Cerebral microdialysis uses the minimally invasive approach to measure solute concentration in the brain. Similar to oximetry, an intraparenchymal probe is introduced. Typical measurement includes the products of anaerobic (lactate as an example) and aerobic oxidative phosphorylation (glucose, pyruvate, etc.).[56,57] Attempts are made to optimize therapeutic measures in response to a predominantly anaerobic and conversion to an aerobic state. These are currently in the investigational stages.

Medical Management of ICP Elevation

Basic principles of medical management of elevated ICP include elevating the head end of the bed and avoidance of factors such as increased intrathoracic pressure (such as PEEP) and intra-abdominal pressure (such as seen in abdominal compartment syndrome). These pressures are directly transmitted to the intracranial space.

Sedation and Analgesia

Effective analgesia is a critical first step in the management of intubated mechanically ventilated TBI patients. Additionally, patients with severe TBI do not have normal complaints or manifestations of pain. Fentanyl is the analgesic of choice because of short half-life and better hemodynamic profile compared with morphine and hydromorphone, which are the alternative choices. Though it may be reasonable to control the sedation with an effective use of analgesia alone, this approach in patients with elevated ICP is considered inadequate. Effective sedation lowers the ICP by lowering the metabolic demand, affecting the CBF and volume.[58] Propofol is the preferred agent for sedation in view of its very short half-life, reduction in ICP, and the ability to evaluate quickly with an awake neurologic examination with discontinuation.[59] Bradycardia and hypotension are common with propofol and this may require vasopressor infusion to maintain the CPP. For patients with severe TBI, with appropriate control of ICP, a Richmond Agitation-Sedation Scale (RASS) of 0 to 2 is preferred.[58] The routine use of neuromuscular paralysis in the control of ICP is not recommended and may actually prove harmful in the long run due to associated critical illness, polymyopathy and neuropathy.

Cerebrospinal Fluid Drainage

Drainage of CSF in patients with EVD is often the first intervention for lowering ICP following sedation and analgesia. The BTF guidelines recommend continuous CSF drainage for better control of ICP compared with intermittent drainage.[23] However, continuous drainage may lead to ventricular collapse and occlusion of the catheter, particularly with slit ventricles.

Osmotic Therapy

Osmotic therapy involves the administration of a hyperosmolar agent in an attempt to reduce the degree of cerebral edema by diffusion of water across the blood–brain barrier. It is generally recommended as the next step following sedation, analgesia, and ICP drainage in patients with refractory ICP. The most common agents used include mannitol and hypertonic saline. Mannitol is used as 0.25 to 1 g/kg body wt as the initial dose for osmotherapy. It can be administered every 4 to 6 hours. It is also known to be a free radical scavenger. However, with its use, no specific hyperosmolar treatment protocol has been shown to improve function outcome or mortality in clinical trials. Hypertonic saline is an effective hyperosmolar agent for the control of elevated ICP.[60,61] With continuous infusion, 3% NaCl may be titrated to an initial sodium goal of approximately 145 to 155 mEq/L. Hypertonic saline could cause extravasation injury when used through a peripheral line and a central line with higher flow is typically preferred. Hypertonic saline has several advantages over mannitol including lesser incidence of hypovolemia and hypotension.[60] However, repeated administration of hypertonic saline can cause serious metabolic abnormalities including hyperchloremia and nonanion gap metabolic acidosis. There is no convincing evidence to clearly state that one agent is better than the other. The effect of hyperosmolar therapy diminishes with time, as a compensatory increase in brain osmoles occurs within 24 hours.[62]

Seizure Prophylaxis

Seizure prophylaxis is generally recommended for all severe TBIs. The incidence of seizures following TBI has been widely reported as 15% to 30%[63] and typically peak in the first 2 weeks following the trauma. Though

the use of anticonvulsant has been shown to reduce the incidence of early seizures, there is no lasting effect identified on the incidence of long-term epilepsy.[64] In the early period following TBI, seizures constitute a well-identified etiology for aggravation of secondary brain insult by increasing the metabolic demand on the brain in addition to increasing CBF and ICP. About one-fourth of all patients with TBI also suffer nonconvulsive seizure activity, typically identified on 24-hour EEG monitoring.[63,65]

Most neurosurgical and trauma programs around the country have switched over from phenytoin to levetiracetam (Keppra) as the drug of choice. Phenytoin use over multiple years has been associated with worse functional outcomes especially in patients with SAH. However, in a head-to-head comparison, there was no difference in efficacy in controlling seizures between these two agents.[66]

Role of Tranexamic Acid

Over the last decade, it has been increasingly clear that pathogenic fibrinolysis following trauma and particularly TBI play an important role in ongoing bleeding, coagulopathy, and therefore increased mortality. Tranexamic acid (TXA) is the agent most used in clinical trials. The most definitive study, the CRASH-3 trial used a pragmatic approach in their study design that included multiple countries including many considered in the low- and middle-income group. The authors concluded that administration of TXA within 3 hours of injury is beneficial in TBI with GCS <13. This benefit translated into mortality improvement particularly when patients with bilateral dilated pupils were excluded from both the placebo and TXA groups.[67]

TXA is administered as 1 g IV infusion over 10 to 15 minutes followed by a gram administered every 8 hours for the first 24 hours in these patients.

Early Enteral Nutrition

Early enteral nutrition either through a nasogastric tube or postpyloric silastic tube is recommended for all patients with TBI. Though there was earlier study to indicate that earlier enteral nutrition is associated with lesser incidence of pneumonia and mortality,[68] a subsequent randomized study did

not show any difference in either pneumonia or mortality rates between early and delayed enteral nutrition.[69]

Others

Trauma including TBI is identified as a unique high-risk factor for the development of thromboembolism. We typically initiate early thromboprophylaxis with enoxaparin as 40 mg/day or 30 mg twice a day once it is established that a repeat CT scan does not show any progression of hemorrhage. This practice is based on a combination of data obtained from multiple clinical and observational studies analyzed in a meta-analysis that showed safety in patients with TBI.[70]

Febrile activity is a known cause of secondary brain injury with its propensity to increase cerebral metabolism, increases CBF and therefore ICP.[71] Therefore, control of fever is strongly recommended either with antipyretics or external and intravascular cooling devices. About 10% of patients also exhibit signs of paroxysmal sympathetic hyperactivity that include hyperdynamic circulatory response in addition to posturing and increased tone. Specific therapy includes hydration and nonselective beta blockade in addition to the exclusion of other diagnoses such as sepsis and pulmonary embolism.

Therapeutic Intensity Level and Management Parameters to Control ICP

In an attempt to understand the interpretation of ICP measurements without realization of the associated therapeutic maneuver undertaken, Maas and co-authors devised a therapeutic intensity level (TIL).[72] The TIL was charted for basic and moderate scales. The basic scale is outlined in **Table 21.6**. Subsequent study has validated the TIL scoring system of the management of ICP in the intensive care units by studying them at 4- and 24-hour time points. The authors concluded that the TIL scale is a reliable measurement instrument with a high degree of validity for assessing the TIL of ICP management in patients with TBI.

Management of Impending Cerebral Herniation

Patients admitted with a severe TBI should be subjected to 2 hourly neurologic assessments. This should include discontinuation of propofol and other sedatives. Neurologic signs of herniation include new-onset fixed and dilated pupils, decorticate or decerebrate posturing, or hypertension with bradycardia. Immediate maneuvers proved to be of benefit are listed in **Table 21.7**. These interventions include brief hyperventilation[73] and osmotherapy.[74,75] It is important to recognize that such interventions are often temporary and a repeat CT scan may be indicated to evaluate the need for additional surgical intervention.

SURGICAL APPROACH

Skull Fracture

Skull fractures are extremely variable in both their presentation and management. Closed linear convexity skull fractures without significant displacement can typically be managed conservatively without any specific restrictions or precautions. Conversely, open fractures with significant depression causing mass effect upon the brain parenchyma typically require washout and elevation of bony fragments. Skull base fractures require special care and evaluation. Clinically, skull base fractures may present with CSF rhinorrhea or otorrhea, raccoon eyes (bruising around the orbit), or Battle sign (bruising behind the ears). On imaging, fluid within the mastoid air cells or sphenoid sinus should raise concern for a skull base fracture. Pneumocephalus can also help identify fractures. Due to their proximity with the intracranial circulation, skull base fractures pose a risk for cerebrovascular injury such as dissection or pseudoaneurysm formation (**Fig. 21.6**). Fracture lines that are in close approximation to structures such as the carotid canal warrant further imaging with CT angiography. Skull base fractures also pose a risk for CSF leak, particularly with fractures in the frontal sinus, cribriform plate, or ethmoid/sphenoid sinuses. Surgical repair may be indicated in these cases. Surgical treatment entails cranialization of

the frontal sinus (removal of the posterior wall of the frontal sinus), stripping of the mucosa in the sinus, and pericranial flap placement along the anterior skull base. Abdominal fat may be harvested to pack the sinuses. In certain cases, endoscopic endonasal approaches may be appropriate rather than open craniotomy.

Table 21.6 Basic Scale for Therapeutic Intensity Level (TIL)

TIL 0—No Specific ICP-Directed Therapy
TIL 1—Basic ICU Care ▪ Sedation for ventilator/endotracheal tube tolerance ▪ Volume/Vasopressors for non-CNS cause (e.g., sepsis, myocardial injury) ▪ Head up positioning (ventilator bundle) ▪ Normocapnia ($PaCO_2$ ≥40 mm Hg)
TIL 2—Mild ▪ Higher levels of sedation ▪ Vasopressors/Volume for CPP support ▪ Low-dose osmotic therapy ▪ Mild hypocapnia ($PaCO_2$ 4.6–5.3 kPa; 35–40 mm Hg) ▪ CSF drainage <120 mL/day (<5 mL/hr)
TIL 3—Moderate ▪ Higher doses of osmotic therapy ▪ Moderate hypocapnia ($PaCO_2$ 4.0–4.5 kPa; 30–35 mm Hg) ▪ Mild hypothermia (>35°C) ▪ CSF drainage ≥120 mL/day (>5 mL/hr)
TIL 4—Extreme ▪ Profound hypocapnia ($PaCO_2$ <4.0 kPa; <30 mm Hg) ▪ Hypothermia <35°C ▪ Metabolic suppression for control of ICP ▪ Surgery for refractory ICP (decompression, lobectomy)

Table 21.7 Immediate Management of Impending Cerebral Herniation

Endotracheal intubation, if not already performed
Elevation of the HOB to 30–45 with the head in neutral position to promote venous drainage
Brief hyperventilation to a pCO_2 of approximately 30 mm Hg[72]
Osmotherapy with either mannitol 1–1.5 g/kg[73] or 23.4% hypertonic saline[74]
Higher mean arterial pressure (MAP), to approximately 80–100 mm Hg, to maintain an adequate cerebral perfusion pressure (CPP) with fluids ± vasopressors
Definitive surgical interventions when indicated

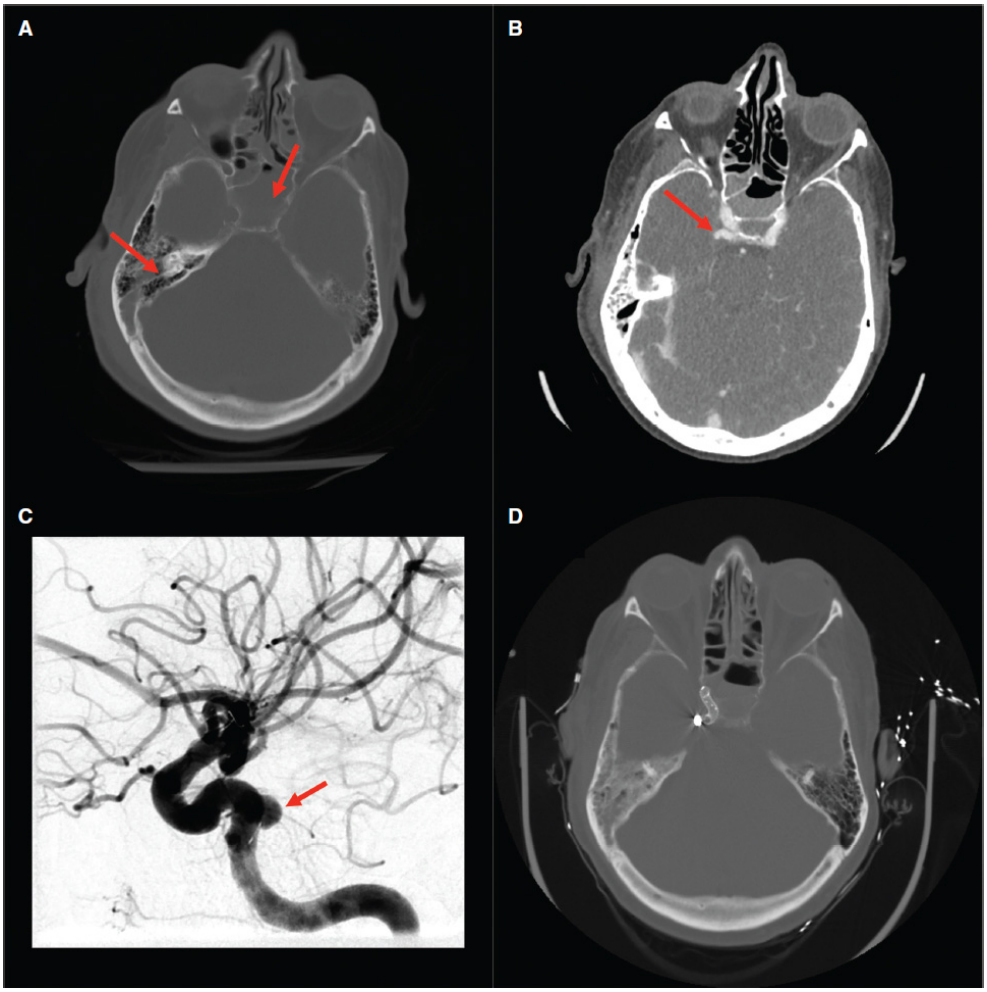

Figure 21.6 **A:** Initial CT showing fluid in the right mastoid air cells and sphenoid sinus (*red arrows*), raising suspicion for skull base fracture. **B:** CT angiography and (**C**) digital subtraction angiography showing a pseudoaneurysm (*red arrows*) of the right cavernous internal carotid artery. **D:** Stent-coil embolization of the pseudoaneurysm.

Epidural Hematoma

Epidural hematomas are typically thought to arise from laceration of the middle meningeal artery, causing arterial bleeding between the dura and skull. In many cases, there is a skull fracture in the pterion. Smaller epidural hematomas, particularly in other locations, can be due to dural lacerations and skull fractures. Hematomas that cross the midline may involve injury to the dural venous sinuses. Given the high pressure and high flow through the MMA, epidural hematomas can rapidly expand, leading to sudden coma and death. Classically, a "lucid interval" is described, where a patient is initially

neurologically intact, with subsequent rapid deterioration. Emergent surgical decompression is warranted for evacuation. A temporal craniotomy is usually sufficient to evacuate the hematoma and coagulate the torn MMA. If performed prior to a herniation syndrome, patient outcomes can be excellent.[76]

Subdural Hematoma

SDHs can present acutely after severe trauma or in a subacute fashion from minor trauma or even in the absence of a history of trauma. In acute severe TBI, an SDH causing significant midline shift (>5 mm) and neurologic deficits may warrant an emergent surgical evacuation. In certain circumstances, ICP monitoring may be pursued in lieu of immediate surgery. Surgery for acute SDH typically involves a large unilateral craniotomy in order to adequately evacuate the gelatinous clot. In many circumstances with elevated ICP, a craniectomy is pursued in order to ensure that the brain is sufficiently decompressed. A randomized trial is currently ongoing to evaluate differences between craniectomy and craniotomy in this population (RESCUE-ASDH).[77] As opposed to acute SDH, chronic or subacute SDH is a disorder of the elderly. As SDHs age, they tend to liquefy. Due to this, chronic or subacute SDH causing neurologic symptoms may be evacuated through burr holes or a small craniotomy (**Fig. 21.7**).

Parenchymal Contusions

Parenchymal contusions pose a difficult dilemma for management. They tend to occur in the basal frontal lobes or in the temporal lobes. Contusions typically “blossom” or enlarge over the course of several days. Therefore, contusions rarely require emergent surgery at initial presentation. However, due to their enlargement, coupled with a significant edematous reaction of the surrounding parenchyma, patients tend to deteriorate 3 to 7 days, post trauma. Close neurologic monitoring should be carried out during this time, and ICP monitoring may be warranted. Patients with temporal contusions are at particular risk for developing uncal herniation even in the absence of ICP elevations. Conversely, patients with bifrontal contusions may develop global ICP elevations. Decompressive craniectomy (DC) is warranted if

medical management is unsuccessful. For bifrontal contusions, a bifrontal craniectomy is typically performed. In the case of temporal contusions, a unilateral craniectomy is performed.

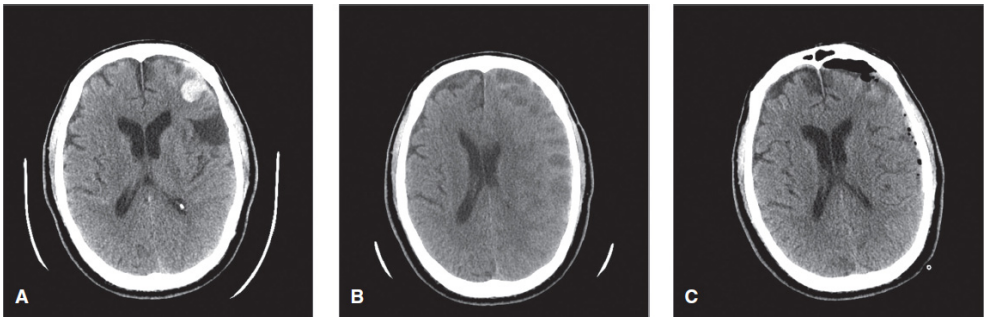

Figure 21.7 **A:** Initial CT showing a left frontal contusion with associated small subarachnoid and subdural hemorrhage. **B:** Follow-up CT at 2 months showing resolution of the contusion, but development of a large loculated subdural hemorrhage causing significant mass effect and midline shift. **C:** Postoperative CT showing evacuation of the hemorrhage with resolution of mass effect.

Diffuse Axonal Injury

DAI occurs due to shearing forces from blunt trauma affecting axons throughout the brain. It can be difficult to identify on CT, but can be seen readily on MRI. DAI can also occur concurrently with other traumatic intracranial pathology. DAI is typically a nonsurgical entity and is managed medically with ICP monitoring.

Penetrating Injuries to the Brain

Gunshot wounds (GSWs) comprise the vast majority of penetrating brain injuries. Most patients with GSWs to the head either die in the field or do not survive initial resuscitation. Physical examination and CT should be used to evaluate the path of the bullet. Bihemispheric injury, and particularly bithalamic injury, portends an extremely grim prognosis. However, if a patient is able to be stabilized hemodynamically and has evidence of brain function, emergent surgical treatment is necessary. Due to the cavitation injury by the bullet, patients develop rapid malignant cerebral edema (**Fig. 21.8**). Therefore, surgery should involve a large DC. Due to the significant risk of direct blood vessel injury, voluminous blood loss is typical and intraoperative death is a major concern. During decompression,

any concomitant hematomas should be evacuated. Similarly, devitalized scalp should be resected, and any air sinuses encountered should be exenterated. Bone and bullet fragments that are deep in the parenchyma should not be retrieved due to the risk of causing further injury.

Non–gunshot-penetrating trauma usually involves low-velocity objects such as knives, arrows, nails, etc. In these cases, preoperative CT angiography is helpful to identify if there is an injury to a major blood vessel. If the object is still embedded when the patient presents, it should not be removed until in surgery. In these cases, a craniectomy is typically necessary with careful extraction of the embedded object. If the object is not embedded, the patient may be managed similar to a closed head injury.

Role of Decompressive Craniectomy

DC continues to be a mainstay in the surgical treatment of severe TBI. The rationale for DC is that it is a rapid, reliable, and sustainable intervention to decrease ICP. It may be performed either immediately at the time of severe TBI (primary DC), or in a delayed fashion if nonsurgical methods for ICP control have failed (secondary DC). Nevertheless, the role and indications for craniectomy continue to be controversial. While control of ICP with DC is undeniable, there has not been definitive evidence that DC leads to improved clinical outcomes.[78]

There have been two major randomized trials evaluating secondary DC. The DECRA trial was first published in 2011.[79] In this study, 155 patients were randomized to bifrontal craniectomy versus standard of care nonsurgical treatments. The inclusion criteria were patients within 72 hours of injury with diffuse severe TBI who had intracranial hypertension. This was defined as ICP >20 mm Hg for over 15 minutes within a 1-hour time period, despite standard of care medical interventions. Surgical treatment was standardized to be a bifrontal craniectomy. Outcomes were measured with the GOS-E at 6-month follow-up. The results of the trial found that while DC led to a decrease in mortality, it also led to more patients in a vegetative state or with severe disability. DECRA was limited by significant flaws. The inclusion criteria ICP led to a median ICP *prior* to randomization of 18 to 22 mm Hg. In addition, only diffuse TBI was included. Finally, a

bifrontal craniectomy was used, which is atypical for practice, particularly in the United States, where hemicraniectomy is preferred.

RESCUEicp was published in 2016.[44] In this trial, 408 patients were again randomized to DC or standard nonsurgical management. Differing from DECRA, the investigators included any severe TBI with an abnormal CT. ICP for inclusion was >25 mm Hg for 1 to 12 hours despite nonsurgical methods. In addition, patients who underwent craniotomy for mass lesion earlier in their course remained eligible. The surgical approach for decompression was not standardized. Primary outcome was GOS-E at 6 months, while secondary outcomes were at 12 months. The results showed that DC again led to a significant improvement in survival with a similar increase in patients in vegetative state or with severe disability. However, at 12 months, surgical patients showed an increased rate of living independently when compared to the medical group. RESCUEicp benefitted from being a more “real-world” situation but was significantly limited by crossover (37.2% of the medical group eventually had a craniectomy).

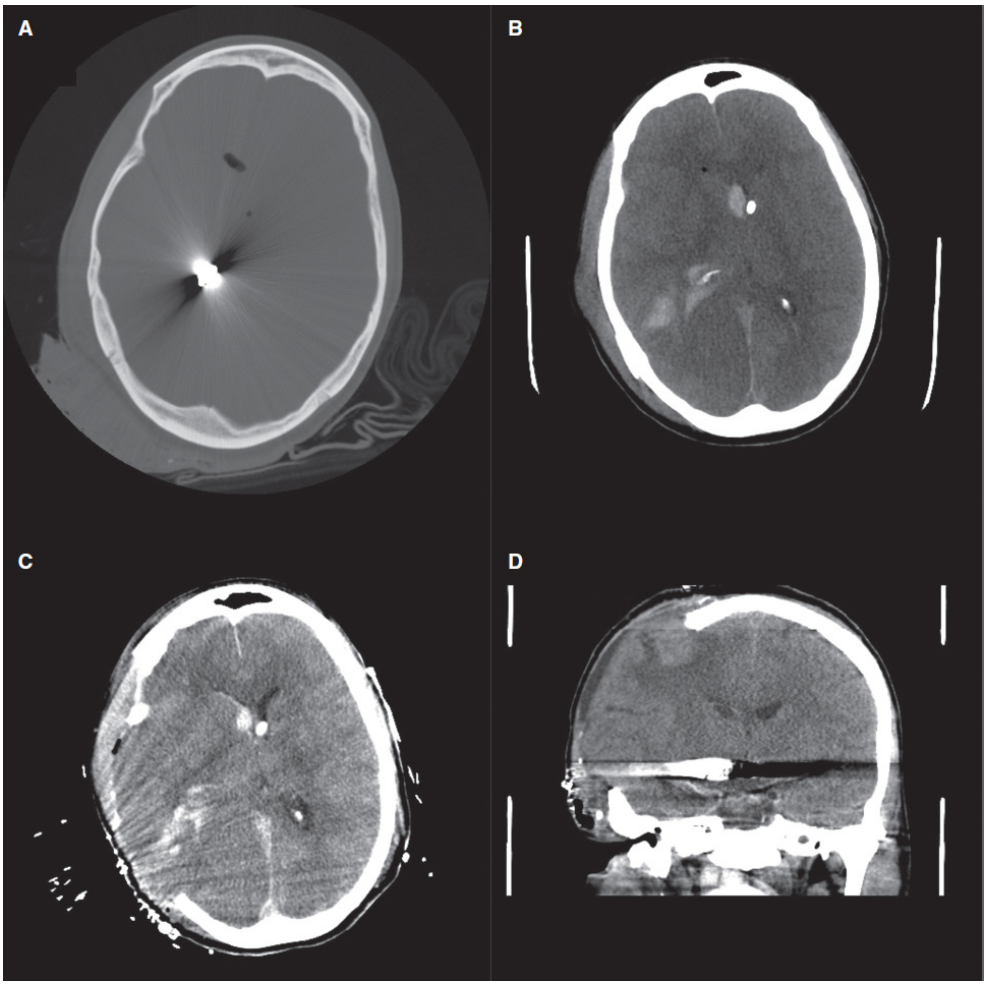

Figure 21.8 **A:** Initial CT showing intracranial bullet fragment. **B:** Development of progressive hemorrhage and mass effect. Ventriculostomy catheter can be seen on the left side. **C, D:** After right decompressive craniectomy, mass effect is relieved and brain parenchyma can be seen herniating through the craniectomy defect.

PROGNOSIS

Outcome from severe head injury is dependent on a range of factors (**Table 21.8**). It is important to remember that none of these factors in isolation are as important as a collective evaluation. While a few studies have utilized biomarkers such as serum and CSF levels of S-100β protein, neuron-specific enolase, and α-synuclein,[80] others are currently being investigated.

Clinical prediction models that incorporate known predictors of death and poor long-term functional outcome have been developed. The CRASH prediction model, which incorporates age, country, GCS, pupillary reactivity, the presence of extracranial injury, and CT findings to predict 2-week mortality and 6-month functional outcome, was developed using data from a large international multicenter clinical trial of glucocorticoids in TBI.[81] The IMPACT model, derived from 8,509 patients, uses age, GCS, pupillary reactivity, the occurrence of hypoxia and hypotension, the Marshall CT grade, presence of traumatic SAH, presence of epidural hematoma, glucose and hemoglobin levels to predict 6-month mortality and functional outcome.[82] These models are best applied to large cohorts, however, and should not be used to guide management decisions in individual patients or counsel families.

Table 21.8 Factors that Determine Prognosis in Patients with TBI

GCS at Presentation (Motor Score—Most Important Prognosticator)
CT—high-grade subarachnoid hemorrhage, cisternal effacement, midline shift
Pupillary function
Age—older age associated with poor prognosis
Presence of factors that cause secondary brain injury—hypotension, hypoxemia, and fever
Elevated intracranial pressure (ICP) and reduced cerebral perfusion pressure (CPP)
Associated coagulopathy
Diffuse axonal injury and brain stem injury

Overall patients with severe TBI (GCS ≤8) have an approximately 30% to 40% mortality. A sizable fraction of patients (1/3 to 2/3) with severe TBI will regain some independence.[83] Considering the degree of injury could be profound and each area of the brain has a different degree of ability to heal or exhibit varying degree of neuroplasticity, functional recovery may take up to a year to fully materialize.[84] It is also known that a small proportion (close to 10%) of patients with severe TBI may end up in a vegetative state.[85]

Among patients with more moderate TBI pretrauma, educational attainment is associated with increased odds of disability-free recovery.[86]

Injury and Violence Prevention: A Public Health Approach

Joseph V. Sakran and Nicole Lunardi

Key Points

1 Injuries are preventable, and we should therefore avoid using the term "accident."

2 Injury prevention requires a multidisciplinary team, including education, health care, criminal justice, legislature, communications/media, business, and community organizations.

3 Violence is a public health problem.

4 Healthcare systems must engage the community in addressing the social determinants of health of disease, which contribute to structural violence in underserved communities.

5 Injury and violence prevention takes place on a continuum: before the injury occurs (primary prevention) or after the injury occurs by minimizing the mortality, likelihood of reoccurrence (secondary prevention), and reducing long-term morbidity (tertiary prevention).

6 Our medical organizations must commit to working together in order to provide constructive actions that reduce injury and death in communities across America.

7 Surgeons have a critical role in social movements and advocating for evidence-based solutions.

HISTORY OF INJURY PREVENTION

1 The field of injury prevention is young. Its roots trace back to occupational hazards in the first half of the 20th century. Injuries, at the time, were considered true accidents: random, unavoidable, or, even, acts of God. Thus, the notion of systematically preventing "accidents" was novel. The National Safety Council, created in 1913, distributed information related to industrial hazards. Simultaneously, thought leaders were studying national trends and analyzing the circumstances of workplace "accidents." Julian Harvey put forth the first framework of accident control in 1923, which became known as the "three Es": education, engineering, and enforcement.

Despite these advancements, many workplace injuries were still considered unavoidable accidents.[1,2]

Starting in the mid-20th century, the paradigm shifted toward developing evidence-based injury prevention. Federal agencies teamed up with local health departments to educate the public and implement prevention programs. Epidemiologists applied the principles used to describe disease to injuries: host demographics, causal agents, environments, seasonal/cyclical trends, distributions, and epidemic episodes.[3–5] By 1972, William Haddon Jr, the director of the National Highway Safety Bureau, proposed a framework to describe the interaction between causal factors regarding the host, agent, and environment before, during and after the injury. The Haddon Matrix allowed for strategic prevention efforts. He is credited as the father of modern injury epidemiology.[6]

In the same period, basic scientists were describing the mechanisms by which energy transfer (kinetic, electric, chemical, etc.) caused tissue damage for the first time.[7] These discoveries allowed for the production of safer products, like padded dashboards, air bags, and seat belts in cars. Product safety along with the development of the first regional trauma systems worked to decrease severity of injury and increase survival through prompt medical treatment.[1]

By the late 20th century, a robust group of stakeholders, including basic scientists, engineers, epidemiologists, healthcare workers, local, state and national health agencies, and nonprofit organizations were building a coalition to establish the science of injury prevention. Representing a true shift in understanding, the word "accident" was replaced with the word "injury" in International Statistical Classification (ICD) codes in 1979.[1,2] The trauma community has worked to shift daily terminology to reflect the firmly grounded principle that injuries are preventable. That is, avoiding the use of "motor vehicle accident" and shifting to "motor vehicle crash."

Advancements in the field were contemporaneous with the emergence of injury as a leading cause of death in the United States. In fact, injury has been in the top 15 causes of death of all Americans since 1965 (https://www.cdc.gov/injury/wisqars/LeadingCauses_images.html).[8] In 1966, the National Academy of Sciences landmark paper, "Accidental Death and Disability: The Neglected Disease of Modern Society," identified the need for improved care of the injured patient.[9] In 1985, the Department of

Transportation along with the National Academy of Sciences and Institute of Medicine drew attention to injury being responsible for more life years lost than cancer and heart disease, but having the smallest funding allocation with no central agency in "Injury in America."[10] That very year, the Centers for Disease Control and Prevention (CDC) Injury Control Pilot Program was created. It oversaw and funded multidisciplinary research centers and demonstration projects. The pilot program was found to be efficacious in a 1988 review. By 1990, the Injury Control Act was signed reauthorizing the CDC-based program.[2] These groundbreaking papers brought the burden and cost of injury into focus, which led to the development of injury prevention infrastructure.

Over the course of the century, the field of injury prevention was created with the overarching goal to reduce the morbidity, 2 mortality, and economic burden of injury. The field is, by definition, multidisciplinary, drawing on the expertise from basic scientists, engineers, epidemiologists, health systems and administrators, healthcare workers, educators, the private sector, and numerous others.

EPIDEMIOLOGY OF INJURY: DEFINING THE PROBLEM

The CDC's National Center for Injury Prevention and Control (NCIPC) collects and stores national injury data on the Web-based Injury Statistics Query and Reporting System (WISQARS: cdc.gov/injury/wisqars/index.html).[8] Made available for the first time in 2000, WISQARS includes the 1981–2018 data on fatal and nonfatal injury, leading causes of death and injury, violent deaths (homicides and suicides), years of potential life lost, and cost of injury. This data is compiled from sources, including the National Vistal Statistics System, National Electronic Injury Surveillance System—All Injury Program, the Pacific Institute for Research and Evaluation, and the National Violent Death Reporting System (NVDRS: cdc.gov/violenceprevention/datasources/nvdrs/index.html).[11] In 2002, the NVDRS started collecting homicide and suicide data from 6 states and has grown to include all 50 states, Puerto Rico, and Washington, DC by

2018. The NVDRS is unique in that it collects data from law enforcement, medical examiners, and death certificates regarding the violent incident (geography, weapon used), characteristics of the victim (mental and physical health problems, toxicology reports, substance abuse, financial problems), and the relationship between victim and suspect (nature of relationship, relationship problems, and intimate partner violence [IPV]).

Injury data can be studied from many different perspectives, with the two most common being by intent and mechanism. Intent, as captured by the ICD codes, falls into the following major categories: unintentional, suicide/self-harm, homicide/assault, and legal intervention. There is a small percentage of cases each year for which the intent is not determined (2.3% in 2018). Mechanism describes the way by which the injury occurred. Common mechanisms of injury include transportation (motor vehicle collision, pedestrian, cyclist), penetrating injury (firearm, cut/pierce), blunt injury (stuck, fall), drowning, suffocation, burns, and poisonings (drug, nondrug). For the purposes of a complete discussion, trends regarding both intent and mechanism will be explored.

Unintentional Injury

Unintentional injury has consistently been among the leading causes of death for Americans regardless of age, race/ethnicity, and sex, claiming 167,127 lives in 2018 alone. It was single leading cause of death for all Americans aged 1 to 44 between 2000 and 2018. The most common mechanisms of these deaths varied based on age: drowning (age 1 to 4), motor vehicle crashes (age 5 to 24), and poisonings (age 24 to 44). For every single fatality, there were 218 nonfatal unintended injuries in 2018.

From 2001–2018, 10,722 fatal and 309,289 nonfatal unintended injuries involved a firearm. While the age-adjusted rates of unintended firearm fatalities has been steadily decreasing (0.76 in 1981 to 0.14 deaths/100,000 population in 2018), the trend in nonfatal firearm injuries has been labile (**Fig. 22.1**).[8]

Suicide and Self-Harm

Overall, suicide is the 10th leading cause of death for all Americans with 48,344 deaths in 2018. Suicide rates are higher in men than women. Men are more likely to use a firearm, whereas women are likely to die from poison or suffocation. Greater than half of all suicide deaths are committed with a firearm (**Fig. 22.2**). Among American men, older White and younger American Indian men have higher suicide rates than Blacks or Asians (**Fig. 22.3**).[8] This racial and age disparity has been well documented.[12,13]

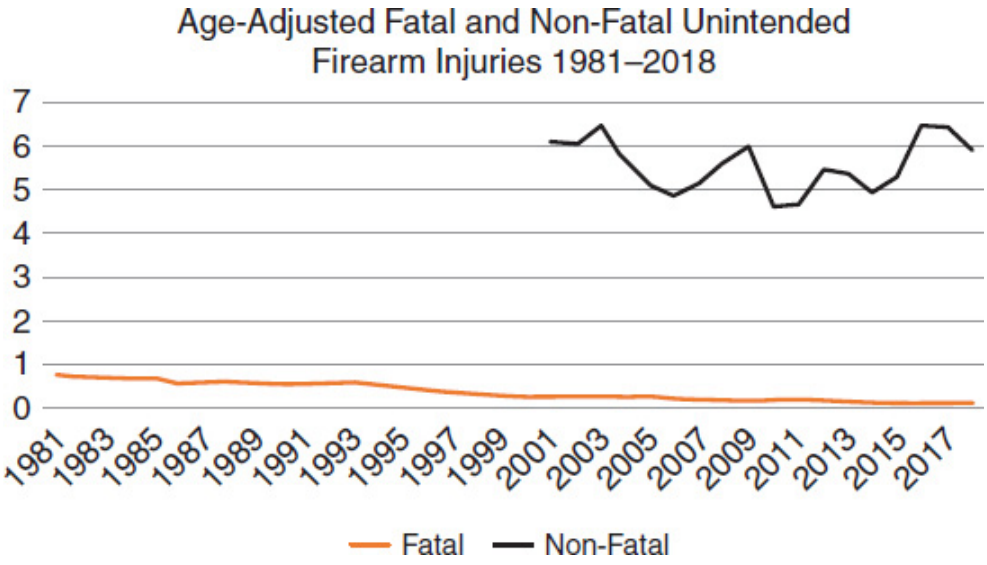

Figure 22.1 Age-adjusted fatal and non-fatal unintended firearm injuries per 100,000 persons. (Data sourced from WISQARS *Data from* National Center for Injury Prevention and Control. WISQARS [Web-based Injury Statistics Query and Reporting System], Injury Center, Centers for Disease Control and Prevention: Injury Prevention & Control Data and Statistic [WISQARS]. https://www.cdc.gov/injury/wisqars/index.html. Published March 30, 2020. Accessed June 15, 2020.)

Between 2001 and 2018, for every single suicide there were 11 self-harm injuries. These nonfatal injuries are more common among women (**Fig. 22.4**) and are most likely to involve poisoning or cutting. There are so few failed suicide attempts involving a firearm that the absolute number is not reported. Surviving a suicide attempt with a firearm is very unlikely given the high lethality of the weapon.[8]

Homicide and Assault

Homicides are less common than unintentional injury and suicides in the United States. The Major Cities Chief Association, representing 70 law enforcement agencies, identified that the homicide rate has been increasing in two-thirds of all major cities.[14,15] In 2018, there were 18,830 homicides. The majority of deaths were among males 15 to 44 years of age (**Fig. 22.5**). Racial and ethnic minorities' risk of death from homicide is significantly higher than non-Hispanic Whites. Young, Black males (aged 15 to 34), in particular, have the highest homicide rate (**Fig. 22.6A,B**). In fact, it is the leading cause of death in this population. Of all homicides between 1981 and 2018, 70% used a firearm. For every homicide death, there are 93 nonfatal assaults. Approximately 4% of nonfatal assaults involve a firearm.[8]

These acts of fatal and nonfatal violence occur daily between strangers, community members, partners, and families. Experiencing or, even, witnessing violence, in all of its forms, increases the risk of being a future victim or perpetrator of violence. Thus, to truly understand the pervasiveness of the problem is to understand the different permutations of interpersonal violence.

Mass Shootings

Mass shootings, as they are discussed here, include four or more shooting victims in a public setting. Between 1966 and May of 2019 there were 176 mass shooting incidents in 42 states and Washington, DC. These acts were committed by 183 shooters, 179 of which were male. Over 1,200 people were killed, with thousands more injured. Mass shootings have been more deadly and occurring more frequently, bringing the topic of gun violence into the public eye. Once occurring on average every 180 days (1966–1999), they now occur once every 47 days (2015–2019).[16,17]

Legal Intervention

Deaths or injury attributed to *legal intervention* are acts inflicted by on-duty law enforcement agents. Within the WISQARS database, there is no indication of legal circumstances of these events. In 2018, there were 618 fatalities and 85,075 nonfatal injuries.[8] There is data to suggest, however, that these incidents are vastly unreported, particularly if the injured individual is lower socioeconomic class or a minority.[18] The majority were young males. Ninety percent of deaths involved a firearm. Age-adjusted death rates were highest among Blacks (0.28) and American Indians (0.26) followed by Whites (0.14) and Asians (0.06). This disparity is consistent with studies that have shown officers are more likely to shoot a Black individual holding weapons faster and more often when compared to White individuals in the same circumstance.[18,19]

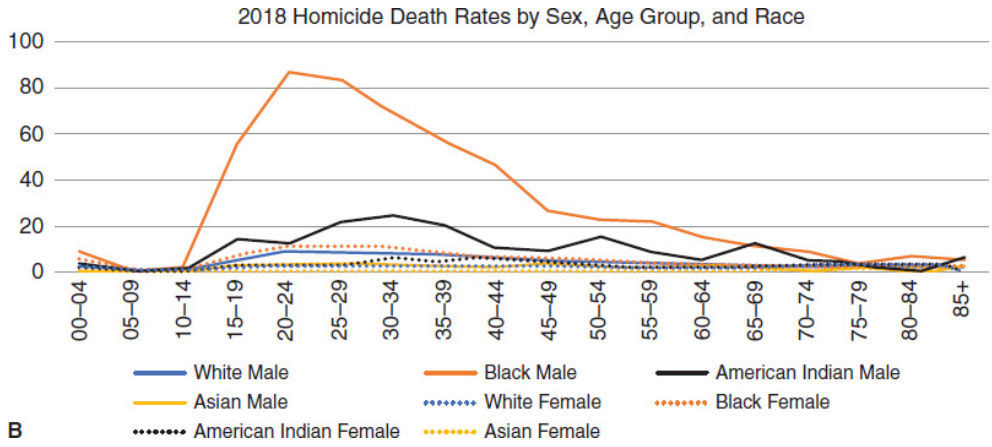

Figure 22.6B Homicide death rates per 100,000 people by sex, age group and race in 2018. (Data sourced from WISQARS *Data from* National Center for Injury Prevention and Control. WISQARS [Web-based Injury Statistics Query and Reporting System], Injury Center, Centers for Disease Control and Prevention: Injury Prevention & Control Data and Statistic [WISQARS]. https://www.cdc.gov/injury/wisqars/index.html. Published March 30, 2020. Accessed June 15, 2020.)

Intimate Partner Violence

Intimate partner violence (IPV) encompasses physical, sexual, emotional, and psychological violence between current or past spouses. In fact, 25% of women and 10% of men have experienced some form of IPV in their life

time. The majority of individuals experienced IPV for the first time before the age of 25. Fifteen percent of men and 21% of women have experienced severe physical violence from a partner. One in six homicides involve intimate partners. Half of all female homicide victims are killed by their spouse. It is estimated that the medical, legal, and lost productivity of IPV cost $3.6 trillion annually.[20]

Child Abuse

Child abuse is defined as physical, sexual, emotional abuse or neglect of a minor by a caregiver. In 2018, one in seven children were victims of child abuse or neglect. Survivors are at increased risk of future injury and violence. While rare, 1,800 children were killed as result of abuse in 2018.[21]

Firearm Injury

The public health burden of injuries has been well documented since the mid-20th century. Prevention initiatives have aimed to reduce the morbidity and mortality attributed to common vectors like motor vehicles, since the 1930s, and firearms, since the 1980s. Over the last 10 years, the age-adjusted death rates for firearm injury first equalized and has now surpassed that of motor vehicles (**Fig. 22.7**). As such, it is an unprecedented time in the history of the field of injury prevention. Firearms are among the top five mechanisms of injury deaths. In 2018, 39,740 deaths were caused by a firearm. The majority, 62%, were suicides. Thirty-five percent were homicides, 1% legal intervention, and 1% unintentional. There were over 900,000 years of productive life lost. Nonfatal and fatal firearm injuries resulted in $45 billion in medical costs and lost wages in 2010.[8]

Firearms play an intricate role in injury mortality in that they are a highly lethal, common vector within unintentional, suicide, homicide, and legal intervention injuries.[22] Contrary to what is depicted in popular media, the victims of gun injuries reflect the diversity of circumstances in which guns are used. This should come as no surprise to the surgical community. It is the older adult suicide attempt, the hunting injury, the child unintentionally wounded after finding and playing with a gun, the teenager shot during an altercation, the battered spouse, and the store patrons present during a mass

shooting—all of whom are rolled into the trauma bay with devastating injuries. Despite the heavily charged political debate about firearms in the United States, decreasing firearm-related deaths and disability should be approached as a public health priority with an emphasis on minimizing death and suffering through broadly based prevention efforts.

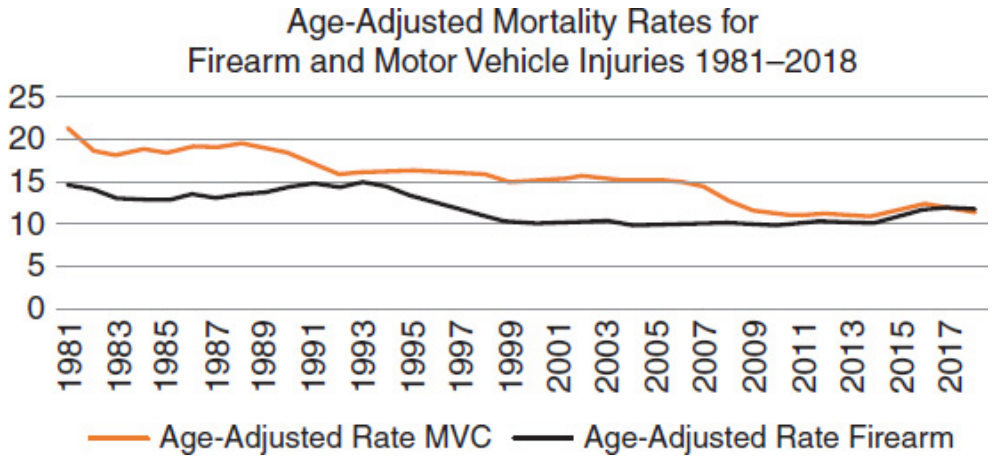

Figure 22.7 Age-adjusted mortality rates per 100,000 for firearm and motor vehicle injuries 1981–2018. (Data sourced from WISQARS *Data from* National Center for Injury Prevention and Control. WISQARS [Web-based Injury Statistics Query and Reporting System], Injury Center, Centers for Disease Control and Prevention: Injury Prevention & Control Data and Statistic [WISQARS]. https://www.cdc.gov/injury/wisqars/index.html. Published March 30, 2020. Accessed June 15, 2020.)

LANDMARK INJURY PREVENTION INITIATIVES

Workplace, motor vehicle, and childhood injuries have been the subject of injury prevention initiatives since the inception of the field. As such, these three areas are heavily represented in the field's landmark achievements.

The Occupational Health and Safety Act created the CDC's National Institute for Occupational Safety and Health in 1970 (NIOSH; https://www.cdc.gov/niosh/).[23] NIOSH aims to keep America's workforce safe through research, partnership, and program implementation covering topics from asbestos exposure to needlestick injury to machine safety. The OSHA blood-borne pathogen standards (1992) along with NIOSH

recommendations (1999) aimed to reduce the nearly 800,000 needlestick injuries each year. Interventions targeted safer sharps and sharp container design, universal precautions, worker education, free hepatitis B vaccinations, and postexposure evaluation and treatment.[24–30] These efforts have proven to be effective, with a decrease in total needlesticks to less than 400,000 by 2015.[31]

Nation-wide motor vehicle and road safety policies, programs, and behaviors have developed over the last century. Starting in the 1920s there was a call for national, uniform, enforced road safety laws, including speed limits, seat belts, child car seats, and maximum blood alcohol limits.[2,32–40] As a mechanism to ensure national adoption of these policies, a stipulation was made that any state that failed to pass these laws would not receive federal highway funding.[32] Widespread behavior change came about with both law enforcement (i.e., sobriety checkpoints) and public education campaigns (Mothers Against Drunk Driving, "Click it or ticket"). Seatbelt use, for example, increased from 11% in 1981 to 91% in 2019. Nearly 15,000 lives were saved by seat belt use in 2017 alone.[32,36,41] States have varying degrees of graduated drivers' license for new, young adult drivers.[42,43] Furthermore, over this time frame, cars have become safer.[34] Despite the 10-fold increase in number of miles driven per year in America between 1920 and 1990, the death rate per mile travelled has decreased by 90%.[32,44]

In addition to the widespread success in car seat use, there have been several other initiatives to mitigate childhood injuries in all settings.[45] The Child Safety Network of the Health Resources and Services Administration spearheads national and state wide efforts on diverse topics like poison control, sports safety, child abuse, and fall prevention (https://www.childrenssafetynetwork.org/).[46] Window guards, stair gates, bike helmets, energy-absorbing playground surfacing, and child supervision improvements have all been shown to successfully reduce falls.[47–55] One specific program example includes the "Children Can't Fly" campaign in New York City. This 1974 initiative required window guards in homes with children less than 10 years old. The result was a 96% decrease in falls from windows.[56] While work-place, motor-vehicle, and childhood injury prevention has developed over the last century, violent injury prevention came into the purview of the field much more recently.

Violence as Public Health Problem

3 Violence was considered purely a criminal justice issue until 1968. It was then that President Lyndon B. Johnson appointed the National Commission on the Causes and Prevention of Violence with the goal of identifying the social underpinnings of violent acts.[57] Thereafter, data was collected and analyzed regarding the morbidity, mortality, and healthcare cost of violent injuries. The Healthy People 1979 report was the first instance in which injury and violent behavior was described as a public health priority.[58] Subsequently, the 1980 Promoting Health/Preventing Disease Report outlined specific objectives for child abuse, homicides, suicides, privately owned guns, and data collection.[59] Violent injury has been identified as a priority in all subsequent Healthy People Reports (https://www.healthypeople.gov/).[60] The CDC then created the Violence Epidemiology Branch in 1983 and the Extramural Research Program for injury and violence in 1986. An infrastructure to treat violence as a public health issue was thereby created.

Two milestones occurred in 1985. The first was the Secretary's Task Force on Black and Minority Health Report which outlined the heavy contribution of violent firearm injury to health disparities among Blacks.[61] This disparity persists to this day. Second, Surgeon General C Everett Koop convened the first Surgeon General's Workshop on Violence in Public Health.[62] Other Surgeon Generals have followed his lead, understanding violence as a public health problem.[63] More recently, there have been calls for an annual Surgeon General's report to deepen understanding of firearm injury causes and effects.[64]

The precedent was set in the 1980s: violence, like other injuries, is a preventable, public health issue. The CDC received its first congressional appropriation for youth violence prevention in 1992, which led to the creation of the NCIPC (cdc.gov/injury/index.html).[65] School- and community-based programming was implemented, monitored, and evaluated. In 1993, the CDC published its findings in "Youth Violence Prevention: A Framework for Community Action" promoting programs that strengthened social, emotional, behavioral, and familial competencies.[66]

Similar to injury prevention, violence prevention called for multidisciplinary teams, including education, health care, criminal justice, legislature, communications/media, business, and community organizations.

The NCIPC ultimately expanded its prevention efforts beyond youth violence to include IPV, sexual violence, child maltreatment, elder maltreatment, and suicide.[2] By 2001, public health violence prevention initiatives were proven to be both efficacious and cost effective in the "Youth Violence: A Report of the Surgeon General."[67]

Federally funded injury and violence prevention research in the 1990s included gun violence. Initial studies identified having a firearm in the home was an independent risk factor of homicide. Unfortunately, firearms have not been a bipartisan topic. Controversy ensued. Through the National Rifle Association's strong lobby and, ultimately, the Representative Jay Dickey's 1996 Omnibus Appropriations Act, the CDC was banned from conducting research that may ultimately promote gun control. In 2012, this ban extended to the U.S. Department of Health and Human Services.[68] Attempts were made to repeal the ban of firearms research in both 2015 and 2017. Both failed. Firearm possession by private citizens remains a controversial, partisan topic of debate in the public arena.[69] However, recent data would suggest a majority of Americans actually agree on particular gun restrictions.[70] The goal of this chapter is to refocus the conversation on the health and well-being of the patients encountered in the trauma bay—in preventing injury, increasing survival, and improving long-term outcomes for the individual, communities, and the nation.

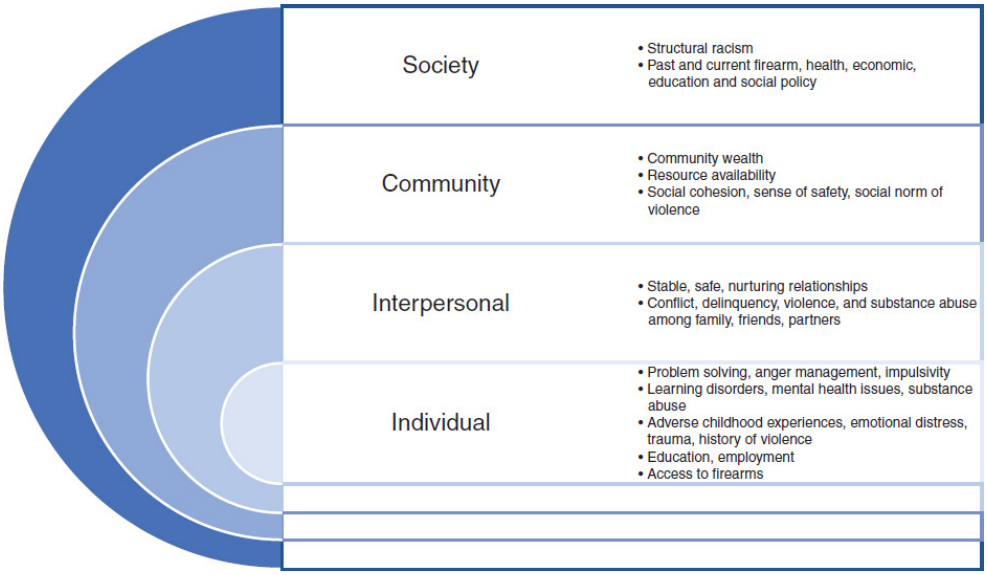

Figure 22.8 Social ecologic model for violence.

THE SOCIAL ECOLOGIC MODEL

4 The social ecologic model is used as a framework for the dynamic risk and protective factors of gun violence on various levels, including individual, interpersonal, community, and society (**Fig. 22.8**). This framework is vital in identifying opportunities to reduce risk, bolster protective factors, and identify stakeholders. The preponderance of factors is unifying across different types of violence (child abuse, IPV, suicide/self-harm, and assault/homicide).[71] Therefore, relevant programing and policy should be recognized as generalized violence prevention.

An individual's personal characteristics, health, experiences, and demographics affect the likelihood of violence. The ability to problem solve, manage anger and control impulsivity are essential skills in conflict resolution. A personal history of learning disorders, mental health issues, and substance abuse all increase risk. Prior adverse childhood experiences, chronic or severe emotional distress, attitudes toward violence, and witnessing or experiencing violence increase the likelihood of becoming a victim or perpetrating violence. Level of education and employment have also been shown to correlate with violence. Easy access to unlocked and unprotected firearms increases risk of suicide and homicide.[67,71–76]

The next level, interpersonal relationships, hinges on social support. The presence or absence of stable, positive social connections among family, friends, and partners can contribute as a risk or protective factor. Unstable, conflict-ridden relationships along with the presence of delinquent, violent (toward self or others), and substance abuse behaviors among family, friends, and partners can negatively impact the individual. Nurturing, safe, stable relationships, however, have the ability to positively influence outcomes even in the setting of other individual, community, or societal risk factors.[67,71,73,74]

Neighborhoods, schools, workplaces, and places of worship are in the community level of the social ecologic model. It is where an individual lives, learns, works, prays, and plays. Community wealth is measured directly by unemployment and poverty levels and indirectly by the residential instability, crowded housing, concentration of liquor stores, and availability of green space and fresh food. Pertinent resource availability includes readily accessible health services (mental health, primary care, trauma

centers, and substance abuse programs) and a trusting relationship with law enforcement. The sense of social cohesion and community safety at this level are important factors. Crime levels and the social norm of violence and substance abuse contribute to the sense of safety. Community-level poverty, lack of resources, and low sense of safety and social cohesion all increase the risk of violence. The violence that results acts as a positive feedback mechanism in that violence lowers property values, drives out resources, and propagates low sense of safety.[76–81]

Society-level factors can be at city, state, and national level. This includes past as well as current firearm, health, economic, education, and social policy that tickle down to lower social ecologic levels. It has been well documented that individual, interpersonal, and community risk factors for violence are not evenly distributed. In fact, this was discussed on the national level as early as President Johnson's National Commission on the Causes and Prevention of Violence.[57] They identified violence as a reflection of a myriad of social problems, including, but not limited to, racial segregation, low income, low levels of education, low home ownership, physical deterioration, and broken homes. The range of extreme concentration of risk factors to extreme concentration of protective factors exists to this day. The dichotomy begs the question: are there forces on a societal level that concentrate risk versus protective factors?

The discussion necessitates careful consideration of structural violence, or the unequal power and opportunity driving social determinants of health.[82,83] The long-standing history of race-based inequity, therefore, is at the root of health disparities. This goes far beyond interpersonal acts of racism, to the institutional level discriminatory policies and practices based on race. As this has occurred across sectors including housing, education, employment, health care, and criminal justice, these discriminatory systems reinforce one another to result in the phenomenon of structural racism.[84–86] The role institutional and structural racism play in the outcome of firearm injury can be illustrated with the example of housing.

When communities were still legally segregated by race, they were economically diverse. In the early 1930s, the Federal Housing Administration initiated a mortgage lending process called Redlining, by which the housing market prices were determined based on race, ethnicity, and religion. After neighborhoods were legally desegregated in the 1960s,

only wealthy minorities could afford to move into nicer communities. This combination resulted in the concentration of poverty among the disenfranchised minority still evident today.[87] Multiple studies have shown that racially segregated, low-income communities have higher rates of firearm injury.[88–93] Even further, restrictive firearm policies may be less effective at decreasing injury in these communities.[94]

Despite the 1960 Civil Rights Act, many laws have systematically targeted poverty-stricken minority populations. The War on Drugs provides just one example. With the crack cocaine epidemic, national rhetoric created a discriminatory stereotype of "crack babies," "crack whores," "gangbangers," and "welfare queens." From 1980 to 2010, crack cocaine sentencing laws were 100 times those for powder cocaine. Even with the Fair Sentencing Act of 2010, the sentencing is still 18 times greater. Laws such as these have contributed to incarceration rates of Blacks being 3 to 10 times higher than non-Hispanic Whites. Mass incarceration has destabilized minority families and communities and further reduced education, employment, and housing opportunities. Similar examples could be discussed within education, policing, and health sectors.[84,95]

This is not to suggest impoverished White communities and wealthy minority communities do not exist with varying degrees of risk and protective factors. Rather, it is to bring attention to the societal-level forces which have systematically concentrated risk factors among minorities over time. Without knowing the societal forces at play, it is all too easy to oversimplify prevention efforts around a "bootstrap" narrative by putting the entire emphasis on the individual.

THE SURGEON'S ROLE IN FIREARM-RELATED INJURY AND VIOLENCE PREVENTION

The scope of the firearm-related injury and violence prevention is vast. It encompasses injury and violence in multiple forms (unintentional, suicide, interpersonal, intimate partner, child abuse) with pertinent risk factors throughout the life span across all ecologic levels (individual, interpersonal,

community, and society). Thus, there are nearly endless opportunities for preventative programming and policy.[96]

5 Firearm-related injury and violence prevention takes place on a continuum: before the injury occurs (primary prevention) or after the injury occurs by minimizing the mortality, likelihood of reoccurrence (secondary prevention), and reducing long-term morbidity (tertiary prevention). The social ecologic risk and protective factors span the timeline of an injury (**Fig. 22.9**). Prevention initiatives, including programs and policies, should involve an array of stakeholders, including gun owners, vulnerable communities, law enforcement, educators, health professionals, public health professionals, and lawmakers.[97] Prior to discussing specific opportunities for surgeon involvement in prevention, it is important to review the standpoint of the surgical community on gun violence.[98–100]

There have been a variety of Association statements, including the American Association for the Surgery of Trauma, Eastern Association for the Surgery of Trauma, and the American College of Surgeons Committee on Trauma (ACS-COT).[101–103] The ACS-COT published a Consensus on firearm-related injury based on member survey (93% response rate) and meetings with surgeon leaders in town halls and professional organization meetings. While the community had varying personal opinions on gun ownership, there was agreement on the need to address the preventable morbidity and mortality of firearm injury. The majority supported healthcare worker rights, education, and training to counsel patients on safe firearm ownership (90%), federal funding for gun violence research, and the development of a research agenda (92%), universal background checks (86%), severe penalties for individuals who illegally supply guns to others (92%), and trauma center involvement in addressing the root causes of firearm injury.[104,105] The ACS-COT also created the Firearm Strategy Team (FAST), a group of firearm-owning surgeons as they offer a truly unique perspective on safe gun ownership and the prevention of injury.[70,106,107]

6 In February of 2019, the ACS hosted the Medical Summit on Firearm Injury Prevention, joining together 44 medical, public health, legal, and injury prevention Associations to develop a consensus, nonpartisan approach to unintentional, intentional, and suicide injury prevention. This meeting, the first of its kind, adopted a public health approach based on epidemiology, program development, evaluation, and dissemination. Programs discussed

included safe storage, patient counseling, patient screening, hospital/community-based violence prevention programs, and public policy. The final consensus statements can be found in **Table 22.1**.[98,103]

Thus, the surgical community, along with the general medical community, has reached a consensus that firearm injury and violence is a cause of preventable morbidity and mortality. It is within 7 the surgeon's scope practice for their patients, hospitals, and communities to address the root causes of violence and make gun ownership safer. The following are specific mechanisms to do so.

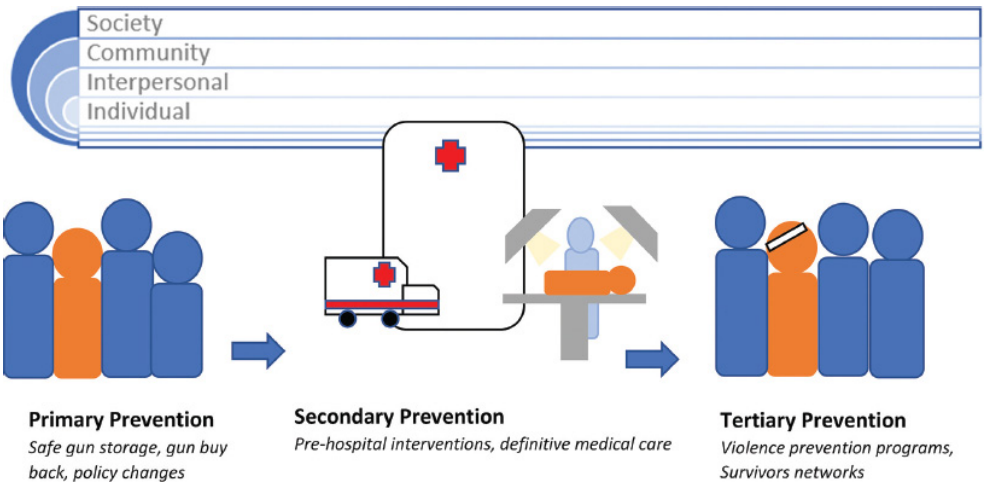

Figure 22.9 Primary, secondary, and tertiary violence prevention.

Table 22.1 Medical Summit on Firearm Injury Prevention Consensus Statements

Reproduced from: February 2019 Medical Summit on Firearm Injury Prevention Consensus Statements
Firearm injury is a public health crisis.
A comprehensive public health and medical approach is required to reduce death and disability from firearm injury.
Research is needed to better understand the root causes of violence, identify people at risk, and determine the most effective strategies for firearm injury prevention.
Federal and philanthropic research funding must be provided to match the burden of disease.
Engaging firearm owners and populations at risk is critical in developing programs and policies for firearm injury prevention.
Healthcare providers should be encouraged to counsel patients and firearm safety and safe storage. Educational and research efforts are needed to support culturally competent messaging.
Screening for the risk of depression, suicide, intimate partner violence, and interpersonal violence should be conducted across all healthcare settings and in certain high-risk populations (such as those with dementia). Comprehensive resources and interventions are needed to support patients and families identified as high risk for firearm injury and who have access to a firearm.
Hospitals and healthcare systems must genuinely engage the community in addressing the social determinants of health of disease, which contribute to structural violence in underserved communities.
Our professional organizations commit to working together and continuing to meet to ensure these statements lead to constructive actions that improve the health and well-being of our fellow Americans.

Primary Prevention

Primary prevention initiatives target the upstream causes of gun injury and violence in order to prevent incidents in the first place.

Access to a firearm is an independent risk factor for homicide and suicide.[108–110] Physicians and their representative professional associations, including internists, pediatricians, and surgeons, have agreed physicians should screen and counsel patients on firearm safety.[111–116] However, the available data suggests few attending physicians and even fewer residents are discussing the topic despite the majority of patients being receptive to the conversation.[117–119] Studies regarding firearm safety counseling in outpatient and hospital settings have demonstrated an increase in the safe storage of firearms, decreased firearm access among suicidal teens, and reduction in firearm injury recurrence. Supplying safety devices to patients increases sustained safe storage of firearms.[117,120–124]

In outpatient and inpatient settings, surgeons can and should be systematically screening and counseling patients on safe firearm storage much like the way we counsel on smoking cessation or weight loss. Various tools can be found to guide this conversation include courses by the American Medical Association, Massachusetts Medical Society, the University of Michigan and Scrubs Addressing the Firearm Epidemic. The ACS-COT has a Gun Safety Brochure available in English and Spanish.[125–129]

The surgeon should illicit access to firearm, safe storage, and intent to harm. Easy access to firearms is particularly risky in households with children and/or individuals with cognitive impairment, dementia, substance use disorder, mental illness, and history of violence. Nearly 5 million American children live in a home where a gun is not safely stored.[130] The patient should be asked to share their opinions regarding firearm storage. Other adults in the home may have similar or conflicting opinions. Patients should be educated that guns should be stored locked, unloaded, separate from ammunition away from any individuals at risk for unsafe use or harm to self or others. If the patient has access to a gun, the physician should assess suicidal or homicidal intention. Any expressed intent to harm should result in the patient being committed for emergent psychiatric evaluation.[131] In some states, there are Extreme Risk Protection Orders which allow healthcare

professionals, family, or law enforcement to file petitions for temporary removal of a firearm from the home.[132] Patients can and should also be made aware of any local gun buy-back programs for unwanted firearms.[133]

Surgeons can be advocates for local, state, and federal policy changes to prevent firearm injury without infringing upon the rights of firearm owners. Data-driven legislation may affect gun licensing, firearm and ammunition availability, and research funding. The number of state firearm laws varies widely (<10 to >100).[134] Studies have demonstrated cities and states with stricter firearm laws are correlated with fewer associated mortalities.[135–141] A state's homicide rates are not only associated with their own laws, but also the laws of surrounding states.[142] Restrictive laws include comprehensive background checks, which may identify a history of protective/restraining orders, domestic violence charges, fugitive status, psychiatric disorders, and misdemeanor crimes in addition to state or federal crime convictions. These features have been associated with overall decreased homicide, including intimate partner homicide, and suicide rates.[143–150] Importantly, studies have identified these laws only have an effect when properly enforced.[151,152] Restrictive legislation, however, is not uniformly beneficial. In particular, these laws were not correlated with lower homicide rate among Blacks.[94,153,154] Given the historical and contemporary structural violence and racism to this population, beneficial legislation may need to target this etiology.

In addition to tighter regulation on who can purchase a firearm, legislation also dictates the type of firearms and ammunition available to the public. High-capacity magazines, gun caliber, semiautomatic weapons, and bump stocks are all features that increase a firearm's lethality, or its capacity to render more severe injuries in a shorter time frame.[155–157] In 2004, the federal ban on assault weapons expired. Seven states have since passed new assault weapon bans. Such laws are vital given that the rate and severity of firearm injuries has been increasing.[158] While there is data to support the merit of stricter firearm legislation, there is a paucity of funding allocated for firearm injury research. This dates back to the Dickey Amendment in 1996, which dried up federal funding for gun violence prevention research. Therefore, legislation to increase and maintain the federal appropriation for firearm injury research is imperative.[159]

Surgeons are poised to leverage clinical experience to advocate for data-driven legislation regarding gun licensing, firearm and ammunition regulation, and research funding.[160–163] The ACS advocates on behalf of and alongside surgeons and their patients. In 2019, this included legislation which would increase in the appropriation for firearm injury prevention research. For the first time in more than 20 years, Congress appropriated federal dollars for gun violence research. Federal agencies received $25 million from Congress to study gun violence in a government spending deal reached by House and Senate negotiators. The deal included $12.5 million each for the CDC and National Institutes of Health to study gun violence and ways to prevent it.[160,164] The College is a major resource for advocacy resources ad activities. Partnering with nonprofit and grassroots organizations, including the Brady Campaign, Gifford's, Mom's Demand Action, is another practical mechanism to identify advocacy opportunities on the local, state, and federal levels.[160]

Social media campaigns have also proven to be an effective mechanism to educate the public and inform policy. In the fall of 2018, front-line trauma workers joined together to share collective experiences treating firearm injury patients using the #Thisisourlane. This campaign was in response to the National Rifle Association's tweet suggesting physicians should "stay in their lane," suggesting a lack of expertise in firearm policy. The public and many policy makers were galvanized as a result of the campaign.[160] While advocacy work may seem overwhelming to some, there are many practical ways for a surgeon to share their professional opinion with the public, local organizations, and policy makers. In 2018, 67 pieces of gun reform legislation were passed.[165] Hopefully, this trend will continue with the support of the surgical community.

Secondary and Tertiary Prevention

Secondary and tertiary prevention initiatives aim to decrease the mortality and morbidity after an injury occurs. Survival after a firearm injury depends on location and severity of the injury as well as expedient and effective prehospital stabilization and definitive hospital care.

Unfortunately, not all regional trauma systems provide the same care resulting in a wide range of geographic-based survival rates. In the 2016

National Academies of Science Engineering and Medicine report entitled "A National Trauma Care System" the argument is made up to 20% of the annual trauma deaths may have been preventable. This landmark paper calls for a national trauma system in which the military and civilian trauma experience is shared to improve quality of care and patient outcomes.[166] These two sectors have relied on one another for high-quality preclinical and clinical research on countless topics including nonoperative versus nonoperative management, prehospital and hospital resuscitation, and mass casualty care.[167–174] This proposed system would provide infrastructure to a longstanding relationship between the military and civilian traumatologists with the goal of having zero preventable deaths due to trauma.[166]

Uncontrolled hemorrhage was found to be a major cause of preventable deaths in the military. To address this problem, the Tactical Combat Casualty Care training was developed. It taught soldiers immediate life-saving maneuvers like applying a tourniquet and combat gauze and relieving an obstructed airway. This program proved to be efficacious.[175,176] These skills translate to civilian traumatic injury.[177] In the aftermath of the Sandy Hook Elementary School shooting in 2013, a wide variety of stakeholders joined to develop the Hartford Consensus. They identified bystanders to injury as the true "first care responders" who, with the proper skill set, can control hemorrhage while waiting for first responders to arrive (EMS, police, fire). In 2015, the White House National Security Council's Office of Medical Preparedness Policy announced the Stop the Bleed campaign which would aim to target the same skill set as the Hartford Consensus based on the military's successful program (https://www.dhs.gov/stopthebleed). In 2016, the initiatives joined to train nonmedical first responders (police and fire) and, ultimately, the public.[178–181] These trainings taught the same skills and made tourniquets available in public settings. Participants reported increased ability and willingness to apply this skills should the need arise.[182]

Survivors of firearm injury face a long mental and physical recovery.[183] There are hospital-based and national trauma survivors networks to assist patients in the aftermath of injury.[184] Victims of violent injury are at increased risk of future victimization or perpetration of violence. These negative effects are felt not only by the victim, but also the community where the violence occurred.[185–187] For these reasons, community and hospital-based prevention programs intervene after an injury as a teachable moment to

address modifiable risk factors. This is a similar principle used in cardiac rehabilitation programs used to change diet and exercise following a myocardial infarction.

While these violence prevention programs are diverse in activities and scope, there are several unifying principles. Employees are typically from the community, who will be deemed credible and relatable to the patients. They are charged with the task of building and maintaining a relationship as mentors and case managers. The program assists the patient overcome barriers to meet basic needs and achieve goals. This is not an easy task, as it requires navigating the systems that have all too often already failed the individual, including health care (mental, physical and substance abuse), employment, education, housing, and legal aid. The patient continues to work with the program after discharge with the ultimate goal of reducing risk and increasing protective factors for future injury.[189]

The Wraparound Program based out of University of California, San Francisco and Violence Intervention Program at University of Maryland are among the well-established and well-studied hospital-based programs.[188,189] Across 22 randomized control trials of 14 different programs, there was an increase in service utilization, change in attitude regarding violence, decrease in violent behavior, and decreased repeat injury. There was a cost–benefit among the intervention arms from reduced hospital readmissions and legal costs of conviction and incarceration.[189–197] As the evidence has grown, several states have increased funding availability for these programs, including California, New Jersey, and Virginia.[189]

The Health Alliance for Violence Interventions (HAVI), formerly called the National Network of Violence Prevention Programs, aims to provide infrastructure to the hospital-, community-, and health department-based programs across the country. HAVI has partnered with ACS-COT and the American Foundation for Firearm Injury Reduction. They provide technical assistance, conduct research, and issue best practice guidelines. While guidelines and evidence have been produced based on program experience, this infrastructure will allow for rigorous evaluation across institutions and program models.[198–200]

As this chapter outlines, the etiologies of intentional (assault and self-harm) and unintentional firearm injuries span multiple disciplines. Policy and programing prevention initiatives, therefore, extend far beyond the hospital.

Surgeons may find opportunities to support other professionals, including law enforcement, education, and public health, in their efforts to reduce firearm injuries locally and nationally.

Neck Injuries

Brandon R. Bruns and Thomas M. Scalea

Key Points

1 An intimate understanding of the neck anatomy is necessary for optimal management of injuries in this region.

2 Obtaining a secure airway is vital for management of all major injuries, especially those in the neck.

3 Gentle digital pressure or balloon tamponade may control life-threatening hemorrhage from vascular injuries in the neck while definitive measures are arranged.

4 Though classic teaching mandated exploration of all zone II injuries with penetration of the platysma, modern trauma care allows some discretion.

5 A high index of suspicion and recognition of injury patterns is necessary to diagnose blunt cerebrovascular injury.

6 Blunt cerebrovascular injury is often present in patients who do not manifest traditional screening criteria and recognition is important as untreated injuries may lead to strokes.

7 A combination of endoscopy and contrast-enhanced radiography presents the best opportunity to diagnose esophageal injury when present.

INTRODUCTION

1 Many vital structures reside within the neck and exist in close proximity to one another. These structures include the aerodigestive tract, blood vessels, bones, and the spinal cord. The close proximity can lead to multiple injuries in a wide variety of structures within a relatively small area. Of penetrating injuries to the neck, the vast majority are caused by stab wounds.[1–3] Blunt injury to the neck is the result of various mechanisms including direct blows, automobile shoulder belts, and various hanging mechanisms with neck hyperextension. The anatomic complexity and diverse injury mechanisms make diagnosing and treating neck injuries challenging.

FUNCTIONAL ANATOMY

The exterior anatomic barriers of the neck include the lower border of the mandible anteriorly, to the nuchal line of the occipital bone posteriorly. Inferiorly, the clavicles serve as the anterior border with a line drawn toward the seventh cervical vertebral spinous process encompassing the posterior border.

Triangles are classically used to divide the neck into zones; however, they are only rarely used to classify and plan treatment in the trauma patients. The posterior triangles are bordered by the sternocleidomastoid muscles anteriorly, the trapezius muscles posteriorly, and the clavicles inferiorly. The sternocleidomastoid muscles, the midline, and the angles of the mandible border the anterior triangles bilaterally.

In 1969, Monson and colleagues[4] arbitrarily divided the neck into three anatomic zones: zone I consisted of the area below the sternal notch, zone II was the area between the clavicles and the mandibles, and zone III was described as the upper cervical region and consisted of the area above the mandibles. Roon and Christensen[5] introduced a more modern version of the neck zones in 1979 and defined zone II as the area between the cricoid and the angle of the mandible, zone I as the area below the cricoid cartilage, and zone III remained the area above the mandibular angle (**Fig. 23.1**).

The zones of the neck are important as the approach to injury within each zone is different and is limited by anatomic barriers. This is particularly true when one considers vascular exposure, as exploration of all major vascular structures in zone II is accomplished via a standard sternocleidomastoid neck incision. Via a single incision, proximal and distal vascular control can both be obtained within zone II, and injuries repaired.

Proximal control for zone I injuries may require control within the chest. Depending on the location of injury, a variety of incisions can be utilized. A full sternotomy provides access to the mediastinal great vessels and the proximal left subclavian artery, along with the origin of the left common carotid artery. A partial sternotomy allows control of the innominate artery through a smaller incision. A periclavicular incision provides access to the bilateral subclavian arteries. In short, full exposure is achieved through a variety of incisions. After proximal control, subsequent distal control is obtained in zone II.

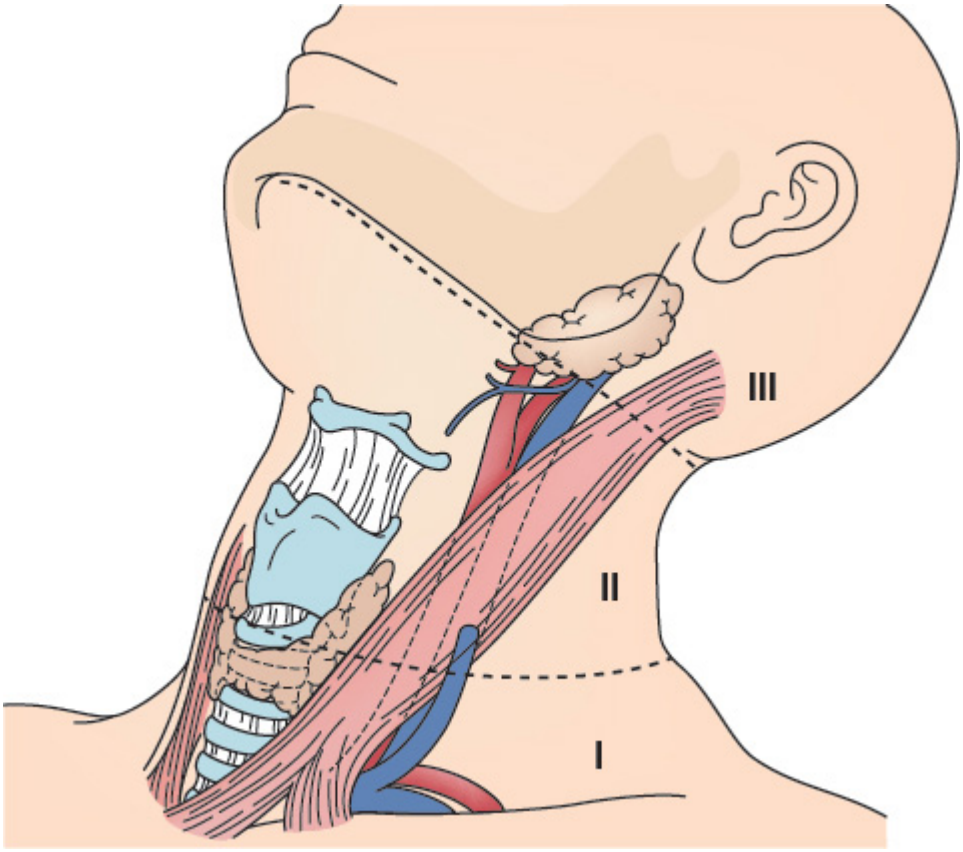

Figure 23.1 Zones of the neck.

Proximal control for zone III injuries can be achieved in zone II without much difficulty; however, distal control may be difficult as the mandible and skull base prevent wide exposure. Several methods, such as mandibular subluxation or osteotomy, have been described to control the carotid artery at the base of the skull.[6] A muscle splitting incision can also help give access to the carotid artery and the base of the skull.[7]

The inferior and lateral extensions of zone I are often contested and debated. While this is not well described, our practice is to classify lateral and inferior (superior mediastinal) injuries by zone I principles. Because proximal control involves a thoracic incision, we believe zone I extends to the junction of the subclavian and axillary arteries laterally and inferiorly to the mediastinal great vessels.

Injury to the posterior neck is inherently different than injury to the anterior neck. It makes sense that tracheal and esophageal injuries would be less common with posterior injury, as they are protected by the spine. Injuries to the spine should be more common in this anatomic region.

Often, more than one zone can be injured by a single trajectory; such as an injury through both zone II and zone I. Management of these "multizone" injuries is guided by the standard principles used for the more challenging zone, usually zone I or zone III.

The platysma muscle envelops the neck and originates from the pectoralis major and deltoid muscles. Though clinical practice has evolved, most classic algorithms of treating penetrating neck trauma stated that injuries penetrating the platysma muscle in zone II of the neck mandated direct operative intervention, whereas those penetrating the platysma in zones I and III mandated additional studies via either angiography or other imaging modalities.[5]

INITIAL MANAGEMENT

Basic trauma management of patients with injury to the neck should proceed as outlined in the American College of Surgeons 2 course, Advanced Trauma Life Support (ATLS).[8] Initial priority is given to securing the patient's airway. Early control of the airway with intubation is considered in every patient with a neck injury. Even in seemingly stable nonbleeding patients, a cough may dislodge a thrombus producing sudden hemorrhage. An airway that had previously been straightforward to control is now much more complicated and may require advanced techniques.

Obvious injury to the neck, with the presence of an expanding hematoma or other hard signs of vascular injury (pulsatile hemorrhage, thrill, bruit), should lead the provider to obtain definitive endotracheal access as the first step in the resuscitation. Similarly, air bubbling through the wound, hoarseness, or an obviously transected trachea, should guide the treatment team toward immediate and definitive airway control.

In the event that orotracheal intubation cannot be accomplished (rapidly expanding hematoma, destructive laryngeal trauma, patient habitus, excessive debris within the oropharynx), an emergent surgical airway should be expeditiously obtained. Cricothyroidotomy and emergency tracheostomy remain the safest and most reliable methods of emergent surgical control of the airway. Some investigators have shown promising results with percutaneous tracheostomy performed in the emergency setting, though this

should only be contemplated by experienced clinicians.[9] If tracheal transection is visualized in the wound, intubation of the distal tracheal segment with an endotracheal tube, or any available airway device, can be lifesaving (**Fig. 23.2**).

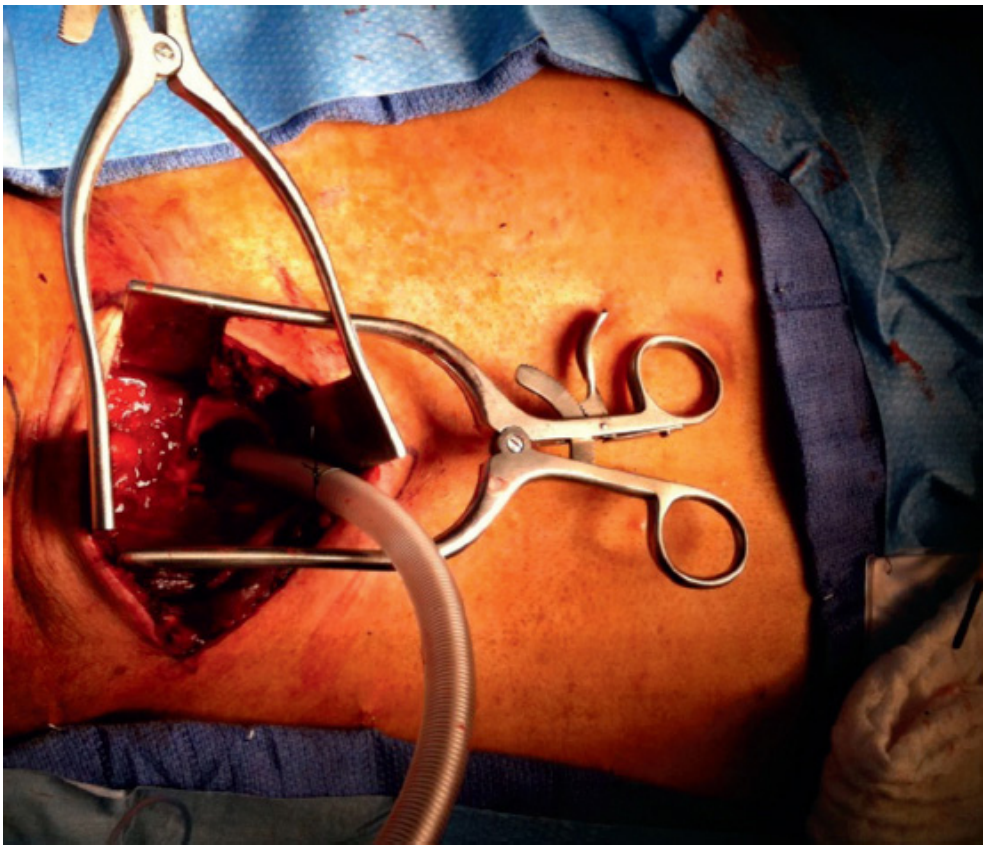

Figure 23.2 Intubation of a distal tracheal transection in the neck.

Though obtaining a safe and definitive airway is the priority in all injured patients with airway compromise, blunt trauma patients are at high risk for cervical spine injury. Maintaining the head and neck in neutral position, with the help of a competent assistant trained in such maneuvers, accomplishes cervical stabilization during intubation attempts. The same caution is not needed in patients with penetrating trauma, as patients presenting alive and neurologically intact are highly unlikely to have unstable cervical spine fractures.[10,11]

After securing an adequate airway, patient care should proceed in an orderly fashion by using ATLS principles with the next priorities being breathing and circulation. In evaluating the chest, the clinician must remain

aware that penetrating injury to zone I can violate the cupula of the lung and result in pneumothorax or hemothorax, which may require evacuation. Circulatory issues focus on intravenous access with resuscitation and assessment of the blood pressure, but it 3 also entails control of any obviously bleeding focus. Pulsatile bleeding emanating from a neck wound is best managed with gentle digital compression. Occasionally, a urinary catheter or a Fogarty catheter can be delicately placed into a bleeding neck wound with gradual inflation of the balloon in an attempt to tamponade hemorrhage. Insert the catheter until it no longer goes easily; inflate the balloon slowly until the bleeding stops.

A rapid assessment of the neurologic state of the patient can give insight into the nature of a neck injury as a dense hemiplegia may be the result of carotid arterial injury and subsequent ischemic stroke. It is imperative to recognize the patient with a lateralizing neurologic defect early, as revascularization may result in hemorrhagic conversion of a cerebral infarction.

After the primary survey and adjunctive radiographic procedures (chest radiograph, abdominal sonography), a thorough secondary survey should be performed, with focus on the structures of the neck. A hematoma across the base of the neck caused by an automobile seatbelt may portend a blunt cerebrovascular injury (BCVI). Extensive subcutaneous emphysema in the tissues of the neck usually represents air tracking up from a pneumothorax, but can represent an injury to the airway. Injury to the esophagus is possible, but subcutaneous air is rarely the only symptom of esophageal injury. Similarly, an audible bruit or palpable thrill may indicate major vascular injury that requires prompt attention.

SELECTIVE VERSUS MANDATORY EXPLORATION

Few would argue that penetrating injuries to the neck, with hard signs of injury (pulsatile hemorrhage, expanding hematoma, shock, air emanating from the wound, and massive hemoptysis), mandate immediate surgical exploration. In the absence of these hard signs of injury, most favor a

selective approach with clinical examination and diagnostic workup. The work up includes radiographs, but may also include non-radiographic modalities such as endoscopy.

Overall Approach

4 Traditional surgical teaching calls for neck exploration in patients with penetrating zone II neck injuries that violate the platysma muscle. Those supporting the concept of mandatory surgical exploration cite the low incidence of significant morbidity with surgical exploration, despite the high likelihood of negative exploration.[2,12] Proponents of operation also point to the lack of physical examination findings in patients that did proceed to have positive findings.[3] In contrast to mandatory exploration, many investigators advocate a more selective approach to operative therapy, suggesting surgery only in symptomatic patients. Authors supportive of the more limited approach cite a low morbidity and mortality associated with observation of zone II injuries and high likelihood of negative exploration.[1]

While diagnostic exploration may make sense for some zone II injuries, diagnostic preoperative evaluation certainly makes sense for injuries in zone I and zone III. Penetrating injury in zone I puts vascular structures, trachea, and esophagus at risk. Physical examination can be misleading and different incisions may be needed depending on which structures are injured and the level at which they are injured. Thus, in stable patients, additional imaging is indicated.

Additional diagnostic adjuncts generally involve endoscopy, contrast studies, or both to investigate the possibility of an esophageal injury. While asymptomatic tracheal injuries are quite rare, many have favored a diagnostic bronchoscopy in these injuries. In the past, vascular structures were investigated by means of catheter angiography, with noninvasive axial imaging as the most common modality in the current era.

Unfortunately, in unstable patients with a zone I trajectory, localization of the injury may not be possible preoperatively. In such a case, the clinician should make an estimate as to which structures are most likely to be injured. The initial incision should be tailored to quickly expose that area. If exposure is inadequate or a different structure has been injured, the incision

should be lengthened, or a second incision should be made. This process continues until the injury is controlled or the patient has died.

Aerodigestive injuries are not an issue in zone III; however, the difficulty in surgical management of vascular injuries in zone III makes preoperative imaging very attractive. In the past, angiography was used as the sole diagnostic test in stable patients. If patients are unstable, clinicians must weigh the difficulty of diagnostic exploration against the time it would take to use alternative hemostatic methods. In some cases, if catheter hemostasis is immediately available, temporary control with finger pressure or a balloon, as a bridge to rapid diagnostic angiography and catheter hemostasis, may actually be quicker than direct operative exploration. In most areas of the world, this approach is only appropriate in a few highly advanced centers. In most centers, while difficult, direct surgical exploration is the wisest course in the unstable patient.

Current Imaging Technology

In recent years, computed tomography (CT) has become the imaging modality of choice to evaluate neck injuries. CT is extremely attractive as it provides a three-dimensional evaluation of the neck and is rapidly available. In patients with injury patterns that put the upper mediastinal structures at risk as well, CT can simultaneously evaluate both areas for injury.

CT may be very effective at excluding injuries in certain cases. For example, a patient with a gunshot wound to the neck that has a clearly demonstrated CT trajectory that avoids all vital structures. In this case, close observation without additional studies is appropriate. Other patients, such as those with significant amounts of subcutaneous air or a trajectory that is close to vital structures, may need additional diagnostic testing (angiography, endoscopy).

Penetrating Neck Trauma

In 2002, Gonzalez et al. prospectively evaluated patients with penetrating injury to zone II of the neck that did not have an indication for emergent surgical exploration.[13] Patients then underwent dynamic CT imaging and had a barium esophagram, followed by mandatory surgical exploration of the

neck. Investigators noted a total of four esophageal injuries. Two of the four were seen on surgical exploration only and were not identified on either CT scan or esophagram; however, both injuries missed on imaging were less than 0.5 cm and were the result of stab wounds. The authors speculated that the injuries may have healed spontaneously. The most commonly missed injury by CT scan was jugular venous injury; which likely needed no therapy.[13]

In a large prospective study involving Los Angeles County, University of Southern California Medical Center and the R Adams Cowley Shock Trauma Center at the University of Maryland, all asymptomatic patients presenting with a penetrating neck injury and no signs of injury were safely observed and investigators reported zero missed injuries. In the same series, patients with soft signs of injury (venous oozing, nonexpanding or nonpulsatile hematomas, minor hemoptysis, dysphonia, dysphagia, and subcutaneous emphysema) underwent multidetector CT angiography (CTA). Investigators achieved 100% sensitivity and 97.5% specificity in detecting all clinically significant injuries.[14]

Blunt Neck Trauma

Plain film radiography is not adequate to identify injuries to structures in the neck; however, pneumothorax, hemothorax, air in the subcutaneous tissues, nasogastric tube displacement, or mediastinal widening are all indicative of potential injuries in the neck.

BCVI diagnosis deserves special mention. In the past, BCVI was typically diagnosed after the patient had a stroke. Diagnostic angiography then virtually always demonstrated an internal carotid artery injury. Therapy included anticoagulation, but was mainly supportive, as the damage was done.

As screening protocols were developed, the incidence of BCVI seemed to increase, even in patients with no identifiable risk factors for BCVI.[15] As CTA became more entrenched as a diagnostic tool, the rate of vascular injury again seemingly radically increased.[16,17] It seems obvious that the patients did not change, but our ability to diagnose injuries did. One must question whether some of these injuries, particularly those of low grade, have significant clinical importance.

Additional debate has focused on the ideal test for diagnosis of BCVI, with some suggesting angiography and some CTA. In a study of 146 patients at risk for BCVI, investigators imaged all patients with 16-slice CTA and four-vessel cerebral angiography. They noted a sensitivity of 97.7% and a specificity of 100% with the utilization of CTA for the diagnosis of BCVI.[18] Authors in Memphis examined 684 patients and found the sensitivity of CTA to be 51% with a specificity of 97%.[19] Despite the disparate findings, survey results illustrate that 90% of trauma surgeons utilize CTA as their preferred diagnostic modality for BCVI.[20]

MANAGEMENT OF SPECIFIC INJURIES

Blunt Cerebrovascular Injury (BCVI)

Blunt injuries to the carotid and vertebral arteries are the result of a direct blow to the vessel itself or an extreme flexion, extension, or lateral rotational injury. If located in the carotid artery, these injuries typically occur at the base of the skull. Vertebral artery injury usually is located in the portion of the vessel protected by the cervical spine. These areas are difficult to explore surgically.

Table 23.1 Signs and Symptoms of Blunt Cerebrovascular Injury
Hemorrhage of potential arterial origin
Expanding cervical hematoma
Cervical bruit in a patient <50 yrs old after trauma
Unexplained lateralizing neurologic deficits, transient ischemic attack, amaurosis fugax, or Horner syndrome after trauma
Cranial neurologic deficits incongruous with brain CT findings
Evidence of cerebral infarction on CT scan

From Biffl WL, Moore EE, Elliott JP, et al. Blunt cerebrovascular injuries. *Curr Probl Surg* 1999;36(7):505–599.

BCVI is reported to occur in 1% to 2% of blunt trauma patients and the incidence of stroke is approximately 25%, with a mortality rate of up to 13%, if left untreated.[16,21–24] Treatment for these injuries is centered on antiplatelet therapy and systemic anticoagulation to decrease the risk of stroke. Early recognition and initiation of treatment has been shown to decrease the rate of cerebral ischemia.[25,26]

The work of Biffl and colleagues in 1999[21,24] highlighted the importance of screening for BCVI when certain anatomic injuries or injury patterns were observed (**Table 23.1**). Subsequently, organizational guidelines have been disseminated by the Eastern Association for the Surgery of Trauma (EAST) based on review of the literature with the aim of guiding screening practices for BCVI (**Table 23.2**).[27] Investigators have shown that up to 30% of patients diagnosed with BCVI may have no radiographic or clinical risk factor that would guide the clinician to screen for these injuries.[15] Recent data has also identified an association between BCVI and nontraditional risk factors such as serious chest injury.[17] Thus, a high index of suspicion 5 must be maintained in order to effectively diagnose and treat BCVI.

Table 23.2 Screening Criteria for Blunt Cerebrovascular Injury

Injury Mechanism
Severe cervical hyperextension/rotation or hyperflexion
Displaced midface or complex mandibular fracture
Closed head injury inconsistent with diffuse axonal injury
Near hanging result in anoxic brain injury
Physical Signs
Seat belt abrasion or other soft tissue injury of the neck resulting in swelling or altered mental status
Fracture in proximity to internal carotid or vertebral artery
Basilar skull fracture involving the carotid canal
Cervical vertebral body fracture

From Bromberg WJ, Collier BC, Diebel LN, et al. Blunt cerebrovascular injury practice management guidelines: The Eastern Association for the Surgery of Trauma. *J Trauma* 2010;68(2):471–477.

Given the seeming inability of screening guidelines to accurately identify patients at risk for BCVI, some centers have gone to blanket screening.[15] All polytrauma patients with a blunt mechanism of injury undergo CT scan of the cervical spine with contrast timed to image the carotid and vertebral arteries in conjunction with a chest and abdominal CT scan, obviating the need for a second contrast study. While data on this blanket screening is limited, it does enable the identification of injuries early in the course of workup and identifies injuries in patients that would otherwise not be screened secondary to lack of criteria.[15] Patients with identified injuries generally receive a formal CT angiogram as their follow-up study.

6 If stroke can be avoided with prompt initiation of therapy, functional outcomes after BCVI are good,[28] however, many patients with BCVI have multisystem trauma and are thus deemed not suitable for antiplatelet therapy or systemic anticoagulation. In a 2009 study, almost one-third of patients with BCVI were identified as not candidates for therapy, with an overall stroke rate of 12% and stroke-related mortality of 50%.[16] Experience with BCVI and stroke has led our institution to a fairly aggressive stance on treating

BCVI judged to be severe, even in the face of concomitant injuries (including traumatic brain injury in certain circumstances).

It is tempting to assign treatment for BCVI to a relatively lower priority. Patients with BCVI often have concomitant injuries such as intra-abdominal solid visceral injury or traumatic brain injuries. The traditional approach has been to simply decide that these patients are not candidates for anticoagulation and defer therapy. While this may be acceptable with low-grade injuries, given the relatively high rate of stroke with higher-grade injuries, this may not be wise. Recent data suggest that in Grade IV carotid injuries (complete occlusion), recanalization and subsequent stroke is extremely common.[29] This would seem to suggest that the presence of higher-grade injuries mandates therapy. For instance, in a patient with splenic injury and carotid artery injury, one should consider whether splenectomy followed by anticoagulation is wiser than nonoperative management and withholding treatment for the BCVI.

OPERATIVE EXPLORATION

As many general surgeons do not routinely operate in the neck, early consideration of potential injuries is important. Immediate availability of vascular instruments, advanced airway devices, endoscopic towers, and scopes are important.

The patient is positioned supine, with a full surgical prep from the chin to the knees. Utilizing a widely prepped surgical field allows easy access to various body cavities. If unilaterality of injury is assumed or known, it may be beneficial to position the patient's head in the direction opposite to the injury, which opens the surgical field for better exploration. Given the very real possibility of a "multizone" injury, a sternal saw should be immediately available for possible entry into the mediastinum. Similarly, a chest retractor and deep vascular instruments should be immediately available.

Penetrating Vascular Injury

The presentation of penetrating vascular injury in the neck is dependent on the vessel injured and its location. Arterial injuries, specifically the carotid

arteries, may present with pulsatile arterial hemorrhage emanating from the wound, a palpable thrill, an audible bruit, or a rapidly expanding hematoma. Venous injuries tend to have a more insidious presentation and may be clinically undetectable. Penetrating vertebral artery injury is rarer given the relatively protected position of the artery within the osseous spinal canal.

Cerebral ischemia secondary to carotid artery injury can lead to stroke and long-term neurologic sequelae, or even death. In some series, patients who present in hemorrhagic shock have a mortality of 41%, but have 50% mortality when presenting with stroke.[30] Patients presenting with any neurologic deficit, short of coma, should undergo carotid arterial repair with revascularization if technically feasible, as results are improved with revascularization. In patients presenting with a Glasgow Coma Scale (GCS) <8 (coma), a poor outcome is likely regardless of the therapy selected.[31,32]

Often, diagnosis of carotid injury occurs intraoperatively, as there is no time for preoperative imaging. Carotid artery injuries are managed using standard principles of vascular repair. Exploration of the neck is through a generous sternocleidomastoid incision. Control of the proximal carotid artery is obtained at the base of zone II. If possible, it is wise to control the artery distally, before entering the hematoma. Unfortunately, distal control is often not possible. As the neck is a compact region, during dissection to control the distal carotid artery, the contained hematoma often ruptures. Digital control should then be utilized to prevent exsanguinating hemorrhage while the distal dissection is performed. Once the distal carotid artery (whether it is the internal carotid artery or distal common artery) is controlled, digital pressure is released and careful dissection performed.

Injuries to the common carotid artery can be primarily repaired, particularly if the injury is caused by a stab wound and has clean edges. More complex injuries, as those from gunshot wounds, usually require resection of the injured segment. Even after resection of a segment of the carotid artery, primary anastomosis may be possible. Full mobilization of the common carotid artery will often give additional length and allow for a tension-free anastomosis. For injuries located more distally, ligating the external carotid artery will give additional mobility to the common carotid artery. If primary anastomosis or repair is not feasible, a bypass graft using either saphenous vein or PTFE is equally acceptable. PTFE should be

avoided in the event of contamination or concomitant tracheal or esophageal injury.

Internal carotid artery injury represents a distinct subset of carotid artery injuries. Unlike common carotid artery injury, the initial neurologic presentation is not a good predictor of final neurologic presentation. Injuries to the internal carotid artery have 20% mortality and the majority of these deaths are secondary to cerebral ischemia.[26] Interventional techniques, including embolization, may be effective in some injuries thus obviating the need for exploration.[27]

Control of the internal carotid artery proceeds along the same principles as with common carotid artery injuries, though distal control may be even more problematic. During the dissection, one must take care not to injure the hypoglossal nerve, which passes across the distal internal carotid artery. The surgeon should ascertain adequacy of back bleeding from the distal internal carotid artery. Pulsatile back bleeding confirms patency of the circle of Willis. In patients with poor back bleeding, use of a shunt should be considered. We routinely use full-dose IV heparin unless there is a contraindication.

The internal carotid artery is repaired using the same principles as mentioned for the common carotid artery, though several scenarios require special mention. If there is injury to the proximal internal carotid artery and the distal vessel is thrombosed, dissection should be carried out as distal as possible. If the vessel is thrombosed as far as is surgically accessible, the surgeon should avoid the temptation to do catheter thrombectomy as this is virtually never complete and, once revascularized, the patient has significant risks of embolic stroke. In addition, one should avoid ligating the thrombosed internal carotid artery at the base. If one forcefully ligates the internal carotid artery, there is high likelihood that distal clot will be dislodged, causing a stroke of clinical significance.

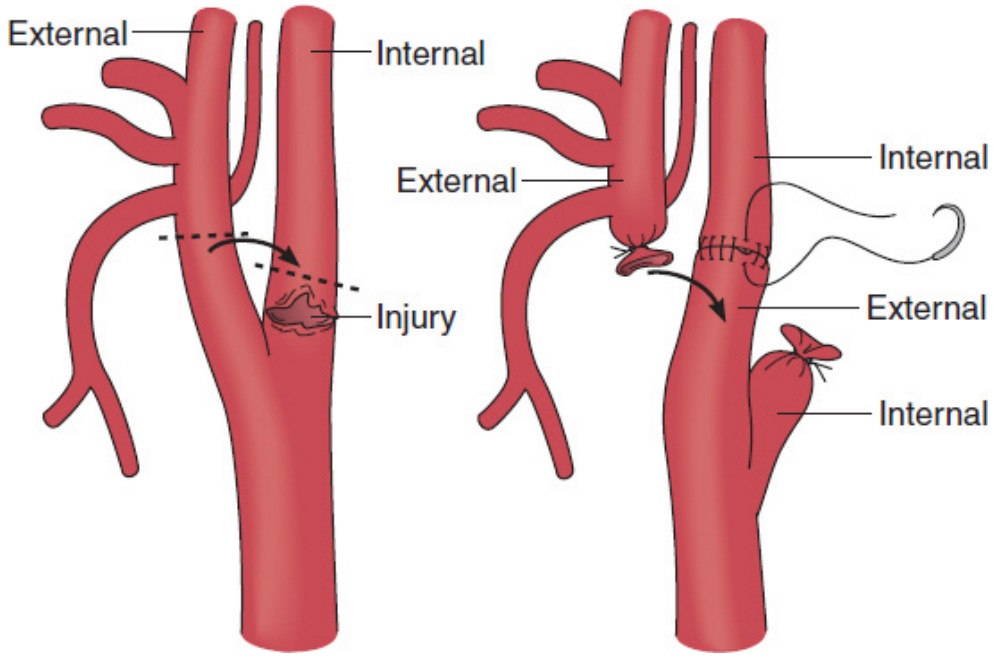

Figure 23.3 A proximal internal carotid artery injury managed with resection and transposition of the external carotid artery to obtain inflow to the native internal carotid artery.

Occasionally, one will encounter an injury in the very proximal internal carotid artery. Once the vessels are controlled, consideration should be given to use the external carotid artery as the conduit, if primary repair is not feasible. The damaged internal carotid artery can be dissected down to the level of the bifurcation (**Fig. 23.3**). The external carotid is ligated at the level of the first branch and the external carotid artery rotated over to use as the conduit. A single vascular suture line then connects the external to the internal carotid artery.

For the most part, the external carotid artery is expendable. If an external carotid artery injury is diagnosed at the time of surgical exploration, it can simply be ligated. Those that are diagnosed preoperatively, with images, are often amenable to catheter-based hemostatic techniques.[29] If there is a distal injury to a branch of an external carotid artery, such as the facial or lingual arteries, particularly if caused by penetrating facial trauma, catheter-based hemostasis is by far the most attractive option. Proximal ligation of the external carotid artery will decrease inflow, but the robust collateral circulation from the contralateral external carotid may be sufficient to cause

continued hemorrhage. Angiographic options are then essentially nil, as the ligated external carotid prevents an angiographic solution.

Secondary to the posterior anatomic location and protection provided by the cervical spine, penetrating vertebral artery injuries are less likely. Additionally, injuries to the vertebral arteries are less likely to cause neurologic sequelae than those to the carotids.[30] Operative exposure of the vertebral artery is quite difficult secondary to its protected location in the posterior neck. If necessary, it is best approached via an anterior approach with proximal ligation of vertebral artery.[31]

Combined carotid and vertebral artery penetrating injuries are very morbid, with mortality rates of approximately 50%.[32] Occasionally, a vertebral artery injury will be discovered at the time of diagnostic neck exploration. This is an extremely challenging situation, as direct pressure will only temporarily control the artery. Rather than attempting to expose the artery by unroofing the cervical spine over the vessel, we have generally maintained digital pressure or controlled the artery temporarily with a Fogarty balloon, after which the patient is transported to a site where angiographic embolization is possible.

Trachea and Larynx

Blunt laryngotracheal trauma is uncommon[33] and low-grade injuries can be clinically occult. Thus, these injuries require a high index of suspicion. The most typical mechanism of injury involves an anterior to posterior vector of force that drives the thyroid cartilage into the rigid cervical spine. Such forces can be the result of a motor vehicle collision with compression of the neck against the steering wheel or dash of the automobile. The most common symptoms include hoarseness, dyspnea, and dysphagia.[33,34] Careful attention must be paid to the airway as laryngotracheal separation can be catastrophic. Definitive diagnosis is made with a combination of CT scanning and endoscopy. Definitive airway management is best obtained with tracheostomy if endotracheal intubation is not prudent.[35]

The presentation of penetrating laryngotracheal injuries are less subtle, as impressive symptoms and physical findings present in high-grade injuries. Management focuses on rapid airway control, either via endotracheal intubation or via a surgical airway. In the rare instance of tracheal transection

in the neck with two visible lumens, the distal lumen should be intubated with any available airway device. Concomitant esophageal injury is a source of major morbidity; therefore, the esophagus should be evaluated with early endoscopy or operative exploration.[36]

Cervical tracheal injuries, particularly if they are isolated, are best approached via a collar incision performed approximately two fingerbreadths above the sternal notch. If other injuries are present and/or if full exploration is needed, the trachea can be exposed and repaired using a sternocleidomastoid incision. If a collar incision is used, subplatysmal flaps are created and the strap muscles are then divided in the midline. The thyroid isthmus can be retracted cephalad and the entire cervical trachea is then clearly visualized. If the location of the tracheal injury in the neck is clearly in zone II, surgical exploration confirms the diagnosis and allows for prompt therapy.

Occasionally tracheal injuries are located closer to the thoracic inlet. In these cases, preoperative bronchoscopy is vital in order to plan the best operative course. If the injury is located in the upper mediastinum, several options exist. The patient can be explored via a collar incision and the anterior trachea identified. The trachea can be mobilized using digital dissection into the upper mediastinum. The trachea can then be grasped with a tracheal hook and retracted up into the neck. It is possible to mobilize the trachea for approximately three rings, thus allowing the surgeon to repair these injuries with a relatively small incision. Injuries that are located in the more distal mediastinum are best approached with a right-sided posterolateral thoracotomy.

Occasionally, tracheal injuries will be located at a level above the endotracheal balloon. When performing diagnostic bronchoscopy, the endotracheal tube must be withdrawn (with the cuff deflated) over the bronchoscope, up to the level of the vocal cords. This allows complete visualization of the proximal trachea. Not pulling back the endotracheal tube risks missing proximal tracheal injuries.

Injuries to the posterior membranous trachea are relatively difficult to approach. In patients with blunt trauma, small injuries may be observed; however, if repair is thought to be prudent, the best way to approach this is through the anterior trachea. The anterior trachea is opened transversely at the level of the injury and the posterior injury is then visualized and repaired.

The anterior trachea is closed primarily. Intraoperative bronchoscopy can help locate the level of the injury.

The blood supply to the trachea enters posterolaterally on both sides; therefore, circumferential mobilization of the trachea risks causing ischemia, which may manifest either as tracheal necrosis, dehiscence of a repair, or postoperative tracheal stenosis. In addition, the recurrent laryngeal nerve runs in the tracheoesophageal groove and care must be taken to avoid damage to it during mobilization or tracheal repair. Postoperatively, patients undergoing tracheal repair should be extubated as soon as possible. It is often tempting to think that the tracheal repair is protected with longer-term tracheal intubation, but the chances of complication are less if the patient is extubated at the end of the operative procedure. One should avoid a tracheostomy in a patient with tracheal repair, because stenosis at the level of tracheostomy and the level of tracheal repair can make future reconstruction exceedingly difficult.

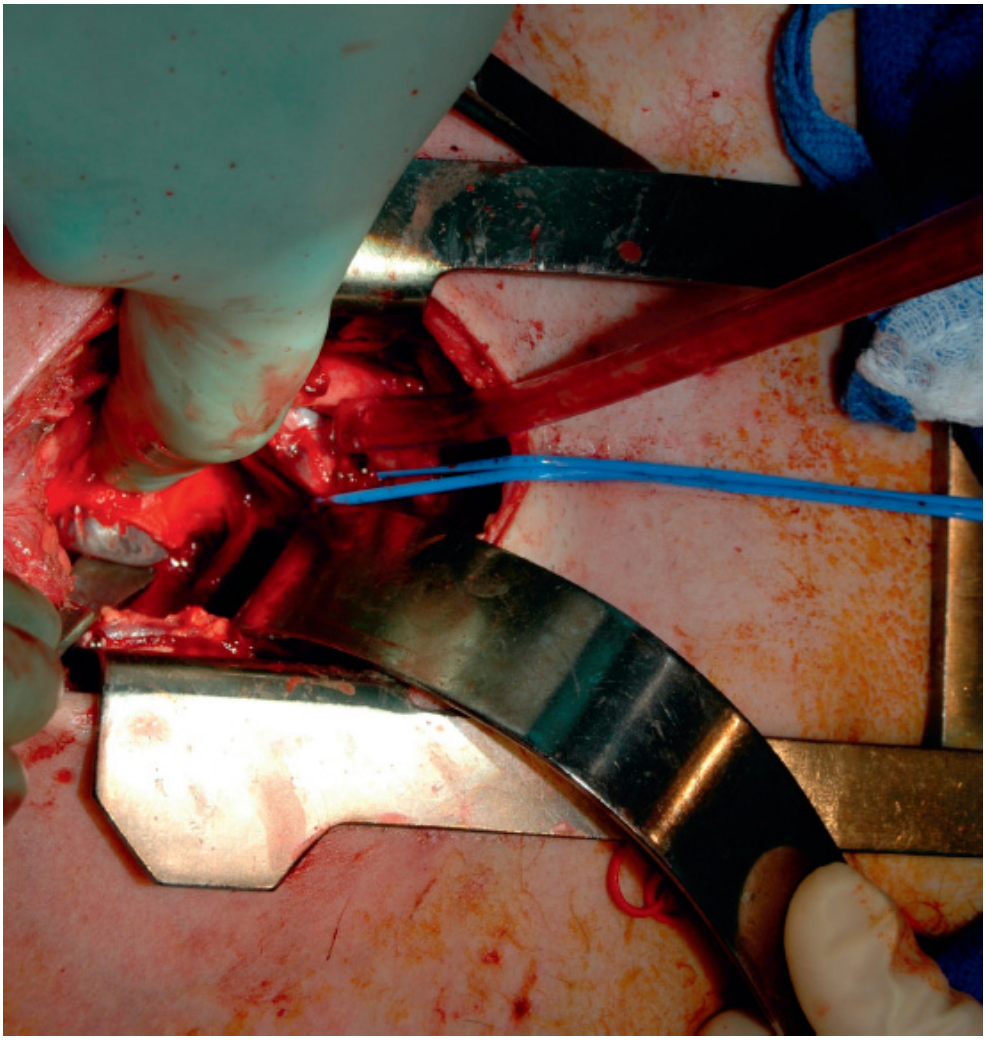

Figure 23.4 Partial sternal split for evaluation of tracheal injury. The endotracheal tube balloon is visualized within the lumen of the injured trachea.

In the event that the injury extends into the thoracic inlet, a partial sternal split (**Fig. 23.4**) or full sternotomy can be performed for better visualization. Tracheal injuries are preferentially repaired primarily with single layer absorbable suture, though resection of up to 2 to 4 cm with primary anastomosis is technically feasible. Suture lines should be buttressed with autologous, well-vascularized tissue, such as strap muscle (**Fig. 23.5**).

Esophagus

Early diagnosis of esophageal injury is imperative, as missed injury and/or a delay in diagnosis can lead to disastrous consequences. In a review of 109

penetrating esophageal injuries, the mortality rate was 2% with immediate operation. Mortality increased to 44% with delayed diagnosis and operation. In this same series, mortality increased to 100% for patients with a delayed diagnosis and no operative procedure.[37]

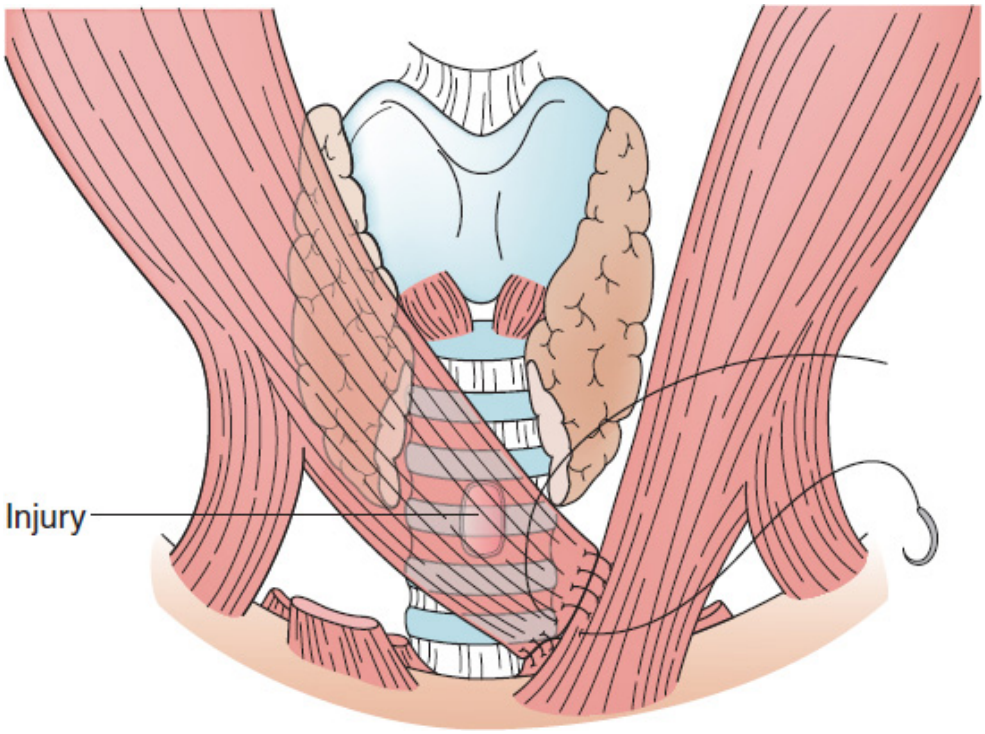

Figure 23.5 Divided strap muscle utilized to buttress tracheal injury/repair.

As the course of the esophagus is relatively superficial within the neck, diagnosis can occasionally be made on physical examination findings alone. Food particles or salivary secretions within the wound are highly suggestive of esophageal injury. Additional physical examination findings may include esophageal or oropharyngeal bleeding, subcutaneous emphysema, and neck hematoma. Plain film radiographic findings may include air within the subcutaneous tissues and pneumomediastinum.[38] In a review of 77 patients with noniatrogenic esophageal injury, 58% occurred in the cervical esophagus, with physical examination findings present in only 26% of the cohort.[39]

Given the pervasive nature of CT scanning in the trauma patient, investigators have evaluated the utility of this imaging modality for esophageal injury. A study from the Aga Khan University Hospital showed

53% sensitivity for CT scanning in diagnosing esophageal injuries.[40] The gold standard for diagnosis 7 of most esophageal injuries remains a combination of esophagoscopy and contrast-enhanced esophagography. When these two imaging modalities are used in combination, an accuracy of almost 100% is achieved.[41] The sensitivity of esophagography alone varies from 50% to 90%, while the sensitivity of endoscopy alone varies from 29% to 100%.[42]

As with the trachea, the location of the esophageal injury defines the approach for repair. Those injuries that are clearly in zone II can easily be approached via a sternocleidomastoid incision. Those in the chest are best approached via a posterolateral right thoracotomy. As with the trachea, localization of the injury, particularly those at the junction between the neck and chest, is the easiest way to ensure optimal exposure. Intraoperative endoscopy can be very helpful in positively identifying the location of an injury and helping to direct therapy.

Small, nondestructive injuries in the hypopharyngeal region can occasionally be managed nonoperatively with antibiotics, upright positioning, limited oral intake, and close clinical observation.[43] The vast majority of cervical esophageal injuries are best managed operatively. Cervical esophageal injuries are most easily approached via a left anterior sternocleidomastoid incision. If a collar incision has been initiated, it can be extended to the left, along the anterior border of the sternocleidomastoid muscle to facilitate better exposure. Preoperative placement of a nasogastric tube may assist with identification of the esophagus in the neck, as the hard nasogastric tube can be palpated within the lumen. After lateral retraction of the sternocleidomastoid muscle, the dissection progresses medially until the esophagus is encountered. Care must be taken to avoid injury to the recurrent laryngeal nerve in the tracheoesophageal groove.

Circumferential dissection of the esophagus and placement of large rubber drain around the organ can facilitate retraction and mobilization. As the blood supply of the esophagus runs vertically within the muscle, the esophagus can be circumferentially mobilized without risk of ischemia. Thus, injuries located in the superior mediastinum can be mobilized into the neck and repaired. After repair, liberal drainage of the injured area is highly recommended in an effort to avoid salivary fistula and deep neck infection.[38,43] Delays in diagnosis of more than 12 hours are associated with

poor outcomes and in these cases, proximal diversion and wide drainage may be the safest option.

Primary repair of the injury is the goal in most circumstances. During repair, the entirety of the mucosal injury must be visualized, as it may extend beyond the field of view under the longitudinal outer muscle of the esophagus. Debridement of all devitalized tissue is required. Repairs are typically performed in two layers with absorbable sutures, though single-layer repair is possible.[38,44] Similar to tracheal repair, a well-vascularized muscle is highly recommended to buttress the repair. Given the likelihood that the patient will be on a restricted oral diet, placement of a small-bore enteral tube, distal to the repair, should be considered intraoperatively. Imaging repairs at 7 to 10 days with a contrast-enhanced swallow study is recommended prior to removal of drains.

Table 23.3 Common Complications after Neck Injury

Pneumonia and ventilator-dependent respiratory failure
Surgical site infection

Trachoesophageal fistula

COMPLICATIONS

As in all forms of injury, neck injuries are associated with a variety of morbidities (**Table 23.3**). The most common complications after tracheal repair include postoperative suture granuloma, pneumonia, and surgical site infection.[45] Complications after tracheal repair were once thought to be numerous; modern studies have questioned this supposition. In a 2013 paper, investigators showed that complications after tracheal injury alone were associated with an exceedingly low rate of complications. In patients with

combined tracheal and esophageal injuries, the rate of complications is drastically increased.[46]

Tracheoesophageal fistula occurs when an abnormal passage forms between the trachea and esophagus, manifesting as respiratory distress and recurrent pulmonary infections. Management includes a variety of operative techniques aimed at restoring the continuity of both the trachea and esophagus and the interposition of well-vascularized tissue flaps between the repairs. Though endoluminal stenting is discussed, its utility is currently minimal.[47]

Esophageal leak from repair dehiscence and anastomotic breakdown creates an ongoing source of intrathoracic infection and inflammation, which makes primary management and repair exceedingly difficult. Though relatively early in the experience, the use of endoluminal stenting in this situation has shown promise and avoids the need for full operative exploration.[48] Leaks in the neck are more easily controlled by opening of the wound and wide drainage with avoidance of enteral nutrition past the site of injury. In rare instances, cervical esophagostomy may be required.

SUMMARY

Management of injuries to the neck requires a thorough understanding of three-dimensional anatomy and an appreciation for the severity of injuries possible in this region. A relatively small anatomic region, the neck contains many structures vital to meaningful survival. Attention to airway is of the utmost importance, because without a secure airway, the remainder of workup is meaningless. In the presence of vascular injury, all management options must be rapidly reviewed and the most easily obtained and efficacious maneuver should be chosen. As nonoperative management of many traumatic injuries continues to expand, it is the obligation of the surgeon to remember basic surgical principles and apply them in an expeditious and safe manner as the situation mandates.

24

Thoracic Trauma

Jill Streams and Marc de Moya

Key Points

1. The mortality associated with penetrating thoracic trauma is higher than blunt trauma.
2. The most common blunt thoracic injury is rib fracture and the most effective pain relief is thoracic epidural analgesia.
3. Occult and small simple pneumothoraces do not necessitate drainage but if drainage is needed for larger pneumothoraces, it can be accomplished effectively with a small caliber catheter (e.g., 8- to 14-Fr pigtail catheter).
4. 28-Fr chest tubes are effective at draining hemothoraces but if there is a significant retained hemothorax after tube thoracostomy, early operative evacuation with video-assisted thoracoscopy should be employed.
5. Operative repair of blunt aortic injuries may be delayed and treated medically in the face of severe associated injuries.

INTRODUCTION

Thoracic trauma is a common occurrence with an incidence of approximately 25% of all traumas.[1] Thoracic injuries are also commonly associated with head and abdominal trauma with a blunt mechanism, the so-called polytrauma patient. The most common thoracic injury is rib fracture and mortality/morbidity increases as the number of ribs fractured increases. Mortality is most pronounced in the elderly where there is a 19% increase in mortality 1 with each additional rib fracture.[2] The majority of deaths from thoracic trauma are due to a penetrating mechanism, but overall 85% of penetrating injuries to the chest can be managed with a chest tube. Regardless of the mechanism or obvious injuries, one should always proceed with a systematic approach to the trauma patient, via Advanced Trauma Life Support (ATLS).[3]

INITIAL IMAGING

The initial imaging in the trauma bay for suspected chest trauma is the screening chest x-ray (CXR) and the extended FAST (eFAST) examination. The CXR is typically a supine anteroposterior (AP) single film to evaluate for life-threatening injuries that require immediate intervention. The screening CXR can also help identify additional injuries such as bony fractures, mediastinal hematoma, pneumothorax, hemothorax, lung contusions, elevated diaphragm, large diaphragmatic rupture, or confirm position of endotracheal tube/any central lines in internal jugular or subclavian positions.[4] If the spine is cleared, particularly in the case of penetrating trauma, then an upright AP film may be obtained, which increases sensitivity for hemothoraces and pneumothoraces. These films are often limited due to movement, clothing, backboards, or inadequate exposure but serve as reasonable screening images (**Fig. 24.1**).

The FAST (focused assessment with sonography for trauma) has become a standard adjunct in the trauma bay. The standard FAST examination views include the right upper quadrant, left upper quadrant, pelvic view, and the pericardium. For the purposes of this chapter, the pericardial view will best demonstrate hemopericardium. Hemopericardium is typically the result of penetrating trauma to the heart but may also be due to blunt rupture of the heart.[5] Rozycki et al.[6] used the FAST examination to evaluate for pericardial

fluid in 1,540 patients with truncal injuries, with 100% sensitivity and 99.3% specificity. The eFAST includes the evaluation of lung and pleural spaces to detect pneumothorax and hemothorax. Sonographic findings of pneumothorax include absence of lung sliding, presence of A-lines, loss of comet tails, and the presence of a lung point sign.[7] When lung sliding and comet tails are absent, the sensitivity and specificity for pneumothorax are 81% and 98%, respectively. The presence of a lung point sign is less sensitive for pneumothorax, but highly specific with reported rates of 98% to 100%.[8,9]

Computed tomographic scans (CT scans) are often employed in thoracic trauma after the secondary survey and provide additional information as they are highly sensitive for hemo/pneumothoraces, fractures, vascular injuries, and lung contusions/lacerations. CT scans are typically performed with intravenous contrast to better visualize vascular injuries and lung parenchyma.

COMMON INJURIES

Rib Fractures

The most common injury in thoracic trauma is the rib fracture, occurring in approximately 10% of all trauma patients. The spectrum of injury patterns ranges from a single nondisplaced rib fracture to large flail segments with severe displacement. Injury patterns are related to age and degree of flexibility of ribs. The younger population has innately more mobile/flexible ribs and therefore requires a higher force to create fractures. This higher force also translates to a higher degree of underlying lung injury. The older population with more brittle ribs requires less force to fracture the ribs and therefore may not have severe associated injuries. The diagnosis is usually made by initial physical examination (tenderness and chest wall paradoxical movement for flail segments) and CXR. However, CXR only visualizes 30% of rib fractures. CT scan is extremely sensitive for rib fractures and also allows quantification of any associated hemothorax, pneumothorax, or contusion.

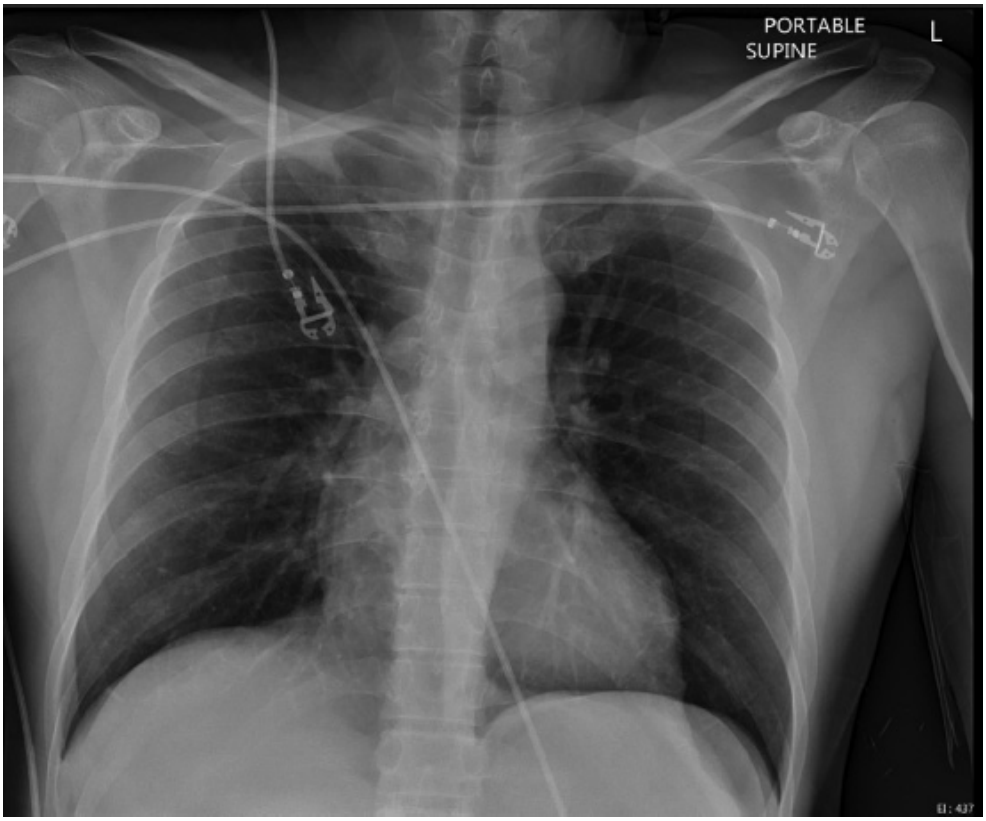

Figure 24.1 Supine AP CXR in the trauma bay.

Flail chest is defined as three or more consecutive ribs broken in two or more places. These segments may exhibit a "mechanical" flail which is the paradoxical movement of the flail segment in relation to the surrounding chest wall. As the patient inspires and expands the chest to produce a negative intrathoracic pressure, the flail segment is pulled inward (**Fig. 24.2A**). The opposite occurs during expiration and the flail segment bulges outward (**Fig. 24.2B**). The respiratory compromise that occurs in the face of a flail segment is multifactorial: (1) underlying lung contusion, (2) pain with respirations, and (3) mechanical disadvantage. Pain control and contusion are the most influential on clinical outcomes when compared to the mechanical disadvantage.

Treatment

2 The most important aspect of care for rib fractures is pain management. The majority of complications are directly related to lack of pain control. A recent EAST practice management guideline conditionally recommends

multimodal analgesia to include acetaminophen, nonsteroidal anti-inflammatory drugs, gabapentin or pregabalin, ketamine, opioids, and regional/neuroaxial blockade, though the supporting literature is sparse for improved outcomes.[10] Additionally, the theoretical basis for multimodal pain control is extrapolated from ERAS protocols. However, there are studies suggesting that thoracic epidurals are superior to intravenous narcotics for treatment of pain related to rib fractures.[11,12] Polytrauma patients may have contraindications to thoracic epidural but other regional analgesia options exist including intercostal nerve blocks, serratus anterior blocks, paravertebral blocks, erector spinae blocks. An aggressive pain management program will allow the patient to be more mobile and promote good pulmonary toilet.

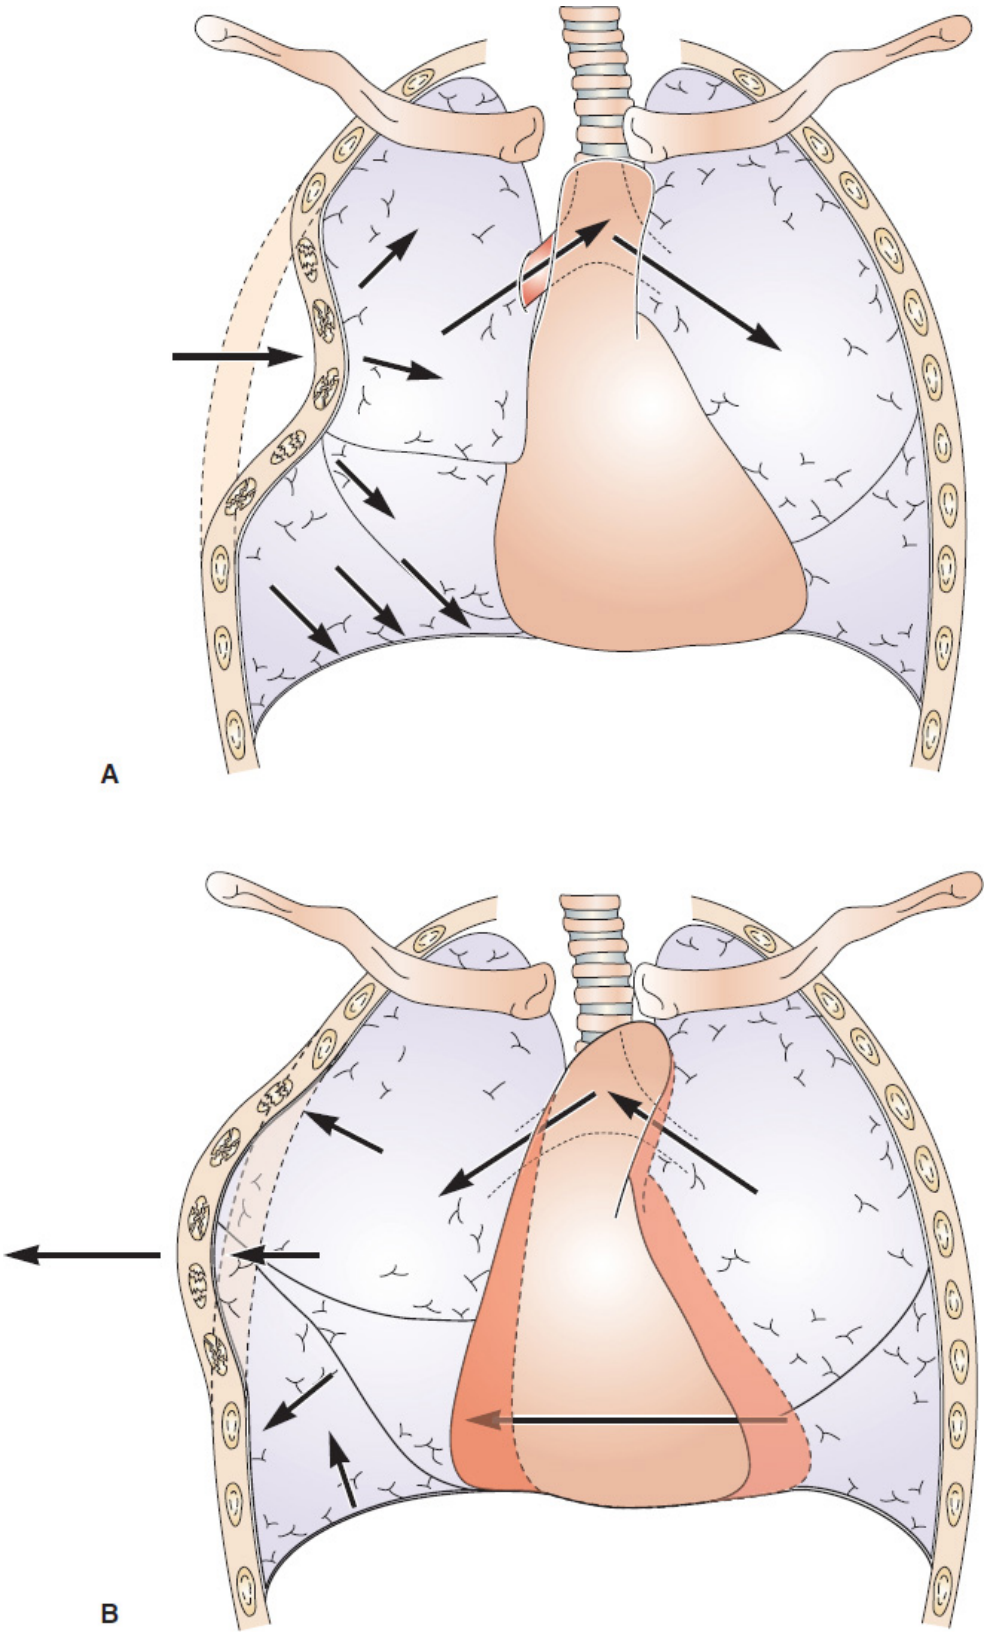

Figure 24.2 Pathophysiology of flail chest. **A:** Inspiratory phase: Chest wall collapses inward, causing air to move out of the bronchus of the involved lung into

the trachea and bronchus of the uninvolved lung, causing a shift of mediastinum to the uninvolved side. **B:** Expiratory phase: Chest wall balloons outward so that air is expelled from the lung on the uninvolved side and enters the lung on the involved side with an associated shift of mediastinum to the involved side.

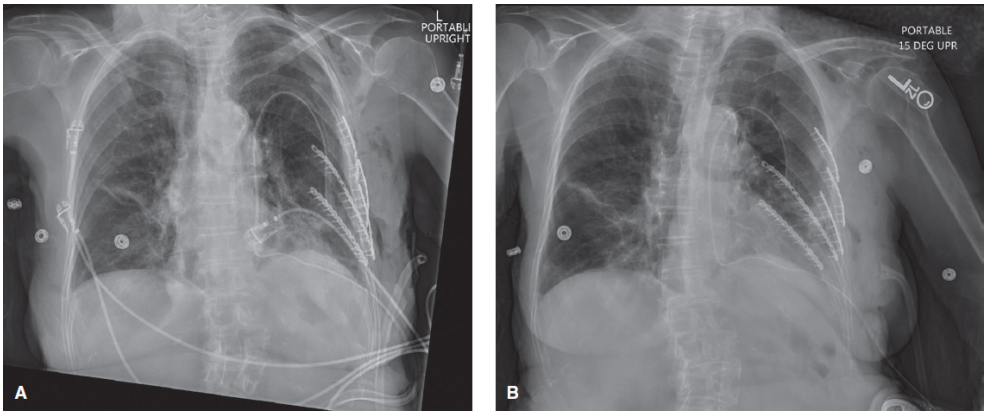

Figure 24.3 **A:** Rib fractures on CXR. **B:** Rib fixation with plates on CXR.

Operative fixation of the ribs (open reduction and internal fixation) has been increasingly utilized in recent years, following several prospective studies demonstrating a benefit to surgical repair of rib fractures (open reduction and internal fixation) versus mechanical ventilation alone in ICU length of stay, ventilator days, and respiratory complications for patients with flail chest.[13–15] However, a recent systematic review was not able to show a mortality benefit to rib fixation,[16] in contrast to previous meta-analysis that did show mortality benefit to operative fixation.[17] Contention exists over the benefit of rib fixation for those patients with multiple, nonflail rib fractures (**Fig. 24.3A**). In general, the author's approach is to consider rib fixation for any patient with three or more ribs fractured with severe displacement (more than the width of a rib) with some physiologic derangement (i.e., poor pulmonary function, inability to control pain, etc.), which is consistent with a recent prospective investigation comparing rib fixation for both flail and nonflail rib fractures to multimodal and multidisciplinary nonoperative management.[18] There are multiple types of rib fixators available (**Fig. 24.3B**) and no system or approach to the repair has proven to be superior. The majority of ribs repaired are number 4 to 9, approached via a thoracotomy incision (**Fig. 24.4**), though more minimally invasive techniques are evolving.

Pneumothorax

Pneumothoraces can be classified into three subtypes: occult, simple, and tension. Diagnosis of pneumothorax can be physical examination, CXR, or eFAST. The standard of care in the trauma bay is upright (if spine is cleared) or supine AP x-ray (if the spine is not cleared). Although radiographs are less sensitive than ultrasound for small pneumothoraces, they are used to screen for other associated injuries as described above. The pathophysiology of pneumothorax is the accumulation of air in the pleural space secondary to underlying pulmonary parenchymal injury or entrainment of atmospheric air from penetrating injury.

An occult pneumothorax is one that is seen on CT scan (which is the most sensitive test for pneumothorax) but not seen on CXR (**Fig. 24.5A,B**). Occult pneumothoraces are detected in 15% to 20% of blunt thoracic trauma. Subcutaneous emphysema on screening CXR should alert the clinician to possible pneumothorax (**Fig. 24.6**). A simple pneumothorax is one that is seen on either CT scan or CXR but is not associated with hemodynamic compromise. Those patients with a pneumothorax and hemodynamic compromise must be considered a tension pneumothorax until proven otherwise. A tension pneumothorax is a pneumothorax that has progressed to the point of pressurizing the pleural space, resulting in shifting of the mediastinum and compromising the venous return to the heart. Kinking of the great vessels leads to an acute decrease in cardiac output and shock. Signs and symptoms of a tension pneumothorax include; shortness of breath, dyspnea, tachypnea, hypotension, distended neck veins, and tracheal deviation (away from the site of injury). If any of these signs are present immediate decompression is necessary.

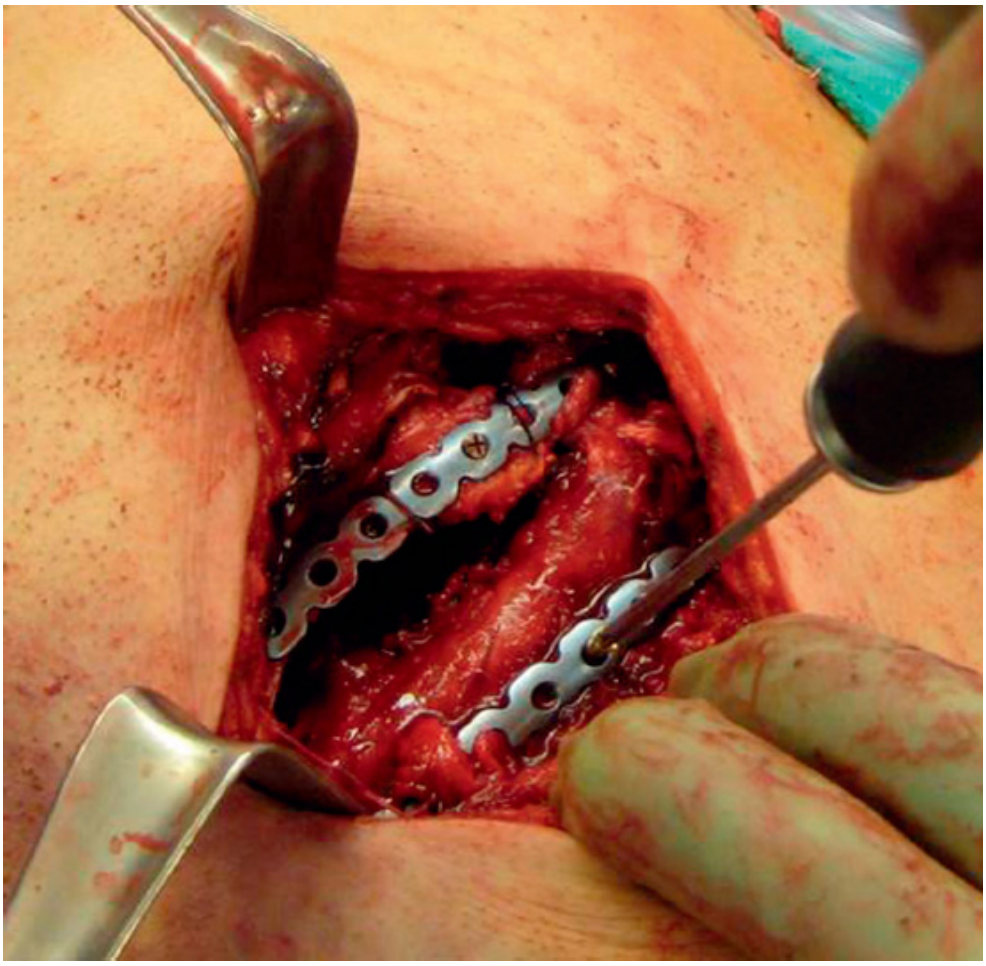

Figure 24.4 Rib fixation with plates (photo).

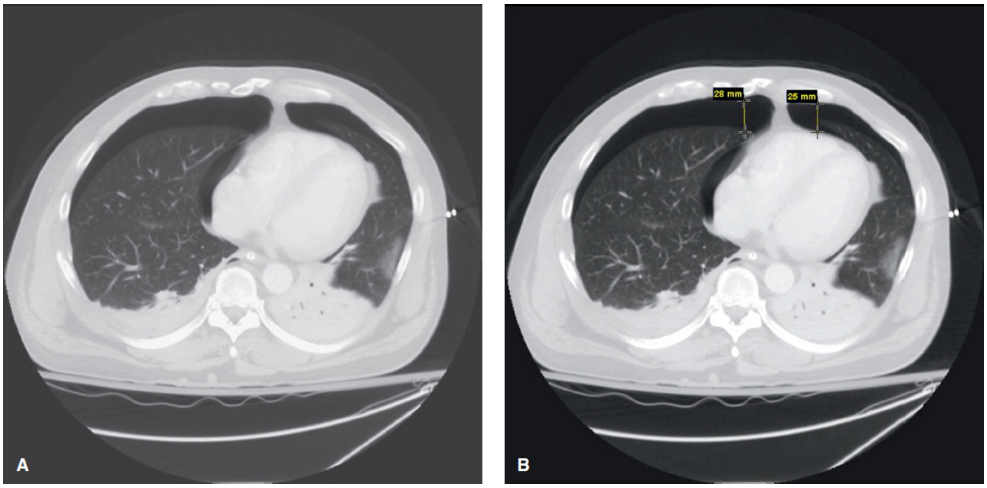

Figure 24.5 **A:** Occult pneumothorax seen on CT scan. **B:** Measurement of largest air pocket in a line drawn perpendicular to the chest wall.

Treatment of Pneumothorax

If the patient is hemodynamically unstable and a tension pneumothorax is suspected, needle decompression or finger thoracostomy may be considered. For needle decompression, a 14- or 16-gauge angiocatheter is inserted into the pleural space at either the anterior second intercostal space in the midclavicular line or the fifth intercostal space in the midaxillary line. There is cadaveric data that suggest that the fifth intercostal space in the midaxillary line has the least distance from the skin to the pleural cavity and therefore, may be superior to the anterior position.[19] This converts the tension pneumothorax to a simple pneumothorax which can subsequently be drained with a proper tube thoracostomy.

Finger thoracostomy achieves the same pleural depressurization as needle decompression. The procedure for finger thoracostomy is essentially the first steps of a traditional tube thoracostomy utilizing only a scalpel and a sterile gloved finger. An incision is made in the fourth or fifth intercostal space in the midaxillary line and carried down sharply above the rib to incise the intercostal muscles and parietal pleura. The pleural space can then be entered with a finger to provide pleural decompression. Advocates of finger thoracostomy argue that it has a higher success rate than needle decompression and can be performed quickly, however, detractors note pain from incision and infectious concerns if the subsequent chest tube is placed via the same incision.

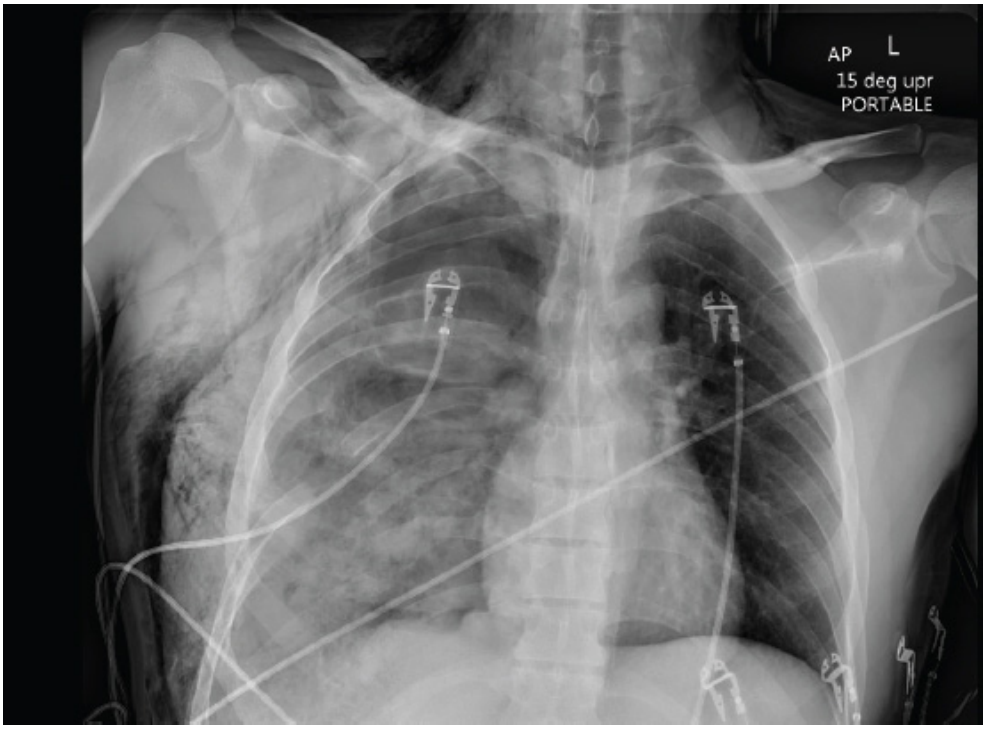

Figure 24.6 Subcutaneous emphysema.

If one has access to a chest tube quickly, there is no need to perform a needle decompression or finger thoracostomy. A tube thoracostomy placed in the zone of safety may be performed expeditiously. The zone of safety is outlined by the pectoralis major lateral border, the nipple line in men (two fingerbreadths above the inframammary fold, women), and the anterior border of the latissimus dorsi. The triangle formed by these borders is a guide for the practitioner for the safe placement of the chest tube (**Fig. 24.7**). If the tube is placed too far caudal, it can inadvertently enter the abdominal cavity. A 28-Fr chest tube may be placed as there is no difference between a 36 Fr and 28 Fr in ability to adequately drain the chest 3 of either pneumothorax or hemothorax but if there is no hemothorax component, one can consider a small caliber tube as described above.[20] In those patients with a pure pneumothorax, an 8.3- to 14-Fr pigtail catheter is acceptable and may be superior, given the significantly less pain/discomfort of the tube as described in a randomized clinical trial.[21,22] Pigtail catheters are placed using a Seldinger technique in the identical areas as the open chest tube technique.

Drainage of all traumatic pneumothoraces via chest tube or pigtail catheter is no longer mandatory even for patients on positive pressure ventilation. For those with small simple or occult pneumothoraces, one should be guided by progression of the pneumothorax or the development of signs/symptoms of cardiopulmonary compromise. In a series of 146 patients with pneumothoraces, 90% of pneumothoraces that were 3.5 cm or less in widest dimension were successfully observed. This holds true in the intubated patient on positive pressure ventilation as well.[23,24] Therefore, as a general rule, if the patient is stable, one should repeat the CXR and should only treat the pneumothorax if it has significantly increased in size or if the patient becomes symptomatic.

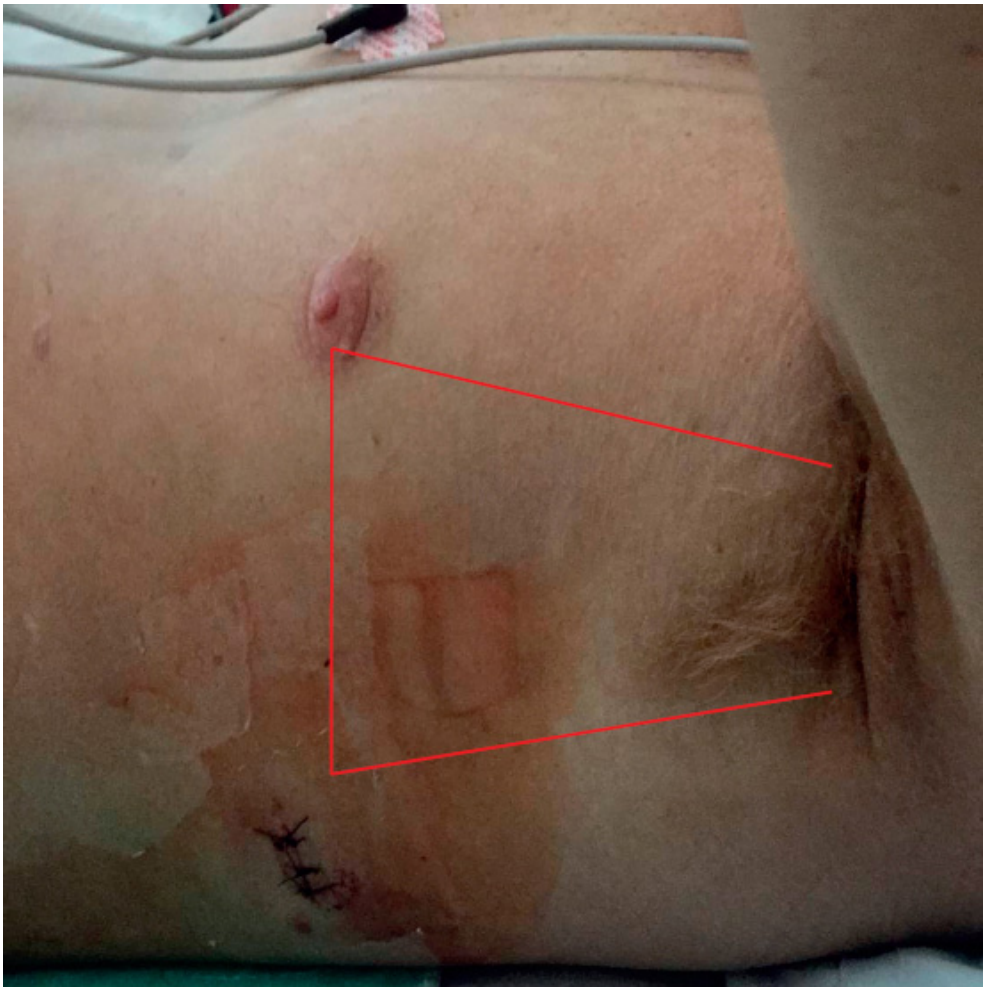

Figure 24.7 Zone of safety.

In the rare circumstance of an open pneumothorax where there is a loss of a portion of the chest wall, the normal negative pressure of the pleural space is lost. Due to the intrinsic nature of the lung parenchyma to collapse, there must be negative pressure in the pleural space to allow for lung expansion. The chest wall defect of an open pneumothorax is usually secondary to a high-velocity bullet or close range shotgun blast. As a temporary measure during transport or early resuscitation, a partially occluding dressing can be applied. This dressing is sealed in a way that allows air to escape from a corner of the dressing while preventing atmospheric air from entering the pleural space. Formal operative closure of the chest wall defect and placement of a chest tube is the definitive treatment. If the defect is large, a rotational flap may be necessary to close the defect or the chest wall may require reconstruction with mesh.

Pulmonary Contusion

The transmission of energy across the chest wall can result in pulmonary contusion from traumatic disruption of pulmonary capillaries and lymphatic vessels. Lung contusion is the extravasation of blood into the interstitial space of the lung parenchyma impairing gas exchange from alveoli to the pulmonary capillary bed. Bleeding may extend to the alveolar space as well in severe cases. One may observe a significant decrease in the PaO_2/FiO_2 ratio with severe pulmonary contusions. Patients with flail chest or multiple rib fractures are most likely to have concomitant contusion. Hypoxia in flail chest is most consistently a result of underlying lung contusion rather than a function of the disruption chest wall mechanics. Diagnosis of pulmonary contusion is typically made with CXR or CT scan. CT scan is more sensitive and specific than CXR with greater than 70% of contusions being seen on CT only.[25]

Treatment

The treatment for lung contusion is primarily supportive care to include minimizing intravenous crystalloid fluid administration, early mobilization, and aggressive pulmonary hygiene. For hypoxia due to contusion, treatment includes the application of positive end-expiratory pressure (PEEP) either

noninvasively (through face mask) or through an endotracheal tube. In a small study, it was found that 100% of patients who had five or more ribs fractures, two-thirds or more of lung affected by contusion, and a decrease in mental status (GCS ≤14) required intubation.[26] Intubations did not necessarily occur on the first day but often on the second day as the contusion "blooms" with surrounding interstitial edema. Therefore, it is important to identify patients at risk for respiratory failure and place them in a higher level of care.

Hemothorax

The causes of hemothorax are varied, the most common being hemorrhage from rib fractures, intercostal muscle bleeding, intercostal artery laceration, pulmonary parenchymal laceration, azygos vein or great vessel injury, or cardiac injury with communication to the pleural space through a pericardial defect.

Initial imaging to detect a hemothorax is the screening trauma bay CXR. This x-ray may make the diagnosis of a hemothorax challenging due to layering of blood posteriorly in a supine patient, thus the CXR may appear hazy when compared to the contralateral side rather than demonstration of a fluid level seen on an upright film. In the face of a large hemothorax, the CXR can appear as a whiteout of the affected hemithorax with or without mediastinal shift. The eFAST examination has a high sensitivity for detecting a hemothorax. Just as occult pneumothorax, small-volume occult hemothorax may only be demonstrated on CT imaging.

The urgency of the treatment of hemothorax is dictated by the physiologic state of the patient with rapid control of hemorrhage being the first priority. Hemothoraces associated with hemodynamic instability or those that drain >1,500 cc immediately or >200 cc/hr for >4 hours after placement of a chest tube should be taken directly to the operating room for exploratory thoracotomy. The recommended size of chest tubes has decreased over time and contemporary data suggest that there is no difference in the ability of the 28-Fr versus the 36-Fr chest tube to effectively drain a hemothorax. Some have advocated using a 14-Fr pigtail catheter for drainage of a hemothorax[27] though multicenter, prospective trials are ongoing. A recent investigation suggests that the position of the chest tube within the pleura does not make a difference in the ability of the tube to drain a hemothorax.[28] This is likely a

result of the pleura being a closed system and therefore, suction applied to one area will apply equal amounts of pressure to other areas of the pleural space. The fluid component of a hemothorax will be drained from any position, however, clotted blood will not 4 be effectively drained even with optimal tube position. The volume of hemothorax that requires drainage is somewhat controversial. In general, patients with a hemothorax greater than approximately 300 cc require drainage when estimated using the following volumetric formula on CT scan: Estimated volume (cc) = $d^2 \times l$, where d equals the greatest dimension in centimeters from the chest wall to the lung or mediastinum across the largest fluid pocket, and l is the craniocaudal height (number of axial slices on the CT scan × the thickness of those slices in centimeter).[29]

Retained Hemothorax

Retained hemothoraces may occur in 30% of the patients.[30] A retained hemothorax is defined as hemothorax that persists despite attempted drainage. Consequences of retained hemothorax include increased risk of empyema, entrapped lung parenchyma, and fibrothorax. Kugler and colleagues reported thoracic irrigation at the time of chest tube placed decreased the rate of retained hemothorax requiring secondary intervention.[31] For retained hemothoraces, there are two therapeutic options: (1) early video-assisted thoracostomy for evacuation or (2) tissue plasminogen activator (TPA) with or without DNase administered via chest tube. The key point is that early intervention allows the clot to be evacuated and prevent a fibrothorax from forming. A meta-analysis of 476 patients undergoing VATS for retained hemothorax demonstrated that earlier intervention (days 1 to 3) was superior.[32] There are no trials comparing VATS to TPA, however, it is the author's practice to utilize VATS for evacuation of retained hemothorax in all appropriate operative candidates, reserving TPA for poor operative candidates only.

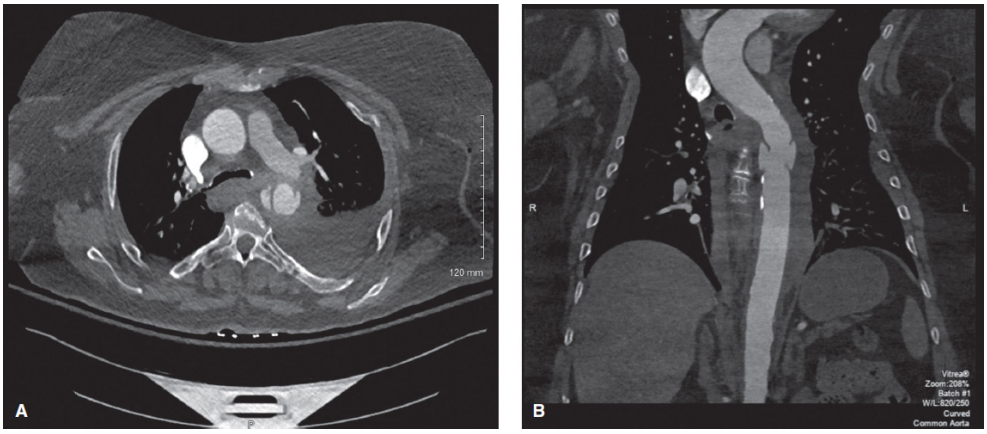

Figure 24.8 **A:** Axial view of type IV blunt aortic injury. **B:** Coronal view of type IV blunt aortic injury.

Aortic Injury

Penetrating injury to the aorta is typically fatal as most patients exsanguinate in the prehospital setting. Those bluntly injured patients with evidence of mediastinal hematoma on CXR (widened mediastinum >8 cm, loss of aortic knob, loss of aortopulmonary window, depression of left mainstem bronchus >110 degrees, deviation of nasogastric tube, apical cap, or tracheal deviation) or those with a high-risk mechanism (i.e., T-bone motor vehicle collision) should have a CT scan of the chest with intravenous contrast to evaluate for aortic injury. CT scan has become the standard of care for diagnosis and classification of aortic injuries. Blunt aortic injuries most commonly occur at points of aortic fixation. These locations in decreasing order of occurrence include: (1) ligamentum arteriosum (just distal to the left subclavian artery), (2) diaphragmatic hiatus, (3) root of the aorta, and (4) left mainstem bronchus. The current classification of aortic injuries divides the extent of injury into four grades: (I) intimal tear, (II) intramural hematoma, (III) pseudoaneurysm, and (IV) periaortic rupture (**Fig. 24.8A,B**).

Treatment

Treatment of blunt aortic injury is dictated by grade of injury. The Society for Vascular Surgery consensus guidelines for management of blunt aortic injury recommends medical management of grade I injuries.[33] Medical management consists of aggressive impulse control (heart rate and blood pressure

control). The recommended goal HR is <80 and goal systolic blood pressure is <100 to 120 mm Hg. This control is achieved with the administration of short-acting beta blocker (i.e., esmolol) with additional agents such as nicardipine or nitroprusside as needed. Beta blockers must precede nitroprusside because of the possible tachycardic side effects of nitroprusside. Antiplatelet therapy with aspirin is also utilized when possible given the patient's other injuries. Repeat CT angiogram to evaluate for progression of the injury is recommended, though the time interval to repeat imaging is variable.

The management of grade II aortic injuries is evolving. Traditionally, it was recommended that these injuries undergo repair either via thoracic endovascular aortic repair (TEVAR) or an open approach, however, there is a trend toward treating these lesions with medical management alone.[34] Fortuna and colleagues reported no aortic-related mortality of grade II injuries treated with medical management alone, however, there may be a selection bias given that some of the grade II injuries in the study population underwent TEVAR.[35]

The EAST and SVS practice management guideline for blunt aortic injuries agree that Grade III and IV injuries should undergo endovascular repair.[33,36] When compared to open clamp and sew repairs, incidence of paraplegia is lower in the endovascular treatment group,[37] which has resulted in its adoption as the contemporary standard of care (**Fig. 24.9**). Timing of repair is dictated by both grade of injury and the presence of other life-threatening injuries. Grade IV injuries are repaired emergently in most situations. For traumatic aortic pseudoaneurysms (grade III injuries), these do not need to be repaired immediately as long as impulse control can be achieved. This allows time for resuscitation and treatment of other traumatic injuries such as intracranial hemorrhage, intra-abdominal 5 bleeding, or severe pelvic fracture. Delayed repair has been shown to be safe and actually has a lower overall mortality rate.[38]

Figure 24.9 Aortic stent graft for blunt rupture.

Diaphragmatic Injuries

Injuries may be the result of either penetrating or blunt trauma. In a 2015 review, there were 3,873 diaphragmatic injuries among the sample size of 833,309 trauma patients giving an incidence of 0.46%.[39] The average size of a diaphragmatic injury for penetrating trauma is approximately 2 cm and the average size of the injury for blunt trauma is 8 cm. Small injuries are unlikely to be detected on initial CXR imaging; however, large injures that allow herniation of stomach, colon, or liver into the chest cavity may be demonstrated on CXR. Even with current 256-slice CT scanners, the sensitivity for diaphragmatic injuries on CT scan is approximately 60%.[40] For the small injuries seen in penetrating trauma, one must maintain a high index of suspicion for diaphragmatic injury based upon the trajectory of the

knife or bullet. Diagnostic laparoscopy or thoracoscopy can effectively rule out a diaphragm injury and can be undertaken in a semielective fashion, unless there is a large injury resulting in respiratory compromise necessitating emergent repair.

Treatment

Once the diagnosis is made (either pre- or intraoperatively), repair of the diaphragm should occur. In the case of the penetrating trauma patient who is undergoing a diagnostic laparoscopy, the repair can proceed laparoscopically. For those with an acute rupture following blunt trauma, the repair is usually undertaken via laparotomy to also evaluate the abdominal organs for injury. For chronic hernia defects, strong consideration is made for repairing from the chest via a thoracotomy or via video-assisted thoracoscopy.

The repair is with a nonabsorbable suture in either an interrupted or running fashion. The classic repair is with an interrupted horizontal mattress suture. The repair must be air tight and a chest tube is usually placed at the time of the repair. It is important to lavage the pleural space and ensure complete evacuation of any hemothorax. When primary suture repair is not possible due to tissue loss, a mesh (synthetic or biologic) may be used or the diaphragm can be sewn to a lower rib, in essence transposing it to a slightly lower position to achieve closure of the hemithorax.

Cardiac

Cardiac injury can occur with either penetrating or blunt mechanisms. The most common chamber affected with penetrating injury is the right ventricle since it has the largest anterior surface area. The right atrium is the most common chamber that ruptures from blunt mechanisms because of its thin wall. Laceration or chamber rupture leads to hemopericardium. The diagnosis of hemopericardium is usually made via the FAST examination which is 95% sensitive and specific for pericardial fluid.[5] The presence of hypotension and hemopericardium defines cardiac tamponade and should be treated emergently.

Treatment

For an awake trauma patient with pericardial fluid, emergent transport to the operating room for median sternotomy is preferred. There is very limited role for pericardiocentesis in the acute trauma scenario, given the difficulties in evacuating clot from the pericardium, though this may be employed by nonsurgeons to temporize a patient for transport to a trauma center. A pericardial window is typically a diagnostic test restricted to those patients who have confounding medical issues, that is HIV-positive with chronic pericardial effusions, or to rule out cardiac injury in patients with a concerning trajectory with an equivocal pericardial windows on FAST exam. However, there are reports of therapeutic pericardial window with drain placement for hemopericardium.[41] Typically, a positive pericardial FAST mandates surgical exploration via a sternotomy or thoracotomy. If the patient has lost vital signs in the trauma bay or is rapidly deteriorating with loss of consciousness, then a resuscitative thoracotomy is indicated.[42,43] This allows rapid opening of the pericardium to relieve tamponade and temporize underlying cardiac injuries.

With impending cardiac tamponade due to hemopericardium, it is important to note that the decrease in preload with induction of anesthesia and positive pressure ventilation may cause the patient to lose vital signs. Therefore, coordination between the anesthesiologist and the surgeon is paramount to quickly perform median sternotomy if needed. The patient should be prepped and draped from the chin to the thighs prior to the induction of anesthesia and should be volume loaded to counteract peri-induction drop in cardiac preload.

Once in the chest preferably via median sternotomy, the pericardium is opened and the cardiac injury identified. The injury can usually be controlled with digital pressure or other adjuncts such as skin stapler, Foley catheter (careful not to rip the thin right ventricle with the balloon), or two stay sutures on either side of the injury that are crossed to close the wound. Formal repair with 3-0 Prolene is then performed with or without pledgets in an interrupted fashion. It is helpful to ask for a suture with a larger needle (i.e., MH). It is important to note the relationship of the injury to the coronary vessels. If the injury is juxtaposed to a coronary vessel, one should perform a horizontal mattress and pass the needle deep to the coronary artery. If the

proximal two-thirds of a coronary vessel are injured, it must be bypassed or repaired. Injuries to the distal third of a coronary vessel can be ligated. Intra- or postoperative echocardiography should be performed to evaluate for valve or septal injury, both of which are indications for cardiopulmonary bypass and expert consultation with a cardiac surgeon.

Blunt Cardiac Injury

There is a spectrum of blunt cardiac injuries. Injuries may cause mild dysrhythmias or lead to wall rupture (**Fig. 24.10**) and death. Any patient who undergoes a rapid deceleration mechanism is at risk for blunt cardiac injury. These patients are screened with a 12-lead ECG and troponin I; if both are normal then blunt cardiac injury is ruled out and the patient does not require observation.[44] If EKG changes (new arrhythmia or conduction abnormality) or troponin elevation is present, then the patient requires cardiac monitoring. If ST segment changes occur, a cardiac catheterization is necessary to rule out coronary dissection. Hemodynamic instability due to blunt cardiac injury may require ICU admission for inotropic support and such patients also need echocardiography to evaluate for valvular insufficiency or other structural issues.

Tracheobronchial Injury

Tracheobronchial tree injury can occur from either blunt or penetrating mechanisms and usually presents with a pneumothorax, subcutaneous emphysema, pneumomediastinum, and air leak after chest tube placement. The patient may be difficult to ventilate due to large air leaks. In rare cases, there may be the need for selective lung ventilation with a bronchoscopically placed bronchial blocker or may even require extracorporeal membrane oxygenation (ECMO) to temporize and allow for surgical repair. The majority of penetrating injuries to the tracheobronchial tree occur in the cervical trachea, while blunt injuries are typically in proximity to the carina. Intrathoracic injuries can be easily visualized via bronchoscopy, however, distal injuries with associated pneumatocele formation can be seen on CT scan.

Treatment

Bronchoscopy provides direction for surgical exposure if the injury is visualized. The majority of intrathoracic injuries are to the right mainstem bronchus and therefore a right posterolateral thoracotomy is the best surgical approach as this also grants access to the carina. Left thoracotomy is reserved for injuries to the left bronchus. Median sternotomy is not the preferred approach to tracheobronchial tree injuries due to limited visualization posterior to the heart. Once surgically exposed, the bronchus or trachea can usually be primarily repaired using a 3-0 absorbable suture. The repair can be buttressed with intercostal muscle or pleural flaps. Care should be taken not to devascularize the tracheal repair with excessive circumferential dissection. Chest tubes are placed and extubation is guided by the underlying lung contusion and hypoxia. Ideally, these patients should be taken off positive pressure ventilation as soon as possible, even immediately postoperatively.

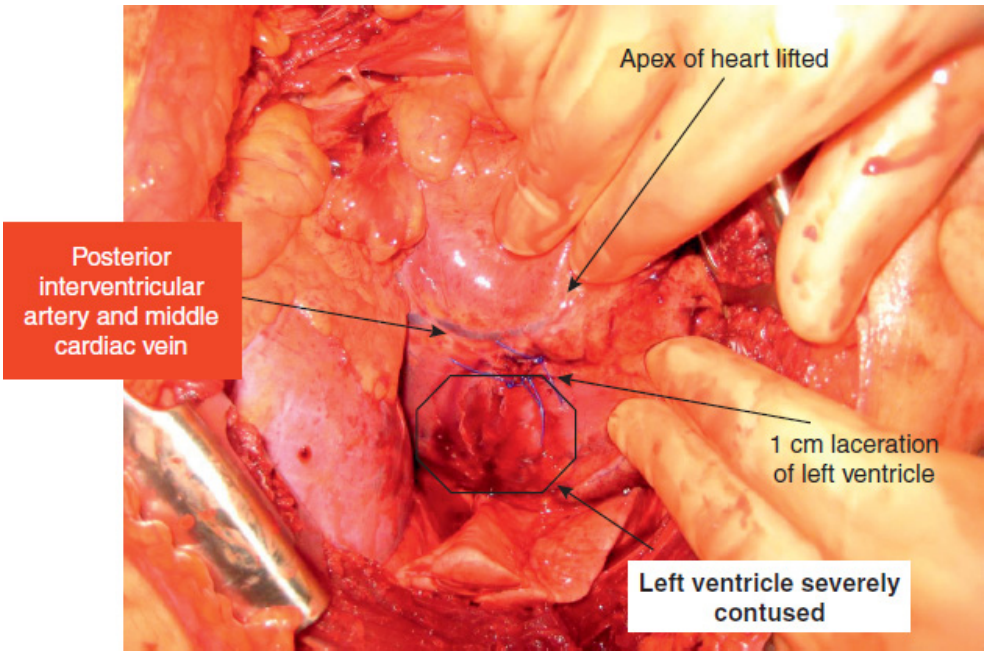

Figure 24.10 Blunt cardiac rupture/contusion.

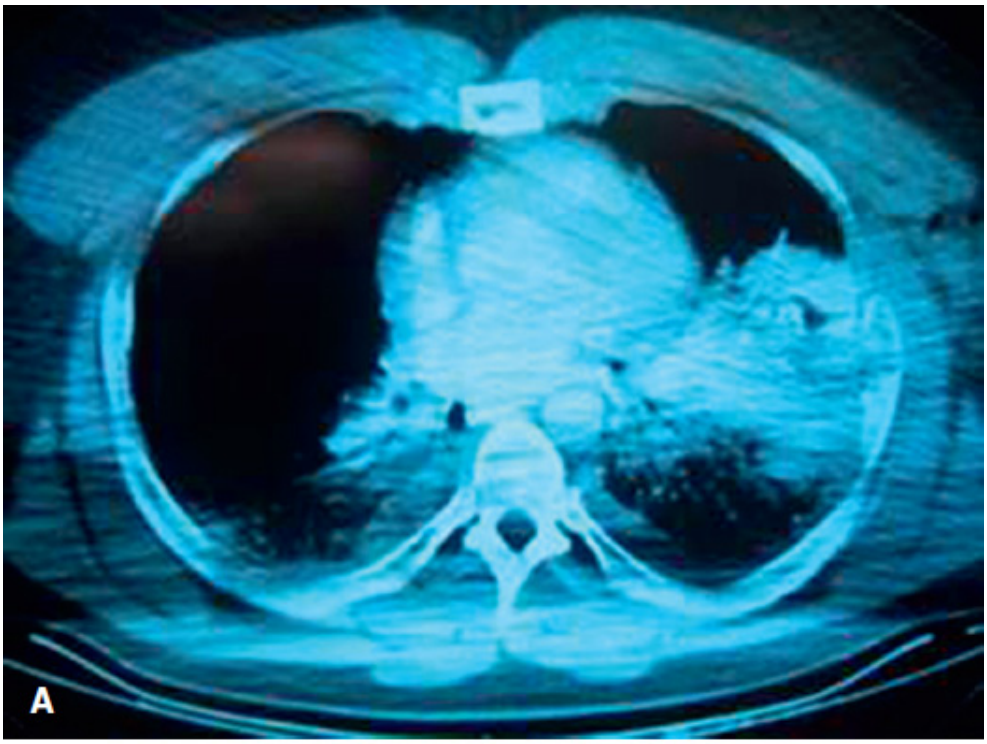
Thoracic Esophageal Injury

Esophageal injuries are almost exclusively secondary to penetrating trauma as blunt rupture of the esophagus is exceedingly rare.[45] If the trajectory of the

penetrating injury crosses the midline, the mediastinal structures must be evaluated. Hemodynamically unstable patients with penetrating torso trauma should be promptly explored in the operating theatre for hemorrhage control and evaluation of injury. If the patient is stable, one may perform diagnostic studies to evaluate the esophagus.

The initial imaging study is a CT scan of the chest with IV contrast to better delineate the track of the missile (**Fig. 24.11A**). Secondary signs of esophageal injury may be present including pneumomediastinum, pleural effusion, or mediastinal hematoma. If the missile track is in close proximity to the esophagus (<2 cm) then additional diagnostic investigations are necessary given the high mortality of esophageal injuries. An AAST multicenter retrospective review reported a 19% overall mortality rate for patients with esophageal injury with increasing mortality directly related to AAST grade of injury.[46] There is also a direct correlation between time to repair and morbidity/mortality, therefore any delay must be minimized. The most commonly utilized diagnostic modality is flexible endoscopy, which has been shown to have high sensitivity and specificity.[47] Otherwise, diagnostic imaging with a water-soluble followed by a barium-contrast study is warranted. The water-soluble contrast is used first in case there is a large leak (**Fig. 24.11B**). If no obvious leak is identified then the water-soluble contrast should be followed up with a barium study to increase the sensitivity for a small leak. If the barium esophageal imaging is negative, one can be assured there is no full-thickness injury to the esophagus.[48]

Distal thoracic esophageal injuries are repaired via a left thoracotomy and the proximal two-thirds are repaired via a right thoracotomy, which allows one to dissect the esophagus up to the thoracic outlet since the aortic arch is not obscuring the view. Once the esophageal injury is identified, it should be debrided and repaired in a full-thickness single layer. The repair should be buttressed with either a pedicled intercostal muscle flap or a pleural patch. Some have used a tongue of omentum for distal esophageal repairs. Of note, single lung ventilation is necessary to adequately visualize the injury and ensure a safe repair.



A

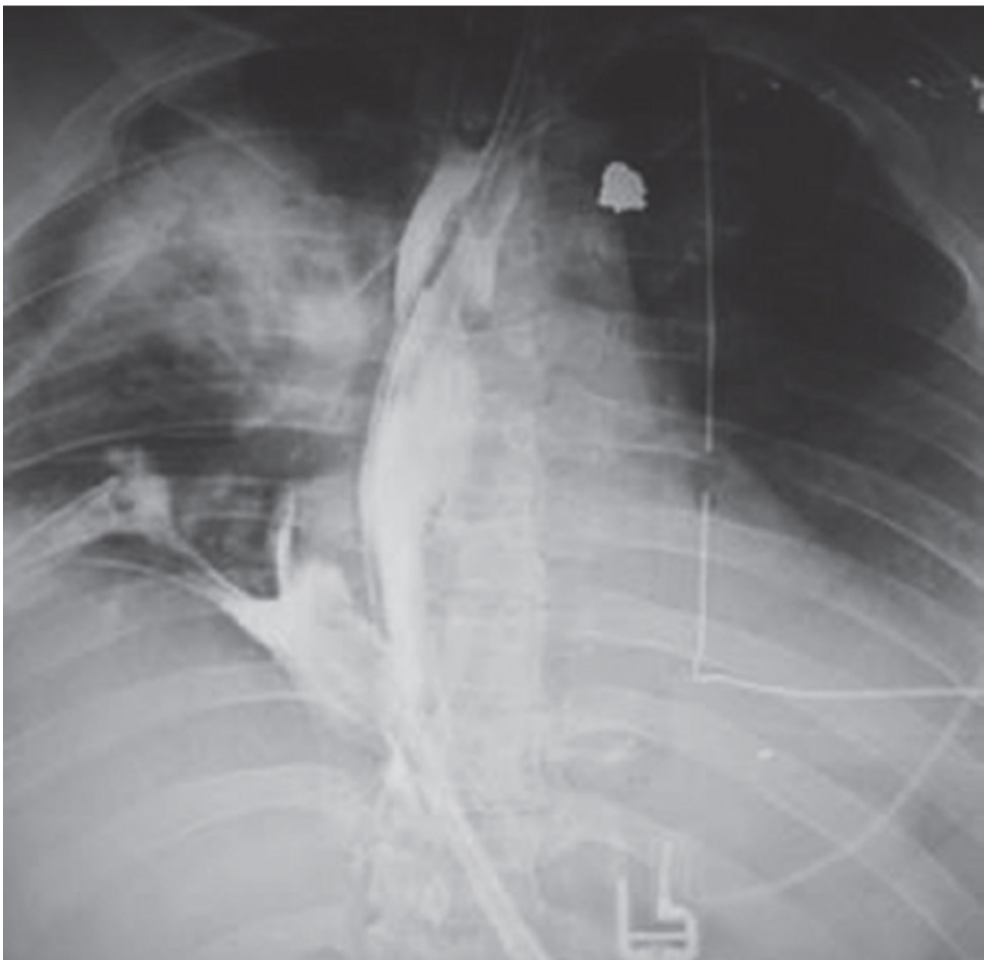


Figure 24.11 **A:** Tract of bullet coursing to posterior mediastinum. **B:** Contrast leaking from an injury to the esophagus.

RESUSCITATIVE THORACOTOMY

Resuscitative thoracotomy is an emergent procedure done to gain primary vascular control of an injured thoracic vessel, open the pericardium to relieve cardiac tamponade, repair cardiac injury, perform internal cardiac massage, gain control of the pulmonary hilum, and cross-clamp the aorta to gain proximal control of intra-abdominal hemorrhage. The resuscitative thoracotomy is a left anterolateral or clamshell thoracotomy (**Fig. 24.12**). The survival from resuscitative thoracotomy is as high as 24% for victims of penetrating thoracic trauma, however, survival decreases to about 4% if the patient arrives without a pulse, assuming a less than 15-minute cardiac arrest time.[49] In blunt trauma, survival after a resuscitative thoracotomy is 1.4% overall.[50] The odds of regaining a blood pressure in bluntly injured patients who lose vital signs in the trauma bay is about 4% but drops to 0.2% if vital signs were lost prior to arrival. For these reasons, the generally accepted indications for an ED thoracotomy in penetrating trauma are if the patient loses vital signs in the trauma bay or within 15 minutes of arrival. For blunt trauma, it is strongly recommended to limit the procedure to the patients who lose vital signs in the trauma bay.

Control of an intercostal artery can be difficult particularly if caudal and posterior. At times, it may be necessary to encircle the rib proximal and distal to the bleeding vessel to compress the vessel indirectly. This suture can be absorbable or even brought out through the full thickness of the chest wall and cut in 48 hours. At times, one may be dealing with a deep hole from a gunshot wound into the musculature of the posterior chest wall. Under these circumstances, aggressive and tight packing may suffice or a Foley catheter may be placed in the tract and inflated to tamponade the bleeding. The Foley may even exit the chest wall via a separate stab incision and be deflated 24

to 48 hours later and removed while the patient is observed for recurrent bleeding.

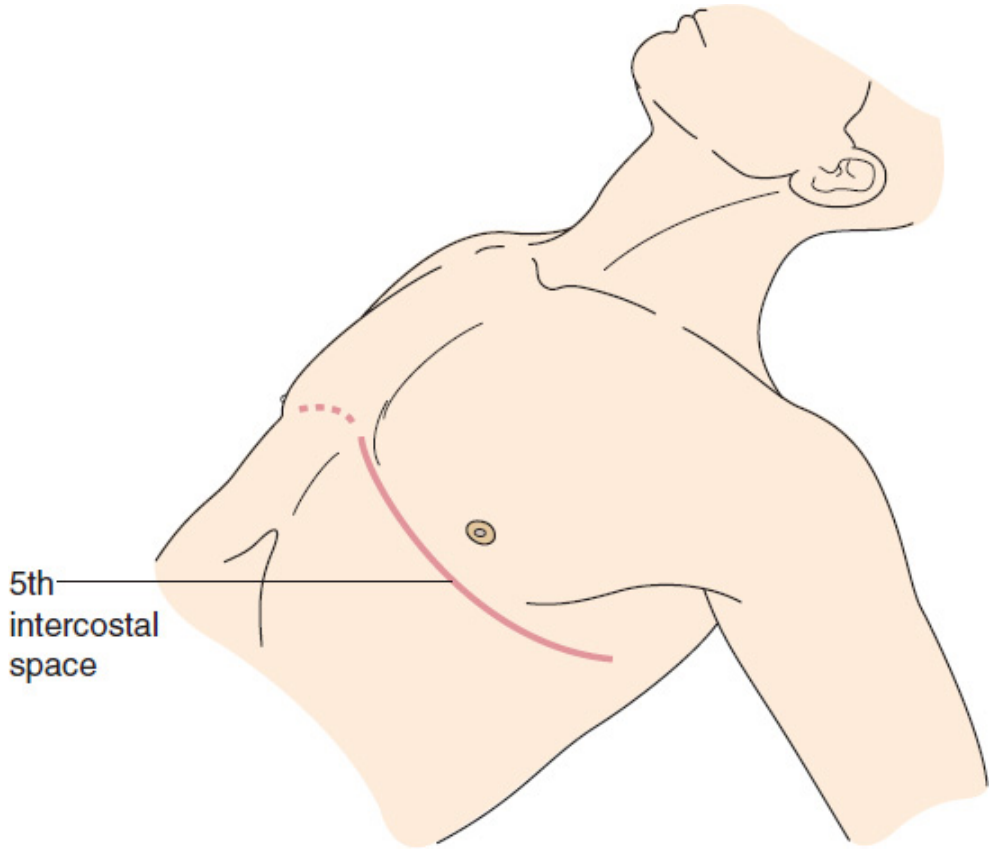

Figure 24.12 Left anterolateral thoracotomy incision.

The other common injury that may be found on exploration is laceration of the lung. It is important to understand that bleeding from the track of a penetrating trauma must not be closed superficially. Closing the entrance or exit holes may simply cause more bleeding into the bronchi or allow air to embolize from the bronchi to the pulmonary venous system. Patients will die from cardiac arrest from air emboli that enter the coronary vessels. Instead the pulmonary tract should be opened (tractotomy) with either clamps or GIA stapling devices. This opens the tract where the raw surface area can be oversewn or stapled while saving lung tissue. Peripheral lesions can simply have wedge resections performed.

CONCLUSION

Thoracic injuries are a common entity with rib fractures being the most common injury. A careful and systematic approach to the trauma patient is key to uncovering significant thoracic injuries. Life-threatening injuries, that is, massive truncal hemorrhage, tension pneumothorax, or cardiac tamponade must be identified quickly within the trauma bay and treated without delay.

Abdominal Trauma

Kenji Inaba, Elizabeth R. Benjamin, and Demetrios Demetriades

Key Points

1. Clinical examination is the cornerstone of the diagnostic workup after blunt abdominal trauma and any patient with peritonitis or instability with a positive FAST requires immediate laparotomy. CT is a high-yield diagnostic modality for the intra-abdominal contents with high degree of sensitivity and specificity for clinically significant injuries.
2. For stable, evaluable patients without peritonitis or evisceration after penetrating abdominal trauma, selective nonoperative management is an acceptable treatment option. For those undergoing nonoperative management, close clinical observation and CT scan are utilized to detect those patients with an occult injury that will ultimately require laparotomy and repair.
3. Rapid access to an operating room with immediate access to the instrumentation, consumables and support services such as the blood bank and radiology are required for the successful treatment of patients with abdominal trauma.
4. Standard positioning is supine, however, for injuries in stable patients where the rectum or perineum is at risk, lithotomy may be utilized. The initial incision is usually a midline laparotomy. Extension into the subcostal regions and across the inguinal ligament or into the thoracic cavity may be required to facilitate exposure.
5. Damage control laparotomy, which consists of rapid bleeding and contamination control, followed by temporary closure and resuscitation with delayed definitive repair of injuries should be considered for any patient who is physiologically depleted, has a burden of injury which will result in compromise if definitive repair is attempted, or has an injury profile beyond the scope of the surgeon skillset or facility resources.
6. Abdominal compartment syndrome can occur after trauma laparotomy and all patients should be monitored closely with bladder pressures in the recovery area. Any elevation in the intra-abdominal pressures warrants consideration of decompressive laparotomy.

7 Angioembolization is an important adjunct for patients who are undergoing damage control surgery and may be of particular benefit for patients with ongoing bleeding from complex solid organ or pelvic trauma.

INTRODUCTION

For patients who have sustained a stab wound (SW), gunshot wound (GSW), or blunt multisystem injury, the abdomen remains a high-risk cavity with the potential to hide occult but life-threatening injuries. Unlike the extremity or neck for example, where bleeding occurs externally, for the abdomen, significant bleeding and enteric spillage can occur with minimal symptoms until late. In patients presenting after both blunt and penetrating traumas, injury to the abdominal contents is common. In the National Trauma Data Bank, the largest repository of trauma registry data that exists in the United States, from 2007 to 2016, of the approximately 7,743,420 patients entered, 12.0% had an abdominal injury, with 75.8% due to a blunt mechanism. Broken down by regional abbreviated injury scale (AIS), 36.4% of these had an AIS 1, 31.2% an AIS 2, 19.0% an AIS 3, 9.4% an AIS 4, and 2.9% an AIS 5 injury.

Abdominal injuries are therefore common and a systematic approach to the rapid diagnosis and treatment of these injuries is essential. This chapter will provide a pragmatic approach to the patient with abdominal trauma, focusing on the acute resuscitation, diagnosis, and treatment of clinically relevant injuries to the abdominal structures.

BLUNT INITIAL EVALUATION AND DIAGNOSTICS

Resuscitation

For the patient that sustains abdominal trauma, unlike the extremity, where a tourniquet can be placed, there are currently no validated prehospital

methods for direct or indirect hemorrhage control. Rapid transport to definitive care therefore remains the primary goal. With the increasing interest in resuscitative endovascular balloon occlusion of the aorta,[1] in the appropriate clinical setting with trained personnel, this procedure could theoretically be performed in the prehospital setting. The general principles of resuscitation that apply to all trauma patients as outlined elsewhere in this textbook should be followed. Specific to patients with abdominal trauma, whenever possible, venous access should be gained in the upper limbs or torso. Resuscitation through a femoral central venous catheter is suboptimal as the return of blood products into the systemic circulation is compromised if the patient has an injury to the iliac system or vena cava. In the resuscitation area, once the diagnosis of an intra-abdominal injury requiring operative repair has been made, travel to the OR should take precedence over continued resuscitative efforts which can be continued concurrent to definitive hemorrhage control.

Diagnostics

The diagnostic workup of a blunt multisystem injury patient is often more difficult than for a penetrating injury patient. In general, the most practical approach to the patient in the resuscitation area depends on hemodynamic status. Patients can be categorized into those that are arresting, unstable, or stable.

For any arresting patient, if the decision to intervene is made, airway control, venous access with blood product infusion, and resuscitative thoracotomy with evaluation for concurrent right chest tube insertion are the immediate priorities. The outcomes for resuscitative thoracotomy performed for traumatic arrest due to blunt trauma are poor,[2] especially if the source of hemorrhage is in the abdomen, however survival to discharge and organ donation are possible in rare cases. If a resuscitative thoracotomy is performed, and the primary source of hemorrhage is in the abdomen, an aortic cross-clamp is placed. If the procedure is successful and a perfusing rhythm is regained, the patient should be taken immediately to the OR for laparotomy and definitive injury management. A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-

content/uploads/2020/07/WTACriticalDecisionsResuscitativeThoracotomy.pdf

For the unstable patient, aggressive resuscitation with blood products should be initiated immediately, and the patient will either stabilize, in which case a complete workup can be performed as described below, or they will remain unstable. If they remain unstable despite resuscitative efforts, rapid hemorrhagic source identification to determine potential operative intervention is the priority. Bilateral diagnostic chest tubes should be considered if chest x-ray (CXR) or ultrasound are not immediately available. Concurrent with the ongoing resuscitation, a focused assessment with sonography in trauma (FAST) should be performed. If free abdominal fluid is visualized, the patient should immediately be taken to the OR and a laparotomy should be performed. If the FAST is negative, a confirmatory diagnostic peritoneal aspirate (DPA) looking for gross blood may be performed. If this is positive, the patient undergoes laparotomy. In the setting of ongoing hypotension and a negative FAST, a pelvic x-ray may be performed to identify retroperitoneal source. If the above studies are negative, alternative sources for the hemorrhage are sought.

In the stable patient, a complete diagnostic workup can be completed. This begins with an external examination for any soft tissue evidence of injury. A seatbelt sign for example has been associated with an eightfold increase in the incidence of intra-abdominal injuries, impacting both the solid organs and hollow viscus.[3,4] While not sufficient to warrant mandatory laparotomy, a very low threshold for imaging with CT should be maintained and the patient should undergo a mandatory period of observation. With this mechanism, the seatbelt can cause a "bucket-handle" type injury (**Fig. 25.1**) where the mesentery is sheared away from the more elastic bowel wall causing ischemia. Clinical evidence of the ischemic GI tract injury can take hours to manifest and close observation is warranted.

1 If on initial examination, the patient already has peritonitis, in the setting of trauma, immediate laparotomy should be performed. This is a high-yield indication for operation. Although data were accrued in penetrating trauma, the urgency of peritonitis was made clear in a study examining 139 patients who were hemodynamically stable with peritonitis as the sole indication for operation. Of these, 97% had an intra-abdominal injury, with 11% having between 750 and 1,500 mL and 7% having >1,500 mL of blood

on opening with 25% sustaining intraoperative hypotension and 39% requiring blood transfusions despite being hemodynamically normal at presentation.[5]

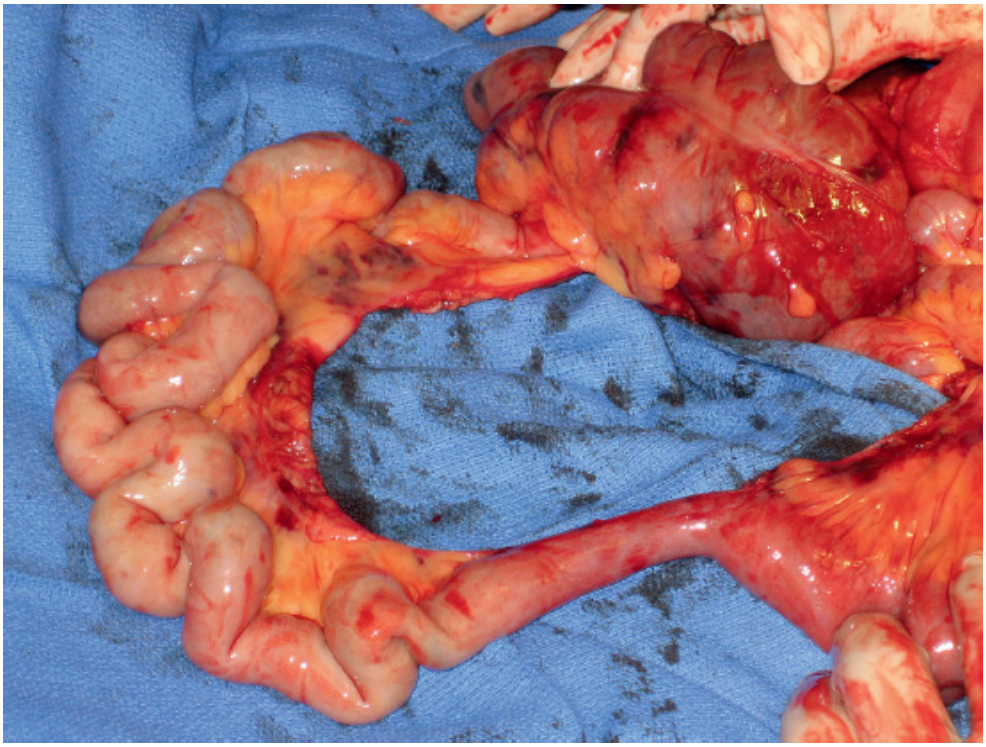

Figure 25.1 Bucket handle–type injury of small bowel.

For patients without peritonitis, the initial imaging modality is FAST. Because cardiac rupture is so rare in blunt trauma patients presenting alive,[6] the abdominal windows are of primary importance. The presence of free fluid is assumed to be blood. The presence of free fluid should trigger additional imaging with CT. For blunt trauma, there is no role for plain radiographs of the abdomen. For the stable patient, a pelvic x-ray is unnecessary especially if the patient is to undergo CT. CT scans should be performed with IV contrast. PO contrast is not required for the initial CT. A baseline creatinine level for all patients and a pregnancy test in females of child-bearing age should be obtained. In general, a CT should be considered in the stable patient when there is external evidence of significant force transfer to the abdomen such as a seatbelt sign, or with free fluid on FAST or when there is significant abdominal tenderness on examination. Mechanism as a sole criterion for deciding which patients require CT scan is unreliable,

but a high-energy mechanism is often considered when making this decision. Based on the CT results, patients can be categorized into three groups, those with no injury, those with an injury, and those with an equivocal finding. If the CT demonstrates no abnormalities, the likelihood of a clinically significant injury is extremely low.[7] For patients with a CT that demonstrates injury, the nature of the injury will determine management. Any hollow viscus injury including the GI tract or bladder, will require operative repair. For solid organ injuries, the indications for operative management will depend on the extent of injury, the physiologic status of the patient including comorbidities, and their tolerance for blood loss and associated injuries. In general, the majority of solid organ injuries can be successfully managed nonoperatively.[8] In centers where there is access to interventional radiology, endovascular solutions, such as stenting or embolization and percutaneous management of complications such as a biloma can also be used as an adjunct to nonoperative management. This will be further elucidated in the following organ-specific sections. This then leaves the patient with equivocal findings of a hollow viscus injury on CT. Equivocal findings would include subtle findings such as mesenteric fat stranding, free fluid without solid organ injury, and bowel wall thickening. These patients should be observed clinically, ideally by a single provider and collateral evidence of injury such as the WBC count, heart rate, temperature, and abdominal examination are used to detect worsening, indicative of a hollow viscus injury requiring operative intervention. The exact period of time required for observation is unknown, however, it is expected that a patient who is improving at 24 hours has a low likelihood of a clinically significant missed injury.

PENETRATING INJURY—INITIAL EVALUATION AND DIAGNOSTICS

General Approach to Penetrating Abdominal Injury

Following the experience of World Wars I and II, with the high rates of destructive injuries, penetrating abdominal trauma was historically treated with universal surgical exploration. Starting in the 1960s with SWs, followed by GSWs, this paradigm began to shift.[9–11] Patient selection for operative versus nonoperative management based on the clinical picture and radiologic evidence began to evolve. With improved access, and the growing body of evidence regarding the potential morbidity of nontherapeutic operations, contemporary evidence now supports a nonoperative approach to the management of penetrating abdominal trauma in select circumstances.[12]

The balance between prompt surgical management of traumatic injury and avoiding unnecessary operation remains a central diagnostic and management challenge in penetrating 2 abdominal injury. Patients who present *in extremis,* with hemodynamic instability, peritonitis, or are unevaluable mandate immediate operation. For the remaining patients, the practice of universal exploration would result in a high rate of nontherapeutic laparotomy which is associated with a morbidity of at least 20%.[13,14] This not only impacts patient-centered outcomes, but also trauma resource utilization as nontherapeutic laparotomy is associated with increased hospital length of stay and healthcare cost.[13,15–18]

Although a subset of patients with penetrating abdominal trauma will ultimately require exploration, a significant number can be managed nonoperatively. In a retrospective analysis of abdominal SWs, mandatory exploration was associated with a negative laparotomy rate of 37%.[13] A Western Trauma Association Multicenter Study including 359 patients with anterior abdominal SWs found that 64% of patients did not require laparotomy.[19] The need for laparotomy is even lower after SWs to the back with only 15% of patients noted to have clinically significant injury.[20] GSWs to the abdomen are more likely to require operative exploration, but the presence of gunshot injury alone does not necessitate mandatory laparotomy. In an analysis of 1,856 patients with abdominal GSWs, had a policy of mandatory laparotomy been employed, 47% of patients would have undergone an unnecessary laparotomy.[18] Similar to SWs, posterior and transpelvic injuries are less likely than anterior injuries to require exploration.[18,21,22]

Indications and Contraindications to Selective Nonoperative Management

Peritonitis and hemodynamic instability in the setting of penetrating abdominal trauma remain absolute indications for laparotomy. Although soft tissue injury can cause local tenderness, diffuse peritonitis after penetrating abdominal trauma is associated with a 97% chance of intra-abdominal injury at laparotomy.[5] Given the central role of physical examination in patient triage, unevaluable patients including those with concomitant head or spinal cord injury or those undergoing urgent nonabdominal operations are not candidates for selective nonoperative management. Although not an absolute contraindication to selective nonoperative management, patients with omental or visceral evisceration after penetrating abdominal trauma should be strongly considered for operative intervention. Significant intra-abdominal injury is present in 46% to 85% of patients with omental evisceration, and even higher rates with visceral evisceration.[17,19,23,24] A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsAbdominalGunshotWounds.pdf https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsAbdominalStabWounds.pdf

Peritoneal penetration alone after penetrating trauma is not an absolute indication for operative exploration. For this reason, invasive evaluation including diagnostic laparoscopy for the sole purpose of determining peritoneal violation is not indicated.

Diagnostics

Radiologic imaging is a key component of the diagnostic workup of patients who have sustained penetrating abdominal trauma, especially those undergoing a trial of nonoperative management. In hemodynamically stable evaluable patients without peritonitis, a detailed evaluation of the external wounds and retained fragments using plain radiographs is imperative to plot missile trajectories. External wounds do not always correspond to internal injury and, especially in the setting of multiple missiles, trajectory may be

misleading from external wounds alone. For example, paired lateral abdominal wall bullet wounds may represent a superficial tangential trajectory or two separate transabdominal injuries with retained missiles. Management will change significantly based on the internal trajectory.

FAST examination is a central component of the early assessment after blunt trauma. The utility of this imaging modality in penetrating trauma, however, is less uniformly accepted. The primary use of the FAST examination in penetrating abdominal trauma is to evaluate for pericardial fluid. A positive cardiac FAST after penetrating trauma mandates immediate median sternotomy. For the intra-abdominal fluid windows, while the FAST examination is highly specific for fluid, the sensitivity is poor ranging from 46% to 67%.[25–27] In the hemodynamically *unstable* patient with multiple cavitary sources of hypotension, a positive FAST can still be helpful as a rapid tool for operative incision planning. For *stable* patients however, it rarely impacts clinical decision-making as the patient either meets criteria for selective nonoperative management and will be undergoing CT, or will be going to the OR, irrespective of the FAST findings.

CT has become universally accepted as an integral component in the evaluation of the penetrating trauma patient undergoing selective non-operative management. For patients undergoing exploration, CT is unnecessary and should not be routinely obtained. For patients with a GSW who are stable, evaluable, and without peritonitis and are undergoing a trial of nonoperative management however, CT is a requisite next step.

GSWs follow a linear path and have an associated air bubble tract that allows for trajectory identification on CT scan. Understanding the missile trajectory provides critical information regarding potentially injured structures and those to which injury is unlikely. CT scan imaging after abdominal GSWs has been shown to be highly reliable for injury identification, with a sensitivity and specificity of 90.5% to 96% and 95% to 96%, respectively.[28,29] The injury tract on CT scan is often more subtle after SWs due to the lower velocity and smaller volume of air bubbles along the tract, and as a result, CT scan has been shown to be a less useful adjunct in patient triage.[30,31]

Based on the CT scan findings, patients may be divided into four groups. (1) Patients with no peritoneal violation on CT scan. In this population, it is exceedingly rare that operative intervention will be required. (2) Patients

with peritoneal violation but no obvious intra-abdominal injury on CT scan. This is the ideal patient population for selective nonoperative management with serial abdominal examinations and observation. (3) Patients with peritoneal violation and evidence of vascular or hollow viscus injury on CT scan. Although there are no strict criteria for diagnosing hollow viscus injury on CT scan, findings concerning for injury include bowel wall edema, missile trajectory traversing bowel, extraluminal fluid, air, or contrast. In this group, laparotomy is mandatory. (4) Patients with peritoneal violation and solid organ injury. In the absence of hollow viscus injury, solid organ injury alone does not mandate laparotomy.[32,33] For patients meeting all other criteria for nonoperative management, this remains a treatment option with a high rate of success.

In patients selected for nonoperative management, clinical observation becomes the next important step. This is the most time-consuming aspect of nonoperative management and one of the primary reasons it is not feasible in all practice settings. This observation should be performed by a consistent team, ideally by the same provider, who can carefully examine for changes in abdominal pain, collateral markers of occult injury such as tachycardia or fever, and laboratory abnormalities such as an increasing white blood cell count. During this observation period, it is expected that a certain percentage of patients initially selected for nonoperative management will progress to operative intervention based on imaging or changes in clinical examination. Selective nonoperative management hinges on the ability to perform frequent, consistent physical examinations. Patients should receive no narcotics, or antibiotics and undergo serial hemodynamic and laboratory testing including white blood cell count, lactate, and hemoglobin levels. Strict adherence to a protocol is necessary to ensure early identification of patients who fail nonoperative management and require operative intervention.

In patients selected for nonoperative management after penetrating abdominal wounds, the duration of observation should meet a minimum standard. After abdominal GSWs, a review of 270 patients found that all injuries requiring laparotomy were apparent within 24 hours of observation.[34,35] Similar results have been described for abdominal SWs with injuries requiring laparotomy detected within 12 hours of observation.[36]

Penetrating left thoracoabdominal injuries, bounded by the nipple, scapular tip, and costal margin, present a unique challenge due to the risk of

occult diaphragmatic injury. Diaphragmatic injuries are notoriously difficult to diagnose on CT scan and are often asymptomatic in the early, postinjury setting. Over time, as the injury expands, the patient will be at risk for visceral herniation and strangulation. This complication is less likely after right-sided injuries due to buttressing of the injury by the liver but is a serious consideration after left-sided injury. The incidence of diaphragmatic injury after thoracoabdominal injury is as high as 17% to 40%.[37–39] For this reason, patients treated nonoperatively for left thoracoabdominal penetrating injuries should undergo a period of clinical observation commensurate with the mechanism. If peritonitis develops, the diaphragm can be directly examined at laparotomy. If the patient passes the period of observation, the patient can be offered diagnostic laparoscopy to specifically evaluate the diaphragm on the left side. As the patient has already been clinically evaluated and other intra-abdominal injury excluded, laparoscopy can be focused on diaphragmatic evaluation and a full exploration is not necessary. Insufflation for this procedure should be done carefully with close monitoring of the vital signs. With any evidence of the development of tension physiology due to a diaphragmatic injury, immediate release of pressure and insertion of a chest tube should be performed before proceeding.

THE TRAUMA LAPAROTOMY

3 For any hospital that cares for trauma patients, the ability to emergently perform an operative intervention is critical. Preparation before the critically ill patient arrives is key. An operating room that is easily accessible from the resuscitation area as well as the ICU should be earmarked for use in these situations. A plan for securing the room for high-profile patients should be in place and there should be a designated waiting area for family members. A contingency plan for multiple casualty situations should be available, with operating rooms located in close proximity to facilitate surgical, anesthesia, and nursing cross-coverage. Transportation of critically ill patients is high-risk, and preplanned routes that minimize distance, elevator use, and public exposure should be well known to all providers. Instruments and disposables should be centrally located and redundant so that multiple casualty situations

can be dealt with effectively. Having a dedicated trauma pack that allows for a laparotomy and thoracotomy, with add on sets for a sternotomy, amputation, and peripheral vascular injuries will facilitate circulator efficiency. With the high rate of retained foreign bodies after emergent trauma cases, the use of radiofrequency detection device embedded fabric is recommended. In higher-volume centers, access to a satellite blood bank with uncross-matched packed red blood cells and plasma is ideal, otherwise a system for communication with the main blood bank and product delivery to the OR should be in place. If a hybrid room is available, the operative and nursing teams should be familiar with the indications for starting an emergent case in this room. For all rooms, access to fluoroscopy and plain films is critical. Because of service line cross-coverage, ongoing in-servicing of the nursing and support staff is important to ensure that practices such as massive transfusion protocols, are universally understood.

4 For all emergent laparotomies, the patient should be placed in the supine position with arms abducted at 90 degrees. Even with a concomitant thoracic injury, this is the preferred starting position. Rarely, for patients with a penetrating injury with a transpelvic trajectory, where endoscopic evaluation may be required, the lithotomy position may be used. Likewise, in the blunt trauma patient where there is external perineal injury, this may be considered. At a minimum, the torso, neck, and upper half of the lower extremities should be prepared into the field for maximum flexibility. With any concurrent limb injuries, the entire extremity should be prepared. If there is any concern of a urethral or bladder injury, the Foley catheter should be prepared into the field to allow manipulation by the surgeon. Forced air warming on the lower half of the extremities, and other warming adjuncts should be utilized. All preoperative patient preparation including venous and arterial access, catheterization, and confirmation of patient identification should be a team effort with full participation by the surgical team.

The trauma laparotomy incision extends from the xiphoid process to the symphysis pubis. Traditionally made with a scalpel, unless emergent, electrocautery can be utilized to minimize bleeding. This extensile midline incision can be extended across the right or left inguinal ligament for distal iliac vascular injuries. Superiorly, a subcostal extension can be added to improve access to the liver on the right, especially with retrohepatic venous injuries, or to the left for gastroesophageal (GE) junction injuries. The

incision can be extended into a sternotomy for concurrent thoracic cavity injuries or to facilitate suprahepatic vena cava control for high-grade liver injuries not amenable to packing. If the patient has a pre-existing right thoracotomy, this can be joined to the laparotomy with incision of the diaphragm to afford the same view of the liver, retrohepatic venous structures, and intrapericardial vena cava.

On entry to the abdomen, the falciform should be taken down so as to minimize traction damage to the liver. Traditionally, blind four quadrant packing was advocated. In reality, this maneuver is not very helpful. In order to prevent iatrogenic damage, it is preferable to remove large amounts of central clotted blood, followed by selected packing of any areas with active bleeding. A rapid examination of the retroperitoneum should also be performed. Focusing on an obvious bowel injury that is encountered first while a retroperitoneal vascular injury remains unattended to is a pitfall. The goal of the initial packing and survey of contents is to identify and temporize any major sources of bleeding. A plan for surgical control can then be made. This includes notifying the circulator of any necessary additional equipment and close communication with anesthesia to optimize the resuscitation needs of the patient. Early consideration of damage control, addressed later in the chapter should be considered. The need for adjunctive services such as angiography prior to proceeding to the SICU should be considered and initiated early to allow lead-time for preparation. Once active hemorrhage has been temporized, a careful and complete survey of all of the abdominal contents should be performed. In the exsanguinating patient who is undergoing a damage control procedure, this may not be possible, but in the stable patient, this is critical. The potential for a missed injury can be mitigated by a systematic approach to the abdominal contents. We recommend that the entire abdomen be reviewed in the same manner for every case, regardless of the mechanism. Specific areas warrant extra care during the examination. For blunt injuries without preoperative imaging, duodenal injuries may present with only a subtle hematoma in the retroperitoneum. For hematomas in this area, a right visceral medial rotation should be performed. For penetrating injuries, especially those due to shotguns, colonic, rectal, and small bowel injuries, especially on the mesenteric surface, may only be visible as a small bloodstain or hematoma in the overlying fat. These need to be inspected carefully. The posterior surface

of the stomach is also a common area for missed injuries and should be inspected carefully.

While exceedingly uncommon for blunt injuries, for both SWs and GSWs, ureteric injuries can be difficult to diagnose and for any trajectories in this region, care should be taken to inspect the at-risk segment of the ureter without devascularizing the structure. Likewise, whereas blunt bladder injuries are often large and located near the dome, penetrating injuries, even those that are intraperitoneal, can be small and asymptomatic. Most small extraperitoneal injuries can be managed nonoperatively with urinary catheter drainage however, large injuries, especially those with an intact connection to the skin can be problematic. If there is an intraperitoneal component of bladder injury, this can be extended and the interior of the bladder visualized. If not, we recommend injection of methylene blue containing sterile water into the bladder retrograde to look for any visible extravasation. If this is identified, the bladder should be taken down and these injuries repaired.

For retroperitoneal hematomas, the abdomen is traditionally broken down into three zones. Zone I is the central portion from the aortic hiatus to the sacral promontory encompassing the aorta, IVC, and major branches. Zone II covers the lateral retroperitoneum which contains the kidneys. Zone III is the pelvis, which encompasses the sacral venous plexus and iliac vessels. For penetrating injuries, all zones undergo exploration. For blunt injuries, traditionally, all zone I hematomas would be explored with zones II and III only warranting exploration if the hematoma was large, expanding or pulsatile. The retrohepatic area is distinct from the remaining areas and we often refer to this as zone IV, containing the retrohepatic IVC and major hepatic veins. This area is difficult to expose and as such, if bleeding is controlled with packing, should not be explored for either blunt or penetrating injuries.

DAMAGE CONTROL LAPAROTOMY

Damage control[40] has become a common practice in the management of patients with complex abdominal trauma and has been credited with saving more lives than many of the other surgical techniques developed over the last

two decades. Abdominal damage control techniques should always be combined with damage control resuscitation, which includes permissive hypotension, early empiric balanced blood component therapy minimizing crystalloid usage, and the 5 prevention and treatment of hypothermia. Abdominal damage control includes three key components: (a) temporary rapid control of bleeding and contamination with early termination of the operation, (b) postoperative resuscitation with correction of coagulopathy, hypothermia, and acidosis, and (c) subsequent definitive repair of injuries.

The standard indications for damage control include: (a) patients with severe physiologic compromise with coagulopathy, hypothermia, or acidosis, (b) bleeding from difficult to control injuries or an injury burden which will result in physiologic compromise if treated definitively at the index operation, and (c) austere environments with limited resources or surgeon skillset, such as in a rural or combat setting. There is evidence that early damage control, even prior to physiologic decompensation, may be associated with better survival and as such, patients with a large injury burden at risk of becoming physiologically depleted should also be considered as candidates for damage control surgery. The exact timing of damage control should be determined by the complexity of the injuries, the physiologic condition of the patient, the available resources, and the experience of the surgical team.

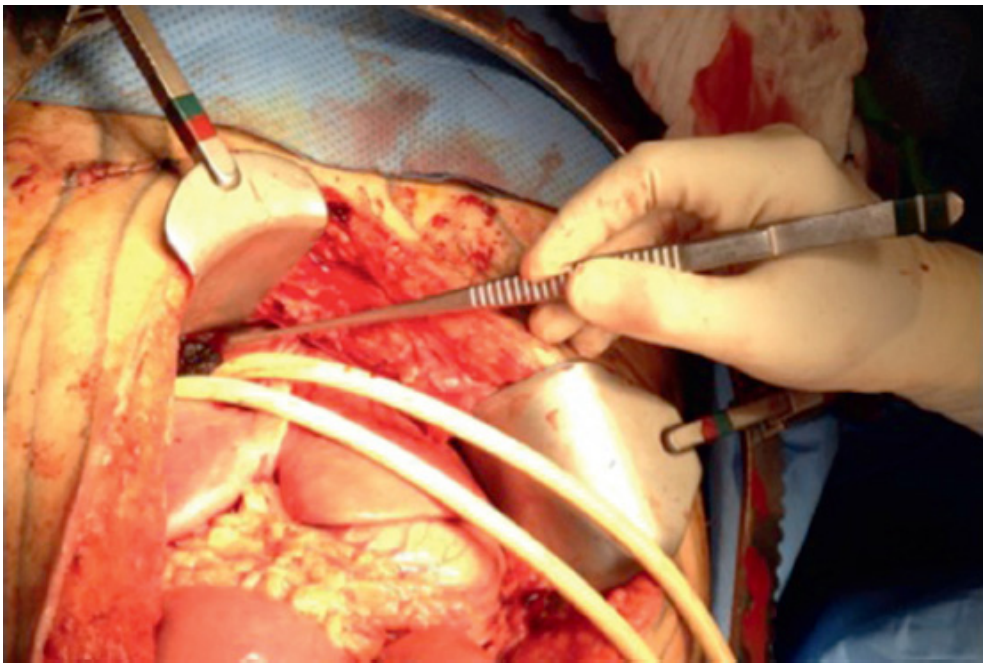

Figure 25.2 Gunshot injury through the center of liver requiring balloon tamponade using Foley catheters for damage control.

Effective temporary hemorrhage control can be achieved by mechanical compression or gauze packing in most cases. However, packing is usually not effective for major vascular injuries and surgical control with ligation or shunting[41] may be necessary. For deep tracts, for example in the liver, balloon tamponade[42] can be very effective (**Fig. 25.2**). Angioembolization may be a useful adjunct for abdominal damage control and should be considered early, immediately following the operation.

Control of intestinal spillage is also an integral part of damage control. Stapling of the bowel, without reestablishing continuity can be considered in severe instability for injuries requiring resection. Definitive reconstruction is performed at a later stage, once the patient is stabilized. As this temporary obstruction may promote bacterial and toxin translocation especially in patients requiring vasopressors, whenever possible, reconstruction of the bowel should be considered at the index operation.

6 Following damage control, the abdominal fascia or skin should never be closed because of the high risk of intra-abdominal hypertension and abdominal compartment syndrome.[43] The ideal method of temporary abdominal closure should prevent evisceration, preserve the fascia and abdominal wall domain, facilitate reoperation, allow effective removal of

toxin-loaded intraperitoneal fluid, reduce the risk of enteroatmospheric fistulas, and help achieve early definitive fascia closure (**Fig. 25.3**). Several systems that utilize negative pressure therapy are described for temporary abdominal closure. A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsManagementOfOpenAbdomenFollowingDamageControl.pdf

Once the patient has had their initial abbreviated procedure and temporary abdominal wall closure, they can then be taken to the ICU for continued resuscitation. After physiologic status has normalized, the patient can then return to the OR for definitive exploration and repair of all injuries. Even prior to normalization of the patient's physiology, if significant bleeding is noted, the patient should return to the operating room for reexploration. Although rare, even with a temporary abdominal wall closure in place, intra-abdominal hypertension may still occur. It is important that bladder pressures are monitored routinely during the first few hours after laparotomy.

Figure 25.3 Temporary abdominal closure after damage control laparotomy.

DIAPHRAGM

Anatomy

The diaphragm consists of a central aponeurotic portion which fuses with the pericardium and a peripheral muscular portion which is attached to the lower sternum, the lower six ribs, and the lumbar spine. During exhalation, the diaphragm rises to the level of the nipples at the fourth to fifth intercostal space. Penetrating injuries of the lower chest or insertion of a thoracostomy tube below the nipple, therefore has the potential to cause injury to the diaphragm.

Epidemiology

Blunt trauma may cause diaphragmatic injury through three different mechanisms which include a sudden increase in intra-abdominal pressure causing a bursting of the diaphragm, fractured ribs perforating the diaphragm, and deceleration injuries causing detachment of the diaphragm from the ribs. For blunt trauma, a diaphragmatic injury is found in approximately 7% of all laparotomies and in about 7.5% of autopsy studies. The left hemidiaphragm is involved in approximately 70% of cases and the right in 30% presumably due to the protective presence of the liver. Blunt tears (**Fig. 25.4**) are usually 7- to 10-cm long as compared with 2 to 3 cm for penetrating trauma (**Fig. 25.5**). A right diaphragmatic rupture indicates a more severe traumatic insult and in almost all cases there are associated intra-abdominal injuries, compared to 77% for left diaphragmatic ruptures.

Diagnostics

Isolated and uncomplicated diaphragmatic injuries are difficult to diagnose as they may be completely asymptomatic or present with minor, nonspecific signs. Classic findings such as shortness of breath, bowel sounds in the chest, GI obstruction, or ischemia, are rare, and require acute herniation of abdominal contents.

The natural history of unrecognized diaphragmatic injuries is unknown and although some small injuries may heal, this is not uniform. For right

hemidiaphragm injuries, the presence of the liver generally protects against diaphragmatic herniation. However, for the left side, unrepaired diaphragm injuries commonly result in a diaphragmatic hernia, which may present within hours, days, weeks, months, or even years after the injury.

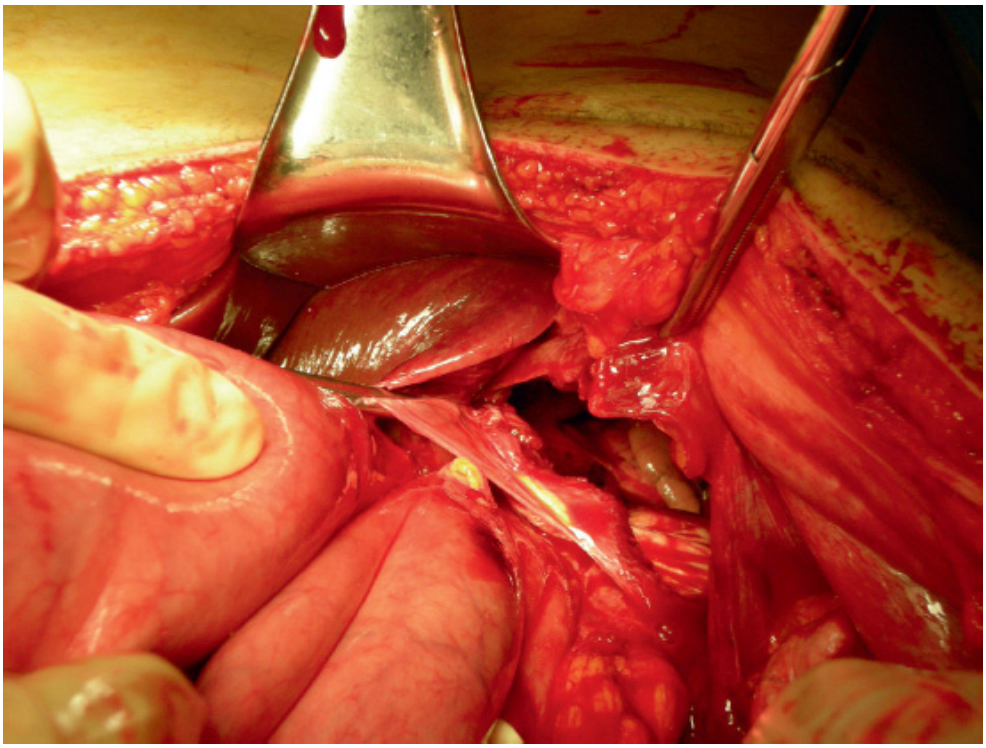

Figure 25.4 Large blunt diaphragm injury.

For blunt injuries, imaging can be useful. Plain radiologic findings suspicious of diaphragmatic injury include an elevated diaphragm, an irregular diaphragmatic contour, and nonvisualization of the diaphragm. Classically, an NG tube may be seen in the thoracic cavity. Once GI tract herniation has occurred, CXR (**Fig. 25.6**) and CT (**Fig. 25.7**) have higher sensitivity. Although injuries are not always detected on CT, this modality is the highest yield study to evaluate for diaphragmatic injury as it allows concurrent evaluation of any associated intra-abdominal injuries.

Treatment

All diaphragm injuries should ultimately have the abdominal contents reduced and the defects repaired. Acutely, diaphragmatic injuries should be

approached through a laparotomy to facilitate exploration of the remaining intra-abdominal contents if needed. In chronic, elective cases, access and repair of the hernia can be performed through a thoracotomy. The repair should be performed using nonabsorbable sutures and if there is contamination of the pleural cavity, extending the incision and washing the cavity out prior to closure are warranted. Tube thoracostomy should be considered in most cases. In rare cases where there is loss of diaphragmatic tissue, synthetic prosthetic reconstruction can be utilized. If the diaphragm has been avulsed from the chest wall, careful reconstruction of the diaphragmatic architecture utilizing nonabsorbable sutures is required. In some cases where there is significant tissue loss, apposition of the remaining diaphragm to the chest wall several rib spaces up may be required to create a tension-free repair.

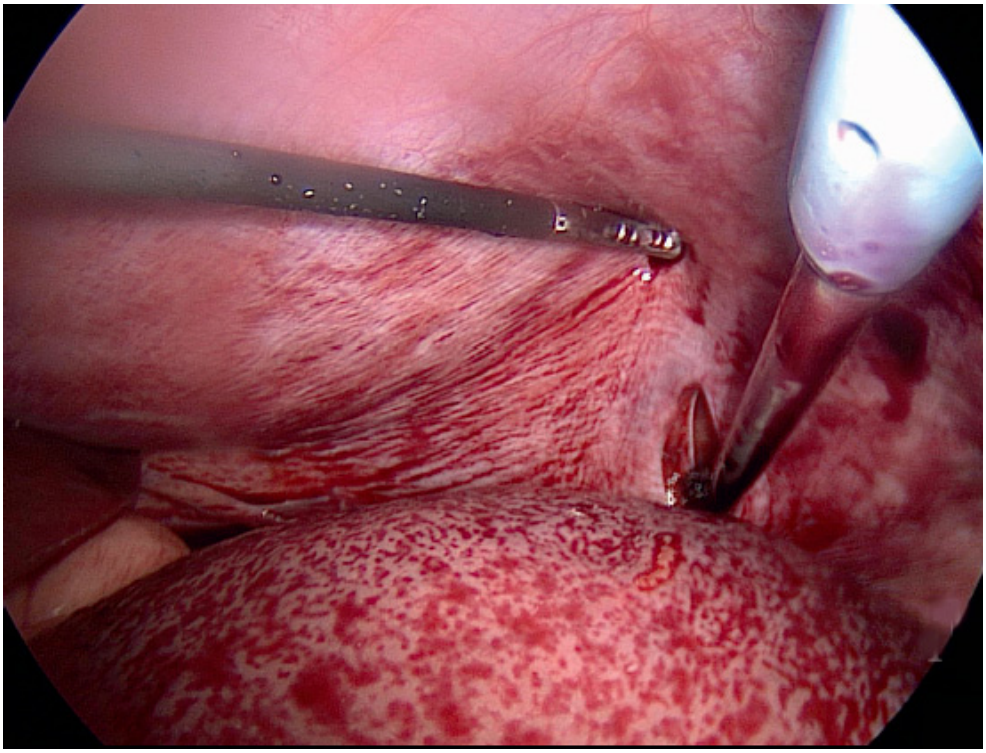

Figure 25.5 Small diaphragm injury after a stab wound to the left thoracoabdominal region.

Figure 25.6 Chest x-ray demonstrating blunt left diaphragmatic injury with herniating gastrointestinal tract.

LIVER AND BILIARY TRACT

Anatomy

The anatomical division of the liver into the classic Couinaud segments has no practical application in trauma. Parenchymal resection should be minimized and does not follow anatomical boundaries. An understanding of the blood supply however is important. The retrohepatic IVC is approximately 8 to 10 cm long and in most patients is partially covered by the liver parenchyma. In approximately 7% of individuals the IVC is completely embedded in the liver. For outflow, there are three major hepatic veins (right, middle, and left), with numerous accessory veins. Only the proximal 1 to 2 cm of the major hepatic veins are extrahepatic. In approximately 70% of individuals, the middle hepatic vein joins the left hepatic vein, near the IVC. The portal vein provides approximately 70% of hepatic blood flow, and 50% of the hepatic oxygenation. It divides into right

and left branches at the level of the liver parenchyma. The common hepatic artery originates from the celiac artery. In most individuals it branches into the left and right hepatic arteries at the hilum of the liver. In some individuals the right hepatic artery originates from the superior mesenteric artery. The left hepatic artery may originate from the left gastric artery. The porta hepatis contains the hepatic artery to the left, and the common bile duct to the right. The portal vein lies posteriorly and between the common bile duct and the hepatic artery. The left hepatic bile duct, the left hepatic artery, and the left portal vein enter the undersurface of the liver, near the falciform ligament.

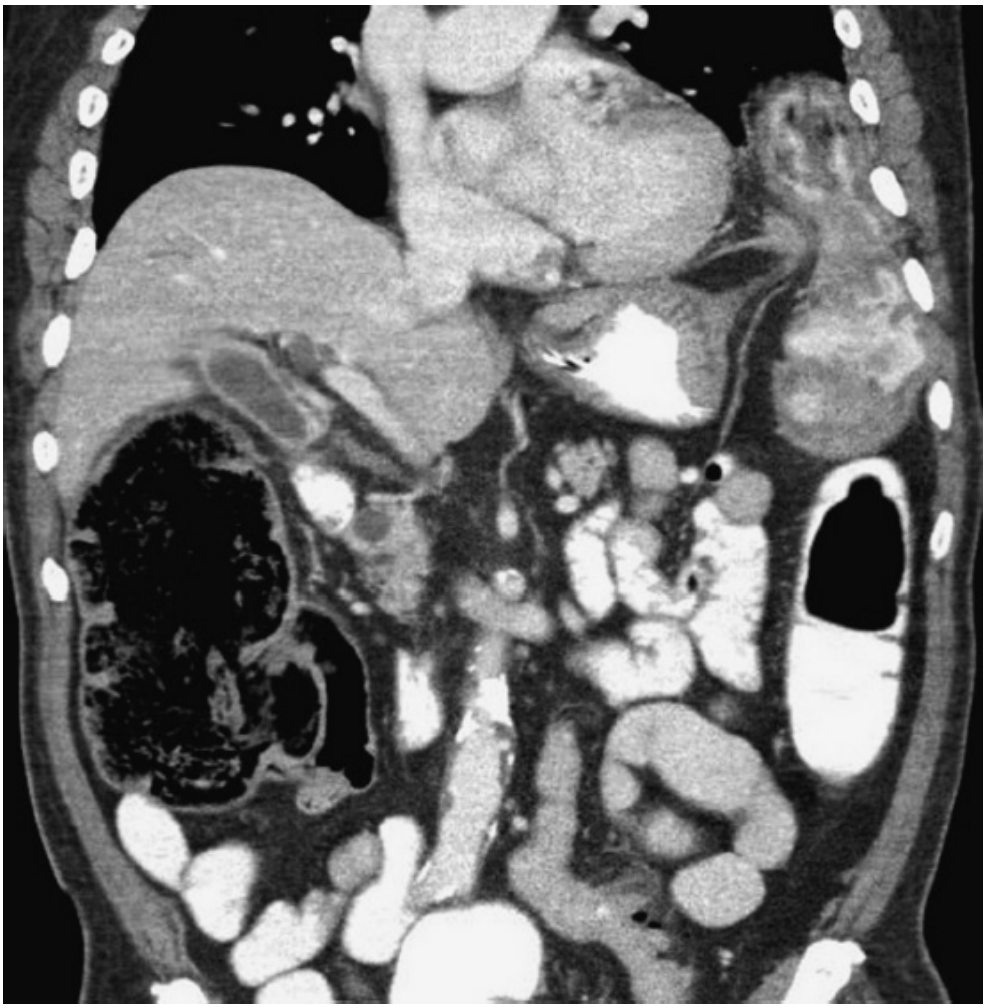

Figure 25.7 CT demonstrating left blunt diaphragmatic injury with herniating gastrointestinal tract contents.

Epidemiology

The liver is one of the most commonly injured intra-abdominal organs following blunt trauma. In penetrating trauma the liver is the most commonly injured solid organ. High-velocity missiles can cause massive tissue destruction and are associated with high mortality. The AAST-OIS grading system (**Table 25.1**) ranges from a mild grade I injury to a grade VI total hepatic avulsion which is lethal.[44] In the modern era of selective nonoperative management of solid organ injuries, the organ injury grading system was updated in 2018 to include radiologic criteria of vascular injury as a component of risk stratification for failure of nonoperative management.[45]

Table 25.1 OIS-AAST Grading Scale for the Liver

Grade[a]	Type	Injury Description
I	Hematoma Laceration	Subcapsular, <10% surface area Capsular tear, <1 cm parenchymal depth
II	Hematoma Laceration	Subcapsular, 10–50% surface area; intraparenchymal, <10 cm in diameter 1–3 cm parenchymal depth, <10 cm in length
III	Hematoma Laceration	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma, >10 cm or expanding >3 cm parenchymal depth
IV	Laceration	Parenchymal disruption involving 25–75% of hepatic lobe or 1–3 Couinaud segments within a single lobe
V	Laceration Vascular	Parenchymal disruption involving >75% of hepatic lobe or >3 Couinaud segments within a single lobe Juxtahepatic venous injuries; that is, retrohepatic vena

		cava/central major hepatic veins
VI	Vascular	Hepatic avulsion

Figure 25.8 Gunshot injury to the liver successfully managed nonoperatively.

Diagnostics

A FAST will detect free intraperitoneal bleeding, but it does not provide any information about the source of this bleeding. An abdominal CT scan with intravenous contrast is the highest-yield imaging modality. CT provides accurate information about the architecture of the injury, the amount of intraperitoneal blood, the presence of active bleeding, pseudoaneurysms or arteriovenous fistulas, and the presence of associated injuries. CT is a valuable tool in the selection of patients for operation, angiographic embolization, or observation (**Fig. 25.8**).

Treatment

Selective nonoperative management of blunt liver trauma is the standard of care. The criteria for selection of patients for nonoperative management include clinical examination, CT scan findings, and the presence or absence of associated injuries. Hemodynamic stability and the absence of peritonitis are absolute requirements for nonoperative management. The success rate of nonoperative management for blunt hepatic trauma, including those with high-grade injuries, is high.[46,47] In a recent National Trauma Data Bank study of 6,402 patients with grade IV or V blunt liver injuries, 68% were managed nonoperatively.[48] For these high-grade injuries, especially with evidence of contrast extravasation (**Fig. 25.9**), angiointervention has been shown to be an independent predictor of survival and should be used liberally as a postoperative adjunct. Most failures of nonoperative management occur within the first 24 hours of admission. There is some evidence that patients with high injury severity score (ISS), severe grade IV or V liver injuries, multiple transfusions, major associated injuries, and associated chronic conditions such as cirrhosis, are at an increased risk for failure of nonoperative management. Angiographic embolization may be a significant adjunctive therapeutic modality which increases the success rate of nonoperative management of high-grade injuries.[47,49] Although selective nonoperative management of blunt liver trauma has become the standard of care, selective nonoperative management of penetrating liver trauma has only recently gained wide acceptance (**Fig. 25.9**).[32,33,50] For both blunt and penetrating injuries being managed nonoperatively, continuous close monitoring in an ICU environment and frequent serial clinical examinations are critical for success. A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsOperativeManagementOfAdultBluntHepaticTrauma.pdf

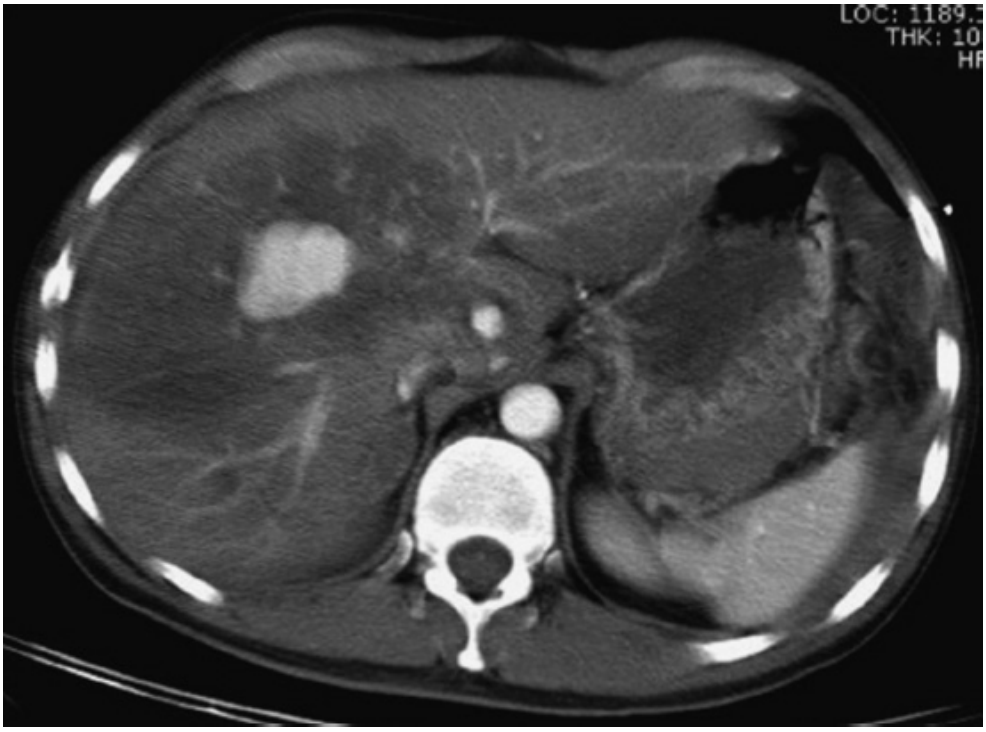

Figure 25.9 High-grade blunt liver injury with active contrast extravasation.

For operative management, the initial incision should be a midline laparotomy. For improved access to posterolateral liver injuries, a right subcostal incision may be added. In rare occasions, addition of a sternotomy may be required in order to obtain access to the intrapericardial inferior vena cava for total vascular isolation of the liver (**Fig. 25.10**), or exposure of the heart for placement of an atriocaval shunt (**Fig. 25.11**). Alternatively, as discussed earlier in the chapter, if the patient has a right thoracotomy, the thoracotomy and laparotomy can be joined with incision of the diaphragm for unimpeded access to the posterior liver and suprahepatic segment of the IVC.

In this case a cuff of diaphragm should be left so that if the patient survives, reconstruction is facilitated. In approximately 80% to 85% of patients undergoing operation, the liver injury can be managed by relatively simple surgical techniques, such as application of local hemostatic agents, electrocoagulation, or superficial suturing. Bleeding from deep liver lacerations can be controlled by clipping or suture ligation of any major vessels, followed by deep, figure-of-eight sutures, on a large blunt liver needle. Omental packing of large liver defects is useful in eliminating any dead space. Significant bleeding from deep bullet or knife tracts in the liver

may require a tractotomy for peripheral wounds or balloon catheter tamponade and perihepatic packing for central wounds.

Severe blunt trauma or high-velocity GSWs associated with extensive parenchymal damage are not amendable to deep suturing. Bleeding control in these cases may be achieved with perihepatic packing, with or without liver resection. Perihepatic packing and damage control is critical in the management of complex liver injuries. In order to be effective it needs to be performed early, before the patient becomes unstable. The presence of intact hepatic ligaments enhances the effectiveness of the perihepatic packing. Laying a piece of absorbable mesh on the raw surface of the liver prior to packing facilitates pack removal at the take back as the mesh with its integrated clot can be left undisturbed once the packs 7 are removed. Angioembolization following perihepatic packing should be considered early postoperatively and ideally, intraoperatively, if a hybrid operating room (**Fig. 25.12**) is available. The perihepatic packing should be removed as soon as feasible after correction of coagulopathy and other physiologic abnormalities. Delaying removal for more than 48 hours may be associated with an increased risk of infection. In general packing is highly effective and major hepatic resections are rarely indicated in the acute setting. Once the patient has stabilized, and the liver has demarcated and the patient is able to tolerate resection, any nonviable parenchyma can be resected. If required acutely, the liver resection can be performed with finger dissection of the parenchyma, with suture ligation of vessels and biliary branches, or with the use of an electrothermal bipolar vessel sealing system. Selective hepatic artery ligation or clipping may be a useful adjunct to packing in rare cases and should be considered if packing by itself is insufficient and temporary occlusion results in reduction of the bleeding.

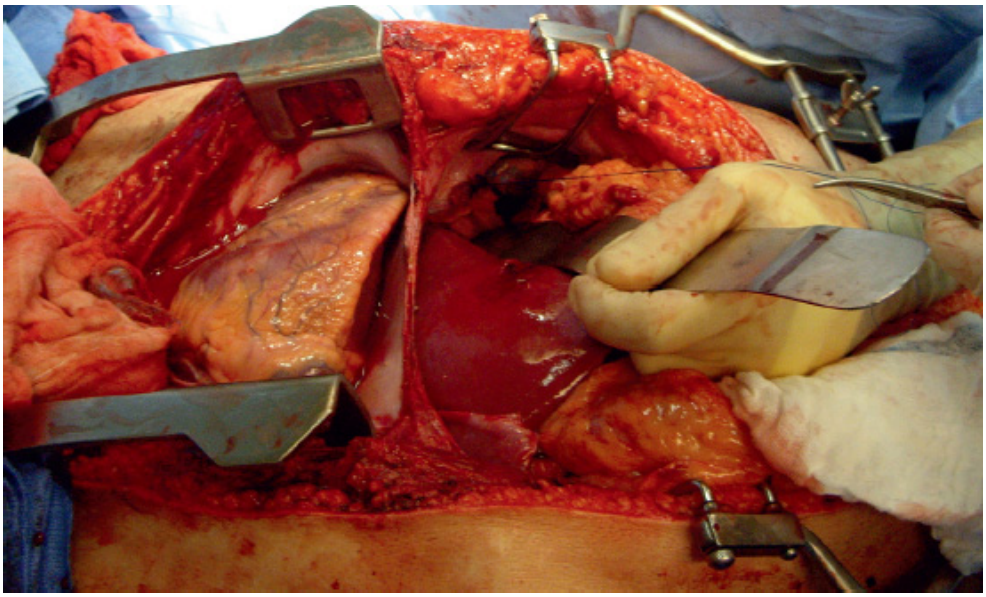

Figure 25.10 Laparotomy and sternotomy demonstrating excellent access to the liver and the intrapericardial segment of the suprahepatic IVC.

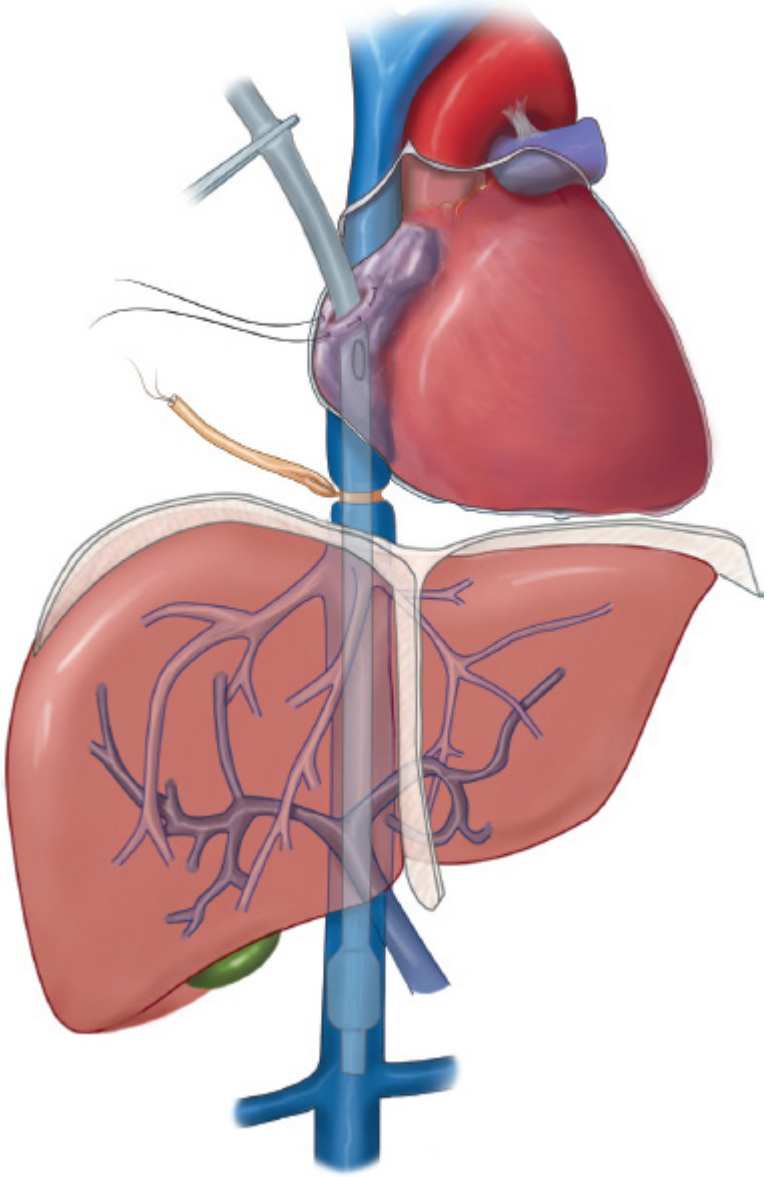

Figure 25.11 Schematic demonstrating an atriocaval shunt. (From Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. New York: Cambridge University Press; 2015, with permission.)

Figure 25.12 Hybrid operating room.

Contained retrohepatic hematomas from blunt or penetrating injury, should not be explored because of the risk of uncontrollable hemorrhage. If the hematoma is not contained and perihepatic packing fails to achieve hemorrhage control or bleeding worsens with anterior retraction of the liver, injury to the hepatic veins or retrohepatic vena cava should be suspected. In this situation, exploration and repair or ligation of the bleeding vessel is mandatory. Total vascular isolation of the liver may be required to identify and repair the injury. The procedure consists of cross-clamping of the infradiaphragmatic aorta, the suprahepatic and infrahepatic inferior vena cava, and the porta hepatis. Control of the suprahepatic IVC is extremely challenging in the intra-abdominal segment as this is usually where the primary source of bleeding necessitating the procedure has occurred. Consequently, it is recommended that the intrapericardial segment is accessed for control.

Addition of a subcostal incision improves exposure of the liver and the retrohepatic veins. Division of the falciform and coronary ligaments allows inferior-medial rotation of the liver and direct visualization of the inferior vena cava and the right hepatic vein. As described earlier, an alternative to

the subcostal incision is a median sternotomy or if the patient already has a right anterolateral thoracotomy, division of the diaphragm, straight down to the inferior vena cava.

The use of an intracaval shunt may be considered in selected complex retrohepatic venous injuries which cannot be controlled with simpler approaches. The procedure involves extension of the laparotomy incision into a median sternotomy and opening of the pericardium. A tape tourniquet is then applied around the intrapericardial IVC. A purse–string suture (2-0 silk) is placed in the right atrial appendage and a size 8 endotracheal tube with a side hole cut at approximately 8 to 10 cm from the clamped proximal end, is then inserted through the purse–string and guided into the IVC. The balloon of the tube is then inflated just above the renal veins and the tape tourniquet around the intrapericardial IVC is tightened.[51] Alternatively, a 36-Fr chest tube, with fenestrations cut into the proximal segment of the tube to allow blood flow from the IVC into the right atrium may be used. The intracaval shunt may reduce bleeding but in reality, rarely achieves complete hemostasis. The reported results with atriocaval shunts are generally poor, and should only be considered if all other techniques have failed.

For completion, other techniques which have been used in the management of retrohepatic venous injuries include intravascular balloons inserted through the femoral vein, extracorporeal venovenous bypass, hypothermic circulatory arrest, and liver transplantation.[52]

The incidence of postoperative liver-related complications after high-grade liver injuries has been reported to be as high as 50%.[53] The clinical presentation of these complications may vary from a few days to many months. Complications include early or late hemorrhage, pseudoaneurysm, arteriovenous fistula, biloma, biliary fistula, liver necrosis, liver abscess, hemobilia, and intrahepatic biliary strictures. Approximately 35% of patients with significant liver-related postoperative complications are asymptomatic and have the complication diagnosed on CT.[53] The majority of these complications can safely be managed nonoperatively, with percutaneous endovascular or endoluminal interventional radiology-based or ERCP-guided solutions.

Extrahepatic Biliary Tract Injury

Trauma to the extrahepatic biliary tree is rare and is usually due to a penetrating mechanism. Bile duct injuries are usually diagnosed during laparotomy, although some cases may present late, occurring even days after injury. The diagnosis may be confirmed with a hepatobiliary iminodiacetic acid (HIDA) scan, MRCP, or ERCP. The management of injuries to the biliary tree is determined by the location and extent of the biliary injury, the time of diagnosis, and the presence of associated intra-abdominal injuries. Injuries to the gallbladder are treated by cholecystectomy. Complete duct transections are best managed with a Roux-en-Y biliary-enteric anastomosis because primary repair is associated with a high stricture rate.

Incomplete injuries to the extrahepatic ductal system discovered intraoperatively, can be managed with primary repair, if the transection involves less than 50% of the duct circumference. Placement of a T-tube through a separate choledochotomy facilitates the repair. Transections involving more than 50% of the circumference of the duct, especially with questionable tissue viability, should be treated like a complete transection. All repairs of the biliary tract should be drained externally with closed suction drains.

In the damage control setting, the duct may be ligated or an external catheter may be placed into the proximal duct and exteriorized through the skin. Definitive repair can be performed after physiologic stabilization of the patient or once expert assistance becomes available.

SPLEEN

Anatomy

The spleen is held in place by four ligaments which include the splenogastric ligament medially, the splenocolic ligament inferiorly, and the splenophrenic and splenorenal ligaments posterolaterally. The splenogastric ligament is the only vascular ligament and contains five to seven short gastric vessels, which originate from the distal splenic artery. The tail of the pancreas is in close proximity to the splenic hilum and is at risk of injury during splenectomy or hilar clamping. The splenic artery courses superior to the pancreas and near the splenic hilum it divides into upper and lower pole arteries. The splenic

vein is located posterior and inferior to the splenic artery, receives the inferior mesenteric vein and joins the superior mesenteric vein to form the portal vein.

Epidemiology

The spleen is a commonly injured intra-abdominal organ following blunt and penetrating trauma. The severity of splenic injury is graded by the OIS-AAST spleen injury scale (**Table 25.2**). Generally, grades I and II are considered minor injuries, grade III a moderate injury, and grades IV and V are severe injuries.

Diagnostics

The clinical presentation of a spleen injury depends on the volume of blood loss and the presence of associated injuries. Many low-grade splenic injuries may be asymptomatic or have only minor local tenderness and the diagnosis is made on CT. Classically, those with large splenic hematomas may experience pain in the left upper quadrant, radiating to the left shoulder (Kehr sign), especially when placed in the Trendelenburg position. Although plain CXRs are not diagnostic, the presence of fractures of the left lower ribs or an elevated left hemidiaphragm can be associated with an increased possibility of splenic injury. The FAST may show free fluid around the spleen. Abdominal CT scan with intravenous contrast is the most widely used and highest-yield investigation (**Figs. 25.13** and **25.14**). It provides accurate information about the grade of injury, the amount of intraperitoneal bleeding, evidence of active bleeding, and associated injuries.

Treatment

Approximately 80% of blunt splenic injuries in adults and 90% to 95% in children can be safely managed nonoperatively.[54] Recent studies suggest that approximately 10% of all penetrating splenic injuries may also be managed nonoperatively.[55] The selection of patients for nonoperative management should be based on clinical examination and CT scan findings. The patient should be hemodynamically stable and have no signs of peritonitis. Although

associated head trauma is not an absolute contraindication for nonoperative management, it should lower the threshold for operative intervention, because head trauma–related coagulopathy increases the risk of splenic bleeding and the splenic bleeding may cause hypotension which would be detrimental to the injured brain. A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsAdultBluntSplenicTrauma-2016Update.pdf

Table 25.2 OIS-AAST Grading Scale for the Spleen

Grade[a]	Type	Injury Description
I	Hematoma Laceration	Subcapsular, <10% surface area Capsular tear, <1 cm parenchymal depth
II	Hematoma Laceration	Subcapsular, 10–50% surface area, <5 cm in diameter 1–3 cm parenchymal depth not involving a trabecular vessel
III	Hematoma Laceration	Subcapsular, >50% surface area or expanding; ruptured subcapsular or parenchymal hematoma; intraparenchymal hematoma, ≥5 cm or expanding >3 cm parenchymal depth or involving trabecular vessels
IV	Laceration	Laceration involving segmental or hilar vessels producing major devascularization (>25% of the spleen)
V	Laceration Vascular	Shattered spleen Hilar vascular injury with devascularized spleen

[a]Advance one grade for multiple injuries, up to grade III.

Moore EE, Cogbill TG, Jurkovich GJ, et al. Organ injury scaling: spleen and liver (1994 revision). *J Trauma* 1995;38:323–324.

Low-grade splenic injuries are much more likely to be successfully managed nonoperatively, but many high-grade injuries may still be managed nonoperatively. Patients with higher-grade splenic injuries selected for nonoperative management should be observed in the ICU. Development of hemodynamic instability, peritonitis or the need for blood transfusion should trigger operative exploration. Most failures occur within the first few days, although in some cases, especially those with subcapsular hematomas or pseudoaneurysms, delayed bleeding may occur days to weeks after the injury. Patients with severe splenic injuries selected for nonoperative management should receive prophylactic vaccinations against *Streptococcus pneumonia, Neisseria meningitidis,* and *Haemophilus influenza,* in case conservative management fails and the patient requires splenectomy.

Figure 25.13 CT image of a high-grade spleen injury.

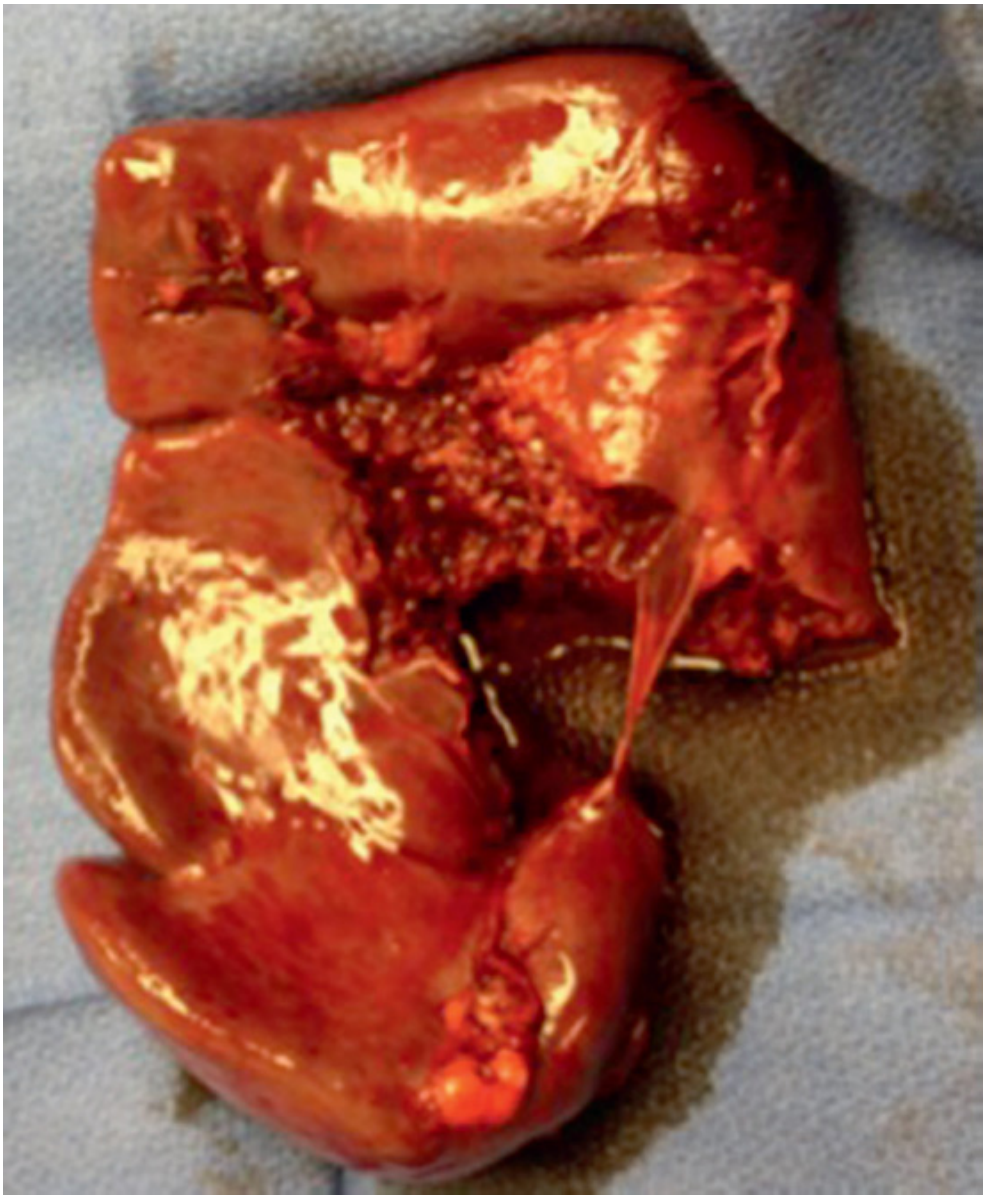

Figure 25.14 Spleen after removal as seen on CT in **Figure 25.13**.

A follow-up CT scan should be performed for all grade III to V splenic injuries within 2 to 3 days of admission to rule out the development of a pseudoaneurysm or progression of the hematoma. Subsequent follow-up CT scan evaluation should be considered in selected cases with high-grade injuries, especially those with subcapsular hematomas.

The duration of avoidance of vigorous physical activities and contact sports should be individualized, taking into account the severity of the spleen injury, the findings on follow-up CT scan, and patient's lifestyle. Most

surgeons recommend a minimum period of approximately 4 to 6 weeks before resumption of full unrestricted activity.

Angioembolization has been used as an adjunct to nonoperative management for patients with CT scan evidence of active contrast extravasation or pseudoaneurysm. Proximal splenic artery embolization consists of coil occlusion of the splenic artery distal to the dorsal pancreatic artery and promotes hemostasis by reducing blood flow to the spleen. Distal selective embolization consists of coil or gelfoam deployment as close to the bleeding site as possible. The available evidence is inconclusive and suggests that the two approaches may be equally effective in preventing significant rebleeding. Both techniques are associated with the same incidence of infarctions and infections requiring splenectomy. Distal embolization is associated with a higher rate of asymptomatic segmental infarctions.[56] A Western Trauma Association multicenter trial which included 140 splenic artery embolizations reported an overall complication rate of 32%, including splenic infarctions in 21% and splenic abscess in 4.3%.[57]

For operative management, after entering the peritoneal cavity any free blood is evacuated and the left upper quadrant is packed for temporary bleeding control. This allows a rapid evaluation of the rest of the abdomen to rule out any other major injuries which may require immediate attention. The next step is the assessment of the type and severity of the splenic injury, in order to determine if the spleen is salvageable. After removal of the temporary packing, the organ is rotated inferomedially. Several laparotomy pads are then placed under the left diaphragm and behind the spleen, aiding in the exposure of the spleen. Excessive traction on the stomach or the splenic flexure of the colon or excessive medial rotation of the spleen may cause avulsion of the delicate splenic capsule, resulting in bleeding and decreasing the possibility of splenic preservation.

Profuse bleeding from the spleen can temporarily be controlled with digital compression of the hilum or direct digital compression of the splenic parenchyma. A vascular clamp can also be placed across the hilum, taking care not to injure the tail of the pancreas.

The critical move for a quick and safe splenectomy is adequate mobilization and inferomedial rotation of the spleen. This is achieved by sharp division of the splenophrenic and splenorenal ligaments posterolaterally and medial rotation of the spleen. The next step is division

and ligation of the vascular gastrosplenic ligament, as far away from the stomach as possible, in order to avoid injury or ischemic necrosis of the gastric wall. Likewise, the splenic artery and vein should be ligated as close to the hilum as possible, in order to avoid injury to the tail of the pancreas. The final step is division of the splenocolic ligament. Although this stepped approach to mobilization of the spleen is applicable to most patients, the order of taking down the splenic ligaments should be determined by the anatomy and may vary from patient to patient. In fact, for acutely injured spleens, many of these ligaments may already be avulsed.

Preservation of the spleen should be considered in low-grade injuries if the patient is hemodynamically stable with a low overall injury burden. In cases with avulsion of the splenic capsule or minor lacerations, hemostasis can be achieved with electrocautery and local hemostatic agents. Splenic lacerations may be repaired with absorbable figure-of-eight or horizontal mattress sutures, on a blunt liver needle. The presence of an intact splenic capsule makes the placement of the sutures technically easier. If the parenchyma is fragile and does not hold sutures, pledgets may be used. An absorbable splenic mesh can also be used (**Fig. 25.15**) as an adjunct to splenorrhaphy, especially in cases with multiple stellate parenchymal injuries.

Early local postsplenectomy complications include recurrent bleeding, pancreatic complications (pancreatitis, pseudocyst, and pancreatic fistula), gastric complications (gastroparesis, necrosis of the greater curvature), subdiaphragmatic abscess, splenic vein thrombosis, splenic arteriovenous fistula, left lower lobe atelectasis, or pleural effusion. Complications after splenorrhaphy include intrasplenic hematoma or abscess, splenic infarcts, and pseudoaneurysms or arteriovenous fistulas. A follow-up CT scan with intravenous contrast should be performed in all high-grade splenic injuries managed with splenorrhaphy. Early postsplenectomy hematologic changes include leukocytosis and thrombocytosis. The leukocytosis is usually moderate, rarely exceeding 16,000 to 18,000/mm^3 and may last several weeks. More severe leukocytosis may indicate an infectious complication, especially in the presence of fever or tachycardia.[58] Thrombocytosis is usually moderate, may last for a few weeks and in most cases is clinically irrelevant.

Postsplenectomy infections may occur early or late. There is evidence that splenectomy is associated with an increased risk of early postsplenectomy infections. A recent prospective observational, multicenter study of 269 patients with blunt splenic injury surviving at least 72 hours, reported that splenectomy had a significantly higher incidence of infectious complications than splenic preservation.[59] A regression analysis identified splenectomy as an independent risk factor for infectious complications.

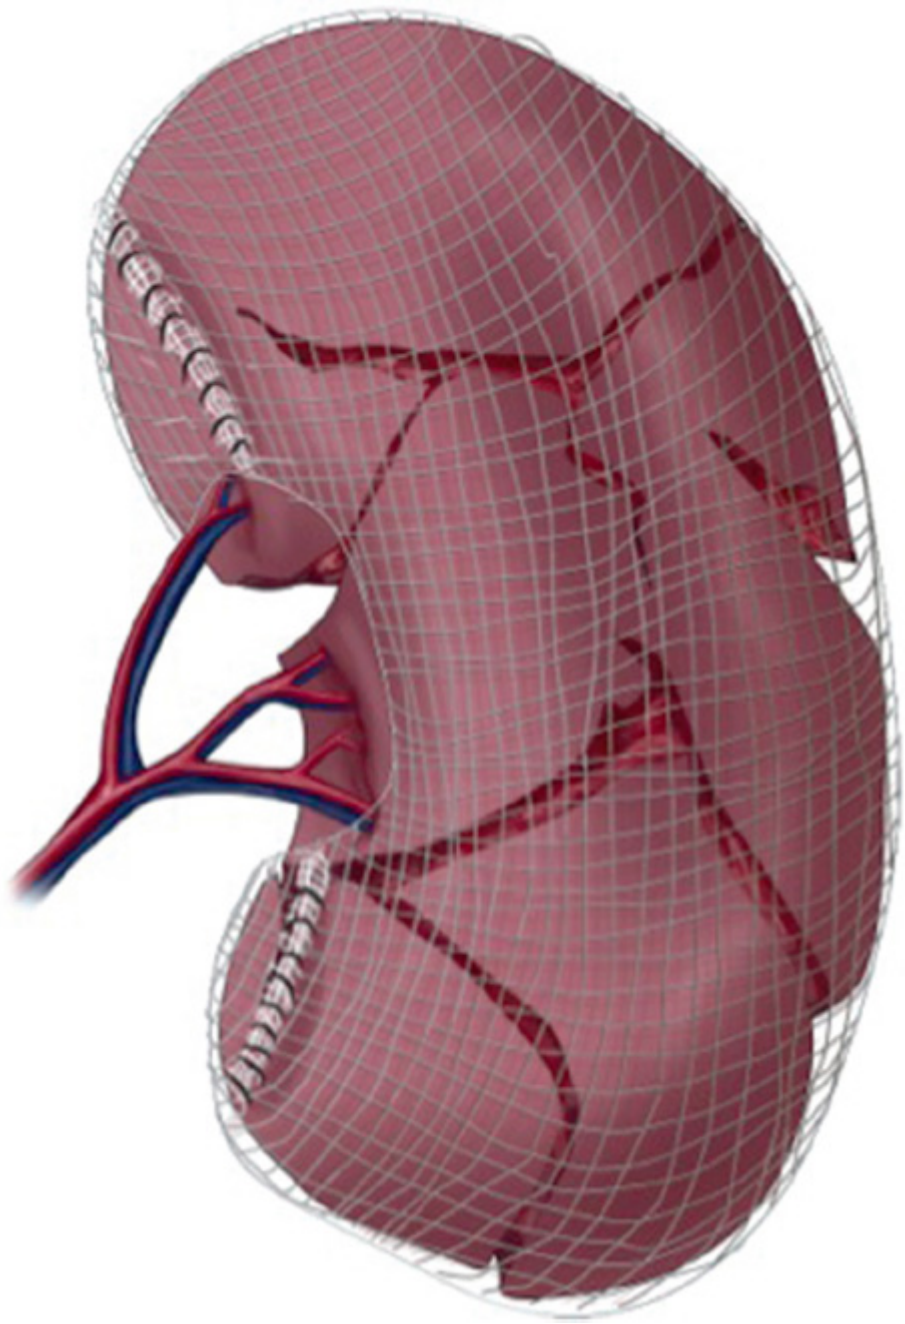

Figure 25.15 Splenic preservation with use of an absorbably mesh bag. (With permission from Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. New York: Cambridge University Press; 2015.)

Overwhelming postsplenectomy infection (OPSI) is a rare but life-threatening complication, especially in children. The reported mortality varies from 10% to 80%. Encapsulated organisms, such as *H. influenza, S. pneumonia,* and *N. meningococcus*, are the most common pathogens.

Although the majority of infections occur within the first 3 to 4 years, OPSI may occur at any time after splenectomy. The Surgical Infection Society recommends that all splenectomized patients 2 to 64 years old receive the 23-valent pneumococcal vaccine.[60] In addition, high-risk patients should receive *H. influenza* and meningococcal vaccines. The timing of administration of the vaccines after trauma may be optimal at 14 days after splenectomy.[61] There is no evidence to support routine long-term prophylactic antibiotic administration in splenectomized patients. Patients should be educated on postsplenectomy sepsis, wear a medical alert bracelet, inform caregivers of their asplenic state, and be advised to seek medical care with the onset of any signs of infection.

PANCREAS

Anatomy

The pancreas is a retroperitoneal organ with its head directly situated over the inferior vena cava and its neck over the superior mesenteric vessels and the proximal portal vein. The body extends over the suprarenal aorta and the left renal vessels, closely related to the splenic artery and vein. The uncinate process wraps around the superior mesenteric vessels. As described for the spleen, the splenic vein courses inferior to the splenic artery and joins the superior mesenteric vein at a right angle to form the portal vein behind the neck of the pancreas. The inferior mesenteric vein drains into the splenic vein behind the body of the pancreas (**Figs. 25.16** and **25.17**).

The major pancreatic duct of Wirsung travels down the entire length of the pancreas and drains into the ampulla of Vater, approximately 8 cm downstream from the pylorus. The lesser duct of Santorini branches off the superior aspect of the major duct, at the level of the neck of the pancreas. This drains into the duodenum, approximately 2 to 3 cm proximal to the ampulla of Vater. The pancreatic head and the proximal duodenum receive their blood supply from the anterior and posterior pancreaticoduodenal arcades. Because these arcades lie on the surface of the pancreas, close to the duodenal loop, separating these can result in ischemic damage to the duodenum.

Epidemiology

Pancreatic trauma is seen in approximately 0.2% of blunt trauma and about 1% of penetrating trauma patients. Overall, about 60% of patients with blunt trauma and about 90% with penetrating trauma will have associated intra-abdominal injuries. The most commonly associated injury in blunt trauma is the spleen. Associated intra-abdominal vascular injuries are common in penetrating trauma and are found in more than 75% of penetrating injuries to the head of the pancreas. A concomitant major vascular injury increases the likelihood of a poor outcome. The most widely used grading system (**Table 25.3**) is the OIS-AAST.[44] The classification is based on CT and operative findings.

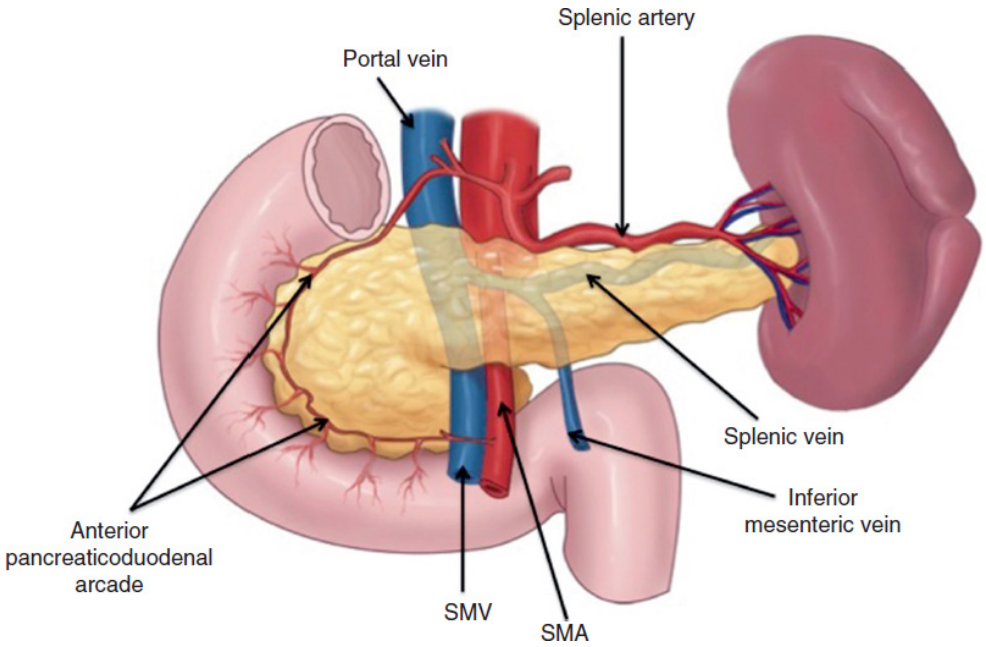

Figure 25.16 Pancreatic anatomy demonstrating relationship to vascular structures and spleen. (With permission from Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. New York: Cambridge University Press; 2015.)

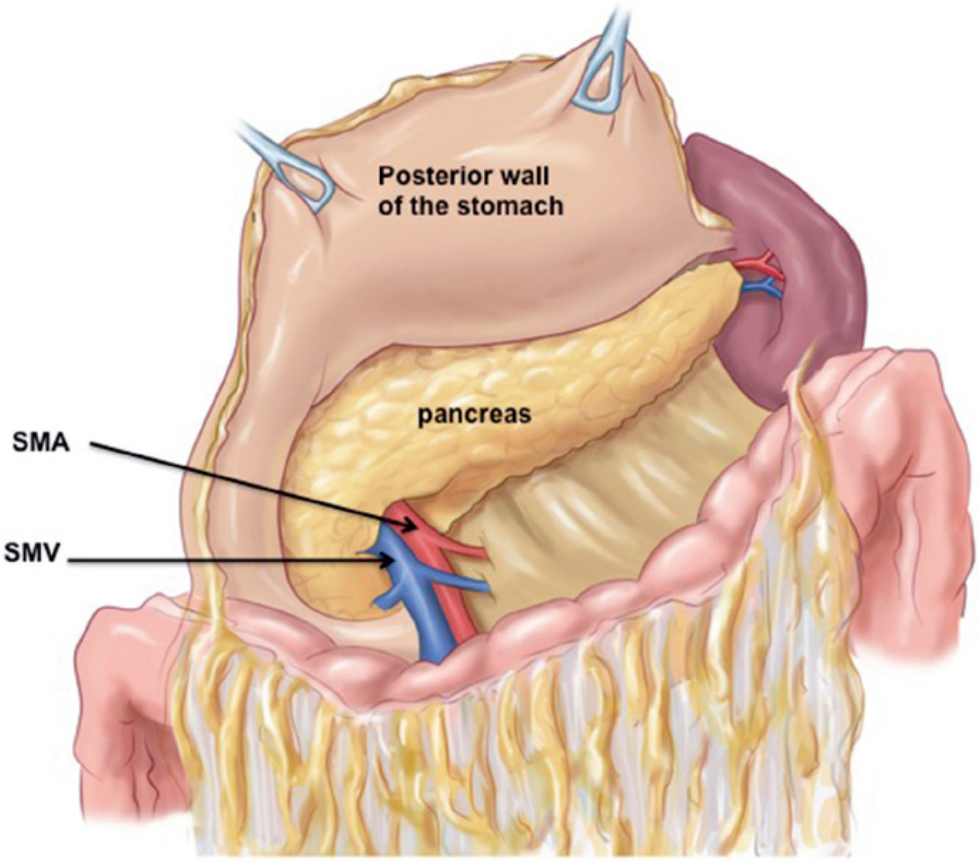

Figure 25.17 Pancreatic anatomy demonstrating relationship to stomach. (With permission from Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. New York: Cambridge University Press; 2015.)

Diagnostics

The diagnosis of penetrating pancreatic injury is usually made intraoperatively. The diagnosis in blunt trauma, especially for isolated injuries, may be difficult because the initial symptoms may be occult. Clinical signs may take hours or even days to manifest. Serial serum amylase and lipase levels may be useful as a screening test for pancreatic trauma but isolated values have poor sensitivity and specificity. Contrast-enhanced CT scan (**Fig. 25.18**) is the investigation of choice in suspected pancreatic trauma.[62,63] Its accuracy increases with time from injury and in cases with an equivocal initial test, a repeat CT scan 6 to 8 hours after the initial investigation should be considered. MRCP or ERCP can be considered in

selected cases with pancreatic trauma to establish the integrity of the pancreatic duct.[64,65]

Table 25.3 OIS-AAST Grading Scale for the Pancreas

Grade[a]	Type	Injury Description
I	Hematoma	Minor contusion without duct injury
	Laceration	Superficial laceration without duct injury
II	Hematoma	Major contusion without duct injury or tissue loss
	Laceration	Major laceration without duct injury or tissue loss
III	Laceration	Distal transection or parenchymal injury with duct injury
IV	Laceration	Proximal transection or parenchymal injury involving ampulla
V	Laceration	Massive disruption of pancreatic head

[a]Advance one grade for multiple injuries to the same organ.

Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. *J Trauma* 1990;30:1427–1429.

Treatment

The management of pancreatic trauma is determined by the mechanism of injury and the presence or absence of pancreatic duct injury. Many penetrating injuries require operative management. However, most patients with isolated blunt trauma to the pancreas with an intact pancreatic duct can safely be managed nonoperatively.[66,67] Complications associated with

nonoperative management include pancreatic pseudocyst and pancreatitis. A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsManagementOfPancreaticInjuries.pdf

For patients undergoing operative management, the pancreas is exposed through the lesser sac. This allows access to the anterior, superior, and inferior surfaces of the body and tail of the pancreas. The posterior aspect of the pancreas can be mobilized by incising the peritoneum over the inferior border of the pancreas and retracting upward. If more extensive mobilization is required for the distal pancreas, this can be achieved by en-block mobilization and medial rotation of the spleen and tail of the pancreas. For the head and uncinate processes, exposure is achieved with an extended Kocher maneuver.

Figure 25.18 CT image of pancreatic transection after blunt trauma. Oval demonstrates the pancreatic transection.

As a general rule, all peripancreatic hematomas should be explored to examine for any underlying ductal injuries.[68] However, hematomas localized to the head of the pancreas may be left undisturbed, because the duct in this

area is deep in the parenchyma and exploration is difficult and potentially dangerous. These injuries should be drained externally with closed drains and postoperatively the integrity of the duct can be evaluated using MRCP or ERCP and treated with stenting.[65]

Low-grade injuries without obvious ductal disruption should be treated with the debridement of nonviable tissue, hemostasis, and wide external drainage. For severe parenchymal injuries with known or suspected ductal disruption, the optimal procedure will depend on the condition of the patient and the site of the pancreatic injury (head and neck vs. tail). Severe pancreatic injuries involving the body to the left of the superior mesenteric vessels are best treated by distal pancreatectomy, with or without splenic preservation (**Fig. 25.19**).[69] For destructive injuries to the head of the pancreas, especially with concurrent duodenal injury, if the operative procedure is to undergo damage control, or if this is beyond the skill set of the operating surgeon, the safest option is hemostasis and external drainage. Damage control packing and temporary abdominal closure with delayed resection and reconstruction can be performed. If, however, a pancreaticoduodenectomy is to be performed, even for hemodynamically stable patients with an experienced surgeon, a two-stage procedure is highly recommended. The initial operation includes temporary control of bleeding by means of packing and in the appropriate cases, arterial shunting or if there is a concomitant venous injury, ligation. The duodenal and pancreatic head resection is performed and the common bile duct is ligated or drained externally. The definitive reconstruction should be performed only after normalization of the patient's physiology. The reconstruction, which includes pancreaticojejunostomy, choledochojejunostomy, and gastroenterostomy, is similar to that in elective cases and should be performed with expert assistance in an optimized patient.

Pancreas-related local complications occur in about 25% of patients and include pancreatic fistulas, pseudocysts, pancreatitis, and perihepatic infection. Most of these complications can successfully be managed nonoperatively or with percutaneous drainage and endoscopic stenting of the duct.[70] Endocrine and exocrine pancreatic insufficiencies may occur after major pancreatic resections, but the incidence of this complication is low.[71]

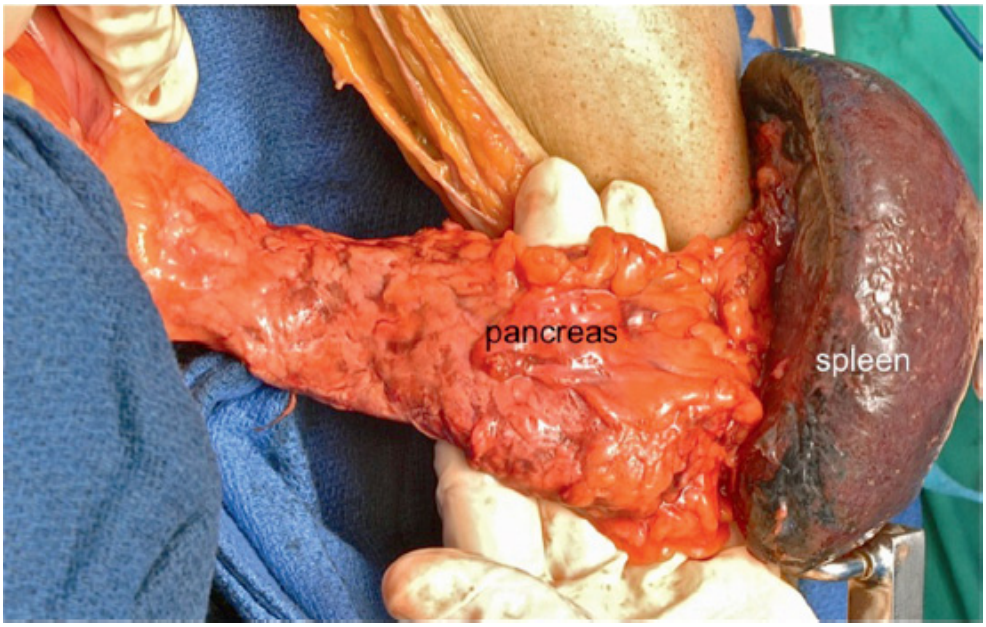

Figure 25.19 Distal pancreatectomy specimen with splenectomy specimen after blunt trauma.

STOMACH

Anatomy

The stomach is a hollow viscus organ located in the left upper quadrant of the abdomen with the fundus, GE junction, and often a significant portion of the body lying above the costal margin. The stomach has a robust blood supply including the left and right gastric arteries, the right and left gastroepiploic arteries, and the short gastric arteries. This level of vascularity can result in significant bleeding after injury but also provides redundancy, making devascularization and necrosis of the stomach relatively rare after trauma.

Diagnostics

Gastric injury usually results from either significant blunt force trauma or after penetrating trauma to the left upper abdomen or lower chest. Presence of blood upon placement of an NG tube is concerning for gastric injury. The majority of patients with full-thickness gastric injury after trauma will

present with spillage of gastric contents and peritonitis resulting in direct transfer to the operating room. Blunt injury to the stomach can cause local contusion with gastric wall hematoma or hollow viscus rupture, similar to bladder rupture, with a large full-thickness defect.

After blunt or penetrating trauma, in the absence of peritonitis or hemodynamic instability, additional diagnostic workup with CT imaging is appropriate. CT scan findings concerning gastric injury include extraluminal contrast, air, blood, or fluid, or localized thickening, or enhancement and discontinuity of the gastric wall.[72–74]

Treatment

Gastric repair is generally well tolerated due to the redundancy of tissue and blood supply of the stomach. After penetrating injury, if a single gastric injury is identified, the operating surgeon must assume there is an additional injury corresponding to the entry or exit site. A single gastric injury is exceedingly rare and even a linear laceration should not be mistaken for a tangential wound unless meticulous inspection has ruled out an additional enterotomy. The anterior border of the stomach is fully inspected from the esophagus to the pylorus. The left lobe of the liver may need to be retracted or mobilized for better visualization of the proximal third of the stomach. The posterior aspect of the stomach is evaluated by accessing the lesser sac below the gastroepiploic vessels. The posterior gastric wall must be fully evaluated and visualized all the way up to the GE junction to avoid missed injury. Blood or fluid upon entry into the lesser sac should alert the surgeon to a likely gastric and/or pancreatic injury. Care must be taken when inspecting the GE junction and greater curvature not to apply excess tension on the gastric fundus as this may result in iatrogenic splenic capsular tear or laceration.

Low-grade injuries including hematomas and contusions should be evaluated and evacuated as appropriate. After hematoma evacuation and hemostasis is achieved, the area may be reinforced with Lembert sutures. Full-thickness injuries can be repaired in one or two layers. A two-layered repair includes an inner layer of running absorbable suture and an outer layer of Lembert sutures. Injuries of the greater curvature or larger injuries of the body can be controlled with a stapling device and wedge resection. In

gunshot injuries, it is important to debride the devitalized tissue surrounding the injury prior to repair. Given the tissue redundancy of the stomach, stapling devices may be used liberally for wedge resection. Care must be taken, however, to avoid narrowing the GE junction or pylorus. Injuries involving the pylorus may be incorporated into a pyloroplasty for repair.

Significant destructive injuries or those involving the GE junction or pylorus may require a proximal or distal gastrectomy with reconstruction. In rare cases, a total gastrectomy with esophagojejunostomy is required. Proximal gastric injuries or those at the GE junction may present a technical challenge for surgeons not accustomed to these operations. Attempts to repair these complex injuries without appropriate experience can lead to significant morbidity and mortality for the patient. In such cases, a two-staged procedure should be considered. At the initial operation, the distal esophagus or proximal stomach may be stapled and internally drained with a nasogastric tube thus controlling the injury in a damage control manner. An additional staple line distal to the injury will prevent reflux contamination. The area may be drained and the patient stabilized with a delayed reconstruction performed under optimal conditions with all of the requisite expertise present.

DUODENUM

Anatomy

The duodenum is the first portion of the small intestine and forms a C-loop around the head of the pancreas. The duodenum is divided into four parts, an anatomic distinction that can help guide management of traumatic injury. The first portion is intraperitoneal and associated with the portal structures and the gastroduodenal artery. The second and third portions are retroperitoneal and curve around the head of the pancreas. The common bile and pancreatic ducts drain into the ampulla in the second portion of the duodenum. The fourth portion of the duodenum ascends to the ligament of Treitz to join the jejunum.

Epidemiology

Duodenal trauma is rare, occurring in less than 5% of all trauma patients, and is associated with a high morbidity and mortality.[75–77] Patients with duodenal trauma frequently have additional intra-abdominal injury, most commonly of the liver, pancreas, and small bowel.

Treatment

Most low-grade duodenal hematomas secondary to blunt trauma without perforation can be managed conservatively with NG tube decompression and supplemental nutrition. The majority of duodenal trauma, however, is secondary to penetrating injury (**Fig. 25.20**) and is identified during operative exploration. Duodenal hematomas encountered intraoperatively require exploration to evaluate for underlying perforation. A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsDiagnosisManagementOfDuodenalInjuries.pdf

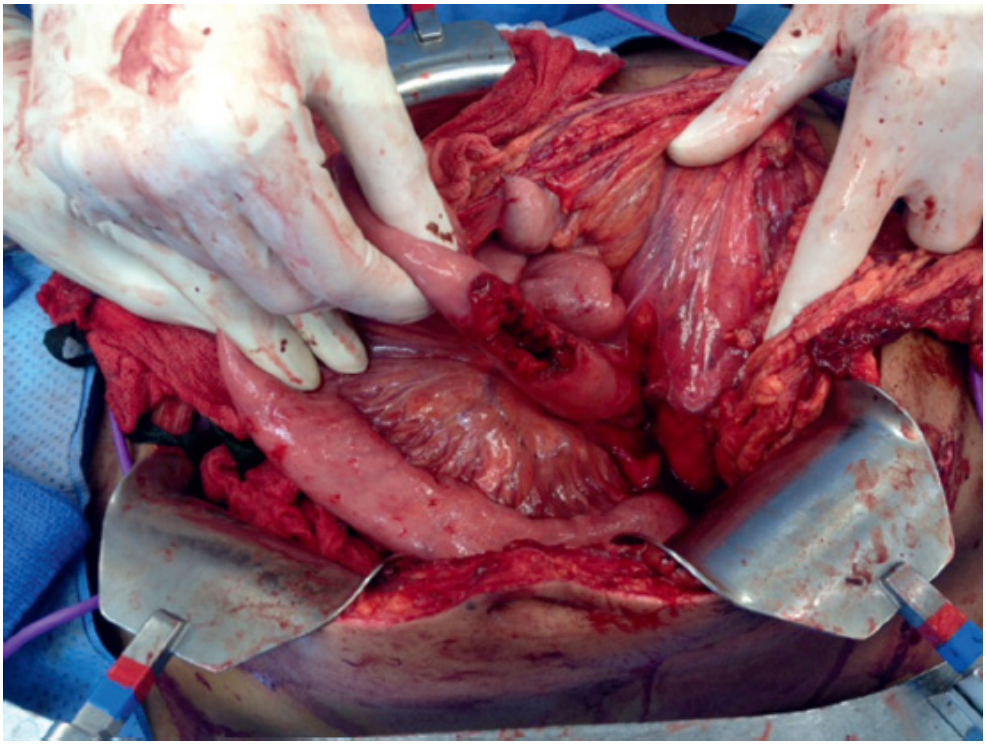

Figure 25.20 Gunshot injury to duodenum just proximal to the ligament of Treitz.

Mobilization of the duodenum is most commonly achieved with a Kocher maneuver. This allows for medialization of the second and third portions of the duodenum, evaluation of the posterior wall, and exposure of the underlying vascular structures to examine for injury. Separation of the second portion of the duodenum from the head of the pancreas is not advised as disruption of the blood supply puts the duodenum at high risk of ischemia.

Most duodenal injuries can be repaired primarily in one or two layers with a transverse closure to avoid luminal narrowing. Segmental resection is rarely needed but, in the event of injury >50% of the duodenal circumference, resection with primary, end-to-end anastomosis may be performed when appropriate. Segmental resection is not recommended for the second portion of the duodenum due to the presence of the ampulla and inability to mobilize the medial wall. In complex injuries, pyloric exclusion with gastrojejunostomy may be utilized to protect the repair, however, routine exclusion should not be used for all duodenal injuries. In an analysis of 193 consecutive patients with duodenal injuries, pyloric exclusion offered no morbidity or mortality benefit over primary repair.[78] If performed, external stapling of the pylorus with a TA stapler and internal cerclage with a suture

are both acceptable techniques for pyloric exclusion. Most frequently, a gastrojejunostomy to restore continuity is performed. Additional surgical adjuncts include a serosal patch and duodenojejunostomy. In the unstable patient, damage control techniques may be safely applied to duodenal injury with delayed repair or diversion.[79] The traumatic Whipple is rarely indicated and carries a high mortality.[80,81] This should be considered only in patients with complex destructive injuries to the duodenum and pancreas, as discussed above.

One of the major complications after duodenal injury repair is fistula formation, occurring in 4% to 33% of patients.[76,79,82] These are managed, when possible, with percutaneous drainage. In rare cases, reoperation and repair or diversion is required.

COLON

Epidemiology

Colon injuries occur in approximately 30% of abdominal GSWs and 20% of SWs undergoing laparotomy. In blunt trauma, approximately 10% of patients undergoing laparotomy will have a colon injury. Many of the blunt trauma injuries are superficial with only 3% of patients undergoing laparotomy having a full-thickness perforation. The presence of an external seatbelt mark sign is associated with an increased risk of colon injury.

Diagnostics

The definitive diagnosis of colon injury is almost always made intraoperatively. Preoperative diagnosis of colon injury following blunt trauma is difficult, especially in unevaluable patients. If a CT is obtained, mesenteric stranding, bowel wall thickening, and unexplained fluid can be seen, increasing the level of suspicion for a bowel perforation. Free extraluminal air is rare. Intraoperatively, all colonic hematomas should be explored to rule out any underlying colon injury without devascularizing the wall. Particular care should be taken for penetrating injuries, especially due to shotgun wounds, where the injury can be hidden within the fat.

The severity of colon injury can be graded by the OIS-AAST colon injury scale (**Table 25.4**), which is based on the operative findings.[44] A practical classification used by many surgeons breaks injuries down into two severity groups, nondestructive injuries involving <50% of the bowel wall without devascularization versus destructive injuries which involve >50% of the bowel wall or demonstrate devascularization.

Table 25.4 OIS-AAST Grading Scale for the Colon

Grade[a]	Type	Injury Description
I	Hematoma	Contusion or hematoma without devascularization
	Laceration	Partial thickness, no perforation
II	Laceration	Laceration <50% of circumference
III	Laceration	Laceration ≥50% of circumference without transection
IV	Laceration	Transection of the colon
V	Laceration	Transection of the colon with segmental tissue loss
	Vascular	Devascularized segment

[a]Advance one grade for multiple injuries to the same organ.

Moore EE, Cogbill TH, Malangoni MA, et al. Organ injury scaling, II: pancreas, duodenum, small bowel, colon, and rectum. *J Trauma* 1990;30:1427–1429.

Treatment

The management of colon injuries has undergone major changes over the last two decades.[83–85] For nondestructive injuries there is sufficient class I and class II evidence supporting primary repair irrespective of risk factors, such

as the site of colon injury, associated injuries, or physiologic status.[86–88] A Western Trauma Association Algorithm outlining the management of this injury is available at: https://www.westerntrauma.org/wp-content/uploads/2020/07/WTACriticalDecisionsManagementOfColorectalInjuries.pdf

For destructive colon injuries, defined as those with loss of >50% of the bowel wall circumference or with devascularization, segmental colonic resection is required. The management of these cases is controversial. These injuries were traditionally managed with diversion because of the perceived high risk for anastomotic leak and intra-abdominal sepsis. Although the safety of primary anastomosis was demonstrated in several small studies,[86–88] for specific circumstances such as a penetrating abdominal trauma index ≥25 or hypotension or large-volume blood transfusions or patient comorbidities, the potential benefit of diversion remains unclear.[88,89]

The Eastern Association for the Surgery of Trauma (EAST) guidelines based largely on class III evidence recommended that diversion be considered in patients with shock, significant associated injuries, peritonitis, or underlying disease.[90] Since these were published, a more recent American Association for the Surgery of Trauma prospective multicenter study examined 297 patients with penetrating colon injuries requiring resection.[91] This was a prospective observational study examining the outcomes associated with diversion versus primary anastomosis without diversion. The overall colon-related mortality was 1.3% and all deaths occurred in the diversion group. The incidence of anastomotic leaks was 6.6%. Multivariate analysis identified severe fecal contamination, >4 units of blood transfusions within the first 24 hours, and antibiotic choice as independent risk factors for abdominal complications. The method of colon management, anastomosis, or diversion did not impact outcomes. For both blunt and penetrating destructive injuries, if the patient meets criteria for a damage control procedure, contamination control with stapling of the colon should be performed. Whenever possible, an anastomosis should be performed at the index operation. The choice of a stapled versus hand-sewn anastomosis has been shown not to make a difference.[92] In a prospective study of 207 patients undergoing resection and anastomosis, the leak rate was 7.8% for hand-sewn and 6.3% for stapled anastomoses. For edematous bowel, often seen at the

take back after an initial damage control resection, a hand-sewn anastomosis may be preferred.

Abdominal complications after colon injuries are common, with an abdominal sepsis rate of approximately 20%. Retained bullets that have passed through the colon are not associated with an increased risk of infection and therefore their routine removal is not required.[93]

Colonic leaks causing abdominal sepsis after repair or resection and anastomosis have been examined in detail. For primary repairs, in a review of 35 prospective or retrospective studies including 2,964 primary repairs, a leak rate of 2.2% was seen.[94] For patients undergoing resection and anastomosis, which are more likely to leak, the rate was 5.5%.[94] Anastomotic leaks occur more commonly with a colon–colon anastomosis when compared to an ileocolic anastomosis.[91]

The majority of leaks can be managed nonoperatively with percutaneous drainage. They are usually small and seal off on their own. CT imaging should be obtained to examine for the presence of any intra-abdominal collections and to guide drainage. Reexploration of the abdomen for drainage and either fecal diversion or resection and reanastomosis is only required if the patient fails percutaneous drainage or develops evidence of generalized peritonitis.

For patients who require a colostomy, there is a significant complication burden associated with the colostomy itself as well as the subsequent closure. In a large series of 528 stomas performed in the trauma setting, approximately 22% of patients sustained an early complication and 3% a late complication.[95] In another study of 110 colostomy closures, a local complication rate of 14.5% was noted.[96]

RECTUM

Anatomy

As the colon continues downstream, the rectum begins where the tenia coli coalesce as the terminal part of the large intestine. The rectum is approximately 12- to 15-cm long and is both intra- and extraperitoneal. Anteriorly, the upper two-thirds and laterally the upper one-third are

intraperitoneal, with the lower third being completely extraperitoneal. The blood supply is derived from the superior rectal artery branching from the inferior mesenteric artery, the middle rectal artery from the internal iliac artery, and the inferior rectal artery which is from the internal pudendal artery.

Epidemiology

Most rectal injuries result from a penetrating mechanism, usually secondary to GSWs although anally inserted foreign body trauma and endoscopic trauma are also seen. Because of its protected location, blunt injury is only seen in approximately 5% to 10% of injuries, and is often associated with a pelvic fracture.

Diagnostics

The clinical presentation of rectal injuries that are intraperitoneal does not differ from that of colon injuries. For extraperitoneal injuries, the clinical symptomatology can be masked by containment of the perforation in the retroperitoneal tissues. As a direct consequence, operative exploration, direct visualization on anoscopy and sigmoidoscopy, or CT rather than clinical examination is used to make the diagnosis.

For blunt trauma patients, because the majority of injuries are in the intraperitoneal segment, the same diagnostic principles for colonic injuries apply. For penetrating injuries, both intraperitoneal and extraperitoneal injuries can occur. The diagnostic approach depends on the patient's clinical presentation. Patients with peritonitis, instability, or who are unexaminable should proceed directly to the operating room. For unstable patients, positioning should be supine with an emphasis on the laparotomy and hemorrhage control. Intraoperative sigmoidoscopy and anoscopy can be performed to examine the extraperitoneal segment of the rectum. For those that have peritonitis or instability, the patient may be placed in lithotomy to facilitate sigmoidoscopy and anoscopy. For those who are stable and who meet the criteria for a trial of nonoperative management, the highest-yield initial examination is CT (**Fig. 25.21**). On the CT, the bullet trajectory is tracked. If the trajectory appears to traverse the rectum, the patient can be

brought to the operating room for laparotomy, sigmoidoscopy, and anoscopy. If the tract is clear of the rectum on CT, no further investigations or treatment is required. For the equivocal CT scan where there is a questionable rectal injury, several options exist. The patient can be brought to the operating room for a laparotomy, sigmoidoscopy, and anoscopy. Another option is to perform diagnostic laparoscopy to look for intraperitoneal breach as well as a sigmoidoscopy and anoscopy. Any entry into the peritoneal cavity can then trigger a laparotomy and closer evaluation.

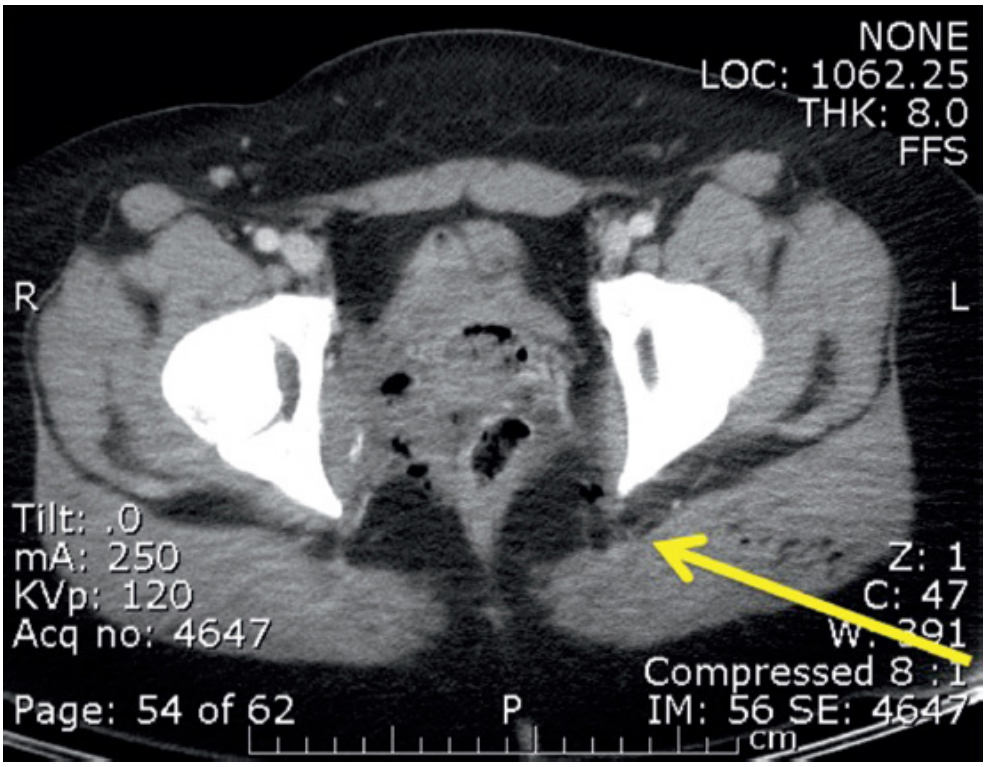

Figure 25.21 CT demonstrating a gunshot wound tract traversing the rectum, *arrow* demonstrates bullet tract.

For intraperitoneal injuries, the management principles are the same as those that apply to colon injuries. The vast majority undergo primary repair without the need for diversion. For extraperitoneal injuries, the management has evolved over the last decade. The classic approach to rectal injuries which included diversion, presacral drainage, and distal rectal washout is no longer performed.[97–106]

For distal extraperitoneal injuries that are accessible through a transanal approach, local repair can be performed without colostomy.[99,105,106] For

higher extraperitoneal injuries inaccessible in this manner, the most common treatment is fecal diversion without taking down the rectum and repairing the injury.[103,104] This can even be done laparoscopically with a low rate of morbidity. The absolute need for colostomy, however, has never been demonstrated.

Figure 25.22 Large perineal and groin avulsion injury after pedestrian struck by train.

If there is an associated bladder injury, a tissue barrier using omentum should be placed between the suture lines as a method of decreasing rectovesical fistula formation, a complication seen in upward of a quarter of patients with combined injuries.[107] In the rare case where there is a combined destructive anorectal injury (**Fig. 25.22**), acutely, hemostasis and diversion are recommended. Once the patient has been stabilized, assessment of the anal sphincter function should be performed, and semielective reconstruction should be performed by a colorectal specialist.

Genitourinary Trauma

Bradley A. Rittenhouse and Martin Schreiber

Key Points

1. Hematuria is the most sensitive indicator of genitourinary trauma, but the absence of hematuria is insufficient to rule out a genitourinary injury.
2. Renal injuries in hemodynamically stable patients can most often be treated nonoperatively and this often reduces the need for nephrectomy.
3. Genitourinary injuries can result in multiple complications including abscess, sepsis, urine leak, stricture of urethra or ureter, hypertension, and renal insufficiency.
4. CT scan is the primary modality for evaluating genitourinary injuries. It must include a delayed phase to evaluate the renal collecting system and ureter and a cystogram to evaluate the bladder if indicated.
5. Intraperitoneal bladder injuries require repair, while many extraperitoneal bladder injuries can be managed nonoperatively with Foley catheter drainage.
6. Urethral injuries are most commonly associated with pelvic fractures and are evaluated with a retrograde urethrogram.

Trauma produces a high healthcare burden both in the United States and throughout the world. As of 2017, unintentional injuries are the leading cause of death for people 1 to 44 years of age, and road traffic deaths alone are the eighth leading cause of death worldwide.[1,2] The genitourinary system is infrequently injured in isolation, but it is involved in 10% of all abdominal trauma.[3–5] These injuries are rarely life threatening alone, but they contribute to significant morbidity. Multiple organizations have guidelines for the evaluation and management of injuries to the genitourinary system including the American Urological Association, European Association of Urology, and the Société Internationale d'Urologie. These recommendations as well as recent updates are reviewed to provide an efficient organized method to evaluate genitourinary injuries in the trauma patient.

KIDNEY

Evaluation

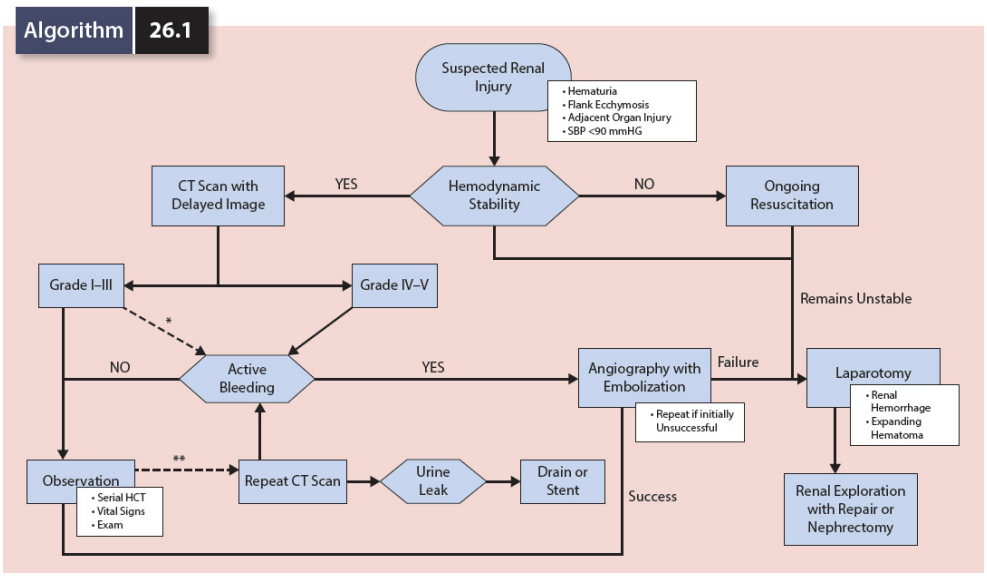
1 Renal injuries are the most common genitourinary injuries. These injuries most often result from blunt mechanisms including road traffic accidents and falls.[6,7] The kidney lies within the rib cage in the retroperitoneum surrounded by perinephric fat and encapsulated in Gerota's fascia. It is associated with adjacent anatomic structures including the liver; adrenal; duodenum and colon on the right; and the spleen, adrenal, and colon on the left. Within the kidney, the collecting system begins with the renal pelvis which then becomes the ureter as it leaves the kidney at the ureteropelvic junction (UPJ). The ureter remains in the retroperitoneum traversing along the psoas muscle crossing the common iliac vessels to enter the pelvis. Injuries result from crush or impact to the renal parenchyma or collecting system from external impact as well as impact against the nearby ribs. Also, deceleration injuries from the kidney's fixation at the renal pelvis and vasculature can result in avulsion injuries. History and physical findings that suggest renal injury includes a direct blow to the flank, lower rib fractures, injury to liver or spleen, flank hematoma or ecchymosis, hematuria, or a penetrating wound to the flank. As with any trauma patient, ensuring hemodynamic stability is paramount before proceeding to additional diagnostic testing. In hemodynamically stable patients with concern for renal injury, **Algorithm 26.1** provides an algorithm for evaluation.[5,8,9]

Hematuria is the most sensitive indication of renal injury, but the amount of hematuria is not indicative of the severity of injury and false-negative rates are as high as 30%.[8,10,11] The primary method for evaluation of renal injuries is the CT scan. The ideal protocol to evaluate for renal injuries is a three phase contrast CT scan with an arterial phase to evaluate for active extravasation, a venous or nephrographic phase to evaluate the renal parenchyma, and a 5-minute delayed phase to evaluate the collecting system. However, a significant number of trauma patients will have a contrast-enhanced CT scan as part of their initial evaluation for intra-abdominal trauma. The addition of a delayed phase (5 to 10 minutes) scan is effective for evaluating renal injury including the collecting system.[5,8] CT imaging provides a basis for grading the severity of injury. The American Association

for the Surgery of Trauma (AAST) organ injury scale (OIS) is the most commonly used grading system, and the recent update in 2018 combines, imaging, operative, and autopsy findings (**Table 26.1**).[12] A single-shot intravenous pyelogram may be used if CT is unavailable or to verify the presence of the contralateral kidney if laparotomy is performed without a CT. MRI offers no benefit over CT, has increased logistical challenges, and is not recommended.[5,8]

Treatment

2 AAST grading provides a basis for treatment decisions. Grade I and II injuries generally do not require additional treatment. Blunt grade III and IV injuries can often be managed nonoperatively, and some grade V injuries are managed through angiography and drainage instead of operative exploration (**Fig. 26.1**). Penetrating injuries are more often treated operatively and are more likely to result in nephrectomy. However, nonoperative management is safe to use in a selected group of stable patients.[13,14] As the availability and sophistication of angiography and less invasive drainage of hematoma and urinoma have increased, high-grade injuries are more frequently treated with less invasive interventions (**Fig. 26.2**). The primary indications for angiography are active bleeding, pseudoaneurysm, and vascular fistula.[15] Patients who are hemodynamically stable and have high-grade injuries defined as grades III–V can be managed nonoperatively in up to 80% of cases without increased hospital stay or complications.[9,16] However, if open exploration is required, nephrectomy is the most common outcome with nephrectomy rates of 0.4% to 4.5% in grade III, 15% to 24% in grade IV, and 57% to 62% for grade V injuries.[17–20]



Algorithm 26.1 Evaluation of renal trauma. *Grade III with active extravasation is frequently self-limited. **Grade IV–V should have routine repeat CT scan at 48 hours. Grade I–III routine repeat CT is not recommended, but should be performed selectively.

Table 26.1 AAST Grading of Injuries to Urologic Structures

Injured Structure	AAST Grade	Description of Injury
Kidney	I	▪ Subcapsular hematoma/contusion without laceration
	II	▪ Laceration <1 cm in depth without collecting system involvement ▪ Perinephric hematoma within Gerota's fascia
	III	▪ Laceration >1 cm in depth without collecting system involvement ▪ Active bleeding or vascular injury within Gerota's fascia
	IV	▪ Urine extravasation from laceration ▪ Laceration of renal pelvis or ureteropelvic disruption ▪ Injury to segmental artery or vein/segmental infarct ▪ Active bleeding outside Gerota's fascia
	V	▪ Shattered kidney

		▪ Avulsion or devascularization at renal hilum
Ureter	I	▪ Contusion or hematoma without devascularization
	II	▪ Laceration with <50% transection
	III	▪ Laceration with >50% transection
	IV	▪ Complete transection with <2 cm of devascularization
	V	▪ Avulsion/Laceration with >2 cm of devascularization
Bladder	I	▪ Contusion, intramural hematoma ▪ Partial thickness laceration
	II	▪ Extraperitoneal bladder wall laceration <2 cm
	III	▪ Extraperitoneal laceration >2 cm ▪ Intraperitoneal laceration <2 cm
	IV	▪ Intraperitoneal laceration <2 cm

	V	▪ Laceration of involving bladder neck or ureteral orifice
Urethra	I	▪ Contusion with blood at urethral meatus, RUG normal
	II	▪ Stretch with elongation of urethra without extravasation
	III	▪ Partial disruption with contrast extravasation at injury site and within bladder
	IV	▪ Complete disruption with contrast extravasation at injury site and none progressing to bladder <2 cm of urethral separation
	V	▪ Complete disruption >2 cm ▪ Extension of disruption into the prostate or vagina

If injuries are bilateral, increase one grade up to III (in table refers to kidney and ureter).

If there are multiple injuries in one organ, use the highest grade (in table refer to kidney, ureter, bladder and urethra).

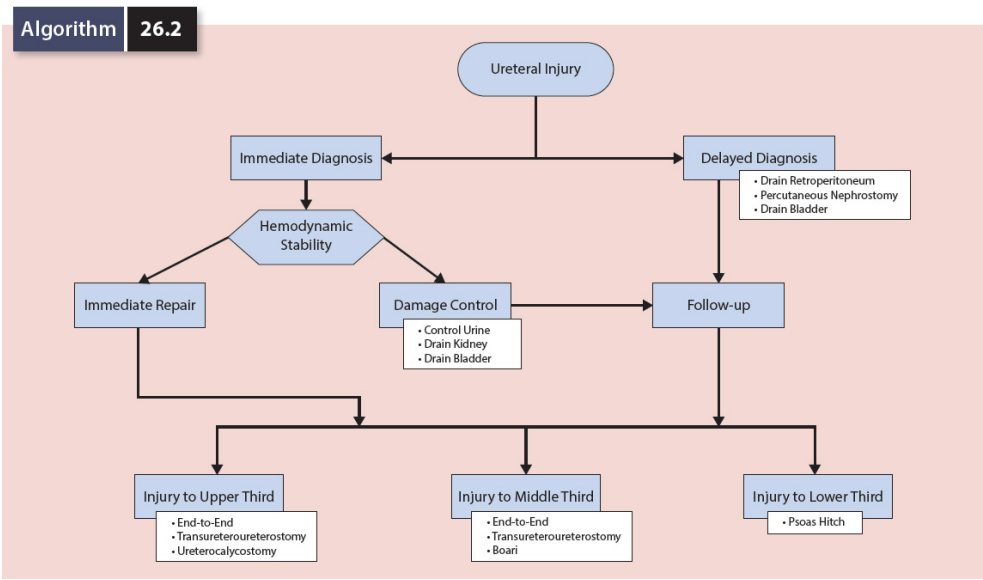
Should operative exploration be required, the kidney and upper urinary tract is accessed through an upper midline incision. Prior to exploring the kidney, proximal control of the renal vasculature can be obtained by creating a window in the posterior peritoneum medial to the inferior mesenteric vein (IMV). This allows isolation of the renal vasculature.[21] However, if rapid access is required, mobilization of the right or left colon will allow access to the kidney and the hilum and allow compression of the kidney and control of the vasculature to stop exsanguinating hemorrhage.[22] The kidney may be explored following identification and opening of Gerota's fascia. Nonviable renal tissue is debrided sharply, preserving the capsule for closure. The collecting system is repaired at this time. Finally, the capsule is closed using absorbable suture. A drain is placed in the retroperitoneum away from the repair and is removed once drainage has decreased. If the volume remains high, the drain fluid is sent for a creatinine level to determine the presence of urine. Vascular injuries of the kidney often require nephrectomy. Left renal vein injuries may be ligated due to collateral drainage through gonadal and lumbar veins; however, this is not the case on the right side and the right renal vein must be repaired or a nephrectomy performed.

Complications

3 Early complications within 1 month include perinephric abscess, urinary extravasation, and urinary fistula. Delayed complications can include hydronephrosis, pseudoaneurysm formation, calculus formation, and hypertension. Hypertension may result acutely from external compression due to perirenal hematoma (Page kidney). Hypertension may also develop in a delayed manner through compressive scar formation, renal artery thrombosis, or renal artery stenosis (Goldblatt kidney). Hypertension from renal trauma is a rare complication but is initially treated medically with ACE inhibitors; however, it may require interventions to drain perinephric hematomas or even nephrectomy if hypertension cannot be controlled.[4,23]

Figure 26.2 Angiogram of grade V renal injury.



Algorithm 26.2 Evaluation of ureteral injury.

URETER

Evaluation

4 Ureteral trauma is rare due to the small size and relative mobility of the ureter. Injury to the ureter accounts for only 1% to 2.5% of urinary tract trauma. Penetrating injuries frequently occur due to gunshot wounds and blast injuries with most blunt injuries associated with pelvic fractures.[24–26] The diagnosis of penetrating ureteral injuries is most often made at laparotomy and should be suspected when nearby structures are damaged including the psoas muscle, kidney, colon, etc. The diagnosis of blunt injuries is more difficult and may be delayed. This injury requires a high index of suspicion with multiple intra-abdominal injuries to nearby, or mechanisms with hyperextension that may avulse the ureter at the UPJ. Hematuria is a poor indication of injury.[5,27,28] Contrast-enhanced CT scan with delayed imaging is the evaluation of choice. In addition to extravasated contrast on the delayed images, unilateral ureteral dilation, urinoma, or ascites may be indications of injury. Exploration is recommended if laparotomy is required for other injuries. Retrograde urography may be performed if the diagnosis is unclear.[5,7,8] Delayed presentation with fever, flank pain, tenderness

atelectasis, urinoma, hematoma, or oliguria is evaluated in a similar manner with contrast-enhanced CT scan (**Algorithm 26.2**).

Treatment

The management of ureteral trauma is operative repair in most instances. Grading is based upon the AAST system (**Table 26.1**). The ureters begin at the renal hilum. They course through the retroperitoneum along the psoas muscle. Entering the pelvis, they course behind the gonadal vessels and over the lilacs to enter the inferior aspect of the bladder. The blood supply is segmental along their course. Patients with ureteral injuries primarily require laparotomy for other associated injuries. During this exploration, the ureter should be examined for injury and viability. In the hemodynamically stable patient, ureteral injuries should be repaired at the index operation.[5,8] The type of repair depends on the location of injury and amount of tissue destruction. **Figure 26.3** demonstrates anatomic considerations for type of repair and **Figure 26.4** describes the techniques utilized.

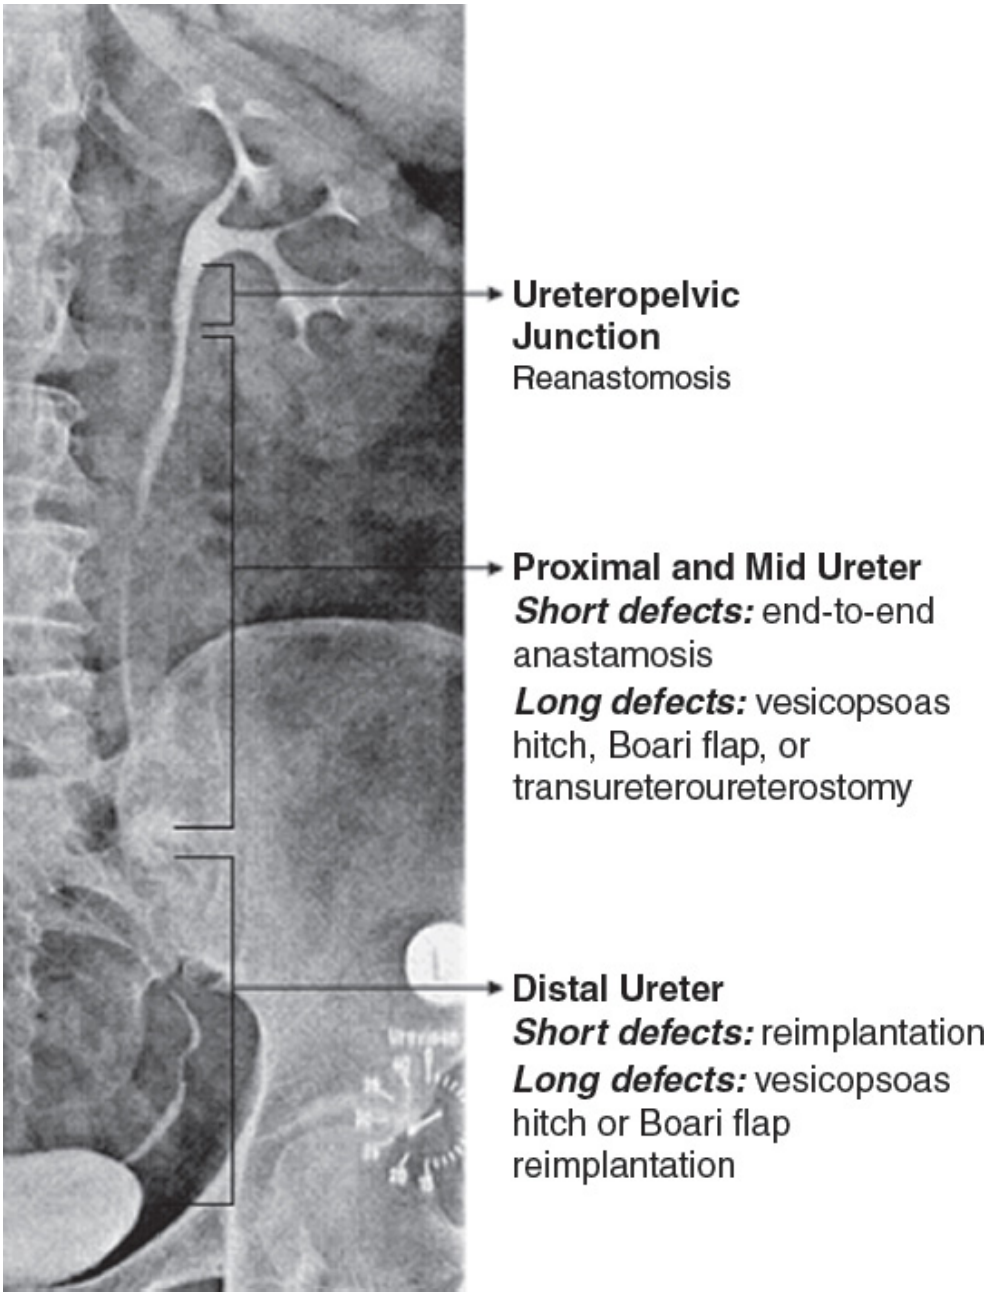


Figure 26.3 Locations of ureteral injury.

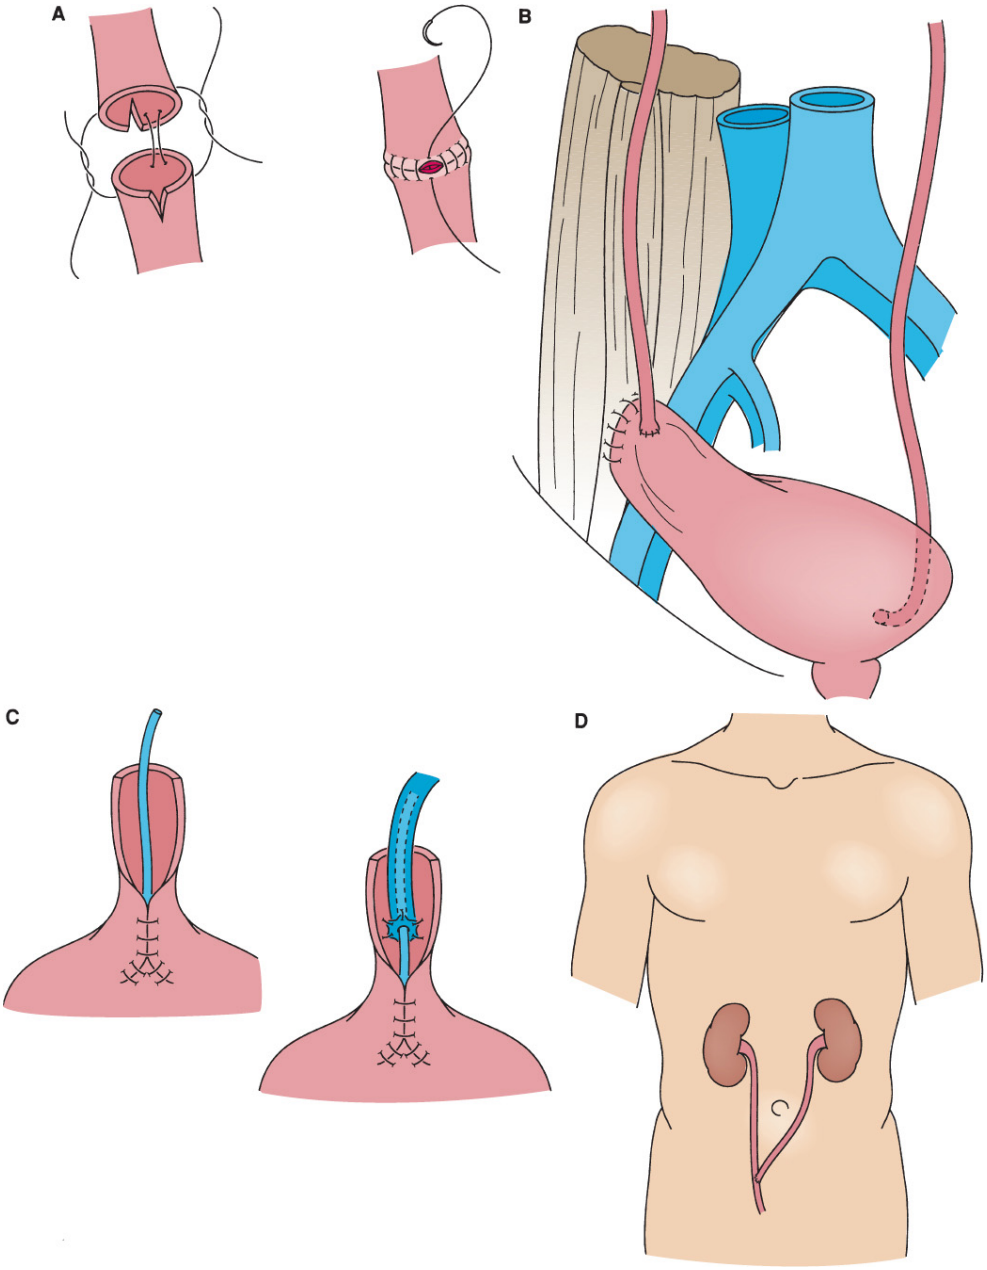

Figure 26.4 Techniques of ureteral repair. **A:** End-to-end ureteroureterostomy. **B:** Vesicopsoas hitch reconstruction with reimplantation performed by suturing of the bladder to psoas tendon after mobilization. **C:** Boari flap performed using a tubularized bladder flap based on the ipsilateral superior vesical artery. **D:** Transureteroureterostomy (TUU). For all repairs, the principles include tension free, watertight, stented, spatulated, mucosa-to-mucosa anastomosis using absorbable suture with drain placement.

In a hemodynamically unstable patient, repair of the ureter is not recommended, given the time required and the risk of ischemia. However,

control of urine is needed. This may be accomplished by draining the retroperitoneum and bladder, ligation with percutaneous nephrostomy or diversion utilizing a drainage tube placed into the injured ureter.

Patients who present in a delayed manner should not undergo operative intervention as this often results in nephrectomy.[29] These patients are initially treated with urinary diversion utilizing stenting, percutaneous nephrostomy, percutaneous drainage of the urinoma, and Foley catheter placement. After 3 to 6 months and resolution of the inflammatory response, reconstruction can be undertaken. Sequelae of these delayed diagnoses can include fistulae, stricture, infection, and obstruction. Patients who have sustained a high-grade ureteral injury should have repeat imaging with ultrasound, radio nucleotide scan, or CT urography to evaluate for stricture or urinoma.

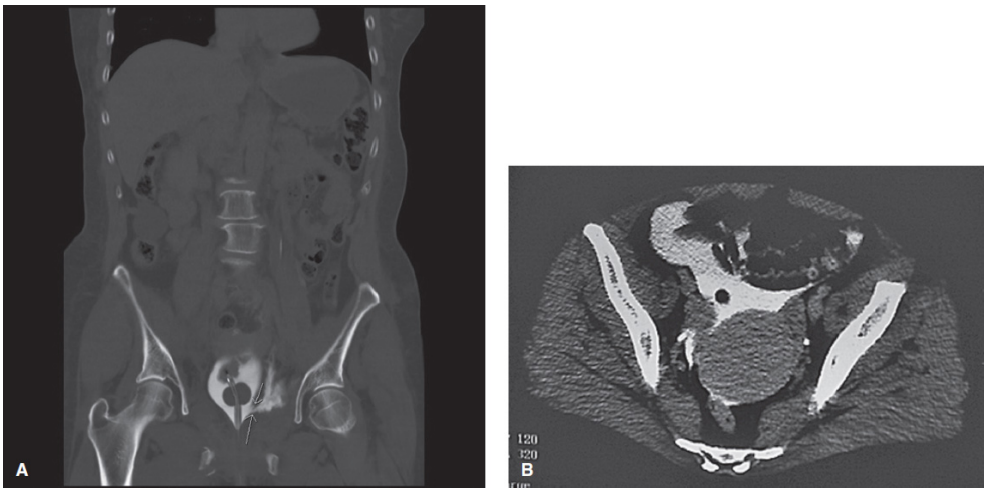

Figure 26.5 CT cystogram with bladder injury. **A**: Extraperitoneal bladder rupture. **B**: Intraperitoneal bladder rupture.

BLADDER

Evaluation

Most bladder injuries result from blunt trauma including motor vehicle crashes and falls. Pelvic fracture is associated with 60% to 90% of these injuries, and other abdominal organ injuries occur in 55% to 68%. However, less than 10% of pelvic fractures have associated urogenital injuries.[8,30,31] Bladder injuries are characterized as either extraperitoneal or

intraperitoneal. Extraperitoneal injuries are associated with pelvic fractures. The mechanism can be from deceleration causing shearing at the attachments of the bladder as well as direct injury from bony fragments. The highest risk for bladder injuries occurs with pelvic ring fractures and >1 cm of displacement.[5,32,33]

Gross hematuria occurs in greater than 90% of bladder ruptures. The presence of gross hematuria with pelvic fracture has a greater than 30% incidence of bladder injury and mandates evaluation.[5,34] In patients without pelvic fractures, evaluation for bladder injury should be strongly considered with gross hematuria and a mechanism that is high risk for bladder injury such as high impact lower abdominal injury, inability to void, imaging consistent with urinary ascites, or uremia.[4,5,8]

Imaging of the bladder is performed with retrograde cystography (**Fig. 26.5**). Either CT cystography or plain film cystography is acceptable.[5,8,35,36] However, CT cystography may be better at identifying bony fragments in the bladder as well as bladder neck injuries.[8] This involves instilling 300 to 350 mL of contrast into the bladder through a Foley catheter and then obtaining images. Simply clamping the Foley catheter during the standard trauma CT scan is inadequate to rule out bladder rupture.[36] Intraperitoneal injuries are identified by visualizing free flow of contrast material into the abdomen where it outlines bowel loops and intra-abdominal organs. Extraperitoneal bladder injuries produce more localized extravasation of contrast that is often described as flame shaped.

Treatment

5 Extraperitoneal bladder rupture is treated with Foley catheter drainage of the bladder for at least 2 to 3 weeks to allow the injury to heal. This observation period is typically followed by repeat cystogram to ensure healing. Complicated extraperitoneal bladder rupture which includes the presence of boney shards within the bladder, concomitant rectal or vaginal injuries should be repaired surgically. Also, repair may be required for injuries to the bladder neck or when internal fixation of pelvic fractures is performed.[4,5,34]

Intraperitoneal bladder injuries must be explored and repaired. The size of these injuries and risk of peritonitis preclude nonoperative treatment.[4,5,8,30]

Bladder exploration includes assessment of the bladder wall as well as the ureteral orifices and bladder neck. These structures are assessed through an anterior cystotomy or the injury itself. Injuries are closed in two layers using a running absorbable suture. Foley catheter drainage following repair is sufficient in most cases. Closed suction drains are placed away from the repair and may be removed in 48 hours unless there is a high volume of fluid that has a creatinine level greater than serum. The urethral catheter can be removed in 7 to 10 days with repeat cystogram.[4,5,8,30]

URETHRA

Evaluation

6 Urethral injuries are most commonly the result of blunt trauma and much more common in males than females. The male urethra can be divided into anterior and posterior portions. Injuries to the anterior portion can result from straddle mechanism or perineal kicks causing compression against the pubic symphysis. Posterior injuries are associated with pelvic fractures. Blood at the urethral meatus in men warrants evaluation with a retrograde urethrogram. Other signs that are suggestive of urethral injury include inability to void with a distended bladder, pain or hematuria, or difficulty/inability to pass a urethral catheter. Also, a rectal examination should be performed to rule out concomitant rectal injury and a "high-riding prostate" may be identified, although this is unreliable.[4,5,8,31] If there is concern for an injury, a retrograde urethrogram should be performed prior to the placement of a urethral catheter. Retrograde urethrography (RUG) is performed by instilling 20 to 30 mL of contrast into the urethra while occluding the meatus. An x-ray is then taken at a 30-degree oblique angle. Any contrast extravasation from the urethra is indicative of an injury (**Fig. 26.6**).[5,32,34] Flexible cystourethroscopy is helpful to differentiate between partial and complete injury, and is preferred with penile fracture as a RUG can be falsely negative in this setting.[8,34,37,38]

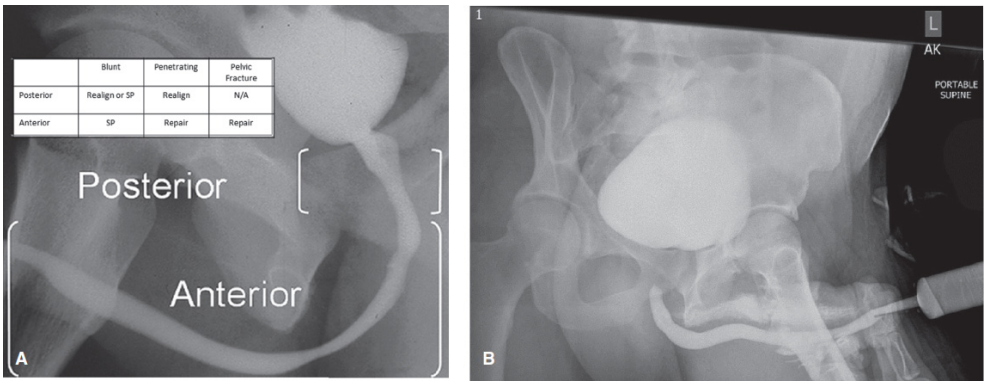

Figure 26.6 Retrograde urethrogram. **A**: Normal. **B**: Partial injury. (Demonstrated by contrast in corpus cavernosum and incompletely opacified posterior urethra.)

Treatment

In hemodynamically stable patients, primary realignment may be attempted. This consists of urethroscopy and fluoroscopy to pass a wire across the injury and then placement of a urinary catheter over the wire. If this is unsuccessful, suprapubic urinary drainage may be performed. Care must be taken as pelvic trauma may distort the normal location of the bladder and ultrasound should be utilized to assist with placement if available. Early realignment may decrease the risk of stricture from nearly 80% to 45% without increased risk of incontinence (5%) or erectile dysfunction (20%).[8,39,40] If realignment is not possible, urethral injuries are repaired in a delayed fashion when swelling and hematomas have decreased. Uncomplicated penetrating injuries should be repaired promptly. However, with associated injuries or high-energy destructive injuries, suprapubic drainage with delayed reconstruction is appropriate.[4,5,8]

Vascular Trauma

Kendal M. Endicott, Shahab Toursavadkohi, and Todd E. Rasmussen

Key Points

1. Vascular injury is the leading cause of mortality and morbidity in both civilian and military trauma.
2. Mechanisms of vascular injury are broadly categorized as either blunt or penetrating.
3. Patient examination is the most important step in evaluation of a suspected vascular injury.
4. Hard signs of vascular injury suggest near or complete disruption of the vessel in question and include pulsatile bleeding, expanding hematoma, palpable thrill, audible bruit, or evidence of acute ischemia distal to the injury site.
5. Contrast-enhanced computed tomography angiography (CTA) is the most widely used diagnostic imaging modality to identify and localize arterial and venous injuries in patients with suspected vascular injury in the emergency setting.
6. In the trauma patient, hemorrhage leads to both the overall metabolic consequences of shock and end-organ ischemia specific to the injured vessel.
7. Damage control resuscitation involves permissive hypotension with concurrent massive transfusion of packed red blood cells, plasma, and platelets in a 1:1:1 ratio.
8. Basic tenants of the operative management of vascular trauma include hemorrhage control, restoration of blood flow, and prevention of further reperfusion injury.
9. Neck trauma is classically divided into three anatomic zones. Zone I is from the thoracic inlet to the cricoid cartilage, zone II is between the cricoid cartilage and the angle of the mandible, and zone III is above the angle of the mandible to the base of the skull.
10. Control of bleeding from vascular disruption within the torso is not readily amenable to control with direct pressure and is therefore referred to as noncompressible torso hemorrhage (NCTH).

11 While open surgical therapy remains the gold standard for treatment for traumatic injuries, endovascular management presents an alternative option particularly with injury to the arch vessels and thoracic aorta.

BACKGROUND

1 Vascular disruption and hemorrhage is the leading cause of mortality and morbidity in both civilian and military trauma.[1–3] Arterial and venous injuries often occur concomitantly due to their anatomic proximity and are frequently associated with injury to other vital structures. Optimal management of traumatic vascular injury requires an understanding of the epidemiology and anatomic distribution of vascular injury patterns, consideration of mechanism, and attention to key tenants of diagnosis and management. The objective of this chapter is to familiarize the reader with current knowledge pertaining to the topic of vascular trauma including the circumstances in which vascular injury occurs and different approaches to diagnosis. Additionally, this chapter will provide guidance to the management of different patterns of vascular injury including extremity, cervical, and torso traumatic injury.

EPIDEMIOLOGY AND MECHANISMS OF VASCULAR TRAUMA

The epidemiology of vascular trauma can be broadly categorized into contextual circumstances (military and civilian), mechanism of injury (blunt and penetrating), and anatomical location of injury (extremity, cervical, and torso).

Wartime Vascular Injury

Contemporary data confirm that exsanguination is the major cause of death in wounded service personnel. The prevalence of wartime vascular trauma has

increased markedly over the past century (**Fig. 27.1**).[1–3] Estimates from allied surgeons in World War I (WWI) suggest overall vascular trauma rates of 0.4% to 1.3%.[4] DeBakey characterized the vascular injury burden in World War II (WWII) and the Korean and Vietnam wars at 0.96% and 2% to 3%, respectively.[4–6]

Coalition militaries engaged in recent combat operations in Afghanistan and Iraq have reported rates of vascular trauma higher than the previously mentioned military campaigns.[2,7–9] In a study reporting the U.S. military experience, White and colleagues analyzed vascular cases entered into the U.S. Joint Theater Trauma Registry (JTTR) from 2002 to 2009 (**Fig. 27.2**).[2] Defining the denominator as battle-related injuries sufficiently severe to prevent return to duty in the combat theater, the specific incidence of vascular injury (defined as the *total incidence injury*) was found to be 12% (1,570 of 13,076 cases). The incidence of injuries requiring an operation (defined as the *operative incidence*) was found to be 9% (1,212 of 13,076 cases). Injuries were most common in the extremities (79%) followed by those in the torso (12%) and cervical regions (8%).

Overall, the authors concluded that the rate of vascular injury in these modern wars was five times that previously reported from Vietnam and Korea (**Figs. 27.1** and **27.2**). An update of that data from the final years of war in Afghanistan from 2009 to 2015 estimated 17.6% of injuries to involve the vasculature, with most involving the extremities (45%). That study also cited an increase in endovascular methods of vascular injury management.[10]

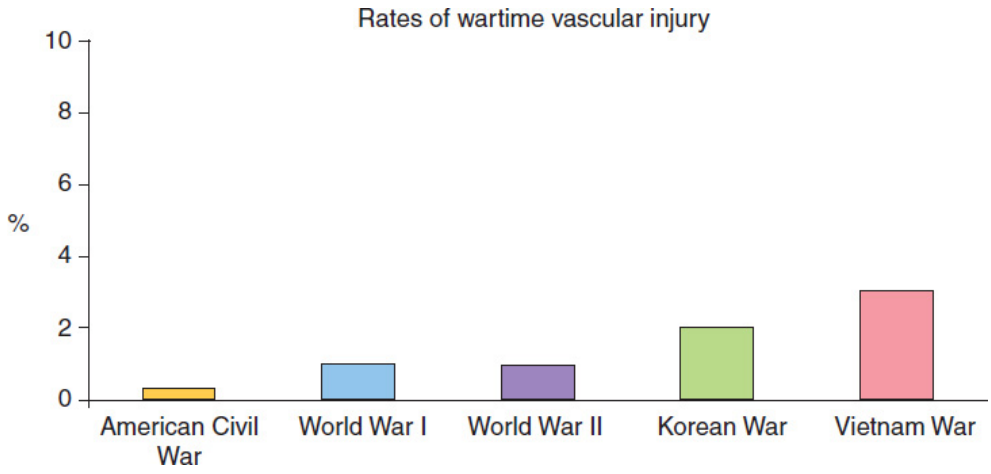

Figure 27.1 The rate of vascular injury reported from the wars of the previous two centuries. (From White JM, Stannard A, Burkhardt GE, et al. The epidemiology of vascular injury in the wars in Iraq and Afghanistan. *Ann Surg* 2011;253(6):1184–1189.)

Civilian Population Vascular Trauma

The impact of vascular trauma in the civilian setting is less well characterized than wartime vascular injury. According to data from the National Center for Injury Prevention and Control, in 2011 in the United States, injuries accounted for 51.3% of all deaths among persons 1 to 44 years of age, which is more deaths than those caused by noncommunicable and infectious diseases combined.[11] Fatalities stemmed mainly from motor vehicle accidents (32%), gunshot wounds (22%), and falls (9%). Vascular injuries represented 1% to 2% of total trauma patients but accounted for more than 20% of all trauma-related deaths and had the highest utilization of resources among the trauma population.[3]

In 2010, Demetriades and colleagues characterized vascular injury in 22,089 patients drawn from a population of more than 1.8 million in the National Trauma Data Bank (NTDB).[12] Acknowledging the reporting bias that accompanies analysis of such retrospective data, it was determined that the incidence of vascular injury (2002 to 2006) was 1.6%. Four-fifths of the injured were male, and the average age was 34 years. Half of the patients (51%) sustained a penetrating mechanism. Just under a quarter of patients presented in hemorrhagic shock and over half had an Injury Severity Score of more than 15. Abdominal and chest injuries accounted for more than 25% and 24% of the injury burden, respectively, with arm and leg injuries

contributing 26% and 18%, respectively. Mortality among those with vascular trauma was 23%, and vessels associated with the highest rates of amputation were the axillary (upper limb amputation rate of 6%) and popliteal arteries (lower limb amputation rate of 15%).[12]

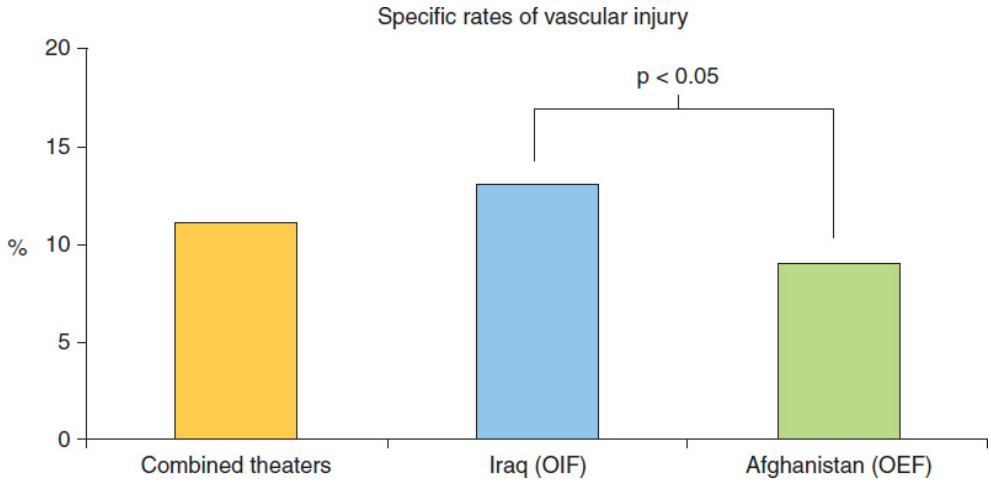

Figure 27.2 The rate of vascular injury reported during the wars in Afghanistan and Iraq. This specific rate refers to the 1,570 U.S. service personnel identified within the Department of Defence Joint Theater Trauma Registry (JTTR) as having sustained vascular injury during the wars (between 2002 and 2009). Note that the overall rate of 12% is severalfold higher than the rate of vascular injury reported in previous wars. (From White JM, Stannard A, Burkhardt GE, et al. The epidemiology of vascular injury in the wars in Iraq and Afghanistan. *Ann Surg* 2011;253(6):1184–1189.)

In other reports of vascular trauma from civilian centers in New York and El Paso, the rates of injury, in the context of all presenting to each trauma center, were 2.3% and 3.4%, respectively.[13,14] These reports confirm the "at-risk demographic" to be young and male, and demonstrate that mortality in those with vascular trauma is twice that of patients without this injury pattern. Not surprisingly, penetrating mechanisms are overrepresented in patients with vascular injury. A single-center study of vascular trauma from Houston in 1988 demonstrated that the wounding pattern in civilian circumstances does not follow that seen in wartime, even where ballistic penetrating injury is common.[3] Torso and neck injuries accounted for two-thirds of all injuries, while lower extremity injuries (including the groin) comprised only 20%.

Mechanism of Vascular Trauma

2 Vascular injuries are broadly categorized by mechanism as either blunt or penetrating. Either mechanism can disrupt the normal integrity of the blood vessel wall (intima, media, and adventitia) with varying degrees of integrity. Blunt vascular trauma is produced by local tissue compression or acceleration–deceleration resulting in disruptive shear forces. Motor vehicle crashes are the main cause of blunt vascular trauma in the civilian setting, and these patients usually have injuries to other areas of the body including extremity fractures or dislocation, brain injury, and injury to structures in the abdomen or thorax including aortic disruption. Blunt mechanism is also recognized as a source of vascular disruption with specific extremity fractures or dislocation patterns (e.g., posterior knee dislocation, tibial plateau fracture, and supracondylar fracture of humerus).

Penetrating mechanisms typically result in direct injury of the vessel causing either laceration or contusion of the wall as well as separation or destruction of soft tissues surrounding the vessel. Penetrating vascular injury may result from simple, low-velocity sharp objects (i.e., knife or glass), irregular fragments from explosives, and uniform munitions fired from a weapon. For ballistic injuries, damage to the vessel and surrounding soft tissues often results from a concussive shockwave that is conducted through the tissues as the object moves through the body dissipating energy. Unlike blunt injuries, which more commonly affect torso vascular structures, penetrating injuries more commonly affect the extremity vasculature.

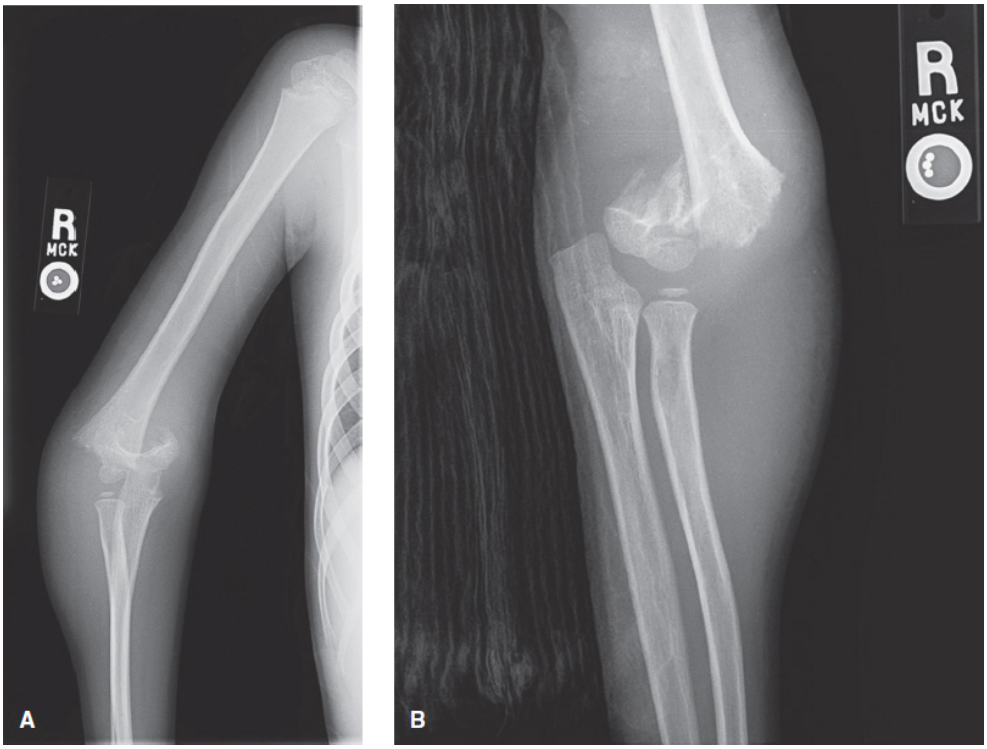

Figure 27.3 **A, B:** Radiographic images of a Gartland type III fracture of the right supracondylar humerus which is commonly associated with brachial artery injury.

DIAGNOSIS OF VASCULAR INJURY

Physical Examination

3 Patient examination is the most important step in evaluation of a suspected vascular injury. The physical examination should include complete exposure of the patient, identification of all wounds, and palpation of all extremities to assess for fracture or dislocation. The extremity vascular examination should also include assessment of distal perfusion by examination of the general appearance of the extremity and identification of pulses. Similarly, the neck and cervical region should be examined for signs of penetrating wounds, the presence of carotid pulses, and bruising or hematoma.[15,16]

Vascular trauma physical examination findings can be divided into hard versus soft signs of injury.4 Hard signs of vascular injury suggest near or complete disruption of the vessel in question and include pulsatile bleeding, expanding hematoma, palpable thrill, audible bruit, or evidence of acute

ischemia distal to the injury site. Depending on the degree of extremity ischemia, a patient may exhibit one or more of the classic six "P's" including pulselessness, pain, pallor, paresthesia, paralysis, and poikilothermia. Soft signs of vascular injury suggest partial disruption of the vessel in proximity and include trauma in proximity to a named vessel (i.e., certain fracture or dislocation patterns) (**Figs. 27.3** and **27.4**), diminished pulse distal to the site of injury, nonexpanding hematoma or severe bruising, and a peripheral neurologic deficit. Although torso vascular injury is more difficult to diagnose with physical examination alone, it should be suspected in patients with asymmetric arm pulses or pressures and those presenting in shock with evidence of fluid in the peritoneum or thoracic cavity.

Adjuncts to the Physical Examination

A plain chest radiograph is frequently performed during the initial evaluation of the trauma bay and is a useful adjunct in the diagnosis of blunt aortic injury. Classic signs of this injury pattern include a widened mediastinum (greater than 8 to 10 cm), an apical cap, loss of the characteristic aortic nob, downward displacement of the left mainstem bronchus, and hemothorax. Although multiple rib fractures are not a sign of aortic injury itself, it is a marker of severe blunt injury with significant shear and should raise one's index of suspicion for injury to the thoracic aorta. In addition, a persistent discrepancy of blood pressure cuff measurements from both arms greater than 20 mm Hg suggests a proximal vascular injury to the subclavian or axillary arteries.

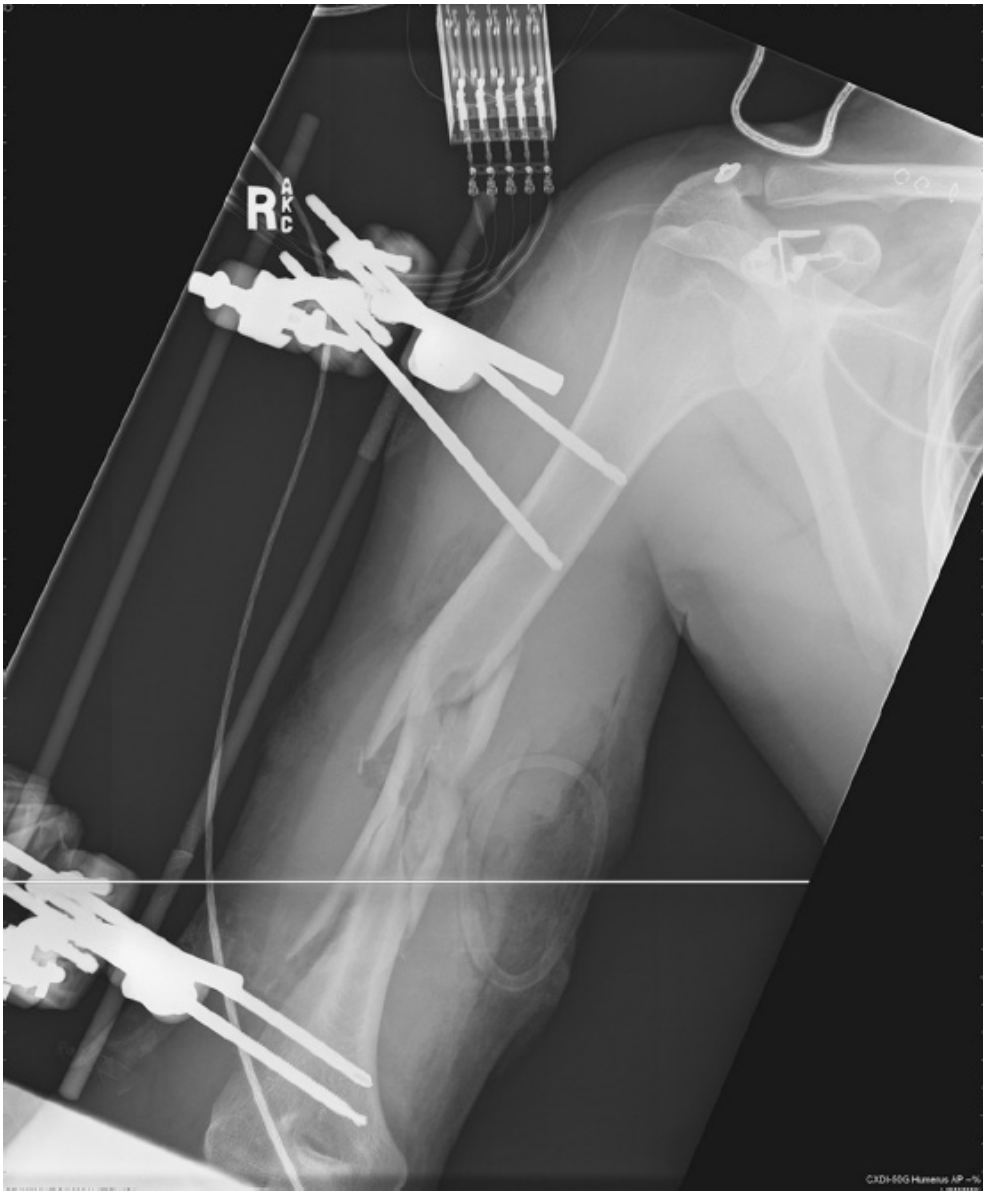

Figure 27.4 Radiograph of right upper extremity demonstrating an open humerus fracture. The brachial artery was found to be severed by the fracture.

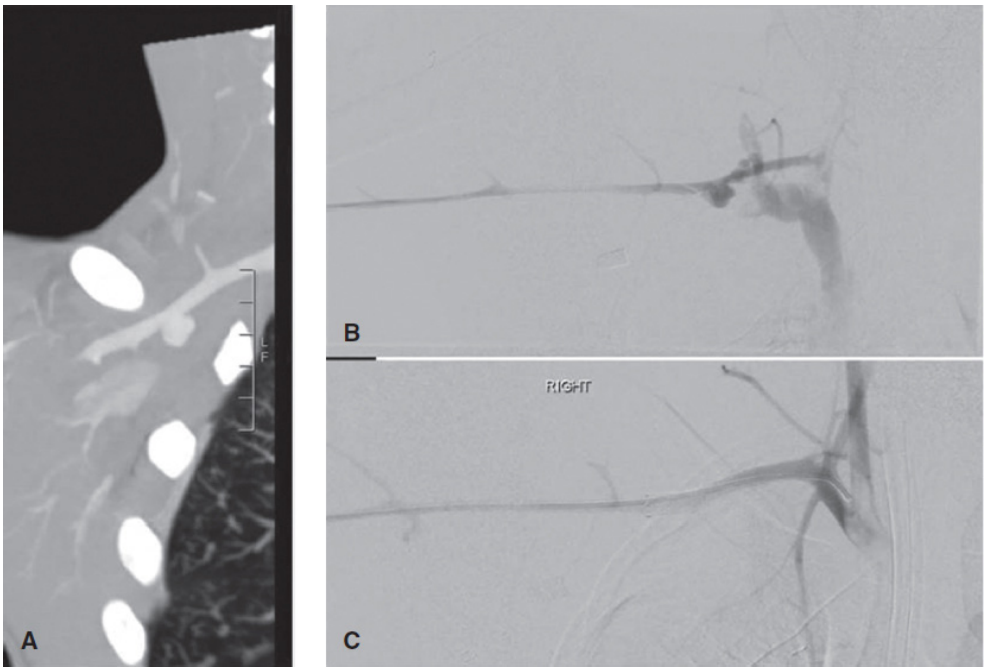

Figure 27.5 **A:** CT angiogram demonstrating a traumatic right proximal axillary artery injury as a result of ballistic injury. **B:** Angiogram demonstrating a small pseudoaneurysm and large arteriovenous (AV) connection with immediate filling of the right axillary vein. **C:** A 7 × 50 mm covered stent was placed across the injury with resolution of both the pseudoaneurysm and AV fistula.

Continuous-wave Doppler is another adjunct to the physical examination of patients in whom there is a concern for vascular injury. Doppler signals in the distal extremity should be recorded as present or absent and, if present, graded as strong and bi- or triphasic or weak and monophasic.[17,18] In the lower extremity, signals should be assessed in the dorsalis pedis and posterior tibial arteries, while in the upper extremity, signals should be examined over the radial, ulnar, and brachial arteries. While describing the quality of Doppler signals can be somewhat subjective, identifying the presence of extremity perfusion by noting the presence of an arterial signal is an important step that is typically less subjective than palpation for a pulse with one's finger.

The addition of a manual blood pressure cuff to continuous-wave Doppler allows one to calculate an ankle branchial index (ABI) or injured extremity index (IEI). The normal ABI or IEI is 0.9 or greater, although caution should be used in interpreting the ratio in patients who are hypotensive, in severe pain, or hypothermic.[16–18] Peripheral vasoconstriction is a normal response

to significant trauma and shock and may result in a transiently decreased ABI or IEI in the absence of an injured axial vessel. In this context, assessment of the Doppler occlusion pressures and measurement of ratios should be viewed as dynamic and repeated after resuscitation, administration of pain control, and rewarming.

Ultrasound is another noninvasive modality that can be used in the evaluation of patients with vascular trauma. Brightness or B-mode ultrasound is ubiquitous in most emergency departments and critical care settings and allows one to make basic assessments that provide insight into the presence and severity of some patterns of vascular injury.[15,16] The focused assessment with sonography for trauma (FAST) examination of the abdomen is based on B-mode ultrasound and is commonly used to determine the presence or absence of fluid in the peritoneum following severe injury. Although not specific for vascular injury, fluid seen on a positive FAST examination in a hypotensive trauma patient should be assumed to be blood. In these cases, the source of bleeding may be a solid organ injury (liver, kidney, or spleen) or a larger named vessel.

Computed Tomography and Magnetic Resonance Imaging for Vascular Trauma

5 Contrast -enhanced computed tomography angiography (CTA) is the most widely used diagnostic imaging modality to identify and localize arterial and venous injuries in patients with suspected vascular injury in the emergency setting.[19] CTA has a high degree of sensitivity in identifying dissection, occlusion, and active extravasation of blood into a contained space (i.e., pseudoaneurysm) or into an open space or cavity (**Fig. 27.5**). CTA is particularly useful in the assessment of anatomic regions where physical examination of the vasculature is limited. Growing experience with CTA in the assessment of the peripheral vasculature and several clinical reports now demonstrate this modality's sensitivity and specificity in the diagnosis of extremity vascular injury.[20] Extremity CTA is particularly appealing for the polytrauma patient who has soft signs of vascular injury as it can be performed with imaging of other body regions (i.e., head, neck, abdomen, and pelvis).[20]

Contrast Angiography

CTA has largely replaced the need for diagnostic contrast angiography in the trauma setting. Exception to this statement is the unstable patient who does not undergo imaging prior to operative exploration. In this circumstance, on-table angiogram can be performed in the operating room while other injuries are addressed with ongoing resuscitation.[21] Angiogram can demonstrate active extravasation of contrast if bleeding from an injured vessel is brisk and ongoing. Extravasation may not however be visualized if the bleeding is slow or under tamponade. Bleeding may also be missed if a contrast bolus is too small, mistimed, or injected into a different vessel not in direct continuity with the injury. Angiographic interruption of vessel continuity usually indicates disruption or thrombosis. With sufficient contrast and time delay, distal reconstitution of flow beyond the injured segment from collateral vessels can typically be demonstrated. Imaging of distal arterial beds can be compromised by hypoperfusion and vasoconstriction, typical manifestations of shock. Vasospasm with tapering of arteries (sometimes to occlusion) and slow flow can be prominent in young patients who have a greater degree of vasomotor reactivity.[19–21] Endovascular therapies such as embolization and placement of covered stents or stent grafts can be placed immediately following injury diagnosis when appropriate.

MANAGEMENT OF THE PATIENT WITH VASCULAR TRAUMA

Trauma Patient Pathophysiology

6 In the trauma patient, hemorrhage leads to both the overall metabolic consequences of shock and end-organ ischemia of the specific injured vessel. Ischemia of both types results in anoxic cell death. Resuscitation is directed toward minimizing ischemia and the "lethal triad" of acidosis, hypothermia, and coagulopathy. Hypoperfusion or ischemia leads to acidosis which causes platelet morphology changes and dysfunction and declining coagulation factor activity leading to decreased thrombin generation and the degradation of fibrinogen. Hypothermia likewise causes platelet dysfunction, less

coagulation factor activity, and the induction of fibrinolysis. Both of these pathways lead to coagulopathy and endothelial damage. Unbalanced massive blood transfusions can also lead to tissue injury, hypoperfused vascular beds, hemodilution, and depletion or dilution of clotting factors and platelets, all of which can contribute to a coagulopathic state.

Reperfusion injury following revascularization can precipitate additional metabolic insults in the trauma patient. Reperfusion of ischemic tissues releases reactive oxygen species and activates multiple proinflammatory processes including lipid peroxidation. This activation causes injury to the microvasculature which increases cell permeability and edema. An increase in interstitial pressure in turn leads to more stasis in microvasculature and therefore worsened ischemia. Ensuing cell lysis, also called rhabdomyolysis, leads to hyperkalemia, metabolic acidosis, and eventually myoglobin-induced renal failure.

Resuscitation of the Trauma Patient

Resuscitation of the trauma patient should begin immediately following initial assessment of injuries. Venous access with large-bore catheters in peripheral veins of uninjured extremities is preferred over central access in the emergent setting. Venous cutdowns are sometimes necessary. Radial or femoral arterial lines are also often placed for hemodynamic monitoring.[22 7] Damage control resuscitation, a term coined in 2005, involves permissive hypotension with a goal of a palpable radial pulse in patients without head injury.[23] Massive transfusion of packed red blood cells, plasma, and platelets should be conducted in a 1:1:1 ratio.[24–26]

General Intraoperative Considerations and Pearls

The principles of "damage control" guide the surgical management of vascular trauma [8] . Basic tenants include hemorrhage control, restoration of blood flow, and prevention of further reperfusion injury.

1. Prep widely, considering all possible sites of injury given the mechanism of disability. In particular, consider the need for autogenous venous conduit,

namely saphenous vein. With chest or abdominal injuries, prep down to bilateral knees. With leg injuries, prep circumferentially and include the chest and abdomen. With neck or upper extremity wounds, include the shoulders and chest.

2. Patients should receive preoperative antibiotics based on local guidelines.
3. Longitudinal incisions parallel to neurovascular bundles should be used for the wide exposure and best control. This may necessitate and "S"-shaped incision over joint spaces.
4. Proximal and distal control for any vascular injury is critical. This may be obtained with a digit, vessel loop, vascular clamps, or a Foley or Fogarty balloon. Consider remote proximal control when hematomas or open blast wounds impede visualization. Shunts should also be considered to decrease ischemic time when orthopedic stabilization or other lifesaving procedures must occur first. Nonbleeding wounds should not be disturbed including removal of debris or foreign objects until surgical control is obtained.
5. Temporary application of a lower extremity tourniquet may be helpful with complex wounds prior to obtaining surgical proximal control. An inappropriately applied tourniquet inflated to venous pressure can however increase exsanguinating hemorrhage. As systemic blood pressure increases with resuscitation, tourniquet pressure may need to be increased to remain effective.
6. Injury may require orthopedic fracture reduction and limb stabilization prior to formal vascular, nerve, or soft tissue repair. Relining of the bony structures will often improve vessel spasm, and vascular examination should be repeated following any orthopedic intervention.
7. Use of systemic heparin is individualized and contingent upon multiple factors including preoperative blood loss, hemodynamic stability, the presence of brain injury, and the overall physiologic status of the patient with regard to acidosis, hypothermia, and coagulopathy. Local administration of heparin and papaverine can be used in the wound and flushed directly into the vessel during repair. In general, systemic heparin can be obviated in young patients with healthy vessels and adequate revascularization.
8. Choice of surgical incision is dictated by the injury pattern and anatomic exposure needed for proximal control and subsequent revascularization

(**Table 27.1**). Aggressive debridement of devitalized tissue may be necessary for adequate visualization and postoperative healing.

9. Inflow and outflow must be assessed before beginning an anastomosis. Thrombectomy of both the inflow and outflow vessels with a Fogarty embolectomy catheter may be required.
10. Decision to perform immediate vascular reconstruction versus shunt placement with delayed reconstruction should consider the overall physiologic status of the patient. Arterial reconstruction should be prioritized over venous reconstruction in most cases.
11. Decision for direct repair with and without patching, primary anastomosis, or interposition grafting should consider factors outlined in **Table 27.2**.
12. Appropriate conduit is obtained, if applicable. Reversed greater saphenous vein of the uninvolved leg is the ideal conduit although synthetic grafts can be used if needed.
13. Repair is performed with nonabsorbable, monofilament running suture.
14. Adjuvant hemostatic agents can be parenteral (tranexamic acid for hyperfibrinolysis) or topical (**Table 27.3**).
15. Following completion of repair, perfusion should be assessed in the operating room with Doppler and arteriogram when indicated.
16. Soft tissue coverage over vascular repairs is necessary to prevent contamination, vessel desiccation, and anastomotic disruption. If large tissue defects are present, vacuum-assisted dressings are useful for tissue approximation and temporary closure.
17. Reperfusion injury and compartment syndrome must be considered and fasciotomies performed as clinically indicated.

Table 27.1 Exposures in Vascular Trauma Surgery

Vessel Injured	Exposure/Maneuver
Right subclavian artery Ascending aorta Innominate artery	Median sternotomy
Left subclavian artery Descending thoracic aorta	Left thoracotomy
Paravisceral, infrarenal aorta Left renal artery Left iliac artery	Left colon mobilization
Inferior vena cava Right renal artery Right iliac artery	Right colon mobilization, extended Kocher maneuver (duodenal mobilization)

Table 27.2 Options for Treatment of Vascular Injuries

Type of Repair	Description of Injury
Primary repair	<25% vessel compromise
Patch angioplasty	<50% vessel compromise
End-to-end anastomosis	<2 cm defect, ends mobilized, spatulated (smaller vessels)
Interposition graft	>2 cm defect, reversed vein graft or synthetic conduit
Extra-anatomic bypass	Extensive defect, multiple level injury, contamination

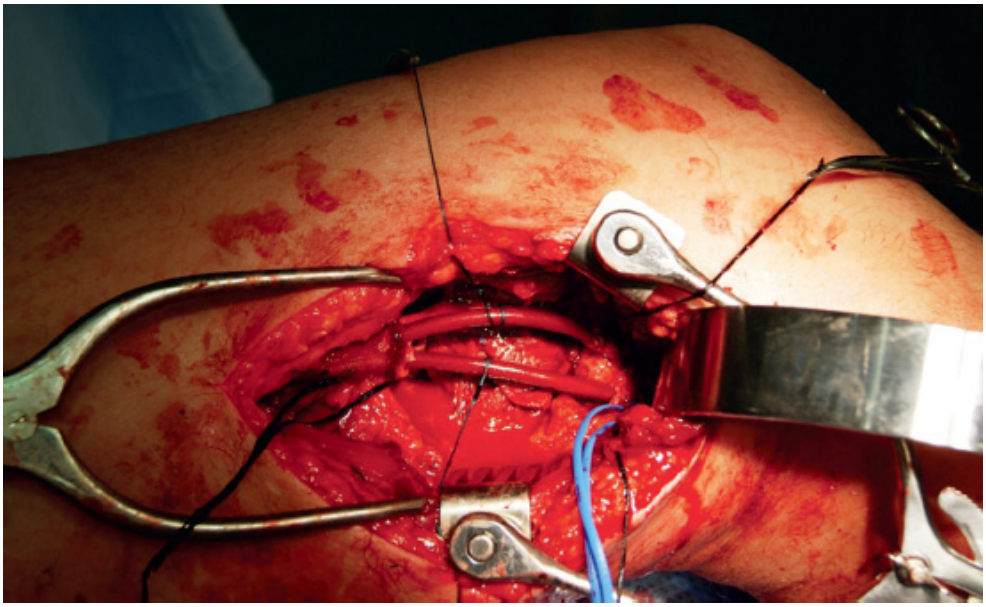

Figure 27.6 Operative photograph showing temporary vascular shunt placement as a damage control maneuver in the proximal popliteal artery and vein of the left lower extremity. The shunts were secured with silk suture ties, and both were patent with Doppler flow several hours following the injury.

MANAGEMENT OF SPECIFIC INJURY PATTERNS—EXTREMITY

Extremity trauma requiring operative intervention is often readily identifiable from physical examination alone. Exceptions to this statement include more proximal vessel injury entering the chest or pelvis including the subclavian and femoral arteries. For all extremity trauma, the goals of management include hemorrhage control, revascularization of an ischemic extremity, and limb stabilization to minimize future disability.[27] Injuries with hard signs of vascular injury should be taken immediately to the operating room for open or endovascular exploration without further imaging workup. Decision to perform immediate reconstruction versus temporary shunt placement should be dictated by the overall physiologic status of the patient (**Figs. 27.6** and **27.7**). "Soft signs" of vascular injury suggest less devastating injury allowing time for further workup, imaging, and potential nonoperative management.[28]

An additional critical issue in all extremity trauma management is evaluation for compartment syndrome. Elevated fascial compartment

pressures can be due to reperfusion, hematoma, swelling from crush injury, or major fractures. Compartment syndrome should be suspected if reperfusion occurs greater than 4 to 6 hours following injury, crush injuries, combined arterial and venous injuries, vessel ligation, and tense muscle compartments on examination. The classic physical examination finding in the awake patient concerning for compartment syndrome is calf pain with passive motion and paresthesia in the 2nd dorsal web space. Compartment pressures can be measured as an adjunctive aid in diagnosis with pressures greater than 30 mm Hg considered abnormal, however, normal pressures in a patient in whom compartment syndrome is clinically suspected should not discourage compartment release. Low threshold for fasciotomy should be adopted as risk of limb loss is high if a compartment syndrome goes undiagnosed.

Table 27.3 Topical Hemostatic Agents

	Indications	Agent Potency/ Mechanism	Uses	Examples
Level I (mechanical hemostat)	Min or mild bleeding, localized	Contact activation ± platelet aggregation	Capillary, arteriolar ooze	Gelfoam, procine gelatin, bovine collagen, surgical, nu-knit, Arista
Level II (Thrombin)	Min or mild bleeding diffuse	Converts fibrinogen to fibrin-activated platelet aggregation Contact activation + fibrinogen converted to fibrin	Capillary, ooze Capillary, arteriolar ooze, spurting	Bovine thrombin, recombinant thrombin Collagen or gelatin + thrombin; Floseal, Surgiflo
Level III (fibrin sealant, combination hemostat)	Mild bleeding diffuse; moderate bleeding	Fibrin sealant, replicates final stage of clotting cascade Synthetic sealant, covalently and mechanically bond Other	Capillary, arteriolar ooze High pressure sealing	Thrombin + fibrinogen ± fibrinolysis inhibitor; Tisseel, Evicel PEG polymer; CoSeal BioGlue

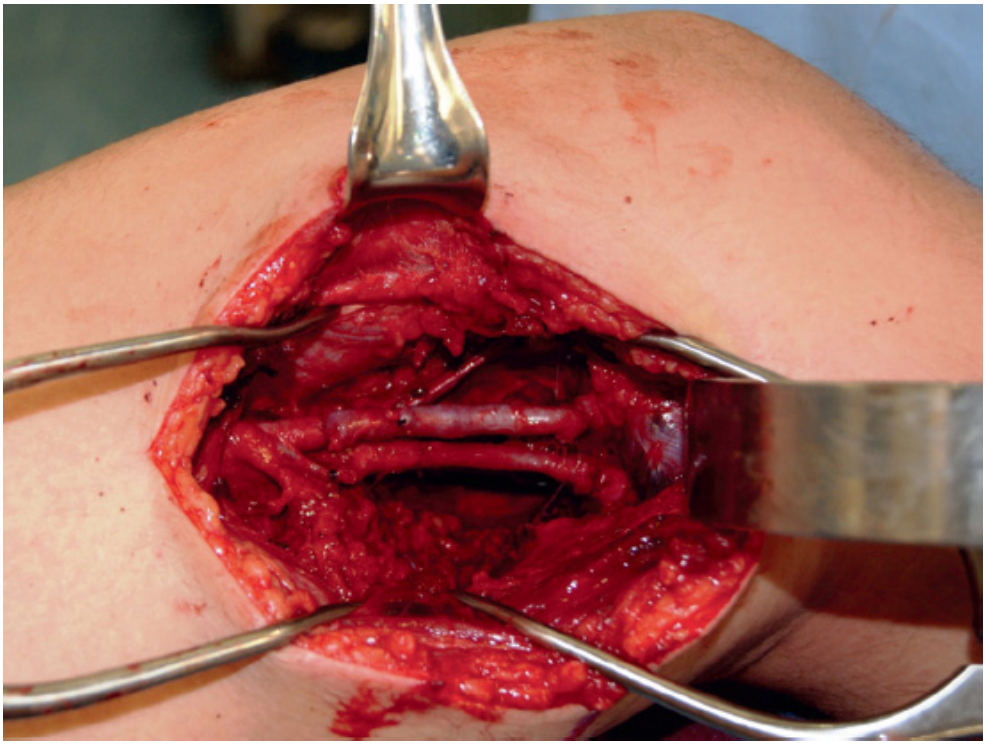

Figure 27.7 Operative photograph showing an interposition vein graft repair of the left proximal popliteal artery and vein. The interposition greater saphenous vein grafts were harvested from the right (contralateral) leg and performed following removal of the temporary vascular shunts.

Postoperatively, patient should be started on low-dose aspirin once hemodynamics permit. Deep vein thrombosis (DVT) prophylaxis is also an essential component of treatment in the polytrauma patient to prevent thromboembolic complications. Elevation of the injured extremity will reduce swelling. Twenty-four hours of antibiotics is adequate following isolated vascular repairs.

Upper Extremity

The axillary artery is defined proximally by the lateral margin of the first rib and distally by the lateral edge of the teres major muscle. The artery is protected proximally within the shoulder from penetrating injury but susceptible to forceful blunt trauma due to its fixation. Proximal exposure may require infra- and supraclavicular incisions to gain control with potential sternotomy if more proximal intrathoracic control of the subclavian artery is needed. The mid- and distal axillary artery can be approached

through a traditional infraclavicular incision. Complications with more distal exposure are due to increasing branches and associated nerve supply in the shoulder and arm. Employing endovascular techniques for temporary balloon occlusion or placement of stent grafts may be advantageous in these locations.[29]

The axillary artery becomes the brachial artery after passing the lower margin of the teres major. The brachial artery runs in the anterior compartment of the arm with the median nerve. The basilic and brachial veins accompany and often crossover the artery in the upper arm. The brachial artery is most often injured during penetrating trauma, but injury should be considered with any humeral fracture, especially posterior or lateral fractures. The brachial artery's main proximal branch, the profunda brachii, can provide significant perfusion to the distal upper extremity if it remains intact.

The radial artery is a terminal branch of the brachial just distal to the elbow and travels in the anterior compartment to become the deep palmar arch. The ulnar artery is the larger terminal branch of the brachial artery and runs to the wrist to form the superficial palmar arch and joins the deep arch. If temporary control of bleeding is needed, a blood pressure cuff can be used as a tourniquet. Evaluation should include a neurovascular examination with addition of the Allen test to determine patency of the palmar arch. Single-vessel injury with no ischemic changes can be ligated if the palmar arch is intact. If both forearm arteries are injured, repair of the usually dominant ulnar is preferred with either mobilization and primary end-to-end repair or interposition vein graft.

Lower Extremity

Femoral artery trauma constitutes 20% of all traumatic arterial injuries. Supracondylar femur and tibial plateau fractures are associated with distal superficial femoral artery and popliteal artery injuries. In the case of exsanguinating hemorrhage, an assistant's digit may be prepped into the field until more formal proximal control can be obtained. Options include tourniquet, temporary balloon catheter, or exposure of the distal external iliac artery in the preperitoneal space with compression against the iliac fossa for femoral triangle injuries. Incision should be longitudinal just below the

inguinal ligament. Primary repair or interposition grafting is the mainstay of therapy as acute ligation of the femoral artery leads to 50% amputation rate.[30] Although vein conduit is always preferred, prosthetic graft can be used when necessary in larger vessels with good muscle coverage.[31] Prosthetic grafts have also been described as a bridge to definitive therapy in the setting of severely injured patients in wartime injuries.[32]

Popliteal trauma is classically due to posterior knee dislocation. Historically, amputation rates were 20% for both penetrating and blunt popliteal injuries.[33] Failure to repair a popliteal occlusion results in amputation rates as high as 60%. Incision should be medial, employing the use of a bump under a slightly flexed leg (**Figs. 27.6** and **27.7**). Repair can be performed primarily following debridement to healthy tissue or with an interposition graft. Primary repair should be attempted only with defects less than 1 cm which can be repaired without tension. Completion angiography is recommended in most situations.

A single terminal vessel including the anterior and posterior tibial artery and peroneal artery can be ligated in the lower extremity in a patient with no signs of ischemia and no preexisting peripheral vascular disease. When all three arteries are damaged, repair of the anterior or posterior tibial artery via lateral and medial calf incisions, respectively, should be performed.

MANAGEMENT OF SPECIFIC INJURY PATTERNS—CERVICAL

9 The location of penetrating trauma in the neck is classically divided into three zones to identify which structures are at risk for injury. Zone I is from the thoracic inlet to the cricoid cartilage, zone II is between the cricoid cartilage and the angle of the mandible, and zone III is above the angle of the mandible to the base of the skull. The carotid and vertebral arteries are at risk in all three zones.[34] In addition to the carotid artery, injury to the jugular veins and branches, nerves (vagus, hypoglossal), trachea, and esophagus must also be considered with wounding in the neck. Hard signs of vascular injury include expanding hematoma, bruit, and hemiparesis.

Zone II of the neck is the most commonly injured region in penetrating neck injuries with vascular injuries in up to 20% of cases. Prior to widespread CTA use, zone II neck injuries mandated operative exploration if the injury violated the platysma. This mantra led to a high negative exploration rate which has now been negated by CT imaging. Currently, CTA of the neck through the aortic arch is utilized in stable patients to rule out injury. Multiple studies have demonstrated a 90% sensitivity and near 100% specificity rate for vascular injuries requiring treatment.[35–37] Of note, significant ballistic fragments in the neck may obscure arterial segments. In these cases, conventional angiography should be considered.

Zone I injuries with hard signs of vascular injury should raise suspicion for injury to the great vessels and may require median sternotomy or a high anterolateral thoracotomy for proximal control. Endovascular attempts at proximal control with balloon occlusion can be attempted, however, should not delay definitive operative control.

Injuries in zone II of the neck with hard signs of injury mandate neck exploration via a cervical incision along the anterior border of the sternocleidomastoid muscle. Occasionally a collar incision may be utilized if both sides of the neck require exploration. Exposure with proximal and distal control of the carotid artery should be performed expeditiously. The internal carotid artery should always be repaired as there is a high reported mortality with ligation (up to 45%).[38] Stab wounds can often be repaired primarily or with a patch as dictated by the degree of vessel disruption, while ballistic injuries typically require segmental resection with an interposition graft. Greater saphenous vein should be used as conduit whenever possible. Heparinization with or without shunting is employed during these repairs unless major contraindications exist in the multi-injured trauma patient. The external carotid artery can be ligated without significant consequence. The internal jugular vein can be ligated in an emergent setting but if possible, should be repaired, especially if injury is bilateral.

Zone III injuries are more difficult to expose using an open approach and can require subluxation of the mandible or mandibulotomy. Endovascular or hybrid strategies can be lifesaving in high injuries inaccessible to open repair.[39]

Vertebral artery injuries are less common and more difficult to expose operatively compared to carotid artery injuries. Vertebral artery injuries are

most often associated with cervical spine transverse process fractures, subluxations, or penetrating injuries to the back of the neck. Open exposure is similar to that for the common carotid artery, however, more lateral. After the sternocleidomastoid and anterior scalene muscles are mobilized, the vertebral artery can be isolated and ligated. In this procedure, care must be taken to avoid injury to the phrenic nerve and thoracic duct. Proximal and distal control of a more distal vertebral artery injury may require endovascular techniques as with a zone III carotid injury. In a recent review of the contemporary management of combat-related vertebral artery injuries, injuries included occlusion, pseudoaneurysms, dissection, and arteriovenous fistula. Injury was most commonly in the V2 segment, and treatment included coils and covered stents.[40]

Blunt cerebrovascular injury (BCVI) includes both carotid and vertebral injuries. While BCVI represents less than 1% of admissions for blunt trauma, these injuries can lead to mortality rates from 23% to 28% with 48% to 58% of survivors having permanent severe neurologic deficits.[41] Given the high morbidity of unrecognized BCVI in the asymptomatic patient, many screening protocols recommend screening CTA in trauma patients presenting with petrous bone fractures, diffuse axonal injury, Glasgow Coma Scale score less than 8, complex C1 to C2 cervical fractures, and Le Fort II or III facial fractures.[42] Treatment is dictated by the severity of the injury as defined by Biffl's grading score (Table 27.4, **Fig. 27.8**).[43] While no prospective data exist to define optimal treatment regiments, low-grade injuries should be treated with antithrombotic agents such as aspirin or heparin. Grade III injuries rarely resolve with observation and medical therapy alone, therefore surgical therapy should be considered. Patients presenting with severe deficits generally do not improve with revascularization.[42]

Table 27.4 Grading of Blunt Cerebrovascular Injury

Injury Grade	CT Characteristics
Grade 1	Intimal irregularity with <25% narrowing
Grade 2	Dissection or intramural hematoma with >25% narrowing
Grade 3	Pseudoaneurysm
Grade 4	Occlusion
Grade 5	Transection with extravasation

MANAGEMENT OF SPECIFIC INJURY PATTERNS—TORSO

10 Control of bleeding from vascular disruption within the torso is not readily amenable to control with direct pressure and is therefore referred to as noncompressible torso hemorrhage (NCTH). Civilian studies demonstrate that NCTH accounts for 60% to 70% of mortality following otherwise survivable injuries clearly emphasize the lethality of this injury pattern. Hemorrhage is also a significant problem in the wartime setting, accounting for up to 60% of deaths in potentially survivable injury scenario. The distinction between compressible extremity hemorrhage and NCTH is notable. There has been a demonstrable reduction in mortality from extremity injury with a better understanding of its epidemiology and the need to rapidly control hemorrhage with tourniquets and topical hemostatic agents. To date, there has been no such reduction in mortality in the setting of NCTH.[44]

The initial management of torso hemorrhage is dictated by a patient's hemodynamic stability and the site of injury. A proportion of patients with NCTH and penetrating trauma present with circulatory collapse with profound hypotensive or cardiac arrest. Management of patients presenting in such a fashion has been extensively studied, and the current civilian standard

of care is a resuscitative thoracotomy (RT) which permits the following maneuvers:

- Release of cardiac tamponade
- Management of thoracic bleeding

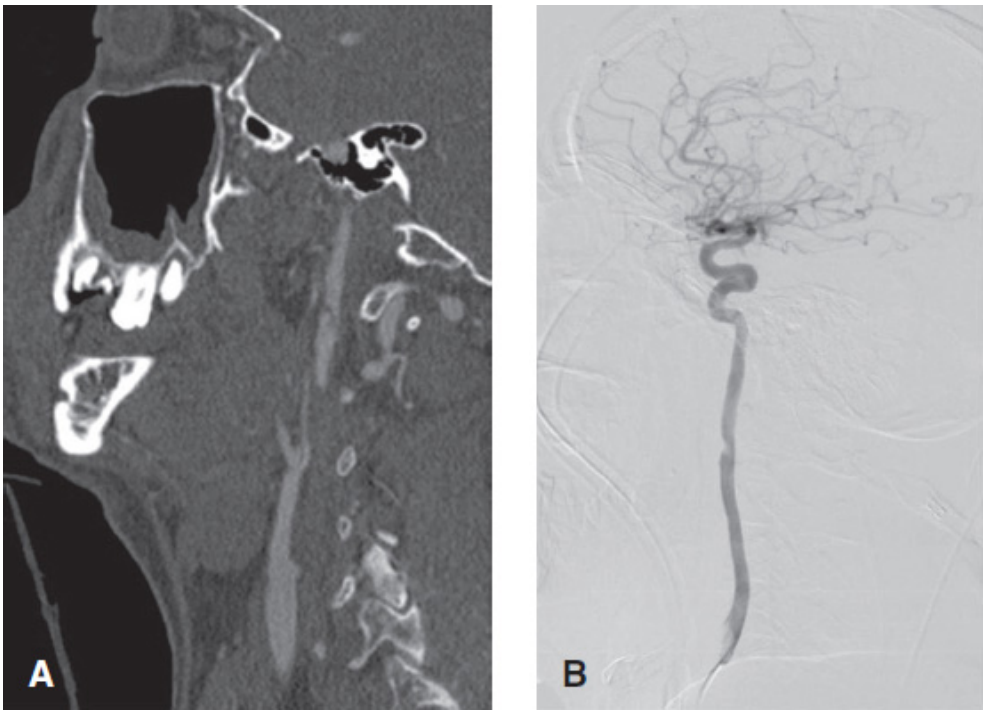

Figure 27.8 **A:** CT angiogram demonstrating a grade 3 blunt cerebrovascular injury to the left internal carotid artery with small pseudoaneurysm. **B:** Corresponding cerebral angiogram of the internal carotid artery.

Figure 27.9 Fluoroscopic image of a compliant balloon inflated in the descending thoracic aorta (resuscitative endovascular balloon occlusion of the aorta or REBOA). This endovascular maneuver was accomplished through a percutaneous sheath in the right femoral artery and can be accomplished in certain scenarios in lieu of resuscitative thoracotomy with aortic clamping. (From Scott DJ, Eliason JL, Villamaria C, et al. A novel fluoroscopy-free, resuscitative endovascular aortic balloon occlusion system in a model of hemorrhagic shock. *J Trauma Acute Care Surg* 2013;75(1):122–128.)

- Control of massive air leaks
- Internal cardiac massage
- Thoracic aortic occlusion

RT provides rapid access to the thoracic cavity via an anterolateral thoracotomy through the 4th interspace with the patient in the supine position. This approach allows extension of this incision across the sternum called a

"clam-shell incision" permitting access to both the mediastinum and contralateral thoracic cavity if needed.

Aortic control permits time for transfusion and enhances cerebral and myocardial perfusion until definitive operative repair can occur. Published neurologically intact survival rates following RT range from 3.9% to 11.7%[45] with penetrating thoracic injury. Patients presenting pulseless with blunt injury demonstrated neurologically intact survival rates from 0.7% to 2.4%. Given the dismal outcomes with RT in the setting of blunt trauma, many centers do not perform RT in the absence of penetrating injury.

The use of resuscitative endovascular balloon occlusion of the aorta (REBOA) has been introduced and studied as an adjunct for temporary hemorrhage control with NCTH (**Fig. 27.9**).[46–48] This technique for hemorrhage control has been used in trauma as early as the Korean War.[49] While increased data have led to more widespread use of REBOA in tertiary care trauma centers across the world,[50–52] the role of REBOA in the control of exsanguinating torso hemorrhage both in the prehospital and emergency room setting remains controversial.[48]

Thoracic Cavity

Patients with vascular trauma to the aortic arch and its major branch vessels often present in shock requiring immediate surgical intervention in the form of tube thoracostomy, RT, or median sternotomy. Aortic arch injuries are associated with multiple other vascular injuries including vena cava, innominate vein, and pulmonary artery injuries. Median sternotomy provides the widest and most versatile exposure for the arch vessels with the exception of the proximal left subclavian artery. This vessel injury is best approached via a left anterior lateral thoracotomy in the 3rd rib space given its origin in the posterior mediastinal. Sternotomy followed by division of the innominate vein allows the pericardium to be opened for release of cardiac tamponade as well as evaluation and repair of a cardiac injury. Exposure of aortic branches more distally can be facilitated by extending the sternotomy incision proximally as a supraclavicular incision with division of the sternocleidomastoid muscle. The descending aorta and pulmonary hilum can be approached most rapidly via a left anterolateral thoracotomy or if patient stability permits, a left posterolateral thoracotomy.

Abdomen and Retroperitoneum

Abdominal vascular trauma is conventionally divided into the intraperitoneal and retroperitoneal area. The retroperitoneum can further be divided into four zones. Zone I is centrally located and contains the aorta and major branches as well as the inferior vena cava (IVC). This zone is further divided into the supramesocolic and inframesocolic areas. Zone II (left and right) contains the kidneys and renal vessels. Zone III includes the pelvic retroperitoneal and contains the iliac vessels. Zone IV includes the perihepatic area containing the retrohepatic IVC and hepatic vines.

The abdomen should be opened through a midline incision from the xiphoid process to the pubic symphysis to permit access to all four quadrants. Initial packing remains the best method of initial hemostasis, allowing time for resuscitation. Packs are then removed in a stepwise fashion allowing for more directed hemostasis. In penetrating trauma, all retroperitoneum hematomas should be explored with the exception of zone IV retrohepatic hematoma. In blunt trauma, only zone I hematomas should be opened unless expanding. Hematomas at the root of the mesentery in the presence of ischemic bowel should be explored to rule out injury to the superior mesenteric artery.

In zone I injuries, proximal control should be obtained of the supraceliac aorta by cross-clamping at the diaphragm. In cases where a retroperitoneal hematoma extends to the aortic hiatus, proximal control may be best approached with surgical control of the thoracic aorta or placement of a REBOA. Supramesocolic bleeding involving the origin of major aortic branch vessels should be exposed via a left medial visceral rotation (the Mattox maneuver) by mobilizing the left colon, spleen, tail of the pancreas, stomach fundus, and left kidney medially. If supramesocolic IVC bleeding is suspected, bleeding can be identified with a right visceral rotation (the Cattell–Braasch maneuver) by mobilization of the right colon, hepatic flexure, and Kocher mobilization of the duodenum and pancreatic head. Inframesocolic bleeding can be exposed with cephalad retraction of the transverse colon and displacement of the small bowel to the right of the abdomen.

Zone II injuries require partial medial visceral rotation on the affected side. Nephrectomy may be required. If there is concern for injury or violation

of the collecting system, drains should be left in the perinephric retroperitoneal space. Zone III injuries should only be explored if large vessel injury is suspected. Dissection of the paracolic peritoneum and medial rotation of the right or left colon may be necessary, as well as mobilization of the terminal aorta. Operative management of zone IV is fraught with difficulty and high mortality. In the absence of exsanguinating hemorrhage, these contained venous injuries should be managed with packing alone.

In general, reconstruction of any major vessel should utilize autogenous vein (typically greater saphenous vein) especially in the presence of intestinal spillage (**Fig. 27.10**). In the setting of damage control laparotomy for patients with severe physiologic derangements, temporary shunting with later definitive repair may be appropriate. Small venous injuries should be ligated, however, large venous injuries should be repaired whenever possible. Because large veins often do not tolerate clamps in the setting of trauma and hematoma, direct pressure should be applied with sponge-sticks or smaller Kittner dissector sponges to allow for visualization.

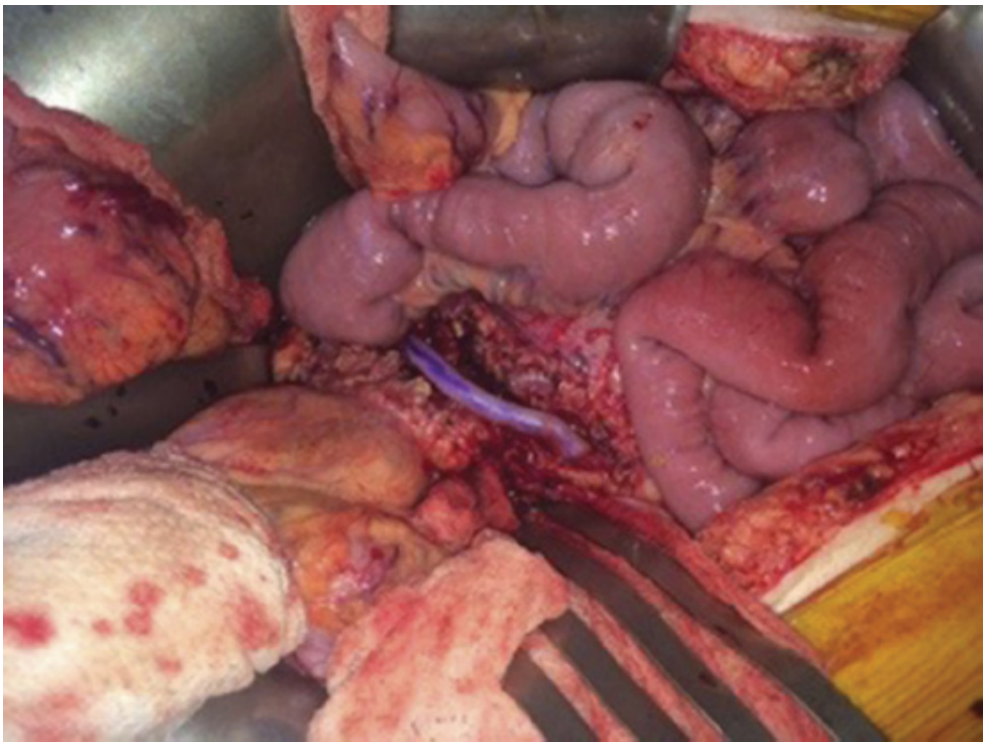

Figure 27.10 End-to-end interposition graft repair of midsuperior mesenteric artery injury with great saphenous vein.

ENDOVASCULAR MANAGEMENT OF TRAUMATIC VASCULAR INJURIES

11 While open surgical therapy remains the gold standard for treatment for traumatic injuries, endovascular management presents an alternative option particularly with injury to the arch vessels and thoracic aorta. The injury pattern in which endovascular therapy has revolutionized treatment algorithms is blunt thoracic aortic injury (BTAI). In those 20% of patients who arrive to the hospital alive following BTAI, endovascular treatment has essentially replaced open aortic repair as the gold standard of treatment due to improved outcomes (**Fig. 27.11**).[53,54] The BTAI grading system can be used to determine which patients are candidates for medical therapy alone versus repair (**Table 27.5**).[55] Studies have also demonstrated that in the absence of free rupture, delayed repair if preferred.[53]

Table 27.5 Grading of Blunt Thoracic Aortic Injury

Injury Grade	CT Characteristics
Grade 1	Intimal tear
Grade 2	Intramural hematoma
Grade 3	Pseudoaneurysm
Grade 4	Free rupture

CONCLUSION

Vascular trauma remains a leading cause of mortality and morbidity following civilian and military injuries despite improvement in damage control protocols and an improved understanding of resuscitation principles. While the operative management of vascular trauma has changed with the growth of endovascular approaches to hemorrhage control, the principles of proximal and distal control remain paramount. Regardless of experience and training level, the foundational principles provided in this chapter will guide

one's attempts to improve management of one of the most challenging and devastating injury patterns in trauma.

The Principles of Orthopedic Surgery for Trauma

Raymond Malcolm Smith

Key Points

1. Establishing bony stability significantly reduces local bleeding.
2. Major pelvic fractures occur in recognizable patterns that predict other injuries.
3. Obtaining bony stability can significantly reduce pelvic bleeding and is an essential part of their initial care.
4. Early stabilization of major fractures in polytrauma patients facilitates general patient care and saves lives.
5. Early radical management of open fractures with adequate debridement by wound excision, bony stabilization, and early healthy soft tissue cover significantly reduces the risk of infection and decreases morbidity.
6. Establishing reliable bony stability is the key for local soft tissue healing.
7. The principles of accurate reduction, stable fixation, preservation of a healthy soft tissue envelope, and early rehabilitation with joint and patient mobility are the keys to general fracture management.

INTRODUCTION—AIMS AND PRIORITIES IN ORTHOPEDIC TRAUMA CARE

The subspecialty of orthopedic traumatology concentrates on skeletal reconstruction after injury and the overall management of these patients. This involves the management of routine fractures but also the more complex problems presented by very severe localized high-energy injury and combination multisystem polytrauma. In critical multisystem injury, it is very important to correctly manage the orthopedic injuries which can easily be underestimated. Their management has a critical role in ensuring survival of the patient and ensuring practical overall clinical management. In severe local injury, life is also at risk but useful limb salvage needs orthopedic management often combined with plastic surgery to manage severe soft tissue

injury. Patients with less severe fractures still have major problems, the orthopedic care should limit the medium- and long-term disability caused by fractures and severe peripheral soft tissue injuries. This overview is illustrated in **Table 28.1**.

ORTHOPEDIC TRAUMA SURGERY TO SAVE LIFE

In patients with severe multisystem trauma, musculoskeletal injuries are commonly a major part of the trauma burden and a threat to life. This threat comes from hemorrhage (from individual or multiple injury sites), the general effect of multiple major skeletal injuries and specific injuries such as vascular injury and compartment syndrome or later complications such as infection, immobility, and thromboembolic disease.[1]

Hemorrhage

The most immediate and absolute need for surgery in trauma is the control of bleeding; this critically involves the orthopedic traumatologist in two scenarios, massive bleeding from multiple high-energy fractures or severe localized bleeding associated with a specific major injury, most typically from the pelvis. Bleeding from multiple fractures is common and often underestimated. In general, early transfusion protocols and early 1 fracture management controls the situation. Bleeding from fractures will be invariably slow and usually stops spontaneously when the fracture is reduced, stabilized, and the compartment tension restored. However, it is very easy to underestimate the collective blood loss from multiple injuries and get too far behind in resuscitation, a situation that can then become uncontrollable. Aggressive transfusion protocols with appropriate attention to replace volume and clotting factors with early use of blood with plasma and platelets are essential in parallel with the provision of skeletal stabilization for early hemorrhage control.[2] This may involve wound debridement and hemostasis in the complex open injury or early long-bone stabilization in multiple closed fractures. Occasionally, temporary external fixation may be required to

provide rapid control of skeletal instability when the more extensive surgery required for definitive stabilization would be inappropriate.

The Bleeding Pelvis

Put simply, patients with major pelvic ring injuries can bleed to death. Often presenting after a high-energy injury, the signs of major hemorrhage from the pelvis may be obvious with massive local swelling and clear instability. At presentation, a primary plain pelvic x-ray remains the best way to quickly understand the fracture. It will allow immediate assessment of the fracture pattern, energy involved, degree of displacement and leads to an estimate of the risk of local bleeding and presence of local or distal associated injuries.[3–7] Today many patients have a binder applied in the field for transport. This is a very effective way to initially control pelvic volume and tamponade bleeding but may reduce the deformity and also lead to the initial x-ray, underestimating the degree of injury.

Understanding the pelvic fracture is essential, Young and Burgess[3,4] (**Fig. 28.1**) presented a classification system based on the implied direction of the initial force and defined injuries essentially as anterior–posterior compression (APC), lateral compression (LC), and vertical shear (VS) injuries. This allows an assessment of the direction of the force applied, the resultant instability, and can predict mortality, transfusion requirements, and 2 associated injuries. In general, injures that make the pelvic ring bigger bleed locally while ones that make it smaller can bleed but are more commonly markers of the injury mechanism and remote injuries, specifically, the associated ipsilateral chest and abdominal injury. The Tile[8,9] (**Fig. 28.1**) system considers the injury with regard to the resultant instability and has now been adopted by the AO Foundation (AO) and Orthopedic Trauma Association (OTA). An "A"-type fracture has a stable pelvic ring and essentially includes more minor avulsion fractures and mechanically stable pelvic ring injuries (includes APC I & LC I). "B"-type injuries are rotationally unstable but vertically stable with an intact posterior soft tissue hinge providing some stability (corresponding to APC II or LC II/III injuries), while "C"-type injuries are both rotationally and vertically unstable, implying that the posterior hinge is torn (corresponding to APC III and VS injuries). The latter carry the highest risk of bleeding and death.

Table 28.1 Why We Operate on Fractures: Priorities in Trauma Care

Orthopedic surgery to save a life
Orthopedic surgery to save a limb
Orthopedic surgery to limit disability

From a surgical management perspective, A-type injuries are unlikely to be a source of major bleeding while B type and, specifically, C types are increasingly life threatening. After initial assessment, primary radiology, and consideration of the response to initial resuscitation, pelvic fractures can then be considered by the mechanical stability resulting from the injury and the resultant hemodynamic response (**Table 28.2**).

Table 28.2 Principles of Management of Major Pelvic Ring Injuries

	Mechanically Stable Pelvis	**Mechanically Unstable Pelvis**
Hemodynamically stable	Nonoperative	Early, planned operative stabilization of pelvic ring
Hemodynamically unstable	Likely extrapelvic cause Angiography/embolization	Emergent provision of mechanical stability ± Packing/angio

The role of the orthopedic surgeon is to assess the injury with regard to the local and associated problems and to provide pelvic mechanical stability when required. A hemodynamically stable patient with a stable pelvic ring injury does not require major active orthopedic management, although it should be noted that rarely even the most apparently simple injury can cause local bleeding and transfusion may be required.[10] The hemodynamically stable patient with a mechanically unstable pelvic ring injury needs early but

not emergent surgery to restore mechanical stability to the pelvis for pain relief, normal daily care, and mobilization. Hemodynamically unstable patients need emergent care to restore their physiologic stability. If the pelvis is mechanically stable, orthopedic intervention has little to offer, either there is an extrapelvic cause for the bleeding or hemostasis should be obtained by provision of appropriate clotting factors and platelets, packing or angiographically.

The patient in hemorrhagic shock with a major unstable pelvic ring is a very different problem.[10,11] Early coordinated multidisciplinary care in the right hospital is essential, with appropriate resuscitation within an established massive transfusion protocol. It is well established that the site of hemorrhage in most bleeding major pelvic fractures is from the fractured bone surfaces and extensive soft tissue injury, and rarely 3 from major named arteries. Fortunately, the majority of pelvic bleeding will slow or stop when skeletal stability is achieved. However, rapid stabilization of the pelvic ring is a major expert intervention at best and is rarely easily achievable in the acute bleeding situation. Initial reduction, stability, and some local tamponade is provided by a pelvic binder. In critical cases, it should not be removed without an available alternative method to provide stability. Internally rotating the hips, slightly flexing the knees, and binding the legs at the thigh should also be used if possible and provides additional effective control. The provision of early pelvic fixation or a primary angiographic approach to bleeding control depends on local expertise and protocol. Recently, a move to emergent operative provision of skeletal stability and packing of bleeding from the pelvis has entered common practice.[2,12] The major bleeding pelvic injury is considered similar to a bleeding liver and where general hemorrhage control is achieved with packing for local pressure. For the severe pelvic injury, a systematic protocol of bleeding control and transfusion that emphasizes the importance of not getting out of control or reacting too late, "The Denver Protocol"[2,12] begins with a patient with shock, a pelvic ring injury, and a failure to respond to 2 L of crystalloid resuscitation and 2 units of blood transfusion (**Algorithm 28.1**). The essential principle is an early trigger to aggressive surgical management for hemorrhage control with preperitoneal packing and rapid blood and factor replacement before the patient becomes grossly coagulopathic. From the orthopedic point of view, restoring skeletal stability

is a critical part of this process and close cooperation with the general traumatologist is essential.

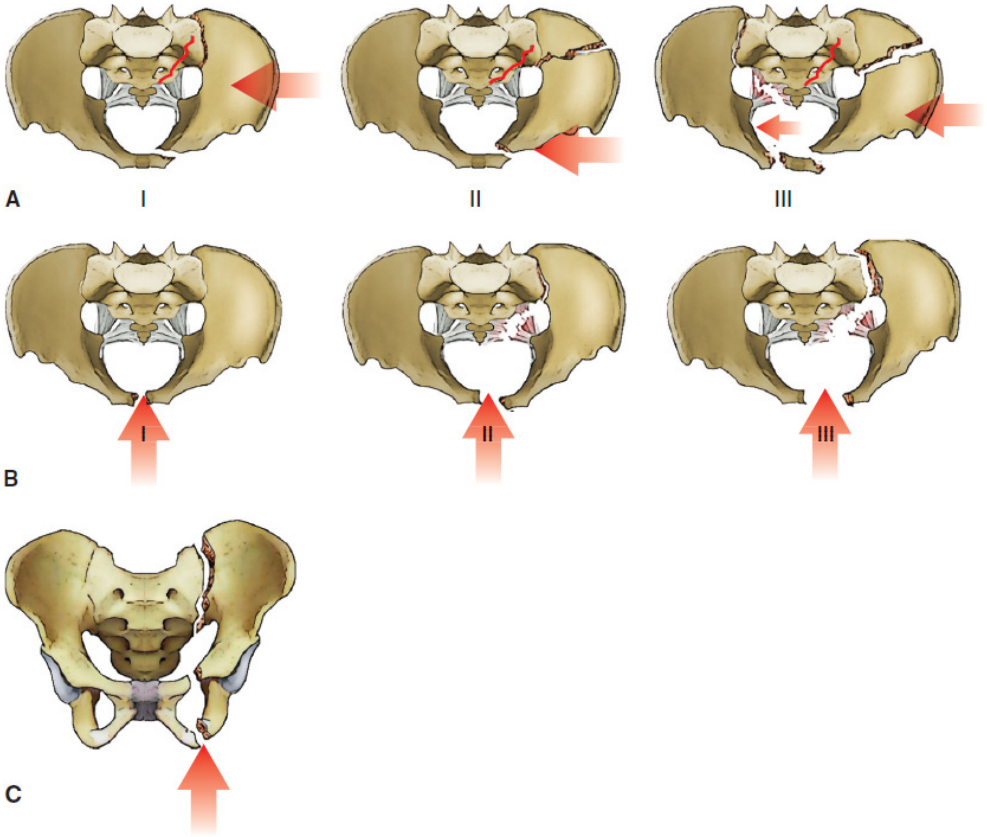

Figure 28.1 **A–C:** Young and Burgess, and Tile (AO/OTA) classifications of pelvic fractures. (From Wiss DA. *Master Techniques in Orthopaedic Surgery: Fractures*. 3rd ed. Philadelphia, PA: Wolters Kluwer Health; 2012.)

Strategies for the management of haemorrhage following pelvic fractures and associated trauma-induced coagulopathy. *Bone Joint J* 2014;96(9):1143–1154.)

Pelvic Packing

The procedure of packing a pelvis for hemorrhage is well within the capabilities of most surgeons but some form of pelvic bony stability has to be achieved first to give a solid base to pack into. In the emergency situation, this commonly means the application of an anterior external fixation frame although if possible, internal fixation has many advantages. Occasionally, emergency provision of posterior stability with emergent percutaneous sacroiliac fixation or application of a "C clamp" can be dramatically effective in restoring stability and markedly slowing bleeding. Preperitoneal packing is done through a small anterior incision just above the pubis. After separating the rectus muscles (which may be avulsed from the pubis), the cavity created by the trauma is entered, the hematoma evacuated and rapid mechanical stability obtained (often temporarily, applying a bone-reduction clamp across the pubis). The bleeding cavity, already produced by the trauma, is then packed with as many packs as required. These should be placed as far back into the true pelvis as possible. The hematoma cavity created by the injury will be obvious and it is not required or desirable to extend the dissection outside this area but it is essential to get the packs right to the back of the cavity. Assuming hemostasis is achieved, the packs are left

in, often for 48 hours and under an open but sealed abdomen before they are changed or simply removed depending on the physiologic response.

COMPLICATED PELVIC INJURIES—OPEN FRACTURES OR ASSOCIATED VISCERAL INJURY

The initial assessment of any patient with a pelvic fracture must also include an inspection of the perineum with rectal and vaginal examination to check for complex open injuries or associated urologic injuries. Open pelvic fractures and those associated with local visceral damage carry significant mortality and need specific treatment based on the wound or specific injury sustained.[13,14] The degree of contamination and size of the zone of injury in the pelvis massively worsens the situation and may prove fatal such that aggressive decontamination and protection of this extensive zone of injury from further contamination by diversion of the fecal stream may be essential.

Complex urologic injuries are commonly seen with specific patterns of pelvic fracture. A significant APC injury is commonly associated with an extraperitoneal bladder rupture of the anterior bladder wall directly in line with the plane of injury. LC injuries may be associated with urethral tears as the inferior ramus cuts the male membranous urethra as it is forced across the midline by the injury. In all cases, the presence of hematuria or blood at the meatus is the pathognomonic sign of injury and necessitates appropriate investigation and joint management with the urologic service. Again from the orthopedic point of view, no soft tissue reconstruction can work without an underlying stable bony skeleton to support the repair and prevent reinjury. In many situations, the best access the urologist will have is at the time of the primary bony stabilization and early urologic repair or diversion avoids many problems, although a staged urologic procedure may be required.

THE ORTHOPEDIC MANAGEMENT OF MAJOR POLYTRAUMA

Major trauma is a surgical problem, and the essence of management is to take control and stay in control of the trauma and 4 limit further harm. From the orthopedic point of view, this means that it is essential to gain control of the skeletal instability. This concept has developed through studies focused on the femur fracture, which has become the index injury in this regard. Essentially, despite the development of long-bone nailing by Kuntscher[15] in the 1940s, though till the late 1980s most Western surgeons generally believed that seriously injured patients were "too sick to operate on" and used traction devices as the primary mode of treatment for major fractures. Concern that this was not the best mode of treatment led to the term "Horizontal Crucifixion" and several early publications[15–17] suggested that early surgical stabilization of the fractures, specifically with femoral nailing was valuable. Johnson[18] confirmed this effect and showed that it appeared to be greater the more severely the patient was injured. In 1989, Bone[19] published his landmark paper, a prospective randomized trial of early against late femoral nailing after severe injury. Essentially, he showed that there was a major advantage in early nailing and the pendulum now swung from nonoperative care to enthusiastic universal early skeletal stabilization after polytrauma. The patient was considered "too sick not to operate on" and a management philosophy now termed "Early Total Care" developed. This practice was soon questioned, specifically in Germany where the orthopedic trauma surgeon is closely involved with intensive care and inevitably observed the combined effect of other injures. Pape et al.[20] again considering the femur, looked specifically at the effect of early and late femoral nailing in severe polytrauma and showed a deleterious effect of an associated chest injury in association with femur fractures treated by early reamed nailing. While statistically the effect seemed more related to the chest injury than the nailing, this alerted the profession to the combination effect of these injuries and stimulated an outpouring of research looking at the general and immunologic effects of orthopedic procedures and specifically of reaming the femur.[21–36] Eventually, an understanding of the general effects of polytrauma and bony injury has become more widely accepted and a concept of the appropriate surgery (damage control orthopedics [DCO]) for the most severely injured patients developed.

Damage Control Surgery in Orthopedics

Damage control in orthopedics means taking control of the musculoskeletal elements of the injury without creating an increased trauma load due to increased surgical bleeding or a lengthy surgery associated with definitive care of complex fractures (**Fig. 28.2**). The priorities are hemorrhage control, wound management, tissue revascularization (including compartment decompression), and general restoration of major skeletal stability usually by the rapid application of external fixators. The basic physiologic parameters are then normalized in a critical care environment unit and definitive stabilization is delayed until the peritraumatic immunologic storm has settled.[25,26,28,29] The most critical element is the speed and accuracy of the initial surgery as the critical injured patient cannot tolerate a long orthopedic procedure. However, the principle of establishing early skeletal stability remains; this is the major lesson from Johnson and Bone[18,19] and is not disputed. The issue is not if, but how this is obtained. Today's question is how do we identify which patients are too sick for what? Long orthopedic procedures and protracted bleeding must be avoided and nailing the femur in a sick, under resuscitated patient seems to be particularly poorly tolerated. A variety of parameters have been investigated to understand this,[25] despite early enthusiasm, interleukin-6[24] has proved mainly to be a research tool and today a spectrum of parameters considering the patient's general condition are commonly used.[30] This essentially means close communication and protocol agreement with the anesthetic/general trauma team to decide what extent of surgery should be done. Basic parameters to be considered include the hemoglobin/hematocrit, ventilation parameters, platelet count and coagulation studies, patient temperature, and a measure of acidosis, usually the lactate level. The latter is now the primary decision-making parameter used by many orthopedic surgeons. Currently, Vallier et al.[30] have suggested a lactate level of 4 mmol/L is a safe cutoff above which it is not safe to continue surgical reconstruction and only DCO can proceed (**Table 28.3**). If DCO has been performed to obtain temporary skeletal stability, it is accepted that the definitive reconstruction should be delayed until the patient is well enough, usually at least 5 days.

Figure 28.2 Early damage control of extensive limb injuries with external fixation.

Table 28.3 Essential Priorities in Orthopedic Damage Control

Principle	Example
Surgical hemorrhage control	Direct control, pelvic packing, long-bone stabilization
Cavity decompression	Compartment syndrome
Debridement/decontamination	Major open wounds/fractures
Revascularization	Repair vascular injury to revascularize the limb if patient is well enough, if not amputate
Fracture stabilization	Usually rapid external fixation of major long-bone injury/pelvis
Critical care	Ongoing resuscitation, rewarming, and factor replacement prior to delayed secondary surgery
Delay reconstructive surgery	Conversion of external fixation to nails, definitive joint reconstruction

Special Polytrauma Situations—Head Injury

There are specific scenarios that change priorities, the most obvious being the associated head injury. When the brain is at risk, the primary aim of care is to maintain cerebral oxygenation and cerebral perfusion pressure (CPP). Orthopedic procedures, especially those that would lead to bleeding, swings in blood pressure and thus episodes of reduced CPP should be avoided. However, this does not eliminate the benefit of the stable skeleton in general critical care such that DCO and appropriate bony stabilization at the right time are still strongly indicated.[37,38]

Special Polytrauma Situations—Chest Injury and Femur Fractures

The effect of the chest injury is discussed above. It was emphasized by Pape and Tscherne and innumerable papers that followed.[20] While multiple studies have shown the advantages of early skeletal stabilization, there is no doubt that the lungs are vulnerable to further insults after injury, and that the acute lung injury can be worsened by fat embolization especially during instrumentation of the femoral canal. While improvements in reamer design reduce canal pressurization and smaller nails have been advocated, delaying definitive nailing for 5 days after initial external fixation in the most critical patient is probably the standard of care. The patient with bilateral femur fractures is at a significantly increased risk and some surgeons avoid bilateral femoral nailing at the same time even in healthy patients.[39–42]

SPECIFIC ORTHOPEDIC SCENARIOS

Major Wounds

The ongoing effect of major wounds can be critical. In the first instance, debridement of necrotic tissue from the trauma is essential and is commonly inadequately done at the initial surgery. Wounds will never stabilize until adequately excised and when associated with fractures, will not heal until bony stability has been established. The management of open fractures is described below; in polytrauma cases the principles remain the same but the ability to obtain early definitive care may be compromised by the patient's general situation.

ORTHOPEDIC TRAUMA SURGERY TO SAVE LIMBS

Open Fracture Principles

Open fractures can range from simple to destructive injuries but in all, the important feature is that the fracture hematoma communicates with the outside environment and the fracture is contaminated. As such, the specific management revolves around limiting the chance of this contamination converting to established infection. General measures include the provision of tetanus cover, early broad spectrum antibiotics, early splintage, and wound dressing and are followed by early surgical management. The latter is designed to reduce the degree of contamination, to remove necrotic or threatened tissue likely to become infected, and to protect the limb by making it unlikely to develop further infection due to an unstable open wound (**Tables 28.4** and **28.5**).

Table 28.4 Op en Fracture Surgical Principles

Debridement to healthy margins and profuse lavage/decontamination
Bony stabilization
Early, healthy soft tissue cover

The debridement of an open fracture is one of the most difficult surgical procedures; it should not be relegated to inexperienced staff and, if possible, not attempted out of normal hours unless the limb is very seriously threatened. The whole zone of injury must be assessed and all dead and dying tissue removed, only nerve and vessel must be preserved and poor muscle specifically removed. It may more appropriately be termed wound excision. Any free bone or fragments attached by flimsy soft tissue should also be removed and the resulting defect dealt with accordingly, although only rarely is a significant defect produced. Wound extensions need to be placed with specific consideration for the later closure and must not make the soft tissue reconstruction more complex. An adequate appropriate debridement must be performed the first time. Repeated debridements “to make sure” are a result of an inadequate initial operation and massively increase delay and the infection rate. This should be avoided at all costs.

Establishing early bone stability is essential, this reduces the chance of late infection and facilitates the subsequent soft tissue reconstruction. In truth, the ability to perform an adequate debridement and the best bony reconstruction depends directly on the orthopedic surgeons’ confidence in the

subsequent soft tissue closure and thus the working relationship with the plastic surgery team. While soft tissue reconstruction is often delayed for practical reasons, there is excellent evidence that the earlier a healthy closure is obtained the better. This is true to the extent that the best data in the most complex (IIIb) injuries are with immediate flap cover after an adequate initial debridement and definitive bony reconstruction as one primary procedure (**Fig. 28.3**). Few units can achieve this at primary presentation, such that definitive debridement, fracture stabilization, and appropriate soft tissue assessment at the primary procedure followed by definitive soft tissue cover at the second visit to the OR (at about 48 hours) after the patient has been appropriately counseled is probably the best achievable standard. Cooperative care with the plastic surgical service from the start is essential.[44–50]

Table 28.5 Open Fracture Classification (after Gustillo & Anderson[43])

Grade I	Small low-energy wound <1 cm, no high-energy features
Grade II	Small low-energy laceration over fracture 1–10 cm, no high-energy features
Grade IIIa	High-energy open fracture (degloving, periosteal stripping, bone comminution) with adequate soft tissue cover
Grade IIIb	High-energy open fracture with inadequate soft tissue cover
Grade IIIc	Any open fracture with a vascular injury requiring repair for viability

Figure 28.3 **A–E:** Management sequence of a major open fracture. This is a III-C injury in a 12-year-old treated by immediate "fix and flap" incorporating the anastomosis for the latissimus dorsi free flap into the vascular repair. The subsequent course shows good soft tissue and bony healing.

VASCULAR INJURIES

An acutely ischemic limb with a fracture or dislocation is a major surgical emergency. At presentation, all fractures must have the distal circulation assessed and documented; if the blood supply is affected, the fracture or dislocation must be rapidly reduced. Fortunately, this commonly results in restoration of circulation and normal fracture care can continue. If not an emergent, combined vascular–orthopedic procedure is required. Sometimes a temporary shunt will be used to obtain distal flow while a bony reconstruction is performed. Bony stability at the correct length must be obtained before definitive vascular reconstruction, both to allow the vascular repair to be at the correct level and tension, and to protect it from disruption. Any subsequent reconstruction must be done with provision for awareness and care of the vascular repair and should include fasciotomy to prevent reperfusion compartment syndrome.

COMPARTMENT SYNDROME

A compartment syndrome is a major surgical emergency as the muscle is acutely ischemic due to an increased compartment pressure reducing tissue perfusion to below a critical level. Accordingly, the classical presentation is pain out of proportion to the injury due to the muscle ischemia. The compartment may be obviously hard with loss of muscle function and distal neurologic symptoms due to pressure on the nerves passing through the compartment. Loss of arterial flow through the compartment is exceedingly rare and not useful diagnostically, the presence of a distal pulse does not contribute to the diagnosis of compartment syndrome. While the diagnosis is often clinical and straightforward, a formal measurement of the perfusion pressure of the compartment (similar to CPP in head injuries) has been popularized by McQueen.[51] Assessing the anterior compartment of the lower leg after tibial fractures with constant compartment pressure monitoring, they showed that if the compartment pressure remained at least 30 mm Hg below the diastolic blood pressure (known as the D*p* >30), the consequences of compartment syndrome (muscle necrosis and contractures) did not occur. Accordingly, today the definitive test for compartment syndrome is a direct measurement of the compartment pressure and comparison to the diastolic pressure. This is particularly seen in situations when the patient is not able to respond appropriately to pain. These include, during anesthesia, particularly under regional anesthesia; patients sedated on intensive care; patients where any strong analgesia is being used; or if the patient is poorly responsive after a medication overdose.[52] The diagnosis must not be missed, as immediate fasciotomy is needed to restore muscle perfusion.

Rarely, compartment syndromes present late when muscle necrosis is established. There will be a high creatinine kinase level, myoglobinuria, and even frank renal failure if several compartments are involved. If compartment syndrome is established at presentation, perhaps if diagnosed after 12 to 24 hours, fasciotomy is not indicated as it will only expose the necrotic compartment to infection. Unless deemed that muscle debridement is the only way to reduce the myoglobin level and reduce the renal damage, the tight limb should be simply observed and the subsequent distal contracture more safely dealt with later by specific muscle or tendon releases.[53]

INDICATIONS FOR AMPUTATION/FAILURE OF RECONSTRUCTION

The indications for amputation can be remembered as the three "D's" referring to a limb that is "Dead," "Dangerous," or a "Damn" nuisance. In the early trauma situation, this may be clearly obvious and early amputation may be lifesaving while the latter refers to later reconstructive scenarios. While limb salvage is always the aim, the injury may be too severe and should not be attempted if it puts life at risk. This requires experienced decision making at the acute stage and, when possible, agreement between staff surgeons. In an isolated injury situation, the decision essentially depends on the degree and site of necrotic tissue and the functional potential of the limb after reconstruction. This can be a most difficult decision and should be made by a surgeon experienced in reconstructive options and their functional outcome. In many situations, an amputee will function as well as, if not better than a poor reconstruction especially if several muscle compartments have been lost. This is clearly a decision for experienced staff and should involve the patient as much as possible. The application of a temporary external fixator to the critically injured limb with a view to appropriate discussion prior to initiating further treatment has much to recommend it.

ORTHOPEDIC TRAUMA SURGERY TO LIMIT DISABILITY—MANAGEMENT OF FRACTURES

6 The management of fractures has been a core medical discipline for millennia and has developed from primitive bone setting, through the guild of army barber surgeons to the modern day orthopedic traumatologist. In general orthopedic practice today, almost half of the work is the care of injury and in most modern trauma centers 80% to 90% of the surgical care of the injured falls to the orthopedic service.

Fortunately, fractures have an intrinsic tendency to heal and bone is one of only two tissues to heal by reforming its own tissue and not with a scar. There are four essential phases in fracture management: assessment, position,

healing, and rehabilitation. The first mandates a full limb assessment with documentation of the relevant clinical signs. This must include assessment and documentation of the neurovascular state of the distal limb. X-rays need to be taken of the whole bone involved and centered on the fracture. For example, an x-ray of the humerus which includes the shoulder is inadequate to assess a specific shoulder injury and separate views of the relevant part must be obtained. These views must include an AP and appropriate lateral specifically of the appropriate part. In many situations, the injury anatomy is still not adequately defined by these views and specific additional x-ray views or a computed tomography (CT) scan will be required to fully understand the injury and for surgical planning. Fracture management then centers on obtaining and holding the position of the fracture through healing. Essentially, middiaphyseal fractures need to be held in a position to maintain overall length, alignment, and rotation but do not need an anatomical reduction of individual fragments. In modern practice, this is usually achieved by intramedullary nailing which also provides the relative stability needed at the fracture site and facilitates healing with callus (**Fig. 28.4**). As a contrast, articular fractures usually need a direct open approach to ensure accurate reduction of the joint surface and stabilization with absolute stability. The recovery of joint function is directly related to the quality of the reduction and provision of stable fixation to allow early motion. In this situation, the bone at the joint would be expected to heal by primary bone union without callus (**Fig. 28.5**).

Essentially, the method chosen to hold the position of the fracture will be more or less stable depending on how firmly it holds the bone. A traditional cast on the tibia will provide only relative stability but should lead to a high rate of healing with callus. There can be a very good functional recovery if an adequate position is maintained and cast complications are avoided, but it essentially provides a less reliable hold than an implant directly applied to the bone. Accordingly, the patient undergoing nonoperative management in cast has to be followed closely, often with weekly x-rays for up to a month or until the position is deemed stable. The cast then stays until bone healing is considered adequate to maintain the position faced with functional loads and the cast can be removed. A stable, painless fracture on clinical examination suggests adequate healing to stay out of cast which should be confirmed by good bone healing on x-ray.

Table 28.6 Bone Healing Timeframes

Guideline Fracture Healing Times (in Cast)	Upper Limb (wks)	Lower Limb (wks)
Children	3	6+
Adults	6	12

Nonoperative fracture management is a highly skilled art that has been practiced for years but in the developed world is used today only for stable relatively undisplaced fractures. This includes undisplaced articular fractures, low-energy nonarticular fractures, and many fractures in children who have a large capacity for remodeling during and after bone healing and obtain bony healing in about half the time adults with excellent function results (**Table 28.6**).

The phase of bone healing from fracture to a stable skeleton progresses from an inflammatory reaction through fibrous tissue and cartilage formation before immature bone and finally mature remodeling. A number of biologic stimulatory molecules and specific mechanical features then drive the normal healing response. Overall, there is a progressive stiffening of the fracture environment until bone can form when the local strain is at or below 2%.[54,55] This may be produced by the gradual tissue stiffening provided by the natural healing process or by an orthopedic implant that creates a local strain environment in conjunction with the specific fracture anatomy and intrinsic fracture stability. Normal healing with splintage or with devices that produce relative stability (some fracture motion under physiologic loads) lead to the progressive stiffening effect described briefly above and healing by callus when the strain reduces to a level where bone can form. If an implant confers absolute stability, usually through direct compression of the fracture surfaces, the strain is less than 2% from the start and the bone heals by a modified remodeling process termed "primary bone healing," callus does not form. In planning a bony reconstruction, the surgeon specifically decides what degree of stability is required to treat a specific fracture 7 and the appropriate implant to do this. This follows basic AO[56,57] principles which are the key to

fracture surgery. Essentially, diaphyseal fractures need treatment with relative stability and indirect reduction techniques to maximize the local healing process. In contrast, articular fractures usually require a direct reduction for perfect anatomy and subsequent fixation with absolute stability (no deformation occurs under physiologic load) to facilitate joint recovery.

The rehabilitation process should be considered as soon as the soft tissues are stable enough to allow dependency and joint motion. This confers the major advantages of mobility to the limb and whole patient. With articular fractures, the cartilage is only nourished by diffusion from joint fluid which is effectively pumped into the hyaline cartilage as a secondary effect of motion. Accordingly, fracture fixation must be stable enough to allow early range of motion (ROM) exercises as tolerated but weight bearing is usually limited to protect the reconstruction from early displacement.

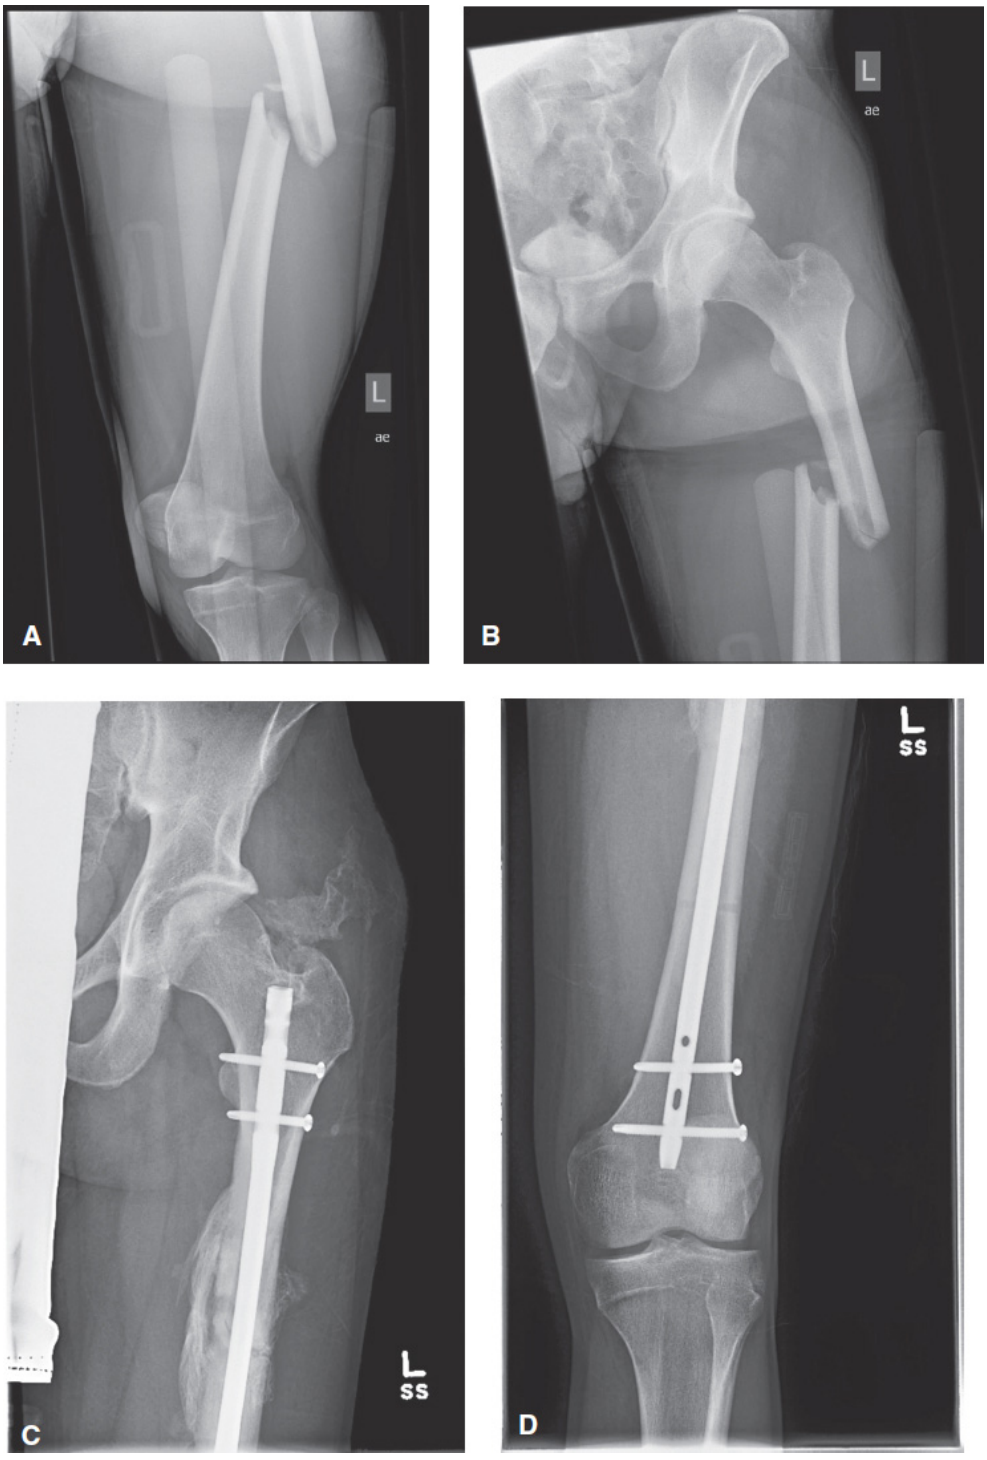

Figure 28.4 Assessment and surgical management of a diaphyseal fracture of the femur. **A, B:** Anteroposterior x-rays of a diaphyseal femur fracture. **C, D:** Reamed fully locked intramedullary nailing of a diaphyseal femur fracture showing progressive healing.

Complex Articular Fractures

Major joint injuries are significant threat to joint function.[58–60] The aim of care involves articular reconstruction with perfect joint anatomy and stable fixation with absolute stability. Surgical reconstruction often requires detailed preoperative assessment with a CT scan and application of specific implants often designed for the specific joint and side involved. The basic principles used for surgical reconstruction of these injuries were developed over 50 years ago by the AO and have only seen minor modifications since. However, modern implants and particularly the development of locking plates have improved the capability of our implants to hold fractures securely and specifically allow fractures to be held in position with less extensile exposures. Occasionally, the primary injury (even if closed) is associated with significant degloving of the local soft tissues, manifest by major fracture blisters and precludes an early open surgical approach.[61] Surgical management then takes the form of temporary bridging external fixation, applied outside the zone of injury which confers some stability and allows the soft tissues to settle prior to conversion to an internal fixation often after 1 to 2 weeks. However, in most fractures, excellent results can be obtained by much earlier surgery which is much easier than a delayed reconstruction.[61]

SPECIAL FRACTURE GROUPS—PROXIMAL FEMUR

Like many injuries, fractures of the proximal femur have a bimodal distribution with rarer high-energy injuries in the young and extremely common bone fragility fractures in the elderly. As a public health issue, osteoporosis and its related fractures are at epidemic proportions.[63] The general medical care of the elderly dominates the clinical picture where the mortality is of the order of 15% to 20% in the 3 months after fracture, and the injured frail elderly produce a major load on hospital and rehabilitation services. In addition, specific attention to long-term bone health is essential. The orthopedic issues of proximal femoral fracture take two forms and produce specifically different problems and solutions. The fractures

essentially occur inside (intracapsular) or outside the hip capsule (extracapsular). Intracapsular fractures carry a risk of avascular necrosis (AVN) of the femoral head depending on the displacement of the fracture, while intratrochanteric fractures are mechanically unstable due to the anatomy and offset of the proximal femur creating marked mechanical instability with a tendency to collapse into varus.

Figure 28.5 Assessment and surgical management of a complex articular fracture of the distal tibia (pilon). Despite virtually anatomic reduction, it progresses to degenerative arthritis in the medium term. **A, B:** AP and lateral x-rays of an intra-articular fracture of the distal articular surface of the tibia. **C, D:** CAT scans show the marked damage and displacement at the joint surface, underappreciated by initial x-rays. **E:** Open reduction and internal fixation to restore the joint surface for function and joint longevity. **F:** After healing and removal of the majority of the hardwear, there is significant degenerative arthritis of the joint that may need joint arthrodesis.

Intracapsular fractures (femoral neck) are classically classified by Garden.[64] Garden grade 1 and 2 injuries are essentially undisplaced and carry a low risk of AVN, they are usually treated by fixation unless the patient's bone quality is considered too poor for fixation. In that situation and in displaced fractures (Garden grade 3 and 4), a replacement of the femoral head with hemiarthroplasty or total hip replacement in a biologically younger patient is required.[65,66]

Extracapsular fractures (trochanteric) are mechanically unstable. They will collapse into varus without fixation and have a tendency to settle and shorten with healing due to the intrinsic bone weakness and pull of local muscles. Accordingly, fixation devices need the ability to mechanically control the angle of the femoral neck and accommodate some shortening without protrusion of the device into the hip. The instability is associated with the degree and position of any comminution which also indicates which device is appropriate to use. Essentially, a sliding hip screw device can be used for any trochanteric fracture unless the lateral wall is incompetent (reverse obliquity injuries or their equivalent) or where there is subtrochanteric extension. In these cases, an intramedullary nail with a retrograde locking device is specifically indicated, although many surgeons use these nails for most fractures. When using a sliding hip screw for a trochanteric fracture, it is essential to get the tip of the screw close to the articular surface.[67,68]

COMPLICATIONS

Infection Nonunion and Malunion

Specific healing problems may require later specialist care.[69] Infection is unfortunately common after complex fracture care, especially if the initial injury was open. Failure of healing (nonunion) is not usually diagnosed before 6 months and commonly suggested by persistence of pain on loading and failure of progression of bone healing on x-ray. Malunion is assessed with regard to the specific deformity and may require corrective surgery for limb alignment, joint function, or longevity. Commonly, infection and failure of bone healing occur together. In principle, infection after fracture creates a

similar situation to osteomyelitis with acute and chronic clinical pictures. In general, the management of infection involves the same principles as the management of open fractures with debridement and lavage, skeletal stability and healthy soft tissue cover; with the addition of long-term antibiotics guided by perioperative cultures and under the supervision of an infectious disease specialist. Again, adequate debridement of the poor often dead infected bone, the provision of bony stability and healthy soft tissue cover is the key to management.

Surgical management of the acute infection before fracture healing involves urgent washout of the wound, biopsy, cultures, appropriate antibiotics, and healthy wound management, often necessitating delayed primary closure after a secondary washout. While unstable fixation should be removed and stability restored, stable fixation should be maintained even if superficially contaminated until adequate fracture union. An implant can then be safely removed and usually any residual infection eradicated. Chronic infection with a united fracture needs similar treatment but if the fracture is stable, the key here is removal of a contaminated implant and debridement of dead bone to remove the source of infection. Local washout and healthy soft tissue closure then proceeds as above. However, in the chronic situation, affected tissues are stiff and nonpliable such that bone and soft tissue debridement may produce a dead space, soft tissue defect, or skeletal instability with a bony defect, each of which may require specific management.[70,71] Unfortunately, often limb salvage carries significant morbidity and may not be the best option for the patient.

Malunions cause considerable disability and can be very rewarding to correct (**Fig. 28.6**). Each needs to be fully assessed for the specifics of the deformity and consideration to a variety of methods of correction given. There are champions of a variety of acute correction methods with an osteotomy and fixation or gradual correction usually with a ring-fixation device.

Orthopedic Injury/Disaster Triage

Given the predominance of orthopedic injuries in the injured patient and the frequency of multiple patient events, surgeons are often faced with prioritizing the care of a number of injuries in one complex patient or of a

number of patients at the same time. In common day practice, a major motor vehicle crash with several victims can stress a system and require appropriate prioritization. In major international disasters, these situations can be extreme. In these situations, simple reliable rules are needed to guide staff through the process especially when there are multiple problems to consider and the situation is critical. ATLS dealt with this superbly with the A, B, C, alphabetic system for the primary survey. While this remains an excellent system for initial patient evaluation and can guide some immediate surgical decisions, it does not help the surgeon who will have to make critical priority decisions beyond this. From the orthopedic traumatology point of view, the variety of injuries often cover the whole spectrum of clinical need and produce complex decision-making situations. The easiest way for the supervising surgeon to plan the care of an individual is to stand back and work along simple priority guidelines, asking "what is needed here to save the life," "what is needed to save a limb," and "what is disability limiting." Considering each injury in turn then allows a logical plan to be made to prioritize the care required. In multiple patient scenarios, the process is the same but modified by the number of patients involved and the medical resources available. With adequate resources, each patient's problems are dealt with individually as needed and no consideration to major disaster triage is required. If resources are available although stressed, patients with life-threatening problems are dealt with first prioritized by their individual acuity while others with important but initially stable issues can be managed later. In the massive disaster situation, priorities change, resources are overwhelmed, and first priority is given to the group of patients who will gain the most while not tying up or exhausting scarce resources. This is extremely difficult to do as the critical patient who would often be dealt with first if more resources were available is not prioritized as their care would swamp the resources available and not allow simpler care to many others.[53] Going into situations (such as the immediate medical relief after the 2010 Haiti earthquake) without preplanning or the experience to deal with difficult decisions like this is not advisable.

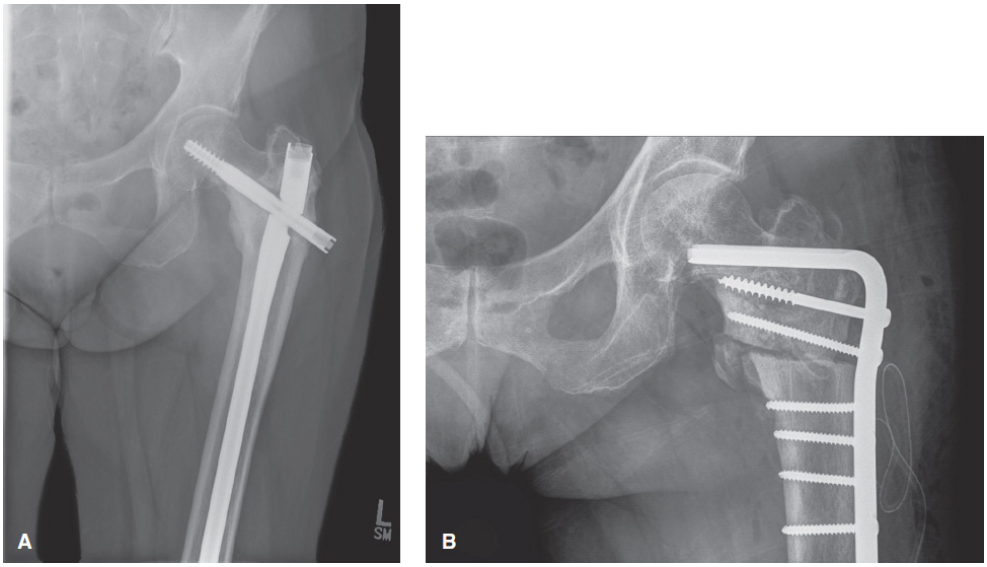

Figure 28.6 Assessment and surgical management of a proximal femoral malunion after implant failure. **A:** Proximal femoral malunion (collapsed into varus) with a broken implant in place. **B:** Correction of the malunion with a valgus osteotomy held with a blade plate.

Pediatric Trauma

Peter T. Masiakos, Cornelia L. Griggs, and Danielle B. Cameron

Key Points

1. **Epidemiology:** Pediatric trauma remains a significant public health problem. Traumatic injuries are the top cause of mortality for children and adolescents in the United States and account for more than 50% of deaths in children younger than 18 years. Management strategies should include emergency medical care as well as injury prevention and systems of trauma care to meet the needs for pediatric patients.
2. **ABCs:** The primary survey should focus on the identification of acute life-threatening injuries. Attention to the airway, breathing, and circulation (ABCs) supersedes all other interventions in the initial resuscitation phase. Centers that care for children should have pediatric resuscitation equipment, such as appropriately sized endotracheal tubes, laryngoscopes, catheters, passive warming lamps, and the Broselow Pediatric Emergency Tape which aides in estimating the weight of the child and facilitates safe, weight-based resuscitation.
3. **Nonaccidental trauma:** Nonaccidental trauma may be difficult to recognize, and a high index of suspicion is needed when evaluating children with injuries. The American Academy of Pediatrics guidelines published in 2015 provide a resource to help identify these children, because unrecognized cases of abuse can represent with serious or even fatal injuries.
4. **Injury prevention:** As policy makers struggle to allocate limited resources to improve population health, injury prevention programs will play a particularly important role. Regulatory efforts specifically aimed at primary and secondary injury prevention, can reduce health care cost, thereby freeing resources for other concerns.

INTRODUCTION AND EPIDEMIOLOGY

Pediatric trauma has a significant impact on the lives of children and families in the United States and around the world. Traumatic injuries remain the no. 1 killer of children and adolescents in the United States. Injury, both accidental and nonaccidental, accounts for more than 50% of deaths in children younger than 18 years.[1] The pediatric mortality rate from trauma in the United States is double that of other developed countries, and for every pediatric death there were more than 2,000 emergency department visits.[2] In the United States alone, more than 50,000 children are permanently disabled after trauma, most commonly as the result of traumatic brain injury (TBI).[2] According to data that are now longer than 20 years, these disabilities account for $14 billion in lifetime medical spending and $66 1 billion in future wages lost.[3] Therefore, pediatric trauma is a significant public health problem, and management strategies that should target not only emergency medical care but also injury prevention and systems of trauma care to meet the needs for pediatric patients.[3]

Although there is a rise in the incidence of penetrating trauma, which now accounts for up to 10% to 20% of trauma activations, the vast majority of pediatric injuries result from blunt trauma with associated closed head injuries that require nonoperative management.

TRAUMA SYSTEMS

The concept of a trauma system was shaped by the publication of a U.S. government report in 1966 "Accidental Death and Disability: the Neglected Disease of Modern Society"[4] and has led to improvements in infrastructure, processes of emergency response, communication, and outcome measurements and quality indicators of responding hospital centers. The Committee on Trauma first categorized Trauma Center designations in 1976.[2] The first Pediatric trauma centers were organized in the 1970–1980s; however, even today in the United States, there are too few designated pediatric trauma centers to care for all pediatric trauma patients. The vast majority of pediatric patients are cared for at adult trauma centers,[5,6] the exchange of ideas between adult and pediatric trauma centers and the development of integrated regional trauma systems remain critically important for our care of injured children.[2,7]

Inclusive trauma systems are comprised of facilities within a region according to a tiered-triage system. Each participating facility receives a level designation, and this is used to appropriately triage and refer patients as necessary. Along with these regionalization efforts, advances in pediatric transport have also improved how we care for injured children. Inclusive systems have been shown to improve outcomes because more timely and appropriate transfers can occur. It has become increasingly important to develop and study various "performance indicators" of the quality of care that is delivered to injured pediatric patients. For example, rate of successful splenic salvage is a commonly cited quality indicator in pediatric trauma, and there are reports that children cared for at an adult trauma center have a fivefold higher risk of splenectomy than those at pediatric trauma center.[6,8,9] Beyond benchmarking mortality rates, other measurable quality indicators include availability of a pediatric intensive care unit with in-house intensivists, radiation exposure from imaging, early neurosurgical intervention for severe head injury, early fixation of femur fractures, operative rates for solid organ injuries, and participation in registry databases to monitor performance over time, such as the Trauma Quality Improvement Program set up by the American College of Surgeons-Committee on Trauma.[10,11] It is unclear whether superior care is offered to injured children in a dedicated pediatric hospital, compared to an adult hospital; however, it has been demonstrated that pediatric trauma certification and expertise in care of trauma patients are both important factors in optimal care.[12–17]

INITIAL ASSESSMENT, RESUSCITATION, AND STABILIZATION

The evaluation and treatment of traumatic injuries of infants and children requires specific knowledge of pediatric physiology and the physiologic response to injury. Generally, the trauma resuscitation of children follows similar rules that have been described for adults by advanced trauma life support standards. However, there are several special considerations in the

initial assessment and subsequent care for children and specific paradigms regarding ancillary studies that are different from those in adults.

As in adults, the primary survey should focus on the identification of acute life-threatening injuries. Attention to the airway, breathing, and circulation (ABCs) is critical in the initial resuscitation phase (**Table 29.1**). All centers that care for children should have sequestered resuscitation equipment designed for children, that is, endotracheal tubes (ETTs), laryngoscopes, catheters, and passive warming lamps. Room temperature should be kept warm to limit insensible heat losses in small children. The Broselow Pediatric Emergency Tape aids in estimating the weight of the child by measuring his or her length. A color-coded bar on the tape measures the length of the child and indicates the appropriate equipment sizes and medication doses to perform emergency resuscitation on the child. Designated resuscitation equipment is contained in corresponding, color-coded equipment pouches or drawers (**Fig. 29.1**).

Vital Signs

Pediatric vital signs vary by age (**Table 29.2**). Children are able to maintain normal blood pressures until late hemorrhagic shock (>30% blood loss), and, therefore, subtle changes in heart rate and respiratory rate must be noted. As a general rule, the lower limit of acceptable systolic blood pressure = (Age × 2) + 70 mm Hg. For newborns, acceptable systolic blood pressure is 60 mm Hg or greater. Initial fluid resuscitation is indicated when there are signs of hypovolemic shock.

2 **Table 29.1** Pediatric Resuscitation ABC's

Airway "A"

- Cardiac arrest most often of respiratory etiology
- Use jaw thrust technique and in-line cervical stabilization
- Key anatomic differences: larger tongue, more narrow and anterior glottis, and shorter trachea
- Miller blade may be easier than the curved Mac blade because the epiglottis is floppy
- Size of ETT can be estimated by the size of pinkie finger or Broselow Pediatric Emergency Resuscitation Tape
- Consider using an uncuffed ETT in a child less than 8 yrs or 60 lb
- With acute airway obstruction, needle cricothyroidotomy with a 14 g catheter is preferential to open cricothyroidotomy

Breathing "B"

- Assess for potential life-threatening thoracic injuries: pneumothorax (open chest wound or tension pneumothorax), hemothorax, flail chest/pulmonary contusions, and rib fractures
- Mediastinum of a child is very compliant and can lead to rapid decline from a tension pneumothorax
- Children are diaphragmatic breathers; ensure stomach is decompressed with nasogastric tube or orogastric tube in infants, who are obligate nose breathers

Circulation "C"

- Hemorrhage is the most common etiology of circulatory compromise in trauma
- Also consider obstructive etiologies (cardiac tamponade and tension pneumothorax) and distributive etiologies (neurogenic shock)
- Assessment of volume status and shock is difficult because children have impressive physiologic reserve
- Tachycardia, tachypnea, altered level of consciousness, and poor peripheral perfusion (mottled cool extremities, weak thready pulses, narrowed pulse pressure, delayed capillary refill) are early but subtle signs of blood loss
- Peripheral intravenous lines are ideal, but when they cannot be obtained, intraosseous lines are quick, reliable, and allow high-volume infusion of any fluid

- Definitive intravenous (IV) access can be obtained with a central line
- Initial fluid resuscitation is indicated when there are signs of hypovolemic shock. Initial bolus consists of 20 mL/kg of warmed normal saline or lactated Ringer solution
- After two initial boluses, all subsequent volume resuscitation should be performed with blood products (10 mL/kg = "1 unit") (**Table 29.3**)
- Massive transfusion protocols may be initiated if indicated
- Once resuscitated, maintenance fluid requirements (**Table 29.3**) can be estimated using the "4-2-1" rule and isotonic fluids should be administered for all children greater than 28 d

Disability "D"

- Perform a brief neurologic assessment
- Head injury accounts for the highest degree of morbidity and mortality in children
- Secondary insults include ischemia, hypoxia, hypotension, hyperthermia, hypercapnia, acidosis, and increased intracranial pressure (ICP)
- The Glasgow Coma Scale (GCS) is modified in young children who are preverbal to measure neurologic function and prognosis. The motor response scale tends to provide the most reliable assessment of function in a preverbal or intubated child (**Table 29.4**)

Exposure ("E")

- Allows for a complete head-to-toe physical examination
- Children have a larger body surface area ratio and, therefore, lose heat and water quickly and can become hypothermic
- Use warm fluids, bare huggers, warming lights, and warm ambient room temperature to prevent heat loss

Figure 29.1 Broselow pediatric emergency resuscitation tape.

Fluid Resuscitation

Initial bolus consists of 20 mL/kg of warmed normal saline or lactated Ringer solution. This may be repeated if there is no response or only a transient response. All subsequent volume resuscitation should be performed with blood products (10 mL/kg = "1 unit") (**Table 29.3**). If there is no time for cross-matched, type-specific blood, "O-negative" blood is indicated. Massive transfusion protocols may be initiated at this time if indicated and should include hemostatic resuscitation with packed red blood cells, fresh frozen plasma, and platelets, targeting high plasma-to-red blood cell and platelet-to-red blood cell ratios.[18] In the most recent advanced trauma life support protocols, this has become known as "damage control resuscitation,"[19] espousing permissive hypotension, minimizing crystalloid resuscitation, and promoting early blood product administration for the treatment of the lethal triad (acidosis, coagulopathy, and hypothermia) of severe uncontrolled hemorrhage. There is, however, no evidence-based support for permissive hypotension strategies in pediatric trauma patients. As

in adults, ongoing hemodynamic instability from blood loss in a child must be controlled expeditiously. Sources of bleeding can be thought of in terms of body compartments: including the chest, peritoneal cavity, retroperitoneum/pelvis, femur fracture/thigh compartment, and external injury (especially the scalp). In an infant, prior to suture closure of the skull, intracranial hemorrhage may produce hemodynamic instability. Once resuscitated, maintenance fluid requirements (**Table 29.3**) can be estimated using the "4-2-1" rule and isotonic fluids should be administered for all children >28 days (**Fig. 29.2**).[20]

Table 29.2 Pediatric Vital Signs

	Pulse (Beats/Min)	Systolic Blood Pressure (mm Hg)	Respiration (Breaths/Min)
Newborn (<1 mo)	95–145	60–90	30–60
Infant (1 mo to 1 yr)	125–170	75–100	30–60
Toddler (1–2 yrs)	100–160	80–110	24–40
Preschool (3–4 yrs)	70–110	80–110	22–34
School age (4–12 yrs)	70–110	85–120	18–30
Adolescent (>12 yrs)	55–100	95–120	12–16

Table 29.3 Fluid Management in Children	
Resuscitation Fluids (NS or LR)	
If hypotension or signs of shock:	Bolus 20 mL/kg. Repeat if transient or no response and then switch to blood transfusions (10 mL/kg)
Daily Maintenance Fluid Requirements (D5 1/2NS or D10 1/2NS)	
Weight <10 kg	100 mL/kg/d
Weight 11–20 kg	1,000 mL + 50 mL/kg/d (for every kg over 10)
Weight >20 kg	1,500 mL + 20 mL/kg/d (for every kg over 20)

SECONDARY SURVEY AND ADJUNCT DIAGNOSTIC MODALITIES

Only after the primary assessment is complete, and ABCs are secured, do we move on to the full secondary survey. In reality, with a team approach to management of the pediatric trauma patient, much of the supportive care happens concurrently with the primary and secondary surveys, including placement of intravenous lines, drawing laboratories, applying monitors and oxygen, and obtaining ancillary diagnostic tests. Adjunct diagnostic modalities and imaging may be used to provide additional information in the evaluation of a pediatric trauma patient. Although diagnostic peritoneal aspiration has been traditionally used to evaluate intra-abdominal injuries in the unstable patient, it has no role in the pediatric population where solid organ injuries are unlikely to require surgery. Focused assessment with sonography in trauma (FAST) examination has significant advantages over more invasive diagnostic maneuvers: the FAST examination can be performed quickly and exposes the patient to no potential harm from delay or ionizing radiation. However, children with intra-abdominal injuries are more frequently managed nonoperatively, and thus the need for rapid decision

making regarding operative management is less common. Children also have a relatively higher incidence of solid organ injury without free fluid, and consequently, a negative FAST examination may not obviate the need for an abdominal computed tomography (CT) when there is a clinical suspicion of significant injury. The FAST examination should not be relied on as a stand-alone screening tool in the pediatric population.[21,22] The utility of the FAST exam in pediatric trauma continues to evolve. To date, the largest prospective trial of FAST in stable pediatric trauma patients showed no evidence of benefit, leading the authors to conclude that their findings do not support the routine use of FAST among hemodynamically normal children treated in an ED following blunt trauma.[23] Despite this, FAST represents an emerging area of study in pediatric trauma and continues to be an integral part of pediatric trauma algorithms. Findings from chest radiography, anteroposterior pelvis radiography, and the FAST examination, along with the primary and secondary surveys, guide decisions regarding further radiographic examination, including CT or plain radiography.

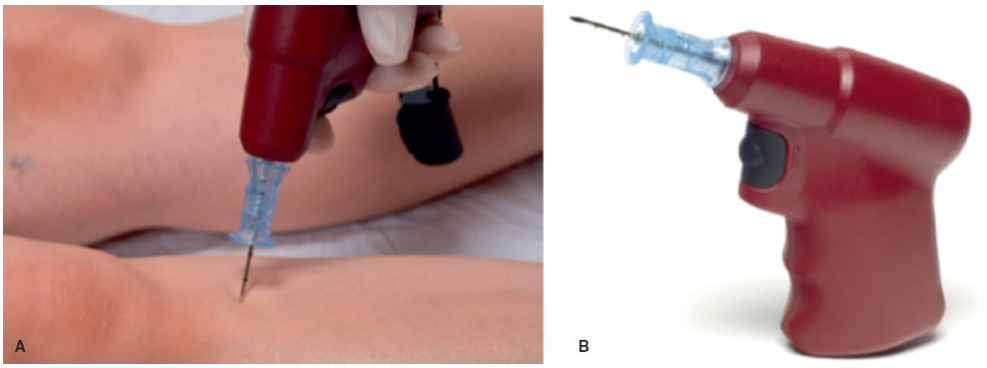

Figure 29.2 **A:** Intraosseous line placement. **B:** EZ-IO drive.

In addition to a full physical examination, a brief history is essential and is often provided by emergency medical services (EMS) personnel or the parents. An "AMPLE" history helps the provider focus on essential information such as Allergies, Medications, Past medical history, Last meal, and Events surrounding the traumatic incident. Blunt trauma is the most common mechanism after which children present for evaluation. Children are more prone to multisystem trauma due to their small body size and more compliant body (less protective bones, muscle, and torso fat). Blunt trauma can result in injury patterns that resemble penetrating injuries, without

significant external signs of trauma. Careful attention to a bruise on the abdominal wall resulting from a bicycle handlebar should lead to a more thorough investigation of the abdomen. A lap belt mark across the abdomen may raise concerns of lumbar spine fracture (Chance fracture), with an associated risk of small bowel injury. A history of significant hemorrhage at the scene may instigate a more thorough investigation of the vessels in the proximity of injury in an otherwise hemodynamically stable patient who has no hard signs of vascular injury. Therefore, a thorough history, mechanism of injury, and focused examination of the entire child is mandated so that signs of forceful impact can be elucidated.

MANAGEMENT OF SPECIFIC INJURIES

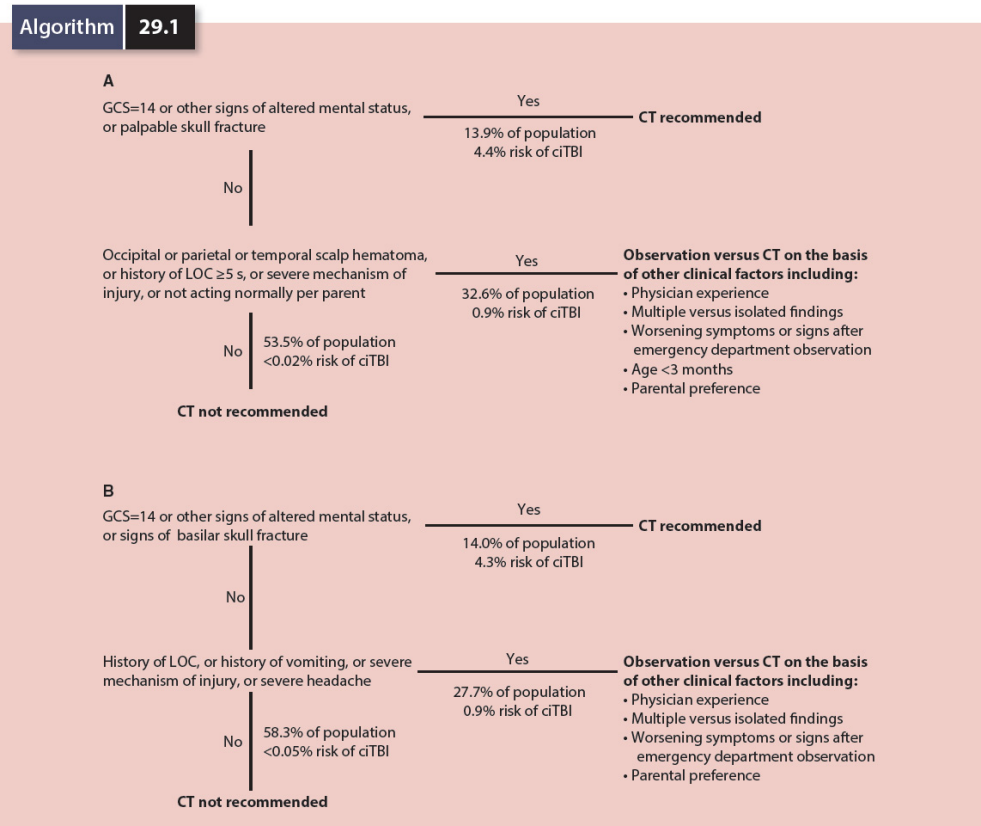
Traumatic Brain Injury

Traumatic brain injury is the leading cause of death and disability in children,[24–26] and is an important determinant of outcome. Nonaccidental trauma is the most common cause of head injury in children younger than 2 years, and blunt head trauma from motor vehicle accidents, falls, or bicycle/pedestrian accidents are responsible for most injuries in children older than 2 years. Injury prevention strategies are necessary for improving outcomes of the primary TBI. However, reduction of secondary injury patterns is critical in children, who have impressive physiologic reserve and potential for rehabilitation after brain injury. The focus must be on preserving cerebral oxygenation and perfusion, and mitigation of toxic exposures to minimize secondary brain injury. This includes treating or preventing hypotension, hypo/hyperoxia, hyper/hypocarbia with generation of ischemia reperfusion free-radicals, hyperthermia, seizures, and intracranial hypertension.

Mild Traumatic Brain Injury

Children with minor head trauma can present the greatest challenge to emergency department personnel. Eastern Association for the Surgery of Trauma (EAST) guidelines define mild traumatic brain injury (MTBI) to be

interchangeable with the term "Concussion," involving a blunt force mechanism with alteration in brain function (i.e., GCS score of 13 to 15) but by definition must have a normal head CT if performed.[27] Significant brain injuries need to be identified early and treatment instituted rapidly. CT scans provide the most accurate and expeditious means of diagnosis but expose many pediatric patients to unnecessary radiation. Evidence-based clinical decision tools have helped identify the population of children who benefit most from radiologic evaluation. The TBI study group for PECARN (Pediatric Emergency Care Applied Research Network) has developed tools for assessment of children after blunt head injury.[27–32] The "PECARN Rules"[29] (**Algorithm 29.1**) identify children at very low risk (<0.05%) of having clinically important TBI requiring intervention. These patients can avoid CT and be discharged safely with appropriate instructions. Children with abnormal GCS score (GCS score of ≤14) or evidence of skull fracture are at the highest risk for clinically important injury and should be evaluated emergently by CT scan. If there is a history of loss of consciousness, severe injury mechanism, abnormal behavior to the parent or nonfrontal scalp location (<2 years), or vomiting and severe headache (≥2 years), then further observation or CT should be offered as reasonable management options. Subsequent analyses also identified children with only isolated loss of consciousness (and no other PECARN predictors) to be at very low risk for clinically important TBI.[29] Children with MTBI (GCS score of 14 to 15) who underwent CT can be safely discharged home without further neurologic monitoring, if their head CT scan is normal.[27,30] Even those with an isolated skull fracture can be discharged home from the emergency department with strict discharge instructions and return precautions.[31–34] At this point, routine structural or functional imaging modalities such as magnetic resonance imaging, functional magnetic resonance imaging, or positron emission tomography for diagnosis or prognosis of MTBI are not supported.[27]



Algorithm 29.1 PECARN rules to identify children at very low risk of clinically important TBI. CT algorithm for children younger than 2 years (**A**) and for those aged 2 years and older (**B**) with GCS scores of 14–15 after head trauma. ciTBI, clinically important traumatic brain injury; GCS, Glasgow Coma Scale; LOC, loss of consciousness. (From Kuppermann N, Holmes JF, Dayan PS, et al. Identification of children at very low risk of clinically-important brain injuries after head trauma: A prospective cohort study. *Lancet* 2009;374[9696]:1160–1170.)

Prognosis and outcome in MTBI, especially as it relates to "return to learn or return to play" after concussion, is still hotly debated. Most studies agree that patients with MTBI return to baseline within 3 months (majority within 10 to 14 days), but certainly symptom resolution can take longer. Lingering symptoms of headache, dizziness, fatigue, sleep disturbance, impairment in memory and concentration, irritability, anxiety, or depression are referred to as the "postconcussive syndrome," which is not a well-understood entity.[27] Standardized tools exist, such as the Immediate Postconcussion Assessment and Cognitive Testing Battery (ImPACT), to aid clinicians in functional assessment of patients with MTBI.[35] The well-known NCAA Concussion Study from 2003 found that high-level athletes were more likely to sustain repeat concussions, which were associated with a longer recovery time,[36]

and it has been increasingly recognized that repeat concussions can have permanent and sometimes devastating effects. In 2010, the American Academy of Pediatrics officially endorsed the International Conference on Concussion in Sport recommendations for a graduated "Return to Play" protocol.[37,38] The CDC HEADS UP guidelines also incorporate these recommendations[39] and provide resources for schools, coaches, and primary care providers on returning to school and sports after a concussion. Data are lacking in the efficacy of these guidelines and their role in preventing recurrent concussions.[40]

Moderate to Severe TBI

More serious head injury needs to be evaluated and treated expeditiously. The GCS (and modified GCS for infants) is a universal tool that can be used for rapid assessment of neurologic function and is based on verbal response, motor function, and eye opening. Moderate TBI is considered GCS score of 9 to 12 or 13 and severe TBI includes GCS score of ≤8, the definition of a coma. The goal of initial assessment and resuscitation in a severely brain injured patient is to minimize or prevent secondary brain injury. Attention to ABCs is critical, with maintenance of normotension and normoxia. Management of severe TBI in the pediatric intensive care unit is largely focused on management of elevated ICP and maintenance of cerebral perfusion pressure.[41] In 2003 and again in 2012, guidelines for the acute medical management of severe TBI in infants, children, and adolescents were published, which represented the first recommendations made specifically for pediatric patients (**Tables 29.4** to **29.6**).[42–45] These guidelines, composed mostly of class II or III evidence, included recommendations on management of intracranial hypertension, hypoxia/airway management, indications for ICP monitoring, thresholds for treatment and management of cerebral perfusion pressure, and hypotension. It also addressed therapies such as cerebrospinal fluid drainage, hyperosmolar therapies, hyperventilation, barbiturates, decompressive surgery, temperature control, corticosteroids, and supportive care such as sedatives/neuromuscular antagonists and nutrition, although the guidelines are mostly based on expert panel opinion rather than large clinical trials. Prehospital management focused on the benefit of pediatric trauma centers rather than adult trauma centers for

children with severe TBI. Supplemental oxygen should be administered. There was no superiority of endotracheal intubation versus bag-mask ventilation in the prehospital setting, but if endotracheal intubation is to be undertaken, specialized training and the use of end-tidal CO_2 monitoring is encouraged. Hyperventilation with hypocarbia (pCO_2 <30 to 35) is to be avoided. There was class II support for ICP monitoring for children with GCS score of 8 or less; using an ICP threshold of 20 mm Hg and a cerebral perfusion pressure of 40 to 65 mm Hg; efficacy of hypertonic saline solutions in lowering ICP; and the role for decompressive surgery in the treatment of elevated ICP. From these guidelines, an algorithm for the management of acute intracranial hypertension was developed on the basis of the expert opinions of the committee (**Algorithm 29.2**), which has served as a template for clinical protocols for patient care and research. The 2012 guidelines changed a few of the recommendations (**Table 29.6**). Only hyperosmolar therapy was supported by two small studies (class II data); the remaining therapeutics could not be supported by the literature, including use of corticosteroids, immune-modulating diets, and induction of moderate hypothermia ("Cool Kids" trial).[44–47] Other topics with class III evidence were added including advanced neuromonitoring (using a brain–tissue oxygen partial pressure of 10 mm Hg), neuroimaging (avoiding routine repeat head CT unless neurologic deterioration), cerebrospinal fluid drainage, and the use of antiseizure prophylaxis (phenytoin prophylaxis) to reduce posttraumatic seizures. For a variety of other topics, including glycemic control, cerebrospinal fluid drainage, and analgesics/sedatives/neuromuscular blockade, definitive recommendations could not be made on the basis of the available literature. Overall, there is still a paucity of high-quality evidence to make specific treatment plans for children with severe TBI, but this allows for a wide variety of clinical approaches that are considered within the guidelines of pediatric care.

Table 29.4 Modified Glasgow Coma Scale in Children

	Infant	Child
Eye Opening		
4	Spontaneous	Spontaneous
3	To verbal stimuli	To verbal stimuli
2	To pain only	To pain only
1	None	None
Verbal Response		
5	Coos and babbles	Oriented, appropriate
4	Irritable cries	Confused
3	Cries to pain	Inappropriate words
2	Moans to pain	Incomprehensible sounds
1	None	None
Motor Response[a]		
6	Moves spontaneously and purposefully	Obeys commands
5	Withdraws to touch	Localizes painful stimuli
4	Withdraws in response to pain	Withdraws in response to pain
3	Abnormal flexion posture to pain	Flexion in response to pain
2	Abnormal extension posture to pain	Extension in response the pain
1	None	None

[a]If patient is intubated, unconscious, or preverbal, the most important part of this scale is motor response and should be closely evaluated.

Spine Trauma

Cervical spine injuries (CSIs) in blunt trauma pediatric patients occur in less than 2% of seriously injured children. Despite this low incidence, it is clear that many clinicians obtain radiographs in order to exclude CSI. The added benefit of routine imaging in the pediatric trauma evaluation is debatable. In recent years, concerns have been raised about the liberal use of plain films, CT scans, and magnetic resonance images in children with reference to imaging-related short- and long-term morbidity, resource consumption, and cost. The increased risk of fatal and nonfatal cancers associated with CT-related radiation has gained attention both by physicians and also by consumers. Both the U.S. Food and Drug Administration (FDA) Center for Devices and Radiological Health and the National Cancer Institute have published guidelines designed to limit unnecessary imaging in children. Although proponents of liberal imaging argue that a single missed CSI may cost more than multiple diagnostic tests, the use of non–evidence-based tests may inspire suboptimal practice with an undefined risk–benefit ratio.

Table 29.5 Summary of Standards, Guidelines, and Options Generated from the 2003 Pediatric TBI Guidelines

Topic	Level of Evidence	Recommendation
Trauma systems, pediatric trauma centers, and the neurosurgeon	Guideline	"In a metropolitan area, pediatric patients with severe TBI should be transported directly to a pediatric trauma center, if available"
	Option	"… should be treated in a pediatric trauma center or in an adult trauma center with added qualifications to treat children in preference to a level I or II adult trauma center without added qualifications …"
Prehospital airway management	Guideline	"Hypoxia must be avoided … and attempts made to correct it immediately. Supplemental oxygen should be administered … no evidence to support an advantage of endotracheal intubation over bag-valve-mask ventilation …"
	Option	"If prehospital

		endotracheal intubation is instituted …, then specialized training and use of end-tidal CO_2 detectors is necessary”
Resuscitation of blood pressure and oxygenation	Guideline	“Hypotension should be identified and corrected … defined as systolic blood pressure below fifth percentile for age or by clinical signs of shock …”
	Option	“Airway control should be obtained in children with a GCS ≤8 to avoid hypoxemia, hypercarbia and aspiration … hypoxia should be identified and corrected … blood pressure should be monitored frequently and accurately …”
Indications for intracranial pressure monitoring	Option	“ICP monitoring is appropriate … (GCS ≤8). The presence of an open

		fontanelle and/or sutures does not preclude the development of intracranial hypertension or negate the utility of ICP monitoring”
Threshold for treatment of intracranial hypertension	Option	“Treatment for intracranial hypertension … should begin at an ICP ≥20 mm Hg”
Intracranial pressure–monitoring technology	Option	“… a ventricular catheter or an external strain gauge transducer or catheter tip pressure transducer device is an accurate and reliable method of monitoring ICP”
Cerebral perfusion pressure	Guideline	“A CPP >40 mm Hg … should be maintained”
	Option	“A CPP between 40 and 65 mm Hg probably represents an age-related continuum for optimal treatment threshold … Hypotension should be avoided”

Sedation and neuromuscular blockade	Option	"… the choice and dosing of sedatives, analgesics and neuromuscular blocking agents … should be left to the treating physician …"
Hyperosmolar therapies	Option	"Hypertonic saline is effective at control of increased ICP … Mannitol is effective for control of increased ICP …"
Hyperventilation	Option	"… Prophylactic hyperventilation … should be avoided. Mild hyperventilation ($PaCO_2$ 30–35 mm Hg) may be considered for longer periods of intracranial hypertension … Aggressive hyperventilation ($PaCO_2$ <30 mm Hg) may be considered as a second tier option in the setting of refractory

		intracranial hypertension …”
Barbiturates	Option	“High-dose barbiturate therapy may be considered in hemodynamically stable patients with refractory intracranial hypertension … appropriate hemodynamic monitoring and cardiovascular support are essential …”
Temperature control	Option	“… Hyperthermia should be avoided …”
Surgical treatment of intracranial hypertension	Option	“Decompressive craniectomy should be considered ….”
Corticosteroids	Guideline	“The use of steroids significantly reduces endogenous cortisol production … may have an associated increased risk of complications of infection”
	Option	“The use of steroids is not recommended for improving

		outcome or reducing ICP …”
Nutritional support	Option	“Replace 130%–160% of resting metabolism expenditure … nutritional support should begin by 72 h with full replacement by 7 d”

CPP, cerebral perfusion pressure (mean arterial blood pressure minus intracranial pressure); GCS, Glasgow Coma Scale; ICP, intracranial pressure; $PaCO_2$, partial pressure of carbon dioxide; TBI, traumatic brain injury.

Table 29.6 Summary of Evidence Generated from the 2012 Pediatric TBI Guidelines

Topic	Level of Evidence	Recommendation
Indications for ICP monitoring	Level III	"Use of ICP monitoring may be considered …"
Threshold for the treatment of intracranial hypertension	Level III	"Treatment of ICP may be considered at a threshold of 20 mm Hg"
Cerebral perfusion pressure thresholds	Level III	"A minimum CPP of 40 mm Hg may be considered … A CPP threshold of 40–50 mm Hg may be considered …"
Advanced neuromonitoring	Level III	"If brain oxygenation monitoring is used, maintenance of a partial pressure of brain-tissue oxygen ($Pbto_2$) ≥10 mm Hg may be considered"
Neuroimaging	Level III	"In the absence of neurologic deterioration … routine repeat CT scan … may not be indicated …"
Hyperosmolar therapy	Level II	"Hypertonic saline should be considered … for intracranial hypertension …

		effective doses … range between 6.5 and 10 mL/kg”
	Level III	“Hypertonic saline should be considered … effective doses as a continuous infusion of 3% saline range between 0.1 and 1.0 mL/kg/h administered on a sliding scale …”
Temperature control	Level II	“Moderate hypothermia … for only 24 h duration should be avoided … moderate hypothermia starting within 8 h after injury and lasting for 48 h duration should be considered to reduce ICP … rewarming at a rate of 0.5°C/h should be avoided”
	Level III	“Moderate hypothermia … for 48 h duration may be considered”
Cerebrospinal fluid drainage	Level III	“CSF drainage through an externalized

		ventricular drain … may be considered … The addition of a lumbar drain may be considered …”
Barbiturates	Level III	“High-dose barbiturate therapy may be considered in hemodynamically stable patients with refractory intracranial hypertension … continuous arterial blood pressure monitoring and cardiovascular support to maintain adequate CPP are required”
Decompressive craniectomy for the treatment of intracranial hypertension	Level III	“Decompressive craniectomy with duraplasty … may be considered for pediatric patients … showing early signs of neurologic deterioration or herniation or are developing intracranial hypertension refractory to medical management …”

Hyperventilation	Level III	"Avoidance of prophylactic severe hyperventilation to a $PaCO_2$ <30 mm Hg may be considered within the first 48 h … If hyperventilation is used … advanced neuromonitoring for evaluation of cerebral ischemia may be considered"
Corticosteroids	Level II	"The use of corticosteroids is not recommended to improve outcome or lower ICP …"
Glucose and nutrition	Level II	"The evidence does not support the use of an immune-modulating diet … to improve outcome"
	Level III	"… glycemic control … should be left to the treating physician"
Antiseizure prophylaxis	Level III	"Prophylactic treatment with phenytoin may be considered to reduce the incidence

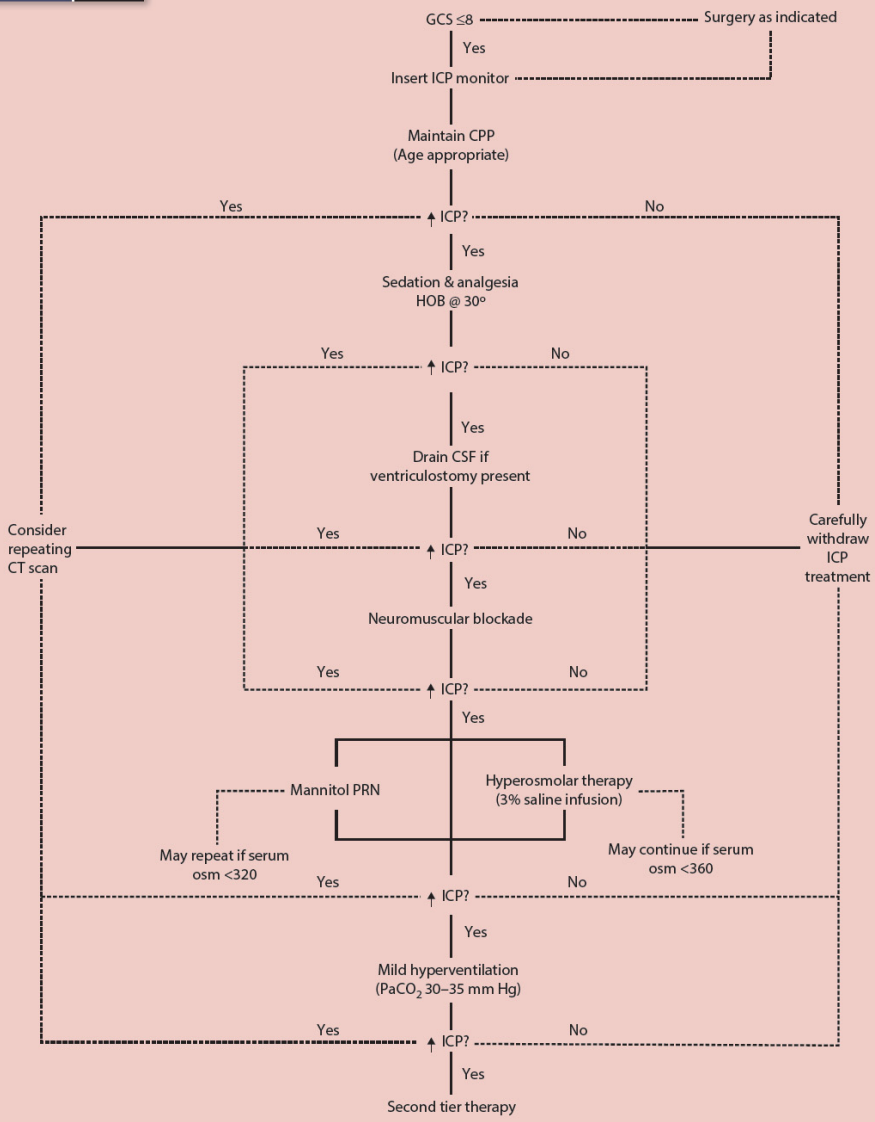
	of early posttraumatic seizures …”

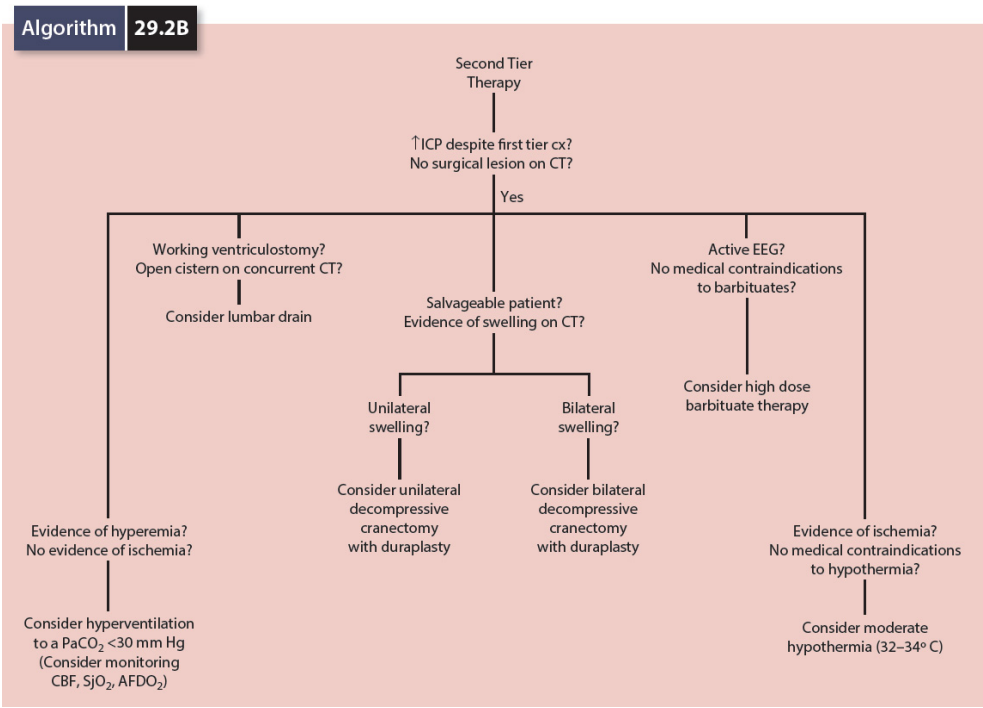
CPP, cerebral perfusion pressure (mean arterial blood pressure minus intracranial pressure); CSF, cerebrospinal fluid; CT, computed tomographic; ICP, intracranial pressure; $PaCO_2$, partial pressure of carbon dioxide.

From Bell MJ, Kochanek PM. Pediatric traumatic brain injury in 2012: the year with new guidelines and common data elements. *Crit Care Clin* 2013;29(2):223–238, with permission.

Two seminal studies (NEXUS and Canadian Cervical Spine Rules [CCR])[48–49] have examined whether clinical criteria (neurologic deficit, cervical spine tenderness, intoxication, decreased mental status, and distracting injuries) can rule out CSI in adults without the need of imaging. These criteria have been applied to pediatric patients in a manuscript by Viccellio and colleagues,[50] who evaluated 3,065 blunt trauma patients younger than 18 years and found that nearly 20% of patients fell into the “low-risk” category where imaging could have been avoided. In another retrospective review of 206 pediatric patients (from birth to 16 years of age), Jaffe and colleagues[51] suggested that the absence of eight clinical criteria (neck pain; neck tenderness; abnormality of reflexes, strength, or sensation; direct trauma to the neck; limitation of neck mobility; abnormal mental status) enabled a clinician to detect CSI in children with a sensitivity of 98% and a specificity of 54%. The PECARN group has also reported on its series of 540 CSIs in children, presenting a model with eight predictors to identify children who should be evaluated for CSIs after blunt trauma.[52] These include altered mental status, focal neurologic deficits, complaint of neck pain, torticollis, substantial torso injury, predisposing condition, diving, and high-risk motor vehicle crash, with a sensitivity of 98%.

Algorithm 29.2A





Algorithm 29.2A Algorithm generated by the Brain Trauma Foundation Committee for the first edition of the *Guidelines for the Medical Management of Severe Traumatic Brain Injury in Infants, Children, and Adolescents* for first-tier therapies (**A**) and second-tier therapies (**B**). $AFDO_2$, arteriovenous difference in oxygen; CBF, cerebral blood flow; CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalogram; GCS, Glasgow Coma Scale; HOB, head of bed; ICP, intracranial pressure; $PaCO_2$, partial pressure of carbon dioxide; PRN, as needed; SjO_2, jugular bulb venous oxygen saturation. (From Bell MJ, Kochanek PM. Pediatric traumatic brain injury in 2012: The year with new guidelines and common data elements. *Crit Care Clin* 2013;29[2]:223–238, with permission.)

The American College of Radiology published updated guidelines based on current evidence and a panel of expert pediatric specialists.[53] These guidelines summarize the best current imaging practice in children with accidental spine trauma. For children ages 3 to 16 years with acute cervical spine trauma that meets low-risk criteria based on PECARN or NEXUS, imaging is not recommended. For children in the same age group with at least one risk factor with a reliable clinical exam, radiographs of the cervical spine are usually appropriate. There was no consensus among the expert panel and there are insufficient data regarding the benefit of CT or MRI of the cervical spine in these patients. For children younger than 16 years with suspected thoracolumbar spine trauma, plan radiographs are usually

appropriate as the initial imaging. There was no consensus among the panel regarding the use of CT or MRI for these patients and similarly there was a lack of high level evidence to support CT or MRI as the initial imaging modality for this cohort.[53]

Location of Injury

Conventional wisdom has taught that the position of a CSI in children was related to age with the predominance of upper C-spine injuries seen in infants and toddlers and lower C-spine injuries seen in adolescents. This was thought to be a result of the mechanism of injury (flexion/extension and axial load, respectively). However, in a recent evaluation of the pediatric national trauma database, Polk et al.[54] identified a greater percentage of injuries to the lower C-spine than previously reported. A large database study evaluated the tendency for injuries to occur at certain levels of the cervical spine over a 5-year period and found that younger children (≤10 years of age) sustained upper (C1–C4) CSI more frequently than lower (C4–C7) CSI (87% vs. 57%).[51] Data from a 24-year retrospective study of patients admitted with CSI to a level 1 trauma center similarly concluded that for younger patients (≤8 years of age), significantly more injuries occurred in the upper cervical spine.[48] However, the National Trauma Data Bank (NTDB) data for this study revealed that the number of fractures to the upper C-spine and lower C-spine was nearly equal (53% and 47%), and that more than half of cervical spinal cord injuries were located in the lower C-spine (53%).[54]

Mechanism of Injury

Motor vehicle crash (MVC) remains the most common mechanism of CSI for the youngest age group.[48–51,55] A study of children younger than 14 years observed that while MVC was the most common mechanism for this large age group, when ages were further stratified, MVC ranked the highest for infants.[56] This same study also found that falls were the most common mechanism for the 2 to 9 years age group. While the focus on children younger than 3 years in this study was unique, conclusions about mechanism of injury remained consistent with previous literature. The frequency of MVC as mechanism for blunt trauma CSI is significantly greater than all other

mechanisms, with falls ranking second (66% and 15%, respectively). Given that this patient population is just learning to walk, falls are a concern. However, the high energy of an MVC has greater potential for major neurologic impairment and mortality.

The observations generated from analysis of the NTDB data suggest that the lower C-spine needs to be adequately evaluated on the basis of the near equal distribution of injuries. In addition, the association of CSI with high-energy mechanisms (i.e., MVAs) warrants a higher index of suspicion of this subset of young pediatric patients. In addition, those patients requiring at scene intubation and/or admission to the intensive care unit (ICU) should also be evaluated thoughtfully. Despite the low incidence of CSI, until the cervical spine is cleared, it should be immobilized, ideally with an age/size appropriate hard collar. Such collars should be stocked in all trauma centers that care for pediatric patients.

The authors of the reviewed paper[56] implemented a similar clinical guidelines strategy emphasizing the use of physical examination and NEXUS criteria in order to clear the cervical spine in children presenting after trauma. The primary outcome measure was to determine the use of CT scans in children younger than 15 years and to compare the extent of use of CT scans for cervical spine clearance 12 months before and after implementation of these guidelines. A total of 233 children were evaluated during the 2-year period (128 before guidelines were in place and 105 afterward). For children clearable by NEXUS criteria, the implementation guidelines had an immediate effect, decreasing CT use by 23%. Furthermore, there were no missed injuries. These results offer additional evidence that much of the imaging obtained for C-spine clearance in a child is unnecessary. The clinical evaluation of pediatric trauma patients with suspected C-spine injury is quite effective in predicting which subset of patients will benefit from cross-sectional imaging. Simple clinical criteria, like GCS, used in concert with the physical examination, can safely predict CSI in children, safely reducing the utilization of imaging for the vast majority of patients (even the very young).

Spinal Cord Injury without Radiographic Abnormality

Spinal cord injury without radiographic abnormality was first defined in a series of children with signs of acute traumatic spinal cord injury in the absence of bony findings on cervical spine radiographs, flexion–extension films, or CT scans.[57] The authors noted that these patients had neurologic deficits or a history of transient paresthesia, numbness, or paralysis, and a delay of symptoms occurred in approximately half of the patients.

In recent years, as efforts to limit ionizing radiation exposure in children have increased, magnetic resonance imaging has become a mainstay in the workup of children with presumed CSI or neurologic deficits on physical examination. As a result, more children have been found to have demonstrable injury to the spinal cord, soft tissue components of the spinal column vertebral body growth plates.[58,59] As a result of this advent of new neuroimaging paradigms, the diagnosis of spinal cord injury without radiographic abnormality has become questionable. Although the trend has been to limit radiography in children (with good reason), it is important to remember that young patients with blunt trauma who have a history of any transient neurologic symptom may have a significant injury to the spinal cord and/or spinal column, and these children warrant thorough radiographic evaluation.

Cerebrovascular Injury

Blunt trauma force to the neck and cervical spine fractures can result in vascular injuries to the carotid or vertebral arteries. Stroke and permanent neurologic deficit are the most feared outcomes from this rare injury, and in children, because of ill-defined screening criteria, neurologic deficit is the most common presenting symptom for diagnosis. 2010 EAST guidelines are aimed at adult patients and provide little evidence toward screening criteria or management in either adults or children.[60] Risk factors for cerebrovascular injury include trauma mechanism with severe hyperextension or hyperflexion with rotation, maxillary or mandibular injuries, TBI with diffuse axonal injury, near hanging, “seat belt sign” or other soft tissue contusion to the neck, and fractures involving the carotid canal or cervical vertebral body, particularly the vertebral foramen. A recent meta-analysis of pediatric blunt cerebrovascular injury recommended

screening high-risk pediatric patients with CT angiography of the neck and treatment with anticoagulation in patients with confirmed injuries.[61]

Thoracic Trauma

Blunt trauma, most commonly from motor vehicle crashes, is the most common mechanism for thoracic trauma in pediatric patients. Children have a more flexible, cartilaginous rib cage, and, therefore, serious intrathoracic injuries can occur in the absence of obvious external trauma or rib fractures. Children also have a more mobile mediastinum, predisposing them to tension pneumothorax with subsequent cardiopulmonary collapse from impaired venous return. The primary survey is designed to identify these acute life-threatening thoracic injuries such as airway injury, tension pneumothorax, open pneumothorax, hemothorax, flail chest with pulmonary contusion, or cardiac tamponade, which require immediate intervention (**Table 29.7**).[62] Once bilateral breath sounds and adequate ventilation and oxygenation are confirmed, CXR is an urgent part of any pediatric trauma evaluation and can identify most other acute thoracic injuries. FAST examination can evaluate for pericardial fluid and in experienced hands can identify pneumothorax or pleural effusion. Many injuries can be observed or managed with tube thoracostomy.

Pulmonary contusions are one of the most common thoracic injuries after blunt trauma. The diagnosis is made on CXR in which infiltrates are identified that do not follow anatomic boundaries. Parenchymal edema peaks at 24 to 36 hours postinjury, as the contusion "blossoms" on CXR, and requires admission for monitoring, oxygen therapy, or intubation and respiratory support if needed. Any evidence of hemothorax or pneumothorax seen on CXR should be managed initially with tube thoracostomy. Stable patients with an occult pneumothorax (seen only on CT scan but not on CXR) may be safely observed without thoracostomy drainage, even if requiring positive pressure ventilation. Traditional indications for thoracotomy in adults include an initial chest tube output of 1,500 mL and a persistent output of 150 to 200 mL/hr for 4 hours. In children, this equates to a chest tube output of approximately 20% of the patient's estimated blood volume, or ongoing output of 2 to 3 mL/kg/hr. However, patient physiology should be the primary indication for surgical treatment rather than the absolute blood

output. The thoracoscopic approach has become increasingly acceptable in stable patients for the management of retained hemothorax, persistent air leak, or select diaphragmatic injuries after penetrating thoracoabdominal trauma. The EAST practice management guidelines for thoracic trauma provide a good overview of the evidence for management of thoracic trauma in adults, but no specific guidelines exist for pediatric patients.[63]

Table 29.7 Acute Life-Threatening Thoracic Injuries

Injury	Diagnosis	Management
Airway obstruction	Apnea or stridor, maxillofacial trauma.	Definitive tracheal intubation (oro- or nasotracheal) or cricothyroidotomy
Flail chest	Paradoxical chest wall motion.	Positive pressure ventilation
Tension pneumothorax (PTX)	Respiratory distress, tracheal deviation, hypotension, distended neck veins, absent unilateral breath sounds, **hyperresonance to percussion**	Needle decompression (2nd interspace, midclavicular line), followed by placement of chest tube (4th interspace, anterior axillary line)
Open pneumothorax	Open wound into chest → "**sucking chest wound**"	Sterile gauze (secure on three sides) and placement of chest tube
Hemothorax	Absent breath sounds, **dullness to percussion**, hypotension	Chest tube placement. Massive hemothorax necessitates thoracotomy
Cardiac tamponade	Distended neck veins, muffled heart sounds, hypotension (**Beck triad**), pulsus paradoxus	Pericardiocentesis (or emergency thoracotomy if pulseless)

Emergency bedside thoracotomy is indicated for patients who present pulseless to the emergency department with signs of life and penetrating thoracic trauma. The evidence is more controversial for patients who do not have signs of life or who sustained penetrating extrathoracic injuries or blunt trauma and should be based on clinical judgment. There is no role for emergency thoracotomy for patients without signs of life after blunt trauma.[64] Advanced trauma life support guidelines recommend application of these guidelines to children on the basis of existing literature,[65,66] but these data are sparse.

Other serious thoracic injuries are very rare in children but include blunt aortic injury and blunt cardiac injury. Aortic injury can be effectively diagnosed with CT scan with IV contrast (CT angiogram). Widened mediastinum on CXR from a physiologic thymic shadow is quite commonly seen in young children. However, with the appropriate mechanism, including blunt thoracic trauma with a significant deceleration mechanism, and abnormal contour of mediastinum, CT chest angiography with contrast may be required to rule out this injury.[67,68] Treatment, as in adults, relies on strict antihypertensive therapy and operative repair, including the endovascular approach in those children who are big enough to accommodate a stent (although this has not been standardized in pediatric patients). Blunt cardiac injury (most commonly myocardial contusion) can also be challenging to diagnose but occurs most commonly after motor vehicle collision or pedestrian trauma. Abnormalities on EKG are the main findings in myocardial contusion. Traditional risk factors such as sternal fracture or upper rib fractures do not appear to correlate with blunt cardiac injury. The new EAST guidelines, although designed for adult patients, recommend an EKG and troponin I if blunt cardiac injury is suspected.[69] If both studies are normal, this effectively rules it out. If either is abnormal, the child should be admitted to a monitored bed. Echocardiogram is recommended only for patients with hypotension or arrhythmias.[66]

Traumatic asphyxia occurs in children because of their flexible thoracic wall in the setting of direct blunt compression, most often after a motor vehicle collision or crush injury. At the time of injury, if the glottis is closed and the thoracoabdominal muscles are tensed, the increased intrathoracic pressure is transmitted through the central venous system (inferior and superior vena cava) to the brain and solid organs. Typical signs of traumatic

asphyxia include subconjunctival hemorrhage and petechiae of the chest, shoulders, and head, with subsequent bronze discoloration of the skin. Supportive care in a monitored setting is the standard of care for these children, watching for signs of airway edema.

Abdominal Trauma

Blunt mechanism of injury is the most common cause of abdominal trauma in children. Assessment of abdominal trauma in pediatric patients can be challenging. Vomiting, abdominal tenderness, and seat belt signs are signs and symptoms that increase the likelihood of abdominal injuries. FAST examination is a standard assessment in adult trauma patients, but its role in pediatric patients is still controversial. In an unstable patient, FAST examination can help identify the presence of hemoperitoneum and triage a patient to the operating room or interventional radiology suite. CT scan with IV contrast is the best assessment for abdominal trauma in a stable pediatric patient. Despite concerns for radiation exposure, this is an important study if indicated. PECARN has similarly developed rules and algorithms to identify a low-risk patient who can safely avoid abdominal CT.[70–72] If an examinable child (GCS score of >13) had no evidence of abdominal or chest wall trauma (including seat belt sign), no abdominal pain, tenderness or vomiting, and normal bilateral breath sounds, the rule had a 99.9% negative predictive value for intra-abdominal injuries requiring intervention[70,72] and was more sensitive than clinical suspicion.[71] After a normal abdominal CT scan, most patients can safely be discharged if otherwise stable (sensitivity 97.8%). However, most missed injuries were hollow viscous injuries, which are difficult to identify on CT and should be suspected in patients with seat belt sign, free fluid on CT, or leukocytosis.[73]

Penetrating abdominal trauma is much less common in children than in adults but should be managed similarly. There is increasing evidence toward a nonoperative, conservative approach to abdominal stab wounds that penetrate the fascia, relying on serial examinations and imaging to guide operative approach. Laparotomy is still largely recommended for gunshot wounds to the abdomen on the basis of the most recent 2010 EAST guidelines, although this area remains controversial.[74]

Damage control laparotomy is an established operative approach for hemodynamically unstable trauma patient in hemorrhagic shock and is utilized in approximately 5% of all laparotomies for trauma in both adults and children. The goal of this approach is to avoid the onset of the lethal triad: hypothermia, coagulopathy, and acidosis. The procedure is abbreviated and focused on maintaining the priorities of hemorrhage control, followed by control of contamination and temporary abdominal closure, with plans to return for definitive repairs after resuscitation and warming in the ICU, usually 24 to 48 hours later. The decision for damage control should be made early in the operative course in order to minimize exposure time in the operating room and avoid irreversible shock and its sequelae. Although well described and widely adopted within the adult trauma population, data are less available in the pediatric population but theoretically of even greater importance as children have small circulating blood volumes and are more prone to hypothermia.[75] As discussed in a previous section, damage control resuscitation is managed in parallel, with a focus on initiating the massive transfusion protocol, minimizing crystalloid fluids, and resuscitating with blood products using a high ratio of plasma and platelets for each unit of red blood cells transfused.[75]

Solid Organ Injuries

Most solid organ injuries (spleen, liver, and kidney) are managed nonoperatively after blunt trauma.[76] Most of these injuries are identified or evaluated by CT and can be graded according to American Association for the Surgery of Trauma (AAST) grading system for prognostic value.[77] In a large series of pediatric patient with solid organ injury, 11% received a blood transfusion, 1.4% underwent angiographic embolization, and 4% required laparotomy.[78] Laparotomy rates ranged from 5.4% at adult trauma centers to 2.8% at freestanding children's hospitals, raising concerns for optimal and consistent management of pediatric patients who are cared for in adult centers.[78–80] Across all institutions, there is wide variability of care of pediatric patients with solid organ injuries. In those managed successfully with nonoperative management, there is no standard of care for level of monitored care (whether children are admitted to ICU vs. floor vs. home), frequency of blood draws, duration of bed rest or bowel rest, and timing of

discharge home and resumption of activities.[78] In the 1990s, the American Pediatric Surgical Association (APSA) proposed an algorithm for posttrauma management of solid organ injuries, which has commonly been adopted by institutions but has never been rigorously verified.[81] These recommendations include ICU admission only for grade IV solid organ injury, observation on the pediatric floor for a duration of injury grade +1 days, liberation of diet and ambulation once the hematocrit has stabilized (and hematuria resolved in renal injuries), and exertional activity restriction for a duration of injury grade +2 weeks. No routine reimaging of injuries is recommended.[81] Indications for laparotomy include hemodynamic instability, ongoing blood loss (hematocrit drop) with blood transfusion requirement of greater than 20 mL/kg, or evidence of hollow viscous injury. More recently, the American College of Surgeons' pediatric trauma consortium (ATOMAC) developed a practice management guideline for solid organ injury, which is now used at many additional pediatric trauma centers throughout the United States.[82] The guidelines support management on the basis of hemodynamic status rather than injury grade. Transfusion triggers have been debated and although there are no class I data to support a number at which blood should be given, it is generally agreed that transfusion should be considered at a threshold of 7.0 g/dL. It supports abbreviated bed rest and earlier discharge than the older APSA guidelines (**Algorithm 29.3**). The approach to angiographic embolization for splenic salvage is still controversial in pediatric patients and has a wide variability among institutions.[82–85] In 2019, the APSA Outcomes and Evidence Based Practice committee published updated guidelines for the management of solid organ injuries in children, suggesting that the length of stay (LOS) for children with isolated solid organ injury should be based on clinical findings and may not be determined by grade of injury, consistent with more recent practice patterns supported by the ATOMAC guidelines (**Algorithm 29.3**). In addition, the updated APSA guidelines queried the role of interventional radiology in the management of isolated solid organ injuries.[86] They concluded that arterial embolization is a useful tool for non-operative management of solid organ injuries with radiographic findings concerning for ongoing bleeding (e.g., blush) and hemodynamic compromise. Finally, these guidelines suggest that routine follow-up imaging for asymptomatic and uncomplicated solid organ injures

is not indicated. These recommendations are based on a systematic review of 202 articles that met inclusion criteria for the study.[86]

The role of FAST examination for diagnosis of solid organ injury in children is still unclear. Whereas its use has long been the standard of care in adults, recent PECARN data of pediatric trauma centers suggest that only 13% of pediatric trauma patients with a suspicion for intra-abdominal injuries undergo FAST examination.[87,88] Sensitivity in pediatric patients ranges from 50% to 92%, with a rigorous meta-analysis suggesting the sensitivity to be around 66%.[21,22,89–91] Specificity is also very low, and in a hemodynamically stable patient, a positive FAST examination should be followed up with an urgent CT. Bedside FAST may have utility in hemodynamically unstable patients to rapidly identify or rule out intraperitoneal hemorrhage when patients cannot undergo CT, but decision making should include other features such as patient physiology, mechanism, clinical suspicion, and responsiveness to initial resuscitation measures.[22,92] As its use in children increases, it is likely that FAST will become more reliable, with greater sensitivity and specificity. Additionally, while strong evidence in favor of the use of FAST as a screening tool is lacking, the sensitivity may increase with improvement in technology and as the pediatric trauma community collectively becomes more experienced with this skill.[93]

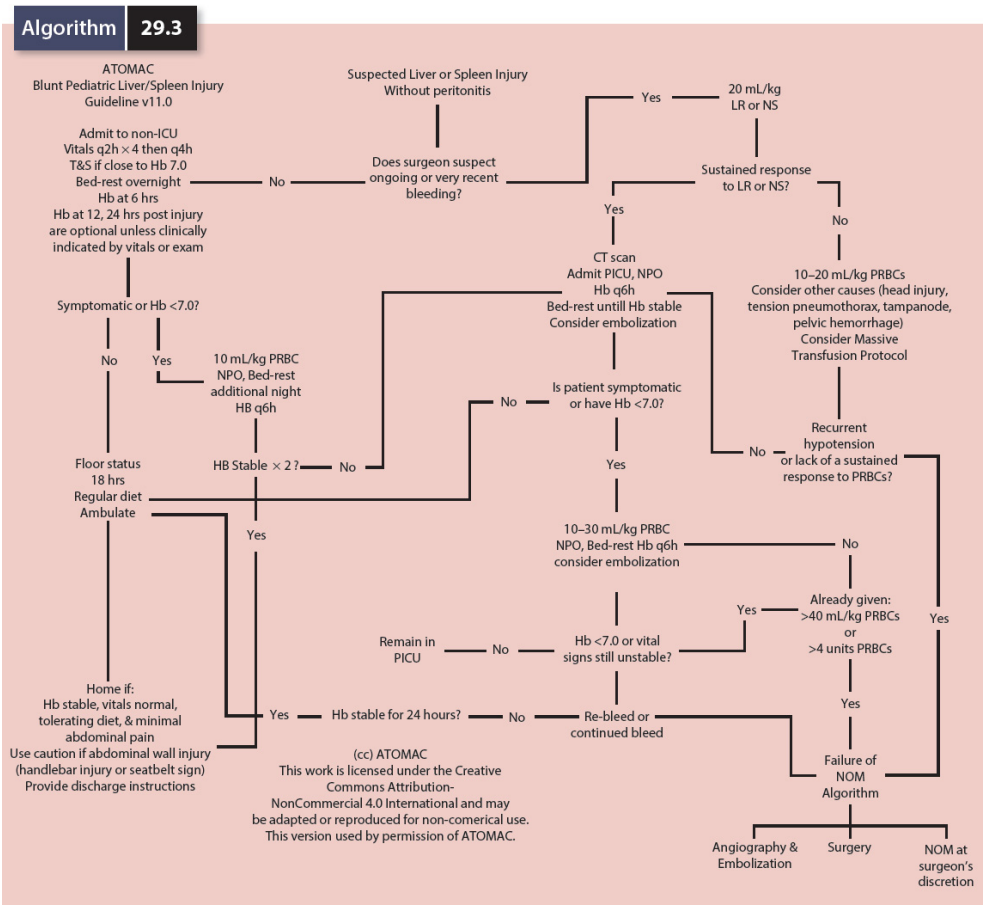
Hollow Viscous Injury

Hollow viscous injuries occur after blunt abdominal trauma, such as bicycle handlebar injuries or lap belt injuries (often associated with Chance vertebral fracture). Diagnosis can be challenging with current radiographic techniques. Findings on CT might include free fluid in the absence of solid organ injuries, free intraperitoneal air, or extravasation of oral contrast. In the setting of abdominal wall ecchymosis (seat belt sign), leukocytosis, or abdominal tenderness, patients should be closely monitored with serial abdominal examinations and blood count. Evidence for evolving peritonitis, fever, leukocytosis, or systemic inflammatory response syndrome physiology should prompt surgical exploration, either laparoscopic or by laparotomy. Intramural duodenal hematomas are managed conservatively without surgical intervention but may take several weeks to resolve, requiring nasogastric tube (NG) drainage and Total Parenteral Nutrition (TPN) in the interim.

Delayed stricture after partial thickness luminal injury or mesenteric injury can present days to weeks after an injury, with symptoms of partial or complete small bowel obstruction.

Pancreatic and Biliary Injury

Pancreatic injury classification by AAST injury grade divides patients into those without ductal injury (grades 1 to 2) and those with duct disruption (grades 3 to 5). Currently there is no universal standard for management of pancreatic trauma in pediatric patients, but evidence is emerging.[94–102] Amylase and lipase are useful to screen for pancreatic injury but may be normal immediately after trauma; by 3 hours after trauma, they are universally elevated (100% sensitivity), although with low specificity.[96] Abdominal CT scan can determine the integrity of the duct, and endoscopic retrograde cholangiopancreatography (ERCP) may be a useful adjunct in some patients. Higher-grade pancreatic injuries with duct disruption typically require operative intervention. Although early literature promoted nonoperative management for pediatric pancreatic injuries,[96–100] recent reports and multi-institutional studies have suggested improved outcomes, reduced need for drainage procedures, and decreased LOS for operative intervention, most commonly distal pancreatectomy.[94,101,102]



Algorithm 29.3 New ATOMAC guidelines for management of pediatric solid organ injury. Hb, hemoglobin; ICU, intensive care unit; LR, lactated Ringer's; NOM, nonoperative management; NPO, non per os; NS, normal saline; PICU, pediatric intensive care unit; PRBC, packed red blood cell; q6h, every 6 hours. (From Notrica DM, Eubanks JW III, Tuggle DW, et al. Nonoperative management of blunt liver and spleen injury in children: Evaluation of the ATOMAC guideline using GRADE. *J Trauma Acute Care Surg* 2015;79[4]:683–693, with permission.)

Biliary injury is rare in children, representing <0.1% of all trauma patients, and includes intrahepatic and extrahepatic ductal injuries, biloma, and gallbladder injury. Literature is sparse but many injuries can be managed nonoperatively with ERCP with biliary stent placement and percutaneous peritoneal drainage. These patients are at risk for delayed stricture and require close follow-up. Hepaticojejunostomy remains the definitive repair for extrahepatic biliary tract transections.[103]

Anorectal Injuries

Anorectal injuries are uncommon in children and usually occur after penetrating mechanism. Isolated anal trauma can be repaired primarily, including sphincter repair. Extraperitoneal rectal injuries should be repaired primarily if possible and often require fecal diversion and/or presacral drainage. Intraperitoneal rectal injuries can be managed similarly to colon injuries, with or without fecal diversion. Associated genitourinary injuries should be sought with examination under anesthesia.[104,105]

Pelvic Fracture and Extremity Trauma

Fractures represent one of the most common injuries in pediatric trauma patients. Children have more malleable bones, more absorptive cartilage, and a higher potential for bone remodeling and healing than adults. Anatomic differences in radiology of pediatric bones can make recognition of injuries challenging. Injury to the growth plates can result in premature fusion and asymmetric limb growth. Greenstick fractures occur when the bone bends before it breaks. Options for stabilization include casting, splinting, traction, internal fixation, or external fixation. A thorough neurovascular examination is essential. Although vascular injury requiring repair is rare, children are more prone to vascular spasm, resulting in asymmetric pulse examination and transient ischemic symptoms.[106]

Pelvic fractures are a source of morbidity and mortality in pediatric patients and occur most commonly after high-mechanism blunt trauma such as MVC or pedestrians struck. Pelvic fractures are usually present in the setting of multiple injuries including TBI, abdominal injuries, and genitourinary trauma. The Young–Burgess Classification system for pelvic fractures is most commonly used in adults and categorizes injuries into lateral compression, anterior–posterior compression, and vertical shear injuries to the pelvic ring. Pediatric classifications exist but are not standard. The pediatric pelvis is more elastic, allowing for significant displacement before fracture. Pelvic hematoma and ongoing hemorrhage requiring angiographic intervention or preperitoneal packing occurs less commonly in children than in adults but should be a major consideration in the hemodynamically unstable child. The 2011 EAST guidelines for the treatment of hemorrhage in pelvic fracture are limited to adult data, but many principles can be extrapolated to the pediatric population.[107] These guidelines recommend the

use of early external stabilization, particularly with a size-appropriate pelvic orthotic device, to stabilize fractures, reduce pelvic volume, and theoretically limit blood loss. The hemodynamically unstable pediatric patient with a pelvic fracture represents a diagnostic challenge—does one proceed to the operating room for abdominal exploration or to the angiography suite for embolization? FAST examination does not have the sensitivity to rule out abdominal hemorrhage. If stable enough, a CT scan of the abdomen and pelvis is preferable to help identify the injuries and determine treatment course. Despite classification systems, fracture patterns on anteroposterior pelvic plain film do not predict bleeding or need for angiographic embolization. Angiographic embolization should be considered in hemodynamically unstable patients after other sources of hemorrhage have been ruled out. In the adult literature, arterial contrast extravasation on CT scan warrants empiric embolization, even in a stable patient, but these data are unclear in the pediatric population. Similarly, preperitoneal packing is a newer technique for the control of pelvic hemorrhage, and its use can be considered alongside pelvic embolization.[107] Treatment of pelvic fractures in children is usually nonoperative with non–weight bearing, Spica casts, or traction. In some cases, external fixation or open reduction, internal fixation (ORIF) is necessary. Fractures involving the acetabulum are complex, especially when the triradiate cartilage complex is involved, as premature fusion can result in long-term problems with leg-length discrepancy and acetabular failure.

Venous Thromboembolism

The incidence of venous thromboembolism in pediatric trauma patients is very low, ranging from 0.02% to 0.3%.[108] Practice guidelines from the Trauma EAST and Pediatric Trauma Societies proposed the following guidelines for the use of chemical prophylaxis in the pediatric trauma population. In children hospitalized after trauma who are at low risk of bleeding, pharmacologic prophylaxis should be considered in children older than 15 years and in younger postpubertal children with and injury severity score greater than 25. Routine pharmacologic prophylaxis in prepubertal children, even with ISS greater than 25 is not currently recommended. Mechanical prophylaxis should be considered either alone or as an adjunct to

pharmacologic prophylaxis in children older than 15 years and in younger postpubertal children with ISS greater than 25.[109] It is worth noting that these guidelines were developed from a thorough summary of the limited literature regarding VTE prophylaxis in children hospitalized after trauma. The authors did note that current available evidence is of very low quality and observational in nature. As such, prophylaxis and detection of venous thromboemobolism in the pediatric trauma population continues to be an area of debate.

Nonaccidental Trauma (Child Abuse)

Nonaccidental trauma is a leading cause of trauma in children, with 650,000 confirmed cases of physical abuse annually in the United States, accounting for 1,500 deaths per year, mostly in 3 children younger than 4 years.[110] Nonaccidental trauma and abuse may be difficult to recognize and a high index of suspicion is needed when evaluating children with injuries. The American Academy of Pediatrics guidelines published in 2015 provide a resource to help identify these children, because unrecognized cases of abuse can represent with serious or even fatal injuries. Features of the history that should increase suspicion include unexplained significant injury, denial of trauma, changes in the story or differences in the story by different witnesses, explanation that is inconsistent with the pattern, age or severity of injury or with the child's developmental capabilities, and delay in seeking medical care. Findings on examination that may suggest abuse include any injury in a preambulatory infant, multiple organ system injuries or multiple injuries at different stages of healing, patterned injuries, injuries to unusual locations (mnemonic "TEN-4" = injury to torso, ears, or neck in a child younger than 4 years), or other evidence of neglect (failure to thrive, dental caries, poor hygiene). Burns with sharply demarcated edges, bite marks, cigarette burns, and other markers of being hit with an object are high-risk injuries. Certain fracture patterns should raise concern for nonaccidental trauma including fractures in nonambulatory patients, multiple fractures, rib fractures, infants and toddlers with midshaft femur or humerus fractures, and other unusual fractures such as scapular and metaphyseal fractures. Skeletal survey is recommended in children younger than 2 years who have suspicion for abuse (see Indications for Obtaining a Skeletal Survey available online from the

study by Christian[110]; see Skeletal Survey Guidelines available from the study by Wood et al.[111]). If there is a reasonable suspicion that a child has been abused, a report to child protective services for further investigation is mandated by law. See Christian, CW[110] for outlines recommending workup in a child suspected of nonaccidental trauma, including blood work, imaging, and consultation of specialists such as ophthalmology, in order to identify injury and obtain forensic evidence.

4 INJURY PREVENTION

In 1968, the National Traffic and Motor Vehicle Safety Act established the National Highway Traffic Safety Administration, which has influenced the improvement of road infrastructure, automobile, and driver and passenger safety, resulting in precipitous drops in roadway fatalities.

There are many examples where comprehensive state and federal laws have resulted in statistical drops in injuries and deaths.[112–114] In the following section, we provide several examples where federal mandates and state laws have been implicated in the reduction of pediatric injuries. In many cases, surgeon advocates where integral in the legislative process.

Smoke Detectors and Carbon Monoxide Detectors

Smoke detectors have been legislated into building codes in all 50 states. As a result, the early warnings of a fire are thought to have prevented thousands of deaths. More than 10,000 Americans are poisoned by carbon monoxide and more than 500 people in the United States die annually from carbon monoxide poisoning. As of August 2015, 30 states have enacted statutes regarding carbon monoxide detectors, and another 11 have promulgated regulations on CO detectors. Several states now require CO detectors in hotels and schools.

Drunken Driving Laws

Alcohol is known to play a role in many MVCs. Drivers younger than 21 years are more likely than older drivers to be involved in fatal crashes, and alcohol use adds to the risk of fatal crashes. This group has been the target of several interventions to reduce alcohol-impaired driving, including "zero tolerance" blood alcohol concentration standards for drivers under the legal drinking age with mandatory license revocation after a first offense.[115]

Junior Driver Laws/Safe Driving Laws

The increased risk of car crashes associated with texting and cell phone use has been well documented—among adults and teens alike. But for teens, who are immersed in a world of smart phones and texting, these types of laws send a powerful message that driving demands their undivided attention. Although not exclusive to children or adolescents, "safe driving laws" ban text messaging for all drivers, prohibit junior drivers from using cell phones, and institute new license renewal procedures for mature drivers, among other provisions. Graduated driver licensing programs that require new drivers to progress through stages allowing them increased driving privileges as they gain experience have, in some form, been enacted in all 50 states. Many states have also incorporated parental education and curfews to these laws and have seen up to a 40% decrease in the number of injuries and fatalities as novice drivers have become engaged in this process.[116,117]

Child Passenger Restraints

Seat belt use around the country has steadily increased. There is mounting evidence that seat belt use and airbag implementation have been the greatest cause for decreased road fatalities per miles driven, which is at an all-time low according to National Highway Traffic Safety Administration statistics. Furthermore, there is evidence that educating pediatricians improves the use of car seats for children. Although the rate of use of car seats for newborns and infants is approximately 75%, their use in toddlers is estimated at only 29%, and more than half of car seats for children are not used correctly. In the child older than 4 years or 40 lb, there is ample evidence that booster seats should be used rather than adult-type restraints. Many states now have legislation aimed at this population.

All-Terrain Vehicle Laws

In the United States, all-terrain vehicle crashes account for a rising number of injuries and deaths in all age. Approximately 30% of the injured/dead are children. In 1988, in response to this trend, the Consumer Product Safety Commission and the all-terrain vehicle industry agreed upon a set of standards designed to limit injury. This included regulations that restricted operators younger than 16 years halted the sale of three-wheeled vehicles and included a mandatory educational safety training module and improved safety warnings. However, in 1998, 10 years after they were established, these consent decrees expired and since that time, the rate of injuries has risen steeply. Several states have recently enacted restrictions on ridership and in Massachusetts, where these restrictions have included an age cutoff, the number of injuries have fallen dramatically (unpublished data).

Finally, as policy makers struggle to allocate limited resources in order to improve population health, injury prevention programs will play a particularly important role. The rationale is straightforward: regulatory efforts specifically aimed at injury primary and secondary prevention, if well designed, can be very successful at health care cost reduction, thereby freeing resources for other concerns.

GUN VIOLENCE PREVENTION

Between 2009 and 2018, mass shootings took center stage in the nation's consciousness. A total of 194 mass shootings resulted in the death or serious injury of nearly 2,000 Americans, and one in four of them were children or adolescents.[118] However, these numbers represent a small fraction of the yearly death toll (nearly 40,000) from modern American gun violence—now an undeniable health epidemic for children and adults living in the United States. Without understanding their implications of the psyche of our children, active shooter drills have become a routine part of school preparedness and emergency planning in over 95% of our nations' schools.[119] While we are constantly reminded about mass shootings, deaths from suicide and homicide contribute far more American lives to this toll and their determinants are poorly understood. Furthermore, nonfatal injuries,

estimated to be greater than 150,000 per year, also strain our healthcare systems and impose a cost that has been shown to exceed the budget of the U.S. department of Education.[120] Recognizing the important perspective that surgeons and healthcare providers bring to the public debate over gun control policy, organized medicine has developed working groups and published statements with the goal of influencing the nation's policy makers. In November 2018, the American College of Surgeons Committee on Trauma (ACS COT) released its initial set of recommendations to develop an effective and durable strategy for reducing firearm injury, death, and disability in the United States.[121] In 2020, the federal budget included $25 million dedicated to the Centers for Disease Control and the National Institutes of Health for gun violence research, the first time federal funding has been dedicated to this cause since the Dickey Amendment was passed in 1996. The authors look forward to more organizations coming forward in this effort.

Geriatric Trauma

Tatiana C. P. Cardenas, Marc D. Trust, and Carlos V. R. Brown

Key Points

1. The physiology of aging affects nearly every organ system including cardiovascular, pulmonary, renal, and gastrointestinal. Altered physiology may also be associated with comorbid conditions in the elderly patient including hypertension, cardiac disease, chronic obstructive pulmonary disease (COPD), chronic renal insufficiency, and altered drug metabolism.
2. The American Geriatrics Society has published the Beers Criteria for potentially inappropriate medication use in older adults that can be used to refine inpatient medication management for elderly trauma patients.
3. Falls are far and away the most common mechanism of injury in elderly trauma patients, causing almost 75% of injuries in elderly patients; nearly 1 in 3 adults over 65 years old will experience ground level falls each year.
4. An underreported but important mechanism of injury in elderly trauma patients is elderly abuse.
5. Imaging with head CT in elderly trauma patients should be used liberally.
6. Severely injured older patients may not display standard signs of hemodynamic instability.
7. Due to the broad range of age-related factors that can contribute to injury and adversely affect recovery in geriatric patients, injured individuals should receive a comprehensive geriatric assessment during their hospital stay.
8. Frailty is a syndrome of decreased physiologic reserve distinct from the normal aging process and other comorbidities. Frailty is associated with higher mortality and complications, and worse functional outcomes after trauma, and is more predictive than age or injury severity of hospital complications, in-hospital mortality, or discharge to an institution.
9. Four-fifths of in-hospital deaths among geriatric trauma patients involve decisions to withdraw or withhold of life-sustaining

therapies.

INTRODUCTION

The elderly population in the United States is steadily growing and according to the U.S. Census Bureau, the number of Americans >65 years old is expected to reach 80 million by the year 2040.[1]

Trauma and acute care surgeons will be increasingly responsible for caring for this complex population of patients. Even prior to injury, the elderly patient brings unique challenges including altered physiology, numerous comorbid conditions, and preinjury medications. The epidemiology and triage complexities of elderly trauma patients make it challenging to ensure these patients are transported to the appropriate receiving facility. Elderly patients are most often injured by a blunt mechanism and are particularly at risk for falls from standing. In addition, they sustain unique injuries that may escape diagnosis during the initial evaluation. Trauma centers may need to alter activation criteria for elderly trauma patients in order to avoid the pitfall of undertriage that is associated with poor outcomes in this population. Though the initial trauma evaluation for elderly patients is similar to younger adults, the trauma surgeon must understand the nuances associated with caring for the injured elderly patient. The elderly trauma patient more frequently has issues that relate end-of-life care in the postinjury period.

PHYSIOLOGY, COMORBIDITY, AND PREINJURY MEDICATIONS

Elderly individuals present with a vast array of body systems affected by the deranged physiology associated with aging. 1 The physiology of aging affects nearly every organ system including cardiovascular, pulmonary, renal, and gastrointestinal. Altered physiology may also be associated with comorbid conditions in the elderly patient including hypertension, cardiac

disease, chronic obstructive pulmonary disease (COPD), chronic renal insufficiency, and altered drug metabolism.

Cardiovascular

The cardiovascular system is most commonly affected by the physiology of aging and has a significant impact on care of the injured elderly patient. Alterations to physiology of the vascular system in the aging adult are primarily the result of changes in the large arteries including elongation, dilatation, and arterial wall thickening as a result of changes in the intima and media.[2] Changes in both small and large arteries lead to decreased compliance, stiffness, and hypertension or other cardiovascular diseases in elderly adults. Decreased endothelial cell turnover resulting in endothelial dysfunction, contributes to and promotes these changes even in atherosclerosis-free, normotensive aging individuals.[3] The aging process will affect cardiac physiology including reduced systolic and diastolic functions of the right ventricle as well as left ventricular hypertrophy with associated impaired contractility and relaxation. Resting cardiac output and ejection fraction are preserved.[4] While there are significant changes in cardiac and vascular physiology in elderly patients at baseline, the lack of cardiovascular response to stress may be the most important component of altered cardiovascular physiology in elderly patients, especially in the setting of hemorrhagic shock. The blunted response to alpha-adrenergic stimulation limits vasoconstriction[2,5] while lack of response to beta-adrenergic stimulation limits the ability to mount a tachycardic response.[4,6] Elderly individuals are also at increased risk to develop atrial fibrillation, ischemic heart disease, and congestive heart failure.

Table 30.1 Changes in Cardiovascular and Pulmonary Physiology and Commonly Encountered Comorbidities in the Elderly

System Involved	Physiologic Changes	Common Comorbidity
Cardiovascular	Elongation, dilatation, and wall thickening of large arteries Decreased arterial compliance and stiffness Reduced systolic and diastolic function of right ventricle Left ventricular hypertrophy Lack of cardiovascular response	Hypertension Ischemic heart disease Atrial fibrillation Congestive heart failure
Pulmonary	Kyphosis Decreased intervertebral height Decreased muscular strength Loss of elasticity and recoil Emphysematous changes Dysfunction of mucociliary system Alterations in lung volumes, gas exchange, and respiratory drive Diminished physiologic response to hypoxia and hypercapnia	Chronic obstructive pulmonary disease (COPD) Asthma Obstructive sleep apnea

Pulmonary

The aging process also brings significant baseline anatomic and physiologic changes to the pulmonary system.[7] The chest wall of the elderly individual changes over time with decreasing strength of intercostal muscles and diaphragm. A decrease in height of intervertebral spaces and the development of kyphosis is associated with decline in FEV1/FVC ratio.[8] Chest wall stiffness resulting from calcification of costal cartilage and joints leads to decreased chest wall compliance.[8] After trauma, these anatomic changes place elderly patients at risk for earlier or more rapid respiratory failure as well as difficulty in liberation from the ventilator.[7,9,10] In addition to alterations in the chest wall, there are several changes in the pulmonary parenchyma of elderly individuals. These changes lead to increased compliance due to loss of elasticity and elastic recoil, emphysematous changes, and dysfunction of the mucociliary system. While anatomic changes are important, the altered pulmonary physiology of aging may lead to significant clinical implications when caring for the injured elderly patient. The elderly individual will have changes to pulmonary physiology including alterations in lung volumes, gas exchange, and respiratory drive.[7] Lung volumes in elderly patients will have increased residual volume and functional residual capacity but decreased vital capacity and FEV1.[11,12] Alterations of pulmonary gas exchange in elderly patients include increased ventilation–perfusion mismatch as well as decreased diffusion across the alveolar–arterial membrane, both associated with a decrease in baseline PaO_2.[13,14] Due to deranged respiratory drive seen with aging, elderly patients will have a diminished physiologic response to both hypoxemia and hypercapnia.[15] Some of the most common pulmonary comorbidities in the elderly trauma patients include COPD, asthma, and obstructive sleep apnea. **Table 30.1** displays changes in cardiovascular and pulmonary physiology as well as common comorbidities encountered in the elderly trauma patient.

Renal and Gastrointestinal

Aging causes deterioration in renal function over time due to alterations in renal vasculature, microanatomy, as well as changes in renal physiology.[16] Over time, glomerular tissue is replaced with fibrous tissue causing 30% to

50% loss of cortical glomeruli by 70 years of age.[17] The aging kidneys also have a diminished capacity to preserve their own function as a result of renovascular dysautonomy.[17] These changes put elderly patients at increased risk for development of acute kidney injury after trauma. Avoiding nephrotoxic agents, intravenous contrast, hyperglycemia, and hypovolemia can help prevent acute kidney injury in elderly trauma patients. Gastrointestinal derangements in the elderly patient may include dysphagia, gastroesophageal reflux, gastroparesis, and diarrhea or constipation.[18] In addition, many elderly trauma patients will present in a state of malnutrition established long before the time of injury. It is important to screen elderly trauma patients for nutritional status and begin enteral nutrition early in the postinjury course.

Elderly trauma patients present with a wide array of altered physiology and comorbid conditions. These pre-existing medical conditions are usually treated in the outpatient setting by primary care providers, and the mainstay of treatment is often a long list of medications. These preinjury medications can have a profound effect on the management and outcomes of elderly trauma patients. In addition, elderly individuals have an altered ability to metabolize the medications they encounter prior to injury as well as during their hospitalization.

Medications

Elderly trauma patients may be taking a variety of medications that may affect initial presentation, evaluation and treatment, and eventually outcomes. As hypertension is the most common comorbidity, elderly trauma patients will often be taking preinjury antihypertensive medications. Diuretics will cause patients to present in a hypovolemic state prior to injury or hemorrhage. Preinjury beta blockers will blunt the tachycardic response and may confound the initial presentation.[19] The most significant preinjury medications in elderly trauma patients are anticoagulants and antiplatelet agents. Elderly patients may be on anticoagulants or antiplatelet agents for a variety of conditions including atrial fibrillation, ischemic cardiac disease, valvular heart disease, cerebrovascular accidents, or thromboembolic disease. The most common outpatient anticoagulant is coumadin (vitamin K antagonist). For many years it was the only anticoagulant on the market and

its use is associated with many food and drug interactions and the need for frequent monitoring. Over the last decade the pharmaceutical industry has developed and brought several novel oral anticoagulants to the market. These include the direct thrombin inhibitor dabigatran as well as the Xa inhibitors, rivaroxaban, apixaban, edoxaban, and betrixaban. The most common antiplatelet agents include aspirin (cyclooxygenase inhibitor) and clopidogrel (ADP inhibitor). Newer antiplatelet agents include newer ADP inhibitors, prasugrel and ticagrelor.

Reversal of anticoagulants and antiplatelet agents in elderly trauma patients can be a challenging and complex clinical scenario. The clinician must balance reversal to eliminate hemorrhage and thromboembolic complications associated with reversing anticoagulation or antiplatelet agents. Coumadin may be reversed with either fresh frozen plasma (FFP) or prothrombin complex concentrate (PCC).[20,21] In recent years there has been more evidence regarding the reversal of direct thrombin inhibitors and Xa inhibitors.[22–25] Dabigatran may be reversed with idarucizumab (Praxbind), a 2015 FDA-approved antidote that binds to dabigatran with 350 times affinity than dabigatran to thrombin.[24] Treatment resulted in complete reversal of the anticoagulant effects of dabigatran with over 98% of patients reaching a median reversal of 100%.[24] Thrombotic complications occurred in 4.8% of patients at 30 days.[24] Intragastric-activated charcoal may be administered if drug has been taken within 2 hours of presentation or hemodialysis may be considered. PCC may be considered for reversal of dabigatran but FFP is unlikely to have any therapeutic effect. Andexanet alfa is a 2018 FDA-approved reversal agent for the Xa inhibitors, rivaroxaban and apixaban.[22] The ability of andexanet alfa to reverse other Xa inhibitors is pending ongoing study. Activated charcoal may be used or PCC may also be considered. Lastly, a new universal antidote called ciraparantag is under investigation by the FDA. It was designed as a broad-spectrum reversal agent for novel oral anticoagulants, unfractionated heparin, and low–molecular-weight heparin activity.[23] Antiplatelet agents may be reversed with either DDAVP or platelet transfusion, but the indications for either therapy have not been elucidated.[26] **Table 30.2** displays common preinjury anticoagulants and antiplatelet agents in the elderly trauma patient.

Once hospitalized, particular attention must be paid to medications ordered for the elderly trauma patient. Elderly patients have changes in

pharmacokinetics and pharmacodynamics including alterations in absorption, bioavailability, distribution, metabolism, and elimination.[27] 2 The American Geriatrics Society has published the 2019 updated Beers Criteria for potentially inappropriate medication use in older adults that can be used to refine inpatient medication management for elderly trauma patients.[28] Of particular importance to the management of the elderly trauma patients is the plan for pain control. Pain medications may have significant side effects in elderly patients including delirium, nausea, vomiting, constipation, renal dysfunction, and gastrointestinal bleeding. A multimodal approach with the lowest effective dose for pain control should be used for elderly trauma patients.[27]

MECHANISM AND INJURIES

Mechanisms of injury for elderly trauma patients are most often a result of blunt trauma with falls, motor vehicle crashes, and pedestrian struck by auto being the most frequent. 3 Falls are far and away the most common mechanism in elderly trauma patients, causing almost 75% of injuries.[19] Nearly 1 in 3 adults over 65 years old will experience ground level falls each year.[17] After hospitalization, older patients are at further risk for inpatient falls.[29] There are a variety of reasons that elderly individuals are at risk for falls including weakness, deconditioning from chronic illness, vision loss, gate and balance disturbances, slowed reaction time, and cognitive impairments.[19] The American Geriatrics Society has developed clinical practice guidelines (**Table 30.3**) for the prevention of falls in older adults.[30]

Table 30.2 Common Preinjury Anticoagulants in the Elderly

Mechanism of Action	Drugs	Reversal Strategies
Vitamin K antagonist	Warfarin	FFP or PCC
Direct thrombin inhibitor	Dabigatran	Reversed with idarucizumab (Praxbind) Intragastric charcoal Hemodialysis Consider PCC
Xa inhibitors	Rivaroxaban Apixaban Edoxaban Betrixaban	Andexanet alfa approved for reversal of rivaroxaban and apixaban only Intragastric charcoal Consider PCC
Antiplatelet agents	Aspirin Clopidogrel Prasugrel Ticagrelor	DDAVP Platelet transfusion

Elderly Abuse

4 An underreported but extremely important mechanism of injury in elderly trauma patients is abuse. Elderly abuse is committed by an individual who has a relationship with and is responsible for the well-being of an elderly individual. Abuse can be further classified as physical abuse, verbal or psychological abuse, sexual abuse, financial abuse, and neglect.[31] Perpetrators of elderly abuse may include family members or caregivers either in the home or at an assisted-living facility. Abuse of the elderly is associated with depression, cognitive impairment, loss of functional capacity, and increased morbidity and mortality.[32] Several risk factors and

warning signs for elderly abuse have been identified and are listed in **Table 30.4**.[33] If elderly trauma patients appear to be at risk for or display warning signs of possible abuse, they may be assessed using a variety of available screening tools[33] including the American Medical Association (AMA) screening tool, the Conflict Tactics Scale (CTS), the Brief Abuse Screen for the Elderly (BASE), the Elder Assessment Instrument (EAI), or the Comprehensive Geriatric Assessment (CGA). Some recommended strategies for intervention in suspected cases of elder abuse are outlined in **Table 30.5**.[31]

Traumatic Brain Injury

Traumatic brain injury (TBI) is a significant cause of morbidity and mortality in elderly trauma patients.[34] In 2013, TBI-related ED visits among the elderly population totaled over 480,000.[35] The most common mechanism causing TBI in elderly patients is falls followed by motor vehicle collisions.[34] Falls account for 55% of all TBIs in patients 65 to 74 years old and 85% of TBIs in patients >85 years old.[34] 5 Imaging with head CT in elderly trauma patients should be used liberally for several reasons: (1) Elderly patients have progressive brain atrophy leading to stretching of bridging veins and increased risk of subdural hemorrhage after trauma,[36] (2) clinical tools such as the New Orleans Criteria and Canadian CT Head Rule exclude elderly patients,[37,38] and (3) neurologic examination may be unreliable in elderly trauma patients.[39,40] The catastrophic combination of TBI and preinjury anticoagulation should prompt to rapid reversal of anticoagulation.[41,42]

Table 30.3 AGS/BGS Clinical Practice Guideline: Prevention of Falls in Older Persons

Summary of Recommendations

Screening and Assessment

1. All older individuals should be asked whether they have fallen (in the past year).
2. An older person who reports a fall should be asked about the frequency and circumstances of the fall(s).
3. Older individuals should be asked if they experience difficulties with walking or balance.
4. Older persons who present for medical attention because of a fall, report recurrent falls in the past year, or report difficulties in walking or balance (with or without activity curtailment) should have a multifactorial fall risk assessment.
5. Older persons presenting with a single fall should be evaluated for gait and balance.
6. Older persons who have fallen should have an assessment of gait and balance using one of the available evaluations.
7. Older persons who cannot perform or perform poorly on a standardized gait and balance test should be given a multifactorial fall risk assessment.
8. Older persons who have difficulty or demonstrate unsteadiness during the evaluation of gait and balance require a multifactorial fall risk assessment.
9. Older persons reporting only a single fall and reporting or demonstrating no difficulty or unsteadiness during the evaluation of gait and balance do not require a fall risk assessment.
10. The multifactorial fall risk assessment should be performed by a clinician (or clinicians) with appropriate skills and training.
11. The multifactorial fall risk assessment should include the following:

Focused History

a. History of falls: detailed description of the circumstances of the fall(s), frequency, symptoms at time of fall, injuries, and other consequences
b. Medication review: all prescribed and over-the-counter medications with dosages

c. History of relevant risk factors: acute or chronic medical problems (e.g., osteoporosis, urinary incontinence, cardiovascular disease)

Physical Examinations

a. Detailed assessment of gait, balance, and mobility levels and lower extremity joint function
b. Neurologic function: cognitive evaluation, lower extremity peripheral nerves, proprioception, reflexes, and tests of cortical, extrapyramidal, and cerebellar function
c. Muscle strength (lower extremities)
d. Cardiovascular status: heart rate and rhythm, postural pulse, blood pressure, and, if appropriate, heart rate and blood pressure responses to carotid sinus stimulation
e. Assessment of visual acuity
f. Examination of the feet and footwear

Functional Assessment

a. Assessment of activities of daily living (ADLs) skills including use of adaptive equipment and mobility aids, as appropriate
b. Assessment of the individual's perceived functional ability and fear related to falling (assessment of current activity levels with attention to the extent to which concerns about falling are protective [i.e., appropriate given abilities] or contributing to deconditioning and/or compromised quality of life [i.e., individual is curtailing involvement in activities he or she is safely able to perform due to fear of falling])

Environmental Assessment

a. Environmental assessment including home safety

Fractures

Elderly patients have decreased cortical bone mass increasing their risk for fractures at lower levels of kinetic energy. As a consequence, older patients have increased risk of rib, spinal, pelvic, and extremity fractures after falls and other low-impact mechanisms than younger patients.

Rib fractures are a significant cause of morbidity and mortality among older patients.[43] Retrospective studies show that in-hospital mortality for patients >65 years is double that of younger patients.[44] The risk of mortality and pneumonia increases with increasing number of ribs fractured, and patients with more than three fractures have worse outcomes.[44,45] Up to a third of older patients with rib fractures develop pneumonia and rib fractures are associated with longer mechanical ventilation days and ICU length of stay.[44]

Osteoporosis, prior fracture, and functional impairment are all risk factors for pelvic fracture.[46] Over 80% of pelvic fractures are caused by falls, and morbidity and mortality after pelvic fractures is significant. In-hospital mortality approaches 8% and is up to five times higher than for younger patients.[47] Many patients after pelvic fracture require a cane or a walker, up to one-third are institutionalized, and 27% will die within a year of injury.[46]

Spinal trauma is increasingly common in elderly patients.[48] The risk of cervical fracture after falls increases with age due to higher rates of cervical stenosis and degenerative disk disease.[19] An estimated 5% to 10% will sustain spinal injury and permanent neurologic deficit after cervical fracture, and 1-year mortality is estimated to be 20% to 30%.[49]

Fourteen percent of elderly patients who sustain hip fracture after falls die within 6 months and almost one-fourth dies within a year.[50,51] Most do not regain prior functional abilities, and patients after hip fracture are five times more likely to live in an institution a year after injury. Hip fracture in older patients often leads to depression,[52] social isolation, and worse overall health. Up to half of patients with hip fracture experience pain for many months after injury.[53] Shorter time to surgery is associated with decreased mortality and fewer complications.[54]

Table 30.4 Risk Factors and Warning Signs for Elderly Abuse

History	**Physical/Mental Status Examination**
Advanced age (>80 yrs)	Indicators of sexual abuse: pain, bruises, lacerations, bleeding in anal–genital areas; bruised breasts or abdomen; signs of venereal diseases
Disability in self-care	Lacerations (including large skin tears, abrasions, burns, and bruises) without adequate explanation, especially on the trunk or other unusual locations
Dementia	Suspicious fractures in sites other than those seen in osteoporotic fractures, that is, wrist, hip, or vertebral body
Depression	Malnutrition
History of hip fracture	Focal findings on neurologic examination
History of stroke	Signs of dehydration
Social isolation	Pressure ulcers
Poor socioeconomic status	Dementia, psychiatric disorders, lack of mental capacity
External family stressors	
Unfavorable caretaker characteristics (mental illness, substance abuse, history of violent or antisocial behavior, depression, or financial dependency on the victim)	
Institutional staffing shortages	
Inappropriate or excessive medications; failure to get needed medications; lack of appropriate monitoring of medications and their effects	
Substance abuse	

Table 30.5 Strategies for Intervention by Physicians in Suspected Cases of Elder Abuse

Suspected Type of Abuse	Intervention Strategies
Neglect	Optimize assistance, including home care Address burden and stress on the caregiver Educate caregiver that care being provided may be aberrant Identify alternative potential caregivers Arrange for social work assistance to ensure benefits and services are optimized Consider nursing home placement Consider adult day care and other respite programs
Verbal abuse	Refer victim for psychiatric or social work assistance Recognize and treat depression and other mental health issues Address burden and stress on the caregiver Educate caregiver that care being provided may be aberrant Identify alternative potential caregivers Address substance abuse
Financial exploitation	Stop the loss of resources as soon as possible Consider power of attorney, daily money management, or guardianship Alert banks and financial institutions to victim's vulnerability

	Consider referral to local law enforcement, district attorney, or both
Physical/sexual abuse	Evaluate, treat, and document physical and sexual violence Refer case to local law enforcement and district attorney Consider filing an order of protection with assistance of law enforcement Consider referral to a shelter for victims of elder abuse Emphasize the need for a safety plan

TRIAGE CRITERIA FOR OLDER PATIENTS

Trauma center care reduces in-hospital mortality for older trauma patients,[55,56] and the benefit of treatment at trauma centers for older patients increases with age.[57] However, triage of older patients can be quite challenging. 6 Even severely injured older patients may not display standard signs of hemodynamic instability. Furthermore, because older patients cannot tolerate large blood loss and shock, some have advocated that systolic blood pressure ≤120 mm Hg should trigger trauma activation to prompt earlier intervention.[58] The Centers for Disease Control suggests that injured patients >55 years should be transferred to a trauma center, regardless of injury severity.[59] The Eastern Association for Trauma (EAST) guidelines recommend that trauma centers should lower threshold for trauma team activation for elderly patients. Further, the guidelines suggest that older patients should be transferred to a level I center if they have a base deficit of −6 or greater, or one body system AIS is >3.[60] In a retrospective study using the National Trauma Data Bank, Pandit et al.[61] showed that shock index (HR/SBP) >1 was associated with higher rates of blood transfusions, exploratory laparotomy, in-hospital complications, and in-hospital mortality.

Based on these findings, the authors recommend that patients with a shock index >1 should be transferred to level I trauma centers.

Despite evidence supporting higher triage, multiple studies show that older patients are routinely undertriaged.[62] Data from the Washington State database showed that the likelihood of being transferred to a trauma center decreased above age 45.[63] Compared to younger patients in the cohort, patients 81 years and older were only 11% as likely to be transported to a level I trauma center from the scene, and only 24% as likely to be transferred from a lower level center to a level I center. The relationship between trauma center admission and longer-term outcome is controversial. One study of severely injured older patients (ISS >15) in three counties in California showed that older patients were less likely to receive care at trauma centers, yet mortality at 60 days after injury was no different.[64]

EVALUATION AND MANAGEMENT

Trauma Evaluation

Although the majority of trauma patients suffer from low energy mechanism of injuries such as ground level falls, initial evaluation of geriatric trauma patients should follow Advanced Trauma Life Support (ATLS) principles. As described previously, older patients are much more likely to have medical comorbidities and extensive lists of medications. It is estimated that approximately 80% of geriatric trauma patient live with at least one comorbid condition.[17] These patients most commonly have hypertension (30%), diabetes (16%), and other cardiovascular comorbidities.[65] These comorbidities along with the changes in physiology described previously should be taken into consideration on assessment of hemodynamic stability. Furthermore, a diligent medication history should be taken to identify beta blockers, ACE inhibitors, anticoagulant and antiplatelet medications. Standard laboratory evaluation should include complete blood counts, comprehensive metabolic panel, coagulation studies such as prothrombin time with international normalized ratio and partial thromboplastin time, lactate, and cardiac enzymes. Imaging should include a chest and pelvis x-ray and focused assessment for sonography and trauma for all high-energy blunt

mechanisms and low-energy mechanisms with signs or physical examination findings concerning for underlying injuries. One should consider the injuries that geriatric patients are more prone to as detailed previously, and CT imaging should be used liberally when concern for a TBI, spinal or rib fractures exists.[66]

Comprehensive Geriatric Assessment

7 Due to the broad range of age-related factors that can contribute to injury and adversely affect recovery in geriatric patients, patients should receive a CGA during their hospital stay. This is a multidimensional and multidisciplinary evaluation including functional ability, physical health, cognition and mental health, and medication review. A recent meta-analysis of 22 randomized trials showed that hospitalized elders who receive a CGA are less likely to die in hospital, have higher rates of discharge home, and improved long-term functional outcomes.[67] Functional status is evaluated with a review of activities of daily living (ADLs) (eating, dressing, bathing, transfers, toileting, continence) and instrumental ADLs (housework, bills, meal preparation, medication management, using the telephone).[68] Physical and occupational therapists can assess gait, balance, home safety, and ability to carry out ADL.

Medications commonly used in older patients can exacerbate injury. Postural hypotension is a common condition in older adults, leading to falls, and can be caused by medication side effects (diuretics, antiarrhythmics, benzodiazepines, antidepressants, and psychotropic agents).[69,70] Antidepressants and psychotropic agents can cause gait impairment. Most patients should receive a nutritional assessment because malnutrition in elderly patients is highly prevalent; 38% of community-dwelling elders are either malnourished or at risk of malnourishment.[71] Social workers can assess social supports, caregiver needs, financial assets and identify resources for the patient and family after hospital discharge. Poverty rates are highest for those 85 and older, and rates are increasing.[72] Social isolation is also a major contributor to poor health in this age group.[73] Those without social support have more frequent hospitalizations and higher healthcare costs near the end of life.[74] They are also more likely to be discharged to institutions. In cases where it is impractical to thoroughly evaluate each

condition during hospitalization, patients should be referred for outpatient follow-up at discharge.

Assessing Frailty

8 Frailty is a syndrome of decreased physiologic reserve, includes physical, cognitive, social and psychological components that can worsen over time, and is distinct form the normal aging process and other comorbidities.[75] Frailty is associated with higher mortality and complications, worse functional outcomes after trauma, and is more predictive than age or injury severity as a predictor of hospital complications, in-hospital mortality, or discharge to an institution.[76] The prevalence of frailty increases with age: 7% of patients at the age of 65 are frail compared to 30% of patients aged 80 and older.[77] Components of the frailty syndrome include shrinkage, weakness, exhaustion, low physical activity, and slowness. Presence of three or more of these indicates frailty.[78]

Frailty can be assessed using a number of different instruments.[79] The Trauma Specific Frailty Index and the Rockwood Frailty Score were recently shown to be better predictors of poor outcomes compared to two other commonly used instruments.[80] A recent meta-analysis sought to identify the optimum frailty assessment tool.[81] The authors noted that despite variations in outcome measures, timing and personnel involved in frailty assessment, and data sources used for assessment, each of the 28 studies reviewed all showed a correlation between frailty and adverse outcomes, and concluded that early assessment of frailty will lead to identification of geriatric patients that may benefit from modified trauma care. Furthermore, frailty has also been shown to correlate with 6-month readmission, recurrent falls, and 6-month mortality.[82] Other investigators have considered sarcopenia, a loss of muscle leading to decreased strength and impaired mobility, as a surrogate measure of frailty in trauma patients. Sarcopenia is associated with more days on the ventilator, and higher postacute care needs, and can be measured using the cross-sectional area of the psoas or masseter muscles.[83,84] The Vulnerable Elders-13 Survey, an assessment of functional status, has been validated as a screening tool to predict discharge to nursing facility, and surgical complication or death in trauma patients 65 years or older. In a

prospective study of 63 geriatric trauma patients, each VES-13 point increased the odds of complication by 1.53.[85]

Patient Management

Data published over the last decade have shown that geriatric trauma patients benefit from care at trauma centers and management by multidisciplinary teams. Various studies have shown that trauma centers with higher volumes and proportions of geriatric trauma patients have lower mortality, fewer complications, and lower rates of failure to rescue.[86,87] This suggests that the greater experience of these centers leads to improved outcomes. Furthermore, there is a great deal of interest in the value of geriatricians to the care of trauma patients. Data also show that routine geriatric consultation leads to lower mortality rates, lower rates of delirium, fewer discharges to facilities among patients admitted from home, and better long-term functional recovery.[88–90]

Some centers have reported success in developing clinical pathways for geriatric trauma patients. Studies evaluating protocolized treatment involving using serial arterial blood gas and base deficit assessment for guided treatment, admission to the ICU, and geriatric consultation show improvement in mortality using these protocols.[91–93] Previously, Mangram et al.[94] described their experience with a dedicated geriatric service and hospital unit, known as the G-60 service, which is a multidisciplinary serviced aimed at providing comprehensive care. Patients were evaluated by a surgeon and a hospitalist at the time of trauma activation and admitted to the surgical service. Other services including physical medicine and rehabilitation, palliative care, physical and occupational therapy, respiratory therapy, the G-60 nurse supervisor, social work, nutrition, pharmacy were also notified at the time of activation and evaluated patients within 24 hours of admission. Surgeon-led multidisciplinary rounds occurred twice weekly. As compared to historical controls, patients on the G-60 service had significantly shorter ED length of stay, time to OR, hospital length of stay, and ICU length of stay. Although mortality was unchanged, there were also significantly lower rates of medical complications. Furthermore, when applied to patients based on frailty rather than age, the use of this multidisciplinary approach was shown to decrease delirium and

readmission.[95] The evidence supporting multidisciplinary care of geriatric trauma patients is strong, and organizations such as the American Association for the Surgery of Trauma and American College of Surgeons Committee on Trauma advocate their implementation at centers caring for these patients.

OUTCOMES

Mortality Outcomes

The relationship between age and adverse outcomes among older trauma patients is well recognized.[96] As compared to younger patients, in-hospital mortalities for older patients are 4.4% versus 1.6% for low severity injuries and 5.9% versus 1.4% for moderate severity injuries. Furthermore, in patients over the aged 85 and older, mortality has been reported as high as 60%.[97] Moreover, mortality among older trauma patients increases with the number of comorbidities; patients with minor injuries and comorbidities are at increased risk of death compared to age-matched counterparts without comorbidities.[98] It is important for clinicians to recognize that significant numbers of geriatric trauma patients die shortly after hospital discharge, and 30 days postdischarge mortality rates have been shown to be double in-hospital mortality.[99] Other than the impact of age and comorbidities on mortality, in-hospital complications such as respiratory failure and delirium are associated with increased mortality. Medications including analgesics and their effect on delirium are well understood. It is imperative to use nonnarcotic options for pain control as first-line treatment in the geriatric patient. Regional anesthesia has long been advocated to minimize narcotic use, and was recently shown to decrease the risk of delirium in geriatric patients with rib fractures.[100]

Functional Outcomes

Most older trauma patients will return to their prior level of function, and thus an initial aggressive approach to treatment in a trauma center is warranted.[60] However, a significant portion of patients experience long-term functional decline after injury. A follow-up study of blunt trauma patients

showed that 87% were functionally independent 1 to 3 years after injury, and another with mean follow-up 2.8 years after injury showed that 63% remained independent but with reduced function.[101] Studies with 12 months or less follow-up show higher rates of decreased functional abilities. In a prospective study of 37 patients >65 years, Kelley-Quon et al.[102] showed that most patients had lost one ADL at 12 months. More recent data from this group show that a geriatric consultation during the index hospitalization is associated with less long-term functional decline.[90] Quality of life in older patients is significantly impaired. Among patients 1 year after hip fracture 90% have reduced mobility, 69% have pain, and 33% who were independent live in a nursing home. As compared to patients without TBI, a cohort of patients >50 years old had poorer cognitive and psychosocial function a year post injury.

PALLIATIVE AND END-OF-LIFE CARE IN THE GERIATRIC TRAUMA PATIENT

Palliative care is an approach to medical care aimed at relieving suffering and improving quality of life for patients with serious illness and for their families. Palliative care is appropriate in the management in a broad range of injured patients who die or suffer with acute and chronic pain, functional disability, or life-limiting conditions such as severe frailty and underlying organ failure.[103] Clinical domains of palliative care encompass symptom management. Spiritual, religious, psychosocial, and bereavement support can be delivered alongside aggressive life-prolonging care and should not be limited to only those patients near the end of life.[104] Thus palliative care can be provided to patients who are "cured" of their illnesses or recover from injury. Palliative care should not be confused with hospice care which is an administrative benefit provided to patients with terminal illness and typically provided to patients expected to survive less than 6 months.

End-of-Life Care

9 Four-fifths of in-hospital deaths among geriatric trauma patients involve decisions to withdraw or withhold of life-sustaining therapies.[105] Advanced directives, including living wills and proxy forms are intended to guide medical decisions in the event a patient loses capacity to make decisions. Unfortunately, many patients, even those with terminal illness, do not have advanced directives or the advanced directives are too specific or too broad to be useful.[106] Therefore, it is critically important that clinicians make every effort to engage patients and their families in conversations about resuscitation status, the overall goals of care, and expectations for recovery early in the hospital course. Patients may forego heroic measures and prolonged life-sustaining treatments if all possible outcomes are not acceptable to them.[107] Furthermore, lack of decision-making capacity, whether it be from pre-existing comorbidities, sequelae of injuries, or delirium, often complicates this discussion with the patient. It is advisable for clinicians to identify healthcare proxies as early in the hospital course as possible should this be the case. Palliative care services, which focus on improving quality of life in seriously ill patients, are an integral part of critically ill geriatric trauma patients.

Physicians play an important role in providing a comfortable death experience for patients and families. In death, patients want to minimize discomfort, to avoid a prolonged dying process, to achieve a sense of control, and time to strengthen relationships with loved ones.[108] Survivors and surrogates suffer high rates of depression, posttraumatic stress disorder, and complicated grief after a loved one dies in the ICU.[109] Better outcomes for survivors are achieved when they feel that they have been well informed and had appropriate responsibility in decision making.[110] It is important for physicians to provide emotional support for surrogates who are often conflicted and distressed.

In cases where the primary goal is comfort, liberal use of opioids can reduce pain and dyspnea. Some clinicians may be reluctant to use opioids for fear of causing respiratory depression and death. Opioid use is ethically justifiable in these scenarios as long as the intent is symptom relief and not euthanasia. Patients should receive doses adequate to achieve comfort; target respiratory rate is 15 to 20 breaths/min. When patients die, physicians should be available to answer questions and address bereavement needs. The way death is communicated is important. In a study of survivors of patients who

died in the ICU, failure to find the physician comforting was most strongly associated with developing a psychiatric diagnosis in the year after death.[109] In another study of 70 survivors of cancer patients, feeling unprepared was a predictor of major depressive disorder up to 9 months.[111]

Hospice

Hospice is an interdisciplinary approach to care that provides comprehensive, medical, nursing, counseling, and bereavement to terminally ill patients and their families. Referral for hospice care is appropriate when patients have a limited prognosis and the primary goal is comfort and symptom management. In the care of geriatric trauma patients, hospice may be relevant to patients with severe TBI or patients who sustain injury in the setting of other advanced serious underlying illnesses with life expectancy 6 months or less. Hospice care is associated with better quality of life, better bereavement outcomes, lower healthcare costs, and either equivalent or improved survival in patients with a terminal diagnosis.[112–115] The impact of transition to hospice on trauma center mortality reporting is unclear. Kozar et al. found wide variation among 167 trauma centers enrolled in the Trauma Quality Improvement Project as to whether they reported patients discharged to hospice as in-hospital deaths or survivors. The authors advised that hospice discharge should be considered death across centers to prevent distortion of actual performances.[116]

Trauma in Pregnancy

Dirk C. Johnson and Kimberly A. Davis

Key Points

1. The management of the pregnant women presents challenges that can impact outcomes for both the mother and child.
2. Treatment priorities remain the same as for the nongravid patient but plans should be tailored for the anatomic and physiologic changes in the gravid trauma patient.
3. Anatomic and physiologic changes in the gravid trauma patient vary by trimester impacting management considerations.
4. Relative hypervolemia of pregnancy may mask physiologic changes associated with massive hemorrhage.
5. Compression of the inferior vena cava (IVC) and hypotension can result from supine positioning. Positioning with a wedge is recommended.
6. A Kleihauer–Betke test should be performed in all pregnant trauma patients >12 weeks of gestation and prophylactic anti-D immune globulin given within 72 hours for high-risk patients.
7. The increased risk for deep venous thrombosis (DVT) should be mitigated with subcutaneous unfractionated heparin prophylaxis.
8. Limit radiation exposure from imaging studies if possible. Ultrasound (including focused abdominal sonography for trauma [FAST]) is a useful imaging modality.
9. Angiography and angioembolization may be useful in life-threatening hemorrhage, recognizing the risks of increased radiation exposure.
10. Intimate partner violence (IPV) and substance abuse are common and should be screened for.

INTRODUCTION

The leading cause of nonobstetric death in women of child bearing age is trauma. Pregnant patients present a unique scenario in that treatment is

required for two (or more) patients 1 simultaneously. The management of pregnant women who suffer trauma is complicated by altered physiology, anatomic distortions, and additional diagnostic considerations. These complexities are highlighted by increased mortality as compared to nonpregnant women.[1,2] More than 1 in 20 pregnancies are complicated by trauma of varying degree which leads to increased rates of preterm labor, placental abruption, and fetal demise.[3,4] Evaluation of pregnant women after trauma can be a daunting task but should follow the same priorities as for nonpregnant patients. Recognition of the predictable changes of anatomy and physiology as gestation progresses, pregnancy-related conditions, and specific challenges in critical care and operative management will guide a knowledgeable provider. Early consultation with an obstetrical provider should be strongly considered.

Pregnancy is a well-known risk factor for intimate partner violence (IPV) but is an often-ignored issue by healthcare providers. The primary focus of resuscitation should be to stabilize the mother. While fetal survival and outcome must be considered, preterm and emergency deliveries are associated with poorer outcomes for infants.

EPIDEMIOLOGY

Women seek medical attention following trauma in 5% to 7% pregnancies but few require hospitalization.[5–8] More than 40% of maternal deaths in the United States are due to trauma. Fetal death is reported in nearly half of pregnancies when the mother has life-threatening injuries, but even minor trauma can be associated with fetal loss. In fact, the majority of fetal loss occurs after minor injuries due to their much higher incidence.[9] Most traumas occur later in pregnancy, with the majority occurring during the third trimester. Motor vehicle collisions are the most common mechanism of injury, followed by falls and interpersonal violence.[10] Motor vehicle collisions are a leading cause of fetal death due to their frequency (207 cases per 100,000 pregnancies).[11,12] Interpersonal violence between intimate partners occurs in up to 30% of pregnant women, with a fetal mortality of 5%. While it is more common earlier in pregnancies, violence is prevalent

throughout gestation and increases immediately after delivery.[13–15] Almost 10% of trauma in pregnant patients is intentional.[16]

MECHANISMS OF INJURY

Phases of fetal maturation and uterine size during pregnancy correlate with injury patterns based on stage of development. Early in pregnancy, before 12 weeks of gestation, the uterus remains thick walled and within the pelvis. As the uterus enlarges, it becomes increasingly thin walled and emerges from the protection conferred by the bony pelvis. By week 20, the uterus reaches the umbilicus and by week 34, the costal margin. Additionally, the relative volume of amniotic fluid decreases further limiting the defenses for the fetus to blunt trauma.

Falls during pregnancy are underreported. When surveyed, 27% of pregnant women reported a fall during their pregnancy.[17] Normal changes in pregnancy (i.e. increased weight, increased joint laxity, and hypermobility) predispose women to falls. Fortunately, most falls result in only minor trauma to the mother, but they still represent a risk to the fetus.

Motor vehicle collisions, the most common mechanism of significant trauma for pregnant women can be mitigated using seat belts. Maternal use is associated with superior outcomes and decreased fetal mortality.[18] With increasing gestational age, the fetus is at higher risk for direct blunt force either from the seat belt or the steering wheel. Trauma to the fetus can results in skull fracture and/or intracranial hemorrhage. Placental abruption, separation of the placenta from the uterus, is the most common direct cause of fetal demise after trauma. Uterine rupture, while rare, is exceptionally lethal with rare fetal survival and maternal mortality of 10%. Maternal pelvic fractures, a high-energy marker, should raise concern for retroperitoneal hemorrhage of the mother and direct injury to the fetal head especially late in pregnancy.

Penetrating trauma in pregnant woman has a high fetal mortality rate, ranging from 40% to 80%, depending on mechanism, gestational age, and location.[16,19,20] Gunshot wounds (GSWs) result in represent 73% of penetration abdominal wounds in pregnancy.[16] Fetal injury is identified in 70% these cases. All abdominal GSWs should be explored but stabs wounds

may be managed nonoperatively in the stable patient if there is no fascial violation.[21]

EVALUATION OF THE PREGNANT TRAUMA PATIENT

2 The American College of Surgeons' Advanced Trauma Life Support guidelines apply for both pregnant and nonpregnant trauma patient.[22] Evaluation begins with a primary survey, according the ABCDE approach pausing to correct immediately life-threatening problems when identified. A complete head-to-toe assessment, the secondary survey, follows. Prioritizing resuscitation of the mother leads to overall the best outcomes for the fetus. A detailed obstetric history including gestational age, prenatal care, complications, and names of obstetrical providers can be invaluable information.

The goals of fetal assessment are to evaluate for fetal injury or death, uteroplacental integrity, and signs of maternal fetal hemorrhage (MFH). Key to the assessment is knowing gestational age and sonography. For viable pregnancies (≥23 weeks) at least 4 hours of electronic fetal heart rate (FHR) and uterine activity monitoring is recommended to start as soon as it is feasible. Heart tones can be heard as early as 10 weeks and should be confirmed but previable fetal monitoring is not indicated.[23] As fetal distress often precedes maternal signs, FHR monitoring can help guide resuscitation. Fetal tachycardia (FHR >160) and bradycardia (FHR <120) are signs of fetal distress and should prompt additional resuscitation for the mother (see **Table 31.1**).

Airway

Pregnant women increase their oxygen consumption 30% to 60% and have a decreased functional expiratory reserve volume and functional residual capacity. The space occupied by a gravid uterus retards diaphragmatic excursion into the abdomen diminishing respiratory reserve potentially leading to precipitous hypoxia of mother and fetus.

Normal weight gain during pregnancy increases BMI and Mallampati scores making airway management more challenging with higher morbidity and more failed intubations.[24] Hormone-related fluid retention leads to generalized edema, including in the tongue, oropharynx, and trachea, further complicating laryngoscopy and intubation. These difficulties lead to much higher rate of failed intubation during pregnancy.[25] The physiologic changes of pregnancy should be accounted for while avoiding hypoxia and hypotension.[22] Pregnant women should be considered high risk for aspiration due to decreased esophageal sphincter tone and upward compression of the stomach from the uterus.

3 **Table 31.1** Physiologic Changes in Pregnancy

Cardiovascular	Increased heart rate (10–15 bpm) Increased plasma volume Decreased systemic vascular resistance Decreased blood pressure (first and second trimesters)
Pulmonary	Elevated diaphragm Increased tidal volume Increased minute ventilation Increased oxygen consumption Decreased functional residual capacity Decreased PCO_2 (30 mm Hg)
Gastrointestinal	Decreased lower esophageal sphincter competency Decreased gastric motility Increased transaminase levels Impaired gallbladder contractions
Genitourinary	Increased glomerular filtration rate Increased renal plasma flow Decreased blood urea nitrogen levels Decreased creatinine levels Hydronephrosis/hydroureter
Hematologic	Relative anemia but increased overall RBC volume Increased WBC counts (9.8–15k) Increased clotting factors VII, VIII, IX, X, XII (hypercoagulability) Increased fibrinogen Decreased fibrinolytic activity (hypercoagulability)

Pulmonary System

4 High concentration of supplemental oxygen should be provided to pregnant women during the primary survey. Chronic hyperventilation and a 30% to 40% increase in minute ventilation during pregnancy is compensatory for a decrease total lung capacity and functional residual capacity due to anatomical changes. Chronic respiratory alkalosis, a side effect of hyperventilation, sets up a gradient for diffusion of fetal CO_2 to the maternal circulation. Overaggressive correction of maternal alkalosis can impact the fetus negatively.[26] Hypocapnia ($PaCO_2$ of <30 mm Hg) is normal in pregnancy and a "normal" CO_2 (~40 mm Hg) may be a sign of impending hypercarbic respiratory failure.

Mechanical ventilation is poorly studied in pregnant patients and there is no consensus on optimal mode for support even in acute respiratory distress syndrome (ARDS). However, as general principle, hypercapnea should be avoided and oxygenation should be optimized.

In cases of pneumothorax or hemothorax, if chest tubes are required, they should be placed one to two interspaces higher than usual late in pregnancy to avoid inadvertent injury to the hemidiaphragm.

Cardiovascular System

Relative hypervolemia of pregnancy can blunt typical signs of shock after hemorrhage. As much as 35% of maternal blood volume can be lost prior to signs and symptoms of shock. The pulse rate is 10 to 15 beats/min faster until delivery and circulating blood volume increases steadily during pregnancy to 150% or more at term.[27] Early and robust volume resuscitation is recommended to maintain maternal circulation. Maternal hypovolemia will lead to fetal compromise. During resuscitation, the patient should be placed in a slight left decubitus position with a wedge to tilt her >15 to 30 degrees or manually 5 displacing the uterus to her left to alleviate the inferior vena cava (IVC) compression and subsequent decreased venous return associated with supine positioning. Spinal precautions should be maintained. If CPR is needed this position decreases effectiveness of chest compressions. Standard

advanced cardiac life support (ACLS) voltage should be used for defibrillation of shockable rhythms for pregnant patients.

Resuscitation should be treated with crystalloid and blood component therapy in accordance with the principles of balanced resuscitation emphasizing early use of blood and blood products for suspected life-threatening hemorrhage.[28,29] Resolution of fetal distress signs may lag up to 30 minutes after maternal stabilization.[30] When deemed appropriate for transfusion, O-negative blood products should be used until type specific or cross-matched blood is available. Pressor support should be reserved for fluid-refractory shock because uteroplacental prefusion is highly sensitive to their use and could decrease fetal perfusion.[23] If needed, ephedrine and phenylephrine have the least effect on fetal circulation and are recommended by some for initial pressor support in pregnant patients. Norepinephrine and epinephrine can be considered, especially in those without a viable pregnancy.[31]

Hematologic System

There is a disproportionate increase in plasma volume relative to the approximately 15% increase in red blood cell (RBC) mass initially yielding a functional physiologic anemia as early 10 weeks. RBC production augments as pregnancy progresses and hematocrits are near normal by term. A hematocrit of 32 is considered normal until the third trimester.[5] White blood cell counts (WBCs) also are also elevated ranging from 9.8 to 15 k/mm.[4]

Maternal and fetal circulations are normally separate but as little as 0.001 mL of fetal blood crossing into the maternal system can trigger sensitization in a Rh-negative mother. Up to a third of pregnant trauma patients have some degree of MFH.[23] Therefore, anti-D immune globulin (RhoGAM™) should be given within 72 hours to all Rh-negative mothers with 6 confirmed or suspected MFH. Kleihauer–Betke (KB) testing is advocated for all Rh-negative mothers with >12 weeks of gestation; its utility in Rh-positive women is less clear.[23,32,33]

Pregnancy is a hypercoagulable state and increases the risk of venous thromboembolic events (VTEs) fivefold.[34] The phenomenon is attributed to an increase in coagulation factor production, decreased fibrinolysis, and

venous stasis from aortic and IVC compression. The hypercoagulability of trauma compounds 7 this risk. The heightened risk warrants prophylactic treatment with heparin, either fractionated or unfractionated, as well as pneumatic compression devices, in conjunction with early ambulation.[34] Warfarin, a known teratogen, should be avoided.[35] Direct-acting oral anticoagulants (DOACs) are not recommended in pregnancy.[36]

FETAL EVALUATION AND MONITORING

After maternal evaluation and resuscitation, examination of the fetus should be performed, including an obstetrical history and examination, including estimation of uterine size and fundal height. A vaginal examination should be performed looking for bleeding, a nonspecific sign of many unfavorable obstetrical conditions including premature cervical dilation, early labor, abruption placentae, and placenta previa. A vaginal examination should be performed to evaluate for rupture of membranes, cervical dilatation, effacement, fetal presentation, and station after previa has been excluded. Cervical dilatation, bleeding, strong contractions, or bulging of the perineum can signal impending delivery. Early involvement of obstetrics and neonatology is advised (see **Table 31.2**).

Table 31.2 Obstetrical Examination Points

Fundal height
Evaluation for vaginal bleeding
Rupture of membranes
Bulging perineum
Contractions
Fetal heart rate and rhythm
Amniotic fluid pooling
Gestational tissue
Perineal lacerations
Cervical dilation and effacement
Bleeding
Fetal presentation
Fetal engagement

DIAGNOSTIC IMAGING

The ideal imaging test in all patients should be convenient, quick, safe, and accurate. The choice of tests balances pressure for expedient diagnosis while minimizing risk to mother and fetus. During pregnancy, radiation exposure should be avoided or minimized whenever possible. Low levels of exposure, less than 5 rad of radiation at any gestational age, is deemed safe and has not been associated with fetal anomalies or fetal demise. The risk is highest in weeks 5 to 10 during organogenesis.[23] Radiation exposure to the fetus can be reduced with proper shielding during plain films (**Table 31.3**). Indicated radiologic examinations should proceed without delay for concerns over fetal radiation exposure. Patients and families should be reassured by the healthcare team that the radiation exposure from a single diagnostic test is not sufficient to cause harmful effects to the fetus.[37] Patients' reluctance often stems from anxieties inconsistent with the actual risks.[8]

8 Focused abdominal sonography for trauma (FAST) is a useful imaging modality to guide initial resuscitation and is safe for both mother and fetus. It has a reported sensitivity of 61% to 83% and a specificity of 94% to 100%

in detecting intraperitoneal free fluid consistent with hemoperitoneum.[38–40] Pregnant women with direct blunt force to the uterus can have massive hemorrhage from engorged uterine vessels. FAST has excellent negative predictive value in detecting pericardial, pleural, and peritoneal free fluid in the hemodynamically unstable mother.[2] Fetal ultrasound is recommended to evaluate for gestational age, cardiac activity, and movement. Ultrasound is particularly useful in the evaluation of intrauterine contents, but can miss 50% to 80% of placental abruptions.[41] Diagnostic peritoneal lavage (DPL) may be useful in evaluating unstable patients but has been largely replaced by FAST. If DPL is performed, it should be performed in the supraumbilical position above the fundus to avoid inadvertent injury to the uterus and fetus.

Table 31.3 Estimated Fetal Radiation Doses from Common Imaging Studies

Diagnostic Test	Fetal Dose (rad)
Chest x-ray	<0.01
Abdominal x-ray	0.1–0.3
Pelvis x-ray	0.04–0.24
Extremity x-ray	<0.01
CT head	<0.05
CT chest	0.1–0.45
CT abdomen	0.24–2.6
CT pelvis	0.73–4.6

Adapted from Williams PM, Fletcher S. Health effects of prenatal radiation exposure. *Am Fam Physician* 2010;82(5):488–493.[45]

Computed tomography (CT) scans are a staple in trauma evaluations because they are very sensitive for identifying injuries. Providers should utilize dose reduction strategies when possible.[42] Head and neck CT scans can be performed with minimal radiation exposure to the fetus. Radiation levels from chest, abdomen, and pelvis CT scans vary but newer scanning

techniques and algorithms can reduce radiation dosing by 25% without significantly degrading diagnostic accuracy.[43]

Magnetic resonance imaging (MRI) poses minimal risk to the fetus but it has very limited role in initial evaluation of trauma patients, largely restricted to the evaluation spine, spinal cord, and neurologic injuries in a delayed fashion. The utility of this modality is limited due to availability, scheduling, length of the examination, and inconvenience relative to imaging techniques. MRI should only be performed in hemodynamically normal patients without ongoing resuscitative efforts.

Angiography and endovascular treatments are increasingly a part of trauma care to control life-threatening hemorrhage. Radiation dosage increases with duration fluoroscopic examination and generally range from 2 to 10 rad/min. Embolization of nonuterine pelvic vessels is feasible and potentially lifesaving in pelvic fractures. However, embolizing the gravid uterus is not recommended (see **Table 31.3**).[44]

The American College of Obstetricians and Gynecologists position on diagnostic imaging for pregnant women states, "With few exceptions, radiation exposure through radiography, CT scan, or nuclear medicine imaging techniques is at a dose much lower than the exposure associated with fetal 9 harm. If these techniques are necessary in addition to ultrasonography or MRI or are more readily available for the diagnosis in question, they should not be withheld from a pregnant patient."[46]

Pelvic Fractures

Of all fractures in pregnancy, pelvic fractures have the worst outcomes. They are associated intrauterine fetal demise (IUFD) up to 40% of the time.[47,48] Hemorrhage from engorged pelvic veins and the hyperdynamic circulation of pregnancy can combine to produce maternal shock leading to fetal death.[8] Angiography and embolization can be helpful to control maternal hemorrhage.

The direct and high-energy blunt force associated with pelvic fractures is also transmitted to the uterus, placenta, and fetus. This can result in abruption or direct injury to the fetus, especially traumatic brain injuries. If the pregnancy continues, a pelvic ring fractures does not contraindicate vaginal delivery, but there is a higher cesarean section rate from multiple factors.[49]

Abruptio Placentae

Abruption, the separation of the placenta from the uterus, is the most frequent etiology of late maternal hemorrhage and the primary cause of intrauterine fetal death following trauma.[50] Severe trauma is associated with a six-fold increase in incidence, but abruption can occur with even minor trauma.[51] Both direct impact and rapid deceleration confer shear forces on the interface of an unyielding placenta against a comparatively pliable uterus resulting in separation, maternal bleeding, and compromised perfusion to the fetus. Fetal mortality may be as high as 70%. More severe cases, more than 50% disruption by surface area, are considered highly lethal and may lead to preterm labor. Smaller insults, less than 30% disruption, may not even show signs of fetal distress.

Table 31.4 Evaluation of Abruption

Maternal Risk Factors	Signs	Symptoms
Previous abruption	Vaginal bleeding	Abdominal pain
Diabetes mellitus/HTN	Intense uterine contractions	Back pain
Advanced maternal age		
Multiparity		
Tobacco use		
Cocaine or methamphetamine use		
Prior cesarean delivery		

Abruption can lead to life-threatening bleeds which may be occult if the blood is retained in the uterus. Even at lower volumes of blood loss, mothers

may develop disseminated intravascular coagulation (DIC) and hemodynamic collapse.[3] Delayed presentation of abruptio placentae has been reported but fortunately the majority presents within the first 6 hours after trauma and nearly all in the first 24. Monitoring of pregnant women with blunt injury to the abdomen is widely accepted as standard.[52] The signs and symptoms, abdominal or back pain with vaginal bleeding, are unfortunately nonspecific. All vaginal bleeding after trauma must be evaluated with at least a sonogram.[3] Ultimately, diagnosis of abruption is clinical and treatment decisions are based on laboratory data and fetal evaluation. Severe placental abruption is potentially fatal for the fetus; expedient Caesarean delivery may result in higher survival (see **Table 31.4**).[23]

Uterine Rupture

Traumatic uterine rupture, which accounts for 17.5% of MVC-related perinatal deaths, is uncommon, but is seen more often in women with uterine scarring from cesarean sections or other causes.[53] Maternal mortality risk is up to 10% and fetal survival is negligible.[9,54] Like pelvic fractures, and placental abruption, uterine ruptures result from direct high-energy blunt force and often have a larger constellation of injuries. Patients may present with abdominal pain as the only symptom of uterine rupture. Excellent outcomes in subsequent pregnancies can be achieved in those with prior uterine rupture who undergo uterine repair.[55]

Amniotic Fluid Embolism

Amniotic fluid embolism is exceptionally rare but may accompany uterine rupture and is thought to be caused by the maternal proinflammatory reaction to exposure of fetal tissue in her circulation. It manifests suddenly as respiratory distress and hemodynamic collapse. It has 20% to 60% mortality in all pregnancies.[56] Diagnosis is rooted in clinical suspicion. Chest imaging may show evidence of pulmonary vascular congestion or bilateral scattered infiltrates like ARDS. DIC may also develop in 30% of these women. There are no proven interventions available only supportive management of affected systems.[57]

Table 31.5 Eclampsia	
Risk Factors	**Signs**
Advanced maternal age (>35 yrs)	Hypertension (most reliable)
Obesity	Edema
Diabetes mellitus	Proteinuria
Prior or family history of preeclampsia	Hyperactive reflexes

Eclampsia

Preeclampsia is new-onset gestational hypertension with evidence of significant end-organ dysfunction. In the context of trauma, preeclampsia is important because it is relatively common (5% of pregnancies), and it can progress to eclampsia, with the new onset of seizures. Development of seizures is infrequent, occurring in about 0.05% to 0.2% of pregnancies. When diagnosed or suspected treatment with intravenous magnesium sulfate is recommended and emergency Caesarian delivery should be considered (see **Table 31.5**).

Disseminated Intravascular Coagulation

DIC is a dysregulation of the clotting cascade triggered by many pathologic conditions in pregnancy some of which can arise from trauma. Normal pregnant women are prone to clot due to the marked elevation of their coagulation factors. The departure from the normal state predisposes their hematologic system to DIC when activated by trauma. Major trauma, especially those with hypoperfusion, abruption, uterine rupture, eclampsia, HELLP (hemolysis, elevated liver enzymes, low platelet count), and amniotic fluid embolism, can lead to DIC. Treatment consists of blood component therapy and supportive care.

EMERGENCY CAESARIAN SECTION

Caesarian section should be deferred in favor of vaginal delivery when it is feasible. Labor can continue in appropriate patients even the onset of labor precedes completion of the trauma evaluation and treatment of identified injuries. This is true even if treatment includes laparotomy or other operative intervention (**Table 31.6**).[58]

Perimortem caesarian section can be considered for fetuses greater than 20 to 22 weeks of gestation depending on local availability of neonatology. This decision can be difficult but must be made expediently as the best fetal outcomes are correlated with time from arrest to delivery. There is also evidence that 60% of mothers have improved circulation after perimortem caesarian sections. Current recommendations advocate for perimortem caesarian section for the viable fetus within 4 minutes of maternal cardiac arrest without return of spontaneous circulation or malignant arrhythmia.[59–61] Early involvement of the obstetrics team facilitates the decision to perform an emergent caesarian section and ensures the timeliest delivery of the child should one be necessary.

Table 31.6 Indications for Emergency Caesarian

Maternal shock
Massive exsanguination
Unstable thoracolumbar spinal injuries
High risk of fetal demise
Facilitation of maternal treatment

SOCIAL CONSIDERATIONS

IPV is much too frequent. It is reported in 10% to 30% of pregnancies. Women from any age group, religion, ethnic background, income level, educational attainment, and sexual 10 orientation can be victims of IPV. Universal screening of pregnant patients for IPV is strongly recommended. Women with multiple episodes of trauma, suspicious patterns of injury, or injuries inconsistent with the reported history are concerning indicators.

Screening during trauma evaluation may not be possible. There are effective brief screening tools that can be used at a slightly delayed time. It is important that screening be performed without the partner, or the information obtained may be inaccurate. Picking up the signs and providing options for safety with referrals to social work and local resources, best ensures the safety of both mother and fetus.[62,63]

Pregnant women are not immune to substance abuse issues. In some urban facilities 50% to 80% of women were screened positive for illicit drugs.[64] Traumas affecting pregnant women were alcohol or drug related 12.9% and 19.6% respectively according to National Trauma Data Bank figures.

TEAM APPROACH TO TRAUMA IN THE PREGNANT PATIENT

Collaborative care delivery with input from prehospital providers, the Emergency Medicine, Nursing, Obstetrics, Critical Care, Neonatology, and Surgery optimizes management of the pregnant trauma patient. Early notification obstetrics (even prior to arrival of the patient) may provide the critical time that can be invaluable for both mother and fetus in extremis.

SUMMARY

Predictably, injured pregnant women are more likely to have a cesarean delivery. The risks of preterm birth and perinatal death seem to be exclusive to deliveries immediately after the trauma, a fortunately rare event attributable to the severity of trauma.[65] Fetal survival is best achieved by appropriate resuscitation and care of the mother. Recognition of the unique issues and potential complications of associated with trauma in pregnancy ensure the best possible outcome for both mother and fetus. Optimal treatment requires special attention to the evolving anatomical and physiologic changes of gestation. Evaluation and management should be tailored to the stage of pregnancy and requires a multidisciplinary, team approach.

Postinjury Management

Audrey C. Pendleton and Paula Ferrada

Key Points

1. Coagulopathy is common in trauma and is multifactorial, with dilution and consumption being contributing factors. Empiric replacement of coagulation factors is an important aspect of early resuscitation.
2. Damage control resuscitation involves limited use of crystalloid fluids and early more liberal use of massive transfusion to restore volume and maintain organ perfusion.
3. Multiple metrics should be used to determine adequate endpoints of resuscitation since vital signs alone can be falsely reassuring.
4. Abdominal compartment syndrome, characterized by increased intra-abdominal pressures and a tense, distended abdomen, causes oliguria, multi-organ failure, decreased venous return and impaired cardiac output, and emergent decompressive laparotomy is required in severe cases.
5. Traumatic brain injury (TBI) is a major cause of mortality and morbidity in trauma patients. Care of these patients must be focused on preventing secondary brain injury by avoiding hypotension, fevers, elevated intracranial pressures and seizures.
6. Early nutritional support is important in trauma patients and enteral nutrition is preferred over parenteral nutrition when possible.
7. Trauma patients can be a source of organ donation. Therefore, resuscitation should be continued even after brain death or irreversible neurological devastation is determined and until the necessary conversations can be held by the appropriate people with the families.
8. Chest trauma and rib fractures are a major cause of mortality and morbidity in trauma patients, especially in the geriatric population. Early, aggressive pain control and pulmonary toilets are essential in preventing pneumonia and respiratory failure. Surgical rib fixation is sometimes indicated to restore chest wall mechanics and effective breathing.

9 Blunt cardiac injury can often be managed with supportive measures. A high index of suspicion must be maintained for more serious cardiac injury as this can be fatal without surgical intervention.

INTRODUCTION

Trauma is now the leading cause of death for ages 46 and below in the United States.[1] Hemorrhagic shock is the most common cause of mortality during the first 6 hours following trauma and 16% to 80% of those deaths may be preventable.[2] Postinjury management predominantly focuses on two goals, early control of bleeding and resuscitation.

ACUTE TRAUMATIC COAGULOPATHY

1 Coagulopathy will worsen posttraumatic hemorrhage and is associated with increased mortality and worse outcomes. Interestingly, up to 25% of trauma patients are already coagulopathic upon arrival to the hospital.[3,4] Current data suggest that coagulopathy develops in the early posttraumatic period even before resuscitation begins and is now referred to as acute traumatic coagulopathy.[4–6] Diffuse endothelial damage, activation of the protein C pathway, and massive catecholamine release are some of the proposed mechanisms for acute traumatic coagulopathy.[7] Acute traumatic coagulopathy is exacerbated by hypothermia, acidosis, and dilution of clotting factors. Hypothermia in trauma patients results from a multitude of factors that include radiant heat losses to the environment, failure of shivering response during anesthesia, intraoperative heat loss from exposed peritoneal surfaces, and tissue hypoxia during hemorrhagic shock with decreased metabolism. Another major cause of hypothermia is the use of relatively cool room temperature resuscitation fluids or cold refrigerated blood products that were not warmed before infusion.[8–10] These cumulative factors produce qualitative and quantitative defects in platelet function and decrease coagulation factor activity.[11–13]

In addition to reducing coagulation factor activity, dilutional coagulopathy from large-volume crystalloid resuscitation and acidosis from prolonged tissue hypoxia perpetuates the bloody vicious cycle.[14,15] The combined presence of three factors, hypothermia, acidosis, and coagulopathy, is known as the "lethal triad." Modern trauma resuscitation is defined as damage control resuscitation (DCR) and aimed at reducing the iatrogenic development of this "lethal triad."

DETECTION OF TRAUMATIC COAGULOPATHY

The early identification of acute traumatic coagulopathy remains a challenge. Conventional coagulation assays like PT, aPTT, and INR are insensitive and unreliable in trauma patients, as they do not provide an accurate assessment of the in vivo state of coagulation. Moreover, these assays are performed at physiologic pH and temperature; because of this they are unable to account for the effects of hypothermia and acidosis on coagulation.[7] Acute traumatic coagulopathy involves changes in both coagulation and fibrinolytic pathways, and detection requires a more dynamic view of all components of the coagulation cascade, which is provided by viscoelastic tests, that is, thromboelastography and rotational thromboelastometry. These assays rely on changes in clot strength to detect coagulation defects and provide an in vivo picture of the coagulation and fibrinolytic processes. These tests also assess the interaction between coagulation factors and platelets and can detect functional changes in platelet function even with normal platelet counts. They can be performed with much more rapidity and have been shown to detect coagulation abnormalities with higher sensitivity as compared to conventional coagulation assays.[16–18]

Table 32.1 Components of Damage Control Resuscitation
Permissive hypotension
Early definitive hemorrhage control
Reduced crystalloid use
Use of hypertonic saline
Early correction of coagulopathy with drugs (Factor Vila, PCC, TXA)
Increased use of blood products in 1:1:1 ratios

PCC, prothrombin complex concentrate; TXA, tranexamic acid.

Viscoelastic tests have also shown to be more accurate in predicting blood product requirements and massive transfusion and can therefore guide blood transfusion in trauma patients.[19,20] Despite these advantages, viscoelastic tests come with inherent disadvantages such as cost and the need for greater expertise in performance and interpretation.

DAMAGE CONTROL RESUSCITATION

2 The primary objective of resuscitation following hemorrhage is to restore effective circulating volume to allow adequate tissue perfusion and oxygenation. Historically, the standard of practice had been to aggressively resuscitate patients with high volumes of crystalloids to restore volume and blood pressure. In recent years, there has been a paradigm shift away from the large-volume resuscitation, and specifically away from large volumes of crystalloid. Current strategies combine the principles of permissive hypotension, liberal use of blood products instead of isotonic fluids, the use of hypertonic saline to pull water back into the vascular system, and early correction of coagulopathy with blood products as well as drugs (**Table 32.1**).

Permissive hypotension aims at restoring systolic blood pressure to 90 mm Hg so that adequate tissue perfusion can be maintained while not exacerbating blood loss, before definitive hemorrhage control is achieved.

Large-volume resuscitation with crystalloids before definitive hemostasis can raise blood pressure which can "pop off" the clot and worsen hemorrhage.[21] A target mean arterial pressure (MAP) of around 60 mm Hg is thought to maintain adequate tissue perfusion without the potential for increased blood loss.[22–25] A brief period of hypotension with a MAP around 60 mm Hg can be safely maintained for short periods of time without risk of irreversible damage or an increase in mortality.[26] Permissive hypotension has been shown to reduce the risk of death and development of coagulopathy.[3,27] However, in patients with hemorrhagic shock and concurrent traumatic brain injury (TBI), the safety of permissive hypotension has not been demonstrated and thus it is not yet recommended.[28] It is important to note that permissive hypotension is intended for young, otherwise healthy patients with penetrating trauma in hemorrhagic shock. It should not be applied to patients with blunt trauma or in elderly patients, especially since the latter are more likely to have comorbidities such as cardiac and carotid disease where hypotension may lead to catastrophic results. Furthermore, hypotension in traumatic brain injury may worsen outcomes and should thus be avoided in that patient population. Up to 5% of civilian trauma patients require massive transfusion, defined as the need for more than 10 units of red blood cells in 24 hours. These patients are at greatest risk for developing dilutional coagulopathy from large volumes of resuscitation even if packed red cell transfusion is used early in the resuscitation phase.

DCR utilizes massive transfusion protocols and early use of red cells, fresh frozen plasma, and platelets in a 1:1:1 ratio in an attempt to reconstitute whole blood. The use of blood products early in the course of resuscitation is not only an attempt to combat the coagulopathy in trauma patients requiring massive transfusion but to also minimize the use of crystalloids and colloids.[29–31] The use of predefined massive transfusion protocols has shown improved survivals and decrease in adverse outcomes.[32,33] This approach requires the ability to predict the need for massive transfusion in trauma patients at the time of arrival which is often difficult even for experienced surgeons. Multiple scoring systems have been developed to help define the cohort requiring massive transfusion.[34,35]

The appropriate ratios of packed red cells, fresh frozen plasma, and platelets in exsanguinating trauma patients have been debated. The concept of

a 1:1:1 ratio stems from military data that show improved survival with the use of fresh whole blood. Since civilian trauma centers do not have fresh whole blood available, component therapy is an attempt to reconstitute whole blood by giving red cells, fresh frozen plasma, and platelets in a nearly physiologic ratio. Most studies have shown improved mortality with the use of high plasma and pRBC ratios with even greater survival in those with early (6 to 12 hours) use of high ratios.[5,8,36–41] The use of a 1:1 ratio for pRBC and platelets has also shown improved survival.[38] Despite the survival advantage with the use of a 1:1:1 ratio for transfusion, the potentially lethal complications of blood transfusion need to be kept in mind. The PROPPR trial was a multicenter prospective randomized study in hemorrhagic trauma patients that demonstrated an early survival benefit when the patients were resuscitated with a 1:1:1 ratio compared to a 2:1:1 ratio but the 28-day mortality was not statistically significantly different. FFP is an essential component of MTP but it is logistically challenging to use because it needs to be stored at −18°C and needs about 30 minutes lead time before use. These requirements can make it difficult to use in a hemorrhaging patient. In patients who require immediate MTP, pre-thawed FFP, which can be stored for 5 days, can be used immediately.[42]

Hypertonic saline has many potential advantages in that it can resuscitate with low volume by pulling water into the vascular space and thus avoids excess water during resuscitation. This concept has advantages especially in the military field environment. Hypertonic saline is also thought to be an immune modulator that potentially decreases inflammation associated with resuscitation injury.[43] However, a multicenter prospective trial in trauma patients with hemorrhagic shock was halted before completion as the outcome was similar between the groups. Overall there was no survival disadvantage in the hypertonic saline arm of the study except in a small subset of patients who did not require blood transfusion. This subset of patients had higher mortality if given hypertonic saline in the field. There was also a subset that required ICU treatment that showed higher survival and decreased multiple organ failure when hypertonic saline was given.[44] Since 7.5% hypertonic saline is not commercially available, an alternative is to use 5% hypertonic saline. Those who use 5% hypertonic saline administer it as a one-time bolus in the initial phase of resuscitation. This approach may

be beneficial in patients with TBI. The safety of using 5% hypertonic saline has been shown in two studies.[45,46]

A caveat of using hypertonic saline is that it causes hyperchloremic acidosis, but clinical significance has not yet been demonstrated. Because of the capability of increasing intravascular volume, the ideal time and place for hypertonic saline use may be in the field, especially in the military setting.[47] Hyperfibrinolysis associated with traumatic coagulopathy may decrease levels of fibrinogen. High plasma:pRBC ratios adequately replenish the fibrinogen pool required for adequate hemostasis and thus the use of cryoprecipitate rich in fibrinogen as an adjunct to DCR is rational.[8] The use of cryoprecipitate has additional advantages as it provides particles that act as a low-volume colloid resuscitation and draw water into the vascular system, and is an adjunct in resuscitation. Tranexamic acid is an antifibrinolytic agent found to be safe and effective in reducing the risk of bleeding if used within 3 hours of injury.[48] The military Tactical Combat Casualty Care Committee has recommended its use in the military setting.

Several other novel strategies have also been used as an adjunct in DCR including the use of activated recombinant factor VII (rFVIIa). rFVIIa activates factor Xa at the site of tissue injury by complexing with tissue factor on the surface of platelets. Use of rFVIIa in the initial studies appeared to reduce blood loss and mortality in trauma patients; but subsequent larger randomized trials failed to confirm these benefits.[49–52] Prothrombin complex concentrate (PCC) is another cost-effective option that reverses coagulopathy in traumatic injury[53]; however, it is not appropriate for every trauma patient and is mostly used as a second line therapy as part of a massive transfusion protocol. While each component of resuscitation is important, it is the combination of these methods that is essential. Specifically, avoiding hypothermia and acidosis, early temporizing measures and expeditious definitive control of hemorrhage with surgical or angiographic methods, use of the correct ratios of blood products and adjunctive pharmacologic agents, such as tranexamic acid and use of viscoelastic assays all compose the hemorrhage control bundle, which has been associated with decreased mortality from hemorrhage and overall improved outcome.[54]

The discussion of DCR should also include damage control laparotomy (DCL). The principle of the DCL is to explore the patient, control hemorrhage, contain contamination, and temporize the damage but to refrain

from definitive repairs that may subject the patient to a prolonged operation before they are properly resuscitated, which would exacerbate the lethal triad and increase chance of death. In these cases, the abdomen remains open and the patient is brought to the ICU for continued resuscitation. One hallmark study suggested that DCL is of benefit in trauma patients with numerous major visceral injuries that also have vascular injury; this study also showed that DCL in patients without major injuries was associated with worse outcome.[55] While the use of DCL is necessary in certain circumstances, there can be significant morbidity associated with them. Specific complications include abdominal abscesses, gastrointestinal fistulas, as well as complex ventral hernias and loss of domain. Furthermore, the prolonged ICU course and multiple trips to the operating room that occur in the patient with an open abdomen contribute to the associated morbidity.

A more recent study evaluated the variability in practice of DCL. There is no strict practice management guideline for its use, but the standard general criteria are major abdominal vascular injury, coagulopathy, acidosis, and hypothermia. Outside of these criteria, its use is left to the discretion of the surgeon. This study examined the variability of DCL in level 1 trauma centers by evaluating patients from the PROPPR Trial who underwent immediate laparotomy and categorized them to having either DCL or definitive surgical management (DSM). The study found that there is significant variability among centers in the use of DCL but that there was no difference in mortality. DCL was associated with higher rates of sepsis and VAP. This study suggests that reducing the use of DCL might lessen the morbidity burden while not affecting the mortality.[56] Definitive laparotomy may have survival benefit with decrease in morbidities known to accompany DCL such as open abdomens and enterocutaneous fistulas. Because of the decreased number of surgeries and morbidities, the cost benefits were significant.[57,58]

ENDPOINTS OF RESUSCITATION

3 The ultimate goal of resuscitation is to ensure adequate oxygen delivery to tissues. Prolonged tissue hypoxia is associated with multiorgan dysfunction syndrome, risk of infection, and increased mortality. Advanced trauma life

support (ATLS) guidelines define the correction of vital signs like blood pressure and heart rate as markers of adequate resuscitation. However, up to 82% of severely injured patients with normalized vital signs have ongoing occult ischemia that is associated with adverse outcomes.[59] While normalization of vital signs may describe the current perfusion status, they do not assess oxygen debt, defined as ongoing oxygen deficits that have accumulated during the period of shock. Oxygen debt is known to be associated with increased mortality.[60,61] Arterial lactate and base deficit may serve as indicators for severity of shock and may help to stratify patients. Trends in serum lactate levels indicate adequacy of resuscitation.

Invasive monitoring with central venous pressure (CVP) and pulmonary artery catheter (PAC) has been extensively used to guide resuscitation. CVP and pulmonary capillary wedge pressure monitoring provide information regarding the intravascular volume, but concurrent factors like mechanical ventilation and changes in ventricular compliance from myocardial dysfunction limit their efficacy in accurately guiding resuscitation.[62] Moreover, PAC use in critically ill trauma patients has not been shown to improve outcomes.[63] $ScVO_2$ and SVO_2 measure central venous oxygen saturation from the upper body and mixed venous oxygen saturation from both the upper and lower body, respectively. Inadequate oxygen supply from ongoing shock or increased oxygen demand leads to an increased tissue extraction of oxygen, which is reflected as a decrease in the values of $ScVO_2$ and SVO_2. SVO_2 of less than 65% even in the presence of normal vital signs indicates blood loss and need for transfusion to optimize oxygen supply and demand.[64] Therefore, $ScVO_2$ and SVO_2 provide a real-time picture of tissue perfusion and are able to detect very subtle changes in oxygen delivery. The ideal marker for resuscitation may be to determine blood volume, but there is currently no simple way to determine ideal circulating blood volume.

ABDOMINAL COMPARTMENT SYNDROME

4 Abdominal compartment syndrome is an undesired consequence of elevated intra-abdominal pressure and a cause of morbidity and mortality.[65] The incidence of abdominal compartment syndrome is decreasing with recent

evolution in resuscitation strategy, suggesting a possible iatrogenic etiology.[66] Intra-abdominal hypertension is defined as a pressure of greater than or equal to 12 mm Hg. Intra-abdominal hypertension is graded based on increasing intra-abdominal pressure (**Table 32.2**). Abdominal compartment syndrome is defined as a sustained intra-abdominal pressure greater than 20 mm Hg (with or without an abdominal perfusion pressure of less than 60 mm Hg) with new organ dysfunction or failure.[67] Experimental data indicate that hepatic arterial, portal venous, and hepatic microcirculatory blood flow are markedly reduced when intra-abdominal pressure is increased.[64,68]

Table 32.2 Grades of Intra-Abdominal Hypertension

Grade	Intra-Abdominal Pressure (mm Hg)
I	12–15
II	16–20
III	21–25
IV	>25

Typically, abdominal compartment syndrome is observed after severe abdominal trauma with intra-abdominal hemorrhage, severe liver and kidney injuries, and in both operatively and nonoperatively managed settings (primary abdominal compartment syndrome).[69–71] Excessive large-volume resuscitation, even in the absence of any direct abdominal trauma, can also lead to abdominal compartment syndrome (secondary abdominal compartment syndrome).[72–74] Recurrent or tertiary abdominal compartment syndrome refers to a condition following a previously treated primary or secondary abdominal compartment syndrome.[62] Risk factors for development of abdominal compartment syndrome include diminished abdominal wall compliance, increased intraluminal and intra-abdominal content, crystalloid resuscitation/leak, and other risk factors such as age, shock, high BMI, coagulopathy, and mechanical ventilation.[75–85]

Abdominal compartment syndrome can even occasionally occur in patients with an open abdomen. The diagnosis often begins with findings of a tense

and distended abdomen in the presence of high end-inspiratory airway pressures and other signs of organ dysfunction (i.e., oliguria, rising serum creatinine). Additional clinical signs consistent with abdominal compartment syndrome are a reduced cardiac output, elevated systemic vascular resistance, and elevated pulmonary capillary wedge pressure with simultaneous low or normal calculated estimates of end-diastolic volume. The standard for monitoring intra-abdominal pressure is bladder pressure measurement via intravesical technique. Bladder pressure is measured in end expiration with the patient supine, by distending the bladder with 25 mL of sterile saline.[86,87] Surgical decompression of the abdomen is an option for established abdominal compartment syndrome with associated organ dysfunction and persistent shock with no absolute thresholds for urine output and airway pressure.[88] Protocols on fluid resuscitation are recommended to avoid a sustained increase in intra-abdominal pressure.[89]

In addition to decompressive laparotomy for abdominal compartment syndrome, numerous medical and minimally invasive therapies have been proposed such as sedation and analgesia for anxiety relief and brief trials of neuromuscular blockade as temporizing measures. Body positioning and colonic/nasogastric decompression are also suggested noninvasive treatment options.[90–92] Patients with abdominal compartment syndrome may have ascites and drainage of fluid with various catheters can be tried before performing decompressive laparotomy as a less invasive alternative. A common factor among all cases of abdominal compartment syndrome seems to be the use of aggressive crystalloid resuscitation causing resuscitation injury. Use of excessive crystalloid resuscitation is discouraged in DCR and studies show decreased rates of abdominal compartment syndrome in association with decreased rates of crystalloid resuscitation.[63] Attempts to achieve "supranormal" endpoints (cardiac index of >4 L/min/m^2 or oxygen delivery index of >600 mL/min/m^2), while theoretically desirable, have not been shown to be effective as this often requires excessive resuscitation volumes that contribute to abdominal compartment syndrome.[93]

As resuscitation has changed with DCR, the incidence of abdominal compartment syndrome has been decreasing. In the trauma setting, abdominal compartment syndrome has been disappearing rapidly but in the general surgery setting, it is more common. Sepsis as a source of inflammation can create abdominal compartment syndrome even when resuscitation injury is

minimized. Source control of the bacterial contamination is the best treatment for abdominal compartment syndrome. End organ failure with microcirculatory disruption and endothelial leak is another source of the syndrome.

TRAUMATIC BRAIN INJURY

TBI remains one of the leading causes of injury-related deaths. Initial management of TBI includes hyperosmolar resuscitation, intracerebral pressure (ICP) monitoring, and prevention of hypoxia and hypotension.

Secondary Brain Injury

5 Injury prevention and better safety are the mainstays for primary brain injury. After the initial insult, the main goal is to prevent or minimize secondary brain injury. Secondary brain injury can be influenced by a cascade of inflammatory responses, occurring as a consequence of the primary injury. Secondary brain injury is also exacerbated by potentially preventable factors such as hypotension, hyperthermia, seizure activity, hyperglycemia, and hypoxemia. Hypotension at any point (even brief time periods) is associated with a doubling of mortality in patients with severe TBI.[94,95] Although hyperventilation temporarily reduces intracranial pressure and may help to prevent herniation, evidence suggests that excessive hyperventilation may be harmful for patients with TBI. Therefore, brief hyperventilation is only recommended in order to reduce ICP temporarily until surgical decompression can be performed.

Imaging in TBI

Computed tomography (CT) scanning remains an essential tool in the initial evaluation and postinjury management of TBI. Patients with mild and moderate TBI who are examinable and not on any anticoagulant medications can be monitored by clinical examination without the need for routine serial CT scans of the head.[96–98] With technologic improvements made to the CT scanners around the world, the incidence of TBI has been increasing. Small

insignificant intracranial radiologic findings are the main reason for the increase in the diagnosis of TBI. With increased awareness of mild TBI and with the increased attention to mild TBI with posttraumatic stress disorder, CT scans of the head are being ordered more often and routinely. In trauma, the single most common reason for obtaining a CT scan of the head has been loss of consciousness. Thus increased screening for TBI and improved technology identifying small clinically insignificant intracranial injuries has resulted in the increase of incidence of TBI.

TBI is a clinical diagnosis and not just a radiographic diagnosis. There are patients with TBI with normal CT scans of the head who have cognitive deficits as well as posttraumatic stress disorder and there are many with radiographic TBI that do not have clinical deficits. Therefore, significant deterioration in neurologic examination should be considered in the decision for whether repeat head CT scan or consultation of a neurosurgeon is needed. CT scans and neurosurgical consultations are valuable resources with costs to the health care system as well as to the patient. The use of routine repeat head CT and neurosurgical consultations should be restricted to patients on prehospital antiplatelet and anticoagulants, and those with depressed skull fractures. A Brain Injury Guideline has been developed which helps guide when the resources should be used (**Table 32.3**).[99–101] Progression of lesions on repeat head CT scan promptly identify patients who require more invasive neurosurgical interventions and medical therapies. Routine repeat head CT is still recommended for those patients with GCS less than 8 and for those who do not have a reliable clinical examination such as patients that are under general anesthesia or patients that are in the ICU under sedation.

Coagulopathy in TBI

A decreased platelet count (less than 100,000/μL) and/or impaired platelet function after TBI is associated with progression of intracranial hemorrhage, need for neurosurgical intervention, and mortality.[102–104] Admission INR greater than 1.5 also predicts progression of intracranial hemorrhage. The treatment of coagulopathy after TBI is multipronged due to the complexity of the problem. Therapeutic strategies should focus on the treatment of the primary cause and controlling the progression of intracranial bleeding. Fresh

frozen plasma, platelets, recombinant factor VII, and PCC can be used in various combinations to improve outcomes.[53,105]

Table 32.3 Brain Injury Guideline

Variables	BIG 1[a]	BIG 2
Neurologic Examination	Normal	Normal/abnormal
Intoxication	Yes/no	Yes/no
CAMP	No	Yes/no
Skull Fracture	No/simple, nondisplaced	Other
SDH	<4 mm	>4 mm
EDH	<4 mm	>4 mm
IPH/Contusion	One location and <4 mm	Other
SAH	Trace/pinpoint	Other
Therapeutic Plan		
Neurosurgical Consult	No	Yes
RHCT	No	Yes
ICU Admission	No	Yes

[a]Patients should meet all criteria for BIG 1.

Intoxication, alcohol/drugs; CAMP, Coumadin, aspirin, Motrin, Plavix; SDH, subdural hematoma; EDH, epidural hematoma; IPH, intraparenchymal hemorrhage; SAH, subarachnoid hemorrhage; IVH, intraventricular hemorrhage; RHCT, repeat head CT; NSC, neurosurgical consult.

Antiplatelet and Anticoagulation Therapy in TBI

Antiplatelet medications, anticoagulants, and nonsteroidal anti-inflammatory drugs are among the most frequently encountered medications in TBI patients, especially the elderly. Existing evidence shows an increased risk of progression of intracranial bleeding in patients on high-dose aspirin and clopidogrel, whereas low-dose aspirin and ibuprofen do not cause progression on CT or neurologic examination.[106–108] A platelet count of less than 135,000/μL in patients on antiplatelet therapy is predictive of both radiographic and clinical worsening.[109] Reversal of the effect of anticoagulants and antiplatelets is suggested to improve the outcomes. Use of newer oral anticoagulants like direct thrombin inhibitors and factor Xa inhibitors is increasing. Despite their safety advantage over Coumadin, concerns for progression of intracranial bleed, and adverse outcomes exist in TBI patients. There are limited reversal agents for the newer oral anticoagulants. Andexanet Alfa is used to reverse Apixaban and Rivaroxaban, but is very expensive and not widely available yet. Oral charcoal administration, hemodialysis, PCC, and rFVIIa have shown some efficacy in the reversal of these agents.[110–115]

Seizure Prophylaxis after TBI

Posttraumatic seizures increase the cerebral metabolic rate, ICP, and may cause secondary brain injury. Seizures after TBI are associated with worse outcome. It is not known if poor outcomes are due to underlying injury which is associated with posttraumatic seizures or if posttraumatic seizures exacerbate injury. Studies have shown that prophylactic therapy with phenytoin during the first 7 days after injury is effective in reducing the number of early posttraumatic seizures.[116] Long-term use of prophylactic anticonvulsants has not been shown to be of benefit. Anticonvulsant prophylaxis is not indicated for late onset posttraumatic seizures (after 7 days). Because phenytoin is cumbersome to use, as it requires frequent drug-level monitoring and can lead to neurodepressive side effects, the use of levetiracetam has become common. However, recent studies have shown that the seizure rate after TBI is very low and the use of levetiracetam has not equated to reduced seizures.[117]

Penetrating Brain Injury

Gunshot wounds to the brain are the most lethal of all firearm injuries. Aggressive postinjury resuscitation is associated with significant improvement in both survival and organ donor eligibility.[118,119] Early aggressive management includes blood products, hyperosmolar therapy, vasopressors, and/or PCC. Early aggressive T4 (levothyroxine) therapy and correction of coagulopathy increases the organ donation rate in nonsurvivable patients.[117,120]

NUTRITIONAL AND METABOLIC SUPPORT

Nutritional support after injury imparts significant acute and long-term effects on outcomes. Understanding of the nutritional and metabolic derangements following injury has increased exponentially over the past few decades. This has resulted in a more focused and goal-oriented approach toward nutritional support. Once patients are stabilized and recovered from shock, attention should be directed to metabolic and nutritional support. The route of administration and timing of initiation of nutritional support have been issues of controversy. 6 Current evidence supports the use of enteral nutrition in all trauma patients as soon as possible.[121–126] There are certain situations where enteral nutrition is not a feasible option; in such patients total parenteral nutrition is an alternative. Even in cases where enteral nutrition cannot be administered due to frequent or impending operative intervention or intolerance of enteral feeding, total parenteral nutrition should be used as a bridging measure. The literature on nutritional support in critically injured trauma patients consistently reports higher septic morbidity in patients on total parenteral nutrition.[123–125,127] Current guidelines on the nutritional support provide a level 1 recommendation on the advantages of enteral nutrition over nutritional support via the parenteral route.[128] Recent recommendations aim for early enteral nutrition. The definition of early varies in the literature, ranging from a few hours after injury up to 72 hours.[125,126] Although the benefits are yet to be established, safety of early (within 24 hours of injury) enteral feeding is well documented.[127] In patients with severe burns it is recommended to initiate enteral feeding within 18

hours of injury.[129] Early feeding in this group of patients reduces the risk of gastroparesis. In the case of severe TBI enteral feeding is safe and should be administered early.[130–132]

Nasogastric and nasojejunal routes are the preferred modes of initial nutritional access. If long-term nutritional support is required, the planning of feeding access should be based on individual patient circumstances. In patients undergoing laparotomy, insertion of a surgical feeding tube either in the stomach or small intestine is a feasible option. For patients in need of long-term nutritional support and not requiring surgical intervention the preferred route is via endoscopically guided percutaneous feeding tube. The percutaneous endoscopic route is increasingly popular, but the literature is not well established on its safety and complications.[133,134] While choosing one route over the other, special consideration should be given to individual patient factors as there is no single feeding access that stands out among the others for safety and efficacy.[135–138]

The goal of nutritional support during postinjury phase is twofold, first to provide enough calories to meet basal energy expenditure and second to complement the special micronutrient requirements of ongoing inflammation. Basal energy expenditure during postinjury phase ranges from 30 to 35 kcal/kg/d. Basal energy expenditure is higher in TBI patients and lower in spinal cord injury patients. The estimation of basal energy expenditure in critically ill patients remains challenging and current calculators frequently overestimate caloric requirements. A high-caloric dietary supplementation is associated with hyperglycemia, hypercapnia, and higher in-hospital complications.[139] While underfeeding is also a concern in critically ill patients, a more balanced approach is permissive underfeeding. Permissive underfeeding focuses more on maintaining nitrogen balance than meeting caloric requirements alone. Diets containing higher protein content and lower caloric value than target serve such a purpose. Permissive underfeeding results in better glycemic control, rapid recovery, and overall better in-hospital patient outcomes.[140–142]

In the setting of trauma and critical illness, the ongoing catabolic response demands special micronutrients and dietary considerations along with standard protein and caloric replacement. Nonessential amino acids such as arginine and glutamine become conditionally essential. Addition of these amino acids along with omega-3 fatty acids to standard dietary formulas has

been shown to improve outcomes and immune function. Enhanced diets containing higher protein content, and including a combination of arginine, glutamine, omega-3 fatty acids, minerals (zinc, copper, etc.), nucleic acids, and vitamins have shown to improve overall immune function.[143–146] The assessment of nutritional requirement in critically ill patients is primarily done by the indirect calorimetry method. The standard measure of nutritional requirement uses a metabolic cart, but this is expensive and cumbersome.[147] An alternative approach uses predictive equations but these are imprecise and often over- or underestimate the nutritional requirement.[148] In recent years, several handheld indirect calorimeters have been marketed. They provide ease of use as they are portable and relatively accurate.[149] To assess the adequacy of nutritional supplementation, anthropometric measurements and biochemical data can be utilized. While there is no single measure which accurately predicts adequacy of nutritional support, prealbumin levels provide a reliable estimate compared to albumin, transferrin, and retinol-binding protein.[150]

ORGAN DONATION

Trauma donors are the major contributor in the organ donation pool.[151] There remains great potential to enhance the conversion rate in this group of trauma donors. Over the past decade significant changes occurred in resuscitation protocols in general and specifically in potential organ donors. These changes in resuscitation have resulted in better organ donation in this group of potential donors. Wide spread acceptance of DCR has led to better end organ preservation, which not only improves outcomes in surviving patients but can improve overall organ donation rates in patients who become brain dead. 7 The guidelines defining organ donor management recommend continuation of this aggressive resuscitative support even after declaration of brain death.[119,152] A feasible goal for resuscitating any potential donors is to follow a rule of 100s, that is, maintaining a systolic blood pressure of >100 mm Hg, heart rate of 100 mL/hr, and PaO_2 >100 mm Hg. Along with hemodynamic resuscitation, focus should also be given to pulmonary edema, coagulopathy, and hypothermia. Coagulopathy and hypothermia are not only

associated with adverse outcomes in trauma patients but also render them ineligible for organ donation.[153]

The focus of resuscitative efforts after declaration of brain death shifts from cerebral preservation to organ preservation. The shift in resuscitation focus is a continuum of ongoing resuscitation.[154] Donors should be managed in a critical care setting and attention should be directed toward moderation of post brain death physiologic changes. Along with ongoing resuscitation, initiation of a T4 protocol should ensue. T4 protocol or hormone replacement therapy takes into account the disruption of hypothalamic–pituitary axis.[155] The essential components of the T4 protocol include methylprednisolone, triiodothyronine (T3)/levothyroxine (T4), arginine, vasopressin, and insulin. The goal of this resuscitative cocktail is to prevent potential cardiac arrhythmias, diabetes insipidus, hypotension, and metabolic acidosis. Early initiation of hormonal therapy has shown improved organ donation rates and should be considered in all brain-dead potential organ donors.[156–158]

Organ donation is a legitimate outcome in trauma patients. As aggressive resuscitation protocols for trauma patients closely align with donor management goals, the spectrum of care in potential organ donors can easily be extended to address organ preservation. Trauma patients presenting with previously fatal neurologic injuries provide an excellent cohort where aggressive resuscitation can not only improve survival rates but also the organ donation rates.[119,159] The care of a potential organ donor is a multidisciplinary task. Involvement of organ procurement networks and social services can improve the communication between the treatment team, procurement agency, and the donor's relatives. Bridging this gap is of utmost importance as family decline still remains a major cause of loss of potential donors.

Rib Fractures

Traumatic rib fractures are most often caused by blunt force trauma 8 to the chest. The mainstay of management is to control the pain and prevent the pulmonary sequelae, such as pneumonia and respiratory failure, which increases mortality. Rib fractures are associated with significant morbidity and mortality and therefore early recognition and aggressive proactive pain

control are essential to good outcomes. Rib fractures occur in approximately 10% of trauma patients and are often markers for significant concomitant internal injuries, such as pulmonary contusion, pneumo- or hemothorax, diaphragm injury, or blunt cardiac injury (BCI).[160,161] There are numerous associated pulmonary complications, most notably pneumonia, retained hemothorax, aspiration and ARDS.[162,163] The number of rib fractures correlates to the mortality and associated complications, which has been demonstrated in several studies.[163] One study that looked at patients in the National Trauma Data Bank (NTDB) over 7 years found that one rib fracture was associated with a 5.8% mortality and the chance of death increased with each rib fractured, culminating in a mortality rate of 34.4% in patients with eight or more rib fractures. Furthermore, increased number of rib fractures was associated with more complications, specifically ARDS, pneumonia, pneumothorax, empyema, and ICU and hospital length of stay.[163] Flail chest is defined both radiographically and clinically. On imaging, it is multiple consecutive rib fractures (>4) unilaterally with fractures in two or more locations in a single rib. Clinically, it is when a segment of the chest wall moves paradoxically within the respiratory cycle. This type of injury has a greater impact on respiratory function and is associated with increased complications.[164]

A particularly vulnerable patient population is the elderly who experience the most significant morbidity and mortality secondary to rib fractures. Patients over the age of 65 with rib fractures have twice the rate of mortality than younger patients with similar injury patterns. Furthermore, for each rib fractured, there is an increase in mortality of 19.4%. The overall mortality in elderly patients with rib fractures has been shown to 20.1% while the mortality rate in this population without rib fractures has been reported at 7.6%.[165] Given the higher risk of death and complications in this patient population, trauma centers often admit elderly patients with rib fractures to the ICU. One study compared two groups of elderly patients once there was a change in protocol regarding admission criteria for patients with rib fractures. Patients over the age of 65 with blunt thoracic trauma and three or more rib fractures were automatically admitted to the ICU regardless of other injuries or respiratory status. The two groups had comparable ISS. They compared outcomes of the patients from before and after the change in admission ICU admission criteria and found that patients in the latter group

had shorter lengths of stay, lower mortality rates, lower rates of unplanned ICU admission, and few complications. The improved outcomes were attributed to the more concentrated nursing care that could provide aggressive pulmonary hygiene, the comprehensive care provided by the multidisciplinary teams and the continuous monitoring that allows for earlier recognition of clinical deterioration.[166]

The cornerstone of management of blunt thoracic trauma with rib fractures is aggressive pain control and pulmonary hygiene so that patients can breathe effectively and mobilize, which helps reduce the risk of pulmonary complications and death. Multimodal pain therapy has become the standard of care and involves a combination of medications including opiates, NSAIDs, acetaminophen, and sometimes ketamine. A common strategy is to use standing doses of acetaminophen and NSAIDs with on-demand opiates via an oral or intravenous route. Each drug class has advantages and disadvantages. NSAIDs are readily available, do not dampen respiratory drive, and have no addictive potential but carry the risk of peptic ulceration and some clinicians are hesitant to use them when there is a concern for bleeding. Opiates are also readily available but depress respiratory function and are addictive. Lidocaine and ketamine infusions are also reasonable options but should be managed with the help of pain specialists. Early consultation of an acute pain service has been shown to be beneficial to patients and outcomes.[167] Regional anesthesia is another mode of therapy that has demonstrated benefits in rib fracture management and includes intercostal blocks, paravertebral catheters, and epidural catheters. Paravertebral catheters are most beneficial in unilateral rib fractures as opposed to bilateral fractures. Studies have reported decreased delirium with the use of regional anesthesia in the management of multiple rib fractures, which is especially important in the elderly population.[168]

Surgical fixation involves open reduction and internal fixation of the fractures. There is no clear consensus on which patients benefit the most from rib fixation or the optimal timing of the procedure and there is much debate among trauma surgeons. However, some common accepted indications include flail chest, symptoms with displaced segments, refractory pain or persistent respiratory failure, and fixation in conjunction with a thoracotomy for another reason.[169] Several randomized studies have been conducted and have demonstrated decreased rates of pneumonia and fewer

days on the ventilator.[168,170,171] On meta-analysis there was no significant difference in mortality but there was a lower rate of pneumonia.[172] The randomized studies have been small and of lower quality so larger multicenter studies are still needed.[170] A single-institution prospective study compared nonoperative and surgical fixation for specific indications (flail chest, >3 displaced fractures, >30% volume loss, and failure of medical therapy) and found that the operative group had a reduced likelihood of respiratory failure and tracheostomy.[173] A different study performed in two trauma centers in Canada demonstrated contradictory results and showed significantly improved outcomes in the nonoperative group in terms of rates of pneumonia, ventilator days, and length of stay in the ICU and in the hospital overall.[174] Given the variable data on the role of surgery in rib fractures and the lack of consensus, each patient should be evaluated individually with regard to the risks and benefits of the procedure. Regarding the technical aspects of the procedures, preoperative imaging with CT scan and 3D reconstruction of the chest wall is important in operative planning. The procedure is usually performed through a thoracotomy incision and there are various plating systems available. The goal of the procedure is to stabilize the ribcage while restoring mechanical function to the chest wall. Careful attention should be paid not to overly restrict the chest wall with excessive fixation so that the breathing mechanics are impaired.[170]

Blunt Cardiac Injury

9 BCI refers to the trauma to the myocardium secondary to blunt trauma. There is a wide range of clinical manifestations, from asymptomatic and clinically silent to life-threatening. Due to this spectrum in severity there is a range in management from monitoring to open heart surgery, however, the majority of cases are managed with telemetry and supportive care.

Severe cardiac injuries often result in instant death. Up to 25% of deaths from trauma were found to have cardiac or aortic injuries.[175] The most common cause is motor vehicle collisions, motorcycle collisions, falls, and crush injuries.[176] Most patients with BCI who survive to the hospital have relatively minor cardiac injury. Therefore, there should be a high index of suspicion whenever there is significant blunt force trauma to the chest. Specifically if there is a sternal fracture, hemopneumothorax, esophageal

injury, or multiple rib fractures and pulmonary contusion since many patients present insidiously and delay in diagnosis increases morbidity and mortality.[177] In a retrospective study that examined NTDB blunt trauma patients over 8 years found that a 0.3% incidence of BCI with hemopneumothorax being the strongest independent risk factor for BCI, followed by sternal fracture and esophageal injury.[177]

There are various types of BCI, including myocardial injury, which involves a laceration of the walls of the heart or papillary muscles, myocardial contusion, for which there is no clear consensus for diagnostic criteria but is generally thought to be bruising of the heart, pericardial laceration, septal injuries, and valvular injuries. The most common chamber injured is the right ventricle due to its anterior location.[177] Myocardial injury carries a high mortality rate, especially when the pericardium is intact because of tamponade.[178]

There is a spectrum of clinical presentations, including chest pain and bruising, arrhythmias, hypotension, and flash pulmonary edema from valvular injury and dysfunction. In addition to ATLS, when evaluating for BCI, the initial workup should include an EKG and a troponin. The negative predictive value of a normal EKG and negative troponin is approximately 100%, so if both are normal then no further evaluation or monitoring for BCI is necessary.[178,179] If these tests are abnormal then the patient should be admitted to a telemetry unit and if there are arrhythmias or any hemodynamic instability, then an echocardiogram should be obtained to evaluate for any wall motion abnormalities, effusion, and valvular issues. Elevated troponin has been associated with higher mortality rates in BCI in retrospective analysis.[180] Hypotension may occur and bleeding should be ruled out as is the case in all trauma patients. Once bleeding has been addressed and ruled out, hypotension secondary to cardiac dysfunction in patients with BCI should be managed with vasopressor support in a monitored setting. Most BCI can be managed nonoperatively, however, if there is valvular, pericardial, or myocardial disruption, rupture or laceration, then surgery is required, often emergently.

Environmental Injuries

J. Patrick Walker and Gregory J. Jurkovich

Key Points

1 Of the 3,700 species of snakes worldwide, only 200 are significantly venomous, with approximately 6 deaths per year in the United States caused by snakebite. In contrast, there are over 150,000 species of Hymenoptera in the world that cause approximately 40 deaths per year, mostly as a result of severe anaphylactic reactions.

2 Snakebite produces immediate pain, edema, and erythema at the site. Spread of the swelling greater than 30 cm/hr indicates severe envenomation. Initial incision and suction and the use of a proximal tourniquet are contraindicated. Use of purified ovine antivenin is effective for serious Crotalidae envenomation and has replaced equine antivenin with its associated risk of serum sickness. Because of the presumed safety of the newer antivenom, overuse is more likely.

3 Snakebite morbidity depends on the type of snake and the degree of envenomation. Venoms consist of numerous polypeptides that can disrupt endothelial cells and blood flow, produce neuromuscular blockade, or generate a coagulopathy via procoagulants. Some snakes (particularly Elapids [represented by the coral snakes in North America]) also have direct neurotoxins and cardiotoxins.

4 Spider bites produce toxicity by local tissue necrosis (brown recluse and hobo spiders) and painful muscle contractions (black widow spider). Death may be caused by stinging Hymenoptera, including bees (particularly aggressive Africanized bees), fire ants, and scorpions. The death is usually secondary to anaphylaxis, but occasionally massive envenomation occurs—especially with Africanized honeybees. The estimated lethal dose is approximately 20 stings/kg in most mammals.

5 The initial response to hypothermia is an intensive sympathetic type reaction with tremulousness, profound vasoconstriction, marked increase in oxygen consumption, and accelerated heart rate and minute ventilation. As core temperature falls to between 33° and 30°C this response is lost and deeper core hypothermia rapidly develops.

6 Hypothermia risk is high in the severely injured patient as a result of exposure, loss of normal protective metabolism (i.e., shivering), rapid massive infusion of cold fluids/blood, and open thoracic and abdominal cavities.

7 Hypothermia increases risk of mortality at every level of traumatic injury. There is no improvement in outcome when hypothermia is applied to the severe TBI; trauma patients rapidly rewarmed require less resuscitation volume and have improved survival.

8 Treating hypothermia begins by preventing further heat loss and allowing endogenous rewarming. Active rewarming has many adjuncts, including warm blankets, heating pads and lights, and immersion in warm water or internally by core rewarming. Internal core rewarming is more effective and includes heated intravenous fluids; heated body cavity lavage; heated moist inhaled air; extracorporeal circulatory rewarming (ECMO or CPB) or closed circuit intravascular countercurrent heat-exchange devices.

9 Frostbite involves ice crystal formation and unpredictable loss of tissue. Early definitive rewarming (avoiding refreezing) by submersion in 40° to 42°C water is preferable with subsequent meticulous care, awaiting demarcation, and avoidance of early debridement to optimize outcomes and tissue salvage.

10 Early thrombolytic therapy might be beneficial in select frostbite patients.

INTRODUCTION

Although most of us will not suffer a gunshot wound or a small-bowel obstruction, we will all receive insect bites and those of us who frequent the outdoors will be exposed to many other facets of the environment. This chapter is about those encounters—the heat, the cold, venomous bites and stings. It is essential that all physicians know the basics of care for injuries produced in this manner.

ENVENOMATION

Snakebite

The legends and lore of snakes are spread across history; with serpents mentioned in 42 Bible verses, implicated in the death of Cleopatra, and the medical field—the snake is essential to the rod of Aesculapius and the Caduceus. Few emergencies have been surrounded with as many types of treatment and little scientific fact as snakebite (some very innovative—electrical shock and TASER®, tourniquets with ice emersion, crosscut of the bite with suction of the wound, etc). We will attempt to address the management of envenomation with as much evidence as possible.

An estimated 5.4 million people are bitten each year with up to 2.7 million envenomations. This results in around 81 000 to 138 000 people deaths each year.[1] In the United States, the CDC estimates there are 7,000 to 8,000 bites per year with 5 to 6 deaths.[2] Most of the deaths are secondary to rattlesnake envenomation, with only two fatalities from Copperhead snakebite in the past 5 years.

1 More than 3,300 species of snakes exist in the world of which approximately 200 are deadly.[3] They range in size from 10 cm to greater than 9 m. Nonvenomous snakes predominate on all continents except for Australia. There are five families of poisonous snakes worldwide: Colubridae, Elapidae, Hydrophidae, Viperidae, and Atractaspididae. The boomslang and the bird snake represent the Colubridae—found mostly in Africa. The Elapids are found throughout the world and include snakes, such as mambas, kraits, adders, and cobras. The only Elapids in North America are the coral snakes. The Hydrophidae are the sea snakes. The Viperids have long hinged fangs. They include the pit vipers that, like the Boidae family (boas and pythons), have infrared sensors in a nasal pit that is located between the nose and the eye (**Fig. 33.1**). These are excellent sensory organs that can differentiate a temperature differential of 0.003°C. All venomous snakes in North America with the exception of the coral snakes are in this family. Poisonous snakes in North America are therefore of the phylum Chordata, class Reptilia, order Squamata, suborder Serpentes, and of the Crotalidae (subfamily Crotalinae) or Elapidae family. Venomous snakes are distributed throughout the United States with at least one species in every

state except for Hawaii, Alaska, and Maine. Water moccasins are found primarily in the southeastern United States. Copperheads are found from Massachusetts westerly to Illinois and to the south from Florida to Texas. Rattlesnakes are found coast to coast. The genus *Crotalus*—the true rattlesnakes—is found only in the New World.

Figure 33.1 Heat sensor—nasal pit. (Photo courtesy of Ronny Stewart, MD.)

Snakes are easily identifiable reptiles, marked anatomically by the large number (greater than 120) of precloacal vertebral bodies. They also have a reduced (almost absent) left lung, a single ventricle (no ventricular septum), and no muscles in the ciliary body of the eye. Despite the absence of a ventricular septum, oxygenated and deoxygenated blood channels separately though the heart.[4] All snakes are strictly carnivores. The size of the snake dictates the size of the prey.

The pit vipers (the genera *Crotalus, Sistrurus*, and *Agkistrodon*) are morphologically distinguished by elliptical pupils, a triangular head (**Fig. 33.2**), and retractable fangs. The fangs are tubular, injecting venom similar to a hypodermic needle. This is in contradistinction to the Elapids in

which the fangs are fixed and grooved—wicking the venom into the victim. Venomous snakes have a single row of caudal plates distal to the anal plate, whereas nonvenomous snakes have a double row of caudal plates. There are 32 species of rattlesnakes in the New World, ranging from southern Alberta to central Argentina.[5,6] Rattlesnakes are only found in the Americas. All true rattlesnakes have a rattle (except for an endangered species in Mexico—the Santa Catalina rattlesnake, which has only a vestigial rattle). The rattle is a series of interlocking segments. A new segment is added with each shedding of the skin, which may occur two to three times per year. There are two genera of rattlesnakes; *Crotalus*—the true rattlesnakes and *Sistrurus*—the pigmy rattlers. There are 14 species of *Crotalus* (**Table 33.1**) in North America. The largest species of rattlesnake in North America is the eastern diamondback (*Crotalus adamanteus*), which is slightly larger than its cousin the western diamondback (*Crotalus atrox*). There are eight members of the *Agkistrodon* genus—moccasins and copperheads (**Table 33.2**).

Florida cottonmouth—*Agkistrodon piscivorus conanti*
Western cottonmouth—*Agkistrodon piscivorus leucostoma*

By far the most critical step in management of snakebite is identification of the offending species. Most snakebites are nonvenomous and require no treatment. Most bites, such as those of copperheads (**Fig. 33.3**) and pigmy rattlers (**Table 33.3**), are almost always self-limiting and require little more than observation. Others such as the diamondback (**Fig. 33.4**) and Mojave rattlers can require intense medical management, occasional surgical management, and even rarely cause death. Identification of the species by the patient is notoriously invalid; however, a detailed description of the offending snake should be taken. The only snake where color is useful in identification is the coral snake—red and yellow kill a fellow, red and black venom lack (**Fig. 33.5**). (Note that this is true only in North America, as there are venomous coral snakes in Central and South America that have red bands touching black bands.) Other clues, such as geography and topography (proximity to water), can also at least help with identification of the genus. All snakebites should, at least initially, be considered an event with potential morbidity and possible mortality.

As snakes are cold-blooded animals, snakebites generally occur in the warm months, with an increase in incidence in the spring and fall. Most snakebites occur in young men, with up to 60% of bites occurring in victims that were deliberately provoking the snakes.

Venom is produced in Duvernoy glands on the dorsal sides of the head (corresponding to parotid glands) enhancing the triangular appearance.

During envenomation the venom is forced through the fangs by the palatine muscles. If a fang is broken off, it will be replaced by the next in a row of "proto-fangs." Any clothing may limit the amount and depth of envenomation. The purpose of the venom is to immobilize or kill the prey and begin digestion. Pit viper venoms are complex—with up to 50 different proteins and enzymes identified.[7–9] Over 90% of the dry weight of venom is proteinaceous in nature. Although it is common to classify the venoms as neurotoxic or digestive in nature, all snakes have varying compositions of venoms. The Crotalids will have a higher percentage of digestive/enzymatic type proteins than the Elapids, which will contain a higher percentage of neurotoxins. Common enzymes are phospholipases, metalloproteases, collagenase, and hyaluronidase (**Table 33.4**). These peptides and polypeptides act by damaging vascular endothelium and other cellular membranes. Compliment is activated, fibrin is degraded, and platelets are activated. The increased permeability of the membranes leads to peripheral and pulmonary edema, hemorrhage, and hypotension. L-amino acid oxidase splits fibrinogen contributing to the induction of DIC. The Elapids in particular contain a higher percentage of proteins that block acetylcholine receptor sites. This can lead to dysphagia, slurred speech, seizures, coma, and death. Despite the very high toxicity of coral snake venom, only one fatality has been recorded in the United States in the past 50 years.

Figure 33.4 Western diamondback.

Figure 33.5 Coral snake.

When evaluating the snakebite victim, it is important to document both local and systemic signs and symptoms. Vital signs should be recorded and repeated at intervals guided by the clinical response. 2 Pain, edema, and erythema at the site are common. Secondary symptoms include muscle twitching, perioral paresthesia, and a metallic taste in the mouth. Marking lines at the site of documented discoloration (**Fig. 33.6**) can help the clinician follow the progression of the envenomation. Swelling in the affected digit or limb should be measured (circumference) and followed closely. The amount of local tissue destruction is an accurate marker of the degree of envenomation. It is probable that if there is no pain or erythema by the time that the patient arrives in the ED, no envenomation has occurred. Intravenous access should be obtained. Laboratory evaluation should include a CBC with platelet count, PT, PTT, CPK, fibrinogen level, creatinine, BUN, and urinalysis. Up to 30% of Crotalid envenomation will show an abnormality in the coagulation profile, although clinical bleeding is exceedingly rare.[10] In Lavonas' (2004) review of 400 copperhead bites from the Carolinas no hypotension, no respiratory failure, and no deaths occurred.[11] Eight patients did have laboratory abnormalities, but none

developed bleeding complications. However, in severe envenomation by one of the larger rattlesnakes, diffuse capillary leakage can lead to pulmonary edema, hypotension, and shock.[12] A consumptive coagulopathy may rapidly develop. Such patients may bleed spontaneously from any site. Acute renal failure may result from nephrotoxins as well as myoglobinuria. An electrocardiogram, or at least continuous cardiac monitoring, should be considered. If there appears to be no evidence of envenomation, the patient may be observed in the emergency department for several hours and discharged home. With evidence of envenomation our recommendation is for admission to the hospital (preferably a monitored bed) for observation and possible intervention for at least 24 hours.

Table 33.4 Composition of Venom

Main Enzymes of Snake Venom

Elastase

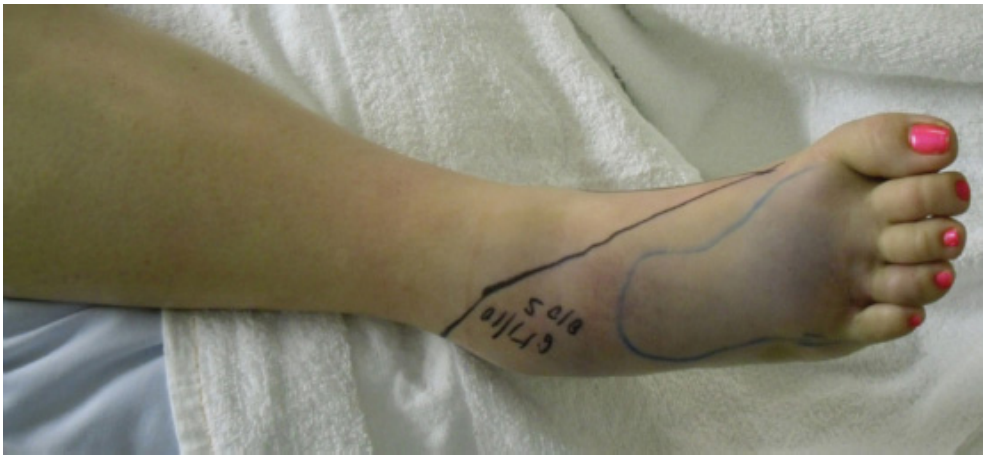

Figure 33.6 Demarcation of hemolysis after bite.

As noted, above treatment is largely dictated by the species of snake and the initial clinical presentation. Although a number of series have noted the appropriate treatment of Agkistrodon (copperhead and moccasin) bite is observation only,[13,14] extrapolation of this data to rattlesnakes could be misleading. In the rattlesnake bite victim with a moderate or severe envenomation, early use of antivenom is appropriate, and should be strongly considered (see below). Although there are a number of snakebite severity indices (grading systems) published, a modification of the simple system proposed by Dart in 1996 is probably the most useful.[15] A grade 1 envenomation is limited to the immediate bite site; a grade 2 envenomation extends onto less than a full extremity and may have non–life-threatening symptoms such as nausea, vomiting, mild tachycardia, and mild hypotension. A grade 3 envenomation involves more than an extremity and includes systemic signs such as severe hypotension/tachycardia or blood dyscrasias or clinically significant clotting abnormalities. Although enzyme-linked immunosorbent assays (ELISAs) have been developed that can directly measure serum venom antigens as well as identify the offending snake, clinical applicability of these types of tests are limited.[16,17]

Initial first aid on the scene should involve immobilization and splinting. There are no data to confirm this will limit the spread of venom but will be more comfortable. The application of ice or heat seems to have little effect on results. A number of historical treatments should specifically be avoided. Incision and suction, advocated for years, is no longer recommended.[18] A surgical incision in the field by a nonsurgeon can possibly involve vessels,

tendons, and nerves and increase morbidity, and only a small amount of venom can be extracted with suction. Limited cooling of the extremity may have some benefit, although a version of this—ligation cryotherapy—is associated with a high rate of amputation.[19] Although placement of a constrictor band may be of benefit in Australia (where Elapids predominate) to prevent rapid dissemination of a systemic neurotoxin, it is probably of little benefit in North America where the offending species is almost certainly a Crotalid. The use of a compression bandage has been shown to slow the systemic absorption of venom.[20,21] This may make it the treatment of choice in the field for a nonnecrotizing envenomation, such as produced by an Elapid. It may however increase local necrosis when used to treat the bite of a pit viper.

The wound should be cleansed, and the location of the puncture sites documented. The distance between the two fang marks is related to the size of the snake. The tetanus immunization status of the patient should be reviewed and updated. Steroids have no benefit in humans although these are often used by veterinarians.[22] Steroids do have a role in treating the infrequent acute allergic as well as delayed-onset serum sickness that may occur after the use of sheep-derived antivenom, as noted below.

The prophylactic use of antibiotics has been evaluated by several studies and does not seem to reduce infection rates.[23–25] Infection after snakebite is surprisingly uncommon and while patients are often given an antibiotic, there is no good clinical evidence for their use. Although many patients will have erythema, edema, and tissue necrosis and will appear infected, these are usually sterile; culture-proven infection occurring after snakebite should be treated appropriately. Culture of organisms in the mouth of the rattlesnake includes *Pseudomonas, Enterobacteriaceae, Staphylococcus,* and *Clostridia.*[26]

If the species is a coral snake or a nonindigenous Elapid, the administration of cholinergic agonists should occur at the first sign of symptoms. Calcium infusion may reduce the onset of seizures.

Certainly, the most controversial decision point in management of snakebite is the administration of antivenom. Although hundreds of antivenoms are available worldwide for various species, for all practical purposes in North America we are only dealing with envenomation by Crotalids. Snakebite by coral snakes is uncommon, and while the venom is

exceedingly toxic, the treatment is only supportive as antivenom is no longer available. Prior to 2000, the primary antivenom available in the United States for the bite of a Crotalid was a hyperimmune serum produced by envenomation of horses. Its use was associated with a high incidence of side effects: anaphylaxis, hypersensitivity, and delayed serum sickness.[27] In 2000, CroFab® (Crotalidae Polyvalent Immune Fab [Ovine]) was introduced obviating the use of now unavailable horse serum products.[11,28] This is now complimented by another purified product—Anavip®. CroFab is composed of small Fab fragment antibodies, while Anavip is made from larger V-shaped F(ab')2 fragments. Anavip has a much longer half-life. This may result in a lower incidence of late coagulopathy. Note that the Crotalidae Immune F(ab')2 antivenom is of Equine origin and may be problematic in those patients with horse allergies.[29] A detailed review of antivenom therapy for pit vipers is provided by Weinsten.[30]

CroFab is truly an elegant drug. It is produced by immunizing sheep with the venom from the western diamondback rattlesnake (*C. atrox*), the eastern diamondback rattlesnake (*C. adamanteus*), the Mojave rattlesnake (*Crotalus scutulatus*) or the cottonmouth water moccasin (*Agkistrodon*). The monovalent immunoglobulin from the sheep is prepared by fractionation of the immunoglobulin from the serum, digesting it with papain, and then utilizing ion exchange and affinity chromatography to separate the Fab fragments specific to each species.[31] The Fc portion of IgG is generally thought to be responsible for high rates of hypersensitivity and serum sickness seen with the horse serum product developed by Wyeth in 1954, and hence this ovine (sheep) version is generally considered safer. The four different monospecific antivenins are then mixed (**Table 33.5**). In a murine model there is good antigenic crossover in treating other North American Crotalid envenomations.[32]

Table 33.5 Components of Antivenom—CroFab® Antibodies
LD50 Neutralizing Units
Crotalus atrox (Western diamondback) 1,350
Crotalus adamanteus (Eastern diamondback) 800
Crotalus scutulatus (Mojave rattler) 5,210
Agkistrodon piscivorus (Cottonmouth water moccasin) 460

LD50, median lethal dose.

Utilizing CroFab to treat Crotalid envenomation is somewhat controversial, primarily because of the cost/benefit ratio. The cost of this drug is a significant factor with wholesale prices up to $3,200 per vial (2019). Certainly, any patient with life-threatening symptoms should immediately be given 4 to 6 vials of the antivenom.[33] Treatment is not based on the body mass of the patient—as the antivenom neutralizes the poison that is injected—this will vary with each envenomation. The lyophilized powder is reconstituted with 18 mL of normal saline, followed by dilution in 250 mL. Each dose is given over 1 hour. It is thought that venom is rapidly tissue bound, therefore the earlier the antivenom can be given, the more likely a favorable response. The packaging information states that treatment should begin within 6 hours of the bite. There is however at least one report of effective use of antivenom after significant delay.[34] Thus is the conundrum—there are certainly snakebites that initially appear innocuous that later become life-threatening. This has led physicians in the emergency room to overtreat large numbers of patients who do not require therapy, and why it is so important that every attempt be made to identity the offending species. Of note is the increasing use of antivenom by emergency room physicians. In a recent study, up to 84% of pit viper envenomations were treated with antivenom.[35] The reason for the high usage may be medicolegal, as it is certainly not to reduce mortality (in some cases it may reduce morbidity). If one can ascertain that the snake is one of the less virulent types (*Agkistrodon* or *Sistrurus* species), the patient can almost certainly be treated without the use of antivenom.[13] However, in the patient with a deteriorating clinical condition, antivenom treatment should always be given. Repeated dosing

should be given until clinical stability is achieved; although this is highly unlikely after 30 to 40 vials. The patient should be monitored for recurrence of symptoms and retreated if necessary.[36] CroFab has an estimated half-life of 12 to 23 hours.

Immediate adverse drug reactions will occur in 6% to 8% of patients.[37–39] This may be related to the rate of infusion. Although anaphylaxis would occur in up to 50% of patients treated with the older equine antivenin, it is an uncommon occurrence with CroFab—maybe up to 14% of patients.[40] It should be treated aggressively when occurring: The antivenin infusion should be stopped and a combination of antihistamines (diphenhydramine), epinephrine, and steroids administered, depending on the severity of the response. The airway should be assessed and secured if necessary. Appropriate volume resuscitation should be instituted. Steroid dosing ranges from a single 125-mg intravenous bolus of methylprednisolone to short-course prednisone pulse dosing (60 mg daily for 5 days).

Serum sickness will occur in 13% to 16% of patients treated with ovine antivenom (CroFab), certainly less common than with the older Wyeth equine antivenom.[27] Serum sickness is a type III hypersensitivity reaction in which soluble antigen–antibody complexes are deposited diffusely in the presence of antigen excess. Symptoms such as urticaria, itching, nephritis, and arthralgia can occur for weeks after the infusion. The treatment for serum sickness is a pulse of corticosteroids tapered over 7 to 14 days.

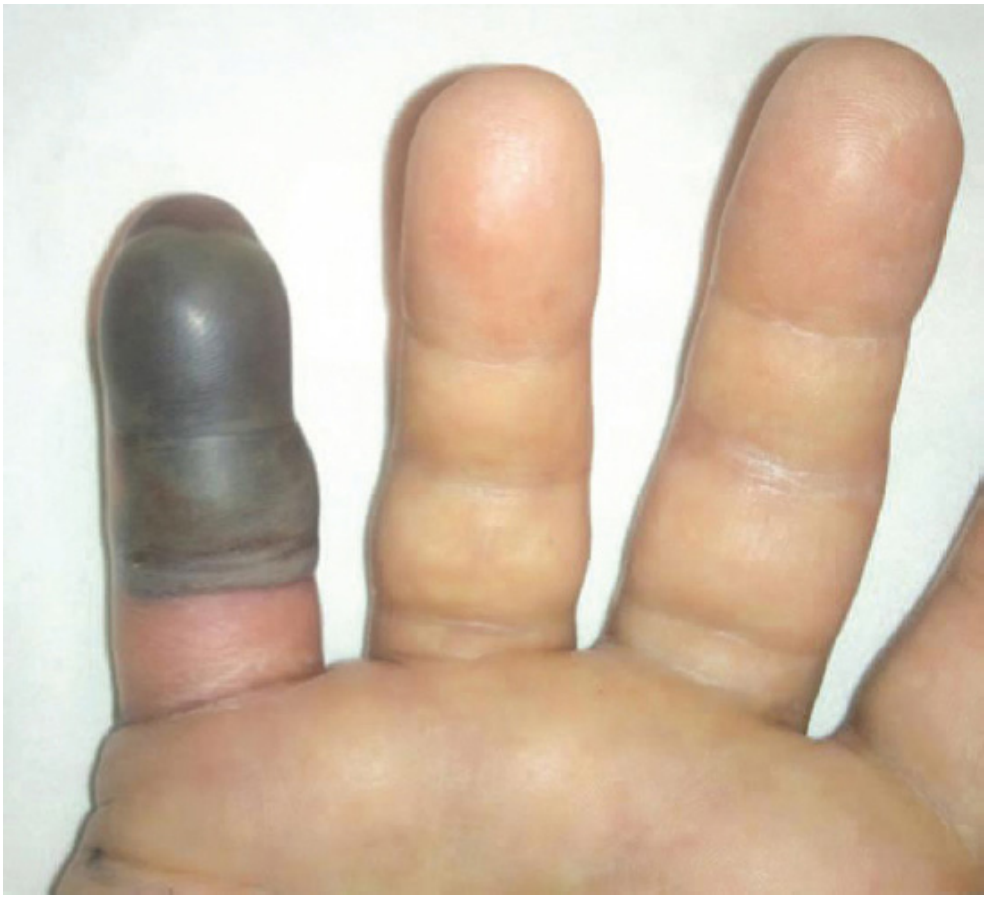

Figure 33.7 Hemorrhagic bulla.

There is no question that the purified ovine antivenin (CroFab), and now Anavip, is much safer than the older horse product.[30,41] This has led to some indiscriminate usage in emergency departments across the country. It should be recognized that the vast majority of snakebite victims will recover uneventfully with only supportive treatment. Each patient must be individually clinically evaluated and limit antivenom use to those in whom the potential benefits outweigh the risk of side. Note that while Anavip is only approved for rattlesnake envenomation, it has been used for Copperhead bites as well.

CroFab has been used extensively in children as young as 14 months,[42–44] and there are beginning to be reports of overuse of CroFab in both children and adults.[45] A special consideration should be use of antivenom in the pregnant patients. Certainly, coagulopathy could be lethal to the mother and fetus. There have been limited reports of use of CroFab in pregnancy.[46] Reports of fetal loss of up to 20% are noted in the worldwide literature with

snakebites of a variety of species. This seems to be improved with the use of antivenom.[47,48] Certainly, the risk/benefit ratio must be carefully weighed, but the general recommendation is to treat pregnant women with CroFab when indicated.

Figure 33.8 First debridement.

Figure 33.9 Second debridement.

In the rare patient that develops clinical bleeding, such as hemoptysis, intracranial hemorrhage, or gastrointestinal bleeding, correction of the coagulopathy should be undertaken with appropriate blood products. Antivenom should be given in these patients as initial therapy. Do not routinely treat thrombocytopenia or severe coagulopathy in the absence of bleeding. Coagulopathy can recur up to 2 weeks later.[36]

The use of surgery in the management of snakebite has a limited role. Although historically snakebite has been treated with various surgical procedures,[49] it should be in an unusual patient that more than simple debridement is needed. Crosscut and aspiration of the puncture sites was utilized for years, but this is no longer recommended. Several studies have shown the limitations of this practice. In dogs, up to one-half of the venom can be removed if incision and suction are begun within 3 minutes. In rabbits up to 37% of antivenom can be removed. However, in human studies only about 11% of the venom may be removed.[50,51] It is rapidly bound to tissues and is difficult to be removed by suction. Both partial and radical surgical excision of the involved bite area has likewise been attempted with no

proven benefit.[52–54] An uncommon finding is a local cytolytic response (**Fig. 33.7**) that produces a hemolytic bulla and requires debridement (**Figs. 33.8** and **33.9**). Actual tissue loss occurs in 7.8% of rattlesnake bites and 3.8% of Copperhead bites.[35] This can be expected to heal by secondary intention with a satisfactory cosmetic response (**Fig. 33.10**).

Figure 33.10 Healed wound.

Another use of CroFab is in the patient with impending compartment syndrome. The great majority of snakebites deposit venom in the subcutaneous tissues, not subfascial. It can sometimes be difficult to differentiate a swollen painful extremity from a true compartment syndrome. When in doubt, compartment pressures should be measured.[52,55] With rising pressures (greater than 30 to 40 mm), antivenom therapy should be initiated (or repeated). With failure of response to adequate dosing of antivenom, appropriate surgical fasciotomy can save extremities. Prophylactic

fasciotomy has no role in treatment. Stewart et al. at the University of Texas Health Science Center in San Antonio have an extensive experience with rattlesnake bites.[56] They have randomized animals to receive an intracompartmental injection of venom from the western diamondback rattlesnake. The animals received fasciotomy with debridement alone, antivenom alone, or antivenom with fasciotomy and debridement. Antivenom therapy prevented muscle loss and improved survival. Surgery alone did not. It was noted that muscle that had been debrided would have survived if treated with antivenom alone. Fasciotomy may increase the severity of local tissue loss.[57,58] When fasciotomy is required because of rising compartment pressures that do not respond to antivenom, consideration for postoperative negative-pressure wound therapy should be given.

Creative attempts at treating envenomation have even included the use of electrical current to neutralize the venom. The use of current from the generator of an outboard motor and an automotive battery has even been attempted.[59] As innovative and entertaining as these efforts may be, there is no improved outcome.[60] The TASER or conductive electrical weapon (stun gun) is a small handheld device that produces a very high voltage with a low current. It is used primarily by law enforcement agencies to temporarily immobilize attackers. A group of physicians practicing in Ecuador reported a series of 34 patients in letters to the editor of *Lancet* in which a modified stun gun was used to treat snakebites.[61,62] They claimed an immediate improvement with no mortality. The snakebites were most likely *Bothrops atrox*—the fer-de-lance—a pit viper. Unfortunately, this reported treatment was not a controlled study. Several animal studies have since proven electrical shock therapy to be ineffective in snakebite.[63–65]

Special Consideration of Elapid Envenomation

As noted, there are only three species of Elapids in the United States—the eastern coral snake, the Texas coral snake, and the Arizona coral snake. The eastern coral snake (*Micrurus fulvius*) is found in the southeastern United States up to Kentucky and North Carolina. The Texas coral snake (*Micrurus tener*) is found in west of the Mississippi across Arkansas, through Louisiana into eastern Texas. The eastern and Texas coral snakes inhabit forests and shrubbery. The Arizona coral snake (*Micruroides euryxanthus*) is found in

the desert climates of the southwestern United States into Mexico. Coral snakes are more active at night and hide under ground cover. Their behavior is elusive, and they will generally try to flee when disturbed. This family of snakes has a common feature—bilateral upper maxillary fangs that are fixed into position and angled down and back. The fangs are grooved for instillation of the venom, which is predominately a neurotoxin. The snakes are oviparous (lay eggs) and have round pupils. Their head is flat, with a smooth tapered tail and of course no rattles. They have characteristic coloration which is mimicked by several other nonvenomous species (such as the king snake and the scarlet king snake) in a biologic phenomenon referred to as batesian mimicry.[66] Although the North American coral snakes are relatively small (less than 5 ft), some Elapids from other continents are very large; the Black mamba is 14 to 15 ft and the king cobra can be up to 18 ft and weigh 25 lb. Although nonnative elapids bites have a substantial risk for death, only one known death from a coral snake has occurred in the United States since 1967 (Bonita Springs Florida, 2006).[2]

The bite of an Elapid is likely to produce much less tissue injury than the bite of a Crotalid.[67] There may be minimal pain. Envenomation may result in immediate neurotoxicity (within 15 to 30 minutes in the case of the mamba or Australian brown snake) or be delayed (2 to 5 hours with coral snakes). There is no longer any antivenom available for North American coral snakes, but local zoos may be able to provide antivenom for more exotic Elapidae. First aid should involve a compression bandage over the wound. The poison generally spreads by lymphatics; therefore, field compression to occlude lymph flow at the site of envenomation can slow toxicity. Symptoms will be related to the neurotoxicity—confusion, muscle spasm, nausea, vomiting, and dizziness. Blurred vision and difficulty with speech will occur. Finally, respiratory paralysis of the diaphragm occurs with resultant death. Cardiovascular and pulmonary support is essential to salvage patients that progress to this state. It should be noted that venom of an Elapid is incredibly toxic. The Taipan and Belcher sea snakes have an LD50 in mice of as little as 0.025 mg/kg of venom.[31] Any suspected Elapid bite should be managed with the possibility of rapid demise of the patient. If the bite is of a nonnative Elapid, antivenom (if it can be found) should be administered promptly at the first sign of clinical demise. Death rates for untreated nonnative Elapids vary from 20% to 30% for cobras to nearly 100% for the mambas.[68] Antivenom

for exotic snakebites may be obtained from the local zoo or through their national organization—the Association of Zoos and Aquariums (https://www.aza.org) or through the American Association of Poison Control Centers at 1-800-222-1222.

Venomous Lizards

There are two venomous lizards in North America: the Gila monster (*Heloderma suspectum*) and the Mexican beaded lizard (*Heloderma horridum*). Both species have heavy bodies with large heads. The Gila monster is found in the southwestern United States, ranging primarily in Arizona, extending into southeastern California, southwestern Utah and New Mexico, and into northern Mexico. There are two subspecies: the banded Gila monster (**Fig. 33.11**) that is found in the northern portion of the habitat and the reticulated that exists in the southern portion of the range. It is the largest lizard in the United States with a length of up to 56 cm. The Gila monster has generated substantial lore in the southwestern United States, because of its characteristic appearance and apparent fetid breath. It lives below ground and spends most of its life in or near its burrow. It is primarily seen in the spring, in the morning hours during breeding season. It has powerful jaws and the bite is characterized by the tendency to hang on with the animal difficult to dislodge. The Poison Control Center reported 105 human–bite-related calls from 2000 to 2011; 40% were seen in a hospital, 16% admitted, about 1/3 to an ICU. There were no deaths.[69]

The Gila lizard has eight labial glands on either side of the lower jaw. The venom is secreted into the floor of the mouth where it is wicked into the victim via grooved lower canine teeth. Envenomation is limited and deaths are virtually unknown.[70] The morbidity is usually secondary to local effects from the toxins present: serotonin, phospholipase A, amine oxidases, hyaluronidase, and proteases.[71,72] These produce pain at the site that usually resolves in less than 24 hours. Hypotension, coagulopathy, and myocardial infarction have been reported. Nausea and vomiting can occur. Malaise may persist for several days. The patient should be admitted for observation and a low threshold for surgical exploration/debridement is given because the teeth often shed into the bite and can serve as a nidus for infection.[73,74]

Figure 33.11 Gila monster.

Figure 33.12 Brown recluse.

The Mexican beaded lizard is found from Sonora to Guatemala and is represented by four subspecies. They are larger than the North American Gila monster; with a maximum size of up to 91 cm. They have similar venom as the Gila monster and bites should be managed in a supportive fashion.

Insect Bites and Stings

4 Although the bite of a venomous snake will certainly draw more attention in the emergency department, in fact insects kill many more Americans (greater than 100 deaths per year) than snakes (about 5 deaths per year).[75] Although most of these deaths are from anaphylactic reactions, some are from overwhelming envenomation, particularly from those of the Africanized honey bee (the "killer" bee). Most of the treatment recommendations below are from expert opinion; few randomized trials have been performed.

Spiders

There are six genera of spiders in the United States that can produce painful bites, tissue necrosis, and rarely death. These fall into three groups—the brown recluse (**Fig. 33.12**), the black widow (**Fig. 33.13**), and the hobo spiders.[76]

Figure 33.13 Black widow spider.

Brown Recluse

There are 13 species of *Loxosceles,* of which 5 have been known to produce tissue necrosis. Probably the species producing the most pathology is the brown recluse (*Loxosceles reclusa*). Envenomation by the hobo spiders (*Tegenaria agrestis*) produces a similar wound. The brown recluse is generally found in the southern states. Hobo spiders are found in the Pacific

Northwest.[77,78] Bites from these two species generally are initially painless and the victim may not recall being bitten. Pain and erythema develop over the next 6 hours. The venom can produce a painful, necrotic, slow-healing wound over the next 48 to 72 hours. Two to 7 days after the bite, an eschar develops with surrounding soft tissue induration. The eschar can conceal an underlying tissue necrosis that can persist for months.[13,79] Treatment is highly variable: eschars can require extensive debridement leading to skin grafting and even amputation, or they can be left alone and allowed to heal spontaneously, often with a residual shallow crater from loss of fat and soft tissue.

The venom is both hemolytic and cytotoxic. The enzyme that is thought to produce the "desmonecrotic arachnidosis" is sphingomyelinase D. The venom also contains hyaluronidase, lipase, arachidonic acid, and prostaglandins.[80,81] Systemic symptoms occur in less than 10% of victims, more commonly in children. Rarely hemolysis, hemodynamic instability, and death have occurred.[82] Initial treatment should include analgesia, wound care, and tetanus prophylaxis. Antibiotics should be reserved for infection/cellulitis. Early debridement should be withheld. Consideration for oral dapsone therapy should be given. Dapsone is thought to work as an inhibitor of polymorphonuclear leukocyte chemotaxis. It has significant side effects and can produce hemolysis in G6PD-deficient patients. Its use is somewhat controversial. It has been shown to reduce the size of the skin lesion and lessen the amount of surgical debridement, but these are not prospective studies. A controlled study of dapsone, electroshock therapy, and no treatment in guinea pigs showed some improvement with dapsone, but none with the electrical therapy. Hyperbaric oxygen has been studied in rabbits and pigs and has failed to demonstrate significant improvement. A trial of hyperbaric oxygen, dapsone, and cyproheptadine in rabbits failed to show any improvement.[83–87] Systemic steroids have not been shown to help. Initial surgical excision of the lesion has no clear benefit. Carlton has reported a favorable response with high-dose diphenhydramine, calling it a "uniquely conservative."[88] Delayed excision of the area of necrosis with skin grafting can be necessary. Recurrent necrosis in the same site can return even years later.

Black Widow Spiders

There are 31 species of the genus *Latrodectus,* the Black Widow spider, of which 4 are found in North America. These are marked by a prominent red hourglass figure on the ventral aspect of the thorax. Although both the male and the female possess venom, only the bite of the female can penetrate human skin. The female is four times the size of the male. The female of the species is known for eating the male after mating, which may or may not occur. The bite may produce only minimal local symptoms, with only a small area of redness, or a "target" appearance, or more dramatic erythema, induration, and purpura (**Fig. 33.14A,B**). The venom contains α-latrotoxin, which is neurotoxic. This produces chest and abdominal pain, and the patient's presentation may be confused as an acute surgical abdomen. Marked cramping and abdominal rigidity may be present. Fasciculations of facial muscles with ptosis and spasm may occur producing a particular facie. Hyperreflexia, paresthesia, cutaneous hyperesthesia, and nausea may also occur. Symptoms may occur within an hour and resolve over several days.[89,90] The muscle spasm should initially be treated with benzodiazepines. Antivenin is available and should be considered in the very young or ill patient. The dose is 1 ampule given in 50 mL of saline, and the response can be quite dramatic and immediate.[91] The antivenom is equine and hypersensitivity testing should be done prior to giving the antivenom.[92] A 1-mL test dose of horse serum is included with the antivenom for topical conjunctival testing. Calcium gluconate was often given in the past but is no longer recommended. Mortality is exceedingly rare.

Figure 33.14 **A, B:** Black widow spider bite.

HYMENOPTERA

More than 100,000 species of Hymenoptera exist. This includes bees, wasp, hornets, and fire ants. The venom injected by these insects is at least as toxic as that of the rattlesnake, but the volume is much less. The venom is primarily a hemolysin and neurotoxin. Anaphylaxis is a common clinical problem produced by the envenomation. Approximately 0.4% of the human population is at risk of anaphylaxis from Hymenoptera stings.[93] The anaphylaxis is modulated by preformed IgE that activates mast cells leading to massive histamine release. This leads to laryngeal edema, pulmonary edema, and cardiovascular collapse. This must be treated aggressively with intravenous diphenhydramine (Benadryl®), epinephrine, and fluid resuscitation, as well as with management of the airway and supplemental oxygen. Most stings are mild, however, resulting in only dermal reactions—pain, erythema, and edema. The stinger should be removed, and ice applied to the site. Application of meat tenderizer might be of some benefit. Patients with a history of insect sting anaphylaxis should be given a prescription for an epinephrine pen and be considered for venom immunotherapy. This is almost 100% successful in desensitization but can take up to 3 years.

Killer Bees

Africanized honeybees (killer bees) are hybrids of the African honeybee and the European honeybee, the one commonly found in the United States. The Africanized honeybee was originally brought from Tanzania to Brazil in 1957, with the hope of better honey production. The bees have spread up through Central America, Mexico, and into southwestern United States. They are continuing to advance at about 100 miles/yr, with some evidence of slowing in more recent years.[94–96] Africanized honeybees are indistinguishable from the European honeybee, so DNA (usually mitochondrial DNA) analysis is necessary to differentiate the subspecies.[97] They are termed "killer bees" because of increased aggressive traits. They show greater defensiveness of the hive, they have a bigger "alarm" area, and they deploy in greater numbers and will pursue perceived threats over much greater distances. Although their venom is of the same potency as the European bees, the number of stings received will usually be much greater. With more than 50 stings, nausea, vomiting, shock, hemolysis, rhabdomyolysis, coagulopathy, coma, and death may occur. Usually most patients will just complain of pain but delayed toxic reactions—6 to 48 hours—may also occur. It is recommended that any patient presenting with more than 50 stings be hospitalized and observed.[98] Laboratory evaluation with coagulation studies, platelet count, and liver function studies should be obtained.

Fire Ants

Fire ants are wingless members of the Hymenoptera order. They were brought to the United States from South America around 1918.[99] The red imported fire ants appear to have been introduced on a ship through Mobile, Alabama. Shipments of infested nursery stock and other agricultural products, natural mating flights, and floating on flood waters have contributed to their spread. Two species of imported fire ant now infect large areas of the Gulf Coast states.[100] Fire ants aggressively attack any perceived danger to themselves or their mound.[101] Each ant can produce multiple stings. The venom is a dialkylpiperidine that induces the release of histamine from increased mast cell reactivity. The fire ant sting produces a sterile pustule,

which does not usually require antibiotic therapy. Infectious complications can occur at the site that may be more common in diabetic or immunocompromised individuals. Fire ant venom shares at least four antigenic proteins with bees and wasps. More than 80 fatalities have been reported from fire ant anaphylaxis, notably in Australia and southern United States. The treatment is the same as with bee/wasp sting anaphylaxis.[102]

Scorpions

More than 1,500 species of scorpions can be found worldwide. Only about 20 or 25 are considered dangerous. They are in the class Arachnida, close relatives of ticks, mites, and spiders. Scorpions prefer dry habitats but may be found throughout the southern United States. Scorpions are nocturnal, hiding during the day and becoming active at night. The scorpion's body has a 5-segmented tail that can be arched over the back and becomes slenderer toward the end. On the end of the tail is the bulb-like poison gland/stinger. Between the last pair of legs are comb like structures called the pectines—sensory organs used to sense surface textures and detect prey. The venom toxicity varies greatly depending on the species, season, and age of the scorpion. Stings from dangerous species may cause paralysis, severe convulsions, cardiac irregularities, breathing difficulties, and death. In the United States most scorpion bites are not life-threatening and only result in local effects. In parts of Brazil, Mexico, North Africa, and Israel, however, the sting may be lethal. In Brazil the mortality rate is as high as 12% for adults and 60% in children.[51] In India, of 34 children admitted to a hospital for a scorpion sting, 14 had hypertension, 9 had acute pulmonary edema, 5 had a myocardial infarction, and 4 died.[103] Antivenins are typically available in areas where dangerous species are found, either from a local zoo or state or university agricultural extension departments. One species in the North America is particularly venomous—the Arizona bark scorpion (*Centruroides sculpturatus*) (**Fig. 33.15**). The sting produces a dramatic neuromotor syndrome and respiratory insufficiency. It has produced several deaths in the United States and hundreds in Mexico. Anascorp (an immune F(ab)2 equine antivenom) is now available for patients with systemic symptoms.[104] It (like CroFab) is very expensive (about $12,000 per vial in the United States—or $100 per vial in Mexico).

Figure 33.16 Asp caterpillar.

Centipedes and Millipedes

There are approximately 3,000 species of centipedes in the world. They are arthropods with a single set of legs on each body segment. The front pair of legs is modified to deliver venom. One of the largest members of this class is the giant desert centipede (*Scolopendra gigantea*). It can grow to 26 cm in length. Significant morbidity, including EKG changes and rhabdomyolysis, can occur from centipede bites, but death is exceedingly rare. The most common symptoms include erythema, swelling, and pain.[105] Treatment is largely symptomatic, with reports of both ice and heat improving symptoms.[106] There are approximately 7,000 species of millipedes. They have two pairs of legs on each body segment. Millipedes do not have a mechanism to inject a venom, but instead secrete an irritating liquid from pores covering their body.[107] This can produce a superficial burn that is self-limiting. Only symptomatic therapy is indicated.

Asp Caterpillars

The asp is a venomous caterpillar found in the southern United States. It is the larval stage of the Southern Flannel Moth (*Megalopyge opercularis*) (**Fig. 33.16**). It has the appearance of soft furry ball, encouraging the unwary to touch it. The long hairs of the asp conceal shorter spikes that discharge venom. Typically, an intense throbbing and pain occurs almost immediately. Erythematous spots occur at the site of envenomation. Symptoms include headache, nausea, vomiting, and the development of lymphadenopathy. Chest pain occurs occasionally. Rarely shock and respiratory distress have been reported. Death is exceedingly rare and is almost certainly because of a hypersensitivity reaction.[108–110] A similar caterpillar found in South America —*Lonomia*—has a death rate of 1.7%. The initial treatment should be to apply adhesive tape and pull it off to remove the spines. Ice packs and antihistamines may provide symptomatic relief. Intravenous calcium and steroids have been suggested as a treatment regimen.[111]

Hypothermia

Humans, like all mammals, will always attempt to maintain a constant body temperature despite changes in environmental temperature.[112] Normal human body temperature is 37° sublingually, 38° in the rectum, 32° at the skin, and 38.5°C deep in the liver, with normal daily (circadian) variation of about 0.5° to 1°C; we tolerate poorly even minor deviations from these norms.[113,114] Although humans have a remarkable capacity to dissipate heat by evaporating body water, our tropical evolutionary heritage has provided us with far less ability to cope with cold conditions. As a result, hypothermia can occur in a variety of clinical settings and from a number of causes (**Table 33.6**).

Table 33.6 Clinical Definitions of Hypothermia and Examples of Settings in Which They Occur

Type	Settings
Accidental	Recreational environmental exposure, cold-water immersion
Therapeutic	Treatment of Reye syndrome, cardiopulmonary bypass, organ preservation
Drug induced	Alcohol, anesthetics, barbiturates, phenothiazines, morphine, other drugs
Central nervous system dysfunction	Transection of spinal cord, hypopituitarism, cerebrovascular accidents
Hypothalamic dysfunction	Wernicke encephalopathy, anorexia nervosa, head trauma, pinealoma, other tumors
Metabolic	Hypoglycemia, hypothyroidism, hypoadrenalism, malnutrition
Dermal dysfunction	Burns, erythrodermas
Traumatic	Occurs after any major injury

Redrawn from Jurkovich GJ, Greiser W, et al. Hypothermia in trauma victims: An ominous predictor of survival. *J Trauma*. 1987;27(9):1019–1024.

Hypothermia is considered to be present in humans if the core temperature drops below 35°C (95°F). Hypothermia is usually classified by temperature zones: mild (32° to 35°C); moderate (28° to 32°C); or severe (<28°C). *Primary* accidental (vs. intentional) hypothermia is defined as a decrease in core temperature that occurs as a result of overwhelming environmental cold stress, such as recreational misadventures that lead to cold-water immersion or prolonged environmental exposure. *Secondary* accidental hypothermia is

considered to be triggered by, or at least associated with, underlying disease. Secondary accidental hypothermia occurs in patients with impaired thermoregulation, decreased heat production, or increased heat loss. These patients become cold despite only mild cold stress. The most significant risk factors are advanced age, mental impairment, and substance abuse (alcohol, primarily), although hypothyroidism, hypoadrenalism, trauma, and hypoglycemia are other risk factors.[114–116] Chronic hypothermia develops in patients with impaired heat generation (i.e., the elderly and infirm) who live in unheated apartments, are under continual cold stress, and after a time are found to have a chronically low temperature as if they have autoregulated to a new, lower-set core temperature.

It is estimated that each year about 1,500 patients in the United States have hypothermia listed on their death certificate, although the exact incidence and associated morbidity and mortality remain poorly characterized.[114] The 2015–2017 death rate from accidental hypothermia per 100,000 in the United States is depicted in **Figure 33.17**.[117] This figure emphasizes the problem of secondary hypothermia (exposure) in rural environments. A multicenter review of 428 cases of accidental hypothermia reported an overall mortality rate of 17%,[113] although other reports document mortality rates as high as 80%, primarily a result of infection and underlying illness. Treatment of accidental hypothermia remains highly variable. A study from Amsterdam reported that over an 8-year period (2000–2008), a total of 84 patients with accidental hypothermia were treated with 14 different rewarming techniques, with an overall mortality of 28.6%.[115] Most recently, Matsuyama reported on the national Japanese registry of hypothermia experience of 537 patients with secondary (accidental) hypothermia with an in-hospital death rate of 24.2%.[118] From 1979 to 2002, the CDC reported that a total of 16,555 deaths in the United States, an average of 689 per year (range 417 to 1,021), were attributed to exposure to excessive natural cold (**Fig. 33.18**).[119] From 1999 to 2002, a total of 4,607 death certificates in the United States had hypothermia-related diagnoses listed as the underlying cause of death for an annual incidence of 4 per 1,000,000 population. Most reported hypothermia-related deaths (67%) occurred in males (**Fig. 33.19**), but the overall death rate is the same for both males and females. Notable is that deaths occur in all states, even those that generally are considered to have warm climates. Hypothermia-related deaths are reported by states with characteristically

milder climates that experience rapid temperature changes and by western states that have high elevations and experience considerable changes from daytime to nighttime temperatures. States with the greatest overall death rates caused by hypothermia are Alaska, New Mexico, Wyoming, and Montana (**Fig. 33.20**).

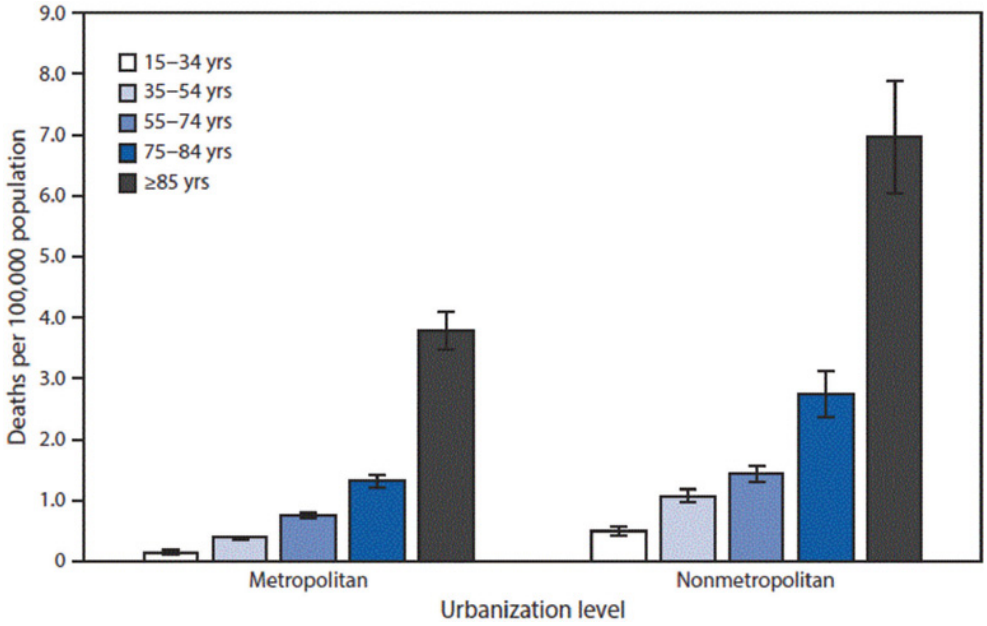

Figure 33.17 Rate of deaths due to hypothermia. Crude rate of deaths per 100,000 population; 95% confidence intervals indicated by error bars. Deaths attributed to excessive cold or hypothermia were identified using the International Classification of Diseases, Tenth Revision underlying cause of death code X31 (Exposure to excessive natural cold) or multiple cause-of-death code T68 (Hypothermia). Urbanization level is based on the Office of Management and Budget's February 2013 delineation of metropolitan statistical areas (MSA), in which each MSA must have at least one urbanized area of ≥50,000 inhabitants. Areas with <50,000 inhabitants are grouped into the nonmetropolitan category. (Adapted from CDC reference QuickStats: death rates attributed to excessive cold or hypothermia among persons aged ≥15 years, by urbanization level and age group —National Vital Statistics System, 2015–2017. *MMWR Morb Mortal Wkly Rep* 2019;68[7]:187.)

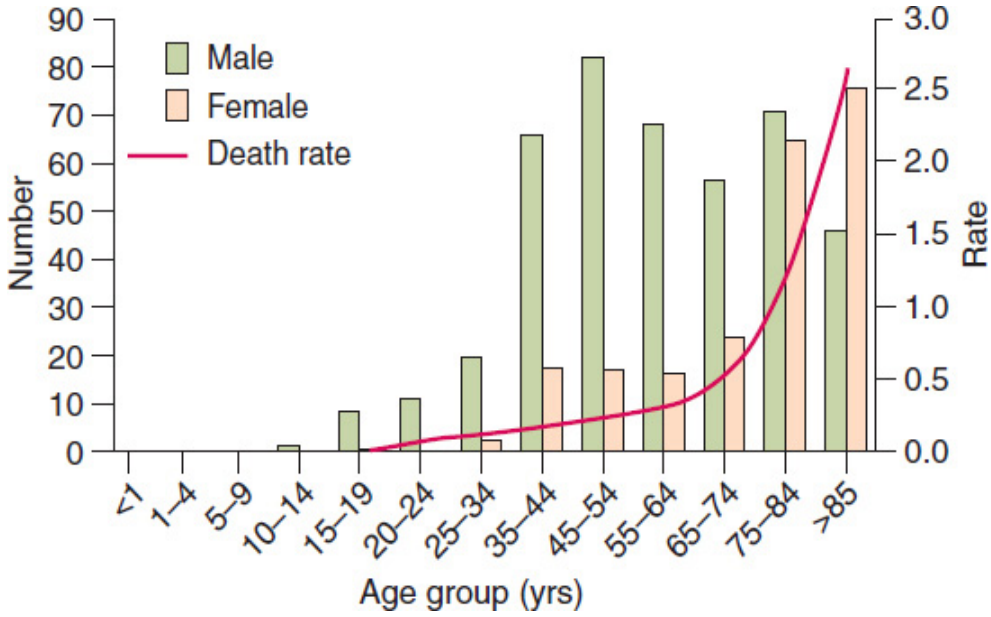

Figure 33.19 Number and rate (per 100,000 population) of hypothermia-related deaths, by age group and gender, in the United States, 1979–2002. (After Hypothermia-related deaths—United States, 2003–2004. *MMWR Morb Mortal Wkly Rep* 2005;54:173–175.)

The physiologic response to hypothermia is one of transitional changes, with few exact temperature-dependent responses (**Fig. 33.21**). Broadly speaking, the transition from a "safe zone" of hypothermia (in which physiologic adaptations to heat loss are working) to a "danger zone" of hypothermia (in which shivering is abolished, metabolism decreases, and heat loss is passively accepted) occurs between 33° and 30°C.[112] 5 The initial effects of hypothermia mimic intense sympathetic stimulation, with tremulousness, profound vasoconstriction, tremendous increases in oxygen consumption, and acceleration of heart rate and minute ventilation. When core body temperature cannot be measured, a four-stage hypothermia classification based on vital signs and level of consciousness has been developed by Swiss clinicians.[114,116] It should be emphasized that the purpose of the Swiss clinical grading is to direct treatment in the absence of the ability to actually measure core body temperature, so it should have its primary purpose in the austere or field care environment.

The cardiovascular response to hypothermia begins with tachycardia, but followed by progressive bradycardia, which starts at approximately 34°C and results in a 50% heart rate decrease at 28°C. Cardiac output initially increases with the tachycardia, and then progressively decreases, with a concomitant fall in blood pressure. The conduction system is particularly sensitive to hypothermia: the PR interval, then the QRS complex, and finally the QT interval become progressively prolonged.[120] As temperature falls below 30°C, atrial fibrillation, bradycardia, and ventricular dysrhythmia become common, with asystole occurring at temperatures below 25°C. Perhaps the most challenging management of an accidental hypothermia patient is the one with temperatures between 28° and 32°C (Swiss stage 2), as these patients are prone to develop poorly perfusing arrhythmias, yet they often can be rewarmed with active external and environmental rewarming if such arrhythmias do not occur. Hence gentle manipulation of such patients is required. Because palpating pulses or measuring blood pressure in cold, stiff, hypothermic patients is difficult, the presence of an organized cardiac electrical rhythm should be taken as a sign of life that contraindicates cardiopulmonary resuscitation chest compressions, despite the absence of a palpable pulse. Such a rhythm may provide diminished but sufficient circulation in patients with severely reduced metabolism, and it is likely that vigorous chest compressions will convert this perfusing rhythm to

fibrillation. Rewarming should occur with close monitoring of rhythm, pulse, and blood pressure. If cardiac arrest occurs (Swiss stage 3 or 4), extracorporeal cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation (ECMO) for perfusion and rewarming is indicated.[114,121,122] Among patients with what is likely Swiss stage 4, those treated with ECMO or CPB have a reported survival rate without neurologic impairment of 47% to 63%, compared to 37% for similar patients treated without active core rewarming and oxygenation techniques. One report noted excellent long-term functional outcomes in 15 of 32 young patients successfully rewarmed with CPB.[121] All patients were intubated and ventilated and had received ongoing cardiac massage during transportation, and all 15 survivors had documented circulatory arrest (ventricular fibrillation or asystole) and fixed, dilated pupils. The mean interval from discovery of the patient to rewarming with CPB was 141 ± 50 minutes; the mean temperature was 21.8° ± 2.5°C. A report from Finland documents a 61% (14 of 23) survival to hospital discharge for adults undergoing CPB after a mean of 70 minutes of cardiopulmonary resuscitation following hypothermic arrest primarily from cold-water immersion or exposure.[123] A recent review of 18 studies in the literature and 286 hypothermic patients in cardiac arrest who underwent extracorporeal support documented a 37% survival rate, with 84% good neurologic outcome.[124] Finally, the lowest recorded temperature from which a person has been successfully resuscitated following accidental or secondary hypothermia is 13.7°C.[125]

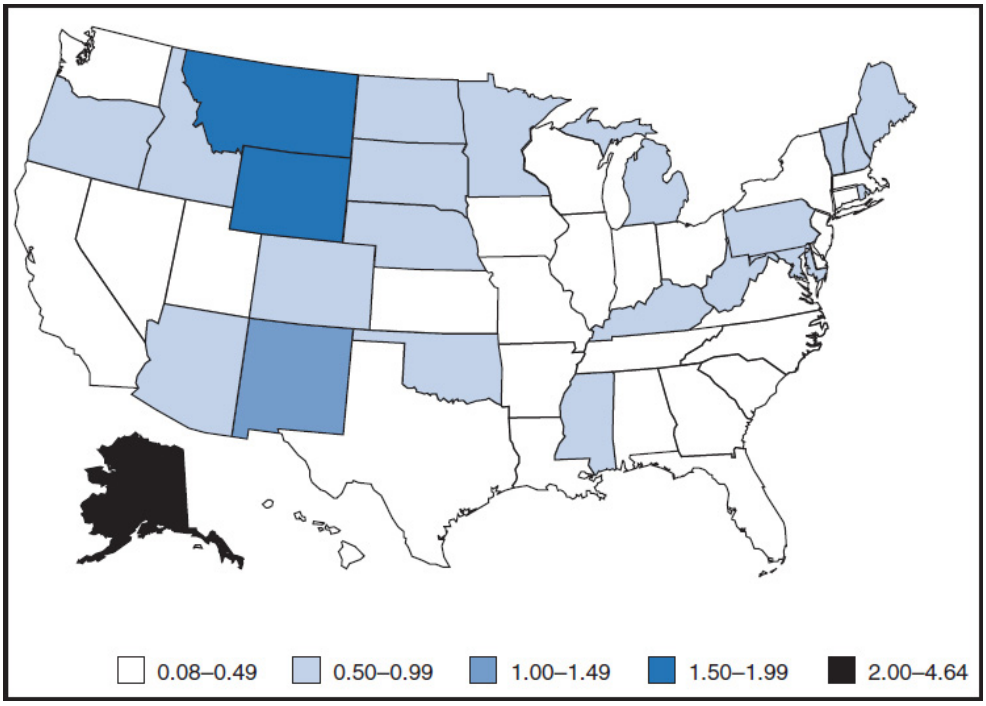

Figure 33.20 Average annual rate per 100,000 of hypothermia-related deaths by state, 1999–2002.

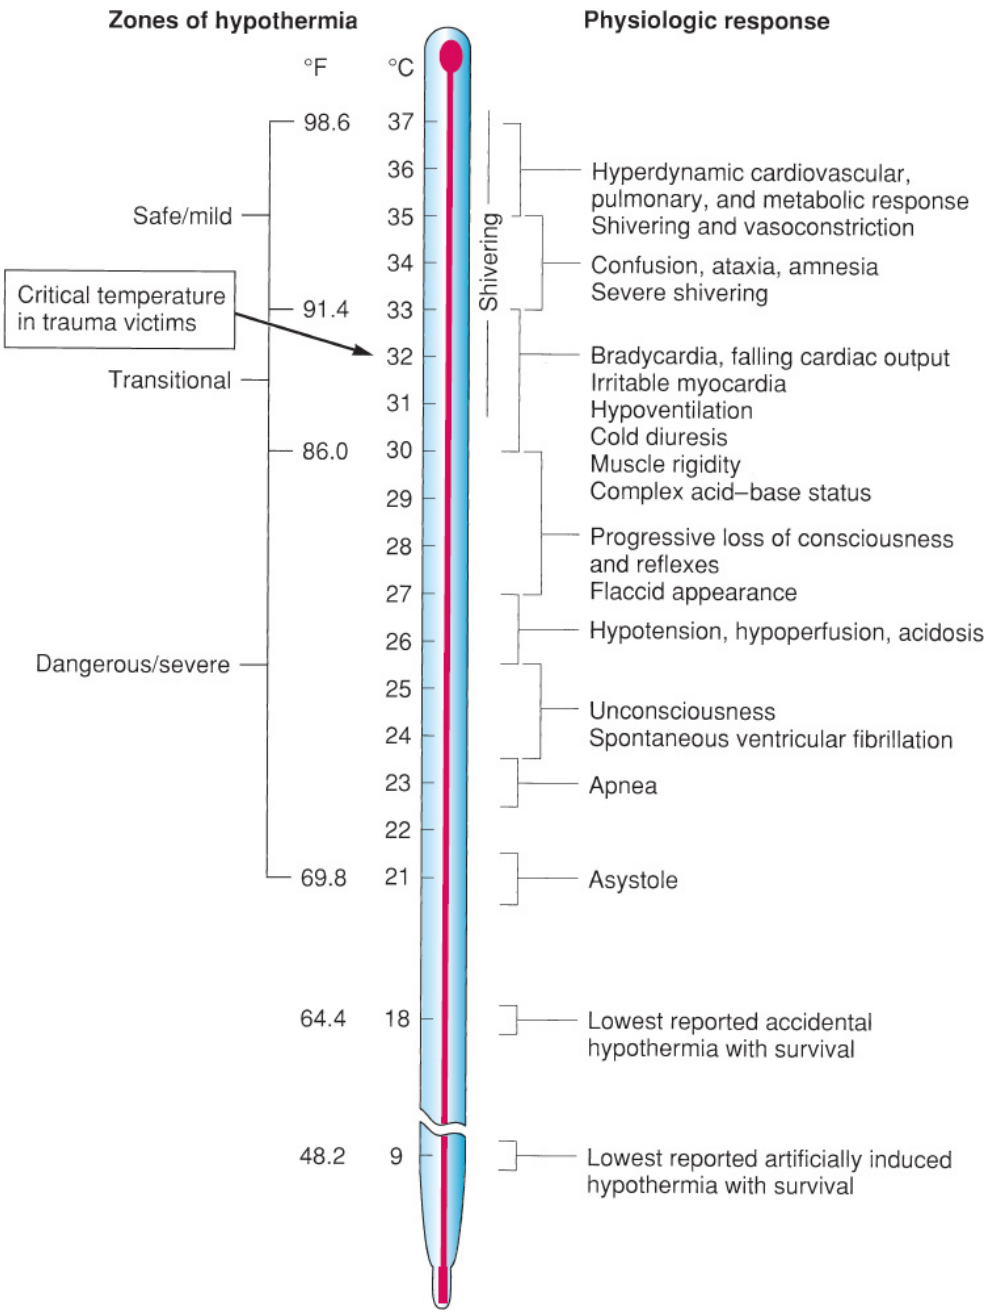

Figure 33.21 Zones of hypothermia and corresponding physiologic responses. Wide biologic variability accounts for physiologic changes rarely occurring at the exact temperatures noted. (Redrawn from Jurkovich GJ, Greiser W, et al. Hypothermia in trauma victims: An ominous predictor of survival. *J Trauma*. 1987;27(9):1019–1024.)

Respiratory drive is increased during the early stages of hypothermia, but below 33°C progressive respiratory depression occurs, resulting in a decrease in minute ventilation. This decrease is not usually a significant

problem until temperatures below 29°C are reached. Occasionally, hypothermia results in the production of a large amount of mucus (cold bronchorrhea).[126] This development predisposes to atelectasis and aspiration as ciliary action and the cough reflex are also depressed. Noncardiogenic pulmonary edema is also occasionally reported, especially in elderly patients and especially after prolonged periods of hypothermia.[127]

The effect of core hypothermia on arterial blood gas interpretation warrants a comment. Arterial blood gas samples are typically warmed to 37°C before measurement. A nomogram of Severinghaus mathematical corrections is then used to estimate the blood gas values at the patient's actual body temperature. With each 1°C temperature reduction, the PCO_2 decreases by 4.4% and the PO_2 decreases by 7.2%. The decrease in partial pressure is related to the increased solubility of gases in cold fluids and is not a result of a change in carbon dioxide content, oxygen content, or serum bicarbonate level. Clinicians often assume that the normal PCO_2 and PO_2 at 37°C are the values that should be attained at all temperatures. However, if normothermic endpoints for PCO_2 were attained in a hypothermic patient, they would have increased total-body CO_2 stores, which would manifest by a rising PCO_2 and a falling pH during rewarming. Likewise, attempts at increasing a PO_2 that reflects normal oxygen content at a lower temperature are also inappropriate. A far simpler strategy is to assess the blood gases at 37°C without temperature correction. Values that are normal and acceptable when reported at 37°C (without temperature correction) correspond to normal values and contents when "corrected" for hypothermic temperatures.

Temperature correction of blood gases for pH management is also unnecessary.[128] The pH of water rises with cooling, causing the pH of blood to rise by 0.015 pH units/°C, without a change in bicarbonate content.[129] Treating a patient with a temperature of 30°C with a pH of 7.40 instead of 7.47 fails to maintain the normal pH offset above the neutral point of water (relative alkalinity) and results in an acidotic cellular and chemical environment that has a multiplicity of effects on enzyme systems. Because blood with a pH of 7.40 assessed at 37°C is reported as having a pH of 7.47 when temperature corrected to 32°C, the simplest strategy when confronted

with a patient with a temperature of 32°C is to assess the blood gas at 37°C only and to use the 37°C uncorrected pH value for management.[129–131]

The neurologic response to hypothermia is heralded by progressive loss of lucidity and deep tendon reflexes and, eventually, by flaccid muscular tone. Patients are often amnestic below 32°C, and between 31° and 27°C they usually lose consciousness. Pupillary dilatation and loss of cerebral autoregulation occur at temperatures below 26°C, and electroencephalography becomes silent at 19° to 20°C.[132] These findings, combined with an unobtainable pulse and apparent rigor mortis, may cause the patient to appear dead. It is important to remember that patients have been revived from core temperatures as low as 13.7°C[125,133] and hence the saying "No one is dead until warm and dead."[134] An exception to this admonition probably includes the patient who has sustained an anoxic event while still normothermic and has a serum potassium level greater than 10 mmol/L, although the Bernese criteria for trauma and hypothermia have picked a level of 12 mmol/L as being nonsalvageable.[114,116,123,135]

The role of hypothermia in brain death determination remains controversial. Brain death is a medically and legally accepted mechanism of death in the United States and worldwide. Yet significant variability in individual institutional policies regarding the determination of brain death occurs. In 2010 the American Academy of Neurology (AAN) issued guidelines on the determination of brain death, reaffirmed in 2014 and 2017.[136] A recent study examined how well 52 organ procurement organizations and 508 unique hospitals have adopted these guidelines, determining that among other variables in policy, only 181 of 228 policies (80%) required the absence of hypothermia (temperature >36°C) in brain death determination.[137]

In classic surgical physiology research, Moyer and Debakey showed that with hypothermia, reduction in blood pressure and cardiac output decreases glomerular filtration rate, but urinary output is maintained because of impairment in renal tubular Na^+ reabsorption (the so-called "cold diuresis").[138,139] Vasoconstriction also results in an initial increase in central blood volume that prompts a diuresis. Ileus, bowel wall edema, depressed hepatic drug detoxification, punctate gastric erosions (Wischnevsky ulcers), hyperamylasemia, and, rarely, hemorrhagic pancreatitis are hallmarks of the intestinal response to hypothermia. Hypothermia inhibits insulin release and

insulin uptake at receptor sites, making hyperglycemia a relatively common finding, especially at temperatures below 30°C.[55] Exogenous insulin administration is unwarranted because it may result in rebound hypoglycemia during rewarming. Serum electrolyte changes are unpredictable, but serum potassium is often slightly increased in hypothermic patients because of renal tubular dysfunction, acidosis, and the breakdown of liver glycogen.[140] Hypothermia also appears to affect endothelial cell adhesion molecule function, which may partially explain increased infectious complications in hypothermic patients.[141] One study demonstrated a drop of 1.9°C core hypothermia triples the incidence of surgical wound infection following colon resection and increases the duration of hospitalization by 20%, leading to the now standard perioperative checklist monitoring of body temperature during surgery.[142]

Body temperature also has a significant effect on oxygen uptake. Oxygen consumption (VO_2) initially increases dramatically with any fall in body temperature. When involuntary muscle contractions in the form of shivering occur, oxygen consumption increases by threefold to fivefold.[143,144] This process is inefficient because shivering produces heat near the surface of the body, causing most of the heat to be lost to the environment, with less than 45% being retained by the patient. As core temperatures fall to between 33° and 30°C, shivering is abolished, and the patient will rapidly sink to ambient temperature.

The thermoregulatory drive is such a powerful one that it takes precedence over many other homeostatic functions. The resultant increase in oxygen utilization may result in anaerobic metabolism, acidosis, and significant cardiopulmonary stress. One study noted a 35% increase in oxygen consumption and a 65% increase in CO_2 production in postoperative patients after resolution of anesthesia, when the thermostatic drive reappeared.[145] In another study, a core temperature decrease of as little as 0.3°C in postoperative patients was associated with a 7% increase in VO_2, and temperature reductions between 0.3° and 1.2°C were associated with a 92% increase in VO_2, with proportional increases in minute ventilation.[144] Shivering can be iatrogenically abolished with low doses of meperidine (Demerol®) and possibly ondansetron (Zofran®, Zuplenz®). Further details of the specific organ system responses to hypothermia are beyond the scope of

this chapter, but the interested reader is referred to several excellent in-depth monographs.[146–149]

Hypothermia in Trauma Patients

Mild hypothermia is very common after traumatic injury. The thermoneutral environment for humans is a humid and warm 28°C (82.5°F) (think tropical islands). When ambient temperature falls below the thermoneutral temperature (i.e., the temperature at which no thermogenesis or heat dissipation is necessary), an increase in heat production is[149] required to maintain a normal body temperature. Combustion is the only source of endogenous heat production, and this process requires an increase in oxygen utilization. After shock or injury, however, oxygen supplies are often limited and further heat loss occurs owing to cold emergency department and operating room environments, cold fluid resuscitation, and open thoracic and abdominal cavities. Anesthetic and neuromuscular blocking agents that prevent the heat-producing shivering 6 response further aggravate this. Thus, the occurrence of hypothermia in surgical or critically injured patients is most often a form of secondary accidental hypothermia.

One study found that 57% of trauma patients admitted to a level 1 trauma center were hypothermic at some time and that temperature loss was most significant in the emergency department.[150] Another study reported that the average initial temperature for 94 intubated major trauma victims was 35°C, with no seasonal variation.[151] Of patients in this study, 66% were hypothermic on admission; 43% were mildly hypothermic (34° to 36°C), and 23% had temperatures below 34°C. Likewise, Jurkovich and Luterman reported that 42% of 71 adult trauma victims with an injury severity score (ISS) of 25 or higher had core temperatures below 34°C and in 13% the core temperature fell below 32°C.[27] Importantly, there were no survivors when core body temperature was below 32°C. Inaba reported that of 118 patients requiring emergent surgery following traumatic injury, hypothermia (<35°C) was present in nearly 30% of patients upon presentation to the operating room, and that a continued decrease in core temperature was associated with increased mortality. This mortality rose to 50% if temperature fell below 32°C.[152] Both mortality rate 7 and the incidence of hypothermia increase with higher ISS, massive fluid resuscitation, and the presence of shock, but

controlling for these variables still demonstrates that the mortality rate of the hypothermic trauma patient is greater than that of the warm trauma patient. Although the mortality rate for moderate (28° to 32°C) degrees of primary accidental hypothermia is approximately 20%,[113,114] moderate levels of hypothermia in trauma and critically ill patients are associated with a much higher mortality rate. Rutherford et al. reported that 9.4% of surgical intensive care unit patients had a core body temperature less than 35°C; the mortality rate of the hypothermic trauma patients was 53%.[153] In fact, compared with other patient populations, the mortality rate associated with hypothermia in the trauma victim is so high that the definition of mild, moderate, and severe hypothermia in the trauma patient warrants special classification (**Table 33.7**).[149] These data have resulted in the standard incorporation of aggressive techniques to prevent the occurrence of hypothermia in trauma patient beginning with field transport with warm blankets and heated IV fluids to routine use of body and fluid rewarmers in emergency departments and operating rooms. Hypothermia is simply not acceptable in any trauma patient, and if it occurs, should prompt a quality of care review.

Table 33.7 Zones of Severity for Hypothermia

Zone	Temperature
Mild hypothermia	36°–34°C (<96.8°–93.2°F)
Moderate hypothermia	34°–32°C (<93.2°–89.6°F)
Severe hypothermia	<32°C (<89.6°F)

Hypothermia appears to occur primarily in victims of relatively severe trauma. Little and Stoner, while reporting on a heterogeneous group of 82 trauma patients, observed that hypothermia occurred only in those patients with an ISS greater than 12.[154] Hypothermia did not occur in less severely injured patients, and shivering, which should be expected, was noted in only one of the hypothermic patients. Mild degrees of injury have, in fact, been associated with small elevations in core body temperature, particularly when the shivering response mechanism has not been abated.[149,155] The recognition

that hypothermia can be prevented has resulted in substantial changes in the management of the acute injured patient. As a result, the "lethal triad" of coagulopathy, acidosis, and hypothermia is much less frequently observed.[156]

The detrimental effect of hypothermia in the human trauma victim is contrasted by a large body of experimental evidence in animals suggesting that hypothermia has a protective role in shock. This extensive body of literature is reviewed elsewhere,[149] but in general, animals subjected to combined hypothermia and shock (hemorrhage, burn, and blunt trauma) usually survive longer than similarly injured but actively warmed animals. Blalock and Mason (1941) were among the first in modern times to recognize the ability of hypothermia to prolong survival times after shock,[157] but they emphasized that the overall survival rate was unchanged, an observation reaffirmed in 2003.[158] However, increases in both survival times and survival rates have been shown in a number of animal models of induced hypothermia after hemorrhagic shock.[159,160] The protective effects of hypothermia in preventing ischemia–reperfusion injury have been described in a number of models, including muscle, intestine, and rabbit ear.[161–163] These observations have prompted some to suggest that there is a role for iatrogenic-induced hypothermia in severe trauma patients, with the goal being a reduction of oxygen consumption in the setting of limited oxygen delivery (hypovolemic shock) to allow surgeons time to repair injured structures and then rewarm and resuscitate the patients.[164–166]

Hypothermia has also been utilized in attempts to protect the traumatically injured brain. The use of therapeutic hypothermia in a patient with traumatic brain injury was first reported in 1943[167] and sporadically over the ensuing two decades. In 2001, Clifton et al. reported a randomized, multicenter, controlled trial of core body hypothermia in trauma patients with severe closed head injury.[168] Select trauma patients (GCS 3 to 7) were intentionally cooled within 6 hours of injury to 32° to 33°C for 48 hours after injury and then rewarmed. The outcome was poor (defined as severe disability, a vegetative state, or death) in 57% of the patients in both groups. Mortality was 28% in the hypothermia group and 27% in the normothermia group (p = 0.79). The patients in the hypothermia group had more hospital days with complications than the patients in the normothermia group. This study has led most authorities to conclude that treatment with total-body hypothermia is not effective in improving outcomes in patients with severe brain injury. Other

authors have also reported higher rates of pneumonia and diabetes insipidus in patients with severe head injury and induced hypothermia.[169] Evidence further supporting the harmful effect of hypothermia in the trauma patient is provided by a prospective, randomized trial of rapid rewarming versus conventional rewarming of 57 multiple-trauma patients.[169] In this study, trauma patients who were rapidly rewarmed with continuous arteriovenous rewarming (CAVR) from less than 34.5°C to greater than 36°C required less resuscitation fluid volume and had a lower early mortality rate than those rewarmed more slowly. Failure to rewarm in either group was uniformly fatal. The survival rate at 3 days after injury was 82% in the rapid rewarm group versus 62% in conventionally managed patients. Approximately 50% of the patients in both groups had a severe head injury, defined as a head-abbreviated ISS of 3 or greater. In this well-controlled study, maintenance of hypothermia not only failed to confer an advantage but also was detrimental to early survival.

The use of hypothermia in the treatment of acute cardiac arrest is beyond the scope of this chapter. However, the principle of this common technique is the same as the principle of organ preservation for transplantation—cooling of the body decreased oxygen consumption and may allow for a longer period of relative anoxia with good recovery.[170–172] The advantage in these patients, or rather the difference between the acute arrhythmia patient and the patient with trauma is likely the total-body tissue injury and its effect in coagulation and the inflammatory response. But the attraction for the concept of "suspended animation" with induced hypothermia in trauma remains seductive.[166,173]

The role of hypothermia in the injured patient remains complex. It is apparent that the physiologic consequence of severe trauma is a drop in core body temperature, either as a protective response to shock or the result of diminished heat production caused by failing metabolism. The frequent presence of lactic acid accumulation in cold, seriously injured patients supports the latter hypothesis. The above-cited clinical studies indicate that even mild hypothermia in the trauma patient is predictive of a poor outcome, given our current capabilities of surgical repair of injured organs. Hypothermia does diminish metabolic demands and oxygen consumption, but the price appears to be malfunction of enzymes and physiologic systems necessary to recover from injury.

The systems most affected by hypothermia in victims of injury are those involved in clotting. Focused attention on the coagulation mechanisms in trauma patients over the past decade has exposed the lack of a comprehensive understanding of the complex relationship between injury, inflammation, and coagulopathy.[174] Temperature is yet another variable in this complexity. Reports of coagulation abnormalities in patients with apparently normal clotting factor levels surfaced shortly after the introduction of hypothermic cardioplegia for cardiac surgery.[175,176] Although hemodilution with volume expanders deficient in clotting factors and platelets is a cause of nonsurgical bleeding, cold platelets are known to undergo morphologic changes that affect adherence, including loss of shape, cytoplasmic swelling, and dissolution of cytoplasmic microtubules necessary for normal motility.[177] Platelet activation is also associated with activation of cell membrane phospholipases that hydrolyze phospholipids to arachidonic acid, a precursor to prostaglandin endoperoxides and thromboxane A2, a potent vasoconstrictor necessary for normal platelet aggregation.[178] Valeri et al. induced systemic hypothermia to 32°C in baboons, but kept one forearm warm using heating lamps and a warming blanket.[179] Simultaneous bleeding time measurements in the warm and cold arm were 2.4 and 5.8 minutes, respectively. This effect, which was reversible with rewarming, appeared to be mediated by cold-induced slowing of the enzymatic reaction rate of thromboxane synthetase, which resulted in decreased production of thromboxane A2. Bleeding observed at mildly reduced temperatures (33° to 37°C) results primarily from a platelet adhesion defect and not reduced enzyme activity or platelet activation; however, at temperatures below 33°C, both reduced platelet function and enzyme activity likely contribute to the coagulopathy,[180] perhaps helping to explain why 32°C is such a critical temperature in the coagulopathic injured patient.

As with blood gases, clinical tests of coagulation are temperature standardized to 37°C. Fibrometers contain a thermal block that heats the plasma and reagents to 37°C before initiating the assay. Thus, tests of coagulation reflect clotting factor deficiencies but are corrected for any potential effect of hypothermia on clotting factor function. A detailed study of the kinetic effects of hypothermia on clotting factor function has been undertaken by Reed et al.[181] He performed clotting tests (PT, PTT, and

thrombin time) on reference human plasma–containing normal clotting factor levels at temperatures ranging from 25° to 37°C. The results showed a significant slowing of all coagulation tests at temperatures below 35°C that was proportional to the degree of hypothermia. The prolongation of clot formation occurred at clinically relevant levels of hypothermia and was equivalent to that seen in normothermic patients with significant clotting factor depletion. For example, assays conducted at 35°, 33°, and 31°C prolonged the PTT to the same extent as would occur in a euthermic patient with reductions in factor IX levels to 66%, 32%, and 7% of normal, respectively.

Clotting factor supplementation is not the answer to a hypothermia-induced coagulopathy; rewarming is. However, in many seriously injured patients, clotting factor depletion exists in conjunction with hypothermia. A potentiating effect of hypothermia on coagulation dysfunction occurs in plasma of patients with deficient clotting factor levels, although there does not appear to be synergy between the two conditions.[182] Hypothermic, coagulopathic trauma patients still benefit from coagulation profile testing. If prolongation of PT and PTT is evident in plasma warmed to 37°C, clotting factor replacement is indicated. If PT and PTT are near normal, rewarming alone reverses the clinically apparent coagulopathy.

8 Treatment

Rewarming techniques are usually classified as passive external rewarming, active external rewarming, or active core rewarming.[183] Passive external rewarming simply implies allowing spontaneous rewarming to occur with the patient removed from a hypothermic environment and is usually used only for the mildly hypothermic patient. Active external rewarming techniques include surrounding the patient with warm blankets or heating pads, infrared heating lights, and immersion in warm water. Active core rewarming includes heated intravenous fluids, as well as heated peritoneal or thoracic lavage; heated gastric, bladder, or colonic lavage; heated and water-saturated inhaled air; and extracorporeal circulatory rewarming. Blood rewarming is currently limited to a maximum temperature of 42°C by the American Association of Blood Banks, but rewarming to 49°C with inline

microwave blood rewarmers has been reported as safe, as has intravenous fluid rewarming to 65°C.[184,185]

The advantages and disadvantages of each technique are regularly debated, particularly regarding the role of external versus core rewarming. It is clear, however, that the rate of heat transfer to the hypothermic patient is greatest using active core rewarming, particularly extracorporeal circulation rewarming. This may be a critical factor in surgical patients for whom rapid restoration of clotting and cardiac function is necessary.

The technique of rewarming the hypothermic victim by extracorporeal circulation has been described by numerous authors, initially based on small personal experiences and using CPB techniques of open-heart surgery.[121–123] This technique has appealed in cases of primary accidental hypothermia, in which maintenance of circulation, correction of hypoxia, and replenishment of intravascular volume may play a role as large as correcting the temperature change itself. The need for systemic anticoagulation has, however, generally limited the usefulness of full CPB rewarming in the trauma patient. More recently the use of ECMO for core hypothermia rewarming has been the subject of numerous publications as more centers become more experienced with this tool.[133,186,187]

A technique of extracorporeal active core rewarming that makes use of the patient's own blood pressure to drive an extracorporeal circuit through an efficient, but small countercurrent heat-exchange device was developed by Gentilello et al., and termed CAVR.[188] Systemic anticoagulation is not necessary as the tubing is heparin bonded and trauma patients are relatively anticoagulated. The ease of use made this device applicable in rewarming severely hypothermic patients not in shock and, in a prospective, randomized trial of rewarming trauma patients, demonstrated its efficacy by improved survival.[169] Unfortunately, the device used in that referenced study by Gentilello et al. is no longer in commercial production.

Direct intracirculation rewarming can be accomplished with commercially available devices that employ either a vena caval countercurrent heat-exchange device (InnerCool RTx®, Philips Healthcare, Best, the Netherlands or Thermogard XP® Temperature Management System, Zoll Medical Corp., Chelmsford, MA) or balloon catheters with large surface areas (Alsius/Zoll Medical Irvine, CA). The ownership and design of these devices changes rapidly, as the clinical need is limited. Although initially developed to cool

patients for neurosurgical procedures, they are now used primarily for inducing and maintaining hypothermia following sudden cardiac arrest; rewarming can be accomplished by simply changing the temperature of the closed loop circulating fluid. Requirements are the commercial bedside console and the specialized endovascular temperature control catheter, inserted via the femoral vein to the vena cava, usually with a larger size introducer (10 to 12 Fr). Data on rewarming cold patients suggest that rewarming can occur up to 3°C/hr compared to 6° to 9°C/hr with ECMO or CPB.[114,189]

The use of body cavity lavage with warm solutions is a simple, less invasive method of accomplishing active core rewarming; however, rewarming rates with body cavity lavage vary greatly based on initial core temperature, dialysate temperature, infusion rate, and dwell time. Several studies support the notion that active core rewarming by peritoneal lavage is preferable to active external rewarming.[146] Moss examined three techniques of rewarming hypothermic and cardiac-arrested dogs, concluding that both peritoneal lavage (55°C dialysate) and partial extracorporeal circulation were faster than active external rewarming with a heating blanket.[190] A frequently stated disadvantage of external rewarming is that the peripheral tissues are rewarmed in advance of the still cool "core," resulting in peripheral vasodilatation leading to shock. In the presence of inadequate volume resuscitation, this rewarming method may result in vascular collapse ("rewarming shock") and a subsequent fall in central temperature ("afterdrop") as the cold peripheral blood returns to the core.[191] Whether or not this process is the mechanism of the core afterdrop is debatable because continued cooling of a patient's core temperature during the initial states of rewarming has been noted to occur in animal models even during complete circulatory arrest. Volume contraction caused by vasoconstriction, cold diuresis, and cellular swelling coupled with inadequate fluid resuscitation may be a more appropriate explanation for circulatory collapse during rewarming.

The thermodynamic principles of heat transfer to the hypothermic patient are reviewed in greater detail elsewhere,[183,192] but a sense of rewarming rates and quantity of heat transferred by various techniques is instructional. Ventilating a patient with a core temperature of 32°C with water-saturated air at 41°C results in a maximum heat transfer rate of 9 kcal/hr. For comparison,

basal metabolic heat generation produces approximately 70 kcal/hr, and shivering produces up to 250 kcal/hr. Given the specific heat of the body (0.083 kcal/kg/°C), 58 kcal is required to raise the temperature of a 70-kg patient by 1°C. Thus, more than 6 hours would be required to warm a 32°C patient using 41°C humidified inspired air.

Heat transfer rates using body cavity lavage can be similarly calculated based on the specific heat of water (1 kcal/kg/°C). If 1 L of 44°C water infused into a body cavity dwells long enough to exit at 40°C, 4 kcal of heat will have been transferred to the patient. Thus, over 14 L of fluid is needed to increase core temperature by 1°C. However, warming becomes less efficient as the patient rewarms because a longer dwell time is required to reduce the temperature of the infusate to 40°C.

Warming by CPB or ECMO or CAVR is the most efficient method of core heating. With flow rates of 15 to 30 L/hr, it is possible to deliver 120 to 240 kcal/hr if the reinfused blood is heated to 40°C, a rate of heat transfer over 10 times that of the other methods. In any case, the urgency with which rewarming must be accomplished depends on how adversely the hypothermia is affecting the patient. With the exception of extracorporeal circulatory methods, most rewarming techniques serve primarily to prevent loss of endogenously generated heat and are ineffective in circumstances in which rapid rewarming is indicated. Early and direct attention to preventing heat loss is therefore essential in surgical patients. With more widespread adoption of ECMO capabilities for treating severe lung disease, centers are starting to report on the use of this modality as a rewarming technique. The combination of injury and hypothermia represents a particular challenge. Swiss physicians with experience in treating injured and hypothermia avalanche victims have developed the Bernese Hypothermia Algorithm, a detailed approach to rewarming techniques and injury care priorities in this population.[193,194]

Cold Injury and Frostbite

Frostbite is a cold injury limited to digits, extremities, or exposed surfaces that is the result of direct tissue freezing. Chilblain (aka pernio) and trench foot are the result of more chronic exposure to an environment just above freezing. Both types of cold injury have been a major cause of morbidity

during war experiences. They resulted in more than seven million lost soldier fighting days by Allied forces in World War II and were reportedly the most common major injury sustained by British soldiers in the Falklands expedition.[140] Upton Sinclair's novel *The Jungle* used the cold exposure of Chicago's meatpacking industry in the early 20th century to depict the pain of frostbite and chilblains and deplored the working conditions and exploitation of immigrants.[195,196]

The terms *chilblain* and *pernio* describe a form of local cold injury characterized by pruritic, red-purple papules, macules, plaques, or nodules on the skin. Chilblains can result in a specific form of a dermopathy secondary to cold-induced skin vasculitis. The lesions are often associated with edema or blistering and are caused by a chronic vasculitis of the dermis[197]; this entity does not appear to be related to hereditary protein C or S deficiency.[198] This pathologic process is provoked by repeated exposure to cold, but not freezing, temperatures. This injury typically occurs on the face, the anterior surface of the tibia, or the dorsum of the hands and feet, areas poorly protected or chronically exposed to the environment. With continued exposure, ulcerative or hemorrhagic lesions may appear and progress to scarring, fibrosis, and atrophy. Treatment consists of sheltering the patient, elevating the affected part on sheepskin, and allowing gradual rewarming at room temperature. Rubbing and massage are contraindicated because they can cause further damage and secondary infection. Chronic treatment strategies are similar to frostbite injuries, with similar limited success (see final paragraph).

Trench foot or cold immersion foot (or hand) describes a nonfreezing injury of the hands or feet, typically in sailors, fishermen, or soldiers, that is caused by chronic exposure to wet conditions and temperatures just above freezing.[199] It appears to involve an alternating arterial vasospasm and vasodilatation, with the affected tissue first cold and anesthetic and then hyperemic after 24 to 48 hours of exposure. With the hyperemia comes an intense, painful burning and dysesthesia; tissue damage is characterized by edema, blistering, redness, ecchymosis, and ulceration. Complications of local infection or cellulitis, lymphangitis, and gangrene may occur. A posthyperemic phase occurs 2 to 6 weeks later and is characterized by tissue cyanosis with increased sensitivity to cold. Treatment is best started during or before the reactive hyperemia state and consists of immediate removal of

the extremity from the cold, wet environment with exposure of the feet (or hands) to warm, dry air. Elevation to minimize edema, protection of pressure spots, and local and systemic measures to combat infection are indicated. Massage, soaking of the feet, or rapid rewarming is not indicated. Demyelination of nerves, muscle atrophy, fallen arches, and osteoporosis may all present long-term complications, and a tendency toward marked vasospasm during subsequent exposure to cold develops in some patients.[200]

Frostnip is the mildest form of cold injury. It is characterized by initial pain and pallor, with subsequent numbness of the affected body part. Skiers and other winter outdoor enthusiasts are most likely to experience this cold injury to the nose, ears, or tips of digits. The injury is reversible and warming of the cold tissue results in return of sensation and function with no tissue loss.

Frostbite is a more severe and common form of cold injury that can result in debilitating long-term irreversible morbidity.[201] [9] Frostbite damage is caused by direct ice crystal formation at the cellular level with cellular dehydration and microvascular occlusion. Indirect cellular injury, also referred to as progressive dermal ischemia, is a progressive microvascular insult. Following thawing, microvascular thrombosis, endothelial damage, intravascular sludging and reperfusion injury all occur, resulting in continued cell injury and death. Current treatment modalities have focused on minimizing the indirect cellular or reperfusion injury as discussed below.

Frostbite is traditionally classified into four grades of injury severity (**Table 33.8**). The affected body part nearly always initially appears hard, cold, white, and anesthetic, regardless of the depth of injury. Because the appearance of the lesion changes frequently during the course of treatment and because the initial treatment regimen is applicable for all degrees of insult, some authorities suggest discarding this classification as a prognostic impossibility and simply classifying frostbite as either superficial or deep.[202]

Table 33.8 Classification of Frostbite

Degree	Description of Frostbite
First	Tissue freezing with hyperemia and edema but without blistering
Second	Tissue freezing with hyperemia, edema, and characteristic large, clear blisters
Third	Tissue freezing with death of subcutaneous tissues and skin, resulting in hemorrhagic vesicles that are in general smaller than second-degree blisters
Fourth	Tissue necrosis, gangrene, and eventual full-thickness tissue loss

Weather conditions, altitude, degree of protective clothing, duration of exposure, and degree of tissue wetness are all contributing external factors to the development of frostbite injury. Because sensory nerve activity is abolished at 7° to 9°C, the disappearance of pain is an early warning sign of cold injury. Acclimation to cold may be protective, whereas a previous history of frostbite probably predisposes to another cold tissue injury. Smoking and a history of arterial disease also are contributing factors. In urban environments, more than 50% of frostbite injuries are alcohol related and in one report, 16% of these patients also had a significant underlying psychiatric illness.[203]

As noted, frostbite injury has two components—the initial freeze injury and a reperfusion injury that occurs during rewarming. The initial response to tissue cooling is vasoconstriction and arteriovenous shunting, intermittently relieved (every 5 to 7 minutes) by vasodilatation, the so-called hunting response.[204] With prolonged exposure, this response fails, and the temperature of the freezing tissue approximates ambient temperature until −2°C. At this point, extracellular ice crystals form, and as these crystals enlarge, the osmotic pressure of the interstitium increases resulting in

movement of intracellular water out of cells and into the interstitium. Cells begin to shrink and become hyperosmolar, disrupting cellular enzyme function. If freezing is rapid (>10°C/min), intracellular ice crystal formation will occur, resulting in immediate cell death.[205] In addition, endothelial cell disruption and red cell sludging associated with freezing result in cessation of circulation.

During rewarming, red cell, platelet, and leukocyte aggregation occurs and results in patchy thrombosis of the microcirculation. These accumulated blood elements are thought to release, among other products, the toxic oxygen-free radicals and the arachidonic acid metabolites $PGF_2\alpha$ and thromboxane A2, which further aggravate vasoconstriction and platelet and leukocyte aggregation.[206,207] However, the exact mechanism of tissue destruction and death after freeze injury remains poorly defined. Animal studies suggest that vascular injury in the form of endothelial cell damage and subsequent interstitial edema, but not vessel thrombosis, predominate as initial events in rewarming injury.[208] A substantial component of severe cold injury may be neutrophil mediated, as suggested by the observation that a monoclonal antibody to neutrophil–endothelial and neutrophil–neutrophil adherence can markedly ameliorate the pathologic process of a severe cold injury.[209] In this rabbit model, animals treated with anti-CD11/CD18 adhesion molecule after cold injury (30 minutes at −15°C) but before rewarming (39°C water bath) had significantly less tissue loss and edema. The implication of these observations is that much of the injury of severe frostbite occurs during rewarming or reperfusion, although the efficacy of intra-arterial thrombolytic therapy suggests that endovascular clotting does occur and can be reversed.[210–213]

Treatment

Prehospital or field care of the victim of cold injury should focus on removing the patient from the hostile environment and protecting the injured body part from further damage. Rubbing or exercising the affected tissue does not augment blood flow and risks further cold injury or mechanical trauma. Because repeated bouts of freezing and thawing worsen the injury, it is preferable for the patient with frostbite of the hands or feet immediately to

seek definitive shelter and care rather than rewarm the tissue in the field and risk refreezing. Although the initial symptoms may be mild and overlooked by the patient, severe pain, burning, edema, and even necrosis and gangrene may appear with rewarming. With severe injury the range of motion progressively decreases, and edema becomes prominent. The injury may progress to numbness and, eventually, to loss of all sensation in the affected tissue.

The emergency room treatment of a frostbite victim should first focus on the basic ABCs (airway, breathing, and circulation) of trauma resuscitation and then systemic hypothermia should be identified and corrected. Most patients are dehydrated, and resuscitation with warm fluids is an important part of early management. Fractures are often accompanied by frostbite in mountaineers, and although manipulation may be required to treat vascular compromise, open reduction is hazardous, and application of traction should be delayed until after postthawing edema has been assessed.

Rapid rewarming is the goal. Gradual, spontaneous rewarming is inadequate, particularly for deeper injuries, and rubbing the injured part in ice or snow often delays warming and 9 results in marked tissue loss.[214] Rapid rewarming should be achieved by immersing the tissue in a large water bath of 40° to 42°C (104° to 108°F). The water should feel warm, but not hot, to the normal hand. The bath should be large enough to prevent rapid loss of heat, and the water temperature should be maintained. Dry heat is not advocated because it is difficult to regulate, and the result of using excessive heat is often disastrous. The rewarming process should take approximately 30 to 45 minutes for digits, with the affected area appearing flushed when rewarming is complete and good circulation has been reestablished. Narcotics are required because the rewarming process can be quite painful.

The skin should be gently but meticulously cleansed and air-dried and the affected area elevated to minimize edema. A tetanus toxoid booster should be administered as indicated by immunization history. Sterile cotton is placed between toes or fingers to prevent skin maceration and extreme care taken to prevent infection and avoid even the slightest abrasion. The affected tissue should be protected by a tent or cradle, and pressure spots must be prevented. In one review, infection developed in 13% of urban frostbite victims, but one-half of these infections were present at the time of admission.[203] Most clinicians reserve antibiotics for identified infections.[215]

After rewarming, the treatment goals are to prevent further injury while awaiting the demarcation of irreversible tissue destruction. All patients should be hospitalized, and affected tissue gently cleansed once or twice a day in warm (38°C) whirlpool baths, with some clinicians adding an antiseptic such as chlorhexidine or an iodophor to the bath. Based on the findings of arachidonic acid metabolites in the blisters of frostbite victims, some authors advocate the use of topical aloe vera (thromboxane inhibitor) and systemic ibuprofen or aspirin. Heggers et al.'s report in a nonrandomized trial in which 56 patients treated with these agents, plus prophylactic penicillin, had less tissue loss, a lower amputation rate, and a shorter hospital stay than 98 patients treated with warm saline, silver sulfadiazine, or sulfamylon dressings.[216] Another report on frostbite treatment in rabbits demonstrated improved tissue viability when systemic pentoxifylline and topical aloe vera cream were used.[217] Uninfected blebs should be left intact because they provide a sterile biologic dressing for 7 to 10 days and protect underlying epithelialization. After resolution of edema, digits should be exercised during the whirlpool bath and physical therapy begun. Tobacco, nicotine, and other vasoconstrictive agents must be withheld. Weight bearing is prohibited until complete resolution of edema.

Numerous adjuvants have been tried to restore blood supply to frostbitten areas. The intense vasoconstrictive effect of cold injury has focused attention on increased sympathetic tone. Sympathetic blockade and even surgical sympathectomy continues to be advocated by some based on the theory that it releases the vasospasm that precipitates thrombosis in the affected tissue.[218,219] This method of treatment has produced inconsistent results and is difficult to evaluate clinically, with no prospective, randomized trials available. Although sympathectomy appears to mollify the pain and hyperhidrosis and vasospasm of cold injuries, it may increase vascular shunting and adversely affect healing. In one series, a more proximal demarcation of injury in sympathectomized limbs was noted than in nonsympathectomized ones, despite apparently equal bilateral injury.[214]

Experience with intra-arterial vasodilatory drugs, such as reserpine, tolazoline, and papaverine, has also been unrewarding. Bouwman et al. demonstrated in a controlled clinical study that immediate (mean 3 hours) ipsilateral intra-arterial reserpine infusion coupled with early (mean 3 days) ipsilateral operative sympathectomy failed to alter the natural history of

acute frostbite injury compared with the contralateral limb.[219] Iloprost (Ventavis®, Ilomedine®), a vasodilator used to treat Raynaud phenomenon and a synthetic analog of prostacyclin PGI2 has also been used in an effort to vasodilate microvascular arcades.[211] Low–molecular-weight dextran has been shown to alleviate postthawing circulatory obstruction as late as 2 hours after thawing and markedly reduced tissue loss in rabbit feet,[220] but similar results in humans have not been demonstrated. Heparin, thrombolytic agents, and hyperbaric oxygen have also failed to demonstrate any substantial treatment benefit, but hyperbaric enthusiasts continue to tout its role.[221] None of these adjuncts is considered routine care.

10 The most recent adjunct to the management of frostbite is the intra-arterial infusion of tissue plasminogen activator (tPA). In a nonrandomized study of a small number (n = 7) of patients who received intra-arterial tPA, the burn team at the University of Utah demonstrated that tPA infusion improved tissue perfusion and reduced amputations (10% vs. 41%) when administered within 24 hours of injury (6 of the 7), as compared with 25 patients managed in a more traditional fashion.[210] Since this 2007 report, isolated case reports have also suggested that this therapy is effective.[213,222] What is termed the "Helsinki frostbite protocol" involves the use of intra-arterial fibrinolytics (tPA) and/or intravenous vasodilator iloprost.[223] Candidates for this therapy should have minimal risk of bleeding from other injuries, have the tPA administered (intra-arterial or intravenously) within 24 hours of frostbite, with no episodes of rewarming or refreezing between injury and treatment, and have clear evidence of full-thickness tissue involvement, as well as abnormal perfusion on either angiogram or pyrophosphate scanning (**Fig. 33.22**, Table 33.9). In one study, 20 patients with frostbite were diagnosed between 2013 and 2016.[223] Nine patients underwent fibrinolytic treatment with tPA and/or iloprost. The overall digital salvage rate was 74.8%. However, as of January 2020 the American Burn Association guidelines stated that the data are insufficient to support routine treatment of all patients with frostbite with thrombolytics,[224] but do allow that patients with cyanosis persisting proximal to the distal phalanx (grade 3 or 4 frostbite injury) and demonstrated loss of perfusion at or proximal to the middle phalanx immediately after rewarming can be treated with thrombolytic therapy in accordance with local hospital protocols. The guidelines also support the concept that time to treatment is an important

quality metric in the treatment of frostbite. The work from Hennepin County Burn Center supports the notion that "time is tissue" similar to that of the treatment of ischemic stroke or myocardial infarction.[225]

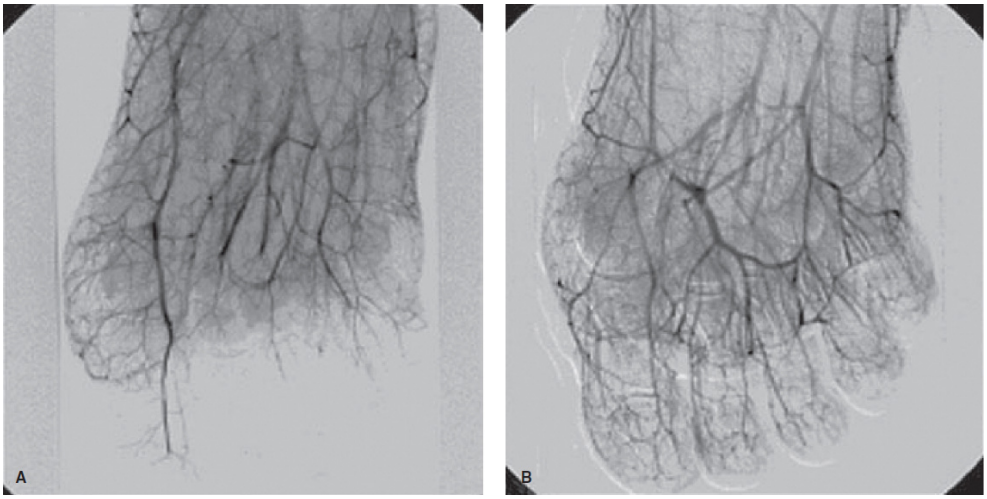

Figure 33.22 Digital angiography of a 19-year-old woman who sustained bilateral lower extremity frostbite following vehicle breakdown. **A:** The image demonstrates poor distal perfusion to the left toes. **B:** Following administration of tissue plasminogen activator via bilateral femoral catheters, angiography demonstrates return of perfusion. All 10 of her toes were saved. (Reproduced with permission from Bruen KJ, Ballard JR, Morris SE, et al. Reduction of the incidence of amputation in frostbite injury with thrombolytic therapy. *Arch Surg* 2007;142:546–553.)

Table 33.9 Amputation Outcomes of Patients Treated with Tissue Plasminogen Activator (tPA) Compared with All Other Patients by Frostbite

Agent	No. of Patients	No. of Involved Extremities	Extremities Requiring Amputation, No. (%)			No. of Digits Amputated/Total Digits Involved (%)
			None	Proximal	Digits only	
No agent[a]	26	57	25 (45)	14 (25)	18 (29)	97/234 (41)
tPA administration, <24 hrs	6	13	10 (77)	0	3 (23)	6/59 (10)[b]
Total	32	70	35 (50)	14 (20)	21 (30)	103/293 (35)

[a]Includes one patient who received tPA starting 48 hrs after exposure.

The difficulty in determining the depth of tissue destruction in cold injury has led to a conservative approach to the care of frostbite injuries.[215,226] For

digit frostbite, the Hennepin score may provide a useful way to track progress and compare experimental therapies.[227] As a general rule, amputation and surgical debridement are delayed for 2 to 3 months unless infection with sepsis intervenes, hence the adage: "frostbite in January, amputate in June." The natural history of a full-thickness frostbite injury is the gradual demarcation of the injured area with dry gangrene or mummification clearly delineating nonviable tissue. Often the permanent tissue loss is much less than originally suspected. In an Alaskan series, only 10.5% of patients required amputation, usually involving only phalanges or portions of phalanges.[199] The need for emergency surgery is unusual, but vigilance should be maintained during the rewarming phase for the development of a compartment syndrome requiring fasciotomy. Open amputations are indicated in patients with persistent infection and sepsis that is refractory to debridement and antibiotics. Mills convincingly demonstrated that of all the factors in the treatment of frostbite that may influence outcome, premature surgical intervention by any means, in any amount, was by far the greatest contributor to poor results.[228]

The use of technetium-99m methylene diphosphonate bone scanning has shown some promise in the early detection of eventual bone and soft tissue viability[229] as has the use of magnetic resonance imaging.[230,231] Technetium-99m "triple-phase" scanning (at 1 minute, 2 hours, and 7 hours) performed beginning 48 hours after admission has been used to assess early tissue perfusion and viability, in an attempt to define the extent of fatally damaged tissues and to allow for early debridement and wound closure.[232,233] The utility of this diagnostic modality continues to evolve, however, with one recent study suggesting that the moderate to severe frostbite lesion identified by technetium-99m scans can be "hibernating" (viable) tissue, which can show improvement up to 6 months following injury.[216,234] A nice review of all imaging studies and their role in the evaluation of frostbite injuries as of 2016 is provided by Millet et al.[235]

Frostbitten tissues seldom recover completely. Some degree of cold insensitivity invariably remains. Hyperhidrosis (in up to 72% of patients), neuropathy, decreased nail and hair growth, and a persistent Raynaud phenomenon in the affected part are frequent sequelae to cold injury.[212,234,236] The affected tissue remains at risk for reinjury and should be carefully protected during any cold exposure. Treatment with antiadrenergic agents

(prazosin hydrochloride, 1 to 2 mg/d) or calcium channel blockers (nifedipine, 30 to 60 mg/d) and careful protection from further exposure is often helpful.[197,234] However, few therapies afford significant relief to the chronic symptoms after tissue freeze injury, although β- and α-adrenergic blocking agents, calcium channel blockers, topical and systemic steroids, and a host of home remedies have been tried with occasional individual success.

Section B: TRANSPLANTATION

34

Clinical Transplant Immunology

Seth A. Waits, Amit K. Mathur, and Satish N. Nadig

Key Points

1. Understanding clinical transplant immunology is predicated on understanding mechanisms of innate and adaptive immunity, as well as T- and B-cell signal pathways.
2. T cells are responsible for regulatory and effector mechanisms in the immune response. T-cell effector activity is coordinated by regulatory cells driven by three signals of antigen presentation.
3. Acute rejection has a clinical phenotype and may involve cellular infiltration of the allograft as well as antibody-mediated mechanisms. Chronic rejection, or chronic transplant dysfunction, is driven by immune and nonimmune mechanisms and results in progressive graft fibrosis that is heretofore irreversible.
4. Clinical immunosuppression involves induction and maintenance therapies.
5. Induction therapies are used to prevent early acute rejection of allografts, and are generally aimed at reducing T-cell signaling. Commonly used drugs are lymphocyte depletion agents, IL-2 receptor antibodies, agents to block costimulatory signals.
6. Maintenance immunosuppression consists of calcineurin inhibitors, mTOR inhibitors, antimetabolite agents, and steroids. All agents have a clinically significant side-effect profile.
7. Major side effects of chronic immunosuppression include calcineurin inhibitor–related nephrotoxicity, major and minor infections, and cancer.

INTRODUCTION

Modern clinical transplantation has continued to evolve rapidly over the past 65 years. Massive advances in surgical technique and biologic science have saved the lives of thousands of patients. The bedrock of success in clinical transplantation is the result of growth in transplant immunology. The discovery era of the immune response to alloantigens and identification of

molecular targets for modern immunosuppressive agents have solidified clinical transplantation as the treatment of choice for patients with organ failure.

1 Understanding transplant immunology requires an in-depth understanding of the molecular mechanisms that lead to acute and chronic rejection. Transplant rejection is the clinical phenotype of organ injury brought on by the recipient immune system's recognition of allogeneity. The aim of this chapter is to review the scientific principles behind the use of modern immunosuppressive agents, the interplay between cell types involved in the alloimmune response, and an in-depth discussion of modern therapeutics. Additionally, the complications of immunosuppressive therapy and evolving therapies will be discussed.

SCIENTIFIC BASIS FOR MODERN CLINICAL IMMUNOSUPPRESSION

The Immune Response to a Solid Organ Transplant

The interaction of a host's immune system with foreign antigen is central to understanding the pathways that modulate organ-directed effector responses. *Operational tolerance* is defined as the immunologic acceptance of an organ allograft while maintaining global immune system integrity; downregulation of host effector mechanisms must be maintained while minimizing the suppression of recipient defense mechanisms. T- and B-cell activation and regulatory pathways are primary targets for conventional immunosuppressive regimens. Immunosuppressive regimens have been developed to impact isolated pathways in T-cell activation by recipient antigen-presenting cells (APCs). As the field of transplantation has matured, these pharmacotherapies have become more specific and less toxic to the host immune system.

The development of mature T cells begins with nascent thymocytes. Thymocytes contain T-cell receptors (TCRs) arranged and rearranged in a random individual-specific manner. These TCR-containing thymocytes are challenged by "self" antigen and undergo programmed cell death if they

express “high affinity” and activate. In contrast, these immature cells are programmed not to proliferate if they express “too low” an affinity. Thymocytes with an intermediate affinity are fostered to survive and differentiate into specific CD4- and CD8-expressing cells which interact with self-restricted major histocompatibility complexes (MHCs) on APCs, such as dendritic cells, in the peripheral blood.

The foundation of the adaptive immune response lies in the presentation of antigen to T cells which takes place via macrophages, B cells, and dendritic cells. Dendritic cells present antigen via their MHC class I or II molecules to $CD8^+$ T cells and $CD4^+$ T cells, respectively. The most common scenario occurs when a T cell interacts with an APC-MHC complex–presenting “self” antigen. In normal (nonautoimmune) circumstances, this is usually a very weak bond and the T cell removes itself from the interaction and begins to recirculate. In the context of infection or transplantation, the APC-MHC complex presents a foreign peptide which the T cells recognize as “nonself” and begin the cascade of activation as well as clonal expansion.

2 T cells are activated by a process that requires three sequential signals. The “three-signal” process of T-cell activation begins with **signal 1** as the TCR interacts with the MHC–foreign peptide complex presented by an APC. T cells become maximally activated only after a threshold number of TCRs have been occupied. Multiple costimulatory–supporting molecules on the periphery of both the APC and T cells travel to the immunologic synapse and begin to interact with each other, comprising **signal 2**. The engagement of TCR by MHC–peptide complexes in combination with the interaction of costimulatory, accessory, and adhesion molecules results in a cascade of signaling pathways. This includes activation of NF-κB and translocation of the nuclear factor of activation and transcription (NFAT) to the nucleus of the T cell which translates and transcribes proteins such as interleukin-2 (IL-2). IL-2, formerly known as T-cell growth factor, then contributes to the clonal expansion of other T-cell populations allowing for cellular expansion to fight against the inciting foreign antigen. IL-2 also engages with CD25 on the T cell itself thereby activating a doublet complex known as the mammalian target of rapamycin, or mTOR. Signaling through mTOR constitutes **signal 3** of activation which affects cell cycling and cytokine production, cellular proliferation, and T-cell differentiation into an effector cell against the

grafted organ. This pathway initiates the slower, more sophisticated, adaptive immune response (**Fig. 34.1**).

Immediately following implantation and reperfusion of an organ allograft, markers of inflammation are upregulated which act as homing signals to effector T cells. These inflammatory mediators also allow for a more efficient uptake of antigen by dendritic cells. Organ-derived dendritic cells are released to the host's secondary lymphoid tissue. Termed "passenger leukocytes," these dendritic cells are primed to present antigen to naive host T cells. These activated $CD4^+$ T cells specialize into subsets of helper T cells each identified by a distinct signature of cytokines. Interferon-γ (IFN)–secreting TH1 cells are central to various cell-mediated rejection responses including acute and chronic or delayed-type hypersensitivity responses. TH2 cells support B-cell production of antibody and secrete cytokines with a suppressive capacity such as IL-4 and IL-10.

Memory T-cell subsets react in a more rapid manner to the graft and incite an accelerated rejection response. Seminal studies investigating memory responses to allografts proved that antigen-experienced memory T-cell subsets can cause graft destruction in the absence of secondary lymphoid tissue. Clinically, these "memory" T cells are generated throughout the life span of a potential recipient due to various infections that the patient may have experienced. Memory T-cell subsets that have been generated by these infections may then react against an organ at the time of transplant if the antigenic response from the organ mimics that of the previous infectious episodes. It is now established that these memory T cells are spared by conventional induction immunosuppression allowing their graft alloreactivity to induce acute rejection responses. Thus, circulating memory responses remain a roadblock to immunologic tolerance.

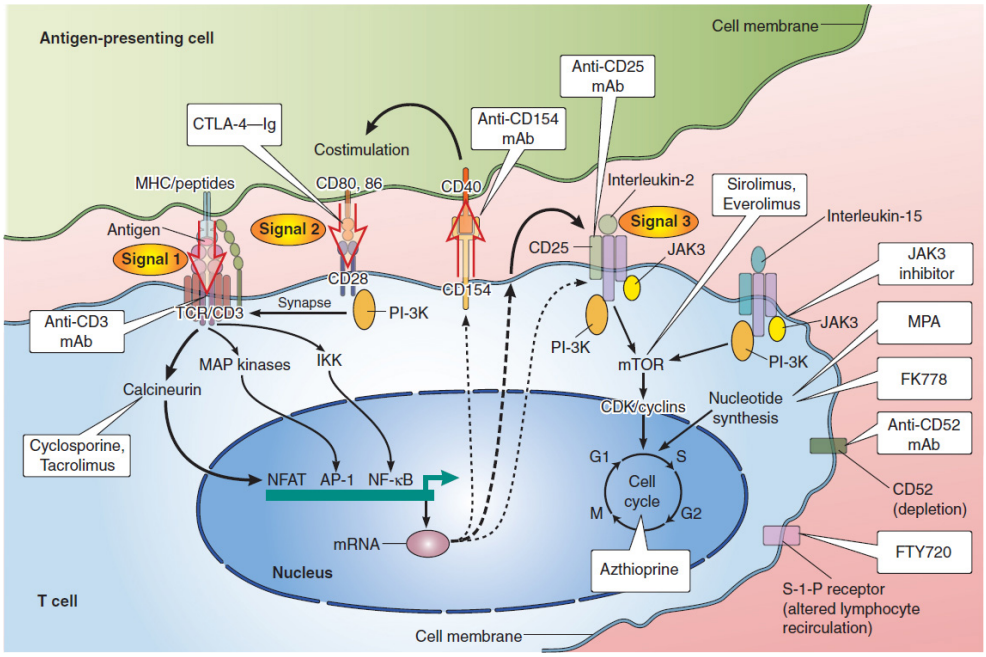

Figure 34.1 The signal hypothesis of T-cell activation and molecular targets of modern clinical immunosuppression. T-cell activation requires three signals to initiate an effector response: antigen presentation of nonself MHC, costimulatory signal, and regulation of cytokine signaling at the cell surface. These three signals are thus targets for therapeutic drugs used in modern clinical immunosuppression in both induction and maintenance phases, as well as in the treatment of rejection. The figure demonstrates the site of action of these agents.

REJECTION IN SOLID ORGAN TRANSPLANTATION

Immunologic rejection can occur minutes to years after an organ transplant. The early phases of rejection, termed hyperacute rejection, can occur on the operating room table to 24 hours after surgery and are mediated by the humoral immune system. Acute rejection is a cell-mediated phenomenon which often manifests days to months after transplant. Chronic rejection occurs in the months to years after transplant and continues to be one of the leading causes of graft loss in the long term. Acute and chronic antibody-mediated rejection (AMR) is a separate phenomenon that may occur days to years after transplant and remains an important barrier to successful engraftment of organs.

Hyperacute Rejection

Hyperacute rejection is rare in modern clinical transplantation. Hyperacute rejection is generally attributed to ABO blood group incompatibility or the presence of preformed anti-HLA antibodies. In the allograft, the capillary endothelium expresses blood group antigens which may join with circulating antibodies to A and B glycoproteins. For example, a blood group B transplant candidate would have circulating anti-A IgG antibodies in blood. If a blood group A kidney allograft were transplanted into that recipient without any other treatment, these antibodies would react with the donor endothelium and activate complement and humoral immunity effector mechanisms, which would lead to endothelial injury, thrombosis, as well as intraparenchymal hemorrhage. This response usually happens within minutes after reperfusion of the allograft and requires removal of the allograft in order to prevent a systemic inflammatory response which may lead to multiorgan failure. Prevention of this type of rejection is central to the practice of clinical transplantation, and mandates confirmation of donor and recipient compatibility via ABO blood group verification and cross-matching prior to implantation of the allograft (**Fig. 34.2**).

Acute Rejection

3 Induction protocols in combination with immunosuppressive therapy successfully prevent the acute rejection episodes. In the case of renal transplantation, induction therapies in combination with maintenance therapies have fostered a significant improvement of 1-year outcomes. Less than 10% of organs experience clinically significant acute cellular rejection (ACR) episodes leading to graft loss at 1 year. ACR is an adaptive response characterized by T-cell interactions with donor antigens either presented directly by the donor APC or indirectly by the recipient professional-presenting cells. Once clonal expansion occurs, “effector” T cells then infiltrate the graft and mediate various methods of organ injury.

The gold standard in pathologic categorization of renal transplant rejection is the Banff classification model. The Banff classification originated at a consensus conference in 1991 aimed at ranking the levels of rejection seen on kidney transplant biopsies based on degree of structural damage, such as

tubulitis, arteritis, and cellular infiltrate. In renal transplantation, the diagnosis of ACR occurs with tissue confirmation after ruling other causes for declining graft function. Treatment of ACR is usually dictated by the Banff classification. For example, borderline rejection characterized by Banff class IA or IB is often treated with pulse corticosteroids and increases in maintenance immunosuppression whereas, more severe ACR is more often treated with multiple doses of thymoglobulin. Today, ACR is often the result of inadequate immunosuppression due to noncompliance/adherence or early immunosuppression withdrawal/underdosing. Repeated episodes of acute rejection are associated with chronic dysfunction and early graft failure.

Chronic Rejection

The clinical sequelae of chronic rejection (chronic transplant dysfunction or CTD) are varied and organ specific. The unifying factor of CTD among all organs transplanted is the histopathologic effect of arterial intimal thickening in the vessels supplying the organ, termed transplant arteriosclerosis or transplant vasculopathy. Both immune and nonimmune stimuli may upregulate pathways leading to progressive graft fibrosis. Immune-dependent mechanisms, including HLA mismatching, inadequate immunosuppression, and episodes of acute rejection, promote the development of CTD and eventual graft failure. Additionally, immune-independent mechanisms, such as prolonged ischemia time and usage of brain-dead donor organs, as well as recipient factors such as native hypertension may also play a role in the onset of CTD.

Clinically, the manifestations of CTD depend on the type of organ allograft. Recipients of renal allografts with CTD often manifest with proteinuria, decreases in glomerular filtration rate (GFR), increases in plasma creatinine, and arterial hypertension. Patients who have undergone liver transplantation may present with abnormal liver function tests or an increase in serum bilirubin secondary to the so-called *vanishing bile duct syndrome*. Bronchiolitis obliterans, detected by computed tomography and altered pulmonary function tests indicate the onset of CTD in lung transplant recipients. Patients receiving cardiac allografts may present with a range of symptoms from arrhythmias to fatal myocardial infarction.

Type of Rejection	Time of Onset	Mechanism	Morphology
Hyperacute	Minutes to few hours	Preformed antibodies bind to graft endothelium	Vessel thrombosis; Ischemic necrosis
Acute Cellular	Days to weeks, months to years	T cells injure graft by direct cytotoxicity and type IV hypersensitivity	Interstitial infiltrates of lymphocytes; Focal necrosis of graft tissue
Acute Humoral (Rejection Vasculitis)	Days to weeks, months to years	Antidonor antibodies against graft antigens	Vasculitis; Intimal thickening; Thrombosis
Chronic	Months to years (Irreversible)	T-cell cytokines stimulate vascular smooth muscle proliferation	Arteriosclerosis; Ischemic atrophy; Interstitial fibrosis

Figure 34.2 Time course, mechanism, and morphology of transplant rejection. Allograft rejection responses have many different phenotypes, which also lead to different therapies. This figure provides a summary of the types of clinically significant rejection episodes, the root cause behind them, and histopathologic features identified on biopsy.

Antibody-Mediated Rejection

AMR can occur in both the acute and chronic phases of transplantation. Increasingly, AMR has been shown to occur in multiple organs including liver and heart. AMR starts with production of donor-specific antibody (DSA) directed to the endothelial lining of organ allografts. DSA–endothelial cell interactions lead to complement activation as well as innate responses resulting in allograft injury. In the chronic setting, persistent DSA leads to microthrombotic events and late graft failure. Diagnostically, along with serum titers of circulating DSA, tissue biopsy reveals deposition of complement split products including C4d and inflammation of capillaries and renal tubules.[1] AMR has also been diagnosed using newer endothelial, cell-specific biomarkers of capillaritis. Liver allografts have shown susceptibility to AMR and DSA in recent studies.

The treatment of acute AMR is based on removal of inciting antibodies. Although there are no high-quality evidence-based treatments for acute AMR, strategies include plasmapheresis, immunoadsorption, use of B-cell toxic

antibodies such as rituximab, newer proteasome inhibitors such as bortezomib, and even splenectomy. In patients with drug-resistant AMR, monoclonal antibodies to complement C5 (eculizumab) have been used off-label with some encouraging results although the extreme expense of the drug has hindered its investigation in randomized control trials.

IMMUNOLOGIC PHARMACOTHERAPY IN SOLID ORGAN TRANSPLANTATION

Induction

Human immunity depends on innate and adaptive responses to foreign antigen. The innate response is rapid and nonspecific when foreign antigen is encountered while the adaptive response develops over time and is focused on recall of foreign antigen. [4] While the innate immune system sets the scene for the adaptive response, it is the specificity of antigens which allows for the activation and proliferation of effector cells to rid the system of the pathogenic insult.[2] Current therapies in clinical immunosuppression target global T-cell activation and proliferation. Induction immunosuppression is used perioperatively as a prophylactic treatment to attenuate acute rejection.

CELL SURFACE RECEPTOR BLOCKADE

In order to interrupt the signal 3 T-cell activation pathway, various pharmacotherapies have targeted signal 2, or costimulation. This effectively targets the clonal proliferation of effector T cells. [5] Costimulation pathways have been targeted by monoclonal antibodies as well as recombinant fusion proteins.

B7/CD28 CTLA4 Blockade

The expression of CD80 (B7.1) and CD86 (B7.2) on the surface of APCs provides T cells with either activation signals, if engaged to CD28, or inhibitory signals, if ligating cytotoxic T-lymphocyte antigen 4 (CTLA4).

CD80 and CD86 interact preferentially with CTLA4 (CD152) when compared to CD28.[3] CTLA4 is also upregulated following the activation process and its ligation results in inhibition of activation thereby controlling clonal expansion. Additionally, CTLA4 is constitutively expressed on regulatory T cells. Blockade of each CD80 and CD86 molecule monotherapy has not led to significant allograft survival in nonhuman primate models. In contrast, blockade of both molecules together did lead to prolonged graft survival but was not able to induce tolerance as rejection occurred once therapy was stopped. An immunoglobulin fusion protein of CTLA4 (abatacept) has been shown to inhibit graft rejection in xenogeneic and allogeneic systems. These promising early results have prompted the development of CTLA4-Ig variants.

LEA29Y (belatacept) is a second-generation molecule, derived as a result of mutating two amino acids of CTLA4-Ig. Belatacept possesses a twofold greater ligation capacity for both CD80 and CD86. The increase in avidity allows for a more complete blockade of the B7 molecules and a 10-fold greater suppression in in vitro assays. Belatacept has shown improved renal function, reduction in chronic allograft nephropathy, decreased calcineurin-related toxicity, and no thromboembolic complications in phase II trials. Phase III trials have evaluated the efficacy and renal protection of belatacept in standard (BENEFIT) and expanded criteria donors (BENEFIT-Ext). There was an increased incidence of posttransplant lymphoproliferative disease in Epstein–Barr virus (EBV)–seronegative patients and acute rejection at 1 year in the belatacept treatment groups compared to calcineurin inhibitors (CNIs). Additional results revealed an improved GFR and lipid profile over a 5-year period.

IL-2 Receptor Blockade

Basiliximab is a chimeric mouse/human IgG1 monoclonal antibody to the α-chain of CD25 (IL-2 receptor) which has proven to reduce acute rejection rates in adult and pediatric renal and pancreas transplant recipients. In clinical trials with 6-month follow-up, basiliximab had a significant impact on acute rejection rates with no increase in infectious complications. Basiliximab can be used as induction therapy for kidney transplant recipients or in liver transplant recipients to spare the nephrotoxic effects of tacrolimus.

Recent studies have cast doubt on the renal protective effects of basiliximab induction and CNI reduction, however long-term follow-up remains to be provided.

LEUKOCYTE DEPLETION

In order to achieve tolerance to an organ transplant, it may be necessary to maximize the potential of engraftment by depleting the alloreactive effector T cells (and B cells in some therapeutic regimens) which mediate a rejection response. Depleting the recipient of leukocytes creates a window of opportunity for an allograft to "settle in" without attack by effector immunocytes.[4] The recipient's transient immunodeficiency is dictated by the strength and duration of depletion. Many investigators have identified the value of monoclonal or polyclonal antibodies designed to bind to peripheral alloreactive lymphocytes. The short-term depletion of leukocytes using antithymocyte globulin, anti-CD3, anti-CD2, anti-CD4, and anti-CD8 has proven successful in terms of long-term graft survival in animal models; these results are further enhanced with thymectomy prior to transplantation in order to prevent posttransplantation peripheral effector cell repopulation.

Polyclonal leukocyte–depleting antibodies, such as thymoglobulin (rabbit antithymocyte globulin [rATG]), are useful as induction agents, and are mainstays of induction therapy in renal transplant recipients. Upon binding various T-cell epitopes, rATG lyses leukocytes using complement-dependent pathways and opsonization leading to mononuclear cell phagocytosis of T cells. rATG also binds to surface receptors on dendritic cells, which impair antigen presentation. Polyclonal antithymocyte globulin is wrought with serious side effects including a predisposition to posttransplant lymphoproliferative disorder and the cytokine release syndrome.

MAINTENANCE IMMUNOSUPPRESSION

Calcineurin Inhibitors

6 One of the greatest medical discoveries of the 20th century was the identification of the CNIs with their effects on T-cell signaling. This class of agents has potent biologic activity and minimal myelosuppressive effects, which were a significant limitation in early clinical transplantation. CNIs, as a class, disrupt regulatory T-cell signaling and lead to a downregulation of IL-2 production, which eventually decreases the activity of cytotoxic T cells. Antigen presentation at the TCR leads to an increase in cytoplasmic calcium levels through a protein kinase and G-protein reaction within regulatory T cells. This calcium binds to calmodulin, a regulatory subunit of the phosphatase calcineurin, prevalent in immunocompetent lymphocytes and nerve cells. Calcineurin is responsible for cleaving the phosphate bound to NFAT (nuclear factor of activated T cells) which in its activated form traverses the T-cell nuclear membrane and promotes transcription of IL-2. Inhibition of calcineurin occurs through the activation of immunophilins, such as cyclophilin and FK-binding protein, which are endogenous cytosolic peptides. The cyclosporine–cyclophilin complex and its counterpart, the FK506-FKBP12 complex, prevent dephosphorylation of NFAT, which in turn leads to reduced IL-2 production and diminished T-cell signal transduction to effector lymphocytes.[5]

Cyclosporine A was the first of these drugs identified, initially found in a soil sample from the fungus *Tolypocladium inflatum.* The clinical efficacy of cyclosporine A was demonstrated in human kidney transplantation, opening the gates to a new era for clinical organ transplantation. Cyclosporine remained the mainstay of clinical immunosuppression for several years and was used across organ types by thousands of patients. In 1984, FK506 (tacrolimus) was identified as another CNI with a similar mechanism of action. FK506 is a macrolide immunosuppressant that was approved by the U.S. Food and Drug Administration for use in liver transplantation. Tacrolimus has become the mainstay of maintenance immunosuppression in solid organ transplant programs due to a gentler side-effect profile and potency of immunosuppression and is used in virtually all solid organ types.

CNIs have a variety of side effects which present challenges in the clinical management of transplant recipients. Common interactions that may boost levels of CNIs occur in patients requiring antifungal therapy, particularly in the azole class, as well as other drugs metabolized by hepatic/intestinal cytochrome P450 3A4 enzyme. The most significant long-term effects include

chronic nephrotoxicity that may precipitate end-stage renal disease, as well as new-onset diabetes mellitus after transplantation. Registry analyses suggest that 7% to 21% of nonrenal transplant recipients are at risk for renal failure, and patients treated with CNIs are at significantly increased risk of requiring dialysis treatment in the months and years after transplant.[6] As implied by the name, calcineurin is also present in nerve tissue as well as lymphocytes. Drug activity in nerve tissue leads to several clinical effects including tremors, seizures, and posterior reversible encephalopathy syndrome. Additional side effects include hyperkalemia, hypercholesterolemia, and gastrointestinal dysfunction including diarrhea. Cyclosporine has also been associated with gingival hyperplasia that is seen less frequently with tacrolimus. Consultation with a transplant pharmacist is integral to the successful management of the posttransplant patient to prevent toxicity and achieve therapeutic immunosuppression goals.

Steroids

Steroids have represented the mainstay of immunosuppressive therapy since the beginning of clinical transplantation. Glucocorticoids are steroids that arise from the zona fasciculata in the adrenal gland. These molecules have a plethora of effects in humans, and their receptors are omnipresent across human cell types. In lymphocytes, glucocorticoids act on cytosolic receptors that in turn lead to a variety of intracellular signals that are responsible for gene transcription, and decrease the expression of several cytokines, including IL-2. Glucocorticoids also reduce the number and function of both T cells and B cells.

Steroid therapy is used in a variety of clinical treatments including maintenance immunosuppression and in high doses as a rescue therapy in patients presenting with acute rejection. There are several side effects to chronic corticosteroid use, which have prompted transplant clinicians and researchers to develop protocols that reduce the need for chronic steroid use. Common side effects include glucose intolerance, weight gain, skin and tissue frailty, osteopenia and osteoporosis, muscle breakdown, neuropsychiatric dysfunction, glaucoma and cataracts, secondary hypercortisolemia, and other effects. Many transplant programs are shifting

toward steroid avoidance in maintenance immunosuppression in low-risk patients.[7]

mTOR Inhibitors

Like CNIs, mTOR inhibitors lead to decreased IL-2 proliferation. The first discovered mTOR inhibitor was sirolimus. Sirolimus (rapamycin) is a bacterial macrolide derived from *Streptomyces hygroscopicus,* found initially in a soil sample from Easter Island (Rapa Nui). Sirolimus binds to FK-binding protein 12, as does tacrolimus. The site of action of the sirolimus–FKBP12 complex is known as the mammalian target of rapamycin, or mTOR. Despite having structural similarity to tacrolimus, sirolimus has limited activity on calcineurin when bound to FKBP12. The complex disrupts signal transduction of the IL-2 receptor and decreases nuclear transcription of molecules active in lymphocyte homing. Sirolimus also has significant antiproliferative properties and inhibits cell cycle activity in lymphocytes and fibroblasts.

Sirolimus has been adopted in a variety of clinical protocols. Sirolimus is currently used primarily in place of CNIs, most commonly in patients who are weeks to months out from the transplant operation. Sirolimus has less nephrotoxicity than CNIs, but has been associated with a higher risk of acute rejection in some studies. In liver transplantation, conversion from tacrolimus to sirolimus in patients with reduced kidney function was associated with more acute rejection episodes but did not have a tangible benefit in terms of kidney function in a randomized control trial. Some have advocated for lower-dose CNIs as maintenance therapy in patients with impaired renal function compared to sirolimus monotherapy, and studies have demonstrated the potential of low-dose CNIs in conjunction with sirolimus for maintenance immunosuppression. Importantly, there is an FDA black box warning against using sirolimus in conjunction with higher-dose CNIs due to higher risk of mortality and graft loss in liver transplantation, as well as an increased risk of hepatic artery thrombosis within the first month after transplant.

Everolimus is another mTOR inhibitor approved for use in kidney and liver transplantation. Everolimus is a hydroxylated derivative of sirolimus, and its preserved structure allows for a similar mechanism of action via

FKBP12 binding and mTORC1 inhibition. In a multicenter prospective clinical trial, patients with reduced-dose tacrolimus and everolimus had improved GFR at 2 years posttransplant compared to patients on standard tacrolimus-based regimens, without any higher risk of biopsy-proved acute rejection or major side effects. This improvement in GFR has also been identified retrospectively in patients converted to everolimus in maintenance immunosuppression.

Sirolimus has been associated with impaired wound healing after transplant, including anastomotic dehiscence in lung transplantation, surgical site infections, and fascial union problems. Surgeons confronted with transplant patients who are on mTOR inhibitors should consult with transplant professionals prior to operative intervention if possible, in order to guide alterations in immunosuppressive therapy to minimize complications. Several other complications have been noted in patients on mTOR inhibitors. Pulmonary toxicity manifested as pneumonitis has been identified, and caution should be taken in administering the drug to patients with pre-existing lung disease. Metabolic complications including hyperlipidemia and new-onset diabetes mellitus after transplant have also been identified as significant side effects. In low- to moderate-risk renal transplant recipients, conversion from tacrolimus to mTOR inhibitors was associated with a higher risk of acute rejection, higher rates of proteinuria, hypercholesterolemia, and anemia.

Antimetabolite Drugs

Antimetabolite drugs in solid organ transplantation comprise a class of agents aimed at suppressing lymphocyte proliferation by 7 reducing the rate of de novo purine synthesis, which prevents effective nucleotide synthesis and DNA transcription. Typically, these drugs are used in combination with CNIs and steroids. One of the first antimetabolite drugs applied in clinical transplantation was azathioprine. While it is effective in reducing T- and B-cell propagation, azathioprine is also a potent suppressive agent of bone marrow, increases the risk of anemia, and is also associated with pancreatitis. A newer antimetabolite, mycophenolic acid (MPA), has emerged as a mainstay in solid organ transplantation. MPA was identified in

a *Penicillium* fungal species and is hepatically metabolized. MPA has less myelosuppressive activity than azathioprine, but side effects are common.

Myelosuppression and leukopenia are common side effects of this class of agents. Mycophenolate is also associated with a significant risk of gastrointestinal dysfunction including diarrhea, nausea, and vomiting. Azathioprine has been recognized as a group 1 carcinogen by the National Toxicology Program in the United States, related to length of use and dosage. Mycophenolate should be avoided in pregnancy or in transplant recipients trying to conceive due to the risk of miscarriage and congenital malformations.

Infections after Transplant

Posttransplant infections are directly related to the level of immunosuppression in the host. In the early period after transplant, when levels of immunosuppression are high and proximal to the use of T-cell–depleting induction agents, the risk of opportunistic infection is highest, and management is focused on antimicrobial prophylaxis. Further from transplant, less immunosuppression is typically required, and prophylaxis is not necessary. However, the prevalence and incidence of infectious diseases in solid organ transplant recipients mandate close monitoring of clinical signs and symptoms, and appropriate diagnostic testing when a clinical suspicion arises of a bacterial, viral, parasitic, or fungal infection. Infections after transplant may consist of donor-derived infections transmitted with the organ, recipient-derived infections due to colonization or other pretransplant exposure, nosocomial infections acquired in the healthcare setting, and community-acquired infections. **Figure 34.3** demonstrates the peak incidence of common opportunistic infections as a function of time after transplant. When faced with a transplant patient with a high clinical suspicion of an infection, transplant providers and infectious disease specialists use this information, clinical history, affected organs and systems, and a battery of cause-oriented diagnostic tests to establish the diagnosis and treatment strategy (see **Fig. 34.3**).

Donor-Derived Infections

Deceased organ donors may be exposed to community-acquired infections prior to death, infectious risk related to lifestyle exposures (i.e., intravenous drug abuse), as well as nosocomial infections acquired during hospital care. Several infectious transmissions have occurred as a result of donor transmission, including human immunodeficiency virus (HIV), West Nile virus, rabies, Chagas disease, and lymphocytic choriomeningitis virus. Careful attention must be paid to the circumstances surrounding the donor's death as well as reported signs and symptoms such as fever and altered mental status. Prior to organ recovery, organ donors are routinely serologically screened for several infectious pathogens, including HIV, hepatitis, cytomegalovirus (CMV), EBV, and syphilis. Routine blood, urine, and sputum cultures may be used in premortem care. Serologic testing consists of antibody testing, which is not 100% sensitive, but the recent inclusion of nucleic acid testing in many centers may help mitigate risk in organ acceptance and aid patient counseling. In the case of CMV, hepatitis, and EBV serologic testing, serologic matching between donors and recipients drives the perception of posttransplant infectious risk and guides antimicrobial prophylaxis decisions and selection of immunosuppression.

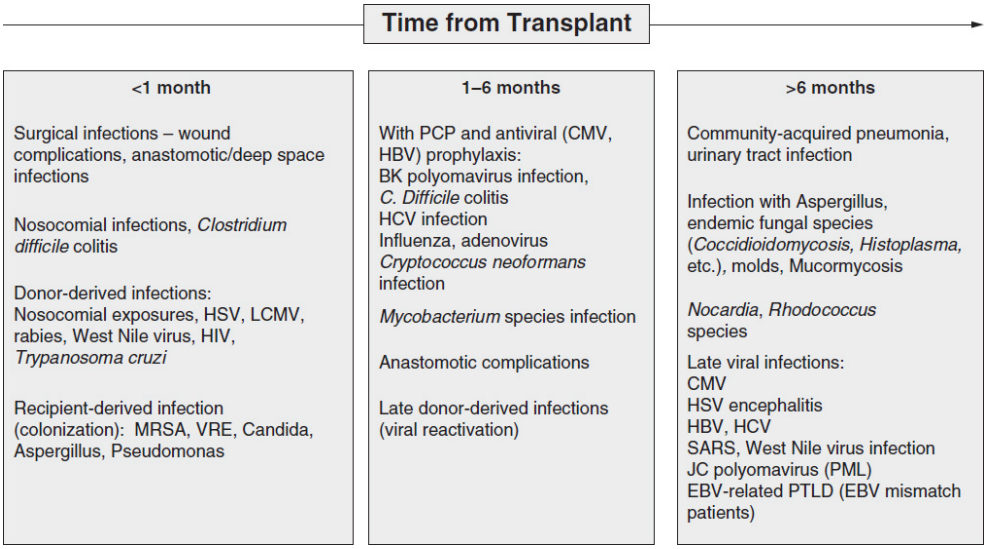

Figure 34.3 Timeline of common infections after transplantation. Immunosuppression predisposes transplant recipients to infection by deterring host defenses. In this context, bacterial, viral, and fungal infections may arise which have distinct peaks of onset. Treatment of these infections usually involves withdrawal or reduction of immunosuppression in most cases, particularly when infections are life-threatening or are causing significant morbidity. (Adapted from Fishman JA. Infection in solid-organ transplant recipients. *N Eng J Med* 2007;357[25]:2601–2614.)

Pathogen	Site of Disease	Disease Manifestations	Prophylaxis	Treatment
Cytomegalovirus (CMV)	CNS, Respiratory, GI tract, Bone marrow	Fever, neutropenia, pneumonitis, diarrhea, mucosal ulceration, chorioretinitis, meningoencephalitis, graft dysfunction	Low-risk patients: Acyclovir High-risk patients: Valganciclovir	Valganciclovir Ganciclovir CMV-immunoglobulin Minimization of immunosuppression
Epstein–Barr Virus (EBV)	Bone marrow, spleen, CNS	B-cell–derived post transplant lymphoproliferative disease (PTLD)	Antiviral prophylaxis such as acyclovir or valganciclovir	Minimization of immunosuppression Chemotherapy Radiation Therapy (CNS) Anti-CD20 antibody therapies
BK Virus	Kidney	Renal Dysfunction	None	Minimization of immunosuppression Experimental antiviral therapies (cidofovir)
Pneumocystis	Respiratory	Pneumonia/pneumonitis	Trimethoprim/sulfamethoxazole Pentamidine Dapsone	

Figure 34.4 Common infections after transplantation, prophylaxis, and treatment strategies. After transplant, while predisposed to multiple infections related to immunosuppression, certain infections are particularly common and virulent. Clinical decisions regarding prophylaxis against these pathogens and how this affects immunosuppression are key decision points in managing the posttransplant patient.

Recipient-Derived Infections

The incidence of posttransplant infections that arises from pretransplant exposure to the recipient is increasingly recognized. Transplanting patients with active infections should be undertaken with extreme caution due to the risk of dissemination of disease with early immunosuppression. Nosocomial pathogens may colonize the recipient prior to transplant, when healthcare utilization may be high due to organ failure, or may infect patients at any point after transplant. Pathogens may acquire antibiotic resistance which may make treatment difficult, such as in cases with vancomycin-resistant *Enterococcus,* methicillin-resistant *Staphylococcus,* azole-resistant *Candida,* as well as in *Clostridium difficile* colitis, several gram-negative enteric pathogens, and fungi. Recipient exposure via travel or residence in geographically endemic areas can also be a risk for infection (fungal infections such as histoplasmosis, aspergillosis, coccidioidomycosis, atypical bacterial infections such as *Mycobacterium tuberculosis,* parasitic infections caused by *Strongyloides* or *Trypanosoma cruzi*), as well as reactivation of dormant viruses (hepatitis, CMV, or varicella-zoster virus). Exposures to relatively benign pathogens may result in major infections after transplant. Respiratory viruses may further weaken natural tissue defenses in the bronchopulmonary tree and lead to superinfection with other pathogens. Fungal infections derived from the soil such as *Nocardia* or *Aspergillus* may arise in this fashion and require changes in immunosuppression to prevent exacerbation of infection.

While the spectrum of potential infectious pathogens is broad, infectious epidemiology in the immunocompromised population guides targeted prophylaxis strategies. Common posttransplant infections are listed in **Figure 34.4**. Immunosuppression management in the infected transplant recipient is often challenging and dependent on the relative immunogenicity of the organ transplanted, the virulence of the pathogen, and the presence or potential of disseminated disease. Minimization of immunosuppression is a mainstay during infectious episodes but must be balanced with the risk of intervening acute rejection.

Cancer

Chronic immunosuppressive therapy weakens host defenses against neoplastic processes. There is well-established evidence that solid organ

transplant recipients of every type have an increased risk of malignancy, both related to immunosuppression and oncogenic viral infections. The most common cancers incurred by solid organ transplant recipients are skin cancers, followed by posttransplant lymphoproliferative disease. In this context, posttransplant patients are strongly recommended to have yearly skin examinations by a dermatologist. Screening for malignancy in chronically immunosuppressed patients follows general screening guidelines. Treatment of cancers is driven by site and extent of disease, but in all cases includes reduction in the amount of immunosuppression.

Organ Retrieval and Preservation

Mary T. Killackey

Key Points

1. Despite advances in survival and expanded indications for transplant, the gap between organ availability and organ supply has widened.
2. Efforts to expand organ donation are critical to save lives. Organ donation must be done within a regulated system that is deeply rooted in ethical standards of care.
3. A balance must be maintained between using every viable donor organ and ensuring each patient a chance of successful posttransplant outcome.
4. Organ retrieval requires coordination of a multi-disciplinary team including surgeons, anesthesiologists, nurses, and organ perfusion technicians. Careful retrieval and perfusion techniques are necessary for a successful outcome.
5. Organ retrieval and storage results in significant alterations in the homeostasis of the organ. The degree of organ preservation injury contributes to organ dysfunction. Current trials aim to rehabilitate injured or otherwise discarded organs.

1 Organ transplantation has become the standard of care for end-organ failure and often it is the only lifesaving therapy available. Despite our significant advances in survival and expanded indications for transplant, the gap between organ availability and organ supply has widened significantly and patients are unable to receive the treatment they need. As of January 2020, in the United States, more than 110,000 patients are waiting for an organ transplant.[1] The total number of transplants has been increasing, reaching almost 40,000 in 2019, due in large part to the increase in opioid-related deaths.[2] Yet the disparity continues as a new patient is added to the waitlist every 10 minutes and on average, 22 patients die each day waiting for transplant (**Fig. 35.1**).[3]

ORGAN DONATION

(**Fig. 35.2**)

Living Donation

Considering high waitlist mortality and long wait times, early transplant for patients with end-organ failure has significant benefits. For example, patients who receive a kidney transplant prior to initiating dialysis (a preemptive transplant) have a lower rate of allograft failure and mortality and a higher quality of life compared to patients who receive a transplant after beginning dialysis (**Table 35.1**).[4]

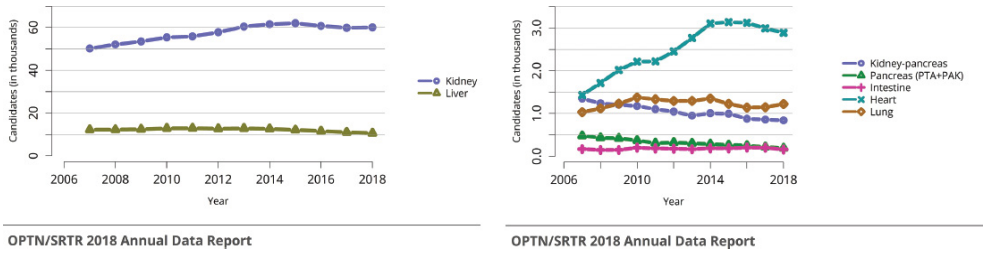

Figure 35.1 Active candidates on the UNOS waitlist as of 12/31/2019 by organ.[1] (Data from UNOS Transplant Trends. http://www.unos.org. Accessed January 2020.)

Living donation facilitates this early intervention and is available to those waiting for liver and kidney transplants. In the United States, 23% of liver and kidney transplants utilize living donor organs.[1] In certain parts of the world, living donation predominates due to multiple ethnic, social, cultural and religious factors resulting in absent or very low rates of deceased donation.[5] Since 2004, living donation had been in a steady decline until recently as a result of intentional efforts to increase living donation. For the third year in a row, the annual volume of living donors has increased and reached a new peak in 2019 (**Table 35.2**).[3]

In paired kidney exchange programs, donor–recipient pairs that were previously determined to be incompatible can swap donors with another pair if appropriately matched by blood type, HLA type, and antibody sensitization (**Fig. 35.3**). Criteria for living donation are strict. Living donors must be excellent surgical candidates with minimal medical comorbidities and a stable psychosocial assessment. Regulation is in place to ensure the donors have not been coerced.

Deceased Donation

In 2019 in the United States, the majority (77%) of organs used for transplantation came from deceased donors.[1] In general, deceased donors are brain dead, previously in good health, and free of life-threatening communicable disease or malignancy. Steadily increasing over the past 5 years, deceased after-cardiac death donors account for 19% of the deceased donors.[3]

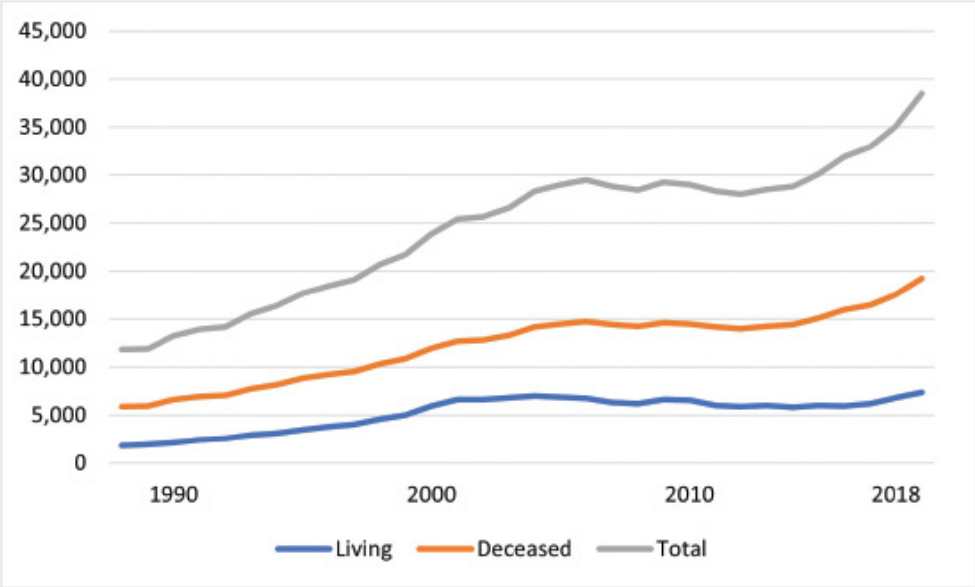

Figure 35.2 Number of annual donors by type as reported on 12/31/2019.[1] (Data from UNOS Transplant Trends. http://www.unos.org. Accessed January 2020.)

2 Considering the desperate need for lifesaving organs, regulations are necessary to ensure fair and equitable distribution across populations. Current issues facing the transplant community focus on the disparity of waiting times, which can vary significantly across the country. In 2018, a lawsuit was filed arguing the current system of distribution violated federal law. HRSA responded by ordering the OPTN/UNOS to remove artificial geographic boundaries from the organ allocation policy which was completed in 2019.[6]

Implementation of these policies in a fair and efficient way is carried out by an organ procurement organization (OPO) which is a not-for-profit entity that is not directly involved in the care of the recipient. The primary role of the OPO is to ensure the safe retrieval of every possible organ available. The OPO, as well as the transplant surgical team, are separated from the declaration of death process. Patients who are not brain dead may donate following cessation of cardiac function; this is known as donation after cardiac death (DCD).

Declaration of Death

In the United States, a patient is considered dead when they have irreversible cessation of brain function (brain dead) or irreversible cessation of

circulatory and respiratory functions. The definition of brain death is established locally by hospitals using rules that conform to the *Harvard Criteria* and comply with the Uniform Determination of Death Act.[7] In 2010, the American Academy of Neurology updated its established guidelines for determination of death (**Table 35.3**).[8] Donors declared brain dead are supported by mechanical ventilation and the necessary medications to maintain a blood pressure, allowing the organs to be perfused by the donor's heart throughout the procurement process.

In an effort to increase transplantable organs, advances have enabled the utilization of organs following cardiac death. In these cases, the donors, who often sustain irreversible neurologic injury, must lose cardiopulmonary function to allow declaration of death. Following family wishes, ventilatory and circulatory support are withdrawn, either in the ICU or the operating room. The patient is declared dead by the caring physician upon cessation of circulation. Each hospital establishes policies and procedures for retrieval of DCD donor organs and it is critical that members of the transplant teams are not involved in the process of declaration of death. After declaration, 2 to 5 minutes must elapse prior to organ retrieval surgery. If the patient does not reach criteria for death within 60 to 90 minutes, kidney recovery is not pursued. For liver, the maximal acceptable agonal time (time from withdrawal to death) is 20 to 30 minutes. While much rarer, if pancreas or lung are recovered, agonal time should be less than 30 minutes. The transplant surgeon rapidly recovers the organs. DCD organs have acceptable but inferior outcomes due to the hypoxia during the agonal phase.[9,10]

Table 35.1 Five-Year Graft Survival of Kidney and Liver Transplant by Donor Type

	Deceased Donor (%)	Living Donor (%)
Liver	71.9	77.3
Kidney	74.4	85.6

OPTN National Data Report: Survival Rates for Transplant Performed 2008–2015. Available at https://optn.transplant.hrsa.gov/data/view-data-reports/national-data/. Accessed January 20, 2020.

Table 35.2 Efforts to Increase Living Donation in the Last Decade

- Improved public education from transplant centers
- Utilization of social media to connect potential pairs
- Transplant center participation on local and/or national paired exchange programs
- Development of protocols for immunologically high-risk transplants

Consent for Donation

Permission for organ donation is obtained from the patient's next of kin prior to organ donation. Organized efforts over the past 25 years have resulted in more than 60% of the U.S. adult population registered as an organ, eye, or tissue donor, often associated with driving licensure.[11] A signed and witnessed organ donor card is sufficient indication of the decedent's wishes to allow organ donation. Despite this declaration, the family's consent is routinely obtained even when a valid organ donor card is present. In conjunction with the OPO, many hospitals have trained specialists who approach families to consent for donation. Explanation of the organ donation process by a trained and empathetic party not directly involved in the care of the deceased patient yields the highest consent rates.

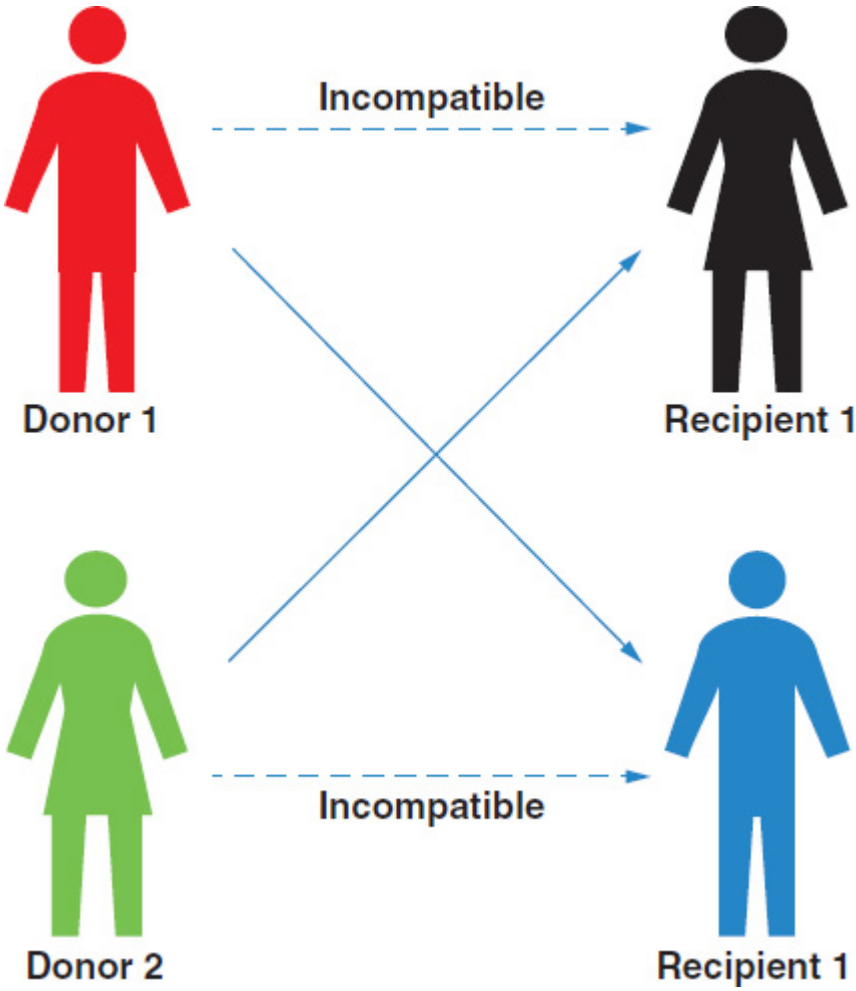

Figure 35.3 Schematic for paired exchange kidney transplant.

Table 35.3 Criteria for Brain Death

- All reversible causes of coma excluded
  - Hypothermia
  - Shock
  - Severe electrolyte abnormality
  - Pharmacologic sedation or paralysis
- Loss of all function of the entire brain, including brain stem[a]
  - No response to noxious stimuli
  - No pupillary light reflex
  - No corneal reflex
  - No oculocephalic reflex
  - No gag reflex
  - No spontaneous respirations
- Preferred confirmatory diagnostic tests (one must be completed)
  - Cerebral angiogram (gold standard)
  - EEG
  - Nuclear medicine perfusion scan

[a]In the United States, one neurologic examination is sufficient in most states.

Data from Wijdicks E, Varelas P, Gronseth G, et al. Evidence-based guideline update: determining brain death in adults. *Neurology* 2010;74(23):1911–1918.

ORGAN SELECTION

3 Organ quality is closely linked to recipient outcomes. A careful balance must be maintained between using every viable organ and ensuring the best possible outcome for each recipient. The transplant team should assess general demographic, health, and social issues of the donor as well as organ-specific function.

Donor History of Cancer

Potential organ donors should be free of cancer as transmission to the organ recipient may result in rapid death related to cancer progression in the setting

systemic immunosuppression. Criteria and guidelines for suitability for donation among cancer survivors are well detailed in the literature.[12]

Donors with a history of melanoma, leukemia, lymphoma or small-cell carcinoma are excluded from donation. For most major cancers associated with systemic progression, organ donors should be disease free for 5 years. Some donor cancers have been shown to have minimal risk of transmission to the recipient. These include nonmelanoma skin cancers without nodal involvement, small renal cell and prostate cancers, and many intracranial malignancies that have not recently had intracranial surgical intervention.

Donor History of Infectious Disease

All donors are screened for transmissible disease and the DHHS has further defined "increased-risk" donors which require nucleic acid testing and the recipients must be tested accordingly after transplant. Potential recipients are required to sign a consent which details the reasoning for determination of high risk.[13]

Donors may spend days prior to donation in the hospital, increasing risk for acquired infections. Treated systemic bacteremia is acceptable while donors with recent fungemia are not donors with undiagnosed viral illnesses. The transplant center needs to follow donor cultures and make sure that the recipient is appropriately treated.

Donors with active HBV (surface antigen positive) are excluded from transplant; however, those with a previous history of hepatitis B infection (core antibody positive) can be used in recipients who have been immunized against HBV. Depending on the organ (hepatic vs. extrahepatic) and the recipient serology, they will require either short- or long-term antiviral therapy.

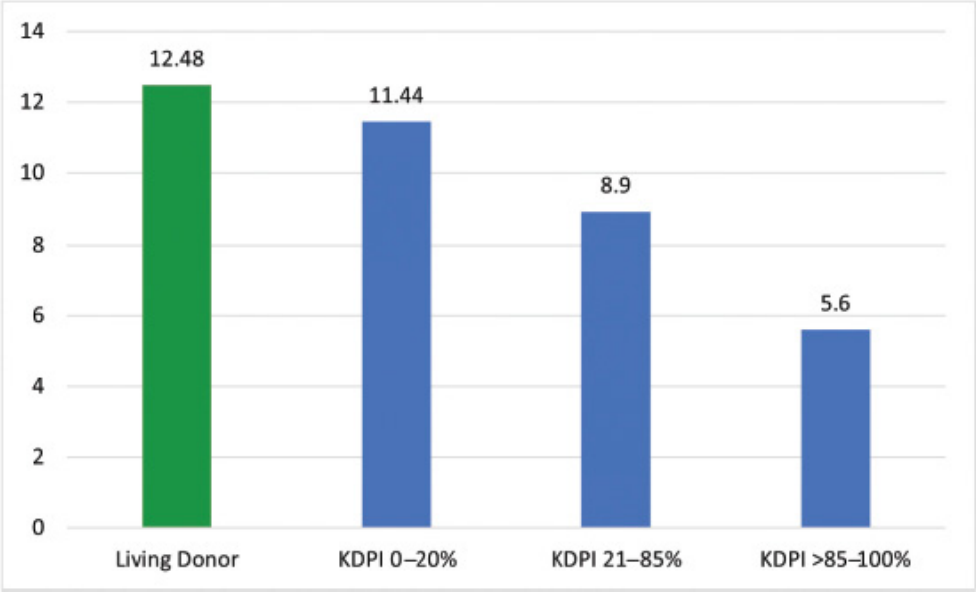

Figure 35.4 Estimated graft half-lives (years) by KDPI as compared to living donor transplant.

Donors with HCV viremia have traditionally been reserved for recipients who are HCV positive. With the development of highly effective antiviral regimens over the last decade, and current literature supporting the utilization of HCV viral positive donors in patients who are HCV naïve, most transplant programs have begun to accept these organs for transplant. Detailed informed consent is essential.[14]

Donors positive for HIV have historically been discarded until the HOPE Act was passed in 2015 allowing their use as part of IRB-approved research protocols. This legislation allowed the transplantation of these organs into HIV-positive recipients exclusively and at centers that meet the specific transplant hospital criteria defined by the NIH and approved by the OPTN.[13]

Other rare but important infectious pathogens such as rabies and encephalitis should raise a red flag and should be discussed with a transplant infectious disease expert prior to accepting any questionable organs.

Organ-Specific Issues

All donors are subject to a global assessment including age, medical history, social history, and cause of death. Each organ has specific considerations:

Kidney

In 2014, the kidney allocation system was significantly revised and began to include a more refined, continuous metric known as the Kidney Donor Profile Index (KDPI). This number combines a variety of donor factors to estimate the likelihood of graft failure after deceased donor transplant (**Fig. 35.4**).

Informed consent is required to be listed for high KDPI organs and both renal biopsy, assessing for glomerular fibrosis, and organ preservation pumping, assessing for circulatory resistance, can aid in graft selection. Kidneys may be preserved for up to 36 hours, though efforts should be made to keep the cold ischemia time (CIT) to less than 24 hours.

Liver

Current liver function and graft size are essential considerations as preterminal liver injury is associated with primary nonfunction of the allograft. A liver biopsy is frequently available from donors with risk factors for liver disease. Greater than 30% macrosteatosis and/or parenchymal fibrosis may preclude transplantation. More than a grade 2 liver laceration generally precludes transplantation. Efforts should be made to keep the CIT to less than 12 hours.

Pancreas

Selection of pancreas allografts must be done with care since recipient complications are common. Donors ideally should be less than 40 years and be free of major comorbidities. On inspection, the pancreas should be soft without significant fat infiltration. Donor iliac vessels used for the vascular conduit should be free of atherosclerotic disease. Pancreatic branches from the splenic and superior mesenteric arteries must be intact (**Fig. 35.5**). Injury to pancreatic parenchyma precludes use of the organ. Efforts should be made to keep the CIT to less than 12 hours.

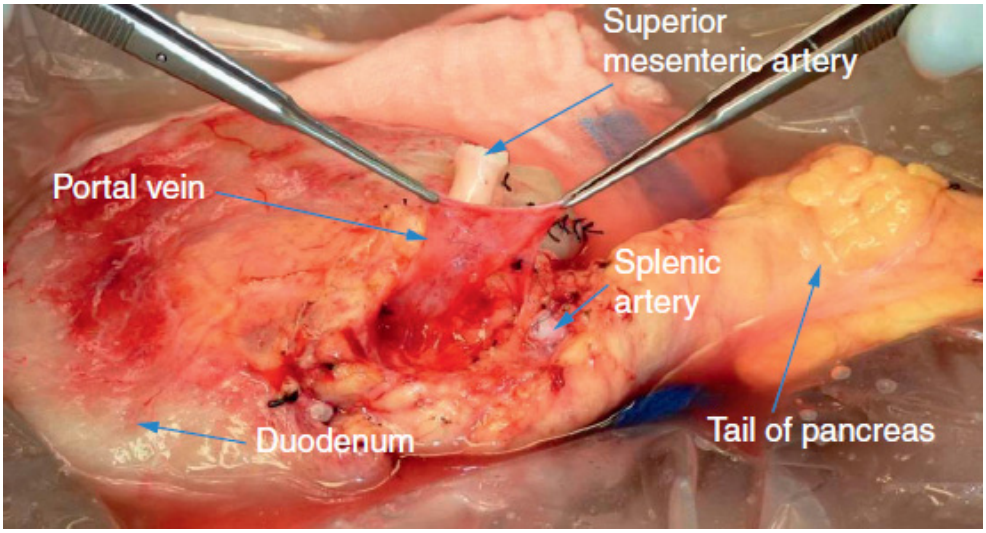

Figure 35.5 Pancreas allograft following procurement, with ample length of portal vein, superior mesenteric artery, and splenic artery.

Heart

Selection of heart allografts includes assessment of an echocardiogram as significant structural cardiac disease or abnormal cardiac function precludes donation. Donors with risk factors for cardiac disease undergo cardiac catheterization to rule out significant coronary artery disease. The relationship between the donor and recipient body size should be considered. Prior to retrieval, the procuring surgeon should examine the beating heart for size and function before the recipient surgeon begins the heart transplant operation. Efforts should be made to keep the CIT to less than 4 hours.

Lungs

Initial assessment of lung donors must determine if there is a history of smoking or pulmonary disease and must consider the events surrounding death (i.e., aspiration or accident with chest injury). Predonation workup includes chest x-rays, arterial blood gases, CT scan, and a bronchoscopy with airway cultures. Lung contusions or pneumonia may preclude transplantation. Donors are ventilated on 100% oxygen to assure high blood oxygen levels. The relationship between the donor and recipient body size is considered. At the time of retrieval, the donor surgeon performs a repeat bronchoscopy and a median sternotomy to physically inspect the lungs for

damage, infection, underlying lung disease, or masses. Efforts should be made to keep the CIT to less than 6 hours.

THE ORGAN RETRIEVAL OPERATION

4 The organ retrieval operation requires coordination of a multidisciplinary team including surgeons, anesthesiologists, nurses, and organ perfusion technicians. By convention, transplant centers send their own teams to procure the heart, liver, lungs, and pancreas. The kidneys are procured by one of the abdominal teams and are shipped to the appropriate transplant center. In most cases, retrieval teams travel to the hospital where the donor is admitted; both air and ground transportation is usually required. In some regions, the donors are transported to a centralized retrieval facility. This has been shown to reduce costs, travel time, and CITs.[15] The recipient liver, lung, and heart operations usually begin before organs return to the transplant center; thus continuous communication and coordination are needed between transplant centers and the retrieval teams.

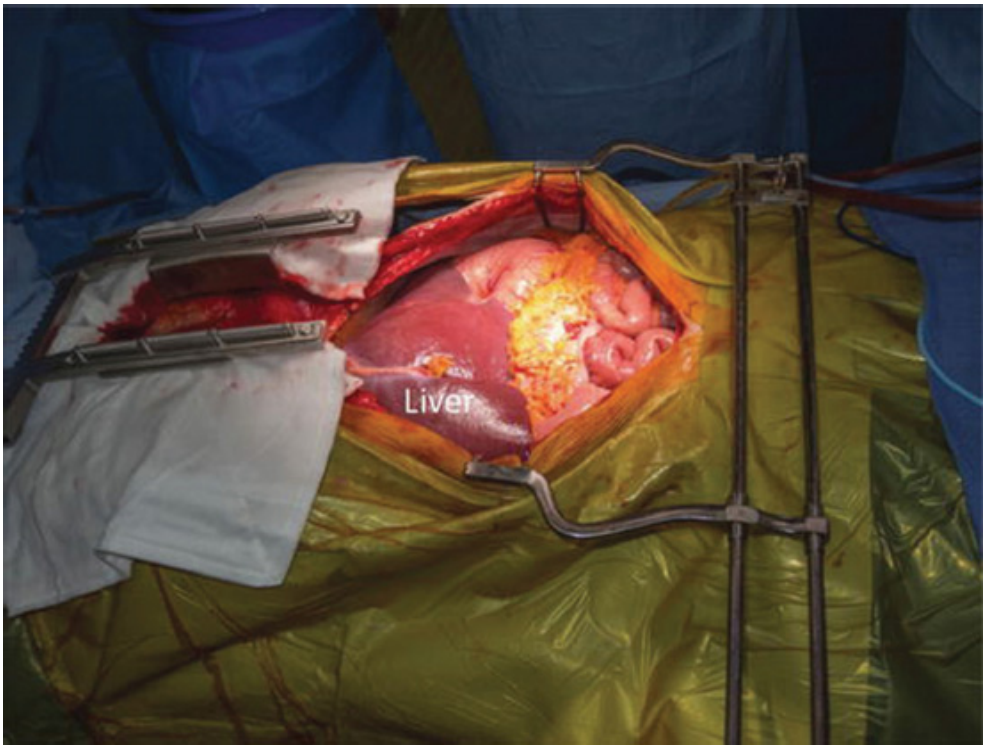

Figure 35.6 Procurement incision/exposure allowing for inspection of thoracic and abdominal cavities.

Upon arrival to the donor operating room, the transplant surgeon must check the appropriate documentation. This includes identification of the donor, consent for donation, and the donor medical chart. The surgery team should discuss hemodynamic and anticoagulation management with the anesthesia team. The donor is placed supine with the arms tucked to facilitate multiple teams working on the donor simultaneously. Prior to incision, it is common to observe a moment of silence to honor the donor and the magnitude of the act of giving. An incision is made from the sternal notch to the symphysis pubis; the abdomen and sternum are opened and the cavities inspected for gross pathologic disease that would contraindicate donation (**Fig. 35.6**). The key organ-specific steps are detailed below.

Heart and Lung Retrieval

A bronchoscopy is done to examine anatomy, remove secretions, and rule out pneumonia. The sternum is opened and a chest retractor placed. The thymus gland is dissected and the innominate vein is identified. The pericardium is

incised and stay sutures are placed. The aorta is mobilized, freeing it from the main pulmonary artery and the right pulmonary artery. The superior and inferior vena cavae are mobilized. The chest and abdominal teams must agree on where to drain the IVC.

When all teams are ready, systemic heparin is administered and the organs are perfused and removed (**Fig. 35.7** and Table 35.4).

Liver Retrieval

Prior to perfusion, the right colon and small bowel are mobilized to expose the entirety of the retroperitoneum, including the infrahepatic vena cava and aorta. The IMV is identified and cannulated for eventual portal perfusion. The superior mesenteric artery is identified and may be encircled at the root of the mesentery close to the aorta (**Fig. 35.8**). The gallbladder is opened and the bile is removed. The left lateral segment of the liver is mobilized and the gastrohepatic ligament is inspected for a replaced or accessory left hepatic artery. If an artery is noted, the surgeon must carefully dissect all of the branches from the proximal left gastric artery, staying close to the lesser curvature of the stomach. Failure to properly manage these small branches will result in a postreperfusion hematoma around this artery, potentially causing arterial thrombosis. The porta hepatis is palpated to assess the location of the arteries. If present, a replaced right hepatic artery is noted to the right and posterior to the common bile duct (**Fig. 35.9**).

The aorta is dissected at its bifurcation to facilitate proximal and distal control (**Fig. 35.10**). The surgeon should assure that there are no renal arteries from the distal aorta or iliac arteries. If there are, the cannulation should occur distal to these arteries to make sure they are flushed. The supraceliac aorta is exposed by retracting the caudate lobe and the left lateral segment of the liver to the right, grasping the crux of the diaphragm, and dividing it with electrocautery. Circumferential control of the supraceliac aorta is not needed, though sufficient exposure for occlusive clamping is a necessity (**Fig. 35.11**). When all teams are ready and heparin is administered, the aorta is clamped and ice is placed into both cavities. The abdominal surgeon works simultaneously with the thoracic surgeon (**Table 35.5**).

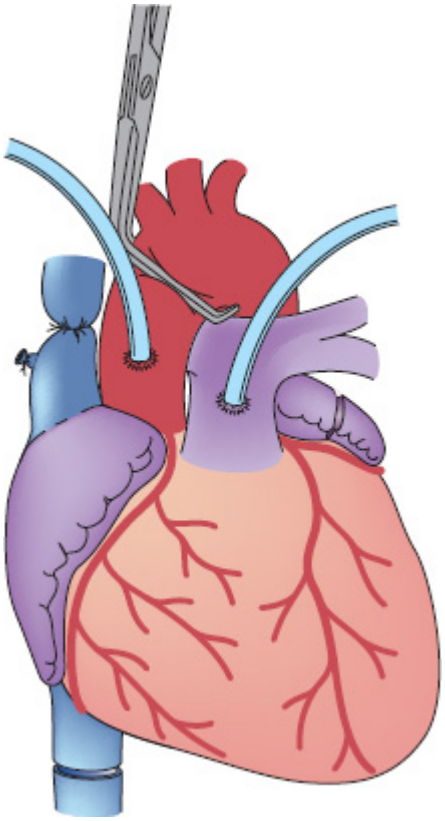

Figure 35.7 Cannulation for flushing and removal of heart then lungs.

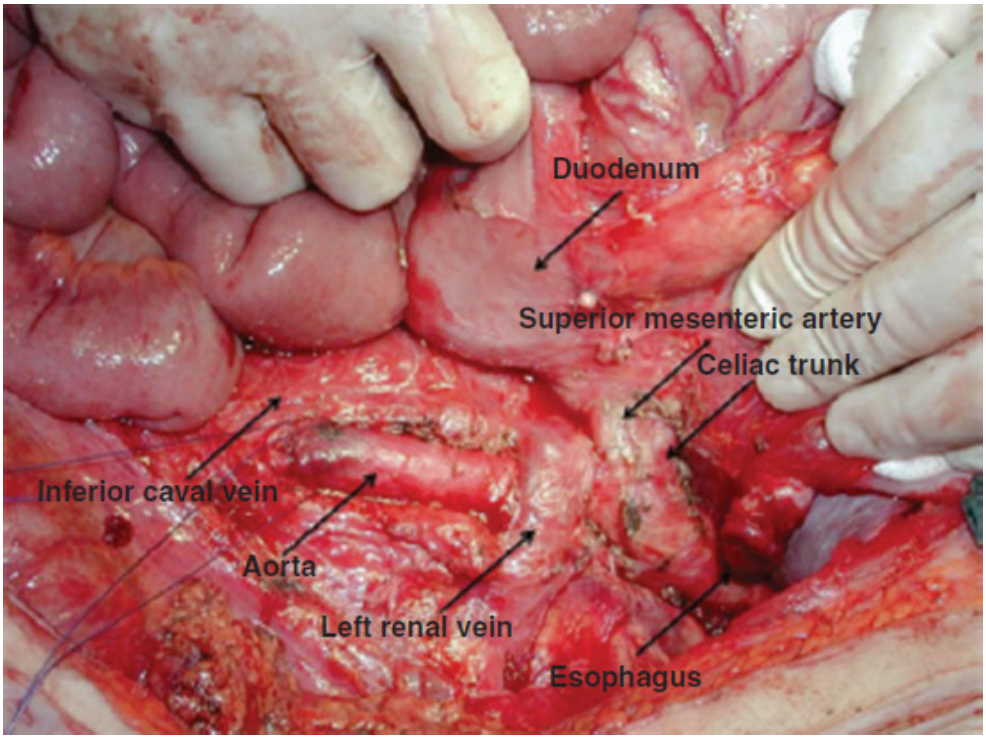

Figure 35.8 Exposure of retroperitoneum following Kocher and Cattell maneuvers.

Table 35.4 Steps for Flushing and Removal of Heart Then Lungs

- The aortic root is cannulated with a standard needle-tipped cannula.
- A purse-string suture is placed on the distal main pulmonary artery through which an "L"-shaped cannula is placed in the pulmonary artery. Prostaglandin is administered into the pulmonary artery.
- The superior vena cava is ligated; the inferior vena cava is incised at the level agreed upon by the liver surgeon.
- An incision is made to vent the heart and the aortic cross clamp is placed distal to the coronary perfusion cannula.
- The heart and lung cold perfusion is started and the organs are surrounded by ice.
- After the flush, the left atrium is divided, leaving an oval cuff of atrial tissue for the pulmonary veins on each lung.
- The pulmonary artery is divided, taking care not to damage the left main pulmonary artery. The aorta is divided just distal to the aortic arch and the heart is removed.
- The lateral and posterior borders of the pericardium are divided.
- The innominate vein is divided and the anterior trachea is identified and encircled as high in the chest as possible.
- The lungs are inflated and the main bronchus and left main bronchus are stapled. The trachea is divided proximal to the stale line and the inflated lungs are removed.

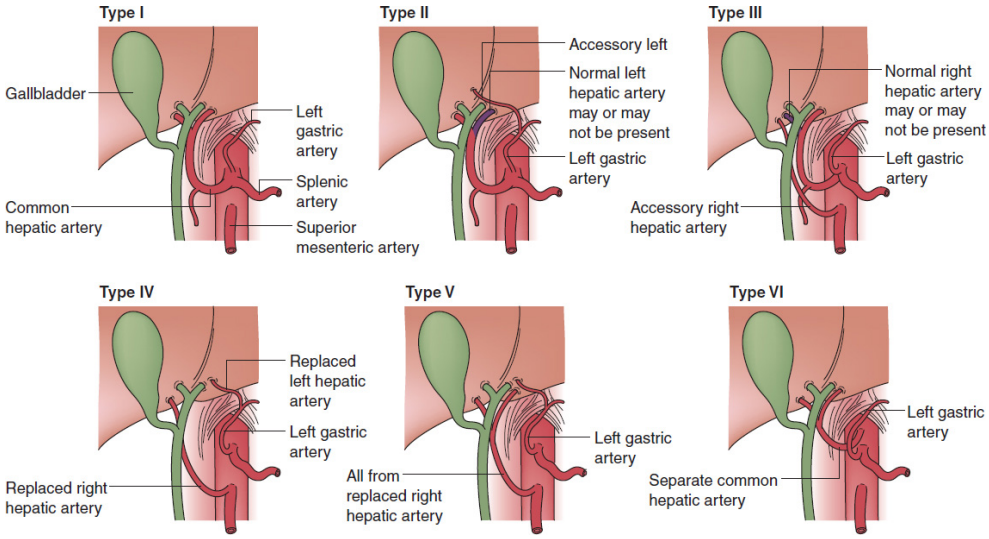

Figure 35.9 Variations in hepatic arterial anatomy. Lack of identification of this anatomy may jeopardize the transplant operation.

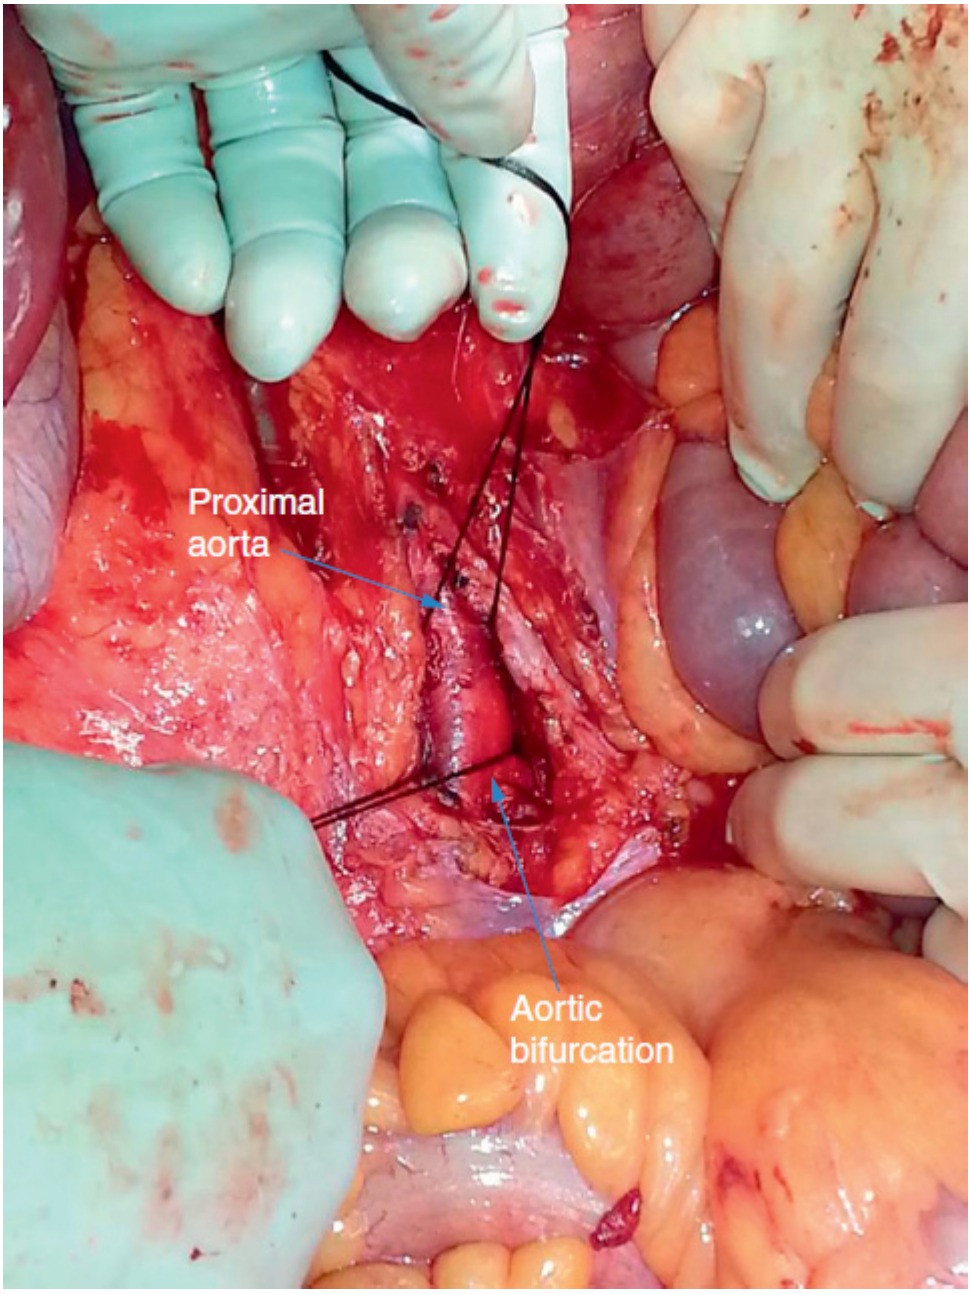

Figure 35.10 Exposure of the distal abdominal aorta in preparation for aortic cannulation.

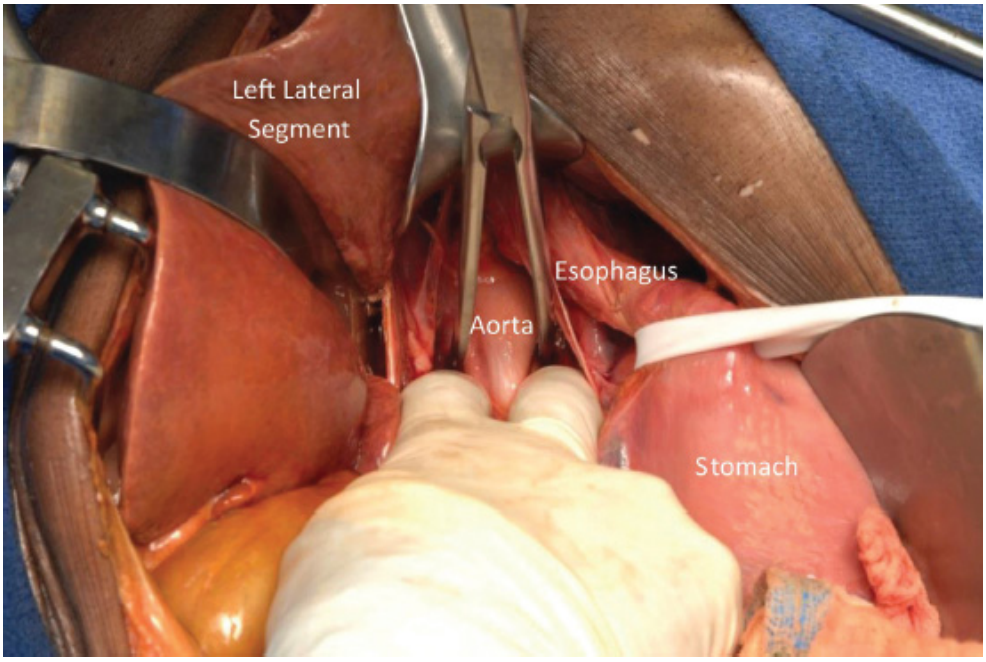

Figure 35.11 Vascular control of the supraceliac aorta in preparation for perfusion. (From Teixeira P, Magee G, Rowe V. Abdominal aorta and splachnic vessels. In: Demetriades D, Inaba K, Velmahos G, eds. *Atlas of Surgical Techniques in Trauma*. Cambridge: Cambridge University Press; 2020:268–285.)

Arterial anatomy has many variations and failure to identify the variation may jeopardize the transplant operation (**Fig. 35.9**). On occasion, dissection of the replaced right hepatic artery can jeopardize the pancreas allograft, but usually both teams can agree to an acceptable dissection plane. The reconstruction of the replaced right hepatic artery can be done in many ways; most common is an anastomosis to the splenic artery with the celiac artery as inflow.

Kidney Retrieval

Kidney retrieval is the final step in the procurement operation. Kidney procurement is significantly easier if the liver has been removed. If the liver has not been removed and will not be used to transplantation, the portal triad and the right diaphragm should be divided. This results in the liver falling into the right chest, greatly facilitating the kidney procurement.

Table 35.5 Steps for Flushing and Removal of Abdominal Organs

- The aorta is cannulated, the supraceliac aorta is clamped, and the abdominal organs are flushed with cold preservation solution.
- The liver is surrounded with ice and flushed with approximately 5 L of preservation solution in the aortic cannula and 2 L in the portal cannula.
- After the flush, the diaphragm is divided with a cuff around the suprahepatic inferior vena cava.
- The infrahepatic inferior vena cava is divided just above the renal veins.
- The bile duct and portal vein are divided.
- The aorta is divided between the SMA and the renal arteries.
- The liver is removed and the portal vein is flushed on the back table if not done in situ and placed in cold storage.

Prior to perfusion, the kidneys are mobilized posteriorly to facilitate packing with ice at the time of the cold perfusion. After flushing, the ureters are divided bilaterally in the pelvis and mobilized upward toward the kidney. The periureteral tissue should be left intact in order to maintain the blood supply to the ureter. The inferior vena cava and the aorta are divided at the bifurcation and the two vessels, along with the ureters are retracted superiorly, and the tissue posterior to the vessels is incised. The left renal vein is divided at the level of the inferior vena cava, leaving the entire inferior vena cava with the right kidney to allow for extension of the short right renal vein utilizing the cava. The kidneys are placed in cold storage or on a perfusion pump.

Pancreas Retrieval

All of the steps necessary for the liver retrieval up to the point of perfusion are completed. The pancreas must be mobilized out of the retroperitoneum with care. This can be done in the cold following perfusion, but mobilization prior to this allows for a careful examination of the organ as well as ensuring that the vasculature is ligated.

The short gastric vessels are divided to widely expose the pancreas. The gland is assessed for fatty infiltration or firmness, both of which may preclude transplantation. The retroperitoneal tissue inferior to the pancreas and behind the spleen is incised. The spleen is retracted both anteriorly and medially. The tissue behind the spleen and pancreas is divided until the aorta is reached. The duodenum is divided distal to the pylorus. A vessel loop is placed around the splenic artery and cold perfusion is initiated.

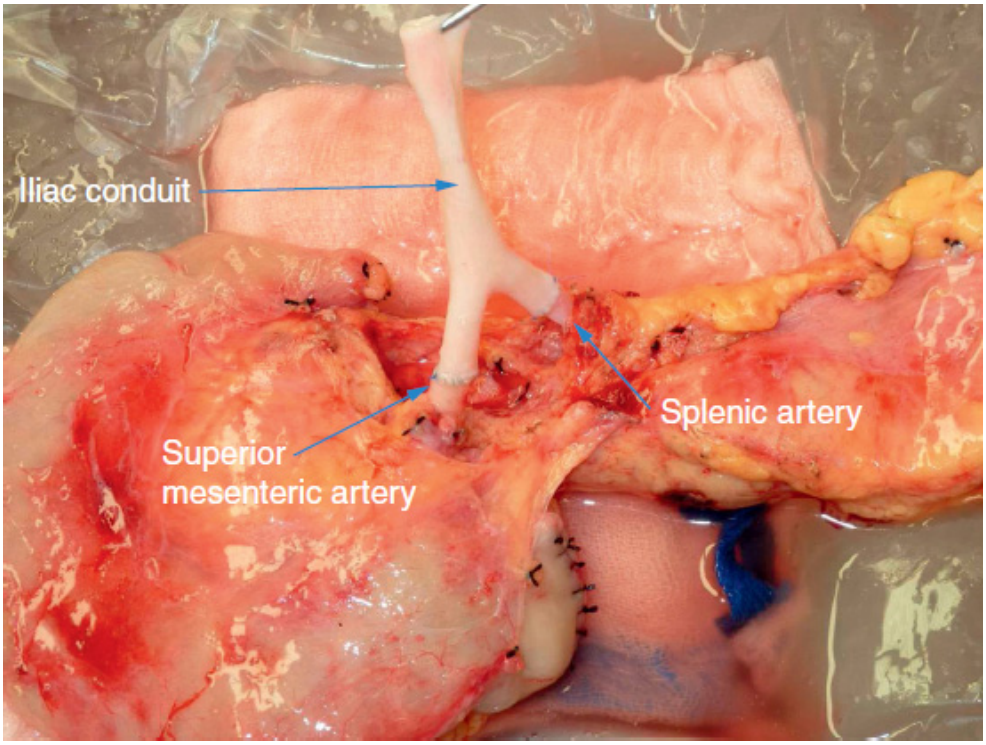

Figure 35.12 Donor superior mesenteric artery and splenic artery with arterial conduit created from the donor iliac artery.

Table 35.6 Key Concepts in Organ Preservation

Prevent thrombosis	▪ Anticoagulation of donor ▪ Rapid and complete organ flush
Maintain organ structural integrity	▪ Maintenance of cell membrane lipid bilayer ▪ Cold storage results in conformational changes of cell membrane resulting in cell swelling ▪ Hypertonic preservation solutions mitigate some of these effects
Maintain ionic composition	▪ Preservation solution electrolyte composition is similar to intercellular composition of Na^+ and K^+ ▪ H^+ accumulated as a result of anaerobic glycolysis ▪ Preservation solution buffers H^+ effects
Maintain cellular energy	▪ Hypothermia reduces metabolism 12-fold ▪ Hypothermia affects the activity of mitochondrial enzymes ▪ Mitochondrial dysfunction results in changes in cellular energy
Reperfusion injury—oxygen-free radicals	▪ The majority of organ injury happens at reperfusion and not during cold ischemia ▪ The sudden availability of O_2 results in the production of reactive oxygen intermediates (O^{2-} and OH^-)

	▪ Free radicals cause cellular injury, largely through lipid peroxidation ▪ Glutathione protects against peroxidation and is useful in preservation solutions
Reperfusion injury—cytokines	▪ Tissue injury results in the release of cytokines ▪ Tumor necrosis factor, interferon gamma, interleukin-1, and interleukin-8 are released at reperfusion ▪ Cytokine exposure results in the upregulation of adhesion molecules, resulting in platelet plugging and leukocyte adherence to the endothelium

After perfusion, the pancreas is removed in situ or en bloc along with the liver. The proximal jejunum is divided as it exits the retroperitoneum. It is critical that the root of the mesentery is securely divided with a vascular stapler. Division of the portal vein, the SMA, and splenic artery should be done in communication with the liver surgeon (**Fig. 35.5**). The iliac artery is retrieved for creation of the Y graft for the transplant operation. The iliac vein is retrieved in case an extension graft is needed for the portal vein (**Fig. 35.12**).

NEW METHODS IN ORGAN OPTIMIZATION AND PRESERVATION

5 Organ retrieval and storage result in significant alterations in the homeostasis of the organ. The degree of organ preservation injury contributes to the degree to which normal organ function is delayed or prevented following transplantation. Organ preservation injury is largely mediated by

ischemia and hypothermia. The duration when the organ is in cold storage is termed "cold ischemic time." Minimizing this time as well as carful organ preservation is critical for successful outcomes (**Table 35.6**).

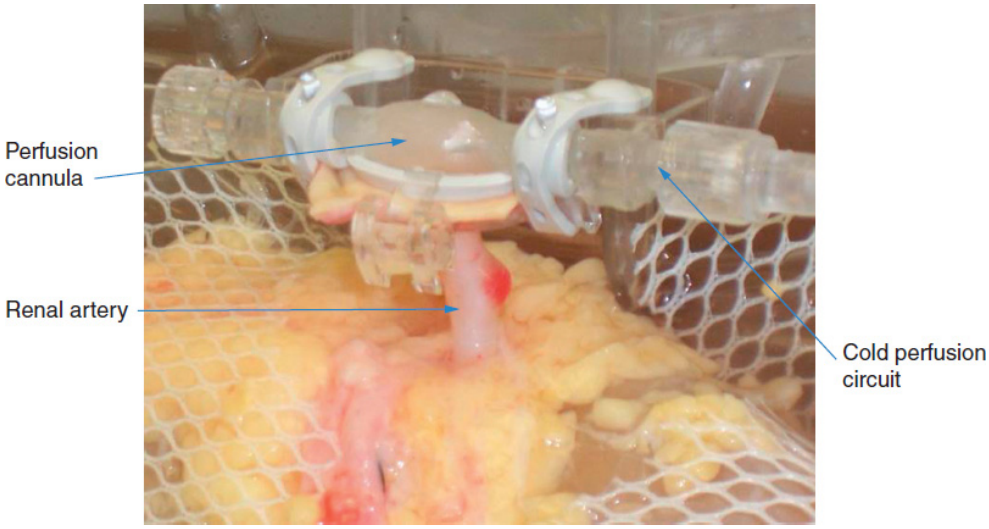

Figure 35.13 Renal machine-cold perfusion circuit with renal artery cannula.

Cold ischemia and subsequent warm reperfusion cause much of the cellular organ damage. As a result, novel strategies for warm perfusion of organs are being used. These techniques involve perfusion with blood or a bloodlike analog with or without oxygenation. Trials of ex vivo liver perfusion machines appear to enhance preservation of donor organs, extending viability and potentially evaluating function in organs previously considered too marginal for transplant.[16] These perfusion techniques remain investigational at this time but offer promise of optimized organ function and potentially expanded donor pool as marginal organs may be rehabilitated.

Machine-cold perfusion is now commonly done in renal transplantation and in some regions is the standard of care for renal preservation. Some of the injury during cold ischemia and reperfusion is related to the accumulation of metabolites; perfusion may mitigate these effects by washing out deleterious metabolites and by maintaining patency of the microvasculature of the organ (**Fig. 35.13**).[17]

Several strategies have been developed to mitigate the effects of ischemia on organs obtained following DCD retrieval procedures. These include the infusion of antifibrinolytics into the donor organ at the time of transplant.[18]

Early reports suggest these strategies result in fewer post liver transplant biliary complications.

Another approach is to resume normothermic perfusion of the abdominal viscera following death using extracorporeal membrane oxygenation (ECMO) circuit. This strategy has several benefits including enabling withdrawal of support in the ICU with the family present, resuscitation of the organs following the agonal period, and avoidance of urgency in the retrieval operation.

Kidney Transplantation

Jayme E. Locke and Peter G. Stock

Key Points

1. The presence of antidonor HLA antibodies is a relative contraindication to kidney transplantation, and is screened by a "virtual cross-match" with increased frequency.
2. Methods to expand living kidney donation include kidney paired exchange and incompatible kidney transplantation.
3. Methods to expand the deceased-donor pool of kidneys include the use of donation after cardiac death donors, high kidney donor profile index kidneys, hepatitis C+ kidneys, and HIV+ kidneys.
4. The etiology of kidney disease resulting in end-stage failure, and the necessity for transplantation is led by glomerulonephritis, diabetes, and hypertension.
5. As a result of the increasing wait times across the United States, the presence of a cardiovascular system which will tolerate a major operation is the biggest barrier to successful transplantation.
6. The kidney transplant is heterotopically placed in the extraperitoneal iliac fossa.
7. Surgical complications of kidney transplantation include vascular, urologic, lymphocele, and wound problems.
8. Hyperacute rejection is humorally mediated by preformed anti-HLA antibodies. Hyperacute rejection occurs within minutes to hours following reperfusion of the kidney.
9. Acute cell-mediated rejection most typically occurs between 1 week and 3 months following transplantation.
10. Chronic rejection leads to loss of graft function over the course of months to several years.

INTRODUCTION

Kidney transplantation has evolved to become the preferred therapeutic modality for patients with end-stage renal failure. Improved patient survival and quality of life as compared with dialysis has been established, with cost-effectiveness achieved after a minimum of 18 months of allograft function. The importance of minimizing time on dialysis, compounded by the exponential growth of patients on the wait list, has led to several strategies to increase the number of deceased- and living-donor organs in an effort to decrease waiting time and mortality on the wait list. These new strategies have been the focus of clinical research in kidney transplantation and will be discussed in this chapter. Other important topics that will be reviewed include immunologic considerations specific to kidney transplantation; preoperative assessment of kidney allograft recipients; the standard surgical approach in kidney transplantation and advances in laparoscopic technology for the donor; current strategies in immunosuppression; management of the technical and immunosuppressive complications; new kidney allocation policies affecting wait list management; and future trends.

IMMUNOLOGY OF RENAL TRANSPLANTATION

The immunologic response to allografted tissue is well defined and under the influence of both T- and B-cell–derived reactions. The cells and cytokines responsible for rejection vary with time post transplant (hyperacute, acute, and chronic rejection) and have a differential response to currently available immunosuppressive agents.

The HLA system is made up of well-defined antigens present on most cell types that are genetically determined for each patient and are termed the *major histocompatibility complex*. These genes reside on chromosome 6 and are distributed in a mendelian fashion to offspring. The HLA system includes several loci, but the most commonly characterized are the HLA-A, HLA-B, and HLA-D regions. Given that each human has two alleles for each locus, there are six potential HLA antigens of clinical significance. These are characterized using tissue-typing techniques and can be used to determine the degree of matching between a donor and potential recipient, that is, one- to

six-antigen match. Improved graft survival is seen when the degree of matching reaches the six-antigen level.

Class I antigens include the HLA antigens A, B, and C, whereas class II antigens include the DP and DR loci. Class I antigens act as targets for cytotoxic T lymphocytes, and class II antigens are important for antigen presentation. Class II antigens are also responsible for triggering lymphocyte proliferation in the mixed lymphocyte culture system.

1 Before a kidney transplant is undertaken, histocompatibility of the donor and recipient is determined. HLA matching is not a prerequisite for proceeding with transplantation. However, the presence of recipient antibodies directed against the donor HLA usually precludes transplantation. Standard pretransplant workup consists of several assays that will help to determine future compatibility with a potential donor. First, donors and recipients undergo tissue typing, which involves characterization of their respective HLA type. Secondly, recipient serum is tested against a panel of antigens that contains the known HLA types, to identify anti-HLA antibodies. The sensitivity for detecting anti-HLA antibodies continues to improve and newer technology uses single antigen beads to detect antibodies against a specific HLA antigen. The amount of reactivity that a potential recipient has against a panel of HLA antigens is indicative of the degree of sensitization. Based on the number of anti-HLA antibodies detected, a calculated percent reactive antibody (cPRA) can be estimated. A cPRA of 70% would suggest that the potential recipient would have anti-HLA antibodies against 70% of the potential-donor pool. Sensitization to HLA antigens occurs as a result of previous exposure to foreign HLA antigen either from pregnancy, previous blood transfusion, or a previous organ transplant. A patient who is highly sensitized is more difficult to transplant because of the greater likelihood of having antibodies to a potential donor.

The last critical test performed prior to transplantation is commonly known as the *final cross-match*. This final cross-match can be performed in several ways. Recipient serum samples collected at different times are mixed with donor lymphocytes in a culture system. This assay will detect preformed cytotoxic antibodies that would result in a hyperacute rejection if the transplantation were performed (see Rejection, later). A more sensitive method of detecting these antibodies uses a fluorescent-activated cell scanner cross-match and is commonly used when evaluating potential recipients who

are highly sensitized or receiving second transplants. Many transplant centers have adopted "virtual cross-matching" based on the detection of anti-HLA antibodies present in a given recipient. The most sensitive technology will be used to detect the presence of anti-HLA antibodies in a given recipient. Based on these antibodies, each recipient will have a list of unacceptable donor antigens. Compatibility with each donor will be determined in the absence of the serum-based final cross-match by eliminating a potential donor based on the presence of unacceptable antigens. This strategy facilitates an expedited transplant and minimization of cold ischemia times, as it avoids the additional time and expense associated with the serum-based final cross-match. The use of the virtual cross-matching is particularly beneficial for determining potentially compatible kidneys allocated to highly sensitized recipients, a scenario occurring with increasing frequency as a result of the new kidney allocation algorithm initiated in December 2014.[1]

In general, kidney transplantation is done between ABO-compatible donor and recipients using the same guidelines as for blood transfusion. However, several groups have reported successful kidney transplantation across ABO blood group barriers, using aggressive pretransplant immunosuppression, plasmapheresis to decrease anti-ABO titers, and in some cases splenectomy.[2,3] This strategy has been implemented in the United States as a result of the marked increases in the waiting times for blood group O and B recipients.[4] However, ABO-incompatible transplants in the United States have not enjoyed the same success as in Japan, where ABO-incompatible living-related donor transplants are the only option for transplantation. Based on the better results observed in ABO-compatible transplants in the United States, most centers have opted to participate in the paired exchange program (see below) rather than proceed with ABO-incompatible transplants. The exception to this is transplantation of blood type A2 and A2B–deceased-donor allografts to blood type B recipients, provided the anti-A titers are acceptably low. In this circumstance, outcomes are comparable to ABO-compatible transplants, and this exception has become part of the United Network for Organ Sharing (UNOS) allocation system in order to decrease the length of waiting times for Blood Type B recipients.[5]

THE DONOR POOL: LIVING DONORS, DECEASED DONORS, AND DONATION AFTER CARDIAC DEATH

There is marked improvement in graft survival for both living and deceased donors when a transplant can be completed before the initiation of dialysis.[6] The significantly better outcomes achieved with preemptive transplantation and minimizations of dialysis times have given rise to several strategies to increase the number of available kidneys.

Living Donors

The first long-term success in kidney transplantation over 60 years ago involved a live-donor transplant between twin brothers. Introduction of laparoscopic donor nephrectomy further revolutionized the field. Despite initial concerns about the safety and efficacy of the laparoscopic technique for the donor procedure, morbidity and mortality rates (0.03%) remain low and comparable with those of the open technique.[7,8]

The evaluation of a potential living kidney donor includes a comprehensive medical, surgical, and psychosocial evaluation. Diabetes, hypertension, and cardiovascular disease generally rule out a potential donor.[9] Testing of a potential donor also involves anatomic definition of the two kidneys and is typically done with either a computed tomography angiogram or MR angiogram, both of which avoid the arterial needlestick and catheters associated with a conventional angiogram. The results of these studies are used to detect any anatomic abnormalities that would exclude a donor and to decide which kidney will be removed. In general, the left kidney is favored for transplant because it has a longer renal vein.

2 Several strategies are currently being considered to increase the frequency of living donation. Potential donors with well-controlled hypertension on a single antihypertensive agent are being considered, although this remains controversial. A national exchange system is currently being designed that matches living donors who were incompatible with their intended recipient (either because of ABO incompatibility or a positive cross-match test) with other recipients with incompatible living donors. Such

exchange systems have already been successful on a regional and national level, and extending this to a single national system will permit many more successful exchanges and further expand the living-donor pool.[10] In addition for those pairs unable to identify a compatible transplant via paired exchange, an important strategy currently being implemented in the United States, as well as internationally, involves the use of desensitization protocols to facilitate transplantation across a known positive anti-HLA cross-match. These protocols may involve pretransplant infusion of gamma globulin in the recipient to bind circulating antibody, plasmapheresis of the recipient to remove circulating antibody, and/or the use of agents, such as rituximab, to decrease antibody production.[11] Lastly, a hybrid approach for the highly sensitized recipient with a cross-match–incompatible donor could involve finding a kidney that is "less incompatible" through an exchange program, and then converting the positive cross-match to a compatible cross-match with desensitization techniques.

Deceased Donors

Procurement of kidneys from brain-dead deceased donors has not increased at the same pace as the rapid growth of the national wait list. Although most deceased donors are brain-dead, there has been an increased use of kidneys from donors who do not meet the strict definitions of brain death but have cardiopulmonary support withdrawn because of a severe brain injury or high spinal cord injury, with little hope of living without the use of ongoing mechanical ventilation and/or the possibility of existing in a persistent vegetative state. Organs are recovered after withdrawal of support, once the heart stops beating, hence the terminology of *donors by cardiac death* or *DCD donors*. Usually support is withdrawn in a controlled setting so that the time of warm ischemia and poor organ perfusion can be minimized. Minimizing the time from cessation of the heart to perfusion of organs with preservation fluid requires an experienced procurement team, and the successful use of these organs is dependent on rapid procurement. [3] Kidneys procured from DCD donors are proving to be an important source of donor kidneys, and studies have demonstrated comparable graft success between kidneys procured from DCD donors and brain-dead donors, although the incidence of initial delayed graft function is higher in DCD

kidneys. The percentage of DCD donors in the United States has progressively increased over the last decade and presently represents about 10% of deceased donors.[12]

Placement of deceased-donor kidneys is guided by a series of complex allocation rules established by the UNOS. Donor kidneys are now assigned a kidney donor profile index (KDPI) score which is used to define donor organ longevity with a lower score corresponding to better-predicted survival of the kidney (better-quality kidney). The new allocation system attempts to match the predicted longevity of the deceased-donor organ quantified by the KDPI with the estimated posttransplant survival (EPTS) of the recipient. The top 20% of kidneys (KDPI scores less than 20%) will be transplanted to recipients with longest EPTS. In the new allocation scheme, the highest KDPI kidneys (KDPI >85%) will be allocated to recipients who have consented to receive an expanded criteria donor (ECD). Highly sensitized patients will receive a significant number of allocation points, so if in the rare event that a compatible kidney becomes available, that kidney will be allocated to the compatible highly sensitized recipient. Highly sensitized recipients with cPRAs of 99% or 100% will get access to the regional and national lists, respectively, to increase the chances of finding a compatible kidney. Finally, waiting times will be backdated to the time of the initiation of dialysis, although patients can still be listed when the glomerular filtration rate drops below 20 mL/min.[13]

Further Strategies for Increasing the Number of Donor Kidneys

Many of the unique approaches for increasing the number of potential living donors, including kidney paired exchange and incompatible transplantation, have been previously discussed in the chapter. Additional strategies include programs aimed at separating the advocacy role from the recipient and including programs such as the Johns Hopkins Champion Program and the University of Alabama at Birmingham Living Donor Navigator Program. Both programs have demonstrated early success, but widespread adoption of such programs remains limited.[14,15]

Further strategies have recently been implemented to expand the number of kidneys procured from deceased donors. In addition to the use of kidneys from DCD donors described earlier, transplant centers have considered using kidneys from donors that are less than optimal (KDPI ≥85%), previously designated as ECDs. These kidneys clearly had a shorter survival compared to younger, healthier donors and therefore potential recipients are required to give consent to receive these kidneys before transplant. The advantage to certain patient groups who were predicted to do poorly on dialysis (i.e., older patients or patients with diabetes) was an increased overall patient survival if they received a timely transplant rather than wait a prolonged time on the list. As mentioned above, the new allocation system also affords the opportunity for blood group–incompatible kidney transplantation in select scenarios, specifically blood group A, subtype A2 donors into blood group B recipients, with the overall goal to increase access to transplantation for ethnic minorities, which have a disproportionate number of blood group B donors. Most recently, in the era of direct-acting antiviral therapy with 99% sustained viral response, kidneys from hepatitis C donors are being offered to select hepatitis C–naive recipients.[16] Initial results are promising, but future work is needed. Finally, an additional source of potential deceased-donor kidneys is now available to HIV+ candidates. With the passage of the HIV Organ Policy Equity Act, HIV+ individuals may donate their organs upon their death. HIV+ to HIV+ kidney transplantation, which is still performed under research protocols in the United States, has met with good success and excellent long-term outcomes abroad.[17]

THE TRANSPLANT PROCEDURE

Recipient Preoperative Assessment

4 The etiologies of kidney disease resulting in end-stage failure and the necessity for transplantation are led by glomerulonephritis, diabetes, and hypertension (**Table 36.1**).[12] Because of the high incidence of cardiovascular disease associated with many of these conditions, most notably diabetes, a careful assessment of the cardiovascular status of the potential recipient is critical. 5 As a result of the increasing wait times across the United States,

the presence of a cardiovascular system which will tolerate kidney transplantation is the biggest barrier. For patients at risk, this assessment should include at a minimum an echocardiogram and an exercise or pharmacologic stress test as a screen for reversible ischemia requiring cardiac catheterization. Controversy remains with regard to the accuracy of noninvasive studies in terms of identifying significant disease of the coronary arteries, particularly in diabetic patients. Nonetheless, for most centers this remains the standard screening strategy, and updated studies should be obtained within 1 year of the transplant procedure. If either coronary artery bypass or stenting has taken place in preparation for renal transplantation, follow-up angiograms and/or stress tests should be repeated within 1 to 2 years of the actual transplant. If stenting of the coronary arteries is required, patients with drug-eluting stents will commonly require clopidogrel (Plavix) for an extended period of time. Although controversial, many centers will proceed with transplantation while recipients are on Plavix, after a waiting period of 6 months following the stenting procedure.

Although the evaluation of potential recipients is focused on the assessment of cardiovascular status, further studies must exclude malignancies and infections that would contraindicate transplantation and immunosuppression. Potential kidney recipients who are infected with hepatitis C should be evaluated by a hepatologist to determine the risks of immunosuppression causing progression to end-stage liver disease. Potential kidney recipients with evidence of advanced liver disease should be evaluated for a combined liver and kidney transplant. For patients with less advanced liver disease, consideration could be given to treatment with newer antiviral drugs before proceeding with kidney transplantation to provide the opportunity for viral clearance.[18] Kidney transplantation was previously contraindicated in people with HIV infection secondary to concerns of exacerbating an already immunologically compromised state. Recent advances in antiretroviral therapy and the ability to provide effective prophylaxis against opportunistic infections have prompted several centers to perform transplantation in people with end-stage renal disease and HIV infection. Early results suggest that progression of HIV to AIDS has not been seen following transplantation and immunosuppression, with early allograft success rates comparable to those in non–HIV-positive recipients.[19] Potential

patients with a previous history of tuberculosis or conversion to purified protein derivative positivity should be evaluated for active disease.

Colonoscopy, mammography, and Pap smear should be performed as dictated by age-specific standard guidelines. For most malignancies, a disease-free interval of 5 years is recommended before kidney transplantation. Controversy exists about pretransplant waiting times for certain malignancies, such as early-stage breast cancer or prostate cancer, and some centers will not require any pretransplant waiting. Similarly, pretransplant wait times are probably not necessary for nonmelanoma skin cancers and early-stage renal cancers. For patients with congenital abnormalities as the cause of renal failure, a complete workup of the genitourinary systems is necessary, including urodynamics and voiding cystourethrograms. These studies are particularly important in children with end-stage disease resulting from posterior urethral valves, to ensure that the bladder will serve as an adequate conduit for the kidney transplant. For patients with severe reflux disease and chronic pyelonephritis, native nephroureterectomy may be required to prevent posttransplant infection secondary to chronic reflux into the native ureters. For patients with inadequate bladder capacity and function, pretransplant-reconstructive procedures such as ileal augmentation or ileal conduits may be required.

Table 36.1 Etiology of Renal Disease as Indications for Renal Transplantation, Ranked in Order of Prevalence

Diabetes mellitus (types I and II)
Hypertension
Polycystic kidney disease
IgA nephropathy
Chronic glomerulonephritis
Focal sclerosis
Systemic lupus
Membranous glomerulonephritis
Pyelonephritis
Focal segmental glomerulosclerosis
Congenital obstructive uropathy
Nephritis
Alport syndrome
Hypoplasia, dysplasia
Wegener granulomatosis
Postinfectious glomerulonephritis
Obstructive uropathy
Hemolytic uremia
Membranoproliferative glomerulonephritis
Goodpasture syndrome
Membranous nephropathy
Analgesic nephropathy
Prune belly syndrome
Medullary cystic disease

Henoch–Schönlein purpura
Nephronophthisis
Scleroderma
Sickle cell anemia
Amyloidosis
Oxalosis

Adapted from Cecka JM. The OPTN/UNOS renal transplant registry. In: Cecka JM, Terasaki PI, eds. *Clinical Transplants 2003*. Los Angeles, CA: UCLA Immunogenetics Center; 2004:1–12, with permission.

For patients with suspected clotting disorders based on a previous history of thromboembolic events (frequent clotting problems with dialysis access) or diseases associated with an increased frequency of clotting disorders (i.e., lupus), a hematologic workup is necessary to determine the necessity for anticoagulation at the time of the transplant. The length of time for anticoagulation is dependent on the severity of the clotting disorder and a history of a previous thrombotic event. This workup should include a determination of serum levels of protein C, protein S, anticardiolipin antibody, factor V Leiden, antithrombin III levels, and the G20210 A prothrombin gene mutation.

Living-Donor Nephrectomy: Open and Laparoscopic

A living kidney donor operation is a unique surgical procedure for two reasons. First, the donor has no medical reason to be in the operating room, and the process is driven only by his or her willingness to help another person with the gift of donation. Second, the removed tissue must be in perfect condition because it will be reimplanted into the recipient. These two features, therefore, necessitate that the donor operation is done safely and well. The original donor operation was done through a generous flank incision, allowing for good exposure and careful dissection of the renal vessels. Unfortunately, this flank approach generally left a large incision,

with its accompanying morbidity, pain, and sometimes adverse cosmetic result. The development of the laparoscopic procedure to remove kidneys has revolutionized the field. With the explosive growth and dissemination of this procedure, it has now become the standard for donor nephrectomy.

The procedure is most commonly done through a transperitoneal approach, although some surgeons prefer to remain retroperitoneal. Once the operative space is expanded with carbon dioxide gas and the scope is inserted, most commonly two to three additional ports are placed to allow for the passage of instruments to dissect the kidney (**Fig. 36.1**). Some centers also favor the use of a gastight "hand port," which allows placement of the surgeon's hand in the operative space to assist in exposure and to have available if sudden bleeding is encountered. Once the kidney vessels are transected and the vessel stumps are controlled by laparoscopic staples, the kidney can be removed through a 2- to 3-in incision, which can be placed in a position that leaves minimal scarring and avoids cutting muscle tissue. Most commonly this is via a Pfannenstiel incision, and recently the use of natural orifice approaches has been described. Additionally, some centers have adopted the use of a robotic-assisted technique, to facilitate the dissection of important vascular structures. Donors who undergo the laparoscopic procedure typically have reduced pain medicine requirements, have a slightly shorter hospital stay, and are able to return to their usual activities sooner.[7,8]

The safety of this relatively new procedure has been established, in addition to the demonstration that kidneys recovered through a laparoscopic approach function as well as kidneys removed in an open operation. There has been an increased interest in live donation, coincident with the introduction of the laparoscopic procedure, suggesting that this procedure has removed some of the disincentives of the donation process.

Recipient Operative Procedure

6 The kidney transplant is heterotopically placed in the extraperitoneal iliac fossa. Attention to detail is imperative to optimize immediate graft function and avoid technical complications resulting in loss of the kidney transplant.

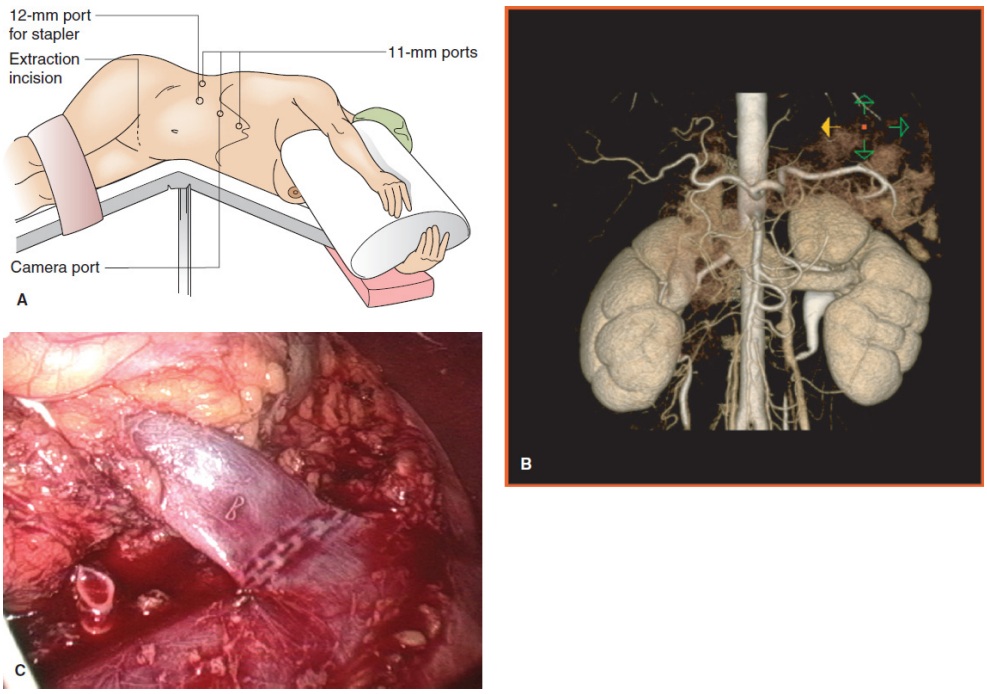

Figure 36.1 **A:** The laparoscopic donor procedure is performed with the donor in a lateral position, typically using three to four ports, with extraction of the kidney through a 6- to 8-cm incision. **B:** Preoperative computed tomography angiogram revealing the arterial and venous anatomy. **C:** Intraoperative photograph of laparoscopic view of right kidney just prior to transection of the renal vein. The artery has already been divided.

The operation is initiated by exposure of the iliac fossa through a curvilinear incision and can be done on either the right or left side. The incision extends from 1 cm above the symphysis pubis to approximately 2 cm medial to the anterior iliac spine (**Fig. 36.2**). The fascia is divided along the lateral border of the rectus sheath, and the contents of the peritoneal cavity are reflected cephalad and medially, exposing the iliac vessels in the retroperitoneum. Lymphatics overlying the iliac vessels are ligated and divided to prevent the development of lymphoceles. In males, the spermatic cord is secured with a vessel loop and can be retracted away from the operative field. In females, the round ligament is suture ligated and divided. The inferior epigastric artery and vein are typically divided to prevent potential compression of the transplanted ureter. Placement of a mechanical retractor should avoid compression of the iliac artery and vein as well as the femoral nerve to prevent neuropraxias.

The living- or deceased-donor kidney is inspected for the presence of multiple vessels, duplication of the urinary collecting system, and parenchymal abnormalities. The artery and vein are dissected from surrounding structures to provide the necessary length for transplantation. In the case of multiple arteries, a decision must be made as to whether to perform ex vivo reconstruction to achieve a single implantable conduit versus implanting the vessels separately. This decision is in part dependent on the quality of the recipient vessels and an assessment as to whether the anastomosis of multiple vessels directly into the recipient would require an unacceptable period of warm ischemia to the kidney. In general, in an adult the anastomosis of the renal artery and vein are performed in an end-to-side fashion to the external iliac vessels, although occasionally the presence of atherosclerotic disease requires transplantation to the common iliac vessels. In children who weigh less than 20 kg, or for third transplants in adults, an intraperitoneal approach is used and the vascular anastomoses are frequently performed to the aorta and inferior vena cava. For kidneys from deceased donors, a Carrel patch of aorta is used to prevent stenosis and to provide a common patch for multiple arteries. Warm ischemia time should be minimized to prevent delayed graft function. Ensuring adequate intravascular volume and stable hemodynamics at the time of reperfusion is extremely important to achieve optimal function of the transplant.

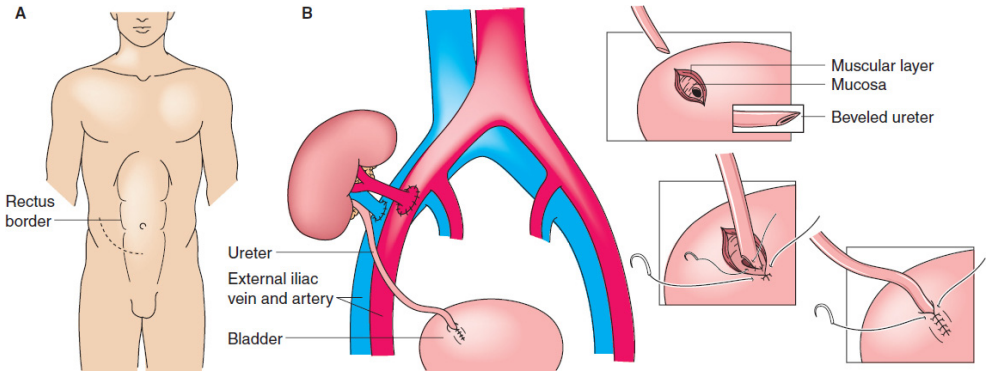

Figure 36.2 **A:** Curvilinear iliac fossa incision used for the kidney-transplant recipient procedure. **B:** Vascular anastomoses completed between the recipient external iliac artery and vein and donor renal artery and vein. *Insets:* ureteral anastomosis performed using the external ureteroneocystostomy technique.

The reimplantation of the ureter is most frequently performed through an extravesicular technique. Following positioning of the revascularized kidney

in the iliac fossa and assurance of hemostasis, the ureter is shortened to permit a tension-free anastomosis with adequate blood supply to the distal ureter. In men, the ureter is placed under the spermatic cord to prevent ureteral obstruction. The bladder is distended to identify a suitable area for ureteral implantation on the dome of the bladder, and a cystotomy is made at this site. An anastomosis between the mucosa of the bladder and transplanted ureter is constructed using an absorbable suture to prevent stone formation. A second layer of the bladder musculature is closed over the distal portion of the ureter to prevent reflux during micturition.

There are alternative techniques to reimplant the ureter, including the Politano–Leadbetter transvesical ureteroneocystostomy. This technique involves tunneling the ureter through the bladder wall from the inside of the bladder. This technique is still preferred by some surgeons who believe the long-term prevention of reflux is superior with the transvesicular approach. However, this technique requires a second cystotomy, and posttransplant hematuria is more common than with the extravesicular technique. A third technique for ureteral implantation in recipients with normal native ureters is ureteroureterostomy over a double-J stent. In general, this technique is reserved as a salvage procedure for reimplantation of transplanted ureters with distal strictures secondary to ischemia. It can also be used as a primary technique if there are questions regarding the blood supply to the distal ureter at the time of transplant. This technique is preferred if the donor ureter was damaged or inadvertently stripped of its blood supply at the time of procurement but is dependent on the availability of normal native ureters to serve as an adequate conduit. The routine placement of a double-J stent is center dependent, with some centers reserving placement of the stent for challenging extravesicular anastomosis to poor-quality bladders.

The surgical procedure has changed little over the last 60 years, with the exception of limited reports of implantation of the kidney with the use of a robotic-assisted laparoscopic approach. The purported advantage is smaller incisions, which appear to have an advantage in obese patients, avoiding some of the frequent wound complications. Widespread adaptation of this technique has not occurred.[20]

COMPLICATIONS

Early Graft Dysfunction

Most kidneys begin to function immediately after implantation, especially in the case of a living donor. When the initial function results in only a slow drop in serum creatinine, the diagnosis of slow graft function is made. When dialysis is needed in the first week because of poor function, the diagnosis of delayed graft function is made. Delayed graft function typically occurs in 15% to 30% of deceased-donor transplants. The diagnosis of slow graft function or delayed graft function is important to establish because other problems, such as rejection, vascular occlusion, or ureteral obstruction, can also result in low urine output and need for dialysis. These other causes must be eliminated before the diagnosis of slow graft function or delayed graft function can be made.

In the immediate postoperative period, careful attention to fluid status is critical. In cases of immediate graft function, fluid orders should include replacement for urine output as well as a maintenance fluid rate. This approach ensures that the patient does not become volume depleted and compromise perfusion to the new kidney. In cases of delayed graft function, fluid should be restricted and dialysis instituted when electrolyte imbalance or fluid overload are evident.

A decrease in urine output in the early postoperative period requires immediate diagnostic and therapeutic intervention. A stepwise algorithm to assist in diagnosing the etiology of oliguria is shown in **Figure 36.3**. Once mechanical obstruction of the indwelling Foley catheter has been excluded by irrigation, the volume status of the patient should be assessed. Fluid replacement to restore intravascular volume should be initiated in the volume-depleted patient.

Radiologic evaluation using various imaging techniques is required if urine output remains low in the face of adequate volume status. Ultrasonography is most helpful to diagnose ureteral obstruction caused by technical complications at the anastomosis or fluid collections that may be obstructing the ureter by extrinsic compression. With the addition of duplex and color Doppler imaging, blood flow to the kidney can be evaluated and technical problems with the vessels can be assessed. Nuclear medicine

techniques are also valuable for assessing renal function. Technetium-99m diethylenetriamine pentaacetic acid (DTPA) and iodine-131 iodohippurate (Hippuran) are the two major radionuclides used in the evaluation of renal allograft function. DTPA renal scans evaluate the vascular flow pattern of the kidney as well as the gross anatomy of the ureter and bladder. Scans are performed over 30 minutes, with uptake of contrast within 6 seconds indicating adequate flow to the graft. Peak activity in the parenchyma should be reached within 2 minutes, followed by a gradual decline in radioactivity in the renal parenchyma and an increase in radioactivity in the urinary collecting system and bladder. Iodine-131 iodohippurate scans are more sensitive in evaluating renal function. Peak activity is also reached in 2 to 4 minutes, with gradual decline over the next 30 minutes. In rejection, acute tubular necrosis and drug toxicity poor uptake and poor excretion are the typical findings with a nuclear medicine scan.

If these imaging techniques do not provide an explanation for poor urine output, the diagnosis of delayed graft function is made. Immunosuppression can then be adjusted to minimize or avoid the calcineurin inhibitors, which can prolong the recovery from delayed graft function, and also to initiate antibody therapy to protect the kidney from rejection. The combination of delayed graft function and early rejection is clearly associated with worse outcome in the long term, and an early biopsy of the kidney that is functioning poorly is helpful to diagnose rejection and guide therapy.

Technical Complications

7 Most surgical complications are experienced in the immediate postoperative period. The two main types of complications can be classified as vascular and urologic.

Renal artery thrombosis is a rare complication occurring in about 1% of transplants. The risk of this complication is higher with size mismatch of donor renal artery and recipient internal iliac artery when an end-to-end anastomosis is performed, in kidneys with multiple renal arteries, in kidneys traumatized because of rough handling, and in the presence of an unidentified renal artery intimal flap. Sudden loss of urinary output, not the result of an obstructed Foley catheter or inadequate vascular volume, should necessitate a workup with duplex Doppler ultrasound. Loss of signal is indicative of no

flow to the kidney. Alternatively, a nuclear medicine renal scan is informative, with lack of isotope uptake by the kidney indicating no blood flow. Prompt return to the operating room for correction of a technical problem is imperative, but often the diagnosis is not made quickly enough to salvage the kidney.

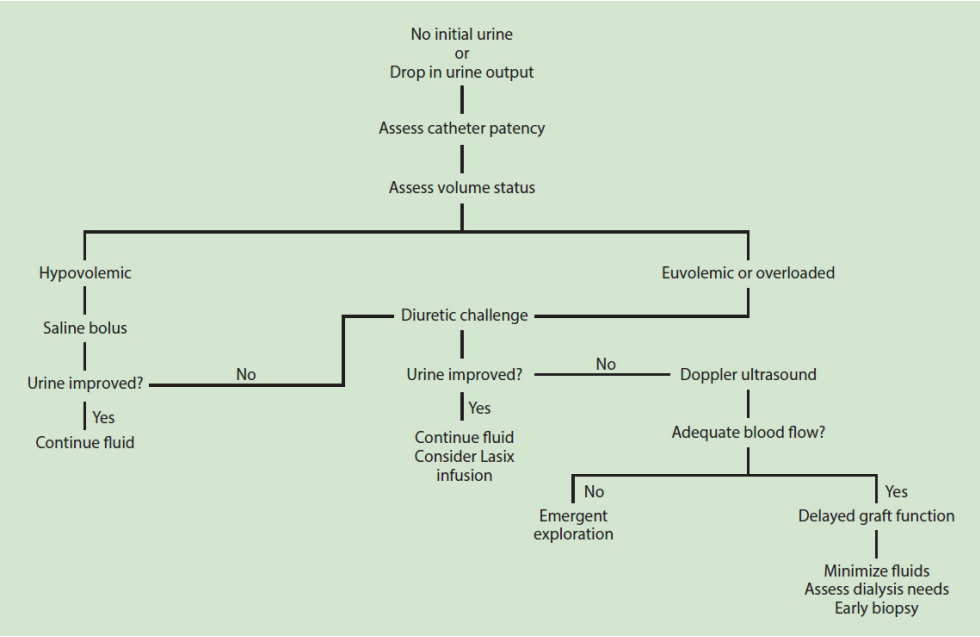

Figure 36.3 Stepwise approach to the management of decreased low urine output post transplant.

Renal artery stenosis occurs in up to 15% of transplanted kidneys. Difficult-to-control hypertension should suggest the possibility of stenosis. Diagnosis with renal duplex ultrasound followed by arteriography to better define the anatomy and degree of stenosis should be done before operative repair or angioplasty. Initial success rates for both methods are similar (75% to 80%), but the restenosis rate following angioplasty is not well defined. Anastomotic strictures respond less well to angioplasty and probably should be repaired by operative intervention.

Aneurysms that occur in the renal artery are either pseudoaneurysms at the anastomotic site or mycotic aneurysms secondary to bacterial or fungal infection. A rapidly expanding, tender pulsatile mass in the region of the kidney suggests a mycotic aneurysm. Arteriography is confirmatory for diagnosis. Treatment consists of appropriate antibiotics and removal of the transplanted kidney.

Venous complications are less frequent, with thrombosis occurring in 1% to 4% of transplants. Causative factors include intimal damage during retrieval, kinking at the iliac vein anastomosis, or pressure secondary to a lymphocele, urinoma, or hematoma. Occasionally, severe rejection can result in venous occlusion. Heparin infusion for incomplete occlusion and transplant nephrectomy for complete occlusion are the indicated therapies. Occasionally, graft salvage is possible if the diagnosis is made before progression of clot into the kidney itself. The classic sign of new-onset hematuria may be an early hint of a renal vein problem and should lead to an ultrasound.

Urologic complications include ureteral obstruction, urinary fistula, or bladder leak. These complications all present with decreased urine output and a rise in serum creatinine. With a urine leak, pain in the region of the transplant may be severe. Mechanical obstruction of the Foley catheter must first be eliminated. Ureteral obstruction occurs in 1% to 9% of transplants, and diagnosis can be made with ultrasonography demonstrating hydronephrosis. A leak is usually diagnosed with a nuclear medicine renal scan. Further definition of a leak or stricture can be obtained via an antegrade pyelogram (**Fig. 36.4**). Early obstruction of the transplant ureter at the site of the bladder anastomosis may respond to internal stenting. Late strictures usually require reoperation, and urine and blood polymerase chain reaction for the polyoma virus should be done in that circumstance, because polyoma viral infection can lead to ureteral stricture. The surgical correction of a ureteral stricture may require reimplantation of the ureter into the bladder, the creation of a Boari flap, or the use of the recipient's native ureter for a ureteroureterostomy (**Fig. 36.5**).

IMMUNOSUPPRESSION, REJECTION, AND IMMUNOSUPPRESSIVE COMPLICATIONS

Immunosuppression

Major advances in the ability to block immune-mediated destruction of the kidney have taken place in the past few years, resulting in a significant decrease in the incidence of acute rejection and improvement in long-term

allograft survival rates.[19] This advance is the result of numerous agents that have been added during the past decade to the immunosuppressive armamentarium of prednisone, azathioprine, and cyclosporine A. These agents include tacrolimus, mycophenolate mofetil, sirolimus, and everolimus (mTOR inhibitors), anti–interleukin-2 receptor blockers, antithymocyte globulin (a polyclonal anti–T-cell agent), rituximab (an anti-CD20 monoclonal agent), and most recently costimulatory blockade with CTLA4-Ig. The addition of various newer drugs targeting different pathways in the alloimmune cascade has permitted the development of regimens that are less dependent on the calcineurin inhibitors or prednisone.[21]

Figure 36.4 Percutaneous nephrostogram revealing a urine leak (*arrow*) from the ureterovesical anastomosis.

Newer strategies in the immunosuppressive pipeline are targeted to block costimulatory pathways; signaling pathways that activate T cells and T-cell proliferation; and trafficking and recruitment of immune cells. The most promising biologic agents targeted to block the costimulatory pathways include a second-generation CTLA4Ig (LEA29Y), a humanized anti-CD11a (anti-LFA1), and a humanized anti-B7.1/B7.2. Promising agents designed to

block T-cell activation and proliferation are the inhibitors of the Janus protein tyrosine kinase (JAK3) and the leflunomide analog FK778. Finally, drugs to block the trafficking and recruitment of immune cells are antagonists against the chemokine receptors CCR1, CXCR3, and CCR5. The chemokine antagonists have been effective in experimental transplantation and will likely be transitioned to clinical trials in the near future.[22]

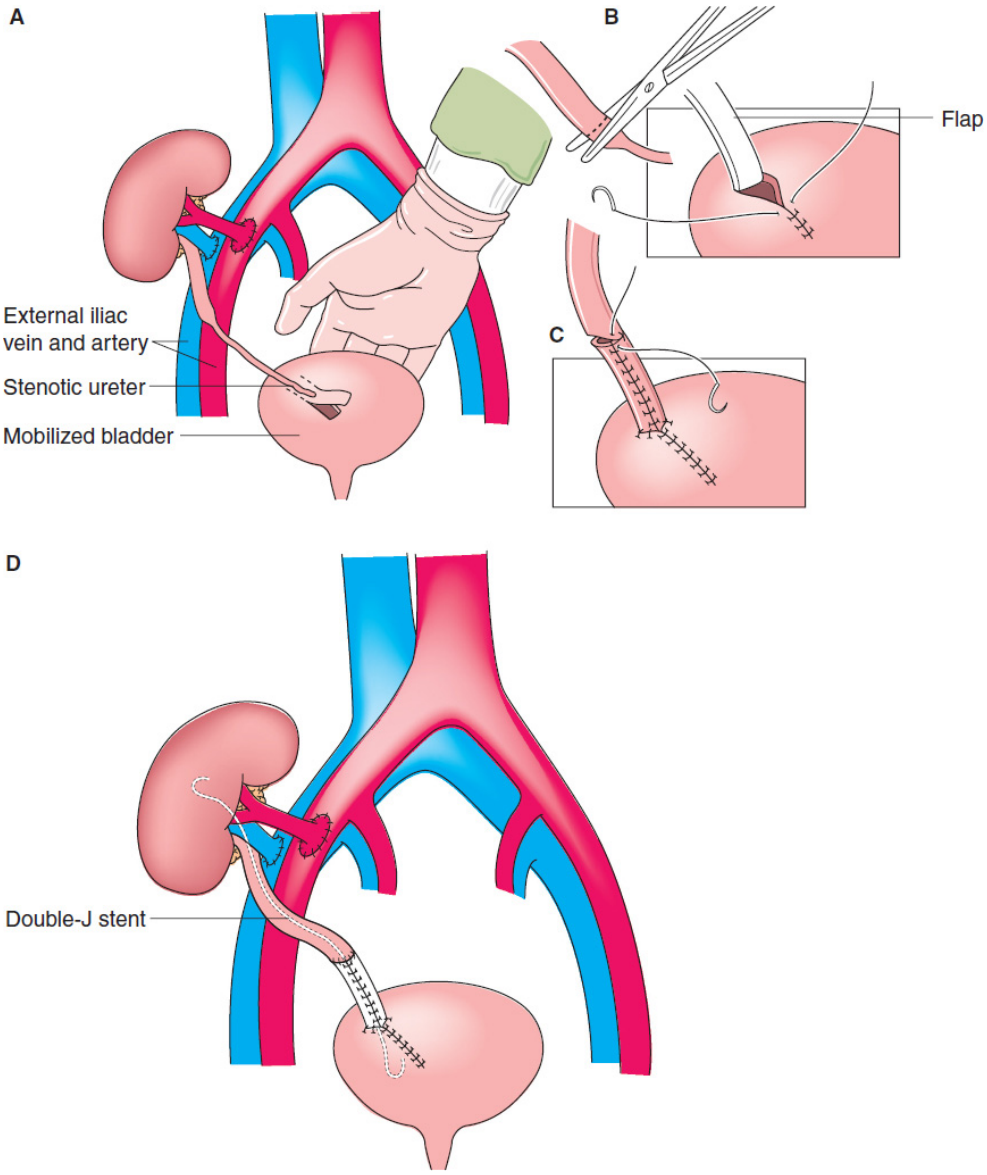

Figure 36.5 **A:** Reconstruction of a stenotic donor ureter, showing resection of the stenotic segment and mobilization of the bladder. **B–D:** A Boari flap is constructed from a tabularized segment of bladder wall and anastomosed end-to-end to the proximal donor ureter.

Rejection

8 Hyperacute rejection is extremely rare and is humorally mediated by preformed anti-HLA antibodies. Hyperacute rejection occurs within minutes to hours following reperfusion of the kidney, whereas classic cell-mediated rejection typically does not occur until 1 to 2 weeks after the transplant. In hyperacute rejection, the anti-HLA antigens bind to the vascular endothelium of the kidney transplant, resulting in activation of the complement cascade and rapid graft thrombosis. The kidney appears blue-black with poor tissue turgor despite adequate blood flow. The characteristic histologic appearance includes the triad of polymorphonuclear leukocytes in the glomerular capillary loops, fibrin deposition, and platelet thrombi. The kidney cannot be salvaged, and a transplant nephrectomy is necessary. The presence of anti-HLA antibodies should be detected in the pretransplant cross-match, and with the sensitivity of current immunologic assays, hyperacute rejection is usually a result of technical or clerical errors in the cross-match procedure. A more common and less intense form of humoral rejection occurring within a few days of transplantation is a result of reactivation of memory B cells following reexposure to alloantigen. The histologic findings are defined by positive C4d staining on vascular endothelium, although lymphocytic infiltrates consistent with classic cell-mediated rejection can be present. Treatment of this aggressive rejection can include plasmapheresis, the anti–B-cell agent rituximab (anti-CD20 monoclonal antibody), and polyclonal antilymphocyte preparations (antithymocyte globulin).

9 Classic acute cell–mediated rejection typically occurs between 1 week and 3 months following transplantation. Most patients with rejection episodes present with decreasing urine volumes and increases in serum creatinine values. Low-grade fever and allograft tenderness may be present, but significant physical symptoms frequently are absent. Immediate workup of increasing serum creatinine should be initiated, beginning with an ultrasound to rule out ureteral obstruction or technical vascular complications as the cause of the deteriorating function. Similarly, toxicity from calcineurin inhibitors needs to be determined by checking drug levels. A percutaneous kidney biopsy is performed to confirm rejection. The severity of the rejection episode is based on the presence of lymphocytes in renal tubules (tubulitis) and vascular endothelium (vasculitis). Mild rejection

is generally treated with pulse corticosteroids and maximizing the maintenance immunosuppression to ensure therapeutic levels of calcineurin inhibitors. More severe rejection with both tubulitis and vasculitis, as well as steroid-resistant rejection, is treated with antilymphocyte antibody preparations, most frequently with rabbit polyclonal antilymphocyte preparations. If the rejection episode occurred while the patients had therapeutic drug levels, maintenance therapy is frequently altered following the antibody therapy. For example, if maintenance therapy consisted of cyclosporine A, the calcineurin inhibitor could be switched to tacrolimus. Other potential strategies include the addition of an mTOR inhibitor to the immunosuppressive regimen, particularly for cases where there is evidence of calcineurin inhibitor toxicity on biopsy.

Each rejection episode takes a toll on long-term function of the kidney transplant. Even well-controlled acute rejection episodes initiate a cascade of events leading to interstitial fibrosis and proliferative changes affecting the vascular endothelium. 10 These histologic and progressive degenerative changes are classified as chronic rejection or chronic allograft nephropathy. These changes lead to loss of graft function over the course of months to several years. Current strategies minimizing calcineurin inhibitor nephrotoxicity are being used to prolong function in kidneys with these chronic changes and involve the addition of TOR inhibitors to replace the calcineurin inhibitors. It remains unclear whether the marked decrease in acute rejection episodes, from greater than 50% to less than 20% observed in the past 5 years, will translate to better long-term function of transplants. Nonetheless, it is evident that immunosuppression strategies minimizing prednisone and calcineurin inhibitors are providing safer and more effective immunosuppression for kidney-transplant recipients while decreasing long-term toxicities associated with immunosuppression.

Immunosuppressive Complications

It would be naive to assume that the intensification of immunosuppressive regimens resulting in decreased acute and chronic rejection rates can be accomplished without sequelae. Infections and malignancy remain significant complications associated with long-term immunosuppression and are the driving force for drug-minimization strategies. Early infections during the

perioperative period are commonly iatrogenic and involve bladder infections or intravenous catheter use. Higher doses of immunosuppressive drugs used in the early postoperative period predispose patients to these infections and emphasize the importance of maintaining sterility during Foley catheter placement and insertion of intravenous catheters. Pneumonia related to mechanical ventilation and poor postoperative inspiratory effort can occur in the early postoperative period, and early incentive spirometry should be encouraged to decrease the potential for this infection. Wound infections are relatively uncommon, although diabetes and obesity are both associated with a much higher incidence of wound complications. Weight reduction to achieve a body mass index of less than 40 kg/m^2 is strongly recommended to facilitate the operative procedure and minimize the risks of wound complications, particularly in the recipient with diabetes mellitus.

Cytomegalovirus (CMV), a herpesvirus, remains a problematic infection in the immunosuppressed patient and can become symptomatic 1 to 2 months following the transplant. CMV-seronegative patients who receive a kidney from a CMV-seropositive donor are at the highest risk for infection, although prophylaxis with acyclovir or ganciclovir is generally provided for all recipients for a period of 3 to 6 months following the transplant. Despite prophylaxis, activation of CMV can occur, accompanied by fever, malaise, pneumonia, gastrointestinal distress, or dysfunction of the kidney transplant. The effective treatment of blood- or tissue-invasive CMV has been one of the major advances in the management of kidney-transplant patients within the past two decades. What was a life-threatening disease in the early era of solid organ transplantation can today be effectively managed with oral antibiotics.

Prophylaxis against *Candida albicans* with fluconazole and *Pneumocystis carinii* with trimethoprim–sulfamethoxazole is also part of most management strategies post transplant. Other potentially life-threatening opportunistic organisms that can affect the chronically immunosuppressed transplant recipient include *Aspergillus, Cryptococcus, Listeria, Nocardia,* and *Mycobacterium.*

More potent immunosuppression regimens used in the current era have been associated with the emergence of polyoma or BK virus, a previously rare infection that may cause graft loss in up to 5% of infected patients. Reduction in immunosuppression is necessary to prevent progression of viral

tubulitis. There has been some experience with the use of leflunomide, ironically an immunosuppressive agent, but with an active metabolite, A77 1726, that has substantial antiviral activity in vitro and in animals. Another potential medication, cidofovir, is a nucleotide analog that inhibits viral DNA polymerase but unfortunately is also nephrotoxic, and its in vivo efficacy has not been proved. Probably the best method to prevent graft loss due to polyoma is the use of monitoring of urine and serum levels of BK virus, with lowering of immunosuppression when early evidence of polyoma is detected.

Patients with a previous history of active tuberculosis or conversion to purified protein derivative positivity should receive appropriate prophylaxis for 6 months to 1 year following the transplant procedure.

More potent immunosuppression regimens will also have an impact on the development of neoplasms following transplantation.[23] Skin cancers are the most common malignancy following transplantation, with more than 90% being squamous or basal cell cancers. The incidence of skin cancers is staggering, with 50% or more of white recipients ultimately developing lesions. The immunosuppressed patient also has a higher incidence of nodal spread, and educating the patient about the importance of avoiding direct sun exposure is essential. Other malignancies that have a particularly high incidence in transplant recipients include non-Hodgkin lymphomas and carcinomas of the anogenital areas. The etiology of anogenital carcinoma is related to the presence of human papillomavirus. Although there have been no prospective trials to date, there is some evidence that TOR inhibitors are advantageous in the setting malignancies as the preferred immunosuppressive agent based on their antiproliferative qualities. Conversion to mTOR inhibitors and minimization of calcineurin inhibitors is a strategy that has been used with increasing frequency in the scenario of malignancies following transplantation.

Posttransplant lymphoproliferative disease is the second most common form of malignancy in transplant recipients and is associated with Epstein–Barr virus. These lymphoproliferative syndromes present as a spectrum of pathology, extending from polyclonal lymphoproliferation to monoclonal B-cell lymphomas. Polyclonal disease has been managed by decreasing or withdrawing immunosuppression, whereas progression to monoclonal lymphomas has required chemotherapy. CD20-positive lymphomas have

been successfully managed with rituximab, an anti-CD20 antibody, with no significant side effects.

CURRENT RESULTS AND FUTURE TRENDS

Over the past three decades, progressive improvement has been made in patient and graft survival, independent of donor source. Overall graft survival, as well as the half-life of the graft, improved incrementally for live-donor transplants, standard deceased-donor transplants, and even deceased-donor transplants using suboptimal or expanded criteria donors.[12] This change is related to improved organ preservation, perfected operative technique, and most important, improved immunosuppressive agents. Current 1-year graft survival rates for living- and deceased-donor transplants are 97.5% and 93.2%, respectively.[24] These remarkable 1-year results continue to be overshadowed by the specter of late graft loss due to chronic rejection. This problem remains unsolved in renal transplantation, and future improvement in long-term survival will be achieved only when the mechanisms of this process are understood.

The exponential growth in waiting lists compounded by the ongoing critical shortage of organs will continue to stimulate creative means of increasing both the living- and deceased-donor pools. Expansion in the number and types of immunosuppressive agents has resulted in marked decreases in the incidence of acute rejection, which it is hoped will translate to prolongation in the long-term function of kidney transplants. Newer strategies in immunosuppressive regimens that minimize nephrotoxic cyclosporine and tacrolimus by adding nonnephrotoxic agents will also benefit the long-term function of transplanted kidneys. The effect of ischemia-reperfusion injury on both early and late graft function, as well as its impact on the development of chronic rejection and transplant glomerulopathy, is an area of active research, and potential therapeutic interventions to minimize this injury are being evaluated. The induction of tolerance to foreign antigen remains the “holy grail” of transplantation. A paucity of tolerizing regimens have been applied clinically, although the use of donor bone marrow or stem cells will likely have a future role in achieving the elusive goal of transplantation tolerance.

Hepatic Transplantation

Benjamin Samstein and Christopher J. Sonnenday

Key Points

1. Liver transplantation remains the only definitive therapy for patients with end-stage liver disease.
2. The three primary indications for liver transplantation in the United States are alcohol-related liver disease, nonalcoholic fatty liver disease (NAFLD), and hepatocellular carcinoma (HCC).
3. Transplantation for early-stage HCC is associated with low recurrence rates and excellent survival, driving interest in expanding criteria for liver transplantation to patients with more extensive but localized tumor burden.
4. The multidisciplinary evaluation of a patient for liver transplantation involves thorough scrutiny of medical, surgical, and psychosocial domains to ensure the benefits of transplant are realized.
5. Recipient, donor, and technical factors dictate the likelihood of major posttransplant complications, which tend to occur in a predictable continuum.

1 Over the past 50 years, liver transplantation has evolved from an experimental procedure to the definitive treatment for patients with end-stage liver disease (ESLD), specific metabolic diseases, and select hepatic malignancies. Dr. Thomas Starzl reported the first three cases of orthotopic liver transplantation in 1963, for a child with biliary atresia, a man with alcohol-related cirrhosis and hepatocellular carcinoma (HCC), and a man with hilar cholangiocarcinoma.[1] None of these patients survived more than 22 days after the operation, but the foundation for the donor and recipient operations was established. Each of those diagnoses remains indications for liver transplantation today, and the survival of liver transplant recipients has improved dramatically. Current 1-year patient survival rates following liver transplantation are 90% to 97%, with median life expectancy for recipients of more than 15 years posttransplant.[2]

As is true of all solid organ transplantation, advances in immunosuppression strategies have had an equivalent or greater impact on outcome as advances in surgical technique. Following the discouraging initial experience in liver transplantation in the 1960s in the United States and the United Kingdom, a relative moratorium on liver transplantation was established by Dr. Starzl and his contemporaries. Very few liver transplants occurred worldwide until the 1980s, following the development of the calcineurin inhibitor cyclosporine by Sir Roy Calne in 1979.[3] This discovery transformed the field, and cyclosporine quickly became the primary maintenance immunosuppression drug for all solid organ transplant recipients. Over the ensuing decade, liver transplantation rapidly expanded such that more than 2,000 cases were performed in the United States in 1989. In 1991, liver transplantation of adults with decompensated cirrhosis was approved for Medicare coverage by the Centers for Medicare & Medicaid Services.[4]

While substantial challenges remain in refining all aspects of liver transplant care including immunosuppression, arguably the greatest barrier in all of solid organ transplantation today is the profound deficit of donor organs to meet the demand of this lifesaving therapy. In recent years, more than 12,000 candidates await liver transplantation in the United States while annual transplant volume is only 8,000 to 9,000.[2] This disparity in supply of donor livers, and the lack of an alternative life-sustaining therapy for ESLD, translates to approximately 2,000 deaths on the waiting list annually. Many of

the recent innovations in liver transplantation over the last 20 years have focused on expanding the number of available donors for liver transplantation, including use of elderly deceased donors, use of grafts with significant steatosis, use of organs from donors with risk of transmission of donor disease (e.g., donors with hepatitis B, hepatitis C, HIV, or malignancy), novel preservation techniques, use of livers from donation after cardiac death (DCD) donors, and living donor liver transplantation (LDLT).

INDICATIONS FOR LIVER TRANSPLANTATION

2 One of the most noticeable changes in liver transplantation over the past three decades has been the significant change in the patients undergoing transplantation—recipients are older, have more comorbidities, and have different primary diagnoses as their indication for liver transplantation. For more than two decades, decompensated cirrhosis related to chronic hepatitis C infection was leading indication for liver transplantation in the United States. The development of direct acting antiviral agents that can effectively eradicate hepatitis C viremia in greater than 95% of treated patients has led to a rapid fall in the number of patients with hepatitis C–related cirrhosis referred for liver transplantation.[5] This change, accompanied with the substantial rise in number of patients with nonalcoholic steatohepatitis (NASH)-related cirrhosis, alcohol-related cirrhosis, and hepatic malignancy referred for liver transplantation, has significantly changed the recipient population (**Fig. 37.1**).

Nonalcoholic Fatty Liver Disease

The epidemic of obesity, metabolic syndrome, and associated nonalcoholic fatty liver disease (NAFLD) have begun to dramatically change the epidemiology of liver disease in the United States and other Western nations. Projections are that ESLD secondary to NAFLD will continue to rise as a primary indication for liver transplantation, advancing a patient population with other substantial comorbidities toward transplant.[6] The incidence of

hepatic steatosis and NAFLD has also begun to affect the health of the deceased donor organ pool, with steatotic donor livers recognized as higher-risk organs particularly as it relates to the risk of early allograft dysfunction. The obesity and comorbid disease associated with NAFLD patients have raised concern that posttransplant outcomes will be inferior in this patient group, but published studies to date do not appear to validate that concern.[7] Clearly though, NAFLD can recur in the transplanted liver, and programs to engage patients in improving their overall health and nutrition posttransplant will be critical to achieving durable outcomes in this patient population. Combining liver transplantation with bariatric procedures to achieve durable weight loss has been demonstrated to be feasible and effective in select patients.[8]

Alcohol-Related Liver Disease

Alcohol-related liver disease (ALD) remains a primary indication for liver transplantation, and recent data suggest a substantial rise in the incidence of alcohol-use disorder and associated transplant referrals in the United States.[9] In addition, the utilization of liver transplantation for select patients with alcoholic hepatitis has emerged as a growing indication for liver transplantation.[10] This practice, which violates traditional arbitrary policies

about length of sobriety necessary to be considered a liver transplant candidate, suggests that select patients without concomitant untreated mental illness and possessing adequate social support can be transplanted for alcoholic hepatitis, a highly lethal condition, with outcomes similar to other diagnosis groups. In general, the ALD patient population is younger and otherwise healthier than other liver transplant candidates but pose substantial psychosocial challenges in evaluation and posttransplant management for centers.[11]

Of note, ALD and NAFLD together appear to account for approximately 50% of HCC cases in the United States,[12] and epidemiologic evidence exists that obesity and type 2 diabetes mellitus increase the risk of HCC among ALD patients. There are, however, distinctions between the presentation of patients with HCC in the setting of ALD versus NAFLD. ALD patients most often develop HCC in the setting of cirrhosis (~80% of cases), have a higher incidence of vascular invasion, and appear to have worse overall survival than patients with NAFLD-related HCC. As many as 50% of HCC cases in NAFLD patients may not yet have cirrhosis at the time of diagnosis and appear to more often present with a large solitary HCC as opposed to multifocal disease. NAFLD-related HCC also may more often be well-differentiated tumors, and less prone to alfa-fetoprotein (AFP) production, which poses additional challenges to screening protocols.[13]

Transplant for Malignancy

3 As the incidence of primary hepatic malignancies has increased, and outcomes of patients transplanted for hepatobiliary malignancies have improved, the indications for transplant have expanded (**Fig. 37.2**), new challenges in recipient selection, immunosuppression management, and cancer surveillance have emerged. Liver transplantation has been established as definitive therapy for select patients with HCC, for the rare neoplasm hepatic epithelioid hemangioendothelioma, for pediatric patients with unresectable hepatoblastoma, and for a select population of patients with hilar cholangiocarcinoma and metastatic neuroendocrine tumor. More uncertainty exists about the role of liver transplantation, and specifically the selection of appropriate patients, in the treatment of patients with intrahepatic cholangiocarcinoma and metastatic colorectal cancer.

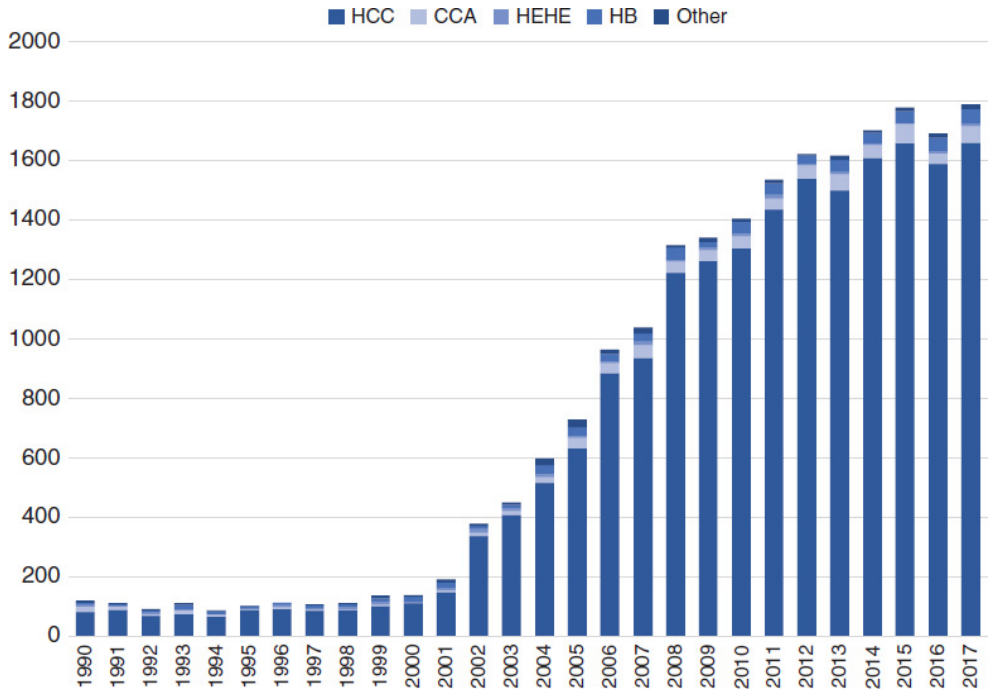

Figure 37.2 Liver transplants performed for malignancy, United States, 2000–2017. HCC, hepatocellular carcinoma; CCA, cholangiocarcinoma; HEHE, hepatic epithelioid hemangioendothelioma; HB, hepatoblastoma. (Source: Based upon UNOS Organ Procurement and Transplant Network data as of January 15, 2018. https://optn.transplant.hrsa.gov/)

Table 37.1 UNOS Modified TNM Staging for Hepatocellular Carcinoma

T stage	T1	Solitary tumor <2 cm
	T2	Solitary tumor 2–5 cm; 2–3 nodules all <3 cm
	T3	Solitary tumor >5 cm; 2–3 nodules with at least one >3 cm
	T4a	4 or more tumors
	T4b	T2, T3, or T4b tumor with gross vascular involvement
N stage	N1	Regional lymph node involvement
M stage	M1	Any extrahepatic metastatic disease beyond regional nodes

Selection of patients with HCC appropriate for liver transplantation has been the seminal challenge in the field, and in fact early series of HCC patients documented excessively high recurrence rates (75%+) with expedited cancer-related mortality.[14] It was not until Mazzaferro's seminal series of patients with early-stage HCC undergoing successful liver transplantation that the primacy of patient selection and tumor burden was established.[15] The Milan criteria established in this study have been stretched and challenged since that time, but they remain the standard for low recurrence risk in this patient population. Cirrhotic patients with T2 tumors (**Table 37.1**), who do not have a resection option either due to tumor burden or severity of liver disease, are considered optimal candidates for liver transplantation.

Numerous efforts have been made to expand eligibility criteria for liver transplantation beyond Milan criteria, although none have been universally accepted in a manner to drive organ allocation. Alternative criteria may be evaluated on the balance between expanding eligibility for transplant to additional patients with HCC with the increased risk of recurrent disease. Consensus in the transplant community has generally established 60% 5-year overall posttransplant survival as the lowest acceptable survival to balance the utility of transplant for HCC with other diagnoses.[16] Among alternative criteria for transplant eligibility among HCC patients, only the University of California San Francisco (UCSF) criteria have been prospectively validated with acceptable outcomes.[17,18] UCSF criteria extend Milan criteria by modestly extending tumor volume criteria (one tumor ≤6.5 cm, three nodules at most with the largest ≤4.5 cm, and total tumor diameter ≤8 cm). These criteria were generated retrospectively based on explant pathology, but prospective validation using preoperative imaging documented a low overall recurrence rate of 10% at 5 years, with only 15% of patients found to exceed UCSF criteria on explant pathology.[18] Despite these excellent outcomes, there has not been national support in the United States to change United Network for Organ Sharing/Organ Procurement and Transplantation Network (UNOS/OPTN) policy to extend selection criteria for HCC candidates.

While extension of HCC eligibility criteria at the time of transplant has not been endorsed broadly in the United States, liver-directed therapy to downstage patients beyond Milan criteria such that they meet UNOS T2 criteria at the time of transplant has been increasingly utilized. Despite this increasing experience and expert opinion supporting the use of downstaging to expand access to transplantation, there is no consensus about the most effective modality for liver-directed therapy.[19,20] A recent systematic review of published series of downstaging suggested that up to 60% of candidates will be successfully downstaged to within Milan criteria, but no clear advantage was demonstrated according to liver-directed therapy modality (transarterial chemoembolization vs. transarterial radioembolization).[21] Critically important to the establishment of uniform downstaging strategies is the utilization of standard criteria for measuring response to therapy by imaging. The modified RECIST (mRECIST) criteria were created by expert consensus convened by the American Association for the Study of Liver Diseases (AASLD) and remain the gold standard for evaluating response to

therapy on contrast-enhanced CT or MRI.[22] The extent of residual viable tumor, rather than measurement of treatment cavity or previous tumor size, is utilized to determine the amount of residual disease. Response to therapy should be observed for at least 3 months prior to consideration of active listing for transplant. Patients who maintain residual tumor volume within Milan criteria or less after downstaging therapy are appropriate for listing and should be monitored for intrahepatic and extrahepatic progression every 3 months until transplant.

In the case of deceased donor liver transplantation, allocation policy must balance the survival benefit of liver transplantation for HCC patients against the needs of patients with noncancer diagnoses. Furthermore, evidence exists that "expedited" transplant of HCC patients may lead to inferior outcomes, as patients with HCC with shorter waiting times for transplant actually have higher recurrence rates relative to HCC patients with longer wait times for transplant.[23] Current UNOS allocation policy delays assignment of HCC exception points for 6 months (with restaging imaging and serum AFP required every 3 months). After 6 months listing with their natural Model of End-Stage Liver Disease (MELD) score, patients with T2 HCC are granted an exception score near the median MELD at transplant in their area. The delay in granting of the HCC exception for 6 months allows for observation of tumor biology and dropout of patients who progressed beyond T2 criteria.

Given the principle that waiting time may actually help select the most appropriate patients for transplantation for HCC, the use of LDLT for HCC recipients poses interesting challenges. While among patients with non-HCC diagnoses, LDLT offers equivalent or superior survival outcomes to deceased donor liver transplantation,[24] LDLT for HCC patients appears to be associated with an increased risk of tumor recurrence.[25] Explanations for inferior outcomes among HCC patients treated with LDLT include differences in pretransplant therapies (such as decreased use of liver-directed therapy), differences in patient selection (potential tendency to consider patients beyond Milan criteria for LDLT), and expedited transplant via LDLT such that a period of observation of tumor behavior does not occur.[26] The most appropriate selection criteria for selection of HCC patient appropriate for LDLT have not been established, but utilization of some observation period (3 to 6 months) after diagnosis of HCC prior to LDLT

may eliminate the possibility of transplanting patients with particularly unfavorable tumor biology and increased recurrence risk.

Patients with ALD, NAFLD, and HCC account for ~60% of patients currently transplanted in the United States, with the remainder accounted for with the diagnoses in **Table 37.2**. Biliary atresia is the most common indication for liver transplantation in infants and children. The cholestatic liver diseases (primary sclerosing cholangitis, primary biliary cirrhosis, Alagille syndrome) and autoimmune hepatitis tend to occur in younger adults and occasionally in adolescents requiring transplant. Viral hepatitis (chronic B and C) remain important causes of cirrhosis and HCC in the United States, although their prevalence as a primary indication for transplant have declined with effective antiviral therapy.

Table 37.2 Indications for Liver Transplantation by Diagnosis	
Nonalcoholic fatty liver disease	
Alcohol-related liver disease	
Hepatic malignancy	Hepatocellular carcinoma Hilar cholangiocarcinoma Metastatic neuroendocrine tumor Hepatoblastoma
Viral hepatitis	Hepatitis B Hepatitis C
Cholestatic liver disease	Primary sclerosing cholangitis Primary biliary cirrhosis Biliary atresia Alagille syndrome
Autoimmune hepatitis	
Budd–Chiari syndrome	
Fulminant hepatic failure	
Metabolic liver disease	Amyloidosis Ornithine transcarbamylase (OTC) deficiency Maple syrup urine disease Crigler–Najjar syndrome Tyrosinemia Cystic fibrosis Wilson disease Alpha-1 antitrypsin deficiency Hemochromatosis

END-STAGE LIVER DISEASE AND EVALUATION FOR LIVER

TRANSPLANTATION

Regardless of their primary diagnosis, the vast majority of patients referred for liver transplantation have ESLD, defined as decompensated cirrhosis with symptoms of hepatic synthetic failure and complications of portal hypertension. Since many of the complications of ESLD are driven by portal hypertension, replacement of healthy hepatocytes alone (such as through a cellular-based therapy, or heterotopic or auxiliary transplant) would not cure patients of portal hypertension. Orthotopic liver transplantation addresses not only the synthetic failure by replacement with a healthy mass of hepatocytes but serves to correct portal hypertension by replacing the scarred, fibrotic liver that serves as a high-resistance circuit to portal blood flow with a healthy, low-resistance liver. Patients without significant hepatic synthetic failure but with significant complications of portal hypertension (refractory ascites or recurrent variceal hemorrhage) might be treated effectively with procedures to address portal hypertension, such as a transjugular intrahepatic portosystemic shunt (TIPS) procedure or a surgical therapy for portal hypertension (splenorenal or mesocaval shunt).

While laboratory measures of hepatic function exist, and the MELD score serves as a helpful predictor of mortality of ESLD,[27] patients referred for liver transplantation should have clinical symptoms that justify transplantation rather than just abnormal laboratory studies. The most common symptoms include jaundice, fatigue, loss of muscle mass and cachexia, and hepatic encephalopathy. Complications of portal hypertension include ascites, hepatic hydrothorax, variceal hemorrhage, and splenomegaly with thrombocytopenia. The development of hepatorenal syndrome, a clinical entity associated with a poor prognosis among patients with ESLD, should also prompt consideration of liver transplantation.[28] The clinical trajectory of patients with chronic liver disease can be variable and difficult to predict and may depend on whether the cause of liver injury can be treated or removed, such as antiviral therapy for chronic hepatitis or alcohol cessation in alcohol-related liver disease. Medical therapies to manage symptoms of decompensated cirrhosis have improved substantially over the past decades, but ultimately no definitive therapies for ESLD exist other than liver transplantation.

In addition to these classic indications for transplant, patients with cirrhosis may develop other rare complications of liver disease that can be cured with transplantation. These include hepatopulmonary syndrome (HPS), characterized by the development of progressive hypoxia caused by the development of intrapulmonary vascular dilations. These acquired vascular anomalies may develop out of proportion to other complications of portal hypertension, and lead to arterial hypoxia by creating a mismatch between alveolar perfusion and ventilation. HPS may be cured by liver transplantation, especially when offered soon after the development of clinically significant hypoxia. Patients with HPS are granted additional MELD exception points to achieve adequate priority on the waiting list, as HPS may occur prior to more significant clinical decompensation otherwise. A room air PaO_2 less than 60 mm Hg is considered as the benchmark indication for liver transplantation and qualification for MELD exception.[29,30] Patients with HPS are considered higher-risk candidates for liver transplantation, but recent outcomes have improved as MELD exceptions have allowed an earlier pathway to liver transplantation.[29]

Portopulmonary syndrome is another more uncommon indication for liver transplantation, defined by the development of pulmonary arterial hypertension in the setting of portal hypertension. Patients typically present with progressive dyspnea and right heart catheterization establishes a definitive diagnosis. Evaluation of these complex patients requires diagnostic evaluation to rule out other causes of pulmonary hypertension. Liver transplantation may also be curative in this patient population, and patients with portopulmonary hypertension may receive MELD exception points after pretransplant medical therapies to optimize the management of their pulmonary hypertension prior to transplant. Similar to HPS, patients with portopulmonary hypertension face higher perioperative mortality but can have acceptable long-term outcomes after liver transplantation.[31]

Acute Liver Injury and Fulminant Hepatic Failure

Currently, less than 5% of liver transplants in the United States are performed for fulminant hepatic failure, a profound clinical syndrome that

may be precipitated by diverse etiologies. Common causes of acute liver injury among liver transplant candidates include acetaminophen toxicity, autoimmune hepatitis, drug-induced injury, viral disease, hepatic ischemia, and idiopathic causes.[32] Fortunately, the majority of patients with acute liver injury will recover with supportive care, but patients who develop fulminant hepatic failure may be considered for urgent liver transplantation. Patients with fulminant hepatic failure may present with jaundice and hepatic encephalopathy and develop multisystem organ failure. However, the urgency of liver transplantation is driven by the development of cerebral edema and brain injury including herniation that occurs in patients with fulminant hepatic failure. Decisions to list appropriate patients for liver transplantation should be made in 24 hours, and patients meeting criteria for fulminant hepatic failure are granted special expedited priority for liver transplantation (Status 1) with the goal of transplantation within 48 to 72 hours of presentation. Outcomes in the select patients with this diagnosis who are able to be transplanted rapidly can be quite good, similar to other diagnosis groups in more recent studies.[33]

Medical and Surgical Evaluation for Liver Transplantation

4 The medical and surgical evaluation of patients referred for liver transplantation must focus on identifying patients whose benefit from the procedure outweighs the substantial risks of the liver transplant procedure and the need for chronic immunosuppression. In addition, given the lack of sufficient donor organs to meet demand, transplant centers must choose candidates for transplant who have a high likelihood of posttransplant survival, as any patient transplanted competes to some degree with other needy candidates. The evaluation therefore must determine the presence and impact of medical comorbidities, psychosocial fitness for transplant, and any technical factors that would increase surgical risk. In addition, given the need for immunosuppression posttransplant, the evaluation must identify risk factors for conditions that could be exacerbated with chronic immunosuppression (e.g., chronic infections and malignancy). While the specific risk–benefit analysis for any individual patient is subject to

transplant center practices, guidelines do exist to guide standard evaluation processes.[34]

As the success of liver transplantation has increased, medical conditions previously thought to be contraindications to transplant have diminished. Broadly speaking, conditions with limited life expectancy, and/or those that compromise short-term transplant outcomes, are still considered relative contraindications to transplant. Examples include end-stage cardiac or pulmonary disease, metastatic malignancy, active substance abuse, untreated mental illness, or active sepsis. A MELD score less than 15 has also been considered a relative contraindication to transplant, as prior studies indicate that below that MELD score the perioperative risks of transplant may exceed the mortality of ESLD.[35] However, it is important to realize that certain patient populations may have conditions where MELD does not reflect their mortality risk (i.e., HPS, portopulmonary syndrome, cancer, metabolic disease). In addition, LDLT may be appropriate and provide a survival benefit for lower MELD patients with significant clinical decompensation refractory to medical management.[36]

The most challenging elements of the liver transplant evaluation in current practice often focus on the evaluation of older candidates with obesity and medical comorbidities, particularly cardiac disease. Obese patients have been shown to have increased perioperative complications and diminished long-term outcomes following liver transplantation in older studies.[37] However, traditional measures of obesity, such as body mass index (BMI), may be difficult to interpret in liver transplant candidates with ascites and anasarca, and more recent studies suggest similar outcomes in selected obese patients relative to nonobese recipients.[38] Obesity and metabolic syndrome are common among liver transplant candidates, particularly those with NASH-related cirrhosis, which has markedly increased the demand for transplant among obese candidates. A BMI over 40 is considered by many centers a relative contraindication to transplant, although recent innovations such as combining sleeve gastrectomy with liver transplantation may show pathways to expanding transplantation to more obese candidates.[8]

Pretransplant cardiac evaluation focuses primarily on identifying risk factors that would compromise perioperative outcomes. The hemodynamic changes experienced during the liver transplant period, associated with the challenges of total hepatectomy, the systemic vasodilation of cirrhosis, and

the circulatory collapse that can be associated with reperfusion injury and early graft dysfunction require that liver transplant candidates have acceptable cardiac function. All liver transplant candidates should undergo noninvasive cardiac testing, typically with echocardiography and some test for inducible ischemia (dobutamine echocardiography or nuclear medicine perfusion scan). Patients with concern for inducible ischemia should be evaluated with coronary angiography if otherwise appropriate transplant candidates and considered for revascularization when treatable lesions are identified.[39] In addition, the cardiac evaluation should carefully scrutinize valvular dysfunction, ventricular dysfunction, and for evidence of pulmonary hypertension, all of which would require further evaluation to determine appropriateness for transplant.

Waitlist Management and Organ Allocation

Once the decision has been made to list a patient for transplant, the patient's priority for transplant is established by United Network for Organ Sharing (UNOS) policy. Current liver transplant allocation in the United States is based upon the MELD-Na score, an adaptation of the MELD-based allocation first adopted in 2002. MELD-based allocation is predicated on the ability of MELD to predict waitlist mortality, and the addition of MELD-Na recognizes the profound effect of significant hyponatremia on outcomes of patients with ESLD.[40] MELD-Na is a relatively sensitive indicator of changes in clinical condition, allowing the sickest patients to rise to the top of the waiting list. Current liver transplant allocation distributes livers according to proximity circles determined by distance of the candidate transplant center from the donor hospital, allowing broader sharing of livers in an attempt to limit geographic variation in transplant rates.

As the MELD system does not represent the waitlist mortality or dropout rate for all patients, a system of MELD exception scores has been created to assign additional points to patients who meet established criteria for specific diagnoses. Patients being transplanted for HCC represent that largest group of MELD exception candidates, though other standard criteria exist for other diagnoses (HPS, portopulmonary syndrome, polycystic liver disease, etc.). Current UNOS policy dictates that exception applications are reviewed by a national review board, with standardized appeal policies when necessary.

This system aims to assign appropriate waitlist priority to patients awaiting transplant. Current UNOS policy prioritizes children, who are allocated livers from young donors preferentially before adults. This policy attempts to overcome the disadvantage children on the waitlist may face due to size mismatch between pediatric candidates and available donor organs. Pediatric waitlist mortality remains low in the current system, although the smallest infants continue to face challenges in identifying appropriate donors.[41]

SURGICAL PROCEDURE: LIVER TRANSPLANTATION

Anesthetic Management

An anesthesiologist with experience in liver transplantation is invaluable to the transplant team. Proper anesthetic management and effective communication between the surgery and anesthesiology teams is necessary to optimize patient care during the surgical procedure. For adult patients, cardiac monitoring is often performed either by pulmonary artery catheterization or intraoperative transesophageal echocardiography. An arterial catheter is placed for blood pressure monitoring. Adequate vascular access, often including central venous catheters, is required for the administration of blood products and the potential for rapid resuscitation in the case of massive blood loss. A device for rapid infusion and the ability to warm blood products or intravenous fluids is required. Low central venous pressures maintained during the hepatectomy phase of the procedure may help avoid excess bleeding.

Intraoperative Management of Coagulopathy

Liver transplantation has the potential for massive blood loss for several reasons. Liver transplant candidates with cirrhosis often have synthetic deficiencies in circulating coagulation factors as well as severe portal hypertension associated with thrombocytopenia and extensive venous collaterals. Intraoperative coagulopathy may be worsened during the

anhepatic phase of the procedure and immediately after reperfusion when hepatic function may be impaired. Finally, liver transplantation involves extensive dissection of major vascular structures including the inferior vena cava, portal vein, and hepatic artery, all with an inherent risk for bleeding. Intraoperatively, coagulation can be monitored by conventional coagulation tests including prothrombin time, partial thromboplastin time, platelet count, and fibrinogen. Viscoelastic tests such as thromboelastography (TEG) and rotational thromboelastometry (ROTEM) assess global coagulation and clot dynamics.[42] Use of these point-of-care tests may reduce transfusion requirements.[43] Normal coagulation is also helped by maintaining normal pH, calcium levels, and normothermia. Following reperfusion of the donor liver, a fibrinolytic state may be encountered. This is related to the global reduction of all coagulation factors and simultaneous generation of tPA.[44] As long as graft function is not significantly impaired, fibrinolysis gradually resolves.

Surgical Technique

Transplantation of the liver is among the most technically demanding surgical procedures. The donor liver must be prepared on the back table for implantation (**Fig. 37.3A**). Bench preparation includes resection of the donor diaphragm and adrenal gland off of the bare area of the liver and vena cava. Meticulous ligation of tributaries from the vena cava (adrenal vein, phrenic vein, and lumbar branches) is performed. The artery is dissected free from the Carrel patch of the aorta up to the gastroduodenal artery. Dissection near the right or left hepatic arteries is avoided to prevent unnecessary injury. The portal vein is circumferentially dissected free. The gallbladder may be removed at this stage or following reperfusion. Tissues surrounding the common bile duct are left intact to avoid injury of the blood supply.

The most commonly used incision is a unilateral or bilateral subcostal incision with a midline extension to the xiphoid process (**Fig. 37.3B**). After dividing the fascia, ascites, which can occasionally be present in a large volume, is evacuated. The ligamentum teres hepatis is carefully divided between clamps and ligated because a large recannulized umbilical vein is often present in patients with severe portal hypertension. After dividing the falciform ligament, a mechanical retractor is used to retract the bilateral

costal margins anteriorly and superiorly for excellent exposure of the upper abdomen. The abdominal cavity and liver are then inspected for any abnormalities including unsuspected malignancy. Following this, liver transplantation occurs in three stages: recipient hepatectomy, anhepatic phase, and postrevascularization.

Recipient Hepatectomy

During the recipient hepatectomy phase, the liver is mobilized from its ligamentous attachments and the porta hepatis is skeletonized. Attention is first directed to dissecting and skeletonizing the structures of the portal triad. The peritoneum overlying the portal triad is divided with electrocautery. The right and left hepatic arteries are dissected free, ligated, and divided leaving adequate length to provide options for the arterial anastomosis. The proper hepatic artery is also dissected free to the level of the gastroduodenal artery allowing enough length for clamping during the anastomosis. A replaced or accessory right hepatic artery, which arises as a branch of the superior mesenteric artery and travels in a posterior position to the common bile duct and lateral to the portal vein. When the replaced right hepatic artery is relatively large and the proper hepatic artery is diminutive in size, the replaced right hepatic artery can be left long and used for arterial inflow for the donor liver. A replaced or accessory left hepatic artery is rarely adequate for arterial inflow.

Conceptually, the common bile duct and common hepatic duct should be dissected free with as much length as possible and without injuring the blood supply to the bile duct. Leaving the recipient bile duct as long as possible allows the length of the donor bile duct, which may have a tenuous blood supply, to be shorter and still avoid tension at the time of anastomosis.

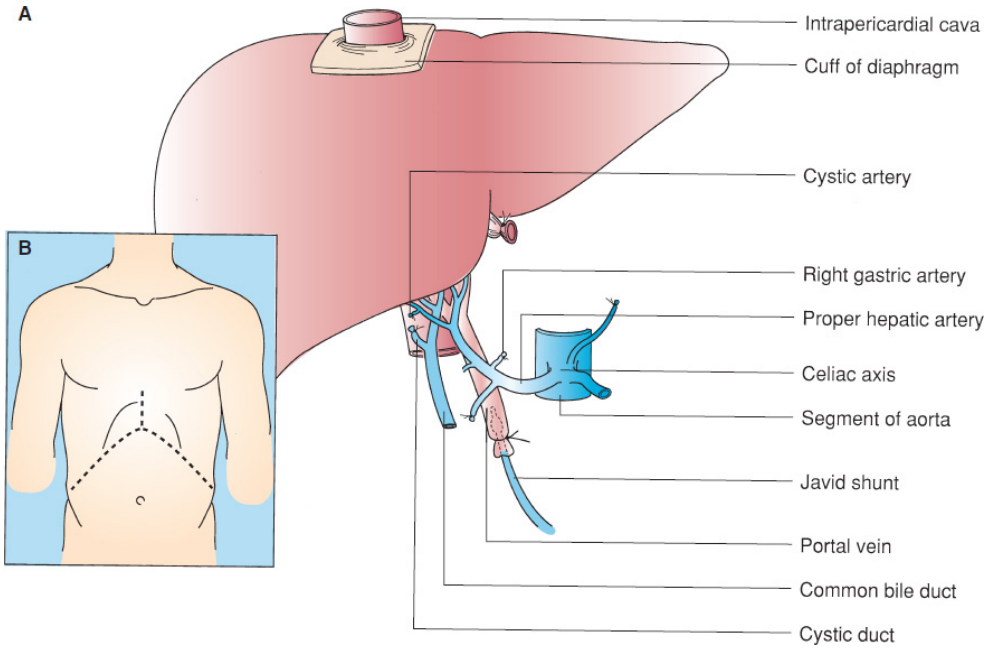

Figure 37.3 **A:** The donor liver after excision and before transplantation. **B:** Bilateral subcostal incision with a subxiphoid extension.

Once the bile duct and the hepatic artery are freed from surrounding tissues, the portal vein can be easily approached from its anterior, medial, and lateral aspects. In general, the portal vein is freed circumferentially from the edge of the duodenum up to its bifurcation of the right and left portal veins. Most patients with severe portal hypertension will not develop hypotension, small bowel edema, or ischemia if the portal vein is clamped and divided because of the presence of portal venous collaterals. However, patients without portal hypertension such as those undergoing liver transplantation for fulminant hepatic failure, metabolic deficiency, or those who have had a TIPS for a prolonged period of time, may develop extensive small bowel edema or hypotension when the portal vein is clamped. Small bowel edema can lead to limited exposure in the right upper quadrant making implantation of the liver extremely difficult. In these situations, the portal vein should be left in continuity for as long as possible, particularly when the use of venovenous bypass is not intended.

For those patients with portal vein thrombosis, portal venous flow can be restored in most cases. A mature portal vein thrombosis may require an eversion endovenectomy. If these maneuvers are unsuccessful, the junction of the splenic vein and superior mesenteric vein may be patent. Dissection of

the portal vein behind the pancreas to this junction can then be performed to allow for future anastomosis. Dissection to the confluence of the splenic and superior mesenteric veins is sometimes necessary in pediatric recipients because of the small caliber of the portal vein within the porta hepatis. In rare cases, all of these maneuvers may be unsuccessful and a venous bypass graft from the superior mesenteric vein may be necessary (**Fig. 37.4**). If the superior mesenteric vein is also occluded, the inferior vena cava or left renal vein can be used for portal inflow, procedures termed cavoportal or renoportal transposition (**Fig. 37.5**). These procedures are associated with acceptable outcomes despite the fact that portal hypertension may not be alleviated.[45] A fourth option for management of portal vein thrombosis is arterialization of the portal vein, using a conduit created by anastomosing donor iliac vessels to the recipient aorta and connecting this to the donor portal vein.[46]

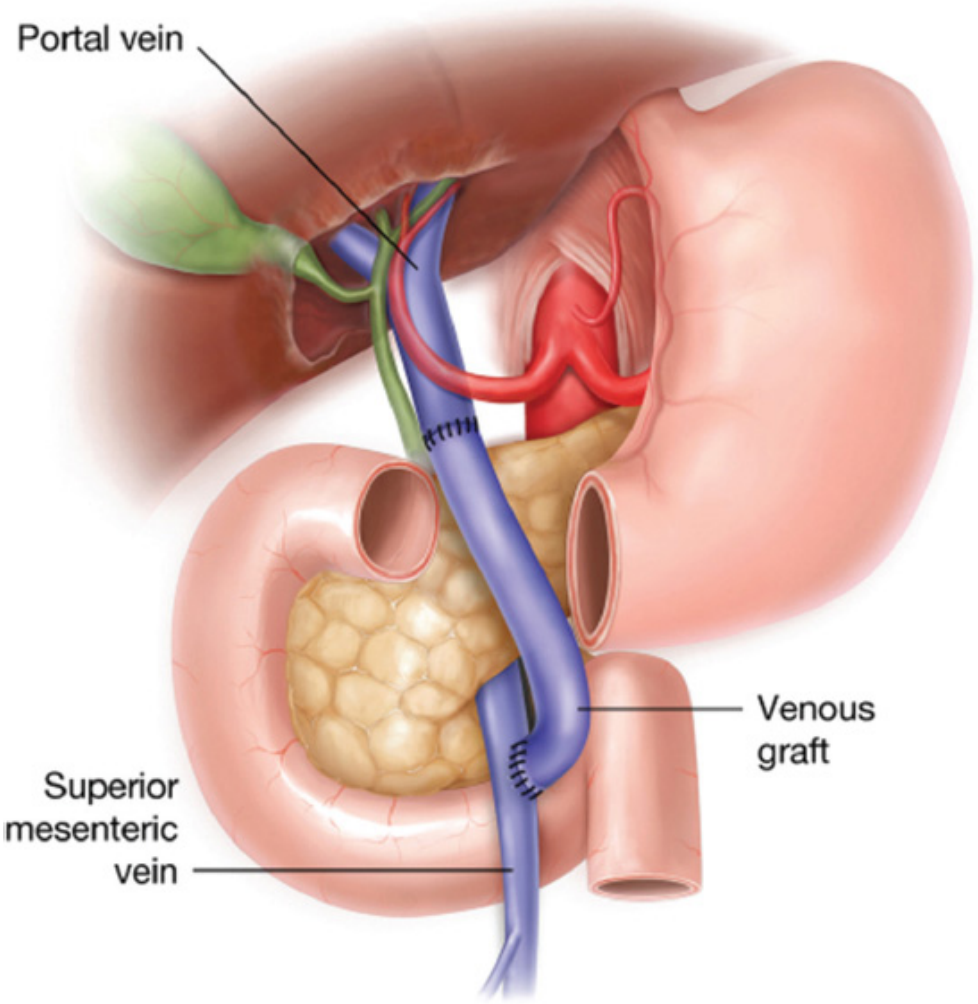

Figure 37.4 Mesoportal venous jump graft in the setting of portal vein thrombosis. The venous conduit is sewn to the superior mesenteric vein and tunneled retrogastric to anastomosis end to end to the donor portal vein.

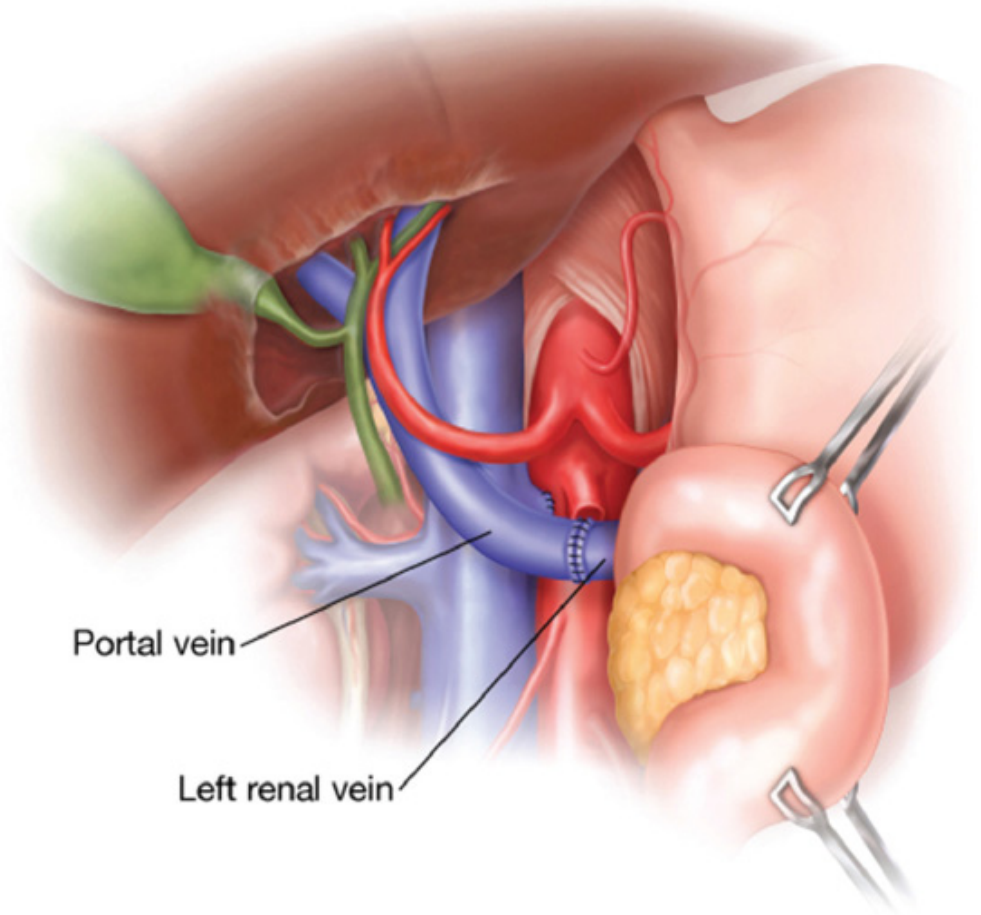

Figure 37.5 Renoportal anastomosis in the setting of portal vein thrombosis. The duodenum and pancreatic head have been mobilized to expose the left renal vein, which is divided at its drainage to the IVC and anastomosed end to end to the donor portal vein.

During mobilization of the liver, the left and right triangular and coronary ligaments are divided using electrocautery. The bare area of the liver is dissected along a plane just superficial to the capsule of the liver. Care must be taken to avoid injury to the phrenic or hepatic veins when freeing the suprahepatic inferior vena cava where it traverses the diaphragm. If a bicaval venous anastomosis technique is used, the vena cava can be circumferentially mobilized near the diaphragm above the hepatic veins as well as in an infrahepatic position. However, if a piggyback or cavocavostomy (side-to-side caval anastomosis) technique is intended, the dissection of the posterior aspect of the vena cava should be avoided to prevent encountering unnecessary bleeding from collateral or lumbar venous branches in this area. The hepatocaval ligament along the right lateral aspect

of the vena cava can be divided using a combination of cautery and ligation as a phrenic venous branch is often present within this ligament. If caval preservation is being performed, the liver is then dissected off the anterior aspect of the inferior vena cava. Small venous branches from the inferior vena cava to the caudate lobe are ligated and divided. Larger branches, such as an inferior hepatic vein, are clamped, divided, and oversewn. Division of the portal vein facilitates exposure for this dissection but is not required. The liver may be gradually retracted and dissected from either the right or left aspects until the right, middle, and left hepatic veins are reached.

Anhepatic Phase and Implantation of the Donor Liver

At this point, the liver has been completely mobilized except for its attachments of the hepatic veins to the inferior vena cava and in some cases, the portal vein. Most patients will tolerate clamping of both the portal vein and the inferior vena cava without difficulty.[47] At this point, communication with the anesthesiologist is essential and the vena cava should be test clamped before division to make sure that adequate cardiac filling and blood pressure can be maintained. If the patient becomes hypotensive during test clamping, the clamp should be removed and additional volume or vasopressor support can be administered. Occasionally, patients will require venovenous bypass, but its use is no longer routine at most centers.

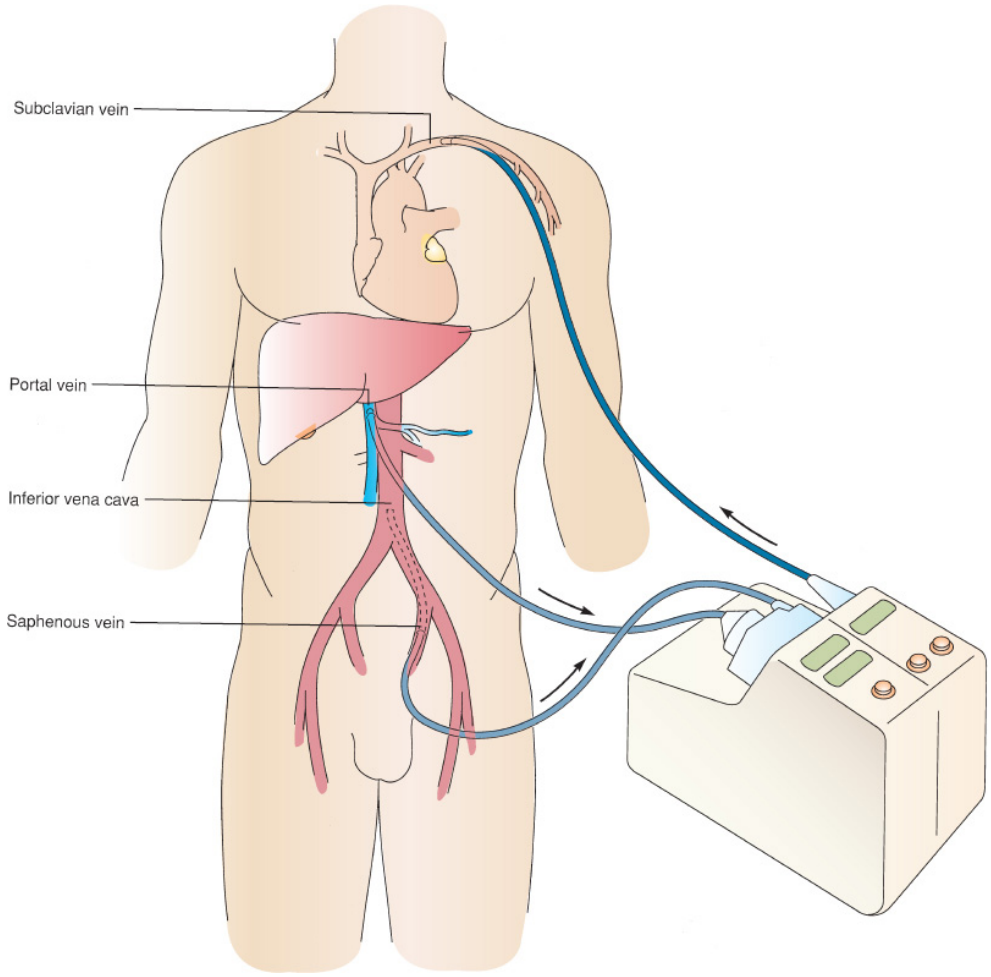

Figure 37.6 Setup for venovenous bypass during hepatic transplantation. Cannulas are placed into the portal vein and inferior vena cava (through the greater saphenous vein). A centrifugal pump is used to deliver bypassed blood to the central circulation by means of a cannula passed into the axillary vein.

If necessary, venovenous bypass can be accomplished from both the portal vein and inferior vena cava simultaneously, or a single cannula in either the portal vein or the inferior vena cava may be used (**Fig. 37.6**). There are several accepted methods of placing cannulas for venovenous bypass. Cannulas may be placed percutaneously in the internal jugular vein and femoral vein prior to beginning the procedure. These cannulas are advanced into the superior and inferior vena cava, respectively. Alternatively, one or both of the bypass cannulas may be placed by cutdown on the axillary and/or the greater saphenous vein. Inferior vena caval and mesenteric blood is delivered to the superior vena cava by a centrifugal pump. The cannulas, tubing, and centrifugal pump head are heparin bonded to reduce the chance of

thrombus formation and subsequent embolism without the use of anticoagulation. Flow rates of 1 to 2 L/min are typical. Once venovenous bypass has been established or the decision to forego bypass has been made, the recipient hepatectomy is completed. If still intact, the portal vein is divided as high in the hilum as possible. Three methods are commonly used for orthotopic liver transplantation: the bicaval technique, the piggyback technique, cavocavostomy (side-to-side caval technique).

For the **bicaval** technique, the recipient liver is excised en bloc with the retrohepatic inferior vena cava after caval clamps have been placed in a suprahepatic and infrahepatic position. The hepatic veins are divided within the substance of the liver to allow the creation of a large suprahepatic cuff compromising the left, middle, and right hepatic veins (**Fig. 37.7**). This technique has the disadvantages of: (a) occluding inferior vena cava flow resulting in renal ischemia and decreased cardiac filling with associated hypotension, (b) requires two vena caval anastomoses prolonging the warm ischemic time, (c) requires increased dissection of the recipient vena cava possibly leading to bleeding. However, complete dissection of the caudate lobe off the vena cava is not necessary in this technique, making the recipient hepatectomy phase somewhat easier and faster.

For the **piggyback** technique, a clamp is placed transversely, partially occluding the vena cava at the level of the hepatic veins. The vena cava is left in continuity and the hepatic veins are divided within the substance of the liver allowing the creation of a common patch of the right, middle, and left hepatic veins for a wide anastomosis. While the intention is to only partially occlude the vena cava allowing venous return to the heart, often a clamp placed for the piggyback technique either occludes or nearly occludes the inferior vena cava. This technique does have the advantage of only requiring a single vena caval anastomosis helping to limit warm ischemic time.

For the **cavocavostomy** technique, liver is excised and the hepatic veins are stapled or oversewn (**Fig. 37.8**). Advantages of the cavocavostomy anastomosis include the following: (a) minimal time that the vena cava is clamped, (b) the vena caval clamp is placed longitudinally only occluding the anterior third of the vena cava leading to minimal or no changes in the recipient's hemodynamics, (c) a broad anastomosis is performed limiting the likelihood of caval stenosis.

The donor liver is then brought onto the operative field. The vascular anastomoses are performed using a running monofilament polypropylene suture. If a bicaval technique is planned, two caval anastomoses are required. The suprahepatic vena caval anastomosis is first performed by suturing the posterior walls from within the lumen using an imbricating technique (**Fig. 37.7**). The anterior wall is then completed. The infrahepatic anastomosis is then completed in a similar fashion. Redundancy in the donor vena cava is avoided to prevent the potential for kinking. The completion of the anastomosis may be left until the time of hepatic revascularization to provide a vent or blood, and for washout of residual preservation solution.

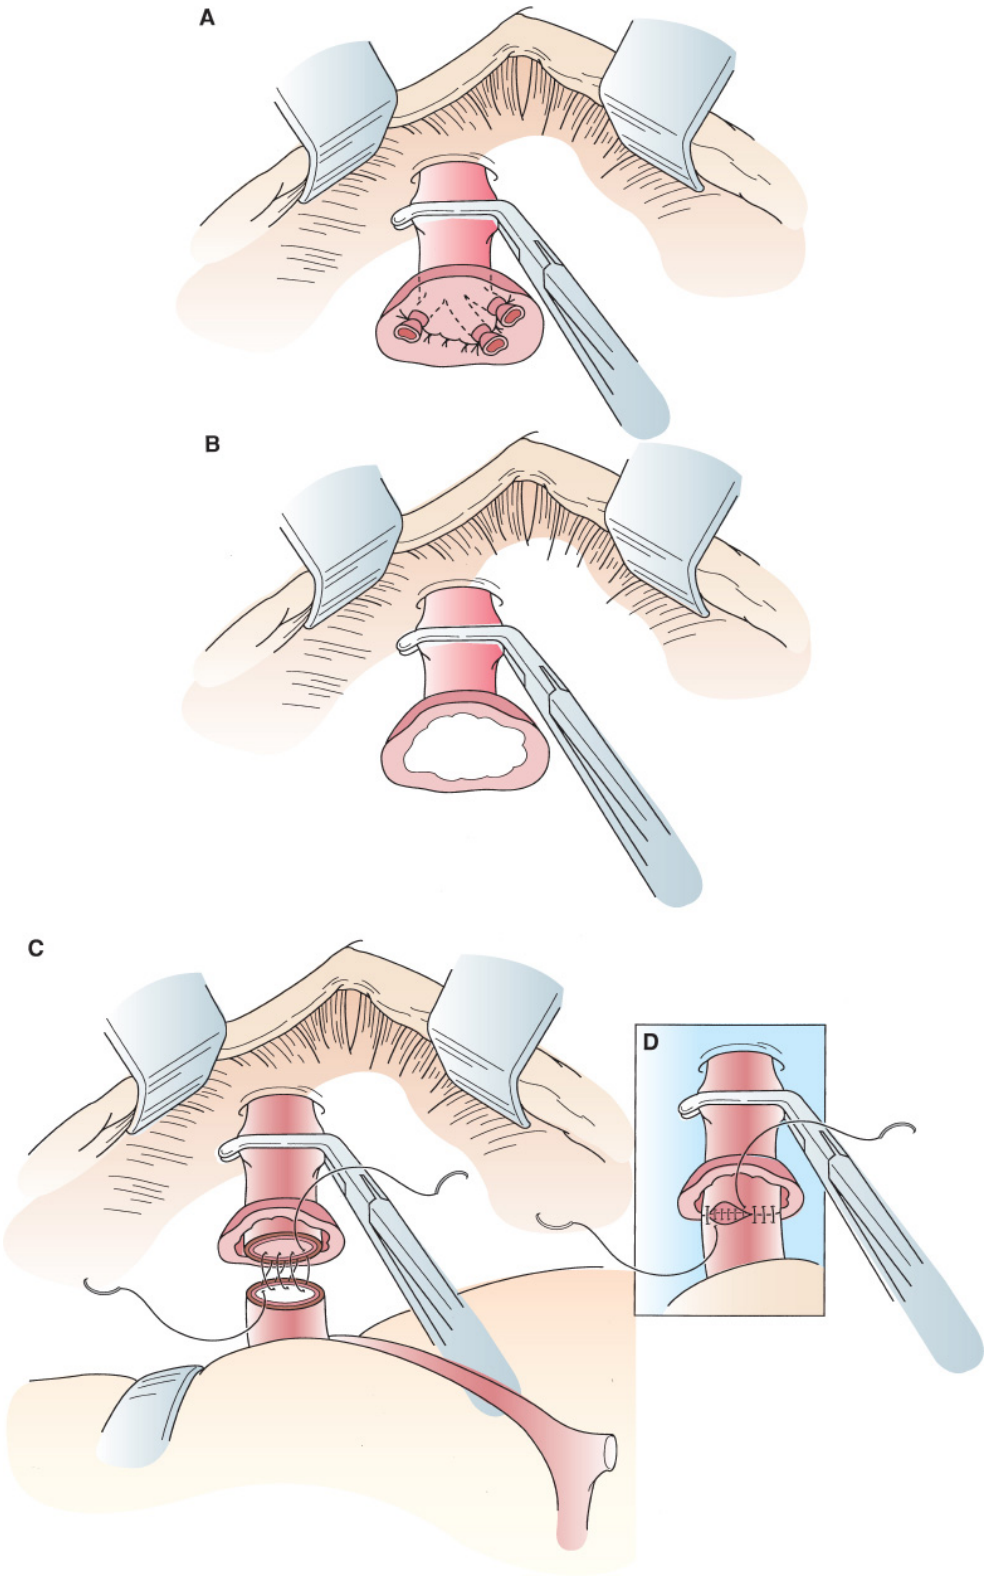

Figure 37.7 Bicaval liver transplant. **A:** The diseased recipient liver is removed by incising the liver below the level of the hepatic veins. **B:** The hepatic veins are then

opened to form a large suprahepatic cuff for the anastomosis. The suprahepatic vena caval anastomosis: posterior suture line (**C**); anterior suture line (**D**).

For the piggyback technique, the donor suprahepatic vena cava is then sewn in an end-to-side fashion to the recipient hepatic vein cuff (**Fig. 37.9**). As described above, an imbricating suture technique is often helpful to prevent gaps in the anastomosis and to compensate for size discrepancies. Venting at the time of reperfusion can either be performed through the suprahepatic anastomosis or at the donor infrahepatic vena cava. The donor infrahepatic vena cava is either oversewn or stapled. For the side-to-side caval technique, a clamp is placed longitudinally on the anterior third of the recipient vena cava. A longitudinal venotomy is made on the anterior surface of the recipient vena cava. The donor supra- and infrahepatic vena cava are either oversewn or stapled closed. A longitudinal posterior venotomy is then made matching the length of the recipient venotomy. The liver then placed in the right upper quadrant in the left lateral segment is elevated. The two vena cavae are then sutured in a side-to-side fashion with the lateral wall sutured from within the lumen and the medial wall sutured from outside the lumen (**Fig. 37.8**). During the caval anastomosis, the donor liver may be perfused with cold fluid via a cannula placed within the donor portal vein to wash out the preservation solution and to help maintain the cold temperature of the liver. This step is not required but may be considered if the liver was preserved with a solution containing a high concentration of potassium or if a prolonged warm ischemic time is anticipated. Once the caval anastomosis or anastomoses are completed, the portal venous anastomosis is completed, and the liver is reperfused. If portal bypass has been used, the portal limb of the venovenous bypass circuit is removed. The portal anastomosis is usually performed in an end-to-end fashion using a running technique. To avoid narrowing and allow for expansion under venous flow, a small air or "growth" knot is used when the suture is tied.

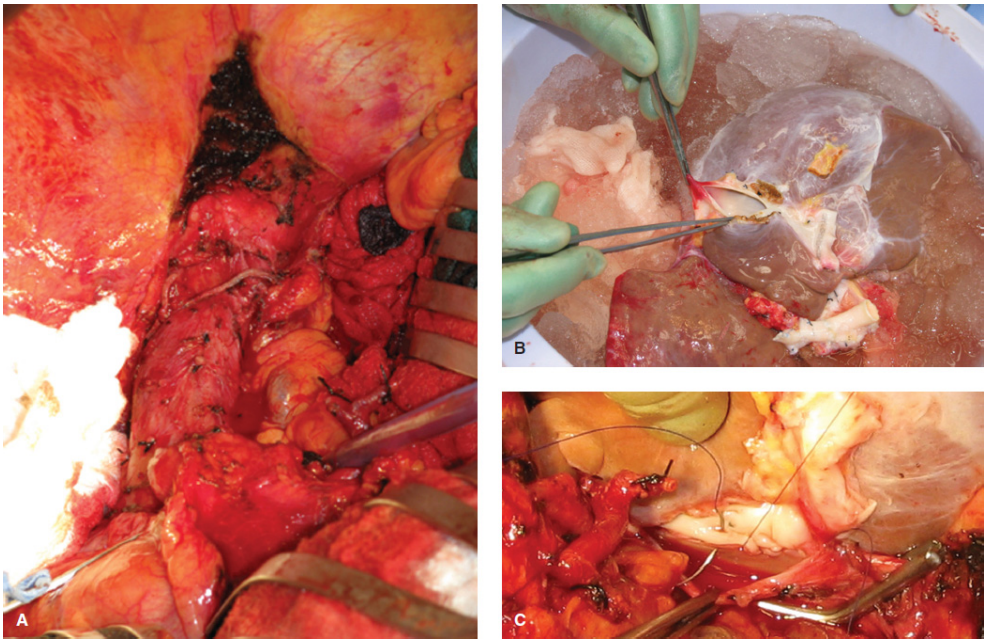

Figure 37.8 Cavocavostomy. **A:** The recipient right and junction of the middle and left hepatic veins are stapled and the inferior vena cava is left in continuity. **B:** The supra- and infrahepatic vena cavae are stapled and a venotomy is made longitudinally on the posterior aspect of the donor liver. **C:** A side-to-side caval anastomosis is performed with a running suture.

At the time of revascularization, flow is restored to the liver through the portal vein and/or the hepatic artery. The first several hundred milliliters of blood may be vented through the infrahepatic vena cava and the knot can be tied completing the caval anastomosis. Alternatively, the caval clamp can be briefly opened and the anastomosis inspected for bleeding and repaired if present. If blood is not vented through the infrahepatic cava, portal blood should be restored gradually to minimize cardiac irritability, bradycardia, and hypotension, all of which routinely result from cold blood circulating through the donor liver and going directly into the right atrium. Close coordination between the surgeon and anesthesiologist is necessary during this phase as hypotension and bradycardia are routinely encountered and cardiac arrest may rarely occur. If venovenous bypass has been used during the anhepatic phase, it can now be discontinued.

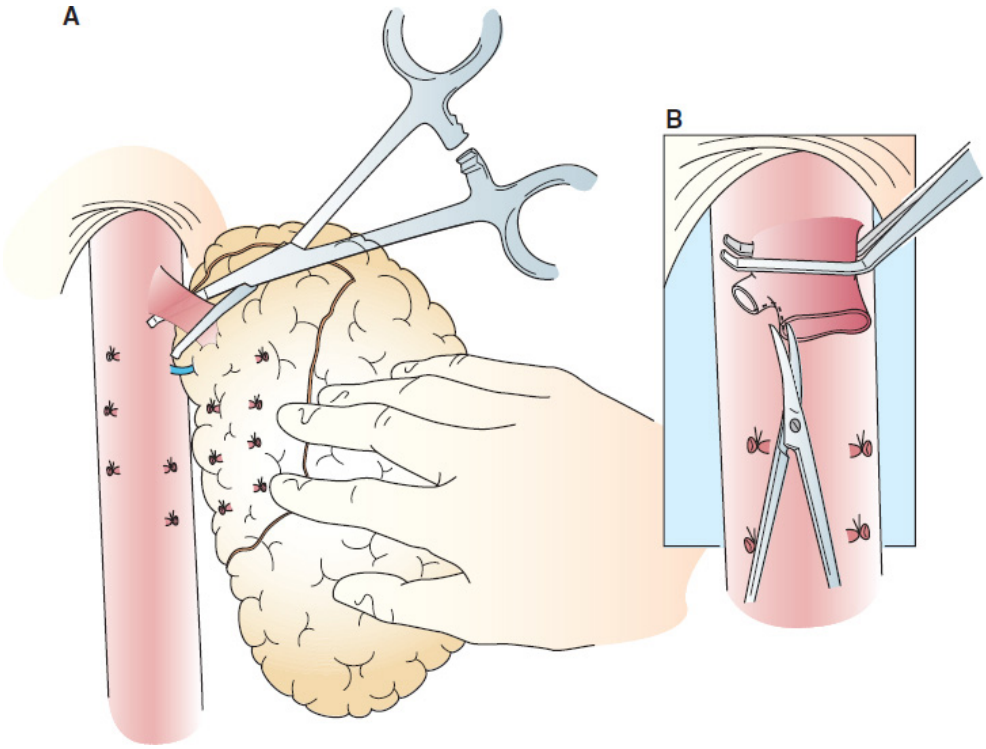

Figure 37.9 Piggyback technique. **A:** Recipient liver is dissected off native inferior vena cava by dividing veins draining directly into the inferior vena cava up to the level of the hepatic veins. **B:** Clamp placed on recipient hepatic veins in preparation of excision of the recipient's native liver and performance of a piggyback anastomosis.

Once hemostasis is obtained and the patient has stabilized, attention can now be turned toward the arterial anastomosis if it has not already been performed. The anastomosis can be performed distally on the donor artery or more proximally leaving the artery long, which allows the artery to lie with a smooth and gentle curve or loop. For this technique, all branches on the donor artery are ligated and the donor aortic Carrel patch, celiac artery, or branch patch of the celiac and splenic artery are anastomosed in an end-to-end fashion to a branch patch of the recipient right and left hepatic arteries (**Fig. 37.10**).

If the recipient arterial inflow is inadequate, an aortic conduit may be constructed. This is often performed using a graft consisting of the donor common and external (or internal) iliac artery. A partially occluding aortic clamp can either be placed in a supraceliac or infrarenal position and the common iliac artery is sutured in an end-to-side fashion to the recipient aorta. The donor Carrel patch can then be sutured in an end-to-end fashion to the external iliac artery of the conduit.

Post-revascularization Phase

Following revascularization, the liver should assume a normal color and consistency within several minutes. If the liver remains pale or is overly soft, problems with portal inflow should be considered. Alternatively, if the liver becomes edematous and overly firm, outflow obstruction should be excluded. Bile production should be seen while in the operating room and is among the first evidence for liver function. Inspection for surgical bleeding should be performed and entails examination of the vascular anastomoses as well as a search for branches of the major vessels that may not have been ligated. If bleeding continues after all surgical bleeding has been resolved, attention should be directed toward correction of coagulopathy as described above.

While biliary reconstruction does not carry the same risk for intraoperative complications when compared to the recipient hepatectomy and reperfusion, it is associated with considerable postoperative morbidity and mortality and requires the same diligence and attention as other steps of the operation. Because of the relatively high complication rate associated

with biliary reconstruction, it has been referred to as the Achilles heel of liver transplantation. The simplest and most common technique is currently an end-to-end choledochocholedochostomy from the donor to the recipient bile duct (**Fig. 37.11**). If a size discrepancy exists, the narrower duct can be spatulated. Running or interrupted sutures can be used. Absorbable monofilament suture is most commonly used to avoid a nidus for future stone formation within the bile duct. Alternative biliary reconstruction methods may be necessary for those with a bile duct of inadequate quality or size or in those whose primary disease is biliary pathology that prevents use of the native recipient duct. The most common option employed in these situations includes a standard Roux-en-Y choledochojejunostomy. Placement of drains may be considered to monitor for biliary leak. Abdominal wall and skin closure are then performed in the standard fashion.

Technique for Partial Liver Transplantation

The remarkable success of liver transplantation has led to challenges with liver availability. In part, motivated by need for more organs, techniques for split and living donor grafts based on Couinaud segmental anatomy (**Fig. 37.12**) were developed.[48,49] Techniques have now developed so that both sides of the liver can be transplanted into two recipients, either a child and an adult or two adults.[50,51] Split liver transplantation has been associated with a decreased survival rate and the potential for increased risk of complications, including primary nonfunction, hepatic artery thrombosis, and biliary complications. Because of this, while widespread adoption of allocation policies to encourage greater utilization of split liver grafts in the adult population has been suggested, split liver transplantation only accounts for a small proportion of transplants performed. In addition, only grafts from "ideal donors" are thought to be suitable to this form of transplantation. Criteria supported by the UNOS for splitting currently include donor age less than 40 years of age, on limited or no vasopressors, transaminases no greater than three times normal, and a BMI of 28 or less.

Living Donor Liver Transplantation

Experiences with deceased donor split liver transplantation and ongoing shortages of deceased donor allografts led to the adoption of the techniques utilized in split liver transplantation for LDLT. While, LDLT now accounts for approximately 5% of all liver transplants performed in the United States, it is the predominant pathway to liver transplantation in many countries. Although initially used in the pediatric recipients, adult LDLT rapidly became more frequent. Early in the LDLT experience, adult recipients with left lobe grafts developed severe hyperbilirubinemia, coagulopathy ascites.[52] This syndrome termed small-for-size syndrome led to increased utilization of larger, primarily right lobe grafts.

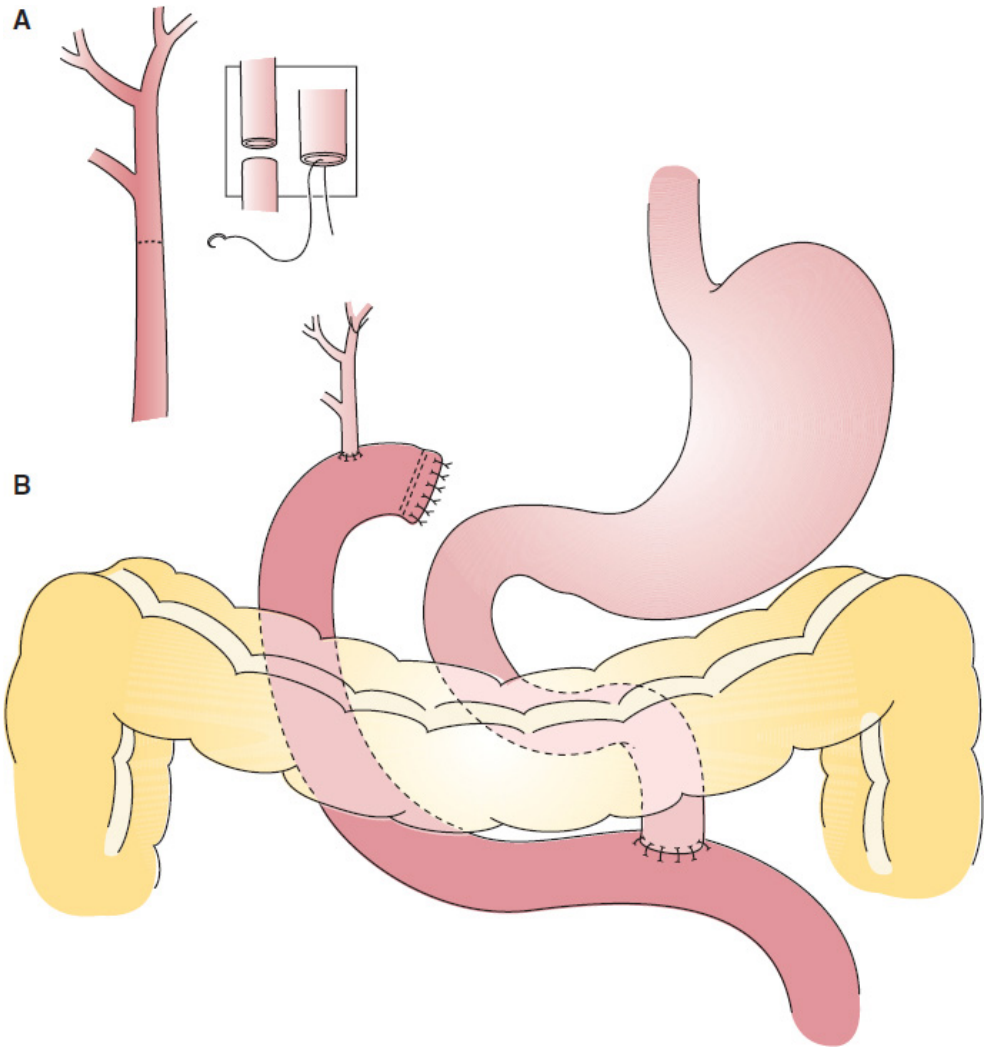

Figure 37.11 Biliary anastomosis. **A:** In most cases, a choledochocholedochostomy is performed, possibly over an internal stent. **B:** Patients with a diseased or unsuitable common bile duct may require biliary reconstruction with a Roux-en-Y choledochojejunostomy.

In many respects, transplantation of a graft from a living donor is similar to transplantation of a whole liver from a deceased donor. However, the recipient vena cava must be left intact. A direct hepatic vein to vena caval anastomosis is used. Establishing adequate outflow of hepatic venous blood is necessary to help prevent congestion of the anterior segment of the right lobe. Therefore, any vein draining segment 5 or 8 greater than 3 to 5 mm in diameter should be reconstructed either by direct anastomosis to the vena cava or using an interposition graft (**Fig. 37.13**). In addition, the length of the portal vein, hepatic artery, and bile duct on the donor graft is considerably

shorter than that available from a deceased donor. Therefore, during the recipient hepatectomy, considerable care should be given to preserving the length of the recipient bile duct as well as the right and/or left hepatic artery and portal vein which are intended for future anastomosis. Advantages of LDLT include lower recipient mortality compared to waiting for a deceased donor, less medical complications, and optimization of timing of transplant.[53,54] However, due to the technical complexity, there are more biliary and vascular complications.

POSTTRANSPLANT CARE AND COMPLICATIONS

5 Management of the post-liver transplant patient requires understanding of the continuum of care from acute perioperative issues to long-term health maintenance and management of immunosuppression. While transplant patients may be challenging to manage, they develop complications across a predictable timeline, and the best clinicians anticipate complications such that rescue may occur (**Table 37.3**).

Recipient Factors

Early posttransplant complications occur in the first 30 to 90 days posttransplant and are typically the most immediately threatening to the survival of the graft and patient. Three critical elements dictate the immediate posttransplant course: recipient health and comorbidity at time of

transplant, donor organ quality, and technical details of the transplant operation. Comprehensive care of the transplant recipient requires detailed knowledge of all three and can guide perioperative care. The clinical status of the recipient at the time of operation can have a profound effect on the perioperative course. Given the current MELD-Na based allocation system, recipients may often have significant renal dysfunction and hyponatremia at the time of transplant. This factor, coupled with an aging recipient population with a higher burden of comorbid disease, explains the high incidence of posttransplant renal dysfunction, with acute kidney injury occurring in up to 50% of recipients, with up to 15% of patients requiring some duration of renal replacement therapy following transplant.[55] Other aspects of recipient clinical status at the time of transplant beyond renal dysfunction, such as frailty, obesity, and malnutrition, can increase recipient vulnerability to posttransplant complications, particularly sepsis. Clinical pathways to promote early extubation, mobilization, and optimization of nutrition act in part to mitigate these recipient-challenges in the early posttransplant period.[56]

Table 37.3 Continuum of Post-Liver Transplant Complications

Time	Event
0–90 d	Primary nonfunction Acute kidney injury Vascular complications Biliary complications Sepsis; surgical site infections Medication adverse reactions Perioperative cardiac events Acute rejection Donor-derived disease
90 d to 1 yr	Acute rejection Atypical/Opportunistic infections Biliary complications
Beyond 1 yr	Chronic kidney disease Cardiovascular disease Cancer Chronic allograft failure

Donor Factors

Donor quality has long been associated with risk of perioperative complications and early graft loss.[57] With increasing demand, transplant centers have increasingly used more marginal grafts (older donors, more steatosis, DCD donors) at risk of early allograft dysfunction. Donor livers of lesser quality, and particularly DCD donor livers, are associated with more robust reperfusion injury and associated downstream consequences for the recipient, including but not limited to coagulopathy and need for more transfusions, prolonged ICU and hospital length of stay, prolonged ventilation, acute kidney injury, and early mortality.[58,59] Given that early graft dysfunction can often be predicted based upon donor characteristics, surgeons may choose to avoid grafts of lower predicted quality for more complex or frail recipients. Improvement in preservation technique,

particularly machine perfusion of donor livers, may help to mitigate some of the reperfusion injury associated with more marginal donor organs, and allow more refined selection of donor livers based upon functional metrics while on machine perfusion systems.[60,61] Primary nonfunction, defined as lack of graft function without associated vascular compromise, is a rare (~1% of liver transplants in most series) occurrence but requires immediate retransplant for rescue as patients can develop sequelae of acute liver failure including cerebral edema and multisystem organ failure.

Technical Factors

In addition to recipient health and donor quality, the difficulty of the transplant operation has a significant impact on the initial perioperative course. Risk factors for more increased perioperative risk include retransplantation, previous abdominal surgery, and portal vein thrombosis. In addition, patients in specific diagnosis groups may pose greater technical challenges including candidates with Budd–Chiari syndrome, polycystic liver disease, and acute alcoholic hepatitis. Technical factors that complicate vascular inflow or outflow to the transplant liver are of particular consequence, with portal vein thrombosis being the most common vascular challenge among liver transplant candidates, occurring in up to 15% of candidates and associated with increased risk of graft loss and patient death.[62,63]

Vascular Complications

Vascular complications in the early posttransplant period can be catastrophic and may lead to the need for immediate retransplantation. Hepatic artery thrombosis, occurring in 1% to 2% of deceased donor whole grafts, may occur at increased frequency with higher-risk grafts including DCD donor livers, partial allografts, and pediatric donor livers. The diagnosis of hepatic artery thrombosis may be suspected by an unexpected rise in serum transaminase levels and confirmed by Doppler ultrasonography and/or CT angiography. When recognized immediately, hepatic artery thrombosis may be rescued with surgical revision and thrombectomy, but given the hepatic artery's preferential blood supply to the biliary epithelium, biliary

complications including ischemic cholangiopathy may be predictable sequelae. Hepatic artery thrombosis that occurs in the first-week posttransplant and is not able to be surgically corrected is an indication for immediate retransplantation. Hepatic artery thrombosis may occur more indolently in a delayed fashion, weeks to month posttransplant, and in that setting, the consequences to graft function and biliary tree may be less severe.

Portal vein thrombosis occurs less commonly than hepatic artery thrombosis in the acute posttransplant setting. The most important risk factor for posttransplant portal vein thrombosis is portal vein thrombosis at the time of transplant. Inadequate thrombectomy, and/or inadequate flow due to robust collaterals that divert mesenteric venous return away from the transplant portal vein may predispose recipients to portal vein thrombosis and persistent or recurrent portal hypertension. Portal vein thrombosis that occurs in the immediate posttransplant period should prompt operative exploration and revision to ensure there is not a technical error in construction of the anastomosis. Management of posttransplant portal vein thrombosis that occurs more indolently requires understanding of mesenteric venous anatomy, such that a venous-phase CT or more formal mesenteric angiography with venous runoff is needed. Ligation or embolization of collateral venous channels may be necessary to ensure adequate flow to keep the transplant portal vein patent.

Hepatic venous outflow stenosis is a rare complication that can be complicated to diagnose and treat. When outflow stenosis presents in the immediate posttransplant period, or even in the primary operation, graft congestion and dysfunction can develop immediately. Surgical revision of the outflow may be necessary, which is a high-risk and difficult procedure that can cause significant graft injury during a time of vascular exclusion. When outflow stenosis develops in the posttransplant period, it is typically characterized with a clinical syndrome that may include persistent ascites, lower extremity edema, and renal dysfunction. Cross-sectional imaging studies and ultrasonography can be suggestive but not definitive for outflow stenosis, so direct caval venography with manometry is needed to make and localize the diagnosis of outflow stenosis. Balloon angioplasty and stenting can fortunately address most subacute venous stenoses without the need for operative revision.

Biliary Complications

Biliary complications are among the most common posttransplant complications, affecting 15% to 30% of recipients.[64] Patients with partial allografts are at highest risk for biliary complications, particularly when reconstruction of segmental ducts is required. Biliary complications are likely multifactorial, related to technical factors, duct size, donor liver quality, and ischemia. Approximately 4% to 12% of patients will experience biliary leaks, which typically present in the first days to weeks posttransplant. Biliary leaks can present with sepsis and peritonitis and should be suspected in any posttransplant patient who develops infectious symptoms, ileus, or other evidence of clinical decline. In the absence of a direct evidence of bile from a surgical drain or peritoneal aspirate, direct cholangiography via ERCP or percutaneous cholangiography is needed to make a diagnosis (**Fig. 37.14**). Management of biliary leaks should be catered to the clinical context and patient condition. Early leaks, particularly when associated with evidence of intra-abdominal sepsis, should prompt consideration of reoperation, washout, and surgical revision. Less acute leaks in stable patients can be managed with drainage of peritoneal bilomas or ascites and endoscopic stenting. Percutaneous transhepatic cholangiography and placement of an external biliary drain may be necessary with a biliary enteric anastomosis.

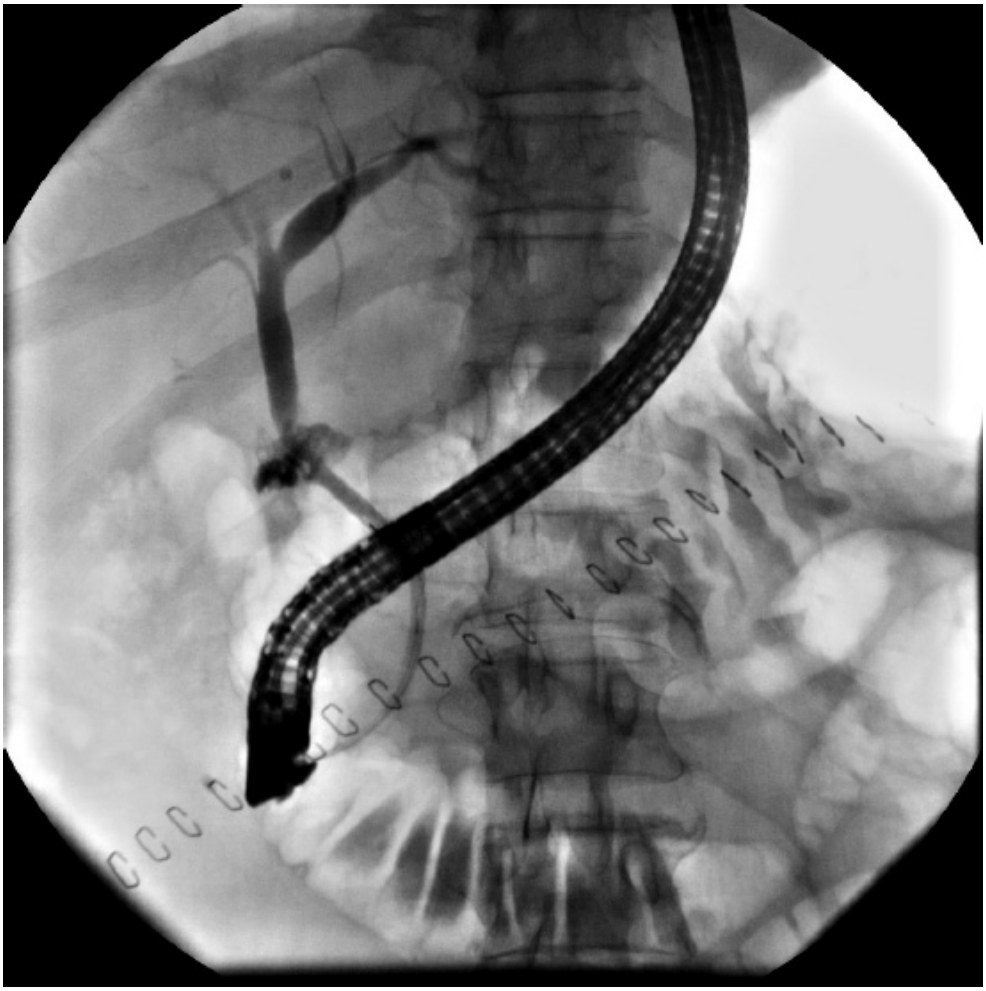

Figure 37.14 Endoscopic retrograde cholangiogram demonstrating a biliary anastomotic leak. (Photo belongs to Dr. Sonnenday.)

Biliary stricture occurs in 10% to 20% of liver transplant recipients and may present months or even years posttransplant. Recipients with a previous leak are at risk for stricture development, as well as patients who receive DCD donor livers and patients with hepatic artery complications.[65] The majority of biliary strictures are anastomotic and can be dealt effectively with endoscopic or percutaneous dilatation and stenting. Use of self-expanding fully covered metal stents has further expanded nonoperative management options with fewer endoscopic procedures.[66] Surgical revision should be reserved for patients who fail endoscopic management.

Immunologic Complications

For reasons that are not fully elucidated, liver transplant recipients require less immune suppression than patients with other types of allografts, such as heart, lung, and kidney recipients. This is somewhat surprising given that the mass of the liver is so great compared with the mass of the other organs. With current immunosuppressive therapy, graft loss from rejection is rare.

Antibody-Mediated Rejection

The liver is relatively resistant to injury from recipient antibodies, regardless of whether they are present at the time of transplant or develop later. This is very different compared with renal and cardiac recipients who experience rapid graft destruction, termed hyperacute rejection, if performed in a patient who has complement-fixing antibodies directed against the donor organ in significant concentrations at the time of transplantation. Hepatic graft injury from pre-existing antibodies directed at donor ABO determinants does occur, but in a much less pronounced fashion than in the context of renal transplantation. The overall results of ABO-incompatible liver transplants are somewhat inferior to those of ABO-compatible transplantations, but only by about a 10% to 20% decrease in 1-year graft survival rates compared to ABO-compatible grafts. Some of this decrease in graft survival rate may be due to the fact that ABO-incompatible transplants are usually performed only in dire circumstances where the patient is so ill that he or she may not survive the wait for a compatible organ. Because preformed antibodies do not seem to be clinically important, most transplantation programs do not perform prospective crossmatch between recipient serum and donor cells before transplantation, and determination of recipient and donor HLA type is no longer considered mandatory.

Why the liver is less susceptible to antibody-mediated destruction than the kidney is not clearly understood. One factor may be the vastly different microcirculation that the liver has compared to the kidney, with a preponderance of sinusoidal channels and a smaller capillary network. It is probable that antibody-mediated injury affects blood flow through the delicate capillary network of the kidney more than it does to the liver sinusoids. In addition, each hepatocyte is exposed to two sinusoidal channels, presumably permitting survival if only one sinusoid is occluded. Finally, differences in HLA antigen expression are known to exist in the two

organs, with the kidney the more antigenic of the two. The clinical impact of antibody-mediated injury in liver transplantation is still being deciphered, with evidence to suggest cumulative injury may compromise allograft function.[67,68]

Cellular Rejection

Typically, acute rejection in liver transplant recipients is cell mediated and occurs frequently but is effectively blunted by antirejection therapy. Acute rejection occurs most commonly in the first two postoperative months and occurs in up to 25% of patients in the first-year posttransplant. In modern practice, cell-mediated rejection is a less common cause of graft loss than are primary nonfunction or hepatic artery thrombosis. Still, the effectiveness of antirejection treatment assumes a relatively early diagnosis and treatment of acute rejection, which is in turn the result of careful monitoring by the transplantation physician and compliance by the patient with frequent laboratory testing. Treatment of acute rejection with enhanced immunosuppressive therapy is highly effective, and an episode of rejection does not affect long-term graft survival. This is very different from renal transplantation, where an episode of rejection decreases long-term graft survival markedly. The diagnosis of cell-mediated rejection is made primarily on a histologic basis. Clinical features can include low-grade fever and malaise, but frequently the patient is completely asymptomatic. Laboratory evaluation of peripheral blood may demonstrate leukocytosis and occasionally eosinophilia. Biochemical changes associated with rejection include elevated and rising levels of serum transaminases and alkaline phosphatase. A prolonged serum prothrombin time and an abnormal serum bilirubin also suggest the possibility of rejection, but frequently these parameters are normal if rejection is detected early. Any of these findings should prompt a biopsy.

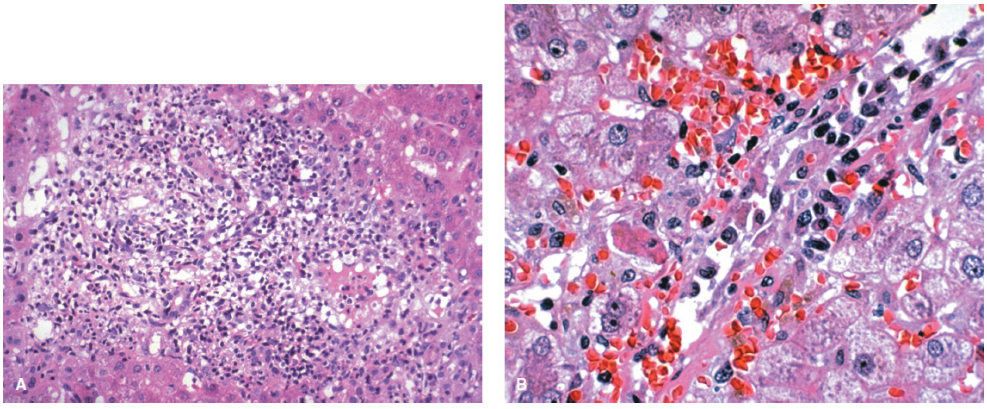

Figure 37.15 Acute rejection of a liver transplant. **A:** A portal tract is expanded by a polymorphous inflammatory infiltrate consisting of large and small lymphocytes, plasma cells, macrophages, and neutrophils. The bile ducts (*arrows*) are damaged and inflamed. **B:** A central vein from the same biopsy exhibits endothelialitis, characterized by swollen endothelial cells and infiltrating lymphocytes. (From Thung SN, Gerber MA. Histopathology of liver transplantation. In: Fabry TL, Klion FM, eds. *Guide to Liver Transplantation*. New York: Igaku-Shoin Medical Publishers; 1988.)

The diagnosis of cell-mediated rejection rests on the finding of a triad of portal lymphocytosis, endotheliitis (subendothelial deposits of mononuclear cells), and bile duct infiltration and damage (**Fig. 37.15**). Various classification schemes have been devised to grade the severity of the rejection process based on the degree of cellular involvement or injury in these areas. Cell characterization studies have documented that the cells in the portal triads are primarily T cells, with fewer macrophages and neutrophils. Bile duct epithelial cells appear to be a prime target of immune attack, and they are known to express large amounts of class II HLA antigen.

If the recipient has hepatitis C, it is critical that recurrent hepatitis C is differentiated from acute rejection. At times, the difference can be subtle, and a pathologist with experience in the interpretation of allograft biopsies is extremely valuable. Enhanced immunosuppression is associated with accelerated rates of hepatitis C viral replication; it is, therefore, important that immunosuppression is kept to a minimum for these patients.

Chronic Rejection

Chronic rejection is characterized by ongoing and often subacute immune injury, with particular impact on small bile ducts. Clinically, the pattern is

one of gradual elevation of alkaline phosphatase and bilirubin, in the absence of obstruction of the large bile ducts. Histologically, small bile ducts are obliterated or completely absent, with a less pronounced cellular infiltrate than is seen with acute rejection. This finding has been termed vanishing bile duct syndrome when bile ducts are absent in 15 of 20 portal triads examined. The loss of small bile ducts is partly the result of lymphocyte-directed attack on biliary epithelium. Relative to other cells in the liver, biliary epithelium tends to express more class I antigen. Thus, biliary epithelial cells are vulnerable targets for host attack because of their antigenicity. Loss of bile ducts may also occur indirectly as the result of ischemia secondary to immune-mediated obliteration of small to medium arteries. While the biliary injury and ductopenia may not improve significantly histologically, patients may stabilize clinically with increased tacrolimus-based immunosuppression.[69]

Immunosuppression Induction and Maintenance

Multiple immunosuppressive protocols achieve acceptable suppression of allograft rejection for liver transplant recipients. Induction with antithymocyte globulin or other induction agents is no longer considered to be mandatory but is used at some centers. Similarly, prednisone therapy, once considered a mainstay of a successful immunosuppressive protocol, is often tapered off rapidly. Treatment with a calcineurin inhibitor, either cyclosporine or tacrolimus, is still considered to be imperative for most liver transplant recipients. These agents are associated with significant long-term morbidity, particularly the development of chronic renal failure. Dosages of these agents have gradually been reduced both to prevent renal insufficiency and to avoid the rapid and aggressive recurrence of hepatitis C infection. Induction antibody therapy with either polyclonal antilymphocyte preparations or with inhibitors of the receptor for IL-2 are still used commonly in the perioperative setting to avoid the nephrotoxicity associated with the immediate use of calcineurin inhibitors.

Because immunosuppression predisposes to infection, prophylactic anti-infective drugs are usually administered. Trimethoprim-sulfamethoxazole,

dapsone, or pentamidine is recommended to prevent *Pneumocystis carinii* infection. Oral mycostatin or fluconazole therapy is used to prevent fungal infections, particularly esophageal *Candida albicans*. Either ganciclovir or valganciclovir is prescribed for patients who are at risk for CMV infection, which includes any patient exposed to CMV in the past and any patient transplanted with organs from a donor who has been exposed to CMV. Patients who are CMV negative who receive CMV-negative organs are not at high risk for CMV infection but should still receive prophylaxis against disseminated herpes simplex infections with acyclovir therapy. The duration of prophylactic anti-infective therapy has not been rigorously defined by evidence-based trials and is therefore dependent on each center's experience with the prevalence of these infections in its patient population.

Treatment of Acute Rejection

Despite the overall effectiveness of the regimen described, acute rejection does occur and must be treated promptly. Several options are available for treatment of acute rejection, depending on the clinical circumstances. Traditionally, high doses of methylprednisolone are administered (usually 500 mg to 1 g) intravenously on a daily basis for 3 days. This treatment is effective in reversing most acute rejection episodes. Alternatively, increased doses of oral prednisone, a calcineurin inhibitor, or the addition of an antimetabolite drug, such as mycophenolate mofetil, will also reverse most episodes of rejection, particularly if the rejection is mild. Rejection that is resistant to these maneuvers or severe is treated with antilymphocyte therapy, typically a polyclonal antilymphocyte therapy such as Thymoglobulin. These treatments are typically administered daily for 3 to 7 days. These agents are highly effective, and it is unusual to lose an allograft secondary to acute rejection. However, these treatments are associated with profound and long-lasting immunosuppression, and it is usually advisable to restart prophylactic anti-infective therapies when they are initiated.

Liver transplantation remains the definitive therapy for patients with ESLD and select metabolic diseases and hepatic malignancies. Despite an aging patient population with more comorbid disease, short- and long-term outcomes after transplantation continue to improve. Graft loss due to immunologic causes is rare, and long-term threats to graft and patient

survival include chronic kidney disease, cardiovascular disease, and malignancy, all of which are associated with the need for lifetime immunosuppression. Given the success of liver transplantation as a durable therapy for ESLD, the primary challenge in the field remains expanding donor organ availability to allow expansion of this lifesaving therapy to more patients with chronic liver disease.

Cardiac Transplantation

Ahmet Kilic and Robert S. D. Higgins

Key Points

1. Heart transplantation is the gold standard of biologic replacement for end-stage heart failure; however, its long-term success and growth is limited by donor availability, perioperative infections, and cellular rejection and the development of malignancies and transplant allograft vasculopathy.
2. Patients with end-stage myocardial dysfunction refractory to conventional methods, including advanced heart failure therapies and revascularization, may require mechanical circulatory support (MCS) as bridge to transplantation (BTT).
3. MCS using left ventricular assist devices (LVADs) has developed as an effective means of circulatory support and end organ perfusion; however, complications of LVADs are common including driveline infection, pump thrombosis, strokes, allosensitization, and gastrointestinal bleeding.

HISTORICAL PERSPECTIVE

The original technique described by Lower and Shumway and perfected in the laboratory at Stanford in the 1960s confirmed that the denervated heart could function to support the circulation in the transplant recipient (**Fig. 38.1**).[1] This technique has evolved over the past 50 years to be the ultimate biologic 1 replacement and surgical intervention for patients with advanced heart failure, refractory to medical therapies. During that time, a number of extraordinary advancements continued to enhance the ability to overcome inherent obstacles imposed by the body's immunologic response to biologic replacement by a foreign organ. In addition to demonstrating the technical aspects of successful transplantation, the development of a technique to perform transvenous endomyocardial biopsies for immunologic surveillance was also a breakthrough milestone at Stanford. This innovation provided tissue to characterize the nature of acute cellular rejection and enable earlier rejection detection, leading to treatment with augmented immunosuppression.[2] One of the most influential advances in the field of modern transplantation was the development and application of cyclosporine, a powerful immunosuppressant used as part of the triple immunosuppression protocol in solid organ transplant programs around the world and a breakthrough clinical application led by the Stanford Group and Roy Calne at Cambridge University.[3] Cyclosporine reduced the activity of the immune system by interfering with the activity and growth of T cells and its immunosuppressant activity is manifest by binding to a cytosolic protein cyclophylin of the lymphocyte. This complex of cyclosporine and cyclophylin then inhibits calcineurin that under normal circumstances is responsible for activating the transcription of interleukin-2 (IL-2). The success of cyclosporine in preventing organ prevention was shown in kidney transplants by Calne et al. at the University of Cambridge and in liver transplants by Thomas Starzl at the University of Pittsburgh. Cyclosporine was subsequently approved for use in 1983.[4]

Stanford Surgeon Switches Heart In Dog–It Lives

By GEORGE DUSHECK

A young Stanford surgeon has successfully transplanted a living heart from one dog to another.

The dog is still alive a week later.

The daring experiment was carried out by Dr. Richard Lower, working with Dr. Norman Shumway at Stanford's new Palo Alto medical center.

Other surgeons have attempted similar heart transplants; the animals all have died within hours.

DR. LOWER'S operation differs in one respect from previous attempts:

He left in the host dog a portion of the wall of the

HEART

Continued from First Page

show "Doctors' News Conference."

Dr. Lower's accomplishment is, as Dr. Cohn put it, "a technical stunt." Nobody expects the dog to survive permanently.

Organs transplanted from one animal to another create

NAMED "RESEARCH DOG HERO OF 1960" by the National Society for Medical Research this month was "Sam," a 4-year old pointer who is living with a trans

Figure 38.2 Hypothermia preservation research in the dog highlights human heart transplant potential at Stanford.

While the history of heart transplantation as documented above highlights a relatively uneventful path from concept to reality, the actual evolution toward human heart transplantation was a much more exciting journey with many

extraordinary twists and turns. Over the course of close to a decade of innovative research and laboratories in Minneapolis, Palo Alto, New York, and other laboratories around the world, the field of heart transplantation exploded in what can only be characterized as an extraordinary human drama.[1]

On the brink of successful transplantation in 1967, four very different surgeons and their groups were on the cusp of medical immorality, including Norman Shumway, who many believe was the father of the modern technique of midatrial excision of the heart and reimplantation developed in his laboratory while studying hypothermia and myocardial protection with his laboratory partner and future competitor Richard Lower (**Fig. 38.2**). Adrian Kantrowitz pushed the process in the hopes of saving neonates and babies with developmental anomalies in New York. Dr. Kantrowitz performed the first pediatric transplant in New York. He also laid the foundation for formulating the brain death criteria, which later was developed by the Ad Hoc Committee on Brain Death Criteria of the Harvard Medical School. However, the ultimate winner of the race to immortality was Barnard, who gained worldwide recognition by capitalizing on the application of this innovative technique to perform the first human heart transplant in Cape Town on December 3, 1967.[5] Although the patient died 18 days later from infectious complications, history was made and the future was defined as advancements in surgical technique, immunosuppression, and patient selection led to improvements in outcomes leading to peaks in heart transplantation performance in the early 1990s.

INDICATIONS FOR TRANSPLANTATION

Over 5 million Americans suffer from heart failure and more than 250,000 die annually. Current therapeutic interventions are focused on the appropriate assessment of myocardial dysfunction as a means to select the right patient for the appropriate procedure using state of the art myocardial viability testing and metabolic testing to determine if patients with advanced heart failure are candidates for conventional interventions, mechanical devices, or transplant. Heart transplantation is the treatment of choice for selected patients with advanced heart failure who have extraordinary limitations in

terms of their overall physical well-being and limited life expectancy, approaching less than 2 years.[6]

Cardiopulmonary stress testing is the most reliable and objective criterion, in addition to clinical criteria, to determine the extent of the critical advanced heart failure and the likely morbidity and mortality associated with class for heart failure (**Fig. 38.3**). The measurement of peak oxygen consumption (VO_2) has been shown to correlate with functional capacity and mortality. Mancini et al. were the first to demonstrate a relationship between peak oxygen consumption and outcomes (**Fig. 38.4**).[7] More recently, other measurements obtained during a metabolic exercise test have been shown to predict mortality in patients with end-stage heart failure. Peak oxygen consumption per unit time (VO_2) of less than 10 to 15 mL/kg/minute with respiratory exchange ratio greater than 1.05 is predictive of severely poor outcome. This value has been used as criterion for transplant waitlist selection.[8] These measurements include the slope of the relationship between ventilation and carbon dioxide production (Ve/VCO_2 slope), end-tidal carbon dioxide (CO_2), the oxygen uptake efficiency slope, and the rate of heart rate recovery.[9] Based on this data, metabolic exercise testing is now routinely performed in the assessment of patients for heart transplantation.[10]

2 Additional criteria of a clinical nature include repeated hospitalizations for heart failure therapy, progressive increases in heart failure medications, and the need for mechanical circulatory support (MCS), such as an intra-aortic balloon pump or MCS with a left ventricular assist device (LVAD). Selection criteria for heart transplantation have been well-defined and suggest that evaluation by a multidisciplinary team of healthcare professionals, nurses, and physical therapists, is the best means to determine those at greatest risk for high mortality and potential benefit for transplantation (**Fig. 38.5**).

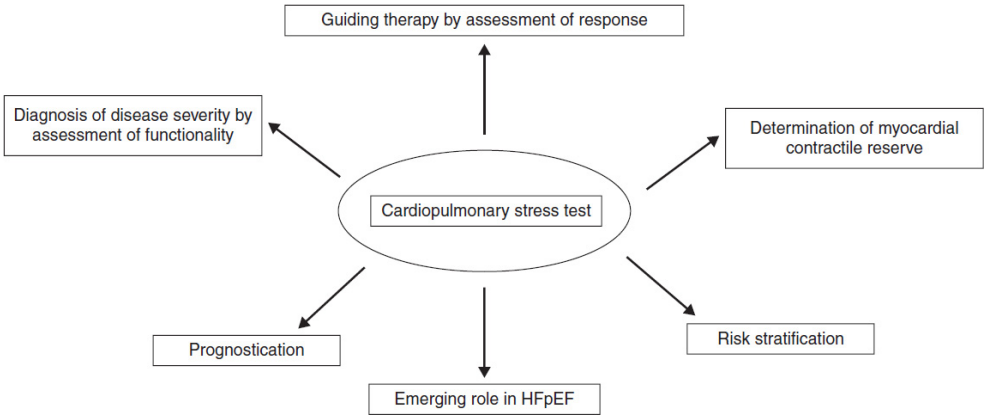

Figure 38.3 Uses of cardiopulmonary stress tests in heart failure.

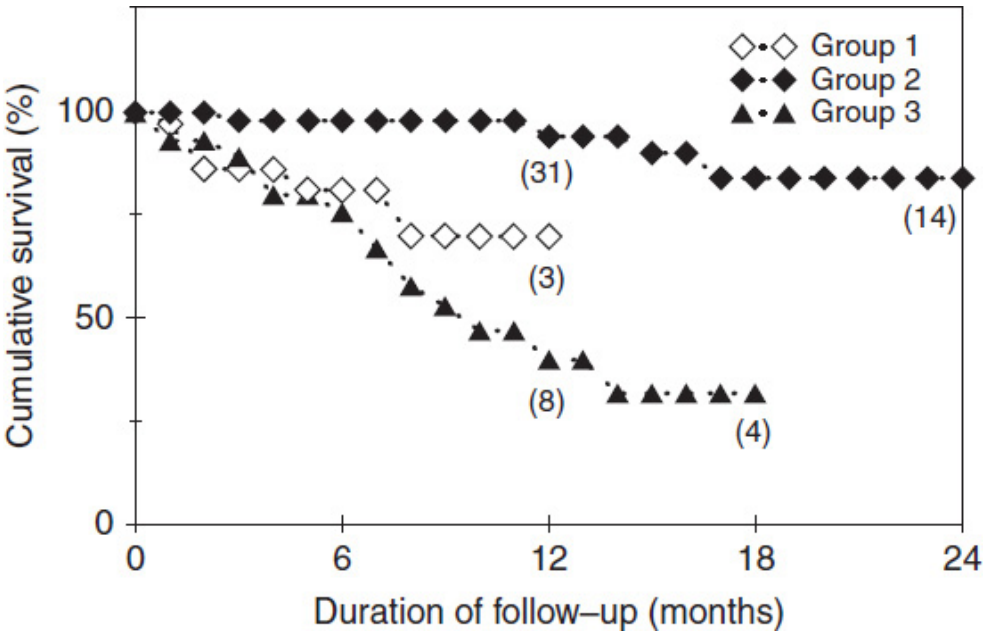

Figure 38.4 Survival curves comparing groups 1, 2, and 3. Survival curves for groups accepted (1) and rejected for transplant (3) are similar but are significantly reduced compared with group 2 ($p < 0.001$).

PRETRANSPLANT MANAGEMENT

During the past decade, there have been significant advancements in the therapy of heart failure. The use of beta adrenergic blockers, aldosterone antagonists, implantable cardioverter defibrillators (ICDs), and biventricular pacemakers (CRT devices) have all been shown to improve mortality in patients with advanced heart failure.[11,12] Despite demonstrated improvement

in mortality, only biventricular pacemakers have led to improved exercise capacity.[13–15]

The majority of patients with advanced heart failure have secondary end-organ dysfunction, including reductions in renal perfusion leading to renal failure, evolution of secondary pulmonary hypertension, and eventual irreversible pulmonary hypertension leading to the risk of right ventricular failure in the immediate perioperative period after transplantation. Therefore, selection criteria related to assessments of pulmonary vascular bed resistance and irrevocable pulmonary hypertension can often eliminate patients from consideration for transplantation. Perioperative assessment of the pulmonary vascular bed is then necessary to avoid patients with irreversible pulmonary hypertension and multiple therapies can be used to mitigate the impact of advanced heart failure, including nitroprusside, nesiritide, dobutamine, and inhaled nitrous oxide. Milrinone, a phosphodiesterase inhibitor, has been highly effective over the years and is often used to determine if pulmonary hypertension is irreversible and/or treatable. If pulmonary hypertension is controlled, then the patient may be considered for transplantation. Other end-organ dysfunction, which may result from advanced heart failure and compromise perioperative success, include:

NYHA Class	Patients with Cardiac Disease (Description of HF Related Symptoms)
Class I (Mild)	Patients with cardiac disease but without resulting in limitation of physical activity. Ordinary physical activity does not cause undue fatigue, palpitation (rapid or pounding heart beat), dyspnea (shortness of breath), or anginal pain (chest pain).
Class II (Mild)	Patients with cardiac disease resulting in slight limitation of physical activity. They are comfortable at rest. Ordinary physical activity results in fatigue, palpitation, dyspnea, or anginal pain.
Class III (Moderate)	Patients with cardiac disease resulting in marked limitation of physical activity. They are comfortable at rest. Less than ordinary activity causes fatigue, palpitation, dyspnea, or anginal pain.
Class IV (Severe)	Patients with cardiac disease resulting in the inabiltiy to carry on any physical activity without discomfort. Symptoms of heart failure or the anginal syndrome may be present even at rest. If any physical activity is undertaken, discomfort is increased.

Figure 38.5 NYHA functional classification. (The Criteria Committee of the New York Heart Association. *Nomenclature and Criteria for Diagnosis of Diseases of the Heart and Great Vessels*. 9th ed. Boston, MA: Little, Brown & Co; 1994:253–256.)

American Heart Association Heart Failure Stages

- **Stage A:** Presence of heart failure risk factors but no heart disease and no symptoms
- **Stage B:** Heart disease is present but there are no symptoms (structural changes in heart before symptoms occur)
- **Stage C:** Structural heart disease is present AND symptoms have occurred
- **Stage D:** Presence of advanced heart disease with continued heart failure symptoms requiring aggressive medical therapy

Figure 38.6 AHA heart failure stages.

- Renal failure
- Diabetes or complications of end-organ diabetes
- Previous malignancy within 5 years of transplant consideration
- Hepatic insufficiency
- Psychosocial noncompliance
- Active substance abuse, including smoking and illicit drug use
- Lack of social support sufficient to address the perioperative needs of the patient

All of these factors serve to limit the success of transplantation in the modern era.

Right heart catheterization is often used to determine the suitability of the transplant patient and allows direct measurement of right atrial pressure, pulmonary capillary wedge pressure, pulmonary artery pressure, and mixed venous artery saturation. It can also be used to guide optimal medical therapy in patients with advanced heart failure and elevated filling pressure despite optimal treatments. Other biomarkers, such as natriuretic peptide levels, can be predictive of prognosis in those with advanced heart failure and used as a marker for improvements with medical therapy.[16] A number of prognostic heart failure scores have been developed, including the Seattle Heart Failure Model and the Heart Failure Survival Score in advanced heart failure populations.[17] These estimates can correlate with American Heart Association Heart Failure Stages to guide additional therapies and improvements in outcomes over time (**Fig. 38.6**).

PRETRANSPLANT ASSESSMENT

A number of pretransplant investigations are necessary as part of the selection process and can often identify contraindications of transplantation as listed. Blood group and tissue typing are also necessary in patients being considered for transplantation, as well as the presence of secondary infection, such as hepatitis B, hepatitis C, HIV, Epstein–Barr virus, hemoglobin A1c, diabetes, herpes simplex, and cytomegalovirus (CMV).

Patients who have been ill and requiring multiple transfusions can often be allosensitized to human leukocyte antigens (HLAs). This sensitization may also occur in women who have been pregnant or previously transplanted. This can have an impact on the chances of successful donor-recipient matching and is factored into the time of listing of heart transplantation.[10,18] Active contraindications include active infection, peripheral vascular or cerebral vascular disease, diabetes with end-organ damage, current neoplasm within 5 years, severe lung disease, irreversible renal dysfunction with a glomerular filtration rate (GFR) estimated less than 30 mL per minute, irreversible liver dysfunction and cirrhosis, recent pulmonary embolism, pulmonary hypertension with systolic arterial pressure greater than 60 mm,

transpulmonary gradient greater than 15, or a pulmonary vascular resistance greater than 5 Wood units. Physiologic manipulation with pharmacologic drugs may unload the ventricle and demonstrate reversibility of pulmonary hypertension.[19]

ORGAN AVAILABILITY AND ALLOCATION

The Organ Procurement and Transplantation Network (OPTN) brings together medical professionals, transplant recipients, and donor families to develop organ transplantation policy. Organ Procurement and Transplant Network (OPTN) policies affect all U.S. transplant centers, organ procurement organizations (OPOs), and candidates waiting for an organ transplant. OPTN maintains data on over 120,000 potential transplant recipients of all organs including heart, lung, liver, kidney, liver, and pancreas. The current OPTN system has identified four major limitations:

- Too many status 1A heart transplant candidates;
- Too many exception requests required for allocation of transplant organs;
- Increased use of MCS devices for patients with advanced heart failure not accommodated by current system; and a geographic sharing scheme that is not equitable for those waiting on the list.[20]

In 2018, the OPTN/UNOS Thoracic Organ Transplantation Committee proposed modifications to the adult heart allocation system to better stratify the most medically urgent heart transplant candidates, reflect the increased use of mechanical circulatory support devices (MCSDs) and prevalence of MCSD complications, and address geographic disparities in access to donors among heart transplant candidates. Concerned that the former three-tier system did not prioritize enough urgency for these patients, UNOS has implemented a six-tier system with more specific guidelines for each tier. The new allocation system assigns patients on extracorporeal membrane oxygenation (ECMO) devices the highest priority.[21] This may evolve as a heart allocation score similar to the Lung Allocation Score (LAS) and the model for end-stage liver disease (MELD) scores utilized for lung and liver transplantation.

In a different approach to enhance organ allocation in EUROTRANSPLANT countries, a cardiac allocation score was developed

and then revised in Germany.[22] The idea behind the cardiac allocation score, similar to the established LAS in lung transplantation, is to provide middle ground between risk and benefit. Risk of mortality on the waiting list is based on the Seattle Heart Failure Model and posttransplant outcomes are predicted by the Index for Mortality Prediction After Cardiac Transplantation score (IMPACT score). Patients who have a high urgency and a high chance of a successful posttransplant outcome will have the highest cardiac allocation score and are assigned the highest priority in the allocation process.[23]

MCS has been employed for advanced heart failure since the 1990s, when the Federal Drug Administration approved volume displacement pumps (LVADs). Two general indications to support the failing heart have evolved since then: to act as a bridge to transplant (BTT) and to be a destination therapy (DT) to support cardiac function for the remainder of the patient's life.[24] Some patients may require support until their general medical condition improves or until they become a better candidate eligible for transplantation (bridge to decision or eligibility).[25]

3 Continuous flow pumps have emerged as the preferred MCS for patients with left ventricular failure awaiting heart transplantation or as DT. LVADs restore cardiac output and tissue perfusion, therefore improving end-organ function. The two currently approved LVADs have inlet and outflow ports with a single rotary element that rotates to propel blood to the aorta, leading to increased arterial blood pressure and flow. Blood is drawn into the pump impeller from the left ventricular apex and delivered to the aorta. There are two LVAD blood flow configurations: axial and centrifugal flow pumps. In the centrifugal flow pump, blood is captured between the blades, which spin at right angles to the outflow. In the axial flow pump, the rotating impeller operates like a propeller in a tube. The three commercially approved LVADs are the Heartmate II and III (Thoratec/St. Jude Corp.) and the Heart Ware HVAD (Heart Ware/Medtronic Inc.) (**Fig. 38.7A–C**). Through documentation and reporting in clinical databases like INTERMACS and the International Society of Heart and Lung Transplantation (ISHLT) Registry, LVADs have demonstrated effective performance profiles, improved systemic perfusion, and enhanced outcomes. The databases also show that complications of MCSDs are common—the most common complications being driveline infections, cannula obstruction, gastrointestinal bleeding, and

device can lead to inflow or outflow obstruction and subsequent device power surges (**Fig. 38.8**). Predisposing factors include shear stresses in blood flow, cannula malposition, disturbances in von Willebrand factor levels (deficiency), and heparin-induced thrombocytopenia. Starling et al. reported an increase in the rate of device thrombosis in patients with HeartMate II in 2014.[26] Based upon data from three institutions with experience in 837 patients, a total of 72 pump thromboses were confirmed in 66 patients. They reported that elevated lactate dehydrogenase (LDH) levels presaged thrombosis. The majority of patients underwent pump replacement and 11 patients underwent urgent transplantation. In the most recent clinical study of 366 patients comparing survival of patients using the HeartMate 3 LVAD to those using the HeartMate II LVAD, they reported that 77.9% of the HeartMate 3 patients, as compared to 56.4% of the HeartMate II patients, survived to 2 years without a disabling stroke and without the need to replace the pump.[27] About 1.6% of the HeartMate 3 patients needed the pump replaced within 2 years, compared to about 12.2% of the HeartMate II patients.

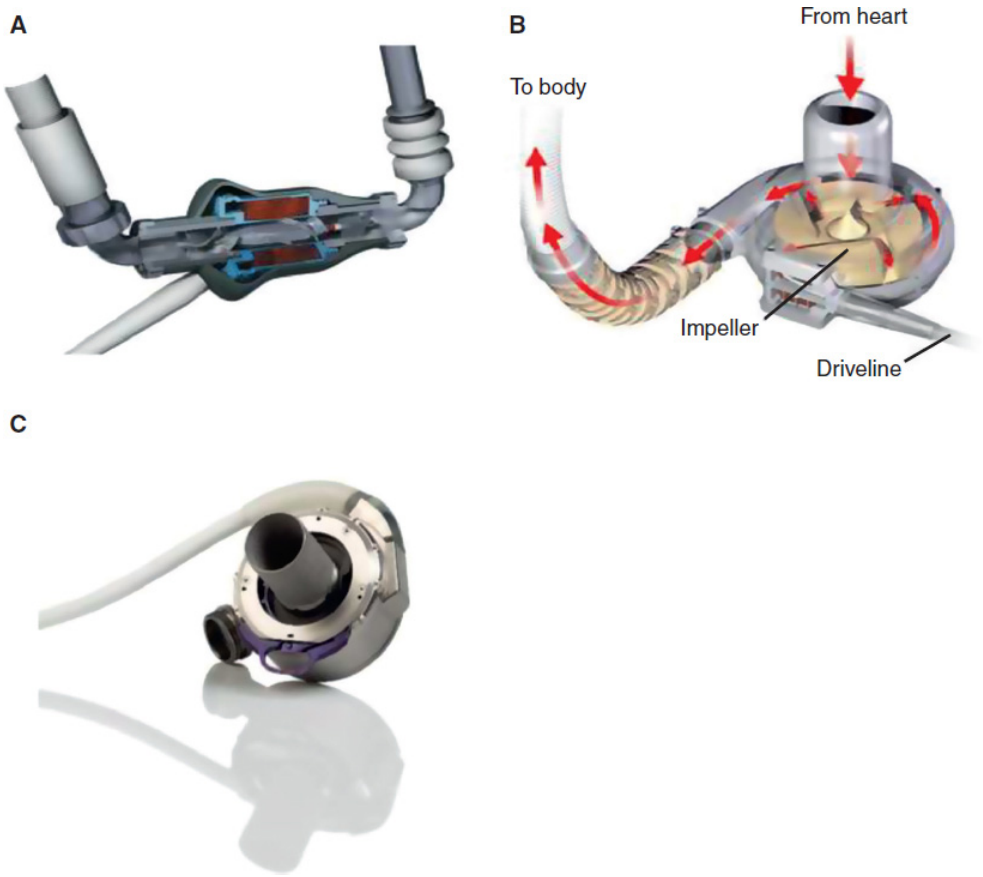

Figure 38.7 **A–C:** Heartmate II and III (Thoratec/St, Jude Corp.) and the Heart Ware HVAD (Heart Ware/Medtronic Inc.).

LVADs can stimulate the development of alloreactive antibodies.[18] Panel reactive antibody (PRA) screening is done in all heart transplant candidates and further evaluation is needed if PRA levels are elevated above 10% to 20%. The factors involved leading to sensitization are homograft use in congenital surgery, female sex, prior pregnancies, Black race, VAD surface exposure, retransplantation, perioperative blood products usage, and infections. Acute antibody-mediated rejection (AMR) occurs in about 10% and this is usually due to antibodies driven by T cells to donor vascular antigens. This leads to B-cell activation and production of plasma cells. While difficult to diagnose, this rejection is typically associated with detection of immunoglobulins, complement fragments, CD 68 positive cells, and de novo anti-HLA antibodies.

Significantly improved survival is associated with treatment of PRA levels greater than 10%, aggressive desensitization with plasmapheresis, intravenous immunoglobulin (IVIG), and rituximab.[28] IVIG is used to

neutralize preformed antibodies before and after transplantation, however the effectiveness is variable. Plasmapheresis is fast, short-lived, and can be done immediately before transplantation. Rituximab (anti-CD20) is frequently used and is effective in the long term. Immunoabsorption and splenectomy are rarely used as the rate of infection is very high with these therapies.

IMMUNOSUPPRESSION

Current immunosuppressive regimens can be classified as induction, maintenance, or antirejection. Induction regimens provide intense early postoperative immune suppression while maintenance regimens are used throughout the patient's life to prevent both acute and chronic rejection. Three general principles govern induction and maintenance immunosuppressive therapy regimens. The first principle is that immune reactivity and tendency toward graft rejection are highest early (within the first 3 to 6 months) after graft implantation and decrease with time. The second principle is to use low doses of several drugs with nonoverlapping toxicities in preference to higher (and more toxic) doses of fewer drugs whenever feasible. The third principle is to avoid overimmunosuppression, because it leads to a myriad of undesirable effects including susceptibility to infection and malignancy.

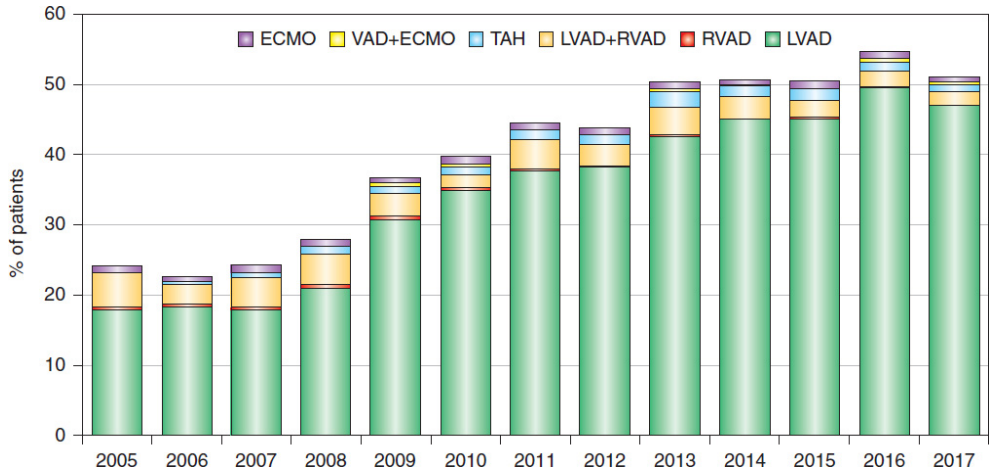

Figure 38.8 Percent of patients bridged with mechanical circulatory support by year and device type. (Adult heart transplants: 2005–2017.) ECMO, extracorporeal membrane oxygenation; LVAD, left ventricular assist device; RVAD, right ventricular assist device.

Most modern immunosuppressive regimens consist of a two- or three-drug regimen, including a calcineurin inhibitor (typically tacrolimus), an antimetabolite agent (typically mycophenolate mofetil), and tapering doses of glucocorticoids over the first year. Although tacrolimus and cyclosporine are both highly effective agents, evidence from clinical trials suggests that tacrolimus-based immunosuppression may offer an advantage over cyclosporine-based regimens with respect to decreased rates of acute rejection and an overall more favorable metabolic derangement profile (decreased incidence of hypertension and hyperlipidemia but higher incidence of posttransplant diabetes). The proliferation signal inhibitors sirolimus and everolimus are typically used in patients with cardiac allograft vasculopathy (CAV) or renal insufficiency. Due to their inhibitory effects on smooth muscle proliferation and absence of intrinsic nephrotoxicity, they have been useful for slowing disease progression in these settings.

Current regimens use IL-2 receptor antagonists for induction therapy and these drugs are now used in 30% of patients undergoing heart transplantation. The currently available agent, basiliximab (Simulect), is a monoclonal antibody that selectively binds to the IL-2 receptor of T lymphocytes, blocks binding of IL-2 to the receptor complex, and exhibits its immunosuppressive effects by inhibiting IL-2-mediated T-lymphocyte proliferation.[29] There was a reduction in the incidence of acute rejection among patients treated with IL-2 receptor antagonists compared with no induction. There were fewer

rejection episodes among patients treated with polyclonal antibody induction compared with IL-2 receptor antagonist therapy, though the numbers of events were small.[30] In a retrospective analysis, antithymocyte globulin (ATG) was associated with better long-term survival at 5 and 10 years as compared to basiliximab.[31]

The absolute indications for induction therapy are not clearly defined, however, those patients at high risk for rejection (>5% at 1 year), younger patients, Black race, patients with a high number of human leukocyte antigen mismatches, and patients supported with ventricular assist devices with high levels of preformed antibodies, may get benefit from the induction therapy.[32]

DONOR SELECTION AND MANAGEMENT

Donor Selection

It is stated that if you have a good donor and a good recipient, you should always have a good outcome. Although this is a somewhat overgeneralization, it is paramount to match the individual recipient with the ideal donor. Particular attention should be paid to the age of the donor, function and quality of the donor heart, donor–recipient compatibility (gender, height, and body mass index), ischemic time, and preformed antibodies.[33] The ideal age for a donor is between 11 and 39 years old according to Kaplan–Meier survival stratified by age group in the UNOS database with a median survival for this age group of 11.5 years posttransplant. Following this, the donor age group of 0 to 10 years has a median survival of 10.6 years, that of 40 to 59 years 9.7 years, and those donors above age of 60 having a 7.4-year median survival. It is interesting to note that despite the scarcity of organs, over the past 30 years, the median donor age in the United States has remained between 25 and 30 years of age whereas in Europe the median age is around 45.[16]

Gender discordance has been recognized as a posttransplant risk particularly when female hearts are transplanted to male recipients.[34–36] In addition to gender matching, the importance of height, weight, body surface area, predicted heart mass, and body mass index have all been reported to potentially play a factor in success.[37–40] Another major influence in outcomes

following heart transplantation has been the ischemic time between the donor cross clamp and recipient reperfusion. This plays heavily in the decision making between donor availability and suitability for organ acceptance with the ideal ischemic time being less than 4 hours with most centers having a cap of around 6 hours. Indeed there is evidence of worse survival and higher rejection episodes within the first year post transplant, as well as higher chance of long-term CAV in those recipients having a longer than 6-hour ischemic time.[16]

Perhaps the single most important variable in donor selection is the quality or function of the donor heart. Oftentimes, the cause of death is secondary to a catastrophic event, such as an anoxic brain injury, stroke, or trauma that can lead to dynamic changes in the heart function. The body's response to the variety of neurohormonal changes are complex and a spectrum of physiologic effects can result including variations in blood pressure, volume status, and metabolic derangements, which all lead to conflicting reports of outcomes following transplantation utilizing these organs.[41,42] An important component of donor management has been the recognition of the sick thyroid syndrome, with most OPOs utilizing continuous thyroxine infusion during the periprocurement brain death period.

As a general rule, the function of the donor heart can be assessed in a step-wise fashion with the first step being the cause of death. Most clinicians would avoid the use of a donor heart where the mechanism of death was attributable to the heart like a lethal arrhythmia, a myocardial infarction, or a traumatic injury. In patients where there is a question as to the underlying cause, an electrocardiogram at admission and serially can help exclude coronary pathology, as well as serial troponin values. In patients with hypertensive stroke as the cause of death, careful evaluation must be made to ensure that the left ventricle is not overly hypertrophied (ideal left ventricular interventricular septum is <1.3 cm), as this can be a predictor for restrictive dysfunction of the allograft in the long term, as well as difficulty in myocardial preservation during the period of organ recovery in the immediate transplant period.

An essential part of the evaluation of the potential donor is an echocardiogram, which gives important information such as the ejection fraction, anatomic and physiologic abnormalities, ventricular hypertrophy, right heart function, the exclusion of masses or vegetation, and regional wall

abnormalities. Care should be taken to look at the amount of inotropic infusion during times of echocardiographic assessment. Whereas pressor requirement does not necessarily affect heart function, the number of and the dosage of inotropic support can serve as an important prognostic measure for the posttransplant primary graft dysfunction (PGD).

In patients with risk factors for coronary arterial disease (age >40, smoking, hypertension, diabetes mellitus, regional wall motion abnormality on echocardiogram), a left heart catheterization can provide information of coronary anatomy as well as left ventricular function and left ventricular end diastolic pressure. A right heart catheterization can be an adjunct test in patients where right heart function is in question. In combination with a central venous pressure, pressures obtained from a right heart catheterization can aid the clinician in deciding to use a potential donor heart.

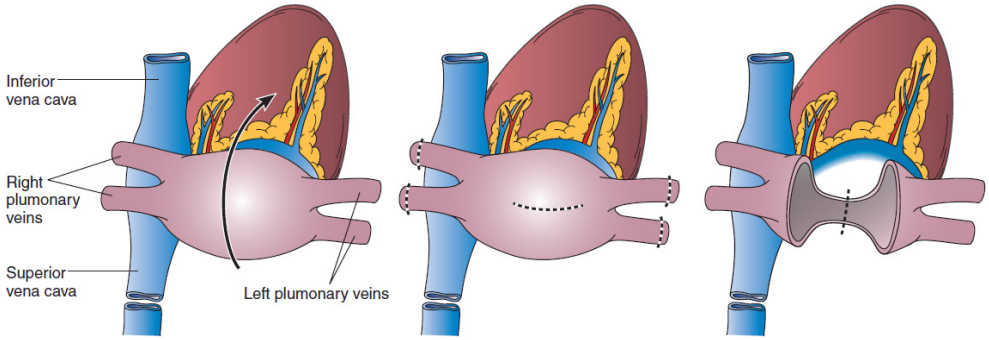

Figure 38.9 Steps to excise the donor heart with emphasis on adequate atrial cuffs (if lung procurement is also performed). (This image was produced by medical illustrator from Johns Hopkins–Timothy Phelps.)

Heart Procurement

After a donor is assessed to be appropriate for a given recipient, the goals of the procurement is to minimize ischemic time of the allograft, ensure no technical procurement injury to important structures, and to ensure optimal myocardial protection during the procurement and transportation. The acceptable ischemic time should have already been discussed prior to accepting an organ by members of the donor and implanting surgical team and constant communication between the procurement team and the recipient team can anticipate any delays or changes in either procedure.

Postprocurement function and myocardial protection during this time relies on ensuring that there is no distension of the heart, immediate induction of a diastolic arrest of the donor heart and avoidance of warm ischemia. During the donor procedure, after the systemic administration of heparin, an aortic cardioplegia line is placed in the midascending aortic portion as to allow safe placement of an aortic cross clamp. Once this is placed and the preservation solution is flushed, the process of organ procurement is started in coordination with the rest of the procurement team. The first steps in the procurement of the heart is to interrupt the systemic return of warm blood back into the heart and to avoid warm distension. To enable this, the superior vena cava (SVC) is ligated or clamped, followed by transection of the inferior vena cava (IVC). Then the aortic cross clamp is applied above the cardioplegia line and the infusion of the hypothermic (−4°C), preservation solution. The preservation solution may or may not contain free radical scavengers, but has a hyperkalemic content to ensure diastolic cardiac arrest for optimal myocardial preservation. It is imperative at this time to ensure appropriate delivery of the cardioplegia solution to the coronary arteries by manually checking the aortic root to make sure it is pressurized. In an expedited fashion and to avoid left ventricular distension, a venting cut must be made in the left side of the heart during this time. Potential sites, pending status of simultaneous lung recovery, are the left atrial appendage, the right superior pulmonary vein, or halfway between the distance of the circumflex artery and the left inferior pulmonary vein. Once again, it is of utmost importance at this time to avoid left ventricular distension and to get tactile and visual feedback to ensure a well-vented and decompressed heart. Simultaneously, topical ice and expeditious topical cooling is critical to check for the color of the effluent solution to turn clear, indicating circulation through the coronary system. Focusing on the technical aspects of the procedure ensure a donor cardiectomy that has appropriate cuffs for safe anastomosing into the recipient without compromise of blood flow (**Fig. 38.9**). The procurement of the heart is orchestrated with other organs—in particular, the lungs if they are to be utilized and to a lesser degree, the liver. The technical goals of the operation are to procure the following: a heart with aorta to the level of the great vessels, a pulmonary artery at the pulmonary bifurcation to not impinge on the pulmonary valve, as much length on the SVC as possible, enough length on the IVC as to be a safe distance

away from the coronary sinus without compromising the suprahepatic cava for the liver team, and most importantly, enough of a left atrial cuff that allows safe course for the left circumflex artery and the coronary sinus without damaging the pulmonary venous drainage for the lung team (**Fig. 38.10**). After ensuring no anatomic damage and the quality of the arrest, the organ is placed in a series of sterile plastic bags, labeled with the appropriate blood type and identification, and readied for transportation on ice.

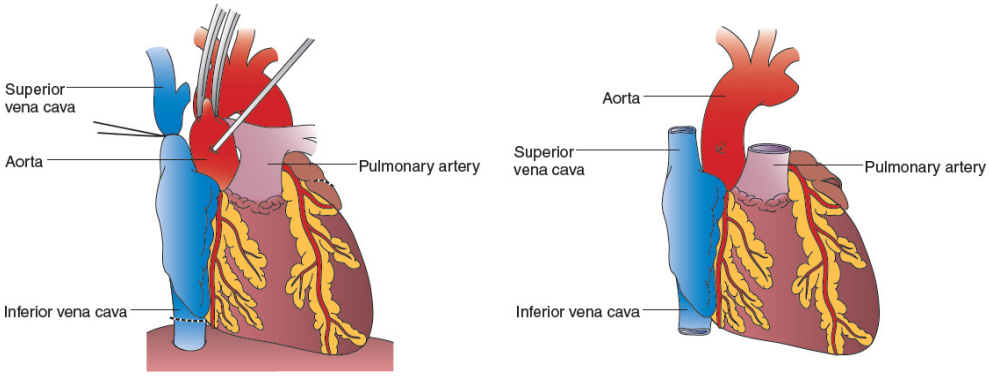

Figure 38.10 Donor heart with preservation canula in aortic root and occlusion of SVC with venting of heart at the IVC level during and after procurement in preparation for bicaval reimplantation. (This image was produced by medical illustrator from Johns Hopkins–Timothy Phelps.)

Key Concept

In summary, donor selection, management, and procurement requires experience, skill, and judgment that is often acquired over a period of time and is best managed in a multidisciplinary decision-making concept. The complex interplay between recipient and donor physiology, the neurohormonal derangements of the donor, and the optimization of the donor allograft before procurement, in transport, and early reperfusion are all key steps in optimizing success.

RECIPIENT MANAGEMENT AND PROCEDURE

There are a variety of indications for heart transplantation and each carries with it a different set of special anatomic and physiologic considerations.[10] Before entering the operating room for the recipient procedure, it is important to ensure one is as knowledgeable about the recipient as possible. Of note, about 50% of heart transplant recipients have had previous cardiac operations and up until the new heart allocation system the previous operation was an LVAD to act as a BTT.[43,44] In patients with a prior sternotomy, a preoperative computed tomography of the chest can help plan reentry as well as safe cannulation strategies.[45]

Patients who either have been maintained on anticoagulation with Coumadin or have other types of coagulopathy should have their effects reversed. This is essential for transplant success especially patients who have had a prior sternotomy and in particular in patients with an LVAD, given their acquired von Willebrand deficiency. The risk of bleeding must be weighed with the risk of thrombosis and this is paramount with early reports showing increased use of short-term mechanical support devices prior to transplantation.[46–48]

After optimization of the recipient before the operating room and in coordination with the donor procedure, the recipient is brought to the operating room with induction of anesthesia, vascular access for rapid volume infusion, venous access with ability to perform invasive hemodynamic monitoring of the new heart, transesophageal echocardiogram, and arterial line monitoring.

The recipient procedure is performed with the major principle of not taking on undue risks while minimizing warm ischemic time.[49] The commencement of the operation occurs after confirmation that the donor heart is of appropriate quality and match. The most common orthotopic techniques for the recipient portion are to utilize either the biatrial, bicaval, or total atriocaval technique of transplantation. In order to accomplish this, safe entry into the mediastinum needs to be achieved to perform a recipient cardiectomy. It should be noted that in cases of patients with LVADs, one must be weary of injury to the outflow graft, as well as the driveline, when trying to achieve safe entry. Likewise, previous patent grafts, coronary anatomy, systemic and pulmonary venous drainage, and other anomalies should be noted.

In order to establish cardiopulmonary bypass (CPB), venous drainage from the body to the circuit needs to utilize drainage from the upper and lower body. Bicaval cannulation is most commonly achieved via a cannula in the SVC and one in the IVC. In some cases, a femoral venous can be advanced into the junction of the IVC and right atrium as to allow safe drainage of the venous blood from the lower part of the body. Return of blood through the CPB circuit back to the body is achieved via arterial access with utilization of the ascending aorta, femoral artery, subclavian artery, and innominate artery all being viable options. Establishment of arterial access is paramount in protecting the patient from harm, especially in cases of prior operations.

CPB is initiated in anticipation of the arrival of the donor organ with some degree of hypothermic circulation. Once appropriate drainage and perfusion to the rest of the body is ensured, the heart is isolated by the use of caval snares. An aortic cross-clamp is applied and a recipient cardiectomy is carried out with the reimplantation technique in mind (**Fig. 38.11**). In general, unimpeded blood flow needs to be established from the systemic and pulmonary venous systems with outflow to the lungs and body being preserved. Prior to the start of the reimplantation, careful assessment and preparation of the donor heart is carried out on the back table.

The implantation procedure starts with the common left atrial anastomosis being the first connection performed using a running nonabsorbable suture for the most posterior structure to allow for clear visualization of all four of the pulmonary veins. This also allows the surgeon to avoid the potential complication of obstruction of the pulmonary venous drainage or an injury to the left circumflex artery that runs in the atrioventricular groove. The sequence of anastomoses can vary from surgeon to surgeon, however in general after completing the superior and inferior vena caval anastomoses, the aortic anastomosis can be performed to minimize the ischemic time, followed by the pulmonary arterial anastomosis. In general this sequence is selected to avoid distension of the nonbeating heart with return of pulmonary venous blood with either a left ventricular vent via the right superior pulmonary vein or by leaving open the left atrial appendage vent site from the procurement procedure.

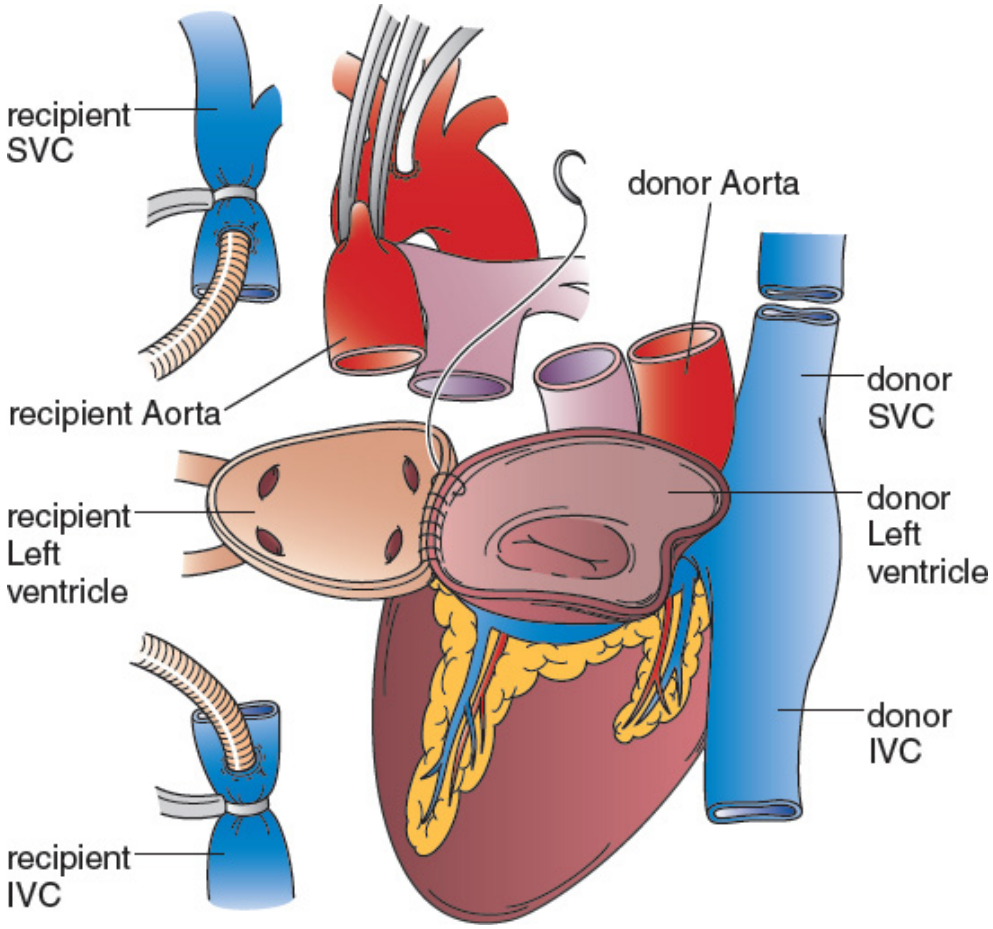

Figure 38.11 Bicaval implantation technique starting with left atrial anastomosis followed by inferior/superior vena cava anastomosis, pulmonary artery and aortic anastomosis. (This image was produced by medical illustrator from Johns Hopkins–Timothy Phelps.)

The systemic venous return anastomosis can either be performed with each cava separately or in a common chamber (biatrial) manner. For the inferior vena caval anastomosis, care must be taken with not only the Eustachian valve, but also the orifice of the coronary sinus. The SVC anastomosis cannot be narrowed by purse stringing the anastomosis, as it can lead to SVC syndrome. In addition, this is the preferred route of access for subsequent endomyocardial biopsies through the SVC to detect graft rejection.

The aorta or pulmonary artery are anastomosed next, but one needs to take care to avoid right ventricular distension if the pulmonary artery anastomosis is performed first. For this reason, if the pulmonary artery is anastomosed first, the anterior suture line is not completed to allow for decompression of the right heart until the aortic anastomosis is established and the heart is

allowed to beat with coronary perfusion. The ischemic time of the heart is deemed completed when the aortic cross clamp is released and coronary arterial blood flow is reestablished. A dose of steroids (500 mg) are often administered just prior to the release of the cross clamp to allow for maximal immunosuppression right before the donor heart is reperfused by the recipient's circulation. In addition, an aortic root vent is placed prior to the cross-clamp coming off and the patient is placed in Trendelenburg position (head down) to ensure that no air is embolized into the systemic circulation and also to aid with deairing of the coronary circulation. In cases of both the aortic and pulmonary anastomosis, the surgeon should be prepared to modify the anastomosis to perform an invagination technique when a large size discrepancy exists between the donor and the recipient vessels. Lastly, the surgeon must avoid excess tension on the anastomosis as well as overt redundancy to avoid kinking particularly of the pulmonary anastomosis.

Upon completion of the anastomosis for the heart, a period of reperfusion is carried out commensurate with the duration of ischemic time while rewarming the recipient to euthermia. During this time of reperfusion, care is taken not to distend the denervated heart with establishment of extrinsic rhythm via atrial and ventricular wires. In principle, tachycardia is welcomed as it avoids myocardial distension by keeping the volume low. To minimize myocardial distension, particularly the right heart which is more prone to dysfunction, a concoction of inhaled pulmonary vasodilators, chronotropic, inotropic, and vasopressor agents can be utilized. In addition to these and the extended time for reperfusion, hyperventilation is used to drive the PCO_2 down and hyperoxygenation can aid the freshly transplanted right ventricle. If these maneuvers are failing and there is evidence of PGD, early institution of MCS such as an intra-aortic balloon pump or even ECMO should be considered.

CURRENT OUTCOMES

Heart transplantation continues to evolve and improve, with major changes in allocation systems and the increasing use of extended-criteria donor hearts, including hearts from donation after circulatory death (DCD) donors, hearts supported with *ex vivo* perfusion, and hearts from hepatitis C viremic

donors. Ironically, the first human heart transplant donor came from a donor after cardiac death before modern legal criteria for brain death determination were developed in 1968.[5] The current use of such nontraditional donor hearts has made transplantation available to a larger number of recipients, but the demand continues to outpace the supply for recipients who are critically ill and waiting for advanced heart failure treatment around the world.

The annual ISHLT adult heart transplant report is based on data submitted to the ISHLT Thoracic Organ Transplant Registry of 146,975 heart transplants in recipients of all ages (including 131,249 adult heart transplants).[40] Since the registry's inception in 1982, a total of 481 heart transplant centers have submitted data, which is estimated to represent approximately 80% of the worldwide transplant activity (**Fig. 38.12**).

Survival

Outcomes following heart transplantation have improved significantly since the report of the first technically successful heart transplant in 1967.[50] The first decade of heart transplantation saw dismal postoperative outcomes with about 60% of patients surviving to 1 year post transplant.[51] The current 1-year survival now exceeds 90% and can be attributed to advancements in every aspect of heart transplantation. Indeed among the many improvements in clinical care has been patient selection (both recipient and donor), myocardial preservation, immunosuppression, importance of graft surveillance, and refined techniques in suppressing rejection episodes with patient-specific immunomodulation. The improvements in survival by era can clearly be seen with the current median survival of a heart transplant exceeding 12 years (**Fig. 38.13**). The median survival after adult heart transplants performed between 2002 and 2009 is 12.5 years extending to 14.8 years among 1-year survivors. As posttransplant survival has improved over time, survival within the first year post transplant and overall survival vary by primary diagnosis. For instance, patients transplanted for nonischemic and ischemic cardiomyopathy have the highest 1-year survival, while retransplants have the lowest survival rate.

Another improvement for outcomes may be the increasing number of patients who are transplanted after the placement of a durable LVAD. Posttransplant survival does not appear to be adversely affected by the

pretransplant use of an LVAD, alone or in combination with right ventricular support in univariate analyses. This strategy has led to improvements in patient survival while on the wait list, as well as equivalent outcomes post transplantation in patients bridged with LVAD to transplantation, as compared to those patients that were not bridged with a durable device.[52,53] However, it is important to recognize that selection bias may affect outcomes, since sicker patients on mechanical support may not survive through transplantation. Survival is notably lower in patients bridged to transplant with ECMO, particularly in the early posttransplant period. This observation is of interest given the recent change to the heart transplant allocation policy in the United States that prioritizes candidates supported with ECMO and other forms of acute MCS.[54]

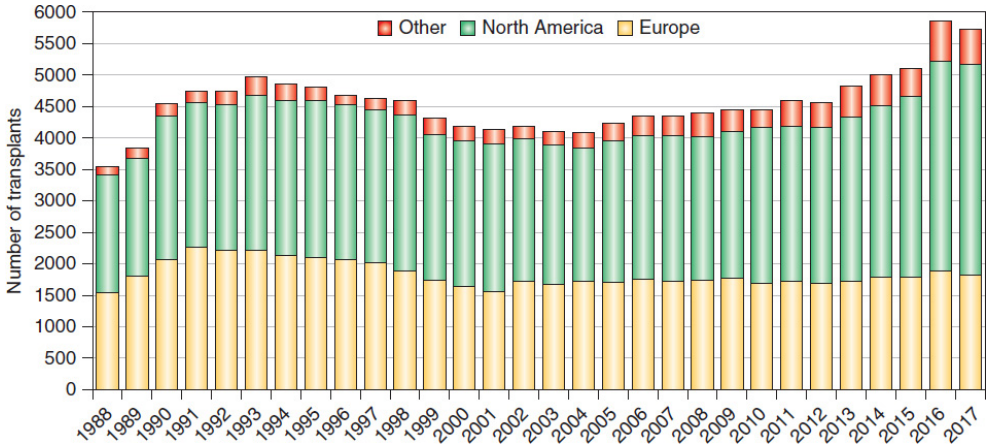

Figure 38.12 Number of heart transplants (adult and pediatric) by year (transplants: 1988–2017) and geographic region. (Khush KK, Cherikh WS, Chambers DC, et al. The international thoracic organ transplant registry of the international society for heart and lung transplantation: thirty-sixth adult heart transplantation report—2019; focus theme: donor and recipient size match. *J Heart Lung Transplant* 2019;38(10):1056–1066.)

In many regards, the quality of life and functional capacity that is restored after heart transplantation is as important as the time of survival post transplantation. Indeed, there is a significant improvement in the quality of life reported after heart transplantation.[55–57] The improvement in quality of life allows for patients to resume full activity, lead productive lives as part of the workforce, and have a higher perception of themselves with improved self-esteem. These metrics are adversely affected by the presence of and

severity of rejection episodes, highlighting the importance of reduction and management of complications for heart transplant recipients.

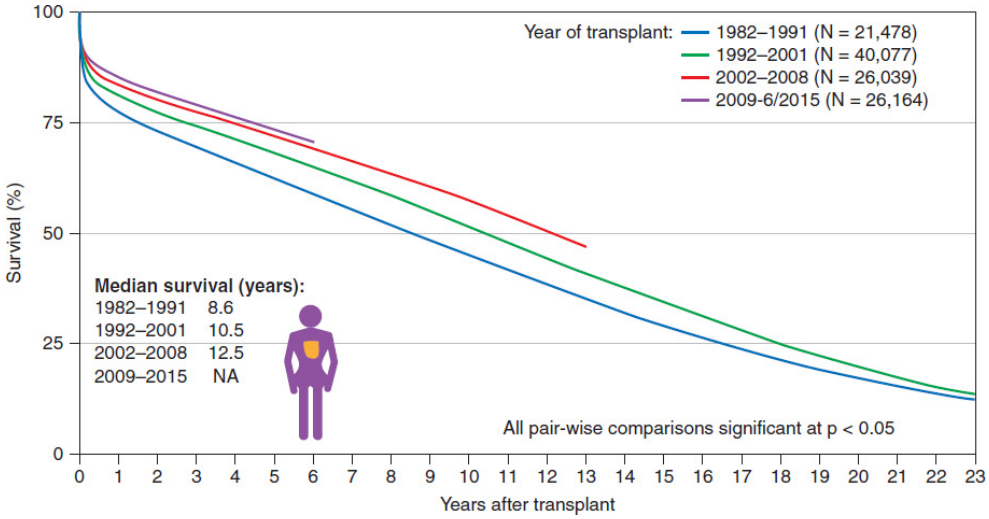

Figure 38.13 Kaplan–Meier survival graph following heart transplantation based on era.

Complications

The most immediate and morbid complication following heart transplantation is PGD. Reports of PGD have been quite varied with a multitude of definitions, diagnostic criteria, and therapeutic options which have been debated. Given these discrepancies, a consensus statement with clear definitions was established stating that PGD must be diagnosed within 24 hours of completion of surgery and that is should be divided into PGD-left ventricle and PGD-right ventricle with PGD-left ventricle being graded as mild, moderate or severe.[58] It was estimated that the incidence of PGD was approximately 7% with an accompanying 30-day mortality of 30% and a 1-year mortality of nearly 35%. Treatment modalities ranged from prophylactic maneuvers to avoid PGD to support of the allograft for recovery with MCSDs, such as intra-aortic balloon pump and ECMO, with hopes for recovery or retransplantation (**Fig. 38.14**). Following PGD, most complications can be divided into early (<3-month posttransplant) and late (>3-month posttransplant) time periods. A major component to all outcomes is the complex balance and management required to prevent rejection by tricking the body into believing that the heart is its own, while simultaneously

avoiding the inherent effects of immunosuppression on infections and neoplastic changes. In addition to early and late time periods, acute episodes of rejection following heart transplantation can be categorized by the mechanism of rejection—cellular, antibody mediated, or mixed rejection.

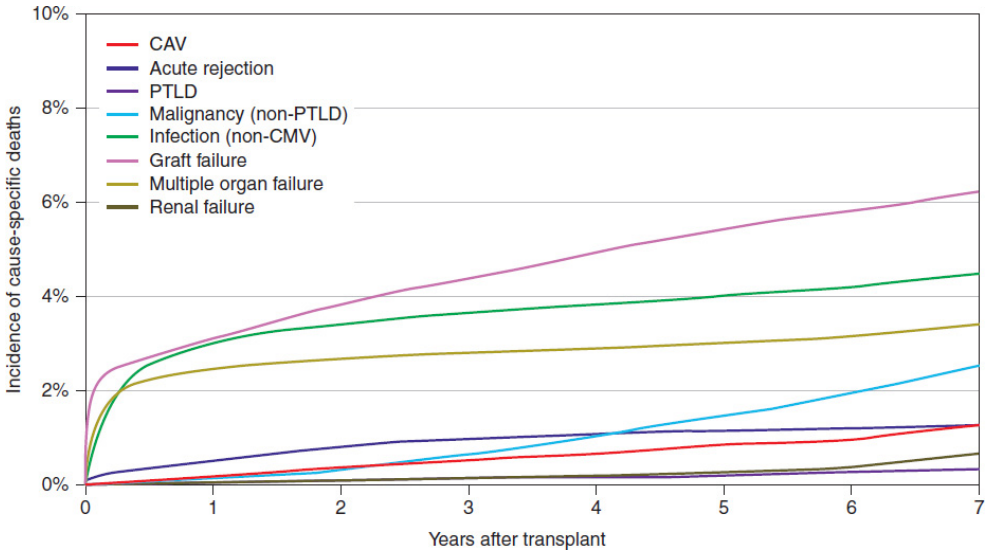

Figure 38.14 Cumulative incidence of leading causes of death (adult heart transplants: January 2010–June 2017). CAV, cardiac allograft vasculopathy; CMV, cytomegalovirus; PTLD, posttransplant lymphoproliferative disorder.

In 2004, the ISHLT revised the cardiac biopsy grading system to ensure a more consistent grading across centers for cardiac allograft rejection.[59] The differences between this system and the previous definitions from 1990 are highlighted in **Table 38.1**. In brief, grade 0 R is no rejection, 1 R—mild rejection, grade 2 R—moderate rejection, and grade 3 R—severe rejection. A 1 R represents interstitial and/or perivascular infiltrate with one focus of myocardial damage; a 2 R represents two or more foci of infiltrate with accompanying myocardial injury; and a 3 R has diffuse infiltrate with multifocal myocardial damage with or without edema hemorrhage or vasculitis (**Fig. 38.15A,B**). AMR, similar to the definition of PGD, was controversial with multiple iterations. A final consensus has been reached abandoning clinical criteria in favor of a pathologic diagnosis.[60] The pathologic diagnosis of AMR depends on the following: morphologic aspects, primary and secondary antibody panels, immunohistochemistry, and immunofluorescence with a combination of these serving as the basis of the grading system (**Table 38.2**).[61]

In general, all three types of rejection—cellular, AMR, and mixed rejection—have been associated with increased risk of mortality and loss of graft function.[61] It is estimated that during the first year, roughly 25% of all patients will have an episode of acute rejection.[62] In the more chronic form of rejection, CAV can develop. CAV is the abnormal coronary endothelial inflammation, injury, fibrosis, and dysfunction that occurs as a result of chronic rejections, as well as nonimmune insults. Unlike acute rejection, which has surveillance diagnosis by endomyocardial biopsies, CAV is usually evaluated by invasive coronary angiography (**Fig. 38.16**). By 5 years post transplant, a third of heart transplant recipients develop CAV and this is the most common cause of death in the long term.[63]

Table 38.1 ISHLT Standardized Cardiac Biopsy Grading: Acute Cellular Rejection

2004		1990	
Grade 0 R[a]	**No Rejection**	**Grade 0**	**No Rejection**
Grade 1 R, mild	Interstitial and/or perivascular infiltrate with up to one focus of myocyte damage	Grade 1, mild A—Focal B—Diffuse Grade 2 moderate (focal)	Focal perivascular and/or interstitial infiltrate without myocyte damage Diffuse infiltrate without myocyte damage One focus of infiltrate with associated myocyte damage
Grade 2 R, moderate	Two or more foci of infiltrate with associated myocyte damage	Grade 3, moderate A—Focal	Multifocal infiltrate with myocyte damage
Grade 3 R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema, ±	B—Diffuse Grade 4, severe	Diffuse infiltrate with myocyte damage Diffuse, polymorphous infiltrate with extensive

	hemorrhage ± vasculitis	myocyte damage ± edema, ± hemorrhage + vasculitis

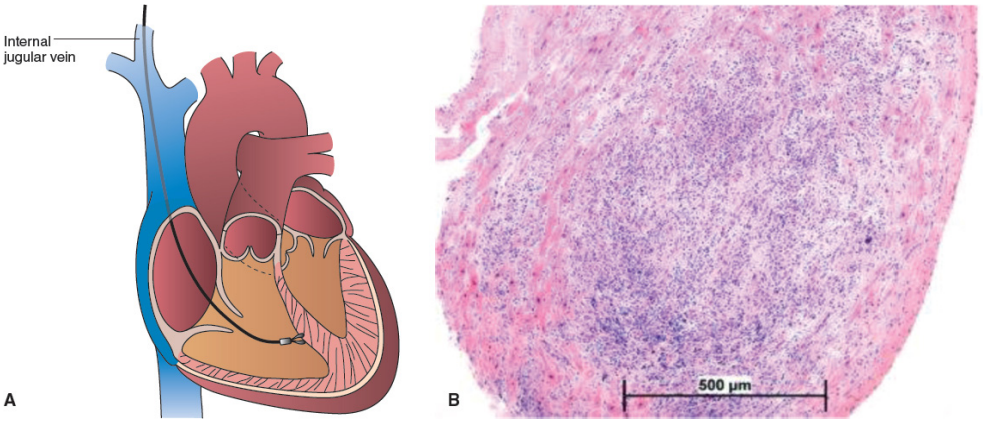

Figure 38.15 **A:** Endomyocardial biopsy via internal jugular vein to detect acute cellular rejection. **B:** Severe acute cellular rejection. This photomicrograph exhibits diffuse myocardial inflammation with associated myocyte damage (ISHLT 1990 grade 3B or ISHLT 2004 grade 3R). (From Maleszewski JJ, Burke AP. Heart Transplant Rejection Pathology. TheHeart.org Medscape.) (This image was produced by medical illustrator from Johns Hopkins–Timothy Phelps.)

In addition to complications from rejection and PGD, other causes of complications following heart transplantation can arise from a variety of different types of issues. Technical issues usually arise in the immediate peritransplant period (anastomotic narrowing, damage to coronary arterial blood flow, infections, bleeding or inappropriate patient–donor matching). Complications can also arise from chronic immunosuppression which can include infectious complications such as viral, bacterial, or fungal infections. Particular attention should be paid to recipients who are CMV negative who receive donor CMV-positive organs. CMV prophylactic therapy during the early postoperative course is routinely employed when immunosuppression is greatest during the first 6 months post transplant. Another complication from immunosuppression can be the development of malignancies such as skin cancer, posttransplant lymphoproliferative disease, and visceral cancers.[64] Lastly, patients on chronic immunosuppression can develop diabetes mellitus, hypertension, and renal failure.

Table 38.2 The 2013 ISHLT Working Formulation for Pathologic Diagnosis of Cardiac Antibody-Mediated Rejection

Grade	Definition	Substrates
pAMR 0	Negative for pathologic AMR	Histologic and immunopathologic studies are both negative.
pAMR 1 (H+)	Histopathologic AMR alone	Histologic findings are present and immunopathologic findings are negative.
pAMR 1 (I+)	Immunopathologic AMR alone	Histologic findings are negative and immunopathologic findings are positive (CD68+ and/or C4d+).
pAMR 2	Pathologic AMR	Histologic and immunopathologic findings are both present.
pAMR 3	Severe pathologic AMR	Interstitial hemorrhage, capillary fragmentation, mixed inflammatory infiltrates, endothelial cell pyknosis, and/or karyorrhexis, and marked edema and immunopathologic findings are present. These cases may be associated with

	profound hemodynamic dysfunction and poor clinical outcomes.

AMR, antibody-mediated rejection.

Berry GJ, Burke MM, Andersen C, et al. The 2013 International Society for Heart and Lung Transplantation Working Formulation for the standardization of nomenclature in the pathologic diagnosis of antibody-mediated rejection in heart transplantation. *J Heart Lung Transplant* 2013;32(12):1147–1162.

FUTURE DIRECTIONS

The future of heart transplantation is undoubtedly bright. The annual number of heart transplants in the United States has continued to rise within the last 5 years with improvements in expansion of the donor pool and postoperative success rates. As stated earlier, these incremental improvements are multifactorial with meticulous patient selection, donor selection, careful operative technique, regimented posttransplant immunosuppression, protocol driven surveillance biopsies to detect early, nonclinical rejection and maintenance of long-term health care needs all contributing to great outcomes. In light of these improvements, numerous areas can continue to be enhanced.

Immunosuppression in its present state is not perfect. Although effective in the immediate period, induction therapy is associated with increased infective complications and a tailored regimen to each specific recipient–donor situation would be ideal. The reliance on triple therapy for maintenance immunosuppression in the early period likewise comes with certain drug-induced toxicities and their unwanted side effects. The development of graft tolerance is the penultimate goal and progress will be made in this arena with an ever growing list of targeted immunosuppressive medications.

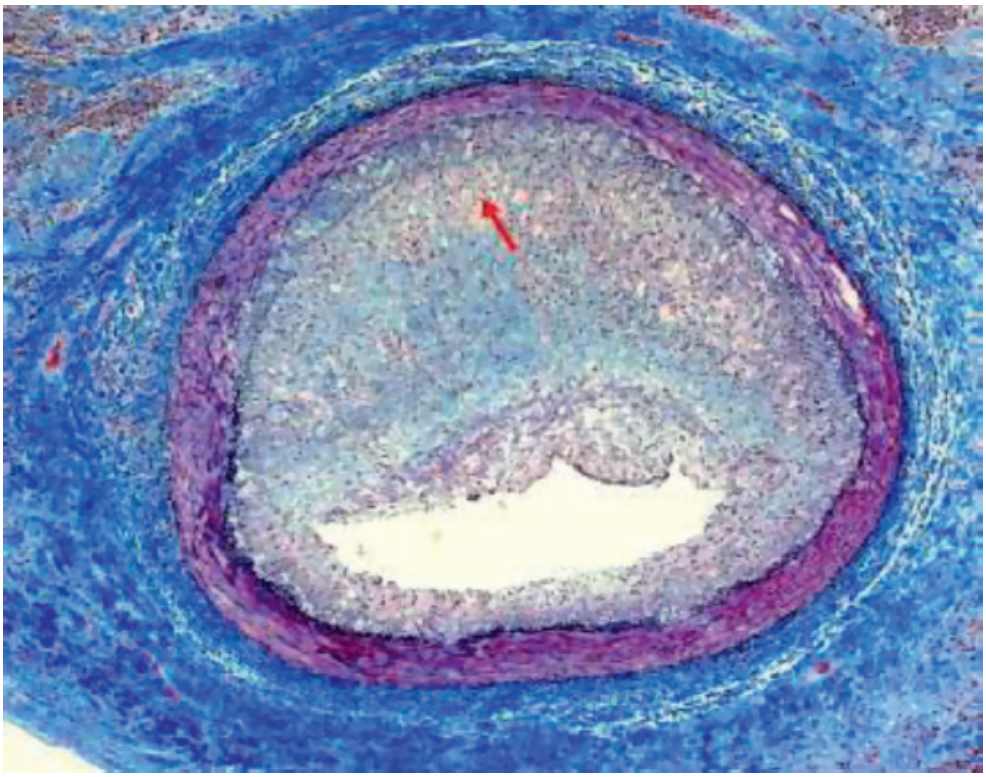

Figure 38.16 Lipid-laden foam cell macrophages in TCAD. Trichrome elastic stain of a coronary artery demonstrating progressive arterial occlusion with lipid-laden foam cell macrophages (*arrow*) in a patient with transplant coronary artery disease (TCAD). (Used with permission from Zimmer R, Lee M. *JACC Cardiovasc Interv* 2010;3(4):367–377. doi: 10.1016/j.jcin.2010.02.007.)

The early detection and treatment of rejection will continue to be refined. Currently, there is a reliance on serial, surveillance endomyocardial biopsies to assess for rejection, as well as yearly cardiac angiography for accelerated chronic rejection leading to atherosclerotic coronary disease. There is increasing data that noninvasive methods such as AlloMap testing can look at genetic expression to detect early rejection.[63] In addition, our understanding of the differences between AMR and acute cellular rejection will enable for more targeted treatment options based upon the specific type of rejection in the future.

From a patient selection perspective, the field had seen a rapid expansion of the use of durable MCS as a bridging option to get patients to transplantation. More recently with the changing of the allocation system and the downgrading of the status of stable patients with LVADs, the role of temporary MCS has increased. Indeed, in the early reports evaluating the

allocation change, there were more patients being transplanted on temporary MCS devices than durable devices.[48] The increased use of ECMO will allow early transplantation of patients that are the most critically ill, preventing the allocation of precious donors to a subset of sick recipients who may not receive the greatest benefit from transplantation.

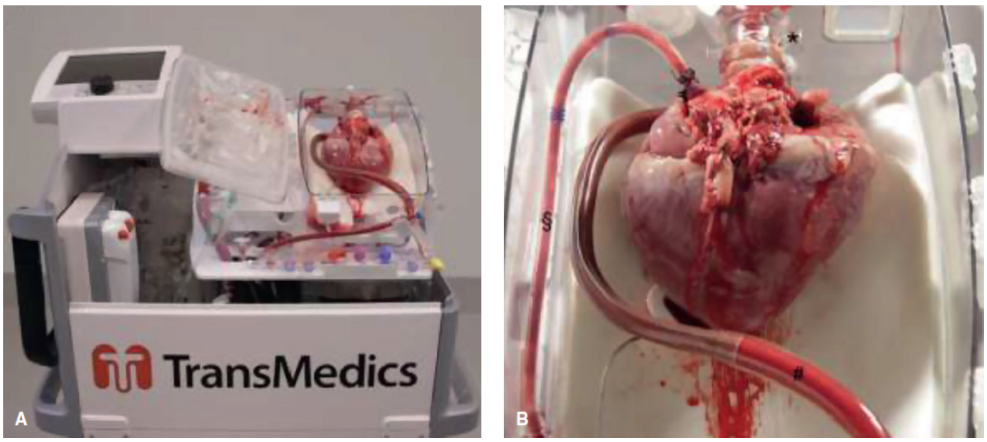

Figure 38.17 **A:** The transport unit of the Organ Care System (Transmedics) with ex vivo perfusion of a porcine heart. The ascending aorta is connected to an artificial circulation circuit filled with donor blood. An inserted oxygenator ensures gas exchange. During warm pump run with controlled perfusion pressure and flow, the heart function is assessed visually together with hemodynamic and laboratory parameters. **B:** The heart is connected to the perfusion line with a connector at the ascending aorta (*). A venous return cannula (#) is placed into the right ventricle via the pulmonary artery with the caval veins being closed. The left ventricle is vented additionally (§). (Photos courtesy of Transmedics.)

There has already been an increased awareness of the utilization of nontraditional donors. Indeed with available medications to treat and potentially cure hepatitis C, donors with hepatitis C are being used increasingly with good early results from this donor population.[65] Human immunodeficiency virus (HIV) is another virus that currently has been effectively treated in the donor population that could be used for heart transplantation. A number of recent studies have reported an acceptable 5-year survival in HIV-positive recipients (88%) in a selected group of recipients.[66]

Perhaps, a bigger impact for the future of heart transplantation will be the inclusion of the nontraditional donor. The traditional donor at this time is the brain-dead donor where a procurement procedure can occur in a

semielective manner while the c still has a functioning circulatory system on mechanical ventilation. In Australia and the United Kingdom, increasing experience is being achieved in DCD.[67,68] The early outcomes following DCD heart transplants has shown some promise with a 1-year survival of 86% as compared to the traditional donors where a 1-year survival was 88%.[69] This technique may allow for more liberal heart organ donation in patients with families who do not believe in brain death donation.

A significant technical hurdle in DCD patients is to ensure a working graft after urgent heparinization following circulatory death followed by a hastily performed preservation of the heart. Another technique that could serve as a litmus test for the use of these hearts could be the utilization of normothermic *ex vivo* perfusion for assessment and potential repair of these organs prior to transplantation. The currently available platform is the Organ Care System from Transmedics that allows continuous normothermic ex-vivo heart perfusion immediately after the procurement of the heart to aid in the reduction of static, cold ischemic time of the organ (**Fig. 38.17**). The added benefit of this device is the ability of the clinician to assess organ function with parameters such as coronary blood flow and lactate clearance in addition to potential resuscitation to recovery for utilization in transplantation.[70,71] Early randomized, multicenter trials (PROCEED II) between this system and the standard hypothermic, standard solution have shown no difference in short-term outcomes.[72]

CONCLUSION

Over the past 50 years, heart transplantation has come a long way, going from a romantic ideal with dismal early outcomes to the gold standard biologic cure for patients suffering from end-stage heart failure. It has developed after decades of innovation, perseverance, and commitment by thousands of dedicated heart failure physicians and surgeons, immunologists and scientists, procurement technicians and professionals, drug development experts, nurses, regulatory and administrative policy experts, and infectious disease clinicians. It is impressive to think there have been over 70,000 heart transplants in the UNOS registry at this time, with 1-year survival surpassing 90%. The careful attention to patient and donor selection, meticulous surgical

technique, surveillance, and early detection of rejection, combined with emerging technologies, is sure to push the field into even greater heights in the future.

Lung Transplantation

Errol L. Bush

Key Points

1. Annual numbers of lung transplants in the United States have been increasing and in 2018, 2,562 lung transplants were performed in the United States, the highest annual number to date and over 15,000 lung transplant recipients were alive.
2. While systematic allocation changes have correlated with sicker candidates being listed, overall there have been improved transplantation rates, lower mortality rates, and fewer days on the waitlist with a median wait time of 2.5 months.
3. Candidacy for lung transplantation should utilize each center's multidisciplinary candidate selection committee to carefully weigh candidates' individual underlying disease severity, medical comorbidities, psychosocial factors, and surgical risk.
4. Idiopathic pulmonary fibrosis (IPF) is the most common subtype of interstitial lung disease and since 2007, IPF has replaced COPD as the most common indication for lung transplantation in the United States. In 2018, restrictive lung diseases represented 60% of all lung transplants performed in the United States.
5. The donor recovery lung evaluation is as important to the success of the lung transplant recipient as the implantation, and an expert recovery surgeon is facile with the multiple required steps, understands their relationship to the success of organ preservation, and able to articulately communicate and troubleshoot abnormalities that arise during the organ evaluation process.
6. Seventy five percent of recipients received a bilateral lung transplant. The technique of double-lung transplantation has evolved considerably since the late 1980s from an en bloc technique to a bilateral, sequential technique. With the patient in the supine position, this operation can be performed through a median sternotomy, bilateral thoracosternotomy (clamshell) incision, bilateral anterior thoracotomies without sternal division, or bilateral muscle-sparing axillary thoracotomies.
7. Most transplant centers attempt to limit organ ischemic time to less than 6 total hours, however, many centers have vast experience comfortably extending cold ischemic time with careful donor selection, organ preservation, and utilization of ex vivo lung perfusion (EVLP) to evaluate extended criteria donors.
8. Primary graft dysfunction (PGD) is an acute lung injury syndrome occurring within the first 72 hours following lung transplantation and is characterized by inexplicable diffuse allograft infiltrates and hypoxemia defined as a PaO_2/FiO_2 ratio (P/F) <300, and results in significant short- and long-term morbidity and mortality.
9. Donor availability remains a limiting factor to successful and timely transplantation, which has led to innovative utilization of techniques that result in increased donor utilization, such as utilization of EVLP, donation after cardiac death donors, and hepatitis C virus--infected organs.

INTRODUCTION

Early Years of Lung Transplantation

In 1963, Dr. James Hardy, Chair of surgery at the University of Mississippi, reported the first human lung transplant in a 58-year-old male incarcerated patient who had end-stage emphysema, an obstructive left mainstem carcinoma and chronic renal disease, utilizing a donor who had suffered a massive myocardial infarction and unsuccessful cardiopulmonary resuscitation.[1] While the surgery was regarded as a success, the recipient died 18 days later of renal failure and with a reported functioning allograft. Over the next 20 years, less than 40 attempts at lung or heart–lung transplantation were performed, all but one dying in less than a month of bronchial dehiscence, and only one midterm survivor, 10.5 months.[2] With the advent of improved

surgical technique, better recipient selection, and the availability of cyclosporine, in 1982, the Toronto Lung transplant group would go on to perform the first long-term successful lung transplant[3] and the recipient survived for 7 years.[2]

Current Status of Lung Transplants in the United States

1 Since 2012, annual numbers of lung transplant in the United States have been increasing and in 2018, 2,562 lung transplants were performed in the United States, the highest annual number to date and over 15,000 lung transplant recipients were alive.[4] These transplants were performed in 67 centers; 55 adult-only centers. The median number of transplants performed per program was 26, although three programs performed more than 100 transplants, which represented 20% of national cases; 75% of candidates received a bilateral lung transplant, and 97.4% of candidates received a primary lung transplant.[4] While allocation changes have correlated with sicker 2 candidates being listed, overall there have been improved transplantation rates, lower mortality rates, and fewer days on the waitlist with a median wait time of 2.5 months. In 2018, 3,134 recipients were added to the waitlist, continuing a trend of donor shortage and resulting in 12% of recipients dying or becoming too sick for transplant while on the list.[4] While still the worst outcome of solid organ transplants, progressive improvements in survival have been realized in lung transplantation; 89.4% of recipients survived to 1 year, 73.5% to 3 years, and 59.4% to 5 years.[4]

THE FINAL RULE

The Organ Procurement and Transplantation Network (OPTN) links all professionals involved in the U.S. donation and transplantation system with the goals to increase the number of and access to transplants, improve survival rates after transplantation, and to promote patient safety and efficient management of the system. The United States Department of Health and Human Services established the regulatory framework to support the OPTN on March 16, 2000, by implementing the Final Rule. The Final Rule states that allocation polices shall be based on sound medical judgment; shall seek to achieve the best use of donated organs; shall preserve the ability of a transplant program to decline an offer of an organ or not to use the organ; shall be specific for each organ type transplanted; shall be designed to avoid wasting organs, to avoid futile transplants, to promote patient access to transplantation, and to promote the efficient management of organ placement; shall be reviewed periodically and revised as appropriate; shall include appropriate procedures to promote and review compliance; and shall not be based on the candidate's place of residence or place of listing, except to the extent required by other aforementioned requirements.[5] In an effort to assure equitable and medical necessity based allocation of donor organs, two major changes to lung allocation have occurred since the implementation of the Final Rule: development of the lung allocation score (LAS) and broader geographic organ allocation.

Lung Allocation

Prior to 2005, lung allocation priority for lung transplantation was based upon wait times, geography, and blood type, which resulted in significantly prolonged wait times and high waitlist mortality. The LAS was implemented in 2005 as a weighted combination of the predicted risk of death on the waiting list and the predicted likelihood of survival during the first year after transplantation.[6] Variables included in the LAS are listed in **Table 39.1**, with addition of BMI <20 kg/m^2. Greater weight is given to waitlist survival and medical urgency than posttransplant survival. Four disease diagnosis groups are utilized and considered in the LAS: group A: obstructive; group B: pulmonary vascular; group C: cystic fibrosis and immunodeficiency; and group D: restrictive (**Table 39.2**). Reevaluation and revision of the criteria utilized to calculate LAS may occur after a substantial evaluation period and has resulted in several influential changes. 2012 noted the addition of cardiac index, CVP, and serum creatinine and their relative weights to other variables. More recently, in February 2015, variables were updated to more accurately reflect disease severity for all candidates, especially those with pulmonary vascular disease. Finally, in November 2017, in an effort to reduce geographic

disparities, the first geographic unit of allocation was changed to a 250 nautical mile radius from the donor circle, eliminating local donor service areas as a unit of allocation.

Despite allocation changes, the median LAS at transplant, 42.3 in 2018, has been relatively stable over the last decade, but represents a 2 point increase from 2017.[4] About 25% of candidates are hospitalized prior to transplant; 13.6% required care in the intensive care unit. Proportions of candidates requiring support with mechanical ventilation (vent) were 1.6%, extracorporeal membrane oxygenation (ECMO) 3.3%, and vent + ECMO 3.1%.[4]

INDICATIONS

3 Ultimately, each center's multidisciplinary candidate selection committee will need to carefully weigh candidates' individual underlying disease severity, medical comorbidities, psychosocial factors, and surgical risk. In 1998, the International Society for Heart and Lung Transplantation (ISHLT) produced the multiorganizational consensus document, International Guidelines for the Selection of Lung Transplant Candidates.[7] The document has since been updated twice, most recently in 2015,[8] and is generally considered by lung transplant programs in their selection criteria (**Table 39.3**). The statement recommends that in general, lung transplantation should be considered for adults with end-stage lung disease who have:

1. High (>50%) risk of death from lung disease within 2 years if lung transplantation is not performed.
2. High (>80%) likelihood of surviving at least 90 days after lung transplantation.
3. High (>80%) likelihood of 5-year posttransplant survival from a general medical perspective provided that there is adequate graft function.

Table 39.4 lists disease-specific listing considerations for the most common disease diagnoses undergoing lung transplantation.

Idiopathic Pulmonary Fibrosis

Table 39.2 Pulmonary Disease Diagnosis Groups

Group A: Obstructive	Group B: Pulmonary Vascular	Group C: Cystic Fibrosis and Immunodeficiency	Group D: Restrictive
Allergic bronchopulmonary aspergillosis	Congenital malformation	Common variable immune deficiency	ABCA3 transporter mutation
Alpha-1 antitrypsin deficiency	CREST—pulmonary hypertension	Cystic fibrosis	Alveolar proteinosis
Bronchiectasis	Eisenmenger syndrome	Fibrocavitary lung disease	Amyloidosis
Bronchopulmonary dysplasia	Portopulmonary hypertension	Hypogammaglobulinemia	Acute respiratory distress syndrome or pneumonia
Chronic obstructive pulmonary disease/emphysema	Primary pulmonary hypertension/pulmonary arterial hypertension	Schwachman–Diamond syndrome	Bronchioloalveolar carcinoma (BAC)
Ehlers–Danlos syndrome	Pulmonary capillary hemangiomatosis		Carcinoid tumorlets
Granulomatous lung disease	Pulmonary telangiectasia—pulmonary hypertension		Chronic pneumonitis of infancy
Inhalation burns/trauma	Pulmonary thromboembolic disease		Constrictive bronchiolitis
Kartagener syndrome	Pulmonary vascular disease		CREST—restrictive
Lymphangioleiomyomatosis	Pulmonary veno-occlusive disease		Eosinophilic granuloma
Obstructive lung disease	Pulmonic stenosis		Fibrosing mediastinitis
Primary ciliary dyskinesia	Right hypoplastic lung		Graft versus host disease (GVHD)
Sarcoidosis with mean pulmonary artery pressure of 30 mm Hg or less	Scleroderma—pulmonary hypertension		Hermansky–Pudlak syndrome
Tuberous sclerosis	Secondary pulmonary hypertension		Hypersensitivity pneumonitis
Wegener granuloma—bronchiectasis	Thromboembolic pulmonary hypertension		Idiopathic interstitial pneumonia
			Idiopathic pulmonary hemosiderosis
			Lung retransplant or graft failure
			Lupus mixed connective tissue disease
			Obliterative bronchiolitis: nonretransplant
			Occupational lung disease
			Paraneoplastic pemphigus associated Castleman disease
			Polymyositis
			Pulmonary fibrosis: other

	Pulmonary hyalinizing granuloma Pulmonary lymphangiectasia (PL) Pulmonary telangiectasia—restrictive Rheumatoid disease Sarcoidosis with mean pulmonary artery pressure higher than 30 mm Hg Scleroderma—restrictive Secondary pulmonary fibrosis Silicosis Sjogren syndrome Surfactant protein B or C mutation Teratoma Wegener granuloma—restrictive

Adapted from the U.S. Organ Procurement and Transplantation Network Policy 10.1.F.i (Effective February 27, 2020).

4 Idiopathic pulmonary fibrosis (IPF) is a progressive fibrosing interstitial lung disease with less than 5 years expected survival following diagnosis, though is improved at younger ages.[9] IPF is the most common subtype of interstitial lung disease and since 2007, mostly secondary to the implementation of the LAS, IPF has replaced chronic obstructive pulmonary disease (COPD) as the most common indication for lung transplantation in the United States.[10] In 2018, restrictive lung diseases represented 60% of all lung transplants performed in the United States.[4]

Chronic Obstructive Pulmonary Disease

COPD is the second most common indication for lung transplantation. It is the most common disease indication in the obstructive diagnosis group, which represented 24% of all lung transplants in the United States.[4] Recipients with COPD share the best 1-year survival with those with cystic fibrosis (CF), but a lower 10-year survival compared to all except IPF.[11]

Table 39.3 ISHLT General Recommendations for Consideration for Lung Transplantation[3]

High (>50%) risk of death from lung disease within 2 yrs if lung transplantation is not performed
High (>80%) likelihood of surviving at least 90 days after lung transplantation
High (>80%) likelihood of 5-year posttransplant survival from a general medical perspective provided that there is adequate graft function

Cystic Fibrosis

CF is the third most common indication for lung transplantation, but the proportion of patients transplanted for CF continues to slowly fall, now representing 13% of total adult lung transplants worldwide,[11] and 10% in the United States.[4] Recipients with CF share the best 1-year survival with those with COPD, and highest overall survival, even up to 20 years.[11] Colonization of the airway with multi- or pan-resistant organisms is common in CF, and some transplant programs consider colonization with pan-resistant strains of *Pseudomonas aeruginosa* or *Burkholderia* species as contraindications to transplantation because of poorer demonstrated posttransplant outcomes. A comprehensive review by Morrell et al. found that patients with pan-resistant *Pseudomonas* seem to have poorer outcomes than sensitive patients with CF undergoing transplantation, but comparable to overall UNOS registrants, and only patients infected with *Burkholderia gladioli* and specific nonepidemeic *Burkholderia cenocepacia* strains demonstrate excess mortality in the first 6 months after transplant.[12]

Table 39.4 Disease-Specific Considerations for Listing for Lung Transplantation[3]

Interstitial Lung Disease—Early Referral Following Radiologic or Histologic Diagnosis, Regardless of Lung Function
Decline in FVC ≥10% during 6 mo of follow-up (note: A 5% decline is associated with a poorer prognosis and may warrant listing)
Decline in DLCO ≥15% during 6 mo of follow-up
Desaturation to <88% or distance <250 m on 6-min walk test or 450 m decline in 6-min walk distance over a 6-mo period
Pulmonary hypertension on right heart catheterization or 2-dimensional echocardiography
Hospitalization because of respiratory decline, pneumothorax, or acute exacerbation
Chronic Obstructive Pulmonary Disease (COPD)
BODE index ≥7
FEV_1 <15–20% predicted
Three or more severe exacerbations during the preceding year
One severe exacerbation with acute hypercapnic respiratory failure
Moderate to severe pulmonary hypertension
Cystic Fibrosis—Early Referral When FEV_1 That Has Fallen to 30% or a Patient with a Rapidly Falling FEV_1 Despite Optimal Therapy (Particularly in a Female Patient) or Increasing Frequency of Life-Threatening Lung Disease Complications
Chronic hypoxic or hypercapnic respiratory failure
Long-term noninvasive ventilation therapy
Pulmonary hypertension
Frequent hospitalization
Rapid lung function decline
World Health Organization Functional Class IV
Pulmonary Hypertension
NYHA functional class III or IV despite a trial of at least 3 mo of combination therapy including prostanoids
Cardiac index of <2 L/min/m^2
Mean right atrial pressure of 415 mm Hg
6-min walk test of <350 m
Development of significant hemoptysis, pericardial effusion, or signs of progressive right heart failure

Pulmonary Hypertension

Pulmonary vascular diseases are included in the group B diagnostic group and in 2018, represented only 6% of the U.S. transplants.[4] The median LAS is highest for this diagnostic group,[4] but considerable debate arises around whether the LAS accurately characterize the clinical urgency of these patients while on the waitlist.

Natural history registry data reported a 3-year median survival,[13] which has improved with optimal medical therapies to 75% at 3 years.[14] Because of the relative success and good response with medical therapies, timing for referral to transplant is variable among centers, as institution and optimization of therapies may delay the need for transplant for some time. However, clinical deterioration may do so rapidly enough to not allow time for a full evaluation, therefore earlier referral for evaluation is recommended. Recipients with IPAH have the lowest 1-year survival, but their 10-year conditional 1-year median survival approaches the best of all recipients, 12 years.[11]

Contraindications to Lung Transplantation

Table 39.5 lists absolute consensus and relative contraindications to lung transplantation.[8] The list represents common comorbid patient concerns and a complex balance between transplant benefit, organ stewardship, and expected recipient and allograft survival. An individualized candidate evaluation should ensue with careful consideration of candidates' individual underlying disease severity, medical comorbidities, psychosocial factors, and in the context of surgical risk for perioperative morbidity and mortality based on the program's relevant experience and expertise. Ultimately, candidate selection is the decision of the transplant program's selection committee. Therefore, a patient may be a suitable or unsuitable candidate at any particular center, and patients are free to be evaluated and/or listed at more than one program, if the recipient finds it beneficial to do so. If a candidate is deemed not a candidate at one particular center for a relative contraindication, then referral to a center with relevant expertise or prior considerations should be made.

Table 39.5 Contraindications to Lung Transplant

Absolute Contraindications
Recent history of malignancy
Multiorgan dysfunction unless combined multiorgan transplant considered correctable
Uncorrected atherosclerotic disease
Acute medical instability, including, but not limited to, acute sepsis, myocardial infarction, and liver failure
Uncorrectable bleeding diathesis
Chronic infection with highly virulent and/or resistant microbes that are poorly controlled pretransplant
Evidence of active Mycobacterium tuberculosis infection
Significant chest wall or spinal deformity expected to cause severe restriction after transplantation
Class II or III obesity (body mass index [BMI] ≥ 35.0 kg/m^2)
Current or history of nonadherence to medical therapy
Psychosocial barriers to posttransplant care adherence
Severely limited functional status with poor rehabilitation potential
Substance abuse or dependence
Relative Contraindications
Age >65 yrs in association with low physiologic reserve and/or other relative contraindications
Class I obesity (BMI 30.0–34.9 kg/m^2), particularly truncal (central) obesity
Progressive or severe malnutrition
Severe, symptomatic osteoporosis
Extensive prior chest surgery with lung resection
Mechanical ventilation and/or extracorporeal life support (ECLS)
Colonization or infection with highly resistant or highly virulent bacteria, fungi, and certain strains of mycobacteria
For patients infected with hepatitis B and/or C, a lung transplant can be considered in patients without signs of cirrhosis or portal hypertension
For patients infected with human immunodeficiency virus (HIV), a lung transplant can be considered in compliant patients with controlled disease with undetectable HIVRNA
Infection with *Burkholderia cenocepacia*, *Burkholderia gladioli*, and multi-drug–resistant *Mycobacterium abscessus*
Prior chest surgery, particular pleurodesis (surgical or chemical)
Patients requiring a mechanical (ventilator or circulatory) bridge to transplant

Adapted from ISHLT Consensus Statement.[8]

OPERATIVE PROCEDURES

Donor Recovery Operation

5 The donor recovery lung evaluation is as important to the success of the lung transplant recipient as the implantation, and is summarized in **Table 39.6**. The experienced recovery surgeon will review the donor's ABO blood group, history, and imaging and then perform a bronchoscopy and manual inspection of the lung(s) to assure no contraindications or problematic anatomy before acceptance communication with the implant team.

Table 39.6 Sequential Steps in Donor Lung Recovery	
1	Review donor blood group, history and imaging
2	Perform bronchoscopy
3	Perform median sternotomy
4	Intraoperative inspection of lungs and thoracic cavity
5	Lung recruitment maneuvers and assessment of lung function and suitability for transplantation
6	Dissection of great vessels as needed
7	Systemic donor heparinization
8	Cannulation of main PA
9	Prostaglandin E1 (500 mg) injected into main pulmonary
10	Division of systemic venous return to decompress right heart
11	Aortic cross-clamp
12	Left atrial division to decompress left heart
13	Initiation of cold lung preservation flush
14	Topical cooling of ventilated lungs
15	Cardiectomy
16	Retrograde lung flush
17	Recovery of lung

A median sternotomy is performed, often concomitant with a laparotomy by the abdominal team. The sternal retractor is often placed toward the head to minimize interference with the abdominal operation. If there is no urgency for cardiac evaluation, the pericardium should be left closed during the lung evaluation to decrease hemodynamic instability with excessive lung manipulation. Bilateral pleura are opened widely with care to avoid damage to the lung parenchyma. Visual and manual inspection then ensues of the pleural cavity and lungs for nodules, masses, consolidation, atelectasis and/or infarction. Compliance is checked by temporarily disconnecting the ventilator, which should result in an immediate collapse of the lungs. If necessary, positive pressure lung recruitment maneuvers are performed, while minimizing risk of barotrauma by restricting peak pressures to 20 to 30 cm H_2O. If an intraoperative systemic arterial blood gas (ABG) is satisfactory, usually a PaO_2/FiO_2 >300 on PEEP 5 with normal CO_2 levels, then proceeding with intended lung recovery and transplantation is applicable. However, if the ABG is not satisfactory, or there is a clinical concern about the independent function or suitability of the lung, individual pulmonary vein gas may be sampled to further evaluate lobar contributions to total pulmonary function.

If no contraindications arise, in preparation for organ recovery, the pericardium is opened, and exposure optimized with the use of stay sutures. The SVC is encircled caudal to the azygous vein while care is utilized to separate the right PA from the back of the SVC and ascending aorta. The paratracheal tissue is accessed between the SVC and the ascending aorta with gentle retraction of both vessels. The trachea is then manually exposed circumferentially. The author prefers to wait on circumferential exposure until after cross-clamp in order to minimize bleeding risk and/or airway injury.

Once all teams have completed dissection, the donor is heparinized as per protocol; usually 250 to 300 units/kg. A purse string suture is placed in the main PA near its midpoint and a perfusion cannula secured. Preferably, to achieve equal distribution of preservation solution, the cannula is oriented in a retrograde fashion toward a competent pulmonary valve. 500 μg of prostaglandin E1 (PGE1) is injected into the main PA directly with less than 1 minute prior to intended cross-clamp as systemic vasodilation and potentially hemodynamic compromise may ensue. Next, the SVC is ligated and the IVC divided at an appropriate level to facilitate intended heart and/or liver transplant. The aorta is cross-clamped. The left atrial appendage is then amputated to allow left heart decompression, prior to beginning pulmonary flush. Three to 4 L of cold Perfadex flush is initiated under pressure by gravity, and the chest cooled with iced saline and with care to avoid thermal injury by direct ice contact with the organ. Ventilation is continued throughout the duration of the flush to facilitate even distribution of perfusate. At completion of the flush, ventilation may be temporarily ceased until just prior to lung extraction. The heart is now extracted by sharply mobilizing the IVC to the level of the right inferior pulmonary vein. While lifting the heart, an incision is made in the left atrium in the midpoint of the left and right inferior pulmonary veins. The atriotomy may now be retracted with a suction device to allow visualization and utilization of scissors to extend the opening superiorly while visualizing the vein orifices. The remaining left atrium is now divided. The great vessels are now divided by dividing the SVC distal to the ligature, the ascending aorta proximal to the head vessels, and the main PA at the level of cannulation. With the heart now removed, a Foley or self-inflating retrograde perfusion catheter is utilized to provide 500 mL of Perfadex flush into each vein orifice until clear of residual blood and clots. Now, the en bloc lungs may be removed by division of bilateral inferior pulmonary ligaments and herniating the left lung toward the right chest, to visualize and develop an anterior paraesophageal plane. Division of the mediastinal pleura just anterior to the esophagus completely into the right chest during gentle upward retraction of the lungs, protects the lung and its vasculature, while avoiding enteric contamination with esophageal injury or division. Finally, the only remnant connection is the trachea. The endotracheal tube is then withdrawn into the proximal trachea, a gentle Valsalva maneuver is performed until atelectasis is resolved, and then the Valsalva is released just before the proximal trachea is divided with a linear stapler, distal to the endotracheal tube. To minimize air leak, two staple firings are usually placed on the extracted trachea. If the lungs will be split for two different recipients, the proximal left main bronchus is divided with a liner stapler to maintain inflation before dividing the left atrium and PA at the midline. The lungs are then bagged in a cold preservation solution and transported on ice.

Recipient Preparation

Before anesthetic induction, patients have epidural catheters placed to aide in perioperative pain management and to facilitate faster extubation and ambulatory rehabilitation. If cardiopulmonary bypass (CPB) is needed intraoperatively, intraoperative use of ECMO is planned, which limits the requirement for heparinization usually to less than 5,000 total units. Double-lumen endotracheal intubation is routine with an appropriately sized tube, but large enough to allow vigorous suctioning of purulent secretions through an adult fiberoptic bronchoscope. Routinely, two internal jugular central venous lines are placed for both volume and medication administration. Also inserted a Foley catheter with bladder temperature monitor, both radial and femoral arterial lines, and a transesophageal echocardiography probe. In my practice, with these adjuncts, I have not needed a Swan-Ganz catheter placed for perioperative management and have therefore avoided intendent risks that arise with the catheter in place during pneumonectomy or with fresh anastomoses. The patient is placed either in a supine position with all extremities padded, shoulders medially rotated and arms tucked at sides for bilateral lung transplants or in the lateral recumbent position for single-lung transplants. A heating blanket may be utilized.

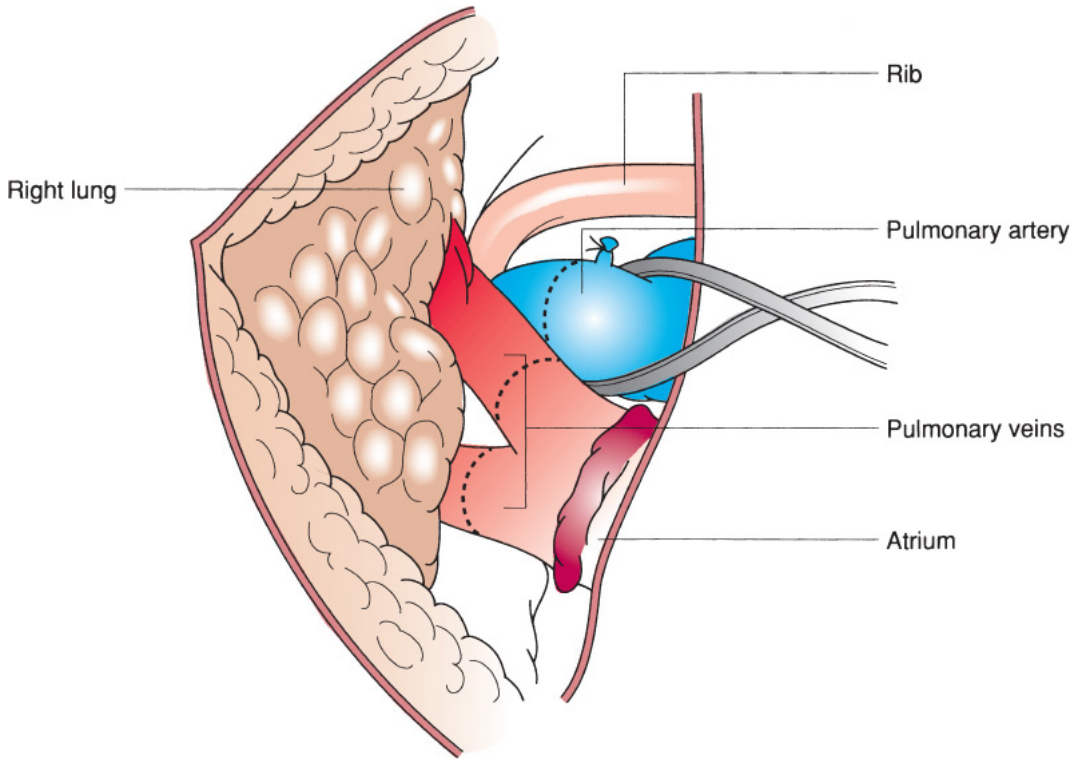

Figure 39.1 Mobilization of the hilum of the right lung. The pulmonary artery is encircled, and the first branch is ligated and divided. The superior and inferior pulmonary veins have been exposed. Both the artery and veins are taken as close to the lung as possible. The bronchus is divided at the level of the takeoff of the upper lobe to minimize ischemia of the airway.

Single Lung Transplantation

In the recipient operation, a standard fifth intercostal space posterolateral thoracotomy is preferred. The groin should always be included in the sterile field. If necessary, CPB can be performed by cannulating the femoral vessels in the groin. The hilar dissection (**Fig. 39.1**, shown with stapler) differs from that of a pneumonectomy in that the main pulmonary artery and the pulmonary veins should be divided within the pulmonary hilum at the level of the lung parenchyma, to allow as great of a vascular stump as possible, for later ease of reconstruction. The pericardium is opened around the left atrial cuff allowing the left atrium to be clamped centrally to the branch point of the superior and inferior veins. On the right, the veins are elongated by mobilizing Waterston's groove. The artery and vein stumps are gently retracted with a 2-0 silk suture through the staple line, away from the bronchus to provide exposure. Care should be taken to preserve the peribronchial lymphatic and areolar tissue in order to maintain the vascular supply of the mainstem bronchus just proximal to the origin of the upper lobe bronchus. However, care should be utilized to clip any divided bronchial or lymphatic vessels during the dissection. In addition, injury to the phrenic nerve must be avoided, especially in the setting of pleural adhesions from previous surgery, severe emphysema, or pulmonary fibrosis, to avoid diaphragmatic dysfunction, which can adversely affect posttransplant functional recovery.

The donor lung is prepared by dissecting the left atrial cuff and the proximal pulmonary artery from the surrounding tissues. Retrograde perfusion is then administered by perfusing the superior and inferior pulmonary veins with cold Perfadex while the lung is still inflated. The bronchial cuff is prepared by transecting the mainstem bronchus approximately two cartilaginous rings from the orifice of the upper lobe bronchus to maximize retrograde perfusion to the bronchial anastomosis.

Implantation of the donor lung progresses from posterior to anterior, with the anastomosis between the donor and recipient bronchus, first. An end-to-end anastomosis is performed with a running 4-0 polydioxanone suture at the cartilagino-membranous junction, continuing along the membranous airway, before reapproximation of the cartilaginous airway. Care to not pursestring the anastomosis is undertaken by the assistant maintaining equal

tension along the suture until completion. Absorbable sutures are used rather than polypropylene to reduce the risk of suture granuloma formation.

The vascular anastomoses are then performed sequentially using running 4-0 and 6-0 nonabsorbable polypropylene sutures for the venous and arterial anastomoses, respectively. Our preference has been to perform the left atrial anastomosis followed by the pulmonary arterial anastomosis. The recipient pulmonary vein stumps are prepared by unifocalization into one left atrial cuff to reduce the risk of pulmonary venous obstruction. In constructing the pulmonary arterial anastomosis, care must be taken to trim the donor pulmonary artery to the appropriate length to avoid kinking of the low-pressure vessel. Once the vascular anastomoses are completed, the lungs are gently ventilated as the vessels are deaired with the patient in the Trendelenburg position, removing the left atrial clamp followed by the pulmonary arterial clamp prior to tying the anastomotic sutures. A 500 mg dose of methylprednisolone is usually given prior to reperfusion to minimize an expected systemic inflammatory response. It is also standard in our institution to initiate inhaled nitric oxide prior to reperfusion of the lung to theoretically minimize risk and complications of primary graft dysfunction (PGD).[15] Progressive reperfusion to the allograft is manually controlled. Both anterior and posterior chest tubes are secured and the chest is then closed in standard fashion.

Bilateral Lung Transplantation

6 The technique of double-lung transplantation has evolved considerably since the late 1980s from an en bloc technique to a bilateral, sequential technique.[16,17] With the patient in the supine position, this operation can be performed through a median sternotomy, bilateral thoracosternotomy (clamshell) incision (**Fig. 39.2**, shown with arms tucked at sides), bilateral anterior thoracotomies without sternal division, or bilateral muscle-sparing axillary thoracotomies. The bilateral thoracosternotomy incision is the author's preference for bilateral lung transplantation and provides the widest exposure facilitating dissection and mobilization of the hilar structures as well as cannulation of the right atrium and ascending aorta if CPB is necessary. This exposure is particularly important in recipients with diffuse dense pleural adhesions as is often seen in patients with chronic infections with bronchiectasis or CF, previous pleurodesis, or with severe apical adhesions after lung volume reduction in patients with emphysema.

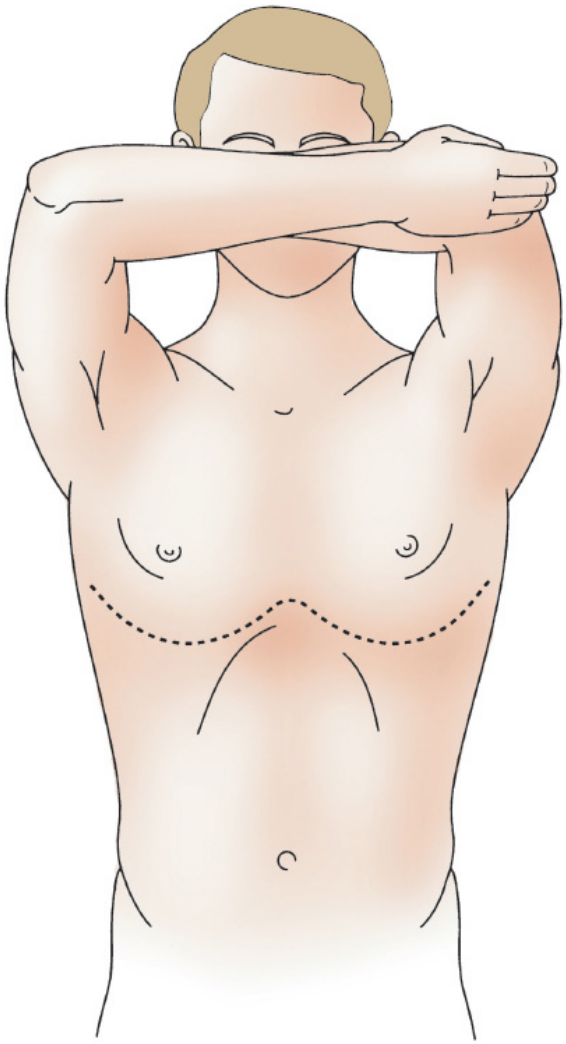

Figure 39.2 Patient positioning for a bilateral, sequential lung transplant. Bilateral anterior thoracotomies are made in the fourth intercostal space with a transverse sternotomy when needed for exposure (clamshell incision).

Although both lungs are replaced, the operation can often be performed without CPB unless the recipient has significant pulmonary hypertension or severely limited gas exchange. By replacing the lung with the least function first, based on the quantitative ventilation perfusion scan or intraoperative pulmonary arterial test clamping, oxygenation and ventilation can be maintained by the native lung. If the patient is unable to tolerate single-lung ventilation due to inadequate gas exchange or worsening right ventricular dysfunction with increasing pulmonary hypertension (near or suprasystemic), then CPB is initiated. If recipient hemodynamics are significantly impaired during retraction and exposure of the left atrial anastomosis, particularly during left lung recipient pneumonectomy and implantation, CPB should be utilized to facilitate the operation. In patients with severe mediastinal shift due to volume loss from pulmonary fibrosis, CPB may be necessary to provide sufficient cardiac decompression in order to obtain adequate exposure to complete the anastomoses.

The donor lungs are prepared leaving a cuff of left atrium around the pulmonary veins on each side. The recipient pneumonectomy is performed one side at a time with the patient maintained using single-lung ventilation of the contralateral lung. Each donor lung is implanted using the same technique as described for single-lung transplantation. The bronchial anastomosis is completed first, followed by the left atrial and pulmonary arterial anastomoses. Once perfusion and ventilation are restored to the first implanted lung, this lung then supports the patient while the remaining lung is removed and the second lung is implanted.

OPERATIVE CONSIDERATIONS

Allograft Ischemic Time

7 Most transplant centers attempt to limit organ ischemic time to less than 6 total hours, however, multiple institutions, including our own, have vast experience comfortably extending cold ischemic time with careful donor selection. Conflicting evidence using older registry data found increased 2-year mortality with donor age >50 years and ischemic times 7 hours or more,[18] yet another analysis demonstrated that prolonged ischemic time was not an independent predictor of mortality.[19] In the current era of widening donor shortages and improved organ preservation techniques, 10% of recipients were reported to have ischemic times >8 hours, and ischemic times up to 12 hours was demonstrated to not be associated with primary graft failure nor survival.[20]

Unilateral versus Bilateral Lung Transplant

Despite almost 30 years of bilateral lung transplant being the predominant lung transplant operation and 75% of candidates currently receiving a bilateral lung transplant,[4] an omnipresent debate over the best strategy to utilize for lung transplantation still exists. While institutional preferences, including ours, favor bilateral lung transplant for recipients without technical and comorbid contraindications to bilateral transplant, single-lung transplants are suggested to be a better utilization strategy for such a limited resource. A recent comprehensive review of literature during the LAS era concluded that the level of evidence supporting either conclusion is conflicted, limited, and varied enough by disease and patient factors that without a randomized trial, which will likely never happen, considerations for the technique should be made on a case-by-case basis.[21]

Intraoperative Cardiopulmonary Support

Traditionally, during implantation in recipients who demonstrate inadequate pulmonary reserve during single-lung ventilation or inadequate cardiovascular reserve, evidenced by hemodynamic instability or progressive right ventricular dysfunction, intraoperative CPB is utilized. However, the risks and side effects of full heparinization resulting in perioperative bleeding and PGD are concerning and desired to avoid if possible. There has been a shift of intraoperative support toward the use of intraoperative ECMO, as the benefits of less heparinization, absence of a venous reservoir, less circuit component interfaces, and ease of conversion to postoperative support as needed, invite consideration of first line deployment over full CPB, when safe to do so. Several institutions have reported their results and experience utilizing the technique with consistent benefits of fewer postoperative complications, such as bleeding, inhospital mortality, prolonged ventilation requirements, and incidence in PGD.[22–26] We have also adopted use of intraoperative ECMO when cardiopulmonary support is necessary, which is only 25% of double-lung transplants and rarely needed for single-lung transplants. Some programs even now advocate routine intraoperative ECMO for all lung transplant procedures, based on demonstrated excellent early allograft function and midterm survival utilizing the technique.[27]

Special Patient Populations

While patient safety and surgical team efficiency are important and improved by standardizing common procedures, it is prudent to review each recipient's specific history preoperatively to recognize patient-specific factors that may complicate or alter the course of the operation or predispose them toward postoperative complications. Those patients with severe pulmonary hypertension and RV failure are at risk for hemodynamic collapse with induction of general anesthesia and the surgical team and perfusionist should be immediately available for emergent institution of CPB or ECMO if needed. In the case of near or suprasystemic PA pressures, preinduction establishment of ECMO should be considered. In patients with severe peripheral vascular disease, history of Raynaud disease or digital ischemia, consideration of avoiding the radial arterial line or minimizing the duration of its insertion should be undertaken. It is also reasonable to consider the application of local heating devices or topical vasodilators to an at-risk extremity, as tolerated.

Surgical Complications

Primary Graft Dysfunction

8 PGD is an acute lung injury syndrome occurring within the first 72 hours following lung transplantation and is characterized by inexplicable diffuse allograft infiltrates and hypoxemia, defined as a PaO_2/FiO_2 ratio (P/F) <300 (**Table 39.7**). The definition has been standardized by ISHLT consensus[28] and later validated and clarified[29] in order to promote improved clinical and scientific progress and potential development of therapeutic strategies. PGD is also characterized by low pulmonary compliance, interstitial/alveolar edema, pulmonary infiltrates on chest radiographs, increased pulmonary vascular resistance, intrapulmonary shunt, and acute alveolar injury, as revealed by diffuse alveolar damage (DAD) on pathology.[30] Recipients who suffer from severe PGD have been reported to have 3 to 5× increased short-term mortality, 30-day, 23%, 1-year, 34%, and long-term mortality.[31,32] Risk of PGD development is thought to result from complex immunomechanistic interactions between donor and recipient characteristics and the conduct of the donor and recipient operations. While no specific pathomechanism has been identified, Diamond et al. published a multicenter prospective multivariate analysis identifying risk factors for severe PGD as donors with any smoking history, FiO_2 >0.4 during allograft reperfusion, preoperative sarcoidosis or pulmonary arterial hypertension, use of CPB, single-lung transplant, large-volume blood product transfusion, elevated pulmonary arterial pressures, and overweight or obese recipient body habitus.[32]

Airway Complications

The lung has a dual blood supply from both the pulmonary and bronchial arteries. Conventional lung transplantation operative techniques interrupt the bronchial artery supply and do not revascularize the bronchial anastomosis, so postlung transplant airway complications remain of concern. Airway complication rates have ranged from 2% to 18% in larger contemporary studies.[33] The current bronchial anastomotic complication rate represents a significant improvement over early lung transplant experience where 55% of recipients were noted to have airway complications,[34] most likely a result of improved operative technique, organ preservation, and patient care protocols.

Table 39.7 Grading of Primary Graft Dysfunction Severity

Grade	PaO_2/FiO_2	Radiographic Infiltrate Consistent with Pulmonary Edema
0	>300	Absent
1	>300	Present
2	200–300	Present
3	<200	Present

Early strategies to minimize airway complications such as tracheal anastomosis for bilateral lung transplant, anastomotic flaps from omentum, intercostal muscle, or pedicled internal mammary artery or pericardial fat pads either significantly worsened, as in the case of the tracheal anastomosis, or did not show any significant reduction in complications.[34,35]

In 1970, Haglin et al. performed the first lung transplant with bronchial artery revascularization (BAR), using an aortic vascular cuff, and proposed the technique as a method to restore bronchial artery circulation. The technique is infrequently described and utilized secondary to concerns for added complexity, operative time, lack of acceptance of improved postoperative airway, and other complications. The largest reported clinical results of BAR was by a group in Denmark reporting 65 patients, 47 undergoing double-lung transplant with the left mammary artery used as BAR conduit and demonstrated excellent success and long-term survival,[36]

superior to their more recent series of non-BAR lung transplants.[37] A recent pilot study at the Cleveland Clinic in 27 bilateral lung transplant recipients demonstrated that BAR resulted in similar operative time and hospitalization, but resulted in reduced airway ischemia and complications, lower biopsy tissue grades, fewer infections, and delay of BOS.[38] Together, these results raise the consideration for the field to investigate more in depth the success and potential impact of more routine use of the technique and if supported, then development of a pathway to disseminate the technique to other centers.

DONOR CONSIDERATIONS

In 2018, 2,407 deceased lung donors were utilized; 4.8% from donation after circulatory death donors, 7.9% from donors with a smoking history of 20 pack-years or more.[4] While the goal of the transplant community should be to improve donor utilization efficiency, be better stewards of organ, and to maintain or improve posttransplant outcomes and quality of life, there remains concern that increased donor utilization strategies may result in higher rates and complications of PGD. Therefore, effective strategies to minimize or treat PGD will remain of utmost importance.

Ex Vivo Lung Perfusion

The circumstances or mechanisms leading to a donor's death often results in pulmonary injury or dysfunction prompting concerns for further postoperative allograft dysfunction or severe PGD. Because of this, lung donor utilization remains around only approximately 20% of multiorgan donors; this is in stark contrast to that of liver and kidney utilization rates of almost 75%.[39] Ex vivo lung perfusion (EVLP) has been proposed as a technique to allow the safe and timely assessment of underutilized donor lungs prior to transplantation. Since the original EVLP description for the evaluation of a DCD lung donor,[40] three basic EVLP techniques have been reported,[41] but the premise is the same; normothermic perfusion and ventilation of donor lungs with the ability to recondition lungs and assess physiologic parameters. The three systems are differentiated based upon four concepts: blood-based perfusate, pulsatility, portability, and atrial reconstruction. A recent meta-analysis demonstrated no differences in outcomes between the use of marginal lungs resuscitated using EVLP compared to standard lungs transplanted without EVLP.[42] The Toronto Lung Transplant program, which has been influential in leading the field in EVLP utilization and experimental therapies recently shared their long-term EVLP results. Since the inception of their EVLP program in 2008, 497 lungs were evaluated with EVLP and 25% of their lung transplants have resulted from EVLP evaluation; representing an almost 70% EVLP to transplant conversion rate, with comparable short- and long-term results.[43]

While the use of EVLP may be more readily accepted for marginal or nonutilized lungs, the benefit of use of EVLP for standard lungs may raise questions. Slama et al. demonstrated that EVLP can safely be used in standard donor lungs, with comparable perioperative outcomes as using standard donor lung preservation techniques, with the added potential to exclude lungs with functional impairment and safely extend total preservation time.[44]

EVLP Clinical Trials

Several informative prospective trials have been completed including the NOVEL trial (United States; XVIVO), the HELP trial (Toronto; XVIVO), the INSPIRE and EXPAND trials (Europe and the United States; Transmedics), the Perfusix trial (United States; Perfusix), the Vienna trial (Vienna; XVIVO), and the DEVELOP trial (United Kingdom; Vivoline). Other than the INSPIRE trial, all studies have demonstrated noninferiority to traditional cold storage methods, even with the use of marginal donor organs after EVLP.[45–50] The international, multicenter randomized controlled trial, INSPIRE, demonstrated that use of the OCS device in standard donor lungs resulted in slightly poorer 30-day survival that normalized at later timepoints, but also demonstrated superiority in reduction of severe PGD at 72 hours and in combination with 30-day survival compared to our traditional cold static storage.[45] The results of this trial resulted in FDA approval of the OCS device as standard of care, and remains the only EVLP device FDA approved as such.

All prior studies have utilized positive pressure ventilation; thus the University of Alberta has proposed in the UA NP-EVLP currently active pilot study (NCT03293043, Canada) to more closely mimic lung physiology by utilizing negative pressure ventilation during EVLP. Preliminary results were just released and demonstrated in 12 extended criteria donor human lungs, that negative pressure ventilation EVLP allows for preservation and evaluation of donor lungs with all grafts and patients surviving to 30 days and recovered to discharge without any patients demonstrating PGD grade 3 at 72 hours nor requiring post-operative ECMO.[51]

While all of these aforementioned options include the use of significant resources and staff from the recipient hospital to recover, resuscitate, monitor, and evaluate organs during EVLP, Lung Bioengineering (Silver Spring, MD) is currently investigating the ability of a centralized facility to evaluate marginal donor lungs utilizing the Toronto EVLP system, usually for targeted recipients, in the EVP-DEV-301 trial (NCT02234128).

Hepatitis C Virus-Infected Organs (HCV)

Prior to 2016, only five HCV+ donor lung transplants had been performed, however, in 2017, willingness of patients to accept and programs to perform HCV+ transplants resulted in 100 total anti-HCV+ (45 nucleic acid test+) lung transplants being performed in 2018.[52] This rise is in direct response to earlier success in abdominal transplant organs and the advent of more effective and less challenging therapeutic regimens in very complex patients, with the FDA approval of second-generation direct-acting antivirals (DAAs) that demonstrate more than a 90% sustained HCV cure rate.[52] In 2019, the DONATE clinical trial investigators published the results of a nonrandomized, open label phase IV clinical trial at Brigham and Women's Hospital in 36 lung transplant recipients, who received organs from donors with hepatitis C viremia and were treated with a DAA regimen for 4 weeks beginning within a few hours after transplantation, prevented the establishment of HCV infection.[53] The findings and potential impact of this study has resulted in progressive adoption of HCV protocols at many institutions. Our institution has also developed experience and success with utilizing HCV+ donor lungs, which so far has not only improved our donor utilization rate, but has also resulted in decreased wait time as well.

CONCLUSIONS

While lung transplant outcomes continue to lag behind other solid organ transplants, improvements in technique, perioperative care, and allocation adjustments continue to advance survival 9 and volume benchmarks. Donor availability remains a limiting factor to successful and timely transplantation, which has led to innovative utilization of techniques that result in increased donor utilization. However, PGD is still of concern with the use of underutilized donor populations and several clinical trials are ongoing, but it is currently unclear the effect that these increased donor utilization strategies will have on the incidence or severity of PGD or if effective therapies will arise to minimize or eliminate the effects of PGD.

Pancreas and Islet Transplantation

Randall S. Sung

Key Points

1. The Diabetes Control and Complications Trial (DCCT) demonstrated that tight control of blood glucose and minimization of hemoglobin A1C delays the progression of secondary complications of diabetes.
2. Recipients with functioning pancreas transplants have normal glycemic control without the need for exogenous insulin, and pancreas transplantation has a beneficial impact on diabetic complications.
3. Pancreas graft survival rates are 90% at 1 year.
4. Most pancreas transplants are performed in patients with end-stage renal disease (ESRD), either concomitant with or following a kidney transplant.
5. In general, eligibility criteria for pancreas transplantation are more stringent than for kidney transplantation alone.
6. Pancreas transplant outcome is dependent on the careful selection of donors and on meticulous pancreas recovery technique.
7. Immunosuppression for pancreas transplantation is similar to that for kidney transplantation.
8. In contrast to kidney transplants, the effect of a pancreas transplant on patient survival is only modest.
9. Islet transplantation does not require an operative procedure.
10. Islet transplant outcomes vary by center; overall, insulin independence is less frequent and less durable than whole-pancreas transplants, but continues to improve.

INTRODUCTION

Diabetes mellitus is a spectrum of impaired glucose tolerance that ranges from gestational glucose intolerance to severe hyperglycemia and

ketoacidosis. Diabetes, which affects approximately 34 million people, or 10.5% of the U.S. population, can be divided into two major classifications.[1] Type 1, previously referred to as insulin-dependent diabetes, is an autoimmune disease characterized by the eventual loss of all pancreatic β-cell function. Type 2 diabetes, previously referred to as non–insulin-dependent diabetes or adult-onset diabetes, characteristically presents in obese patients over age 40.[1] Many of these individuals eventually require insulin therapy. The prevalence of type 2 diabetes is increasing as the prevalence of obesity increases, especially in younger age groups. Overall, the age-adjusted incidence of diabetes peaked in 2009 and has actually declined since then, although the incidence of both type 1 and type 2 diabetes in those under age 19 continues to increase. Prevalence of diagnosed diabetes for 2017 to 2018 was highest among American Indians/Alaska Natives (14.5%), people of Hispanic origin (12.5%), and non-Hispanic blacks (11.7%).

While the mean age of onset is in the early teenage years, the disease may present as early as the first year of life. Type 1 diabetes afflicts approximately one in every 400 to 500 children and adolescents.[2] Patients may present as late as the fourth decade of life, and these patients may be misclassified as type 2 diabetics, despite clearly possessing the physiology of type 1 diabetes. The disease classically presents in a lean patient with polyuria, polydipsia, and polyphagia. It may present at the time of a concurrent illness. While there may be a brief "honeymoon" period after presentation where insulin is not required, exogenous insulin is always required to replace that lost by the complete destruction of β-cell mass. While hyperglycemic episodes from poorly controlled diabetes, or hypoglycemic events from insulin, may be life threatening, the major morbidity of type 1 diabetes stems from the myriad long-term manifestations of the disease, particularly those that are due to accelerated atherosclerosis.

PATHOPHYSIOLOGY

The classic pathophysiology of diabetes is that of insulin secretory failure in type 1 diabetes and peripheral insulin resistance in patients with type 2 diabetes. The etiology, epidemiology, and pathogenesis of diabetes are much

more complex than is reflected in early characterizations of the disease. Type 1 diabetes is classically described as an autoimmune disorder manifested by destruction of β-cells, with proinsulin being the most likely primary target.[3] Although there are rare monogenic, immune-mediated forms of type 1 diabetes, the common form is thought to be determined by multiple genetic and environmental factors. The concordance for type 1 diabetes in monozygotic twins is less than 100%, and although type 1 diabetes aggregates in some families, it does not segregate with any clear mode of inheritance.[4]

There is multigenic susceptibility to type 1 diabetes. Genes within the HLA region, especially those that encode antigen-presenting molecules, confer the greatest part of the genetic risk of type 1 diabetes. The likelihood that these many genes may individually only have weak effects make them more difficult to identify precisely, and may explain the heterogeneity of inheritance of type 1 diabetes. This genetic susceptibility background is thought to interact with environmental triggers, perhaps infectious, that lead to autoimmunity and insulitis, the characteristic pathologic lesion of type 1 diabetes, although definitive proof of these triggers is lacking.

The incidence of type 1 diabetes has been progressively increasing during the past several decades, particularly among children younger than 5 years. In children at genetic risk, diabetes-related autoantibodies appear, followed by the evolution of metabolic abnormalities and the eventual clinical appearance of the disease. If individuals identified by genetic markers subsequently undergo seroconversion and develop two or more diabetes-related autoantibodies, their risk of progression to type 1 diabetes is 75% over 10 years and appears to be almost certain over 20 years.[5] A recent study of patients with diabetes-related autoantibodies who were treated with teplizumab, a monoclonal antibody that reduces the actions of CD8+ T lymphocytes on targets such as beta cells, showed significant reductions in annualized rates of type 1 diabetes and an increase in the median time to diagnosis of type 1 diabetes.[6]

Mucosal tolerance has been exploited in secondary prevention studies using nasal insulin and in secondary prevention and recent-onset type 1 diabetes studies using oral insulin.[7] However, these studies have not been successful in altering the course of the disease. In the Diabetes Prevention Trial–Type 1 (DPT-1), a secondary prevention study of oral insulin, those

with high levels of insulin autoantibodies at baseline had a projected 4.5- to 5-year delay in the development of clinical diabetes. A subsequent analysis showed continued beneficial effects even after oral insulin was discontinued.

In type 2 diabetes, while β-cell hypersecretion initially may exist, ultimately loss of β-cell mass ensues. β-Cell apoptosis is mediated by glucotoxicity from insulin resistance, and is exacerbated by fatty acids, lipoproteins, leptins, and cytokines, all of which are elevated in type 2 diabetes and obesity.[8] Because of peripheral insulin resistance, many patients require insulin in amounts that exceed one unit per kilogram, far greater than typically required by type 1 diabetics.

The observation that type 1 and type 2 diabetes frequently occur in the same family has raised the possibility that they are opposite ends of the same disease spectrum, and ample evidence suggests the two are more similar than initially believed.[9,10] Families with mixed diabetes histories tend to have an intermediate diabetes phenotype: insulin resistance in type 1 and lower BMI and C-peptide concentrations in type 2 patients. β-Cell destruction is common to both types, and obesity and insulin resistance have both been shown to be risk factors for childhood type 1 as well as type 2 diabetes. The "accelerator hypothesis" of diabetes proposes three determinants of disease in all types of diabetes: the intrinsic rate of β-cell apoptosis, insulin resistance, and autoimmunity (which would apply only to a subset). Genetic studies suggest there may be a common predisposition. However, the cytokines, signal transduction pathways, and other soluble mediators of apoptosis are quite different between the insulitis of type 1 diabetes and the lipotoxic or glucotoxic processes of type 2 diabetes, and thus at minimum represent distinct mechanisms of β-cell destruction.[11]

The relatively recent discovery of the replicative potential of a variety of adult tissue types, and their roles in the pathogenesis of disease, has relevance to the pathogenesis of diabetes. In such a model, diabetes occurs due to a failure of regeneration of β-cells, and individual variation in the ability to regenerate β-cells is an important determinant of diabetes development. This hypothesis is partially supported by the finding of associations of type 2 diabetes with genes having identified roles in cellular development. While it is broadly agreed that failure of β-cell replication is an important contributor to diabetes development, increased susceptibility of replicating β-cells to apoptosis in a proapoptotic environment may also lead

to loss of β-cell mass. There is also evidence that deficits of β-cell secretion are as important as those of replication. Furthermore, the range of β-cell mass in adult diabetic and nondiabetic humans is very wide, and exceeds the apparent capacity for expansion of β-cell mass in response to regenerative stimuli. Thus it appears more likely that insufficient growth of β-cell mass during development may be more likely to have a role in the predisposition to diabetes than specific deficits in regeneration.[12]

Alternatively, β-cell dedifferentiation, rather than death, may be the mechanism responsible for β-cell failure in type 2 diabetes.[13] When normal β-cells are challenged by mild hyperglycemia or insulin resistance, they produce and secrete more insulin, thus maintaining euglycemia. Current thinking suggests that oxidative stress and/or endoplasmic-reticulum stress results in β-cell dysfunction, leading to increased secretion of incompletely processed proinsulin, which may trigger apoptosis. Stressed β-cells may undergo dedifferentiation, decreasing expression of β-cell–specific genes, including the enzyme that processes proinsulin; this may explain increased proinsulin secretion in type 2 diabetes. Dedifferentiation may also promote expression of embryonic progenitor-cell markers, and these cells may later secrete non–β-cell hormones such as somatostatin and glucagon.

SECONDARY COMPLICATIONS OF DIABETES

Diabetes mellitus is responsible for tens of thousands of deaths each year in the United States. The high incidence of cardiovascular complications in diabetics is primarily responsible for the twofold increase in the risk of death in diabetics compared with those without diabetes.[2] Clinical complications of diabetes include end-stage renal disease (ESRD), retinopathy, peripheral vascular disease, coronary artery disease, and neuropathy. Diabetic nephropathy is responsible for nearly 40% of all cases of ESRD; diabetes is also the leading cause of blindness and amputations in the United States.[1] The total direct estimated costs of diagnosed diabetes increased from $188 billion in 2012 to $237 billion in 2017.[1]

Improvements in diabetes care have reduced the long-term impact to some extent. Rates of all five major diabetes complications (acute myocardial infarction, hyperglycemic crisis, stroke, amputations, and ESRD) have

declined since 1990, with the smallest decline in ESRD. However, when expressed as rates for the overall population, in which a change in prevalence also affects complication rates, there was a decline in rates of acute myocardial infarction and death from hyperglycemic crisis, but not in rates of amputation, stroke, or ESRD. Thus, while rates of diabetes-related complications have declined substantially in the past two decades, a large burden of disease persists because of the continued increase in the prevalence of diabetes.[14]

While diabetic complications have a multifactorial etiology, they are ultimately secondary to structural alterations in nerves, blood vessels, and connective tissue. Excess glucose is converted to sorbitol by aldose reductase, leading to the reduction of cellular content of myoinositol, abnormal phosphoinositide metabolism, and reduction in Na^+-K^+-ATPase activity. In experimental animals, aldose reductase inhibitors prevent diabetic neuropathy, cataracts, and retinopathy.[15] The accumulation of advanced glycosylation end products (AGEs), due to abnormal nonenzymatic glycosylation of proteins, and extensive crosslinking of these proteins, is likely to be pathogenic.[16] Ligation of endothelial cell receptors by AGEs results in the release of proinflammatory cytokines and activation of the coagulation cascade. Microangiopathy is characterized by thickening of capillary basement membranes, which increases with the duration of disease, and altered capillary permeability.

1 The Diabetes Control and Complications Trial (DCCT) demonstrated that tight control of blood glucose prevents and delays the progression of secondary complications of diabetes.[17,18] This study, in which patients with type 1 diabetes were randomized to conventional treatment with one or two doses of daily insulin versus intensive treatment with three or more injections per day, demonstrated a dramatic reduction in the risk of progression of retinopathy, microalbuminuria, albuminuria, peripheral neuropathy, and cardiovascular disease in the subjects randomized to intensive treatment. However, the major side effect of intensive treatment was a threefold increase in the risk of severe hypoglycemic episodes; approximately 10% of patients in the intensive insulin therapy cohort experienced five or more episodes of seizure or coma during the study period. Even in the absence of overt brain injury, multiple episodes of severe hypoglycemia have been associated with cerebral perfusion abnormalities

and poor neuropsychiatric performance. In addition, there is a significant risk of accident during hypoglycemic episodes. Frequently, as hypoglycemia becomes more frequent and autonomic neuropathy worsens, patients may develop a syndrome of unawareness to hypoglycemia where the typical symptoms of tremor and anxiety do not occur. Such patients with hypoglycemic unawareness may develop profound hypoglycemia, especially if left unsupervised, and risk severe neurologic and traumatic injury.

In a similar trial, patients randomized to intensive insulin therapy, compared to those randomized to conventional therapy, had lower all-cause mortality. The most common causes of death were cardiovascular disease (22%), cancer (20%), and acute complications (18%).[19] The long-term risk of an impaired glomerular filtration rate (GFR) was significantly lower among persons treated early in the course of type 1 diabetes with intensive diabetes therapy than among those treated with conventional diabetes therapy.[20] Notably, all-cause mortality was significantly higher among those with higher mean hemoglobin A1C (HbA1C) levels and with renal disease during the 20-year follow-up.[19]

The overall management of diabetes is focused upon maintaining blood glucose as close to normal range as possible while attempting to minimize significant hypoglycemic episodes. Although the frequency and extent of hyperglycemia is important in the assessment of glucose management, long-term glycemic control is best assessed by evaluation of blood levels of HbA1C which measures the extent of glycosylation of hemoglobin. Although the incidence of diabetes is increasing, the overall treatment efficacy has improved. The use of subcutaneous insulin pumps is being increasingly employed, inhaled insulin has been used in selected patients, and infusion devices which also assess serum glucose and automatically adjust insulin dose accordingly are being developed.[21,22] Fully automated artificial-pancreas systems have been developed which link glucose sensors with insulin pumps through computerized control algorithms, which dictate insulin delivery in response to real-time sensor data.[23] Recent studies that have been carried out both in hospitals and in outpatients have shown that such systems can improve glucose control and reduce the risk of nocturnal hypoglycemia in children, adolescents, and adults.[24,25]

Nevertheless, until such systems are widely adopted, many diabetics still have difficulty maintaining tight glucose control without hypoglycemic

complications.[26] In addition, most type 1 diabetics, even if on optimal insulin therapy, are unable to maintain HbA1C levels in the normal range, and most will ultimately develop progressive diabetic complications.

PANCREAS TRANSPLANTATION

Overview

Pancreas transplantation, while not technically a cure, represents an important therapeutic insulin replacement option 2 for many type 1 diabetics. Recipients with functioning pancreas transplants have normal glycemic control without the need for exogenous insulin. Initial experience with pancreas transplantation, from the first pancreas transplant performed by Kelly and Lillehei in 1966 until the 1980s, was marked by low success rates and high mortality.[27] In 1980 the 1-year graft survival rate for pancreas transplantation was only 21%, and there was tremendous skepticism about the utility of the procedure. 3 Advances in surgical technique and immunosuppression dramatically improved graft survival rates to the current rate of around 90% at 1 year. In addition to the development of cyclosporine, the introduction of bladder drainage of the donor pancreas, first introduced by Sollinger in 1985 using a button of donor duodenum, and subsequently modified by Corry in 1986 using an entire segment of duodenum anastomosed to the urinary bladder, dramatically improved the results of pancreas transplantation (**Fig. 40.1**).[28,29] Graft survival continued to improve throughout the 1980s and 1990s, especially for isolated pancreas transplantation (pancreas transplant alone [PTA], or pancreas after kidney transplantation [PAK]), the results of which have been historically inferior to simultaneous kidney–pancreas transplants (SPK). Both short- and long-term survival of pancreas transplants have improved much more slowly over the past decade. Because bladder drainage is associated with significant morbidity, most pancreas transplants are currently performed with enteric exocrine drainage and venous drainage into the systemic circulation. However, pancreas transplantation may also be performed by draining pancreatic venous blood into the recipient portal circulation, usually via the superior mesenteric vein.

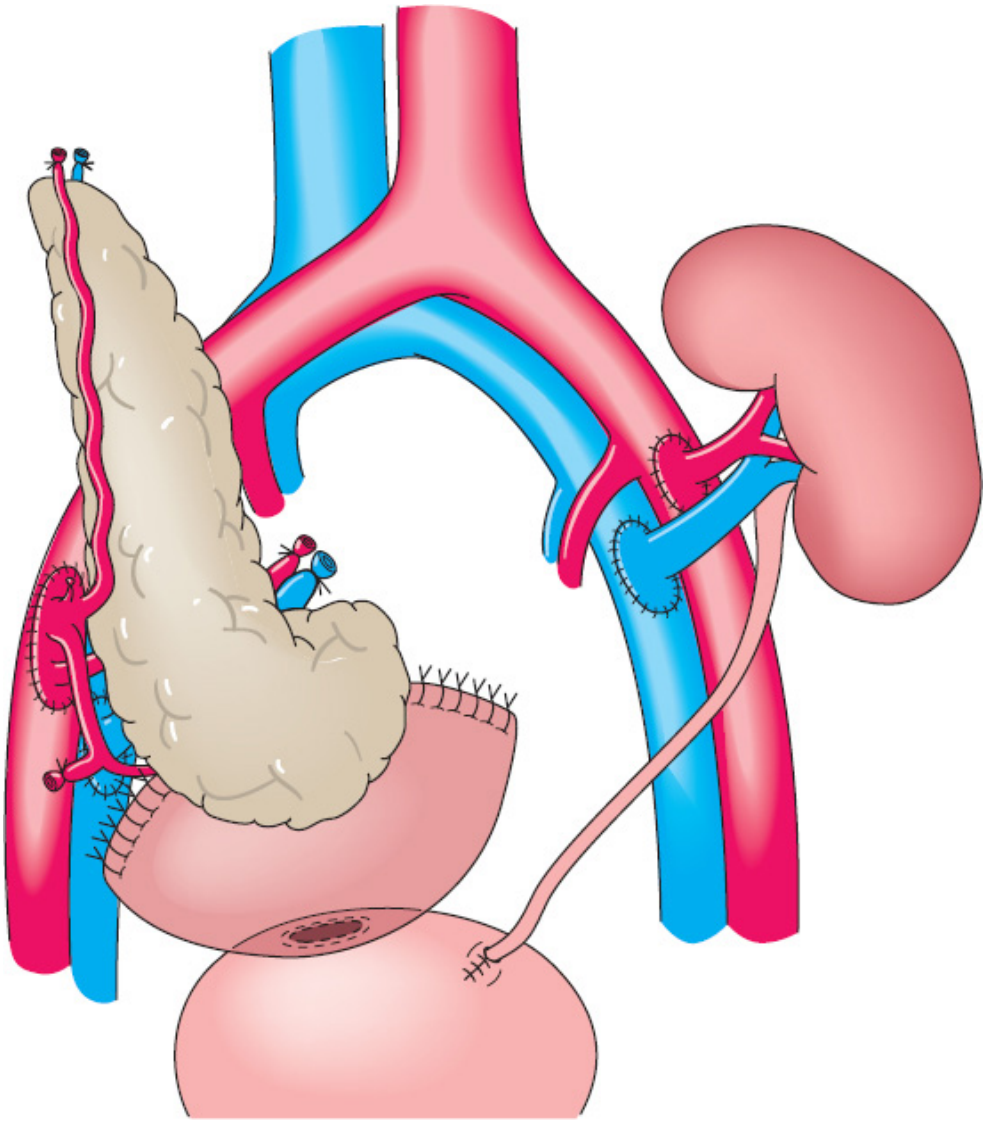

Figure 40.1 Simultaneous pancreas kidney transplantation performed with drainage of the pancreatic exocrine secretions into the urinary bladder (bladder drainage). This technique has been predominant until recently. Note that a segment of the second portion of the duodenum is left attached to the pancreas. Despite its heterotopic location, the transplanted pancreas responds to gastrointestinal hormones with a marked increase in secretion of pancreatic juice that has very high bicarbonate content. Also note that the portal vein drains into the iliac vein (i.e., systemic venous drainage). In healthy individuals 50% of the secreted insulin is extracted from the circulation in the first pass through the liver. Transplant recipients with systemic venous drainage have peripheral insulin levels two to two and one half times higher than normal.

Patient Selection

Pancreas transplantation is usually performed in patients with type 1 diabetes. The diagnosis of type 1 diabetes is relatively straightforward for most individuals. A history of juvenile or young adult onset, diabetic ketoacidosis, a lean body habitus, and a low insulin requirement (<0.7 units/kg) all support the diagnosis of type 1 diabetes. In contrast, older age of onset, obesity, an interval of treatment with diet or oral agents, or high insulin requirements are all suggestive of type 2 diabetes. A subset of adult-onset diabetics will display characteristics otherwise associated with type 1 diabetes, including absence of insulin production. Whether these individuals are properly classified as type 1 or type 2 diabetics may be subject to debate, but these individuals may certainly benefit from pancreas transplantation. Individuals with type 1 physiology but adult age of onset and who make low levels of endogenous insulin may also be considered for pancreas transplantation. Outcomes for these recipients are similar to those with type 1 diabetes. Recognition of these excellent outcomes has resulted in an increase in pancreas transplant recipients classified as having type 2 diabetes up to 14%.[30] As these are typically highly selected individuals without significant insulin resistance, most type 2 diabetics would not be considered candidates. Some type 1 diabetics may develop insulin resistance as a result of years of insulin therapy; this is frequently accompanied by increased body weight and insulin requirements. While insulin resistance may improve after transplantation in such patients, or may be managed with additional oral hypoglycemic agents, these patients are at higher risk for remaining on insulin after pancreas transplantation.[31] While provocative tests for insulin resistance exist, they are not commonly employed.

A small percentage of pancreas transplant recipients do not have type 1 or type 2 diabetes, but have diabetes from other causes. Several have undergone pancreatectomy for chronic pancreatitis or other conditions.[32] Some pancreas transplants (<1%) are performed as part of a multivisceral transplant that includes liver and small intestine in patients who do not have diabetes; in these transplants, the pancreas is included in the graft to facilitate the technical conduct of the operation and to reduce complications.[33]

4 Most individuals evaluated for pancreas transplantation have chronic renal disease. These patients may present prior to onset of dialysis, while currently receiving dialysis, or following kidney transplantation. For individuals without a functioning kidney transplant, potential options include

simultaneous deceased donor kidney/pancreas transplantation (SPK), living donor kidney transplantation followed by PAK, simultaneous living donor kidney–deceased donor pancreas transplantation (SPLK), or simultaneous living donor kidney–pancreas transplantation. Of these options the former two are by far the most common.

Simultaneous Kidney–Pancreas Transplantation

SPK from a deceased donor is the most commonly performed pancreas transplant option, with the number exceeding all other types combined. An SPK transplant has the advantage of requiring only one operation for both transplants. Since alloreactivity against the transplanted pancreas tends to be concordant with activity against the kidney, pancreas rejection may be heralded by signs of kidney rejection, which are more sensitive and present earlier. Consequently, SPK pancreas outcomes have been historically superior to those of solitary pancreas transplants.

Pancreas after Kidney Transplantation

If a living kidney donor is available, candidates have the option of receiving a living donor transplant, followed by a deceased donor pancreas transplant. This approach has the disadvantage of requiring two separate operations, but the recipient enjoys the benefit of a living donor kidney transplant that in many circumstances occurs sooner than would an SPK from a deceased donor. Since the primary survival benefit of the kidney–pancreas transplant comes from the restoration of renal function, this is a significant advantage. However, since a PAK is essentially a solitary pancreas transplant immunologically distinct from the kidney transplant, pancreas outcomes are worse than for SPK.

Simultaneous Living Donor Kidney–Deceased Donor Pancreas Transplantation

SPLK is another option previously performed at a few centers, but now done rarely.[34] Candidates with identified living donors are listed for deceased donor pancreas transplantation. When a deceased donor pancreas becomes available, the living kidney donor transplant is performed at the same time as the pancreas transplant. This approach has the advantages of sequential living donor kidney followed by PAK transplants while requiring only one operation. It does require that the potential living donor be available to donate at any time, a requirement that excludes some donors from this approach. It also has the disadvantage of potentially delaying a kidney transplant for the recipient if the waiting time for a deceased donor pancreas is long.

Living Donor Kidney–Pancreas Transplantation

A few centers perform living donor kidney–pancreas transplantation, with a single living donor donating the tail of the pancreas as well as the kidney (**Fig. 40.2**). This approach has all the advantages of a single operation, a single donor, and no waiting time. Results have been comparable to deceased donor SPK transplants.[35,36] Widespread adoption of this approach has been limited by concerns about donor morbidity from the pancreatectomy. Serious complications such as pancreatitis, fistula, abscess, or pseudocyst can occur. Glucose intolerance and frank diabetes have occurred, although this problem has been nearly eliminated with more stringent donor selection criteria.[36,37]

Pancreas transplant candidates with renal failure may be counseled in a variety of ways depending on the availability of a living donor. How individuals are counseled depends in part on factors particular to the potential living donor and recipient, and also on the expected waiting time for SPK and PAK transplantation, which vary greatly by geographic region. Since the mortality benefit of a kidney–pancreas transplant derives primarily from the kidney transplant, priority is generally given to achieving kidney transplantation expeditiously. In geographic regions where the waiting time for SPK is longer (3 years is not unusual), living donor kidney transplantation is advised. Recipients of living donor kidney transplant can then be listed for PAK which can be performed following recovery from the

living donor kidney transplant. Individuals without living donors or those with borderline living donors in areas with short waiting times can be listed for SPK. Interestingly, there does not appear to be the same adverse impact in outcome with a limited interval of pretransplant dialysis (less than 2 years) in SPK recipients that is observed in kidney-alone recipients, whether deceased or living donor.[38] Therefore, even candidates with living donors may reasonably opt for SPK if anticipated waiting times are short.

Pancreas-Alone Transplantation

A small number of type 1 diabetics are evaluated for PTA. These individuals are generally extremely labile diabetics who have progressive complications but do not have nephropathy. In these individuals the risk–benefit equation is quite different than those uremic diabetics evaluated for kidney–pancreas transplantation. For nonuremic diabetics evaluated for pancreas transplantation the risk of immunosuppression in addition to the surgical procedure must be weighed against the potential benefits from transplantation. This contrasts to uremic diabetics, for whom the risk of immunosuppression is already assumed by virtue of the need for a kidney transplant. This risk includes renal failure due to chronic calcineurin inhibitor use. This is commonly cited as justification to not perform PTA, and recent evidence suggests the 10-year risk is at least 20% and is related to pretransplant GFR.[39] Whether PTA for type 1 diabetes results in a significant survival benefit is controversial. PTA in most centers is generally offered only in the most exceptional cases, the most common indication being frequent life-threatening hypoglycemic events. However, several transplant programs have a different philosophical outlook on the risks and benefits of PTA, and these referral centers generally perform large numbers of PTA. Most PTAs are from deceased donors, with a small number of centers offering living donor PTA. Living donor pancreas transplants carry a higher rate of technical failure but a lower rate of immunologic failure.[40,41]

B

Figure 40.2 Live donor pancreas and kidney transplantation. **A:** Provided that the donor has a normal glucose tolerance test, a living donor may donate the segment of the pancreas that is to the left of the superior mesenteric vessels. **B:** Transplantation of tail of the pancreas is based on the splenic artery and vein.

Evaluation and Screening

5 In general, eligibility criteria for pancreas transplantation are more stringent than for kidney transplantation alone, since the operation and recovery are more rigorous, the potential complications more serious, and the benefits less pronounced compared with kidney transplantation. Candidates should have excellent functional status in anticipation of the more extensive surgery and more frequent complications. Age is not tightly related to outcome, but patients over the age of 60 are carefully scrutinized.[42] A detailed history of the patient's diabetes and treatment is obtained, including current glycemic control, hypoglycemic events, secondary complications, insulin requirements, and overall quality of life. Obesity in and of itself is not a contraindication, as outcomes for carefully selected obese (BMI >30) recipients are similar to nonobese recipients, although surgical complications and the likelihood of remaining insulin dependent may be slightly higher.[43] Selection practices vary widely—for some centers, pancreas transplantation is reserved for those with significant complications and poor glycemic control who have failed alternative treatments, while for others the presence of type 1 diabetes and a full understanding of the risks and benefits are sufficient, with patient preferences playing a significant role. Because of the added need for immunosuppression in PTA, these diabetes-related criteria are often more stringent than for SPK or PTA, where the risk of immunosuppression is already assumed by virtue of the kidney transplant.

All candidates should have at the least noninvasive cardiac stress testing such as dobutamine stress echocardiography or adenosine thallium stress scintigraphy. Potential candidates with reversible myocardial defects undergo coronary angiography, and many centers perform angiography on all candidates. The decision to perform pretransplantation coronary revascularization must be made with consideration of both peritransplant mortality and long-term survival. Although survival outcomes are diminished

in recipients with coronary artery disease,[44] a history of coronary revascularization is not necessarily a contraindication; individuals with extensive myocardium at risk and without revascularization options are frequently excluded.

Screening for peripheral vascular occlusive disease is often performed. Although distal peripheral vascular occlusive disease is characteristic of long-standing diabetes, aortoiliac disease and femoral popliteal vascular disease may also be present. Femoral popliteal disease is generally not a contraindication to transplantation, unless there are clinical signs of arterial insufficiency such as severe claudication or nonhealing ulcers. The presence of iliac disease is more problematic, as it can compromise inflow to the transplanted organs or increase the risk for postoperative arterial complications. In addition, diabetics may have significant vascular calcification which could preclude transplantation even in the absence of flow abnormalities. Screening for peripheral vascular occlusive disease, in addition to a thorough physical examination, may include noninvasive flow studies and/or CT scanning to evaluate vascular calcification. Candidates with a history or examination findings suggestive of cerebrovascular disease should be screened for hemodynamically significant carotid occlusive disease.

Other evaluations, as with other types of organ transplants, are tailored to the individual medical history, and differ among centers. Screening for malignancy commonly includes mammography and pap smears for women, and colonoscopy, generally in accordance with established screening guidelines for the general population. Individuals with a prior history of treated cancer and who are judged to be at low risk for recurrence are usually candidates following an appropriate disease-free interval. This interval is decreasing as greater experience with transplantation in individuals with a history of cancer has accumulated, and can be as little as 2 years for many solid epithelial tumors to none for carcinoma in situ or early prostate cancer.[45] Screening for chronic viral infections such as hepatitis B, hepatitis C, and HIV is commonly performed, and pancreas transplants in selected individuals with chronic hepatitis are being performed with increasing frequency.[46,47] As with liver and kidney transplantation, early experience with pancreas transplantation in carefully selected individuals with HIV infection has been encouraging.[48] Social work and/or psychiatric

evaluation is performed to rule out psychiatric disease, inadequate social environments, and other issues that may impact the recipient's ability to participate in posttransplantation management.

The Waiting List and Recipients

The number of patients on the waiting list for pancreas transplant has gradually decreased from over 3,500 in 2007 to approximately 2,500 in 2018.[49] The majority of patients are white (58%), though the percentages of white candidates is decreasing, while the percentage of minority candidates (black, Asian, Hispanic) patients continues to increase. The number of patients on the waiting list has decreased since 2000 for all adult age groups except those in 50 to 64, and the age distribution has shifted upward. While the majority are ages 35 to 49 (52% in 2018), the percentage who are older (ages 50 to 64) and younger are increasing slightly. The annual death rate on the pancreas waiting list was 58 per 1,000 patient years in 2018, compared with 45 per 1,000 in 2017 and 69 per 1,000 in 2007.

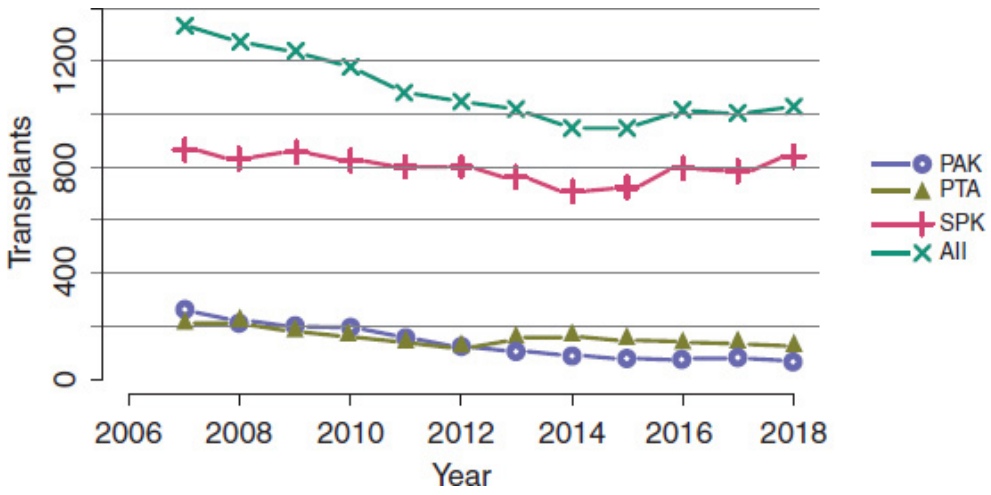

Figure 40.3 Number of U.S. simultaneous pancreas–kidney (SPK), pancreas after kidney transplantation (PAK), and pancreas transplantation alone (PTA) pancreas transplants performed by year. (Data from Scientific Registry of Transplant Recipients. 2018 *Annual Data Report.* Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2020.)

The overall number of pancreas transplants performed has increased over the last several years after a decade long decline. There were 1,027 pancreas

transplants performed in 2018, compared with 1,002 in 2017 and a low of 947 in 2015. The increase has been due to increases in SPK transplants, as a slight downward trend continued in numbers of PAK and PTA transplants (**Fig. 40.3**). Median times to transplant have declined over the past 3 years for SPK (13.5 months in 2017–2018) and PTA (19.7 months). Time to transplant is longer for African American and Hispanic recipients. While the majority of SPK recipients are white and males, the percentage of nonwhite recipients is increasing. The age distribution of recipients generally parallels that of the waiting list.

Deceased Donor Pancreas Allocation

As with many organs, deceased donor pancreas allocation is determined primarily by geography, with most organs offered to centers in the donation service area (DSA) of donor origin. The base organ allocation unit is the organ procurement organization (OPO) which serves the population within the DSA. The 58 DSAs are organized into 11 regions, which serve as the second-tier of organ allocation. As with other organs, pancreata are allocated according to nationally determined policies.[50] There is mandatory sharing of pancreata to highly sensitized candidates that are completely matched to the donor; beyond this, pancreata are allocated to these pancreas candidates first locally, then regionally, then nationally based primarily on waiting time.

If the pancreas candidate is an SPK candidate, then a kidney from the same donor is usually also allocated to the SPK candidate, regardless of the candidate's place on the kidney waiting list. While such a policy promotes pancreas utilization, it has been somewhat controversial, since preferential allocation of kidneys to simultaneous kidney–pancreas (SPK) candidates prevents allocation to kidney-alone candidates who have generally been waiting longer. Solitary pancreata can be difficult to place compared with SPK because their outcomes are slightly worse, but are more easily shared voluntarily since OPOs are obligated to share kidneys along with pancreas for outside SPK candidates only under certain circumstances (highly sensitized or 0-HLA antigen mismatch candidates). Thus, shared pancreata are usually restricted to PTA or PAK candidates.[51]

Pancreas allocation is also complicated by the fact that the pancreas donor selection criteria for islet transplant and whole-organ transplant overlap, leading to competition among certain types of organs. In determining whether a given pancreas will be allocated to a solid organ or islet transplant candidate, donor age and BMI are considered. Donors under age 50 and with BMI <30 are allocated for whole-organ pancreas transplant locally. If there is no local acceptance, the pancreas is offered regionally and then nationally. If there is no candidate for whole pancreas, the pancreas is then allocated for islets. For donors older than age 50 or with BMI >30, whose pancreata are rarely used for whole-organ transplant, the organ is first offered for pancreas transplant locally; if there are no local candidates, the pancreas is then offered for islets.[50]

Pancreata are significantly underutilized compared to other solid organs such as liver and kidney. As discussed below, donor selection criteria are more rigorous. Restrictions on cold ischemia time for whole-pancreas transplantation and particularly for islet transplantation make the placement of pancreata that are not used by the recovering center difficult. There is significant geographic variation in pancreas use, which correlates with activity by local transplant centers.[52] A recently approved change in organ distribution for abdominal organs designed to address this disparity will eliminate the use of DSA in allocation, relying instead on distance of the transplant center to the donor hospital. The principles of local, regional, and national allocation still apply but instead are represented by increasing distances (<250, 250 to 500, and >500 miles).[53]

Donor Evaluation

6 The selection of appropriate pancreas donors is perhaps the most important determinant of successful pancreas transplantation. Many of the early complications of pancreas transplantation are thought to be secondary to processes related to organ quality and preservation, rather than the technical conduct of the recipient operation. While the ideal donor is young, nonalcoholic and nonobese, very few donors meet this description, and the surgeon frequently needs to consider pancreata from imperfect donors. Donor selection criteria may vary among surgeons and transplant centers, and may depend upon past experience, waiting time, and recent outcomes. Primary

criteria are the age of the donor, donor BMI, donor cause of death, and the gross appearance of the organ at the time of recovery. Additional information that may influence the decision include aspects of the medical and social history, donor hemodynamics, laboratory values, HLA matching, and anticipated preservation time. As with donor selection with other organs, the decision-making process often involves consideration of multiple factors in aggregate.

The importance of donor age on graft outcomes has been confirmed by multiple studies, and the maximum age threshold is significantly lower than for liver and kidney transplantation.[54,55] Many centers use an age threshold, which may range from 40 to 50, above which donors are selected very carefully. The mechanism by which age affects outcomes is not firmly established: age appears to influence both early technical and late graft loss.[55,56]

Donor BMI has been found to be a determinant of graft failure by single-center and transplant registry analyses.[57,58] Very few pancreata from donors with BMI greater than 30 are used for solid-organ transplant, and are more likely to be recovered for islet transplant.[51] More recent registry data suggest that carefully selected donors with BMI up to 35 can successfully be used as pancreas donors.[59] It is not known whether associations with BMI relate to fatty infiltration of the pancreas or by a separate mechanism.

The circumstances of death and the condition of the donor influence donor selection. Pancreata from donors with stroke as a cause of death have reduced graft survival. Although experience from donors after cardiac death (DCD) remains relatively limited (<5% of all pancreas transplants), outcomes have been good with careful donor selection.[49,60,61] Laboratory values, including serum amylase and lipase, play a relatively minor role in donor selection. Insulin administration is generally not considered a contraindication to pancreas donation. While the presence of donor hyperglycemia may raise concerns about latent diabetes, in most donors this reflects the rapid administration of dextrose-containing solutions, corticosteroids for cerebral edema, and high-dose catecholamines for blood pressure support rather than latent pancreatic endocrine insufficiency. Abnormal HbA1C has been utilized as a relative contraindication, but recent single-center data suggest that levels up to 6.2 mg/dL are not associated with graft outcomes.[62] Evidence of injury to other organs such as liver and

kidneys, as a marker of abdominal ischemia, while not ordinarily a contraindication, may be considered in marginal cases.

Donors with a history of type 2 diabetes, excessive alcohol use or pancreatitis may be used. A history of cardiovascular disease or cardiac risk factors are also not contraindications but may influence decision making or be associated with mesenteric atherosclerotic disease. A social history which suggests an increased risk of transmission of hepatitis or HIV should be evaluated, as with other organs, in the context of the degree of perceived risk relative to the benefit of the transplant.

Intraoperative evaluation of the donor organ is said to be the most important determinant of donor selection. Evidence of inflammation or fibrosis, which may manifest as focal or diffuse firmness to palpation, is considered to be a contraindication. Fatty infiltration of the pancreas, trauma and pancreatic edema are also adverse findings, although the latter may be correctable with donor management. Traumatic injury to the pancreas or hematoma within the substance of the pancreas would preclude transplantation. However, a prior splenectomy is not a contraindication, provided that the tail can be dissected atraumatically.

Factors not intrinsic to the donor may bear on the decision to perform a transplant. The higher risk of graft failure associated with solitary pancreas transplants leads some centers to have more stringent selection criteria for PTA and PAK. While cold ischemia is a risk factor for graft survival, pancreata from selected donors can be transplanted with cold ischemic times approaching 24 hours with good outcomes. Attention to HLA matching varies by center; the many analyses performed suggest that any relationships between matching and graft outcome that may exist are not likely to be very significant.[56,58,63]

As for deceased donor livers and kidneys, a Donor Risk Index for pancreas has been described.[52] The pancreas DRI (PDRI) is based on 10 factors demonstrated to have significant impact on pancreas transplant outcomes. These include age, gender, race (black or Asian), BMI, height, CVA as cause of death, cold ischemia time, DCD, and terminal creatinine greater than 2.5 (**Table 40.1**). There is great variation in outcome by PDRI: the difference in graft survival at 1 year between the lowest 20% of PDRI (best outcomes) and the highest 20% is about 11% for SPK transplants and 16% to 17% for solitary transplants (**Table 40.2**). In addition to predicting

outcomes for individual patients, indices like the PDRI are useful in assessing trends in pancreas utilization, which is variable by geography and by transplant center.[52]

Recovery Technique

The importance of the pancreatic recovery cannot be overstated. It is thought by many pancreas transplant surgeons to be more critical to the success of the transplant than the recipient procedure. Because the pancreas is susceptible to traumatic injury, it must be carefully dissected and manipulated to avoid injury to the pancreatic parenchyma. Typically, the pancreas is recovered along with the liver and kidneys. This is performed in standard fashion through a midline incision which extends from the sternal notch to the pubic symphysis. After a generous Kocher maneuver, mobilization of the right colon, and isolation of the distal and supraceliac aorta to prepare these vessels for clamping, the pancreas is mobilized. This is most commonly achieved by entering the lesser sac, dividing the gastrocolic omentum. This dissection continues with division of the short gastric vessels and the avascular gastrosplenic ligament. The pancreas is dissected from the pancreatic bed using the spleen as a handle. The tail is lifted from the pancreatic bed using blunt dissection and the occasional use of electrocautery. The proximal jejunum is dissected at the ligament of Treitz. An antibiotic and/or a betadine-containing solution are frequently instilled into the duodenum through a nasogastric tube for decontamination. The duodenum is divided both at the ligament of Treitz and at the pylorus using a stapler. Division of the middle colic vessels permits exposure of the proximal small bowel mesentery, which is divided distal to the pancreas with a vascular stapler. The mobilization of the pancreas may be performed either prior to or following the aortic perfusion procedure described below.

Table 40.1 Summary of Pancreas DRI

Donor Characteristics	Reference Donor (DRI = 1.00)	Change Factor Value to	DRI
Gender	Male	Female	0.87
Age	28	45	1.56
Black race	No	Yes	1.27
Asian race	No	Yes	1.17
BMI	24	30	1.17
Height (cm)	173	190	0.9
Cause of death: CVA/stroke	No	Yes	1.23
Cause of death: CVA/stroke in PAK	No	Yes	0.93
Pancreas preservation time (hrs)	12	20	1.13
DCD	No	Yes	1.39
SCr >2.5	No	Yes	1.22

Equation: pDRI = exp(−0.13792 × I[Female Donor]) – 0.034455 × I[Donor Age <20] × [Donor Age – 20] + 0.026149 × [Donor Age – 28] + 0.19490 × I[Donor Creatinine > 2.5] + 0.23951 × I[Donor Black Race] + 0.15711 × I[Donor Asian Race] – 0.000986347 × [Donor BMI – 24] + 0.033274 × I[Donor BMI > 25] × [Donor BMI – 25] − 0.006073879 × (Donor Height – 173) + 0.21018 × I[Donor COD CVA] – 0.28137 × I[Donor COD CVA for PAK txp] + 0.014678 × [Preservation Time – 12] + 0.33172 × I[DCD]).[40]

Perfusion of the pancreas is generally achieved through an intra-arterial cannula placed in the distal aorta following clamping of the supraceliac aorta and the aortic bifurcation. This is typically achieved with approximately 1 to

3 L of University of Wisconsin or HTK (histidine–tryptophan–ketoglutarate) solution while the entire abdominal organs are packed in saline slush. Preservation solutions are generally regarded to be equivalent.[58,64,65] A minority of centers will also perfuse the abdominal viscera with a portal perfusion cannula, typically through the inferior mesenteric vein, although some surgeons maintain that overperfusion of either the arterial or the venous circulation may result in pancreatic edema and an increased risk of complications.

The pancreas can be removed either en bloc with the liver and kidneys, en bloc with the liver, or separately, following removal of the liver. Whatever the technique, the portal triad is dissected out in cooperation with the liver recovery team. Typically the portal vein is shared by dividing it at the level of the coronary vein. Only in the rarest of circumstances should there be any difficulty using both the liver and the pancreas from the same donor even in the presence of hepatic arterial anomalies. In the presence of a replaced right hepatic artery, the superior mesenteric artery (SMA) can be divided just distal to the replaced right hepatic artery, leaving a very short cuff of SMA on the pancreas. Alternatively, the replaced right hepatic artery, if large enough to be safely reconstructed by the liver transplant team without a cuff of SMA, can be transected as it exits superiorly from behind the head of the pancreas. This is also true in the rare case where a completely replaced hepatic artery emerges from the superior aspect of the head of the pancreas; usually the artery in this case is long enough and large enough to be used for liver transplant without a celiac axis or aortic cuff. The bile duct and gastroduodenal artery are ligated on the pancreas side and divided on the liver side. Dissection then proceeds along the superior aspect of the pancreas along the proper hepatic artery. The splenic artery, which constitutes the other arterial blood supply to the pancreas, is divided a few millimeters from its origin to allow for adequate length on the pancreas while allowing the stump to be oversewn without compromising flow to the liver. Once the pancreas is removed or split from the liver, the pancreas is packed in preservation solution; the entire common iliac artery and its two main branches, the internal and external iliac arteries, are packaged along with the pancreas for back-table reconstruction. A graft of donor iliac vein is also included in case the portal vein needs to be extended, which is done by some surgeons. Although most centers transplant the pancreas as soon as possible,

up to 24 hours of cold ischemia time (time between perfusate infusion and organ reperfusion) has not been associated with reduced graft survival in carefully selected donors.[53,56]

Table 40.2 Unadjusted 1-Year Pancreas Allograft Survival by DRI and Transplant Type

	SPK		PAK		PTA	
DRI Group	Adjusted% Graft Survival	95% Confidence Limits	Adjusted% Graft Survival	95% Confidence Limits	Adjusted% Graft Survival	95% Confidence Limits
0.64–0.85	88	(87, 90)	84	(81, 87)	84	(76, 89)
0.86–1.15	87	(86, 89)	77	(73, 79)	82	(77, 87)
1.16–1.56	82	(79, 84)	75	(70, 79)	70	(61, 77)

2.12–2.86	77	(70, 82)	67	(46, 81)		

Back-Table Preparation of the Pancreas

The pancreas is placed on ice and remains cold at all times on the back table. The spleen is removed by dividing all vessels near the spleen, either by ligature or stapling, taking care to avoid injury to the tail of the pancreas which should be clearly identified. Some surgeons elect to wait until reperfusion of the pancreas in the recipient to remove the spleen. Significant peripancreatic fat, if left on at the time of recovery, should be trimmed. Both ends of the distal duodenum are shortened to the point where they are immediately adjacent to the head of the pancreas. Both stapled ends of the duodenum may be oversewn with silk or polypropylene sutures. Some surgeons elect to reinforce the mesenteric staple line by oversewing with polypropylene suture. The iliac artery Y-graft is typically attached by anastomosis of the internal iliac artery to the splenic artery and anastomosis of the externally iliac artery to the SMA (**Fig. 40.4**). In the absence of a Y-graft, the splenic artery may be implanted in end-to-side fashion to the SMA. The portal vein is mobilized by freeing from surrounding adventitial tissue to the confluence of the splenic vein and superior mesenteric vein. This should allow an adequate length of portal vein for anastomosis, as only 1 to 2 cm of portal vein length is generally needed. However, some surgeons routinely

add an end-to-end venous extension graft from donor iliac vein to lengthen the portal vein on the back table.

Recipient Operation

The pancreas transplant is typically performed through a midline incision, although a lower quadrant incision similar to a kidney transplant incision may be used. The recipient should receive broad-spectrum antibiotics preoperatively. The pancreas transplant, for systemic venous drainage, is placed preferably on the right side, and can be oriented either head up or head down. After dissection of the recipient artery and vein, the portal vein is anastomosed in end-to-side fashion to the systemic vein. The distal inferior vena cava, common iliac vein, or external iliac vein may be used; the recipient vein segment should be mobile enough for the portal vein to reach without tension. The common iliac artery component of the donor Y-graft is then anastomosed in end-to-side fashion to either the recipient external iliac artery or common iliac artery; the distal aorta can also serve as the site of anastomosis. A pancreas placed on the left side in the recipient may be placed either medial or lateral to the sigmoid colon. Multiple variations have been described.

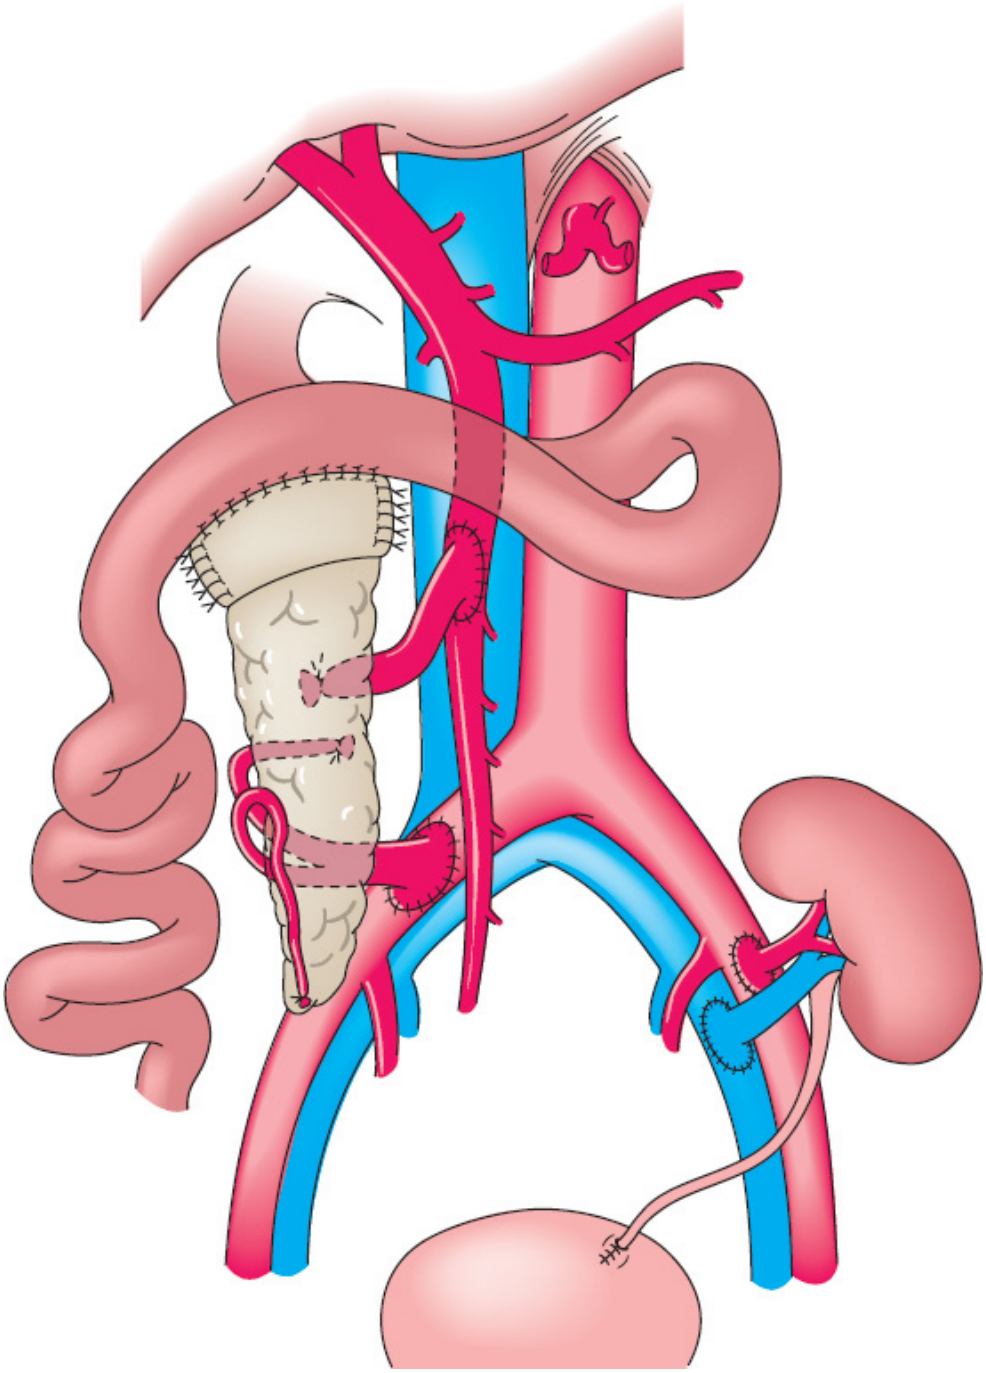

Figure 40.4 Simultaneous pancreas–kidney transplantation performed with drainage of the pancreatic exocrine secretions into the proximal jejunum (enteric drainage). This technique has been adopted by most transplant centers in the United States for simultaneous pancreas–kidney transplants. For solitary pancreas transplantation, some centers still utilize bladder drainage to allow monitoring of the urinary amylase. Note that the donor portal vein drains into the recipient superior mesenteric vein (portal venous drainage), preventing peripheral hyperinsulinemia. Many centers continue to place the pancreas in the pelvis, combining enteric

drainage and systemic venous drainage. This placement requires enteric anastomosis to a more distal segment of jejunum or ileum.

Because of concerns about the systemic hyperinsulinemia that invariably develops with systemically drained pancreas transplants, portal venous drainage is also utilized (**Fig. 40.5**). As 50% of insulin is removed with the first pass through the liver, systemic drainage leads to elevated peripheral insulin levels, which is not observed following portal venous drainage. Since hyperinsulinemia has been associated with dyslipidemia and accelerated atherosclerosis, portal venous drainage theoretically ought to decrease cardiovascular risk compared with systemic drainage.[66] Portal drainage is associated with stimulation of the IGF-I/GH axis, contributing to glucose control despite lower insulin levels.[67] However, despite a nearly 10-year experience with the procedure, no difference in cardiac morbidity or mortality has been observed between the two techniques, and graft and patient survival are essentially equivalent.[68–70]

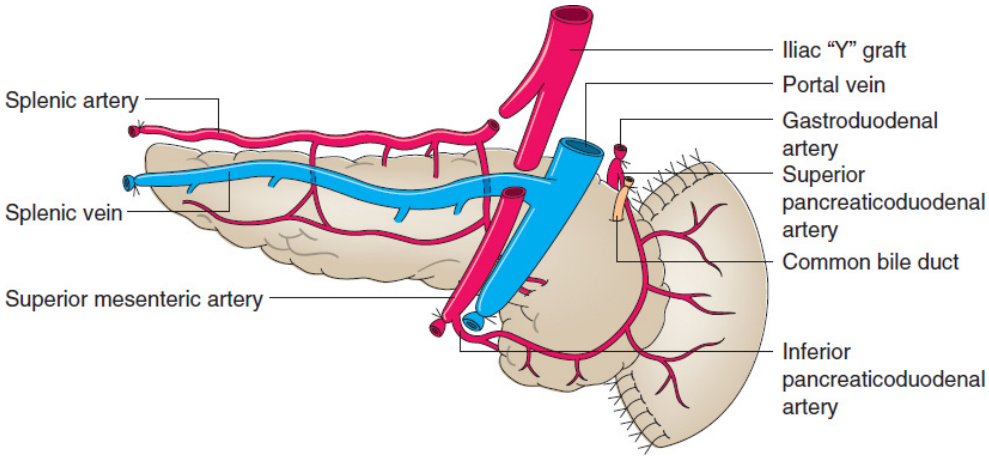

Figure 40.5 Back-table preparation of the pancreas. Before transplantation, the pancreas must be prepared in a slush-filled basin to maintain cold preservation. Preparation includes unifying the arterial blood supply of the pancreas by anastomosis of the donor external iliac artery to the superior mesenteric artery and the donor internal iliac artery to the splenic artery. The donor common iliac artery is used for anastomosis to the recipient iliac artery. During back-table preparation, donor splenectomy is performed.

Although the type of venous drainage typically depends on the preferences of individual surgeons or transplant centers, the decision to perform portal or systemic drainage may also depend upon the anatomy of an individual

patient. Patients with multiple previous abdominal operations or who have a thickened mesentery may be more suited for systemic venous drainage. Alternatively, patients who have had multiple transplants or other operations on the iliac vessels may be candidates for portal venous drainage.

For portal venous drainage the superior mesenteric vein is dissected out just below the transverse mesocolon.[71] The right common iliac artery is almost completely dissected. An end-to-side anastomosis of the donor portal vein to the recipient superior mesenteric vein is performed with the duodenum oriented superiorly and the tail pointed inferiorly. The iliac artery graft of the donor is then passed through a hole created in the small bowel mesentery, and anastomosed to the recipient common iliac artery.

Most centers currently use enteric exocrine drainage for simultaneous kidney/pancreas transplant and some centers use enteric drainage for all transplants including solitary pancreas transplantation. This shift to enteric drainage occurred as a result of the significant morbidity associated with bladder-drained pancreas transplants. Morbidity includes recurrent urinary tract infections, hematuria, chemical urethritis, severe bicarbonate wasting, and dehydration. Historically, approximately 25% of individuals who receive a bladder-drained pancreas transplants require enteric conversion because of persistent complications,[72] but an additional percentage endure significant morbidity early after transplant. The major advantage of bladder drainage is the ability to monitor urinary amylase, a decrease in which can be associated with rejection. This can be helpful in solitary pancreas transplants, but is perhaps less important for simultaneous pancreas/kidney transplants where graft function may be monitored by serum creatinine. Improved immunosuppression and an increased utilization of biopsy to diagnose rejection have led to a decreased reliance on urinary amylase.[73]

Enteric drainage is achieved by creating a side-to-side or end-to-side anastomosis of donor duodenum to recipient jejunum. This may be a loop of jejunum, or a Roux-en-Y configuration may be created. For bladder drainage a side-to-side anastomosis between the donor duodenum and the bladder is performed. Enteric drainage is always used for pancreas transplants with portal venous drainage or those with systemic venous drainage oriented head-up, because the orientation of the pancreas precludes anastomosis of the duodenum to the bladder.

If a simultaneous kidney–pancreas transplant is performed, the kidney transplant is usually placed in the left iliac fossa, although some surgeons place both organs on the right side, with the pancreas anastomoses to the common iliac vessels, and the kidney to the external iliac vessels. The anastomoses, as with a kidney transplant via a retroperitoneal incision, are typically to the external iliac artery and external iliac vein. The kidney is typically placed in an intraperitoneal location, which increases the potential for torsion of the kidney on its vascular pedicle compared with kidney-alone transplants which are usually placed in a retroperitoneal location. Some surgeons prefer to raise a retroperitoneal flap to place the kidney retroperitoneally after implantation. Advantages to this approach include improved percutaneous access should biopsy be required, and a decreased risk of postbiopsy hemorrhage.

Following revascularization of the pancreas, attention is paid to bleeding from the pancreas which can be quite brisk. This is controlled with ties or suture ligatures. Since thrombosis is a common complication of pancreas transplantation, anticoagulation in the perioperative period may be employed, particularly for solitary pancreas transplantation. Thrombosis is less frequent in simultaneous pancreas–kidney transplantation, where uremic platelet dysfunction is protective. The extent of anticoagulation may range from the intraoperative administration of heparin prior to clamping of vessels, followed up by low-dose heparin infusion and warfarin anticoagulation, to more conservative approaches such as the use of low-dose heparin for a limited interval postoperatively, or the use of aspirin or other antiplatelet agents.[74] Hypercoagulability states may predispose to graft thrombosis in a significant number of individuals, although definitive data are lacking; anticoagulation is individualized based on risk.[75] Whatever the approach, patients should be monitored for bleeding, since as many as 10% of patients experience postoperative hemorrhage requiring reoperation.[76]

Following revascularization serum glucose levels are obtained hourly. It is common for the blood glucose to decline significantly following revascularization, and it is not uncommon for it to fall to normal levels soon after the patient's arrival in the recovery room. At some point intravenous fluids should be converted to dextrose-containing solution in order to prevent hypoglycemia. Pancreas transplant recipients with enteric drainage require only maintenance fluid with consideration of third-space losses.

Simultaneous kidney–pancreas transplant recipients may require the additional fluid replacement that would be administered following kidney transplantation alone. Individuals who receive bladder-drained pancreas transplants require replacement of pancreatic exocrine losses, which can be quite profound in the early postoperative period.

Immunosuppression

7 Immunosuppression for pancreas transplantation is similar to that for kidney transplantation. The immunogenicity of a pancreas transplant is considered to be greater than the majority of solid-organ transplants because of the extensive lymphoid component of the gland. In addition, the difficulty in diagnosing rejection compared to other solid-organ transplants makes the choice of immunosuppression more significant for pancreas transplants. Most centers use some forms of triple maintenance therapy utilizing a calcineurin inhibitor, an antiproliferative agent, and steroids, although steroid-free regimens are not uncommon. According to data from the Scientific Registry of Transplant Recipients, over 90% of pancreas transplant recipients receive tacrolimus.[49] Mycophenolate mofetil is the antiproliferative agent of choice in pancreas transplantation, with over 90% of recipients in 2018 receiving it. About two-thirds of recipients are on steroid-containing regimens.

The use of induction therapy to inhibit lymphocyte function is common. Several large randomized multicenter trials utilizing either T-cell–depleting antibody induction (OKT3, ATGAM, and thymoglobulin) or interleukin-2 (IL-2) receptor antibody inhibition (daclizumab and basiliximab) showed a reduction in the incidence of acute rejection but failed to demonstrate a significant effect on patient or graft survival.[77,78] Despite this modest impact on overall graft outcome, about 90% of pancreas transplant recipients received induction therapy in 2018, 81% T-cell–depleting agents, and around 10% IL-2 receptor antibody.[49] The International Pancreas Transplant Registry (IPTR) demonstrated a lower risk of pancreas graft loss in all categories of pancreas transplantation with the use of tacrolimus, and also demonstrated similar associations with the use of mycophenolate mofetil.[56] Consistent with the multicenter trials, IPTR analyses also fail to demonstrate a beneficial effect of induction therapy on patient and graft survival.

Several groups have reported excellent intermediate-term patient and graft outcomes utilizing steroid minimization protocols.[79–81] These protocols generally employ an induction agent (usually a depleting T-cell antibody), tacrolimus, and either MMF or sirolimus. Steroids are given for a maximum of 3 days. These steroid minimization protocols, as in kidney transplantation, aim to avoid the significant short- and long-term side effects associated with corticosteroids. Regimens employing maintenance monotherapy have also been successfully employed but are currently rarely used.[48,82]

Complications

Thrombosis of the pancreas transplant is the most common cause of graft loss in the early postoperative period, occurring in 5% to 10% of transplants. Why pancreas transplants are more prone to thrombosis than other solid-organ transplants is uncertain. The most likely mechanism is that ischemia reperfusion injury in the pancreas, characterized by the release of cytokines and activation of pancreatic enzymes, leads to accelerated injury and a procoagulant state. Diabetic patients have impaired fibrinolysis and are, therefore, relatively hypercoagulable. The relatively low venous flow through the portal vein, which leads to diminished flow velocity, may be contributory. Thrombosis is slightly more common in solitary pancreas transplantation than in SPK, probably due to the absence of uremic platelet dysfunction present in SPK recipients. The risk of thrombosis has been associated with donor factors such as older patient age, renal dysfunction, cold ischemic time, body mass index, DCD status, and cerebrovascular cause of death.[55,83,84]

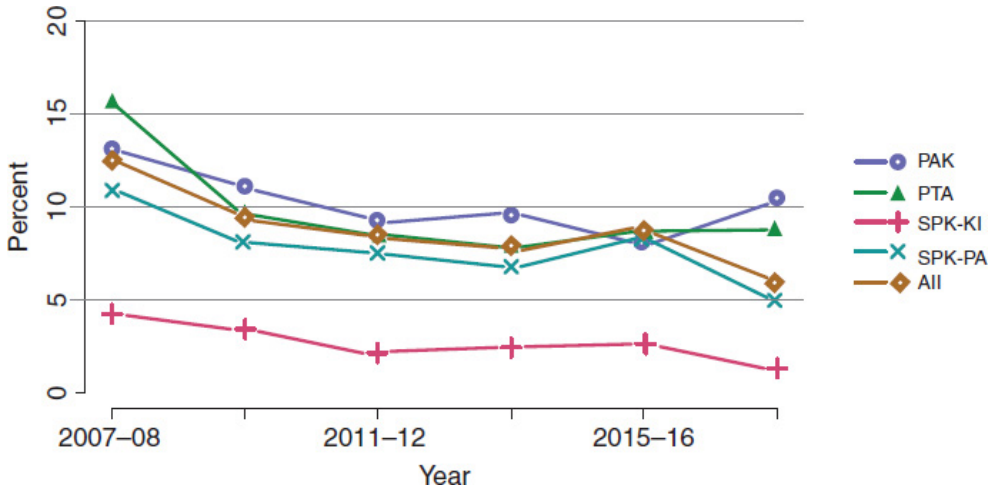

Figure 40.6 Graft failure within the first 90 days posttransplant among adult pancreas transplant recipients by year. (Data from Scientific Registry of Transplant Recipients. 2018 *Annual Data Report.* Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2018.)

Pancreas transplant thrombosis is usually heralded by a sudden rise in blood glucose in a pancreas that was previously functioning. Confirmation of the diagnosis is usually obtained with duplex ultrasound. Although anecdotal reports have described successful surgical and angiographic thrombectomy or thrombolysis in restoring flow to the pancreas,[85,86] the usual treatment is removal of the infarcted pancreas. While this usually occurs immediately after diagnosis, some centers opt to relist the patient urgently and wait until another pancreas transplant becomes available. Depending on the waiting time for another pancreas, the added morbidity of delaying the graft pancreatectomy is usually not significant. In contrast, asymptomatic thrombosis, whether partial or even complete, has been successfully managed with anticoagulation, especially if late in onset.[87,88] Because of the high risk of thrombosis, some degree of anticoagulation is frequently employed after pancreas transplantation.[89] It is likely due to these efforts and improvements in immunosuppression that the thrombosis rate for simultaneous pancreas–kidney transplants has decreased to less than 5% for simultaneous pancreas–kidney transplant and to less than 10% for isolated pancreas transplants (**Fig. 40.6**).

Bleeding is another frequent cause for reoperation in the early postoperative period. Because of the large number of vessels that enter and exit the pancreas, bleeding following reperfusion is not unusual. While

readily controllable, it is not uncommon for bleeding points to emerge later in the procedure, and postoperatively. This can be minimized by meticulous attention to ligating vascular structures during pancreas recovery. The use of anticoagulation in the perioperative period, as described above, adds to the bleeding risk. Pancreas transplant recipients are monitored carefully in the early postoperative period for signs and symptoms of intra-abdominal hemorrhage.

The other major early complication is leak from the donor duodenum. Duodenal leaks occur in approximately 5% to 10% of cases, usually 1 to 2 weeks after the transplant.[90] A leak may present as fever, abdominal pain, leukocytosis, lower abdominal tenderness, and persistent ileus. The diagnosis may be supported by the finding of a focal fluid collection near the head of the pancreas on CT scanning or ultrasound. Alternatively, diffuse peritonitis may reflect disseminated contamination. For bladder-drained pancreas transplants, the diagnosis may be made by cystography.

The management of a suspected duodenal leak is operative. This is caused by the growth of organisms transmitted into the peritoneal cavity during performance of the duodenal anastomosis. The peritoneum should be lavaged and all necrotic debris removed. If a leak is present it is usually at the stapled end of the duodenum rather than at the anastomosis. The likelihood of success for repair of a duodenal leak depends on the viability of the duodenum at the point of the leak, the patient's overall hemodynamic stability, and the degree of surrounding inflammation. Usually one attempt at repair is made, but failure may necessitate removal of the pancreas in order to control life-threatening sepsis. Some surgeons have adopted a practice of managing leaks from duodenal enteric anastomoses by conversion to bladder drainage. This minimizes the risk of recurrent contamination of the peritoneal cavity with enteric contents and allows for Foley catheter decompression of the duodenum, but has the morbidity associated with bladder drainage. Drainage of infection without primary repair of the duodenal leak has been successfully employed in situations where inflammation is so profound that the leak could not be primarily repaired. However, the morbidity associated with these duodenal fistulas dictates that these options be employed only when definitive repair is not possible. Peripancreatic abscess also can occur in the absence of a frank duodenal leak. Those patients with abscess and

without systemic sepsis can be treated with percutaneous CT-guided drainage.[91]

In contrast to renal transplantation, the complications of pancreas transplantation can be severe and life threatening if not properly managed. Even in the most experienced centers, occasional patients who suffer extended intensive care unit stays are not unusual. This is a consequence of both the tenuous medical status of long-standing diabetics and the substantial morbidity of pancreas transplant complications. Nevertheless, the risk of death form perioperative complications is low (0.5% in the first month after transplant). Given the limited survival benefit of pancreas transplantation, particularly compared with kidney transplantation, patients should be counseled frankly about the potential magnitude of these complications so that they have a realistic expectation of outcomes. Even with honest discussion and informed consent, most individuals will elect pancreas transplantation, and many will pursue multiple pancreas transplants even with a history of complications from previous pancreas transplants.

Diagnosis and Treatment of Rejection

The timely and accurate diagnosis of pancreas transplant rejection is one of the most important and challenging aspects of posttransplant management. As with kidney transplant rejection, pancreas rejection, whether acute cellular rejection or antibody-mediated rejection, is associated with inferior graft survival.[92] Furthermore, both pre- and posttransplant donor-specific antibodies (DSAs) are associated with antibody-mediated rejection and reduced pancreas and kidney graft survival.[92,93] The incidence of pancreas rejection was about 13% in the first year for transplants performed in 2016–2017. The incidence is higher (20%) in PTA recipients.[49] Therefore, the implications of delayed or missed antirejection treatment can be profound.

There is no single laboratory abnormality capable of diagnosing rejection. Amylase and lipase serum levels are commonly elevated, and can arouse suspicion, but are not specific. Hyperglycemia is also nonspecific. If hyperglycemia is due to rejection, it occurs late in the process and reflects significant pancreatic endocrine injury and a dismal prognosis. While imaging modalities including ultrasound may identify abnormalities in parenchyma or perfusion, they are neither sensitive nor specific.[94] Hence, the

diagnosis of rejection is best made with histologic examination of a pancreatic biopsy specimen.[95] The pancreas graft in SPK transplants benefits by monitoring of the kidney transplant by serum creatinine, as there is some degree of concordance rate for rejection between kidney and pancreas grafts. However, isolated pancreas rejection clearly occurs, and neither a normal creatinine nor a normal kidney biopsy can rule out pancreas rejection.[96,97] Improvements in the outcome of solitary pancreas transplants are attributable to improvements in overall quality of immunosuppression, and to more accurate diagnosis and treatment of pancreas rejection.

The technique of pancreas transplant biopsy has evolved over the years. In the era of bladder-drained pancreas transplants, cystoscopic biopsy of both the pancreas and transplant duodenum was common.[98] As more enteric-drained pancreas transplants have been performed, a greater reliance on percutaneous biopsy has developed, using either ultrasound or CT-guided techniques.[99] Laparoscopic-assisted or open pancreas biopsy may be utilized for patients whose pancreas transplant is not accessible to percutaneous approaches, although the need for operative biopsy is decreasing as the percutaneous procedure has become more routine.[100] Enteroscopic biopsy has been described, and a high jejunal anastomosis can facilitate utilization of this method.[101] The indications for pancreatic biopsy include hyperamylasemia, hyperlipasemia, hyperglycemia, or unexplained pain in the vicinity of the pancreas transplant. The differential diagnosis includes pancreatitis, cytomegalovirus (CMV) infection, and toxicity from calcineurin inhibitors and, in the early postoperative period, peripancreatic infection. The histologic grading system developed at the University of Maryland for determining rejection grade in pancreas biopsies is generally used (**Table 40.3**).[102] Indeterminate rejection may be treated with increases in calcineurin inhibitor dose or pulse corticosteroids. More substantial rejection is generally treated with depleting antilymphocyte antibody therapy.

As long-term survival of pancreas transplants becomes more commonplace, chronic rejection is now an important problem.[103] Unfortunately, as with kidney transplantation, while newer agents have improved short-term survival by preventing acute rejection, improvement of short-term survival has not translated into improved long-term graft survival.[104] Chronic rejection is histologically characterized as expansion of fibrous septa within the pancreatic parenchyma. This may progress to lobular

atrophy or loss of both acini and β-cells. Although there are parallels to chronic allograft nephropathy, whether chronic calcineurin inhibitor toxicity contributes to chronic pancreas rejection is unknown.

Recurrent Autoimmunity

Selective β-cell destruction in pancreas transplants may occur in a pattern similar to the insulitis seen in type 1 diabetes. This pattern is histologically distinct from cellular rejection. Although recurrent autoimmunity has been documented in both immunosuppressed pancreas transplant recipients and nonimmunosuppressed living donor recipients from identical twin siblings, well-documented case series have been infrequent. A variety of associations have been suggested with autoantibodies to glutamic acid decarboxylase (GAD-65) and islet cells (IA-2), but patterns of autoantibody expression have not proven reliable enough to establish their etiologic relevance or prognostic value.[105,106]

Posttransplant Viral Infections

The higher level of immunosuppression given to pancreas transplant recipients compared with kidney transplant recipients, particularly with respect to lymphocyte-depleting induction therapy, places pancreas transplant recipients at risk for conditions known to be influenced by overall immunosuppressive exposure. While rates of CMV infection are generally higher than for kidney recipients, especially when the donor is known to carry the virus, the use of intravenous and oral ganciclovir has reduced the incidence of significant CMV-associated disease.[107,108] The incidence of CMV disease may also be lower in those recipients receiving steroid-free immunosuppression.[108] Data are mixed with respect to the incidence of polyoma-associated, or BK, nephropathy, with some analyses suggesting a higher rate and other an equivalent incidence in SPK recipients compared with kidney-alone recipients.[109,110] As with kidney-alone recipients, those SPK recipients with BK nephropathy have inferior kidney graft survival. Posttransplant lymphoproliferative disorder (PTLD), often associated with Epstein–Barr virus (EBV) infection, has a 5-year incidence of approximately 2%, which is similar to or higher than kidney recipients.[111,112] Pancreas

recipients with PTLD have a worse prognosis than other abdominal organ transplants recipients with PTLD.

Table 40.3 Revised Banff Classification for Diagnosis and Grading Pancreas Allograft Rejection[102]

Category	Findings
1. Normal	Absent inflammation *or* inactive septal, mononuclear inflammation not involving ducts, veins, arteries or acini. There is no graft sclerosis. The fibrous component is limited to normal septa and its amount is proportional to the size of the enclosed structures (ducts and vessels). The acinar parenchyma shows no signs of atrophy or injury.
2. Indeterminate	Septal inflammation that appears active but the overall features do not fulfill the criteria for mild cell-mediated acute rejection.
3. Acute T-cell–mediated rejection	Grade I/Mild acute T-cell–mediated rejection—Active septal inflammation (activated, blastic lymphocytes and ±eosinophils) involving septal structures: venulitis (subendothelial accumulation of inflammatory cells and endothelial damage in septal veins), ductitis (epithelial inflammation and damage of ducts), *and/or* focal acinar inflammation. No more than two inflammatory foci per lobule with absent or minimal acinar cell injury. Grade II/Moderate acute T-cell–mediated rejection (requires differentiation from AMR)—Multifocal (but not confluent or diffuse) acinar inflammation (≥3 foci per lobule) with spotty (individual)

	acinar cell injury and dropout *and/or* mild intimal arteritis (with minimal, <25% luminal compromise). Grade III/Severe acute T-cell–mediated rejection (requires differentiation from AMR)—Diffuse (widespread, extensive) acinar inflammation with focal or diffuse multicellular/confluent acinar cell necrosis *and/or* moderate or severe intimal arteritis, >25% luminal compromise *and/or* transmural inflammation—necrotizing arteritis.
4. Antibody-mediated rejection	Confirmed circulating donor-specific antibody (DSA)—Morphologic evidence of tissue injury (interacinar inflammation/capillaritis, acinar cell damage swelling/necrosis/apoptosis/dropout, vasculitis, and thrombosis). C4d positivity in interacinar capillaries (IAC, ≥5% of acinar lobular surface). Acute AMR 3 of 3 diagnostic components—Consistent with acute AMR 2 of 3 diagnostic components. Requires exclusion of AMR 1 of 3 diagnostic components. Chronic active antibody-mediated rejection—Combined features of categories 4 and 6 in the absence of features of category 3.
5. Chronic allograft arteriopathy	Arterial intimal fibrosis with mononuclear cell infiltration in fibrosis.

6. Chronic allograft rejection/graft fibrosis	Stage I (mild graft fibrosis)—Expansion of fibrous septa; the fibrosis occupies less than 30% of the core surface but the acinar lobules have eroded, irregular contours. The central lobular areas are normal. Stage II (moderate graft fibrosis)—The fibrosis occupies 30–60% of the core surface. The exocrine atrophy affects the majority of the lobules in their periphery (irregular contours) and in their central areas (thin fibrous strands criss-cross between individual acini). Stage III (severe graft fibrosis)—The fibrotic areas predominate and occupy more than 60% of the core surface with only isolated areas of residual acinar tissue and/or islets present.
7. Islet pathology	Recurrence of autoimmune DM (insulitis and/or selective β-cell loss). Islet amyloid (amylin) deposition.
8. Other histologic diagnosis	Pathologic changes not considered to be due to acute and/or chronic rejection. For example, CMV, pancreatitis, PTLD.

Results of Kidney–Pancreas Transplantation

Current kidney graft survival at 1 and 5 years following SPK transplantation is 96% and 85%, respectively.[49] African Americans have historically had

somewhat poorer 5-year graft survival than whites. Kidneys from older donors have the poorest graft survival. As opposed to previous decades, 5-year kidney graft survival is not associated with HLA matching.

In 2018, the OPTN and SRTR codified definitions of pancreas graft failure to make reporting more consistent. Since return to insulin can occur due to pancreas dysfunction or insulin resistance, and there was previously no defined threshold of C-peptide level or insulin use for graft failure, center reporting had been variable for events other than pancreatectomy, relisting, or death.[49] Prior to that, pancreas graft survival at 1 and 5 years following SPK transplantation was 86% and 73%, respectively. Worse 5-year graft survival has been seen in African American recipients compared with whites. Recipients with a previous transplant (kidney, pancreas, or both) have worse pancreas graft survival. As with SPK kidney survival, there is no difference in 5-year pancreas graft survival with increasing levels of HLA mismatch. While contemporary estimates of long-term graft survival cannot yet be made under the current definition of 0.5 units/kg/d of insulin use, 90-day survival in SPK transplants appears to be improved, presumably owing to a reduction in technical graft loss (**Fig. 40.6**).[49] Recent studies suggest a relationship between center volume and graft failure.[113]

Registry analyses demonstrate a mortality benefit of SPK transplantation compared with dialysis[114] or deceased donor kidney transplantation alone.[115] These benefits diminish with higher-risk donors, particularly older donors.[116] Patient survival at 1 year and 5 years following SPK transplantation is 98% and 92%, respectively (**Fig. 40.7**). Race, ethnicity, gender, and transplant center volume are not associated with decreased patient survival at 5 years, and patient survival has improved since 1995 but not appreciably in the past 15 years.[49]

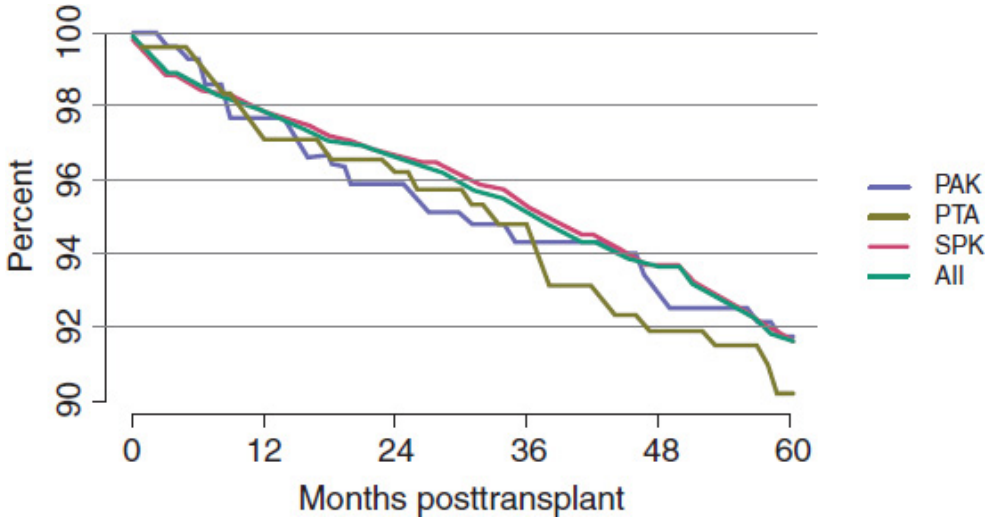

Figure 40.7 Patient survival among adult deceased donor pancreas transplant recipients, 2011–2013 by transplant type. (Data from Scientific Registry of Transplant Recipients. 2018 *Annual Data Report.* Rockville, MD: Health Resources and Services Administration, Department of Health and Human Services; 2018.)

Results of Solitary Pancreas Transplantation

Over time, the 1-year reported pancreas graft survival for recipients of a PAK transplant improved from 78% for PAK transplants performed in 2005 to 88% for transplants performed in 2011.[49] The last reported graft survival for PAK at 5 years was 53% in 2011. One-year pancreas graft survival for PTA was 80% at 1 year and 53% at 5 years. Graft survival rates for PTA are better than PAK early, but the rate of graft failure in the long term is greater for PTA than for PAK. Patient survival for both PAK and PTA recipients is excellent, around 98% at 1 year and >90% at 5 years for recipients transplanted in 2011–2013 (**Fig. 40.7**).

Whether pancreas transplantation positively impacts patient survival is controversial. One study reported that registrants on the waiting lists for PAK and PTA had better survival rates than recipients who underwent these procedures.[114] Subsequently, another group, using a similar cohort but different analytical methods, reported better survival rates for recipients of solitary pancreas transplantation than registrants on the waiting list.[117] These discrepancies are in part related to the differing methodologies used in the two studies with respect to deaths among those removed from the waitlist and also to variability in the year-to-year death rates on the waiting list. In

contrast, both studies demonstrated a conclusive benefit for SPK recipients compared with remaining on the waiting list, which illustrates the importance of restoration of kidney function in this population, as with kidney-alone transplant. 8 While opinions on the specific benefit of the pancreas transplant differ in light of the differing conclusions of these two studies, together the studies indicate any survival benefit conferred by the pancreas transplant is likely to be modest. In fact, most studies do not demonstrate a graft or patient survival advantage of SPK over living donor kidney transplant.[115,118] The survival benefit of SPK over deceased donor kidney transplant alone has been recently further quantified, and while statistically significant, the survival benefit was not considered clinically meaningful.[119]

Effect of Pancreas Transplantation on Secondary Complications of Diabetes Mellitus

There are data that clearly demonstrate the impact of pancreas transplantation on the course of secondary complications of diabetes. This could be predicted from the results of the DCCT, in that pancreas transplantation leads to a complete normalization of blood glucose and glycosylated hemoglobin levels that are vastly superior to those achievable by intensive insulin therapy. Therefore, it should not be surprising that pancreas transplantation has an impact on diabetic complications.

For example, while type 1 diabetic recipients of kidney transplants alone show typical findings of diabetic nephropathy following transplantation, SPK transplantation prevents the development of recurrent diabetic nephropathy.[120] In addition, native diabetic nephropathy, including microvascular structural abnormalities has been demonstrated to reverse 10 years following successful isolated pancreas transplantation.[121,122] These reports demonstrate convincingly that pancreas transplantation has a significant impact on diabetic nephropathy.

Effects on diabetic neuropathy have also been documented using nerve conduction studies, which are significantly improved following pancreas transplantation and SPK.[123] Small corneal nerve fiber regeneration can be detected.[124,125] Furthermore, clinical progression of diabetic neuropathy is

significantly diminished compared to nontransplanted controls. However, no study has been able to demonstrate symptomatic clinical improvement in existing diabetic neuropathy following transplantation. There is also an impact on autonomic neuropathy, with clinical improvement in epinephrine responses to hypoglycemia.[126]

While the DCCT demonstrated a relationship between glycemic exposure and retinopathy, the effect of pancreas transplantation on retinopathy is only modest. While stabilization of moderate retinopathy has been demonstrated, long-term graft function (>3 years) is required.[127,128] Many pancreas transplant candidates have advanced retinopathy, and an effect has not been demonstrated in these individuals. Early acceleration of retinopathy, a phenomenon that has been noted with other methods of improving glycemic control, can occur in the first 6 to 12 months following transplant.

Pancreas transplantation also appears to have a modest impact of cardiovascular disease parameters. Despite the findings of the DCCT trial, assessment of the clinical impact of pancreas transplantation on the progression of cardiovascular disease lacks a definitive large-scale study. Positive effects on lipid profiles, hypertension, carotid intimal thickness and left ventricular ejection fraction have been demonstrated.[129–131] Some centers have demonstrated a positive impact on peripheral vascular occlusive disease.[132,133] One recent study showed similar progression of coronary artery disease in SPK recipients as in recipients of living door kidney-alone.[134]

Regardless of the magnitude of objectively demonstrable benefits of pancreas transplantation, most recipients enjoy a dramatic improvement in quality of life.[97,135–137] While many diabetics can adapt quite well to the dramatic glucose fluctuations and the associated morbidity of diabetes, the freedom from insulin and the avoidance of hyper- and hypoglycemia offered by a functioning pancreas transplant is a primary motivator for many recipients. The fervor with which many candidates pursue pancreas transplantation, especially retransplantation, is an indication of the significant benefit on quality of life for these individuals.

ISLET TRANSPLANTATION

Overview

The notion that insulin-producing–β-cells could be physically separated from the pancreas and transplanted for the treatment of diabetes has long been recognized. Islet transplantation, as a cellular transplant, has significant potential 9 advantages over whole-organ pancreas transplantation. Islet transplantation does not require an operative procedure.[138] In addition, the potential ability to preserve islets opens up possibilities with regard to distribution, allocation, transportation, and preparation of the islet recipient. Pretreatment of the graft to reduce immunogenicity or enhance survival and function is also possible.[139] Recipients of successful islet transplants can have glucose metabolism and insulin secretion profiles that are close to normal, and maintain metabolic control in a manner equivalent to whole-pancreas transplantation.[140] Although effects on long-term mortality and progression of diabetic complications are unproven, these benefits are also anticipated. From a long-range perspective, the development of islet transplantation sets some of the procedural, technical, and regulatory groundwork for the eventual establishment of stem-cell–derived β-cell transplantation. Furthermore, technologic advances in islet isolation for allotransplantation have been very successfully utilized in autotransplantation following pancreatic resection.

History

The development of islet transplantation was historically limited by poor graft survival. The first human islet allograft in a type 1 diabetic was performed in 1974 by the University of Minnesota.[141] The first islet autograft for the treatment of chronic pancreatitis was performed at Minnesota in 1977. Despite intense research in islet transplantation over three decades, until 2000 clinical islet transplantation met with minimal success.[142] While transplanted islets were capable of physiologic function, as evidenced by the 66% rate of insulin independence at 1 year in the 163 recipients of islet autografts from 1974 to 1995, even these recipients had significantly reduced functional β-secretory reserve.[143] Allotransplantation presented an even greater hurdle; in the 96 islet allograft recipients with type 1 diabetes from 1990 to 1994, C-peptide production and insulin independence at 1 year were

25% and 7%, respectively.[142] Of the 270 recipients until 1999, only 6 had achieved insulin independence for greater than 2 years.

The dramatic improvement in islet transplant outcome reported by the Edmonton Group in 2000 stimulated an increase in islet transplant activity.[144] Several important refinements in islet isolation and immunosuppression were credited for the improvement, including careful attention to pancreas recovery; minimization of cold ischemia time of the pancreas prior to islet isolation; avoidance of xenoproteins in the isolation process; and avoidance of steroids in the immunosuppressive regimen. The use of sequential infusions to achieve insulin independence has been critical to success for many centers. Subsequently, the enthusiasm that accompanied this success was tempered by the inability for many new centers to replicate the success of more established centers,[145] the disappointing long-term survival of the transplants,[146] and the costs associated with islet transplants, which are still not reimbursed by third-party payers and Medicare.[147] As a result, the volume of islet transplants and the number of centers performing transplants contracted over the next decade, and are currently at a steady state of low volume; in 2015, 4 North American centers performed islet transplants in 10 recipients.[148] Nevertheless, incremental improvement in efficacy and long-term outcomes in selected centers, as well as progress toward a biologic license from the U.S. Food and Drug Administration (FDA) has sustained optimism that this procedure will ultimately be reimbursed by Medicare and thus be regarded as a realistic alternative to pancreas transplantation.[149,150]

Islet Isolation

The precise separation of the islets from the other tissues of the pancreas (exocrine cells, lymphatics, and vascular structures) is the most important determinant of successful islet transplantation. One of the limitations of islet isolation is the difficulty in getting a large number of high-quality islets, and consistent success in islet isolation is a combination of science, art, and experience. Although a variety of methods have been utilized, most currently employ some modification of the semiautomated method described by Ricordi in 1988.[151] This method combines mechanical distension with enzymatic digestion of the pancreas. After cleaning the pancreas of surrounding fat, the pancreatic duct is cannulated with an angiocatheter and

the pancreas is distended and loaded with warm collagenase solution, which digests the pancreas.[152] The pancreas is then placed into a sterile chamber, which also contains a number of stainless steel or glass spheres. Additional collagenase solution is added, and the chamber is attached to a shaking apparatus or agitated by hand. The collagenase solution is recirculated and kept at 37°C as the chamber is agitated. Agitation of the chamber allows the spheres to continue to disrupt the structural integrity of the pancreas as it digests. Following digestion, the separation of islets from nonislet tissue is performed via density gradient centrifugation. After suspension in culture media, islets are counted and assessed for sterility, purity, viability, and functional capacity. As islet isolation in the United States is regulated by the FDA, stringent product release criteria are in place to ensure the quality of the transplanted islets.

The percentage of islet isolations that result in a transplantable preparation varies widely among centers, between 25% and 70%, and depends both on donor selection practices and the experience and expertise of the particular center. Many elements of the process, such as collagenase batch or type, gradient preparation, the use of culture and culture conditions, and additives to prevent islet loss, are not standardized. This variability reflects both the need for improvements in isolation efficiency and the art/science currently inherent in the process. The ultimate goal is to develop a reproducible process with enough fidelity to allow islet preparations to be biologically licensed, which appears to be a major barrier to federal funding for the procedure, which will be necessary for broader application.

Patient Selection

Candidates for islet transplantation are selected in a similar manner as for whole-organ pancreas transplantation. Islet transplantation is currently limited to adult type 1 diabetics with progressive diabetic complications who have failed intensive insulin therapy. Because islet transplantation remains experimental therapy with limited availability, the procedure is generally offered only to ideal candidates with minimal medical conditions other than diabetes. Most centers require evaluation and/or a period of treatment by an experienced endocrinologist specializing in diabetes. Candidates with coronary artery disease, chronic infections, including

hepatitis B and C, or a prior solid-organ transplant are excluded. Nonuremic candidates must be free of renal insufficiency, due to concerns about aggravation of nephropathy by calcineurin inhibitors. Since efficacy of the islet transplant appears to be related to the number of islets transplanted per kilogram of recipient body weight, only lean (<70 kg or BMI <28) recipients are selected. Although most islet transplants are currently performed in nonuremic diabetics, islet transplants either concurrent with or following kidney transplantation are also performed.[153,154]

Donor Selection/Recovery/Preservation

Donor selection for islet isolation differs from that for whole-pancreas transplantation in several respects. While the ideal donor for islet isolation is still young and healthy, the age and weight criteria are less stringent than for whole-pancreas transplantation. Donors greater than age 50, donors on vasopressors, and especially obese donors are all perfectly suitable for islet isolation. Since the ideal pancreas is easily distensible and digestible, fatty pancreata are felt to be especially suitable, whereas fibrotic pancreata are not. As previously mentioned, pancreata from older and obese donors (which are infrequently used for whole pancreas) are preferentially allocated for islet transplantation rather than for regional and national sharing for whole-pancreas transplantation.[50]

The pancreas is recovered in a manner similar to whole-pancreas transplantation. However, less attention to preservation of vascular structures is required. Attention is paid to surface cooling following flushing of preservation solution, and avoidance of pancreatic injury. A number of reports have highlighted the importance of a dedicated team trained in pancreas recovery in the success of islet isolation.[155,156] Expanded use of the two-layer technique of pancreas preservation, using both standard preservation solution (UW solution or HTK) and oxygenated perfluorocarbon solution, has resulted in increased islet yields.[157–160] The two-layer technique also permits the successful use for islet transplantation of pancreata subjected to prolonged cold ischemia as long as 18 hours. Success with pancreata from DCD has been reported.[161]

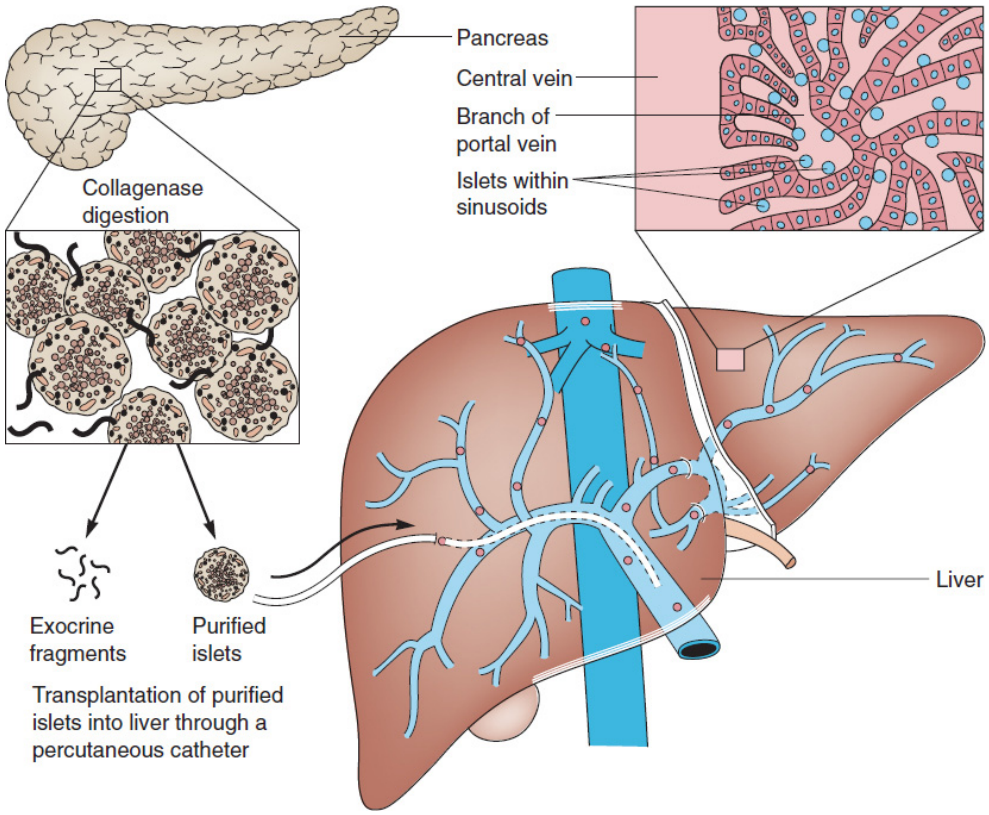

Figure 40.8 Islet transplantation. The pancreas is recovered as a whole organ from the donor. The islets are isolated from the pancreas and are purified and infused into a cannula placed in a branch of the recipient's portal vein.

Transplant Techniques

The portal circulation of the liver is currently the preferred site for islet transplantation (**Fig. 40.8**).[162] This can be performed by a minilaparotomy, with infusion of the islets into a peripheral mesenteric vein. However, most centers utilize interventional radiology techniques, avoiding both a surgical incision and general anesthesia. Percutaneous transhepatic portal vein catheterization is done under ultrasound and fluoroscopic guidance, with usually a small gauge (4-French) catheter. The islets are infused into the portal vein through the catheter by either gravity from an infusion bag or by hand injection, and the islets lodge in the hepatic parenchyma. Portal vein pressure is monitored intermittently throughout the procedure. Following infusion of the islets, hemostasis is usually achieved using a combination of coils and gelfoam. Recipients receive heparin in the islet preparation, systemically during the procedure, and in the perioperative period as

prophylaxis against portal vein thrombosis, a now rare but serious complication.

Perioperative Care

Although islet transplantation is in theory an outpatient procedure, it is not uncommon for recipients to receive a few days of inpatient care for monitoring purposes. Immediately following the islet transplant, patients are maintained on bed rest for a short interval and monitored for bleeding. Liver function tests are monitored, and a liver ultrasound is frequently done to assess portal venous flow and to check for hematoma. It has been demonstrated that intensive glycemic control with insulin in the immediate posttransplant period is beneficial for islet function.[163] Hence, many centers will give insulin postoperatively to keep the serum glucose tightly controlled, in order to "rest" the islets. Additional adjuncts to prevent the instant blood-mediated inflammatory reaction (IBMIR), which results in early islet loss and reduced β-cell mass in the recipient, may include antioxidants such as vitamin E, etanercept (anti-TNFα antibody), anakinra (IL-1β antagonist), reparixin (CXCR1/2 inhibitor), pentoxifylline, and others.[164]

Immunosuppression

Immunosuppresssive regimes for islet transplantation have evolved in the 21st century. Earlier regimens used basiliximab induction, and maintenance therapy with low-dose tacrolimus and sirolimus. However current regimens more commonly used T-cell–depleting antibody therapy for induction, and calcineurin inhibitors and IMPDH inhibitors such as mycophenolate mofetil.[148] The best results for islet–kidney transplantation are cases where steroids are avoided or eliminated at the time of islet transplantation. While long-term effects of either the islet transplant or steroid elimination on kidney function are not known, steroid avoidance in kidney transplant recipients is now routine.[49] Regimens that avoid both steroid and calcineurin inhibitors have also been successfully used.[165]

Metabolic Control

Islet recipients show significant improvement in metabolic function and glycemic reserve, although hormonal counter regulation to hypoglycemia is diminished, actual hypoglycemic events are rare.[166] Data from the Collaborative Islet Transplant Registry show that nearly 80% of islet-alone transplant recipients maintained HbA1C level of <7.0% at 1 year, and over 60% at 5 years after transplant.[148] These rates are approximately 10% lower in islet-after-kidney recipients. Over 90% of are free of severe hypoglycemic episodes at 1 year, and this is maintained over 5 years. Islet recipients also demonstrate a reduction in behaviors adopted in avoiding hypoglycemia and attenuation in concerns about hypoglycemic episodes.[167] Islet transplantation also results in improved insulin sensitivity mediated by effects at both the liver and skeletal muscle.[168] However, islet recipients have significantly diminished β-cell reserve than do recipients of whole-pancreas transplants, which may account for their reduced long-term survival.[169] Acute insulin response to intravenous glucose is commonly used to determine islet engraftment, and is a robust early metabolic marker to predict return to insulin therapy.[170] Analyses of the impact on diabetic complications and mortality await further experience.

Complications

Morbidity from islet transplantation is substantial but much less than for whole-pancreas transplantation. The most common serious complication is bleeding (1% to 5%). Most cases of bleeding can be managed nonoperatively with adjustments in anticoagulation, though occasionally laparotomy is required. The side effects of immunosuppression, such as hyperlipidemia and mouth ulcers in sirolimus-containing regimens, are much more common and can significantly affect quality of life.[171] Renal insufficiency is an uncommon but serious consequence.[148] Transient elevations of portal venous pressure during islet infusion and elevations of liver function tests following infusion are common and usually well tolerated.[172,173] However, reduction in liver perfusion during the islet infusion has been linked to premature graft failure.[174] The demonstration of late steatosis has raised concerns about chronic liver disease; to date this has not been reported.[175] CMV infection is rare. Mortality is virtually nil.

Sensitization and the development of posttransplant DSA, which was originally thought not to occur following allogenic islet transplantation, are now recognized as a significant challenge. Recent experience has shown that most recipients have increases in DSA or autoantibody (de novo expression or titer increase) after islet transplantation. Recipients who have an increase in posttransplant antibody have similar initial performance but significantly lower graft survival than patients without an increase.[176] Patients with complete graft loss who discontinue immunosuppression had significantly higher levels of anti-HLA antibodies than those with functioning grafts still on immunosuppression.[177] Ways to minimize sensitization in these recipients includes minimizing the number of islet donors used per recipient, and in the absence of donor-specific anti-HLA antibodies, repeating HLA mismatches with subsequent islet infusions.

Results

10 The short-term results of islet transplantation at high-volume centers are approaching that of whole-pancreas transplantation. The most successful centers achieve insulin independence rates of 80% to 90% at 1 year.[145,178,179] In the Immune Tolerance Network multicenter trial of the Edmonton Protocol, success rates at the most successful centers (Edmonton, Minnesota, and Miami) were significantly higher than at the other centers.[145] However, long-term rates of insulin independence are worse than whole-pancreas transplants, but continue to improve. Overall, insulin independence is 50% at 1 year and 20% to 30% at 5 years after the last infusion for those transplanted in the years 2010 to 2013. In experienced centers the 5-year insulin independence rate approaches 50% which approaches the graft survival of PTA.[145,148,149] Generally, long-term outcomes are more favorable in recipients older than 35.

One of the shortcomings of islet transplantation compared with whole-pancreas transplantation is the inability to reverse diabetes with the islets from one pancreas. This is due to extensive early beta-cell loss from recipient inflammatory responses to the transplanted islets. Most recipients in the modern era have required two or more islet infusions to achieve insulin independence. However, some centers have successfully employed single-donor islet transplantation by utilizing careful donor and recipient

selection, usually by transplanting islets from pancreata from large donors into small recipients.[178,180,181] As long-term outcome appears to be related to β-cell mass, which is likely to be lower for single-donor infusions, these recipients may return to insulin or require retransplants earlier.[182] At the recipient level, administration of anti-inflammatory agents, whether nonspecific or directed at specific molecular targets, has become the mainstay of perioperative treatment. The ability to maximize the use of islets and minimize islet requirements and pancreas utilization for an individual recipient is critical if islet transplantation is to compare favorably with whole-pancreas transplantation.

Graft Failure

Graft failure appears to occur earlier than for whole-pancreas transplants. This may be related to a lower initial islet mass or the inability to histologically diagnose and treat islet rejection, since the islets are scattered about the liver parenchyma. As with pancreas graft failure, there is no true agreement on what constitutes graft failure; recipients may require insulin yet still make C-peptide and have improved glycemic control compared with before transplant. Most outcome measures focus on insulin independence as the most stringent, and C-peptide production as the least stringent. Recent findings indicate that immunologic markers of rejection or recurrent autoimmunity, and metabolic indicators may identify recipients at risk for inferior outcomes and impending graft failure, although treatment algorithms based on these predictors are not standardized.[170,176,183,184] A number of investigators have demonstrated the ability to label and identify islets in vivo in recipients in order to monitor functional islet mass—an example of this is ferucarbotran-labeling of islets, which enables their long-term noninvasive visualization by MRI and correlates with sustained C-peptide production.[185]

Recipients with prior graft function who have returned to insulin are candidates for retransplantation. In fact, some centers have used transplanted islets from isolations where yields are insufficient for a primary transplant as retransplants, where the islet requirement may be less if there is still sufficient residual graft function.

Alternative Methods

As islet allotransplantation has progressed toward wider clinical application over a long period of time, other alternative methods have also advanced. There continues to be interest in the use of encapsulated islets. These capsules can be made from a variety of materials designed to be permeable enough to permit the passage of insulin and glucose, but to isolate the islet from the immune system. Several pilot clinical trials in humans, with transplantation into the peritoneal cavity without immunosuppression have been reported, which confirms the safety of the procedure and the demonstration of graft function, if not insulin independence.[186,187] No allo- or autoantibody has been detected in this small number of recipients. Encapsulated human islets can also be shipped safely for long distances after encapsulation and culture without compromising viability and function.[188] The major barriers to graft function and longevity have been the tendency of the capsules to cluster and fibrose, which limits their efficacy.

Artificial delivery systems that contain beta-cells or islets have been developed that can be implanted either in the abdomen or subcutaneous tissue. These artificial pancreata have semipermeable barriers that allow diffusion and neovascularization but afford immunoprotection, and have the advantage of being reloadable and less prone to fibrosis. Other devices are vascularized, which are more complex to implant and can be complicated by thrombosis, but provide better oxygenation and fast exchange of nutrients. They also better maintain concentration gradients by preventing local buildup of molecules, which is a potential limitation of nonvascularized systems. However, these technologies have still not advanced to human clinical trials.

Animal studies suggest that bone marrow precultured with human islets may enhance the survival and function of transplanted islets, thus significantly improving the therapeutic efficacy of islet transplantation.[189] Other investigators have cotransplanted mesenchymal stem cells with islets, which may be beneficial for islet engraftment by promoting cell survival/angiogenesis and reducing inflammation.[190,191]

The emergence of pancreatic beta-cells as potential renewable source of insulin-producing cells to treat diabetes has shifted interest and funding somewhat away from islet transplantation. Beta-cells can be isolated from mature islets but can also be derived from either mature or embryonic stem cells, as the biology of beta-cell development and differentiation has been well established. These engineered beta-cells produce insulin and exhibit

glucose responsiveness in vitro. They also reverse diabetes in animal models. Despite this promise, technical hurdles with scalability and bulk production have limited progress toward clinical application, and the cells still require protection from allioimmune and inflammatory host responses. Pilot studies in humans have not been conducted to date.

More recently, decellularization of organs and recellularization with islets is an emerging approach in bioartificial pancreas development.[192] This preserves important extracellular matrix components that enhance viability of implanted islets. Other approaches utilizing 3-D bioprinting of islets or beta-cells into an organ-like scaffolding are early in development.[193]

THE FUTURE OF PANCREAS AND ISLET TRANSPLANTATION

Many challenges remain in determining the ideal insulin replacement therapy for type 1 diabetics. While the current allocation system designed to maximize whole-pancreas transplantation ensures the most efficient use of donor pancreata, improvements in the efficiency of islet isolation may require that further refinements be made to allocation policy. Current outcomes support the prioritization of whole-pancreas transplantation over islet transplantation, and sufficient long-term survival reproducible among a larger number of centers is required to move islet transplantation into the mainstream. If this occurs, the reduced morbidity of islet transplantation may mean that a large number of candidates who are not surgical candidates for pancreas transplantation may be islet candidates in the future. Many centers have taken the philosophical step to offer islet transplantation primarily to diabetics who would not otherwise receive immunosuppression, that is, nonuremic diabetics. This is somewhat in contrast to PTA transplantation, which is offered to only the most exceptional candidates. Taken further, islet transplantation could theoretically be open to a large number of type 1 diabetics that would surely exhaust the limited supply of human donor pancreata. However, the experience gained by the development of islet transplantation would apply to technologies not affected by human donor supply, such as islet xenografts or engineered β-cells, which could have a

profound impact on the devastating effects of diabetes on the public health worldwide.

Section C: HEAD AND NECK

41

Head and Neck

Kelly Michele Malloy

Key Points

1. Patients with new onset hoarseness of 2 weeks or greater duration should be evaluated via flexible fiberoptic laryngoscopy.
2. Airway obstruction is a potential concern in many head and neck conditions, be they infectious or neoplastic. Assessment of the airway with nasopharyngolaryngoscopy (NPL) is crucial to safe management of these patients and should be considered early in the evaluation of patients with stridor or other signs of airway compromise.
3. A cystic neck mass in an adult represents a cervical metastasis until proven otherwise; this should be worked up with imaging and fine needle aspiration (FNA) biopsy and should not be incised and drained.
4. Thoughtful, functional reconstruction of the oral cavity and pharynx is equally important as sound oncologic resection in head and neck surgery.

INTRODUCTION

The head and neck comprises one of the most functionally sensitive anatomic regions of the human body. Disorders of hearing, sight, speech, swallowing, smell, and taste are some of the most frustrating and life altering. Cosmetic and self-image concerns also arise when the head and neck is affected by disease. There is a great breadth and depth of disease that impacts the head and neck, from infectious abscesses and congenital cysts to rare tumors. This chapter provides a high-level review of the presentation, assessment and management of more common head and neck disorders, as well as a template for consultation and collaboration with multidisciplinary specialists when needed.

PATIENT EVALUATION

History and Physical Examination

A thorough patient history is critical to accurate diagnosis of head and neck disease. Symptoms such as mass/swelling, pain, drainage, and changes in breathing, swallowing, or speech need to be further explored with questions about timing of onset, pace of progression, and relationship to any constitutional symptoms like weight loss and fevers. Social history is particularly meaningful in head and neck patients. Habitual tobacco and alcohol use increases the risk of head and neck malignancy, with increasing pack years augmenting risk in dose-dependent fashion.[1] Sexual history has become important as increasing number of oral sexual partners is associated with an increased risk of human papilloma virus (HPV)-related oropharyngeal cancer (OPC).[2]

A complete head and neck examination includes systematic inspection of the head and neck, including each mucosal subsite (**Table 41.1**) via otoscopy, anterior rhinoscopy, and often flexible fiberoptic nasopharyngolaryngoscopy (NPL). Dentures should be removed prior to inspection and bimanual palpation of the oral cavity and oropharynx. Gross craniofacial and/or neck deformity, skin lesions, previous scars, and any radiation sequelae should be noted. Complete cranial nerve examination is critical as even subtle changes in function can guide diagnosis. [1] The head and neck examination also relies

on auditory cues: hoarseness, garbled voice, stridor, stertor, and hyper- or hyponasality are all important features of head and neck disease.

Indirect mirror laryngoscopy to visualize the larynx and hypopharynx requires practice, skill, and specialized office equipment to perform well; moreover, patients with active gag reflexes or with larger tongues may be difficult to examine adequately via mirror examination. NPL examination provides improved visualization of the nasal cavity, nasopharynx, larynx and pharynx, including assessment of airway patency, dynamic function of the vocal folds, and sensation of the pharynx; NPL also affords the ability to record images and video when coupled with appropriate equipment, critical to assessing treatment response in cases of malignancy and for enhanced medical record keeping. **Figure 41.1** demonstrates the view of the larynx provided by office NPL.

The neck should be inspected and palpated carefully with particular attention to both salivary glands and cervical lymph nodes. Location of adenopathy or neck mass should be described by level, from I to VI as described by Robbins et al. (**Fig. 41.2**)[3]; tenderness and mobility should also be described. Lymph nodes tend to be mobile in all directions early in disease, but fixation to deep tissues or invasion of overlying skin indicates more advanced disease. A lateral neck mass that is mobile in the anteroposterior dimension, but not superior–inferiorly raises suspicion of paraganglioma or schwannoma. A pulsatile mass suggests a vascular pathology and should not be biopsied without imaging. The larynx and trachea should be palpated to determine any disruption to the normal architecture, tenderness, or deviation due to neck or thyroid masses. The thyroid gland is also palpated as part of every head and neck examination, the specifics of which are addressed in a separate chapter.

Cranial neuropathies deserve special attention and the clinician must be vigilant for subtle neurologic signs of underlying disease. Hyposmia may be a sign of sinonasal pathology, either due to nasal obstruction or to direct involvement of the olfactory nerve. Extraocular movement abnormalities are presenting symptoms of orbital or skull base pathology. Facial numbness or progressive facial pain raises concern for trigeminal nerve involvement by malignancy. Facial weakness or twitching in the setting of a parotid mass suggests malignancy. Bell palsy, like trigeminal neuralgia, are diagnoses of exclusion and underlying malignancy must be considered during workup of

these cranial neuropathies. Ipsilateral vocal fold paresis or impaired palatal elevation suggests involvement of the vagus nerve by neoplasm. Shoulder weakness in the setting of cervical lymphadenopathy indicates spinal accessory nerve invasion by tumor, and would prompt preoperative discussion of radical neck dissection over nerve- and muscle-sparing techniques. Tongue weakness/deviation raises concern for hypoglossal nerve involvement by primary tumor or by level I/II neck disease. Horner syndrome in the context of head and neck malignancy prompts suspicion for sympathetic chain invasion of deep cervical lymphatics.

Table 41.1 Anatomic Subsites of the Head and Neck

Subsite	Anatomy
Anterior skull base	Nasal cavity Paranasal sinuses Orbit
Oral cavity	Anterior 2/3 tongue/floor of mouth Lip/buccal mucosa/teeth/gingiva/retromolar trigone Hard palate
Pharynx	Nasopharynx Oropharynx (soft palate, palatine tonsils, posterior 1/3 tongue/lingual tonsils, posterior pharyngeal wall above the hyoid to level of palate) Hypopharynx (piriform sinuses, postcricoid space, posterior pharyngeal wall below the level of the hyoid)
Larynx	Supraglottis Glottis Subglottis
Salivary	Parotid Submandibular gland Sublingual gland Minor salivary glands
Lateral skull base	Parapharyngeal space Infratemporal fossa Temporal bone

Figure 41.1 Office NPL demonstrates a normal larynx with glottis open.

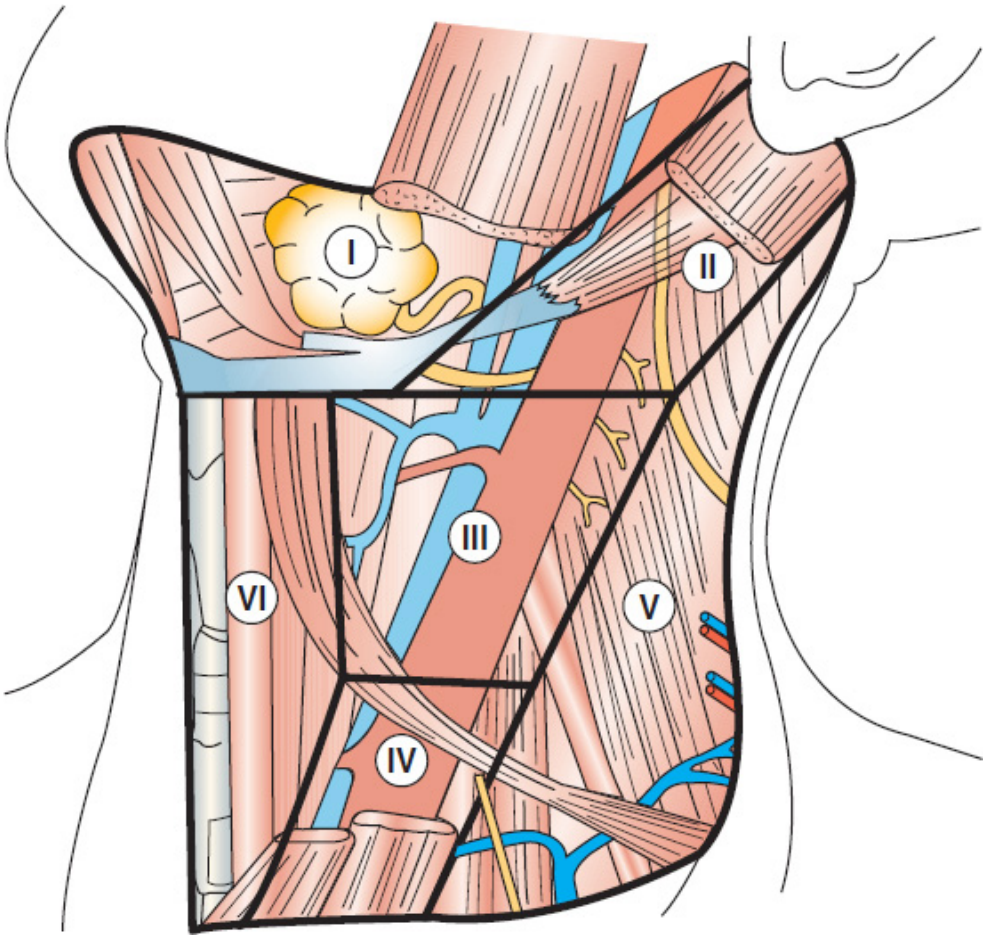

Figure 41.2 The anatomic levels of the cervical lymph nodes.

Workup

In the setting of an accessible tumor (e.g., oral tongue, tonsil), biopsy may be performed in the office under local anesthesia. For more distal tumors or in the presence of severe pain, trismus, or brisk gag, operative direct laryngoscopy is warranted. For palpable salivary or cervical masses, fine-needle aspiration (FNA) biopsy is easily performed without image guidance; however, in office ultrasound guidance may prove useful for smaller lesions. Obtaining imaging prior to needle biopsy is reasonable in any circumstance when vascular pathology or proximity of pathology to vascular structures is of concern. CT with contrast is the preferred imaging modality for most head and neck pathologies. MRI is useful to evaluate for perineural spread of tumor and for orbital and dural assessment. When malignancy is diagnosed, metastatic workup with PET/CT or chest CT should be performed.

Airway Concerns

2 The presence of head and neck disease may impact the patient's airway on presentation, but it may also complicate safe airway management during planned surgery. This requires a thoughtful, multidisciplinary approach. A number of patient factors have been described in the anesthesia literature as predictors of difficult direct laryngoscopy, including sternomental distance, thyromental distance, Mallampati score, and mouth opening.[4] Imaging may assist with assessment and NPL examination by an expert practitioner is critical to evaluate airway patency. A large laryngeal or oropharyngeal mass may lead to failure of mask ventilation and difficulty passing an orotracheal tube; lesions prone to bleeding may cause similar problems. Trismus secondary to advanced tumor or radiation fibrosis may also impede orotracheal intubation. Extrinsic compression or deviation of the airway by thyroid or neck nodal mass is another situation where head and neck surgeons can assist in airway assessment and management. A prospective study of intubation in patients with head and neck pathology found that a diagnosis of cancer, particularly of the supraglottis or glottis, as well as history of radiation, predicted difficult airway.[5] Surgeon and anesthesiologist thus must communicate clearly about the airway plan prior to induction.

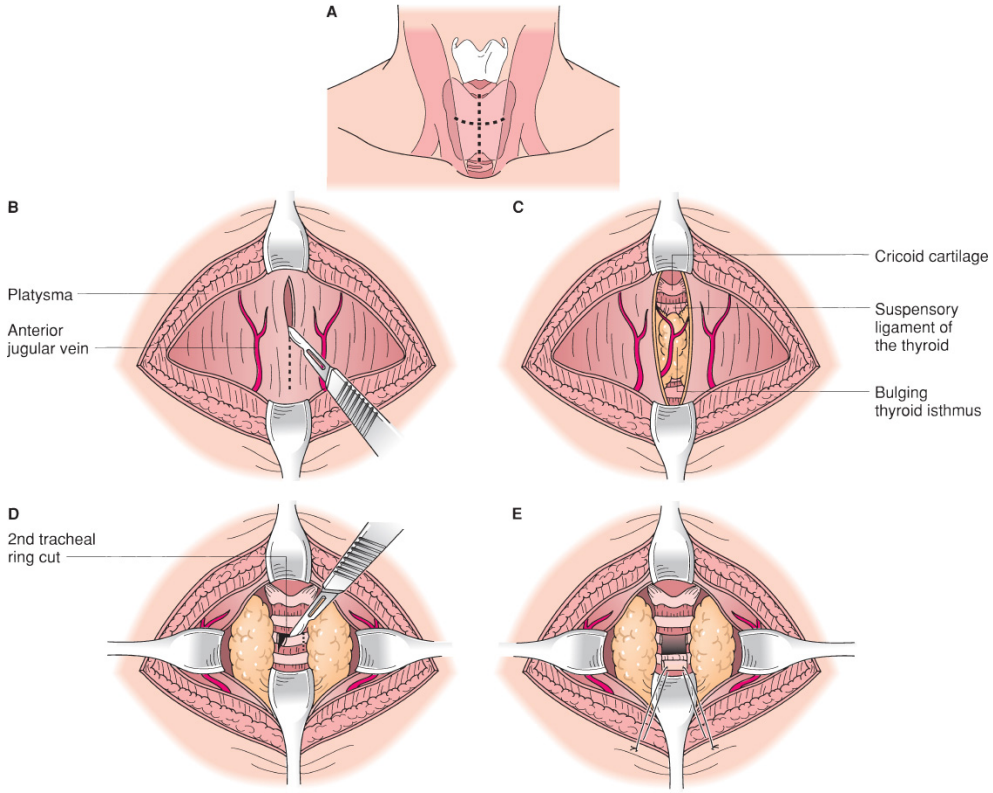

Figure 41.3 Tracheostomy. **A:** The incision for an elective tracheostomy is typically placed on a horizontal axis, approximately two-finger breadths above the sternal notch. A vertical incision allows for less bleeding when the procedure must be performed emergently. **B:** The strap muscles are separated in the midline. **C:** The thyroid isthmus is then encountered and may require division with cautery and/or inferior retraction. **D:** The trachea is entered horizontally, preferably between rings 2 and 3. **E:** An inferiorly based flap (i.e., Bjork flap) is developed in the tracheal wall and sutured to the skin or subcutaneous tissues. This allows for easy access to the trachea while the tract is maturing.

Awake fiberoptic intubation (FOI) may be safely performed in many such cases with the patient spontaneously breathing, using topical anesthesia and mild sedation to intubate via the nasotracheal or orotracheal route. A tracheotomy kit should always be available for emergent cricothyrotomy or tracheotomy should FOI prove impossible or the airway becomes further compromised. In cases where NPL examination indicates imminent airway collapse, planned awake tracheotomy is the safest option. Early consultation with otolaryngology-head and neck surgery is strongly encouraged in difficult airway cases. **Figure 41.3** demonstrates the steps of a tracheotomy.

INFECTIOUS AND INFLAMMATORY DISEASE OF THE HEAD AND NECK

Neck Abscesses

The most common head and neck abscess is the peritonsillar abscess (PTA). A complication of untreated bacterial pharyngitis, it may lead to bacterial invasion of the parapharyngeal space if not adequately drained. Trismus is a hallmark of PTA, alongside symptoms of dysphagia, odynophagia, and a muffled "hot potato" voice. Physical examination reveals soft palate and tonsillar bulging with uvula deviation toward the unaffected side. CT neck is typically unnecessary but may have a role in equivocal cases. Drainage is performed at bedside under local anesthesia. An 18-gauge needle can be used to localize the pus collection and plan an incision. An 11 or 15 blade is then used to make a cruciate incision superolaterally, and a hemostat or Yankauer suction used to probe the space and drain the collection (**Fig. 41.4**). Antibiotics with broad coverage (e.g., amoxicillin–clavulanate or clindamycin) should be thereafter prescribed for 10 to 14 days. Patients with a history of multiple PTAs should be considered for subsequent tonsillectomy.[6,7]

Patients with epiglottitis may present similarly to PTA with odynophagia, muffled voice, and drooling; trismus, however is usually absent, and epiglottitis patients have impending airway compromise. Lateral neck plain films demonstrate a classic "thumbprint sign" of an edematous epiglottis. NPL examination can be used to confirm the diagnosis, but early securing of the airway in the operating room via FOI or awake tracheotomy is paramount.

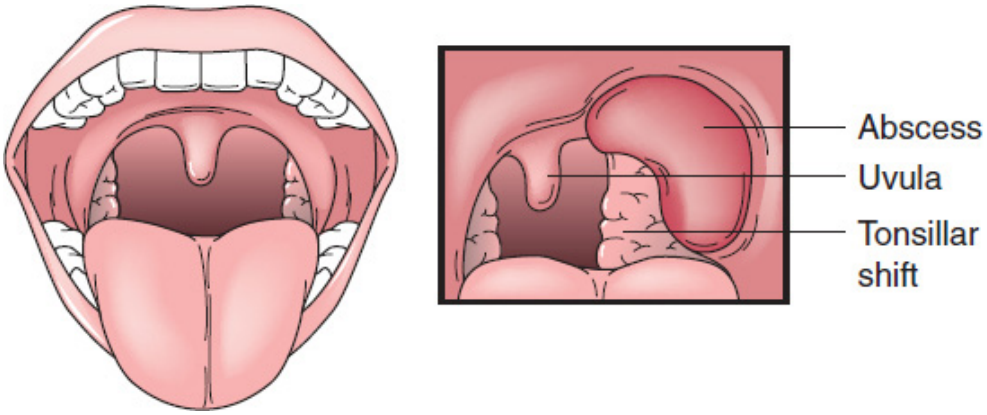

Figure 41.4 Schematic representation of a peritonsillar abscess. Purulence develops between the tonsillar capsule and the superior pharyngeal constrictor muscle. As a result, the palate bulges and the tonsil are deviated medially. Inflammation in the region of the pterygoid muscles results in pain and trismus which may be significant.

Odontogenic and pharyngeal infections can progress to deep neck space infections, particularly in diabetic patients. Early evaluation of the patient's airway is critical as airway compromise may evolve rapidly. Elective intubation should be considered and tracheotomy may be necessary in the setting of prolonged airway edema. Of particular concern are infections involving the floor of mouth, or Ludwig angina, which cause airway compromise via posterior displacement of the base of tongue. Infections in other neck spaces, including retropharyngeal, parapharyngeal, and prevertebral spaces, may spread quickly and cause rapid decompensation via mediastinitis. **Figure 41.5** lists the relevant deep neck spaces and paths of spread.

Incision and drainage with copious irrigation and placement of dependent drains is the treatment of choice for deep neck space infection, and reexploration is occasionally needed. Culture-guided antibiotics and control of blood glucose levels are also indicated. If odontogenic in origin, the source tooth should also be addressed.

Complications of Rhinosinusitis

Acute rhinosinusitis may be viral or bacterial and presents with fever, facial pressure, pain, nasal obstruction, and purulent or discolored nasal discharge. The American Academy of Otolaryngology-Head and Neck Surgery Clinical

Practice Guideline for adult sinusitis notes that the vast majority of upper respiratory tract infections (URIs) are viral, and that bacterial rhinosinusitis should be suspected when symptoms persist after 10 days or worsen after a period of initial improvement.[8,9] Surgery is not indicated for patients with acute sinusitis unless orbital or intracranial involvement occurs. Complicated acute bacterial rhinosinusitis (**Table 41.2**) should be suspected when visual, mental status, or neurologic changes are present. Proptosis, chemosis, and periorbital edema may signify orbital abscess (**Fig. 41.6**). Contrast-enhanced CT and MRI are warranted in most cases. Prompt consultation with otolaryngology, ophthalmology, and/or neurosurgery is imperative.

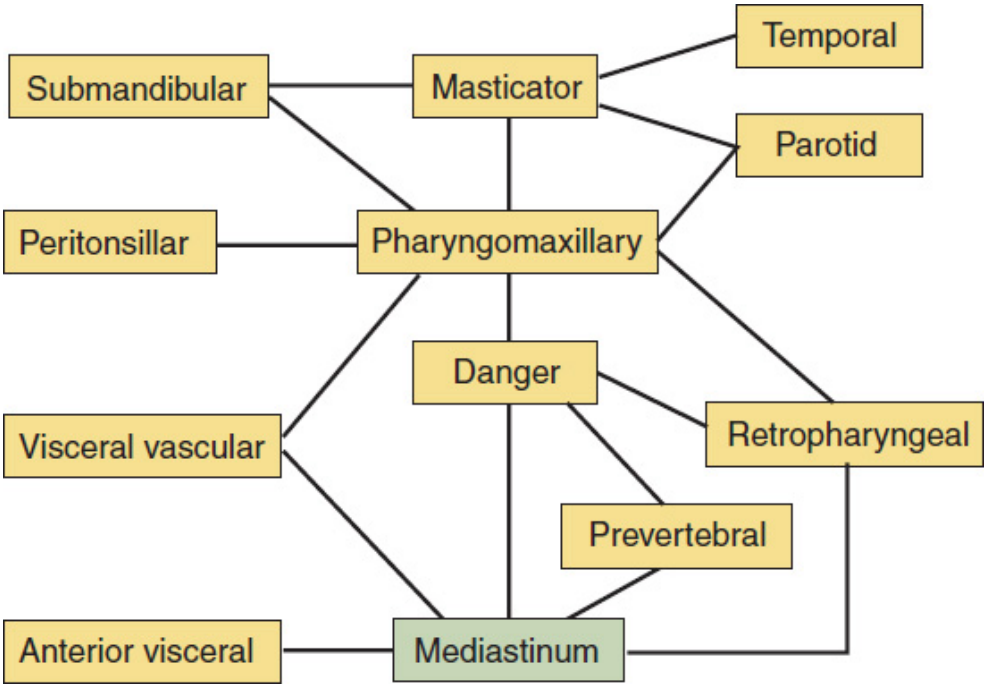

Figure 41.5 The deep spaces of the neck are distinct but interconnected compartments. Infections in any one of these may spread to involve other potential spaces and critical structures contained therein.

From Epstein VA, Kern RC. Invasive fungal sinusitis and complications of sinusitis. *Otolaryngol Clin North Am* 2008;41(3):497–524; with permission.

Rapid onset, severe rhinosinusitis in the immunocompromised (neutropenic, HIV, poorly controlled diabetic or transplanted patients) prompts concern for acute invasive fungal sinusitis. Rapidly progressive and fatal if untreated, the organisms most commonly associated are from the genera *Aspergillus, Rhizopus, Mucor, Rhizomucor,* and *Absidia*.[10] Nasal endoscopy demonstrates pale or black necrotic mucosa of the turbinates or septum. Frozen section biopsy is performed as immediate diagnosis is imperative. The patient should be emergently and aggressively debrided to bleeding tissue in the operating room, tissue sent for cultures, and antifungal therapy initiated in consultation with Infectious Disease specialists. Reversal of the underlying immunocompromised state (i.e., aggressive control of blood glucose) improves prognosis as well.

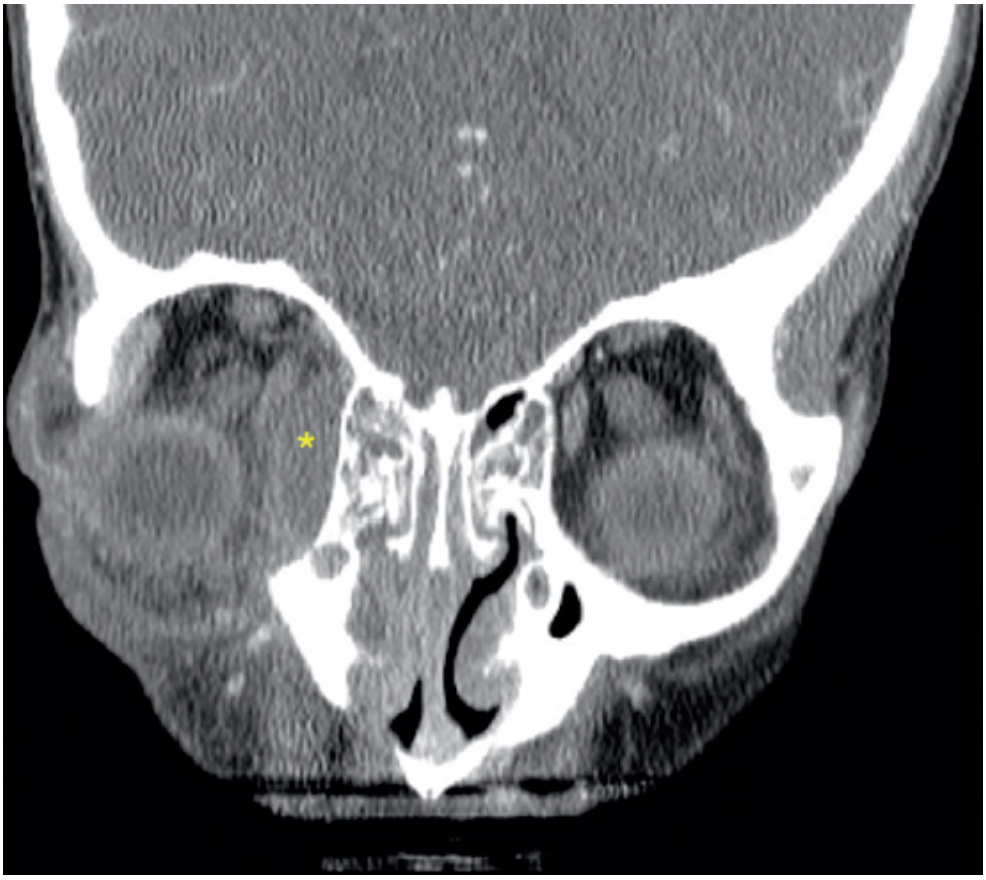

Figure 41.6 Coronal CT sinuses with contrast demonstrates a right-sided periorbital abscess (*asterisk*) arising in a child with acute bacterial ethmoid sinusitis. Urgent ophthalmologic consultation was obtained, which revealed increased intraocular pressure. The child was taken for endoscopic ethmoidectomy and orbital decompression.

Sialadenitis

Patients who are debilitated, dehydrated, or have decreased salivary flow due to medications or xerostomia are predisposed to salivary gland infections. Sialadenitis is a clinical diagnosis, based on tense, tender swelling of the affected gland(s), fevers, and presence of purulence from Warthin or Stensen duct. Viral sialadenitis tends (mumps, HIV) tends to be bilateral. Bacterial sialadenitis is most often caused by *Staphylococcus aureus,* although a variety of anaerobes and other oral pathogens may be cultured.[11]

Patients with uncomplicated sialadenitis should be treated with hydration, sialogogues, gland massage, and broad-spectrum antibiotics if bacterial

pathogens are suspected. Worsening of symptoms after initiation of therapy should prompt consideration of abscess development, and imaging with ultrasound or contrast-enhanced CT should be performed. Recurrent or chronic salivary infections should prompt suspicion for structural or inflammatory disorders. Structural disease includes salivary stones or strictures, while connective tissue disorders, such as Sjögren syndrome, rheumatoid arthritis, and sarcoidosis may present with or develop sialadenitis. When sialadenitis recurs, CT imaging should be undertaken to evaluate for stones or underlying duct-obstructing tumor. Abscess drainage must be thoughtful of the course of the facial nerve, with carefully placed incisions and dissection parallel to its branches.

NECK MASSES: CYSTIC NECK INFECTION OR MALIGNANCY?

3 A neck mass, solid or cystic, should be presumed malignant until definitive expert evaluation proves otherwise. Congenital cystic neck masses and infectious/inflammatory adenopathy remain on the differential diagnosis for adult neck masses (**Table 41.3**), but they are rare and the first thought must be of neoplastic etiologies. HPV-related oropharyngeal squamous cell carcinoma (SCC) frequently presents with a cystic neck mass as the only symptom (**Fig. 41.7**); central necrosis with hemorrhage or superinfection can cause pain and rapid growth, thus mimicking an infected congenital mass or suppurative node. Incision and drainage must be avoided in cases of possible malignancy, as this seeds the neck soft tissues with tumor and may limit treatment options and efficacy. In cases where there is doubt, initiation of antibiotics with close monitoring for improvement may be considered, but prompt imaging with contrast-enhanced CT, FNA biopsy, and referral to a head and neck surgical oncologist will avoid delays in cancer diagnosis and treatment. If FNA does not yield sufficient material for diagnosis, open *excisional* biopsy may be considered provided the surgeon sends for frozen section analysis and is prepared to perform completion neck dissection at the time of surgery for the appropriate diagnosis.

Table 41.3 Differential Diagnosis of a Neck Mass	
Congenital	Branchial cleft cyst Vascular malformation Thyroglossal duct cyst Dermoid
Infectious	Tuberculosis Atypical mycobacteria Cat scratch disease Mononucleosis Odontogenic Sialadenitis
Inflammatory	Sarcoidosis Sialadenosis

Neoplasm	Epithelial (SCC, melanoma, adenocarcinoma) Salivary Neurogenic (schwannoma, paraganglioma) Sarcoma Lipoma Lymphoproliferative

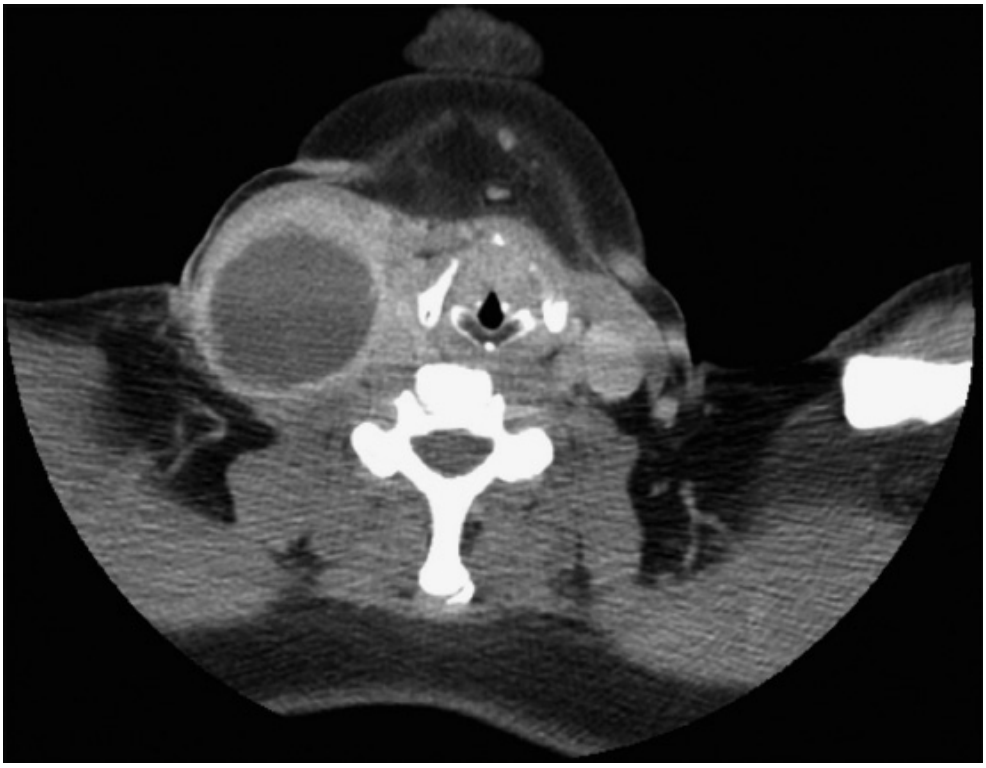

Figure 41.7 Axial CT neck with contrast shows a large cystic mass involving the right level III/IV neck. Image-guided FNA confirmed HPV-positive squamous cell carcinoma.

Algorithm 41.1 is a suggested approach to the adult with a lateral neck mass.

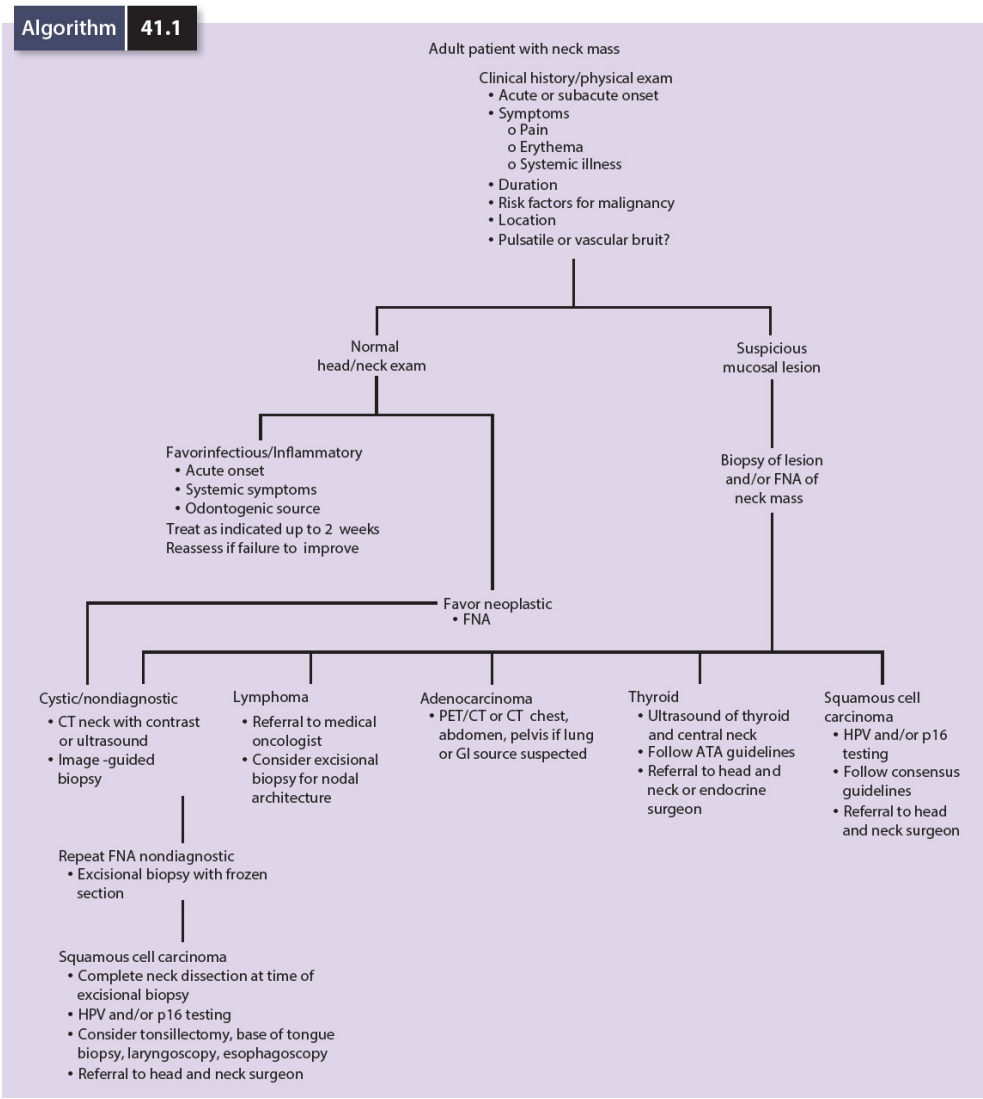
HEAD AND NECK NEOPLASMS

Whenever possible, patients with head and neck cancer should be referred to a multidisciplinary center with specialized head and neck surgeons, radiation oncologists, medical oncologists, dentists, pathologists, radiologists, speech therapists, and social workers. Both surgery and radiation may impact speech, swallowing, and taste, and anticipatory treatment of these consequences of treatment is critical.

Salivary Neoplasms

Salivary tumors include a diverse array of benign and malignant pathologies (**Table 41.4**). The parotid is the most commonly affected gland and ~80% of parotid tumors are benign. Pleomorphic adenoma, or benign mixed tumor, is the most common benign tumor. Warthin tumor, or papillary cystadenoma lymphomatosum, another common pathology noted predominantly in male smokers, may be bilateral and tends to locate in the tail of the parotid gland. These and other benign salivary tumors present as a painless firm mass of the affected gland, though those arising in the deep lobe of the gland or in the parapharyngeal space may grow quite large before they are noted clinically.[12–15]

Figure 41.8A,B demonstrates MRI characteristics of a pleomorphic adenoma on MRI.



Algorithm 41.1 Workup of a neck mass in an adult patient.

A salivary mass that presents with pain, rapid growth, or facial nerve weakness must prompt immediate suspicion for malignancy. There is an inverse relationship between size of the gland and rate of malignancy: ~20% of parotid tumors harbor malignancy, 50% for the submandibular gland, and as high as 86% for the sublingual gland. Mucoepidermoid carcinoma (MEC) is the most common malignant salivary tumor, followed by adenoid cystic carcinoma (ACC) and adenocarcinoma.[12] **Table 41.5** lists the American Joint Committee on Cancer (AJCC) T-staging for salivary cancer.[14]

FNA biopsy should be considered prior to surgery alongside imaging (contrast-enhanced CT or MRI). The surgeon should be aware that the specificity of FNA for neoplasia and malignancy is high, however the

sensitivity is lower.[16] That said, proper workup can direct the surgeon toward more aggressive surgery in the presence of known malignancy, avoid surgery in cases of lymphoma or inflammatory disease, and even to help counsel patients in the presence of benign tumors. FNA of the parotid demonstrating SCC indicates metastatic disease to parotid lymph nodes, and would further direct investigation to locate a primary skin cancer of the scalp or face.

Some benign tumors, like Warthin tumors, may be observed, while a pleomorphic adenoma should be excised due to the long-term risk of malignant transformation to carcinoma ex pleomorphic adenoma. The risk of this transformation is around 6%, and increases with time.[20] Superficial parotidectomy is typically adequate in these circumstances, taking care to dissect and preserve facial nerve branches.[17–19] Pleomorphic adenomas may have "tumor pseudopodia," thus resection with a margin of normal gland where possible is favored.[21] Often the tumor is sitting directly on nerve branches at its deep margin, however, and meticulous dissection to preserve the nerve and avoid tumor spillage is critical. Tumor spillage may lead to multifocal recurrence in the operative bed. Surgical salvage is recommended in these cases, but radiation may provide local control in multiply recurrent cases.

Table 41.4 Salivary Tumors

Benign	Malignant	Malignant Nonsalivary and Metastatic
Pleomorphic adenoma	Mucoepidermoid carcinoma	Lymphoma
Warthin tumor (papillary cystadenoma lymphomatosum)	Adenoid cystic carcinoma	Squamous cell carcinoma
Basal cell adenoma	Adenocarcinoma	Melanoma
Oncocytoma	Acinic cell carcinoma	
Hemangioma	Carcinoma ex-pleomorphic adenoma Salivary duct carcinoma	

Figure 41.9 demonstrates the steps performed in superficial parotidectomy with facial nerve dissection.

Total parotidectomy may be required in cases of malignancy, however, a diagnosis of malignancy may not be confirmed until final pathology; an en bloc resection of tumor with good margins is adequate in most small cancers.[19] Total parotidectomy is more challenging to perform en bloc with respect to the facial nerve, which should always preserved if functional or not grossly invaded by a pathology-confirmed malignant tumor. If nerve sacrifice is warranted, it should be immediately reconstructed with a nerve graft.

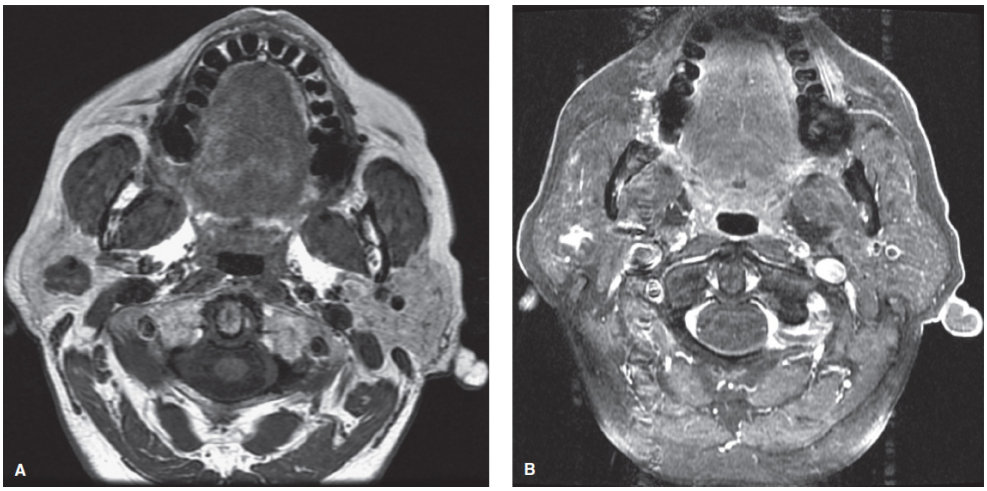


Figure 41.8 Precontrast (**A**) and postcontrast (**B**) T1 MRI demonstrate a lobulated, heterogeneous mass within the right parotid gland just posterior to the retromandibular vein, consistent with a pleomorphic adenoma.

Parotidectomy alone is adequate in low-grade malignancy (ACC and polymorphous low-grade adenocarcinoma), but in high-grade cancers (salivary duct carcinoma, high-grade MEC, most adenocarcinomas, and carcinoma ex-pleomorphic adenoma), the regional lymphatics must be addressed via ipsilateral neck dissection. Adjuvant radiation should be considered for stage III/IV disease, high-grade pathology, and perineural invasion.

Sinonasal Neoplasms

Sinonasal neoplasms are rare, and often present with nonspecific symptoms like unilateral nasal obstruction or drainage, epistaxis, or decreased smell. The most common pathology is benign inverted papilloma, but there are over 70 different pathologies that may arise in the paranasal sinuses, over half of which are malignant.[22] The maxillary sinus is the most common subsite, followed by the ethmoid, sphenoid, and frontal sinuses.[23]

Surgery is the standard of care for most sinonasal tumors, and is usually undertaken by a multidisciplinary surgical team that includes otolaryngology, neurosurgery, and ophthalmology depending on the extent of disease. Inverted papilloma is typically resected via endoscopic sinus surgery and requires drilling out of the site of tumor origin for an essential en bloc resection; this is to prevent recurrence as there is an ~10% malignant transformation rate to

SCC. SCC is the most common malignant sinonasal tumor (40% to 50%), followed by adenocarcinoma and ACC.[24–26] "Round blue cell" tumors are less common, but represent numerous different pathologies, including esthesioneuroblastoma, sinonasal undifferentiated carcinoma (SNUC), neuroendocrine carcinoma, small cell carcinoma, mucosal melanoma, lymphoma, and various sarcomas. As such, consultation with a head and neck pathologist is critical because high-grade pathologies (SNUC, small cell) tend to metastasize early and are also often treated with induction chemotherapy and radiation or concurrent chemoradiation over primary surgery. Sinonasal rhabdomyosarcoma, most frequently noted in the pediatric population, is also treated with primary or induction chemotherapy with radiation over initial surgery.[27,28]

Table 41.5 Staging of Major Salivary Gland Tumors

T1	Tumor ≤2 cm without extraparenchymal extension
T2	Tumor >2 cm but ≤4 cm without extraparenchymal extension
T3	Tumor >4 cm or with extraparenchymal extension
T4a	Any size tumor with involvement of skin, mandible, ear canal, or facial nerve
T4b	Any size tumor with carotid artery encasement or pterygoid plate/skull base invasion

HEAD AND NECK SQUAMOUS CELL CARCINOMA

SCC is the most common malignancy of the upper aerodigestive tract. AJCC 8th edition TNM staging is provided in **Tables 41.6** to **41.8** for oral cavity, oropharynx, and larynx cancer, while **Tables 41.9A** and **41.9B** provide the new nodal staging that accounts for the prognostic differences of nodal disease in HPV-positive versus HPV-negative SCC.[14] Generally speaking, patients with AJCC stage I/II tumors are often considered for single-modality treatment, either primary surgery or primary radiation in most cases. Patients with stage III/IV require multimodality treatment, often including systemic therapy; as such, most patients will benefit from evaluation and treatment in a multidisciplinary head and neck cancer program.

Oral Cavity

Cancers of the oral cavity should be considered for primary surgery to optimize oncologic outcomes and to avoid complications of definitive radiation or chemoradiation (i.e., osteoradionecrosis of 4 the mandible) whenever possible. Given the sensitive functional nature of the structures of the oral cavity, thoughtful reconstruction is as important as oncologically sound resection of malignancy for these patients to achieve quality survivorship. Microvascular free tissue reconstruction is a mainstay of oral cavity malignancy surgery as it restores structure and function of the oral cavity to maintain speech and swallowing.

Supraglottis	
T1	Tumor limited to one subsite of supraglottis with normal vocal cord mobility
T2	Tumor invades mucosa of more than one adjacent subsite of supraglottis or glottis or region outside supraglottis (base of tongue, vallecular, medial wall piriform) without fixation of larynx
T3	Tumor limited to larynx with vocal cord fixation and/or invades any of the following: pre-epiglottic, paraglottic space, postcricoid area, and/or inner cortex of thyroid cartilage
T4a	Tumor invades outer cortex of thyroid cartilage and/or invades tissues beyond larynx (trachea, soft tissues, neck including deep extrinsic tongue muscles, strap muscles, thyroid, esophagus)
T4b	Tumor invades prevertebral space, mediastinal structures, or encases carotid artery
Glottis	
T1a	Tumor limited to one vocal cord, with normal mobility
T1b	Tumor involves both vocal cords, with normal mobility

T2	Tumor extends to supraglottis and/or subglottis, and/or with impaired cord mobility
T3	Tumor limited to the larynx with vocal cord fixation and/or invasion of paraglottic space and/or inner cortex of thyroid cartilage
T4a	Tumor invades through outer cortex of thyroid cartilage and/or invades tissues beyond larynx (trachea, cricoid, soft tissues, neck including deep extrinsic tongue muscles, strap muscles, thyroid, esophagus)
T4b	Tumor invades prevertebral space, mediastinal structures, or encases carotid artery

Lip carcinomas pose both functional and cosmetic concerns. Lower lip cancer is more common than upper lip cancer and is most often caused by sun exposure; it has a very low incidence of occult cervical metastases (<15%) thus the bilateral necks may be observed in cT1–2 N0 disease as noted in consensus guidelines. The upper lip has unilateral nodal drainage but a higher incidence of occult nodal involvement compared to cancers of the lower lip. Reconstruction of the lip ranges from primary closure (after wedge resection of the primary) to local advancement or rotational flaps to free flap reconstruction for larger and more complex lip defects.[30]

Depth of invasion (DOI) in oral tongue and floor of mouth cancer is important for prognosis, so much so that the AJCC 8th edition added DOI to

the staging system (**Table 41.6**). Thin tumors (<2 mm) have less regional lymphatic metastatic potential compared to thick tumors (>8 to 9 mm). Many head and neck surgeons recommend elective neck dissection for patients with T1 tumors and DOI >4 mm; sentinel node many be considered in experienced hands for tumors 2 to 4 mm DOI.[31,32] T1–T2 tongue tumors may be resected and closed primarily or with a skin or acellular dermis graft; larger defects and those involving the floor of the mouth require microvascular reconstruction to restore the tongue mound and facilitate recovery of articulation and swallowing. Similarly, small floor of mouth resections may be closed primarily or skin grafted, but free tissue is needed for larger defects, particularly when simultaneous neck dissection is performed.

Table 41.9B Clinical and Pathologic Nodal Staging for HPV-Positive Oropharynx Cancer

cN0	No regional lymph node metastases
cN1	One or more ipsilateral nodes, none >6 cm
cN2	Contralateral or bilateral nodes, none >6 cm
cN3	Lymph node(s) >6 cm
pN0	No regional lymph node metastases
pN1	Metastasis in four or fewer nodes
pN2	Metastasis in more than four nodes

SCC of the retromolar trigone and buccal mucosa/buccal space often demonstrates early involvement of the muscles of mastication. Pterygoid or masseter invasion causes trismus and pain, and may make preoperative examination a challenge for both patient and surgeon. Marginal mandibulectomy is necessary when a retromolar trigone tumor is attached to mandibular periosteum. Composite resection of a segment of mandible

should be performed when tumor invades bone (noted clinically or on preoperative CT) or when tumor surrounds a tooth root. Osteocutaneous free tissue reconstruction is the gold standard for segmental defects. While an unreconstructed lateral mandible defect ("mandibular swing") causes malocclusion and cosmetic asymmetry, failure to reconstitute the anterior mandibular arch leads to swallowing and airway compromise; once known as the "Andy Gump deformity," loss of the anterior mandibular arch causes the lip and chin to migrate posteriorly and inferiorly into the neck, releases the tongue posteriorly, and thus adversely impacts oral competence, deglutition, speech, and airway. Tempting as it may be to place a titanium reconstruction plate across a segmental defect of the mandible, this should be avoided due to inevitable delayed hardware extrusion that occurs with mere plating and soft tissue coverage alone. This reinforces the need to refer complex oral cavity cancer patients to a center where microvascular free tissue reconstructive surgery of the head and neck is available.

Nasopharynx

Nasopharyngeal carcinoma (NPC) is endemic to certain parts of Asia, particularly southern China. The most important causal factor is Epstein–Barr virus (EBV).[33–35] The World Health Organization classifies NPC into three types: keratinizing SCC (I), nonkeratinizing SCC (II), and undifferentiated carcinoma (III).[22] Endemic NPC is 95% type III, which is associated with the best prognosis, and types I and II are more common in nonendemic areas.

NPC most commonly presents with bulky cervical adenopathy. Primary tumors do not typically cause symptoms until quite advanced. Unilateral otitis media in an adult should prompt a scope examination of the nasopharynx as this may be due to Eustachian tube obstruction by tumor. More advanced tumors may present with nasal obstruction or changes in speech due to palatal involvement. Cranial neuropathies are a hallmark of skull base invasion. Interestingly, large-volume lymphadenopathy alone is less prognostic in NPC than in other head and neck malignancies; it is the involvement of the supraclavicular nodes that portends a worse prognosis. This is reflected in a separate nodal staging paradigm for NPC.[14]

Endoscopic biopsy of the nasopharynx or FNA of lymph nodes confirms NPC; staining for EBV is also performed, and is key to making the diagnosis from a neck node. Imaging should include contrast-enhanced CT and MRI to evaluate the skull base and infratemporal fossa. PET/CT is also obtained for complete staging and planning of radiation fields. The primary treatment for NPC is chemoradiation which has been shown to be superior to radiation alone in advanced disease.[36,37] Surgery is reserved for recurrent/persistent localized disease in select cases; small tumors may be amenable to an endoscopic approach, but may require an open transfacial approach with maxillary disarticulation for adequate exposure and protection of the carotid artery.[38–40]

Oropharynx

The overall incidence of head and neck SCC in the United States has decreased in concert with the decrease in tobacco abuse in recent decades; a notable exception to this trend is in cancers of the oropharynx. OPC incidence has risen over the past two decades due to the increase in HPV transmission and chronic infection. HPV, particularly subtypes 16 and 18, appears to be responsible for approximately 80% of OPC.[41] Interestingly, HPV-associated OPC is associated with a more favorable prognosis compared to the tobacco-related "classic" HPV-negative cancers of the head and neck, even in advanced local and regional disease states.[42,43] This difference in prognosis led to changes in the AJCC staging system that account for the differences between HPV-positive and HPV-negative tumors (**Tables 41.7A and 41.7B**). These include the findings that nodal metastases are less impactful on survival for HPV-positive OPC patients, and extranodal extension of tumor does not appear to impart the same poor prognosis as in HPV-negative SCC disease (**Tables 41.9A and 41.9B**).[14]

T1 and T2 tumors of the palatine tonsils are typically amenable to transoral resection, but radiation and chemoradiation have been used since the 1990s to treat less accessible (i.e., lingual tonsil) and larger tumors due to equivalent effectiveness and decreased morbidity and mortality compared to open surgical approaches (i.e., mandibulotomy/transmandibular approach, transcervical and transpharyngeal approaches).[44] Both the increasing prevalence of HPV-positive OPC patients with favorable prognoses and the

advent of transoral, minimally invasive approaches to the oropharynx, have led to increased interest in primary surgery to avoid the long-term sequelae of chemotherapy and even radiation in these younger patients. Transoral laser microsurgery (TLM) and transoral robotic surgery (TORS) have emerged in the past 10 to 15 years as viable treatments for T1–T3 OPC with acceptable oncologic and functional outcomes.[45–48]

Hypopharynx

The hypopharynx is the area between the oropharynx and cervical esophagus. Cancers of the hypopharynx usually present in advanced stages as symptoms are delayed until the tumor is large enough to impede swallowing or invade the larynx. Patients report gradually increasing dysphagia, hoarseness, neck mass, and referred otalgia via Jacobson and Arnold nerves (branches of cranial nerves IX and X, respectively).

Hypopharyngeal SCC has the poorest prognosis of the head and neck subsites, with an overall survival of only 30% to 35% in early-stage cancer,[49] and a rate of distant metastases of up to 60%.[50] Surgical resection usually requires total laryngectomy with partial or complete pharyngectomy due to the intimate proximity of the piriform sinuses/postcricoid mucosa and the larynx; as such primary chemoradiation approaches predominate initial treatment algorithms. Small tumors of the posterior pharyngeal wall may be amenable to resection via transoral laser or robotic techniques.[51,52] Due to the rich lymphatics of the hypopharynx, bilateral neck treatment is required for regional control. Recurrent hypopharyngeal SCC following chemoradiation typically requires salvage total laryngopharyngectomy; free tissue reconstruction is critical to reconstitute the pharynx, either with a tubed fasciocutaneous free flap or an enteric flap such as the gastro-omental free tissue transplant.

Larynx

The glottic larynx, composed primarily by the true vocal folds, is the most common site of origin of laryngeal SCC, involved, followed by the supraglottis (tip of the epiglottis to the laryngeal ventricle), and subglottis (just below the true vocal folds to the inferior border of the cricoid

cartilage). The glottis consists of nonkeratinizing stratified squamous epithelium overlying a complex lamina propria over the thyroarytenoid ligament and muscle. Early glottic tumors have a low rate of metastasis to regional lymphatics due to the investing fibroelastic structure of the conus elasticus and quadrangular membrane. By way of contrast, supraglottic and subglottic are known for their risk of nodal metastasis even in early disease.

Early (T1–T2) glottis cancers may be managed with single modality treatment—either radiation or endolaryngeal surgery—with long-term control rates of approximately 90% for T1 and 75% for T2 tumors. Surgical treatment is performed via transoral resection, often using CO_2 laser. Surgery has no statistically significant difference in local control, overall or disease-free survival compared to narrow-field radiation, although laryngeal preservation rates appear to be higher in surgical patients based on retrospective studies.[53–55] Supraglottic carcinoma has a high incidence of occult nodal metastasis and is an anatomic subsite with bilateral lymphatic drainage. Thus for both surgical and radiation based treatments of the supraglottis, bilateral level 2–4 neck nodes must be addressed alongside the primary tumor.

Advanced laryngeal cancer (T3–T4, N positive) requires multimodality treatment. This may be primary surgery followed by radiation or concurrent chemoradiation. The landmark "VA Larynx Trial" demonstrated equivalent survival between surgery followed by radiation versus induction chemotherapy followed by radiation, with 64% laryngeal preservation in the nonsurgical arm.[56] The RTOG 91–11 trial demonstrated the superiority of concurrent chemoradiation compared to radiation alone or after induction chemotherapy for laryngectomy-free survival and local control.[57] However, the 10-year follow-up to this study did not demonstrate an advantage of concurrent chemoradiation versus induction chemotherapy and radiation in overall survival, local control, or overall laryngeal preservation.[58]

Surgical treatment for advanced-stage laryngeal cancer is typically total laryngectomy with bilateral neck dissections. Speech is restored via esophageal speech training, tracheoesophageal puncture with prosthesis, or electrolarynx. These patients are permanent neck breathers and education for patients and caregivers on the implications of a separated airway and digestive tract is critical to ongoing safety. Open partial laryngectomy,

including supraglottic or supracricoid partial laryngectomy, may be used in selected cases based on tumor anatomy but has long-term impact on swallowing and airway protection that requires both surgical and speech language pathology expertise to manage.

While the aforementioned chemoradiation trials have led to the term "laryngeal preservation" treatment, there are instances where caution should be used when considering this approach. High-dose radiation may cause chondroradionecrosis and osteoradionecrosis, and it is less effective in tumor-invading cartilage and bone. As such it is felt to be inferior to total laryngectomy in T4 laryngeal cancers[59]; moreover, even if the tumor is eradicated, the secondary and long-term changes from chemoradiation may render the larynx dysfunctional. Tumors with extensive paraglottic spread and vocal cord fixation may present with airway compromise necessitating tracheostomy and dysphagia requiring gastrostomy tube placement. These patients may not regain vocal fold mobility posttreatment, and are likely to remain tracheostomy-dependent postradiation.[60] Permanent gastrostomy tube is also a risk due to dysfunctional larynx after chemoradiation.

NECK DISSECTION

Given the risk of nodal metastasis in SCC of the head and neck, even in early T stages for many subsites, decision making regarding treatment of the neck is critical. In most cases, the cervical lymph nodes are treated via the same modality as the primary tumor. In the example of oral cavity cancer, neck dissection is performed alongside primary tumor extirpation and reconstruction. In the same vein, the radiation oncologist contours their treatment fields to incorporate draining lymphatic basins in oropharyngeal or laryngeal cancers selected for definitive radiation. Elective neck dissection or elective neck radiation is performed in the N0 neck when the risk of occult nodal metastasis is greater than 15%.

First described by George Crile in 1906, the radical neck dissection includes comprehensive removal of cervical lymphatics with sacrifice of the sternocleidomastoid (SCM) muscle, internal jugular vein, and spinal accessory nerve. The modified radical neck dissection removes levels I to V nodes with preservation of one or more of the aforementioned three

structures. Eventually, head and neck surgeons migrated to the concept of selective oncologic lymphadenectomy, based on tumor subsite drainage patterns, with decreased morbidity.[61] Known as selective neck dissection, careful but comprehensive removal of the at-risk nodal basins with preservation of normal structure is now the standard of care.[62] "Node plucking" or random sampling of neck nodes is inappropriate and should be avoided.

Head and neck patterns of lymphatic drainage are well described by Lindberg and Shah, and these studies allow for thoughtful subsite-based surgical planning.[63,64] As a general rule, oral cavity cancers require dissection of levels I–III, and possibly IV depending on nodal burden, while dissection of levels II to IV is performed for cancers of the oropharynx, larynx, and hypopharynx (**Fig. 41.10**). Level V is rarely involved except in NPC and some advanced skin cancers. Sentinel lymph node biopsy may be considered in early T-stage, clinically N0 oral cavity cancer, but does require technical experience, and one should be prepared to complete the neck dissection at the time of biopsy[65]; this technique is under investigation in OPC as well.

The boundaries of the "lateral neck dissection," encompassing levels II to IV, extend from the posterior belly of the digastric muscle's insertion on the mastoid where it meets with the SCM superiorly to the plane of the clavicle inferiorly, and from the posterior edge of the SCM to the strap muscles anteriorly. The depth of the dissection is defined by the cervical sensory rootlets in level III and the deep layer of deep cervical fascia that invests the deep musculature in level II (levator scapulae) and level IV (anterior and middle scalenes). Care should be taken to preserve the deep layer of deep cervical fascia in order to protect the phrenic nerve and brachial plexus. As the dissection completes inferiorly in level IV, attention must be paid to controlling the lymphatics as they course towards the thoracic duct on the left and the lymphatic duct on the right. When level IB is dissected, the marginal mandibular nerve must be identified and preserved to allow for safe resection of the submandibular gland and perifacial nodes. Level V neck dissection requires identification of the spinal accessory nerve just above Erb's point, followed by meticulous dissection to its entry into the trapezius. The nodes are then removed from the trapezius superiorly, the posterior edge

of the SCM anteriorly and the clavicle inferiorly, all while preserving the accessory nerve.

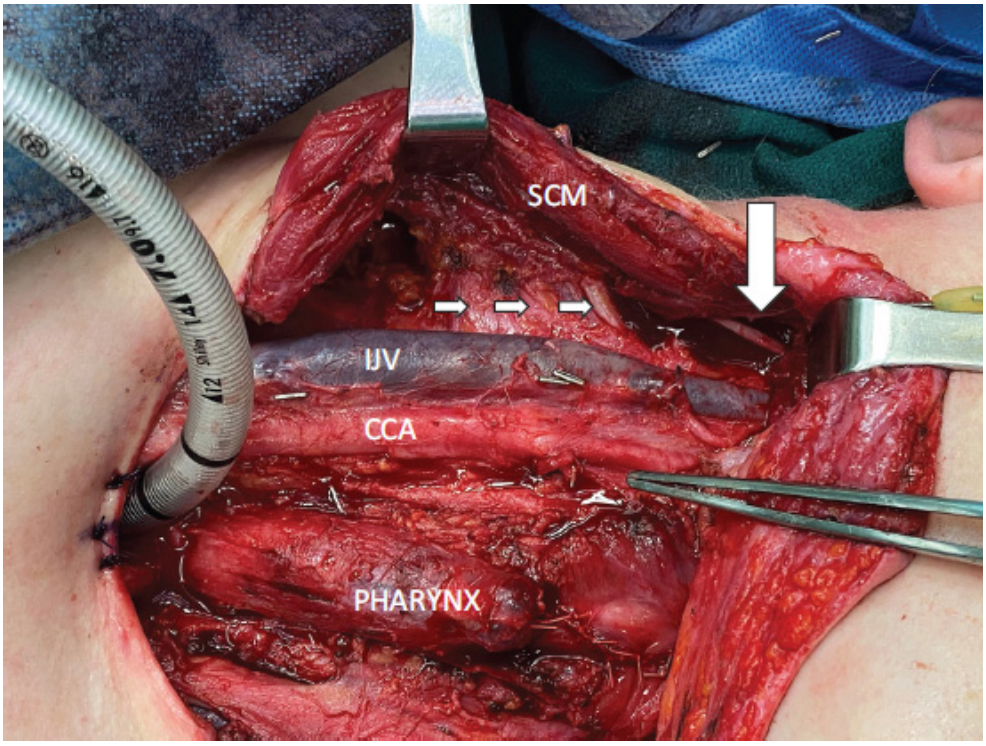

Figure 41.10 Intraoperative photograph demonstrating the right neck after performance of a selective, level II-IV neck dissection. Selective neck dissection is generally a low-morbidity procedure. Vital structures such as the internal jugular vein (IJV), common carotid artery (CCA), and spinal accessory nerve (*large arrow*) are carefully preserved. Also preserved and noted here are the sternocleidomastoid muscle (SCM), and cervical sensory rootlets (*small arrows*). The forceps is highlighting the external carotid artery. This patient also underwent laryngectomy for laryngeal cancer; the endotracheal tube is positioned in the permanent tracheostomy and the pharyngeal reconstruction is noted superior to the stoma (PHARYNX).

Table 41.10 Complications of Head and Neck Surgeries
Tonsillectomy/Adenoidectomy
Hemorrhage
Velopharyngeal insufficiency
Lingual neuropraxia
Endoscopic Sinus Surgery
Intranasal adhesions
Hyposmia
Epistaxis
Orbital injury/hematoma
Cerebrospinal fluid leak
Internal carotid artery injury
Parotidectomy
Great auricular nerve injury
Hematoma/seroma
Frey syndrome (gustatory facial sweating)
Facial nerve injury
Submandibular Gland Removal
Hematoma/seroma
Marginal mandibular nerve injury
Lingual nerve injury
Neck Dissection
Spinal accessory nerve injury
Marginal mandibular nerve injury
Hypoglossal nerve injury
Great vessel injury
Chyle leak
Total Laryngectomy
Pharyngocutaneous fistula
Parathyroid injury with hypocalcemia
Hypoglossal nerve injury
Esophageal stricture

COMPLICATIONS OF HEAD AND NECK SURGERY

Table 41.10 lists both common and rare complications of various head and neck procedures. Knowledge of these potential adverse outcomes, avoidance thereof, and disclosure of risk to patients during informed consent is crucial.

Section D: ESOPHAGUS

42

Esophageal Anatomy and Physiology and Gastroesophageal Reflux Disease

Yulia Zak, Micaela Esquivel, and Mary T. Hawn

Key Points

1. Esophageal anatomy: the cervical, thoracic, and abdominal esophagus each have distinct physiologic and pathologic differences.
2. The three layers of the esophageal wall: mucosa, submucosa, and muscularis propria. There is no serosa of the esophagus.
3. During a swallow, the lower esophageal sphincter (LES) relaxes at the initiation of the swallow and remains open until the peristaltic waves passes down through the body and through the LES.
4. The LES retains its competence as a barrier to gastric reflux by three factors: length, resting pressure, and position.
5. Diagnostic modalities of the esophagus include: endoscopy, fluoroscopy, manometry, ambulatory pH monitoring, and impedance planimetry.
6. Ambulatory pH monitoring remains the gold standard for confirming gastroesophageal reflux.
7. Endoluminal functional lumen imaging probe (EndoFLIP) is an impedance planimetry system used to evaluate real-time pressure, diameter, and distensibility of the esophagus and gastrointestinal sphincters.
8. Barrett esophagus is defined as having the presence of both endoscopic mucosal changes and microscopic findings of cardiac mucosa with goblet cells or intestinal metaplasia.
9. Preoperative functional assessment of the esophagus and LES are pivotal to determining which type of antireflux operation is most appropriate.
10. Surgical treatment options for gastroesophageal reflux disease (GERD) include total and partial fundoplication repair and magnetic sphincter augmentation. Concurrent hiatal hernia repair must be performed.
11. Two main endoscopic approaches for treating GERD include the Stretta procedure and transoral incisionless fundoplication (TIF

2.0).

ESOPHAGEAL ANATOMY AND FUNCTION

1 The esophagus is an approximately 25- to 30-cm muscular tube that connects the pharynx to the stomach. It starts at cricopharyngeus or upper esophageal sphincter (EUS) and travels from the superior mediastinum to the posterior mediastinum, ending at the lower esophageal sphincter (LES) as it enters to stomach (**Fig. 42.1**). The esophagus has specific anatomical relationships to critical structures and organs within the mediastinum, and requires a detailed knowledge to these relationships to not only workup esophageal pathology, but to also manage and expose the esophagus intraoperatively. The cervical, thoracic, and abdominal esophagus each have distinct physiologic and pathologic differences.

Cervical Esophagus

The cervical esophagus begins just below the cricopharyngeus muscle and is an apparent continuation of the inferior constrictor muscle of the pharynx. The cervical esophagus is the first 3 to 5 cm of the esophagus. A Zenker diverticulum occurs in the cervical esophagus at a natural area of weakening at Killian triangle. This is the space between the posterior left and right inferior constrictor muscles and immediately above the cricopharyngeus muscle (**Fig. 42.2**). The carotid sheaths lie laterally, and the recurrent laryngeal nerves lie in the grooves between the trachea and esophagus, important landmarks for thyroid and parathyroid operations. The cervical esophagus is more frequently approached surgically from the left due to the more variable course of the right recurrent laryngeal nerve. The trachea and larynx are immediately anterior to the cervical esophagus, and posteriorly is the prevertebral space, with the cervical esophagus immediately anterior to the vertebral bodies. The cervical esophagus passes from the retropharyngeal space superiorly to the posterior mediastinum superiorly, allowing mediastinitis from oropharyngeal infections. When evaluating x-ray or CT

imaging, the cervical esophagus is located from C6 to the lower border of T1.

Thoracic Esophagus

The thoracic esophagus begins at the thoracic inlet and is approximately 18 to 20 cm long (**Fig. 42.1**). In the upper thorax the esophagus is immediately posterior to the trachea, and just above the level of the tracheal bifurcation the esophagus lies to the right of the aortic arch and descending aorta. It then courses to the left as it passes behind the tracheal bifurcation and left main bronchus. The esophagus remains on the left in the lower thorax as it passes through the diaphragmatic hiatus. The thoracic esophagus can be constricted as it passes behind the aortic arch and left mainstem bronchus. The thoracic duct and azygos vein are both closely related to the esophagus and require particular consideration during esophagectomy (see Chapter 42).

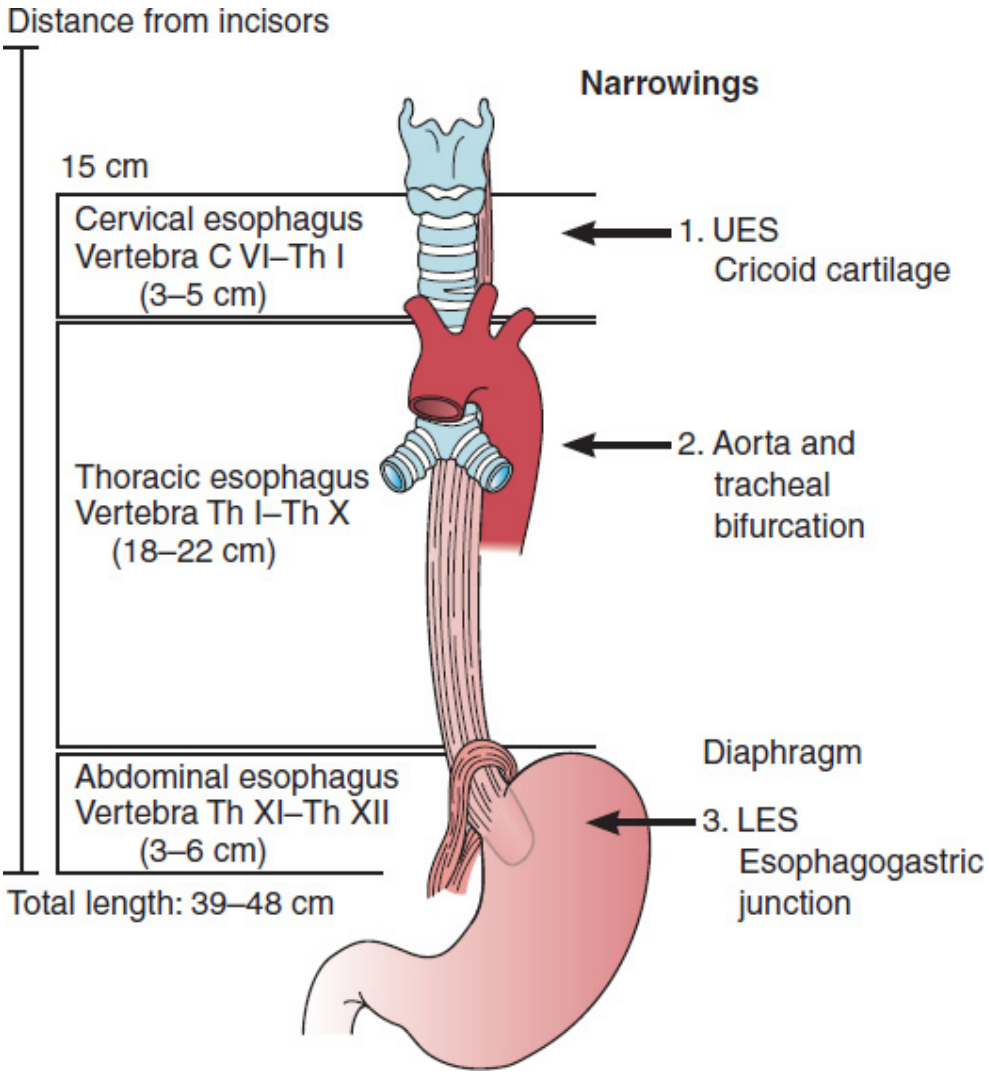

Figure 42.1 Anatomy of the esophagus.

Abdominal Esophagus

The abdominal esophagus starts at the diaphragmatic hiatus is approximately 3 to 6 cm in length and consists of the abdominal portion of the LES. The phrenoesophageal membrane surrounds this section of the esophagus circumferentially and courses to approximately 1 to 2 cm above the level of the hiatus at its upper leaf. Its lower leaf merges with the serosa of the stomach, and in this area there is a notable fat pad, marking the location of the gastroesophageal junction (GEJ) (**Fig. 42.3**).

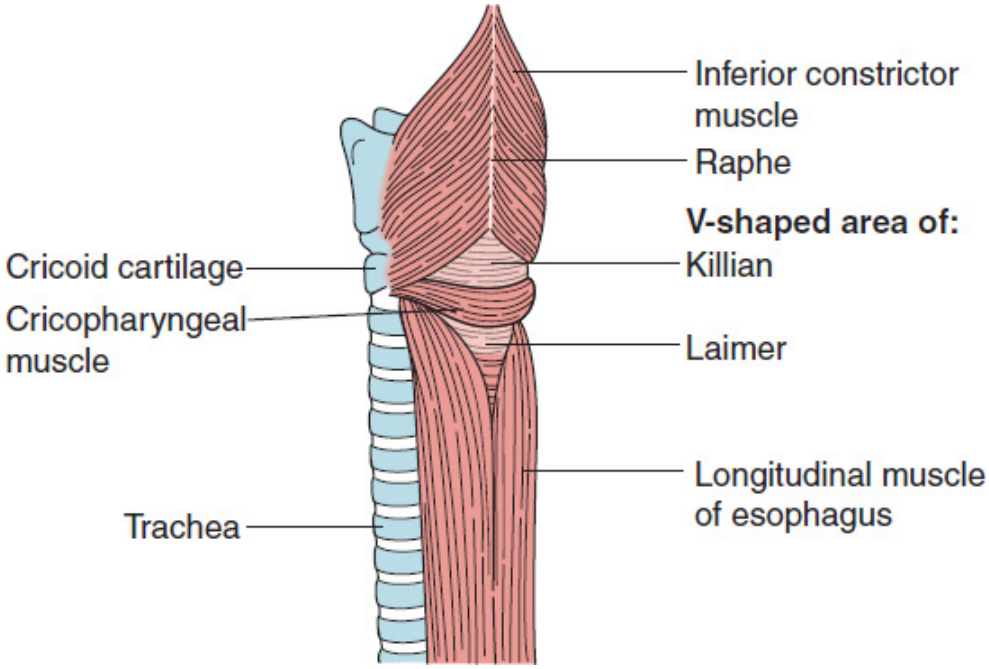

Figure 42.2 Posterior view of cervical esophagus.

The LES is a high pressure zone about 3 to 4 cm in length at the distal esophagus.[1] The LES has no visible macroscopic appearance changes on the inner mucosal lining or the outer surface of the esophagus. The left and right crura form the esophageal hiatus, and together they form a "sling" of diaphragmatic skeletal muscle around the esophagus.

These muscles originate from tendinous bands attached to the anterolateral surface of the first lumbar vertebra (**Fig. 42.4**). The median arcuate ligament, a tendinous arch, lies immediately anterior to the aorta, and attaches the crura posterior to the esophagus.

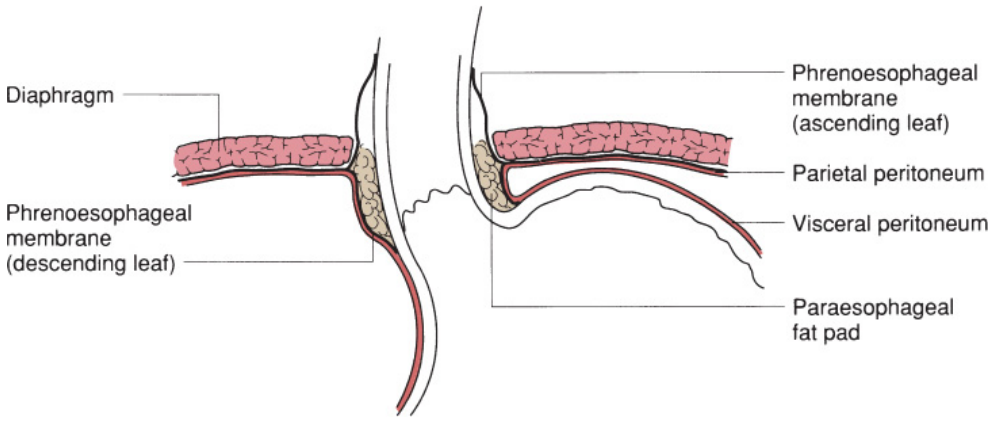

Figure 42.3 Anatomy of the esophageal hiatus and relationship to the phrenoesophageal membrane.

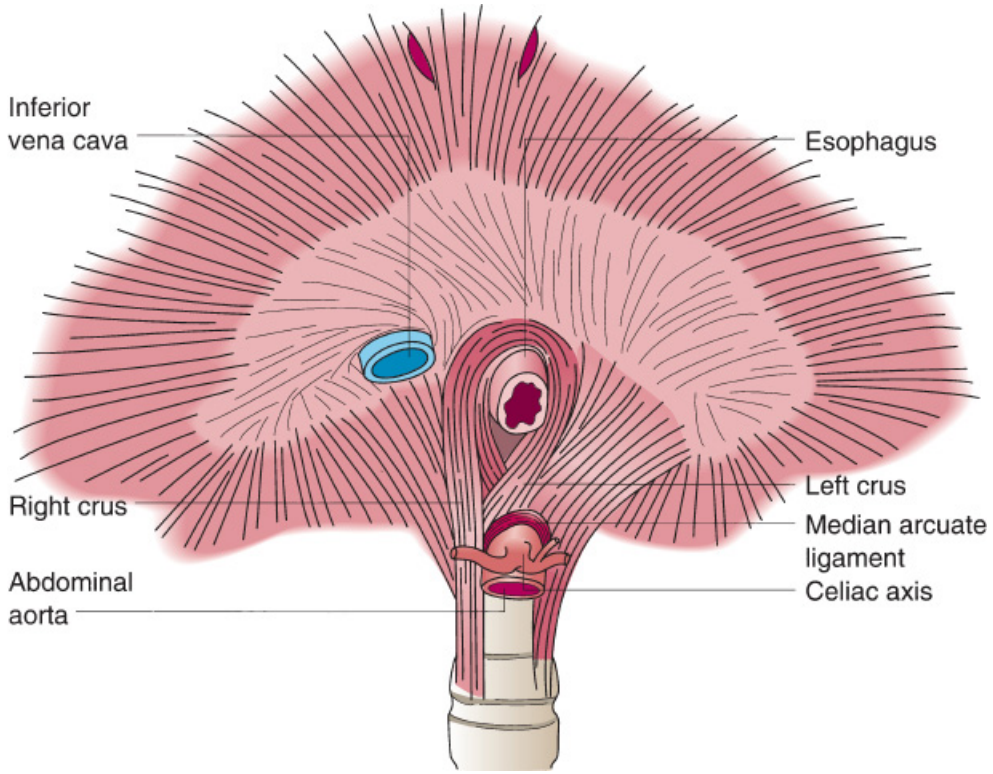

Figure 42.4 Inferior view of diaphragm and anatomy of the esophageal hiatus.

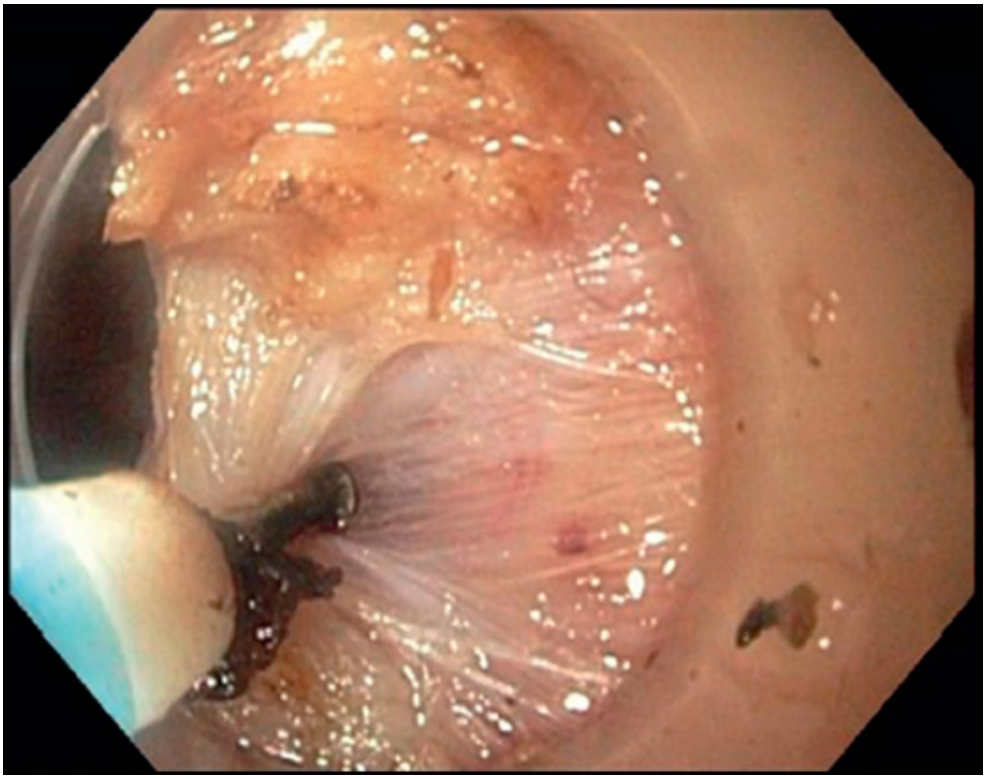

Figure 42.5 Endoscopic view of esophageal muscle layers during a peroral endoscopic myotomy (POEM) for achalasia. The endoscopic knife is lifting and cutting the circumferential circular muscle fibers, leaving the longitudinal muscle fibers intact.

Structure of the Esophageal Wall and Mucosa

2 The mucosa, submucosa, and muscularis propria are the three principal layers of the esophageal wall. In contrast to the rest of the gastrointestinal tract, there is no serosal layer, making the mucosa the strength layer of the esophagus. The mucosal layer is composed of nonkeratinized stratified squamous epithelium. The muscularis mucosa is located immediately below the basement membrane and above the submucosa. Tumors that penetrate this layer and into the submucosa carry a higher likelihood of lymph node metastases.[2] The submucosa contains the extensive lymphatic plexus throughout the esophagus, with collecting branches that penetrate the muscularis propria to connect with the thoracic duct and regional lymph nodes. This lymphatic web is the reason esophageal cancers can spread longitudinally and produce skip metastases.

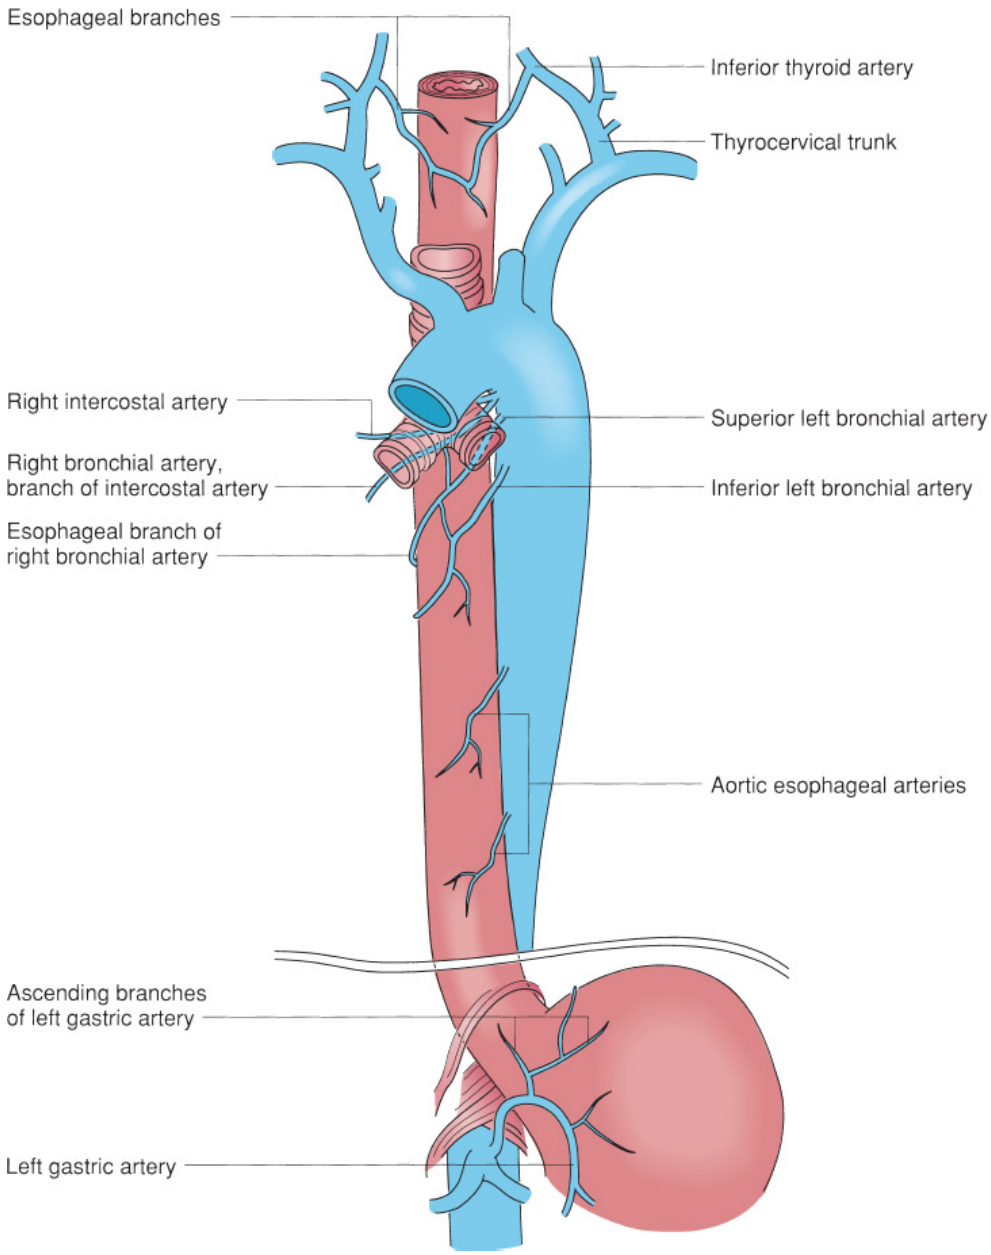

Figure 42.6 Arterial anatomy of the esophagus.

Intramucosal tumors have a rate of regional lymph node metastases of <5%, compared to 20% to 50% for submucosal tumors.[3] Additionally, the mucous glands of the esophagus are also located in the submucosal layer and drain into the esophageal lumen. The muscularis propria has an outer longitudinal muscle layer and a thicker inner circular muscle layer, composed of striated muscle in the uppermost portion that transitions to smooth muscle near the junction of the upper and middle third of the

esophagus. Both the muscle layers have a spiraling orientation, with the longitudinal rotating nearly 90 degrees as it courses down to the stomach (**Fig. 42.5**). This organization of the two muscle layers allows for the esophageal waves of peristalsis.

Blood Supply, Lymphatics, and Innervation

The cervical, thoracic, and abdominal portions of the esophagus each have a specific blood supply (**Fig. 42.6**):

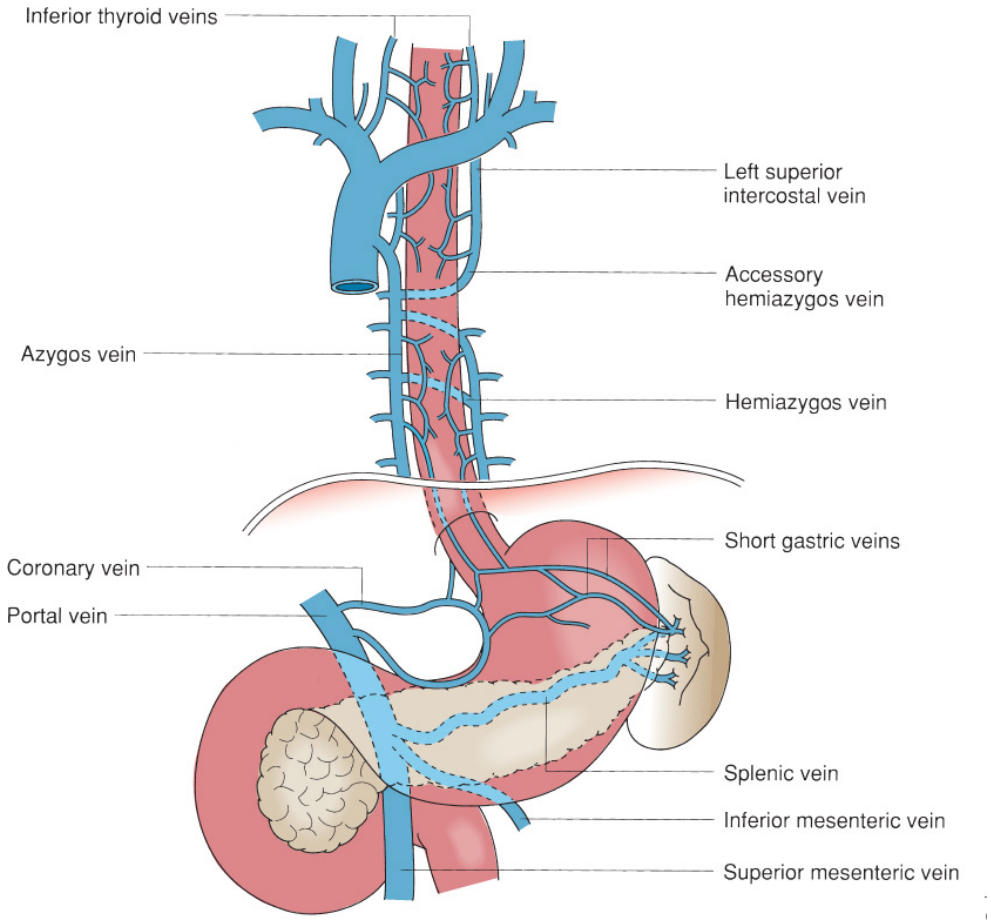

Figure 42.7 Venous anatomy of the esophagus.

- Cervical: inferior thyroid artery
- Thoracic: bronchial (frequently two right sided and left one left sided) and esophageal arteries (frequently two directly from the aorta)
- Abdominal: ascending branch of left gastric artery and bilateral inferior phrenic arteries

In the muscular layer of the esophagus these vessels branch extensively to make an extensive longitudinal vascular plexus, allowing for esophageal mobilization to the aortic arch with no ischemia.[4] The venous drainage of the esophagus is as follows (**Fig. 42.7**):

- Cervical: empties into inferior thyroid vein
- Thoracic: empties into the bronchial, azygos, and hemiazygos vein
- Abdominal: empties into the coronary vein

Esophageal lymphatic channels form a very dense plexus located in the submucosa, just below the muscularis mucosa. Lymph flows primarily in the longitudinal direction, and particularly in the thoracic esophagus, can travel a long distance prior to penetrating the muscle layer to enter the lymphatic channels and lymph nodes. It is for this reason that esophageal tumors in this region have a higher rate of skip metastases. See **Figure 42.8** for lymph channels and nodal drainage.[5] (See Chapter 42: Esophageal Tumors and Injury for more detail.)

The vagus nerve, or cranial nerve X, is the primary innervation of the pharynx and the esophagus. The right and left recurrent laryngeal nerve, branches from the vagus nerves, innervate the cricopharyngeal sphincter and cervical esophagus (**Fig. 42.9**). Injury to these nerves causes impaired movement of the vocal cords as well as impaired function of the cricopharyngeal sphincter and cervical esophageal motility, thus significantly increasing aspiration risk during swallowing. The left recurrent laryngeal nerve and both vagus nerves innervate the upper thoracic esophagus. As the right and left vagus nerves descend into the mediastinum they lie immediately on the outer surface of the esophagus, and rotate in a counter-clockwise fashion. Thus, the left vagus nerve rotates to be anterior vagal trunk, while the right rotates to become posterior vagal trunk.[6] Esophageal and cardiac symptoms are similar, as they share the same afferent visceral sensory pathways, and end in the first four segments of the thoracic spinal cord.

PHYSIOLOGY

The Swallowing Mechanism

Swallowing can be intentional or reflexive secondary to stimulation of the tonsillar pillars or the posterolateral walls of the hypopharynx. The glossopharyngeal nerves and the superior laryngeal branches of the vagal nerves are the afferent sensory nerves of the pharynx. Once these are simulated, the swallowing center (or the medulla) then triggers neurons via cranial nerves V, VII, X, XI, and XII and the motor neurons of C1 through C3 to complete a swallow. This swallowing impulse follows an incredibly coordinated pattern that once started, cannot stop, and lasts for about 0.5 seconds. Swallowing occurs in six distinct steps (**Fig. 42.10**):

1. Elevation of tongue
2. Posterior movement of tongue (propels food bolus into hypopharynx)
3. Elevation of soft palate (this closes the passage between the oropharynx and nasopharynx)
4. Elevation and anterior movement of hyoid
5. Elevation and anterior movement of larynx (thus enlarging the retropharyngeal space)
6. Tilting of epiglottis (thus closing the laryngeal inlet to prevent aspiration)

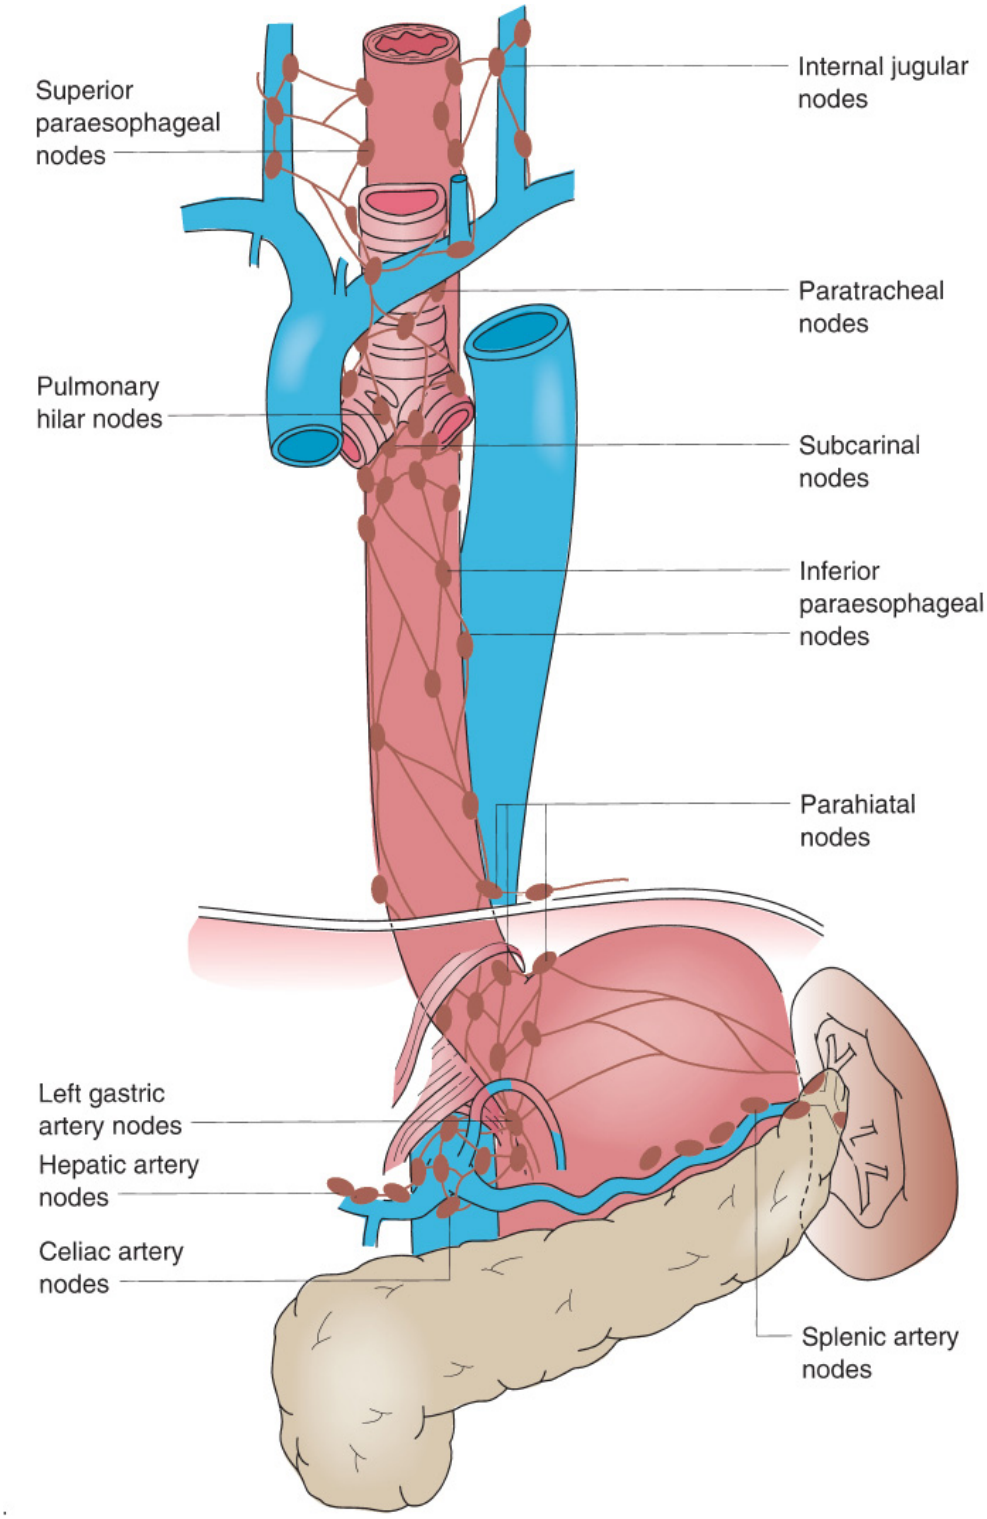

Figure 42.8 Lymphatic anatomy of the esophagus.

Pressure gradients starting in the hypopharynx helps propel the movement of food from the hypopharynx into the esophagus as the cricopharyngeus, or

EUS, relaxes.

The timing of relaxation of the UES and compliance of the cervical esophagus is pivotal to accepting the bolus. Deviations from this function may result in pharyngeal dysphagia. Step 5 above, the elevation of the larynx, pulls the hyoid bone by attached muscles and pulls the EUS open at the same time the EUS muscle is relaxing. The relaxation of the EUS is a neurologically mediated reflex that results in decreased tone of the cricopharyngeal muscle. The EUS then closes within half a second after the swallow is initiated, and the postrelaxation pressure is nearly two times the resting pressure (of 30 mm Hg). This high closing pressure of the EUS prevents reflux back into the pharynx. This postrelaxation contraction flows down the esophagus to form a peristaltic wave (**Fig. 42.11**). At the conclusion of a swallow, the EUS returns to its baseline resting pressure.

When a swallow is initiated, the longitudinal muscles of the esophagus contract, or shorten, to then enlarge the lumen of the esophagus to better accept a bolus. The circular smooth muscle contraction is responsible for the peristaltic wave. The 3 peristaltic waves produce an occlusive pressure of 30 to 120 mm Hg. The rise and fall of these contracts can engage one point in the esophagus for 3 to 5 seconds, as the wave rising peaks by 1 second, maintains peak pressure for 0.5 seconds, and subsides in about 1.5 seconds.[7,8] After the initiation of a swallow, the peak of the primary peristaltic contraction waves down the esophagus 2 to 4 cm per second, and will reach the distal esophagus about 9 seconds later. The LES will relax at the start of the peristaltic wave and will remain open and relax until the wave passes through the LES. Similar to the UES, there is then a distinct postrelaxation contraction of the LES. This esophageal wave will be reproduced with a consecutive swallow 20 seconds after the first, though if a swallow occurs sooner, the esophagus will be functionally unresponsive (deglutitive inhibition).

These peristaltic contractions must have sufficient amplitude or pressure to effectively occlude the esophageal lumen and be organized to successfully propel a bolus distal toward the stomach. There are three primary categories that cause impaired peristalsis. The first is a result of a neural abnormality resulting in defective organization of the peristaltic wave, resulting in a primary motility disorder, such a diffuse esophageal spasm. The second is noted by a decrease in the amplitude with maintenance of peristalsis, most

frequently due to muscle damage and fibrosis, often seen in longstanding gastroesophageal reflux disease (GERD) or connective tissue disorders (e.g., scleroderma). The third is caused by altered anatomy of the esophagus, most often seen with large hiatal hernias where the distal esophagus is not anchored.

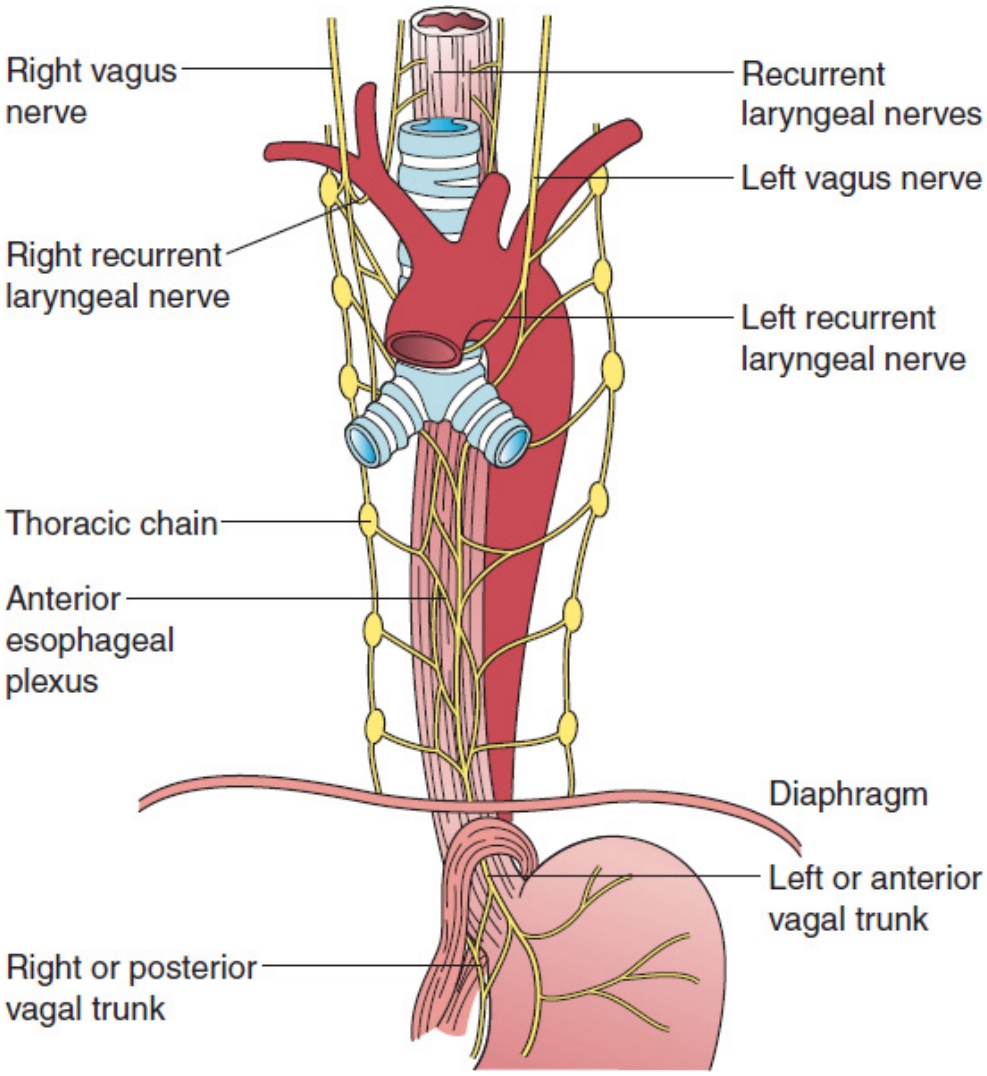

Figure 42.9 Relationship of the esophagus to the vagus nerves and their branches.

The Gastroesophageal Barrier: Lower Esophageal Sphincter

The LES functions as the barrier that prevents the esophageal mucosa from injury from refluxed gastric contents. Failure of the LES to open, or relax

appropriately, prevents the esophagus from effectively pushing a bolus into the stomach and if severe, can lead to achalasia. Failure of the LES to close effectively can lead to GERD, or increased exposure of the esophageal squamous epithelium to acidic gastric contents. Though the LES has no anatomical landmarks endoscopically, on manometry, it can be localized due to an area of pressure over the baseline gastric pressure. At baseline it is a "high-pressure zone" except during swallowing to allow a bolus to pass, or during belching to allow gas to be released. Passage of gastric juice from the higher-pressure area of the stomach to the lower pressure area of the esophagus is prevented due to the barrier of a competent LES. In early GERD, this is often due to a transient loss of the barrier, while in advanced GERD it is frequently a permanent loss of LES barrier.[9]

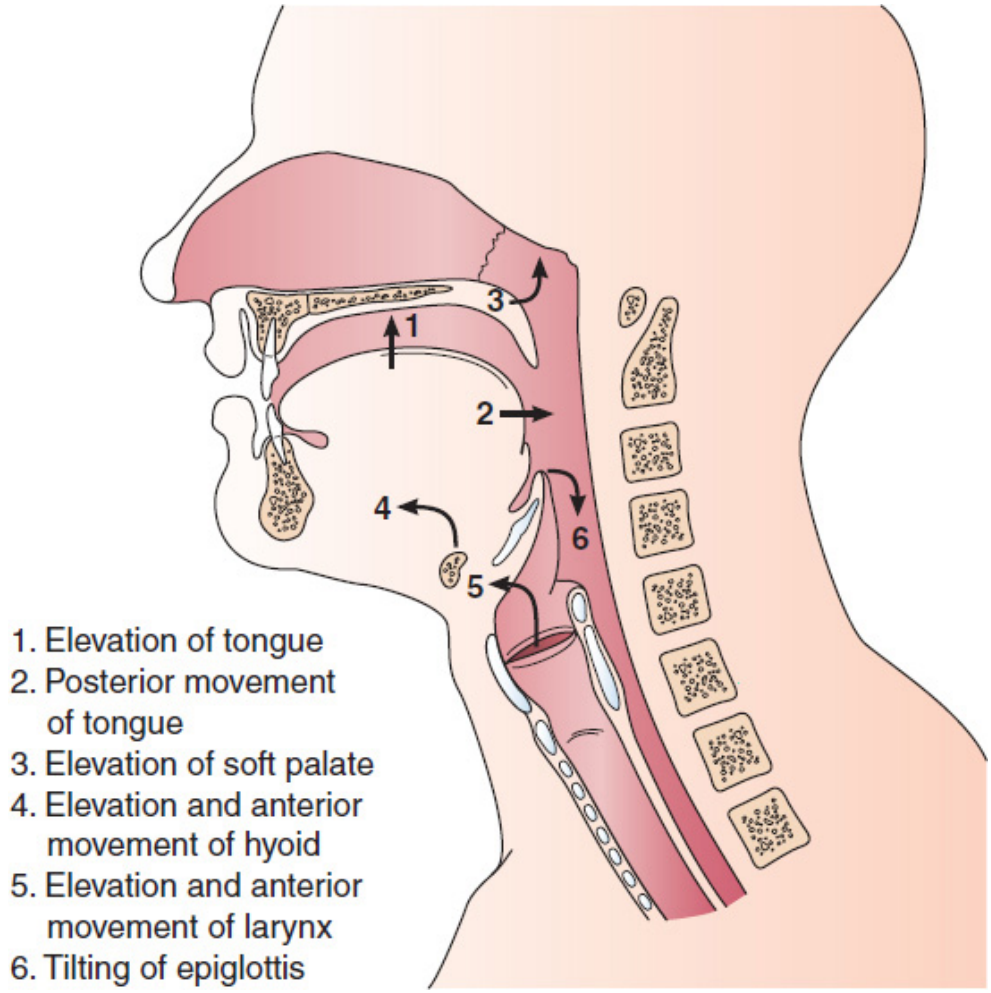

Figure 42.10 Overview of the act of swallowing.

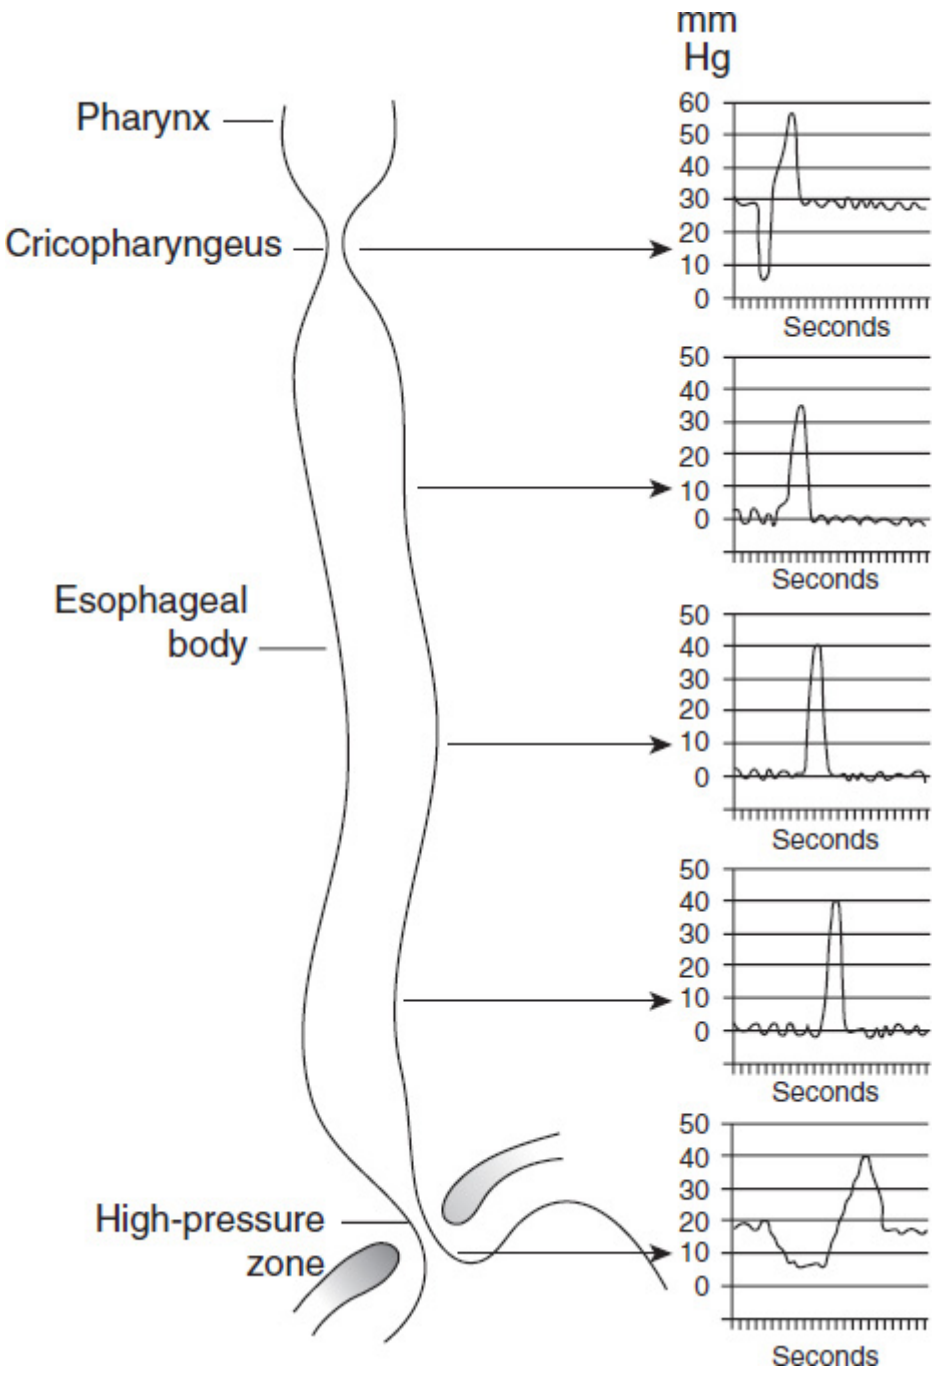

Figure 42.11 Overview of esophageal body peristalsis. (From Waters PF, DeMeester TR. Foregut motor disorders and their surgical management. *Med Clin North Am* 1981;65[6]:1235–1268, with permission.)

There are three primary characteristics of the LES to allow it to maintain its function, even with high intragastric and intra-abdominal pressures. These LES characteristics include:

1. 4 Length
2. Pressure
3. Position

The LES length and pressure work closely together to maintain LES effectiveness. The shorter the LES length, the higher the LES pressure must be to maintain competence.[10] Additionally, the impact of a normal LES pressure can be negated by a short LES length and the impact of a normal LES length can be negated by a low LES pressure (**Fig. 42.12**).

The LES shortens due to gastric filling, as the terminal esophageal length is reduced by the expanding fundus—the greater the gastric volume, the shorter the LES length (**Fig. 42.13**).[11] Overeating causes excessive gastric distension which in turn critically shortens the LES to the point of impairing its ability to close. The LES pressure then abruptly drops and reflux occurs (**Fig. 42.14**).[12] Additionally, if the LES is already permanently shortened, even normal-sized meals can cause postprandial reflux. The abnormal anatomy of the cardia, such as a sliding hiatal hernia, also impacts the ease in which the LES is shortened due to gastric distension. Less gastric distension is required to open the LES barrier in patients with a hiatal hernia.[13] The funnel or dome shape of a hiatal hernia changes the wall tension and allow the barrier to be pulled open more easily, accounting for the frequent association of hiatal hernia with GERD.[14] The position of the LES is also pivotal to its function. A segment of the LES is intra-abdominal and exposed to the higher intra-abdominal pressures. If these pressure were only applied to the stomach, the barrier of the LES would be easily overcome (and therefore reflux would occur) if the intra-abdominal LES were not also experiencing those same pressures.[15] A minimum of 1 cm of abdominal LES is critical to its proper function.

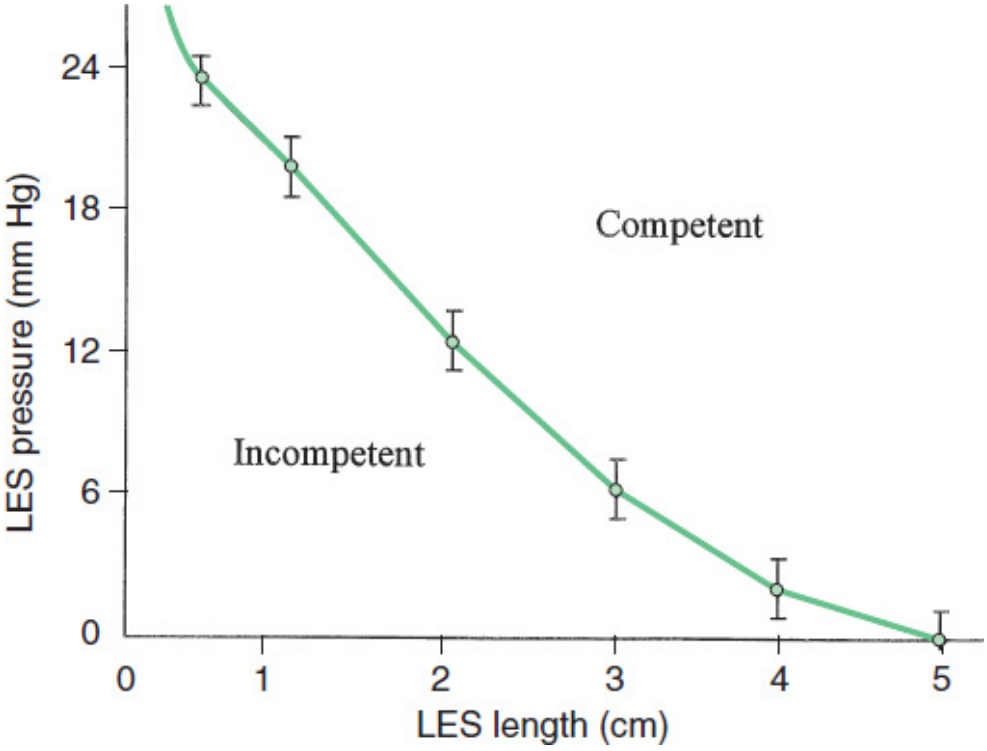

Figure 42.12 Relationship of the length and pressure of the lower esophageal sphincter in maintaining competence of the gastroesophageal barrier.

When LES length, pressure, and position are not adequate, this will lead to an incompetent LES. In these cases, even when fasting continued reflux can occur leading to chronic esophageal injury (**Fig. 42.15**).

5 EVALUATION OF ESOPHAGEAL FUNCTION

Thorough assessment of esophageal anatomy and function is imperative to both medical and surgical management of esophageal disease. There are four core diagnostic tests commonly utilized, these include: upper endoscopy, barium esophagram, ambulatory pH monitoring, and high-resolution esophageal manometry. We also recommend esophageal impedance planimetry (endoluminal functional lumen imaging probe or Endoflip) for assessment of esophageal distensibility and function.

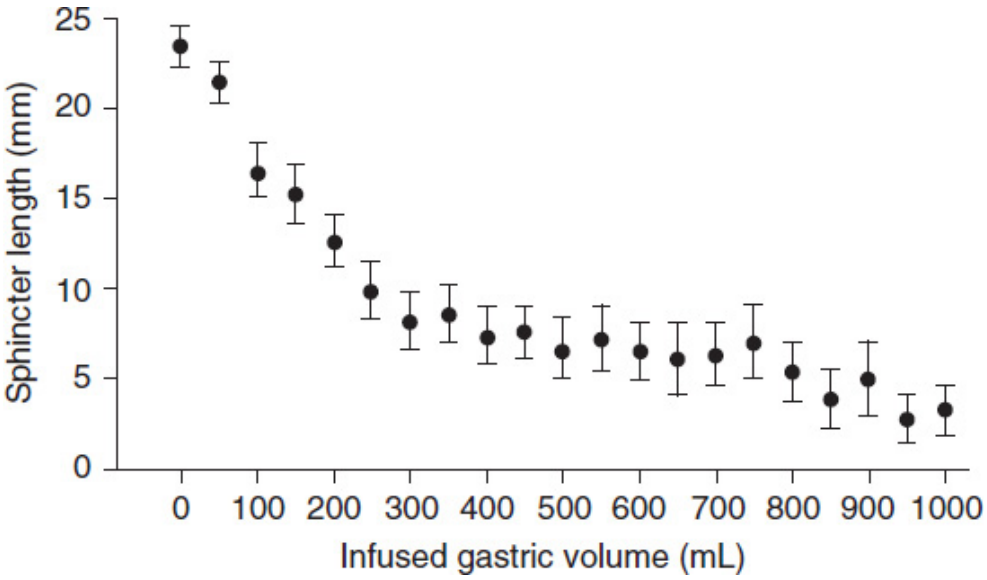

Figure 42.13 Effect of increasing gastric volume on the shortening of the lower esophageal sphincter length. As the stomach expands, the gastric body takes up the inferior aspect of the sphincter causing its length to shorten. (From Mason RJ, Lund RJ, DeMeester TR, et al. Nissen fundoplication prevents shortening of the sphincter during gastric distention. *Arch Surg* 1997;132[7]:719–724; discussion 724–726, with permission.)

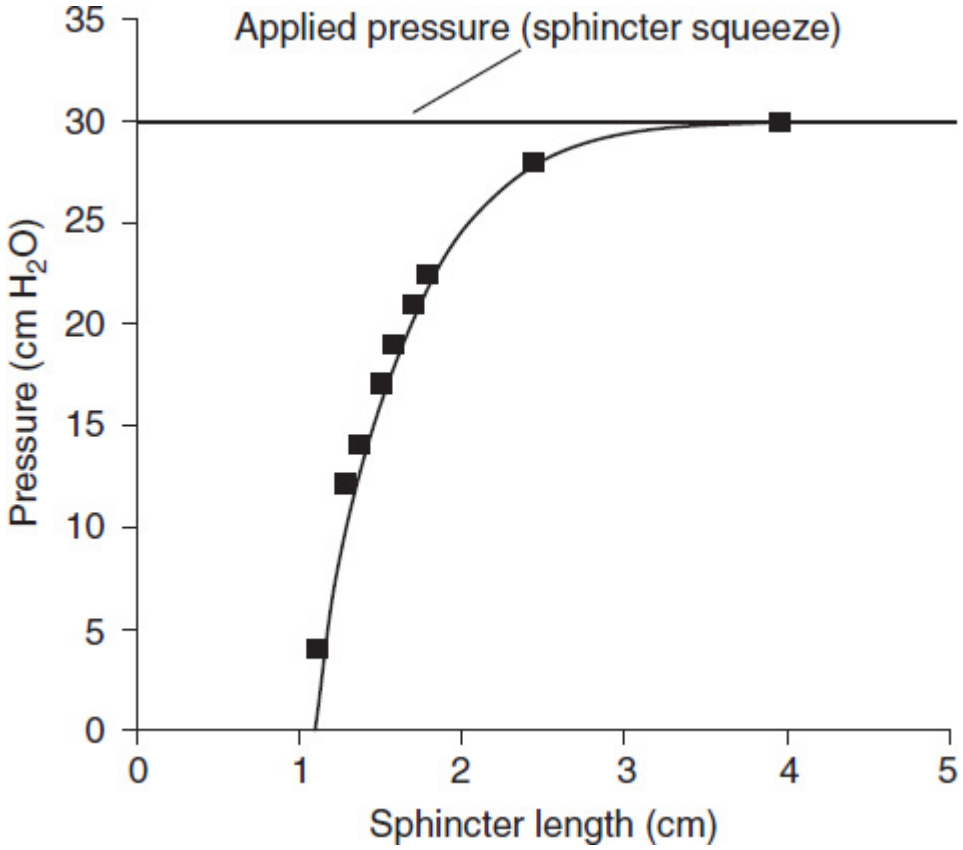

Figure 42.14 Representation of the loss of competence of the lower esophageal sphincter with shortening of its length. As a critical length is reached, there is a precipitous drop in sphincter pressure reflecting loss of competence. (From Pettersson GB, Bombeck CT, Nyhus LM. The lower esophageal sphincter: mechanisms of opening and closure. *Surgery* 1980;88[2]:307–314, with permission.)

Upper Endoscopy

An esophagogastroduodenoscopy (EGD) is indicated in every patient being evaluated for GERD, and is a critical physical examination of the foregut. A thorough visual evaluation of the entire foregut is necessary with particular attention to the location and appearance of the squamocolumnar junction. This junction is noted by the transition of the lighter squamous epithelium and the darker rose (or velvet)-colored columnar epithelium. Narrow band imaging (NBI) is particularly helpful in distinguishing these two cellular types. If erosive esophagitis is encountered, application of the Los Angeles classification system should be applied (**Table 42.1**).[16]

Table 42.1 Modified Los Angeles Classification of Esophagitis

Grade	Lesion
A	One (or more) mucosal break of longer than 5 mm that does not extend between the tops of two mucosal folds
B	One (or more) mucosal break more than 5 mm long that does not extend between the tops of two mucosal folds
C	One (or more) mucosal break that is continuous between the tops of two or more mucosal folds but that involves <75% of the circumference
D	One (or more) mucosal break that involves at least 75% of the esophageal circumference

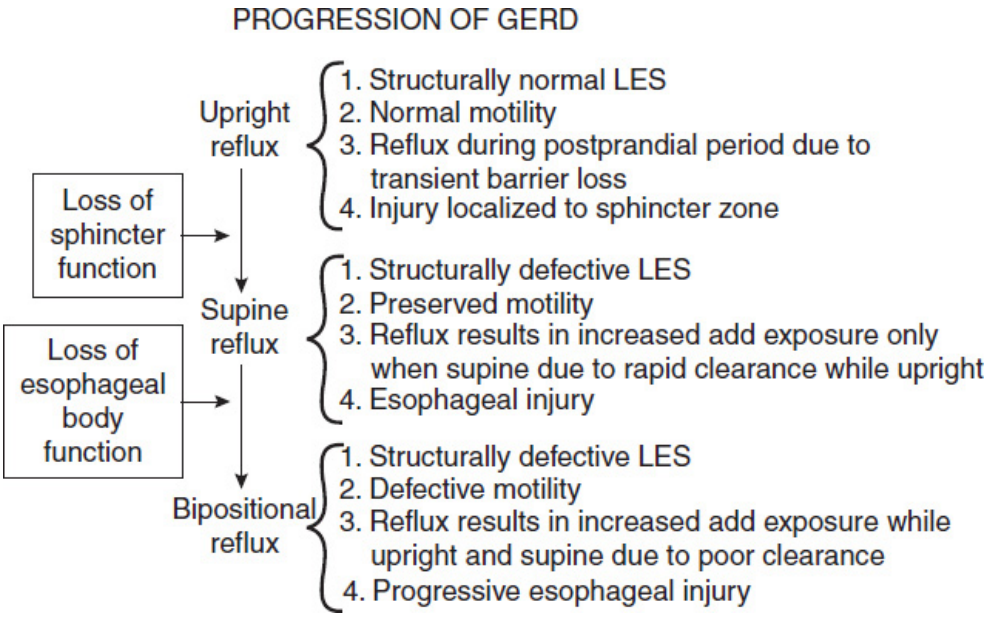

Figure 42.15 Overview of the progressive nature of GERD and the effect of the lower esophageal sphincter and esophageal body on reflux in the upright and supine positions.

If columnar metaplasia is observed during endoscopy, this raises a concern for Barrett esophagus and the area must be biopsied (four-quadrant every 2 cm of columnar metaplasia). The cardia and GEJ should be visualized for abnormalities by retroflexion as this will also assess the competency of the gastroesophageal barrier. The Hill grading system is commonly used to categorize the appearance and competence of the gastroesophageal barrier (**Fig. 42.16**). The grading is I to IV, a higher grade with worsening architecture and thus higher likelihood of acid exposure through the GEJ.[17]

A hiatal hernia is seen when there is a separation of the GEJ from the crura, and by definition is present when a minimum of 2 cm of rugal folds are above the pinch of the diaphragmatic crura. GERD is frequently associated with a notable sliding hiatal hernia. It is important to assess for presence of gastritis or Cameron ulcers within the hiatal hernia. During the removal of the endoscope it is important to again slowly examine the esophagus. The larynx and vocal cords should also be visualized to assess inflammation and movement, as chronic acid reflux can injure these structures.

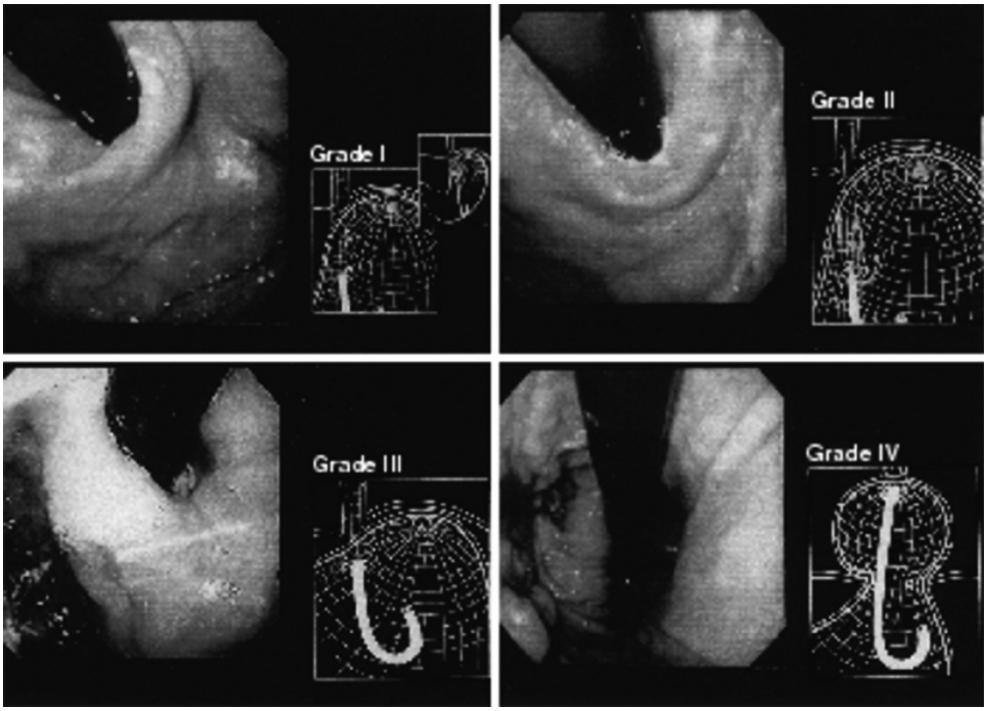

Figure 42.16 Endoscopic grading of the gastroesophageal junction during the retroflex view. (From Oberg S, Peters JH, DeMeester TR, et al. Endoscopic grading of the gastroesophageal valve in patients with symptoms of gastroesophageal reflux disease [GERD]. *Surg Endosc* 1999;13(12):1184–1188, with permission.)

Radiologic Evaluation

A barium esophagram is one of the first critical diagnostic tests to assess the anatomy and function of the esophagus and upper stomach. Historically, the barium esophagram has been used as the "road map" of the esophagus as it can provide real-time visualization of bolus transport, esophageal motility, size of hiatal hernia, and structural abnormalities. The first part of the esophagram includes an assessment of the UES and pharynx in the upright position, to evaluate the coordination of pharyngeal transit. Bolus transit on esophagram complements information from esophageal manometry and clearance can be assessed with both liquids and solids (tablet), and is done in the upright and supine positions. A primary peristaltic wave strips the bolus through the esophagus and into the stomach during a normal swallow and adequate contractility is shown by full lumen approximation. Disorders of esophageal motility result in a segmented appearance of barium within the esophagus. This can be due to disorganized peristalsis or simultaneous

esophageal contraction, resulting in a beading or corkscrew appearance. A 13-mm barium tablet is a useful proxy to determine how solid material transits through the esophagus, and assists in identifying areas of clinically significant narrowing as well as functional obstructions, as luminal narrowing below 13 mm frequently results in dysphagia.

Hiatal hernias are best visualized in the prone position as the increased intra-abdominal pressure pushes the hernia above the diaphragm. Hiatal hernias >5 cm or hernias that do not reduce are more likely to be associated with chronic reflux and esophageal foreshortening. Though reflux of contrast can be seen on UGI, it is not always consistent with a true diagnosis of reflux. Evoked reflux and spontaneous reflux to the distal esophagus are not correlated to a positive pH, though spontaneous reflux to the thoracic inlet more frequently does correlate. Additionally, the absence of reflux seen on an UGI does not exclude the disease.

Esophageal Manometry

High-resolution manometry (HRM) provides a detailed assessment of esophageal contractility, coordination, and sphincter function. The most common HRM system utilizes 36 circumferential sensors spaced at 1-cm intervals, with each transducer able to detect pressure over a length of 25 mm in 12 radially dispersed sectors (**Fig. 42.17**).

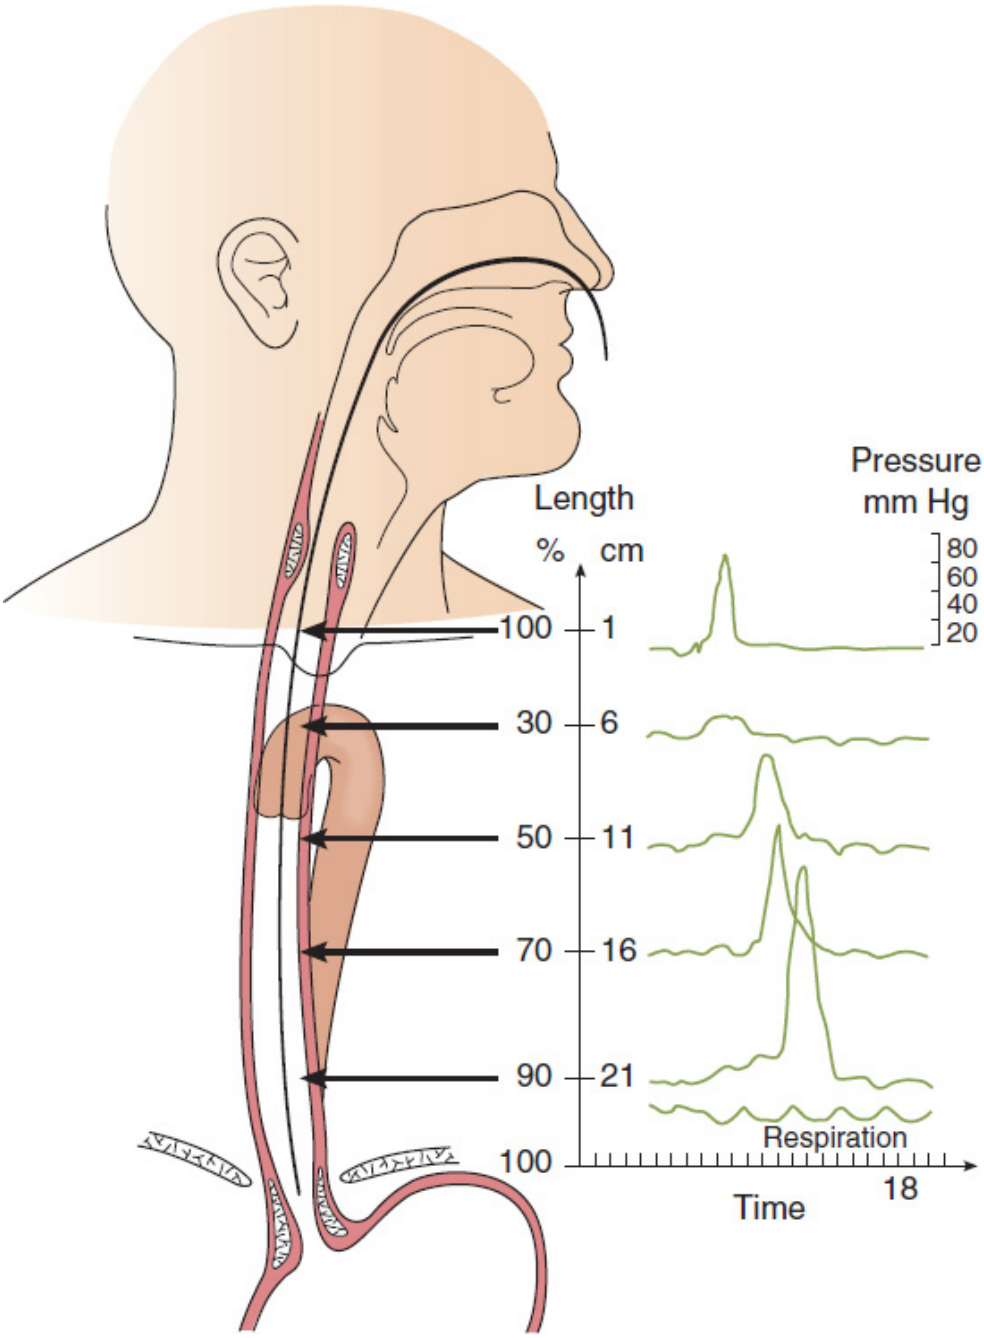

Figure 42.17 Illustration of the position of a five-channel esophageal motility catheter during the esophageal body portion of the study.

The pressures at each sector are averaged, providing a large amount of data that is then converted via a topographic plotting algorithm to a Clouse plot, or esophageal pressure topography (**Fig. 42.18**). HRM is generally performed by passing a lubricated catheter through the nasopharynx, into the esophagus and stomach, though endoscopic guidance is recommended in

large paraesophageal hernias and achalasia to confirm no coiling within the esophagus. The patient then completes 10 swallows (supine with head elevated), with at least 30 seconds between swallows (to prevent deglutitive inhibition) and quiet breathing between for better assessment of baseline resting pressures of UES and LES. The full HRM assessment includes contraction amplitude, waveform, esophageal body coordination, UES function, structural characteristics of the LES, and LES relaxation.

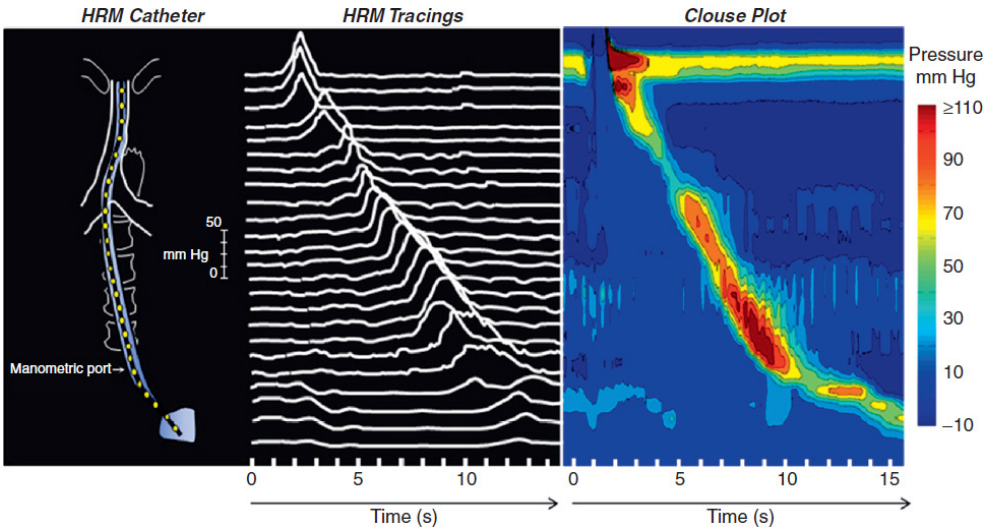

Figure 42.18 High-resolution manometry with line tracings and converted pressure topography or Clouse plot view. (From Pandalfino JE, Roman S. High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thor Surg Clin* 2011;21[4]:465–475, with permission.)

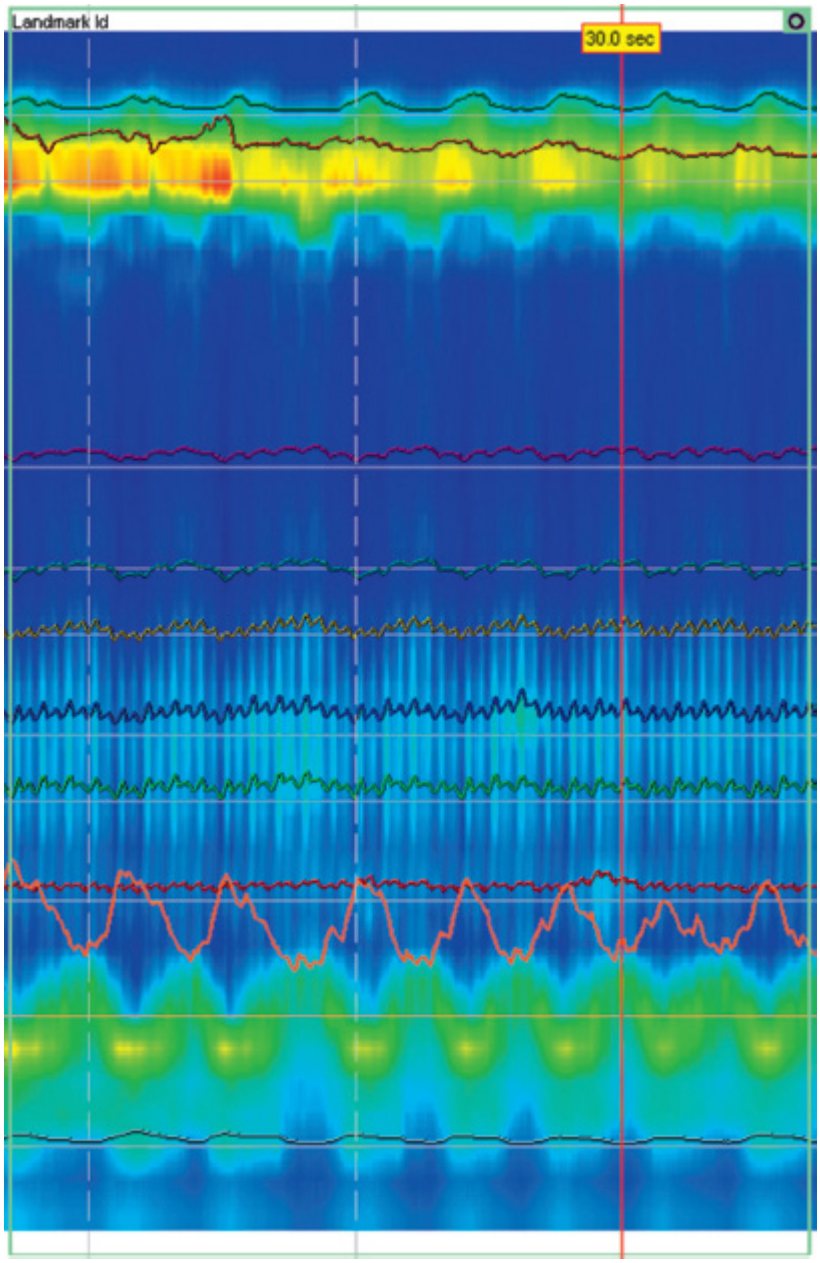

Figure 42.19 High-resolution esophageal manometry showing the landmark frame. The upper and lower esophageal sphincters are observed at the **top** and **bottom** of the frame, respectively. Resting pressure and length measurements of the sphincters can be determined in this portion of the study while the patient is refraining from any swallowing. (From Pandalfino JE, Roman S. High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thor Surg Clin* 2011;21(4):465–475, with permission.)

HRM is indicated in symptoms of dysphagia, odynophagia, regurgitation, and heartburn. HRM plays a critical role in confirming and differentiating

primary esophageal motility disorders including diffuse esophageal spasm, nutcracker esophagus, achalasia, and a hypertensive LES. Systemic diseases (including scleroderma, polymyositis, and dermatomyositis) as well as long-standing GERD can result in ineffective esophageal motility (IEM). HRM can identify a noncompetent LES and determine its location for placement of an ambulatory pH monitor.

Lower Esophageal Sphincter

The LES is initially assessed with the landmark frame, which lasts for 30 seconds without swallowing and is calculated as an average over this time period (**Fig. 42.19**). The proximal border of the LES is where the sphincter pressures equals the esophageal baseline, and the distal border is where its resting pressure rises above the gastric baseline.[18]

Utilizing the HRM technique, expected LES measurements compared to noncompetent LES measurements are shown in **Table 42.2**.

Generally, the LES pressure drops to the baseline gastric pressure immediately after a swallow is initiated, and will remain open and relaxed until the peristaltic wave reaches the stomach. After the passage of the bolus, the postrelaxation contraction of the LES is observed to ensure LES closure and prevention of reflux. The LES relaxation is assessed by the integrated relaxation pressure (IRP), which is a 4-second time period between initiation of swallow and when peristalsis reaches the LES. An IRP over 15 mm Hg is elevated and can result in resistance of flow through the LES.

Table 42.2 Normal and Abnormal Lower Esophageal Sphincter Measurements on HRM

Overall Length	**2.7–4.8 cm**	**<2 cm**
Pressure	13–43 mm Hg	<6 mm Hg

Esophageal Body Motility

HRM assesses esophageal body motility by quantifying contraction amplitude, duration, velocity, slope, and even morphology (type of peak of amplitude). Pathologic gaps in peristalsis occur if there are >2 cm long

breaks in isobaric contour along the esophagus or any break at the LES. The distal contractile integral (DCI) provides a global assessment of esophageal contractile function, and calculated by: amplitude (mm Hg) duration (sec) × length (cm). Normal values for DCI range between 500 and 4,300 mm Hg · s · cm (**Fig. 42.20**). Current clinical practice recommends a DCI >500 to prevent postoperative dysphagia after an antireflux procedure, as a pressure above that is required to overcome the resistance produced from such a procedure.

Ambulatory pH Monitoring

The development of ambulatory pH monitoring was pivotal to obtaining 6 an objective assessment of acid exposure in a continuous setting, and can correlate symptoms to high acid exposure.[19] It has the highest sensitivity and specificity for confirming the diagnosis of GERD and is indicated in patients with GERD who require ongoing therapy or have atypical symptoms of GERD. The test is performed in two ways, one with a transnasal catheter and one with an endoscopically placed capsule (Bravo capsule, Medtronic Inc., Minneapolis, MN).[20] Both are positioned ~5 cm above the upper border of the LES. Both communicate with a portable device that is kept with the patient and records the pH continuously for a set period of time, often 24, 48, or even 96 hours. This test is ideally done off acid suppression therapy; 2 weeks for proton pump inhibitors (PPIs), and 2 days for H_2 blockers. During the study the patient is asked to remain upright during the day and to avoid highly acidic or basic foods which can impact the reliability of the results. The patient is to note timing of meals, timing of sleep and wake, as well as document the presence and duration of symptoms. The pH tracing can be seen in **Figure 42.21**. Several key measurements include percentage of time the pH is less than 4, the number of reflux episodes and their duration.[21] DeMeester and Johnson developed a composite scoring system that assesses six different components of the pH measurements into a single score, the DeMeester Score. These include: number of refluxes per day, number of long refluxes per day (over 5 minutes), longest reflux, total time below pH of 4.0, upright time below pH 4.0, and supine time below pH 4.0. A normal DeMeester Score is <14.7, and the normal total time spent in reflux is

<4%.[20,22] The ambulatory pH study is the most reliable way to quantitively measure the degree and pattern and of esophageal acid exposure, which can have an impact on the decision to operate for GERD.

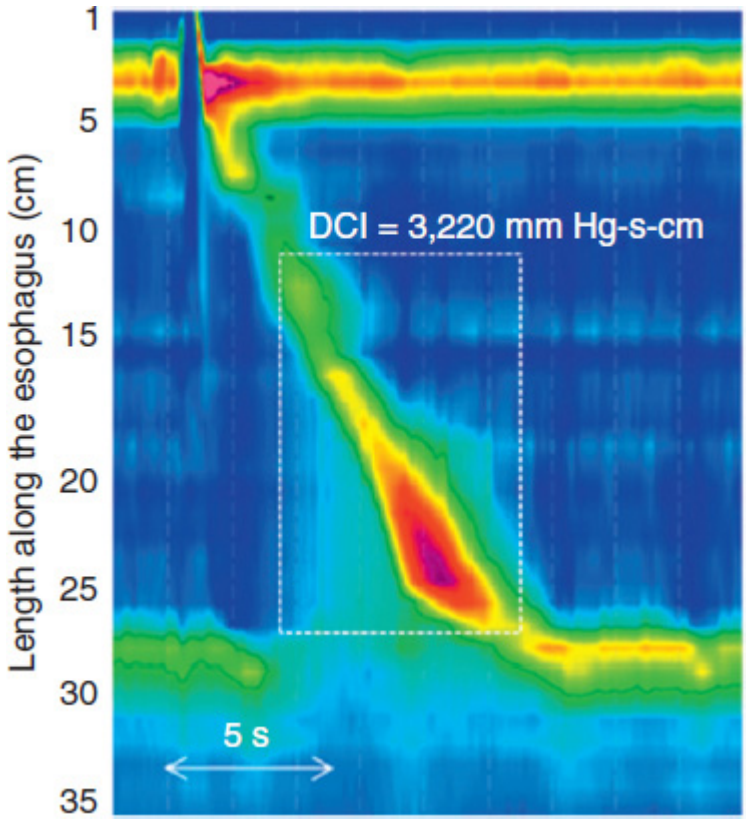

Figure 42.20 High-resolution esophageal manometry during a swallow. The initiation of swallowing is reflected by transient relaxation of the UES followed by a peristaltic pressure wave progressing down the esophageal body. Note the LES relaxes at the initiation of swallowing. A characteristic peristaltic break is observed in the upper third of the esophageal body at the transition zone between the striated and smooth muscle. (From Pandalfino JE, Roman S. High-resolution manometry: an atlas of esophageal motility disorders and findings of GERD using esophageal pressure topography. *Thor Surg Clin* 2011;21[4]:465–475, with permission.)

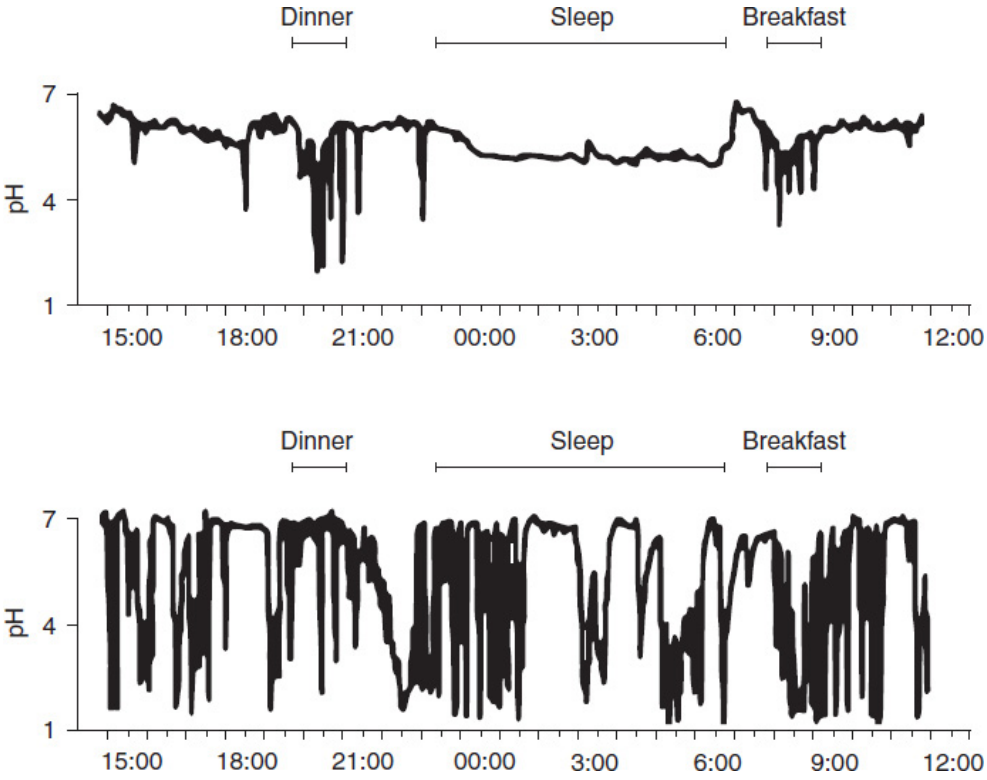

Figure 42.21 Dual-probe 24-hour pH tracing of patient. The top tracing is of the pH sensor located below the upper esophageal sphincter and the bottom tracing is of the pH sensor located 5 cm above the top of the lower esophageal sphincter. Episodes of pH <4 are considered acid events. In this example, the patient has abnormal acid exposure in the distal esophagus with several reflux events extending into the proximal esophagus.

Multichannel Impedance Testing

Multichannel intraluminal impedance (MII) uses a catheter with multiple pressure and impedance sensors separated by 1 to 2 cm, which allows evaluating the direction and effectiveness of bolus transit in addition to esophageal pressure abnormalities. It also permits the detection of both acid and nonacid gastroesophageal reflux when combined with pH testing, and can be done both on and off PPIs. This method is preferred for the assessment of patients with atypical symptoms and those with incomplete or no response to acid-suppressive therapy. MII-HRM classifies swallows as "complete bolus transit," "incomplete bolus transit" (no bolus exit identified at any one of the distal impedance-measuring sites), and "esophageal transit abnormality" (30% of liquid swallows or 40% of viscous swallows with incomplete bolus transit). MII-pH can establish the association of the

patient's symptoms with reflux episodes by providing the symptom index (SI; 50% indicates symptomatic reflux on PPI therapy) and the symptom association probability (SAP; 95% is considered indicative of a good temporal association between the patient's symptoms and reflux).

Impedance Planimetry

7 Endoflip is an impedance planimetry system used to evaluate real-time pressure, diameter, and distensibility of the esophagus and gastrointestinal sphincters.[23] The balloon catheter can be passed with transorally with endoscopic guidance or through the endoscope. There is an 8-cm long and a 16-cm balloon catheter, both of which can be used to assess the GEJ and LES, as well as the pylorus if indicated. The 16 cm is better suited for assessment of the esophagus proximal to the LES. The balloon is then filled with 30 cc, 40 cc, 50 cc, 60 cc, or 70 cc and the metrics documented (note, the 8-cm balloon should only be filled to 50 cc). There are several primary metrics and these include the maximum diameter (mm) of the narrowest luminal area, the cross-sectional area (mm^2), balloon pressure (mm Hg), the distensibility index (mm^2/mm Hg), and esophageal contractile pattern categories (repetitive antegrade contractions, repetitive retrograde contractions, absent contractile response, or disordered/diminished contractile response). Endoflip can be easily completed with upper endoscopy to immediately assess the competence of the LES, in workup for dysphagia, esophageal motility disorders such as achalasia, or symptoms of GERD. Endoflip allows an improved functional assessment of the LES, with detailed diameter assessment of the GEJ and of notable clinical importance, its distensibility, or ability to open at varying pressures (**Fig. 42.22**).

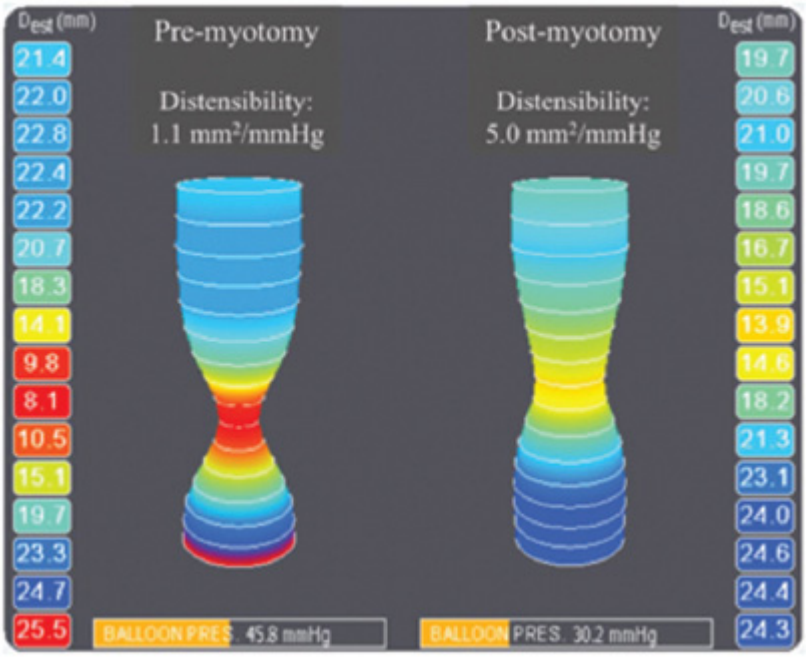

Figure 42.22 Visual representation of changes in the lower esophageal sphincter before and after myotomy for achalasia using Endoflip with a 40-mL volume fill.

CONCLUSIONS

The anatomy and physiology of the esophagus is unique and requires a detailed understanding to ensure safe workup and management. A deep appreciation of the anatomic relationships to other critical structures is pivotal to safe operations on the esophagus. The anatomic and functional studies outlined guide clinical decision making and surgeons should mater their use and interpretation.

GASTROESOPHAGEAL REFLUX DISEASE

Definition and Epidemiology

The most widely used definition for GERD is "a condition which develops when the reflux of stomach contents causes troublesome symptoms and/or complications."[24] It is difficult to accurately estimate the prevalence of GERD due to heterogeneity in the design of published studies, but

approximately 20% of people in the United States experience GERD symptoms at least weekly.[25] Worldwide, GERD is most prevalent in South Asia and Southeast Europe (>25%) and lowest in Southeast Asia, Canada, and France (<10%).[26] Its prevalence was increasing into the early 2000s but appears to have now leveled off.[25] However, it is still responsible for 110,000 hospital admissions annually in the United States, and deaths from end-stage benign esophageal disease are on an upward trend,[27] despite dramatic improvements in the efficacy of treatment options.

Two epidemiologic trends may be contributing to the increasing prevalence and severity of GERD over the past several decades. The first is the increasing prevalence of obesity, which is a significant risk factor for GERD. Jacobson et al. have shown that compared to normal-weight women, underweight women (BMI <20) were one-third less likely and overweight women (BMI 25 to 27.4) two times more likely to have frequent GERD symptoms. Obese women (BMI >30) had a nearly three times higher risk of frequent GERD symptoms.[28] Recent meta-analyses confirm this association between increasing BMI and the presence of GERD.[26] High-resolution motility studies have shown a significant correlation with BMI and both increased intragastric pressure and abnormal gastroesophageal pressure gradients, providing a physiologic explanation for the BMI–GERD association.[29] Specifically, central obesity has been shown to be especially associated with erosive esophagitis (OR 1.87), Barrett esophagus (OR 1.98), and esophageal adenocarcinoma (OR 2.51).[30]

The second risk factor is *Helicobacter pylori*, which has an inverse relationship with GERD. Epidemiologic data show that the decline of *H. pylori* infection is one of the reasons behind the increasing incidence of GERD-related diseases, including Barrett esophagus and esophageal and cardia adenocarcinoma in the Western world. Barry Marshall and Robin Warren from Perth, Australia, were awarded the Nobel Prize for their demonstration of the pathogenic role of *H. pylori,*[31] which induces a significant inflammatory and immune response in the affected host, resulting in persistent inflammation in infected subjects. It has been postulated that *H. pylori*–induced chronic corpus gastritis may protect against the development of GERD and its malignant transformation. Available evidence shows that the prevalence of *H. pylori* infection in patients with GERD or Barrett esophagus is lower than in healthy control populations.[32–35] The cagA+

strains of *H. pylori* have been specifically implicated in this correlation,[36,37] and studies have confirmed an inverse relationship between the presence of cagA positivity and adenocarcinoma of the esophagus and the GE junction.[38] As the incidence of duodenal ulcers and distal gastric cancer has decreased, the incidence of erosive esophagitis and gastric cardia cancer has increased, further supporting the theory that there is likely an inverse epidemiologic relationship between GERD and *H. pylori*. There are two main categories of GERD: nonerosive disease (NERD) and erosive disease (ERD).

Up to 70% of patients have NERD, but over time, patients may progress from NERD to erosive esophagitis and from ERD to Barrett esophagus.[39,40] The progression or regression of GERD complications was assessed in a cohort of nearly 4,000 patients with predominant heartburn who were treated with antisecretory medications over a 2-year period. After 2 years, 25% of patients with nonerosive GERD progressed to ERD, 1.6% with mild erosive esophagitis worsened to more severe esophagitis, and nearly 8% progressed to Barrett esophagus; the latter predominantly in patients with Los Angeles grade C/D ERD at baseline. On the other hand, 50% to 60% of patients with baseline esophagitis improved to a milder grade or no ERD and 22% were off medications at 2 years. A follow-up study at 5 years on 2,721 of the originally enrolled patients reported that while in most the disease was stable or esophagitis had improved, a minority of patients progressed despite pharmacologic treatment. At 5 years, 6% of patients with NERD, 12% with LA grade A/B esophagitis, and 20% of those with LA grade C/D esophagitis had developed Barrett esophagus. Risk factors for progression of disease included family history of GERD, baseline esophagitis or remaining unhealed after initial treatment, alcohol intake, and regular use of PPIs.[41]

Clinical Presentation

The most common symptoms in patients with GERD are heartburn, regurgitation, and dysphagia. Dysphagia may be an indication of more serious underlying pathology, including esophageal carcinoma, and should prompt an upper endoscopy. Heartburn is typically characterized as a substernal “burning” discomfort often radiating from the epigastrium to sternal notch. Occasionally patients will refer to it as chest or epigastric pain or indigestion. Typically, heartburn occurs postprandially and is exacerbated

by acidic foods, chocolate, coffee, and alcohol. It is commonly relieved by antacids, histamine-2 blockers, or PPIs. Importantly, the severity of symptoms is not necessarily related to the severity of the underlying disease as characterized by endoscopic findings (**Fig. 42.23**).

Regurgitation is the spontaneous return of gastric contents proximal to the GE junction, without necessarily reaching as high as the pharynx or mouth. It is typically worse at night in the recumbent position or when bending over or lying down after a meal. Patients commonly compensate by not eating late at night or by sleeping partially upright with several pillows or in a chair. This symptom is less often improved with antacid treatment. Dysphagia is generally described as the sensation of food being temporarily "stuck" in the esophagus. Dysphagia that is limited to solid food with normal passage of liquids is suggestive of a mechanical problem, such as a hiatal hernia, benign esophageal stricture, or tumor. Dysphagia with both solids and liquids is more typical of a functional or motor disorder such as achalasia. Patients usually adjust their eating habits as dysphagia progresses without realizing it, and dietary history including questions regarding the consistency of consumed food is an important component of patient assessment.

Many patients with GERD often also manifest extraesophageal symptoms, such as cough, asthma, hoarseness, and noncardiac chest pain. Atypical symptoms are the primary complaint in 20% to 25% of patients with GERD and are secondarily present in association with heartburn and regurgitation in many more. It is considerably more difficult to prove a cause-and-effect relationship between atypical symptoms and GE reflux than it is to do so for the typical symptoms, and the etiology of these symptoms is often multifactorial. Often a trial of high-dose PPIs is helpful, but it takes several months to evaluate the full impact of the therapy since it takes time for that inflammation to improve or resolve with medications. Antireflux surgery can provide symptom relief in these patients, but careful testing to document GERD is critical particularly in those with little or no response to medical therapy.

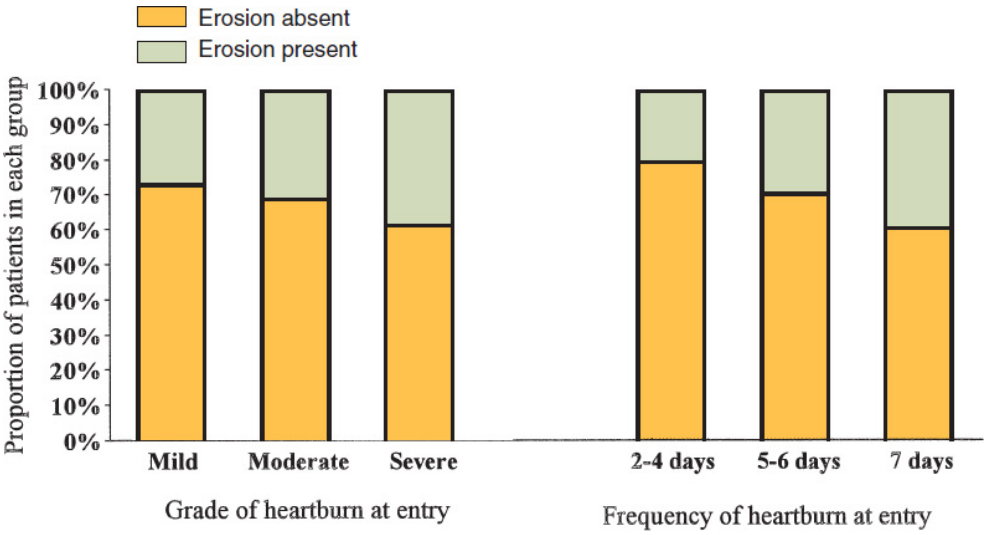

Figure 42.23 Prevalence of erosive esophagitis in 994 patients with varying severity and frequency of reflux symptoms. (Reproduced with permission from Venables TL, Newland RD, Patel AC, et al. Omeprazole 10 mg once daily, omeprazole 20 mg once daily, or ranitidine 150 mg twice daily, evaluated as initial therapy for the relief of symptoms of gastro-oesophageal reflux disease in general practice. *Scand J Gastroenterol* 1997;32[10]:965–973.)

The symptoms above are not specific to GERD and the differential diagnosis includes achalasia, diffuse spasm, esophageal carcinoma, pyloric stenosis, cholelithiasis, gastritis, gastric or duodenal ulcer, and coronary artery disease. In fact, the diagnosis of GERD based on symptoms alone is correct in only approximately two-thirds of patients.[42] This underlines the importance of objective diagnosis before the decision is made for surgical treatment.

Physiology of the Antireflux Barrier

The common feature of both physiologic or pathologic gastroesophageal reflux is the loss of the normal gastroesophageal high-pressure zone and the resistance it imposes to the flow of gastric juice from an environment of higher pressure (the stomach), to an environment of lower pressure (the esophagus). This barrier, composed of both anatomic (flap valve and diaphragm) and physiologic (LES) components, acts to prevent reflux. The key determinants of the barrier include:

1. The frequency of swallow- and non–swallow-induced transient relaxations of the LES
2. The structural integrity of the LES
3. Anatomic alterations of the diaphragmatic crura and gastroesophageal flap valve represented by the angle of His

The presence or absence of pathologic esophageal acid exposure (i.e., abnormal 24-hour pH studies) is not only influenced by the degree of barrier loss but also by esophageal and gastric functional characteristics including esophageal clearance, intra-abdominal pressure, and gastric emptying abnormalities.

Transient Relaxation of the Lower Esophageal Sphincter

Non–swallow-induced transient relaxations of the lower esophageal sphincter (TLESRs) are a major mechanism of belching and physiologic reflux in individuals with normal LES and hiatal anatomy, but a less significant contributor to GERD.[43] These spontaneous relaxations occur without pharyngeal contraction and are associated with relaxation of the diaphragmatic crura. Gastric distention, upright position, and meals high in fat have all been shown to increase the frequency of TLESRs.[44,45] The latter observations suggest that unfolding of the sphincter may be responsible for the loss of sphincter pressure.

Structural Integrity of the Lower Esophageal Sphincter

The pressure, overall length, and the length exposed to the positive pressure environment of the abdomen are the three characteristics of the LES that maintain its resistance or barrier function to intragastric and intra-abdominal pressure increases. The resistance of the LES is a function of its pressure and the length over which this pressure is exerted. The shorter the overall length of the high-pressure zone, the higher the pressure must be to maintain sufficient resistance to remain competent (**Fig. 42.12**). If the overall length of the sphincter is abnormally short, then with minimal gastric distention there

will be insufficient sphincter length for the existing pressure to maintain sphincter competency, and reflux will occur even in the presence of "normal" resting sphincter pressure.[10]

The third characteristic of the LES is its position, specifically the length of the high-pressure zone that is exposed to positive intra-abdominal pressure. If the abdominal length is inadequate, the sphincter cannot respond to an increase in applied intra-abdominal pressure by collapsing, and reflux is more likely. This usually occurs as a result of a hiatal hernia, and is the most common cause of a permanently defective sphincter.

If the LES has an abnormally low pressure, a short overall length, or minimal exposure to the abdominal pressure environment in the fasting state, then uninhibited reflux of gastric contents into the esophagus occurs. Such a *permanently defective sphincter* is identified by having one or more of the following:

- high-pressure zone with an average pressure of less than 6 mm Hg
- average overall length of 2 cm or less
- an average length exposed to the positive pressure environment of the abdomen of 1 cm or less[46]

A permanently defective sphincter is commonly associated with esophageal mucosal injury, difficulty to control symptoms with medical therapy, and esophageal dysmotility.

Anatomic Alterations

Hiatal Hernia

Hiatal hernia is a common abnormality in patients with GERD, although its contribution to the pathophysiology of this disease has been debated through the years. It has now been demonstrated that the diaphragmatic crura are important in preventing reflux during periods of loss of LES pressure,[47] and that the physiologic flap valve created by the angle of His is a contributing barrier to gastroesophageal reflux.[17] The presence of a normal acute angle of His or the abnormal dome architecture of a sliding hiatus hernia influences the ease with which the sphincter is pulled open, and a higher intragastric pressure is needed to open the sphincter in patients with an intact angle of His when compared to patients with a hiatal hernia (**Fig. 42.24**).

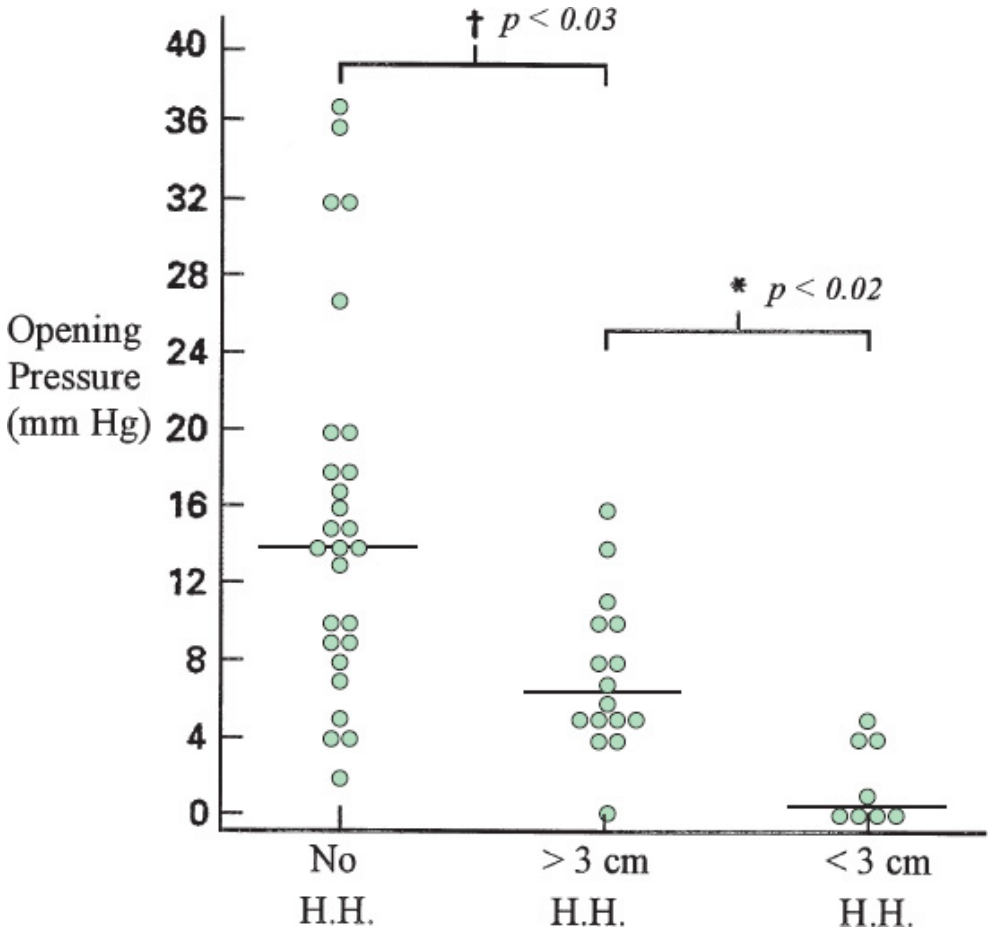

Figure 42.24 The intragastric pressure at which the lower esophagus endoscopically opened in response to gastric distention by air during endoscopy. Note that the dome architecture of a hiatus hernia (HH) influences the ease with which the sphincter can be pulled open by gastric distention. (Reproduced with permission from Ismail T, Bancewicz J, Barlow J. Yield pressure, anatomy of the cardia and gastro-oesophageal reflux. *Br J Surg* 1995;82[7]:943–947.)

The presence of a hiatal hernia also leads to impaired esophageal clearance due to loss of anchorage of the esophagus in the abdomen. Kahrilas et al. have shown that complete esophageal emptying was achieved in 86% of swallows in control subjects without a hiatal hernia, 66% in patients with a reducing hiatal hernia, and only 32% of patients with a nonreducing hiatal hernia.[48] Thus, there is overwhelming evidence that hiatal hernia does indeed play a significant role in the pathophysiology of GERD.

Gastric Distension

When the stomach is distended from overeating, aerophagia, or delayed gastric emptying secondary to the high-fat Western diet, the vectors produced by gastric wall tension pull on the GE junction with a force that varies according to the geometry of the cardia. Thus, when increased intragastric pressure occurs in the presence of a hiatal hernia, the force is applied more directly. This pulls on the terminal esophagus, reducing the length of the sphincter until a critical length of 1 to 2 cm occurs, when the pressure drops precipitously and reflux occurs. This results in postprandial reflux, which is a common complaint in the initial stages of GERD. After gastric venting, the length of the high-pressure zone is restored and competence returns until the next episode of distention. This sequence results in the common complaints of repetitive belching and bloating in patients with GERD. The patients' repetitive swallowing in an effort to neutralize the refluxed acid then contributes to repeat gastric distension.

Fletcher et al. identified an area of acid at the GE junction unaffected by the buffering action meals, which extends across the squamocolumnar junction an average of 1.8 cm into the lumen of the esophagus. The authors concluded that this was the source of postprandial esophageal acid exposure. The same process was shown to occur in patients with endoscopy-negative dyspepsia and normal conventional esophageal pH monitoring 5 cm above the upper border of the LES.[49] Importantly, dietary nitrate was also shown to result in potentially mutagenic levels of concentration of nitric oxide at the GE junction (**Fig. 42.25**).[50] These observations provide the fundamental basis for the observations of inflammation and other alterations in the epithelium known to occur at the squamocolumnar junction in both overt and unrecognized GERD.

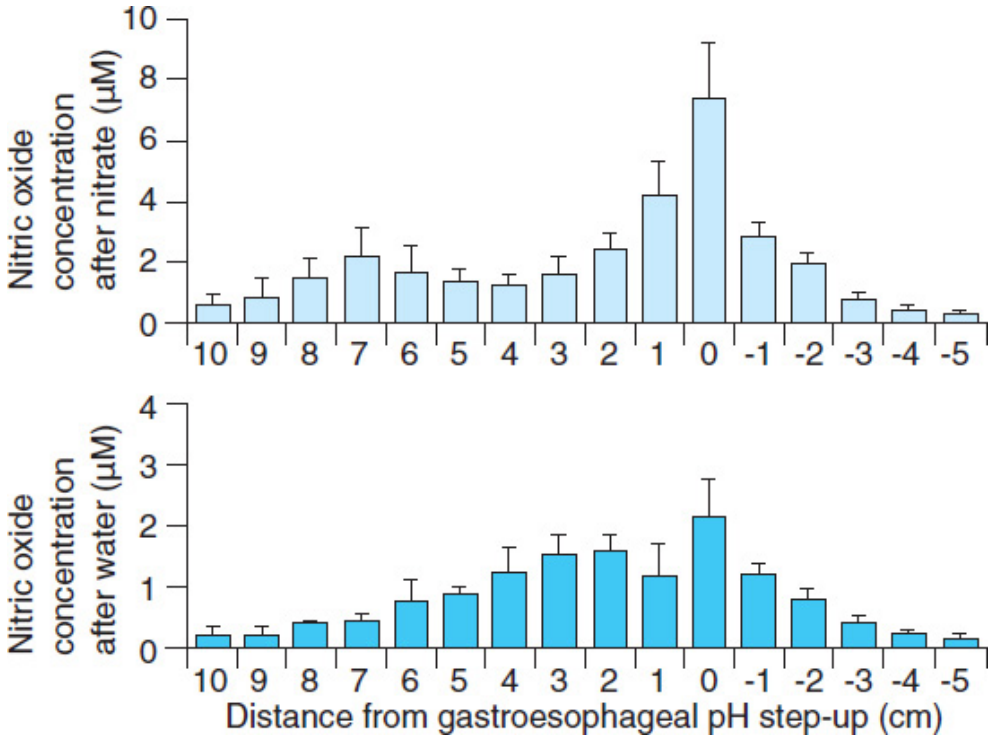

Figure 42.25 Mean (±SEM) nitric oxide concentrations in the upper stomach and lower esophagus after administration of water with 2-mmol nitrate (upper tracing) and water alone (lower tracing) (**$p < 0.01$, *$p < 0.05$ compared with value at gastroesophageal junction pH step-up). (Reproduced with permission from Iljima K, Henry E, Moriya A, et al. Dietary nitrate generates potentially mutagenic concentrations of nitric oxide at the gastroesophageal junction. *Gastroenterology* 2002;122[5]:1248–1257.)

Repeated exposure of the squamous epithelium of the distal esophagus to gastric juice causes inflammation, columnarization, and carditis. In early disease the esophagitis is mild and commonly limited to the very distal esophagus. The patient compensates by increased swallowing, allowing saliva to bathe the injured mucosa and alleviate the discomfort induced by exposure to gastric acid. Increased swallowing results in aerophagia, bloating, and repetitive belching. The distention induced by aerophagia leads to further exposure and repetitive injury to the terminal squamous epithelium and the development of cardiac-type mucosa (carditis). The process can lead to a fibrotic mucosal ring at the squamocolumnar junction (Schatzki ring). Extension of the inflammatory process into the muscularis propria causes a progressive loss in the length and pressure of the distal esophageal high-pressure zone associated with an increased esophageal exposure to gastric juice and the symptoms of heartburn and regurgitation. The loss of the barrier

eventually results in the permanent loss of LES resistance and the extension of the disease into the esophagus with progression to severe esophagitis. Intestinalization of the cardiac-type mucosa can occur at any time during this process, setting the stage for malignant degeneration.

Implications

Implications of recognizing anatomic alterations as component of GE barrier:

1. Transient LES relaxation is likely a consequence of sphincter shortening by gastric distention and is the underlying mechanism for belching and physiologic reflux. It does not play a major role in patients with symptomatic gastroesophageal reflux, particularly those with ERD, Barrett esophagus, or those referred for surgery.
2. Efforts to augment the gastroesophageal barrier either pharmacologically or endoscopically will commonly fail when a hiatal hernia is present.
3. Patients with abnormal esophageal acid exposure in the presence of normal LES characteristics and no hiatal hernia have an uncommon reason for reflux and these patients require additional evaluation since gastric or esophageal clearance failure may be present and may impair the outcome of a fundoplication.
4. Both reduction of hiatal hernia and augmentation of the LES are necessary to maximally restore gastroesophageal barrier competence.
5. Although acid control without regard to barrier incompetence will improve heartburn and heal esophageal ERD, it results in increasing numbers of patients with pulmonary manifestations of GERD.

Complications of Gastroesophageal Reflux Disease

The complications of gastroesophageal reflux result from the damage caused by the reflux of gastric juice onto the esophageal mucosa or laryngeal or respiratory epithelium (**Fig. 42.26**). Complications can be conceptually divided into (a) mucosal complications such as esophagitis and stricture; (b) extraesophageal or respiratory complications such as chronic cough, asthma, and pulmonary fibrosis; and (c) metaplastic (Barrett esophagus) and

neoplastic (adenocarcinoma). The prevalence and severity of complications is related to the degree of loss of the gastroesophageal barrier, defects in esophageal clearance, and the content of refluxed gastric juice (**Fig. 42.27**).

Mucosal Complications

The potential injurious components that reflux into the esophagus include gastric secretions, such as acid and pepsin; biliary and pancreatic secretions that regurgitate from the duodenum into the stomach, and toxic compounds generated in the mouth, esophagus, and stomach by the action of bacteria on dietary substances.

Acid alone does minimal damage to the esophageal mucosa, but the combination of acid and pepsin is highly deleterious. Similarly, the reflux of duodenal juice alone does little damage to the mucosa, while the combination of duodenal juice and gastric acid is particularly noxious. The components of duodenal juice thought to be most damaging are bile acids, which have been found in the esophagus of GERD patients in abnormally high concentrations when supine and during the upright period following meals. Reflux of bile and pancreatic enzymes into the stomach can either protect or augment esophageal mucosal injury. For instance, the reflux of duodenal contents into the stomach may prevent the development of peptic esophagitis in a patient whose gastric acid secretion maintains an acid environment, because the bile salts would inhibit pepsin and the acid would inactivate the trypsin. Such a patient would have bile-containing acid gastric juice that, when refluxed, would cause less esophagitis than if the refluxate contained acidic gastric juice with pepsin or alkaline gastric juice, where trypsin is not uninhibited. The latter patient may have minimal heartburn because of the absence of hydrogen ions in the refluxate but have endoscopic esophagitis because of the bile salt potentiation of trypsin activity on the esophageal mucosa.[51]

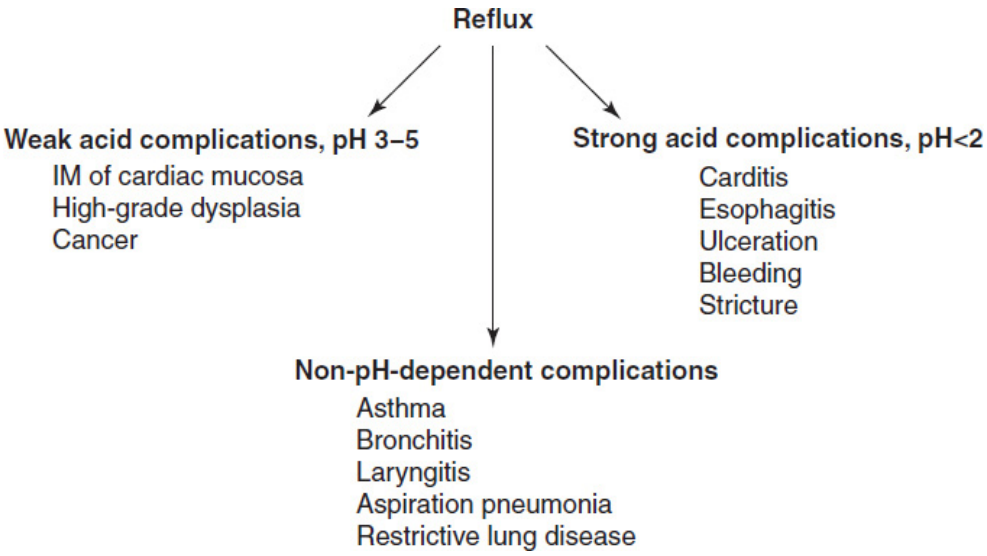

Figure 42.26 Schematic representation of the types of complications of gastroesophageal reflux disease.

In addition to acid and bile injury to the GEJ mucosa, dietary nitrate (e.g., present in green vegetables) has been shown to be potentially mutagenic.[50] Approximately 25% of ingested nitrate is resecreted into the mouth via the salivary glands, where it is transformed to more toxic nitrite, swallowed, and later converted to nitric oxide and other toxic compounds in the stomach.

Respiratory Complications

Reflux has been implicated as causative of asthma and idiopathic pulmonary fibrosis (IPF), with 35% to 50% of asthmatics shown to have abnormal esophageal pH, esophagitis, and a hiatal hernia.[52] Others have shown that the prevalence of reflux symptoms exceeded 50% in patients with asthma and CF.[53,54] In addition, patients with COPD and gastroesophageal reflux are twice as likely to have significant COPD exacerbations than their nonreflux counterparts,[55] and reflux symptoms correlate with airway obstruction in COPD patients.

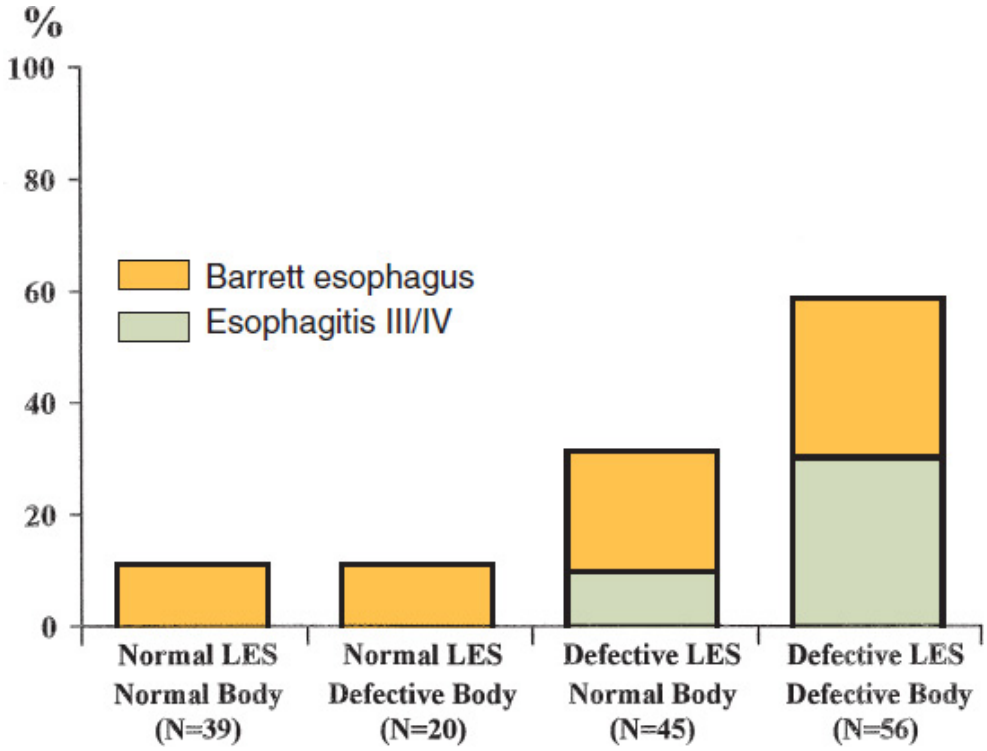

Figure 42.27 Prevalence of esophageal mucosal injury related to the presence of a defective lower esophageal sphincter, esophageal body motility, or both.

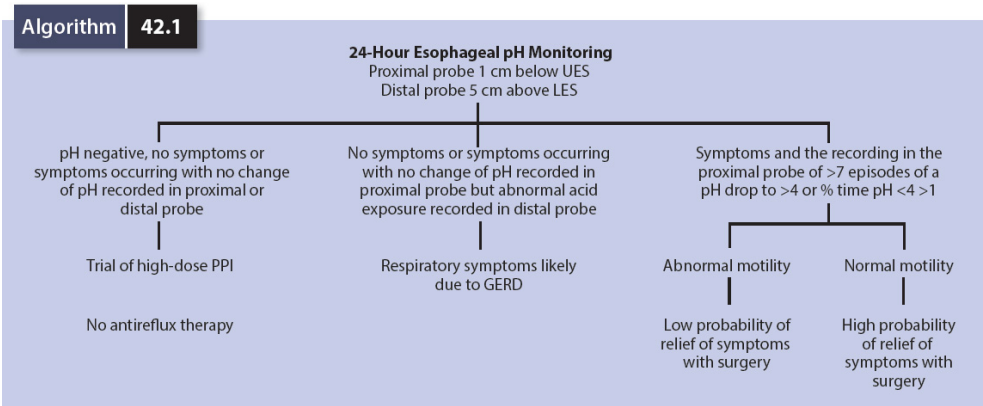
Pathophysiology of Reflux-Induced Respiratory Symptoms

Two mechanisms have been proposed as the pathogenesis of reflux-induced respiratory symptoms. The *reflux* theory postulates that respiratory symptoms are the result of the aspiration or microaspiration of gastric contents which results in pneumonitis, epithelial damage, and airway resistance. The *reflex* theory maintains that vagally mediated bronchoconstriction follows acidification of the lower esophagus via a reflex neurologic arc. The evidence supporting a *reflux* mechanism includes the findings that patient with pulmonary fibrosis have an increased prevalence of hiatal hernia on upper GI series,[56,57] while elderly patients with large hiatal hernias have a significantly increased frequency of pleural scarring on chest CT scans.[58] In addition, erosive esophagitis is found at a high frequency in patients with asthma, pneumonia, chronic bronchitis, and pulmonary fibrosis.[52] Third, patients with chronic lung diseases have a significantly higher frequency of positive 24-hour pH studies,[58,59] and simultaneous tracheal and esophageal acidification have been documented on pH monitoring in these patients.[60]

Finally, medications used to treat chronic lung diseases, in particular, bronchodilators, relax esophageal sphincter tone.[61]

A *reflex* mechanism is primarily supported by the fact that bronchoconstriction occurs following the infusion of acid into the lower esophagus.[62–64] This can be explained by the common embryologic origin of the tracheoesophageal tract and its shared vagal innervation.

The primary challenge in implementing treatment for reflux-associated RSs lies in establishing the diagnosis because in a substantial number of patients with reflux-induced RSs, gastroesophageal reflux is silent and respiratory symptoms dominate the clinical scenario. For example, D'Ovidio et al.[65] found that 72% of patients awaiting lung transplant for IPF, scleroderma, COPD, or CF had a hypotensive LES, 33% abnormal esophageal body motility, and 38% abnormal 24-hour pH testing. A high index of suspicion is therefore required in patients with poorly controlled respiratory diseases despite appropriate medical therapy. These patients should be investigated with upper endoscopy, manometry, and dual-probe pH monitoring, often combined with multichannel intraluminal impedance (MII-pH), where the proximal probe is positioned in the proximal esophagus close to (but not above) the UES. Loss of the normal alkalinity in the cervical esophagus has been shown to be a sensitive indicator of proximal reflux.[66] If the initial 48-hour Bravo pH is normal, the addition of the Restech pH probe to evaluate pharyngeal reflux exposure has been recommended.[67]



Algorithm 42.1 24-Hour esophageal pH monitoring.

Laryngopharyngeal Reflux

The term *LPR* is used for a broad category of atypical symptoms that may be secondary to gastroesophageal reflux. These may include laryngitis, pharyngitis, hoarseness, sinusitis, sleep disturbance, dental erosions, and globus.[68,69] Mechanisms for these symptoms are difficult to prove and available clinical studies are heterogeneous and frequently of low quality.[70]

Treatment of Extraesophageal Complications

Once gastroesophageal reflux is suspected or thought to be responsible for extraesophageal symptoms, treatment may be with either prolonged PPI therapy or antireflux surgery. Initially, a 3- to 6-month trial of high-dose PPI therapy may help confirm (by virtue of symptom resolution) the fact that reflux is partly or completely responsible for the symptoms. If symptoms are improved, patients can be treated with maintenance medical therapy or may be offered surgical treatment to control the reflux. The persistence of symptoms despite PPI treatment, however, does not necessarily rule out reflux as being a potential contributor. In patients with laryngopharyngeal reflux whose symptoms that are not relieved by acid suppression, small case series suggest that neuromodulating agents (tricyclic antidepressants, gabapentin, pregabalin) can provide some benefit.[71,72] **Algorithm 42.1** bases clinical decisions on the results of dual-probe 24-hour pH monitoring and is a useful starting point.

Based on reported observations, relief of RSs can be anticipated for 25% to 50% of patients with reflux-induced asthma treated with antisecretory medications,[73–75] although patients with pulmonary fibrosis in particular may have an inherent resistance to standard-dose PPIs.[76] Fewer than 15% of asthmatics with symptom relief, however, have been shown to have objective improvements in their pulmonary function. Antireflux surgery has better outcomes, improving RSs in nearly 90% of children and 70% of adults with asthma and reflux disease.[75,77] Improvements in pulmonary function were demonstrated in around one-third of these patients. It is important to note that patients with non–reflux-induced esophageal dysmotility have inferior outcomes after antireflux surgery.

The lung transplantation literature shows that there is a benefit of antireflux surgery in improving both symptoms and pulmonary function tests in patients with bronchiolitis obliterans pre- and post–lung transplant patients, with acceptable morbidity outcomes.[78–80]

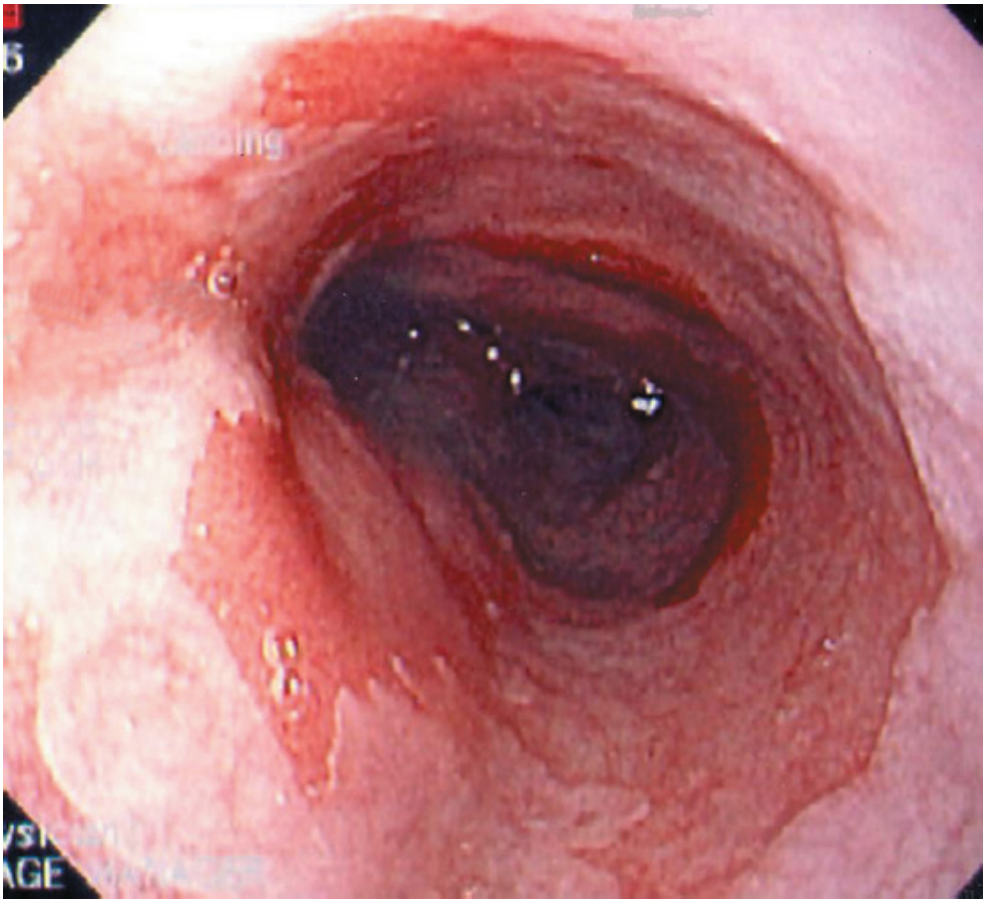


Figure 42.28 Endoscopic appearance of Barrett esophagus. Note the pink metaplastic mucosa as opposed to the normal whitish squamous lining of the esophagus.

Metaplastic (Barrett) and Neoplastic (Adenocarcinoma) Complications

8 Barrett esophagus occurs in 7% to 10% of patients with GERD, and represents the end stage of the natural history of this disease (**Fig. 42.28**).[81] Diagnosis of Barrett esophagus is made from any length of endoscopically visible tissue that is intestinal metaplasia on histology (**Fig. 42.29**) or columnar replacement of the esophagus of 3 cm or more.

Factors predisposing to the development of Barrett esophagus include early-onset GERD, abnormal LES, and esophageal body physiology, and mixed reflux of gastric and duodenal contents into the esophagus.[82] In fact, increased esophageal exposure to duodenal juice in patients with GERD is most dramatically related to Barrett esophagus.[83]

Pathophysiology of Barrett Metaplasia

Recent studies suggest that the metaplastic process at the GEJ may begin by conversion of distal esophageal squamous mucosa to cardiac-type epithelium due to exposure of the distal esophagus to excess acid and gastric contents via prolapse of esophageal squamous mucosa into the gastric environment. This results in inflammatory changes at the GEJ and/or a metaplastic process, both of which may result in the loss of muscle function and a mechanically defective sphincter allowing free reflux with progressively higher degrees of mucosal injury.

Treatment

The goals of treatment in this patient population are the relief of symptoms, healing of esophageal mucosal injury, and the prevention of disease progression. Antireflux surgery should be considered when patient factors suggest severe disease or predict the need for long-term medical management, both of which are almost always true in patients with Barrett esophagus. PPI therapy, is an acceptable treatment option in patients with Barrett esophagus. Once initiated, however, most patients with Barrett esophagus will require lifelong treatment. Complete control of reflux with PPI therapy can be difficult, and 40% to 80% of patients continue to experience abnormal esophageal acid exposure despite PPI administration.[84,85] An important consideration is that patients with Barrett esophagus generally have severe GERD, with its attendant sequelae such as large hiatal hernia, stricture, shortened esophagus, and poor motility. Compared to mild and nonerosive reflux disease, severe ERD and Barrett esophagus are associated with significantly greater loss of the mechanical antireflux barrier because of associated hiatal hernias and a hypotensive LES. Antireflux surgery likely results in more reproducible and reliable elimination of reflux of both acid and duodenal content than medical treatment. Studies focusing on the symptomatic outcome following antireflux surgery in patients with Barrett esophagus document excellent results in 79% to 92% of patients at up to 12 following surgery.[86–90] Objective outcome studies suggest that histologic regression of Barrett metaplasia is seen in 22% to 41% of surgical patients post fundoplication, though as many as 25% of them will have persistent pathologic esophageal acid exposure confirmed by 24-hour pH studies.[86–88]

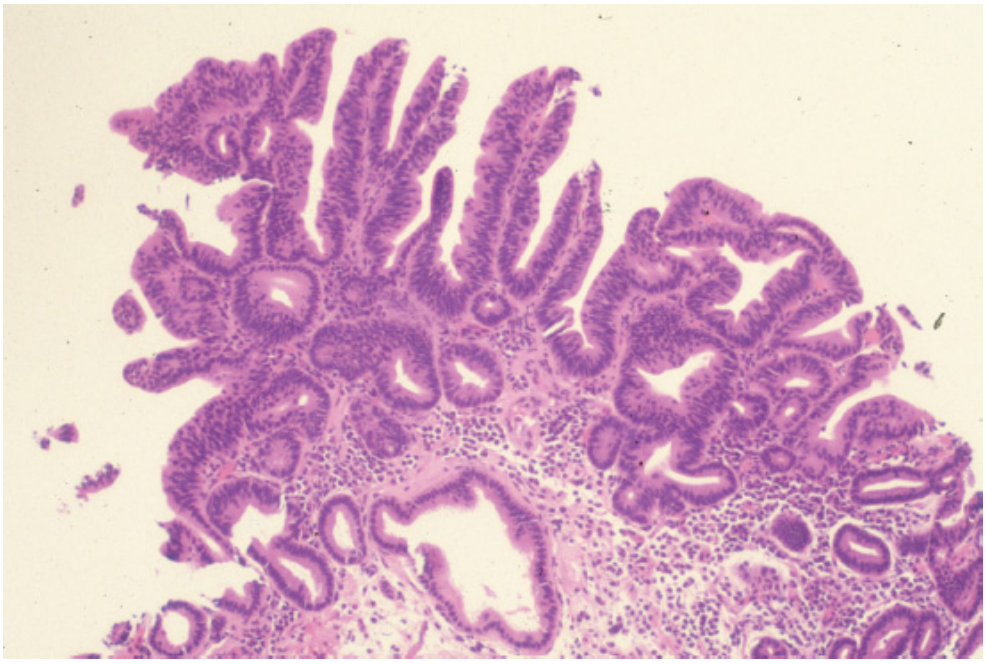

Figure 42.29 Histologic appearance of Barrett esophagus. To the left of the photograph, columnar mucosa with abundant goblet cells is seen. This is intestinal metaplasia, which is the histologic hallmark of Barrett esophagus. To the right of the photomicrograph, cardiac epithelium is present.

In addition to symptomatic and physiologic improvement in reflux after surgery, there is evidence that mediators of esophageal inflammation implicated in carcinogenesis are decreased as well. Cyclooxygenase-2 (COX-2) gene expression is elevated in the distal esophagus of reflux patients, but the expression of COX-2 and another inflammatory mediator, interleukin 8, can be decreased in the distal esophageal mucosa after a fundoplication.[91–93]

Dysplasia in Barrett Esophagus

The prevalence of dysplasia at diagnosis in patients presenting with Barrett esophagus ranges from 15% to 25%, and approximately 5% of patients will develop dysplasia each year. Barrett metaplasia is currently classified into four broad categories:

1. No dysplasia
2. Indefinite for dysplasia
3. Low-grade dysplasia
4. High-grade dysplasia (HGD)

The overall annual risk of progression to esophageal adenocarcinoma among patients with Barrett esophagus is 0.29%, and the risk of progression is significantly higher in patients with low-grade dysplasia than in those without it at baseline.[94] Therefore, Barrett esophagus complicated by dysplasia should undergo aggressive therapy. Patients whose biopsies are interpreted as indefinite for dysplasia should be treated with a medical regimen consisting of 60 to 80 mg of PPI therapy for 3 months and rebiopsied. The presence of severe inflammation makes the microscopic interpretation of dysplasia difficult, and the purpose of acid suppression therapy is to resolve inflammation that may complicate the interpretation of the biopsy specimen. Persistent indefinite or low-grade dysplasia should be a relative indication for a Nissen fundoplication given the evidence that in most patients, low-grade dysplasia reverts to nondysplastic intestinal metaplasia after a fundoplication. Radiofrequency ablation or cryotherapy are acceptable alternative treatments to reduce the risk of progression to cancer in these patients.

Approximately 50% of patients thought to have only HGD will harbor a focus of invasive carcinoma somewhere in the columnar mucosa.[95–97] Any patient with dysplasia, particularly HGD, requires careful endoscopic evaluation with high-definition white-light endoscopy to look for any nodules or lesions. If no lesion is present then ablation therapy should be performed to reduce the risk of progression to cancer in patients with HGD. If a lesion is present, endoscopic mucosal resection should be performed to determine if it is malignant and allow assessment of the depth of invasion and tumor characteristics. Endoscopic resection is preferred over esophagectomy for BE patients with intramucosal esophageal adenocarcinoma (T1a) given a significantly better safety profile, 96% complete response rate, and similar rates of recurrence. The remaining Barrett epithelium should be ablated after all visible lesions are resected. Risk factors for failure of endoscopic therapy include ultra–long segment (>8-cm) Barrett, poorly controlled reflux disease, and high-grade tumor differentiation. Metachronous lesions and local recurrences are treated following the same algorithm.[98] Treatment of more advanced esophageal cancers is discussed in Chapter 43.

Treatment of Gastroesophageal Reflux Disease

Medical Treatment

GERD is one of the most prevalent conditions encountered in general medical practice. As a result, medications for control of GERD comprise one of the largest pharmaceutical markets in the United States and abroad. Omeprazole is the seventh most commonly prescribed medication, and there are over 100 million PPI prescriptions given yearly, accounting for over $10 billion in expenditures.[99] GERD is such a common condition that most patients with mild symptoms self-medicate with over-the-counter H_2-receptor antagonists (H_2RAs) and PPIs. When first seen with symptoms of heartburn or regurgitation without obvious complications, patients can reasonably be placed on 8 to 12 weeks of acid suppression therapy before extensive investigations are carried out. This is done in addition to counseling on dietary and lifestyle modification with avoidance of acidic foods, alcohol, tobacco, and weight loss for those with a BMI >25. In many situations, symptoms will successfully resolve. Patients should be advised to elevate the head of the bed; avoid tight clothing; eat small, frequent meals; avoid eating their nighttime meal shortly before retiring; lose weight; and avoid alcohol, coffee, chocolate, and peppermints, which may aggravate the symptoms.

Patients with persistent symptoms should be given PPIs, such as omeprazole, which result in up to 80% to 90% reduction in gastric acidity and up to 95% reduction in esophageal acid exposure. H_2RAs are less effective in decreasing esophageal acid exposure (80%). PPI doses of 40 mg/d will usually heal mild esophagitis, though healing occurs in only three-fourths of patients with severe esophagitis. It is important to realize that in patients who reflux a combination of gastric and duodenal juice, inadequate acid suppression therapy may give symptomatic improvement while still allowing mixed reflux and persistent mucosal damage in an asymptomatic patient. Unfortunately, within 6 months of discontinuation of any form of medical therapy for GERD, 80% of patients have a recurrence of symptoms.[100]

Despite their effectiveness, periods of acid breakthrough occur in 75% to 80% of patients taking PPIs, primarily at nighttime.[101,102] This is particularly pertinent because it is during the nighttime and early morning that asthma symptoms are most pronounced and that peak expiratory flow rate is at its lowest. Ranitidine 300 mg at bedtime appears superior to omeprazole 20 mg at bedtime in preventing acid breakthrough, likely due to the abolition of histamine-mediated acid secretion in the fasting state.

While PPIs are very well tolerated in the short term, there is increasing evidence suggesting potential adverse consequences to their long-term use. Increased relative risk of bone fractures due to calcium malabsorption, pneumonia, chronic kidney disease, dementia, myocardial infarction, renal disease, GI malignancies, B_{12} deficiency, hypomagnesemia, *Clostridium difficile* infection, and interactions with antiplatelet medications have all been reported. Most of the evidence is weak and obtained from observational studies. However, special attention should be given to elderly patients with significant comorbidities, those on many other medications, and patients with known osteoporosis when considering maintenance PPI therapy.[103,104]

Failure of acid suppression to control symptoms or immediate return of symptoms after stopping treatment suggests that either the diagnosis is incorrect or the patient has relatively severe disease. Endoscopic examination at this stage of the patient's evaluation provides the opportunity for assessing the severity of mucosal damage and the presence of Barrett esophagus. Both of these findings on initial endoscopy should prompt 24-hour pH monitoring and manometry to assess the LES and the function of the esophageal body. These studies identify features that predict a poor response to medical therapy, frequent relapses, and the development of complications of GERD. Patients who have these risk factors should be given the option of surgery as a primary therapy.

Antireflux Surgery

Indications

Antireflux surgery is indicated for the treatment of objectively documented, relatively severe GERD. Candidates for surgery include patients with erosive esophagitis, stricture, Barrett esophagus, as well as those without

severe mucosal injury who are dependent on PPIs for symptom relief. Patients with atypical symptoms who have a good response to intensive medical treatment are also candidates. The option of antireflux surgery should be given to all patients who have demonstrated the need for long-term medical therapy, particularly if escalating doses of PPIs are needed to control symptoms. Antireflux surgery may be the preferred option in patients younger than 50 years, those who are noncompliant with their drug regimen, those for whom medications are a financial burden, and those who favor a single intervention over long-term drug treatment. It may be the treatment of choice in patients who are at high risk of progression despite medical therapy, such as those with nocturnal reflux on 24-hour esophageal pH study, a structurally deficient LES, mixed reflux of gastric and duodenal juice, and mucosal injury at presentation.[105]

Preoperative Evaluation

9 The preoperative evaluation of GERD is imperative to determining a diagnosis and establishing an optimal treatment plan for each individual patient. **Table 42.3** outlines four important goals in the diagnosis of suspected GERD and those being considered for antireflux surgery. Please refer to the prior section in this chapter for details on preoperative studies, the below will be a summary.

Table 42.3 Goals of the Diagnostic Approach to Patients Suspected of Having GERD and Being Considered for Antireflux Surgery

Establish that GERD is the underlying cause of the patient's symptoms.
Estimate the risk of progressive disease.
Determine the presence or absence of esophageal shortening.
Evaluate esophageal body function and, occasionally, gastric emptying function.

GERD, gastroesophageal reflux disease.

Table 42.4 Predictors of Outcome after Laparoscopic Fundoplication: Stepwise Logistic Regression Results of 199 Patients

Predictor	Status	Adjusted Odds Ratio (95% Confidence Intervals)	Wald p Value
Composite Acid score	Increased	5.4 (1.9–15.3)	<0.001
	Normal	—	—
Symptom	Typical	5.1 (1.9–13.7)	<0.001
	Atypical	—	—
Response to Medical Therapy	Complete/partial	3.3 (1.3–8.7)	0.02
	Minor/none	—	—

Odds ratios and corresponding p values are adjusted for age and for all other factors in the model.

From Campos GM, Peters JH, DeMeester TR, et al. Multivariate analysis of the factors predicting outcome after laparoscopic Nissen fundoplication. *J Gastrointest Surg* 1999;3(3):292–300.

Patient selection is critically important and the studies outlined in the prior section of this chapter increase the degree of certainty of a diagnosis of GERD. In addition, three specific factors have been identified as predictive of a positive outcome after antireflux surgery.[106] These factors include: abnormal score on 24-hour esophageal pH monitoring, present of typical symptoms of GERD (heartburn or regurgitation), and symptomatic improvement in response to acid suppression therapy (**Table 42.4**).

Endoscopic Assessment. Upper endoscopy is the true physical examination of the foregut and is important preoperatively to determine complications of GERD and anatomical landmarks. The location of the diaphragmatic crura, the GE junction, and the

squamocolumnar junction must be identified. The GE junction is located where the tubular esophagus meets the rugal folds, which is often just proximal to the squamocolumnar junction, which is where there is a visible change from the velvety (and darker) columnar epithelium to the lighter squamous epithelium. Additionally, the presence of endoscopic esophagitis must also be classified and the presence of Barrett esophagus must be determined (**Table 42.1**). As mentioned above, identification of the gastroesophageal valve with Hill grading and determination of presence of a hiatal hernia is also imperative to operative planning.

Twenty-four–Hour Ambulatory pH Monitoring. Ambulatory pH testing is widely considered to be the "gold standard" to diagnose GERD, and gives the most direct method for determining the relationship between symptoms and gastric acid exposure. It is highly sensitive and specific and gives an objective assessment of acid exposure. More frequently, the ambulatory pH study is reserved for those patients with atypical symptoms of GERD and/or no evidence of reflux (esophagitis) on upper endoscopy.

Ambulatory Combined Impedance-pH Monitoring. Combined impedance-pH monitoring allows for measurement of both acid and nonacid refluxate. The Sleuth system (Sandhill Scientific, Denver, Colorado) uses a single catheter to measure both (**Fig. 42.30**). This multichannel impedance (MII-pH) has been validated, and has interestingly shown that PPI therapy does not change number of reflux events; it solely converts those events to a neutral pH.[107,108] This modality is generally used in patients who have atypical symptoms of GERD or who are resistant to medical therapy, with one study demonstrating superior accuracy compared to pH monitoring alone.[109]

Radiographic Evaluation. Radiographic evaluation of the esophagus is important for assessment of anatomy and function. These include assessment of presence and size of hiatal hernia, esophageal peristalsis and bolus transit, anatomic abnormalities, as well as

presence of esophageal shortening (**Fig. 42.31**). In addition, the presence of reflux can also be visualized, and is particularly reliable if spontaneous while the patient is upright.

A barium upper GI study or esophagram generally follows a protocol to ensure a complete detailed examination of the esophagus is completed (**Table 42.5**).

Assessment of Esophageal Function. Esophageal body function influences the decision to do a partial or complete fundoplication and can impact the improvement of symptoms after surgery. Esophageal motility is best assessed with esophageal manometry, a study that consists of 10 wet swallows with 5 mL of water that records amplitude, duration, and morphology of esophageal contractions (**Fig. 42.18**).

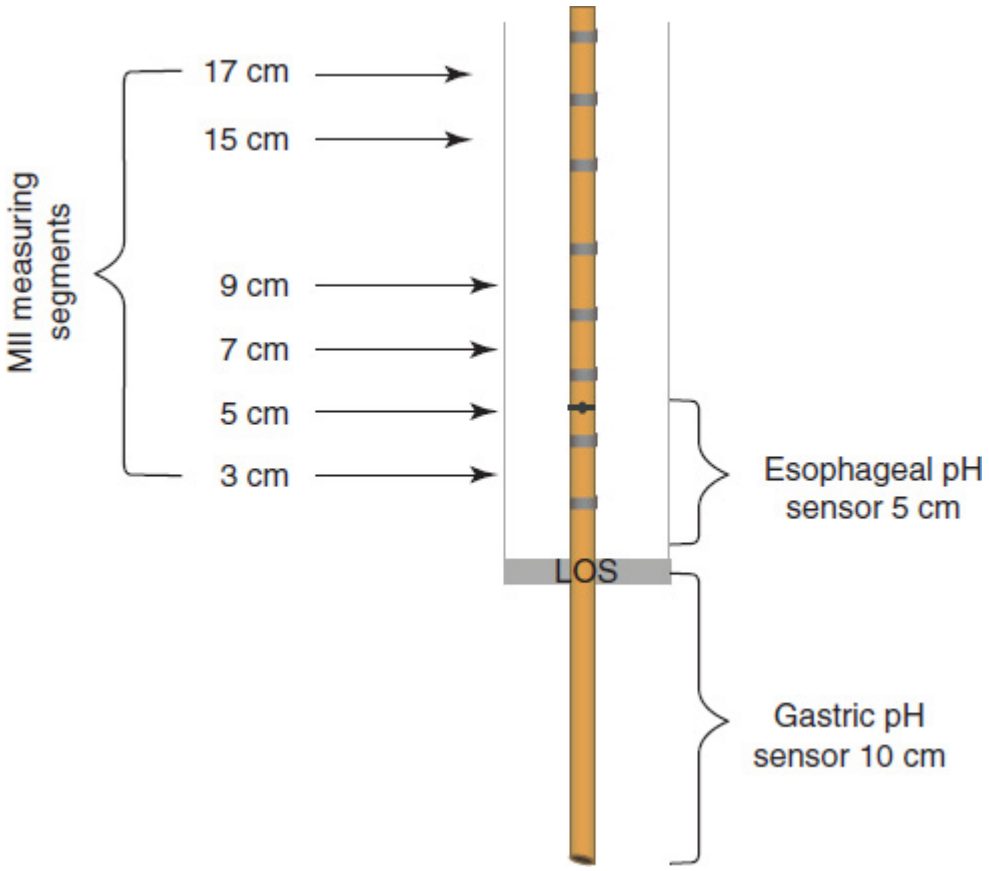

Figure 42.30 Combined multichannel intraluminal impedance–pH catheter. (Reproduced with permission from Mainie I, Tutuian R, Agrawal A, et al. Combined multichannel intraluminal impedance-pH monitoring to select patients with persistent gastro-oesophageal reflux for laparoscopic Nissen fundoplication. *Br J Surg* 2006;93[12]:1483–1487.)

Figure 42.31 Barium-filled esophagogastric segment in a patient with a short esophagus. Note that the gastroesophageal junction is well above the hiatus.

Assessment of Gastric Function. Patients who suffer from nausea, epigastric pain, early satiety, bloating, or burping may have impaired gastric motility. Gastric emptying studies are necessary in these patients and these symptoms should be evaluated for every patient with refractory GERD. Gastric emptying studies are completed with

radionuclide-labeled meals with interval imaging to assess percent and timing of passage of both liquids and solids.

Table 42.5 University of Southern California Protocol for Video Esophagram Studies

Patient Position	Purpose	Technique
Prone RAO	Esophageal body function	Five separate 10-mL swallows, 15 sec between each, follow bolus on videotape Video swallow over thoracic inlet and another over distal third of esophagus without panning
	Esophageal diameter	Rapid swallow of several gulps to distend esophagus maximally
	Gastric function	Video-record activity of stomach and duodenum for 30 sec in prone position
Supine	Relationship of GE junction to hiatus	Two or three individual swallows focused on distal esophagus and GE junction
Erect	Cricopharyngeal function	Lateral and anteroposterior views of oropharynx and upper esophagus
	Mucosal injury	Spot of collapsed esophagus for mucosal detail

	Reducibility of hernia	Video images of one or two swallows focused on distal esophagus and GE junction
	Gas distention of distal esophagus	
Erect	Solid bolus transport	Record video images of passage of two contrast-coated hamburger boluses from oropharynx to stomach

GE, gastroesophageal; RAO, right anterior oblique.

Impedance Planimetry. Endoflip is an impedance planimetry system used to evaluate real-time pressure, diameter, and distensibility of the esophagus and gastrointestinal sphincters.[23] This is particularly useful to assess the LES during workup of achalasia, and can also be used intraoperatively, for fundoplication or myotomy to assess diameter, pressures, and distensibility pre- and postintervention.[110]

Partial versus Complete Fundoplication

10 The decision between partial and complete fundoplication requires considerable judgment. Randomized studies have shown equivalence of these approaches in terms of operative time, perioperative morbidity, and hospital stay.[111,112] Resting and residual LES pressures seem to be greater after complete fundoplication and esophageal clearance prolonged in patients after complete fundoplication compared with after posterior partial fundoplication.[112] In the first 2 years after operation, partial fundoplication was linked to a greater overall level of patient satisfaction, lower incidence of dysphagia, inability to belch, and excessive flatus.[113] Long-term results of randomized trials between Nissen and Toupet fundoplication reveal no significant differences in heartburn, regurgitation, or dysphagia scores.[114,115] Several randomized trials comparing laparoscopic Nissen fundoplication to

an anterior 180-degree partial fundoplication similarly revealed no significant differences between the two groups with regard to reflux symptoms and patient satisfaction in up to 10 years' follow-up, but with some studies showing lower rates of dysphagia and gas-related symptoms.[116]

These observations, however, must be tempered by reports questioning the durability of partial fundoplications. Jobe et al.[117] found that 51% of patients studied by 24-hour esophageal pH monitoring after Toupet fundoplication still had pathologic acid exposure. Disturbingly, only 40% of the refluxers were symptomatic. Broeders et al. found higher total esophageal acid exposure time, more frequent acid reflux episodes, and lower mean LES and relaxation pressures in patients 14 years after anterior 180-degree fundoplication.[118] The presence of a defective LES function, an aperistaltic distal esophagus, and higher grades of esophagitis are risk factors for partial fundoplication failure.[114,117] Bell et al. reported recurrent reflux in 14% after Toupet fundoplication. The presence of mild esophagitis and a normal LES were associated with a 3-year success rate of 96%, whereas the presence of complicated esophagitis or a defective LES lowered this value to 50%.[119]

These findings lead to the question whether total fundoplication should be applied more liberally to patients with severe reflux disease and associated esophageal dysmotility. Patti et al. reported on 357 patients undergoing antireflux surgery, 235 undergoing a "tailored approach" with either a partial or total fundoplication, depending on the results of preoperative manometry and 122 more recent patients undergoing a total fundoplication regardless of the quality of esophageal peristalsis.[120] In the first group, heartburn from pathologic reflux, confirmed by postoperative ambulatory esophageal pH monitoring, recurred in 19% after partial fundoplication and in 4% after total fundoplication. In the latter group, heartburn recurred in 4% after total fundoplication.

Importantly, the incidence of postoperative dysphagia was similar in the two groups. Given this evidence, we believe that partial fundoplication is best reserved for patients with severe esophageal dysmotility approaching aperistalsis, such as occurring in scleroderma, or in combination with a distal esophageal myotomy for achalasia.[121]

Laparoscopic Nissen Fundoplication

Table 42.6 lists the most critical steps in the performance of laparoscopic fundoplication and concurrent hiatal hernia repair as necessary.

Port Placement. Five ports are used. The camera is placed superiorly and to the left of the umbilicus, roughly one-third of the distance to the xiphoid process to optimize the visualization of the hiatus. The liver is retracted with flexible retractor placed through a 5-mm incision in the right subcostal region along the anterior axillary line. A retraction port is placed slightly above the level of the umbilicus, in the left anterior axillary line. The surgeon's right-hand 11-mm port is placed 1 to 2 cm below the costal margin approximately at the lateral rectus border to allow triangulation between the camera and the two working instruments. The surgeon's left hand 5-mm port is placed last, after the left lateral segment of the liver has been retracted, to visualize the best trajectory under the falciform ligament toward the hiatus.

Crural Dissection. In patients without a large hiatal or paraesophageal hernia dissection begins with division of the gastrohepatic omentum and identification of the right crus of the diaphragm. Care is taken to preserve the hepatic branch of the anterior vagus nerve. Alternatively, when a paraesophageal hernia is present, the hernia contents are reduced as much as possible first, and sac excision is started at the 2 o'clock position at the hiatus to avoid injuring the left gastric vessels that are routinely up in the chest on the right side of the hiatus.

Table 42.6 Elements of Laparoscopic Fundoplication

1. Crural dissection with identification and preservation of both vagus nerves
2. Circumferential dissection of the esophagus and mobilization of the gastric fundus
3. Crural closure
4. Creation of a short, loose fundoplication around the distal esophagus

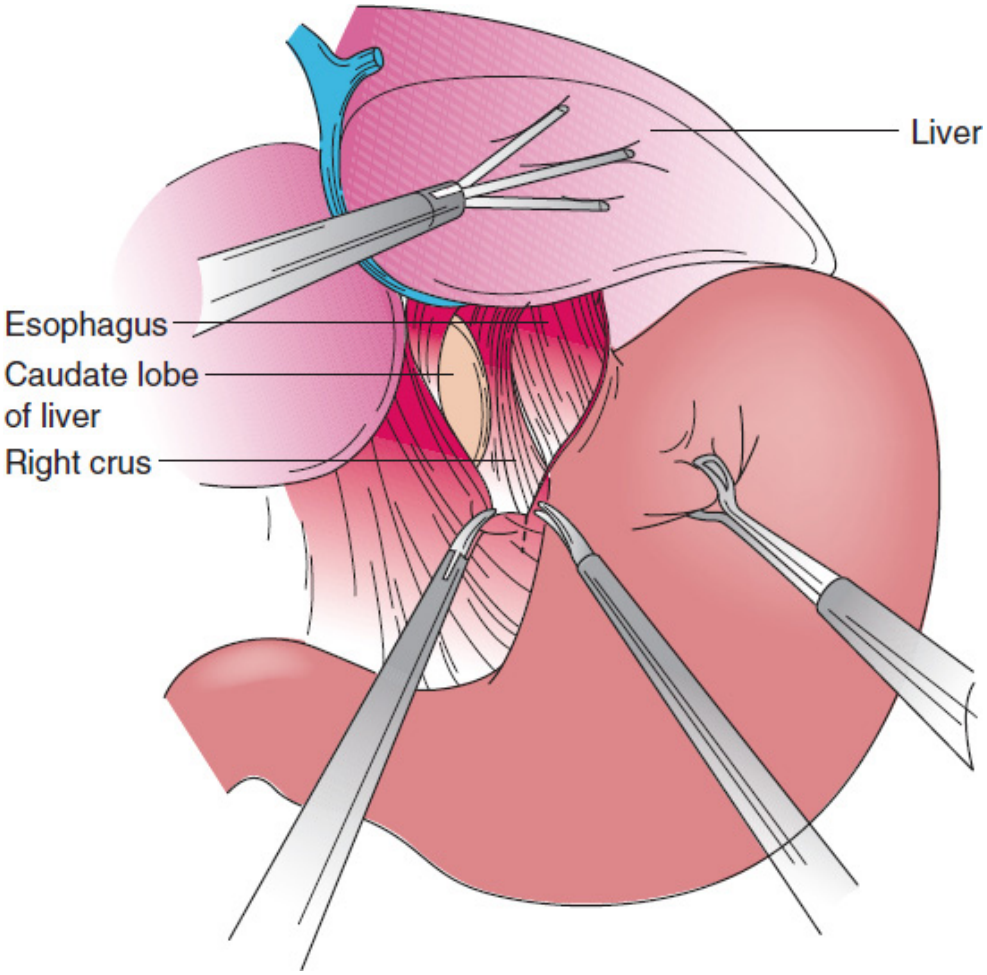

Figure 42.32 Illustration of the initial dissection of the esophageal hiatus. The right crus is identified and dissected toward its posterior confluence with the left crus.

A replaced left hepatic artery arising from the left gastric artery is present in up to 25% of patients; it should be identified and can typically be clipped and divided, but a pulse in the hepatoduodenal ligament should be confirmed first. The peritoneum overlying the anterior aspect of the right crus is incised and the plane between the esophagus and right crus developed (**Fig. 42.32**).

The dissection is then continued anteriorly, and the esophagus and anterior vagus nerve are swept downward away from the phrenoesophageal ligament. The anterior crural tissues are divided and the left crus identified. The anterior vagus nerve often "hugs" the left crus and can be injured in this portion of the dissection if not carefully searched for and protected. The left crus is dissected as completely as possible, including taking down the angle of His and the attachments of the fundus to the left diaphragm (**Fig. 42.33**).

The short gastric vessels are divided along with the posterior pancreatic vessels to completely mobilize the gastric fundus. A window behind the GE junction is then created and a Penrose drain passed around the distal esophagus for retraction.

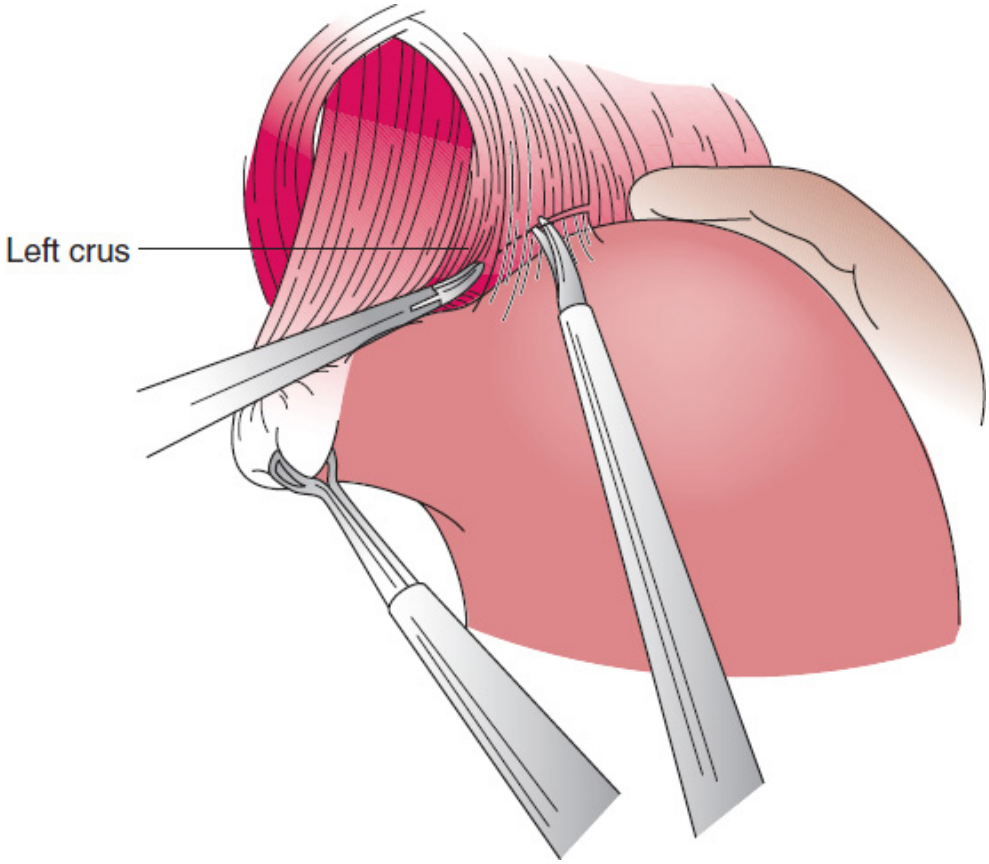

Figure 42.33 Left-sided crural dissection. The left crus is dissected as completely as possible and the attachments of the fundus of the stomach to the diaphragm are taken down.

Esophageal Mobilization and Crural Closure. The esophagus is mobilized circumferentially into the posterior mediastinum centimeters to provide at least 3 cm of intra-abdominal esophageal length. Both the anterior and posterior vagus nerve should be identified and protected. The right and left pleural reflection often come into view and should be avoided, although if a pleural opening is created it is well tolerated provided the hole is made large enough to prevent a ball valve tension pneumothorax from developing. Following mobilization and an assessment of intra-abdominal esophageal

length, the hiatus is closed. The esophagus is retracted anteriorly and to the left, and the crura is approximated with interrupted 0-Ethibond sutures, starting just above the aortic decussation and working anteriorly. The authors prefer using absorbable pledgets to reinforce the repair. Care must be taken to identify the anterior surface of the aorta during this step in order to avoid inadvertent injury to it while suturing the left crus. If the crura cannot be approximated despite maximal mobilization, a right-sided relaxing incision in the diaphragm is recommended to allow the crura to be closed without tension. The defect created in the diaphragm is then repaired with permanent mesh to avoid herniation of abdominal contents into the thorax. The authors prefer a Gore-Tex patch for this purpose and reinforce the primary crural closure with an absorbable or biologic mesh. When the right-sided relaxing incision is inadequate (with a very large hernia or in reoperations), a left diaphragm relaxing incision may be necessary. Synthetic mesh bridging the crura should be avoided because it leads to the highest risk of mesh erosion. There are some studies showing that reinforcement of a primary crural closure with biologic or resorbable mesh may help prevent early hiatal hernia recurrence, but this advantage disappears with long-term follow-up, and may increase the complexity of a reoperation if one is necessary in the future.

Creation of the Fundoplication. A 2-cm loose fundoplication is created after ensuring that there is no twisting of the wrap (**Fig. 42.34**). The mid-posterior fundus is grasped and passed left to right behind the esophagus to ensure that the posterior fundus is used for the posterior aspect of the fundoplication (**Fig. 42.35**). One should gently bring the posterior fundus behind the esophagus to the right side with an upward, rightward, and clockwise twisting motion. A 0-0 silk suture can be placed in the mid-posterior fundus 6 cm down from the GEJ to facilitate this step, and grasping it from the right side helps bring the posterior fundus around to create the fundoplication. The anterior wall of the fundus is then folded over the esophagus to meet the posterior at about the 9 o’clock position such that the

esophagus is imbricated within the fundus rather than having the fundus twisted or spiraled around the esophagus.

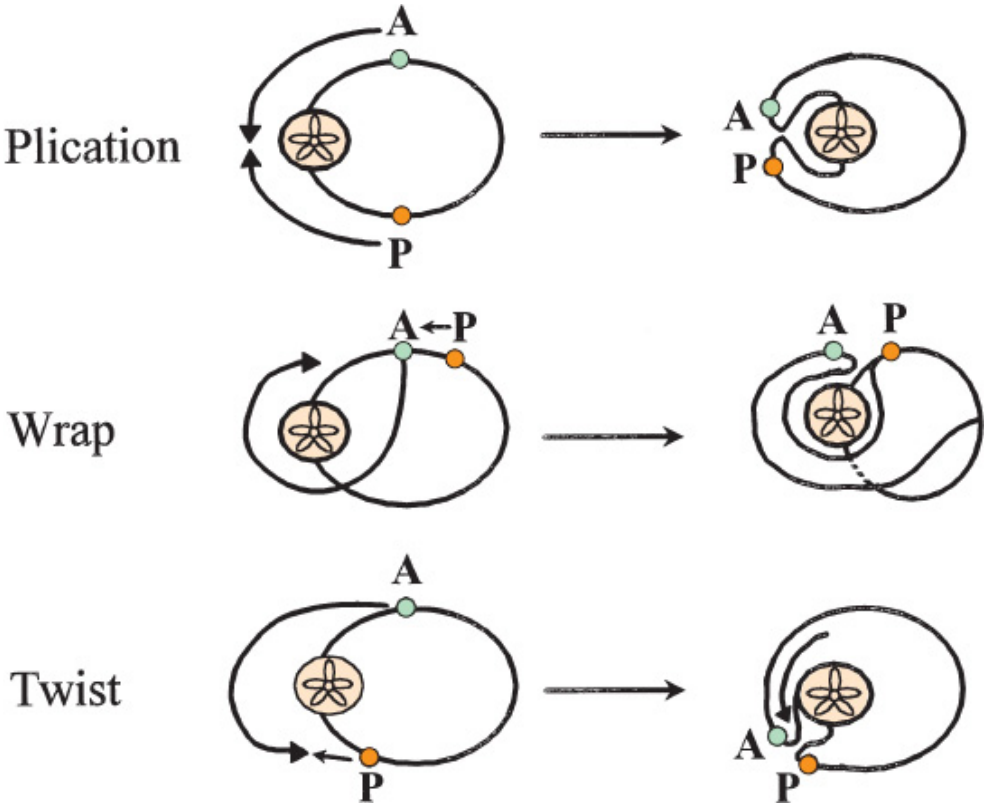

Figure 42.34 Schematic representations of the various possibilities of orientation of a Nissen fundoplication. The **top** set of figures represents the preferred approach, whereas the **bottom** two sets can be seen to result in twisting of the fundoplication.

The posterior and anterior fundic lips should be maneuvered (as in a "shoe shine") to allow the fundus to envelop the esophagus without twisting. The esophagus should comfortably lie in the untwisted fundus prior to suturing. Adequate size of the posterior opening must be ensured to avoid any compression of the posterior fundus, and there must be sufficient mobilization of the posterior fundus to avoid undue tension on the fundoplication. A 60-Fr bougie is passed to properly size the fundoplication, and the "lips" of the fundoplication sutured utilizing three interrupted 2-0 silk sutures buttressed with absorbable pledgets. The middle stitch can incorporate the muscular wall of the esophagus to facilitate a more secure fundoplication. The most common error is an attempt to grasp the anterior portion of the stomach to construct the right lip of the fundoplication rather

than the posterior fundus. When finished, the suture line of the fundoplication should be facing in a right anterior direction (**Fig. 42.36**). One may also consider a single-stitch pexy of the wrap posteriorly to the closed crura at this point to help prevent reherniation.[122]

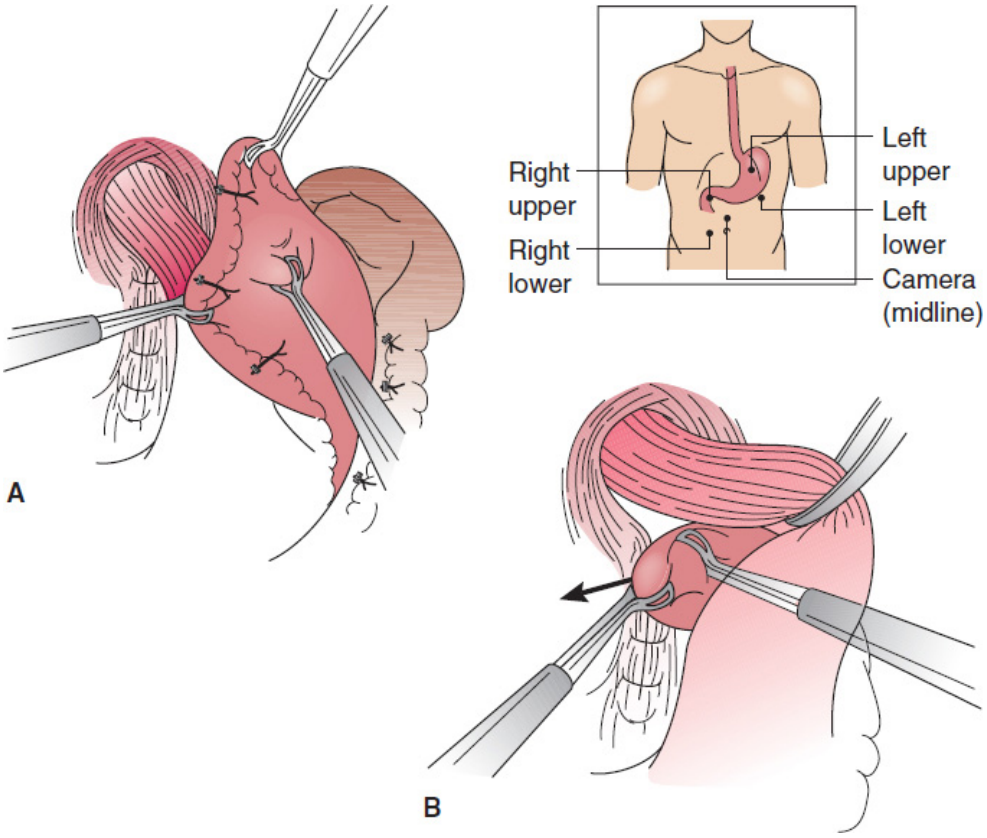

Figure 42.35 Placement of Babcock on the posterior fundus in preparation for passing it behind the esophagus to create the posterior or right lip of the fundoplication. The posterior fundus is passed left to right and grasped from the right through the right upper trocar. **A:** Location of posterior fundus for passage to the right side. **B:** The posterior fundus passed underneath the esophagus and grasped on the right.

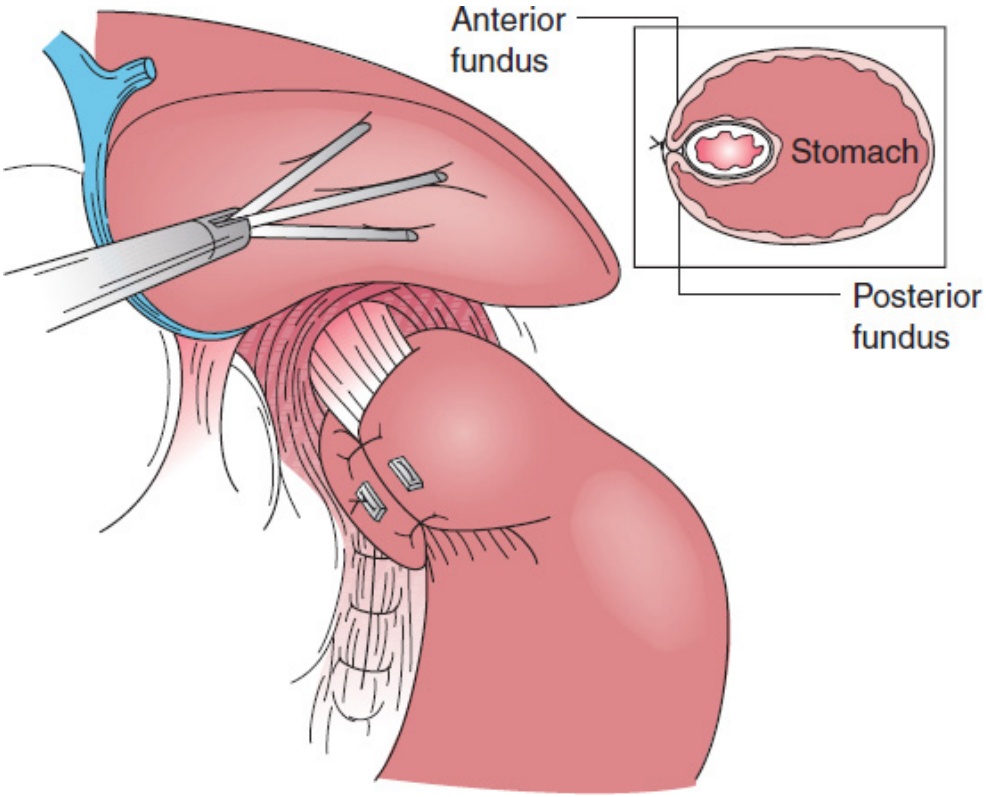

Figure 42.36 Fixation of the fundoplication. The fundoplication is sutured in place with pledgeted interrupted 2-0 silk sutures. A 60-Fr bougie is passed through the gastroesophageal junction prior to fixation of the wrap to ensure a floppy fundoplication. Inset illustrates the proper orientation of the fundic wrap.

Transthoracic Nissen Fundoplication

The indications for performing an antireflux procedure by a transthoracic approach are given in **Table 42.7**.

In the thoracic approach the hiatus is exposed through a left posterior lateral thoracotomy incision in the sixth intercostal space. When necessary, the diaphragm is incised circumferentially 2 to 3 cm from the lateral chest wall for a distance of approximately 10 to 15 cm. The esophagus is mobilized from the level of the diaphragm to underneath the aortic arch. Mobilization up to the aortic arch is usually necessary for repair in patients with a shortened esophagus to prevent undue tension. Failure to do this is one of the major causes for subsequent breakdown of a repair and return of symptoms. The cardia is then freed from the diaphragm. When all the attachments between the cardia and diaphragmatic hiatus are divided, the fundus and part of the body of the stomach are drawn up through the hiatus into the chest. The vascular fat pad that lies at the GEJ is excised. Crural

sutures are then placed to close the hiatus though are not tightened until later. The fundoplication is constructed by enveloping the fundus around the distal esophagus in a manner similar to that described for the abdominal approach. When complete, the fundoplication is placed into the abdomen by compressing the fundic ball with the hand and manually maneuvering it through the hiatus. The previously placed crural stitches are then tightened and knotted.

Collis Gastroplasty

In patients with a short esophagus secondary to a stricture, Barrett esophagus, or a large hiatal hernia, the esophagus can be lengthened with a Collis gastroplasty to allow a tension-free fundoplication around the newly formed gastric tube. Prior to considering a Collis, one must perform an extensive mediastinal mobilization of the esophagus at least 6 cm above the GE junction. If this does not achieve at least 2 cm of intra-abdominal esophageal length, a gastroplasty should be performed. With the bougie in place, a point approximately 3 cm below the angle of His is marked on the stomach with electrocautery. A 45-mm EndoGIA stapler (Universal EndoGIA, USSC, Stamford, Connecticut) is then used to fire horizontally toward the bougie at that level. A vertical staple line is then created alongside the bougie, as the assistant retracts the resected wedge laterally. This results in a 3- to 4-cm neoesophagus, which is then tested with methylene blue or saline to rule out a leak prior to proceeding with the fundoplication.[123]

Table 42.7 Indications for Performing an Antireflux Procedure by a Transthoracic Approach

Indication	Explanation
Previous hiatal hernia repair	In this situation, a peripheral circumferential incision in the diaphragm is made to provide simultaneous exposure of the upper abdomen. This allows safe dissection of the previous repair from both the abdominal and thoracic sides of the diaphragm.
Concomitant procedure	Concomitant esophageal myotomy for achalasia or diffuse spasm.
Short esophagus	This is usually associated with a stricture or Barrett esophagus. In this situation, the thoracic approach is preferred to allow maximum mobilization of the esophagus, the performance of a Collis gastroplasty, or, if necessary, placement of the repair without tension below the diaphragm.
Sliding hiatal hernia that does not reduce below the diaphragm during a roentgenographic barium study in the upright position	This can indicate esophageal shortening and, again, a thoracic approach is preferred for maximum mobilization of the esophagus and, if necessary, the performance of a Collis gastroplasty.
Associated pulmonary pathology	The nature of the pulmonary pathology can be evaluated and the proper pulmonary surgery, in addition to the antireflux repair, can be performed.

Obesity	The abdominal repair is difficult because of poor exposure, whereas the thoracic approach gives better exposure and allows a more precise repair.

Outcomes following Antireflux Surgery

Symptomatic and Objective Outcomes after Antireflux Surgery. Multiple studies of long-term outcomes following laparoscopic fundoplication document its ability to relieve typical reflux symptoms (heartburn, regurgitation, and dysphagia) in more than 90% of patients at follow-up intervals averaging 2 to 3 years and 80% to 90% of patients 5 years or more following surgery.[124–127] The results of laparoscopic fundoplication compare favorably with those of the "modern" era of open fundoplication.[126] Of note, atypical reflux symptoms (cough, asthma, laryngitis) after surgery are relieved in only two-thirds of patients.[128]

When compared to patients on PPIs, laparoscopic fundoplication leads to a better GERD-specific quality of life, fewer heartburn symptoms, but a higher risk of adverse events. The treatment failure rates are significantly lower after antireflux surgery in follow-up of 5 to 12 years,[127] with 5% to 18% requiring revision surgery. The most common reason for reoperation is dysphagia, which occurs in 2% to 16% of the patients. Rates of recurrent hiatal herniation are largely dependent on the size of the underlying hiatal hernia. While the need for reoperation after fundoplication for GERD is only approximately 5% over a patient's lifetime, it can be as high as 42% after repair of a giant paraesophageal hernia.[129]

When assessing some of the unpleasant side effects of antireflux surgery such as hyperflatulence and inability to belch or vomit, these symptoms are significantly more common than in patients on medical therapy. Nevertheless, studies have shown an improvement in quality of life following antireflux surgery, outperforming medical therapy on some parameters.[130–134]

Looking at objective physiologic outcomes, patients after antireflux surgery experience significantly greater reductions in 24-hour esophageal acid exposure when compared to the medical treatment cohort in long-term

follow-up.[135] Laparoscopic fundoplication also results in a significant increase in LES pressure and length, generally restoring these values to normal. Esophageal acid exposure is restored to normal in >90% of Nissen fundoplications versus 50% of patients with a partial fundic wrap.[117] There is still a significant proportion of patients (62%) who continue to take acid suppression medications postoperatively,[136] but only a quarter of these patients have been found to have abnormal pH scores.[137] Based on these data, objective evidence of reflux should be obtained prior to restarting acid suppression medications in patients with symptoms after a fundoplication.

Complications of Antireflux Surgery. Laparoscopic Nissen fundoplication has been extensively studied and its complications are well documented. Postoperative complications occur in approximately 8% of patients, with the rate of conversion to an open procedure of about 4%. The most common perioperative complication is early wrap herniation (1.3%), defined as occurring within 48 hours of surgery.[138]

Both pneumothorax and pneumomediastinum have been reported secondary to the breach of either pleural membrane. Accumulated carbon dioxide usually dissipates following release of pneumoperitoneum by a combination of positive pressure ventilation and absorption, and creating a large pleural defect prevents tension pneumothorax. Intraoperative complications are rare, and include trocar injury, gastric or esophageal perforation, hemorrhage, retractor trauma to the liver, splenic injury, and vascular injury to the aberrant left hepatic vein or inferior vena cava. Generally, immediate recognition and repair of injury is the key to avoiding a major complication. Major vascular injury mandates immediate conversion to an open procedure to achieve hemostasis. Mortality rate has been reported at 0.08%.

Roux-en-Y Gastric Bypass. Bariatric surgery is the procedure of choice in patients with refractory GERD and a BMI ≥ 35.[35] Fundoplication alone in this patient population poses a significant risk of failure or hernia recurrence without significant weight loss. Of the available bariatric procedures, Roux-en-Y gastric bypass (discussed in detail elsewhere in this text) has been demonstrated to be the most

effective at treating GERD, while sleeve gastrectomy carries the potential to exacerbate GERD symptoms and is contraindicated in patients with known esophagitis.

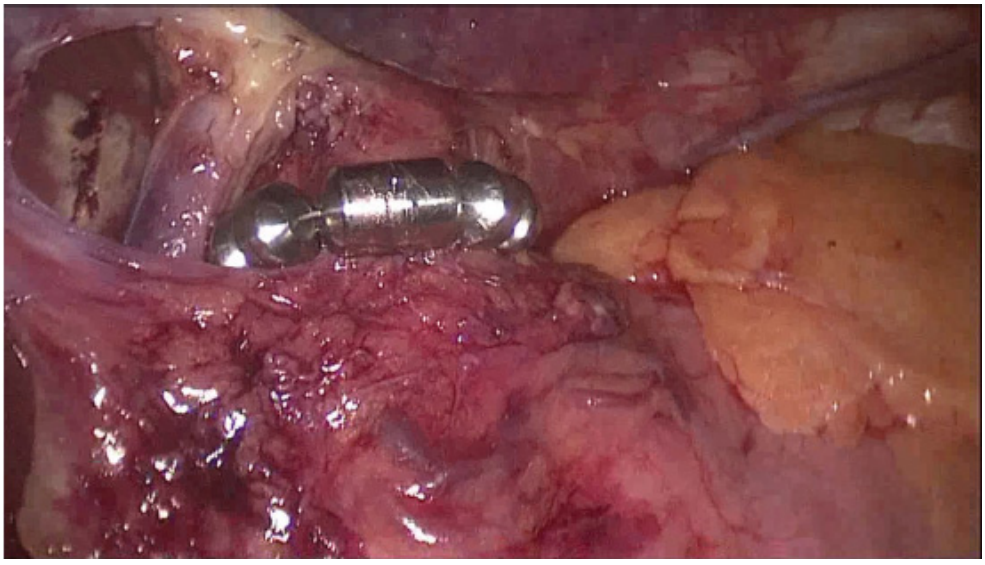

Figure 42.37 Magnetic sphincter augmentation device (LINX) placed around the gastroesophageal junction.

Magnetic Sphincter Augmentation. The LINX Reflux Management System (Torax Medical, Shoreview, MN) is a ring of titanium magnetic beads that is placed around the GEJ laparoscopically to mimic and augment the function of the LES (**Fig. 42.37**). The ring increases the natural resistance of the LES to opening but expands to allow food passage with swallowing. Concurrent hiatal hernia repair is performed during LINX placement, although patients with large hernias (>3 cm) and/or Barrett esophagus have traditionally been excluded from this procedure. Other exclusion criteria include those with allergies to titanium, stainless steel, nickel, or iron. Caution should be taken in those who need ongoing MRI screening, although the newest version of the device is compatible with 1.5-Tesla MRI.

Single-arm studies have shown that 80% to 90% of patients stop PPI use at up to 5 years after LINX placement, with a normalization of esophageal pH in 70%.[139,140] Importantly, all patients retain the ability to belch and vomit. Ganz et al.'s pivotal trial showed that dysphagia is present in about 68% of the patients in the first several months postoperatively, but decreases to 4%

by 3 years. Five percent of patients required endoscopic balloon dilation or removal of the device for severe dysphasia.[141] Subsequent studies have also demonstrated that device erosion occurs in about 1.2% of the patients.[142] Nonrandomized controlled trials have shown comparable outcomes of the LINX to Nissen fundoplication with lower rates of gas bloat and greater ability to belch and vomit in the LINX patients, with comparable safety, rates of PPI suspension, and postoperative GERD-HRQL scores.[143] Long-term data on hernia recurrence in patients with magnetic sphincter augmentation and concurrent large hiatal or paraesophageal hernia repair is missing. However, short-term results are encouraging, with a 10% endoscopic recurrence rate reported at 12 months. Less than a third of these patients were symptomatic and required operative intervention.[144]

Endoscopic Management of GERD

11 Medical therapy for GERD and antireflux surgery both have inherent drawbacks. Major limitations of acid suppressive medications include the inability to prevent regurgitation of weakly acidic or nonacidic refluxate and the need for chronic, continual therapy, not to mention the cost, inconvenience, potential side effects, and need for ongoing dietary and lifestyle modifications. In addition, current therapy does not address the main pathophysiologic contributor to the presence of GERD, the mechanically defective LES Fundoplications, while intended to permanently restore the LES, suffer from the potential for perioperative complications, a high initial cost, the risks inherent in general anesthesia, as well as possible short- and long-term side effects. For all these reasons, there is an interest in developing endoscopic means of restoring LES competence. The two main endoscopic approaches for treating GERD include the Stretta procedure and transoral incisionless fundoplication (TIF 2.0).

Radiofrequency Ablation. Stretta (Curon Medical, Sunnyvale, CA) involves the application of controlled radiofrequency energy (RFA) to the LES region using a four-channel RF generator and catheter system that is introduced endoscopically. Multiple lesions are created in the region 2 cm above and below the z-line, and thermocouples at each needle tip ensure that the lesion temperatures stay below 100°C to minimize collateral tissue damage. Appropriate candidates

for this procedure include patients who have relatively normal esophageal peristalsis and adequate relaxation of the LES, nonerosive reflux, or mild esophagitis (LA grade A or B), and are refractory to or wish to discontinue long-term medical therapy. Those with large hiatal hernias, significant dysphagia or esophageal aperistalsis, or advanced esophagitis are not good candidates for Stretta.

This procedure has been shown to reduce the rate of postprandial transient LES relaxations and esophageal acid exposure.[145,146] Stretta also decreases the compliance of the GEJ and causes a reduction in esophageal acid sensitivity, leading to a decrease in GERD symptoms.[147,148] RCTs and cohort studies show a significant reduction in PPI use at up to 10 years of follow-up.[149–151] One small cohort study has suggested that RFA may also improve gastroparesis via an unknown mechanism.[152]

Nonrandomized studies comparing RFA to fundoplication show that 51% to 58% of the Stretta patients are able to discontinue PPI use at 5 years of follow-up, compared to 91% to 97% of the patients after a Nissen.[153] Although there was a significant improvement in symptoms after RFA, up to 59% of those patients subsequently required antireflux surgery.[154] The complication rate is very low at <1%, with small erosions and mucosal lacerations being the most common adverse events.[155]

Transoral Incisionless Fundoplication (TIF 2.0). TIF is performed using the EsophyX Z+ device (EndoGastric Solutions, Redmond, WA), which creates full-thickness serosa-to-serosa plications with polypropylene H-shaped fasteners to reconstruct a valve that is 200 to 300 degrees in circumference and 3 cm in length,[156] mimicking a partial fundoplication. TIF 2.0 has been shown to reduce GEJ distensibility and increase resting LES pressures, thereby decreasing the number of transient LES relaxation episodes. It is appropriate for patients with a dysfunctional LES without a significant hiatal hernia (Hill grade I or II). Several RCTs comparing TIF 2.0 to PPI therapy showed that the procedure is superior to medical treatment in eliminating regurgitation and extraesophageal symptoms, and allowed 66% to 72% of patients to stay off PPIs for at least 5 years.[157,158] The reported complication rate is 2% to 2.5%, and most commonly

consists of gastrointestinal perforation, bleeding, and pneumothorax.[159] Comparative data to surgical fundoplication is pending.

Esophageal Tumors and Injury

Natalie S. Lui, Mark F. Berry, Yulia Zak, and Leah M. Backhus

Key Points

1. The incidence of esophageal adenocarcinoma is increasing but squamous cell carcinoma is the most common cancer histology worldwide.
2. The latest AJCC esophageal cancer staging system separates the clinical, pathologic, and post-neoadjuvant stage groups and has different staging systems for squamous cell and adenocarcinoma.
3. Resection remains essential to cure of esophageal cancer for most patients who do not have metastatic disease. The mortality of esophagectomy has improved over time, particularly in high-volume centers. Minimally invasive techniques are increasingly used, but the procedure remains complex with relatively high morbidity.
4. Esophagectomy without induction therapy is recommended for superficial tumors that involve the submucosa (T1bN0M0) so that lymph nodes can be removed for diagnostic and therapeutic purposes.
5. Whether to give neoadjuvant therapy before esophagectomy for T2N0M0 esophageal cancer is controversial.
6. Neoadjuvant chemoradiation improves overall survival and disease-free survival over primary surgery in patients with locoregional disease.
7. Esophagectomy is rarely indicated for patients with metastatic esophageal cancer but palliative procedures can improve comfort, possibly restore swallowing ability, and provide nutritional support.
8. Choice of esophagectomy (three-incision, transhiatal, Ivor Lewis, or thoracoabdominal; open or minimally invasive) depends on the tumor location, patient characteristics, and surgeon experience.
9. Leiomyomas are the most common benign esophageal neoplasm and can often be resected by endoscopic submucosal dissection or surgical enucleation.

MALIGNANT ESOPHAGEAL NEOPLASMS

Epidemiology and Histology

Esophageal cancer is the most common indication for esophagectomy. Although relatively uncommon in that it represents only 1% of all new cancer cases, the number of cases of esophageal cancer in the United States has risen from less than 14,000 new cases annually in the 2000s, to almost 17,000 annual new cases in 2012, and now to an estimate of 18,440 in the year 2020.[1–5] Adenocarcinoma and squamous cell carcinoma are by far the most common esophageal cancer 1 histologies. Squamous cell carcinoma is much more common worldwide, with an estimated 398,000 squamous cell carcinoma cases and only 52,000 adenocarcinoma cases in 2012.[6] The epidemiology in the United States has evolved such that adenocarcinoma (64% of esophageal cancer cases) is now more common than squamous cell carcinoma (31% of cases).[1,2,5]

Esophageal cancer in the United States is most frequently diagnosed among people aged 65 to 74 years, with a median age at diagnosis of 68.[1] Tumor histology appears to differ by race: 71.4% of cases diagnosed among Caucasian patients are adenocarcinomas, while 75% of cases diagnosed among Black patients are squamous cell carcinoma.[1] Interestingly, the incidence of esophageal cancer among white men has almost doubled since 1975 while the incidence among black men and women have significantly decreased.[1] Tobacco use and a history of mediastinal radiation are risk factors for both tumor types.[2,7] Other risk factors for adenocarcinoma include male sex, gastroesophageal reflux disease (GERD), obesity, and Barrett esophagus.[2,8,9] Barrett esophagus with high-grade dysplasia is considered a premalignant condition as 13% to 50% are found to harbor intramucosal carcinoma or invasive carcinoma at the time of biopsy or resection.[2] Additional risk factors for squamous cell carcinoma are conditions that cause chronic esophageal irritation and inflammation such as alcohol abuse, achalasia, esophageal diverticuli, and frequent consumption of extremely hot beverages.[2] Approximately three-quarters of all adenocarcinomas are found in the distal esophagus whereas squamous cell carcinomas are more evenly distributed throughout the distal two-thirds.[2]

Clinical Presentation and Diagnostic Evaluation

The Society of Thoracic Surgeons has published guidelines on the diagnosis and staging of patients with esophageal cancer.[10] The workup often starts because patients present with symptoms of dysphagia (74%) and weight loss (57%) with less common symptoms being heartburn, odynophagia, shortness of breath, chronic cough, hoarseness, and hematemesis.[11] The physical examination is usually unremarkable.[2]

Upper gastrointestinal (GI) tract contrast studies and upper endoscopy with biopsy are commonly the initial diagnostic tests. An upper GI contrast study typically shows a stricture or ulceration when malignancy is present. Upper GI endoscopy typically shows a friable, ulcerated mass, and allows identification of tumor location and length and biopsy for pathologic examination. In addition to identifying the cancer and providing tissue for histologic confirmation, the endoscopy should also report detailed information on the location of the tumor as well as the presence of other areas of Barrett esophagus which are particularly important to the selection of surgical approach. For distal tumors that involve the gastroesophageal junction, the extent of gastric involvement should be carefully evaluated. Tumors with epicenters in the lower esophagus that extend to the junction (Siewert Type I) and tumors of the true gastric cardia with epicenter within 1 cm above and 2 cm below the junction (Siewert Type II) should be treated as esophageal cancers. Tumors with epicenter between 2 cm and 5 cm from junction but infiltrate the junction from superior extension (Siewert Type III) should be treated as gastric cancers though surgical approach will likely involve some degree of distal esophageal resection to obtain negative margins and complete resection.[12]

After a histologic cancer diagnosis has been obtained, subsequent studies are performed to determine clinical stage as accurately as possible before treatment is initiated to optimize esophageal cancer outcomes. Accurate staging and appropriate treatment can avoid both inadequate and unnecessary treatment to balance the potential benefits of improving prognosis with risks of treatment-related morbidity. A computed tomographic (CT) scan of the chest, abdomen, and pelvis with oral and intravenous contrast should be

obtained when esophageal cancer is detected. This study is useful in evaluating for distant metastatic disease such as in the liver or lungs, though CTs are not generally useful for detecting nodal disease or identifying or determining the extent of early-stage cancers localized to the superficial aspect of the esophageal wall.[9] Positron emission tomography (PET) scans improve staging and will detect previously unsuspected metastatic disease in up to 15% to 20% of patients. They should be considered in place of CT scans or as an additional study when the CT scan does not show metastatic disease.[13,14] Further studies that evaluate T and N status would not typically impact treatment and therefore are generally unnecessary if distant disease is identified and subsequently confirmed by biopsy.

If CT and PET do not demonstrate distant disease, subsequent evaluation determines the extent of locoregional disease. Endoscopic ultrasound (EUS) is often the next test.[2,3,15] EUS provides more accurate evaluation of the depth of tumor invasion (T stage) and the extent of lymph node involvement (N stage) than both PET and CT.[16,17] However, the specific information obtained from EUS alone does not often change the clinical management of patients with esophageal cancer. For patients with significant symptoms from bulky tumors, the local extent of the tumor is almost certainly at least T3 with a high chance of local lymph node involvement. In these cases, EUS is likely only to confirm the clinical suspicion or to be unable to provide a complete evaluation due to luminal narrowing by the tumor, and therefore not changing the planned management. Conversely, EUS is generally less accurate for early-stage lesions such as T1 or T2 compared to more advanced tumors.[18–22] The accuracy of T staging can also be improved via endoscopic resection, which can be therapeutic in some cases as discussed below.[15,23,24] Finally, most incidences of understaging from EUS are due to missing nodal disease, and the specificity and the sensitivity for identifying lymph node disease are better when EUS is combined with fine-needle aspiration (FNA) compared to EUS alone.[25]

Additional studies prior to treatment may be indicated in certain circumstances. Bronchoscopy should be considered for tumors in the upper and middle esophagus to rule out airway invasion, which would preclude an eventual attempt at surgical resection. Airway evaluation is ideally done prior to starting any therapy in cases where there is a high suspicion due to imaging or clinical symptoms such as cough or pneumonia that could be due

to an esophageal-airway fistula, as distinguishing between treatment changes and definite tumor invasion can be difficult after patients have been treated with chemotherapy and radiation. In addition, distant metastases are unfortunately missed even with completion of the staging evaluation described above. Small liver or lung metastases can be missed by both PET and CT scans, and patients can also have undetected pleural or peritoneal disease.[26] Staging via minimally invasive surgical techniques of thoracoscopy and laparoscopy improves the accuracy of the above noninvasive testing.[26–28] Use of these invasive techniques is relatively uncommon but should be considered in select patients, such as those who may be considered to have a high risk of treatment-related complications. Staging laparoscopy may particularly have a role for patients with adenocarcinoma of the esophagus or gastroesophageal junction.[29]

Staging

Esophageal cancer staging is defined by the American Joint Committee on Cancer (AJCC) Staging System that establishes tumor–node–metastasis (TNM) subclassifications based on the depth of invasion of the primary tumor (T), involvement of regional lymph nodes in the adventitia or periesophageal tissue from the upper esophageal sphincter to the celiac artery (N), and presence of metastatic disease (M).[30] The most recent 8th edition used the Worldwide Esophageal Cancer Collaboration database to expand on the 7th edition and provide distinctive and homogeneous stage groups with monotonically decreasing survival (**Fig. 43.1**).[31] **Figure 43.2** and **Tables 43.1** and **43.2** show the specific 8th edition TNM definitions. Grade is important for pathologic staging of early-stage cancers. Location is important to subgroup pT3N0M0 squamous cell carcinoma. The definition of the gastroesophageal junction was also revised in the new edition, such that cancers involving it with epicenters no more than 2 cm into the gastric cardia are staged as esophageal cancers and those with more than 2-cm involvement of the gastric cardia are staged as stomach cancers.

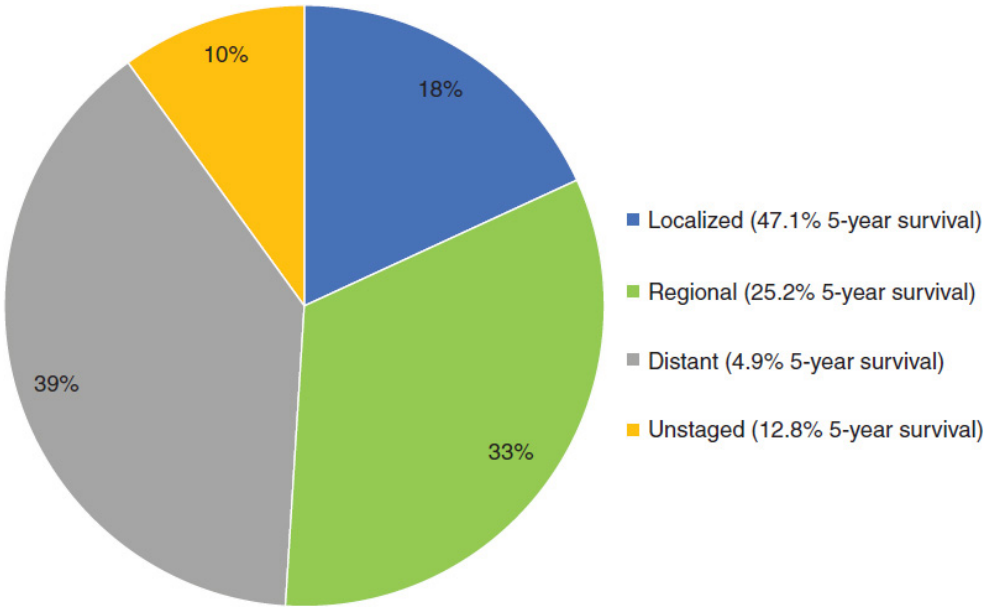

Figure 43.1 Distribution and survival of esophageal cancer by stage. (Adapted from Howlader N, Noone AM, Krapcho M, et al, eds. In: *SEER Cancer Statistics Review, 1975–2017, National Cancer Institute*. Bethesda, MD, https://seer.cancer.gov/csr/1975_2017/, based on November 2019 SEER data submission, posted to the SEER web site, April 2020.)

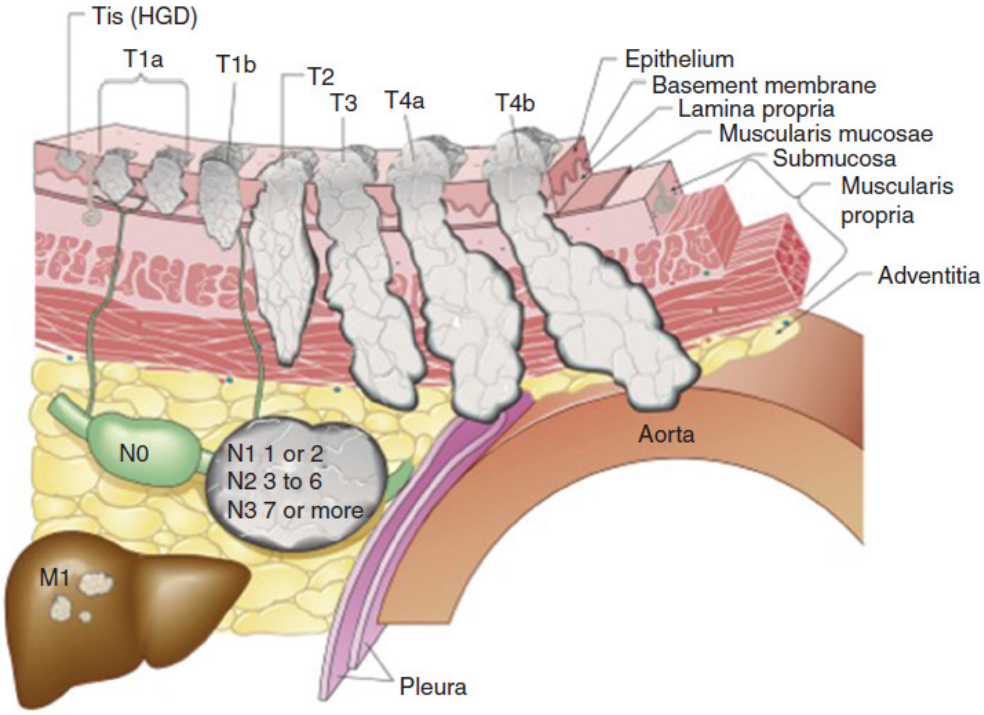

Figure 43.2 TNM categories. T is categorized as Tis: high-grade dysplasia (HGD). T1 is cancer that invades the lamina propria, muscularis mucosae, or submucosa and is subcategorized into T1a (cancer that invades the lamina propria or muscularis mucosae) and T1b (cancer that invades the submucosa); T2 is cancer that invades the muscularis propria; T3 is cancer that invades the adventitia; T4 is cancer that invades the local structures and is subcategorized as T4a (cancer that invades adjacent structures such as the pleura, pericardium, azygos vein, diaphragm, or peritoneum) and T4b (cancer that invades the major adjacent structures, such as the aorta, vertebral body, or trachea). N is categorized as N0 (no regional lymph node metastasis), N1 (regional lymph node metastases involving one to two nodes), N2 (regional lymph node metastases involving three to six nodes), and N3 (regional lymph node metastases involving seven or more nodes). M is categorized as M0 (no distant metastasis) and M1 (distant metastasis). (Reproduced from Rice TW, Ishwaran H, Ferguson MK, et al. Cancer of the esophagus and esophagogastric junction: An eighth edition staging primer. *J Thoracic Oncol* 2017;12(1):36–42.)

Table 43.1 T, N, and M Categories for Esophagus and Esophagogastric Junction Cancer in the 8th Edition of the American Joint Committee on Cancer (AJCC) Cancer Staging Manual

Category	Criteria
T Category	
TX	Tumor cannot be assessed
T0	No evidence of primary tumor
Tis	High-grade dysplasia (malignant cells confined by the basement membrane)
T1a	
T1b	
T2	Invasion into the lamina propria or muscularis mucosae
T3	
T4a	Invasion into the submucosa
T4b	Invasion into muscularis propria
	Invasion into adventitia
	Invades resectable adjacent structures (pleura, pericardium, azygos vein, diaphragm, or peritoneum)
	Invades unresectable adjacent structures (aorta, vertebral body, or trachea)
N Category	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	1–2 positive regional lymph nodes
N2	3–6 positive regional lymph nodes
N3	7 or more positive regional lymph nodes
M Category	
M0	No distant metastases
M1	Distant metastases

Adapted from Rice TW, Ishwaran H, Ferguson MK, et al. Cancer of the esophagus and esophagogastric junction: An eighth edition staging primer. *J Thoracic Oncol* 2017; 12(1):36–42.

A major change from the 7th edition is that the 8th edition has separate classifications for clinical (cTNM), pathologic (pTNM), and post-neoadjuvant (ypTNM) stage groups (**Tables 43.3** to **43.5**). 2 Clinical and pathologic groups were separated based on survival profiles. A separate post-neoadjuvant pathologic stage group was added to account for pathologic information that may not have been available after induction therapy and different survival profiles across groups.[31]

Treatment

Consensus guidelines provide recommendations for the treatment of esophageal cancer. Treatment options include local mucosal resection or ablation therapies, esophagectomy, chemotherapy, and radiation therapy. Recommended treatment is primarily dictated by stage, tumor location, and patients' medical fitness for receiving a potential therapeutic modality. However, definitive data from randomized trials to guide the treatment of esophageal cancer is lacking for many clinical situations. Consensus guidelines reflect the lack of definitive evidence and often allow a spectrum of potential treatments for many clinical situations. Given both the generally poor overall prognosis and the potential morbidity associated with therapy, multidisciplinary evaluation by surgery, medical oncology, and radiation oncology should be considered for all patients before a treatment strategy is initiated. Treatment that does not follow guidelines should probably only be used in the context of clinical trials. In addition, all treatment strategies should include careful nutritional assessment and counseling, as well as smoking cessation advice if indicated. In some situations, placement of a pretreatment feeding tube can be integral in allowing a patient to adequately start and maintain therapy.

The stage groupings described above are very useful for both providing prognosis and guiding treatment. However, patients can be categorized more simply when considering treatment. When considering treatment for esophageal cancer patients, the approach is initially dictated by whether the patients have been determined to have early-stage superficial cancers, cancers that are locally advanced with locoregional disease but no distant metastases, and cancers with distant disease. The 3 general treatment

guidelines for each of these categories are discussed in the following sections.

Table 43.2 Histologic Grade (G) and Squamous Cell Carcinoma Location (L) Categories for Esophagus and Esophagogastric Junction Cancer in the 8th Edition of the American Joint Committee on Cancer (AJCC) Cancer Staging Manual

Category	Criteria
Adenocarcinoma G Category	
GX	Differentiation cannot be assessed
G1	Well differentiated, with >95% of the tumor composed of well-formed glands
G2	Moderately differentiated, with 50–95% of the tumor showing gland formation
G3	Poorly differentiated, with tumors composed of nests and sheets of cells with <50% of the tumor showing gland formation
Squamous Cell Carcinoma G Category	
GX	Differentiation cannot be assessed
G1	Well differentiated, with prominent keratinization with pearl formation and a minor component of nonkeratinizing basal-like cells, tumor cells arranged in sheets, and mitotic counts low
G2	Moderately differentiated, with variable histologic features ranging from parakeratotic to poorly keratinizing lesions and pearl formation generally absent
G3	Poorly differentiated, consisting predominantly of basal-like cells forming large and small nests with frequent central necrosis and with the nests consisting of sheets or pavement-like arrangements of tumor cells that

	are occasionally punctuated by small numbers of parakeratotic or keratinizing cells
Squamous Cell Carcinoma L Category	
LX	Location unknown
Upper	Cervical esophagus to lower border of the azygos vein
Middle	Lower border of the azygos vein to lower border of the inferior pulmonary vein
Lower	Lower border of the inferior pulmonary vein to the stomach, including the esophagogastric junction

Adapted from Rice TW, Ishwaran H, Ferguson MK, et al. Cancer of the esophagus and esophagogastric junction: An eighth edition staging primer. *J Thoracic Oncol* 2017;12(1):36–42.

Superficial Cancers

Patients with T1-2N0 esophageal cancer typically are recommended to undergo resection without induction therapy as noted in consensus guidelines. The prognosis for patients treated for intra- and submucosal (T1) esophageal cancers is significantly better than the prognosis for all other patients found to have esophageal cancer, even those also found in other relatively early-stage disease.[33] These early-stage cancers are generally either found incidentally during endoscopies done for other reasons or during endoscopies done for Barrett monitoring, though fewer than 15% of esophageal adenocarcinomas are detected during surveillance endoscopies.[9]

Esophagectomy is effective oncologically for these superficial cancers but is associated with considerable morbidity and mortality despite improvements over time and the development of minimally invasive techniques.[34–40] Although recent data from high-volume centers have shown low mortality rates of 1% to 3.5%, studies involving population-based databases or multicenter trials have shown esophageal resection to have perioperative mortality rates as high as 8.8% to 14%.[35,37,40–42] Local

treatments with modalities such as endoscopic mucosal resection (EMR), endoscopic submucosal dissection (ESD), radiofrequency ablation, cryotherapy, and photodynamic therapy can provide effective cancer treatment for superficial cancers with much less treatment-related morbidity.[43–56] These local treatments are good treatment options for patients with superficial tumors that involve only the mucosa (T1a), but pathologic examination should confirm complete resection with negative margins and close endoscopic surveillance should be planned post treatment.

Local mucosal therapies at the present time are generally not considered appropriate for superficial tumors that involve the submucosa (T1b) which have occult lymph node involvement in as many as 50% of patients.[57,58] Therefore, esophagectomy without induction therapy rather than endoscopic therapy is recommended for superficial tumors that involve the submucosa (T1b) so that the lymph nodes can be removed for both diagnostic 4 and therapeutic purpose. Patients undergoing esophagectomy without induction therapy should have at least 15 lymph nodes removed during surgery for adequate nodal staging.[59]

The optimal management of esophageal cancer clinically staged 5 as T2N0M0 is somewhat more controversial.[60] Clinical staging modalities for this subset are somewhat unreliable, with significant percentages of patients being both under and over staged.[18,61–64] Perhaps because clinical staging inaccuracies lead to a relatively high incidence of patients actually having nodal disease present at the time of surgical resection, induction therapy use

in this setting has been increasing and was shown recently to exceed 50% for cases that were reported to the Society of Thoracic Surgeons General Thoracic Database in 2011.[61] However, data that proves a survival benefit to induction therapy over surgery alone is still lacking.[65,66] Consistent with the uncertainty of optimal treatment, consensus guidelines for medically fit patients allow a wide spectrum of treatment possibilities that include definitive chemoradiation and esophagectomy with or without induction or adjuvant therapy. One clinical approach to patients with cT2N0 disease is proceeding with primary esophagectomy when the tumor was incidentally found on endoscopy or during workup for very mild symptoms and using induction therapy in cases where patients had symptoms more consistent with a bulky or locally advanced tumor.

Locoregional or Locally Advanced Disease

Approximately 33% of esophageal cancer patients have regional disease at the time of diagnosis, with a 5-year survival of only 10% to 30%.[1,2,33] Surgery is considered integral to achieving cure in patients with esophageal cancer, as one study showed the 5-year survival rates for patients with stages I through III esophageal cancer treated with and without surgery to be 28% and 10%, respectively.[67–69] Definitive chemoradiation is generally reserved for those patients who refuse surgery or are not surgical candidates as noted in consensus guidelines. Areas of esophageal cancer in which definitive chemoradiation is recommended in place of surgical resection are squamous cell carcinoma of the cervical esophagus and patients with T4b (unresectable) tumors.[70–73] Some data suggest that definitive chemoradiation could be adequate for some patients with squamous cell carcinoma in other esophageal locations, but surgery is considered integral to potential cure for adenocarcinoma in which pathologic complete response rates are generally less common.[74–77]

The treatment for locally advanced esophageal cancer that does not have distant metastases and is potentially resectable (T3-4aN0, T1-4aN1M0) is highly variable in practice.[78] The poor survival rate after esophagectomy alone for patients with locally advanced but not metastatic disease led to many studies of multimodality therapy in efforts to improve outcomes.[4] Although not all trials demonstrated a benefit to induction therapy, recent

evidence suggests that induction chemoradiation followed by surgical resection is the optimal treatment for 6 patients with T3-4a tumors or nodal disease.[79–84] Most importantly, the Dutch Chemoradiotherapy for Oesophageal Cancer followed by Surgery Study (CROSS) randomized trial demonstrated a survival benefit to induction chemoradiation followed by surgery compared to surgery alone (47% vs. 33% 5-year survival after an 84-month median follow-up) for esophageal or gastroesophageal junction cancer.[85,86]

Induction therapy is currently used in most patients with locally advanced disease.[87] However, the optimal induction regimen has not been precisely determined. Induction chemotherapy without radiation has also been shown to be beneficial for distal esophageal and gastroesophageal junction adenocarcinomas and is used by some high-volume centers.[88,89] Although combined chemoradiation has the theoretical advantage over chemotherapy alone of providing local benefit in addition to systemic control as well as possibly facilitating resectability, a definitive survival benefit has not been demonstrated.[90] The FLOT chemotherapy regimen (docetaxel, oxaliplatin, leucovorin, and fluorouracil) has recently been shown to have survival advantages over previous standard chemotherapy regimens for gastric and gastroesophageal junction adenocarcinomas.[91] Currently, there are several major ongoing randomized trials comparing induction chemotherapy versus induction chemoradiation.[92,93]

Metastatic or Unresectable Disease

Approximately 40% to 50% of patients have evidence of distant metastatic disease at the time of diagnosis.[1,2] Palliative therapy is recommended for these patients, and can include chemotherapy, clinical trial enrollment if available, or best supportive care. Best supportive care is often the most appropriate treatment option. Patients' performance status should determine whether chemotherapy is added to best supportive care. Specific symptoms that often need palliation include dysphagia, pain, and nausea. Oncologists generally avoid feeding tubes in patients with stage IV cancer but feeding tubes may be reasonable options in some select patients with limited metastatic disease. Radiation or endoscopic management techniques such as dilation and stenting can be used to palliate dysphagia or cases of bleeding

from esophageal tumors. Palliative esophagectomy for patients with metastatic disease may have 7 a role in very few cases and should be considered very selectively given the morbidity of surgery and the poor prognosis with or without surgery.

Prognosis

Survival of esophageal cancer has improved from <5% at 5 years in 1975 to approximately 20% currently.[1,94,95] There are multiple factors responsible for this improvement, including a change in the stage distribution and more diagnoses of early-stage cancers secondary to the recognition of the importance and need for surveillance of Barrett esophagus, development of low-risk but highly effective endoscopic therapies for early-stage superficial cancers, improvements in the knowledge of the importance of multimodality for locally advanced cancers, and improvement in the outcomes associated with esophagectomy in general. As expected, survival correlates with the stage at presentation. Patients with localized disease have a 5-year survival of 47.1%, while patients with regional disease and distant disease have 5-year survival of 25.2% and 4.9%, respectively.[1] Specific survival is obviously impacted by not only stage, but therapy as discussed above. Survival curves after esophagectomy for various specific stage presentations are shown in **Figure 43.3**.[96]

ESOPHAGECTOMY

Surgery is recommended as possible treatment for most cases of esophageal cancer that do not have invasion of unresectable structures or distant metastatic disease. Several studies have provided evidence that complete surgical resection provides the best chance for cure for these patients.[67–69] However, surgery for locoregional esophageal cancer is utilized in less than half of potentially resectable cases, perhaps because esophagectomy is historically associated with significant morbidity and mortality and disappointing long-term results.[68,97,98] Mortality following esophagectomy has decreased over time but still exceeds that of most surgical procedures, and long-term survival generally remains poor. Consequently, minimizing

perioperative morbidity in any manner possible is critically important, such that primary nonsurgical treatment is reserved for those who refuse surgery, have unresectable cancers, or are not thought to be surgical candidates for other reasons.

Techniques of Esophagectomy

Resection of the esophagus for malignancy is a technically complex procedure. The esophagus traverses three body regions (neck, chest, and abdomen) and the anatomy of the esophagus in the posterior mediastinum is such that its accessibility is very different at various positions in the chest. In addition, an appropriate conduit must be prepared in order to reestablish GI continuity, and this conduit must be placed in a location such that its blood supply will remain viable. Esophageal resection generally requires access to at least two body cavities, and often requires at least two incisions as well as patient repositioning and lung isolation with single-lung ventilation. Structures at risk of intraoperative injury include the spleen, trachea, and mainstem bronchi as well as major vascular structures in the chest such as the aorta.

Esophageal resection can be performed via several different techniques, with the most appropriate technique for any specific individual patient being dependent on both patient and surgeon factors. The most common surgical techniques used for esophagectomy are listed in **Table 43.6**. Minimally invasive techniques with either laparoscopy and/or thoracoscopy have been reported for all approaches except the left thoracoabdominal approach.

Specifics for each surgical technique are described below, with advantages and disadvantages listed in **Table 43.7**. The approach chosen for a patient depends on personal surgical experience and preference, institutional tradition, and patient characteristics. [8] Relevant factors include stage of disease, associated lesions such as Barrett esophagus or achalasia, other medical comorbidities, pulmonary function, and previous surgical history. In general, proximal and distal margins of at least 5 cm are desired; thus, the location of the tumor is a critical factor in determining surgical approach.[99,100] Also, the importance of the total number of lymph nodes involved and removed during surgery is increasingly recognized, so transthoracic approaches may be preferred over others that do not provide as

optimal access to the relevant nodes.[59,101–106] Interestingly, an individual surgeon's skills are probably more critically important than variations in surgical approach in optimizing the long-term survival after esophagectomy for esophageal cancer.[107]

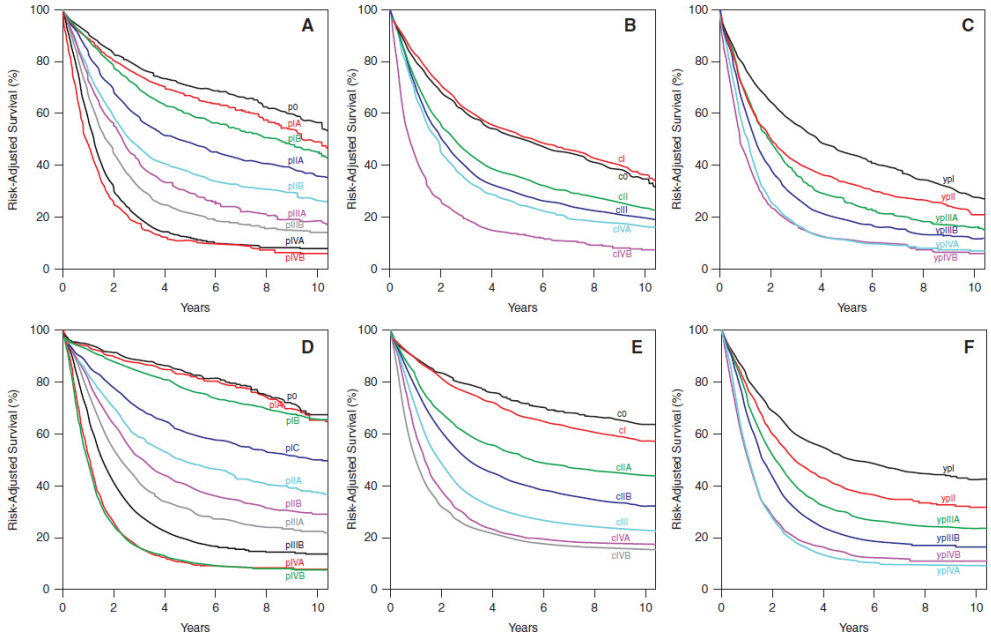

Figure 43.3 Risk-adjusted survival for squamous cell carcinoma (**A**) pathologic, (**B**) clinical, and (**C**) post-neo adjuvant stage groups, as well as adenocarcinoma (**D**) pathologic, (**E**) clinical, and (**F**) post-neoadjuvant stage groups. (Reproduced from Rice TW, Gress DM, Patil DT, et al. Cancer of the esophagus and esophagogastric junction-Major changes in the American Joint Committee on Cancer eighth edition Cancer Staging Manual. *CA Cancer J Clin* 2017;67(4):304–317.)

For all approaches, patients undergo preoperative upper endoscopy to confirm tumor location prior to resection to ensure the planned approach is appropriate. Patients with tumors in the mid-esophagus or more proximal esophagus should have bronchoscopy to evaluate for airway involvement. Most surgeons place an orogastric or nasogastric (NG) tube prior to the start of the procedure to assist in esophageal mobilization. These tubes are manipulated during the procedure as requested and guided by the surgical team. Jejunostomy feeding tubes are routinely placed in many patients because there may be a delay in the return of normal eating during the postoperative period. However, feeding tubes themselves are associated with complications and some surgeons selectively place feeding tubes.[108,109]

Surgeons overwhelmingly choose to use the stomach as the final conduit and most of these patients have good or excellent functional results.[110] Patients generally express good satisfaction with their life after esophageal replacement with a gastric conduit, but post-esophagectomy patients do fare worse in some physical and social functioning factors compared to the general population.[111] Patients who have had prior gastric surgery or another chronic condition such as diabetic gastroparesis may require a colon or jejunal interposition to reestablish GI continuity.[112–114]

Table 43.6 General Operating Room Set-Up for Different Esophagectomy Approaches

Procedure	Position	Order of Operation	Anastomosis	One-Lung Ventilation
Three-incision	1) Left lateral 2) Supine	1) Right thoracic 2) Abdominal with left cervical	Left cervical	Yes
Transhiatal	Supine	Abdominal with left cervical	Left cervical	No
Ivor Lewis	1) Supine 2) Left lateral	1) Abdominal 2) Right thoracic	Right chest	Yes
Left thoracoabdominal	Supine with chest bumped 45 degrees	Left thoracoabdominal	Left chest	Yes

Table 43.7 Advantages and Disadvantages of Different Esophageal Approaches

Esophagectomy Approach	Advantages	Disadvantages
Three-incision	All tumors Good nodal access Maximal margins ↓ risk of GERD Access to thoracic duct No thoracic anastomosis	Thoracic incision ↑ risk of pulmonary complications Requires intraoperative repositioning ↑ risk of RLN injury
Transhiatal	No thoracic incision No thoracic anastomosis Maximal margins Minimally invasive approach possible ↓ risk of GERD	Poor access to nodes Blunt thoracic dissection ↑ risk of RLN injury Risk of hemorrhage, dysrhythmia, tracheal injury, hemodynamic instability
Ivor Lewis	Good access to nodes ↓ risk of RLN injury Access to thoracic duct No cervical incision Minimally invasive approach possible	Thoracic anastomosis Thoracic incision Not good for tumors in proximal third of esophagus Requires intraoperative positioning
Thoracoabdominal	Easier access to hiatal area of patient has extensive abdominal adhesions secondary to previous surgeries	Only for tumors beyond 30–35 cm Very large incision ↑ rate of residual positive margins

	↑ risk of GERD due to low thoracic location of anastomosis

RLN, recurrent laryngeal nerve; GERD, gastroesophageal reflux disease.

The optimal location for the esophageal anastomosis after resection (cervical vs. intrathoracic) is controversial, although the majority (almost 60%) in the past were placed in the cervical region.[110] The advantages of a cervical anastomosis include better access for a wider primary esophageal resection, avoidance of potentially morbid thoracotomy incisions, and less severe postoperative symptoms of reflux due to less residual esophageal mucosa.[99,115] Conversely, advantages of an intrathoracic anastomosis include a lower incidence of anastomotic leaks and injuries to the recurrent laryngeal nerves as well as a lower risk of postoperative stricture formation.[99,115,116] In the current era, mortality associated with cervical and intrathoracic leaks are similar, although intrathoracic leaks are more likely to require surgical intervention.[99,115,117,118]

Three-Incision Esophagectomy (McKeown)

The three-incision esophagectomy or McKeown approach combines left cervical, right thoracic, and abdominal incisions (**Fig. 43.4A**). This approach is especially useful for tumors of the mid and upper esophagus and for tumors when a long Barrett segment is present. The patient is initially positioned in the left lateral decubitus position for a right thoracotomy or thoracoscopy and one-lung ventilation is required for the thoracic portion of the case. The esophagus is mobilized from the thoracic inlet to the esophageal hiatus and a lymph node dissection performed. The azygos vein is routinely ligated in this approach, and recurrent laryngeal nerve injury can occur during this portion of the procedure. The thoracic incisions are closed after placement of a chest tube and the patient is repositioned in the supine position with a roll placed under the scapula to extend the neck. The head is turned to the right to maximally expose the left neck. An upper midline laparotomy or laparoscopy is then performed, and the gastric conduit is mobilized and created. Surgeons

selectively place jejunostomy feeding tubes and perform pyloroplasty to enhance gastric emptying.

A left cervical incision is then made, and the cervical esophagus is dissected free in the neck. The recurrent laryngeal nerve is at risk of injury during this dissection. The NG tube is withdrawn to a specific depth under direct supervision of the surgeon, and the cervical esophagus is divided. A suture or a rubber drain is fastened to the distal end of the divided esophagus and the distal esophagus is withdrawn through the esophageal hiatus into the abdominal incision. The prepared gastric conduit is then pulled back through the hiatus and up into the neck with care to avoid torsion. The cervical anastomosis is then performed, and the NG tube is guided through the anastomosis under direct supervision by the surgical team.

Transhiatal Esophagectomy

The transhiatal esophagectomy combines abdominal and left cervical incisions (**Fig. 43.4B**). This approach is probably ideal for patients with Barrett's and high-grade dysplasia where lymph node dissection is not as critical for staging purposes. The abdominal portion of this procedure is performed as described above for the three-incision technique. The hiatus is dilated, and the surgeon's hand is inserted into the mediastinum to bluntly dissect the esophagus free from other intrathoracic structures. A left cervical incision is then made, and the esophagus is dissected in a similar manner from the neck into the chest but with special care to avoid injury to the recurrent laryngeal nerve. After complete esophageal mobilization, the esophagus is divided, and the anastomosis is performed in the neck as described above for the three-incision technique.

Excellent surgical outcomes for this technique have been reported by high-volume surgeons.[42] However, the use of this technique has decreased in the United States. An esophagectomy analysis of the American College of Surgeons-National Surgical Quality Improvement Project of the years 2005–2011 showed 52.5% of patients had a transhiatal approach, but a subsequent study that included the years 2005–2014 found that only 41.7% had the transhiatal approach.[119,120] The decrease in the utilization of this technique was probably influenced by both the recognition of the importance of lymph node resection to prognosis as well as the increasing use of minimally

invasive techniques that also provides the transhiatal advantage of avoiding the morbidity of a thoracotomy.[59,121]

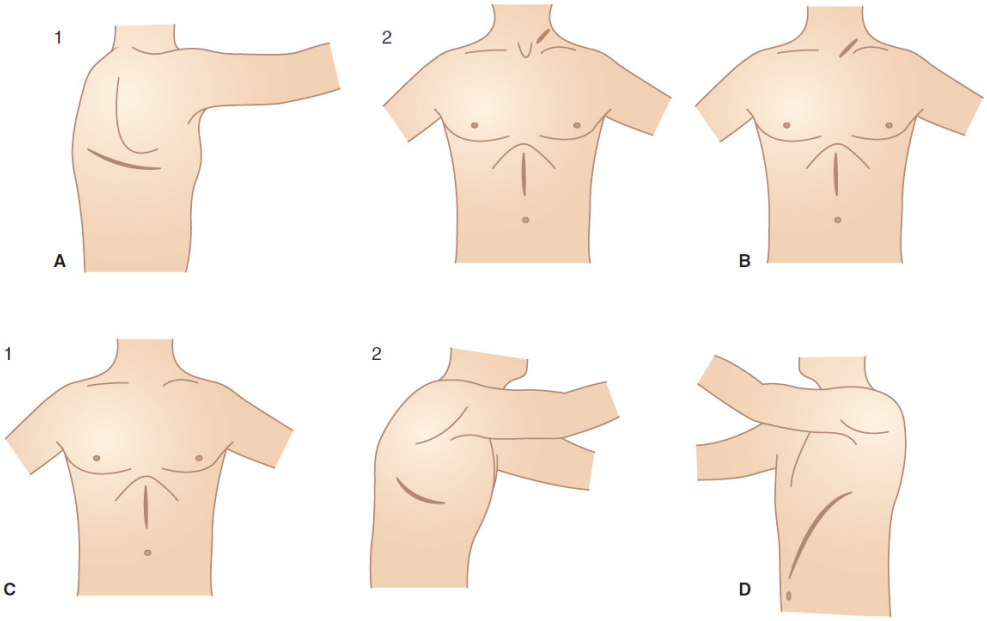

Figure 43.4 Incisions used for (**A**) three-Incision or McKeown, (**B**) transhiatal, (**C**) Ivor Lewis, and (**D**) left thoracoabdominal esophagectomies.

Ivor Lewis Esophagectomy

The Ivor Lewis esophagectomy resembles the modified McKeown approach, but involves only two incisions: right thoracic and upper abdominal (**Fig. 43.4C**). Although it also requires one-lung ventilation, the Ivor Lewis begins with the patient in the supine position for laparotomy or laparoscopy for preparation of the gastric conduit. The gastric tube is then advanced into the chest as far as possible and the abdomen is closed. The patient is then repositioned in the left lateral decubitus position for right thoracotomy or thoracoscopy. In the chest, the esophagus is mobilized and divided. The gastric conduit is pulled further into the chest and the anastomosis performed. The thoracotomy or thoracoscopy incisions are closed after placement of a chest tube.

Left Thoracoabdominal Esophagectomy

The left thoracoabdominal approach (**Fig. 43.4D**) can be performed with acceptable morbidity and mortality but is generally only considered for

patients with tumors limited to the distal esophagus, and even in those cases is associated with high rates of residual disease.[122] This approach necessitates one-lung ventilation, and the patient is positioned in the right lateral decubitus position but with the abdomen rolled back approximately 45 degrees. A thoracoabdominal incision is made along the 7th intercostal interspace across the costal margin, and the diaphragm is taken down circumferentially from the chest wall (**Fig. 43.4D**). Esophageal and gastric mobilization and resection are performed as described for the Ivor Lewis technique but with reconstruction of the diaphragm prior to closure. This approach is not often utilized due to the limited amount of esophageal resection that can be achieved, and also the postoperative pain and morbidity associated with this approach. However, a thoracoabdominal option may be optimal for patients who have previous abdominal surgeries that could make a midline abdominal approach more difficult.

Minimally Invasive Esophagectomy

Minimally invasive techniques to achieve esophagectomy have been utilized for decades and are becoming increasingly more common.[123,124] Essentially, the chest and the abdominal components of the different esophagectomy approaches described above can all be done using minimally invasive techniques via laparoscopic, thoracoscopic, and robotic approaches. Considering the multiple approaches that can be used to achieve an esophagectomy, specifically defining a minimally invasive esophagectomy (MIE) not surprisingly is problematic. One proposed MIE definition is "an operation that removes part or all of the esophagus, does not retract, lift, spread or remove any part of the chest or abdominal wall and the surgeon's and assistant's vision of the operative field is via a monitor, the patient's tissue is manipulated only by instruments that are controlled by the operating surgeon or team, except for during the neck portion if used."[125] Procedures that are done with not all but at least one component minimally invasively are generally considered to be "hybrid" procedures.[126]

A MIE can be performed by experienced surgeons with low conversion rates and a median reported hospital stay of 7 days.[123,127] These techniques can be associated with longer operative times early in surgeon experiences, and morbidity and mortality rates can still be as high as 46% to 61.5% and

3.3% to 6%, respectively.[123,128–130] However, MIE has been associated with less major morbidity, particularly pulmonary-related, and shorter postoperative recovery times.[126,131,132] Studies have also shown mortality rates to be as low as 2.1% in multi-institutional settings, and as low as 0.9% in very experienced centers.[121,133] Multiple studies have shown that a minimally invasive approach does not compromise the oncologic efficacy of the procedure.[124,126,132,134] The improved results and benefits seen with minimally invasive techniques are probably due not only to the differences in surgical approach, but also to the fact that they are being performed by experienced and highly trained esophageal surgeons at high-volume centers. Robotic techniques are feasible, though use of the robot may be more important for the surgeon rather than the patient, as a recent NSQIP analysis found no significant difference in the incidence of 30-day postoperative outcomes between robotic and other minimally invasive approaches.[135,136]

Intraoperative Complications

Cardiac dysrhythmias occur in up to 65% of patients undergoing esophagectomy.[137,138] These occur commonly during transhiatal procedures during the blunt dissection portion of the case but are mostly well tolerated. Most are atrial tachydysrhythmias, but more than 50% of these are of combined atrial and ventricular origin. Interestingly, in a closely monitored observational study, there was no correlation between the incidence of dysrhythmias and that of hypotension, but there was a strong correlation between hypotension and the duration of manipulation.[137]

Other serious intraoperative events that can occur are hemorrhage and airway injury. While massive bleeding is rare, it may require rapid conversion from a minimally invasive to an open technique, or even an emergent change in patient position to facilitate surgical exposure of the involved vessel. In general, if severe bleeding occurs in the mid- or upper esophagus, it may require conversion to a right thoracotomy for approach to the azygos vein; and if from the lower third of the esophagus, a left thoracotomy may be required to access a bleeding esophageal branch from the aorta. Fortunately, such vascular injuries occur in less than 2% of transhiatal esophagectomy cases.[139] Similarly, airway injury is rare, <1%.[140] These injuries are mostly limited to the distal membranous trachea or

proximal bronchi and may be detected by the smell of inhaled anesthetic in the field or a feeling of airflow by the surgeon with each ventilator-delivered breath. Injuries are rarely large enough to be detected by loss of ventilator volume. If an airway injury is detected, deflation of the endotracheal tube cuff and advancement of the tube past the injury with manual guidance by the surgeon should be performed. An airway injury can be amenable to primary repair, though an intercostal muscle flap to buttress the repair is advisable. If the patient remains stable when an airway injury occurs, completing the procedure as planned should be accomplished. In any case of airway injury, though, extubating the patient immediately postoperatively is critically important to minimize pressure on or manipulation of the repair.

Immediate and Long-term Outcomes Following Esophagectomy

Even with advances in surgical technique, anesthetic, and critical care, esophagectomy continues to be a source of significant morbidity and mortality in both the immediate perioperative period and for long-term survivors. Perioperative mortality rates have historically been reported as 8.8% to 14% but was still 2.7% to 3.4% in a recent Society of Thoracic Surgeons General Thoracic Surgery Database and Targeted esophagectomy NSQIP studies; major morbidity is still 25% to 33%.[11,35–40,42,115,117,127,128,141–145] Patients undergoing esophageal surgery have long hospital stays and prolonged overall recovery periods, which are more than doubled when significant complications occur.[39,115,142,146] It is perhaps for these reasons that surgical resection is pursued for less than half of all potentially resectable stage I, II, and III esophageal cancers.[68,98]

Interestingly, clinical studies have shown that surgical and center experience is much more important in determining ultimate outcome than choice of procedure. Prospective trials have failed to demonstrate any significant differences in short- or long-term survival or quality of life between transthoracic and transhiatal esophagectomies, although some evidence suggests that the transhiatal approach has a slightly lower rate of perioperative complications and these patients may achieve better activity levels postoperatively.[36–38,146–148] However, centers and surgeons that

perform high volumes of esophageal surgery report mortality rates that are significantly lower for both transhiatal and transthoracic procedures than those reported in multicenter studies or national databases.[41,42,99,149,150] In fact, it appears that the mortality rate for low versus high-volume centers and surgeons may differ by as much as 50%. Interestingly, high volume has been defined as >12 or >5 cases/year for centers and surgeons, respectively, and low volume as <5 or <2 cases/year for centers and surgeons.[38,151–153] Similarly, improvements reported in long-term surgical outcomes are significantly better for high-volume centers and surgeons, with some centers reporting recent mortality rates as low as 1%.[39,42,149,154–157] Specialty training also appears to have a significant effect on outcome, with surgeons without specialty training having 37% to 50% higher mortality than those with specialty training.[142,151,158]

Morbidity Following Esophagectomy

A summary of complications following esophagectomy is listed in **Table 43.8**. Risk factors for major morbidity are pulmonary disease, older age, Black race, congestive heart failure, coronary artery disease, peripheral vascular disease, malnutrition, decreased functional status, hypertension, insulin-requiring diabetes, higher American Society of Anesthesiology rating, and use of tobacco or steroids.[35,37,141,142] Preoperative predictors of mortality based on multivariable analysis include higher Charlson score (a measure of comorbid conditions), older age, renal dysfunction, diabetes, alcohol abuse, decreased functional status, intraoperative transfusion, and ascites.[35,40] Tumor location and histology are also important, with squamous cell carcinomas and upper third esophageal tumors being associated with worse outcomes.[141,159,160] As noted above, undergoing surgery at a center where less than 12 esophagectomies are performed per year is also a risk factor for postoperative mortality.[40] Neoadjuvant therapy has been variably identified as a predictor of significant morbidity and mortality in the postoperative period.[35,142]

Considering the overall poor prognosis for esophageal cancer patients, the impact of surgical complications on survival and quality of life cannot be overstated.[99,161] However, surgical technique and perioperative care has implications beyond immediate perioperative survival. Improved long-term

survival and quality of life are often directly related to avoidance of postoperative complications.[162] Measures that have been successful in reducing perioperative morbidity include aggressive preoperative conditioning, minimizing intensive care unit stays, aggressive pain management, early ambulation, involvement of a dedicated intensivist in the perioperative care team, and an overall multidisciplinary, multimodal approach to management.[42]

Table 43.8 Perioperative Morbidity and Mortality After Esophagogastrectomy

Complication	Incidence
Technical	
Anastomotic stricture	16–48%
Anastomotic leak	6–14%
Conduit necrosis	0.5–2%
Vocal cord palsy	2–14%
Wound infection	5.3–12%
Fascial dehiscence	2–5%
Delayed gastric emptying	1.8–3.7%
Chylothorax	0.8–9%
Pulmonary (total)	28.5–29.7%
Pneumonia	8–26%
Reintubation	6–17%
Respiratory failure	1.8–16%
Aspiration	7%
Atelectasis requiring bronchoscopy	4.5%
Miscellaneous	
Deep venous thrombosis	0.9–2%
Myocardial infarction	0.7–1.2%
Pulmonary embolism	0.7–1.7%
Atrial fibrillation	14–17.5%
Renal failure	0.9–3.4%

Anastomotic and Conduit Complications

Anastomotic leaks occur in 6% to 14% following esophagectomy and traditionally were associated with extremely high mortality. However, with improvements in surgical technique and critical care, mortality rates as low as 3.3% have been achieved.[117,163,164] Clinical features commonly associated with leaks include fever, leukocytosis, pleural effusion, and sepsis, although small leaks are often identified in asymptomatic patients.[165] Many leaks (57%) can be managed nonoperatively although operative alternatives include stent placement, primary anastomotic repair, anastomotic tissue reinforcement such as with a muscle flap, and esophageal diversion.[166–168] Early leaks (within 5 days) and those associated with gastric tip necrosis (incidence 2% to 3%) are most likely to require surgical treatment.[164,165] Necrosis of the gastric conduit is generally uncommon but is associated with high mortality and requires immediate intervention with resection of the compromised tissue and diversion.[169] High-volume centers have reported leak rates as low as 5%, though recent reports from the Society of Thoracic Surgeons and an NSQIP analysis showed leak rates even in recent years to be 12.9% and 14%, respectively.[121,141,145]

Anastomotic strictures are somewhat common after esophagectomy. Although generally not life threatening, strictures can cause significant patient discomfort and can put patients at risk for aspiration if they have dysphagia or regurgitation secondary to the stricture. The rate of stricture occurrence has been reported to be as high as almost 50%, though a recent population-based analysis found an incidence of 16.7%, with 6.6% of patients requiring three or more dilations as therapy.[170]

Respiratory Complications

Respiratory complications are the most common cause of death following esophagectomy.[115] Respiratory issues typically are due to poor clearance of secretions or postoperative aspiration. Factors that can increase the risk of aspiration or pulmonary complications include postoperative recurrent laryngeal nerve dysfunction, conduit emptying issues, and swallowing dysfunction. Risk of pneumonia appears to be highest in those approaches that involve a thoracotomy incision. Reducing pulmonary complications with the use of epidural analgesia and aggressive use of bronchoscopy for

clearance of pulmonary secretions appears to reduce perioperative mortality.[171] Other strategies include careful assessment of swallowing abnormalities and risk of aspiration by cineradiography or fiberoptic endoscopy before initiating oral intake.[41,115]

Issues with emptying of the conduit can also predispose patients to both short- and long-term pulmonary complications. Patients are at risk of aspirating contents from a full or dilated intrathoracic stomach, particularly when lying down after meals or when sleeping. A very important step to prevent this situation is to only pull the amount of stomach into the chest necessary to achieve a tension-free anastomosis and avoid having excessive redundant stomach in the chest. Performing a pyloric drainage procedure to enhance gastric drainage is also advocated by many surgeons, to avoid the risk of delayed gastric emptying that could occur from a functional gastric outlet obstruction secondary to resection of the vagus nerves during the esophagectomy.[172] However, a significant number of surgeons prefer very selective use of a pyloroplasty to avoid the risk of biliary reflux and dumping symptoms, as emptying issues can be somewhat easily managed with medications or endoscopic procedures such as balloon dilation, Botox injection, or a gastric per-oral endoscopic myotomy.[173] The evidence supporting either strategy is variable. Early studies showed fewer issues with emptying when a gastric drainage procedure was performed, but more recent studies have not consistently shown a benefit.[174,175]

Recurrent laryngeal nerve injury manifesting as early postoperative hoarseness is a risk of esophagectomy given the course of the recurrent laryngeal nerves in the trachea–esophageal groove. Such injuries occur in 4% to 14% who have a cervical anastomosis, and in 1% to 4.8% of patients who have an intrathoracic anastomosis.[42,121,144,176] Hoarseness is often transient and can resolve in 2 to 12 weeks if the injury was only a nerve palsy. Patients with persistent vocal cord paralysis require cord medialization procedures, as long-term persistent hoarseness is associated with debilitated performance status, as well as swallowing and pulmonary dysfunction.[177] Patients with evidence of aspiration should undergo early cord medialization, as this has been shown to decrease the incidence of pneumonia and need for bronchoscopy.[177]

BENIGN ESOPHAGEAL NEOPLASMS

There are several types of benign esophageal neoplasms that are rare and often asymptomatic (**Table 43.9**). They are important to distinguish from esophageal malignancy so they are managed appropriately. Some can be managed conservatively, while others should be removed (endoscopic or surgically) for definitive diagnosis, local symptoms, or rare malignant potential. Generally, if the tumor is subepithelial and resection is indicated, then surgical enucleation or ESD is performed. If the tumor is large or at a difficult location such as the gastroesophageal junction, then a larger resection such as esophagectomy may be required. It is important to coordinate care with an experienced thoracic surgeon and interventional gastroenterologist. The most common benign esophageal neoplasms are discussed here, but all of them should be considered during formulation of a differential diagnosis.

Table 43.9 Classification of Benign Esophageal Neoplasms by Cell Type

Epithelial
Squamous cell papilloma
Fibrovascular polyp
Adenoma
Inflammatory pseudotumor
Inflammatory polyp
Nonepithelial
Leiomyoma
Schwannoma
Lymphangioma
Fibroma
Neurofibroma
Hemangioma

Algorithm 43.1 Evaluation and management of esophageal leiomyoma.

Leiomyoma

Leiomyomas comprise about two-thirds of the benign neoplasms of the esophagus.[178,179] The incidence of leiomyoma of the esophagus reported in autopsy range from 0.005% to 5.1%. 9 They arise from smooth muscle and thus are usually found in the middle and lower esophagus. Approximately 80% of leiomyoma originate from the muscularis propria and are located intramurally, but they have also been found arising from the muscularis mucosa and protruding into the esophageal lumen.[180] They are usually single lesions, but multiple lesions have been reported.[181] They are generally slow-growing tumors and may not change for many years.

Patients have been diagnosed at all ages, with a peak incidence at 30 to 59 years, and the incidence in men is almost twice that in women.[179] Over 50% of patients are asymptomatic, and slow onset of dysphagia and chest

discomfort are the most common symptoms.[182] Rapid onset of symptoms and weight loss are concerning for malignancy.

Evaluation of a patient suspected of having a leiomyoma should begin with a barium swallow, CT scan of the chest, endoscopy, and EUS (**Algorithm 43.1**). Barium swallow demonstrates a smooth, rounded filling defect with an acute angle at the junction with the esophageal wall, indicating that the mucosa is not involved (**Fig. 43.5**). CT scan of the chest shows a smooth, ovoid mass of muscle attenuation that may narrow the lumen (**Fig. 43.6**). It is not always necessary but can confirm the differential diagnosis and rule out any other chest pathology. Endoscopy shows normal, smooth mucosa overlying a mobile mass that may narrow the lumen without obstruction (**Fig. 43.7**). Endoscopic biopsy is usually unsuccessful because of the subepithelial location. Any mucosal abnormality such as ulceration is concerning for malignancy such as esophageal carcinoma or leiomyosarcoma.

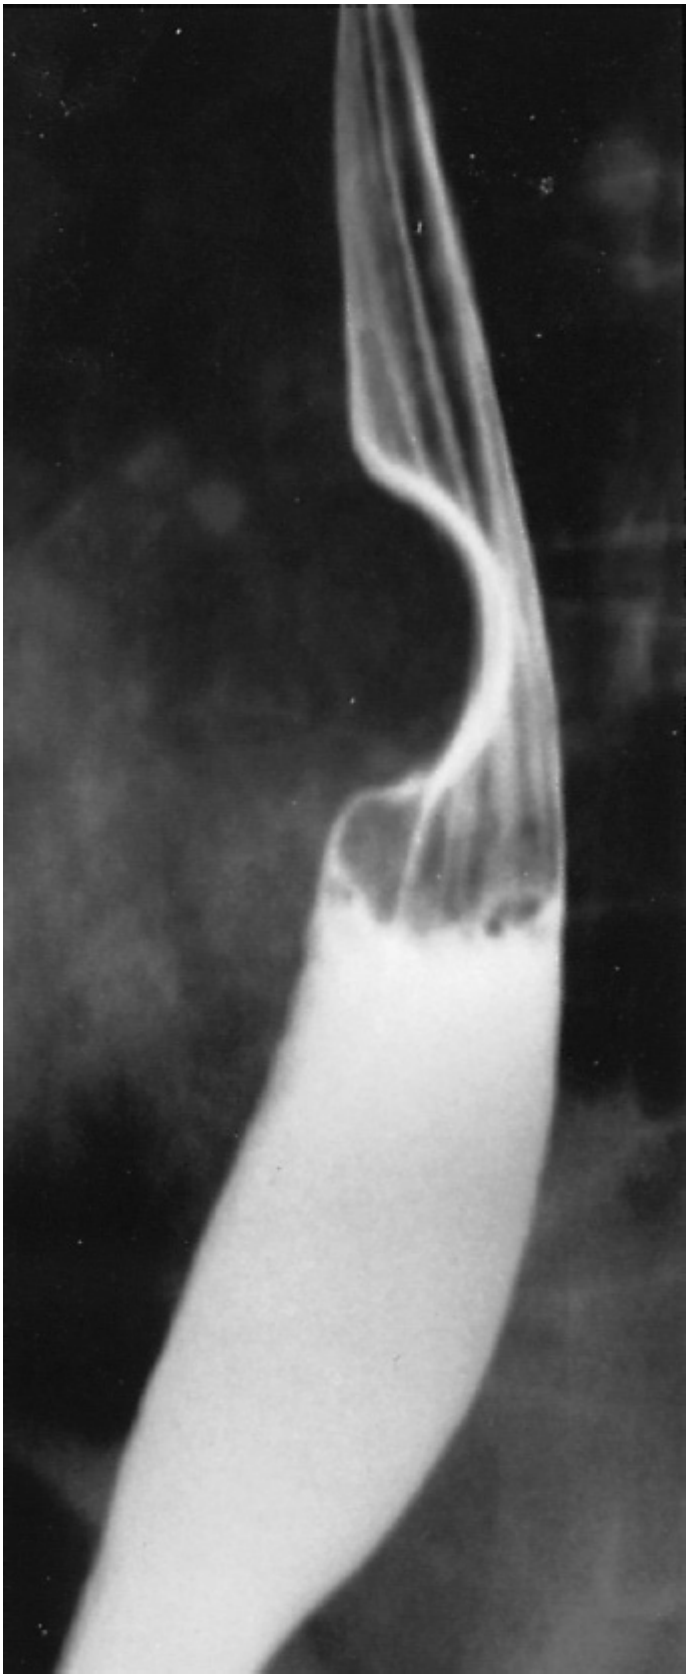

Figure 43.5 Esophagram of a leiomyoma. The acute angle at its junction with the esophageal wall is typical, indicating that the mucosa is not involved. (Reproduced with permission from Orringer MB. Tumors of the esophagus. In: Sabiston DC Jr, ed. *Textbook of Surgery*. 13th ed. Philadelphia, PA: AWB Saunders; 1986:736.)

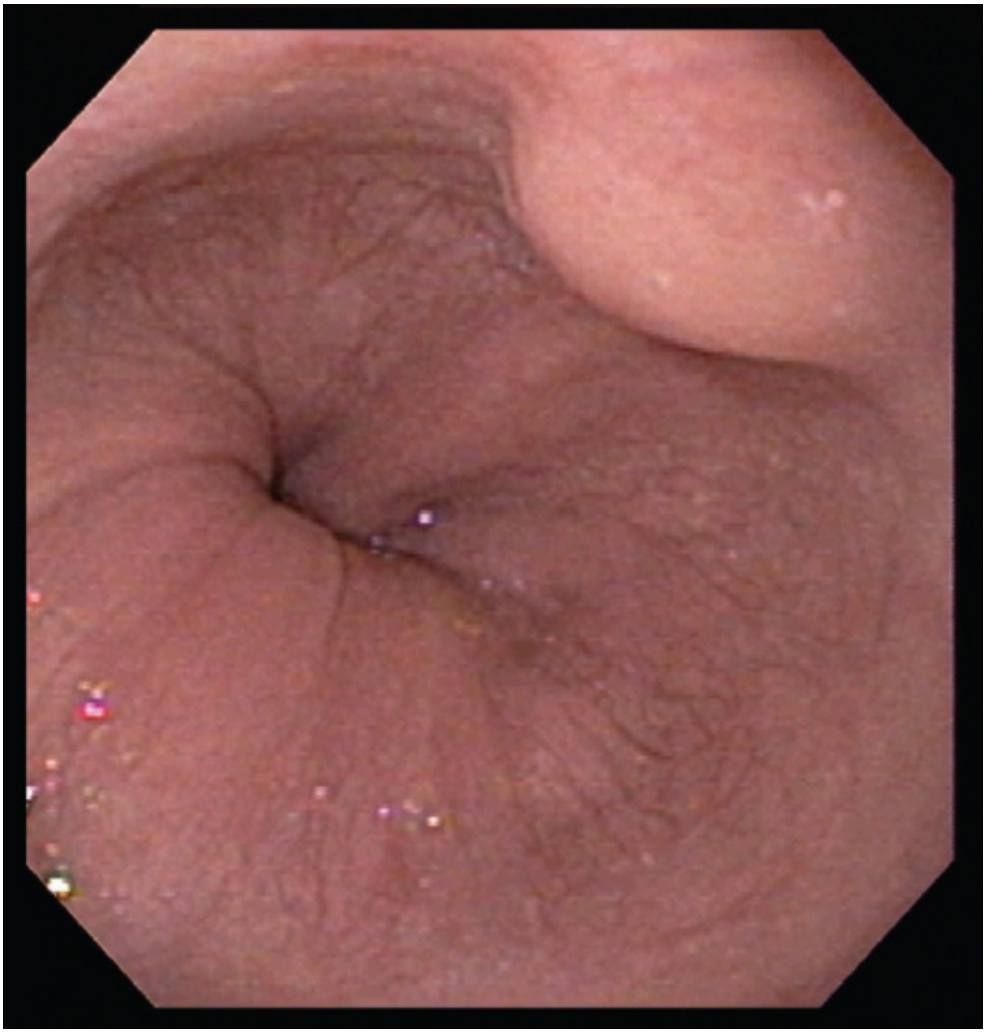

Figure 43.7 Endoscopic appearance of an esophageal leiomyoma in the distal esophagus just proximal to the gastroesophageal junction. The mucosa is smooth and normal overlying the mass, indicating that it is not involved. (Courtesy of Michael L. Kochman, MD, Hospital of the University of Pennsylvania, Philadelphia, PA.)

EUS can confirm the layer of origin, and FNA can be used to obtain tissue for diagnosis and distinguish leiomyomas from the much rarer malignant gastrointestinal stromal tumor (GIST) and leiomyosarcomas. Leiomyomas are positive for smooth muscle actin and desmin, whereas GISTs are positive for CD117 and CD34. Leiomyosarcomas have significant cellular atypia. FNA should not be performed routinely if a clinical diagnosis can be made, since scarring may increase the risk of mucosal perforation during resection. If resection is not necessarily planned or there are any features concerning for malignancy, FNA should be performed.

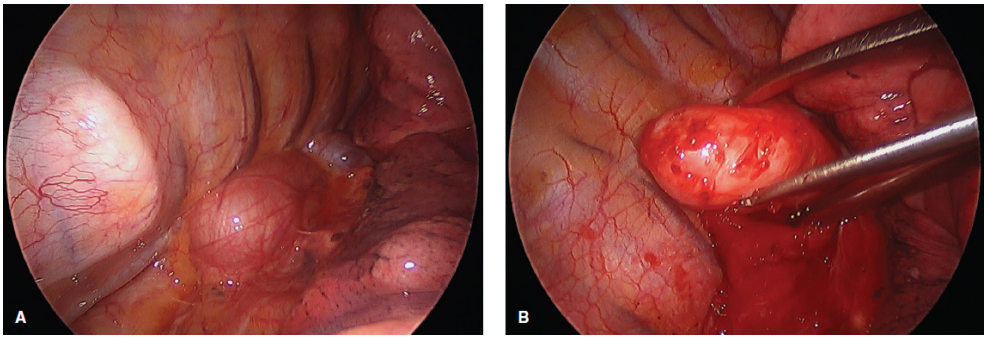

Figure 43.8 Intraoperative photos of a mid-esophageal leiomyoma before (**A**) and after (**B**) the pleura was opened via a right thoracoscopic approach. (Courtesy of Natalie S. Lui, MD, Division of Thoracic Surgery, Stanford University, Stanford, CA.)

Indications for resection are symptoms, increase in size, wish for a definitive diagnosis, and any concern for malignancy such as mucosal ulceration or heterogeneity. Small, asymptomatic leiomyomas may be monitored since they grow slowly and malignant transformation to leiomyosarcoma is rare.[183] Endoscopic submucosal resection can be used for small tumors. Surgical resection is generally performed by enucleation, most commonly through a right thoracotomy or thoracoscopy (**Fig. 43.8**), or through a left thoracotomy for distal esophageal or abdominal for gastroesophageal junction tumors.[184] The tumor is separated from the underlying mucosa, which must be repaired if injured, and the muscle layer is closed over the mucosa. Large tumors greater than about 8 cm and annular tumors may require esophagectomy. Most patients are free of symptoms after surgery and recurrence is rare.[180]

Fibrovascular Polyp

Fibrovascular polyps are rare benign neoplasms of the esophagus. They are extremely rare, described only in case reports and small case series. Recent studies have shown that many of these tumors may actually be liposarcomas, confirmed by review of morphology and MDM2 immunohistochemistry and fluorescence in situ hybridization.[185] They are intraluminal tumors that arise from a stalk near the cricopharyngeus muscle and range from small polyps to large tumors encompassing the entire esophagus (**Fig. 43.9**). They are thought

to grow from excessive mucosal folds in the cervical esophagus that elongate with peristalsis.

Patients are most commonly diagnosed at 50 to 70 years of age, and the incidence is higher in men. They are usually symptomatic and most present with dysphagia. Odynophagia, regurgitation, neck pain, weight loss, and respiratory symptoms have also been reported.[186] Some patients describe coughing or vomiting the tumor out of their mouths, holding the tumor outside the mouth or between the teeth, and swallowing the tumor back into the esophagus.[187,188] Tumors can also cause airway obstruction leading to life-threatening presentations.[189,190] On endoscopy, it may be difficult to identify the stalk, and the polyp may even be missed if it is mistaken for esophageal mucosa. CT scans reveal sausage-shaped tumors of fat or soft tissue density.

Resection is indicated to avoid symptoms including airway obstruction and has been described via endoscopic or surgical approaches, most commonly left cervical esophagotomy. For very large tumors, a combined approach may be required, with stalk division by endoscopy or left cervical esophagotomy and removal of the tumor by right thoracotomy or gastrotomy (**Fig. 43.10**).[188,191] Control of the stalk is important since it contains feeding vessels. Recurrence has been reported, so surveillance endoscopy has been recommended.[188]

The base of the stalk was divided endoscopically, and seen here is the tumor being removed through an esophagostomy via right thoracotomy. (Courtesy of Joseph Shrager, MD and Jeffrey Yang, MD, Division of Thoracic Surgery, Stanford University, Stanford, CA.)

Schwannoma

Schwannomas are neurogenic tumors that comprise less than 2% of benign neoplasms of the esophagus, described by case reports only.[192] They are thought to arise from the neural plexus within the esophageal wall and do not involve a distinct nerve, as compared to schwannomas that arise from the vagus nerve and grow into the esophagus.[193] They can present at all ages and are much more common in women. The most common symptom is dysphagia, but they can also cause compressive symptoms. They are most commonly located in the upper thoracic esophagus.

They can be difficult to distinguish preoperatively from the more common leiomyomas. CT scan of the chest reveals a homogeneous mass with smooth

borders that may compress nearby structures such as the trachea.[194] Endoscopy shows smooth, normal mucosa overlying the mass. Of note, schwannomas have been found to be FDG-avid on PET scan.[195] EUS-FNA may be able to yield a preoperative diagnosis.

Resection is indicated if tumors are symptomatic, greater than about 3 cm, increasing in size, or concerning for malignancy. Endoscopic resection in small tumors [196] and surgical enucleation are most common, while large tumors requiring esophagectomy have been reported.[197] Several case reports describe mucosal injury during enucleation which was repaired. Pathologic examination shows palisading spindle cells that are positive for S-100 protein and neuron-specific enolase, but negative for smooth muscle actin or desmin (leiomyoma), or CD34 or CD117 (GIST). A few cases of malignant schwannoma have been reported, including one with lymph node involvement.[198] Prognosis is good after resection.

Lymphangioma

Lymphangiomas are extremely rare benign neoplasms of the esophagus and described only in case reports. They arise from dilated lymphatic vessels within the esophageal wall, most commonly in the lower esophagus. They most commonly present at 50 to 70 years of age, and they are more common in men. Patients present with dysphagia or chest or epigastric discomfort.[199]

Endoscopy shows a pale, translucent subepithelial tumor. Endoscopic biopsy is often unrevealing and should not be performed if tumor could possibly be an esophageal varix. CT and MRI of the chest show that the tumor has fluid density. Most tumors are smaller than 2 cm, but very large tumors have been reported.[200] Resection is indicated if the tumor is symptomatic, large, increasing in size, or when the diagnosis is unclear. Resection has been described by EMR, submucosal endoscopic resection, surgery, and even laser treatment.[201] Recurrence after complete resection and malignant transformation have not been reported.[202]

ESOPHAGEAL INJURY

Esophageal Perforation

Epidemiology

Esophageal perforations are a major source of morbidity (10% to 60%) and mortality (4% to 50%); Accurate diagnosis and early treatment are essential to the successful management of these complicated and often significantly ill patients.

The causes of esophageal perforation are listed in **Table 43.10**. Generally speaking the incidence of iatrogenic perforation (59%) far exceeds the second most common cause that being spontaneous perforations (15%).[203] Other less common injuries include foreign-body ingestion (12%) and trauma (9%). Ingestion of foreign bodies or caustic materials most commonly causes perforations in the anatomic areas of narrowing: cricopharyngeus, level of aortic arch, and the level of left mainstem bronchus (**Fig. 43.11**). Also included in the area at risk is the lower esophageal sphincter zone. External penetrating trauma can occur at any level but is seen more commonly in the cervical esophagus as the mediastinal portion is posterior and protected by the thorax. The morbidity and mortality of penetrating esophageal trauma is usually related to associated injuries including major vascular and airway structures.[204] Blunt traumatic perforation of the esophagus is exceedingly rare.

Table 43.10 Causes of Esophageal Perforation

Instrumental Endoscopy Dilation Intubation Sclerotherapy Laser therapy
Noninstrumental Barogenic trauma Postemetic (Boerhaave syndrome) Blunt chest or abdominal trauma Other (e.g., labor, convulsions, defecation)
Penetrating neck, chest, or abdominal trauma
Operative trauma Esophageal reconstruction (anastomotic disruption) Vagotomy, pulmonary resection, hiatal hernia repair, esophagomyotomy
Corrosive injuries (acid or alkali ingestion)
Erosion by adjacent infection
Swallowed foreign body

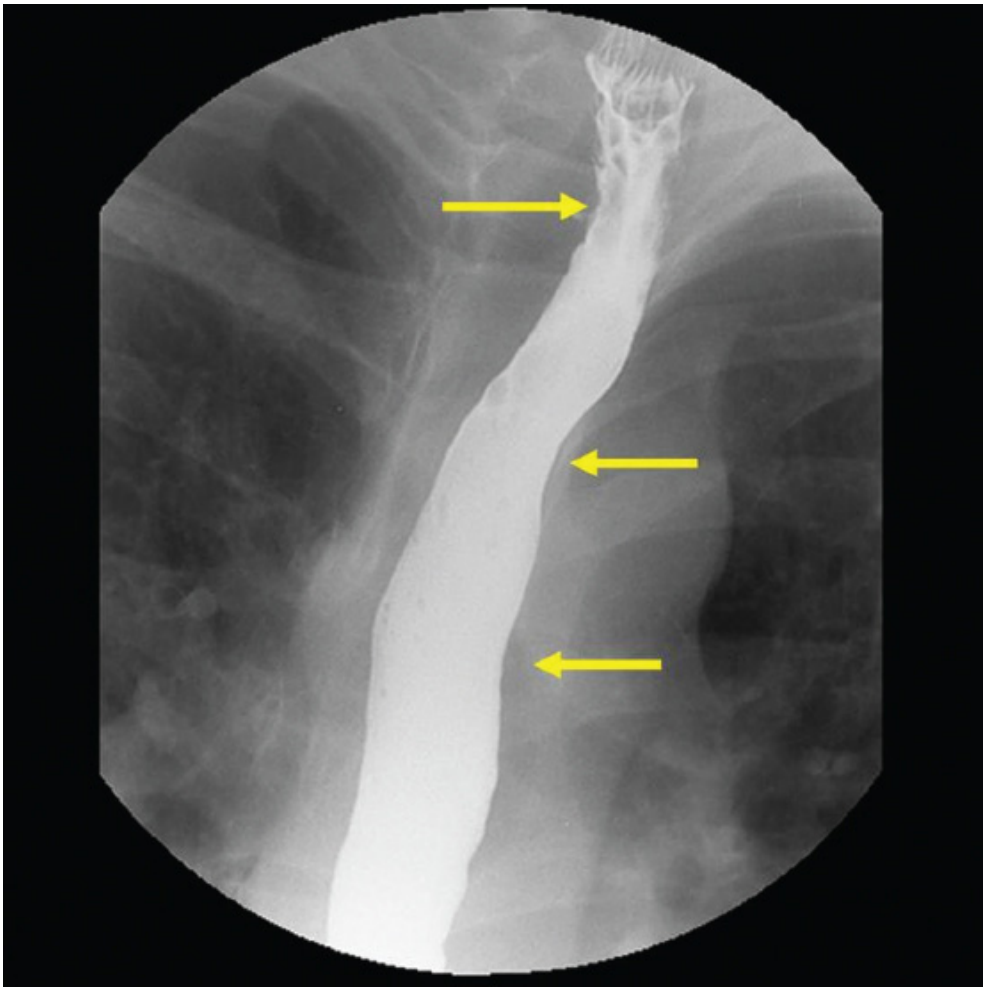

Figure 43.11 Barium esophagram showing the constrictions caused by the cricopharyngeal muscle, aortic arch, and left mainstem bronchus (*arrows*). Indentations of the esophagus made by external structures are important anatomic landmarks and are often sites of perforation due to instrumentation.

The incidence of perforation has risen in the modern era due to the rise in use of advanced endoscopic interventions including EMR, ESD, and per-oral endoscopic myotomy for treatment of achalasia (POEM). A recent report examining the treatment trends for early-stage esophageal cancer identified utilization of endoscopic therapy increased from 42.7% to 50.6% with a reciprocal decrease in esophagectomy from 21.7% to 12.8% from 2010 to 2014.[205] Others have noted similar trends.[206] The incidence of esophageal perforation following EMR and ESD is estimated at 1.9% to 5.8%[207,208] and 2.8% to 6% following POEM.[209]

Spontaneous perforation results from a sudden increase in intraesophageal pressure. The most commonly discussed is Boerhaave syndrome:

spontaneous perforation of the distal esophagus following extensive ingestion of food or alcohol. This leads to violent emesis resulting in a distal esophageal perforation, frequently into the left chest. Perforation can also be associated with hyperemesis, childbirth, seizure, or prolonged coughing.

Clinical Features

The presenting features of esophageal perforation depend on the location of the injury and the time interval from injury to presentation. Underlying comorbidities may also have an influence on the presentation dictated by the patient's physiologic reserve. Patients with cervical perforation present with dysphagia, neck pain, dysphonia, and subcutaneous neck emphysema. Often cervical perforations present earlier than distal perforations given the intolerability of discomfort of neck symptoms. Intrathoracic perforations may present with a spectrum of clinical features ranging from simple persistent substernal chest pain to symptoms of frank mediastinitis and sepsis. Mediastinitis is characterized by chest pain, tachycardia, tachypnea, fever, and leukocytosis. Perforations of the intra-abdominal esophagus may present as an acute abdomen with diffuse abdominal pain in addition to the above. More significant perforations and longer intervals to presentation contribute to the features of systemic sepsis, shock, and rapid deterioration. In a recent systematic review including 2,380 patients, 72.6% presented with perforation of the intrathoracic esophagus of which 46.5% were due to iatrogenic causes. Sepsis on admission was observed in 23.3% of cases. A significant proportion of cases (42%) were diagnosed more than 24 hours post injury which is known to significantly increase the mortality risk.[210]

Diagnosis

The diagnosis of esophageal perforation needs to begin with the clinician and their index of suspicion. Any patient who presents with pain following an endoscopic intervention needs to be carefully evaluated for perforation. The initial workup involves careful history and physical examination, laboratory studies including leukocyte count, and chemistry panel for acidosis. Chest x-ray is a good screening test for other diagnoses in the differential. Contrast esophagography remains the gold standard for diagnosis as the study will diagnose and localize the site of the perforation. This study also gives

important information about coexisting pathology of the esophagus and the degree of extravasation and its trajectory. Water-soluble contrast (e.g., Gastrografin) is the initial agent utilized, followed by thin barium to enhance the sensitivity of the study. Water-soluble agents demonstrate 50% of cervical perforations and 80% of intrathoracic perforations.[211] Thin barium will identify 60% of cervical and 90% of intrathoracic perforations.[212] If there is a chance of aspiration or high concern of tracheoesophageal fistula, thin barium should be used from the outset because the hyperosmolar water-soluble contrast agents may cause rapid pulmonary edema and respiratory compromise. Note that barium would interfere with any subsequent CT scan.

CT scan is very useful in the diagnostic evaluation of the patient with concern for esophageal perforation. Often a CT scan is the first test obtained following a chest x-ray as it affords the clinician the ability to narrow the differential diagnosis. CT may be useful for identifying the site of perforation and any associated mediastinal or pleural fluid collections. It is very common for a CT scan finding to prompt thoracic surgical consultation or facility transfer as it provides additional information routinely utilized in forming the management plan. Although CT scan is very useful, its accuracy in the diagnosis of esophageal perforation is estimated at 38.7% thus it is still limited as a confirmatory test even when performed with the administration of properly timed oral contrast.[210] Thus, it should be emphasized that the barium swallow study is the procedure of choice for optimal diagnostic accuracy unless there is a significant risk of aspiration. The barium esophagram is regarded as a real-time image, whereas the contrast delivery of the CT scan does not provide the same functional and anatomic details of the site and tracking of the leak, thus we prefer both when possible.

Although flexible esophagoscopy raises the concern of worsening the clinical condition of the patient due to contamination of the mediastinum, use of insufflation, and aspiration, it should be utilized liberally in the diagnostic evaluation of the esophagus and in the planning of treatment options. Its diagnostic accuracy is highly variable depending on type of injury and time to presentation, however in a large series it is quoted as 37.4%.[210] Endoscopy also has a distinct advantage in potentially serving as a means of primary treatment intervention in a significant number of cases. The scope is utilized to directly visualize the area of perforation and identify any potential

associated pathology. It has a sensitivity of over 95% and a specificity over 80% depending on the experience of the physician.[213] We routinely perform flexible endoscopy as the initial step in the operating room when considering all options for patient management (**Fig. 43.12**). The vast majority of patients will require an endoscopic evaluation at some point and the timing of this will depend on clinical presentation and findings on radiologic imaging. For very small defects in stable and nontoxic patients, in the absence of free extravasation, we may opt to hold off on an endoscopy in select cases.

Algorithm 43.2 Evaluation and management of esophageal perforation.

Management

Some investigators suggest aggressive operative intervention (e.g., surgical exploration and repair or gastric conduit takedown with diversion) for patients with post-esophagectomy intrathoracic anastomotic leak, while others recommend nonoperative management with stenting, jejunostomy feeds, perianastomotic drainage, and broad-spectrum antibiotics. The decision is influenced by the location and size of the perforation, the timing and mechanism, the degree of periesophageal soiling and extravasation, coexisting pathology of the esophagus, the patient's overall clinical condition, and the experience of the surgeon. The goal of treatment is to stabilize the patient, stop ongoing soilage, control infection, and maintain esophageal continuity if possible. Additional consideration should be given to the need for long-term enteral access predicted by the severity of the injury and condition. **Algorithm 43.2** provides general guidelines to the management of patients with esophageal perforations. Several well-established factors determine treatment strategy and prognosis: (1) time interval between injury and presentation, (2) location of the perforation along the esophagus, (3) severity and size of the perforation, (4) presence of signs of systemic sepsis, (5) presence of underlying esophageal pathology, and (6) experience of the care team.

Two potentially modifiable risk factors for poor outcomes are hospital volume and time to presentation. High hospital volume has been associated

with reduced mortality following esophageal perforation.[214] For patients presenting with spontaneous esophageal rupture (Boerhaave syndrome) diagnosis is often either missed or delayed leading to a mortality rate approaching 60% if time to definitive treatment exceeds 48 hours. This is in stark contrast to the overall mortality in cases managed within 24 hours of presentation which is associated with a 20% mortality.[215] Some have sought to address both delays in care and low-volume centers by developing a regional esophageal emergency referral program emphasizing multidisciplinary care at high-volume institutions with early reports of favorable outcomes.[216] Still others report success in using the Perforation Severity Score (PSS) in an attempt to better triage patients.[217] The PSS is a clinical score based on pre-existing esophageal pathology and clinical findings at the time of presentation (**Table 43.11**). Patients are risk stratified into low-, intermediate-, and high-risk groups according to increasing morbidity and mortality outcomes. The main benefit of such a score is its ability to identify patients at high risk for failure of nonoperative therapy thereby lowering the threshold for operative intervention.

Table 43.11 Perforation Severity Scoring (PSS) Criteria

Clinical Criterion	Weighted Score
Age >75 yrs	1
Tachycardia	1
Leukocytosis	1
Pleural effusion	1
Fever >38.5°C	2
Noncontained leak	2
Respiratory compromise	2
Presentation >24 hrs from injury	2
Hypotension	3
Malignancy	3

Adapted from Schweigert M, Sousa HS, Solymosi N, et al. Spotlight on esophageal perforation: A multinational study using the Pittsburgh esophageal perforation severity scoring system. *J Thorac Cardiovasc Surg* 2016;151(4):1002–1009.

Nonoperative Treatment

For properly selected patients with esophageal perforation, nonoperative management may be appropriate. In fact, in more than 50% of patients presenting with known or suspected esophageal perforation, initial management is nonoperative[210] with a success rate close to 60%.[217] Recently, the rates of nonoperative management have seen a significant increase from 48.6% between 2001–2003 to 54.9% between 2010–2012. Accordingly, there has also been a significant reduction in the utilization of surgery over the same period down to 12.7%.[214] Iatrogenic and traumatic perforations are more likely to be treated nonoperatively (68%) potentially due to the more immediate suspicion and presentation at the time of the procedure that resulted in the injury. By contrast, spontaneous perforations are more likely to be managed operatively most likely due to their relatively delayed presentation.[218] Timing for nonoperative therapy is critical as those

repaired within 24 hours of injury have significantly improved outcomes compared to those with delayed surgical intervention (either primarily or due to failure of initial medical therapy).

Current guidelines for patients who can be managed nonoperatively include those with no transmural perforation and those with a contained transmural perforation. There must also be no associated esophageal pathology such as malignancy and no signs of systemic illness. The nonoperative approach begins with the administration of broad-spectrum antimicrobials, the suspension of oral intake, and vigilant clinical monitoring. Initial broad-spectrum antimicrobial therapy is directed to cover common gram-negative bacteria, anaerobic bacteria, and fungi. We generally use a beta-lactam agent in combination with fluconazole, which is usually sufficient. We adjust therapy to culture findings. Duration of therapy is patient dependent, but it is typically continued for 10 to 14 days after resolution.

The patient is followed clinically and reimaged as needed, generally within 48 to 72 hours with a CT scan and esophagram if clinically indicated. If the patient improves during that time and testing is favorable, the diet may be advanced to clear liquids with the patient eventually being discharged on oral antibiotics and full liquids until reevaluation with imaging in the outpatient setting in 2 weeks. Any signs of sepsis such as fever, tachycardia, or leukocytosis suggest failure of this approach and further intervention should be expeditiously considered.

Esophageal Stents

Endoscopic placement of endoluminal stents for esophageal perforations has been a concept discussed for several decades.[219] In the last 10 years, the technology of stents has improved such that deployment is easier and indications have expanded. Starting with small limited series,[220–226] their use has increased dramatically to the point that they have become one of the main tools in the management of select, contained perforations. Their use in the management of benign esophageal perforation increased over fourfold in just 8 years from 7% in 2007 to 30% in 2014.[227] Highly selected patients with perforations are candidates for stenting in the context of a thoracic surgical consultation according to the principles outlined in this section. Successful stenting facilitates source control, may minimize stricture formation, and

frequently allows for early oral intake. However, success depends on a uniform approach that focuses on appropriate patient selection, proper stent placement technique, thorough drainage procedures (e.g., tube thoracostomy or decortication) which cannot be overemphasized, and meticulous postoperative care.

Patient Selection

For perforations proximal to the cricopharyngeus, stents have little or no role. For perforations 2 cm or more distal to the cricopharyngeus, a stent may work if the proximal extent seats just below the cricopharyngeus muscle. If the stent seats at or above the cricopharyngeus, patients experience intolerable foreign-body sensation during deglutition, and reflux and coughing are generally severe. Also of note, stents placed in the proximal esophagus may cause pressure and compression of the posterior membranous trachea leading to dyspnea and, in severe cases, critical airway compromise. If a stent is considered for placement in the proximal esophagus, the physician should strongly consider performing a simultaneous bronchoscopy to assess airway patency. Distal esophageal injuries may be better candidates for stenting when there is limited perforation, and there is good purchase of esophagus above and below the site of the perforation. This might include perforations associated with malignancy and in benign diseases such as iatrogenic perforation, Boerhaave syndrome, and select cases of achalasia. Patients with perforations from near-obstructing cancers can be ideal candidates for stents as the stent will purchase well against the tumor, leading to sealing of the perforation and relief of any coexisting blockage above or below the level of perforation. In addition, operating on perforated cancers can be a significant clinical challenge as this may represent their initial diagnosis at the time of perforation without the benefit of clinical staging. Perforation may also occur during treatment for esophageal cancer with chemotherapy or radiation. In either event, the patient may have contamination from tumor spillage thus making stenting our procedure of choice in the setting of malignancy.

We emphasize aggressive source control, and operative drainage of any extraluminal material. Stent placement without drainage in the setting of mediastinal soilage is a risky approach and if it is done, one may question whether the perforation was small enough to need intervention. If larger, we

would typically perform a VATS or thoracotomy to debride any soilage. If patients deteriorate clinically following any treatment, consideration of the presence of undrained sepsis should always be considered. At times, a patient might require several interventions to control the local and regional sepsis. Source control measures vary depending on clinical and anatomical findings. In general, the presence of mediastinal air without fluid collection represents the highly select group for which antibiotics only without additional source control measures as an adjunct to stent therapy can be considered. The presence of mediastinal fluid collection or abscess most often requires formal operative drainage. The operative approach to drainage will vary by anatomical location. Cervical esophageal injuries with fluid collections in the neck and superior mediastinum can be approached through lower vertical neck incision with blunt mediastinal dissection, irrigation, open packing, and, if deemed appropriate, drain placement. Often the use of a mediastinoscope can facilitate drainage of fluid collections extending down into the superior mediastinum without the need for formal chest exploration. Collections within the middle mediastinum are best approached via right thoracoscopy or thoracotomy with wide pleural incision, drainage, irrigation, and large-bore chest tube(s) placement. Left thoracoscopy or thoracotomy are best reserved for isolated collections in the lower posterior mediastinum but can also provide the potential for extension down into the abdomen for access to the gastroesophageal junction and upper abdomen.

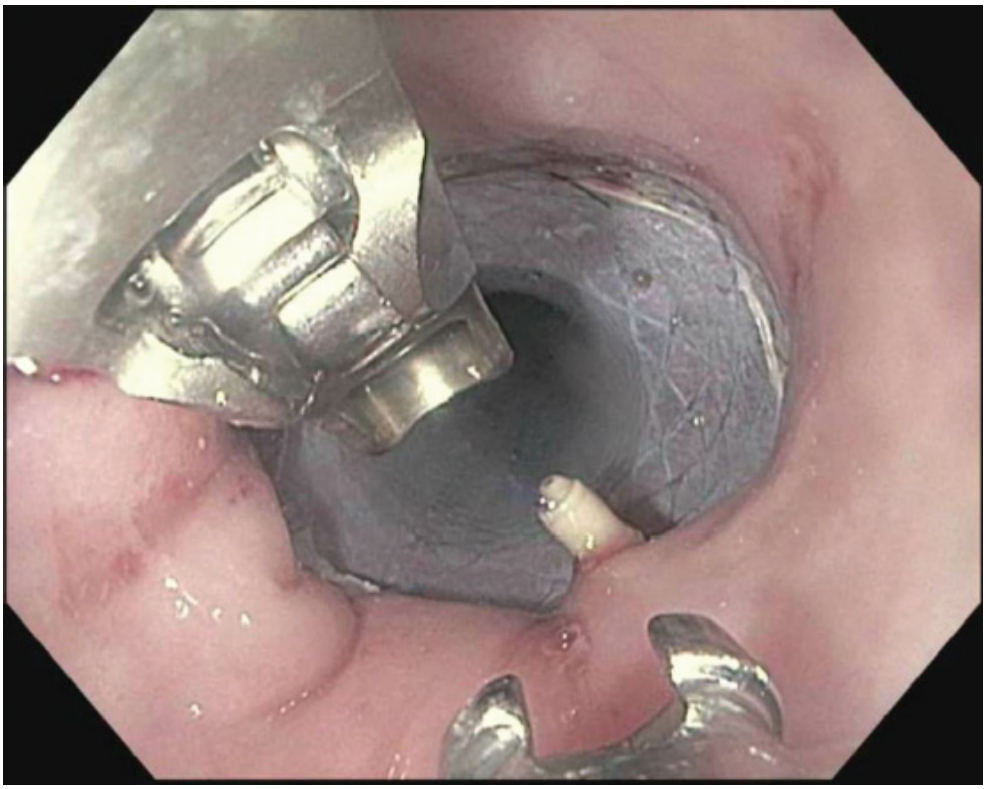

Figure 43.13 Endoscopy showing proximal suture fixation of esophageal stent. (Courtesy of Joo Ha Hwang, MD, Division of Gastroenterology and Hepatology, Stanford University, Stanford, CA.)

Stent Placement

Numerous stents are available for use. Longer stents (15 cm) that are fully covered work better to cover defects than uncovered stents. Newer covered stents which are uncovered at the proximal and distal end offer an advantage over fully covered stents to minimize migration. The procedure can be performed either in the endoscopy suite or the operating room. We prefer the latter with general anesthesia so that the stent can be placed immediately following diagnostic endoscopy followed by surgical exploration for mediastinal and pleural drainage in one setting. Fluoroscopy is useful to aid in optimal stent positioning using radiopaque skin markers. Additionally, fluoroscopy is useful if intraoperative esophagram is required for a small leak that is difficult to localize endoscopically. Ideal stent placement will depend on the location and size of the perforation. The goal is to cover at least 3 to 4 cm above and below the site of leak or perforation with a minimum distance from cricopharyngeus muscle (upper esophageal

sphincter) of 1 to 2 cm. In the case of distal esophageal perforation centering the stent at the site of injury may result in crossing the GE junction which is associated with higher risk of stent migration. In this case, we suggest using a longer stent oriented such that the distal end is lodged against the greater curvature of the stomach which acts as an additional fixation point to minimize migration with peristalsis. Proximal stent fixation using endoscopic sutures or clips is also useful to reduce the risk of stent migration (**Fig. 43.13**). Following placement, intraoperative evaluation of stent position and proper sealing is confirmed with a final endoscopy. It is easier to "pull" a stent back more proximally than to "push" it more distally thus we recommend erring on the side of more distal placement and repositioning, if needed to be done via pulling technique.

Poststent Management

Enteral feeding access should be ensured as soon as possible, preferably at the time of endoscopic and operative interventions. This can be accomplished with laparoscopic or open jejunostomy, percutaneous gastrostomy (PEG), or nasoenteric tube in order of decreasing invasiveness. Anticipation of good stent placement with limited time estimate for enteral access can be managed with nasoenteric tube only which can be placed at the conclusion of the endoscopy. PEG may be ideal for those not requiring laparotomy for other reasons and can also be placed at the time of endoscopy but before stent placement. PEG placement after stent placement has the potential to displace the stent. Daily chest radiograph is performed to monitor stable stent location for several days following placement. We obtain chest radiography immediately after the procedure and daily thereafter to monitor for migration. Ongoing sepsis is generally due to poor source control and/or nonsealing of the perforation. Reintervention is tailored to the situation but might require aggressive surgical intervention and stent removal and/or replacement.

Outcomes

Outcomes for stent therapy for esophageal perforation have a reported success rate of 77% to 84%.[228] Stent migration is the leading complication following stent. It occurs in 30% to 55% of cases of stent placement and proximal fixation with sutures or clips is associated with a reduction in stent

migration and need for replacement.[229] Once stent migration is confirmed radiographically, replacement is required unless the leak has resolved. This is typically not an emergency but should be addressed in a timely fashion. We generally repeat endoscopy at 3-week intervals and remove the stent each time. If a small leak persists, a new stent is placed so that the distal end of the stent is slightly proximal or distal to that of the previous stent to allow the area of inflamed mucosa to heal. Resumption of oral intake depends on the clinical scenario. A speech pathologist evaluates every patient before an esophagram. Only patients who are safe to swallow undergo an esophagram. Oral intake is then resumed and represents a major advantage of stent placement which allows for the possibility of oral nutrition while the perforation is healing.

Esophageal stenting is also a useful tool in the setting of failed primary repair or anastomotic leak. Technical success of esophageal stenting for anastomotic leak is reported as high as 71.4% requiring a median treatment duration of 28 days.[230] Secondary interventions following stent placement for patients with perforation are estimated at 33.7%. Major complications include sepsis (28.1%), pneumonia (17.1%), and multiorgan failure (11.6%). Overall mortality is 15.1%.[231] According to the latest systematic review, the overall technical and clinical success rates of esophageal stenting for esophageal perforation are 91% and 81%, respectively, with mortality of 13% likely reflective of diligent patient selection.[232]

Endoscopic Clipping

Endoscopic interventions in the form of clipping or suturing are gaining in popularity with promising early results (**Fig. 43.14**). Endoscopic clipping can be performed either using a through-the-scope (TTS) method or an over-the-scope (OTSC) system. The OTSC system is a clipping method for mechanical compression of tissues in the GI tract first designed for the management of bleeding, perforation, and fistula. Similar to other interventions for perforation, endoscopic clipping is a viable option only when performed early after the injury. After 24 hours post-injury, tissue integrity becomes a major limitation hindering successful primary repair, and the rate of failure of endoscopic therapy increases significantly.[233] TTS clips are best for defects 10 mm or less in greatest dimension while bigger (<20

mm) lesions can be treated successfully with the OTSC method. Larger defects are best considered for stent placement or surgical repair. In either endoscopic treatment, a significant source of failure is overlooking the need for drainage and treatment for associated mediastinitis as a source of sepsis. Thus, concomitant surgical or nonsurgical drainage of the mediastinum is imperative to accompany the endoscopic intervention as outlined for stenting.

Vacuum-Assisted Closure Therapy

Endoluminal vacuum-assisted closure (EVAC) therapy is a novel treatment modality for managing esophageal perforations. EVAC therapy facilitates tissue healing by overcoming physiologic negative pressure in the thorax, reducing mediastinal contamination and enabling tension-free approximation of tissue. The procedure can be performed in the endoscopy suite or the operating room under general anesthesia. The endosponge is created using a modified NG tube connected to a tailored wound vac sponge that is trimmed to size per endoscopic examination. The endosponge is then exteriorized for

connection to the wound VAC suction system with continuous negative pressure at 175 mm Hg, on high intensity.[234] There are small series reporting success using EVAC therapy as primary treatment for esophageal perforations and leaks.[228,234–236] Successful closure is reported to range between 91% and 100% closed after a mean duration of 27 days requiring an average of 6 endosponge changes every 4.8 days. An additional advantage of EVAC therapy is the potential to treat patients outside of the 24-hour early presentation window with facilitated drainage of any mediastinal abscess cavity.

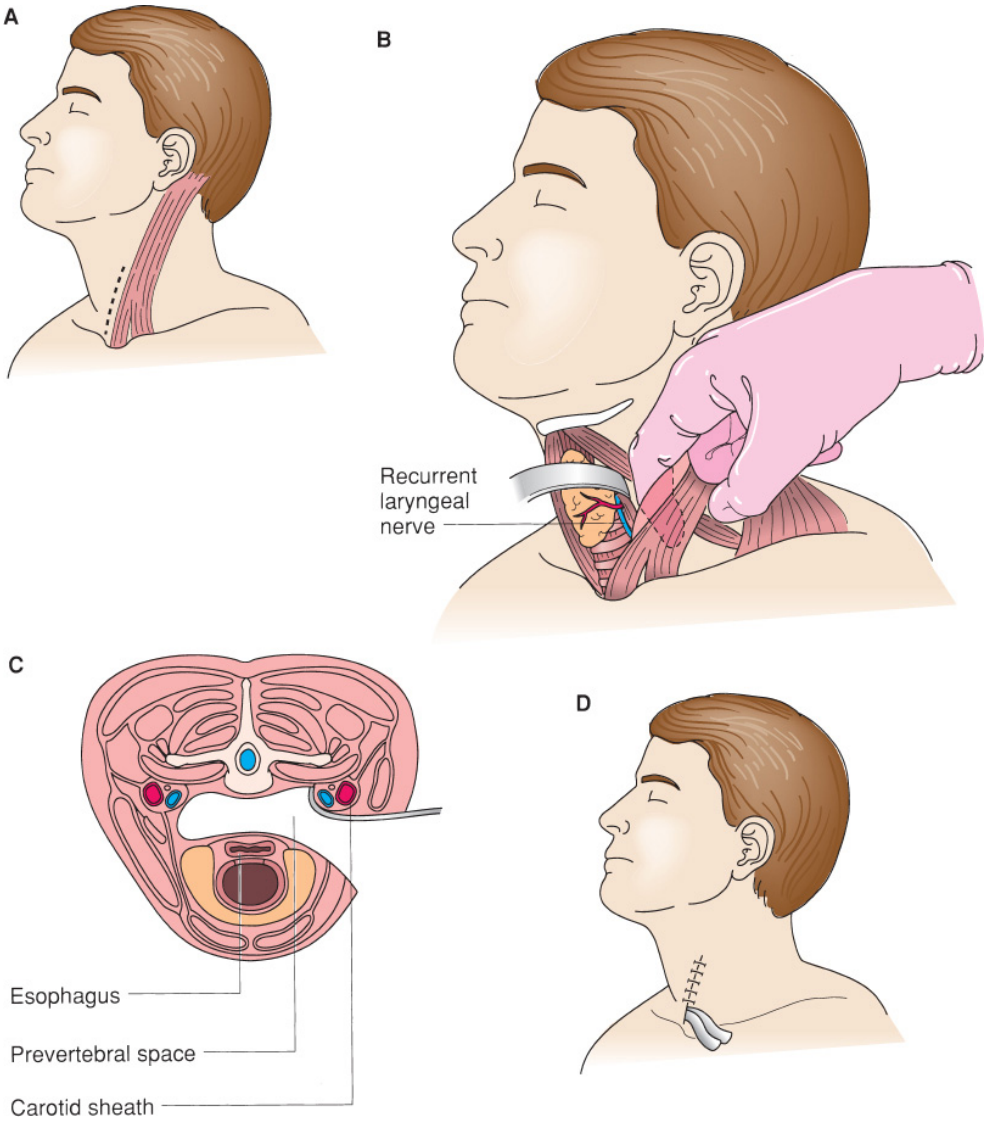

Figure 43.15 Approach for drainage of a cervical esophageal perforation. **A:** Skin incision parallel to the anterior border of the left sternocleidomastoid muscle, extending from the level of the cricoid cartilage to the sternal notch. **B:** With the sternocleidomastoid muscle and carotid sheath retracted laterally and the trachea and thyroid gland retracted medially, blunt dissection is performed along the prevertebral fascia in the superior mediastinum. Injury to the recurrent laryngeal nerve in the tracheoesophageal groove must be avoided. **C:** Schematic drawing of the prevertebral space drained by this cervical approach. **D**: Penrose drains placed into the superior mediastinum are brought out through the neck wound to allow establishment of an esophagocutaneous fistula, which usually heals spontaneously.

Surgical Repair

The operative management of esophageal perforation is dictated by the location of the injury, extent of injury, and underlying pathology. Operative

approaches include drainage alone, primary reinforced repair, esophagectomy with immediate or delayed reconstruction, and esophageal exclusion.

Perforations of the upper third of the esophagus to the level of the carina should be approached via a left neck incision (**Fig. 43.15**). Traditionally it is not necessary to find or close the perforation when approached this way as the injury will seal during the process of healing. In order for this to be successful, however, wide and complete drainage must be accomplished. Preoperative CT scan will aid in ensuring that the important areas of contamination are addressed surgically. In the operating room we liberally use on-table flexible endoscopy to evaluate the defect and the location of the defect. If the defect is identified and it is small, we advocate for an attempt at primary closure. The neck incision is loosely reapproximated with staples over a drain. Typically, a contrast esophagram is obtained 5 to 7 days postoperatively, the patient's diet is advanced, and the drain is removed. If there is continued leak, the patient is left NPO or on clear liquids and restudied in 1 week. There should be no distal obstruction on the contrast study and if there is a stricture that prevents normal contrast flow, we advocate for dilation to aid in eventual closure of the esophageal fistula. As long as there is no underlying pathology or distal obstruction, most cervical injuries will heal spontaneously with adequate drainage.

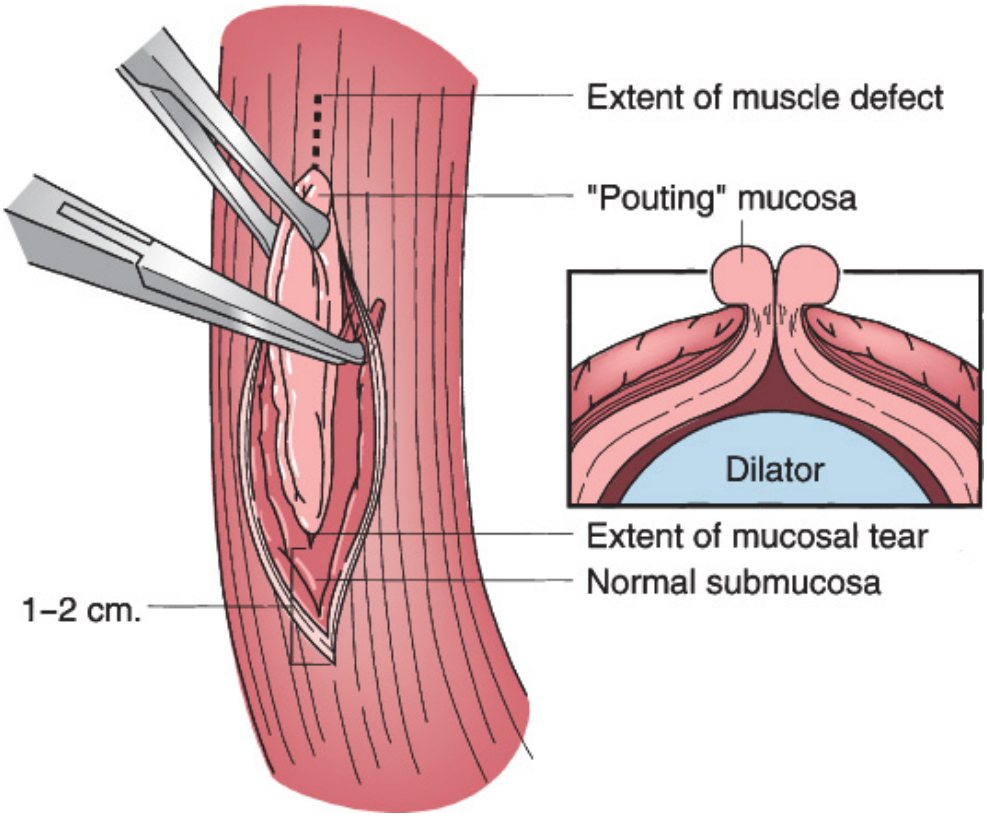

Figure 43.16 Primary repair of esophageal perforation. The edematous mucosa pouting through the muscular defect (*inset*) is grasped with Allis clamps and elevated. A 1-cm vertical esophagomyotomy is made at either end of the muscular defect to expose the entire limits of the mucosal tear. This is facilitated by using a right-angle clamp to direct muscularis away from underlying submucosa around the entire circumference of the tear. The result of this mobilization is exposure of a circumferential rim of normal submucosa that can then be closed.

Perforations of the middle third of the esophagus are best approached via a right fifth interspace posterolateral thoracotomy. We routinely start thoracoscopically, but typically these patients are very ill thus one should have a low threshold for conversion to thoracotomy. At the time of entry into the chest, an intercostal muscle flap is routinely taken. The mediastinal pleura is opened widely and all pleural collections are drained, the lung is decorticated, and the site of perforation identified. Necrotic tissue at the site of the perforation is debrided and the esophagus is mobilized. A vertical myotomy is performed to expose the mucosa and determine the full extent of the tear (**Fig. 43.16**). The mucosa is repaired with simple interrupted or running absorbable suture. The muscular layer is reapproximated with interrupted fine silk suture. On-table endoscopy is performed to ensure the

leak is repaired. The intercostal muscle is then secured as an onlay patch. Large chest tubes are placed and a malleable Blake drain is left in the area of the repair and placed to bulb suction. Nutritional access can be addressed at the index operation if the clinical condition of the patient is favorable. If not, this can be accomplished at a later date. On postoperative day 7, a contrast study is obtained and if there is no leak, the diet is advanced. Persistent leaks are treated with continuation of the surgical drains and potentially placing additional drains via interventional radiology if there are any undrained collections. Esophageal stenting may be used to exclude any persistent leak as outlined above. If there are signs of clinical sepsis despite the above, esophageal exclusion may be required with cervical esophagostomy and establishment of long-term enteral access via jejunostomy or gastrostomy. Esophageal resection can be performed at the time of diversion or delayed depending on the clinical conditions. Patients can be considered for delayed reconstruction 6 to 12 months following perforation most commonly approached as a gastric pull-up, colonic interposition, or jejunal flap placed in the substernal position. Perforations of the distal third of the esophagus can be approached via a left seventh intercostal space thoracotomy using the same principles for repair and drainage.

Operative treatment in the presence of underlying pathology deserves special attention and can be quite challenging. If there is distal obstruction, this must be dealt with. Strictures can be dilated or stented and often support the healing of a proximal perforation. Patients with achalasia who are perforated during pneumatic dilation are especially challenging. Many are candidates for nonoperative intervention as they have small perforations that are asymptomatic and the patients are clinically nontoxic. This is acceptable provided the distal obstruction has been relieved. For those who fail nonoperative management or are not candidates, operative management should be tailored to the individual and their pathology. In patients with preserved motility, the perforation should be repaired primarily and a vertical myotomy should be performed 180 degrees opposite the injury. These patients, and those for whom esophageal motility status is unknown, should have a partial fundoplication performed. For stable patients with advanced achalasia, esophagectomy should be considered. For unstable patients, esophageal exclusion should be performed. Unstable patients with advanced pathology such as cancer should undergo esophageal stenting if

appropriate or exclusion. This includes stapled esophageal diversion with resection of the diseased segment of the esophagus. A linear stapler is deployed on the esophagus proximally and at the gastroesophageal junction. The esophagus is resected. An end cervical esophagostomy is created saving as much esophageal length as possible. Pleural drainage is accomplished. Subsequently the patient undergoes placement of gastrostomy (+/− jejunostomy tube) with repair of the diaphragmatic defect from the abdominal side via laparoscopy or laparotomy. The components of operation may be staged based on the severity of patient illness. If the patient survives and is a candidate for reestablishment of continuity, this can be investigated later once they have recovered. Additionally, consideration should be given to end-of-life discussions depending on the extent of the cancer.

Surgical Resection

Fortunately, esophagectomy is necessary in only a small percentage of patients following perforation. It may be indicated following failed primary repair or as primary treatment with or without immediate reconstruction. The presence of pre-existing benign or malignant stricture or large perforation (>5 cm) is associated with increased risk for need for an urgent esophagectomy.[250] When clinically indicated, emergent esophagectomy represents a safe treatment option with observational studies demonstrating mortality rates comparable between operative and nonoperative management (31% vs. 20%).[237–239]

Caustic Injury

Epidemiology

Caustic burns of the esophagus result from ingestion of substances with pH <2 or pH >12. In children these ingestions are usually accidental, while in adults they are most often associated with suicide attempts. Liquid alkaline agents (e.g., household cleaner) are more likely to be swallowed and subsequently cause more injury. Although mortality from caustic ingestion is low, the morbidity associated with caustic ingestions is significant. Acute

morbidities include perforation and necrosis. Late morbidities are more prevalent and include stricture formation and cancer.

The extent of injury to the esophagus caused by ingested caustic material is dependent on the volume and nature of the ingestion. Injuries resulting from ingestion of liquids are much more severe than those caused by ingestion of solids. The patient usually spits particulate matter out and, thus, it rarely moves beyond the oropharynx. Liquid caustic agents contribute to pathology down the length of the esophagus. Strong acid and alkali ingestions comprise the majority of caustic ingestions. These substances are sold in various liquid and solid/particulate forms. The most commonly ingested strong acids include industrial and swimming pool cleaning solutions, battery fluids, and antirust compounds. Commonly ingested strong alkaline-containing substances include household cleaning products and personal hygiene products. The most commonly ingested weak alkali is ammonia hydroxide, which is found in most bleach solutions.

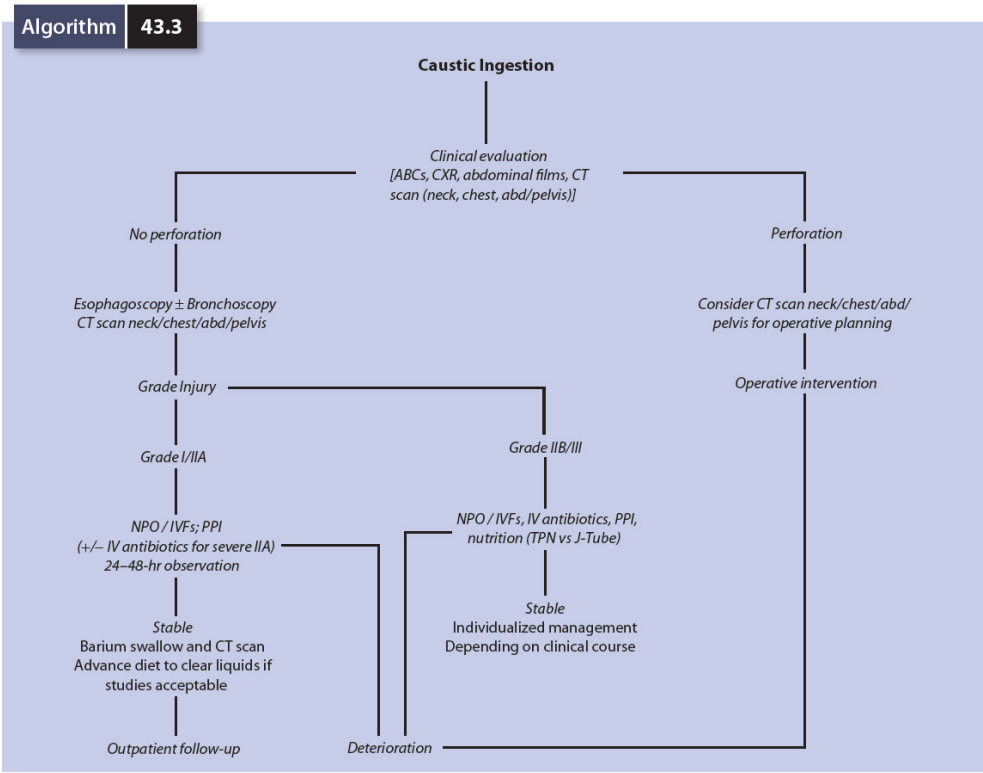
Injury from alkaline ingestion tends to be more severe than acid ingestion, resulting in significantly higher rates of morbidity and mortality and higher incidence of associated stomach injuries (43% vs. 13%).[240] Alkaline burns are characterized by liquefactive necrosis, leading to far greater penetration at the level of the oropharynx and esophagus. Solid alkali has a propensity to adhere to the oropharynx, whereas liquid alkali is rapidly swallowed. Thus, liquid alkali results in more distal esophageal and gastric injury. Frequently there is penetration of all layers of the esophagus causing substantial secondary edema. Commensurate with this, the potential for perforation and circumferential scar formation is greatest with an alkaline ingestion. In contrast to acid ingestion, alkali substances are typically odorless and tasteless, which enhances the potential for deeper injury.

Acids cause more severe damage to the stomach but similar damage to the esophagus when compared to alkalis.[241] The burns from acid ingestion cause coagulative necrosis and a superficial eschar that protects the deeper layers of the esophagus from damage. Fortunately, acids tend to taste bitter and cause immediate pain, thus the patient will usually spit the substance out well before it reaches the esophagus and stomach. When acids are ingested in liquid form, they move quickly, typically spare the oropharynx, and produce skip injuries to the esophagus. Acids in liquid form cause gastric and duodenal injury more frequently than esophageal injury.

Clinical Presentation

The initial clinical presentation comprises oropharyngeal pain; irritability; and, in severe cases, excessive salivation, dysphagia, and airway compromise. Ingestion of particulate caustic substances results in signs of contact readily visible in the oropharynx. Hoarseness and stridor are signs of serious airway injury that mandate intubation. Retrosternal pain, neck crepitus, and sudden onset of epigastric pain imply full-thickness esophageal damage. Many patients present without symptoms and a significant proportion have injuries that will require intervention. Thus, a 24-hour period of observation is reasonable, even for asymptomatic patients, especially if there is any question about the circumstances of the ingestion or extent of injury.

As with any acute situation, management should begin with the standard assessment of the ABCs (airway, breathing, and circulation) (**Algorithm 43.3**). As with most foreign-body ingestions, the most common sites for pathology within the esophagus are its three areas of narrowing: the cricopharyngeus, the level of the aortic arch, and the gastroesophageal junction (**Fig. 43.11**). A stable patient may undergo imaging via posteroanterior and lateral upright chest and abdominal radiographs to evaluate for pleural effusion or free air. CT of the chest and abdomen can provide important anatomical definition of injury. Patients with no visible symptoms or only lip swelling or redness can be observed in the hospital or a short-stay unit for 24 hours to ensure they can tolerate oral feedings. This is typically for pediatric patients. Patients with oral lesions should undergo esophagoscopy and bronchoscopy. The bedside insertion of an NG or orogastric tube is discouraged when the extent and depth of injury have not been fully evaluated.



Algorithm 43.3 Evaluation and management of acute caustic ingestion.

After radiographic imaging, rigid or flexible esophagoscopy to characterize the location and extent of injury should be the next course of investigation. This should be performed within the first 24 hours as the risk of procedural complication increases with time. In a large retrospective study of 21,682 patients following caustic ingestion, patients undergoing endoscopy delayed greater than 48 hours after injury experienced a threefold increased risk for poor clinical outcome.[242] Others advocate for assessment with repeat endoscopy on post-injury day 5 reporting that delayed examination is a better predictor of esophageal and gastric cicatrization than day 1 exam alone, which significantly overestimates the grade of injury.[243] The indications for esophagoscopy include stridor, vomiting, drooling, and intentional ingestion. Caution should be used when moving beyond the first sign of pathology below the cricopharyngeus. If there are respiratory symptoms, laryngoscopy and bronchoscopy should be performed. The latter of which should direct the procedure to be done in the operating room. When injury is identified, the standard grading of the esophageal burn should be reported (**Table 43.12**).

Management

The initial clinical presentation comprises oropharyngeal pain, irritability and, in severe cases, excessive salivation, dysphagia, and airway compromise. Hoarseness and stridor are signs of serious airway injury that mandate intubation. Retrosternal pain, neck crepitus, and sudden onset of epigastric pain imply full-thickness esophageal damage. Many patients present without symptoms but have injuries that will require intervention. Thus, even asymptomatic patients should be observed closely for the first 24 hours.

Patients with grade I injuries have superficial burns causing edema and hyperemia. These patients can be observed, a normal diet can be advanced, and the patient ultimately can be followed in an outpatient clinic. Superficial grade I injuries cause mucosal sloughing and should heal without a stricture. Grade II injuries penetrate into the muscular layer of the esophagus and can result in either patchy (IIA) or circumferential (IIB) injury. Ulcerations (superficial and deep) and pseudomembranes are found during endoscopy (**Fig. 43.17**). Once circumferential injury is identified, the risk of stricture formation increases dramatically. Grade III injuries are full-thickness injuries, and mediastinitis or peritonitis occurs within 48 hours. Grade III findings are characterized by gray mucosal slough, thrombosed submucosal vessels, and black eschar. All grade III burns and >75% of circumferential grade IIB burns cause esophageal stricture and, as expected, are associated with a higher incidence of infection.

Table 43.12 Endoscopic Grading of Acute Caustic Injury to the Esophagus

Injury	Endoscopic	Depth of Grade Appearance Injury
I	Superficial hyperemia	Mucosal
IIA	Sloughing mucosa, superficial ulceration	Patch partial thickness
IIB	Deep ulceration	Circumferential
III	Eschar, necrosis	Full thickness

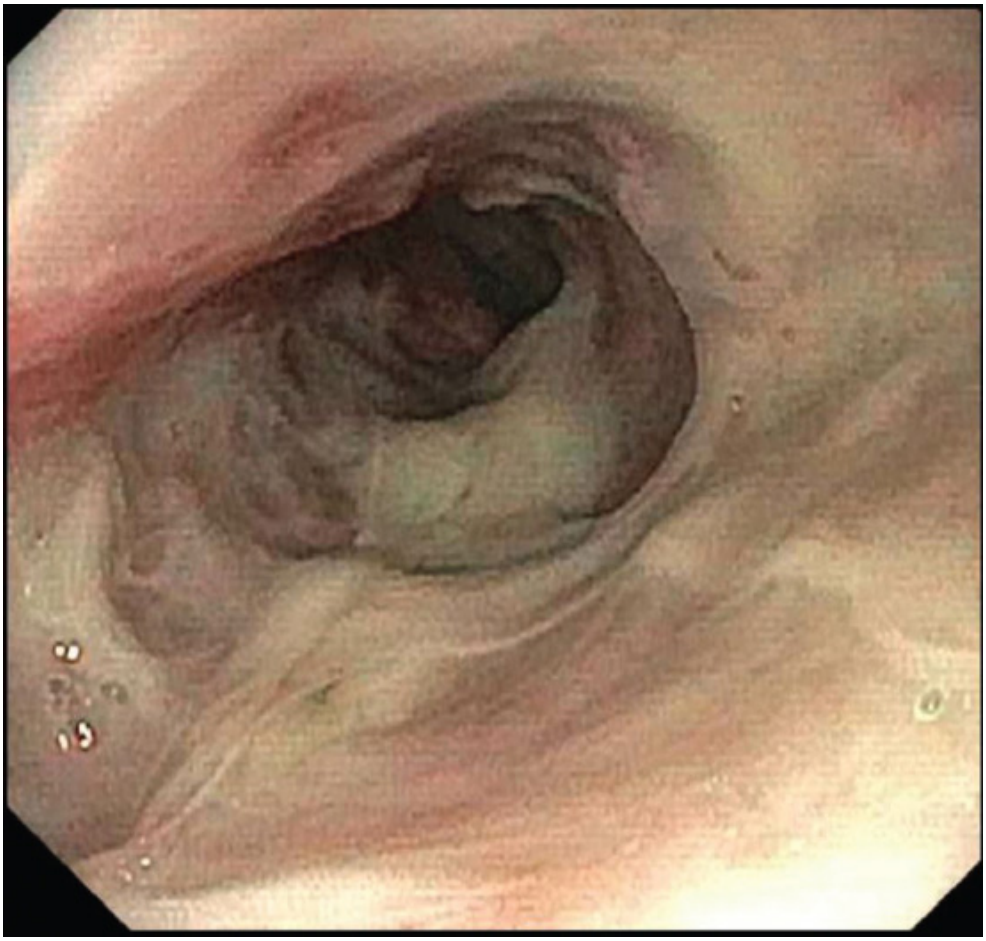


Figure 43.17 Endoscopy showing acute caustic ingestion. (Courtesy of Joo Ha Hwang, MD, Division of Gastroenterology and Hepatology, Stanford University, Stanford, CA.)

Acute management of caustic ingestion should be dictated by the endoscopic grading of the esophagus and the clinical status of the patient (**Algorithm 43.3**). If there is no evidence of perforation, patients with mild exposure (e.g., bleach or detergent ingestion) can be observed for 24 to 72 hours (depending on the clinical presentation). Generally, patients should be kept nil per os (NPO) until pain free. Enteral feedings can likely be introduced within 48 hours for all patients with grade I or IIA burns.

Patients with grade IIB or grade III esophageal burns without evidence of perforation should be placed in a monitored setting, kept NPO, and given IV fluids and IV antibiotics (penicillin derivative or clindamycin). Patients should also be maintained on proton pump inhibitors to reduce acid exposure of the esophagus as this may decrease the stricture incidence. Steroid

administration is controversial, does not prevent stricture formation, and may mask findings in the serial abdominal examination. If corticosteroids (2 to 2.5 mg/kg/d) are used, they should be instituted within the first 24 hours of ingestion and for 3 weeks thereafter. Early introduction of parenteral nutrition is essential for all patients with esophageal perforation and for patients with poor gastric motility. Depending on the extent of injury, the patient may require mechanical ventilation. Esophagram (or CT scan with oral contrast) may be used as an adjunct evaluation. If free contrast extravasation into the mediastinum is visualized, drainage of the mediastinum into the pleural space is indicated. Further, esophageal resection may be required with findings of necrosis. On occasion, a contained mediastinal leak, which returns contrast material back into the esophagus, may be observed without the need for immediate drainage. Pneumoperitoneum is an absolute indication for laparotomy and resection of all dead tissues. Laparoscopic evaluation may be useful to evaluate the abdomen if there is isolated mediastinal pathology.

Surgical Resection

One of the challenges associated with esophagectomy for caustic ingestion is availability of the stomach as a possible replacement conduit. In the case of associated gastric necrosis, the stomach may itself be injured thereby limiting its use as a conduit or it may be completely necrotic requiring concomitant gastrectomy. Initial resection can be performed as outlined above with or without immediate reconstruction. Delayed esophagectomy being done for sepsis or refractory stricture may be best performed in a staged fashion with esophagectomy and esophagostomy followed by substernal interposition graft of either colon or jejunum. Patients with extensive full-thickness esophageal and gastric necrosis should undergo total esophagogastrectomy with cervical esophagotomy and feeding jejunostomy. Of course, any operative intervention should include assessment of other organs involved and complete drainage/resection of necrotic tissue. Options for esophageal replacement have been outlined above.

Complications

Strictures of varying degrees occur in almost all patients following caustic ingestion and, thus, careful follow-up is recommended. The esophagus and stomach should be evaluated via barium swallow 3 weeks, 3 months, and 6 months after the ingestion to rule out stricture formation or gastric outlet obstruction. Esophagogastroduodenoscopy (EGD) is typically performed 3 weeks after the ingestion for full evaluation. Early endoscopy is warranted during the phase of cicatrix formation, and dilation is repeated at varying intervals. Risk factors for development of post-ingestion stricture include initial symptoms such as dysphagia or hematemesis, and grade IIa or higher esophagitis identified on initial endoscopy.[244] The ideal interval for intervention is patient dependent and clinically dictated by the amount of dysphagia or interval to recurrence of dysphagia, the initial severity of burn, and findings on radiographic studies.

In most patients, management of esophageal strictures that develop as a result of caustic burns is the primary operative consideration. Circumferential grade IIB burns can be managed with an open gastrostomy and insertion of a string through the gastrostomy that exits transnasally. Four weeks after the burn, serial dilations using progressive antegrade bougienage from the oropharynx or retrograde stringing bougienage through the gastrostomy is effective. Retrograde string bougienage or antegrade dilations should be performed at 2- to 3-week intervals for consecutive dilations (**Fig. 43.18**). Optimal caliber bougienage is 48 to 50 for adults and 34 to 36 for children. The majority of patients with acid-induced corrosive esophageal stricture are refractory to dilatation with failure rates of 75% of patients. Concomitant cricopharyngeal stricture, long stricture length, requiring frequent dilatation, and stricture refractory to greater than 11-mm dilatation are factors associated with failed dilatation.[245]

Esophageal stenting is another approach for second-degree esophageal burns, which may be more palatable than string bougienage. A removable, fully covered stent is placed endoscopically shortly after injury and left in place for 3 weeks. It can then be removed. Recent reports have suggested that this is an appropriate intervention to prevent stricture formation in some patients. Injection of the stricture with triamcinolone (30 mg/mL) may also be effective, especially in those strictures that are focal. Esophageal replacement is usually considered if a stricture fails to resolve after 1 year of dilations, stricture injections, and antacid therapy. Malignant degeneration is

possible at the area of the stricture, and esophageal cancer occurs at a 1,000-fold greater frequency in individuals with a caustic injury to the esophagus than in the general population.

Esophageal Fistulas

The increasing use of endovascular and advanced interventional cardiology procedures has been associated with uncommon complications of fistulization between the esophagus, pericardium, aorta, or cardiac chambers. Between 1990 and 2005, there were an estimated 133,000 radiofrequency ablations performed in the United States[246] with another 120,000 cases of cryoablation done for atrial fibrillation worldwide since 2011.[247] Fortunately, despite increased use of cardiac ablation procedures, esophagopericardial fistulas are uncommon and are typically related to upper GI malignancy or as complications of esophageal injury, such as caustic ingestion, or prior surgery. Their rarity makes them a diagnostic challenge to clinicians. They are also a known complication of esophageal stents. The radial forces within esophageal stents combined with motion from esophageal peristalsis, respirations, and cardiac pulsatility, can contribute to fistula formation if the stent is left in place for a prolonged period of time.[248]

Most patients will have a delayed presentation of weeks to months after initial insult or index procedure. A systematic review identified a median of 21 days between cardiac ablation and presentation, but patients may present as long as 60 days post procedure. Most common presenting symptoms are fever (73%), neurologic (72%), GI (41%), and cardiac (40%) symptoms.[249] Cardiac tamponade may be present and its severity will depend on the size of the defect and rapidity with which air and/or fluid has accumulated within the pericardial space. Severe clinical symptoms only occur once the pressure in the pericardium exceeds a threshold and most patients do not require pericardial drainage. Plain radiographs may demonstrate pneumopericardium and echocardiography may show tamponade physiology if a large pericardial effusion is present. CT scan can be useful in diagnosing and localizing the site of the fistula. It is important to note that when atrioesophageal fistula is suspected, instrumentation of the esophagus with endoscopy or transesophageal echocardiography is contraindicated, as insufflation of the esophagus can result in the formation of air emboli causing devastating

neurologic injury and death. If either are to be performed, they should be done at the time of surgical repair, and despite limiting the endoscopic examination, insufflation should not be used. Staged repairs may be the most appropriate way to deal with this highly morbid condition. In the case of aortoesophageal fistula, this may consist of a combined endovascular approach as a temporary measure to stabilize the patient followed by a definitive surgical repair or resection.[250] The condition carries a high mortality estimated at 55%. Mortality is significantly less for patients undergoing surgical repair (33%) compared with those undergoing endoscopic treatment (65%) or conservative management (97%).[249]

Esophageal Foreign Body

Foreign-body ingestion and food bolus impaction are common occurrences that physicians can encounter when dealing with the esophagus, commonly seen in children between the ages of 6 months and 3 years, with over 100,000 new cases occurring in the United States annually. Pediatric foreign-body ingestion is typically accidental and most frequently involve coins, followed by toy parts, batteries, bones, and food.[251] Typically, esophageal foreign bodies tend to pass through the GI tract spontaneously. However, roughly 10% to 20% of cases may require nonoperative intervention, with <1% requiring surgery.[252–254] A large percentage of objects that do not pass spontaneously remain in the cervical esophagus. Complete obstruction can lead to inability to tolerate secretions, airway compromise, and death. Pediatric patients are the most common population affected, while in adults, edentulous patients are at greatest risk.

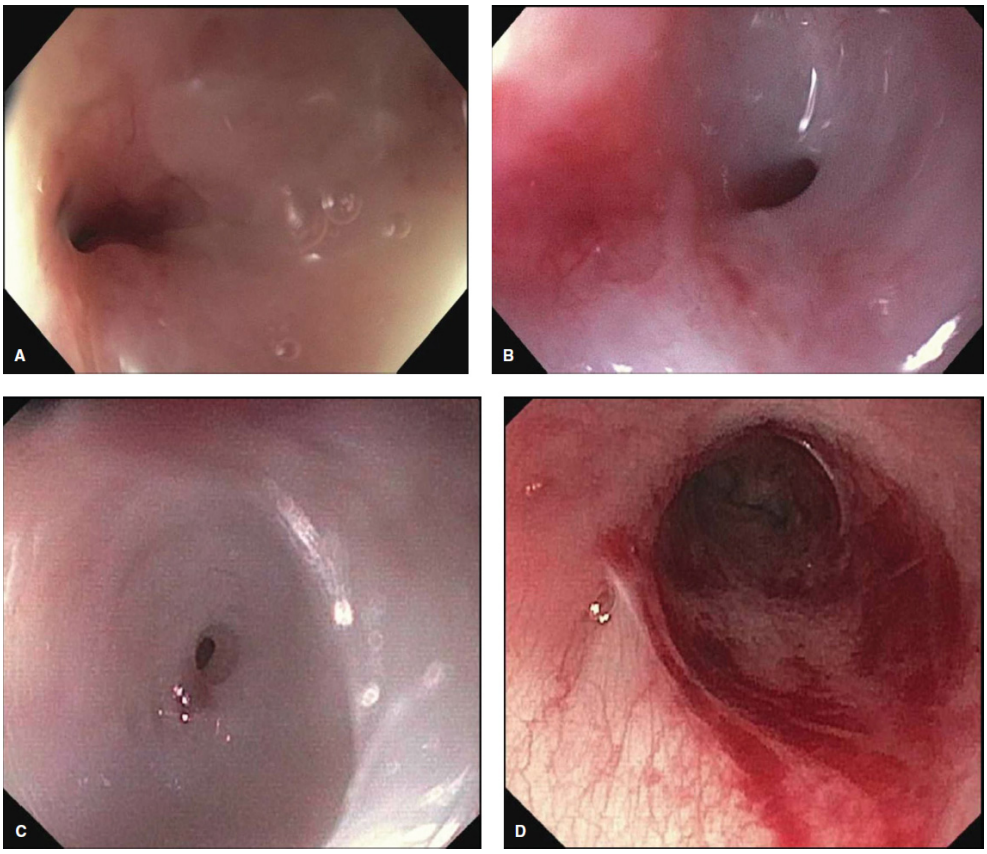

Figure 43.18 Endoscopy showing a stricture at the upper esophageal sphincter after caustic ingestion at baseline (**A**), 3 months after injury (**B**), 6 months after injury (**C**), and after balloon dilation (**D**). (Courtesy of Joo Ha Hwang, MD, Division of Gastroenterology and Hepatology, Stanford University, Stanford, CA.)

Plain radiographs may be a sufficient diagnostic study if the object is known to be radio-opaque in order to determine location and number of foreign bodies. UGI or barium swallow studies are not recommended because of the risk of aspiration and the presence of contrast that may potentially obscure visualization during any subsequent endoscopic examination.[255] Management in the setting of an asymptomatic patient usually consists of simple observation. Others have advocated for the use of glucagon and other effervescent agents as adjuncts to nonoperative treatment. Glucagon is known to decrease lower esophageal sphincter tone by causing smooth muscle relaxation thus making it one of the most widely accepted agents for esophageal foreign-body impaction. This is despite the fact that the literature supporting its use is controversial and of poor quality.[256–258]

Following observation, endoscopy is the gold standard first-line treatment and is much more likely to lead to resolution of symptoms than medical therapy alone (98% vs. 28%).[259] Timing of endoscopy is indicated by the risk of esophageal wall damage or aspiration, as well as the clinical status of the patient. Urgent intervention using endoscopy may be required in patients with severe distress, unable to swallow their own secretions, or with foreign bodies that are batteries or have sharp edges. Patients who do not fit these criteria and have no evidence of severe obstruction can be handled less urgently. Retrieval is the goal when dealing with foreign bodies that are not subjected to spontaneous passing. General anesthesia is recommended during the entirety of this procedure. Flexible endoscopy is the preferred method for most foreign bodies. A rigid endoscope is useful in the retrieval of foreign bodies lodged in the proximal esophagus at the level of the cricopharyngeus muscle. Rigid esophagoscopy is a rarer procedure and one should be familiar with the technique. The object should be reoriented with a grasper and removed safely. When using the flexible esophagoscope, we have found the overtube to be a very useful tool for removal of foreign bodies such that the esophagus is not injured proximally upon extrication of the object. Esophagotomy may be required when the lodged foreign bodies are large, have sharp edges, are embedded in the mucosa, or exceed the diameter of the rigid endoscope in all orientations. Following removal of the foreign body, completion esophagoscopy and contrast esophagoscopy should be performed to rule out injury. If there is a perforation, it should be managed according to the algorithm in **Algorithm 43.2**.

Perforation from esophageal foreign body is also rare with an estimated incidence of 4%.[260] In an analysis of over 1,200 patients presenting with foreign-body impaction, independent risk factors for complications were age ≥60, duration of impaction longer than 1 day, impaction in the esophagus, and sharp foreign body (e.g., chicken or fish bones). Duration of impaction longer than 1 day was associated with 2.5-fold increase in the risk of complications and increased risk of failure of endoscopic retrieval.[261] Sharp foreign-body ingestion is associated with worse outcomes than other object types, however some have advocated for conservative management with good results. The overall mortality rate for esophageal perforation from foreign-body ingestion is 5.3%.[262]

Finally, the prevalence of concomitant motility disorder among patients presenting with esophageal foreign-body impaction cannot be overlooked. Its incidence is estimated at 10%,[260] thus follow-up for these patients should include additional studies to examine for any underlying esophageal pathology including motility testing. Compared with control subjects, patients with foreign-body impaction have marked reduction in amplitude and duration of esophageal contraction in the proximal esophagus.[263]

Section E: STOMACH AND DUODENUM

44

Gastric Anatomy and Physiology

Michael W. Mulholland

Key Points

1. The stomach is an extremely well-vascularized organ, supplied by a number of major arteries and protected by a large number of extramural and intramural collaterals.
2. Oxyntic glands occupy the fundus and body of the stomach and contain the oxyntic or parietal cells, which are the sites of acid production. Oxyntic glands also contain chief cells, the site of gastric pepsinogen synthesis.
3. The most important stimulant of gastrin release is a meal. Postprandial luminal pH also strongly affects gastrin secretion.
4. The basolateral membrane of the parietal cell contains specific receptors for histamine, gastrin, and acetylcholine, the three major stimulants of acid production.
5. Pepsins are a heterogeneous group of proteolytic enzymes that are secreted by the gastric chief cells.
6. The gastric mucosa is the site of production of intrinsic factor, which is necessary for the absorption of cobalamin from the ileal mucosa. Total gastrectomy is regularly followed by cobalamin malabsorption, as is resection of the proximal stomach or atrophic gastritis that involves the oxyntic mucosa.

GROSS ANATOMY

The stomach and duodenum, along with the esophagus, liver, bile ducts, and pancreas, are derived from the embryonic foregut. During the fifth week of gestation, the future stomach is marked as a dilation in the caudal portion of the foregut. Cranial to this dilation, the trachea forms as a bud from the future esophagus. At this time, the primitive stomach is invested with both ventral and dorsal mesenteries. The embryonic ventral mesentery is represented in postnatal life by the falciform ligament and by the gastrohepatic and hepatoduodenal mesenteries that form the lesser omentum. The celiac artery, the major blood supply to the foregut, passes within the dorsal mesentery.

The primitive dorsal mesentery ultimately forms three structures: the gastrocolic ligament, the gastrosplenic ligament, and the gastrophrenic ligament.

During the sixth and seventh weeks of gestation, the typical morphology of the stomach is established. Accelerated growth of the left gastric wall, relative to the right, establishes the greater and lesser curvatures. This unequal growth also rotates the stomach and causes the left vagal nerve trunk to assume its anterior position, whereas the right vagal trunk is located posteriorly. The growth of structures cephalad to the stomach causes the organ to descend. During the sixth week, the primitive stomach lies between the T10 and T12 vertebral segments. By the eighth week, the stomach is located between the T11 and the L4 segments. In adult life, the stomach is most commonly located between the T10 and the L3 vertebral segments.

The stomach can be divided into anatomic regions based on external landmarks (**Fig. 44.1**). Although this division is commonly referred to in surgical texts and is useful in discussing gastric resective procedures, it does not necessarily reflect the secretory or motor functions of the mucosal and muscular layers of the stomach. The gastric cardia is the region of the stomach just distal to the gastroesophageal junction. The fundus is the portion of the stomach above and to the left of the gastroesophageal junction. The corpus constitutes the region between the fundus and the antrum. The margin between the corpus and antrum is not distinct externally but can be defined arbitrarily by a line from the incisura angularis on the lesser curvature to a point one-fourth the distance from the pylorus to the esophagus along the greater curvature. The gastric antrum is bounded distally by the pylorus, which can be appreciated by palpation as a thickened ring of smooth muscle.

The stomach is mobile in most people and is fixed at only two points, proximally by the gastroesophageal junction and distally by the retroperitoneal duodenum. Therefore, the position of the stomach varies and depends on the habitus of the person, the degree of gastric distention, and the position of the other abdominal organs. Anteriorly, the stomach is in contact with the left hemidiaphragm, the left lobe and the anterior segment of the right lobe of the liver, and the anterior parietal surface of the abdominal wall. The posterior surface of the stomach is related to the left diaphragm; the left kidney and left adrenal gland; the neck, tail, and body of the pancreas; the aorta and celiac trunk; and the periaortic nerve plexuses. The greater

curvature of the stomach is near the transverse colon and the transverse colonic mesentery. The concavity of the spleen contacts the left lateral portion of the stomach.

1 The stomach is an extremely well-vascularized organ, supplied by a number of major arteries and protected by a large number of extramural and intramural collaterals. Gastric viability can be preserved after ligation of all but one primary artery, an advantage that can be exploited during gastric reconstructive procedures. Also, the rich network of anastomosing vessels means that gastric hemorrhage cannot be controlled by the extramural ligation of gastric arteries. Most gastric blood flow is ordinarily derived from the celiac trunk (**Fig. 44.2**). The lesser curvature is supplied by the left gastric artery, which is the first major branch of the celiac trunk, and by the right gastric artery, which is derived from the hepatic artery. Branches of the left gastric artery also supply the lowermost portion of the esophagus. The greater curvature is supplied by the short gastric and left gastroepiploic arteries, which are branches of the splenic artery, and by the right gastroepiploic artery, a branch of the gastroduodenal artery. In instances of celiac trunk occlusion, gastric blood flow is usually maintained from the superior mesenteric artery collaterally by way of the pancreaticoduodenal arcade. In general, venous effluent from the stomach parallels the arterial supply. The venous equivalent of the left gastric artery is the coronary vein.

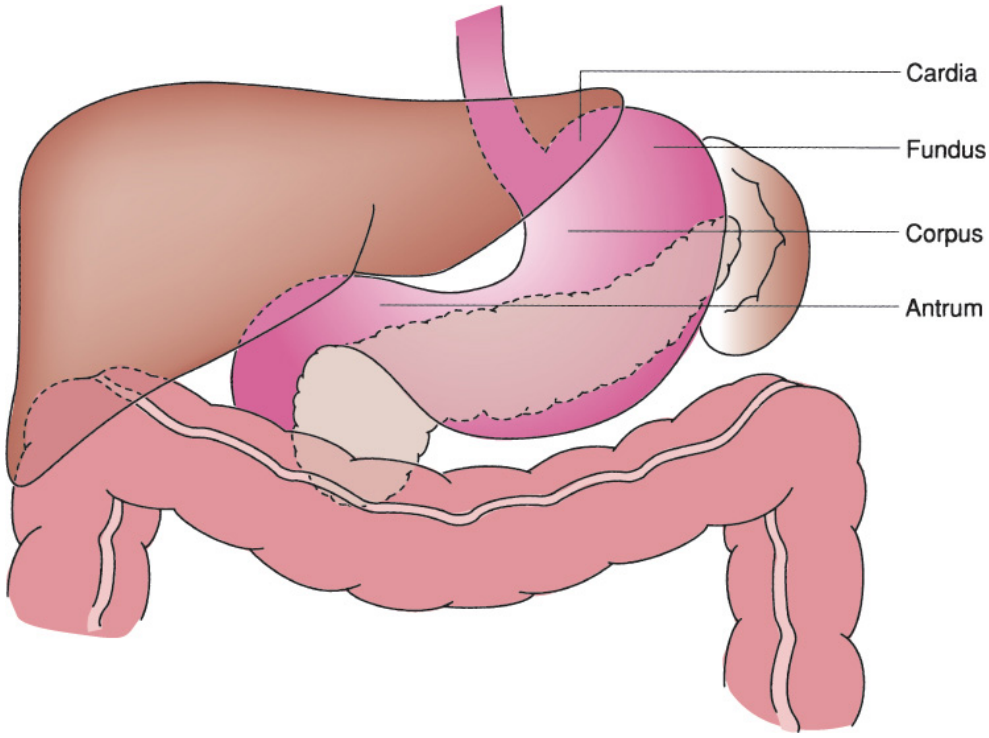

Figure 44.1 Topographic relations of the stomach.

As a first approximation, the lymphatic drainage of the stomach parallels gastric venous return (**Fig. 44.3**). Lymph from the proximal portion of the stomach along the lesser curvature first drains into superior gastric lymph nodes surrounding the left gastric artery. The distal portion of the lesser curvature drains through suprapyloric nodes. The proximal portion of the greater curvature is supplied by lymphatic vessels that traverse pancreaticosplenic nodes, whereas the antral portion of the greater curvature drains into the subpyloric and omental nodal groups. Secondary drainage from each of these systems eventually traverses nodes at the base of the celiac axis. These discrete anatomic groupings are misleading. The lymphatic drainage of the human stomach, like its blood supply, exhibits extensive intramural ramifications and a number of extramural communications. As a consequence, disease processes that involve the gastric lymphatics often spread intramurally beyond the region of origin and to nodal groups at a distance from the primary lymphatic zone.

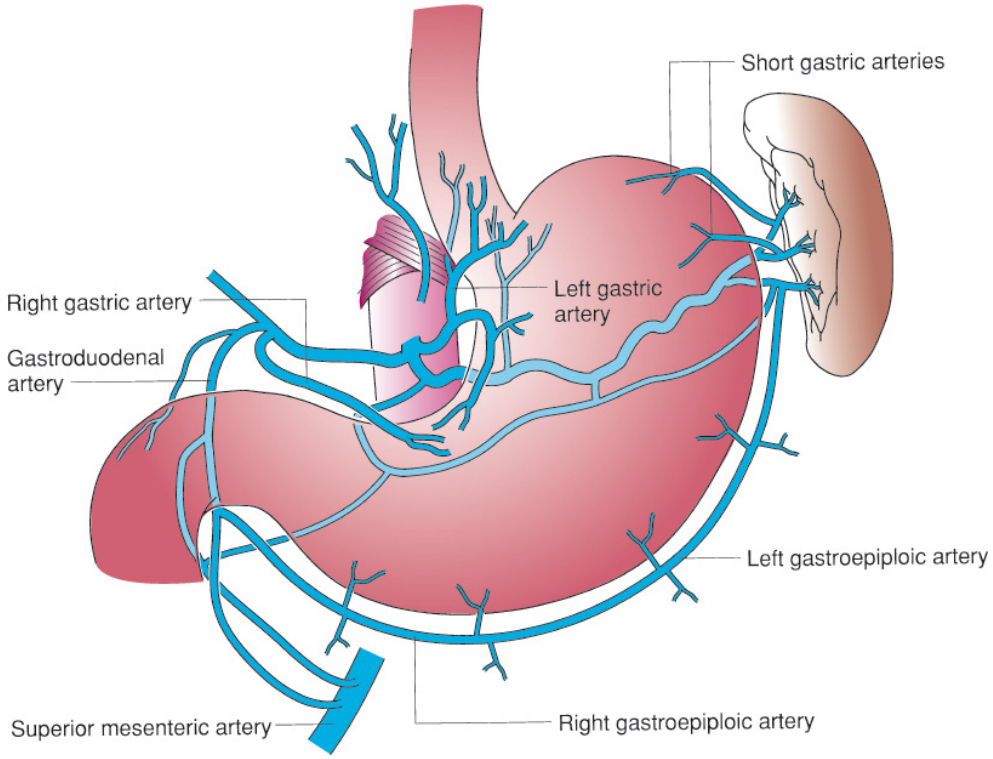

Figure 44.2 Arterial blood supply of the stomach.

The left and right vagal nerves descend parallel to the esophagus within the thorax before forming a periesophageal plexus between the tracheal bifurcation and the diaphragm. From this plexus, two vagal trunks coalesce before passing through the esophageal hiatus of the diaphragm (**Fig. 44.4**). The left vagal trunk is usually closely applied to the anterior surface of the esophagus, whereas the posterior vagal trunk is often midway between the esophagus and the aorta. The anterior vagus supplies a hepatic division, which passes to the right in the lesser omentum before innervating the liver and biliary tract. The remainder of the anterior vagal fibers parallels the lesser curvature of the stomach, branching to the anterior gastric wall. The posterior vagus nerve branches into the celiac division, which passes to the celiac plexus, and a posterior gastric division, which innervates the posterior gastric wall.

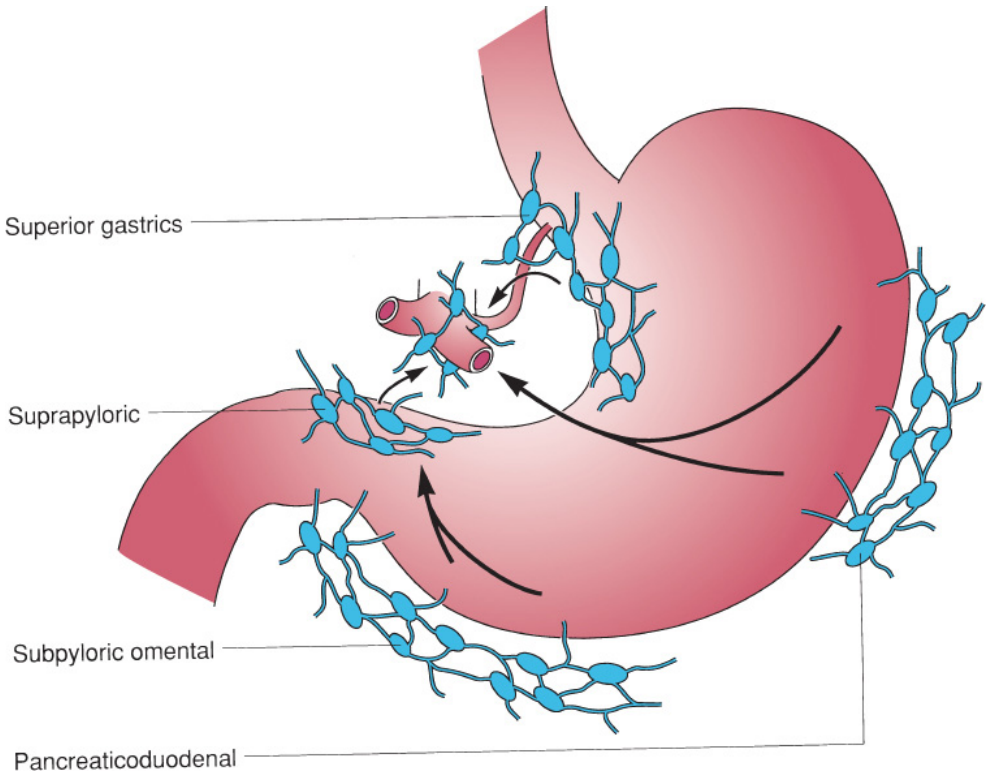

Figure 44.3 Lymphatic drainage of the stomach.

Approximately 90% of the fibers in the vagal trunks are afferent, transmitting information from the gastrointestinal tract to the central nervous system (CNS). Parasympathetic afferent fibers are not responsible for the sensation of gastric pain. Only 10% of vagal nerve fibers are motor or secretory efferents. Parasympathetic efferent fibers contained in the vagus originate in the dorsal nucleus of the medulla. Vagal efferent fibers pass without synapse to contact postsynaptic neurons in the gastric wall in the myenteric and submucous plexuses. Secondary neurons directly innervate gastric smooth muscle or epithelial cells. Acetylcholine is the neurotransmitter of primary vagal efferent neurons.

The gastric sympathetic innervation is derived from spinal segments T5 through T10. Sympathetic fibers leave the corresponding spinal nerve roots by way of gray rami communicantes and enter a series of bilateral prevertebral ganglia (**Fig. 44.5**). From these ganglia, presynaptic fibers pass through the greater splanchnic nerves to the celiac plexus, where they synapse with secondary sympathetic neurons. Postsynaptic sympathetic nerve fibers enter the stomach in association with blood vessels. Afferent

sympathetic fibers pass without synapse from the stomach to dorsal spinal roots. Pain of gastroduodenal origin is sensed through afferent fibers of sympathetic origin.

MICROSCOPIC ANATOMY

The glandular portions of the stomach are lined by a simple columnar epithelium composed of surface mucous cells. The luminal surface, visualized by scanning electron microscopy, appears cobblestoned, interrupted at intervals by gastric pits. Opening into the gastric pits are one or more gastric glands that impart functional significance to the gastric mucosa. The mucosa of the human stomach is composed of three distinct types of gastric glands—cardiac, oxyntic, and antral.

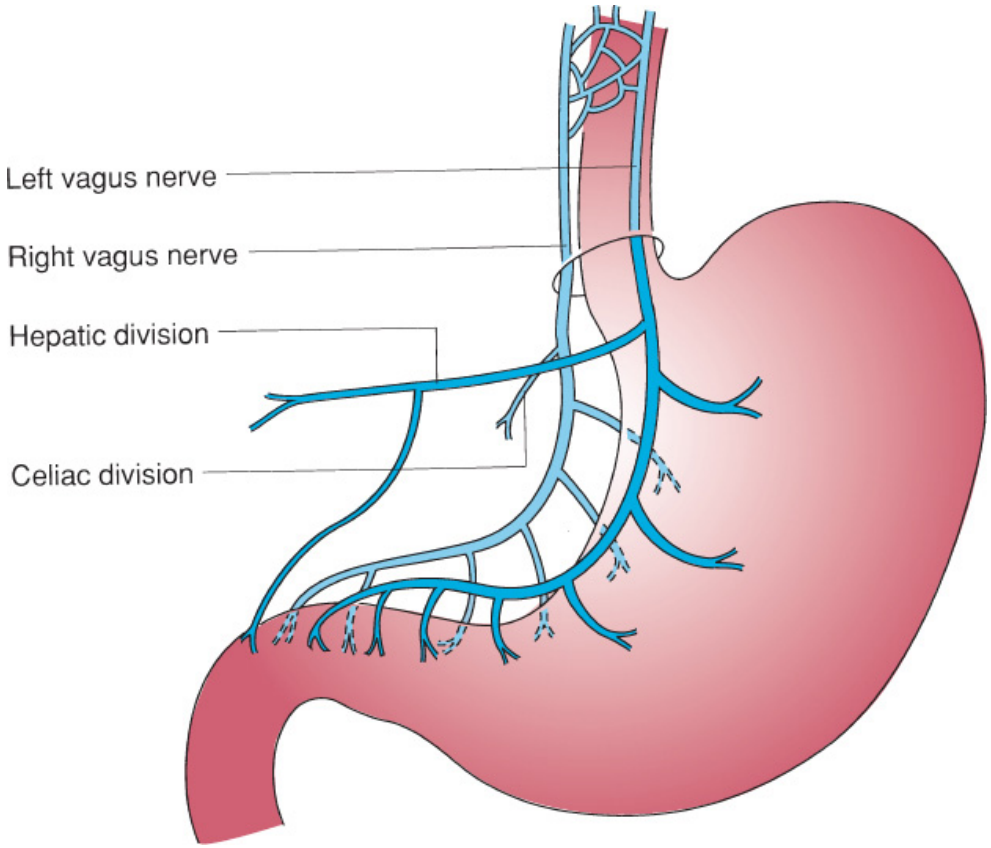

Figure 44.4 Vagal innervation of the stomach.

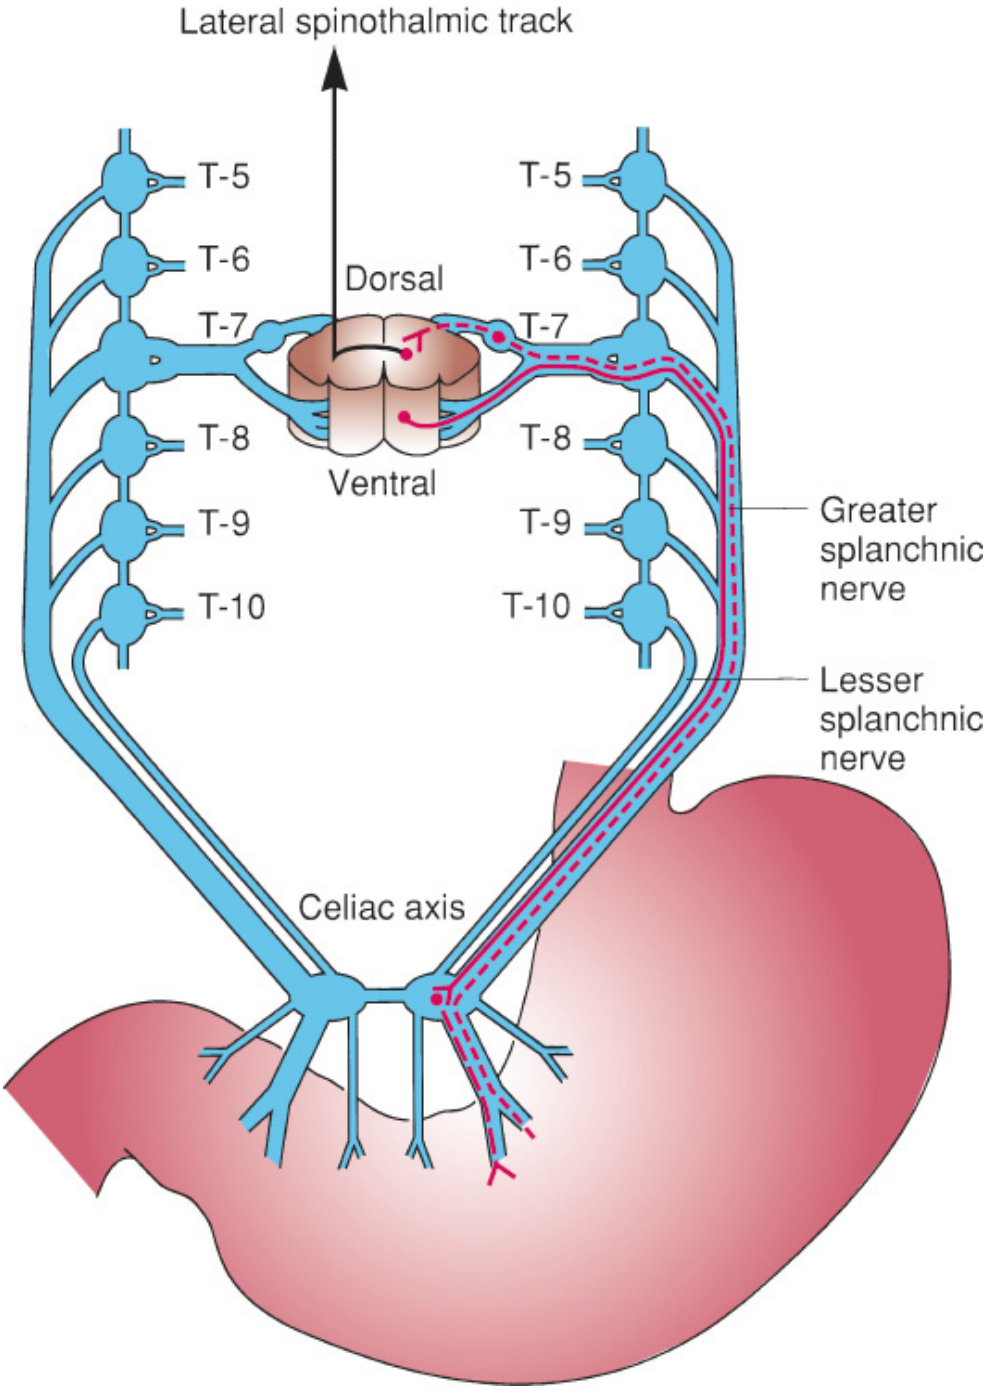

Figure 44.5 Derivation of gastric sympathetic innervation.

In humans, cardiac glands occupy a narrow zone adjacent to the esophagus and mark a transition from the stratified squamous epithelium of the esophagus to the simple columnar epithelium of the stomach. The surface and gastric pit mucous cells of the cardia are not distinguishable from those in other areas of the stomach. Cardiac glands contain mucous and

undifferentiated and endocrine cells but not the parietal or chief cells that are prominent in the adjacent oxyntic mucosa. Cardiac glands are usually branched and connect with relatively short gastric pits. The functional properties of cardiac glands include the secretion of mucus.

2 Oxyntic glands are the most distinctive feature of the human stomach. They occupy the fundus and body of the stomach and contain the oxyntic or parietal cells, which are the sites of acid production. Oxyntic glands also contain chief cells, the site of gastric pepsinogen synthesis. Endocrine cells are scattered throughout all three regions of oxyntic glands.

The most distinctive cell of the gastric mucosa is the acid-secreting parietal cell. Parietal cells have an unusual ultrastructural specialization in the form of intracellular canaliculi, a network of clefts extending to the basal cytoplasm and often encircling the nucleus, which is continuous with the gland lumen (**Fig. 44.6**). The surface area provided by the intracellular secretory canaliculi is large and is further magnified by microvilli lining the canaliculi. In parietal cells that are not stimulated to secrete acid, the secretory canaliculi are collapsed and inconspicuous. On stimulation, a severalfold increase in canalicular surface area occurs, the intracellular clefts become prominent, and the communication with the luminal surface is readily identified. These changes create an intracellular space in communication with the gastric lumen into which hydrogen ions are secreted at high concentration.

In addition to parietal cells, the oxyntic glands contain the gastric chief cells, which synthesize and secrete pepsinogen. Chief cells are most abundant in the basal region of the oxyntic glands. The cells have a morphology typical of protein-secreting exocrine cells and are similar in ultrastructural appearance to pancreatic acinar cells. Zymogen granules containing pepsinogen are most concentrated in the apical cytoplasm. Pepsinogen is released by exocytosis from secretory granules at the apical surface of chief cells.

Antral glands occupy the mucosa of the distal stomach and pyloric channel. Although most cells in the antral glands are mucus secreting, gastrin cells are the distinctive feature of this mucosa. Gastrin cells are pyramid shaped, with a narrow area of luminal contact apically and a broad surface overlying the lamina propria basally (**Fig. 44.7**). Gastrin cells are identified immunocytochemically by the presence of the peptide. Granules ranging from

150 to 400 nm in diameter are the sites of gastrin storage and are most numerous in the basal cytoplasm. Gastrin is released by exocytotic fusion of the secretory granule with the plasma membrane. In contrast to secretion from chief cells, emptying of gastrin-containing granules occurs at the basal membrane rather than at the apical region of the cell. Gastrin thus released diffuses to and enters submucosal capillaries in close apposition to the lamina propria.

GASTRIC PEPTIDES

The stomach contains a number of biologically active peptides in nerves and mucosal endocrine cells, including gastrin, somatostatin, ghrelin, gastrin-releasing peptide, vasoactive intestinal polypeptide (VIP), substance P, glucagon, and calcitonin gene–related peptide.

Gastrin

The synthesis, secretion, and action of gastrin have been extensively studied, and many aspects of the biology of gastrin appear to be shared by other gastrointestinal peptide hormones.[1] The human gastrin gene contains three exons; two exons consist of coding sequences. The major active product is

encoded by a single exon. In adults, the gastrin gene is expressed primarily in mucosa cells of the gastric antrum, with lower levels of expression in the duodenum, pituitary, and testis.

The human gene encompasses approximately 4,100 base pairs and directs the synthesis of a peptide of 101 amino acids (**Fig. 44.8**). The resulting peptide, preprogastrin, contains the sequence of gastrin within its amino acid sequence. Preprogastrin consists of a signal peptide of 21 amino acids, an intervening peptide of 37 amino acids, the 34-residue region of the gastrin molecule, and a carboxyl-terminal extension of 9 amino acids. Gastrin is derived from its preprohormone by the sequential enzymatic cleavage of the signal peptide, the intervening peptide, and the carboxyl-terminal extension.

The signal peptide region of preprogastrin consists of a series of hydrophobic amino acids that direct the nascent peptide into the endoplasmic reticulum as it is translated from messenger RNA. After directing the preprogastrin molecule into the rough endoplasmic reticulum, the signal peptide is removed. The remaining peptide is termed *progastrin.* Progastrin is further processed as it traverses the endoplasmic reticulum to mature secretory vesicles. Enzymatic cleavage at a pair of basic amino acid residues proximal to the gastrin 34 (G_{34}) sequence removes the intervening peptide. A similar cleavage removes a six-amino-acid fragment at the carboxyl-terminal end. The peptide that remains has a Gly-Arg-Arg sequence at the carboxyl terminus. Carboxypeptidase cleaves the Arg residues, and the peptide that results is termed *glycine-extended gastrin.* G_{34} is formed by cleavage of the Gly-Arg-Arg sequence and amidation of the carboxyl-terminal phenylalanine. Gastrin, like most gastrointestinal peptide hormones, requires terminal amidation for biologic activity. Gastrin 17 (G_{17}), the most abundant form of gastrin in the human antrum, is formed by further processing that removes the first 17 amino acids at the amino terminus of G_{34}. G_{34} is the predominate molecular form of gastrin in the duodenum.

3 The most important stimulant of gastrin release is a meal. Small peptide fragments and amino acids that result from intragastric proteolysis are the most important food components that stimulate gastrin release. The most potent gastrin-releasing activities are demonstrated by the amino acids tryptophan and phenylalanine. Ingested fat and glucose do not cause gastrin release. Gastric distention by a meal activates cholinergic neurons and

stimulates gastrin release. As the meal empties and distention diminishes, VIP-containing neurons are activated, which stimulate somatostatin secretion and thus attenuate gastrin secretion.

Postprandial luminal pH also strongly affects gastrin secretion. Gastrin release is inhibited when acidification of an ingested meal causes the intraluminal pH to fall below 3.0. Conversely, maintaining intragastric pH above 3.0 potentiates gastrin secretion after ingestion of protein or amino acids.[2] Pernicious anemia and atrophic gastritis, which produce chronic achlorhydria, are associated with fasting hypergastrinemia and an exaggerated gastrin meal response. Release of mucosal somatostatin occurs with gastric acidification and this peptide has been implicated in the inhibition of gastrin release that occurs when luminal pH falls.

The vagus nerve appears to both stimulate and inhibit gastrin release.[3] In humans, vagally-mediated stimulation of gastrin release can be demonstrated by sham feeding, insulin-induced hypoglycemia, and administration of the vagal stimulant γ-aminobutyric acid. In contrast to these stimulatory vagal effects, hypergastrinemia, observed after vagotomy, suggests that inhibitory vagal effects on gastrin release may also exist. Cholinergic neurons stimulate gastrin secretion directly by actions on gastrin cells.

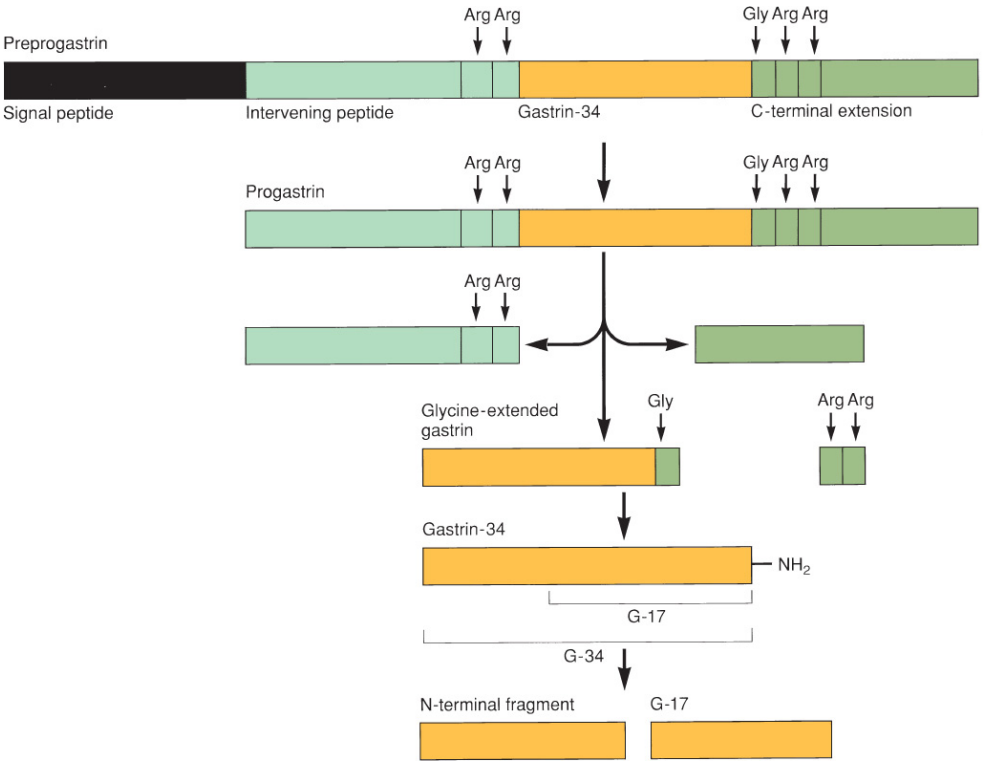

Figure 44.8 Sequential processing of preprogastrin molecule.

Chronic gastric infection with *Helicobacter pylori* causes increased acid secretion by altering gastrin release.[4,5] *H. pylori* has been observed to upregulate proinflammatory cytokines, including interleukin (IL)-6, IL-8, and tumor necrosis factor-α (TNF-α). Several inflammatory mediators have been demonstrated to stimulate gastrin release from isolated gastrin cells. The putative gastrin secretagogues include IL-1, IL-8, TNF-α, interferon-γ, and leukotrienes C4 and D4. The same factors that affect gastrin release also influence gastrin mRNA expression. Food ingestion increases gastrin mRNA abundance, whereas fasting and somatostatin decrease gastrin mRNA production. Chronic achlorhydria, as seen in pernicious anemia, increases gastrin mRNA production.

In addition to stimulating acid secretion from gastric parietal cells (detailed later in this chapter), gastrin has important physiologic actions in the control of gastrointestinal mucosal growth. The acid-secreting oxyntic mucosa is particularly sensitive to the trophic actions of gastrin, but the mucous membranes of the duodenum, colon, and pancreatic parenchyma are also affected. Stimulation of mucosal growth by gastrin is enhanced by the presence of solid food in the diet. The 17- and 34-amino-acid forms of

gastrin are equipotent in stimulating mucosal growth. Prolonged stimulation by high levels of gastrin, as seen in the Zollinger–Ellison syndrome, is associated with hypertrophy of the gastric mucosa. Smaller increases in circulating gastrin, such as those that follow vagotomy, do not cause mucosal hypertrophy.

Somatostatin

Somatostatin, like gastrin, is very significant in gastric physiology. Somatostatin was first isolated from hypothalamic tissues and was named for its ability to inhibit the release of growth hormone. The peptide was subsequently localized in neurons in central and peripheral nervous systems, and in endocrine cells in the pancreas, stomach, and intestine.[6] The wide tissue distribution of somatostatin suggested important regulatory functions, a concept validated by many investigations.

The human somatostatin gene is located on chromosome 3 and encodes for a precursor of 116 amino acids (**Fig. 44.9**). Gastric somatostatin release responds to luminal, hormonal, and neural signals. Luminal acidification is associated with increased somatostatin release, whereas somatostatin release decreases when luminal pH is increased. A number of peptides have been demonstrated experimentally to release somatostatin from the stomach, including gastrin, cholecystokinin, and secretin. β-Adrenergic agonists have also been shown to release somatostatin. In contrast, electrical stimulation of vagal nerves inhibits somatostatin release, as does the cholinergic agonist methacholine.

The most important gastric function of somatostatin appears to be regulation of acid secretion and gastrin release. Circulating somatostatin appears to be important in modulating gastric acid secretion; locally released somatostatin functions to regulate gastrin release. In each instance, somatostatin serves an inhibitory function, decreasing acid secretion and diminishing the release of gastrin. In animals, antral or duodenal acidification has been associated with an increase in circulating somatostatin. Increases in circulating somatostatin are followed, in turn, by decreased gastric acid secretion. Infusion of exogenous somatostatin in doses that produce somatostatin levels similar to those observed postprandially has also been shown to inhibit acid secretion. In humans, concentrations of

somatostatin capable of inhibiting acid secretion can do so without altering serum gastrin levels, indicating a direct action on the acid-secreting fundic mucosa.

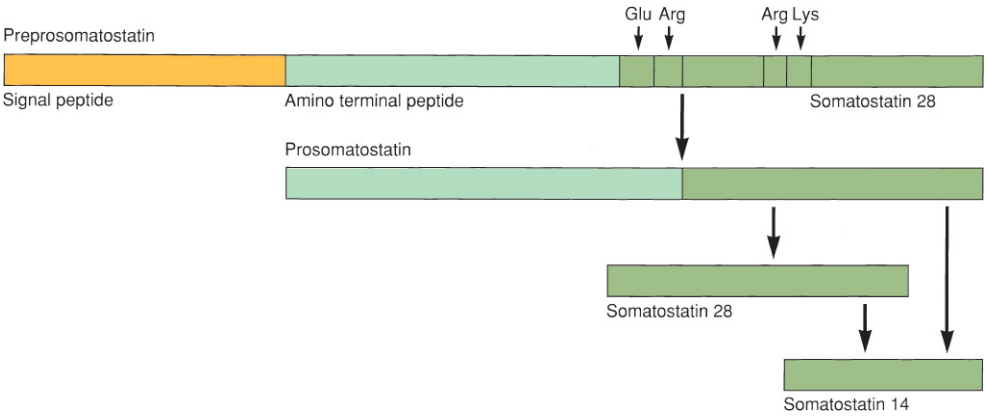

Figure 44.9 Derivation of somatostatin 14 from preprosomatostatin precursor.

Somatostatin is believed to influence gastrin secretion through a locally active intramucosal mechanism. Local actions of somatostatin are supported by ultrastructural studies of antral somatostatin cells, which demonstrate long cytoplasmic processes that make intimate cell-to-cell contact with antral gastrin cells. The presence of somatostatin at these sites of cellular contact implies that somatostatin cells influence the function of gastrin cells through local release of the peptide. Increases in somatostatin release are often associated with decreased gastrin secretion. A family of five somatostatin receptors has been cloned. Inhibition of gastrin-stimulated gastric acid secretion is mediated by somatostatin receptor subtype 2.[7]

GASTRIC ACID SECRETION

Cellular Events

An appreciation of the mechanisms that control gastric acid formation is essential to a discussion of gastric disease. An understanding of the cellular basis of acid secretion by the gastric parietal cell also provides a foundation for discussing the pharmacologic 4 suppression of acid secretion. The basolateral membrane of the parietal cell contains specific receptors for histamine, gastrin, and acetylcholine, the three major stimulants of acid

production.[8] Each stimulant reaches the parietal cell by a different route. Histamine is released from mastlike cells within the lamina propria and diffuses to the mucosa, acetylcholine is released in close proximity to the parietal cells from cholinergic nerve terminals, and gastrin is delivered by the systemic circulation to the fundic mucosa from its source in the antrum and proximal duodenum (**Fig. 44.10**), activating protein kinase A, which in turn catalyzes protein phosphorylation. The target protein molecules for this phosphorylation, in turn, stimulate acid production.

Acetylcholine and related cholinergic agonists activate parietal cells after binding to muscarinic receptors. The stimulatory effects of acetylcholine and its congeners can be abolished by atropine. The action of acetylcholine is mediated by muscarinic receptor subtype 3 (M_3).

Although histamine, acetylcholine, and gastrin occupy separate receptors on the parietal cell, each secretagogue ultimately acts by means of a specialized ion transport system called the *parietal cell proton pump.* This membrane-bound protein is located in the secretory canaliculus of the parietal cell; the peptide has not been identified in other gastric cells or in significant amounts in other organs. The proton pump is an H^+-K^+-adenosine triphosphatase (ATPase) that electroneutrally exchanges cytosolic H^+ for luminal K^+. Hydrogen ions are concentrated 2.5-million-fold within the secretory canaliculus, and the hydrolysis of ATP is the energy source for transport against the steep electrochemical gradient generated. For each H^+ ion transported to the luminal surface of the canalicular membrane, one K^+ ion is transported to the cytosolic surface (**Fig. 44.11**). This cotransport requires that K^+ be continuously supplied to the luminal surface of the secretory membrane.

Activation of the H^+-K^+-ATPase significantly increases intracellular OH^- generation, with potential cellular toxicity. Carbonic anhydrase, which is associated with the canalicular membrane, converts OH^- to HCO_3^-. The HCO_3^- produced is disposed of by exchange for Cl^- at the basolateral membrane. Intracellular Cl^- thus acquired supplies the necessary Cl^- on a one-to-one basis for each H^+ secreted. The transcellular exchange of H^+ for HCO_3^- ensures that the voluminous secretion of hydrochloride at the luminal surface of the gastric mucosa is matched by an equivalent delivery of base to

submucosal capillaries. Parietal cell ionic transport pathways are shown in **Figure 44.12**.

The function of the proton pump is highly regulated. In the unstimulated state, the enzyme is sequestered in cytoplasmic structures termed *tubulovesicles* that are not connected to the gastric lumen. Tubulovesicle membranes in this state have a low permeability to KCl. Stimulation of acid secretion causes tubulovesicles to fuse with apical secretory membranes and increases membrane permeability to KCl. In this way, the fusion of tubulovesicle membrane exposes the H^+-K^+ pump to the gastric lumen and simultaneously provides the K^+ substrate necessary for acid secretion.

Parietal cells also contain membrane receptors that inhibit acid secretion. Specific receptors for somatostatin have been identified using isolated gastric cells. Activation of isolated parietal cells by histamine, pentagastrin, or the cholinergic agonist carbachol can be blocked by somatostatin 28. Gastric parietal cells also contain receptors for prostaglandins, notably prostaglandin E_2 and its derivatives. Prostaglandin E_2 is a potent inhibitor of histamine-stimulated parietal cell activation, probably by a mechanism that inhibits formation of cAMP.

These considerations of the cellular basis of acid production demonstrate how parietal cell function can be altered pharmacologically. Gastric acid production can be blocked by receptor antagonists for each of the three primary stimulants—gastrin, acetylcholine, and histamine. Direct inhibition of acid production can be effected by derivatives of somatostatin or prostaglandin E_2. All forms of stimulated acid production can be blocked by agents that act as inhibitors of the parietal cell proton pump. Agents that act at each of these points have been developed, and their appropriate clinical applications are discussed in subsequent chapters.

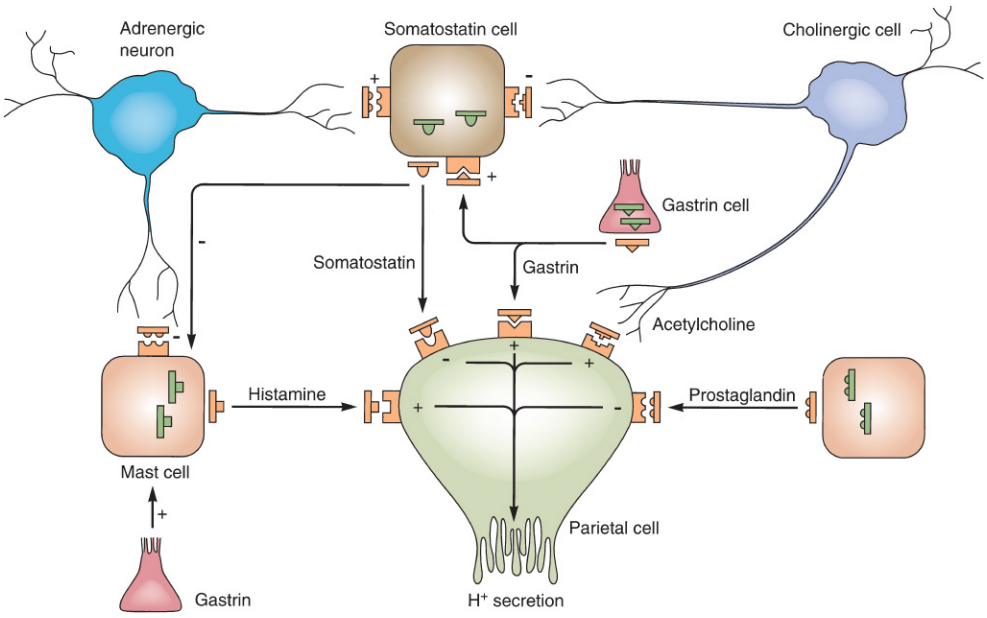

Figure 44.10 Interactions of cell types that affect parietal cell acid secretion.

Regulation of Acid Secretion

Given the multiple receptors on parietal cells, it is not surprising that a great deal of secretagogue interdependence, both stimulatory and inhibitory, exists in humans. Parietal cell activation, and the resultant acid secretion, is greater in response to a combination of agonists than it is in response to the total effect of agents used singly. This increase in responsiveness is defined as *potentiation*. Thus, histamine strongly potentiates the acid-secretory response to pentagastrin or to carbachol in humans. Conversely, blockade of receptors to one stimulant also decreases responsiveness to the other agonists. For example, blocking histamine receptors with agents such as cimetidine decreases responsiveness to pentagastrin, even though gastrin receptors are not directly affected. These inhibitory interactions are exploited therapeutically in the treatment of acid–peptic diseases.

Humans normally secrete 2 to 5 mEq/hr of hydrochloride in the fasting state, constituting basal acid secretion. Both vagal tone and ambient histamine secretion are presumed to be important in determining the rate of basal acid secretion. In humans, truncal vagotomy decreases basal secretion by approximately 85%. Similarly, H_2-receptor antagonists also inhibit basal

acid secretion by approximately 80%. Gastrin does not have an important role in determining basal acid secretion in normal people.

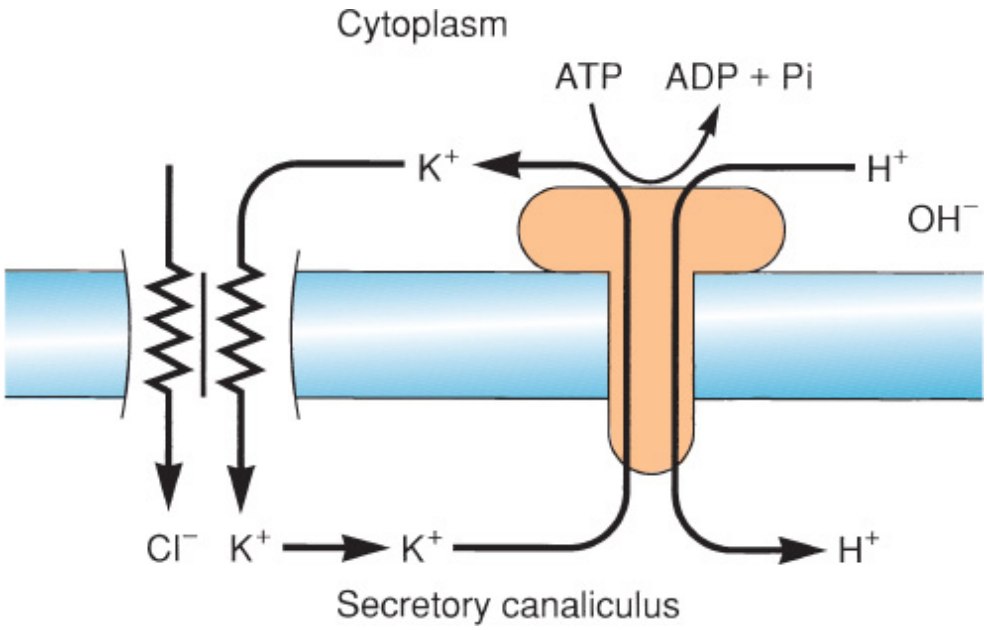

Figure 44.11 Gastric H^+-K^+-adenosine triphosphatase (ATPase). ADP, adenosine diphosphate; ATP, adenosine triphosphate; Pi, phosphate ion.

Stimulated acid secretion begins with the thought, sight, or smell of food. This cephalic phase of gastric acid secretion is mediated by the vagus nerve. Vagal discharge directs a cholinergic mechanism, and the cephalic phase of acid secretion can be inhibited by administering atropine. The cephalic component of acid secretion can be measured in normal people and is approximately 10 mEq/hr. The cephalic phase approximates 40% of the maximal acid-secretory response to gastrin infusion.

The gastric phase of acid secretion begins when food enters the stomach. The presence of partially hydrolyzed food constituents, gastric distention, and the buffering capacity of food all stimulate acid secretion. In normal humans, acid-secretory rates after a mixed meal average 15 to 25 mEq/hr, approximately 75% of the maximal response achieved with infusion of exogenous gastrin or histamine. The meal response is less than the maximal response to exogenous stimulants because food also causes the release of somatostatin and initiates other inhibitory responses. In humans, 90% of meal-stimulated acid secretion is mediated by gastrin release.[9]

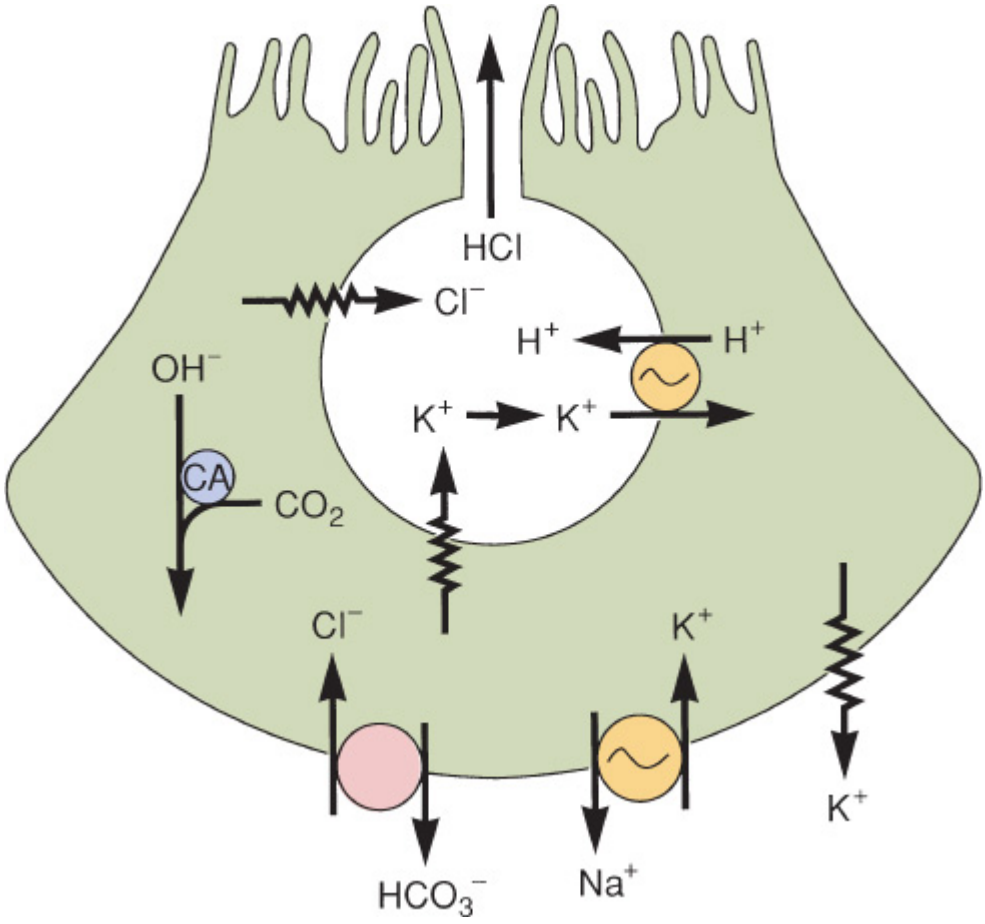

Figure 44.12 Ionic fluxes associated with acid secretion by the parietal cell.

In humans, the most important and clearly established gastric inhibitory influence is the suppression of gastrin release when the antral mucosa is exposed to acid. When luminal pH falls to 2.0, gastrin release stops. Antral acidification also suppresses the gastrin response to an ingested meal. Somatostatin acting locally in the gastric mucosa as a paracrine agent may mediate this important inhibitory response. Release of gastric somatostatin is reciprocally linked to that of gastrin; acidification of the antrum causes increases in somatostatin release and decreases in gastrin secretion. Antral distention also inhibits stimulated acid secretion.

The entry of digestive products into the intestine begins intestinal-phase inhibition of gastric acid secretion. Acidification of the duodenal bulb inhibits acid secretion.

PEPSIN

5 Pepsins are a heterogeneous group of proteolytic enzymes that are secreted by the gastric chief cells. Pepsin is derived under acidic conditions from pepsinogen by the autocatalytic loss of a variable amino-terminal sequence of the parent compound. This conversion occurs slowly at pH values of 5.0 to 6.0 and occurs rapidly when luminal pH approximates 2.0. Pepsin catalyzes the hydrolysis of a wide variety of peptide bonds that contain acidic residues, with a pH optimum for hydrolysis between 1.5 and 2.5. Once activated, pepsin is sensitive to ambient pH values; it is irreversibly denatured at pH 7.0 or greater.

The most important stimulus for pepsinogen secretion is cholinergic stimulation. Acetylcholine and its derivatives stimulate pepsinogen secretion by a mechanism that can be antagonized by atropine, indicating a muscarinic receptor. Endogenous cholinergic stimulation through the vagal nerve results in the formation of a gastric secretion that is rich in pepsin. The oxyntic mucosa contains somatostatin cells near chief cells. Pepsinogen secretion in response to a variety of stimuli has been demonstrated to be inhibited by somatostatin.

The major physiologic function of pepsin is to initiate protein digestion. Pepsin is highly active against collagen and may be important in the digestion of animal protein. Intragastric protein hydrolysis by pepsin is incomplete, and relatively large peptides enter the intestine, although amino acids and small peptide fragments are released. These products of partial hydrolysis are important signals for gastrin and cholecystokinin release, which in turn regulate digestive processes. In this way, pepsin also contributes to the overall coordination of the digestive process.

INTRINSIC FACTOR

The gastric mucosa is the site 6 of production of intrinsic factor, which is necessary for the absorption of cobalamin from the ileal mucosa. Total gastrectomy is regularly followed by cobalamin malabsorption, as is resection of the proximal stomach or atrophic gastritis that involves the oxyntic mucosa.

The parietal cell is the site of intrinsic factor synthesis and storage in humans. Intrinsic factor secretion, like acid secretion, is stimulated by histamine, acetylcholine, and gastrin. Unlike acid production, intrinsic factor secretion peaks rapidly after stimulation and then returns to baseline. The amount of intrinsic factor secreted usually greatly exceeds the amount needed to bind and absorb available dietary cobalamin.

GASTRIC BLOOD FLOW

Because the gastric mucosa is metabolically highly active, control of mucosal blood flow is of great physiologic importance. In addition, studies have implicated perfusion abnormalities in the development of mucosal lesions during periods of stress. Mucosal blood flow is regulated by neural, hormonal, and locally active influences.

Postganglionic sympathetic nerve fibers reach the stomach in association with its blood supply and richly innervate small mucosal arteries. Mucosal capillaries do not receive adrenergic innervation. Electrical stimulation of sympathetic nerves supplying the stomach is followed by decreased total gastric blood flow, decreased flow in celiac and gastroepiploic vessels, and diminished blood flow to the mucosa. Studies in animals demonstrate that vasoconstriction of the gastric vascular bed is mediated by α-adrenergic receptors and that vasodilation is mediated by β-adrenergic receptors.

Stimulation of the vagus nerve is followed by a prompt increase in blood flow, suggesting a dilatory effect of parasympathetic nerves. The effects of vagal stimulation on mucosal blood flow are complicated by accompanying increases in acid secretion. Almost all stimuli that increase acid production also increase blood flow secondarily.

A number of gastrointestinal peptide hormones affect gastric blood flow, most because of their ability to increase or decrease acid secretion. Thus, gastrin, because it is a potent stimulant of acid secretion, also increases mucosal blood flow. Cholecystokinin appears to have direct vasodilatory effects on the gastric vasculature. Vasopressin has been well demonstrated to have direct vasoconstrictor activity.

Nitric oxide modulates basal gastric vascular tone and controls gastric vasodilation and hyperemia. Nitric oxide mediates the hyperemic response

that accompanies increases in acid secretion, although the molecule has no direct stimulatory role in acid production.

Prostaglandins are important mucosally produced compounds that have clear effects on the gastric vasculature. Prostaglandins of the E class have been shown in animals and humans to increase gastric blood flow at doses that decrease acid secretion. Indomethacin, in doses sufficient to inhibit prostaglandin formation, decreases the diameter of submucosal blood vessels and reduces basal blood flow. Complete inhibition of cyclooxygenase activity causes an approximate 50% reduction in resting blood flow. These studies suggest that endogenous, locally produced prostaglandins are crucial to maintaining basal gastric blood flow in humans and probably act in concert with endogenous nitric oxide.

GASTRIC MOTILITY

Gastric Smooth Muscle

Consideration of gastric motility requires that the stomach be viewed in functional terms as two different regions, the proximal one-third and the distal two-thirds. These areas are distinct in terms of smooth muscle anatomy, electrical activity, and contractile function. The regions do not correspond to the traditional anatomic divisions of fundus, corpus, and antrum.

In the proximal stomach, three layers of gastric smooth muscle can be distinguished: an outer longitudinal layer, a middle circular layer, and an inner oblique layer. In the distal two-thirds of the stomach, the longitudinal layer is most clearly defined, and the inner oblique layer is usually not distinct. The gastric smooth muscle ends at the pylorus.

The smooth muscle of the proximal stomach is electrically stable, whereas the smooth muscle of the distal stomach demonstrates spontaneous, repeated electrical discharges. Gastric smooth muscle exhibits myoelectric activity that is based on a highly regular pattern called the *slow wave*.[10] In the stomach, slow waves occur with a frequency of three cycles per minute. Slow waves do not, by themselves, lead to gastric contractions, but they do set the maximum rate of contractions at three per minute. Gastric contractions

occur when action potentials are phase locked with the crest of the slow wave.

Extracellular electrical recording from the serosal surface of the stomach also demonstrates the intrinsic electrical activity of the distal stomach in the form of pacesetter potentials. Pacesetter potentials reflect partial depolarization of the gastric smooth muscle cell and are recorded during relatively long periods (2 or 3 seconds). Pacesetters originate along the greater curvature at a point in the proximal third of the stomach. Pacesetter potentials, discharging at a rate of three times per minute in humans, drive cells located distally. Spread of the pacesetter potentials is faster along the greater curvature, so that a ring of electrical activity reaches the pylorus simultaneously along both curvatures. The pacesetter potentials do not result in smooth muscle contraction unless an additional depolarization is superimposed in the form of an action potential. When action potentials occur, a ring of smooth muscle contraction moves peristaltically along the distal stomach toward the pylorus.

Duodenal slow-wave frequency and maximum rate of phasic contractions are higher than those observed in the stomach. The duodenal rate is approximately 12 cycles per minute; the contraction rate declines progressively to 9 cycles per minute in the distal ileum.

The smooth muscle activity of the proximal stomach is fundamentally different from that of the distal stomach. There are no pacesetters or action potentials in the proximal stomach. As a result, peristalsis does not occur. Proximal gastric contraction is tonic and prolonged, and increases in luminal pressure are often sustained for several minutes.

Coordination of Contraction

Important vagally mediated reflexes influence intragastric pressure, presumably by affecting contractile activity of smooth muscle in the proximal stomach. The most important reflex is termed *receptive relaxation* and occurs with ingestion of a meal. Increasing gastric volumes are accommodated with little increase in intragastric pressure by relaxation of the proximal stomach. This receptive relaxation allows the proximal stomach to act as a storage site for ingested food in the immediate postprandial period. Afferent impulses, presumed to originate from stretch receptors in the

gastric wall, are carried along vagal fibers; efferent vagal discharges are inhibitory. Receptive gastric accommodation is lost after either truncal or proximal gastric vagotomy. After the meal has been ingested, proximal contractile activity increases; alterations in proximal gastric tone cause the compressive movement of gastric content from the fundus to the antrum.

Food that enters the antrum from the proximal stomach is propelled peristaltically toward the pylorus. A number of observations indicate that the pylorus closes 2 or 3 seconds before the arrival of the antral contraction ring. This coordinate closing of the pylorus allows a small bolus of liquid and suspended food particles to pass while retropulsing the main mass of gastric contents back into the proximal antrum. The churning action that results mixes ingested food particles, gastric acid, and pepsin, and contributes to the grinding function of the stomach. Solid food particles do not ordinarily pass the pylorus unless they are no larger than 1 mm.

A consistent finding in humans ingesting a mixed solid–liquid meal is that liquids empty more quickly than solids. Characteristically, solid food empties only after a lag period, whereas liquid emptying begins almost immediately. A traditional interpretation of these human observations has been that the proximal stomach is the dominant force in determining how quickly a liquid meal empties by the gastroduodenal pressure gradient generated by proximal gastric contractions. The distal gastric segment has been postulated to control solid emptying through its grinding and peristaltic actions. This traditional concept of the two-component stomach is useful in considering observations in patients who have undergone gastric operative procedures. Patients who have undergone proximal gastric vagotomy exhibit accelerated emptying of liquids but have normal solid emptying. Because of loss of receptive relaxation, the denervation of the proximal stomach is presumed to increase intragastric pressure and accelerate liquid emptying while leaving the distal gastric segment unaffected. Conversely, vagal denervation of the antrum interrupts gastric emptying of solids to a greater degree than liquids. Although this model of gastric emptying oversimplifies the many mechanisms (gastric, pyloric, and intestinal) that work in concert to control gastric emptying, it provides a useful framework for considering the effects of gastric surgical procedures.

Gastroduodenal Ulceration

Michael W. Mulholland

Key Points

1. Mucosal infection with *Helicobacter pylori* is the factor that contributes to ulcer pathogenesis in most patients.
2. *H. pylori* virulence factors include vacuolating cytotoxin A (VacA) and cytotoxin-associated gene A (CagA).
3. As a group, patients with duodenal ulcers have an increased capacity for gastric acid secretion relative to normal people.
4. Current treatment of peptic ulceration involves a combination of an antisecretory drug, usually a proton pump inhibitor, with antibiotics.
5. Hemorrhage is the leading cause of death associated with peptic ulcer. Patients with recurrent hemorrhage and elderly patients are at greatest risk of death.
6. For perforation, current therapy includes omental patch closure with postoperative anti–*H. pylori* therapy. Minimally invasive approaches are becoming standard practice.
7. Major trauma accompanied by shock, sepsis, respiratory failure, hemorrhage, or multiorgan injury is often accompanied by acute stress gastritis.

EPIDEMIOLOGY

Peptic ulceration remains a major public health problem worldwide. Worldwide prevalence of peptic ulcer disease ranges from 0.1% to 4.7% with an overall incidence of 0.2% to 0.3%.[1] With improving public hygiene and effective treatment of *Helicobacter pylori,* most epidemiologic studies are now reporting falling incidence rates. The surgical treatment of peptic ulcer has changed fundamentally. New insights into disease pathogenesis, especially the realization that gastric infection has a role in most cases of peptic ulceration, have been especially exciting. Antibiotics are now front-line antiulcer therapy. A number of powerful antisecretory drugs have been introduced into clinical practice. Medical, endoscopic, and surgical therapies are frequently integrated in the care of individual patients.

PATHOPHYSIOLOGY

The pathogenesis of peptic ulceration is complex and multifactorial but increasingly understood. Approximately 75% of peptic ulcer cases are caused by *H. pylori,* with almost all other cases due to use of nonsteroidal anti-inflammatory drugs (NSAIDs).[2] Both NSAID use and *H. pylori* infection are independent risk factors for development of peptic ulcer disease. The development of peptic ulceration is often depicted as a balance between chronic inflammatory injury, acid–peptic secretion, and mucosal defense, with the equilibrium shifted toward disease. Although acid–peptic secretion is crucial in the development of ulcers, usually a defect in mucosal defense induced by bacterial infection also exists to tip the balance 1 away from health. Mucosal infection with *H. pylori* is the factor that contributes to ulcer pathogenesis in most patients.

Helicobacter pylori

The relation between *H. pylori* infection and ulceration is overwhelmingly strong. Many lines of evidence establish *H. pylori* as a factor in the pathogenesis of duodenal ulceration:

- *H. pylori* is the primary cause of chronic active gastritis, characterized by nonerosive inflammation of the gastric mucosa. Antral gastritis is nearly always present histologically in patients with duodenal ulcer, and *H. pylori* can be isolated from gastric mucosa in almost all cases.
- Gastric metaplasia is extremely common in duodenal epithelium surrounding areas of ulceration. *H. pylori* binds only to gastric-type epithelium, regardless of location; metaplastic gastric epithelium can become colonized by *H. pylori* from gastric sources. Gastric metaplasia of the duodenal bulb is a nonspecific response to damage and is the means by which antral gastritis with *H. pylori* is converted to active chronic duodenitis.
- Eradication of *H. pylori* with antimicrobials that have no effect on acid secretion leads to ulcer healing rates superior to those seen with acid-suppressing agents.
- Relapse of duodenal ulcer after antimicrobial therapy is preceded by reinfection of the gastric mucosa by *H. pylori*.

In addition, half of patients evaluated for dyspepsia, but without ulceration, have histologic evidence of mucosal bacterial infection. Furthermore, 20% of healthy volunteers harbor the bacteria; the incidence of bacterial carriage in the healthy, asymptomatic population increases with age. The occurrence of peptic ulcers in only a small proportion of people who carry the organism suggests that other factors must also act to induce ulceration. The ability of *H. pylori* infection to induce alterations in gastric acid secretion is a prerequisite for ulcer development in most patients.

H. pylori is the most common bacterial infection worldwide. *H. pylori* infection is usually acquired in childhood and lasts lifelong in the absence of specific therapy. Epidemiologic studies suggest that *H. pylori* infection occurs via person-to-person contact, usually among family members. Transmission is believed to occur during a bout of gastroenteritis; the highest risk is associated with vomiting.

H. pylori is the only human bacterium to persistently infect the stomach. The organism is actually somewhat fragile, being killed by exposure to high levels of oxygen and to the low pH found in the acidic lumen of the stomach. To avoid the bactericidal activity of the stomach, the organism has evolved mechanisms to move within the gastric environment, to adhere to gastric

mucosa, and to protect itself from the harmful effects of acid. Over 300 genes of *H. pylori* are regulated by acid.

H. pylori bacteria are spiral shaped with polar flagella. Most bacilli are free swimming within the mucous layer covering the gastric epithelium. The organisms orient according to a pH gradient, moving away from the lower pH of the lumen toward the epithelium. The majority of organisms remain motile within the mucous layer, but contact promotes adherence to epithelial cells, particularly in the region of intercellular junctions. The products of more than 30 genes are expressed on the outer membrane of the bacterium and function as adhesins to promote attachment to the gastric cells' surface. Adhesion triggers the expression of other bacterial genes, including bacterial virulence factors.

All strains of *H. pylori* cause persistent infection and all strains induce gastric inflammation. Yet, only 15% of infected individuals develop peptic ulceration and only 1% develops gastric adenocarcinoma. Differential expression of bacterial virulence factors is presumed to account for these observations.[2] Two virulence factors are best characterized: vacuolating cytotoxin A (VacA) and cytotoxin-associated gene A (CagA) (**Table 45.1**).[3]

VacA is a pore-forming cytotoxin. Upon secretion from the bacterium, the protein moves to the host cell membrane, where it forms a ring structure in the shape of a flower.[4] This ring complex inserts into the membrane of the host cell, creating a pore. VacA pores are permeable to anions and small neutral molecules, including urea. Pore formation may be a mechanism by which the organism obtains nutrients from gastric epithelial cells.

The second major virulence factor in *H. pylori* is termed *CagA.*[5,6] The CagA gene is part of a region of DNA that is inserted into the genome of more virulent strains of *H. pylori,* termed a *pathogenicity island.*[5] The genes in this island that are adjacent to the CagA gene encode proteins, which function as microscopic needles for the transfer of bacterial products into host gastric cells. CagA is transferred to host cells through this injection mechanism.

Table 45.1 *Helicobacter pylori* Virulence Factors
Vacuolating Cytotoxin A (VacA)
Forms ring structure in the shape of a flower
Inserts into gastric cell membrane, forming pore
Inserts into endosomal membranes, causing cellular swelling
Damages mitochondrial membranes
Causes leakage of ions and small molecules
Cytotoxin-Associated Gene A (CagA)
Contained within pathogenicity island DNA sequence
Injected into host cells
Phosphorylated by cellular oncogenes
Activates growth factor receptor–like signaling
Disturbs normal proliferation, adhesion, cytoskeletal function
Disturbs intercellular junctions, causing disruption of epithelial permeability
Elicits inflammatory response

After CagA protein is transferred to host cells, it becomes phosphorylated on tyrosine residues by host cell kinases. Phosphorylated CagA activates a number of cellular-signaling pathways involved in cellular polarity, cytoskeletal protein function, and cellular proliferation and differentiation. As a consequence, infected gastric cells change shape and become more elongated. Apical junctions between cells become disrupted, gaps develop between epithelial cells, and epithelial barrier function is lost. CagA protein also stimulates transcription factors involved in regulation of cellular proliferation. Disturbance of cellular function in favor of apoptosis affects epithelia restitution and may inhibit ulcer healing.

Acid-Secretory Status

The formation of duodenal ulcers depends on gastric secretion 3 of acid and pepsin. As a group, patients with duodenal ulcers have an increased capacity for gastric acid secretion relative to normal people (**Table 45.2**). The maximal acid output of normal men is approximately 20 mEq/hr in response

to intravenous histamine stimulation, whereas patients with duodenal ulcer secrete an average of approximately 40 mEq/hr. Considerable overlap exists between these two groups, and the values for most people with duodenal ulcer fall within the normal range.

Groups of patients with duodenal ulcer demonstrate a prolonged and larger acid-secretory response to a mixed meal than do groups of normal subjects. As with histamine-stimulated acid output, overlap exists between patients with duodenal ulcer and normal subjects. Disturbances in gastric motility can exacerbate meal-stimulated acid-secretory abnormalities.

Patients with duodenal ulcer have accelerated emptying of gastric contents, particularly liquids, after a meal, and duodenal acidification fails to slow emptying appropriately. In such patients, the duodenal mucosa can be exposed to low pH for prolonged periods relative to normal subjects.

Groups of patients with duodenal ulcer also demonstrate increased basal secretion of acid. Increased basal secretion can be demonstrated by nocturnal collection of gastric secretions.

Studies indicate that most of these secretory abnormalities are a direct consequence of *H. pylori* infection. Paradoxically, the earliest stages of *H. pylori* infection are accompanied by a marked decrease in gastric acid secretion. Acute antral gastritis is followed by fundal inflammation. Fundal inflammation is associated with mucosal production of a number of cytokines, including interleukin (IL)-1β, IL-6, IL-8, and tumor necrosis factor-α (TNF-α). IL-1β is a potent inhibitor of gastric acid secretion. Investigators have postulated that acute reduction in gastric acid secretion facilitates further gastric colonization with *H. pylori.* Acute hypochlorhydria resolves despite persistence of *H. pylori* and is followed by a state of chronically increased acid secretion.

Table 45.2 Pathogenesis of Peptic Ulcer

Helicobacter pylori infection

Endocrine Consequences

- Increased basal serum gastrin
- Increased gastrin response to a meal
- Increased responsiveness to gastrin-releasing peptide
- Production of N^{α}-methylhistamine
- Decreased density of somatostatin cells
- Decreased mucosal somatostatin content

Gastric Acid Secretion

- Increased acid = secretory capacity
- Increased basal secretion
- Increased pentagastrin-stimulated output
- Increased meal response
- Abnormal gastric emptying

Mucosal Defense

- Decreased duodenal bicarbonate production
- Decreased gastric mucosal prostaglandin production
- Increased apoptosis of epithelial cells
- Disruption of epithelial barrier function
- Inhibited epithelial restitution

Basal and peak acid outputs are increased in patients with duodenal ulcer infected with *H. pylori* relative to uninfected healthy volunteers. With eradication of *H. pylori* infection, basal acid output returns to normal within 4 weeks, and peak acid output declines to the normal range by 6 months.

Abnormalities in acid secretion and parietal cell mass appear to be due to *H. pylori*–induced hypergastrinemia.[7] *H. pylori*–infected patients have increased basal serum gastrin levels, increased gastrin responses to meal stimulation, and an augmented gastrin response to intravenous gastrin-releasing peptide. Eradication of *H. pylori* infection causes serum gastrin levels to return to baseline. Gastric mucosal inflammatory cells and epithelial cells are activated by *H. pylori* infection to release cytokines such

as IL-8, interferon-γ, and TNF-α. These cytokines are stimulants of gastrin release from cultured canine gastrin cells.

Mucosal Defense Against Peptic Injury

Gastric surface epithelial cells secrete mucus and bicarbonate, creating a pH gradient within the mucous layer that is nearly neutral at the mucous cell surface, even when the lumen is highly acidic. Failure of normal bicarbonate secretion locally would, in theory, result in exposure of surface epithelial cells to the peptic activity of gastric secretions at low pH. Patients with duodenal ulcers have been demonstrated to have significantly lower basal bicarbonate secretion in the proximal duodenum than normal subjects. In addition, in response to a physiologically relevant amount of hydrochloric acid instilled into the duodenal bulb, stimulated bicarbonate output was approximately 40% of the normal response. Abnormalities in duodenal bicarbonate secretion normalize after elimination of *H. pylori* in infected patients. These results suggest one mechanism by which ulceration could occur, even in patients secreting normal amounts of acid.

Diminished mucosal prostaglandin production has also been proposed to exist in subsets of patients with duodenal ulcer. Prostaglandins and prostaglandin analogs have been shown to exert cytoprotective effects, to accelerate healing of established duodenal ulcers, and to decrease acid secretion. In patients with active duodenal ulceration, gastric mucosal production of prostaglandin E_2 and other prostanoids has been shown to be diminished. An increase in prostanoid synthesis within the gastric mucosa characterizes ulcer healing.

Inflammatory responses to *H. pylori* infection are central to the pathogenesis of peptic ulceration. While *H. pylori* infection always induces inflammation, the patterns of response are not uniform. Three major patterns have been recognized.[8,9] The most common pattern is a mild to moderate inflammation of all regions of the stomach. This form is not associated with major alterations in gastric acidity and most individuals are asymptomatic and do not develop peptic ulceration. Approximately 15% of infected individuals develop an antral-predominant form of gastritis. These individuals exhibit an intense inflammation limited to the antrum without

involvement of the mucosa of the gastric corpus. Gastrin levels are elevated and acid secretion is high. Inhibitory control of gastric acid production is impaired in this form of gastritis. As a result, duodenal and prepyloric ulcers are common. The third form of inflammatory response, occurring in 1% of infected individuals, is least common but most serious. This form is characterized by corpus-predominant gastritis, hypochlorhydria, and gastric atrophy. This form of inflammatory response is considered a precursor state for gastric cancer.

Environmental Factors

NSAIDs have emerged as a significant risk factor for the development of acute ulceration. Although acute mucosal injury caused by NSAIDs is more common in the stomach than in the duodenum, NSAID-induced ulcer complications occur with equal frequency in these two sites. NSAIDs produce a variety of lesions, ranging from hemorrhage, to superficial mucosal erosions, to deeper ulcerations. In the duodenum, it appears likely that invasive NSAID-associated ulcers result from underlying peptic ulcer diathesis compounded by the direct injurious effects of these drugs.

The ulcerogenic actions of NSAIDs have been attributed to their systemic suppression of prostaglandin production. Ulcers associated with NSAIDs usually heal rapidly when the drug is withdrawn, corresponding to the reversal of antiprostaglandin effects. All available NSAIDs appear to pose the hazard of gastroduodenal ulceration. Clinically important ulceration (of both the stomach and duodenum) is estimated by the U.S. Food and Drug Administration to occur at a rate of 2% to 4% per patient-year. The risks inherent with NSAID use appear to be increased by a history of *H. pylori* infection, by cigarette smoking, and by alcohol use. The incidence of NSAID-caused ulcer complications is highest in older patients, as is the attendant mortality rate. Peptic ulcer disease is rare in individuals who are *H. pylori* negative and who are not receiving NSAID medications.

A role of NSAIDs in upper gastrointestinal (GI) hemorrhage is widely recognized. The risk of bleeding is particularly acute for peptic ulceration. NSAIDs have been linked to 50% to 75% of bleeding peptic ulcers, one-third of deaths due to hemorrhage, and 30% of hospitalizations.[10,11] Use of

NSAIDs increases the risk of bleeding from peptic ulcer threefold for those under 65 years of age, but by eightfold for individuals over 75 years of age.

Because of the risk of gastrointestinal side effects, a selective class of cyclooxygenase-2 (COX-2) inhibitors was developed for long-term pain relief and anti-inflammatory therapy. Selective COX-2 inhibitors have reduced potential to injure the gastrointestinal mucosa relative to standard NSAIDs.[11] Concurrent use of aspirin with COX-2 inhibitors significantly undermines the safety advantages of the COX-2 agents, as does smoking.[12]

DIAGNOSIS

The cardinal feature of duodenal ulceration is epigastric pain. The pain is usually confined to the upper abdomen and is described as burning, stabbing, or gnawing. Unless perforation or penetration into the head of the pancreas has occurred, referred of pain is not common. Many patients report pain on arising in the morning. Ingestion of food or antacids usually provides prompt relief. In uncomplicated cases, abnormal physical findings are minimal. The differential diagnosis is broad and includes a variety of diseases originating in the upper gastrointestinal tract. The most common disorders to be distinguished include nonulcerative dyspepsia, gastric neoplasia, cholelithiasis and related diseases of the biliary system, and both inflammatory and neoplastic disorders of the pancreas. In dyspeptic patients, the principal diagnoses that must be differentiated definitively are peptic ulceration and gastric cancer.

The evaluation of patients with suspected peptic ulceration usually involves endoscopy, the standard against which other diagnostic modalities are measured. Endoscopy is employed because it permits biopsy of the esophagus, stomach, and duodenum.

Duodenal ulcer is characterized by lesions that are erosive to the bowel wall. When viewed endoscopically, the ulcers have a typical appearance. The edges are usually sharply demarcated and the underlying submucosa is exposed. The ulcer base is often clean and smooth, although acute ulcers and those with recent hemorrhage can demonstrate eschar or adherent exudate. Surrounding mucosal inflammation is common. The most frequent site for peptic ulceration is the first portion of the duodenum, with the second portion

less commonly involved. Ulceration of the third or fourth portions of the duodenum is unusual, and occurrence in these sites should arouse suspicion of an underlying gastrinoma. Ulceration in the pyloric channel or the prepyloric area is similar in endoscopic appearance to duodenal ulceration, and ulcers in these areas demonstrate other clinical features similar to duodenal ulcers. Endoscopic demonstration of a duodenal ulcer should prompt mucosal biopsy of the gastric antrum to demonstrate the presence of *H. pylori* and guide subsequent therapy.

The ulcer can extend for a variable distance through the wall of the duodenum, including the full thickness of the bowel in cases of perforation.

DRUG TREATMENT OF ULCER DISEASE

In the absence of active treatment, *H. pylori* infection is lifelong. [4] Spontaneous healing of infected mucosa is very rare, occurring in less than 0.5% per patient-year. Current treatment of peptic ulceration involves a combination of an antisecretory drug, usually a proton pump inhibitor, with antibiotics.[13] This therapy is rational for most patients who are *H. pylori* positive and results in a high rate of sustained ulcer healing.

A large number of drug regimens have been described, but the most widely used treatment protocols combine a proton pump inhibitor, usually omeprazole, with two antibiotics, usually clarithromycin and metronidazole or amoxicillin. A combination of antibiotics is more effective than one antibiotic alone in almost all series. This triple therapy is administered for 7 or 14 days. Triple-drug therapy is cost effective and associated with a low rate of side effects, low rates of antibiotic resistance, and acceptable levels of patient compliance. *H. pylori* eradication rates of greater than 90% have been reported.

After elimination of *H. pylori,* ulcer recurrence rates reflect the rate of reinfection. In developed countries, reinfection rates of less than 10% at 5 years have been reported. Eradication of *H. pylori* improves quality of life, as measured by symptoms, drug prescriptions, physician visits, and days of missed employment. To date, antibiotic resistance has been low, approximately 18% for clarithromycin, 14% for levofloxacin, and 35% for metronidazole. Resistance to amoxicillin has been low.[14]

HISTAMINE-RECEPTOR ANTAGONISTS

Histamine, released into the interstitial fluid by cells in the fundic mucosa, diffuses to the mucosal parietal cell. Histamine stimulates acid production by occupying a membrane-bound receptor and activating parietal cell adenylate cyclase. Histamine is released in response to a number of physiologic stimuli; blockade of histamine receptors inhibits most forms of stimulated acid secretion in humans. All clinically useful gastric histamine receptor antagonists are of the H_2 type.

H_2-receptor antagonists bind competitively to parietal cell H_2 receptors to produce a reversible inhibition of acid secretion. An enormous worldwide experience has accumulated with the use of H_2-receptor antagonists. The agents are effective and safe when used in the treatment of peptic ulcer. The various compounds have similar efficacy in terms of ulcer healing when used in doses that produce similar reductions in acid output. It is clear that H_2-receptor blockers do not affect the underlying ulcer diathesis; if H_2-receptor antagonists are stopped, recurrent ulceration occurs in more than half of patients within 1 year. The current understanding of the role of *H. pylori* in ulcer pathogenesis has changed the role of H_2-receptor antagonists from primary therapy to that of a substitute for proton pump inhibitors in conjunction with antibiotic treatment.

PROTON PUMP BLOCKERS

Acid secretion by the gastric parietal cells is due to the active transport of hydrogen ions from the parietal cell cytoplasm into the secretory canaliculus in exchange for potassium. Because this so-called *proton pump* is tissue specific, being present only in gastric mucosa, its blockade would be expected to have minimal effects on nongastric functions. Omeprazole is representative of a family of compounds that selectively block the parietal cell proton pump.

Omeprazole binds to the membrane-bound H^+-K^+-adenosine triphosphatase (ATPase) of the parietal cell. Because the compound is a weak base, omeprazole accumulates selectively within the acidic

environment of the parietal cell secretory canaliculus; 4 hours after administration, the drug is detectable in appreciable quantities only in the gastric mucosa. If enough drug is administered to occupy all parietal cell–binding sites, anacidity can be produced. Omeprazole, in doses from 20 to 30 mg, causes nearly complete inhibition of stimulated gastric acid secretion within 6 hours. At 24 hours after drug administration, a 60% to 70% reduction in acid secretion persists.

Repeated daily dosing with omeprazole results in increasing inhibitory action on gastric secretion and thus in decreased intragastric degradation of the drug. Acid suppression stabilizes after approximately 3 days. Because of tissue accumulation, the secretory actions of omeprazole do not correlate with plasma levels. Several studies have demonstrated a significant inhibition of peak acid output, marked relief of epigastric pain, and decreased use of supplemental antacids during omeprazole therapy. Direct comparisons with H_2-receptor antagonists have generally favored omeprazole in terms of pain relief and rate of ulcer healing.

OPERATIVE TREATMENT OF ULCER DISEASE

Surgical Goals

Operative intervention is reserved for the treatment of complicated ulcer disease. Three complications are most common and constitute the indications for peptic ulcer surgery—hemorrhage, perforation, and obstruction. The first goal in the surgical treatment of the complications of ulcer disease is treatment of coexisting anatomic complications, such as pyloric stenosis or perforation. The second major goal should be patient safety and freedom from undesirable chronic side effects. To achieve these goals, the gastric surgeon can direct therapy through endoscopic or operative means, the appropriate choice depending on the clinical circumstances.

Operative Procedures

A number of operative procedures have been used to treat peptic ulcer, but with decreasing frequency in the past decade. There is currently no indication for surgical treatment of uncomplicated ulcer disease. Operative treatment of gastric outlet obstruction has decreased by approximately 50%. Most surgical patients are now treated emergently for the complications of bleeding or perforation.

Three procedures—truncal vagotomy and drainage, truncal vagotomy and antrectomy, and proximal gastric vagotomy—were widely used in the past in the operative treatment of peptic ulcer disease. With increasing frequency, surgical therapy of peptic ulcer is directed exclusively at correction of the immediate problem (e.g., closure of duodenal perforation) without gastric denervation. The underlying ulcer diathesis is then addressed after surgery by antibiotic therapy directed at *H. pylori*.

Hemorrhage

5 Hemorrhage is the leading cause of death associated with peptic ulcer, and the incidence of this complication has not changed since the introduction of H_2-receptor antagonists. The lifetime risk of hemorrhage for patients with duodenal ulcer ranges from 19 to 57 per 100,000 indvivduals.[15] Most hemorrhages occur during the initial episode of ulceration or during a relapse, and patients who have hemorrhaged previously have a higher risk of bleeding again. Patients with recurrent hemorrhage and elderly patients are at greatest risk of death, and these two groups should be resuscitated vigorously, investigated promptly, and treated aggressively.[16,17] The 90-day all-cause mortality for patients with bleeding peptic ulcer is surprisingly high at 15%.[15]

Operative risk is increased in patients who have shock at admission, recurrent bleeding, delay in operative intervention, or coexisting medical illnesses. Surgical delay may lead to recurrent hypovolemia and, subsequently, multisystem organ failure.

Upper gastrointestinal endoscopy is the appropriate initial diagnostic test when hemorrhage from duodenal ulceration is suspected. Endoscopy can correctly determine the site and cause of bleeding in more than 90% of patients. An ulcer should be accepted as the bleeding source only if it has

one of the stigmata of active or recent hemorrhage. Active hemorrhage is defined by an arterial jet, active oozing, or oozing beneath an adherent clot. The signs of recent hemorrhage include an adherent clot without oozing, an adherent slough in the ulcer base, or a visible vessel in the ulcer. The ability of these endoscopic findings to accurately predict recurrent hemorrhage has been extensively validated. Approximately 30% of patients who have stigmata of recent hemorrhage experience rebleeding, and most of the patients who experience recurrent hemorrhage require emergency treatment. The occurrence of hypovolemic shock, rebleeding during hospitalization, and a posteroinferior location of the ulcer are additional clinical features that have been associated with increased risks of recurrent bleeding. The role of gastric acidity as a cause for in-hospital rebleeding appears to be inconsequential, and reduction of acid secretion by H_2-receptor antagonists or omeprazole is not sufficient to prevent recurrent hemorrhage.

The ability to visualize bleeding duodenal ulcers endoscopically has led to development of methods to treat hemorrhage endoscopically. There are many different methods of endoscopic therapy, but the most established consist of thermal coagulation or injection of sclerosants. Thermal coagulation can be achieved by bipolar electrocoagulation or direct application of heat through a heater probe. Injection of epinephrine into the base of the bleeding ulcer is also effective in control of ulcer hemorrhage.

Proof of efficacy, in the form of lowered rebleeding rates and avoidance of operation, has been convincingly demonstrated for all of these methods of endoscopic hemostasis. The analysis of reports of endoscopic treatment of hemorrhage is complicated by the 70% rate of spontaneous, although sometimes temporary, cessation of bleeding without intervention. In addition to endoscopic stigmata, hemodynamic instability, need for continuing transfusion, red stool or hematemesis, age older than 60 years, and serious medical comorbidity are clinical features that mandate endoscopic therapy. Rebleeding during hospitalization and the endoscopic findings of visible vessel, oozing, or bleeding associated with an adherent clot are other indications for endoscopic hemostasis. Ulcers with clean bases require no treatment.

Table 45.3 Situations in Which Operative Intervention Is Appropriate

Massive hemorrhage leading to shock or cardiovascular instability
Prolonged blood loss requiring continuing transfusion
Recurrent bleeding during medical therapy or after endoscopic therapy
Recurrent hemorrhage requiring hospitalization

Failure of endoscopic hemostasis is usually due to inaccessibility because of scarring, to rapid active bleeding obscuring the endoscopic view, or to an adherent clot. Patients treated endoscopically should be observed closely for further hemorrhage. Patients who rebleed within 72 hours of initial endoscopic control may be successfully retreated without increasing the risk of mortality. Transcatheter arterial embolization has emerged in recent years as an alternative to surgery for patients that fail endoscopic control measures.[18] This method should be considered as a salvage option for patients in whom endoscopic control is not effective.

Table 45.3 lists situations in which operative intervention is appropriate. The need for emergency surgery significantly increases surgical risks; mortality rates are increased approximately 10-fold. Operative therapy should consist of duodenostomy with direct ligation of the bleeding vessel in the ulcer base.

Postoperatively, patients should receive antibiotics directed against *H. pylori*. This treatment paradigm is based on the observation that peptic ulcer hemorrhage recurs in 20% of patients in whom *H. pylori* is not eradicated, whereas rebleeding is reduced to 3% in patients who receive *H. pylori* eradication therapy (**Algorithm 45.1**, **Fig. 45.1**).[19]

Perforation

The lifetime risk for perforation in patients with duodenal ulceration who do not receive therapy approximates 10%. In contrast, ulcer perforation is unusual if initial ulcer healing has been achieved.

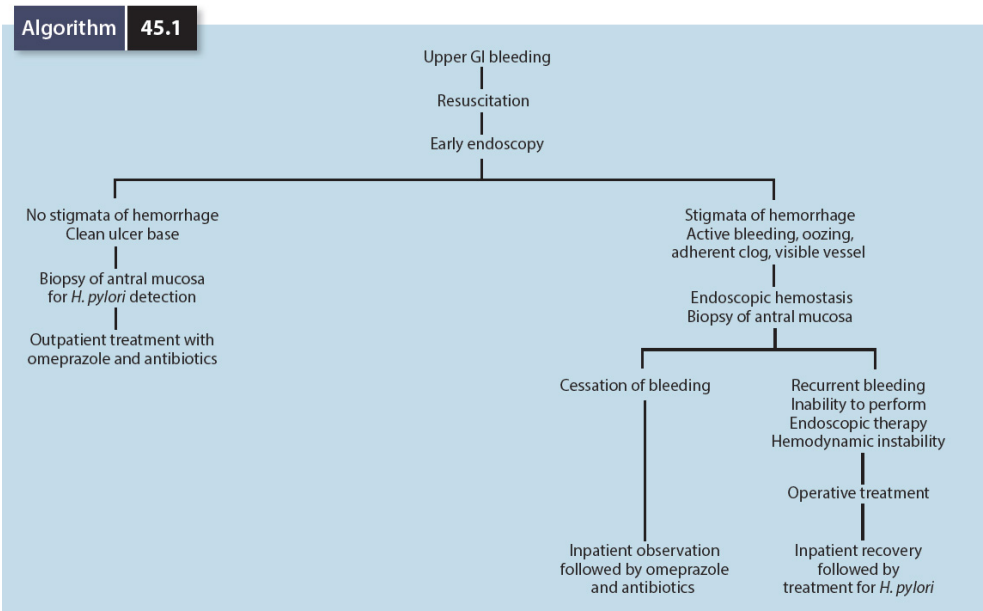
Perforation of a duodenal ulcer is usually accompanied by sudden and severe epigastric pain. The pain, caused by the spillage of highly caustic

gastric secretions into the peritoneum, rapidly reaches peak intensity and remains constant. Radiation to the right scapular region is common because of right subphrenic collection of gastric contents. Occasionally, pain is sensed in the lower abdomen if gastric contents travel caudally through the paracolic gutter. Peritoneal irritation is usually intense and most patients avoid movement to minimize discomfort.

Physical examination reveals low-grade fever, diminished bowel sounds, and rigidity of the abdominal musculature. Usually, upright abdominal radiographs reveal pneumoperitoneum. Computed tomography of the abdomen is very sensitive for demonstrating perforation if pneumoperitoneum is not demonstrated but perforation is still suspected.

Perforation remains a strong indication for surgery in most circumstances. Laparotomy or laparoscopy affords the opportunity to relieve intraperitoneal contamination and to close the perforation (**Fig. 45.2**).

Signs of antecedent duodenal ulceration, in terms of history of prior symptoms and anatomic evidence of duodenal scarring, should be sought. Before the role of *H. pylori* was appreciated, simple omental closure of duodenal perforation resulting from chronic ulceration did not provide satisfactory long-term results; up to 80% of patients so treated had recurrent ulceration, and 10% experienced reperforation if untreated. Approximately four-fifths of all patients with perforation have *H. pylori* infestation and therefore are at risk of recurrent disease.



Algorithm 45.1 Treatment of bleeding duodenal ulceration.

The mortality of emergent ulcer operations is most clearly correlated with the following circumstances: preoperative shock, coexisting medical illness, and presence of perforation for more than 48 hours.[20] Mortality with perforated peptic ulcer disease has also been correlated with the American Society of Anesthesiology (ASA) score and the Peptic Ulcer Perforation (PULP) score.[21]

6 Current reports advocate omental patch closure, often laparoscopically, with postoperative anti–*H. pylori* therapy. This approach presumes that most duodenal ulcers are caused by *H. pylori,* that secure closure of the perforation can be obtained, and that further surgical therapy will be obviated by the effects of medical therapy. Minimally invasive approaches are becoming standard practice.

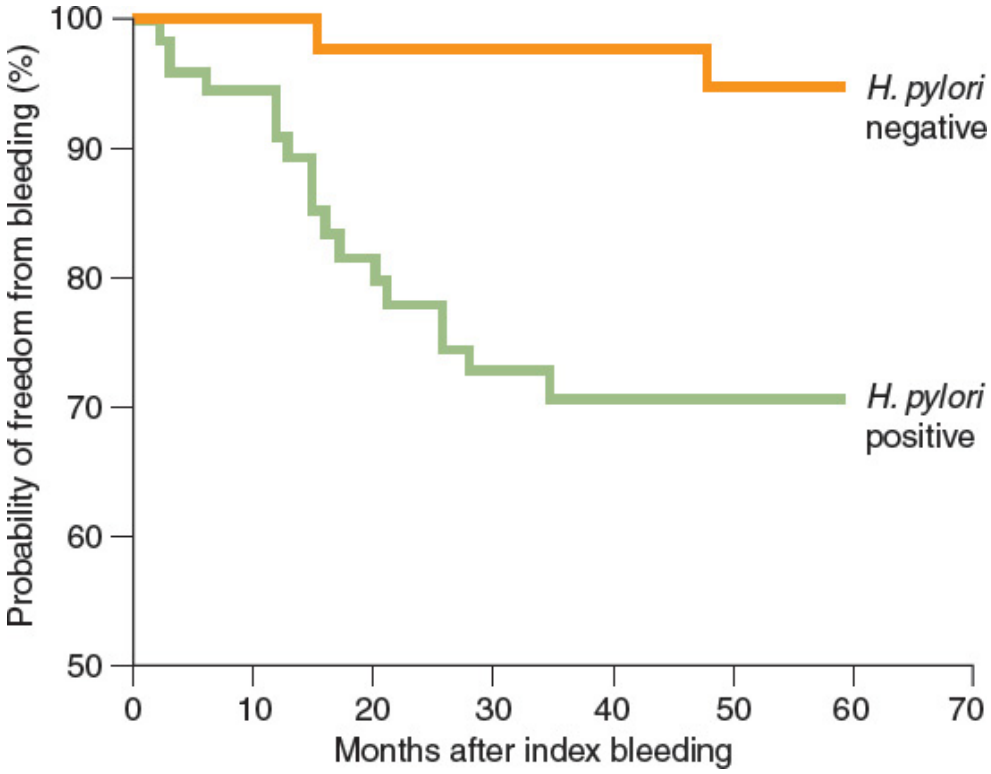


Figure 45.1 Probability of freedom from recurrent hemorrhage according to posttreatment *H. pylori* status.

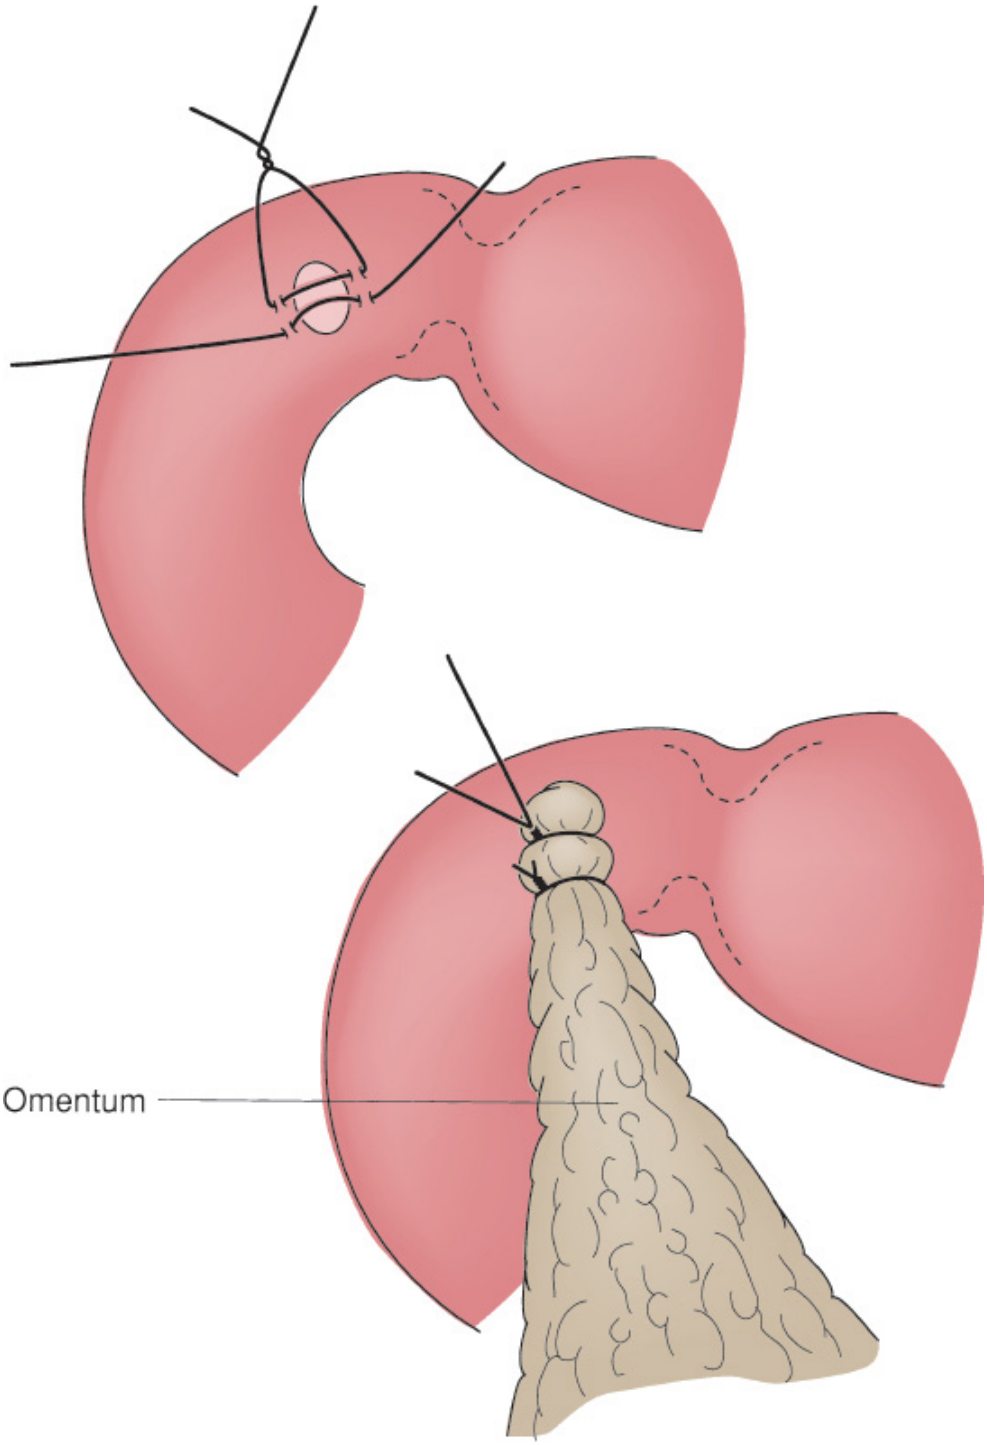

Figure 45.2 Omental patching of perforated duodenal ulcer.

In-hospital analgesic use has been consistently demonstrated to be lower in laparoscopically treated patients, and hospital length of stay shorter for these patients.[22] Overall rates of postoperative complications were not

statistically different between the two approaches, but most studies demonstrate a lower rate of wound infection in the laparoscopic group. Return to normal daily activities and work favor the laparoscopic group. Mortality is similar between patients treated via open or laparoscopic approaches, suggesting that underlying septic complications are more important that the means of access to the abdominal cavity. Peptic ulcer perforation is a serious physiologic challenge to frail patients with increased mortality risk that persists much longer than the acute postoperative period. In population-based studies, 90-day, 1- and 2-year mortality are 19%, 23%, and 25%, respectively.[23]

Obstruction

Gastric outlet obstruction can occur acutely or chronically in patients with duodenal ulcer disease. Acute obstruction is caused by edema and inflammation associated with ulcers in the pyloric channel and the first portion of the duodenum. Pyloric obstruction is suggested by recurrent vomiting, dehydration, and hypochloremic alkalosis due to loss of gastric secretions. Acute gastric outlet obstruction is treated with nasogastric suction, rehydration, and intravenous administration of antisecretory agents. In most instances, acute obstruction resolves with such supportive measures within 72 hours.

Repeated episodes of ulceration and healing can lead to pyloric scarring and a fixed stenosis with chronic gastric outlet obstruction.

Upper endoscopy is indicated to confirm the nature of the obstruction and to exclude neoplasm. Endoscopic hydrostatic balloon dilatation of pyloric stenoses can also be attempted at this time (**Fig. 45.3**). Approximately 85% of pyloric stenoses are amenable to balloon dilatation. Only 40% of patients with gastric stenoses have sustained improvement by 3 months after balloon dilatation. Recurrent stenoses are presumably due to residual scarring in the pyloric channel. Thus, although pyloric dilatation is occasionally durable, in most cases operative correction is required.

Operative management of gastric outlet obstruction should be focused on relief of the anatomic abnormality. Antrectomy has been used with success in this circumstance, with low ulcer recurrence rates and with satisfactory restoration of gastric emptying.

GASTRIC ULCER

Benign gastric ulcers are a form of peptic ulcer disease, occurring with one-third the frequency of benign duodenal ulceration. In the United States, gastric ulcer is somewhat more common in men than in women and occurs in a patient cohort approximately 10 years older than for duodenal ulceration.

Endoscopic Diagnosis

Upper gastrointestinal endoscopy is the preferred method for diagnosing gastric ulceration. The ulcer base in benign disease is commonly smooth and flat and often covered by a gray, fibrous exudate. The margin is usually slightly raised, erythematous, and friable. Differentiation of benign and malignant gastric ulcers is reliably made only by histologic examination. Visual endoscopic differentiation of benign from malignant ulcers is not reliable. All gastric ulcers should have multiple biopsies taken from the perimeter of the lesion. The addition of lesional brushings to biopsy increases diagnostic accuracy to approximately 95%.

Benign gastric ulcers may occur in any location in the stomach, but approximately 60% are located along the lesser curvature proximal to the incisura angularis. Less than 10% of benign gastric ulcers are located on the greater curvature. Virtually all gastric ulcers lie within 2 cm of the histologic transition between fundic and antral mucosa. With increasing age, this mucosal transition zone moves proximally along the lesser curvature. Movement of this transition zone is reflected by the greater prevalence of proximal ulcers in elderly patients.

As with benign duodenal ulceration, *H. pylori* plays a central role in the pathogenesis of benign gastric ulcers.[24] Benign gastric ulcers associated with *H. pylori* respond to antibiotic therapy at a rate equivalent to that of duodenal ulceration. The recurrence rate of ulcerations in these patients after *H. pylori* eradication is equal to the rate of reinfection.

A strong association of benign gastric ulceration with the use of NSAIDs has been recognized. Cigarette smoking is associated with development of gastric ulceration, and continued smoking impedes medical therapy. Gastric and duodenal ulcers have been noted in patients receiving hepatic artery

chemotherapy in whom improper placement of the catheter permits perfusion of gastric and duodenal mucosae.

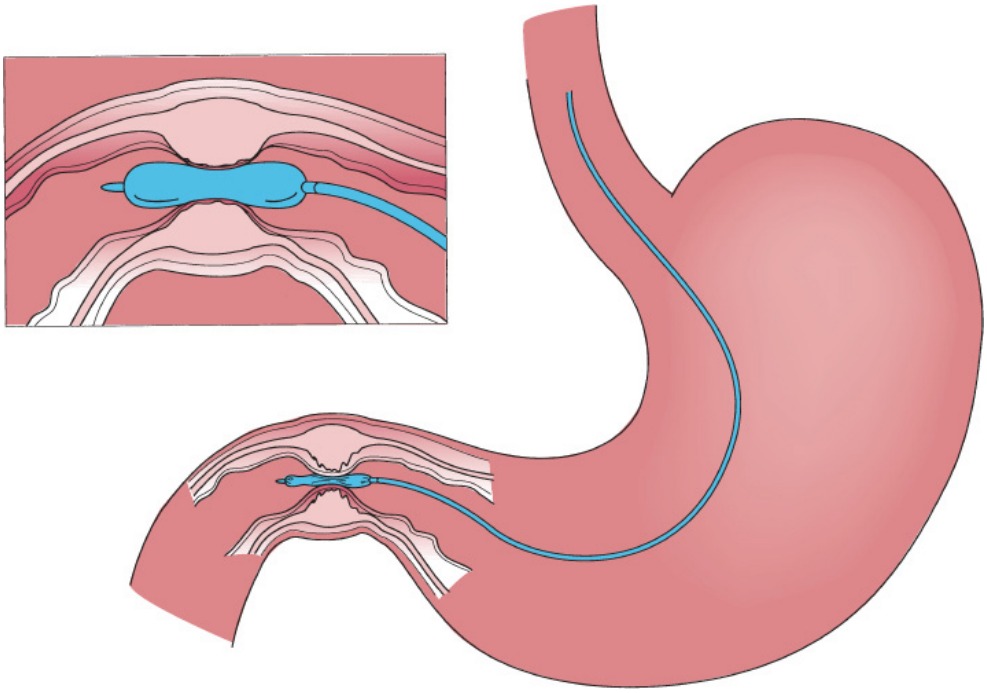

Figure 45.3 Schematic representation of balloon dilatation of pyloric stenosis.

Therapy

The primary therapy for benign gastric ulceration in most patients is antimicrobial treatment of *H. pylori* infection. The treatment protocols are similar to those used for benign duodenal ulceration. For many patients, cessation of NSAID therapy is also required.

Indications for surgical treatment of gastric ulcer include hemorrhage, perforation, failure of a recurrent ulcer to respond to medical therapy, and inability to exclude malignant disease.

For benign gastric ulcers, the elective operation of choice is usually a distal gastrectomy with gastroduodenal (Billroth I) anastomosis. The ulcer should be included in the gastrectomy specimen. With this approach, operative mortality rates of 2% to 3%, with ulcer recurrence rates of less than 5%, have been reported.

The occurrence of a gastric ulcer near the gastroesophageal junction represents a difficult surgical problem. When possible, the ulcer should be

excised. This usually requires a distal gastrectomy with an extension along the lesser curvature near the esophageal wall and reconstruction with gastrojejunostomy.

Emergency operations performed for hemorrhage or perforation require ulcer excision. Distal gastrectomy, performed with gastroduodenal reconstruction, is usually the procedure of choice. Operative mortality rates average 10% to 20% in the presence of hemorrhage or perforation.

STRESS GASTRITIS

7 Major trauma accompanied by shock, sepsis, respiratory failure, hemorrhage, or multiorgan injury is often accompanied by acute stress gastritis. Acute stress gastritis is particularly prevalent after thermal injury with greater than 35% total surface area burned.[25] Multiple superficial ulcerations and erosions are noted in the proximal, acid-secreting portion of the stomach, with fewer lesions in the antrum and only rare ulcerations in the duodenum.

The most sensitive diagnostic test for stress ulceration is endoscopic examination. If patients are examined within 12 hours of the onset of injury, acute mucosal ulcerations may be observed that appear as multiple, shallow areas of erythema and friability, often accompanied by focal hemorrhage. The lesions are progressive during the first 72 hours after injury. When lesions are examined histologically, they are seen to consist of coagulative necrosis of the superficial endothelium with infiltration of leukocytes into the lamina propria. Chronic disease, characterized by fibrosis and scarring, is not observed. With resolution of the underlying injury or sepsis, healing is accompanied by mucosal restitution and regeneration.

Clinical observations and a large number of experimental studies suggest that mucosal ischemia is the central event underlying the development of stress gastritis. In clinical practice, most patients who contract stress gastritis do so after an episode of sepsis, hemorrhage, or cardiac dysfunction accompanied by shock. Experimental studies that cause depletion of high-energy phosphate compounds such as ATP predispose to the development of stress gastritis. Luminal gastric acid secretion, although not the sole cause of stress gastritis, appears to be a necessary concomitant process. A number of

experimental observations suggest that a critical concentration of luminal acid is required to initiate injury in the setting of mucosal ischemia. The fall in mucosal energy supply permits proton back-diffusion into the mucosa; the resultant decrease in mucosal pH exacerbates ischemic damage.

Clinical risk factors that predict development of stress gastritis include adult respiratory distress syndrome, multiple long-bone fractures, a major burn over 35% of the body surface, transfusion requirement above 6 units, hepatic dysfunction, sepsis, hypotension, and oliguric renal failure. Scoring systems of critical illness, exemplified by the Acute Physiology and Chronic Health Evaluation (APACHE) system, accurately predict risk for acute stress gastritis.

The major complication of stress gastritis is hemorrhage. While admission to an intensive care unit is not an independent risk factor for bleeding, development of respiratory failure or coagulopathy (platelet count less than 50,000/mm^3, international normalized ratio [INR] >1.5, or partial thromboplastin time [PTT] greater than two times normal) imparts the greatest risk for hemorrhage.

Diagnosis

Clinical studies that use bloody nasogastric discharge as a sign of stress gastritis probably underestimate its incidence in critically ill patients. Conversely, studies based on endoscopy overestimate the incidence of clinically important stress gastritis. Severely burned patients have endoscopic evidence of gastric erosions in greater than 90% of cases, whereas significant upper gastrointestinal hemorrhage occurs in between 25% and 50% of patients with burn wound infection.

Treatment and Prophylaxis

Critically ill patients are at risk for development of acute stress gastritis. Because hemorrhage associated with stress gastritis significantly increases mortality, these patients should be treated prophylactically.[25–27] Proton pump inhibitors are effective at maintaining gastric pH above 4.0. Stress ulcer prophylaxis with these agents is associated with colonization of the upper GI tract with potentially pathogenic gram-negative organisms.

Early enteral feeding was first introduced as a component of burn care. Enteral feeding was designed to address the hypermetabolic state that develops after burn injury and to prevent visceral protein loss due to catabolic metabolism. Enteral nutrition has also been demonstrated to prevent bacterial translocation across the intestinal wall. In addition, enteral nutrition has been noted to maintain intragastric pH >3.5, suggesting that this modality may be used to prevent gastric hemorrhage from stress ulceration. In burn patients, early enteral feeding decreases upper GI hemorrhage, effects that are not potentiated by the addition of H_2-receptor antagonists.

Management of Obesity

Dana A. Telem and Robert W. O'Rourke

Key Points

1. Obesity is chronic disease and is defined and categorized using body mass index (BMI, weight [kg]/height [m]^2) based on World Health Organization (WHO) definitions.
2. BMI directly correlates with the risk of multiple metabolic diseases and long-term mortality.
3. Lifestyle interventions as treatment for obesity, including diet, exercise, and psychological therapy, are of limited efficacy; evolving strategies directed toward environmental manipulation demonstrate potential.
4. Current pharmacotherapy for obesity includes a wide range of agents that act via multiple mechanisms, are prone to side effects, and are of limited efficacy; active research in pharmacotherapy for obesity holds significant promise.
5. Bariatric surgery is safe and highly efficacious in treating obesity and metabolic disease, and includes a wide range of procedures that have evolved over decades.
6. Current dominant bariatric surgery operations include gastric bypass and sleeve gastrectomy.
7. Classic mechanisms of action of bariatric surgery include restriction of caloric intake and malabsorption of ingested calories, but evolving data suggest that other mechanisms predominate, including but not limited to alterations in gut and satiety hormone homeostasis, bile acid metabolism, and enteroenteric and enterocentral nervous systemic communications.

DIAGNOSIS AND EPIDEMIOLOGY

Obesity and Metabolic Disease

Excess adipose tissue is the defining feature of obesity, and metabolic disease arises in adipose tissue. Metabolic disease is diverse, involving every organ system. The correlation between obesity and metabolic disease, while strong, is not perfect—some patients develop metabolic disease at low body weight, while others who are very obese are protected. Visceral adiposity imparts greater risk than subcutaneous adiposity, and heterogeneity of visceral and subcutaneous adiposities partly explains the imperfect correlation between obesity and metabolic disease. Lean patients also develop metabolic disease, albeit less frequently than the obese, demonstrating that non-adipose tissue–based mechanisms contribute to metabolic disease as well. It is beyond the scope of this chapter to discuss the wide spectrum of specific treatment strategies for individual metabolic diseases. Rather, we will discuss the treatment of obesity itself, the goal of which is reduction in adipose tissue mass, because despite the variable relationship between body weight and metabolic dysfunction, in the vast majority of patients, regardless of initial weight, weight loss has beneficial effects on virtually all metabolic diseases. Treatment options for obesity may be broadly divided into medical and surgical approaches.

Diagnosis

1 Body mass index (BMI, weight [kg]/height [m]^2) is the primary metric used to define obesity. Originally devised in the 19th century by the Belgian polymath Adolphe Quetelet as a general measure of human body habitus, BMI was co-opted in the 1940s by the insurance industry and used to stratify humans into high- and low-risk subpopulations based on actuarial data for the purpose of setting life insurance rates. The medical community subsequently used BMI to estimate risk of morbidity and mortality. Much debate exists regarding the appropriate BMI cutoff points for optimal health, with various health and professional organizations setting different values. World Health Organization (WHO) definitions, set in 1995 and agreed upon by the U.S. Centers for Disease Control (CDC), are most commonly utilized and define overweight as BMI >25 and <30 and obesity as BMI ≥30, and categorize obesity into classes 1 (BMI 30 to 34.9), 2 (BMI 35 to 39.9), and 3 (BMI ≥40).[1]

BMI correlates with long-term mortality and metabolic disease in a J-shaped curve, the nadir of which is debated, but may 2 be as low as 20 or as high as 25.[2] BMI in the obese range (≥30) is clearly associated with an increased risk for long-term mortality and multiple metabolic diseases relative to BMI <30. For individuals with BMI 40 to 50, this risk translates into a 10-year decrease in life expectancy. In contrast to obesity, data demonstrating a correlation between overweight BMI and health risk are conflicting. Analyses are complicated by numerous confounding variables including but not limited to sex, age, ethnicity, smoking, cancer, and diabetes. In addition, the choice of control/referent group alters outcomes; for example, the correlations between overweight BMI and clinical outcomes weaken significantly and may be masked when referent groups span a larger BMI range (e.g., 18 to 25) relative to comparison with referent groups spanning a narrow BMI range (e.g., 21 to 23). Despite these conflicting data, the preponderance of evidence suggests that BMI in the overweight range is associated with an increased risk of long-term mortality, albeit lower than the risk associated with BMI in the obese range.[3] Furthermore, mortality aside, compelling data demonstrate that overweight BMI is associated with an increased risk of cardiovascular disease, diabetes, and other metabolic diseases, and is associated with an increased risk of future progression to frank obesity with its attendant risks. Taken together, these observations suggest that overweight should be considered a serious health risk and a predecessor to obesity.

These complex data demonstrate that BMI is not a perfect measure of adiposity. Indeed, muscular athletes may have BMI within the obese range despite low body fat levels and an absence of metabolic disease, while elderly people with a paucity of muscle mass may have low BMI despite increased adiposity and metabolic disease. Ethnic differences further confound the predictive power of BMI, as certain ethnicities, for example, Asians develop metabolic disease at lower BMI, prompting the WHO in 2004 to propose BMI cutoffs of 23 and 27.5 for overweight and obesity, respectively in Asians. In certain subpopulations, including patients with heart failure, renal failure, and other chronic diseases, overweight and obesity are associated with decreased mortality, a phenomenon termed the "obesity paradox."[4]

These observations have led to a search for other measures of adiposity. Waist circumference and waist–hip ratio are easily measured and in many studies correlate more accurately with metabolic disease than BMI, reflecting the disproportionate effect of visceral adiposity on metabolic disease.[5] Water displacement, dual-energy x-ray absorptiometry scanning, double-labeled isotope water measurement, bioelectrical impedance analysis, and quantitative magnetic resonance imaging may provide more accurate measures of adiposity and better predict metabolic disease. More recently a novel CT imaging approach, analytic morphomics, has been used to quantify adipose tissue and risk stratify various patient populations as well as determine adequate drug therapy dosing.[6] However, such methods have not gained widespread acceptance due to cost and complexity. Despite its limitations, BMI remains the most commonly used metric for obesity.

Epidemiology, Disease Burden

Human obesity has existed for millennia as evidenced by prehistoric figurines of obese humans (e.g., Venus of Willendorf) and periodic concerns regarding past obesity "epidemics" over the past two centuries. Nonetheless, the worldwide prevalence of overweight and obesity has increased dramatically over the past 50 years. BMI, like many clinical characteristics, spans a bell curve. Three large U.S. epidemiologic datasets, the National Health and Nutrition Examination Survey (NHANES), the National Health Interview Survey (NHIS), and the Behavioral Risk Factor Surveillance System (BRFSS), demonstrate similar trends, with a rightward shift of the BMI bell curve over the past three decades, mean BMI increasing from 25.5 in the 1970s to 28.5 in 2005, and the prevalence of obesity more than doubling in the same interval.[7] The CDC reports that as of 2017–2018, 42% of U.S. adults were obese and 18.5% of U.S. children between 2 and 19 were obese.[8] To put this in context, the prevalence of obesity in adults increased 30.5% from 1999 to 2000. Sex, ethnic, and regional differences complicate obesity epidemiology. The

rate of increase is higher in women compared to men, and while rates of increase are similar across ethnicities, mean BMI is highest in Blacks, followed by Hispanics, then Caucasians. Data regarding the association between obesity and socioeconomic status are conflicting; evidence suggests an inverse correlation between low socioeconomic status and obesity in low- and middle-income countries but a positive correlation in industrialized countries. Obesity prevalence is increased in rural compared to urban environments in the United States, although this relationship is inverted in developing countries.[8]

The disease burden associated with obesity is substantial. Multiple confounders complicate quantification of risk, not the least of which is variability in the degree of obesity itself, with increasing BMI being associated with increasing risk of mortality and disease in a dose-dependent but nonlinear fashion. Obesity is associated with decreased lifespan. Data from the Framingham Heart Study demonstrate a loss of 3 and 6 years of life for overweight and obese men, respectively,[9] while NHANES data demonstrate a loss of 13 years of life for severely obese men (BMI >45).[10] Overweight and obesity are associated with an increased risk of multiple diseases, among which type II diabetes is particularly important. The association between obesity and diabetes is robust; relative risks for diabetes range from 2 to 15 for BMI in the overweight range and 20 to 90 for BMI in the obese range. The CDC estimates that in the United States in 2018, the prevalence of type II diabetes was 13% among all adults and 27% among those over 65 years of age. Furthermore, 35% of all U.S. adults, and 47% of U.S. adults over 65 years of age have elevated fasting blood glucose or HbA1c consistent with prediabetes. If current trends persist, the prevalence of diabetes in the United States in 2050 will exceed 30%, and worldwide trends parallel these U.S. data.[8]

Obesity is associated with an increased risk of multiple diseases, including atherosclerosis, hypertension, hyperlipidemia, hepatic steatosis and steatohepatitis, sleep apnea, osteoarthritis, gallbladder disease, endocrine disorders, autoimmune disease, allergy and atopy, multiple types of cancer, infertility and depression. Metabolic disease encompasses all of physiology. Risk ratios for overweight and obesity-related diseases vary substantially depending on BMI, ranging from 2 to 5 for class I obesity with dramatic dose-dependent increases in risk with increasing BMI. For example, the prevalence of hepatic steatosis in the general population is generally estimated to be approximately 30%, increases progressively with increasing BMI, and exceeds 90% in obese patients with BMI >40. In the NHANES population, the prevalence of sleep apnea was 3% in nonobese men and 12% in obese men (BMI >30),[11] but in a separate study of patients with severe obesity (BMI >40), prevalence exceeded 70%.[12] This disease burden is associated with significant economic costs. While accurate quantification of obesity-related healthcare costs is challenging and complicated by regional variability in payer systems and patient demographics, the estimated costs directly attributable to overweight and obesity in the United States exceed 100 billion dollars annually and constitute 5% to 10% of total U.S. healthcare spending.[13]

MEDICAL MANAGEMENT

Treatment Strategies

The medical management of obesity falls into two primary categories: lifestyle intervention and pharmacotherapy. Both strategies, with rare exceptions, achieve similar results, with modest weight loss and high recidivism. Nonetheless, both strategies hold significant untapped promise, with advances expected in coming decades, particularly in the areas of environmental engineering and pharmacotherapy.

Lifestyle Interventions

3 Lifestyle interventions for obesity include any or all of three basic components: diet modification, exercise, and psychological therapy. Interventions may be unsupervised or administered under the supervision of clinicians, dieticians, or commercial weight loss plans, and may be individualized or administered in group programs.

Diet modification is the mainstay of lifestyle intervention. Diet strategies vary with respect to macronutrient composition, daily caloric intake, and food and caloric measurement methods, and include low-carbohydrate diets, low-fat diets, meal replacement strategies, Mediterranean diets, very low–calorie diets, and multiple commercial diet plans. No clear evidence demonstrates advantages of any specific diet plan over others. Specifically, macronutrient composition does not impact on weight loss when caloric intake is controlled—total calories, rather than the macronutrient composition of those calories, is the variable that determines weight loss. In contrast to weight loss, conflicting evidence exists regarding the role of macronutrient composition in improvement of metabolic disease, with some evidence suggesting that low-carbohydrate diets (which include low-glycemic index–

high-fiber diets and very low-carbohydrate diets), when compared to low-fat diets, may be associated with greater improvements in insulin resistance and triglyceride levels, and higher resting energy expenditure. These studies must be interpreted with caution as follow-up is relatively short, and low-carbohydrate diets may be associated with adverse changes in low-density lipoprotein levels.[14] Low-carbohydrate diets also appear to provide better compliance than other diet strategies over short-term follow-up of less than 6 months, but compliance differences vanish at follow-up exceeding 1 year.

Physical activity is a central component of lifestyle intervention for obesity. Exercise alone achieves only modest weight loss, but exercise and diet potentiate each other. Importantly, exercise reduces obesity-related mortality and cardiovascular disease risk independent of weight loss. Data regarding the optimal type, duration, frequency, and intensity of exercise are conflicting and specific evidence-based guidelines remain elusive. High intensity exercise may be more effective for weight loss, but many obese patients are unable to engage in even moderate intensity exercise due to comorbid diseases such as osteoarthritis. Increased daily activities such as walking and stair use nonetheless may provide modest weight loss and cardiovascular health benefits.

Of the wide range of psychological techniques used to treat obesity, cognitive-behavioral therapy is most common. Cognitive-behavioral therapy achieves modest weight loss in the obese of approximately 2 to 3 kg at 1-year follow-up, with increased weight loss when combined with diet and/or exercise. Increased frequency of psychological intervention and group therapy compared with individual therapy are associated with greater weight loss.[15]

Intensive lifestyle interventions are supervised multicomponent plans that involve a combination of diet, exercise, and behavioral modification, with periodic monitoring by coaches and dieticians, and individual or group psychological counseling. Two NIH-sponsored randomized controlled trials suggest that intensive lifestyle interventions provide more durable results than standard lifestyle interventions, although long-term outcomes of metabolic disease are conflicting. The Diabetes Prevention Program randomized 3,234 overweight or obese insulin-resistant patients (mean BMI 34) to one of three experimental arms: intensive lifestyle interventions, metformin treatment, or placebo treatment.[16] After a mean follow-up of 2.8 years, average weight loss in the intensive lifestyle interventions group was 5.6 kg compared with 2.1 kg and 0.1 kg for the metformin and placebo groups, respectively; at 10 years an average weight loss of 2 kg was maintained in both intensive lifestyle interventions and metformin arms relative to the placebo arm. The cumulative risk of incident diabetes was 34% lower in the intensive lifestyle interventions arm and 18% lower in the metformin arm relative to the placebo arm. The NIH-sponsored Look AHEAD (Action for Health in Diabetes) study randomized 5,145 overweight or obese diabetic patients to a 4-year intensive lifestyle intervention involving diet and exercise modification with regular on-site visits and counseling, or standard primary care provider-supervised diabetes and weight loss education. After 8 years, mean weight loss was 4.7% and 2.1% in the intensive lifestyle intervention and standard care arms, respectively.[17] Nonetheless, the study was halted after 11 years after no difference in cardiovascular events was observed. These studies demonstrate that while modest, weight loss may be maintained over long periods with intensive lifestyle interventions, although the effects on metabolic disease are equivocal. Of importance, in Look AHEAD, a subset of patients in each arm (27% and 17% in intensive lifestyle intervention and standard care arms, respectively), maintained a loss of >10% of total starting weight, suggesting that subpopulations of patients are more responsive than others to lifestyle interventions, and that identification of predictors of responsiveness would permit better allocation of care.

Assessing the overall efficacy of lifestyle interventions for obesity is challenging, as results vary depending on the subgroup studied, follow-up is variable and often short, and program and outcome reporting methods are widely disparate. The resultant complex body of literature limits our current understanding of the efficacy of such interventions. Nonetheless, a preponderance of data suggests that results of lifestyle interventions for obesity are modest, with mean weight loss between 2% and 10% of total body weight over follow-up periods from 6 to 48 months. Unsupervised individual efforts underperform more intensive, multicomponent, supervised, group interventions. Compliance is a critical issue; individual diet programs are associated with attrition that may exceed 90% over a year or more while attrition for intensive supervised efforts is less. Weight regain after program discontinuation is common and long-term adherence to lifestyle changes is low. Despite these limitations, modest weight loss, or exercise in the absence of weight loss, appears to have measurable if modest beneficial effects on metabolic disease, with a subset of patients being responsive to such interventions. As such, lifestyle interventions should be a component of the treatment of all obese patients, but only rarely achieve dramatic and durable results.

Pharmacotherapy

4 The history of pharmacotherapy for obesity is replete with drugs that have been introduced with much enthusiasm and variable efficacy but subsequently withdrawn due to unacceptable and in many cases life-threatening side effects that became apparent only after widespread use. Sheep thyroid extract was used in the late 19th century, while in the early 20th century, workers in the dye industry exposed to 2,4-dinitrophenol were observed to lose weight, leading to its use as a weight loss drug in the 1930s. Amphetamines were popular weight loss drugs in the 1950–60s. All these agents were abandoned due to prohibitive side effects. The modest efficacy of weight loss drugs is testament to the multiple redundant physiologic systems that act to defend adipose tissue stores in the face of interventions designed to reduce those stores. The frequent adverse effects of weight loss drugs speak to the interface between body weight regulation and multiple fundamental physiologic processes, manipulation of which entails substantial risk.

The largest class of weight loss drugs targets monoamine signaling mediators (norepinephrine, serotonin, dopamine, histamine) involved in CNS/hypothalamic control of satiety and hunger. Many of these agents regulate multiple pathways and demonstrate overlapping activities. Sympathomimetic agents that primarily potentiate norepinephrine release include phentermine, introduced in 1959 and still in use today, and phenylpropanolamine, used as a decongestant and also as a weight loss drug since the 1970s, but withdrawn from the market in 2000 after being associated with an increased risk of stroke. Drugs that primarily potentiate serotonin activity include fenfluramine, introduced in 1973 and withdrawn from the market in 1997, sibutramine (Meridia), a serotonin, norepinephrine, and dopamine reuptake inhibitor with primary effects on serotonin and norepinephrine, introduced in 1997 but withdrawn in 2010 after being linked to increased risks of myocardial infarction and stroke, and lorcaserin (Belviq), a selective serotonin 2C agonist approved by the FDA in 2012, but withdrawn from the market in 2020 after being linked to a possible increased risk of cancer. Drugs that target dopamine signaling are currently being studied in clinical trials (e.g., bupropion, tesofensine). Targeting multiple monoamine signaling pathways provides synergy. The combination drug fenfluramine/phentermine ("Fen-phen"), introduced in 1992, demonstrated increased efficacy over either agent alone, but was withdrawn from the market in 1997 after widespread use revealed serious morbidity attributable to fenfluramine, including pulmonary hypertension and cardiac valvular disease. In 2013, the FDA approved a combination drug of phentermine and topiramate, an antiepileptic with multiple CNS activities (Qsymia). A combination formulation of bupropion and naltrexone, an opioid antagonist which stimulates pro-opiomelanocortin neurons, is currently being studied in research trials.
