outcomes and the program was retired in 2015.[7] While multiple reasons for SCIP's failure have been cited, chief among them is that the development of wound infections is complex. This complexity could not be easily translated into what were overly simplistic process measures.

The third type of quality improvement metrics consists of outcome metrics. In contrast to structural and process metrics, outcome metrics are the most proximate measure to what matters to patients. Another benefit to outcome metrics that make them attractive for quality improvement is that they are simple to understand (e.g., mortality, length of stay, infection). In contrast to structural and process metrics, however, outcome metrics present other pragmatic challenges. Most importantly, outcome metrics can be difficult to analyze. Risk adjustment is critically important and successful risk adjustment can be limited by the availability of variables that affect that outcome, such as social determinants of health. Results are also sensitive to adequate statistical techniques. For example, outcomes must be reliability adjusted to account for inaccurate assumptions that might result from differences in sample size.

Despite these limitations, outcome metrics have remained attractive and new classes of outcome metrics are being explored. Patient Reported Outcome Measures (PROMs) and patient experience metrics (e.g., the Hospital Consumer Assessment of Healthcare Providers and Systems, or HCAHPSs) are increasingly used for quality reporting. Another newer outcome metrics that is unique to surgery is "failure to rescue" (FTR). FTR is defined as the number of patients who die after developing a surgical complication. Outcome metrics continue to evolve with the hope that improved data capture and statistical technique will ensure higher-quality metrics.

2 Structure, process, and outcome metrics all have their strengths and limitations. As a result, it is important to include on the list a fourth category of quality improvement metrics—balancing measures. Balancing measures

are not quality mea 3 sures per se, but instead are measures of unintended consequences that might result as a consequence of a quality improvement effort. For example, if there is a desire to decrease the use of an expensive medication that has bioequivalency to a generic, it should not drive the use of another expensive medication.

QUALITY IMPROVEMENT PROCESSES

Outcome Based

The field of quality improvement in healthcare continues to grow. Surgeons have historically led and innovated in this space, 4 particularly for those that have used outcome metrics. Peer review has served as the cornerstone of these quality efforts. While peer review has always been a part of surgical culture, surgeons continue to improve on the process. More recently, this has involved formalizing peer review within surgical departments to ensure fair and transparent processes. These efforts are often coupled with other activities, such as the establishment of a Surgical Quality Council within a surgical department. The American College of Surgeons has recently published a guide that describes the role of such a council, as well as how such a structure fits into the broad array of surgical quality.[8]

An extension of the historic peer review process is a locoregional collaborative where surgeons compare outcomes and best practices in a geographic region. The leading example for this is the Michigan Surgical Quality Collaborative (MSQC). The MSQC is a collaborative of over 2,000 surgeons and 70 Michigan hospitals that share data and best practice. This collaborative has been shown to both reduce complications and save substantial costs.[9]

Surgical quality improvement efforts have also extended the peer review concept to a national level by engagement in collaborative peer networks. Collaborative networks allow for an organization to benchmark its outcomes against those of peer institutions. Examples of these networks include the American College of Surgeons National Surgical Quality Improvement Program (ACS NSQIP). Such programs allow participants to track their

progress through the regular issuance of reports, and to identify best practice by learning from others in the network.

Culture and Quality

More recently has been the recognition that organizational culture can have a strong influence on quality. This has been described as a "culture of safety." The concept did not originate within healthcare, but in other industries where it was recognized that there were organizations that consistently minimized adverse events. These companies were deemed to be "high-reliability" organizations. High-reliability companies achieved success through commitment at every level toward promoting a culture of safety. Components of such a culture involves ones where communication founded on mutual trust, where the importance of safety is recognized at all levels of the organization, and where there is confidence that measures undertaken to improve outcomes will be successful. This is in contrast to a culture that seeks to place blame on individuals and/or groups for bad outcomes. These concepts are now being applied to the challenges with improving quality in healthcare. Healthcare organizations have made resources available for those interested in improving the culture of safety including the Agency for Healthcare Research and Quality (AHRQ),[10] the Institute for Healthcare Improvement,[11] and The Joint Commission.[12]

QUALITY IMPROVEMENT POLICY AND REGULATION—THE MOVE TOWARD VALUE

Healthcare is one of the most heavily regulated industries with multiple layers of quality-ensuring policies and regulations. 5 These range from individual physician board certification and licensing, to hospital accreditation by The Joint Commission, and quality-based reimbursement models. Many of these mechanisms are under continuous evolution and exist in various stages of maturity. Of these, the most notable in recent history has been the shift from fee-for-service (FFS) toward value-based reimbursement. Collectively these are called value-based purchasing (VBP) models. The

notion behind VBP is that incentives in a pure fee-for-service payment structure encourage poor quality—incursion of a complication will result in more payments to a provider rather than less. Shifting the burden of risk onto the provider financially aligns the interests of payers and providers. These reimbursement strategies are being employed by both private and public payers, and the CMS plan to transition completely from FFS to VBP models.

An example of a VBP program is the CMS Hospital-Acquired Condition (HAC) Reduction Program. The program began to reduce payments to hospitals for a list of conditions that were deemed preventable in 2008. The success of the program is still largely argued. The reason for this is due to challenges inherent to the use of outcome metrics—appropriate risk adjustment and avoidance of bias. There is no universal agreement that the HAC methodology is sufficient to produce fair results and therefore that it is able to accomplish its intended goals.

Another VBP model is the concept of an Accountable Care Organization (ACO). The ACO is a provider or a collaborative of providers who work together to ensure that the patients cared for by the entity remain healthy. This is achieved through aligning incentives via capitated payments for each covered life. If an ACO can keep patients out of the hospital or from receiving costly care, they receive a greater margin. While the alignment of incentives is an attractive mechanism to ensure high-performing providers are rewarded for delivering quality care, it is not clear that these arrangements work. Initial results from the 2014 CMS ACO implementation did not show financial savings. Furthermore, with regard to surgery and ACOs, surgery has not been prioritized as a target area for improvement. Surgical-specific VBP have largely been focused on specific procedures such as hip replacement surgery or coronary artery bypass surgery.

New VBP-based programs continue to be developed and existing programs evolve. No dominant model has yet been determined. That said, it is reasonable to expect that the concept of reimbursement based on value rather than services rendered is one that will continue to drive quality improvement efforts from payers in the foreseeable future.

SUMMARY

There are opportunities to improve the quality of surgical care at every level from the individual provider to policymakers. Surgeons have led in the quality improvement space and there is a need for them to continue to do so. Peer review processes and benchmarking remain a cornerstone of these efforts. It is important that surgeons continue to strive to make these even more effective tools than they are today. Furthermore, policymakers and payers require guidance by those with experience caring for surgical patients and improving quality at home as they make the change to value-based strategies. The need for continued surgical quality leadership is clear.

Global Surgery

Tiffany E. Chao, Jahnavi K. Srinivasan, and Sherry M. Wren

GLOBAL SURGERY DEFINED

The provision of comprehensive perioperative care in a resource-lacking environment, typically a low-income country, is often termed "global surgery." The working definition for global surgery is rooted in the Koplan et al.[1] broader characterization of global health as "an area of study, research, practice, and advocacy that seeks to improve health outcomes and achieve health equity for all people who require surgical care, with a special emphasis on underserved populations and populations in crisis."[2] Critical to this definition is an emphasis on systemic problems that contribute to overall poorer determinants of societal health. Thus, care is not necessarily centered only in low- and middle-income countries (LMICs) but rather where there is the greatest inequity. Although surgery has long been minimized in the greater global health discourse, the rising burden of noncommunicable diseases (NCDs) has led to the increasing recognition of the important role of surgery in global health.[3]

HISTORY

Before 1990, "global public health" and "tropical medicine" focused mostly on communicable diseases, namely, malaria, tuberculosis, and HIV. These diseases were highlighted mainly due to their prevalence and

transmissibility, the cost-effectiveness of their treatments, and strong advocacy by public health efforts. Surgical pathologies were not traditionally included in "global health" for a number of reasons, including their noncommunicability, underestimations of the surgical disease burden, beliefs that surgery was not a cost-effective intervention, and a high level of investments required to develop infrastructure and human resources. Because of this, public support and political will to address these issues were limited.

A diverse group of conditions comprise surgical burden of disease, including, but not limited to, obstetric care, trauma/injury, intra-abdominal emergencies, cancer care, correctable congenital anomalies, hernias, cardiovascular disease, and head and neck pathology such as dentistry, cleft palate, and cataracts.[4] Over the past three decades, the prevalence of NCDs has increased around the world, now outpacing communicable diseases and accounting for 70% of the estimated annual deaths worldwide[5] (**Fig. 17.1**).

Global health researchers identified this shift, and a number of notable publications began to highlight the role surgery can play in global health. It was once estimated that 11% of the global burden of disease is surgical disease, although better recent estimates are closer to 29% to 32%.[6,7] Reports on the total volume of global surgery performed in 2008 highlighted the role surgery could play in global health.[8] Safety initiatives such as the World Health Organization's (WHO) Surgical Safety Checklist or efforts to increase pulse oximetry in operating rooms identified areas in which quality could be improved.[9,10] Surgical capacity in various resource-limited settings was evaluated using a variety of tools, including the WHO Situational Analysis Tool, the Harvard Humanitarian Initiative's surgical capacity assessment tool, and the Surgeons OverSeas' (SOS) Personnel, Infrastructure, Procedures, Equipment and Supplies (PIPES) survey. Data about cost-effectiveness underscored an economic argument for providing surgical care.[11]

In 2013, the Lancet Commission on Global Surgery was formed to discuss the role of surgery as a fundamental component of public health. During the opening meeting of the Commission, President of the World Bank, Jim Kim, declared that "surgery is an indivisible, indispensable part of health care and of progress towards universal health coverage."[12] 2015 was a "banner year" in global surgery, with the publications of the Commission's findings,

Disease Control Priorities Third Edition (DCP3) Volume 1 *Essential Surgery*, and the adoption of World Health Assembly (WHA) resolution 68.15—"Strengthening emergency and essential surgical care and anesthesia as a component of universal health coverage."[13] This progress reflects the work done by professional societies, nongovernmental health organizations, government agencies, and academic institutions to study the scope of the problem and subsequently garner economic support and implement initiatives to improve the delivery of surgical care worldwide.

CHALLENGES OF PROVIDING SURGICAL CARE

Many barriers have been identified that pose difficulties in providing safe and well-distributed surgical care globally. One issue is the degree of government investment in health infrastructure. Many hospitals and health facilities in LMICs lack basic equipment needed to provide surgical care, or if the equipment exists, they do not have the proper maintenance capability. In particular, operating rooms, equipment, and consumables need to be available, as well as sterility of the materials and an adequate supply chain for maintenance of this infrastructure. Laboratory and pathology testing and radiologic investigations are also important to determine the need for surgical intervention.

From a human resources standpoint, a competent surgical and anesthesia provider must be present, as well as a trained perioperative team that includes intraoperative and perioperative care managers. The surgical care capacity in LMICs is highly correlated with the availability of surgeons and a perioperative workforce, and the issues with development, recruitment, training, and retention are major hindrances to having an adequate workforce. It is often the case that providers may complete training in their residential area and elect to immigrate to a different region of their country or another country altogether due to a combination of higher salaries, more resources, and other benefits. These workforce issues are particularly dramatic in surgery, due to the lengthy and intensive training required to become a surgical provider, typically at least 4 years of postgraduate training,

compared to general practitioners who may require just 1 year of training. Surgically trained providers are therefore both highly desirable and difficult to replace. Task shifting of surgical care to medical officers or nonphysician clinicians has been a common strategy in many nations to address the lack of sufficient surgeons. Depending on the country, as many as 90% of obstetric surgeries, 38.5% of general surgery procedures, and 43% of nonobstetric laparotomies are performed by both nonsurgeons and nonphysicians.[14]

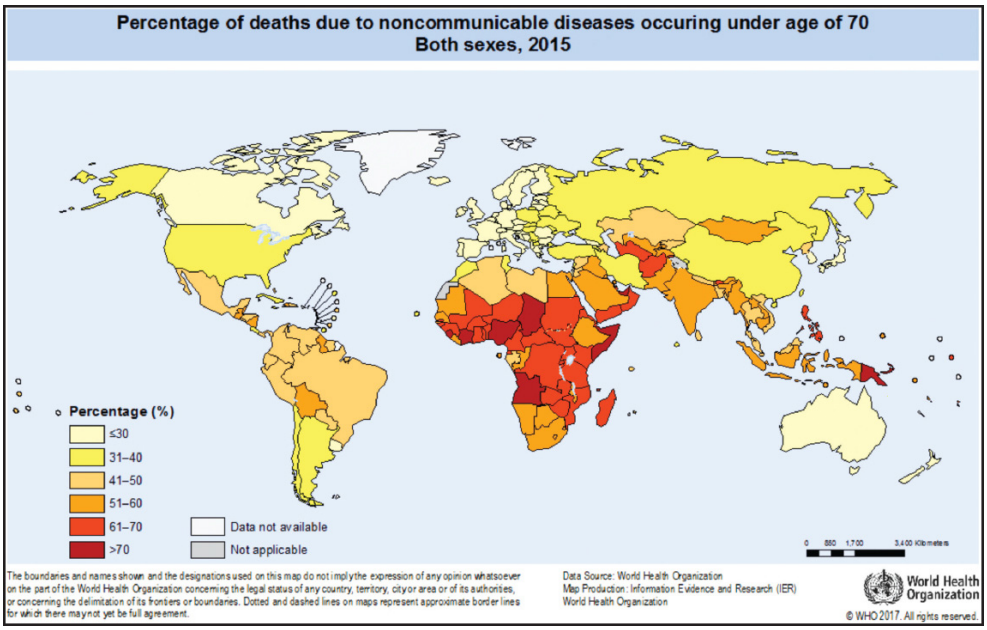

Figure 17.1 Percentage of deaths due to noncommunicable diseases occuring under age of 70. (Reprinted with permission from the World Health Organization.)

From a systems perspective, another limitation in surgical care is the lack of prehospital and emergency services systems coordination, which often creates delays in transportation, hindering appropriate and timely care delivery. In-hospital system limitations pose challenges in patient safety monitoring and quality care improvement. Some political and environmental barriers also exist, such as corruption and mismanagement of health care funds, lack of policies and advocacy, and inaccessibility of referral facilities.

EPIDEMIOLOGY

The WHO Initiative for Emergency and Essential Surgical Care defines necessary surgical care as "interventions that are critical for specific conditions in preventing premature death and disability."[15] These essential services are widely acknowledged to encompass surgical, obstetric, and anesthetic provision. There have been a number of methods used to estimate the prevalence of surgically treatable conditions. Population cluster-based surveys with and without physical examinations have demonstrated a prevalence of 11% of surgically treated conditions and that 25% of deaths are potentially avoidable if care could be accessed.[16,17] The Lancet Commission on Global Surgery reports in 2015 have become the most common cited definitions and statistics for the field. Their model created a framework using variables such as the proportion of serious injuries transported by ambulance, use of pulse oximetry, and the amount of out-of-pocket costs.[18] This framework emphasizes that various barriers to surgical care exist: Can the patient get to a hospital in a timely fashion? Once there, is surgical provision available? If yes, is the surgical provision safe? Once performed, will the patient be free of catastrophic health expenditures? It is estimated that currently 5 billion people worldwide lack full access using this definition[19] (**Table 17.1**).

Striking disparities in surgical access exist between high- and low-resource countries. Over a third of the world's population lives in LMICs, but their populace only receives 3% to 6% of the estimated 234 to 313 million procedures performed annually worldwide.[19,20] It should also be noted that surgical provision does not only refer to operations; there are many disease states, such as management of nonoperative head trauma or wound care, that require surgical expertise but never result in operative intervention.[21] A 2015 survey of global health providers throughout North America, sub-Saharan Africa, and Southeast Asia estimated that 32.9% of worldwide deaths were attributable to surgical pathology.[7] In 2011, WHO global health estimates more specifically calculated that annually about 270,000 women died of pregnancy-related complications and 5 million from injuries.[21] Sixty-five percent of cancers require some form of surgical intervention as part of their treatment paradigm, 25% of disabilities are treatable with some type of surgical intervention, and an estimated 2 million lives can be saved in LMICs by scaling up trauma care.[22]

Table 17.1 Core Indicators for Monitoring Universal Access to Safe, Affordable Surgical and Anaesthesia Care When Needed[a]

Indicator	Definition	Rationale	Data Sources	Responsible Entity	Comments	Target
Group 1: Preparedness for Surgical and Anesthesia Care						
Access to timely essential surgery	Proportion of the population that can access, within 2 hr a facility that can do cesarean delivery, laparotomy, and treatment of open fracture (Bellwether procedures)	All people should have timely access to emergency surgical services. Bellwether procedure performance predicts accomplishment of many other essential surgical procedures; 2 hr is a threshold of death from complications	Facility records and population demographics	Ministry of Health	Informs policy and planning regarding location of services in relation to population density, transport systems, and facility service delivery	A minimum of 80% coverage of essential surgical and anesthesia services per country by 2030
Specialist surgical workforce density	Number of specialist surgical, anesthetic, and obstetric physicians who are working per 100,000 population	The availability and accessibility of human resources for health are crucial components of surgical and anesthesia care delivery	Facility records and data from training and licensing bodies	Ministry of Health, Ministry of Education	Informs workforce, training, and retention strategies	100% of countries with at least 20 surgical, anesthetic, and obstetric physicians per 100,000 population by 2030
Group 2: Delivery of Surgical and Anesthesia Care						
Surgical volume	Procedures done in an operating theater per 100,000 population per year	The number of surgical procedures done per year is an indicator of met need	Facility records	Facility, Ministry of Health	Informs policy and planning regarding met and unmet needs for surgical care	80% of countries by 2020 and 100% of countries by 2030 tracking surgical volume; 5,000 procedures per 100,000 population by 2030
Perioperative mortality rate (POMR)	All-cause death rate prior to discharge among patients who have undergone a procedure in an operating theater, divided by the total number of procedure, presented as a percentage	Surgical and anesthesia safety is an integral component of care delivery; perioperative morality encompasses deaths in the operating theater and in the hospital after the procedure	Facility records and death registries	Facility, Ministry of Health	Informs policy and planning regarding surgical and anesthesia safety, as well as surgical volume when the number of procedures is the denominator	80% of countries by 2020 and 100% of countries by 2030 tracking perioperative mortality; in 2020, assess global data and set national targets for 2030
Group 3: Impact of Surgical and Anesthesia Care						
Protection against impoverishing expenditure[b]	Proportion of households protected against impoverishment from direct out-of-pocket payments for surgical and anesthesia care	Billions of people each year are at risk of financial ruin from accessing surgical services; this is a surgery-specific version of a World Bank universal health coverage target	Household surveys, facility records	Ministry of Finance, World Bank, WHO, USAID	Informs policy about payment systems, insurance coverage, and balance of public and private services	100% protection against impoverishment from out-of-pocket payments for surgical and anesthesia care by 2030
Protection against catastrophic expenditure[c]	Proportion of households project against catastrophic expenditure from direct out-of-pocket payments for surgical and anesthesia care	Billions of people each year are at risk of financial ruin from accessing surgical services; this is a surgery-specific version of a World Bank universal health coverage target	Household surveys, facility records	Ministry of Finance, World Bank, WHO, USAID	Informs policy about payment systems, insurance coverage, and balance of public and private services	100% protection against catastrophic expenditure from out-of-pocket payments for surgical and anesthesia cure by 2030

[a]Access, workforce, volume, and perioperative mortality indicators should be reported annually. Financial protection indicators should be reported alongside the World Bank and WHO measures of financial risk protection for universal health coverage. These indicators provide the most information when used and interpreted together; single indicator provides an adequate representation of surgical and anesthesia care when analyzed independently. Equity stratifiers are listed in report's discussion.
[b]Impoverishing expenditure is defined as being pushed into poverty or being pushed further into poverty by out-of-pocket payments.
[c]Catastrophic expenditure is defined as direct out-of-pocket payments of >40% of households income net of subsistence needs.
USAID, U.S. Agency for International Development; WHO, World Health Organization.

COST-EFFECTIVENESS

While the human resources and infrastructure required for surgical care require significant investment, studies have demonstrated that basic surgical services can, in fact, be remarkably cost-effective. The disability-adjusted life-year (DALY) is a metric that serves to quantify morbidly and mortality from conditions, as well as the cost-effectiveness of interventions. In simple terms, a DALY is considered one lost year of *healthy life*. An estimated 77.2 million DALYs could be annually averted by scaling up basic surgical care in LMICs.[4] In 2013, a systematic review and analysis of individual studies that assessed cost-effectiveness of surgical procedures demonstrated that the median cost-effectiveness ratios of cleft lip/palate repair ($47.74/DALY), general surgery ($82.32/DALY), hydrocephalus surgery ($108.74/DALY), and ophthalmic surgery ($136/DALY) are comparable to that of the BCG

vaccine ($51.86 to $220.39/DALY).[11] In addition, median incremental cost-effectiveness ratios (ICERs) of cesarean sections ($315.12/DALY) and orthopedic surgery ($381.15/DALY) are significantly less than those of medical treatment of ischemic heart disease ($500.41 to 706.54/DALY) and HIV treatment with multidrug antiretroviral therapy ($453.74 to $648.20/DALY). Data demonstrating cost-effectiveness of U.S. $5.07/DALY for cataract repair in Nepal, U.S. $7.38/DALY for circumcisions in Mozambique, and U.S. $10.93/DALY for general and obstetric surgery implementation in Bangladesh suggest that these low-cost operations are comparable even to the U.S. $9.07/DALY cost of the Expanded Program on Immunization (EPI) with tuberculosis, diphtheria, pertussis, tetanus, polio, and measles vaccinations. Notably, in contrast to infectious or chronic diseases, which may require ongoing or recurrent treatment, surgery is often curative. Additionally, surgical conditions frequently affect the young working population and therefore correcting these conditions results in greater reductions in death and long-term disability.

SCALING UP SURGICAL CAPACITY

Workforce Shortages

Appropriate and early recruitment, education, and retention are crucial to increasing workforce density and building surgical capacity worldwide. It is estimated that an additional 1.27 million surgeons are needed globally to meet the goal of 20 to 40 surgeons per 100,000 population recommended in order to meet surgical need worldwide. While it has been estimated that training this number of physicians over 15 years would cost $45 billion, this number is small relative to the estimated losses in gross domestic product (GDP) that would occur over the same time from not treating the top five surgical conditions affecting 90% of the world's population—estimated to be $20.7 trillion.[19] Making this investment is economical, lifesaving, and beneficial to society, as healthy and more productive people can enter the workforce.

Not only well-trained surgical and anesthesia providers are in short supply but also this workforce is unevenly distributed across the globe. For

example, the WHO Global Health Observatory notes the African, Eastern Mediterranean, and Southeast Asia regions host only 17% of the world's licensed surgeons but account for 47% of the global population.[23] The Observatory also estimates there is a mere one licensed anesthesiologist per 1 million population in the WHO Africa and Southeast Asian regions. A regional study of five countries in East Africa demonstrated that there were only 237 anesthesiologists in that region for a population of 142.9 million people, providing an average workforce density of 0.13 anesthesiologists per 100,000 population.[24] Further contributing to the problem is the tendency for licensed health care providers to congregate and provide services in urban areas, leaving wide gaps for care delivery in the rural areas. Engagement of women into the surgical workforce is critical, without which the deficit in surgeons will not be solved. For example, women make up less than 10% of the surgical workforce in Africa (9%) as well as Japan (6%), which affects access to surgical care.[25,26]

Training and Education Models

Postgraduate Surgical Training Programs

To address physician shortages, many countries have developed postgraduate surgical training programs. A review of 64 articles describing surgical residency training programs in 34 LMICs and six regions performed in 2016 demonstrates there is much variability between programs.[27] Local curricular requirements fit the local context. For example, the general surgery curriculum from the College of Surgeons of East, Central, and Southern Africa (COSESCA), a 14-country consortium for education and certification, lists OB-GYN procedures (caesarean section, dilatation and curettage, oophorectomy, salpingectomy, hysterectomy, vesicovaginal fistula repair) as well as orthopedics (fracture reduction and treatment with external and internal fixation) as part of the required curriculum. Training challenges exist because there are not enough surgical trainers for the increasing number of medical school graduates in many countries. Postgraduate general surgery programs range in duration from 2.5 to 7 years after completing an undergraduate program ranging from 3 to 8 years. The curricula are not standardized across countries, with a variety of didactic and practical

experiences at rural and district hospitals. Testing is conducted at differing intervals throughout the training with a mix of oral, written, and clinical examinations. Nevertheless, the development of regional organizations, such as the West African College of Surgeons (WACS), COSECSA, and the Pan-African Academy of Christian Surgeons (PAACS), has provided structure in terms of standardizing final examinations, consolidating resources, and unifying curriculum content and are excellent organizations for North American surgical programs to collaborate with.

In general, programs in low-resource settings face many challenges—clinical responsibility versus educational time conflicts, financial and resource limitations, and early independence with limited supervision due to the constraints of the supervising surgeons. Conflicts also can arise when Ministries of Health govern physician positions and hospital salary allowances while Ministries of Education provide oversight to graduate and postgraduate education. Program development and successful implementation may require planning across sectors that do not historically work together. Through coordinated efforts, a region or country's investment into a tailored and structured surgical education training curriculum can improve workforce density, build capacity, and decrease morbidity and mortality from surgical conditions in the short and long terms.

Train the Trainer

Other training models such as the "train-the-trainer" program work to complement postgraduate training programs and build capacity in subspecialty surgical care. Those programs generally consist of experienced and/or specialized surgeons providing intensive workshops to surgeons in areas with few specialists in order to train them to perform specific procedures and to develop local centers of referral. For instance, IVUmed, a pediatric urology medical and surgical education program, works to pair physicians and nurses in low-resource settings.[28] They create peer-to-peer interface through interactive workshops, live case demonstrations, and resource provision with the end goal of establishing a self-sustaining educational program. A mobile training project for endoscopic third ventriculostomy (ETV) procedures led to a subsequent program to develop neurosurgery as a permanent specialty in Kenya and Zanzibar.[29]

Short-term pediatric training programs have not only increased specific surgical procedure numbers but also promoted the development of regional specialty care and training centers.[30,31] This model maintains care locally, builds mentoring relationships, and establishes the infrastructure to train future residents.

Academic Partnerships and Collaborations

Another method of improving surgical training capacity and enhancing resources is forming academic partnerships between high-income and low- to middle-income countries. These are generally longitudinal, multiyear commitments established at an institutional level with an overarching commitment to improving educational programs, building research capacity, enhancing clinical care, and promoting infrastructure strengthening. Collaborations can be multidisciplinary or specialty-focused and can be formed with universities, nongovernmental organizations, and academic associations.[31,32] Most importantly, the goals and responsibilities must be driven by local priorities and mutual respect. An initial needs assessment can evaluate existing strengths and weaknesses, available human and physical resources, and infrastructure capability and identify the most frequent surgical pathologies and procedures performed. This evaluation can then guide curriculum development appropriate to the local or regional environment in partnership with the local program, with frequent feedback from stakeholders. Ideally, exchange will be bidirectional, with local trainees and health care providers receiving access to expertise and resources not previously accessible and external professionals will learn about local pathologies and innovative, low-resource techniques to enhance patient care. Some of the major benefits of a long-term institutional-level partnership include building trust and relationships over time, opening access to numerous disciplines and specialists, and developing common goals and mutually beneficial programs over time. U.S. programs need to be cautious about trying to send trainees to participate in “medical tourism” or experiences that are more about bragging than embedding and working with the local partners in a way that is mutually beneficial.

Virtual and Simulation-Based Education

Simulation-based education is another supplement to any training program and an important way to build expertise and capacity. Simulation is a valuable tool for skill acquisition and improvement in general surgery, providing a safe and low-risk environment for trainees and surgeons learning new skills. Procedures and skills can be taught in person or virtually depending on mentor availability and then repeated as often as needed until proficiency and comfort are achieved. Webinars, virtual lectures, and e-curricula can also be a good way to improve local education programs when teaching surgeons are stretched thin. These techniques have led to improvements in knowledge and confidence, allowed for flexible scheduling, and can provide an ample library with little to no space.[33,34] While costly access and limitations to Internet availability can be barriers, the world of telecommunication and telemedicine is rapidly expanding and is a very viable option for improving surgical proficiency in a safe, reliable setting at a local level.[35]

Task Sharing

Task sharing or task shifting is another model that has been employed in some LMICs to solve the workforce density shortages. Task sharing involves training nonsurgeons or nonphysicians in specific surgical procedures. Some examples are training medical assistants and clinical officers in providing anesthesia, performing cesarean deliveries, and placing external fixators on fractures.[36,37] This practice has been particularly successful in areas with a shortage of physicians, which is often the case in LMICs. Moreover, as technology advances, virtual supervision is becoming more prevalent and possible. Organizations such as CapaCare work to increase the level of skilled health staff at district hospitals to perform lifesaving surgical and obstetrical procedures in areas where there are no surgeons.

LOGISTICS AND SPECIAL CONSIDERATIONS

Whether entering another country for a clinical, research, or education-based experience, there is quite a bit of advanced planning that should be considered in order to make sure time in country is safe and appropriate. Obtaining visas, applying for medical licensure in the country of interest,

organizing travel and evacuation insurance, signing up for the U.S. State Department's Smart Travelers Enrollment Program (STEP), and visiting a travel clinic for the appropriate vaccinations and/or malaria prophylaxis are some important issues to consider. Being aware of the current political climate, and anticipating any blockades, violence, or social unrest (particularly around election times), is important.

Another recommendation to help ensure the safety of all team members prior to travel is to provide or endorse a cultural competency course specific to the country or region of the program. Understanding current and historical ethnic conflicts, warring factions, cultural hierarchies, customs, language and greetings, social norms, gender relations, and appropriate dress codes can help ensure team members do not unknowingly put themselves in an uncomfortable or harmful situation. Ethical issues should be anticipated, and team members should agree in advance about what types of medical care they feel comfortable and safe performing. In the end, at no point should the safety of the visiting team, local partners, or patients being treated be jeopardized for the purpose of the program, so a cautious and reasonable approach is recommended. The Berman Institute of Ethics free online ethics course http://ethicsandglobalhealth.org/ is an excellent resource for trainees to complete before going to another setting.

Research

When conducting research, it is critical to involve local collaborators including partner clinicians, hospital administrators, university researchers, the Ministry of Health, or all of the aforementioned in the development of research questions and in study design. There may be a misalignment of incentives when it comes to research; it is important to assess existing research projects, current clinical weaknesses, and stakeholder-identified future research directions to ensure the research addresses local needs and not solely the academic curiosity of the visiting team. Advance investigation should be made to determine if a local Institutional Review Board or Ethics Committee exists at the hospital, municipal, or national level where you will be working. Understanding the policies and authorization process, which may include manual delivery of paper copies of the research protocol or signed letters of authorization, with an effort to receive approval prior to the study

start date, is the most appropriate and ethical way to conduct research with international partners. Moreover, conversations with in-country partners should be conducted to inform study design and avoid barriers or challenges that have been faced by other local or international researchers prior to your arrival. Troubleshooting as many issues as possible in the planning phase can make the transition to implementation a smoother process. Increasingly, surgical journals are setting expectations about authorship when manuscripts are being submitted with data from LMICs. For example, the *World Journal of Surgery* expressly states that manuscripts must include one or more local coauthors who live and work in the country where the data have been collected.

Humanitarian Surgery Considerations

There are surgeons who are interested in working in humanitarian settings. These are typically in either conflict or disaster zones. It is critical to make sure that the surgeon has sufficient training and experience to work in these environments because of significant resource limitation, wide scope of procedures, and security concerns. The care provided after the 2010 Haiti earthquake exposed the inadequate training and coordination of emergency medical personnel, which resulted in care that was described as "medically shameful."[38] Best practice would be to work with designated humanitarian organizations such as *Médecins Sans Frontières* (MSF, also known as Doctors Without Borders), Samaritan's Purse, and the International Committee of the Red Cross. Providing care in these settings requires surgeons to have functional knowledge of the unique rules and ethics that govern the decisions for caring for injured people regardless of their combatant status in volatile and unpredictable settings. Surgeons must have a basic understanding of the Geneva Conventions and sections of International Humanitarian Law.[39]

Another important consideration of a program that includes humanitarian surgery as a component is affirming that surgical providers are appropriately trained in the operations they will be performing. Board-certified general surgeons in the United States may not have the skill set to match the broader range of pathology treated during humanitarian outreach programs. A study comparing MSF procedure logs to U.S. general surgery resident case logs

only noted overlap for 44% of procedures—the majority of which were general surgery operations such as herniorrhaphies and bowel resections.[40] However, MSF surgeons recorded 46.8% of cases to be obstetrics and gynecology and 21.2% to be orthopedics—specialties in which general surgery residents have very little exposure during traditional residency tracks. To address these inconsistencies and give residents more exposure to specific procedures such as caesarian sections, hysterectomies, amputations, long bone fixations, and suprapubic tube placements, some programs provide global and rural surgery residency tracks or fellowships or humanitarian skill workshops.[41] Providing surgeons with the appropriate clinical skills for the environment they are entering is essential for safe and suitable patient care as well as better incorporation into the local hospital and workforce.

GETTING INVOLVED

At every level of training and throughout the surgical career, there are ways to get involved in global surgery activities. In this section, opportunities are broken down by training level and activity type.

Students

Two international networking organizations exist specifically for students: InciSioN (incisionetwork.org) and their U.S. affiliate the Global Surgery Student Alliance (GSSA—www.globalsurgerystudents.org). The mission of these organizations is to engage students early in sustainable global surgery projects and to create a worldwide network of peer-to-peer partnerships and foster student–faculty mentor relationships. They have a number of international chapters with active social media presence to facilitate local and multinational collaboration. Moreover, their websites highlight resources, ways to get involved, and events, including an annual symposiums and regional conferences. Engaging undergraduate and medical students early will instill drive, passion, and the academic skill set to keep them ethically engaged in global surgery or global health throughout their careers.

Residents and Fellows

Over the last 10 years, academic opportunities in global surgery have increased significantly for resident surgeons. In terms of networking, the Global Surgery Working Group within the American College of Surgeons Resident and Associate Members Society (ACS-RAS) meets quarterly to bimonthly each year. The group has hosted webinars and hangouts on global surgery topics, and member work has been featured in the *RAS Newsletter*. A Communities message board provides members a way to connect on similar projects and share resources. Future directions for the working group include enacting an international residency training needs assessment and an RAS-COSECSA trainee co-mentorship program.

Many general surgery programs across the United States have developed global and rural surgery training opportunities, varying from 4- to 6-week international rotations to 1- to 2-year research fellowships to integrated track positions. A study from 2015 determined that 42 of 239 (16%) general surgery program websites had information about international surgical opportunities, and this number has only increased.[42] Several programs have written about their experiences with international surgery partnerships and the attendant benefits and challenges of responding to local needs, forming long-term partnerships, building capacity, promoting research, and providing guidance for other programs.[43–45] The University of Colorado Humanitarian Surgical Skills Workshop is held annually for residents to acquire subspecialty skills that are useful in low-resource environments.

Postgraduate Surgeons

There are also hands-on workshops that are geared specifically toward developing a humanitarian surgical skill set. The International Humanitarian Aids Skills Course hosted by the Stanford Center for Continuing Education occurs annually every February. The course spans 1.5 days with didactic and practical sessions. The hands-on portion with cadaveric or realistic models provides exposure to procedures such as orthopedic fixation, basic flaps, burns grafting, craniotomies, caesarian sections, and emergency gynecologic management. Participants can hone clinical skills in a safe, simulated setting. There is a Global Health Competencies and Cognitive Skills precourse offered at the American College of Surgeons Clinical Congress, with a simulation skills course offered every 3 years.

For the licensed general or specialty surgeon, the types of activities and the level of possible involvement vary broadly. As a general overview, two organizations have created world maps with pins highlighting clinical and research opportunities for surgeons, subspecialists, and trainees to collaborate internationally—the Association for Academic Global Surgery (https://www.academicglobalsurgery.org/maps) and Intersurgeons (https://intersurgeon.org). The interactive maps can be utilized to promote individual work, solicit clinical or academic partners, or locate particular needs in your region of interest.

Another option for identifying academic or clinical international work is through international or national academic societies, which are numerous and beyond the scope of this chapter. Some examples include the American College of Surgeons' Operation Giving Back, the Global Initiative in Children's Surgery, Global Affairs Committee of the Association for Academic Surgery (AAS), the Society for University Surgeons (SUS) Global Academic Committee, and the Society of American Gastrointestinal and Endoscopic Surgeons (SAGES) Global Affairs Committee. The Royal College of Surgeons' Global Affairs Committee, the International Society of Surgery (ISS), and the Society of Asian Academic Surgeons (SAAS). COSECSA, WACS, and PAACS are some examples of well-known, multinational organizations that organize surgeons and surgical training in sub-Saharan Africa. Membership in these societies and involvement on the committees can provide access to educational and clinical opportunities, research support, and access to far-reaching networks with opportunities for bidirectional exchange and collaboration.

There are a number of well-known short- or long-term clinical opportunities to work internationally. MSF is a politically independent humanitarian organization that responds to crisis situations across the world and often partners with other organizations that are listed on its website (https://www.msf-me.org/other-organisations-working-field). Other groups that may accept volunteer surgeons or perioperative workforce include International Committee of the Red Cross, International Medical Corps, Médecins Du Monde, Samaritan's Purse, and Mercy Ships. There are other organizations, such as Operation Smile, Healing the Children, Touching Hands, Team Heart, and Mission Urology, which focus on specific pathologies. Some considerations when deciding which organization to

partner with are the organization's track record, longitudinal presence, philosophy or religious background, and the time and financial commitment required.

CONCLUSION

Global surgery is rapidly evolving and represents a growing interest for surgeons and trainees. There are many opportunities for those interested in forming collaborative partnerships in service, research, and education. To build sustained and successful engagements, it is important to ensure that individuals working overseas have had proper clinical and ethics training, relevant clinical experiences, and an understanding of research logistics and they are working in sync with the local collaborator.

Patient Safety

Kiran Gupta and Elizabeth C. Wick

Key Points

1. Safety events are usually rare occurrence but when examined in aggregate may reveal themes.
2. "Measuring" how safe an hospital is in the traditional sense is difficult.
3. Most safety events occur as a result of poorly defined systems as opposed to an error on the part of an individual.
4. Developing a culture of safety is a long term commitment that requires close collaboration and alignment between hospital leadership, management and frontline staff.
5. Root cause analyses are the most common approach for evaluating serious safety events in a hospital.

INTRODUCTION TO PATIENT SAFETY

In 1999, the National Academy of Medicine (NAM, formerly called the Institute of Medicine) published *To Err is Human: Building a Safer Health System,* which highlighted the large number of Americans dying every year

from medical errors and has been largely credited with catalyzing the modern patient safety movement.[1] Before *To Err is Human*, it was largely believed that errors in medicine resulted from "bad apples," but the report elucidated how mistakes in health care frequently result from poor system design. Many began to draw analogies to and learn from other high stakes industries such as aviation, pointing out how broad system reform that prioritized safety had led to better outcomes in other fields. This shift in thinking launched sweeping efforts to improve the 1 safety of the health care delivery system in the United States, prompting important changes in measurement of safety, event reporting, culture, training, regulation, and technology. While much progress has been made over the last two decades, significant opportunity remains to improve safety, particularly in complex procedural areas like operating rooms. To be effective in helping to transform surgical culture and ensuring safe care for patients, it is critical that all surgeons have a working knowledge of patient safety as well as a general awareness of the principles of improvement.

ADVERSE EVENTS AND ERRORS

After *To Err is Human*, numerous studies were published further supporting the pervasiveness of mistakes and associated adverse outcomes for patients across all health care settings including surgery. It is important to understand that in health care, adverse patient outcomes can result both from underlying disease processes and from medical care received. The latter are typically referred to as adverse events, or medical harm which is defined by the Institute for Healthcare Improvement as: "unintended physical injury resulting from or contributed to by medical care (including the absence of indicated medical treatment) that requires additional monitoring, treatment, or hospitalization, or that results in death."[2] Adverse events can be further subdivided into those that are thought not to be preventable, resulting from appropriate medical care without 3 any error, and those that are preventable, resulting from errors on the part of an individual or a poorly functioning system, or a combination of both. In health care, an error or mistake is defined as "an act of commission (doing something wrong) or omission (failing to do the right thing) that leads to an undesirable outcome

or significant potential for such an outcome."[3] Not all errors or mistakes lead to adverse outcomes for patients and one that does not may be referred to as a "near miss." Within the field of patient safety, the focus has shifted from measuring and reducing errors to measuring and reducing the totality of preventable adverse events or preventable harm. It is important to acknowledge that what is defined as preventable harm may continue to evolve over time. For example, central line–associated blood stream infections (CLABSIs) were once thought not to be preventable and now it is well established that with proper techniques and protocols in place, CLABSI rates can be driven close to zero.[4]

While medical errors can occur across all health care settings, there are some forms of harm that are unique to the perioperative area (**Table 18.1**). Some of the errors that receive the most attention include patients undergoing surgery on the wrong limb, retention of foreign objects after the patient leaves the operating room and mislabeling of critical specimens. As the science of safety has advanced, systems have been put in place to try to prevent these events such as marking of the planned surgical site and side prior to the patient going back to the operating room (wrong-site surgery), using radio frequency identification or digital counting to account for all surgical laparotomy pads (retained foreign objects) and implementing team debriefings (mislabeled surgical specimens). But, despite these interventions, events still occur. In this chapter, we provide a brief background on patient safety; summarize the role of culture, teamwork, and communication in improving safety; and highlight the importance of working toward zero preventable harms in surgical patients.

MEASUREMENT CHALLENGES

2 Despite advances in the field of patient safety over the last two decades, measuring safety remains an ongoing challenge and some have aptly stated that "what you see depends on how you look."[5] Health care organizations often choose to measure safety in numerous ways. Many have established voluntary event–reporting systems in which employees can share information about errors, mistakes, and near misses. Commonly referred to as "incident-reporting systems," these databases contain information only about what

frontline health care workers choose to report. A high rate of reported incidents could either reflect a strong safety culture and comfort with sharing concerns, or reflect true safety problems. It can be hard to tell whether fluctuation in the rate of reported incidents reflects changes in the culture of reporting or true changes in safety. In addition, different types of health care providers might note different concerns and because nurses file incident reports far more frequently than physicians, these reporting systems might not adequately reflect physicians' safety concerns.[6] Despite their inherent flaws, incident-reporting systems are one major way that health care systems keep track of concerning events and trends.

Table 18.1 National Quality Forum Never Events

1. Surgical or Invasive Procedure Events
   1A. Surgery or other invasive procedure performed on the wrong site (updated)
   Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
   1B. Surgery or other invasive procedure performed on the wrong patient (updated)
   Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
   1C. Wrong surgical or other invasive procedure performed on a patient (updated)
   Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
   1D. Unintended retention of a foreign object in a patient after surgery or other invasive procedure (updated)
   Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
   1E. Intraoperative or immediately postoperative/postprocedure death in an ASA Class 1 patient (updated)
   Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices

2. Product or Device Events
   2A. Patient death or serious injury associated with the use of contaminated drugs, devices, or biologics provided by the health care setting (updated)
   Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities
   2B. Patient death or serious injury associated with the use or function of a device in patient care, in which the device is used or functions other than as intended (updated)

Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

2C. Patient death or serious injury associated with intravascular air embolism that occurs while being cared for in a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, long-term care/skilled nursing facilities

3. Patient Protection Events

3A. Discharge or release of a patient/resident of any age, who is unable to make decisions, to other than an authorized person (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

3B. Patient death or serious injury associated with patient elopement (disappearance) (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

3C. Patient suicide, attempted suicide, or self-harm that results in serious injury, while being cared for in a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4. Care Management Events

4A. Patient death or serious injury associated with a medication error (e.g., errors involving the wrong drug, wrong dose, wrong patient, wrong time, wrong rate, wrong preparation, or wrong route of administration) (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4B. Patient death or serious injury associated with unsafe administration of blood products (updated)

Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4C. Maternal death or serious injury associated with labor or delivery in a low-risk pregnancy while being cared for in a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers

4D. Death or serious injury of a neonate associated with labor or delivery in a low-risk pregnancy (new)
Applicable in: hospitals, outpatient/office-based surgery centers

4E. Patient death or serious injury associated with a fall while being cared for in a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4F. Any stage 3, stage 4, and unstageable pressure ulcers acquired after admission/presentation to a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, long-term care/skilled nursing facilities

4G. Artificial insemination with the wrong donor sperm or wrong egg (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices

4H. Patient death or serious injury resulting from the irretrievable loss of an irreplaceable biologic specimen (new)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

4I. Patient death or serious injury resulting from failure to follow up or communicate laboratory, pathology, or radiology test results (new)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5. Environmental Events

5A. Patient or staff death or serious injury associated with an electric shock in the course of a patient care process in a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5B. Any incident in which systems designated for oxygen or other gas to be delivered to a patient contains no gas, the wrong gas, or are contaminated by toxic substances (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5C. Patient or staff death or serious injury associated with a burn incurred from any source in the course of a patient care process in a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

5D. Patient death or serious injury associated with the use of physical restraints or bedrails while being cared for in a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

6. Radiologic Events

6A. Death or serious injury of a patient or staff associated with the introduction of a metallic object into the MRI area (new)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices

7. Potential Criminal Events

7A. Any instance of care ordered by or provided by someone impersonating a physician, nurse, pharmacist, or other licensed health care provider (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term

care/skilled nursing facilities

7B. Abduction of a patient/resident of any age (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

7C. Sexual abuse/assault on a patient or staff member within or on the grounds of a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

7D. Death or serious injury of a patient or staff member resulting from a physical assault (i.e., battery) that occurs within or on the grounds of a health care setting (updated)
Applicable in: hospitals, outpatient/office-based surgery centers, ambulatory practice settings/office-based practices, long-term care/skilled nursing facilities

Using administrative date, the Agency for Healthcare Research and Quality (AHRQ) developed patient safety indicators (PSIs) as triggers to identify safety issues.[7] Over time and not without controversy, PSIs have been incorporated into public-reporting and pay-for-performance programs.[8,9] However, reliance on administrative data may not always adequately capture true safety concerns. Other approaches including retrospective chart review, trigger tools and hospital standardized mortality ratios all pose challenges as well.[10–12] In reality, organizations use a variety of approaches to measure safety and identify harm; incident reporting, administrative data, publicly reported measures, retrospective chart review, trigger tools, and even patient-reported concerns are those most frequently utilized.

SYSTEMS THINKING

A key shift in patient safety has been the realization that adverse events often occur because of poorly designed or poorly functioning systems, rather than because of the actions of a single individual. Historically, the approach was

to place blame for a bad outcome on a particular individual caring for a patient. In the past, medical errors were thought to reflect incompetence and as a result, clinicians frequently tried to keep them undercover, preventing organizations from learning from these events and promoting a lack of transparency. While there has been a significant shift away from blame in the last decade, there is still significant opportunity to integrate appropriate analysis of the health care system into discussions regarding adverse events.

The adoption of such "systems" thinking in health care—the idea that humans are human and as such will inevitably make mistakes and that systems need to be designed to be resilient, mitigating the possibility of error or identifying risk before harm results—has transformed the ability to realize safety. Systems thinking often involves redesigning systems using a combination of frontline provider input, human factors principles, systems engineering, and health information technology to significantly decrease the risk of adverse events and harm. James Reason's "Swiss cheese model" is frequently referred to when discussing how a series of defects in a system can align to cause inadvertent harm and worth becoming familiar with.[13]

Health care is considered a high-risk industry with a high error rate, but other high-risk industries, such as nuclear power and commercial aviation, have managed to achieve and maintain an impeccably low error rate.[13] Much of the credit for the safety record in these areas can be attributed to the culture, characterized by individual responsibility and accountability, attention to detail, professionalism, transparency, and respect for all team members. It is the culture in these industries that facilitates high-quality communication under high-risk, high-stress conditions. As health care's views on patient safety have matured, improvement efforts have largely shifted from remediating individual providers to buttressing the "system" by simplifying processes and building in the use of tools such as checklists and read-backs that facilitate redundancy and standardized approaches where possible.[14]

DISTINCTION BETWEEN QUALITY AND SAFETY

Although the lines can be blurred at times, there is a distinction between quality and safety. In 2001, NAM published another well-known report, *Crossing the Quality Chasm*, in which it defined six aims for achieving a high-quality health care system: safe, effective, patient-centered, timely, efficient, and equitable.[15] Within this framework, safety is defined in a way as one aspect of high-quality care. When analyzing events, safety and quality problems may both be present.

CREATING A CULTURE OF SAFETY

4 Culture is to an organization what personality is to an individual—a difficult to precisely define, yet unifying set of characteristics and attributes that provide meaning and direction.[16] Organizations with effective safety cultures share a constant commitment to safety as a top-level priority that permeates the entire organization—from the frontlines (learners, technicians, clerks, nurses, anesthesia providers, surgeons, sterile processing staff) to the leadership (perioperative executives, chief operating officers, clinical department leadership). Organizations that are able to align and promote an effective culture of safety in the surgical areas are generally characterized the following qualities[17]:

1. Recognize the high-risk, error-prone nature of surgery and perioperative services.
2. They have fostered a nonpunitive environment where individuals are able to report errors or close calls without fear of punishment or retaliation; sometimes called a "Just Culture."
3. They develop forums and expectation for collaboration across disciplines and ranks to seek solutions to vulnerabilities and identified safety breeches.
4. They express a willingness to direct organizational resources (project management, dedicated nonclinical time for key personnel, health information resources, etc.) to address safety concerns.

It is important to acknowledge that traditional surgical culture stands at odds to some of the core principles of a culture of safety. The operating room has historically been a hierarchal environment where the surgeon was considered to be the "captain of the ship." The emphasis was solely focused

on executing the surgeon's orders and requests and not on speaking up if there were concerns or even valuing collective input. Furthermore, surgeons have been hesitant to discuss errors as mistakes have been equated with incompetence. Discussions of errors have usually taken place only among peers in morbidity and mortality forums. Surgeons also tend to minimize the effects of stress on their ability to make decisions.[18] Establishing clarity of roles as well as a culture that promotes raising concerns are key steps on the journey toward optimal safety culture in the operating room; hierarchy can prevent nurses and other operating room staff from pointing out potential errors or mistakes made by the team resulting in potentially preventable adverse events. It is important to note that although progress in perioperative areas has been slower than in others, fear of speaking up is not limited to the operating room. The culture of medicine in general strongly values professional autonomy, which frequently promotes individualism over cooperation, often to the detriment of patient care.[19] Although often viewed as important, safety culture is seldom promoted from an organizational priority to an organizational value. Organizations often do not feel the need to devote resources to overhauling their patient safety systems to achieve optimal culture as long as they perceive their existing processes to be adequate. It is a common refrain to hear that hospital-based patient safety teams are underresourced and are not able to convene essential groups or provide the necessary follow-up and systems-level changes after a safety event—key steps required to accelerate the journey to realizing strong culture of safety and to becoming a high reliability organization.[20]

MEASURING SAFETY CULTURE

It is important to establish a unifying culture of patient safety throughout an organization because culture evolves at multiple levels: within health care systems, hospitals, departments, and units. Efforts to foster cultural change within an organization with regard to patient safety have been limited in the past by the inability to measure the impact of any given intervention. However, studies have shown that surveys determining what is important and what attitudes and behaviors are rewarded, supported, expected, and accepted, with regard to patient safety are associated with error reduction

behaviors in aviation and with decreased rates of CLABSIs.[4] The Safety Attitudes Questionnaire (SAQ) and the Survey on Patient Safety Culture (SOPS) are validated survey instruments that can be used to measure culture in a health care setting.[21] The SOPS has been adapted for multiple settings including ambulatory surgery centers, outpatient practices, nursing homes, and pharmacies. More recently, additional optional questions have been developed around health information technology and value. The Joint Commission encourages all hospitals to measure safety culture every 18 months to 2 years.

Although perceptions of safety culture domains can differ as a function of one's role in the OR (i.e., technician, surgeon, nurse, anesthesia provider, environmental services worker, clerk), perceptions of the overall climate has been shown to be relatively consistent across OR providers in a given hospital.[22] Using a survey, hospitals can compare culture between different types of health care workers within a work area as well as culture between work areas throughout the institution. Scores can be compared to those of other participating institutions to have a sense to how the hospital compares to other similar sized hospitals. Importantly, in addition to simply awareness, the survey and scores can be used to evaluate the effectiveness of safety interventions by comparing the survey safety climate scores post implementation to baseline scores.

Teamwork and Communication

According to The Joint Commission, communication breakdown is one of the top three root causes of sentinel events such as a wrong-site surgery. Poor communication contributed to over 60% of sentinel events reported to the Joint Commission on Accreditation of Healthcare Organizations in 2011.[23] Good communication is an essential component of teamwork and is especially important in the OR, one of the most complex work environments in health care.

Within the realm of patient care, there are enormous amounts of information being exchanged between health care providers on a daily basis. Much of this information, if prioritized correctly, has the potential to prevent unintended medical errors and serious harm to patients. The importance of good communication in preventing medical error is undeniable; however, it

is difficult to achieve. The traditional surgical hierarchy can prevent OR personnel from sharing important patient data and expressing safety concerns. One perioperative field study showed a 30% rate of communication failure in the OR, with 36% of these breakdowns having a substantial impact on patient safety.[24]

MEASURING TEAMWORK

Research in commercial aviation has demonstrated a strong correlation between better teamwork and improved safety performance. Cockpit crew members' reluctance to question a captain's judgment was long ago identified as a root cause of aviation accidents. Good attitudes about teamwork are associated with error-reduction behaviors in aviation, improved patient outcomes in ICUs, and decreased nurse turnover in the OR.[22] It is also associated with higher job satisfaction ratings and less sick time taken from work.

Safety culture surveys can be used to measure teamwork and provide benchmarks for departments or hospitals seeking to measure and improve their teamwork climate.[25] The teamwork scores are responsive to interventions that aim to improve teamwork among operating teams, such as the implementation of crew resource management or team training, executive walk rounds, and preoperative briefing team discussions. The communication and collaboration sections of the surveys reflect OR caregiver views on teamwork and can be used to distinguish meaningful interventions from impractical and ineffective programs.

In a survey of operating room personnel across 60 hospitals, the SAQ identified substantial differences in the perception of teamwork in the OR depending on one's role.[26] Physicians frequently rated the teamwork of others as good, while nurses at the same institutions perceived teamwork as poor. These discrepancies can be attributed to differences in the communication skills that are valued by surgeons and nurses. For example, nurses describe good collaboration as having their input respected, while physicians describe good collaboration as having nurses who can anticipate their needs and follow instructions. Efforts to improve the communication that takes place between physicians and nurses can directly improve the

perception of teamwork and collaboration by the OR team. Empowering well-respected surgeons to promote principles of teamwork and communication can go a long way toward transforming attitudinal and behavioral changes in fellow physicians as well as other members of the surgical team. Surgeons are increasingly encouraging the respectful and timely voicing of concerns of OR personnel.

Ultimately, a strong safety culture and prioritization of teamwork and communication will help organizations chart new territory more nimbly and successfully. This was exemplified at our hospital in the era of COVID-19 in the operating rooms. All patients scheduled for elective surgery were required to undergo SARS-CoV-2 testing. In order to have testing results available to inform surgical decision making, patients were instructed to undergo testing 2 to 4 days prior to surgery. However, 100% compliance was hindered due to travel distance, lack of social support, shelter-in-place orders, as well as taxed testing resources.

On the third day of our preoperative universal testing protocol, one patient arrived without a SARS-Cov-2 test. He was asymptomatic and had been sheltering at home. Therefore, it was decided to proceed with surgery. A nasopharyngeal swab was obtained the evening after surgery. The following morning, a positive test result was reported. His complex case and hospitalization potentially exposed multiple health care workers to SARS-CoV-2 leading the team to conclude that the communication and teamwork pertaining to perioperative SARS-CoV-2 testing had failed. We could have improved preoperative communication about the need for testing or arranged for testing the night or morning before surgery. **Figure 18.1** illustrates the complex intersection between technical work like a SARS-CoV-2 testing protocol and the adaptive work, the culture, communication and teamwork in the workplace.

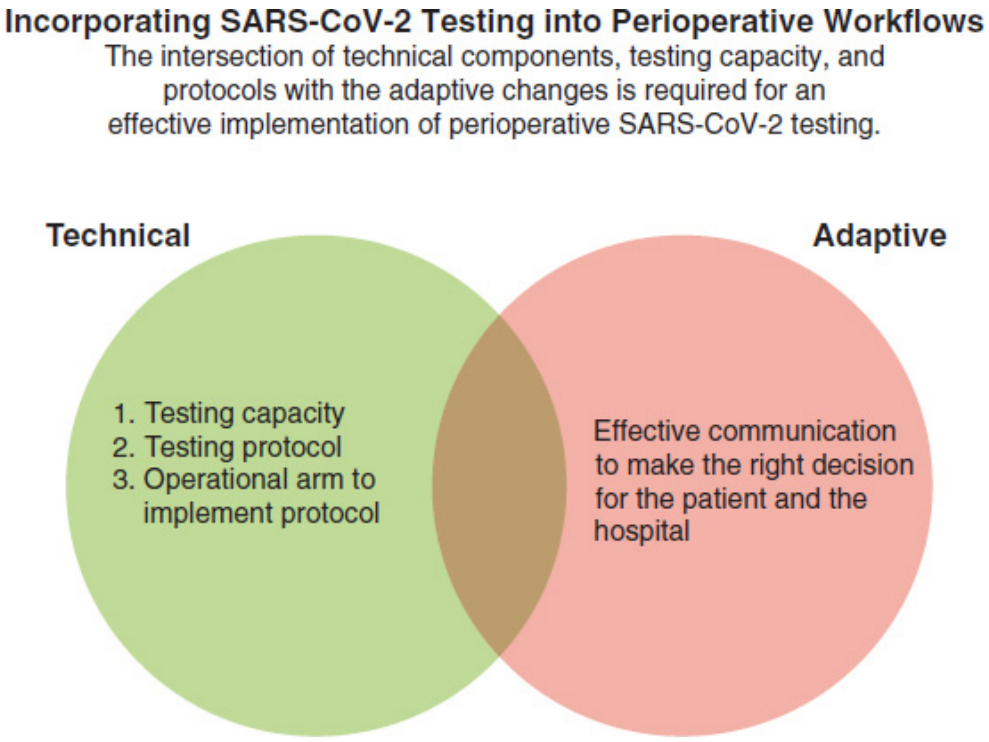

Figure 18.1 Intersections between technical and adaptive work. (Reprinted with permission from NEJM Catalyst [catalyst.nejm.org] © Massachusetts Medical Society.)

TOOLS FOR IMPROVING SAFETY CULTURE, TEAMWORK, AND COMMUNICATION

A hallmark of high reliability organizations is the frequent use of tools such as prompts, checks, standard operating protocols, and communication interventions such as team briefings and debriefings. These tools identify and mitigate hazards and allow an organization to complete tasks more efficiently. They also foster a culture of open communication and speaking up if a team member identifies a safety concern. Safety checks and standardized team discussions serve as prompts to help "engineer out" human error, providing quality assurance and improving information flow. They also can prevent errors related to omissions, which are more likely to occur when there is information overload, multiple steps in a process, repetitions in steps, planned departures from routine processes, and when there are other interruptions and distractions present while the process is being executed.

These same interventions have been shown to improve patient safety in ORs and ICUs.[20,27]

Preoperative briefings and checklists, when used appropriately, help to facilitate transfer of information between team members. A briefing, or checklist, is any preprocedure discussion of requirements, needs, and special issues of the procedure. Briefings are best when locally adapted to the specific needs of the specialty. They have been associated with an improved safety culture, including increased awareness of wrong-site/wrong-procedure errors, early reporting of equipment problems, reduced operational costs, and fewer unexpected delays. In one study, 30.9% of OR personnel reported a delay before the institution of OR briefings, and only 23.3% reported delays after briefings were instituted.[28,29] OR briefings are increasingly being used to ensure evidence-based measures, such as the appropriate administration of preoperative antibiotics and deep vein thrombosis (DVT) prophylaxis, are used. Briefings allow personnel to discuss potential problems, before they become a "near miss" or cause actual harm.

The World Health Organization (WHO) has developed a comprehensive perioperative checklist as a primary intervention of the "Safe Surgery Saves Lives" program—an effort to reduce surgical deaths across the globe.[30] The WHO checklist includes prompts to ensure that infection prevention measures are followed, potential airway complications are precluded (e.g., anesthesia has necessary equipment and assistance for a patient with a difficult airway), and the groundwork for effective surgical teamwork is established (e.g., proper introductions of all OR personnel). Aspects of The Joint Commission's preprocedure "Universal Protocol" (or "time-out") are also included in the checklist (e.g., checks to ensure operation performed on correct patient and correct site). The initial WHO checklist study was associated with significant reduction in mortality worldwide but follow-up studies evaluating the efficacy of the checklist in governmental programs have failed to reproduce the same impact on morbidity and mortality. It is now understood that the efficacy of checklists are largely dependent on the safety culture in which they are implemented.[29] Simply mandating use is unlikely to change the quality of care delivered but comprehensive interventions to improve safety culture and implement checklists will likely

result in meaningful improvement. It is important to adapt checklists to the local environment (**Fig. 18.2**).

Tools such as checklists, sign-outs, briefings, and debriefings improve communication between health care providers and create a safer patient environment. Although their use in health care is still highly variable, specialties that have incorporated them, such as intensive care and anesthesia, have made impressive strides in patient safety. Currently, communication breakdowns, information loss, frequent handoffs, multiple competing tasks, and high workload are considered "annoying but accepted features" of the perioperative environment. As physician attitudes toward error mitigation, stress reduction, and optimizing teamwork become more favorable, medicine will likely achieve many of the milestones in safety that high-reliability industries such as aviation already have.

The comprehensive unit based safety program (CUSP) is a tool that was initially designed for the intensive care unit, but has been translated to different clinical areas.[31] CUSP is an effective approach for improving both safety culture and clinical outcomes. Every clinical area that implements CUSP assembles a multidisciplinary team and follows five iterative steps: training on the science of safety, identifying patient safety hazards, partnering with senior executive, learning from defects and implement tools to improve teamwork, and improving communication. All teams include providers from relevant disciplines such as nurses, physicians, hospital infection control practitioners, technicians, advanced practice providers, resident physicians and clerks. This approach has been successfully used to reduce colorectal SSIs from 27% to 18% in a university-based setting.[31] It has been adapted to other perioperative settings across the country through a national implementation project in collaboration with the American College of Surgeons. Subsequently the approach has been used to disseminate enhanced recovery after surgery (ERAS) pathways across multiple service lines.

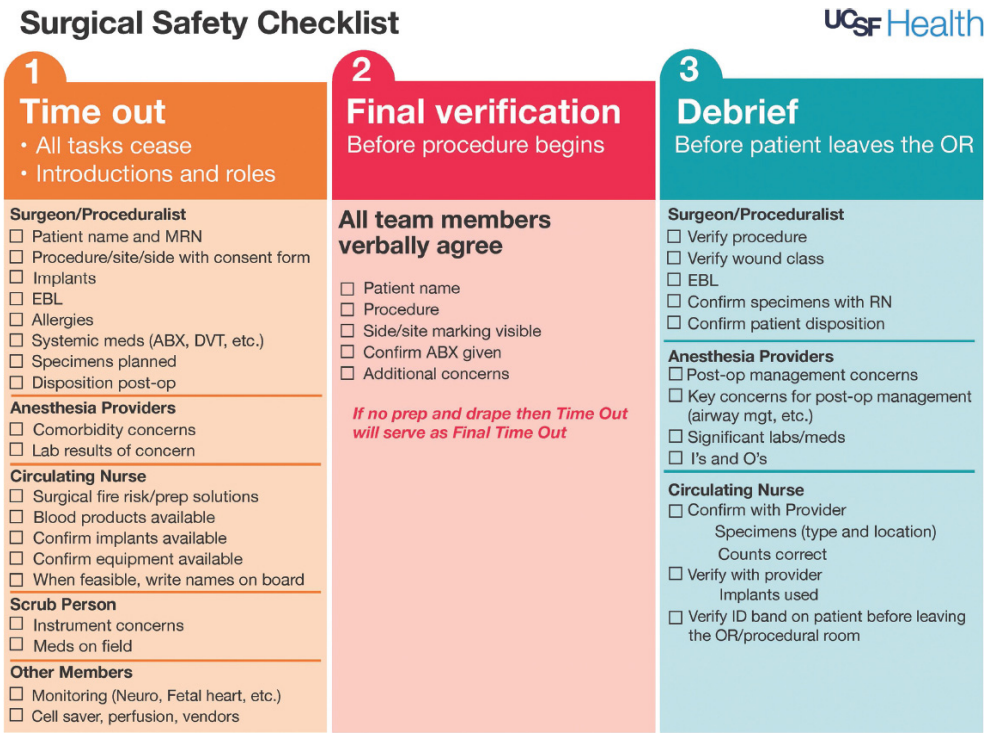

Figure 18.2 University of California, San Francisco perioperative briefing and debriefing checklist.

INVESTIGATING A SAFETY EVENT: ROOT CAUSE ANALYSIS

5 The approach to analyzing adverse events and mistakes has shifted from assigning blame to using frameworks that help elucidate contributing factors so that improvements can be put in place to make the system more resilient, thereby preventing similar harms or near misses from occurring in the future. Division and department morbidity and mortality conferences (M&Ms) have long provided a protected space in which clinicians from similar fields can openly discuss clinical decision making, including errors. The focus of the discussion can at times be very technical. However, M&Ms are not always the optimal forum for discussing cases in which broad systems-issues beyond the purview of a particular division or department may have played a role. Furthermore, M&Ms have traditionally been focused on surgeons and attendance by nonsurgeon personnel is usually restricted, further limiting both the scope and impact of the discussions. In addition, there are certain events

that occur, often referred to as sentinel events or never events, for which health care institutions are required by certain states and The Joint Commission to conduct thorough, detailed systematic reviews, often with the engagement of the appropriate hospital leadership. The process most commonly employed by health care organization for such systems-level analysis is referred to as root cause analysis (RCA).

The goals of the RCA process are two-fold: 1) to identify the systems factors that contributed to the adverse event, error or near miss and 2) to identify improvement opportunities to prevent similar events in the future. When conducting a RCA, it is important to consider:

- Selecting an experienced and skilled facilitator to lead the discussion
- Using structured tools to help identify possible contributing factors
- A multidisciplinary approach that engages a diversity of clinicians, staff, and hospital leadership with time for those involved in the case to share their perspective
- Development of action items for improvement to mitigate the risk of future harm and weighing the relative strength of those action items (e.g., educational intervention or policy change vs. a true systems fix)
- Implementing processes for accountability and sustainment of action items as well as dissemination of learnings from the discussion throughout the organization
- A framework that refers aspects of a case involving an individual's decision making to the appropriate peer review forum for further discussion so that the RCA can focus on systems issues
- Establishing appropriate support resources for staff and providers who may be particularly impacted by the case and for whom the discussion may also be hard.[14,32]

What a Surgeon Should Consider When Preparing to Attend an RCA?

- Debrief with your supervisor/division chief/department chair about the case and consider requesting that the case undergo M&Ms in advance of the RCA so that care management issues and decision making are well understood and expert surgical colleague input can be had.
- Consider using a structured approach such as the "5-Whys" or a fishbone diagram to help identify possible contributing factors to the system defects so that you are prepared to share your thoughts at the RCA.

- If the case was particularly impactful for other team members, it can be helpful to debrief with them prior to the RCA.
- If there are concerns about risk and disclosure, seek the advice of risk management at the time of the event to ensure appropriate documentation and discussion with the patient and family.
- Try to avoid placing blame on others during the discussion and speak openly about your concerns related to system issues and why you think things did not go as planned.
- Be sure to recommend inclusion of key people that might not be obvious based on record review.

ESTABLISHING A COMPREHENSIVE SAFETY PROGRAM

Historically, safety issues and concerns were managed in a fragmented manner within divisions and departments, at times falling under the purview of a single hospital leader such as the Chief Medical Officer. Many larger organizations have now developed robust infrastructure dedicated to managing safety at an institutional level. Safety programs are at times embedded within the broader quality efforts of the organization (e.g., under a Chief Quality Officer) and frequently engage closely with the risk management department.

Most comprehensive hospital safety programs employ a safety officer or manager to help oversee various aspects of the work which usually includes the following[14]:

- The incident-reporting system which for a large institution like ours can result in well over a thousand incidents a month that need to be investigated and addressed
- Addressing safety data from various sources including outcome data related to a variety of externally reported safety and quality measures (readmissions, mortality, PSIs, etc.)
- Addressing issues from cases referred from division and departmental review processes
- Safety culture survey and intervention efforts
- The Joint Commission survey related work

- Engaging relevant clinical and operational leadership in event review to motivate needed change
- Ensuring appropriate review of serious errors and sentinel events
- Establishing a high-level patient safety committee to discuss strategy and priorities related to safety
- Engaging frontline clinicians and clinical leaders in safety-related efforts

CONCLUSIONS

The fields of quality and safety have evolved tremendously in the past two decades. Much of the terminology is now commonplace and many frontline providers are routinely engaged in efforts related to quality and safety. Yet, there remains tremendous opportunity to improve culture and communication to ensure safe care for patients. As surgeons we must be dedicated to acquiring competency in the areas described above so that we can serve as leaders in advancing patient safety in our hospitals and operating rooms.

Part Two Surgical Practice

Section A: TRAUMA

19

Trauma and Trauma Care: General Considerations

John W. Scott and Hasan B. Alam

Key Points

1. Injuries are the leading cause of death in young Americans and account for one out of every 10 deaths in the world.
2. The three most common mechanisms of injury-related deaths are motor vehicle collisions, firearms, and falls; however, fall-related deaths are rapidly rising, reflecting the aging population.
3. Bleeding is the number one cause of preventable deaths.
4. Early hemorrhage control is the major priority along with balanced resuscitation using an appropriate ratio of blood products.
5. The vast majority of trauma-related deaths are within the first few hours (<6 hours) after sustaining injuries.
6. Establishment of trauma systems that use evidence-based triage and treatment protocols saves lives.
7. Recent military conflicts have rapidly advanced trauma care in many domains, and these developments are now being transferred to the civilian trauma settings.

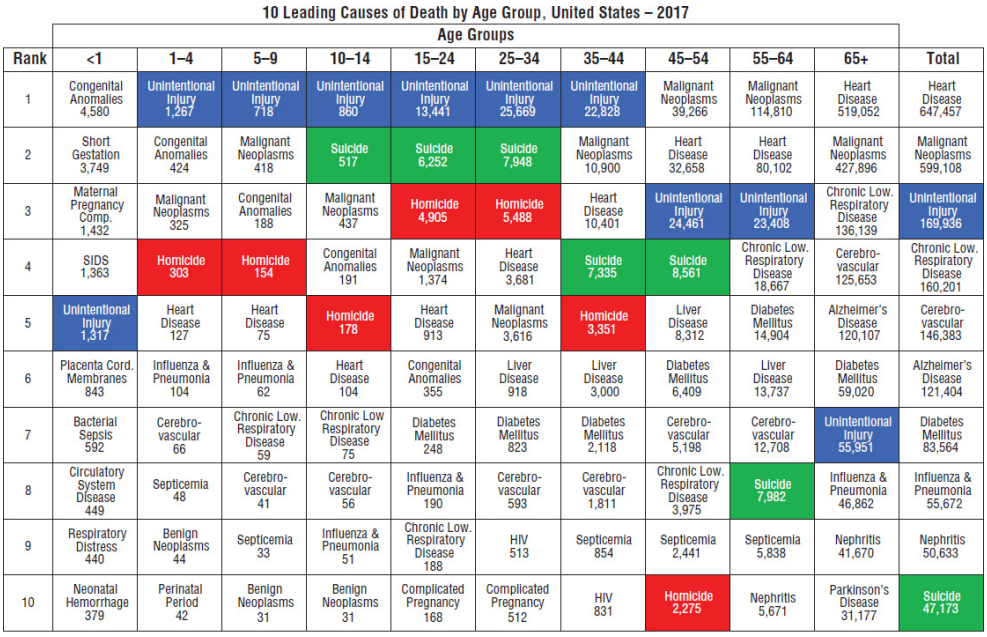
BURDEN OF DISEASE

Injuries and violence affect everyone, regardless of age, race, or economic status. According to the Centers for Disease Control and Prevention (CDC), National Center for Injury Prevention and Control, injuries account for over 243,000 deaths per year.[1] As opposed to cancers, cardiovascular diseases, and strokes, injuries disproportionally strike people in the prime of their lives.[1] Injury is the number one cause of death for Americans younger than 60 years.[1] In fact, 54% of all 1 deaths among people of 1 to 44 years of age in the United States are due to injuries, which are more than all noncommunicable diseases and infectious diseases combined.[1] **Figure 19.1** shows the top 10 causes of death in different age groups in the United States, whereas **Figure 19.2** shows the top 10 causes of injury-related deaths, highlighting the unintentional causes.[1] Excluding drug overdoses, the top three mechanisms of injury-related deaths in the United States are motor vehicle collisions 2 (MVCs), firearms, and falls—each of which account for just under 40,000 deaths annually (**Table 19.1**).[1] On the global scale, injuries account for over 10% of the entire global burden of disease.[2] Each year, almost 100 million people are injured and nearly 5 million people die from injuries—more deaths than from HIV/AIDS, malaria, and tuberculosis combined.[2]

Although striking, the mortality data do not tell the entire story. In 2017, there were approximately 30 million injured patients treated in emergency departments, and there are approximately 3 million hospitalizations for injuries.[3] The overwhelming majority of these patients survive, but they may face lifelong mental, physical, social, and financial challenges. These challenges may greatly impair a patient's functional status and limit their ability to return to school, work, or preinjury activity level. At the population level, the resultant economic toll on our society is staggering. In 2013, the total cost of injuries in the United States was estimated to be $671 billion.[4] The costs associated with fatal injuries were $214 billion, while nonfatal injuries accounted for over $457 billion.[4]

EVOLVING MECHANISMS OF INJURIES WITH CHANGING POPULATION DEMOGRAPHICS

Trauma represents a heterogeneous group of injury mechanisms that have a dynamic relationship with societal and demographic changes over time (**Fig. 19.3**). For example, better roads, safer cars, more frequent use of seat belts, and a reduction in drunk driving over the last few decades have resulted in a decrease in the MVC fatality rate despite a marked increase in the number of cars on the roads and overall miles driven (**Fig. 19.4**).[5–8] Conversely, falls—which are more common in older adults—are rapidly becoming a major health care issue due to increasing age of the population.[9] In the United States today, one in nine Americans is 65 years or older, which by 2050 will increase to one in five.[9] The fall-related death rates have been climbing since the early 1990s (**Fig. 19.5**) and are expected to increase even more dramatically over the next few decades. These patients also have many more comorbid problems, and the various age-related anatomic, physiologic, and immunologic changes make it especially challenging to care for them.[9,10] Firearm deaths also demonstrate the complex interplay of injury and society. The overall firearm death rate, including both homicide and suicide, decreased significantly from the mid-1970s through the mid-2000s.[11] This trend has mirrored the national trends in overall violent crimes, which have fallen significantly over the same time period.[12] However, over the past decade, firearm-related deaths are no longer decreasing. Gun suicide rates have been increasing since 2006, and gun homicide rates have been increasing since 2014 (**Fig. 19.6**).[11] Both of these trends are mostly concentrated among males. In 2017, there were 39,773 firearm-related deaths in the United States, 60% of which were suicides.[11] The crude and age-adjusted firearm-related death rates in 2017 were the highest recorded rates in the last 20 years.[11] Over the past few years, there is an increasing awareness that reducing firearm-related deaths will require a public health approach, as advocated for by the 2019 Medical Summit on Firearm Injury Prevention.[13]



10 Leading Causes of Death by Age Group, United States – 2017

Rank	Age Groups <1	1–4	5–9	10–14	15–24	25–34	35–44	45–54	55–64	65+	Total

BIOMECHANICS OF INJURY

At the most basic level, injuries are caused by energy transfer that results in deformation and damage of bodily tissues. In general, mechanisms of injury are categorized as penetrating (e.g., stab and gunshot wounds), blunt (e.g., falls and MVCs), or thermal (e.g., flame burns and electrocution). Penetrating trauma causes injury to the tissues that are in the path of the foreign body, whereas blunt trauma causes damage either through crush or by shear forces. Different types of energy transfer will result in different classically described patterns of injury. Understanding this link between the mechanisms of energy transfer and their associated patterns of injury will greatly aid the initial patient evaluation and subsequent management priorities in the prehospital setting, the trauma bay, the operating room, and the intensive care unit (ICU).

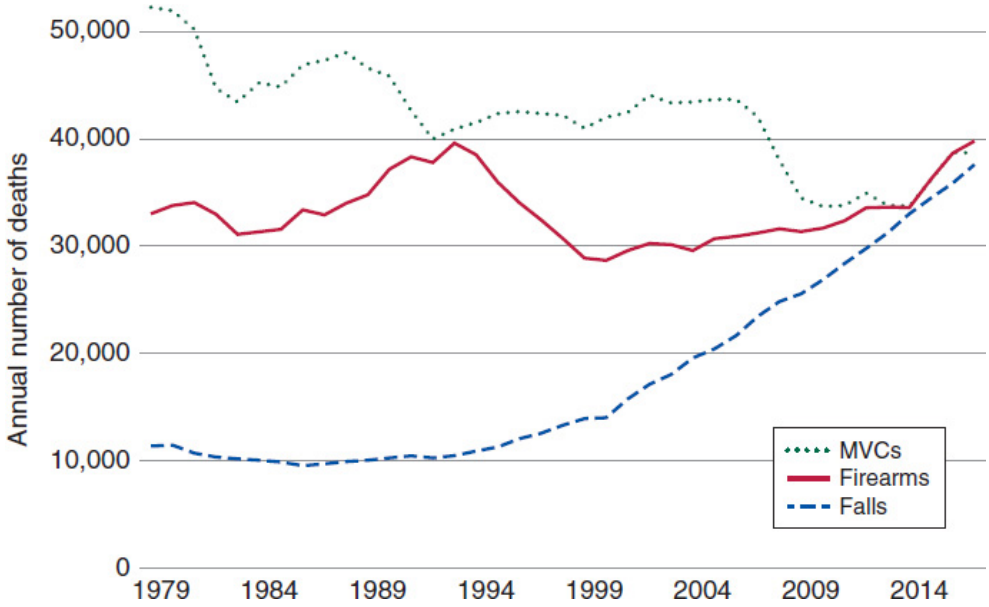

Figure 19.3 Top three causes of injury-related mortality over time in the United States. (From Centers for Disease Control and Prevention, Web-based Injury Statistics Query and Reporting System. Fatal injury data. Available at https://www.cdc.gov/injury/wisqars/fatal.html. Accessed December 31, 2019.)

Blunt trauma is best understood by applying the rules of kinetic energy transfer: KE = $(M \times V)/2$, where KE is kinetic energy, M is mass of the object, and V is velocity. Thus, a head-on collision between two large sport utility vehicles (approximately 6,000 lb each) traveling at 65 mph can

generate enormous amounts of forces. Various safety mechanisms in the modern vehicles direct this force away from the occupants of the vehicle, but the clinicians have a tendency to underappreciate the forces and the vectors involved in the collision. With frontal impact, the vehicle stops abruptly, and the occupants continue to move forward (if not belted) and either hit the steering wheel or slide under to hit their knees against the dashboard, resulting in classically described injury patterns (**Fig. 19.7**). In a rear impact, the kinetic injury generated depends upon the differences between the velocities of the two vehicles, and the occupant of the front vehicle abruptly accelerates forward, resulting in cervical spine hyperextension ("whiplash"). Lateral impact imparts rotational forces and often results in significant protrusion of the passenger compartment. In addition to limb trauma, this can result in major torso (chest, abdomen, and pelvis) injuries. The rotational forces are also more likely to cause torsion injury, where the mobile areas join relatively fixed structures (e.g., aortic laceration, cervical spinal ligamentous injuries). Rollover crashes are especially dangerous as the vehicle is impacted from various angles repeatedly during the process. The occupants of the vehicle are thrown around and may even be ejected from the vehicle. Ejection increases the chances of death by approximately 10-fold. Similarly, death of another occupant is considered a high-risk event, as it is a surrogate for the severity of impact or the complexity of the forces involved. The clinician also must specifically look for clinical evidence of energy transfer. For example, a "seat belt" sign across the abdomen must raise suspicion for energy transfer across the bowel, mesentery, pancreas, and the lumbar spine. Similarly, wedge fracture of L1 vertebra in this setting mandates ruling out a pancreatic injury as the pancreatic body drapes across the anterior aspect of L1. In fact, orthopedic injuries should be considered markers of kinetic energy transfer and make the clinicians proactively look for injuries to adjacent organs, nerves, vessels, and tendons (**Table 19.2**).

Penetrating injuries result in either lacerations or puncture wounds. Lacerations are usually straightforward, as the structures in the depth of the wound can be examined and injuries to critical organs ruled out by careful visual inspection. Conversely, low-energy puncture wounds (e.g., stab wounds) often present a greater challenge when it comes to ruling out occult injury to deeper structures. For example, a stab wound to the neck[14] can cause injuries to the airway, esophagus, blood vessels, thyroid gland, or

intrathoracic organs. In the absence of obvious vascular or aerodigestive tract injury, a complete workup may include a computerized tomographic (CT) scan to evaluate the blood vessels in the neck, laryngoscopy and bronchoscopy to evaluate for a missed airway injury, and both a video esophagoscopy and a confirmatory esophagram to rule out an occult esophageal injury. Stab wounds to the trunk may be characterized as involving the anterior abdominal wall, the back/flank, the thoracoabdominal area, or the chest.[15,16] Diagnostic and operative decision making is driven by the likelihood of underlying injury. For hemodynamically normal patients with stab wounds to the anterior abdominal wall, the decision to operate is based on evidence of intraperitoneal penetration.[15] Flank stab wounds may involve retroperitoneal structures that will not elicit peritonitis on examination and thus often require evaluation with a CT scan enhanced with intravenous (IV), oral, and rectal contrast.[15] Hemodynamically normal patients with stab wounds to the chest often mandate a placement of a chest tube and close evaluation of both initial and ongoing chest tube outputs.[16] In all three scenarios, a hemodynamically abnormal patient is assumed to have uncontrolled hemorrhage and should thus be immediately taken to the operating room for emergency exploration and prompt hemorrhage control.[14–16]

Fatal motor vehicle crashes: overview. Available at https://crashstats.nhtsa.dot.gov/Api/Public/ViewPublication/812826. Accessed December 31, 2019.)

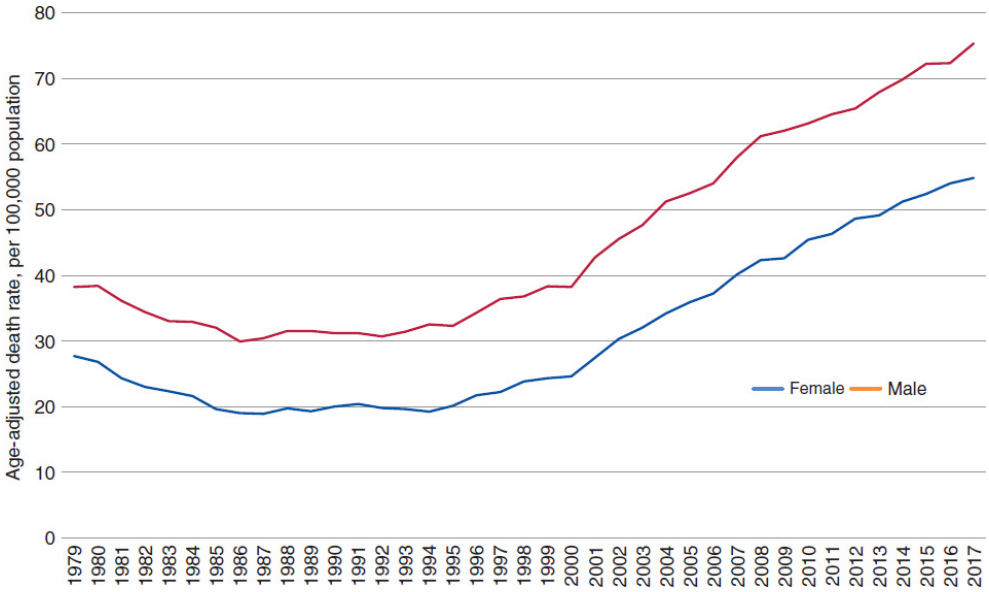

Figure 19.5 Age-adjusted death rates from unintentional falls for ages 65 years and older, by sex. The figure is a line graph showing the age-adjusted death rate for unintentional falls among males and females 65 years and older from 1979 to 2017. (From Centers for Disease Control and Prevention, Web-based Injury Statistics Query and Reporting System. Fatal injury data. Available at https://www.cdc.gov/injury/wisqars/fatal.html. Accessed December 31, 2019.)

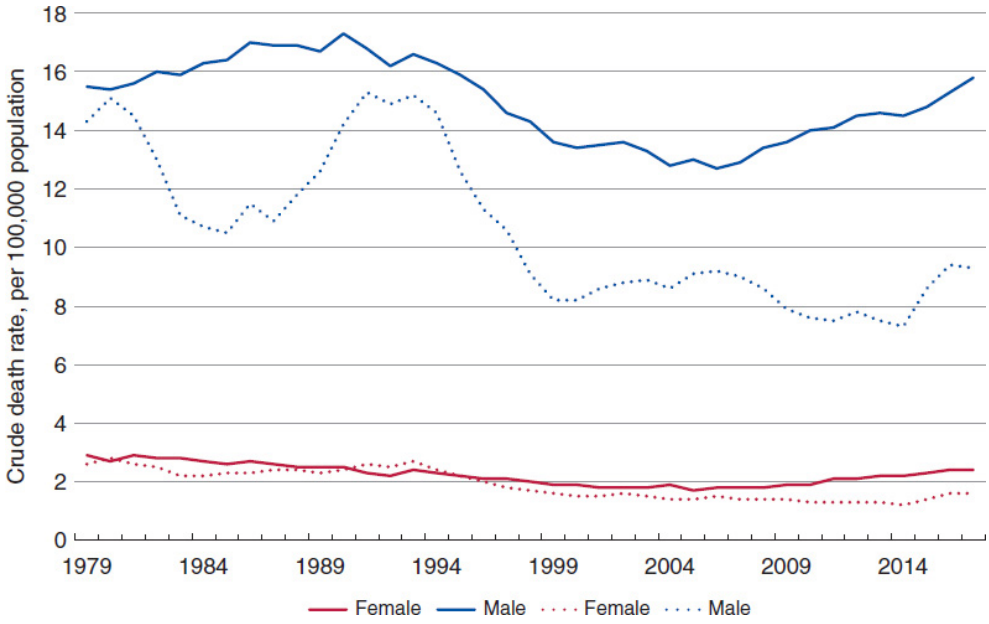

Figure 19.6 Gun-related crude death rates for ages 15 years and older, by sex. *Solid lines* represent gun suicide rates, and *dotted lines* represent gun homicide rates. Gun-related death rates fell dramatically from a peak in the early 1990s through the mid-2000s. Since 2013, however, gun-related death rates are now increasing. (From Centers for Disease Control and Prevention, Web-based Injury Statistics Query and Reporting System. Fatal injury data. Available at https://www.cdc.gov/injury/wisqars/fatal.html. Accessed December 31, 2019.)

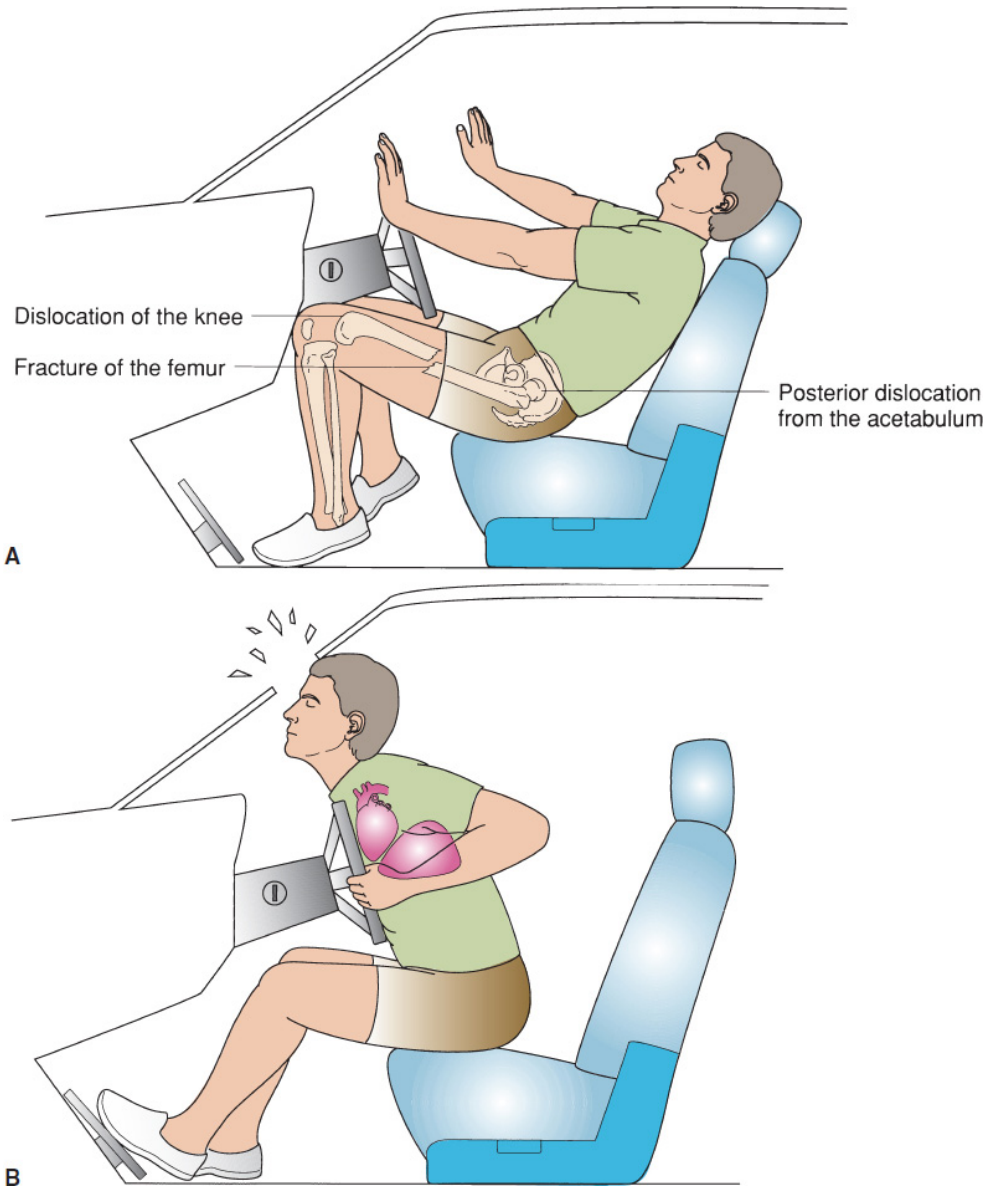

Figure 19.7 **A, B:** Frontal deceleration impact.

Bullet wounds differ from stab wounds not only in the fact that the bullets impart significant kinetic energy depending upon their velocity and weight (**Table 19.3**) but they can also cause "cavitation" effect. Cavitation occurs as tissues impacted by the bullet recoil and transmit the kinetic energy outward, creating a cavity due to the rapid acceleration and deceleration. This can injure organs/tissues that are adjacent to the bullet track even if not hit directly by the projectile. In addition to the kinetic energy, the actual area of injury is influenced by factors such as profile of the bullet, tumble (spin and yaw), and fragmentation. A jacketed bullet does not deform much, whereas a

hollow point bullet fragments, spreads, and deforms (increasing the area of damage). Similarly, tumbling of the bullet increases the area of energy exchange and much larger zone of damage. Generally, low-velocity (<1,200 ft/sec) or medium-velocity (1,200 to 2,000 ft/sec) firearms are more common in urban trauma, with high-velocity wounds seen typically in combat settings. The cavitation effect is significantly more pronounced in high-velocity injuries, and the kinetic energy differences translate into a much larger area of destruction, more devitalized tissues, and contamination (cavitation can pull in debris, clothes, etc., into the wound). Injuries to multiple organs and structures, even in different body cavities, are possible with bullet wounds. For example, a bullet injury to the anterior wall of the stomach can easily pass through the posterior wall, through the pancreas, duodenum, vena cava, and the kidney, depending upon the trajectory. While trying to determine the trajectory, it is important to *not* assume that the subject was in a "normal" anatomical position (standing straight front facing with arms by his or her side) when shot. Typically, victims assume a variety of odd positions in an effort to avoid getting hit. In addition, bullets do not necessarily travel in a linear track and can bend and bounce off in atypical directions. Thus, gunshot wound to the chest can easily result in injuries not only in the chest (ipsilateral or contralateral) but also in the abdomen, pelvis, or the neck depending upon the course of the projectile. It is also wrong to notice two holes and assume that they represent a through and through gunshot wound. It is equally likely to be two separate gunshot wounds, with both bullets still inside the body. As a general rule, the number of gunshot wounds and the number of retained bullets should add up to an even number; otherwise, you are missing either a hole or a bullet. Even in critically ill patients, quick x-rays of the chest/abdomen/pelvis, as a "bullet survey," can be very helpful before rushing to the operating room. This information can be critically important in planning the surgical approach and in deciding which body cavity to tackle in what sequence.[17]

Table 19.2 Patterns of Injury to the Head, Neck, Trunk, and Extremities Associated with Orthopedic Injuries

Diagnosed Injury	Associated Injury
Fracture—temporal, parietal bone	Epidural hematoma
Maxillofacial fracture	Cervical spine fracture
Sternal fracture	Cardiac contusion
First and second rib fracture	Descending thoracic aorta, intra-abdominal bleeding
Fractured scapula	Pulmonary contusion
Fractured ribs 8–12, right	Lacerated liver
Fractured ribs 8–12, left	Lacerated spleen
Fractured pelvis	Ruptured bladder, urethral transection
Fractured humerus	Radial nerve injury
Supracondylar humerus	Brachial artery injury fracture
Distal radius fracture	Median nerve compression
Supracondylar femur fracture	Popliteal artery thrombosis
Anterior dislocation shoulder	Axillary nerve injury
Posterior dislocation of hip	Sciatic nerve injury
Posterior dislocation of knee	Popliteal artery thrombosis

IMMEDIATE, EARLY, AND LATE DEATHS AFTER INJURY

Although life-threatening injuries result from a variety of blunt and penetrating mechanism, deaths tend to occur in a well-described temporal

pattern and due to only a few underlying causes. The classical trimodal distribution of trauma deaths was first described by Trunkey[18] in 1983, based on the patterns of posttraumatic deaths in several counties of Northern California. In that report, nearly half of the deaths occurred within minutes after injury due to disruption of major blood vessels, devastating central nervous system (CNS) injuries, or a combination. A smaller second peak, lasting a few hours, followed that first major peak in mortality (approximately 30% of the deaths) where depending upon the mechanism of trauma, ongoing hemorrhage and CNS injuries played an almost equal role. The third peak was noted days to weeks after injury due to infections, multiple-organ failure (MOF), and various late complications. An understanding of these patterns of death has led to significant advances in the arenas of injury prevention, trauma systems development, early hemorrhage control, balanced resuscitation, avoidance of trauma-associated coagulopathy (TAC), and improvements in surgical critical care.

Table 19.3 Muzzle Velocity, Kinetic Weight of Projectile, and Approximate Maximum Kinetic Energy of Frequently Used Firearms

Description (Caliber)	Projectile Weight (g)	Muzzle Velocity (ft/sec)	Kinetic Energy (ft/lb)
Pistols			
.22 Short	.29	.1,000	.72
.38 Special	.158	.870	.263
9-mm Luger	.125	.1,150	.440
.45	.250	.860	.410
.357 Magnum	.158	.1,430	.695
.44 Magnum	.240	.1,470	.1,150
Rifles			
.22 Long	.40	.1,150	.150
.56-mm M-16	.55	.3,200	.1,248
.30-30 Winchester	.170	.2,200	.1,830

"Immediate deaths" that occur within first few seconds to minutes after injury will only be avoided by altering the nature and severity of the energy transfer to the body or by prevention of the injury altogether. As mentioned earlier, improved roads, safer car design, increased seat belt use, and enforcement of speeding and drunk driving laws result in thousands of avertable deaths each year.[5–8] For MVCs that do occur, these same factors may reduce the energy transfer to the body and convert what would have been an instantly fatal injury into a survivable injury that can be attended to by modern trauma care. Based on a recent multi-institutional review of preventable trauma deaths by the Western Trauma Association,[19] 60% of preventable prehospital deaths were due to hemorrhage and 30% were due to

neurotrauma. As more patients survive the first few moments of injury and as prehospital transfer to definitive care improves, opportunities to reduce preventable deaths exist in the prehospital setting, the trauma bay, the operating room, and early intensive care.

"Early deaths," those occurring within the first 1 to 24 hours after injury, are overwhelming due to exsanguination and traumatic brain injury (TBI).[20–23] Of these two conditions, bleeding is clearly more treatable, 3 which makes it the number one cause of *preventable* deaths. If patients can survive these first few hours, modern data show that even among massively bleeding patients (without head injuries), mortality beyond the first 24 hours is only approximately 10%.[24] Although there is still a great deal of work to do in reducing preventable mortality among this patient population, tremendous advances in survival have been made among patients at risk of "early death" due to massive hemorrhage primarily due to reducing early exsanguination from hemorrhage and reducing TAC.

The most fundament way to prevent early death from exsanguination is definitive hemorrhage control. The location of hemorrhage dictates the most effective modality of definitive control. For example, most bleeding extremity wounds can be classified as compressible hemorrhage. Serious but survivable extremity injuries can lead to death by exsanguinating in a matter of minutes if not addressed. However, these life-threatening injuries can be temporized with direct pressure, the use of hemostatic gauze and topical agents, and tourniquets. Early containment of compressible hemorrhage is the basis of the "Stop the Bleed" course run by the American College of Surgeons-Committee on Trauma (ACS-COT), which teaches members of the public to act as first responders to prevent death secondary to compressible hemorrhage.[25] Noncompressible life-threatening hemorrhage in the chest, abdomen, retroperitoneum, or pelvis is a far greater challenge and requires definitive treatment in the operating room. Interventions such as a resuscitative thoracotomy or the emerging use of retrograde endovascular balloon occlusion of the aorta (REBOA) are only meant to reduce exsanguination long enough to enable definitive control of the source of intracavitary bleeding.

The reduction in early deaths among bleeding patients is also driven by prevention and correction of TAC. Appropriate resuscitation with whole blood, component blood therapy, IV fluids, and other medications that impact

the body's coagulation and fibrinolytic pathways is critically important before, during, and after obtaining definitive hemorrhage control.[26,27] Over the past few decades, valuable lessons have been learned from advances in military trauma care and Department of Defense–funded research, which have improved our ability to both treat and even prevent TAC. For example, shifting from salt-based solutions (crystalloids) to balanced resuscitation with blood components, or even whole blood, has led to less TAC and better outcomes.[28] Blood is a complex fluid that contains thousands of proteins, cells that carry oxygen to the tissues (red blood cells) and generate clot to stop bleeding (red blood cells and platelets), various clotting factors, buffers, enzymes, and hormones. As crystalloids lack all of these, their administration results in rapid dilution of cells, clotting factors, and proteins, which can worsen bleeding. 4 Thus, aggressive crystalloid resuscitation, especially in the absence of early hemorrhage control, is impractical, inadequate, and potentially harmful in many circumstances.[27–31]

Once in the operating room, early deaths are avoided by continued prioritization of hemorrhage control and avoidance of TAC. Although an in-depth description of operative decision making in trauma is outside of the scope of this introductory chapter, the basic principles of the trauma laparotomy include prepping and draping from chin to knees and from table to table, rapid entry into the abdominal cavity, early control of bleeding, temporary control of contamination, exploration of the entire intra-abdominal cavity, and finally either definitive repair of injured structures or a damage control operation with temporary abdominal closure. "Damage control laparotomy" refers to an abbreviated laparotomy focused on hemorrhage control and temporary control of contamination, followed by temporary abdominal closure, resuscitation in the ICU, and a return to the operating room for definitive management within 24 to 48 hours.[32,33] This serves to reduce the likelihood of entering the deadly "bloody vicious cycle" of uncontrolled acidosis, coagulopathy, and hypothermia[34] that will develop when the severely injured patient undergoes a prolonged operation. Common indications for a damage control operation are found in **Table 19.4**.

Finally, some of the most obvious gains in injury-related mortality reduction have occurred among the so-called "late deaths" occurring weeks to months after injury. In more contemporary studies, the trimodal distribution has now evolved into a predominately bimodal distribution, where 61% of

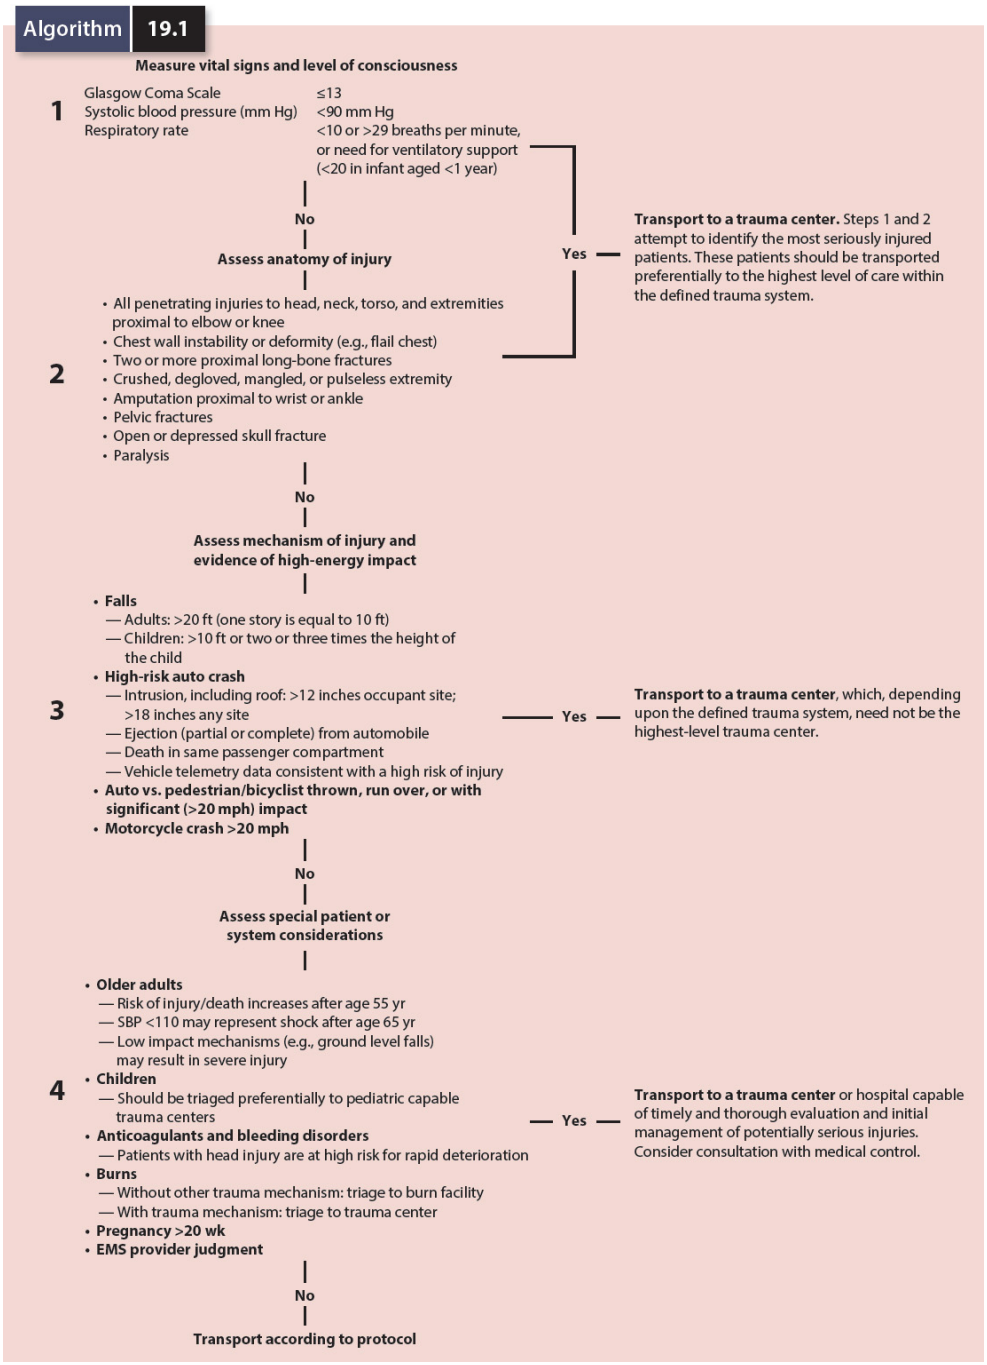
the deaths are immediate, 29% early, and only 10% are late.[35] Compared with the classical description, the percentage of immediate deaths remained unchanged and early deaths occurred much earlier (median 52 vs. 120 minutes). However, unlike the classical trimodal distribution, the late peak has markedly diminished, most likely due to significant improvements in surgical intensive care. Mortality rates for many of the reasons for late death are rapidly dropping with wider adoption of best care practices for managing critical care illnesses.[36–38] For example, due to more judicious resuscitation practices, severe respiratory failure after trauma has become a fairly rare occurrence.[39] Clearly, critical care is resource intensive and adds significantly to our health care costs, but it has "flattened" the third peak. In other words, not only the incidence of late complications has dropped but also our ability to "rescue" patients has markedly improved even if they develop the complications. This predominately bimodal distribution of trauma deaths was reiterated by a recent multinational trial of more than 5 20,000 patients,[40] which once again demonstrated that the majority of deaths (even in developing and underdeveloped countries) occur within a few hours after injuries, with <2.5% of the injured succumbing to MOF.

Table 19.4 List of Proposed Indications for Damage Control, Including Range of Values Reported in Various Articles

1. Core temperature <35°C (34°–35°C)
2. pH <7.20 (7.10–7.30)
3. Base deficit >14
4. Systolic blood pressure persistently <80 mm Hg (70–90 mm Hg)
5. Blood transfusion >10 units packed red blood cells
6. Estimated blood loss >4 L
7. Operating room fluid replacement >10 L
8. Associated life-threatening injuries in second anatomical location
9. Vascular injuries in inaccessible locations
10. Inability to close the abdomen due to visceral edema
11. Clinical evidence of coagulopathy (nonsurgical bleeding)

FIELD TRIAGE DECISIONS AND EARLY PRIORITIES

Broadly speaking, the trauma patients can be divided into three categories: patients with (a) rapidly fatal injuries, (b) potentially fatal injuries, and (3) all others. A key component of effective prehospital triage is to properly place the injured into these categories based on the available data (mechanism of injury, age of the patient, comorbid diseases, physiologic status, and injury patters) and then make a rapid decision about what type of facility is the most appropriate for the patient. The ACS-COT has developed detailed criteria for designating hospitals into different levels depending upon the resource availability, from the highest (level 1) to the lowest (level 4). These criteria can easily be found in the Resources for Optimal Care of the Injured Patient—2014.[41] Working with the CDC, the ACS-COT has also developed a guideline for the prehospital triage of the injured patients (**Algorithm 19.1**).[42] The document also contains very detailed guidelines about which patients should be transferred from lower-level to higher-level trauma centers (**Table 19.5**).[41] Appropriate and timely triage to the right facility saves lives. Results from the National Study on the Costs and Outcomes of Trauma were published in *The New England Journal of Medicine* (*NEJM*) in 2006 and demonstrated that 6 treatment at a level 1 trauma center, compared to treatment at a nontrauma center, was associated with a 20% lower odds of death—with even larger benefits among those with more severe injuries.[43]



Algorithm 19.1 2011 Guidelines for the field triage of the injured patients. (From Sasser SM, Hunt RC, Faul M, et al; Centers for Disease Control and Prevention. Guidelines for field triage of injured patients: recommendations of the National Expert Panel on Field Triage, 2011. *MMWR Recomm Rep* 2012;61(RR-1):1–20. Available at https://stacks.cdc.gov/view/cdc/23038/Share. Accessed December 31, 2019.)

Table 19.5 Criteria for Consideration of Transfer from Level 3 Centers to Level 1 or 2 Centers

1. Carotid or vertebral arterial injury
2. Torn thoracic aorta or great vessel
3. Cardiac rupture
4. Bilateral pulmonary contusion with PaO_2:FiO_2 ratio <200
5. Major abdominal vascular injury
6. Grade IV or V liver injuries requiring transfusion of >6 units of red blood cells in 6 hrs
7. Unstable pelvic fracture requiring transfusion of >6 units of red blood cells in 6 hrs
8. Fracture or dislocation with loss of distal pulses
9. Penetrating injuries or open fracture of the skull
10. Glasgow Coma Scale score of <14 or lateralizing
11. Spinal fracture or spinal cord deficit
12. Complex pelvis/acetabulum fractures
13. More than two unilateral rib fractures or bilateral rib fractures with pulmonary contusion (if no critical care consultation is available)
14. Significant torso injury with advanced comorbid disease (such as coronary artery disease, chronic obstructive pulmonary disease)

Data from American College of Surgeons, Committee on Trauma. Resources for Optimal Care of the Injured Patient 2014.

In concert with appropriate triage, the key priorities during the prehospital phase are the ABCs (airway, breathing, and circulation) of trauma care, with a major focus on hemorrhage control and appropriate resuscitation. In patients who are in hemorrhagic shock but are breathing and maintaining adequate airway/oxygenation, intubation and mechanical ventilation should be avoided (especially for short prehospital times) as administration of sedating drugs and an increase in the intrathoracic pressure (due to positive pressure ventilation) further decrease the preload, which could precipitate an arrest. Judicial administration of crystalloid fluids is acceptable, but aggressive fluid resuscitation in the absence of hemorrhage control can worsen outcomes. In a landmark 1994 study published in *NEJM*, hypotensive

patients with *penetrating injury to the torso* were randomized to routine fluid resuscitation or resuscitation was delayed until bleeding had been surgically controlled.[30] The results showed a survival advantage in the delayed resuscitation group (70% vs. 62%, $p = 0.04$). In fact, a systematic analysis of all the published data failed to find any support in favor of (or against) large-volume crystalloid resuscitation in bleeding trauma patients.[44] As these studies had focused on young patients with penetrating trauma, the question remains whether these findings can be generalized to the blunt trauma population. The blunt trauma patients are typically older, may have a higher incidence of coronary and carotid stenosis, and about 20% to 30% have associated TBI (which can worsen due to hypotension). Furthermore, as opposed to penetrating trauma, the sources of bleeding can be multiple and not always surgically correctable in the blunt trauma victims. Because of all these reasons, limited volume ("controlled") resuscitation rather than no resuscitation is logical in this population. This is also supported by an early pilot prospective randomized trial where 192 patients with an out-of-hospital systolic blood pressure (SBP) of 90 mm Hg or lower were randomized to receive controlled resuscitation (CR) or standard resuscitation (SR).[45] While the SR group received 2 L initially and additional fluid as needed to maintain an SBP of ≥110 mm Hg, the CR patients received 250 mL of fluid if they had no radial pulse or an SBP of <70 mm Hg, and additional 250-mL boluses were given only to maintain a radial pulse or an SBP of ≥70 mm Hg. This protocol was maintained until hemorrhage control or 2 hours after arrival in the hospital. The results showed that among the cohort of patients with blunt trauma, 24-hour mortality was 3% and 18% in the CR and SR groups, respectively, with an adjusted odds ratio of 0.17 (0.03 to 0.92).[45] At present, published data only support careful small-volume crystalloid resuscitation to keep the injured alive during transport and aggressive crystalloid resuscitation should be avoided. New data are now emerging regarding the role of prehospital administration of component blood products. In the Control of Major Bleeding After Trauma (COMBAT) trial, plasma-first resuscitation was not shown to have a survival benefit in a single-center randomized trial at a large urban trauma center.[46] In the multicenter, cluster-randomized Prehospital Air Medical Plasma (PAMPer) trial, 501 hypotensive patients requiring air medical transport were randomized to 2 units of thawed plasma or SR.[47] The group receiving plasma had a 24-hour

mortality of 23.2%, while the SR group had a mortality of 33.0% ($p = 0.03$). The plasma group also had a lower 30-day mortality rate and a shorter time to normal coagulation parameters ($p < 0.05$ for both). Notably, subsequent secondary analyses from two randomized prehospital plasma trials have demonstrated that the survival benefits of prehospital plasma are primarily in the blunt trauma patients and not evident in patients with penetrating injuries.[48] Also, the duration of the prehospital transport is a critical variable, and plasma resuscitation is associated with a survival benefit when transport times are longer than 20 minutes.[49] Further work in this area is ongoing.

While these advances are promising, for now, rapid transport to a specialized trauma center ("scoop and run") appears to be the most reasonable strategy in urban environments where the transport times are relatively short. In fact, a prospective comparison between Advanced Life Support (ALS) and Basic Life Support (BLS) transport[50] showed that patients transported by ALS units more often underwent prehospital interventions (97% vs. 17%; $p < 0.01$), including endotracheal intubation, needle thoracostomy, cervical collar, IV placement, and crystalloid resuscitation. While ALS ambulance on-scene time was significantly longer than that of BLS ($p < 0.01$) and had more prehospital interventions (1.8 ± 1.0 per ALS patient vs. 0.2 ± 0.5 per BLS patient; $p < 0.01$), 69.5% of ALS patients and 88.4% of BLS patients ($p < 0.01$) survived to hospital discharge. The message is clear—Less is more in the prehospital arena, and time to definitive care is the most critical variable. Other studies also support the argument that rapid transport to the trauma center is more important than prehospital interventions in urban victims of penetrating trauma.[51]

EARLY HOSPITAL CARE AND PRIORITIES

The Advanced Trauma Life Support (ATLS) program has put together a systematic, concise approach to the care of a trauma patient.[52] ATLS was developed by the ACS-COT and was first introduced in 1980 and is now taught in 60 countries across the world. The ATLS program provides

participants with a safe, reliable method for immediate management of the injured patient and the basic knowledge necessary to:

1. assess the patient's condition rapidly and accurately.
2. resuscitate and stabilize the patient according to priority.
3. determine if the patient's needs exceed a facility's capacity.
4. arrange appropriately for the patient's interhospital transfer (who, what, when, and how).
5. ensure that optimum care is provided and that the level of care does not deteriorate at any point during the evaluation, resuscitation, or transfer process.

The basic concepts of ATLS include a primary survey focusing on the ABCDE (airway, breathing, circulation, disability, and exposure) to identify and address the life-threatening issues, followed by a secondary survey to identify all the injuries. The specific treatments of various injuries have been addressed in the different chapters that follow. However, the key points to emphasize are that the two main killers during the early hospital period ("golden hour") are the same as those in the prehospital setting—*bleeding and TBI.* As treatments of TBI remain mostly supportive, bleeding remains the number one cause of *preventable* deaths during the first 6 hours following trauma. In a bleeding patient, the priorities are to identify and control the source of bleeding in the shortest possible period of time. Sometimes the bleeding source is obvious and can be controlled by direct compression (e.g., stab wound to the femoral artery in the groin), tourniquets (e.g., mangled extremity), or sutures (e.g., scalp laceration), but often it is inside a body cavity. Localization of the hemorrhage source is relatively easy for penetrating trauma that is limited to a specific body region but is notoriously difficult in the blunt polytrauma patients. In these patients, it helps to remember that a person can only lose significant volumes of blood in five locations: (1) pleural space, (2) intra-abdominal, (3) pelvis/retroperitoneal space, (4) soft tissues at the site of long bone fractures/sheer injuries, and (5) externally. With a quick examination and a chest x-ray, three of these possibilities can be easily ruled out, and the choice typically comes down to deciding between the abdomen and the pelvis. If the pelvic x-ray shows a significant pelvic fracture, then the possibility of pelvic bleeding source is significant, and a pelvic binder should be applied promptly (or pelvis

wrapped tightly with a sheet) for appropriate fracture patterns (e.g., suitable for open book fracture but potentially harmful for severe lateral compression). Focused assessment with sonography for trauma (FAST) can also be helpful in determining the source of hemorrhage. If it shows free fluid in the abdomen in a hypotensive patient, then emergent laparotomy for hemorrhage control is justified. While the reported false-negative rate in the literature has been reported to be as low as 2%,[53] others have reported a significant false-negative rate even in experienced hands.[54] Although diagnostic peritoneal lavage has largely been abandoned, a bedside diagnostic peritoneal aspiration (DPA) can be very helpful in these patients. Percutaneous DPA can be performed in 1 minute, and it has been shown to be accurate, safe, and superior to FAST for the diagnosis of abdominal blood as the source of hemodynamic instability in multitrauma patients.[55]

In addition to hemorrhage control, massive transfusion protocol (MTP) should be activated in patients who are actively bleeding to avoid development of TAC. Normal coagulation homeostasis depends on a delicate balance between clot formation and breakdown. Normally, trauma tilts the balance in favor of clot formation at the site of injuries to stop the bleeding. However, major injuries, excessive blood loss, prolonged tissue hypoperfusion, and TBI with disruption of the blood–brain barrier have all been shown to upset the normal coagulation homeostasis, resulting in TAC.[56,57] This can manifest as abnormal clot formation and/or excessive or rapid clot breakdown (fibrinolysis). Unless treated promptly, this coagulopathy leads to further bleeding, which sets up a vicious cycle resulting in the "lethal triad" of coagulopathy, acidosis, and hypothermia that is associated with an extremely high mortality.[34,58] An analysis of TAC suggests that depletion coagulopathy results in abnormalities of traditional coagulation parameters (international normalized ratio, partial thromboplastin time) and predicts mortality whereas fibrinolytic coagulopathy predicts infection, end-organ failure, and mortality, without a detectable difference in international normalized ratio or partial thromboplastin time.[59]

Damage control resuscitation (DCR) or hemostatic resuscitation has recently emerged as a potential solution for the prevention and reversal of TAC.[29,60,61] This approach advocates early hemorrhage control, permissive hypotension (until control of hemorrhage), avoidance of crystalloids, and

early use of blood components such as fresh frozen plasma (FFP) and platelets (in 1:1 or 1:2 ratios). A recent prospective randomized multi-institutional trial enrolled 680 patients with severe trauma and major bleeding to test two different blood component ratios.[24] In this study, early administration of plasma, platelets, and red blood cells in a 1:1:1 ratio compared with a 1:1:2 ratio did not result in significant differences in mortality at 24 hours or at 30 days. However, more patients in the 1:1:1 group achieved hemostasis and fewer experienced death due to exsanguination by 24 hours.[24] It must be emphasized, however, that high-ratio protocols do not improve survival in patients who do not require massive transfusion (10 units of packed red blood cells [PRBCs] in 24 hours).[62] In fact, inappropriate infusion of plasma in patients who are not massively bleeding can worsen their outcomes.[63] So, while the exact ratio of PRBCs to FFP and platelets may be debatable, contemporary resuscitation practices have moved to early delivery of component therapy in the setting of massive bleeding, using standardized protocols (see later). Also, it should be emphasized that resuscitation is an adjunct to early hemorrhage control and not a substitute. In a bleeding patient, initiating DCR is a great idea, but the patient's eventual survival depends on the ability (or inability) to obtain rapid and reliable hemorrhage control. In addition, prevention and active reversal of hypothermia (e.g., use of fluid warmers, body warming devices) and correction of acidosis and hypocalcemia are critically important while resuscitation protocols are carried out.

We also know that development of a clot is just the initial part of the process, and rapid breakdown of the clot may be equally detrimental. It has been shown that development of fibrinolysis is a highly lethal event in severely injured patients,[64,65] and treatment with blood products alone is incapable of reversing this process. Despite ongoing debate about precise ratios of blood products,[66] there is general agreement that blood products should be administered in the form of an MTP to optimize the processes of care and to improve outcomes. Cotton et al.[67] tested the effectiveness of a trauma exsanguination protocol by comparing patients treated with the protocol (n = 94 over 18 months) to a cohort of similar patients admitted during the prior 18 months (n = 117). The study found that implementation of the protocol reduced 30-day mortality (51% vs. 66%, $p < 0.03$), decreased intraoperative crystalloid administration (4.9 L vs. 6.7 L, $p = 0.002$), and

reduced postoperative blood product use (2.8 vs. 8.7 units of PRBCs, $p < 0.001$; 1.7 vs. 7.9 units of FFP, $p < 0.001$; 0.9 vs. 5.7 units of platelets, $p < 0.001$). Dente et al.[68] conducted a similar study of an MTP (1:1:1 ratio of platelets, FFP, and PRBCs) by comparing matched patients during a 1-year period before and after the implementation of protocol (73 patients in the protocol group and 84 matched controls). Implementation of the protocol was found to reduce mortality in the first 24 hours (17% with MTP vs. 36% pre-MTP, $p = 0.008$) and at 30 days (34% vs. 55%, $p = 0.04$), with a more pronounced impact in the patients with blunt trauma.[68] This study also showed that MTP patients required fewer overall transfusions of PRBCs and FFP after the first 24 hours (2.7 vs. 9.3 units of PRBCs, $p < 0.0001$; 3 vs. 7.5 units of FFP, $p < 0.05$). The University of Michigan MTP is provided for reference (**Fig. 19.8**).[69] It should be emphasized that to be effective, these protocols should not only incorporate the best available evidence, which is constantly changing, but also reflect the resources and realities of the individual institutions.

LESSONS LEARNED FROM THE BATTLEFIELD

Every major war has catalyzed rapid advances in trauma care. As the medical systems grapple with the challenges of taking care of massive numbers of injured people (military and civilian), often in very austere settings, they quickly evolve, adapt, and improvise. Wars also prompt significant financial investment by the governments in research and development and attract some of the best minds to the field. Many of the things (various operative interventions, drugs, fluids, dressings, rapid transport systems, trauma teams, in-field care, and many more) that are taken for granted today in the civilian trauma centers can be traced back to the wars of the past. Interestingly, as the war medicine improves and evolves to take care of worse injuries, the war industry responds by developing more lethal weaponry. Thus, the percentage of injured who die in the battlefield (killed in action or KIA rate) has remained relatively static during the 20th century, hovering around 25% (**Table 19.6**). The current conflict is the first

time in modern warfare that the KIA rate has dropped down to 10%.[70,71] This dramatic drop is clearly multifactorial in etiology and reflects the focus on prevention strategies with widespread use of superior protective body armor and deployment of better-designed 7 military vehicles. In addition, the current ongoing conflicts have fundamentally altered how we take care of the injured, which has resulted in not only improved survival rates but also markedly superior functional outcomes. A brief list of the key advancements can be found in **Table 19.7**.

FUTURE DIRECTIONS

The future of trauma care will require novel advances at both the basic science level and the health systems level. Even with development of robust trauma systems, improvements in early hemorrhage control, a focus on balanced resuscitation, institution of MTPs, and adoption of standardized best practices in modern surgical critical care, an estimated one in five trauma deaths is still preventable. Many of these individuals have underlying injuries that are potentially survivable, but they die before getting definitive care. While resuscitation restores tissue perfusion, it does not have any specific prosurvival properties. By the time the injured gets to the hospital, nothing can be done to reverse the "irreversible shock." A much more exciting approach would be to improve the survival by administering specific pharmacologic agents in the field that could immediately upregulate prosurvival genes and proteins to create a *prosurvival phenotype*[107] or use strategies to induce a state of "suspended animation" to keep the organs preserved until the source of hemorrhage can be controlled.[108,109] In the not too distant future, early trauma resuscitation may be very different from what we currently practice due to advances in our understanding of the cellular response to injury. Promising, ongoing work suggests that one day we may see advances such as the development of specific prosurvival drugs that can be given in the prehospital setting to keep the injured alive long enough to get evacuated to higher levels of care; ability to temporarily "suspend" life using hypothermia or hibernation strategies for patients who have potentially survivable injuries, but need more time for surgery or transfer; individualized therapy with administration of specific pharmacologic agents based on the individual's cellular disturbances; and monitoring of response to therapy that goes beyond measurement of physiology and looks at the reversal of cellular disturbances.

Table 19.6 Lethality of War Wounds among U.S. Soldiers

Table 19.7 Translating Lessons from Military Experience to Civilian Trauma Care

Domain of Trauma Care	Lessons from Military Experience	Translation to Civilian Trauma Care
Prevention	Improvements in body armor and armored transportation have resulted in changing injury patterns[72] and decreased case fatality rates.[73] Kevlar helmets have made otherwise lethal injuries now survivable, such that mild TBI was the most common injury from the Iraq war.[72] Mortality from direct chest trauma has fallen to 10%, with the most common injury being pulmonary contusion as opposed to lethal injury to vital organs in the chest.[73]	The Multi-Disciplinary Multi-Institutional Mortality Investigation in the Civilian Prehospital Environment (MIMIC) study is funded by the US Department of Defense and will help create reliable measures for prehospital time and distance to definitive care and also help determine which injured civilians who die before reaching the hospital had a potentially preventable cause of death.[74]
Management of Extremity Hemorrhage	Advanced hemostatic bandages were quickly developed, rigorously tested, and expeditiously deployed by the military.[75–79]	These same hemostatic dressings are now used widely for intracavitary hemorrhage control in the operating room.[80]

	Military experience demonstrated that survival rates improved markedly for casualties that had injuries suitable for tourniquets.[80]	Both advanced hemostatic dressings and windlass tourniquets are used widely by EMS first responders for temporary control of compressible or extremity hemorrhage. Increased tourniquet use in the civilian population has been associated with a survival benefit in patients with extremity vascular injuries.[81] The ACS-COT's "Stop the Bleed" course has trained over 1 million civilian first responders in the application of direct pressure, the use of advanced hemostatic dressings, and windlass tourniquets for compressible hemorrhage. Bleeding control kits are increasingly available in public places such as airports, stadiums,

		and schools, akin to automatic external defibrillators.[25]
Management of Junctional and Truncal Hemorrhage	Junctional injuries to the very proximal extremities are not amenable to windlass tourniquets, but the Combat Ready Clamp and the SAM Junctional Tourniquet have been developed and tested in the military setting.[82,83] Military and civilian collaboration has led to the development and refinement of the resuscitative endovascular balloon occlusion of the aorta (REBOA) device.[84–86] Military guidelines suggest a role for REBOA in the prehospital setting when used by advanced combat medical personnel with specialized training in an effort	Junctional tourniquet devices are now used for temporary hemorrhage control by prehospital EMS personnel and at trauma centers around the United States.[90] REBOA is now used in trauma centers throughout the United States. While there have been numerous series demonstrating promising results,[91,92] the most recent data to date suggest that further work is needed to properly define when and in which patient population REBOA offers benefit.[93] The Reducing Exsanguination Via In-Vivo Expandable Foam (REVIVE) trial started in late 2019 at five civilian

	to reduce death from noncompressible hemorrhage.[87,88] DARPA-funded research led to development of novel injectable foam to temporize pelvic hemorrhage.[89]	trauma centers in the United States.[94]
Damage Control Resuscitation and the Prevention and Treatment of Trauma-Associated Coagulopathy	Many DoD agencies, such as the Office of Naval Research (ONR), the US Army Medical Research and Material Command (MRMC), and Defense Advanced Research Projects Agency (DARPA), just to name a few, have been long-standing sponsors of resuscitation research. In the late 1990s and early 2000s, experts from three national consensus conferences agreed that aggressive resuscitation is deleterious, an "ideal" fluid is yet	The DoD-funded Prospective, Observational, Multicenter, Major Trauma Transfusion (PROMMTT) study was performed at 10 U.S. level 1 trauma centers and showed that higher ratios of plasma and platelets early in resuscitation was associated with lower mortality.[61] As a follow-up to the MATTERs trial, the Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage (CRASH-2) trial took place in 40 countries and again

not available, and that low-volume resuscitation (hypertonic, colloid, or combination) is the most logical choice for the military needs.

Most current recommendations of the Tactical Combat Casualty Care (TCC) guidelines emphasize hypotensive resuscitation, avoidance of crystalloids, early blood product use, high ratios of plasma and platelets to RBCs, and administration of TXA when appropriate.[95]

The Military Application of Tranexamic Acid in Trauma Emergency Resuscitation (MATTERs II) took place in a Role 3 Combat Surgical Hospital in southern Afghanistan and showed that the

showed that both all-cause mortality and death due to hemorrhage were lower in TXA-treated patients than in placebo.[40]

Massive Transfusion Protocols (MTPs) have been shown to save lives among bleeding patients[24,61] and are now standard of care at civilian trauma centers, and these are based on military data and DoD-funded research that prioritize avoidance of crystalloids, use of TXA in appropriate patients, and 1:1:1 ratio of RBCs, plasma, and platelets.

The U.S. Army Medical Research and Materiel Command funded the recent PAMPer trial, which demonstrated a survival benefit from prehospital

	addition of cryoprecipitate independently added to the benefits of TXA in the seriously injured in the battlefield.[96] However, this study also showed higher rates of VTE among soldiers receiving TXA.	administration of plasma in hypotensive blunt trauma patients requiring air medical transport.[47]
Rapid Evacuation and Long-Distance Transport	In 2009, the U.S. military mandated that the prehospital helicopter transport of critically injured combat casualties should be ≤60 min. Median transport time was cut into half, and follow-up data showed significant reductions in total casualty rate and case fatality rate, resulting in hundreds of lives saved.[97] Operation Iraqi Freedom and Operation Enduring Freedom provided new insight into the	The lessons learned regarding the safety, and the survival benefit, of long-distance transport for severely injured patients have important applications to civilians injured in rural areas, where they may be far from the nearest level 1 trauma center.

	rapid movement of critically injured casualties within hours of wounding. Review of the Critical Care Air Transport Team and Joint Theater Trauma Registry databases shows that for severely injured (mean ISS = 23.7) that were evacuated to the Landstuhl Regional Medical Center in Germany, the en route mortality rate was <0.02%.[98]	
Rehabilitation	Lower-extremity injuries account for 60% of all injuries to the U.S. troops in Iraq and Afghanistan, which are mostly due to explosive devices.[99] But unlike previous wars, temporary vascular shunts have been used more widely,[100,101] and early vascular reconstruction has	Complex extremity care in civilian trauma systems has learned a great deal from the more recent military experience with regard to both initial injury management and the needs of longer-term functional recovery.[106]

	being performed more frequently with excellent outcomes.[102,103]
Modern development and implementation of comprehensive rehabilitation strategies[104] and cutting-edge technology in prosthetic limbs[105] to treat the injured service members with complex lower-extremity trauma from combat have resulted in some of the best functional outcomes in the history of warfare.	

At the other end of the spectrum, there is significant work underway at health systems level to better understand which deaths are potentially preventable and how the current organization of trauma delivery systems can be further optimized. In the 2016 report by the National Academies of Science, Engineering, and Medicine (NASEM),[110] "A National Trauma Care System: Integrating Military and Civilian Trauma Systems to Achieve Zero Preventable Deaths," the ACS-COT joined a broad coalition of trauma stakeholders including the National Highway Traffic Safety Administration (NHTSA), the U.S. Department of Defense, NASEM, and the National Institutes of Health to develop a national trauma action plan. The action plan identified existing gaps in our current trauma care systems including regional variation in emergency medical services (EMS) care, mismatch of level 1

and 2 trauma center location and population distribution, and inadequate funding for research to improve care of the injured patient. The NASEM report highlighted the need to develop a national trauma research plan, share innovation between the military and civilian sectors, engage the public through programs such a Stop the Bleed campaign, and empower trauma survivors and their families to be key advocates for advancing trauma care. Ultimately, it will take innovation at the basic science level, the clinical science level, and the health systems level to achieve the goal of "zero preventable deaths" in trauma.

Prehospital and New Advances in Resuscitation

Jason L. Sperry and Christine M. Leeper

Key Points

1. Triage is an active process with the goal of transporting patient to most appropriate trauma center in the shortest time while avoiding over or under triage situations.
2. Prehospital assessment should follow ABCDE (Airway, Breathing, Circulation, Disability and Environment); providers should perform only necessary critical interventions while avoiding delays in transfer to definitive care.
3. Direct pressure and hemostatic dressings can be used for control of hemorrhage; however, large-volume extremity hemorrhage may need to be addressed with placement of a tourniquet.
4. Prehospital fluid resuscitation follows damage control principles of permissive hypotension and whole blood or balanced blood products if available while minimizing crystalloid.
5. Prehospital use of Resuscitative Endovascular Balloon Occlusion of Aorta (REBOA) is not recommended at this time, though its application in hospital settings in the United States and internationally is increasing.

INTRODUCTION

Trauma continues to be the leading cause of death for 1- to 44-year olds and has risen to the overall third leading cause of death for all age groups.[1] The care of the injured patient is a tightly integrated exercise combining the expertise of the prehospital care team and the trauma team once they arrive at the hospital. The likelihood of patient survival is vastly increased by timely transport and proper interventions on arrival to definitive care centers. The care of the injured patient begins immediately following injury. This may be rendered initially by nearby civilian bystanders or a variety of trained first responders. The main goal of a prehospital system is expedient assessment and care for the injured patient, then transportation to the most appropriate hospital for definitive care as quickly and safely as possible. At times the

most appropriate hospital may be the closest, and at others it may be more distant but with the capabilities more suitable to a particular patient. Most commonly, a phone call placed to a 9-1-1 dispatcher activates the emergency medical system (EMS) and quickly allocates resources to the location where help is needed.

PREHOSPITAL CARE

Personnel

Prehospital personnel are comprised of civilians, emergency medical technicians (EMTs), paramedics, firefighters, police, nurses, and less commonly physicians. The Hartford Consensus III placed nonmedical civilians on the forefront of hemorrhage control as a ready force of immediate responders; prompted by this call to action, more than one million civilians to date have received basic training in bleeding control principles to provide immediate care until first responders arrive.[2] There are multiple levels of EMTs whose capabilities can vary slightly by system. In general, the EMT-B or basic level has training capable of providing basic life support (BLS). BLS maneuvers include triage and transport, external hemorrhage control, administration of supplementary oxygen, spine immobilization, cardiopulmonary resuscitation, and application of an automated external defibrillator (AED). Prehospital advanced life support (ALS) was first employed as a "mobile intensive care unit" in 1967.[3] Paramedics require additional training, upward of 1,200 hours, and may administer ALS techniques. In addition to the maneuvers administered by BLS personnel, an ALS unit can typically provide cardiac drugs, pain control, blood pressure management, glucose control, needle decompression of tension pneumothoraxes, and anticonvulsant medication. There is much debate as to whether ALS is superior to BLS in the prehospital setting for injured patients. A recent meta-analysis concluded that ALS provides a survival advantage only to nontrauma patients.[4] However, there may be some benefit to the presence of ALS providers for injured patients who require advanced lifesaving maneuvers in the prehospital environment, even at the expense of prolonged scene time.[5] In certain U.S. cities, a physician medical director of

EMS is available at all times to advise to ground crews and dispatch centers. Some physicians may also respond in person to certain calls as needed. Their role includes providing quality control, education, and approval of drug administration outside of set protocols. Outside of the United States some countries have full-time physicians riding with ambulance crews at all time. While physician presence increases transport time, which may not be beneficial for trauma patients, there is evidence of an increase in survival in patients with acute myocardial infarction and respiratory distress.[6]

Triage

1 Triage is an active process that takes into account multiple factors with the goal of transporting the patient to the most appropriate trauma center in the shortest amount of time. The Centers for Disease Control and Prevention publish guidelines helping to facilitate proper triage of injured patients. These guidelines underwent their most recent update in 2011 and use physiologic, anatomic, and the mechanisms of the injury to guide the triage of the patient.[7] Changes specific to the 2011 update include lowering GCS for the physiologic criteria, broadening the definition of injuries in the anatomic criteria, and addressing the differences in older adult trauma patients relative to young trauma patients. The implementation of these guidelines is key to preventing both under- and overtriage of the acutely injured patient. Undertriage is the practice of sending an acutely injured patient to a lower tier in the trauma system that may lack resources to adequately care for that patient. This leads to prolongation to definitive care for injuries, multiple transfers to identify the correct level of care, and overall worse outcomes for the patient. Overtriage is transferring a patient to a highest-level trauma system when their injuries do not warrant that level of care. This allocates scarce resources to patients who ultimately do not need them, and as such may prevent those who need that resource appropriately from getting it and increases healthcare costs.[8] The development and validation of prehospital prediction models that could translate to user-friendly prehospital applications is an area of active investigation.

A special triage situation occurs when multiple patients are injured. A multicasualty event is where a hospital is able to manage the number of casualties with local resources. The majority of level 1 trauma centers are

able to take care of a small multicasualty event without significant strain on their work environment. A mass-casualty event exists when the numbers, severity, and diversity of injuries overwhelm the local medical resources. Mass-casualty events require coordination at the state and national level, and extensive practice at implementing triage criteria.

Scoop and Run versus Stay and Play

Traditionally, two paradigms that dictate the amount and type of care that patients receive in the prehospital setting are the "Scoop and Run" and the "Stay and Play." The overarching premise of the Scoop and Run technique is to get the injured patient to a facility that can provide definitive care in the shortest period of time. The proponents of this system cite the increasing amount of evidence that prehospital interventions are fraught with complications from both their intervention as well as the resultant delay in arriving at a trauma facility.[9] Stay and Play advocates feel that the early control of life-threatening injuries is considered of critical importance in the management of the injured patient, and initiating therapy for such injuries in the prehospital environment may improve patient survival.[10] The truth to which paradigm is best for the patient most likely lies somewhere in the middle of the two and depends on the resources available. In an urban setting with readily accessible trauma facilities it makes sense to extract the patient and get them to the closest center, performing limited, lifesaving interventions during transport. In a rural environment, where access to a hospital may be delayed by prolonged ground transport time or wait for helicopter transport arrival, it may be necessary to provide care on site allowing for stabilization of the patient's injuries.

SCENE ASSESSMENT AND MANAGEMENT

Airway

Once on scene, it is paramount for the prehospital provider to determine the status of the patient's airway quickly. Evaluating the patient's Glasgow Coma Scale (GCS), chest rise, extent and nature of injuries provides vital insight

into whether or not the patient is and will be able to maintain their airway. Supplemental 2 maneuvers such as suctioning, chin lift/jaw thrust, placement of oropharyngeal airways, and use of bag-mask devices can temporarily restore oxygenation in the acutely injured patient (**Table 20.1**). These maneuvers will usually maintain airway patency for the patient during their transport to definitive care; for those who are unable to do so, advanced airway maneuvers are key to securing a patent airway. Tracheal intubation provides a definitive airway with a cuffed endotracheal tube that will facilitate oxygenation, ventilation, and prevent aspiration. The skills required to successfully intubate are difficult to achieve and even more difficult to maintain, as this is a low frequency event often performed under challenging conditions.[11]

Table 20.1 Prehospital Assessments and Interventions

A	Chin lift/jaw thrust, oropharyngeal airway, nasopharyngeal airway
B	LMA, King tube, surgical airway, needle decompression, chest tube, capnography
C	Tourniquet, needle decompression, permissive hypotension, early blood products
D	C spine immobilization, backboard placement, splinting of extremity fractures
E	Clothing removal, exposure of wounds, warming devices

There is conflicting literature regarding field intubation, with the majority of studies suggesting that prehospital intubation does not improve survival and prolongs time to definitive care.[12,13] The only randomized controlled trial of prehospital intubation versus bag-mask ventilation occurred in 2000 with pediatric patients, which showed that the addition of out-of-hospital

intubation did not improve survival or neurologic outcomes.[14] A meta-analysis evaluating emergency intubation for the acutely ill did not show a benefit for trauma patients in the urban environment.[15] A retrospective review of prehospital intubation versus bag-mask ventilation by Stockinger and McSwain showed no survival advantage to intubation and an increased prehospital time.[11] Moreover, a pediatric cohort from a conflict region showed increased mortality with prehospital intubation after controlling for other factors associated with death.[16] One study that did show a mortality benefit was a retrospective review of blunt trauma patients with severe head injury, who had a statistically significant decrease in mortality when intubated in the field compared to those who were not.[9]

While the majority of situations in the prehospital setting do not require intubation, there are certain scenarios in which it may be prudent to secure an airway. For instance, patients who have evidence of extensive facial trauma with airway compromise and those patients who are apneic due to suspected cervical injury may be appropriate to be intubate in the prehospital setting. The reflexive intubation to "protect" the airway should be avoided, and further randomized studies are required to truly answer the question of who and when to intubate in the prehospital setting.

There are alternative measures to endotracheal intubation that can be taken for those who need to establish an airway: laryngeal mask, Combitube, and King airway all require less training and skill for insertion, though they have not been shown to increase survival. While video-assisted airway insertion devices are commonly utilized in the hospital setting for "difficult" airways and increasingly for standard airways as well, data regarding their use in the prehospital setting is limited. A randomized controlled trial of direct laryngoscopy versus video laryngoscopy in a prehospital cohort failed to show a difference in intubation success rate, tracheal intubation times, number of attempts, or difficulty. Notably, the number of technical problems with the equipment was increased in the video group.[17] As technology advances, the use of video-assisted airway devices may allow for more successful prehospital intubation, though whether this will translate to a survival benefit is unknown at this time.

A surgical cricothyroidotomy (CRIC) can provide an emergency airway in the hands of skilled practitioners. This maneuver requires much training and is utilized infrequently, mainly by personnel in austere environments or after

failed orotracheal intubation efforts. A retrospective review by the Israeli Defense Force showed a 93% success rate with CRIC for patients requiring an emergency airway[18]; a review of the Netherlands Hospital EMS database reported a comparable 94% success rate.[19] A retrospective review of the Department of Defense Trauma Registry reported that CRIC was an infrequent event in combat settings that did not confer a survival advantage over the less technically challenging supraglottic airway in a comparable comparison cohort.[20]

Breathing

Assessment of patient's breathing occurs concurrently with airway assessment. Evaluation of symmetric chest rise, obvious signs of chest trauma, and presence of bilateral breath sounds give the first responder an idea of the patient's status. The presence of a tension pneumothorax is a life-threatening event that may lead to obstructive shock, hemodynamic collapse, and potentially death. Signs of tension pneumothorax may include tracheal deviation, neck vein distention, and cyanosis. Prompt decompression of the thoracic cavity with a needle is necessary to reverse the tension effect. While the traditional landmark has been the midclavicular line, cadaver and computerized tomography evaluations had demonstrated more consistent evacuation of air using the anterior axillary, especially in females.[21] Further management with tube thoracostomy will be addressed once the patient arrives at their receiving facility. Large sucking chest wounds that permit the rapid equilibration of pleural and atmospheric pressure can be rapidly fatal. These wounds prevent the lung from expanding and preclude alveolar ventilation. These large wounds cause hemodynamic collapse rapidly unless an airway is obtained that allows for positive-pressure ventilation. The very rare smaller open sucking chest wounds are amenable to a three-sided dressing that allows for gas to exit from the chest wall defect but prevents gas from entering the chest wall. These can be fashioned in a field expedient manner and function as a temporizing action until definitive therapy with a chest tube can be achieved.

Mismanagement of ventilation in the intubated patient, specifically those with traumatic brain injury (TBI), can result in inadvertent harm. Intentional hyperventilation in the prehospital setting had been previously advocated and

is unfortunately still occasionally practiced. Current recommendations from the Brain Trauma Foundation[22] target normocapnea or $PaCO_2$ between 30 and 39 mm Hg, as overventilation causes acute vasospasm and an overall decrease in the cerebral blood flow in patients with a severe TBI. The resulting cerebral ischemia is one mechanism for secondary brain injury and increased mortality in patients with severe TBI.[23,24] Unintentional hyperventilation is also an issue given that many prehospital personnel ventilate patients via bag-valve devices connected to either a face mask or directly to an endotracheal tube; with bag volumes in excess of 1,200 mL, injudicious ventilation can easily result in hyperventilation. Some have advocated, therefore, for the use of end-tidal CO_2 ($ETCO_2$) monitoring by prehospital providers. The use of $ETCO_2$ as a means for measurement of exhaled CO_2 is the standard found in the operating room and emergency departments; however, its use in the prehospital setting was not commonplace 10 years ago. As technology has advanced, the ease of use and application of $ETCO_2$ monitoring has become more commonplace. $ETCO_2$ was first used as a way to confirm placement of endotracheal tubes in the prehospital setting using colorimetric CO_2 detector.[11] Esophageal intubation rates have been reported as high as 17% to 25% in emergency airway management of nonarrest patients.[25] The use of the colorimetric detector in conjunction with auscultation and symmetric chest rise make the likelihood of esophageal intubation near zero. Silvestri et al.[26] showed that there were no misplaced endotracheal tubes in patients who had continuous $ETCO_2$ monitoring (0/93) whereas 23.5% of misplaced (14/60) prehospital intubation did not use monitoring in the prehospital setting.

While their utility in confirming endotracheal intubation is more clear, $ETCO_2$ monitors are an imperfect device to guide ventilation in the setting of trauma. The relationship between $ETCO_2$ and arterial $PaCO_2$ is complex in the injured patient, as $ETCO_2$ is dependent on metabolism, expired CO_2, and pulmonary perfusion status. In one 2009 study, $ETCO_2$ in prehospital intubations did not correlate to arterial blood gas $PaCO_2$, with patients most likely being underventilated ($PaCO_2$ >40) 80% of the time and severely underventilated ($PaCO_2$ >50) 30% of the time.[27] Therefore, $ETCO_2$ in

injured patients may reflect poor perfusion status rather than hyperventilation and lead providers astray if interpreted in isolation.[23]

Circulation

Prehospital Control of Hemorrhage

3 Evaluation of circulatory status begins with initial evaluation of mental status and inspection for obvious signs of active hemorrhage. Direct pressure and hemostatic dressings can be used for control of hemorrhage; however, large-volume extremity hemorrhage may need to be addressed with placement of a tourniquet. Tourniquet use for injury has documentation as far back as 6 BC in Hindu texts for the treatment of a snakebite.[28] Recent experience in combat environments supports the extension of this historically military practice to the provision of civilian trauma care. In the Vietnam War, surgeons recognized that of the casualties killed in the war, 2,590 lives could have been saved with better prehospital hemorrhage control.[29] Analysis of the casualties of Operation Gothic Serpent, the 1993 battle fought between U.S. forces and the militias in Somalia, showed 7% of fatalities resulted from penetrating extremity trauma and that hemorrhage control in the form of tourniquet use should be more widely adopted.[28] The current conflict in Iraq and Afghanistan provided the strongest data supporting the use of prehospital tourniquets. A prospective study of casualties over a 7-month period in 2006 at a combat hospital in Baghdad showed tourniquet application with the absence of shock was strongly associated with survival, no amputations resulted solely from tourniquet use, and only four nerve palsies at the level of the tourniquet occurred all of which resolved without issue.[29]

Studies have detailed successful civilian application of this concept. Most recently, a multicenter retrospective review of all patients sustaining peripheral vascular injuries admitted to 11 level I trauma centers compared tourniquet and nontourniquet groups. Mortality was 5.2% in the nontourniquet group compared with 3.9% in the tourniquet group, with adjusted odds ratio of survival = 5.86 in tourniquet group. Delayed amputation rates were not significantly different between the two groups.[30] A systematic review in 2018 included eight trauma centers (n = 718) and one national database (n = 2,048) study reporting prehospital tourniquet use. The aggregate data

reported >90% effectiveness of tourniquet, 6% mortality rate, 5.4% amputation rate, 4% extremity compartment syndrome, 3.7% peripheral nerve dysfunction, and 4% wound infection.[31] The overall mortality and limb amputation rate was less than that seen in similar cohorts of military patients. Additional quality research in civilian trauma patient is required to support whether tourniquet use leads to increased survival and limb salvage. In addition to their use in adult combat and civilian trauma, CAT tourniquets have been shown to be effective in preschool and school-age children[32] and are recommended by the Pediatric Trauma Society in the prehospital setting and during the resuscitation of children suffering from exsanguinating hemorrhage from severe extremity trauma.[33]

A final, more fatal, type of hemorrhage is junctional hemorrhage, defined as bleeding from the pelvis, groin, perineum, axilla, and neck. These wounds are seen extensively in the current era of combat as the use of improvised explosive devices (IEDs) has increased. Holcomb et al. reviewed preventable causes of death in U.S. Special Forces Soldiers in 2007 and found that junctional or noncompressible trauma was implicated in 47% of deaths.[34] The junctional tourniquet has shown in healthy volunteers to occlude blood flow to the lower extremity,[35] and requires effectiveness and implementation data prior to widespread utilization in prehospital trauma protocols.

Resuscitation

Once the circulatory status of the patient has been addressed, sites of rapid compressible exsanguination identified and treated, the decision is made for intravenous access and possible use of intravenous fluid. Placement of peripheral intravenous or intraosseus access should be performed only if it does not delay the transport of the patient. In patients without evidence of hemorrhage or in prehospital settings where blood and blood products are not available, numerous choices of fluid are available. However, most fluid options are actually poor choices for resuscitation of injured patients. Normal saline (0.9% sodium chloride) has an average pH of 5.5, with a sodium and chloride concentration of 154 mEq/L. Normal saline is often preferred as a universal solution for prehospital settings as it is “compatible with blood,” contains no potassium, and is cheap to carry; with a low overall

cost and extended shelf life. Lactated Ringer, initially developed to support organs in the lab (because of calcium content) and later championed for treating cholera, has only a slightly better physiologic profile. Lactated Ringer gives the clinician a better average pH of 6.5, with lower sodium (130 mEq/L) and chloride content (109). The optimal fluid, however, is Plasmalyte/Normosol which has an average pH of 7.4 and an electrolyte content that resembles a normal metabolic profile (sodium—140 mEq/L, potassium—5.0 mEq/L, chloride—98 mEq/L, and magnesium—3.0 mEq/L). In addition to its superior profile, Plasmalyte is compatible with all blood products and has been shown in a randomized trial to result in improved acid–base status and less hyperchloremia at 24 hours postinjury.[36]

Prehospital Transfusion Protocols

Resuscitation practice is rapidly evolving based on the imperative that the prehospital setting is the ideal place to begin early resuscitation with blood products. Hemorrhage is the leading cause of preventable death in trauma, responsible for 33% to 56% of prehospital casualties. Trauma-induced coagulopathy is common in severely injured trauma patients, and contributes to morbidity and mortality. Severely injured patients are now receiving blood and blood product transfusion in the prehospital setting to facilitate early hemostatic resuscitation and prevention of coagulopathy complications.

Early studies focused on transfusion of packed red blood cells (RBCs) versus standard practice (crystalloid); the evidence overwhelmingly supports transfusion of RBCs for patients in hemorrhagic shock. Shackelford et al. described a cohort of military combat casualties with traumatic amputation or hemorrhagic shock. In comparing those who received blood product transfusion prehospital (RBCs, plasma, or both) to those who received delayed or no transfusion, patients who received early product transfusion had decreased 24-hour (adjusted HR = 0.26) and 30-day (adjusted HR = 0.39) mortality.[37] Brown et al. conducted a retrospective, case-controlled analysis of patients who received prehospital RBCs (n = 240) against those who did not (n = 480).[38] Those receiving prehospital transfusion had an increased likelihood of 24-hour survival, lower odds of shock, and lower overall 24-hour blood products transfused. A subsequent study from these investigators evaluated over 2,000 blunt trauma patients presenting to care

within 2 hours of injury,[39] comparing those who received RBCs in the prehospital setting (n = 3.5%) to those who did not. Those who received prehospital RBCs had a 95% reduction in the odds of 24-hour mortality, 64% reduction in 30-day mortality, and an 88% reduction in the incidence of trauma-induced coagulopathy. In a multicenter study of over 1,400 injured patients with evidence of shock, patients receiving prehospital RBCs had increased 24-hour and 30-day survival, as well as less coagulopathy on arrival in those patients receiving prehospital RBC transfusions.[40] Subsequently, the Houston group published their aeromedical experience comparing patients who received prehospital plasma and RBC (n = 137) versus those who received crystalloid (n = 1,540). Those who received products had improved acid–base status on hospital admission, decreased use of blood products over 24 hours, and reduced 6-hour mortality in the sickest cohort.[41] In another prehospital study comparing four different resuscitation groups (crystalloid only; PRBC; plasma; and PRBC + plasma), the group receiving plasma and PRBC had the greatest risk-adjusted 30-day mortality benefit.[42]

4 Further interest in prehospital plasma administration resulted in two concurrent trials: PAMPER and COMBAT. Sperry et al. enrolled 501 patients in a multicenter cluster-randomized trial comparing the administration of thawed plasma with standard-care resuscitation during air medical transport. Mortality at 30 days was significantly lower in the plasma group than in the standard-care group, as was median prothrombin time on arrival to the trauma center.[43] In the COMBAT trial, 125 eligible patients in the as-treated analysis dataset were compared, 65 receiving plasma and 60 receiving crystalloid. There was no difference in 28-day mortality, the lack of benefit posited to be due to short transport times and rapid presentation to high-volume, high-quality care centers[44]; a post hoc analysis of these combined datasets did show a significant mortality benefit when transport times were greater than 20 minutes.[45] Further research is focusing on the use of freeze-dried plasma (FDP) to increase the shelf-life in systems and locations where maintaining a supply of fresh frozen plasma is not practical. Early studies indicate that the use of FDP in military combat settings at the point of injury[46] and in prehospital civilian trauma systems[47,48] is feasible and acceptable.

Current transfusion practice emphasizes a balanced transfusion strategy with high ratios of plasma and platelets to packed RBCs that attempts to mimic or "reconstitute" whole blood composition. The foundation for this practice comes from the landmark PROPPR trial, which included patients who received blood transfusion prehospital and showed that more patients resuscitation in the 1:1:1 group versus 1:1:2 group achieved hemostasis and fewer experienced death due to exsanguination by 24 hours.[49] In the last decade, in keeping with the desire to transfuse in 1:1:1 ratios, the pendulum has swung back toward utilizing whole blood as opposed to reassembling it from its component part. Transfusion of cold-stored low titer group O whole blood (LTOWB) as the first resuscitative fluid is now the standard of care in over 70 civilian trauma centers and prehospital settings[50] in the United States. There are theoretical concerns regarding the safety of group O WB administered to non–group O recipients, as hemolysis might occur due to the anti-A and -B that are naturally occurring in all group O WB units. However, studies in both adult and pediatric trauma patients demonstrate an excellent safety profile and no increased risk of hemolysis among the non–group O recipients compared to the group O recipients of WB who are not susceptible to hemolysis following LTOWB transfusion.[51,52] Advantages to whole blood include higher hematocrit, greater platelet and factor concentrations, and less saline and additive solution compared to an equivalent volume of "reconstituted" whole blood (**Table 20.2**). Further, cold stored platelets (1° to 6°C) have better performance in in vitro coagulation testing as compared to room-temperature platelets.[53] Importantly, cold storage also permits a lengthy storage time, and facilitates the utilization of a platelet-containing blood product in prehospital settings where maintenance of conventional room-temperature platelets would not be feasible.[50] Further, LTOWB is a single product that can be transfused more efficiently than multiple component products, as evidenced by the significantly faster time to transfusion of at least one unit of RBCs, plasma, and platelets among pediatric trauma patients who received LTOWB versus conventional components (median = 15 minutes vs. 303 minutes, respectively).[51] In a single-center comparison of LTOWB versus component therapy in adult trauma patients, LTOWB was associated with a 53% reduction in post-ED blood product transfusion and twofold increase in likelihood of 28-day survival compared to component therapy after controlling for age, injury

severity, and prehospital physiology.[54] Patients receiving fewer transfusions are therefore exposed to fewer donors overall, decreasing the associated inherent risks. Further study is required to determine if whole blood transfusion will improve other patient outcomes.

Table 20.2 Components of Whole Blood versus Reconstituted Component Products

	Whole Blood	Components
	1 unit whole blood	1 unit red blood cells 1 unit plasma 1 pack platelets 1 unit cryoprecipitate
Product volume (mL)	570	675
Hematocrit (%)	38–50	29
Platelet count	150,000–400,000	88,000
Factor activity (%)	100	65
Fibrinogen (mg)	1,000	750

Permissive Hypotension

The concept of permissive hypotension involves keeping the blood pressure low enough to avoid exsanguination while maintaining perfusion of end organs.[55] It is an integral part of Damage Control Resuscitation protocols that dates back to World War I. The work of Walter Cannon and John Fraser while serving with the Harvard Medical Unit in France involved the observation that artificial elevations in blood pressure may overcome the clot preventing further hemorrhage, and the patient will lose sorely needed blood.[56] In 1994 Bickell et al. presented a randomized prospective control trial showing delayed fluid resuscitation in adults with penetrating torso injuries lead to greater survival and overall shorter hospital length of stay.[57] These results have been repeated in subsequent studies showing no benefit to targeting physiologic or supernormal blood pressures in either blunt or

penetrating trauma. A multicenter, randomized study[58] randomized hypotensive blunt trauma patients to receive small boluses of fluid (250 mL) if they had no radial pulse or a systolic blood pressure lower than 70 mm Hg or to receive a 2-L fluid bolus and additional fluid needed to maintain a systolic of 110 mm Hg or greater. The permissive hypotension group received 1 L less of fluid, had less deaths (5% vs. 15%) at 24 hours after admission, and among patients with blunt abdominal trauma 24-hour mortality was 3% versus 18%, all statistically significant. There was, however, no difference in mortality among patients with penetrating trauma. This data suggests that controlled resuscitation in the out-of-hospital setting may offer an early survival advantage to the blunt trauma patient.

This strategy of permissive hypotension remains controversial in patients with severe traumatic brain injury in light of well-described evidence on secondary brain injury and poor outcomes due to even a single episode of prehospital hypotension. Further confusion is generated for prehospital providers as recommendations for permissive hypotension in trauma literature on damage control resuscitation[59] directly contradict the Advanced Trauma Life Support guidelines that advocate for early administration of 2-L crystalloid bolus for those patients manifesting signs of shock. Additional studies are necessary to clarify this issue and at which level fluid administration may be paused; however, the general paradigm prehospital trauma providers should follow includes minimizing intravenous fluids, tolerating systolic blood pressures in the 90 mm Hg range, and not resuscitating to supernormal values with crystalloids. Importantly, children do not tolerate hypotension. They have the physiologic reserve to maintain normotension to the verge of circulatory collapse; hypotension therefore is a sign that a child is in extremis and should be treated with expedient fluid resuscitation, not observation.

CONTROVERSIES

Resuscitative Endovascular Balloon Occlusion of Aorta

5 Resuscitative endovascular balloon occlusion of aorta (REBOA) is a balloon placed via the femoral artery to occlude the aorta and prevent life-threatening hemorrhage. While the technology is new, the concept was described in the journal Surgery in 1954. While initially popularized as a substitute for resuscitative thoracotomy, it is probably best suited for temporizing pelvic hemorrhage (before the patient has lost pulses) as a bridge to embolization in interventional radiology, or as an adjunct in the operating room.[60] High-volume centers who utilize REBOA in a protocolized fashion report feasibility, faster time to aortic occlusion, fewer early deaths, and improved overall survival as compared with resuscitative thoracotomy (37.5% vs. 9.7%).[61,62] The Japanese have published a retrospective review of their experience with the safety and feasibility of REBOA for trauma in 2014.[63] Their data show that REBOA was feasible for trauma resuscitation, however, there was an increased risk of lower limb ischemia that occurred in 12.5% of their patients. While the majority of U.S. trauma centers do not perform REBOA placement, and those that do perform only a few each year (median = 6),[64] it is feasible that continued training in endovascular skills may lead to greater implementation of this skill.

Safety concerns with REBOA include the following: (1) Prolonged aortic occlusion may lead to spinal cord ischemia; (2) ischemia reperfusion injury can lead to acute kidney injury and multisystem organ failure; (3) femoral access complications (dissection, hematoma, pseudoaneurysm, etc.) may result in limb loss or need for complex vascular repair/reconstruction; (4) balloon rupture or overinflation can result in rupture or thrombosis of aorta or iliac vessels; (5) Prolonged attempts to complete the procedure, in particular in obtaining vascular access, can delay definitive hemorrhage control.[65] Measures to reduce the risks and maximize success of REBOA include adequate training and preparedness of a skilled multidisciplinary team, having the resources for urgent operative or catheter-based hemostasis following REBOA placement as soon as possible, using a smaller-diameter sheath devices (<8 Fr), limiting aortic occlusion time, and attentive assessment of lower extremity perfusion.[64]

There have been case reports of REBOA placement by physicians in prehospital settings outside of the United States. However, prehospital placement of REBOA is not recommended in the United States at this time due to lack of clear “safe” duration of aortic occlusion, difficulty defining

reliable and appropriate patient selection criteria, lack of safety data in prehospital settings, and potential to delay transport to definitive care.

LTOWB Rh-Positive Transfusion in Children and Women of Childbearing Potential

Concerns regarding the transfusion of Rh(D)-positive whole blood to Rh(D)-negative children and women of child-bearing potential (WCP) are sometimes raised as a barrier to the transfusion of whole blood to these populations in emergencies. The risk in this scenario is that a woman who is Rh(D) negative will be exposed to Rh(D)-positive RBCs in the transfusion of whole blood and could become alloimmunized to Rh antigen. If she goes on to carry a Rh(D)-positive fetus, maternal anti-D antibodies would cross the placenta, and bind and destroy fetal RBCs. This hemolytic disease of fetus and newborn (HDFN), if untreated, may cause death or significant developmental neurologic morbidity in the child.

One strategy to avoid this would be transfusion of Group O Rh(D)-negative whole blood, which is the practice in some pediatric protocols currently. However, this is an incredibly rare product and is not available in quantities sufficient to support all whole blood programs. Another strategy is recognizing that the risk of demise of a future fetus as a result of receiving Rh(D)-positive whole blood is 0.3% in adult women, and even lower in children due to decreased alloimmunization rates after exposure to Rh antigen.[66] This number is small compared to the lifesaving benefits of early blood product administration in a bleeding emergency. Further, with modern medicine, severe HDFN is much less common with timely diagnosis and treatment.

Rapid Sequence Intubation versus Non-RSI

While standard of care in the inpatient setting, the use of rapid sequence intubation (RSI) in the prehospital setting is debated among experts with published data to both support and refute the practice. The drugs that are used for RSI are highly variable and include combinations of the following: succinylcholine, rocuronium, vecuronium, midazolam, diazepam, lidocaine,

ketamine, and etomidate. Many argue that the complications that are associated with RSI, including the consequences of multiple failed intubation attempts, unnecessary exposure of patients to dangerous procedure, and complications of the medications do not value the implementation of RSI in the prehospital setting. A 2005 paper published on the use of RSI in the out-of-hospital setting was unable to predict which patients had severe TBI and over half the patients experienced a desaturation during the RSI procedure, while only one-quarter of they were hypoxic before RSI.[67] A further study from the United Kingdom showed an incidence of 18.3% for hypoxemia during prehospital RSI and 13% developed hypotension lower than pre-RSI blood pressures. This paper attributes its lower incidence of hypoxemia and hypotension to the fact that in the United Kingdom board–certified physicians preform all the prehospital RSI and intubations, while in the San Diego paper the entire procedure was carried out by EMTs. Using a propensity-adjusted model, investigators showed no statistical difference in mortality between prehospital intubations with and without RSI. Further randomized, prospective trials are necessary to prove a benefit to prehospital RSI.

CONCLUSION

Prehospital trauma care is a constantly evolving field. Much of our advances from recent military conflicts are being rapidly implemented in the civilian prehospital setting. Further research and developments are necessary to continue the previous success seen in saving the critically injured trauma patient.

Head Injuries

Jacob R. Joseph, Krishna Rajajee, and Krishnan ("Raghu") Raghavendran

Key Points

1. Traumatic brain injury accounts for a significant mortality and morbidity worldwide.
2. Factors that worsen primary brain insult such as hypoxia and hypotension should be aggressively treated.
3. A noncontrast computed tomography (CT) is the preferred imaging modality in any trauma patient with suspected traumatic brain injury (TBI).
4. Management goals for treatment of severe TBI include ongoing resuscitation with priority for maintenance of airway, breathing, and circulation.
5. We recommend the use of invasive intracranial pressure (ICP) monitoring in all patients with severe TBI.
6. A tiered approach for the management of elevated ICP is recommended.
7. Prompt surgical intervention should be performed in patients with large mass lesions and with refractory medical management of elevated ICP.

INTRODUCTION

1 In 2013, it was estimated that about 973 million people sustained injuries that warranted health care and injury accounted for 4.8 million deaths.[1] It is estimated that about 16,000 people die from injuries every day. Eighty-five percent of all traumatic injuries occur in developing countries, and trauma is the leading cause of mortality in the 5 to 40 age group, worldwide. Even in high-income countries, unintentional injuries, self-inflected injuries and injuries related to interpersonal violence account for the majority of deaths in the 15 to 45 age group.[1] The additional burden of the sequelae from trauma with significant morbidities account for a very large part of the disability spectrum. There are major economic effects of trauma. In the United States, trauma accounts for a substantial burden. Estimates from the year 2005 suggest that mortality from unintentional injuries resulted in $1,374,873,000 in medical costs. The economic burden of disability for the same year is much higher at $82,942,825,000. Economic effects in developing countries are dramatic; India forfeits 3% of annual GDP to accidents. Additionally, major disability imparts tremendous societal and economic burdens.

Craniocerebral injuries account for the majority of deaths following trauma across the world including 30% of the deaths in the United States. Traumatic brain injury (TBI) is also the leading cause of death in the military setting. Additionally, they represent the leading cause for disability in the United States and the world. In the current chapter we will discuss the epidemiology, clinical assessment, treatment paradigms, and prognostic elements associated with head injuries and in particular TBI.

EPIDEMIOLOGY

Although TBI has traditionally been a disease of the young, its epidemiology is shifting toward an elderly population due to falls and the wider use of anticoagulation. The TBI-related hospitalization as a result of motor vehicle crashes in the younger population gradually declined till 2007. However, every day about 155 patients die in the United States from TBI.[2] This was accompanied by an increase in hospitalizations for TBI in elderly population as a result of falls. In fact, fall-related TBI in the elderly has

disproportionately increased by 54% in the last decade.[2] Patients in this category tend to do poorly due to additional comorbidities, anticoagulant therapy for other conditions and lesser neuroplasticity.

Additionally, there has been an increase in the incidence of intentional injuries that include self-inflicted and interpersonal violence. Data reported from the United Nations Office on Drugs and Crime (UNODC) suggest that while the incidence of homicide is decreasing in Asia and Europe, it is increasing in South America and Eastern and Southern Africa.[3] The proportion of TBI secondary to violence has proportionally risen accounting for 7% to 10% of TBI.[1] Self-harm is the second leading cause of death from injuries including TBI and the global trend suggests an uptick, particularly observed during the recent global economic downturn. Other risk factors that account for increased incidence of TBI include lower socioeconomic status, the use of alcohol and drugs, as well as the presence of neurologic and neuropsychiatric disorders.[4] In adolescents, sports-related injuries account for a substantial proportion of TBI.[5]

Though most of the clinical diagnostic and treatment paradigms are relevant for moderate and severe TBI, a notable inclusion would be the epidemiologic factors of mild TBI including concussion and persistent postconcussive states. It is estimated that between 70% and 90% of hospital admissions fall into the category of mild TBI (Glasgow Coma Scale [GCS] 13 to 15). This condition has gone through varying definitions. A recently concluded WHO task force has changed the guidelines to include confusion and disorientation instead of altered mental status in addition to the presence of focal signs, seizure, and intracranial lesion that do not require any surgical intervention. Moreover, the WHO definition allows for the GCS of 13 to 15 to be estimated at later time points beyond 30 minutes. Overall, mild TBI continues to be a problem with varying diagnostic elements and definitions. However, there has been an emerging body of evidence to indicate that neuropsychological evaluations and targeted interventions may help recovery from mild TBI.[6]

CLASSIFICATION

TBI is a heterogeneous disease. It can vary from physiologic disturbances in the brain to significant macroscopic anatomic alterations in the brain that lead to loss of brain function and sometimes death and disability. Though there are multiple ways to characterize the nature of this disease (etiology, pathology, severity, and prognosis), one must take into consideration the treating bedside clinician into account. For this reason, a scoring system that is simple, easy to estimate, and reproducible is likely to be of most help. Important other considerations include nature of trauma (e.g., blunt vs. penetrating injuries, blast injury) that may affect the type and severity of the pathologic insult on the brain. Finally, the importance of extracranial injuries in a multisystem trauma cannot be overemphasized. These injuries are present in about 35% of trauma patients[7] and additional systemic hypotension from blood loss and lactic acidosis combined with the presence of hypoxia have been identified as important potential reasons for deterioration of secondary brain injury.

Clinical Scoring System

Using the GCS, TBI has traditionally been classified using injury severity scores. This is the most commonly used across most emergency departments and ICU in the world. It includes three separate components: eye opening, motor score, and a verbal score (**Table 21.1**). A GCS of 13 to 15 is considered mild injury, 9 to 12 is considered moderate injury, and 8 or less is considered severe TBI. GCS is widely followed mainly because of its simplicity. However, it has also been recognized for its reproducibility and ability to prognosticate the severity of the injury. Because of these factors, GCS is recognized as the single most important assessment for an injured patient with suspected TBI. It has been universally adapted by the bedside clinicians, prehospital providers, and plans for specific training of the GCS have been provided by the brain trauma foundation. While it is considered a single score, the best way to provide the scores is by each of the separate components. As an example, a patient with a GCS of 8 is better described as E2V3M3. The primary reason behind this practice is that the motor score has been recognized as the single most important portion of the score in terms of severity and prognosis, particularly with severe TBI. The presence of an endotracheal tube obviates the verbal score. Other limiting factors for GCS

include medical sedation, neuromuscular paralysis, and intoxication with drugs and alcohol. These confounding issues are often particularly prominent in patients with a low GCS.[8] On the other hand, the eye opening and verbal responses appear to be more helpful in the characterization of mild TBI. GCS has also been applied to describe conscious states other than TBI and has found broad application in the ICUs for comparative assessment across time.

Table 21.1 Glasgow Coma Scale

Response	Score
Eye Opening	
No eye opening	1
To pain	2
To speech	3
Spontaneously	4
Best Verbal Response	
None	1
Incomprehensible sounds	2
Inappropriate words	3
Patient confused	4
Patient oriented	5
Best Motor Response	
None	1
Extensor response to painful stimulus	2
Flexion to painful stimulus	3
Withdraws from pain	4
Localizes to pain stimulus	5
Obeys commands	6

There exist other scoring systems. For example, the Full Outline of UnResponsiveness (FOUR) score has been developed mainly by including a brainstem examination.[9] However, this score is more complicated to perform

particularly by nonneurologists and therefore has not found broad applicability, like the GCS.

Neuroimaging Scales

A detailed discussion of the radiologic tools for diagnosis is described under the section of radiologic assessment. For all practical purpose, a computed tomography (CT) scan remains the cornerstone for early diagnosis and establishing guidelines for therapy in patients with TBI. Based on the CT assessments, two different scales are currently in use. The Marshall scale uses CT findings to classify injuries in six different categories based on the presence of cisterns, lesion, and midline shift (**Table 21.2**).[10] There are multiple studies which have shown a clear increase in mortality with increasing severity by the Marshall grading system. However, it does not describe traumatic subarachnoid hemorrhage, does not characterize the type of lesion (such as epidural/subdural), and does not characterize the extent of compression of the cisterns.

The Rotterdam scale is a more recent CT-based classification developed to overcome the limitations of the Marshall scale (**Table 21.3**). It includes the presence of subarachnoid hemorrhage (SAH), presence or absence of epidural lesion, and adds a category for compression of cisterns. Though it has shown promising early results,[11] its applicability remains subject to a broader validation.

PATHOPHYSIOLOGY OF TBI

The pathophysiology of brain injury is classified into primary and secondary brain injuries. The primary brain injury occurs at the time of impact and mainly involves disruption of the brain parenchyma along with the blood vessels. Secondary injury is mainly related to additional factors such as hypotension, hypoxia, effects of intracranial pressure (ICP) elevation, and other biochemical factors that have the ability to potentiate the primary structural damage. The major tenets of treatment of TBI are predicated on the fact that mitigation of the secondary insults has the potential to reduce the overall effect of the injury on the brain. While surgery may be needed for a

very small number of primary brain injuries, for the vast majority of patients, the identification, prevention, and treatment remain the mainstay for amelioration of secondary brain injury through appropriate neurologic critical care.

Table 21.2 Marshall Classification for Radiologic Assessment of TBI

Diffuse Injury I (no visible pathology) ▪ No visible intracranial pathology
Diffuse Injury II ▪ Midline shift of 0–5 mm ▪ Basal cisterns remain visible ▪ No high or mixed density lesions >25 cm^3
Diffuse Injury III (swelling) ▪ Midline shift of 0–5 mm ▪ Basal cisterns compressed or completely effaced ▪ No high or mixed density lesions >25 cm^3
Diffuse Injury IV (shift) ▪ Midline shift >5 mm ▪ No high or mixed density lesions >25 cm^3
Evacuated Mass Lesion V ▪ Any lesion evacuated surgically
Nonevacuated Mass Lesion VI ▪ High or mixed density lesions >25 cm^3 ▪ Not surgically evacuated

From Marshall LF, Marshall SB, Klauber MR, et al. The diagnosis of head injury requires a classification based on computed axial tomography. *J Neurotrauma* 1992;9 Suppl 1:S287–S292.

Primary Brain Injury

Mechanisms of direct trauma to the brain include direct impact, movement of the brain within the skull producing impact with the inner table (coup and

contrecoup injuries). As an example, direct frontal impact has the potential to produce frontal lobe injuries whereas the contrecoup mechanism could result in the injury to the occipital lobe. Other impact forces that cause primary brain injury are forces associated with rapid acceleration and deceleration, typically sustained in a high-speed motor vehicular accident or fall from a height. Penetrating bullet wounds with cavitational effects on the brain parenchyma are particularly devastating. Bullet wounds that are bihemispheric are associated with significant mortality and early herniation. Injury encountered around IED explosions mainly involves blast waves.[12,13] These waves have the potential to cause serious injury and presence of a helmet does not adequately protect the brain from acoustic injuries. Through these varied mechanisms, external energy transfer results in serious injuries to the brain parenchyma, white and gray matter neurons in addition to vascular injury, and disruption of the blood–brain barrier. One particular type of injury, diffuse axonal injury (DAI) is thought to be related to rotational forces inside the cranium resulting in disruption of the white matter often described as gray–white matter dysjunction.[14] Magnetic resonance imaging (MRI; in particular diffusion tensor imaging) is more sensitive than CT for detecting DAI.[15] Rotational and torsion injuries particularly at the site of the brain stem (fixed portion) can be devastating.

Table 21.3 Rotterdam Scale for Radiologic Assessment of TBI

Basal Cisterns ▪ 0: normal ▪ 1: compressed ▪ 2: absent
Midline Shift ▪ 0: no shift or ≤5 mm ▪ 1: shift >5 mm
Epidural Mass Lesion ▪ 0: present ▪ 1: absent
Intraventricular Blood or Traumatic SAH ▪ 0: absent ▪ 1: present

From Maas AI, Hukkelhoven CW, Marshall LF, et al. Prediction of outcome in traumatic brain injury with computed tomographic characteristics: A comparison between the computed tomographic classification and combinations of computed tomographic predictors. *Neurosurgery* 2005;57(6):1173–1182.

Cerebral contusions are the most commonly observed injury in TBI patients and occur as a result of direct impact as well as acceleration/deceleration injuries. They are most commonly seen in the basal frontal and temporal areas. Direct trauma-induced disruption of the blood vessels or the coalescence of cerebral contusions may result in an intraparenchymal hematoma. Vascular trauma may also result in the development of pseudo or true aneurysms of the cerebral vasculature with immediate or delayed consequences.

Extra-axial hematomas are defined as those occurring outside the substance of the brain and within the layers of the covering dura. They include epidural, subdural, and subarachnoid hemorrhage. A typical description of the kinematics of epidural hematoma is described as a glancing blow to the side of the head resulting in a temporal fracture and bleeding from the branches of the middle meningeal artery. They tend to be

lenticular in shape and considering there is no underlying brain parenchymal injury, have a very good prognosis with timely care.[11] On the other hand, subdural hematomas (SDHs) result from injury to the bridging veins of the cerebral cortex. They are particularly common in older patients who suffer minimal trauma and patients with cerebral atrophy with increased space between the brain and the dura. They are typically crescent shaped and are often associated with underlying cerebral injury. SAH can occur with disruption of pial vessels. They commonly occur in the sylvian fissures and interpeduncular cisterns. The distribution of posttraumatic SAH is different from SAH related to a ruptured cerebral aneurysm. The distribution pattern should lead the clinician to investigate the possibility of a ruptured aneurysm that result in loss of consciousness and subsequent motor vehicular crash. On the other hand, intraventricular hemorrhage occurs from injury to the subependymal veins, or by direct extension from adjacent intraparenchymal or subarachnoid hemorrhage.

Secondary Brain Injury

Though the cellular processes involved with secondary injury to the brain are complex and include mitochondrial dysfunction, neuronal apoptosis, and secondary ischemic insults, it is important to discuss the remediable causes that have been identified 2 to significantly impact the injured brain. Examples include hypotension and hypoxia (which decrease substrate delivery of oxygen and glucose to injured brain), fever and seizures (which may further increase metabolic demand), osmotic changes, increased ICP (ischemic insult), and hyperglycemia (immune modulation).[16]

However, a critical aspect of ameliorating secondary brain injury after TBI is the avoidance of secondary brain insults, which would otherwise be well tolerated but can exacerbate neuronal injury in cells made vulnerable by the initial TBI.

Hypotension

Systemic hypotension has long been recognized as a factor that determines the impact on the evolution of secondary brain injury and thereby affects mortality. In a meta-analysis, hypoxia (PaO_2 <60 mm Hg) and hypotension

(systolic blood pressure [BP] <90 mm Hg) were present in 50% and 30% of patients, respectively, and were associated with a higher likelihood of a poor outcome: hypoxia (odds ratio [OR] 2.14); hypotension (OR 2.67).[17] In a more recent study, using balanced controls of patients with severe TBI, a mean arterial pressure (MAP) of less than 65 mm Hg at presentation was associated with a fourfold increase in mortality.[18] In fact, a single episode of hypotension has been linked to adverse outcomes. Episodes of hypotension can be particularly devastating in patients with severe TBI and elevated ICP as discussed in the next section, the impact of maintaining the cerebral perfusion pressure (CPP) is one of the mainstays in the management of severe TBI. For all these reasons, appropriate resuscitation and maintenance of MAP over 65 remain the cornerstone of therapeutic strategies in TBI.

Hypoxia

It has been known for quite some time that neurons in particular are highly sensitive to hypoxia. Multisystem trauma patients are particularly prone to systemic hypoxia in view of high incidence of aspiration-induced lung injury, lung contusions, and rib fractures with associated atelectasis. Additionally, the therapeutic measures including crystalloid administration, blood transfusion, and particularly administration of FFP have been all linked to respiratory failure and ARDS. Moreover, patients particularly with severe TBI and associated reduction in the level of consciousness often are unable to protect their airway and thereby become candidates for endotracheal intubation and mechanical ventilation. Though these respiratory interventions are easily accomplished in a well-equipped and trained emergency department, such an undertaking in the field can be challenging. In a large study of moderate and severe TBI patients in the prehospital setting, the authors concluded that endotracheal intubation is an independent risk factor for increased mortality.[19] However, subsequent studies have established that the experience of the paramedics at the scene and intubations performed in the hospital settings can be achieved safely.[20,21] Additional work by different groups has identified as oxygen saturation less than 90% as an independent risk factor for mortality.[22] The current guidelines established by the BTF suggest maintenance of oxygenation as an important principle in the management of TBI.[23] As in any critical illness, the threshold of

administration of blood transfusion has been consistently lowered to hemoglobin of 7 g/dL. It is currently understood that critical illness is associated with deficits in oxygen uptake at the tissue level and merely raising the concentration of hemoglobin is not effective, considering the adverse effects of blood transfusion with immunologic alterations and cardiac overload.

Intracranial Hypertension and Cerebral Autoregulation

The Monroe–Kellie doctrine simply states that the total volume of contents remains constant within the skull that is rigid and nonexpansile. The contents of the cranial cavity include the brain, the vasculature, and the CSF. Therefore, the injured brain tissue and volume increase have to occur at the cost of reduction in other components, which typically involve compression of the venous reservoir and the CSF. However, once a threshold of displacement of the venous system and CSF is reached, the ICP begins to increase.

The CPP is clinically defined as the difference between MAP and the ICP. It is important to understand the concept of cerebral autoregulation. The precapillary venules have the regulatory ability to undergo vasoconstriction and dilatation. This response is mainly controlled by the MAP. Through autoregulation, the cerebral vasculature, particularly the venules maintains an adequate cerebral blood flow (CBF) across a wide range (50 to 150 mm Hg) of MAP (**Fig. 21.1**). There appears to be a direct correlation between the degree of brain injury and loss of autoregulation. Cerebral autoregulation is disrupted in approximately one-third of patients with severe TBI.[24,25] In these patients, a rise in MAP can lead to elevated ICP due to increased cerebral vasodilatation, thereby increasing the cerebral blood volume. In such patients with the loss of autoregulation, decreases in the MAP lead to hypoperfusion and therefore ischemia. A goal CPP of 60 to 70 mm Hg is recommended for all patients with moderate and severe TBI. However, every attempt should be made in addressing the factors leading to increased ICP prior to the institution of vasopressors to elevate the MAP. Numerous studies have shown that these strategies are associated with improved survival and favorable neurologic outcomes.[26] Though studies using a higher target of CPP

were associated with increased survival, a routine use of these maneuvers are not recommended based on higher incidence of ARDS.[27]

The effects of elevated ICP, particularly when persistent could lead to herniation of the brain. Herniation occurs across compartments with incomplete barriers. Typical sites of herniation include the transtentorial, across the falx cerebri, and through the foramen magnum. In addition to the compression of the brain, herniation compresses the cerebral vasculature leading to ischemic insults.

Hyperglycemia and Hypoglycemia

Over the last decade, there has been a raging controversy on the best management practice for glycemic control. While this is true for any critical illness including moderate and severe TBI, the pendulum seems to have shifted to a target blood glucose of 140 to 180. Intensive insulin therapy targeting a blood glucose of 80 to 110 is not regularly practiced as the benefits of tight glycemic control is offset by a higher incidence of hypoglycemia. Hypoglycemia can be particularly ominous in TBI patients as they have altered mental status and the symptoms may not be easily recognized. Both hyper- and hypoglycemia are associated with worsened outcome in severe TBI.[28,29] Hyperglycemia could lead to aggravation of secondary brain injury. Though the cellular mechanisms of hyperglycemia-induced cerebral injury are unclear, the possibilities include free radical generation with oxygen scavenging and alteration of the blood–brain barrier.

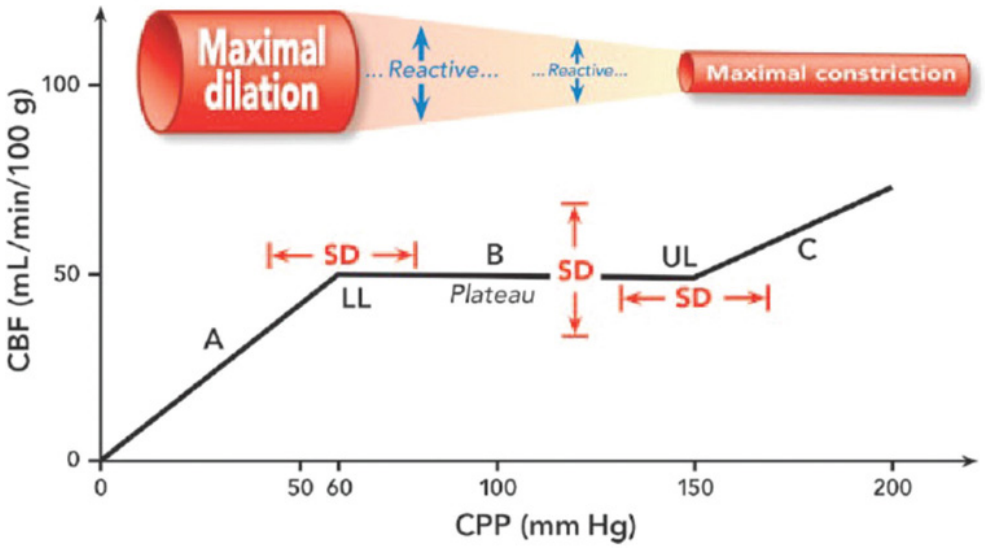

Figure 21.1 Cerebral autoregulation depicted in a graph with cerebral blood flow (CBF) in y axis and cerebral perfusion pressure (CPP) in x axis. Typically the autoregulation is maintained at CPP of 50 to 150 mm Hg. Cerebral vascular reactivity is additionally illustrated. (Adapted from Meng L, Gelb AW. Regulation of cerebral autoregulation by carbon dioxide. *Anesthesiology* 2015;122:196–205.)

Coagulopathy

Another potential reason for worsening of the primary insult is the effect of bleeding associated with coagulopathy. It is estimated that about one-third of patients with severe TBI develop a coagulopathy. The presence of coagulopathy, either from a primary neurologic injury or from blood loss and multivisceral trauma, are both associated with worsening of the neurologic outcomes and death.[30,31] It is equally important to recognize that patients with TBI with existing medical conditions placed on warfarin, aspirin, and antiplatelet agents have the potential of significant expansion of bleeding.

Other factors that have been shown to have the potential to increase brain injury include aggressive resuscitation with sodium free containing fluids and elevated intrathoracic and intra-abdominal pressure. Conditions such as fever and seizure activity that lead to increased metabolic demands on the brain add further insult to the injury as well.

Molecular and Cellular Mechanisms in TBI

The complexity of the brain combined with the heterogeneous nature of TBI makes it hard for one to characterize the precise nature of the biochemical

and cellular changes that occur in the brain following injury. It is well understood that neuroinflammation and neurodegeneration contribute significantly to the neurologic disability seen in patients with TBI. Though the acute traumatic event involves tissue and vascular disruption, it is important to recognize that there is abundant activation of glial cells, generation of inflammatory cytokines, and neutrophil recruitment. The microglia appear to be the major resident immune cell in the brain. Additional changes that have been documented acutely include alteration of calcium channels and sensors, apoptotic cell death, and generation of reactive oxygen species further increasing injury and inflammation. There is broad agreement about disruption of the blood–brain barrier that can lead to protein deposition in the extravascular space and this process can continue for prolonged periods of time. Persistent and chronic changes associated with microglial inflammation and posttraumatic neurodegeneration contribute to the long-term disability. Regardless of the better understanding of the pathophysiology of the brain, modulation of these processes has yet to translate into meaningful clinical therapeutic interventions.

CLINICAL ASSESSMENT

Assessment of a TBI patient in the emergency department should be run along the guidelines and principles established by the Advanced Trauma Life Support (ATLS). These are specific with respect to airway, breathing, and circulation, which take precedence over other areas enlisted under disability. Ongoing resuscitation along with securing large-bore IV lines, obtaining specific laboratory samples including an arterial blood gas and chest x-ray, are performed concurrently.

The importance of identification and treatment of associated injuries in a multisystem trauma patient cannot be overemphasized. Care must be taken to stop bleeding from external sources by application of direct pressure or a tourniquet. Identification of torso hemorrhage sources such as blunt injury to the spleen or pelvic fractures may require concurrent surgery or evaluation in a hybrid suite. Injuries that cause hypotension and hypoxia in patients with TBI have to be emergently addressed and additional secondary brain insults mitigated.

RADIOLOGIC ASSESSMENT

A noncontrast CT is the preferred imaging modality in any trauma patient with suspected TBI. This test should be done as soon as possible. The presence of hemodynamic instability can be an impediment with timely imaging by CT can. Focused assessment by sonography in trauma is a very valuable test in such situations. Combined with a chest x-ray, a negative FAST examination can provide guidance for further management in patients with suspected TBI in ruling out major thoracoabdominal hemorrhage as a cause of hypotension. A quick CT of the head and C-spine can be performed in such patients. On the other hand, a patient with hemodynamic instability with a positive FAST with blood in the abdomen with a GCS of 15 can be taken for an emergent laparotomy without any additional radiologic assessment of the head. The CT in addition could detect skull fractures, intracranial hematomas, and presence of cerebral edema. In addition to a GCS of ≤14, a full list of indications for obtaining CT scans and other radiologic techniques in patients with mild TBI is outlined in **Table 21.4**.

A follow-up repeat CT scanning should be performed with clinical deterioration. A repeat imaging in 6 hours is also indicated in patients with an extra-axial hematoma or intracerebral hematoma with a propensity to expand, such as seen in patients on anticoagulation. Additional CT scans may also be indicated in patients with a GCS <9,[32] particularly in patients where an awake examination cannot be safely performed. Evolution of CT findings is common and is likely to change the treatment strategy in a significant proportion of patients with severe TBI. In the absence of clinical deterioration contrast extravasation within the brain parenchyma may predict a higher risk of hemorrhage progression.[33]

The findings on the CT scan that carry the most ominous signs include cisternal compression with a midline shift of >5 mm. These signs are indicative of significant ICP elevation. Additional signs of elevated ICP that may require immediate intervention include severe cerebral edema and loss of gray–white matter junction. Epidural hematomas are typically distributed over the anterior and posterior portions of the temporoparietal area. They are lenticular in shape of mixed or high density depending on the age of presentation (**Fig. 21.2**). SDHs are crescentic lesions distributed over the convexity of the brain as they occur frequently from disruption of the bridging

cortical veins (Fig. 21.3). The incidence of underlying brain injury in the SDHs is much higher than with epidural hematomas. The underlying brain injury in these patients, and not the bleeding, correlates with neurologic outcomes and the degree of cerebral edema. Intracerebral hematomas are common following trauma and are seen as high-density lesions in the brain parenchyma (Fig. 21.4). Their distribution is related to the site of impact on the skull and has the potential to have a blossoming effect over time. Close observation and repeat imaging are considered as part of clinical guidelines in their management.

Table 21.4 Indications for Obtaining CT Scans in Mild TBI

High Risk for Neurosurgical Intervention
GCS less than 15 at 2 hrs after injury
Suspected open or depressed skull fracture
Any sign of basilar skull fracture (raccoon eyes, CSF otorrhea or rhinorrhea, hemotympanum)
Vomiting (more than 2 episodes)
Age more than 65 yrs
Use of anticoagulants
Moderate Risk of Brain Injury on CT
LOC for more than 5 min
Amnesia before impact (more than 30 min)
Dangerous mechanism (pedestrian vs. motor vehicle, fall more than 3 ft or 5 stairs)

From Steill IG, Wells GA, Vandemheen K, et al. Canadian CT head rule for minor head injury. *Lancet* 2001;357(9266):1391–1396.

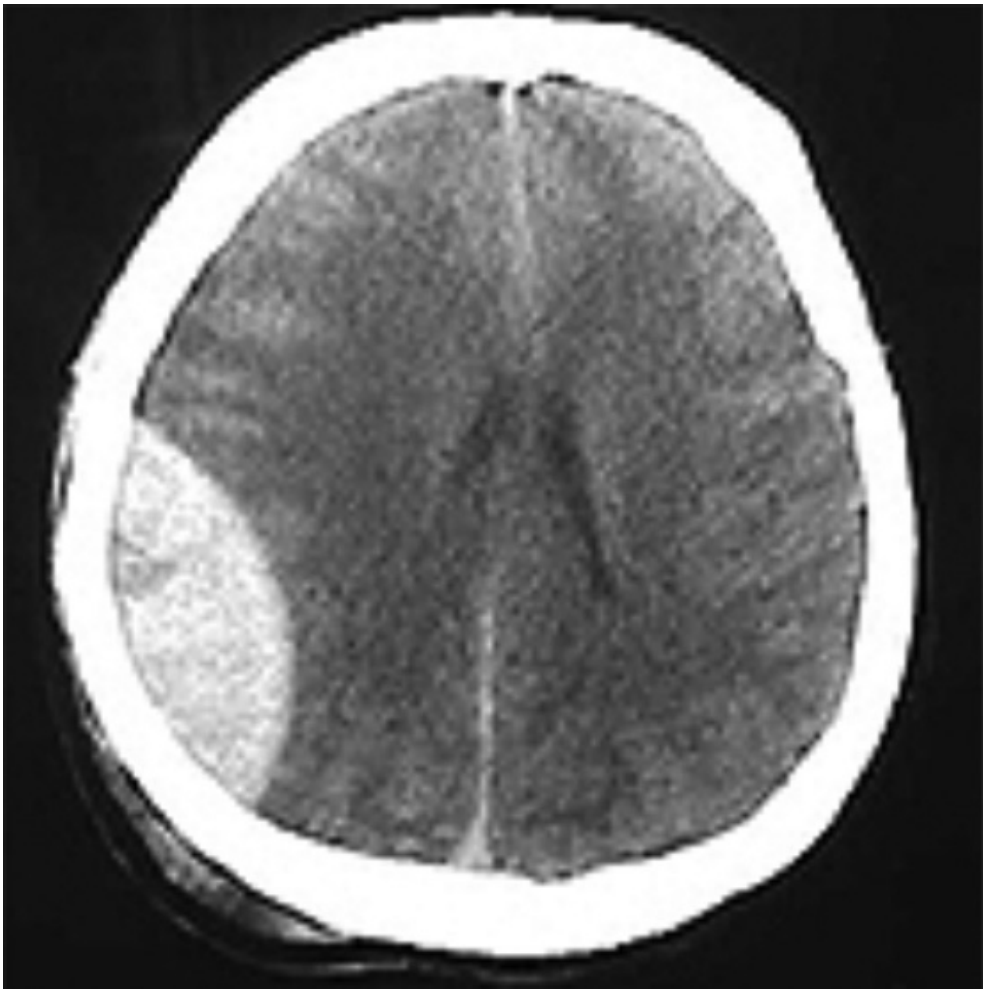

Figure 21.2 CT showing acute posttraumatic epidural hematoma.

Figure 21.3 CT showing acute left subdural hematoma with severe midline shift.

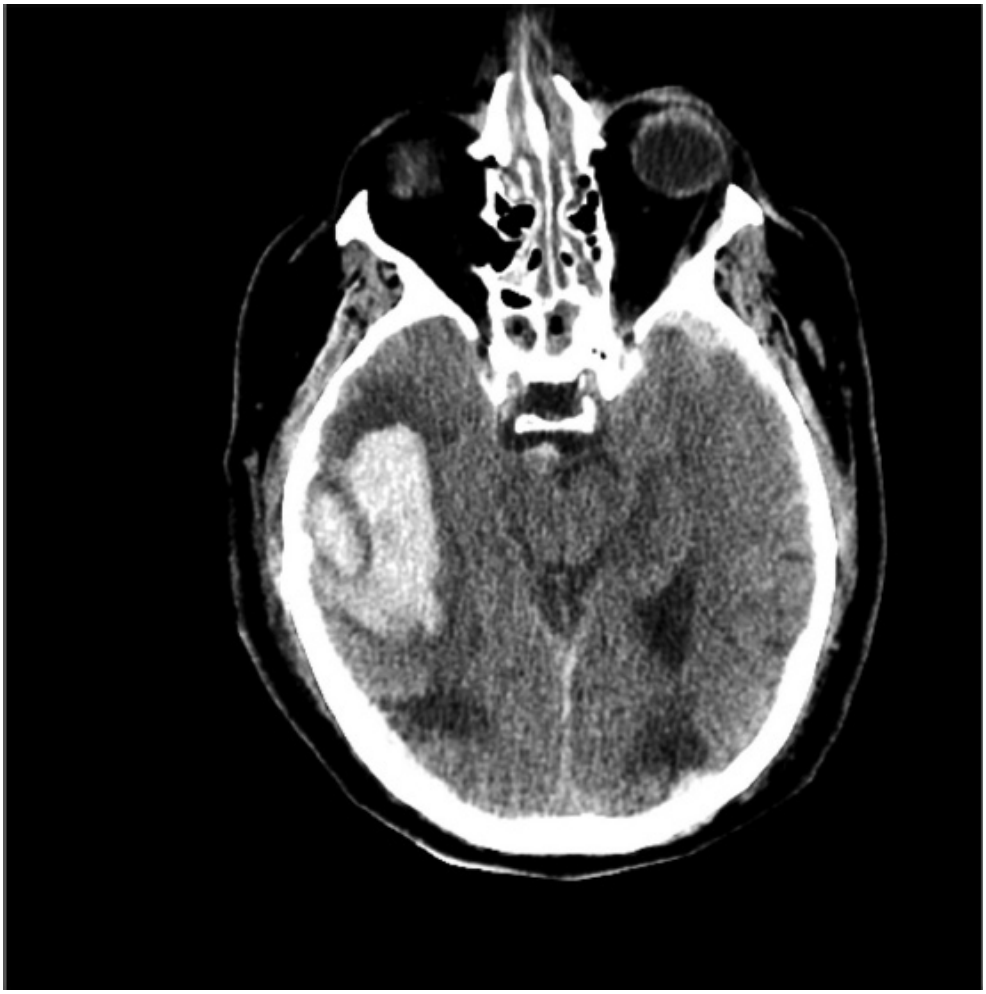

Figure 21.4 CT showing large right temporal contusion.

Subarachnoid hemorrhage appears as thin layer of blood on the surface of the parenchyma (**Fig. 21.5**). Careful study of the location of these hemorrhages helps differentiate posttraumatic SAH from ruptured intracranial aneurysms.

Other radiologic findings that help with the delineation of a therapeutic plan and prognostication in patients with TBI include the presence and degree of depressed skull fractures, extent of cerebral hematomas in addition to hemorrhagic contusions of the thalamus, basal ganglia, and the brain system.

3 Other radiologic tools such as MRI and diffusion tensor imaging[34] may be helpful in specific circumstances but not used frequently in the acute management of TBI. Studies involving nuclear medicine cisternography are

sometime indicated to delineate the site and presence of CSF rhinorrhea and otorrhea.

Figure 21.5 CT showing acute bifrontal traumatic subarachnoid hemorrhage.

MANAGEMENT OF BRAIN INJURIES

Broad Goals of Management

The key principles of management of a trauma patient remain the same, regardless of the specifics of injury. A major goal is to avoid the development of the "lethal triad" of hypothermia, acidosis, and coagulopathy. Additionally, the injured patient requires adequate oxygenation with

prioritization of injuries, reducing ongoing blood loss and treatment of hypotension.

Initial Resuscitation

Once airway, breathing, and circulation have been assessed and necessary interventions have been carried out to stabilize the patient, clinical assessment with GCS needs to be performed. Pupillary evaluation is of paramount importance. Handheld pupillometry is more commonly being used in the ICUs. They appear to be more reliable especially considering the poor interrater reliability of the qualitative pupillary examination. The pupilometer could be used to calculate the normalized neurological pupil index (NPi).[35,36] Pupillary dilation or loss of light reflex without significant changes either in the level of consciousness or other indicators of TBI should raise the possibility of local ocular injury or oculomotor dysfunction.

4 With TBI, early endotracheal intubation should be performed for all patients with a GCS <9.[23,37] Other reasons for emergent intubation include the inability of the patient to protect the airway (concurrent drugs/alcohol) and hypoxia due to other causes and inability to maintain SpO_2 >90% despite the use of supplemental oxygen. A notable inclusion is for patients who are identified as showing signs of clinical herniation or at risk for impending herniation. These signs include pupillary asymmetry, unilateral or bilateral fixed and dilated pupils, decorticate or decerebrate posturing, and the Cushing reflex of hypertension with bradycardia.[38]

The fluid of choice in early resuscitation involves a restrictive use of crystalloids including lactated Ringer's with a potential for correcting the metabolic acidosis from lactate accumulation. Additionally, balanced crystalloid solutions (e.g., lactated Ringer's and plasmalyte) have been associated with a reduced risk of acute kidney injury in critically ill patients. For patients with a dominant TBI, normal saline would be appropriate for its isotonicity. In TBI patients enrolled in SMART ICU study, no benefit was seen with the use of balanced fluids.[39] Electrolyte imbalances are common in patients with TBI and should be regularly assessed along with other laboratory parameters.

Current evidence indicates that rather than crystalloids, blood loss in trauma needs to be resuscitated with pRBC and component products. A ratio of 1:1:1 pRBC:FFP:platelets is the preferred mode of administration of blood products.[40,41] Most trauma centers follow the principles outlined in damage control resuscitation (**Table 21.5**).

There has been a resurgent role of thromboelastography or TEG in the management of bleeding trauma patient. For patients requiring massive transfusion, we suggest early TEG–based goal-directed resuscitation and management of fibrinolysis rather than treatment based on standard coagulation assays, when the technology is available.[42] However, the evidence for TEG is based on multiple clinical studies but without adequate randomization.

Table 21.5 Principles of Damage Control or Hemostatic Resuscitation

Damage Control or Hemostatic Resuscitation

- Prioritize hemorrhage control
- Permissive hypotension
- Avoid crystalloids
- Early component therapy (protocol driven)
- Adjuncts:
  - Correct hypothermia, acidosis, hypocalcemia
  - Antifibrinolytics

Neuromonitoring

ICP Monitoring

5 Elevated ICP is a strong predictor of subsequent neurologic deterioration in patients with severe TBI.[43] The primary rationale for ICP monitoring is therefore to detect potentially life threatening, but clinically occult, intracranial hypertension before clinical deterioration, cerebral herniation and death, or permanent neurologic injury occurs. Early detection of clinically occult intracranial hypertension permits the early initiation of ICP-targeted therapy. The previous edition of BTF guidelines for ICP monitoring

in TBI patients was broadly classified into the category of patients with a GCS ≤8 and an abnormal CT scan. However, the current guidelines recommend the use of invasive ICP monitoring in all patients with severe TBI, based on observational data that suggest reduction in short-term mortality with the use of ICP-targeted management.[26]

6 An external ventricular drain (EVD) connected to a transducer is considered the gold standard and cost-effective method of ICP monitoring. Additionally, an EVD can be used to treat elevated ICP with appropriate drainage of CSF. However, the presence of a midline shift and compressed ventricles (slit ventricles) make the placement technically challenging with a higher risk of bleeding. Intraparenchymal monitoring of ICP by placement of an intraparenchymal catheter is easier to perform and has a lower risk of hemorrhage and infection. An I7 CP goal ≤22 mm Hg is recommended for therapy as values above this level are associated with the increased probability of mortality and unfavorable neurologic outcomes.[44]

While monitoring of ICP has been considered the gold standard for management of severe TBI, a randomized study of patients with severe TBI (BEST TRIP) found no differences in outcomes where the management of the patients was subjected to a clinical and radiologic evaluation without ICP measurement.[45] The study was conducted in a low resource setting of Ecuador and Bolivia, where placement of ICP can be costly and associated with a higher risk of meningoencephalitis. The study also had a number of patients with delayed treatment and significant differences in the way the therapy was carried out in the two arms. Other studies[46,47] have, however, suggested that ICP monitoring is associated with an independent reduction in the inhospital mortality rates.

Pressure Reactivity Index

As indicated above, cerebral autoregulation is an important mechanism to preserve tissue perfusion, especially in patients with severe TBI and increased ICP. In an attempt at measuring the degree of cerebral autoregulation in individual patients, a few studies have evaluated the use of continuously monitored correlation coefficient between mean ICP and MAP. A direct correlation of ICP with MAP (pressure reactivity index [PRx] value = 1) would suggest that there is complete loss of autoregulation. On the other

hand, a lower PRx value such as 0.05 suggests the presence of cerebral autoregulation. In one study using this value, the investigators were able to predict survival and favorable outcome, respectively, in one study.[48] However, these measurements have not been routinely used in other centers.

Noninvasive ICP Monitoring

Optic nerve ultrasound (ONUS) is one of the best-evaluated noninvasive tools for the detection of intracranial hypertension, and is already in clinical use in several emergency departments and in settings where ICP monitoring is unavailable.[49–52] The optic nerve sheath (ONS) is a continuation of the dura and contains the subarachnoid space. An increase in ICP is transmitted through the subarachnoid space and results in distension of the retrobulbar ONS.[49–52] The optic nerve sheath diameter (ONSD) can be measured posterior to the globe using point-of-care ultrasound, and a threshold ONSD used to identify the presence of elevated ICP. Several studies have reported high accuracy of ONSD for the detection of elevated ICP.[49–52] However, the ONSD threshold to identify elevated ICP has varied greatly between studies. At present, this test is under investigation and based on the current understanding cannot be recommended as standard of care. Transcranial Doppler has also been evaluated for noninvasive ICP assessment, with mixed results.[53,54]

Role of Cerebral Oximetry and Microdialysis

Tissue oximetry has been investigated as a marker of tissue perfusion in many different types of vascular beds. Notable examples include sublingual, gastric, and cutaneous circulations. Measurement of brain tissue oxygen tension ($PbtO_2$) by placement of an oxygen electrode into the white matter is a similar technique that assesses tissue perfusion of the brain. While values above or equal to >20 $PbtO_2$ mm Hg are considered normal, persistent levels of $PbtO_2$ below 15 mm Hg are associated with worsened outcome.[23] A randomized clinical trial (BOOST-2) concluded that ICP and brain tissue oxygenation monitoring with a specific protocol reduced brain tissue hypoxia with more favorable outcomes than the ICP-only treatment arm.[55] Currently recruitment is being actively performed for a phase 3 trial (BOOST-3).
