- Administer antibiotics as ordered. *Prompt administration of antibiotics is essential to control the spread of a UTI up to the renal system.*
- Administer pain medication as ordered. *Pain medications may be necessary to manage the pain associated with PKD.*

### ■ Teaching

- Immediately report clinical manifestations of infection. *Patients with PKD are at high risk for UTIs due to the compression of the tissues by the cysts impairing elimination. Prompt attention is necessary to halt the spread of infection to the renal tissue.*
- Follow prescribed dietary restrictions. *Following required prescribed dietary restrictions is required to avoid the serious metabolic complications that are associated with renal failure.*
- Follow prescribed antihypertensive therapy. *Following prescribed medications is essential to avoid uncontrolled high blood pressure that can lead to heart disease or stroke.*
- Follow prescribed antibiotics for diagnosed UTIs. *Following prescribed antibiotics is important in order to prevent the spread of infection to the renal tissue and to prevent antibiotic resistance.*

### Evaluating Care Outcomes

The goal of treatment for patients with PKD is to prevent complications. Complying with prescribed medications such as antihypertensives to maintain normal blood pressure and the use of antibiotics to treat UTIs is essential to the treatment plan for PKD. Diets restricting sodium, potassium, fluid, and phosphorus are necessary if renal failure is present. Vital signs within reasonable limits and the absence of infection are indicative of maintaining health for patients with PKD.

## CASE STUDY: EPISODE 2

Continued evaluation of Ms. Flood reveals an increase in abdominal girth and tenderness in the costovertebral area with palpation. Urinalysis reveals cloudy urine and hematuria. Ms. Flood has the classic signs of PKD as evidenced by left flank pain, increased frequency, urgency, hematuria, and abdominal distention combined with hypertension. The diagnostic test IVP confirms the diagnosis. The healthcare provider implements measures to prevent ESRD...

## PYELONEPHRITIS

### Epidemiology

Pyelonephritis is one of the most common renal diseases. The incidence is roughly 12 to 13 cases annually per 10,000 population in women and 2 to 3 cases per 10,000 in men. Young women are most often affected, probably reflecting sexual activity in that age group and the associated increased susceptibility to UTIs. Infants and older adults are also at increased risk as a result of anatomical variations and hormonal status.

The major risk factor associated with pyelonephritis is multiple pre-existing UTIs, treated or untreated. These infections may be caused by:

- Vesicoureteral reflux, which is a retrograde flow of urine from the bladder to the ureters
- Obstructions such as benign prostatic hypertrophy (BPH), a stricture, or a urinary stone
- A long-term indwelling urinary catheter
- Pregnancy is implicated in the development of acute pyelonephritis, known as pregnancy-induced acute pyelonephritis, as a result of the physiological changes associated with pregnancy, specifically hormonal changes and anatomical changes that lead to the retention of urine
- Sexual activity in women

### Pathophysiology

Pyelonephritis is an inflammation of the renal parenchyma and urinary collecting system. The most common cause is a bacterial infection that occurs as a result of contamination of the urinary meatus with bacteria found in the GI tract that ascend via the ureters to the renal tissue (Fig. 62.2).

An inflammatory process occurs as a result of the bacterial invasion of the renal parenchyma. Acute pyelonephritis usually begins in the renal medulla and spreads to the renal cortex. Although many viruses and bacteria can cause pyelonephritis, the bacterium *Escherichia coli* is the most common cause. Other causative agents include fungi, protozoa, and viruses.

### Clinical Manifestations

Clinical manifestations include signs of infection, which include fever, chills, nausea, and vomiting. Back or flank pain is also typically present. Costovertebral tenderness and enlarged kidneys are noted by palpation on physical examination. Patients may also present with clinical manifestations of a UTI, such as frequent and painful urination, and hematuria. The presence of fever, acute dysuria, new or worse urinary urgency or incontinence, gross hematuria, and suprapubic or costovertebral pain are more discriminating symptoms among the elderly for diagnosing pyelonephritis.

### Connection Check 62.3

The nurse correlates which clinical manifestations with the pathophysiology of acute pyelonephritis? (Select all that apply.)

- A. Nausea and vomiting
- B. Hematuria
- C. Flank pain
- D. Fever
- E. Abdominal pain

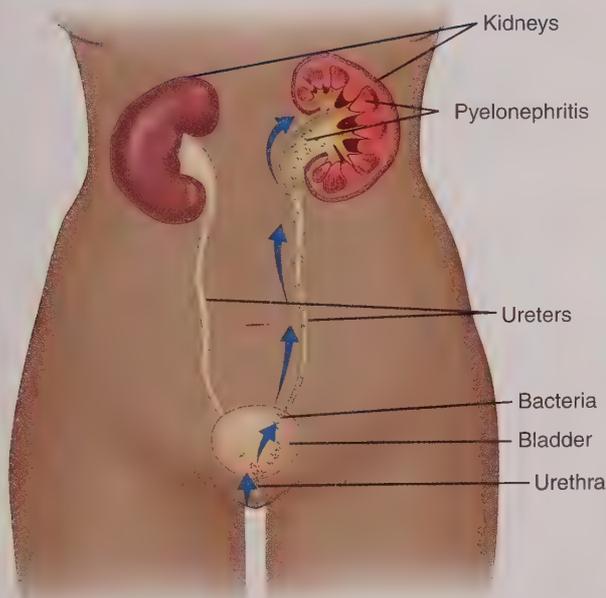

### Management

#### Medical Management

#### Diagnosis

Pyelonephritis may be diagnosed by history and physical examination combined with laboratory results. Laboratory testing includes urinalysis, urine culture, blood cultures, and complete blood count (CBC). Urinalysis can show pyuria, bacteriuria, and hematuria. White blood cell (WBC) casts may be present in the urine, and a complete WBC count shows leukocytosis (increased WBCs) with an increase in immature neutrophils (bands); this is referred to as a “shift to the left.” A shift to the left typically indicates acute infection. Once the urinalysis is obtained and shows infection, a urine culture must be conducted to identify the specific pathogen and medication sensitivities. Blood cultures are usually obtained before starting antibiotic therapy. Histological examination of renal tissue, if done, reveals inflammation of the renal cells.

Imaging studies may be necessary in cases that present insidiously, more subtly, or gradually. A CT scan or ultrasound may reveal renal structures that are reduced in size or hydronephrosis, (edema or retained fluid in the kidney)

**FIGURE 62.2** Pyelonephritis: an infection typically caused by bacteria migrating up the ureter to the kidney.

sometimes due to obstruction. Pathology shows loss of functioning nephrons, infiltration of parenchyma with inflammatory cells, and fibrosis.

### Treatment

Hospitalization allowing treatment with IV antibiotics is usually appropriate for patients suffering from pyelonephritis, which is especially true for pregnant women because of the concern for premature labor with treatment. Elderly or severely ill patients with comorbid conditions (e.g., diabetes, immunodeficiency, or lung disease) also benefit from hospitalization to manage or prevent potential complications. Outpatient treatment may be acceptable for patients with mild to moderate illness and those who can be stabilized with oral antibiotics and adequate hydration and discharged under close supervision. Patients with frequent infections may be treated prophylactically on low-dose antibiotics. Unfortunately, long-term antibiotic use can lead to antibiotic resistance, which poses a challenge in finding effective treatment over time.

### Medications

Medications used in the management of pyelonephritis are typically antibiotics. Management varies depending on the severity of symptoms. The treatment includes outpatient treatment with oral antibiotics or short-stay hospitalization with IV antibiotics with the possible continuation of oral antibiotics upon discharge from the hospital. Broad-spectrum antibiotics combined with an aminoglycoside are typically used. Trimethoprim-sulfamethoxazole (Bactrim) is commonly used because of its effectiveness and low cost in comparison to other antibiotics, but it is contraindicated in patients with a sulfa allergy. Other antibiotics used for pyelonephritis include fluoroquinolones such as ciprofloxacin (Cipro). Caution should be used when antibiotics such as trimethoprim-sulfamethoxazole and the fluoroquinolones are used because these antibiotics are contraindicated in children and child-bearing women as a result of the teratogenic effect on bone growth. Urine culture and sensitivity testing are essential in selecting antibiotics that will eliminate the pathogen and avoid the use of stronger antibiotics that will increase the risk of antibiotic resistance.

### Supportive Interventions

In addition to antibiotic therapy, supportive measures may be necessary, such as fluid replacement. Patients are encouraged to drink at least eight glasses of fluid daily. Intravenous fluids may need to be administered during hospitalization if the patient requires fluid replacement to help “flush out” the kidneys and bladder or if the patient is dehydrated as a result of vomiting. Nonsteroidal anti-inflammatory drugs or narcotic analgesics can be administered to reduce pain. Antipyretic medications can be prescribed to help reduce elevated temperatures that may be associated with the infection. Specific urinary analgesics such as phenazopyridine (Pyridium) help to relieve the symptoms associated with ailments of the lower urinary tract. Drinking cranberry

juice was once believed to increase the acidity of urine, creating an environment that is not conducive to pathogen growth. More recent research indicates it may prevent bacteria from sticking to the urinary tract structures. Regular use is associated with less frequent UTIs in some patients, but it is not a cure or prevention for everyone. Intake of large amounts of vitamin C may also inhibit the growth of bacteria by acidifying the urine.

### Complications

Recurrent infections or poorly treated pyelonephritis can lead to scarring, **chronic kidney disease (CKD)**, or permanent damage. It may also progress to urosepsis. The bacteria can migrate to the bloodstream from the urinary tract, releasing endotoxins that initiate the inflammatory cascade—releasing cytokines and initiating the complement cascade. Widespread inflammation alters metabolism and can cause multisystem organ failure as a result of septic shock. Changes in mental status, fever, tachycardia, tachypnea, hypotension, **oliguria**, and leukopenia are the early signs of urosepsis (see Evidence-Based Practice). Sepsis is discussed in detail in Chapter 14.

## Evidence-Based Practice

### The Association of Urinary Tract Infections and Neuropsychiatric Disorders, Including Delirium, in the Elderly

Urinary tract infections (UTIs) account for an estimated 25% of infections among the elderly. Delirium is prevalent in up to 30% of the elderly population in the United States. For many years, delirium was perceived as a symptom of UTI in the elderly, causing providers to note UTI as a causative factor. They routinely initiate a work-up for UTI when delirium occurs and frequently find bacteriuria and initiate treatment. One systematic review identified a strong correlation between UTI and neuropsychiatric disorders, including delirium.

Evidence-based nursing recommendations:

- Assess for common symptoms of UTI (dysuria, urgency, frequency) when delirium is present.
- Assess for patient baseline cognitive function.
- Confirm laboratory results before administering antibiotics.
- Consider all plausible etiologies when caring for a patient with delirium.
- Consider the presence of comorbidities (e.g., Alzheimer’s dementia, neurological deficit).

Chae, J. H. J., & Miller, B. J. (2015). Beyond urinary tract infections (UTIs) and delirium: a systematic review of UTIs and neuropsychiatric disorders. *Journal of Psychiatric Practice*, 21(6), 402–411.

## Surgical Management

Emergency surgery may be indicated for patients who experience fever persisting longer than 48 hours or positive blood culture results. These clinical manifestations may be indicative of an abscess or/and obstructing calculi, requiring surgical intervention. Surgery may also be indicated in cases where a structural anomaly is potentially causing an obstruction that is the cause of the infection.

## Nursing Management

### Assessment and Analysis

The clinical manifestations observed in patients with pyelonephritis are related to the inflammatory process that occurs because of the infection. Symptoms include low back or flank pain. The patient may complain of bladder spasms and burning during urination. Other urinary symptoms include frequency, urgency, hesitancy, and nocturia. Urine is noted to be hematuric, cloudy, and foul-smelling. Older women may experience nonspecific urinary symptoms such as dysuria or urinary incontinence. In addition to the pain and urinary symptoms, the patient also exhibits the following symptoms:

- Fever
- Chills
- Nausea and vomiting
- Anorexia

### Nursing Diagnoses

- **Infection** related to an impaired urinary elimination
- **Ineffective therapeutic regimen management** related to inadequate knowledge of the disorder

### Nursing Interventions

#### Assessments

- Assess vital signs.

*Hypertermia is a response to infection to kill the microorganisms. Poorly treated infection may result in hypotension and tachycardia as a result of the vasodilation that occurs in the inflammatory response.*

- Assess pain level.

*Back, flank, or groin pain is a diagnostic indicator of pyelonephritis. Continued pain assessment helps evaluate pain-control efforts.*

- Laboratory analysis

- Assess urinalysis and urine culture

*Urine tests are the primary diagnostic tool for pyelonephritis. The urinalysis would indicate pyuria, bacteriuria, and hematuria. A urine culture will help identify the pathogen.*

- Complete WBC count

*A complete WBC count reveals leukocytosis and immature cells, indicating infection.*

- Blood cultures

*Positive blood cultures indicate septicemia, an infection within the bloodstream.*

#### Actions

- Administer prescribed antibiotics as ordered.  
*Administering prescribed antibiotics is important in eradicating the pathogen. Following the prescribed antibiotic regimen helps to reduce antibiotic resistance.*
- Administer prescribed pain medications.  
*Following the prescribed medications helps in providing comfort to the patient.*
- Provide adequate hydration, PO or IV as ordered.  
*Adequate hydration is important in maintaining good urine flow to avoid urine stasis. Hydration may also be necessary to maintain adequate circulating volume in the face of vasodilation associated with inflammation.*

#### Teaching

- Explain the disease condition to the patient and family.  
*It is important that the patient and family can detect early signs and symptoms of pyelonephritis in order to obtain treatment in the early stages, avoid the use of more aggressive antibiotic therapy, reduce antibiotic resistance due to lack of knowledge regarding prescribed medication regimen, and prevent further complications such as chronic pyelonephritis.*
- Instruct the patient and family on how to avoid UTIs (Box 62.1).  
*Instructing the patient and family on avoidance of frequent UTIs helps to prevent complications such as chronic*

## Box 62.1 Teaching Measures to Reduce the Incidence of Urinary Tract Infections

Teaching the patient and family measures to reduce the incidence of urinary tract infections should include:

1. The importance of taking antibiotics as prescribed. Tell the patient and family that symptoms may improve in 1 to 2 days; however, the prescribed antibiotic medication regimen should be completed.
2. Proper hygiene, including instruction on the careful cleansing of the perineal area with soap and water with bathing and after defecating, moving back the folds of the labia, and cleaning the area from front to back with each cleaning, especially after urination
3. The importance of emptying the bladder before and after sexual activity in order to avoid the risk of pathogens entering the urinary tract
4. Urinating regularly throughout the day, suggesting a micturition frequency of every 3 to 4 hours
5. The importance of adequate fluid intake. A full eight glasses of water per day is recommended.
6. Avoiding the use of vaginal douches, harsh soaps, bubble baths, powders, and sprays in the perineal area
7. The signs and symptoms of urinary tract infection, such as frequency, urgency, hesitancy, change in urine color (e.g., cloudy appearance), pain on urination, and fever
8. The use of unsweetened cranberry juice for the prevention of urinary tract infection

*pyelonephritis, possible renal failure from frequent infections as a result of scarring and damage of the renal parenchyma, and antibiotic resistance to the repeated use of antibiotics.*

- Take prescribed medications as ordered.  
*Taking the prescribed medications is important in eradicating the pathogen and preventing antibiotic resistance and providing appropriate pain relief and comfort. Instruct the patient regarding the change in the color of the urine to orange when using phenazopyridine (Pyridium).*
- Instruct the patient and family on the importance of rest.  
*Rest is important for the restorative process during illness.*

### Evaluating Care Outcomes

With proper treatment, follow-up care, and prevention, the prognosis for pyelonephritis is good, and complications such as damage to renal structures, scarring, and chronic pyelonephritis can be avoided. A well-managed patient does not experience the symptoms associated with pyelonephritis, such as burning or pain on urination, urinary frequency, hesitancy, urgency, nocturia, and hematuria. Self-care efforts and compliance with treatment are evident from improvements in symptoms and reductions in recurrent infections.

## ACUTE GLOMERULONEPHRITIS

### Epidemiology

**Glomerulonephritis** is an inflammation of the **glomeruli** of the kidney. It is the third-leading cause of renal failure in the United States. It is caused by autoimmune disorders, such as Goodpasture's syndrome or lupus, vasculitis (blood vessel inflammation), or an infection such as *Streptococcus*. Glomerulonephritis is typically classified as acute or chronic based on the presentation of symptoms. Acute glomerulonephritis develops acutely, typically as a result of a complication from an infection, and can be found in patients across the life span but is most often seen in children and young adults. Chronic glomerulonephritis can result from some of the same causes as acute or may be genetic. It develops more slowly with fewer symptoms and may result in irreversible damage. It may also result from unresolved acute glomerulonephritis. The prognosis of the disease is based on the causative agent and the extent of damage to the glomeruli and surrounding renal structures and functions. Risk factors associated with glomerulonephritis are infections such as recent strep infections, immune diseases such as lupus, vasculitis, hypertension, and diabetes.

### Pathophysiology

Glomerulonephritis is an inflammation of the glomeruli within the Bowman's capsule of the kidney triggered by an immunological mechanism. The glomerulus is a key structure in the nephron consisting of a network of capillaries and is where the first step of filtration and urine formation takes place.

There are two types of antibody-induced immunological conditions affecting the glomerulus in glomerulonephritis.

In type 1, the antibodies produced are specific for antigens within the glomeruli and glomerulus basement membrane (GBM). As a result of that interaction, immunoglobulins and complement are deposited along the basement membrane.

In type 2, the antibodies react to antigens not specific to the glomerulus but still deposit immune complexes along the GBM. Both type 1 and type 2 result in the accumulation of antigens, antibodies, and complement in the glomeruli and GBM, which ultimately results in injury to the glomerular membrane and a decrease in effective filtration through the glomeruli. There is an overall decrease in the **glomerular filtration rate (GFR)** and an increase in permeability to larger-size proteins.

### Connection Check 62.4

What is the etiological process in glomerulonephritis?

- Tubular necrosis caused by bacteria and antibody reactions
- Deposition of immunological complexes and complement along the GBM
- Deposition of bacteria and immunological components within the loop of Henle
- Destruction of proteolytic enzymes contained in the GBM

### Clinical Manifestations

As a result of the increased permeability, protein and blood are seen in the urine as well as WBCs and casts. Patients present edematous, with decreased urine output and hypertension. Renal laboratory tests such as BUN and creatinine are elevated.

### Management

#### Medical Management

#### Diagnosis

Diagnostics of glomerulonephritis include a complete medical history and physical examination and laboratory tests. A urinalysis may reveal the presence of WBCs, RBCs, proteins, and casts. Other laboratory tests include the CBC and differential, which would demonstrate increased WBCs and serum chemistries indicating increased serum BUN and creatinine levels. Decreased albumin and complement levels would also be present. Decreased complement components indicate an immune-mediated response. The diagnosis of acute post-streptococcal glomerulonephritis is made based on a history of group A beta-hemolytic streptococci infection in the throat or a skin lesion. Erythrocyte casts in the urine also suggest acute post-streptococcal glomerulonephritis.

#### Treatment

Treatment is based on the cause of the disease and symptom management. It involves medications and supportive care. Medications focus on antibiotic treatment, most specifically

penicillin for post-streptococcal glomerulonephritis if the infection is actively present. Diuretics and other antihypertensives may need to be added to treat hypertension. The edema is treated with the restriction of sodium and fluids. If the BUN is elevated, reductions in dietary protein may be necessary to reduce the buildup of metabolic waste. Corticosteroids are not always recommended but may be indicated to modulate the inflammatory response triggered by an immunological mechanism. Plasmapheresis may also be considered to reduce the immune-triggered inflammation. Plasmapheresis is an extracorporeal separation of the blood components to filter out immune complexes created as a part of the immunological response. The filtered plasma is discarded while the red blood cells and a replacement colloid such as donor plasma are returned to the patient. Lastly, rest is the most important means of restoration and symptom relief.

### Complications

Ninety-five percent of patients with glomerulonephritis recover if the condition is treated early in the course of the illness, but if untreated or if the patient is unresponsive to treatment, acute or chronic kidney disease may develop. A rapidly progressive form of glomerulonephritis can progress to renal failure within weeks to months.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of glomerulonephritis are present because of the damage to the GBM. They include:

- Hematuria
- Oliguria
- Periorbital edema
- Peripheral edema of lower extremities
- Generalized body edema
- Ascites
- Abdominal or flank pain
- Hypertension

#### Nursing Diagnoses

- **Impaired urinary elimination** related to effects of damage to the glomerular membrane
- **Ineffective therapeutic regimen management** related to lack of knowledge regarding the treatment regimen

### Nursing Interventions

#### Assessments

- Vital signs  
*Hypertension is a common finding because of fluid retention associated with glomerulonephritis. Hypertension is a risk factor for cardiovascular disease, stroke, and renal failure.*
- Daily weights  
*Weight gain is associated with sodium and water retention.*
- Intake and output  
*Measuring intake and output of fluids is essential in assessing the accumulation of fluids. Increases in fluid retention can develop because of the potential sodium retention associated*

*with renal impairment. Fluid retention is a risk factor for elevated blood pressure and heart failure.*

- Measuring abdominal girth or extremity size  
*Measuring abdominal girth and extremity size is important in assessing fluid retention. Fluids tend to pool in dependent areas such as the abdomen or extremities.*
- Skin condition  
*Edema can increase the risk of skin breakdown.*
- Monitor dietary intake  
*A patient with glomerulonephritis has the potential for malnourishment from the excessive loss of protein in the urine because of the damage of the glomeruli. Excess sodium intake can cause fluid retention, resulting in elevated blood pressure and heart failure. Protein intake may need to be limited if the BUN is elevated and there are no signs of malnutrition.*
- Laboratory analysis
  - Renal function tests  
*BUN/creatinine should be monitored to track renal function.*
  - WBC count  
*Elevations in WBC indicate infection.*
  - Urinalysis  
*Protein and RBCs can be found in the urine because of damage in the GBM.*

#### Actions

- Administer antihypertensives as ordered.  
*Diuretics are used to combat sodium and fluid retention. Other antihypertensives such as ACE inhibitors may be prescribed to control blood pressure adequately.*
- Administer corticosteroids as ordered.  
*Corticosteroid agents may be indicated to modulate the inflammatory response triggered by the immunological mechanism.*
- Maintain low- to moderate-protein diet  
*Care must be taken to limit protein intake if the BUN is elevated, but a low- to moderate-protein diet may be needed to treat protein loss through the urine.*
- Dietary sodium and fluid restriction  
*Sodium and fluid restriction is necessary to prevent fluid retention, which can cause elevated blood pressure and heart failure.*

#### Teaching

- Overview of the disease process  
*It is important for the patient and family to understand the disease process and the signs and symptoms associated with glomerulonephritis.*
- Prescribed medications  
*It is essential for the patient and family to understand the medications and their side effects and to report the side effects to the healthcare provider. Medication adherence must be emphasized.*
- Dietary restrictions  
*It is important for the patient and family to understand the salt and water restrictions and the rationale for the restrictions. The amount of protein intake must be followed*

*as prescribed in order to obtain the necessary amount in the event of protein loss.*

- Avoid infections.  
*The patient and family should be instructed on avoiding exposure to infectious diseases, especially if on corticosteroids.*

### Evaluating Care Outcomes

Evaluating care is based on improvements in kidney function and the symptoms associated with glomerulonephritis. Monitoring serum BUN, creatinine, and electrolytes is important in assessing the condition of the patient. Patient teaching can be evaluated by the patient's verbalization of information regarding the condition. A well-managed patient has a blood pressure within normal limits, no edema, and renal function within normal limits.

## RENAL CANCER

### Epidemiology

Renal cancer or kidney cancer is one of the most common cancers in the United States. The United States is projected to have about 63,000 new cases of renal cancer per year. Approximately 14,000 people die from renal cancer per year. Renal-cell carcinoma (adenocarcinoma) is the most common type of renal cancer and occurs more often in males 50 to 70 years old than in females. African Americans and American Indians/Alaskan Natives have slightly higher rates of renal cancer for unknown reasons. The use of cigarettes, pipes, and cigars poses a high risk for the development of renal cancer. Chewing tobacco and other forms of smokeless tobacco such as snus or snuff constitute a significant source of cancer-causing nitrosamines that can increase the risk for several types of cancers, including renal cancer. A familial association has been linked to first-degree relatives and the incidence of renal cancer. Other risk factors associated with adenocarcinoma are obesity; hypertension; exposure to certain substances, such as asbestos, some herbicides, cadmium, and gasoline; certain medicines, such as diuretics; and a cystic disease that occurs with ESRD.

### Connection Check 62.5

Which of the following risk factors has been associated with renal cancer?

- Aspirin use
- Alcohol abuse
- Use of artificial sweeteners
- Cigarette smoking

### Pathophysiology

Renal cancers are usually found in the cortex or pelvis of the kidney. Malignant tumors in the kidney are more frequent than benign tumors. Kidney tumors compress underlying tissues, reducing circulation to the renal structures and damaging underlying tissues. This compression

can lead to compromised renal functioning or renal failure. Thirty percent of malignant tumors have metastasized by the time of diagnosis. Locations of metastasis include the long bones, lungs, and liver. Extension of cancer into the renal vein and vena cava is common.

### Clinical Manifestations

Most patients are asymptomatic initially in the course of the disease. The eventual stretching, compressing, and invading of tumors within the renal structures can cause the classic triad, which includes a flank mass, flank pain, and hematuria. Other symptoms include weight loss, fatigue, hypertension, fever that is not related to infection, and anemia. If there is compression of the testicular vein due to the mass, there may be a varicocele, an enlargement of the venous plexus in the scrotum, present.

### Connection Check 62.6

The nurse recognizes that which patient has the highest risk of renal cancer?

- A 76-year-old African American female
- A 50-year-old Caucasian male
- A 24-year-old Caucasian male
- A 50-year-old African American male

## Management

### Medical Management

#### Diagnosis

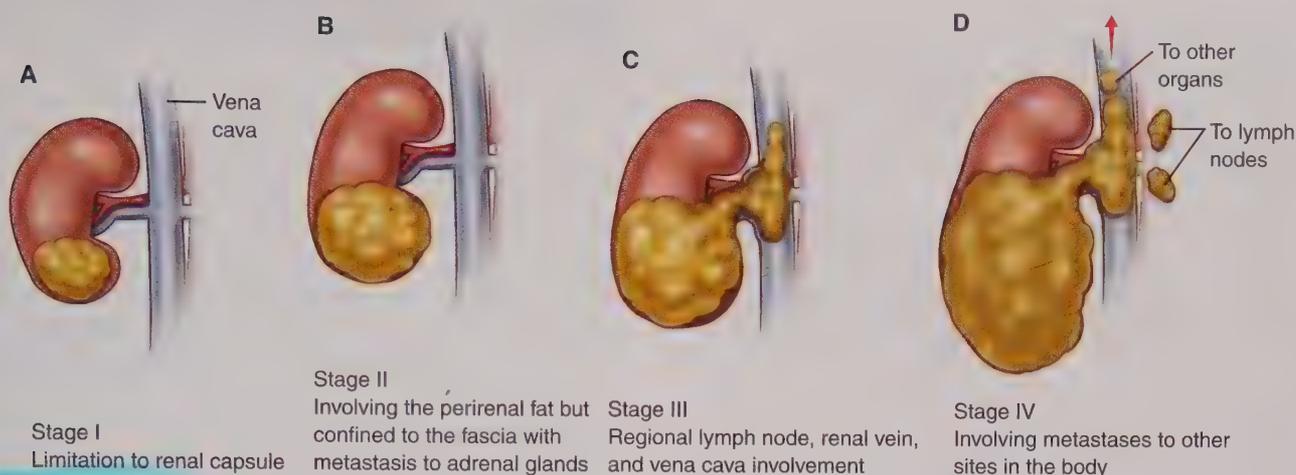

Several studies are needed to diagnose renal cancer. Ultrasound is widely used to differentiate between a solid mass, tumors, and cysts. Other tests for diagnosing renal cancer include angiography, percutaneous needle aspiration, CT scan, and MRI. Radionuclide isotope scanning is used to detect metastasis. Urine cytology testing shows the presence of neoplastic or atypical cells. Renal biopsy is sometimes utilized to look for cancerous tissue cells. Once diagnosed, cancer can be staged to aid in treatment decisions. Robson's system of staging renal carcinoma is one staging system utilized (Fig. 62.3).

#### Medications

Biological immunotherapy such as cytokines, interleukin-2, or interferon can be used to boost the immune system to aid in the destruction of cancer cells. Some targeted medications can be used to block the growth of cancer cells. These therapies can shrink cancer in a small number of patients. Unfortunately, renal cancer cells are resistant to chemotherapy, and thus chemotherapy is not the standard medical treatment.

#### Surgical Management

Treatment of renal carcinoma usually involves surgery. The typical treatment for renal cancer is radical nephrectomy for patients with type I and type II staging and particular

**FIGURE 62.3** Robson's system of staging renal carcinoma.

stage III tumors. Radical nephrectomy involves removal of the affected kidney, adrenal gland, and surrounding tissues, such as the fascia, part of the ureter, and the draining lymph nodes. With early detection, renal cancer has shown a 60% to 70% 5-year survival after undergoing radical nephrectomy. If an early or small-stage cancer, partial nephrectomy or nephron-sparing surgery is considered for treatment. In this procedure, the surgeon attempts to remove just the tumor. When metastasis involves the lungs and long bone or the tumor is inoperable, radiation therapy is used as a palliative measure. Metastatic renal cancer has a survival rate of 3% to 10% at 5 years.

### Complications

The complications of renal cancer involve the disease process as well as the treatment. By compressing and stretching the tissues, renal cancer causes pain and reduces the circulation needed by the tissues. The renal system is highly sensitive to reductions in circulating oxygenated blood and nutrients. If untreated, the reduced circulation can cause end-stage renal failure. If the tumor is not identified in the early stages and treatment initiated, the overall prognosis of the condition is reduced, and the survival rate is poor.

### Nursing Management

#### Assessment and Analysis

Early symptoms of renal cancer are rare in occurrence. The following symptoms can be seen as a result of the size of the mass and compression of the renal tissues:

- Hematuria
- Flank or abdominal pain
- Palpable mass
- Weight loss
- Fever
- Hypertension
- Anemia
- Fatigue

### Nursing Diagnoses

- **Acute pain** related to renal cancer
- **Impaired urinary elimination** related to obstruction of tissues secondary to the tumor
- **Ineffective therapeutic regimen management** related to lack of knowledge regarding the disease process

### Nursing Interventions

#### Assessments

- Vital signs  
*Hypertension may accompany renal cancer. Tachycardia may be an indicator of pain.*
- Pain

*Pain is commonly present because of the size of the mass and compression of the underlying tissue. Assessing pain identifies the need for and effectiveness of pain-control measures. Nurses must assess both objective signs of pain, such as a number from 1 to 10, and other nonverbal signs, such as facial grimaces, tense body position, elevated blood pressure, and rapid pulse or respirations.*

#### Preoperative assessment

- Knowledge  
*Assess the knowledge of the patient and family regarding the disease condition so that they can make informed decisions regarding care and treatment.*
- Full systems assessment  
*Documentation of a full nursing assessment and a plan of care is necessary for baseline comparison data for the postoperative phase.*

#### Postoperative assessment

- Vital signs  
*Accurate assessment of vital signs is crucial to assess recovery. Hypotension and tachycardia may reflect dehydration after surgery and the need for fluid replacement. Increased temperature may indicate surgical site infection. Decreasing SpO<sub>2</sub> may indicate postoperative atelectasis.*

- Monitor intake and output, color, consistency, and amount of urine output.  
*Adequate urine output reflects a good fluid volume status. Urine may be pink initially, but bright red blood in the urine indicates bleeding. Cloudy urine may indicate infection.*
- Incision/site/wound care/patency of tubes and catheters  
*Incisions should be clean, dry, and intact. Red or warm incisions with purulent drainage indicate infection. Drains should be patent. Limited drainage through drains may indicate an obstruction, which may need to be cleared to keep the wound clean.*

### ■ Actions

- Administer medication as ordered.  
*Biological immunotherapy such as cytokines, interleukin-2, or interferon can be used to boost the immune system to aid in the destruction of cancer cells.*

### Postoperative

- Administer pain medication as ordered.  
*Adequate pain control is necessary for the healing process, reducing stress, and allowing the patient to move freely, cough, and breathe deeply, lessening respiratory complications.*
- Administer IV hydration as ordered/encourage PO hydration as ordered.  
*Adequate hydration postoperatively is necessary to maintain circulating volume.*
- Encourage respiratory exercises.  
*Coughing and deep breathing, the use of incentive spirometry, and position changes and ambulation are necessary to prevent respiratory complications.*
- Appropriate care of catheters, stents, nephrostomy tubes, or drains  
*Maintain patency of all drainage tubes; label and document for clarity and communication among providers; maintain gravity drainage as appropriate to prevent backflow of drainage, which increases the risk of infection.*
- Perform wound care as ordered.  
*Change dressing as ordered. Inspection of the site for the presence of redness, swelling, edema, or drainage is important and, if present, indicates infection.*

### ■ Teaching

- Teach the patient and family about the condition and any procedures or diagnostic tests.  
*Explain to the patient and family any anticipated tests or procedures; provide instruction regarding the disease process. Providing instructions can help to alleviate stress and improve recovery.*
- Teach the patient and family regarding medications.  
*Provide information on prescribed medications, including purpose, dose, scheduling, and potential adverse effects, to facilitate compliance with the medication regimen.*
- Provide appropriate resources for counseling regarding the disease process, tests and procedures, changes in body image, and financial concerns  
*Appropriate resources and counseling help alleviate stress and grief. Grief can affect the outcome of care procedures.*

### Evaluating Care Outcomes

A well-managed patient has an understanding of the disease and treatment options. Assessments of a patient's and family's knowledge of the disorder and its management are essential. The patient and family members should be able to report changes in the condition and adverse symptoms throughout the illness and after any procedures. Improvements in elimination patterns and changes in the color of the urine should be monitored for early detection of changes or complications. A well-managed postoperative patient has good pain control, a clean incision, and adequate elimination free from blood or signs of infection.

## RENAL TRAUMA

### Epidemiology

The incidence of renal trauma correlates with the number of motor vehicle collisions, violent crimes, and other accidents that involve speed or poor judgment in an action that may result in damage to the kidneys. This includes any falls, automobile accidents, sports activities, gunshot wounds, stabbings, or significant traumatic injuries, especially if they involve the abdomen, flank, or back. Pelvic fractures can cause perforation and tearing of the tissues in the renal system. A sharp blow may cause contusions, tearing, or rupture of the kidney. The kidneys are vulnerable to injury because of the lack of bone to protect the area as compared to other organs such as the heart, which is protected by the rib cage. Most accidents involve males less than 30 years of age and represent blunt-force trauma.

### Pathophysiology and Clinical Manifestations

The extent of the injury depends on the mechanism of injury, the force, and the speed of the impact. Injuries to the renal system can range from contusion or hematoma to a shattered kidney. Renal trauma is graded according to the extent of the injury (Table 62.1). Urinary output can be reduced or absent as a result of the trauma depending on the damage to the renal system. Hematuria may be present when trauma occurs in the kidney, bladder, or urethra. The amount of hematuria does not necessarily predict the degree of damage to the renal system from the trauma. If bleeding is extensive, clinical manifestations of shock may be present. The patient may complain of back or flank pain; extensive bruising may be present.

### Management

#### Medical Management

#### Diagnosis

Diagnosis of the injury to the renal system is determined by imaging studies such as ultrasound, CT scan, IVP, MRI, or renal arteriography. Both kidneys should be assessed and the findings compared. Urine is evaluated for the presence of blood. A CBC and serum chemistry levels are also

**Table 62.1 Renal Trauma Grading**

Grade	Description
1	Hematuria, contusions, normal imaging studies
2	Nonexpanding hematomas, superficial lacerations
3	Renal lacerations greater than 1 cm in depth not involving the collecting system
4	Renal lacerations or fracture extending into the collecting system  Injuries of the renal artery or vein—controlled hemorrhage  Expanding hematomas compressing the kidney
5	Shattered kidney—severe fracture so that kidney is fragmented  Laceration or thrombus of the renal artery or vein

From the American Association for the Surgery of Trauma (AAST) classification. Retrieved from <http://www.aast.org>.

obtained to reveal complications of the injury, such as the extent of bleeding or damage to renal function.

### Connection Check 62.7

The nurse providing care for the patient post-motor vehicle accident with a suspected injury to the renal system anticipates which of the following orders?

- A. Perform an electrocardiogram (ECG).
- B. Send a urinalysis to the laboratory.
- C. Administer diuretics.
- D. Administer antihypertensives.

### Treatment

Management is based on the extent of the injury. Treatment focuses on stabilizing the patient and surgically repairing any perforations or lacerations. Initial treatments focus on controlling bleeding, preventing shock, and promoting urinary drainage. These treatments include careful monitoring of vital signs, intake and output, and hematocrit levels to assess bleeding. Pain assessment is important and can indicate such conditions as urethral colic or obstruction. Surgery may be required to control severe bleeding; however, small areas of bleeding may be allowed to heal by rest until the hematuria resolves. If the kidneys are intact, rest and observation may be indicated.

### Surgical Management

A small percentage (9%) of injuries require surgical exploration to determine the extent and type of damage. Approximately 11% of these patients require nephrectomy. Nephrectomy is indicated in cases of severe bleeding due to damage of the kidney itself or severe renovascular injury.

### Complications

The most significant complication to consider when taking care of the patient with an injury to the renal system is the extent of damage to the function of the kidney. Bleeding is also a major concern when an injury to the renal system occurs. In rare cases, renal shattering can occur, leading to major renal vascular laceration. As a result, the patient experiences significant hemorrhage, which may be life threatening.

### Connection Check 62.8

Prior to the patient's CT scan, which information should be obtained from the patient or family member?

- A. A family history of CT scans
- B. Time of patient's last meal
- C. List of patient's allergies
- D. Time of last pain medication

### Nursing Management

#### Assessment and Analysis

Clinical manifestations are based on the extent of renal trauma. They include:

- Gross hematuria
- Flank pain
- A palpable flank mass
- Back/flank bruising
- Hypotension and tachycardia with severe blood loss

#### Nursing Diagnoses

- **Acute pain** related to renal trauma
- **Impaired urinary elimination** related to trauma or blockage of the ureters or urethra

#### Nursing Interventions

##### Assessments

- Vital signs  
*Changes in vitals can provide valuable information regarding the patient's overall status. Hypotension and tachycardia may indicate blood loss.*
- Pain  
*Nursing interventions focus on assessing the need for pain control and the effectiveness of pain-relief measures. Increased pain may indicate the severity of the injury.*
- Urine output and color  
*Oliguria may indicate an obstruction. Hematuria may indicate extensive damage and bleeding.*
- Laboratory values
  - Urinalysis  
*A urinalysis may reveal microscopic blood that is not immediately apparent.*
  - Renal function  
*Baseline renal function should be established to determine changes as time progresses.*
  - Hemoglobin/Hematocrit  
*Decreasing hemoglobin/hematocrit may indicate bleeding.*

- Knowledge  
*Assess the knowledge of the patient and family regarding the trauma, medication, procedures, or surgery so that they can make informed decisions regarding care and treatment.*

#### ■ Actions

- Administer pain medications as necessary.  
*Adequate pain control is necessary for the healing process, reducing stress and promoting the patient to move freely, cough, and breathe deeply, lessening respiratory complications.*
- Administer fluids as ordered.  
*Adequate hydration is necessary to maintain circulating volume, especially if bleeding is present.*
- Provide incision care as ordered.  
*If surgery has occurred, inspection of the site for the presence of redness, swelling, edema, or drainage is essential to evaluate healing. Complications such as infection or bleeding may be apparent.*
- Encourage rest.  
*Rest may be the preferred treatment to allow the kidneys to heal if surgery is not indicated.*

#### ■ Teaching

- Teach the patient and family about the condition and any procedures or diagnostic tests.  
*Explain to the patient and family any anticipated tests or procedures; provide instruction regarding the disease process. Providing instruction can help to alleviate stress and improve the recovery process.*
- Teach the patient and family regarding medications.  
*Provide information on prescribed medications, including purpose, dose, scheduling, and potential adverse effects.*

#### Evaluating Care Outcomes

Evaluating nursing outcomes is based on monitoring the patient's condition through vital signs and the amount of bleeding. Fluid replacement or blood transfusions may be necessary to maintain homeostasis. A well-managed patient has vital signs within reasonable limits, minimal bleeding, and adequate urinary output and good pain control.

## RENAL FAILURE

Renal failure is the partial or complete inability of the kidneys to filter waste products and water from the blood through glomerular and tubular filtration. The function of the kidneys is essential to the entire body. If the kidneys fail to function properly, the remainder of the organ systems will be affected, and multisystem organ failure will occur. **Acute kidney injury (AKI)** is a rapid, acute disease process that, in most cases, is reversible if addressed in a responsive and timely manner. However, if AKI is not addressed immediately, chronic kidney disease (CKD) is inevitable.

Chronic kidney disease usually develops more slowly than AKI and can occur over months to years. The treatment for CKD is long-term dialysis or a renal transplant for survival. Advances in technology, interventions, and

medication therapies have improved the life expectancy of individuals with CKD. Careful monitoring of CKD and compliance by the patient with the treatment plan can improve outcomes.

## ACUTE KIDNEY INJURY

### Epidemiology

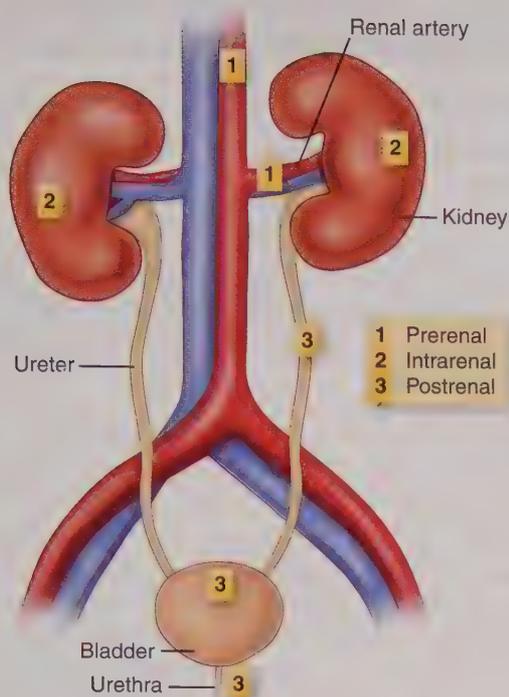

Acute kidney injury is a condition characterized by an acute, rapid loss of renal function. Evidence indicates that the incidence of AKI is increasing, particularly among hospitalized patients with acute illness or those undergoing major surgery. Recent data suggest 2,000 to 3,000 cases annually or 200 to 300 cases per million population annually. The increase in incidence might be partially attributable to higher sensitivity in classification. Other causes could be increased incidence of cardiovascular disease and diabetes mellitus and an expanding list of modifiable risk factors, such as sepsis, administration of contrast media, and exposure to nephrotoxins. Also, an aging population increases the incidence of AKI. Older adults are more vulnerable to AKI because of the decline in the number of nephrons with aging.

### Pathophysiology

Acute kidney injury is defined as rapid and progressive azotemia, an accumulation of nitrogenous waste products such as urea, nitrogen, and creatinine and progressive increases in potassium. Oliguria may be present and is defined as a reduction of urine output to 400 mL per day. Uremia may be present and is defined as a renal function decline that involves multiple body systems. Fifty percent of AKI cases are nonoliguric. Patients with nonoliguric failure generally recover much more quickly than oliguric patients and have fewer complications. Oliguric patients are at an increased risk for CKD if circulating fluid volume is not returned to normal. The causes of AKI vary, but there are three major categories: prerenal, intrarenal, and postrenal (Fig. 62.4).

### Prerenal Causes

Prerenal causes, the most common cause of AKI, are a result of external factors (those that are not related to the anatomical structures of the urinary system) that reduce renal blood flow and lead to decreased glomerular perfusion and filtration. Decreased renal perfusion affects the clearance of waste products, also known as azotemia. Hypovolemia, decreased cardiac output, decreased peripheral vascular resistance, and vascular obstruction can affect circulation. The renal system senses the decrease in perfusion, which stimulates the renin-angiotensin-aldosterone system (RAAS). The RAAS is a compensatory mechanism that conserves sodium and water in order to maintain blood pressure. The result is low urine output with an increase in BUN and creatinine (ratio of > 10:1) and an inability of the kidneys to conserve sodium. If renal perfusion remains compromised and compensatory mechanisms fail, then

**FIGURE 62.4** Causes of acute kidney injury. Prerenal causes include external factors that reduce renal blood flow. Intrarenal causes involve direct damage to the renal system. Postrenal causes involve mechanical obstruction of the lower urinary tract.

intrarenal damage to renal tissue may occur. Prerenal conditions account for 60% to 70% of the conditions leading to intrarenal damage. If assessment and treatment occur quickly, the intrarenal damage is typically resolved once the cause is removed.

### Intrarenal Causes

Intrarenal causes of AKI involve direct damage to the renal parenchymal tissues, resulting in impaired nephron functioning. The **nephron** is the functional unit of the kidney, and any direct assault to the nephron significantly compromises the perfusion and filtration of waste products. The damage occurs as a result of prolonged ischemia, exposure to nephrotoxins such as aminoglycoside antibiotics, contrast dye used in imaging studies, hemoglobin released from hemolyzed RBCs, or myoglobin released from necrotic muscle cells. Nephrotoxins cause crystallization or damage to the epithelial cells of the tubules. Hemoglobin and myoglobin block the tubules and cause renal vasoconstriction. Acute glomerulonephritis and acute tubular necrosis (ATN) are also causes of AKI.

Acute tubular necrosis is an intrarenal condition caused by ischemia, nephrotoxins, or pigments and accounts for 90% of all intrarenal cases. The ischemia of the basement membrane and tubular epithelium seen in ATN results in a decreased GFR. Acute tubular necrosis is reversible if it is identified early and appropriate measures are taken. In most cases, nephrotoxic agents such as aminoglycoside antibiotics are the causative factors, and removal of these substances aids in reversing the disease process.

### Postrenal Causes

Postrenal causes involve mechanical obstruction of the lower urinary tract (the ureters, bladder, and urethra). As the urine leaves the kidneys, flow is obstructed at some point at the ureters or below, causing reflux into the renal pelvis, impairing kidney function. Postrenal causes include BPH, prostate cancer, calculi, trauma, and tumors. Postrenal causes account for fewer than 5% of all cases, and the potential associated intrarenal damage is typically reversible if the obstruction is removed quickly. If the obstruction is not removed, AKI occurs.

### Connection Check 62.9

Which is a prerenal cause of AKI?

- Acute glomerulonephritis and neoplasms
- Septic shock and nephrotoxic injury from medications
- Pyelonephritis and calculi formation
- Hypovolemia and myocardial infarction

### Phases of Acute Kidney Injury

Acute kidney injury may progress through four phases: the initiating, or onset, phase when kidney injury first occurs; the oliguric phase when urine output decreases because of renal tissue damage; the diuretic phase when the healing begins; and the recovery phase when renal function begins to improve.

#### Initiating Phase

The initiating, or onset, stage is the beginning phase of the insult, continuing until signs and symptoms appear. This phase can last for hours to days. Triggering events typically arise from prerenal conditions that result in an approximate 25% decrease in circulating volume, resulting in an equal decrease in tissue oxygenation. Compensatory mechanisms cause the release of angiotensin II, aldosterone, norepinephrine, and antidiuretic hormone to preserve the blood flow to essential organs. Vasoconstriction occurs along with sodium and water retention. A decrease in urine output accompanied by a high specific gravity of urine and a low urine sodium concentration are observed in the initiating phase. If the prerenal cause is corrected, the condition is reversible.

#### Oliguric Phase

A clinical manifestation of the oliguric phase is a urine output below 400 mL per day. Oliguria in this phase, in contrast to the oliguria seen in prerenal failure or in the initiating phase before intrarenal damage occurs, is characterized by urine with a fixed specific gravity (between 1.007 and 1.010) and a high sodium concentration (> 40 mEq/L [ $> 40$  mmol/L]). A high sodium concentration with a fixed specific gravity indicates intrarenal damage that does not respond to the compensatory mechanisms of RAAS. Complicating the diagnosis is the fact that 50% of patients may not exhibit oliguria, allowing more damage to occur before disease detection.

Also in this phase, there are increases in BUN/creatinine, electrolyte abnormalities, acidosis, and fluid overload as a result of reduced GFR. This phase may last up to 14 days or longer depending on the initiation of definitive treatment such as dialysis. The longer the oliguric phase lasts, the poorer the prognosis.

### Diuretic Phase

This phase occurs when the cause of AKI has been corrected. There is an osmotic diuresis resulting from high urea levels. Urine output can increase from 1 to 3 L to 3 to 5 L a day. The patient may experience severe fluid loss as a result of increased urination, leading to dehydration and causing electrolyte imbalances. This phase can last from 1 to 3 weeks. As this phase ends, acid-base, electrolytes, BUN, and creatinine levels begin to normalize.

### Recovery Phase

The recovery phase begins as the kidney begins to return to its regular excretory function. During this stage, the basement membrane is restored, and the GFR increases up to 70% to 80% of normal. Fluid and electrolyte balance normalize. The recovery phase can last from several months to 1 year.

### Clinical Manifestations

Clinical manifestations include signs of volume overload due to decreased urine output, such as edema, pulmonary edema and shortness of breath, heart failure and jugular vein distention, hypertension, and dysrhythmias; chest pain; or pressure. Electrolyte imbalances include increased potassium, phosphorus, BUN/creatinine; decreased calcium, sodium, and pH; and metabolic acidosis (Table 62.2). Patients may suffer from anorexia, nausea, constipation, or diarrhea. Patients may become confused and lethargic, and with severe fluid and electrolyte imbalances, they may suffer seizures or coma.

### Connection Check 62.10

When the patient is in the diuretic phase of AKI, the nurse must monitor which serum electrolyte imbalance?

- Hypokalemia and hyponatremia
- Hypokalemia and hypernatremia
- Hyperkalemia and hyponatremia
- Hyperkalemia and hypernatremia

### Management

#### Medical Management

The goals of managing AKI are to eliminate the cause, prevent complications, and assist the patient in recovery. It is primarily supportive and involves ensuring adequate circulating volume, correcting fluid overload, and correcting biochemical abnormalities. Assessment of adequate hydration is essential for maintaining appropriate intravascular

**Table 62.2 Manifestations of Kidney Disease**

Manifestation	Cause
<b>Urine volume decreases</b>	<ul style="list-style-type: none"> <li>● Initiating phase—urine output decreases because of decreases in circulating volume and the resulting compensatory mechanism of RAAS</li> <li>● Oliguric phase—decreased filtration through damaged renal tissues</li> </ul>
<b>Fluid overload</b>	Overload due to decreases in urine output
<b>Increased potassium</b>	Impaired excretion
<b>Decreased sodium</b>	Inability to conserve sodium
<b>Decreased calcium/ increased phosphorus</b>	<ul style="list-style-type: none"> <li>● Decreased GI absorption of calcium due to the kidneys' inability to activate vitamin D</li> <li>● Decreased calcium stimulates the parathyroid gland to release parathyroid hormone, which stimulates the release of calcium and phosphorus from bone.</li> <li>● Decreased phosphorus clearance</li> </ul>
<b>Metabolic acidosis</b>	<ul style="list-style-type: none"> <li>● Decreased acid excretion</li> <li>● Increased loss of bicarbonate</li> <li>● Increased production of nonvolatile acids such as lactic acid or phosphoric acid</li> </ul>
<b>Anemia</b>	Impaired erythropoietin production
<b>Increased BUN</b>	Impaired clearance, dehydration, increased protein intake and breakdown
<b>Increased creatinine</b>	Impaired clearance—the best indicator of renal failure

BUN, Blood urea nitrogen; GI, gastrointestinal; RAAS, renin-angiotensin-aldosterone system.

volume and cardiac output. Assessment includes monitoring of blood pressure, heart rate, urine output, and clinical signs such as the quality of pulses, skin color, temperature, and respiratory status. Fluid intake and output must be carefully and closely monitored and documented.

#### Medications

Diuretic therapy may be used, including loop diuretics such as furosemide (Lasix) or bumetanide (Bumex), and an osmotic diuretic (mannitol) to treat fluid overload. Nephrotoxic agents such as contrast dyes should be avoided or used with extreme caution. Treatment of hyperkalemia, an essential component of care, is discussed under “Complications.”

#### Nutrition

Nutritional therapy is an important element of supportive care for patients in AKI. The goal of nutrition for patients

in AKI is to provide calories to prevent catabolism despite the restrictions required to prevent electrolyte and fluid disorders and azotemia. If the patient does not receive proper nutrition and calories, then catabolism of body protein will occur, which causes urea, phosphate, and potassium levels to increase. Adequate carbohydrate, protein, and fat are necessary components of the diet. Potassium and sodium are strictly regulated. Sodium is restricted to prevent edema, hypertension, and congestive heart failure; potassium is restricted to avoid the cardiac complications of hyperkalemia.

### Dialysis

Dialysis may need to be considered in the short term to allow recovery of the renal tissue while preventing possible life-threatening disorders. Indications for dialysis include:

- Severe volume overload resulting in heart failure or severe respiratory distress
- Elevated potassium level with ECG changes
- Severe metabolic acidosis
- Altered mental status
- Pericarditis, pericardial effusion, and cardiac tamponade

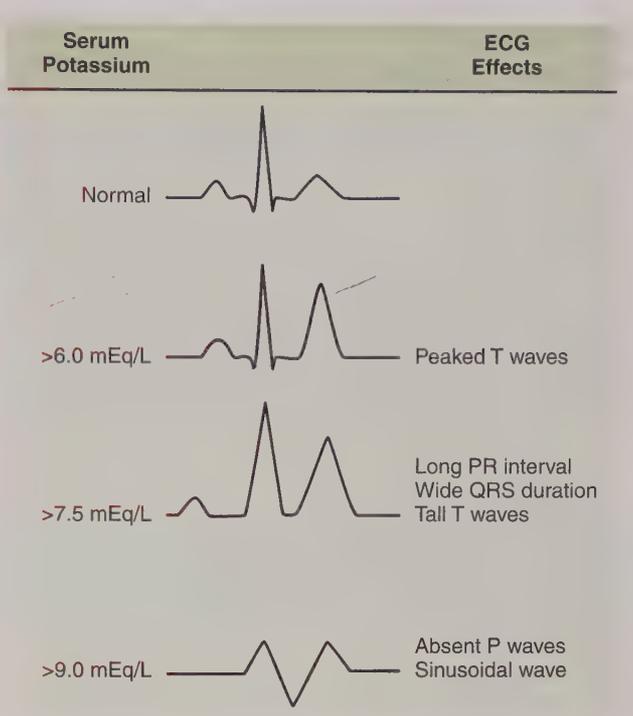

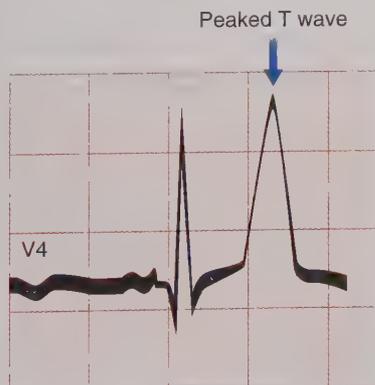

Dialysis is discussed in detail later in the chapter.

### Complications

Hyperkalemia is a severe complication in AKI because of the risk of life-threatening cardiac arrhythmias (see Safety Alert).

#### **Safety Hyperkalemia Alert**

Hyperkalemia decreases the threshold necessary to generate an action potential, which can result in life-threatening dysrhythmias such as ventricular fibrillation, ventricular tachycardia, or asystole. The initial indication of hyperkalemia on ECG is peaked T waves. Worsening hyperkalemia is indicated by a widening of the QRS complex, the loss of the P wave, and finally the presence of the sine wave.

Hyperkalemia is a medical emergency because it can lead to cardiac arrest. The primary goals of medical management include:

- Stabilize the myocardial cell membrane through the administration of IV calcium gluconate or calcium chloride. Calcium chloride is more concentrated than calcium gluconate but can cause severe irritation and pain when given intravenously.
- Enhance cellular uptake of potassium.
  - Administration of IV glucose followed by IV regular insulin. Insulin facilitates the intracellular movement of potassium. *Glucose is given first to avoid the hypoglycemia that could result from IV insulin administration.*
  - Administration of albuterol, a beta agonist, facilitates the intracellular movement of potassium.
  - Administration of bicarbonate stimulates an exchange of hydrogen ions and potassium ions, moving potassium into the cell.
- Enhance total body elimination of potassium.
  - Administration of PO (or per rectum) sodium polystyrene sulfonate (Kayexalate), which binds with potassium and facilitates elimination in the stool. The patient should be monitored for water and sodium retention because of the fluid shifts that result from this treatment. Kayexalate should never be given to a patient with paralytic ileus because the fluid shift creates a risk of necrotic bowel.
  - Administration of IV furosemide (Lasix), a loop diuretic, facilitating the elimination of potassium in the urine.
  - Emergent hemodialysis (HD)

## Nursing Management

### Assessment and Analysis

The clinical manifestations of AKI are related to the decreased glomerular filtration, resultant fluid overload, and impaired clearance of electrolytes and waste products. They include:

- Urinary output decrease to less than 400 mL in 24 hours
- Laboratory abnormalities
  - Serum BUN elevation
  - Serum creatinine elevation
  - Normal or below-normal levels of serum sodium
  - Calcium deficit
  - Phosphorus excess
  - Elevated potassium level
  - Anemia
  - Metabolic acidosis
- Fluid volume overload as evidenced by
  - Neck vein distention
  - Bounding pulse
  - Edema
  - Hypertension
  - Heart failure, if uncorrected
  - Pulmonary edema, if uncorrected
  - Pericardial and pulmonary effusion
- Lethargy
- Stupor

### Nursing Diagnoses

- **Excess fluid volume** related to renal failure and fluid retention
- **Fatigue** related to anemia, metabolic acidosis, and uremic toxins
- **Potential complications:** dysrhythmias arising from electrolyte imbalances
- **Potential complications:** metabolic acidosis related to the inability to excrete  $H^+$ , impaired  $HCO_3^-$  reabsorption, and decreased synthesis of ammonia

### Nursing Interventions

#### Assessments

- Vital signs  
*Hypotension and tachycardia may be present initially, reflecting a hypovolemic state causing the AKI. Later, hypertension will be present because of fluid overload.*
- Urine output  
*Urine output is decreased initially because of decreased circulating volume. Later, it will be decreased because of impaired clearance.*
- Laboratory values
  - BUN/creatinine  
*Increased because of the reduced clearance*
  - Potassium  
*Increased because of the reduced clearance*
  - Sodium  
*Decreased because of the kidney's inability to conserve sodium*
  - Hemoglobin/hematocrit  
*Decreased because of the kidney's decreased production of erythropoietin*

- Calcium/phosphorus  
*Calcium is decreased because of the kidney's inability to activate vitamin D. Phosphorus is increased because of the release of parathyroid hormone (PTH) in response to low calcium, releasing both calcium and phosphorus from the bone.*
- Arterial blood gases  
*Metabolic acidosis due to inadequate clearance of acid, increased loss of bicarbonate, and increased production of nonvolatile acids*
- Oxygenation and breath sounds  
*Breath sounds may reveal rales due to fluid overload and pulmonary edema decreasing oxygenation and  $SpO_2$ .*
- Peripheral vascular system  
*Signs of fluid overload include edema and jugular vein distention.*

#### Actions

- Manage fluid balance.  
*Initially, cautious fluid administration may be necessary to ensure adequate circulating volume. Later, fluid restriction may be necessary to ease or prevent complications of fluid overload.*
  - Administer diuretics as ordered.  
*Diuretics are necessary to relieve fluid overload.*
  - Administer potassium-lowering therapy as necessary.  
*Elevated potassium can cause lethal dysrhythmias.*
  - Positioning, ambulation, cough, and deep-breathing exercises  
*Positioning or ambulation as the patient tolerates eases the work of breathing and prevents complications of immobility such as atelectasis and pneumonia.*
  - Weigh the patient daily.  
*Increased weight may reflect fluid overload. Weight is used to make the dialysis plan (discussed under "Dialysis" later in the chapter).*
  - Skin care  
*Edema decreases tissue perfusion and increases the risk of decubitus. Keep the skin clean and dry, and change the patient's position frequently.*
  - Monitor and document food intake.  
*Monitoring food intake provides information regarding nutrition status, which is important for the healing process. Consult with a dietitian to assist the patient and family with food preparation for special diets such as reduced sodium and potassium.*
- #### Teaching
- Knowledge of the cause and treatment of AKI  
*To help manage anxiety and maximize compliance with treatment, the patient should have a good understanding of the cause of AKI and treatment, which includes fluid and dietary restrictions (decreased sodium, limited protein), careful monitoring of urine output, avoiding nephrotoxic substances (NSAIDs, some antibiotics, radiological contrast dye, alcohol), and dialysis (if necessary).*

### Evaluating Care Outcomes

A well-managed patient complies with the prescribed treatment regimen and returns to normal urine excretion with the elimination of waste products from the circulation through

proper glomerular membrane perfusion and filtration. Complications such as heart failure, prolonged hypertension, pulmonary edema, dysrhythmia, or renal failure are avoided. The patient has a complete recovery.

## CHRONIC KIDNEY DISEASE

### Epidemiology

Chronic kidney disease (CKD) is a worldwide public health problem with a steadily increasing incidence and prevalence. One in seven Americans has CKD. The absolute prevalence of CKD is anticipated to increase by 60% from 484,995 in 2005 to approximately 785,000 by 2020, according to data from the U.S. Renal Data System. The absolute incidence is anticipated to increase by 41% by 2020. Data from 2010 and 2015 reveal an incidence of 120,253 in 2010 and 132,978 in 2015. The prevalence is higher for individuals 60 or older. Rates are higher in African Americans and Native Americans than in Caucasians and are higher in men than in women. The most common causes of CKD are diabetes and hypertension. Other risk factors include hyperlipidemia; smoking; the use of recreational drugs and

NSAIDs; obesity; glomerulonephritis; and other disorders such as PKD, lupus, and atherosclerosis.

### Connection Check 62.11

The risk factor or factors most often associated with CKD include which of the following? (*Select all that apply.*)

- A. Hypertension
- B. Diabetes mellitus
- C. Malnutrition
- D. Peripheral vascular disease
- E. Smoking

### Pathophysiology

Chronic kidney disease is the progressive, irreversible loss of kidney function. It is characterized by slow increases in BUN and creatinine. Different from AKI, it has a longer, more insidious onset and is typically caused by a long-term disease or medical comorbidities such as hypertension, diabetes, lupus, PKD, and pyelonephritis (Table 62.3).

**Table 62.3 Acute Kidney Injury Versus Chronic Kidney Disease**

	Acute Kidney Injury (AKI)	Chronic Kidney Disease (CKD)
<b>Etiology</b>	<p>Usually caused by an event that leads to kidney injury:</p> <ul style="list-style-type: none"> <li>● Dehydration</li> <li>● Hypovolemia</li> <li>● Surgery</li> <li>● Infection</li> <li>● Medications</li> <li>● Injury or trauma</li> </ul>	<p>Usually caused by a long-term disease that leads to decreased renal function over time:</p> <ul style="list-style-type: none"> <li>● Uncontrolled diabetes</li> <li>● Uncontrolled hypertension</li> <li>● Malnutrition</li> <li>● Polycystic kidney disease</li> </ul>
<b>Clinical features</b>	<p>Rapid onset may be reversible; symptoms may develop at the time of the event that causes the injury:</p> <ul style="list-style-type: none"> <li>● Electrolyte imbalances</li> <li>● Oliguria</li> <li>● Azotemia</li> <li>● Hypertension</li> <li>● Decreased GFR</li> <li>● Fluid retention</li> </ul>	<p>Slow onset, chronic disorder; may be asymptomatic until very little renal function remains:</p> <ul style="list-style-type: none"> <li>● Anemia</li> <li>● Calcium and vitamin D deficiency</li> <li>● Oliguria</li> <li>● Azotemia</li> <li>● Hypertension</li> <li>● Decreased GFR</li> <li>● Fluid retention</li> <li>● Uremia</li> </ul>
<b>Laboratory values</b>	<ul style="list-style-type: none"> <li>● Sudden increases in BUN and creatinine levels</li> <li>● Increased urine specific gravity</li> <li>● Sudden reduced GFR</li> </ul>	<ul style="list-style-type: none"> <li>● Slow increases in BUN and creatinine</li> <li>● Decreased serum calcium</li> <li>● Decreased hemoglobin and hematocrit</li> <li>● Increased serum phosphate</li> <li>● Increased urine protein</li> </ul>

BUN, Blood urea nitrogen; GFR, glomerular filtration rate.

It may also be the result of poorly managed AKI. Chronic kidney disease may be asymptomatic until very little renal function remains. Advanced stage kidney disease is referred to as end-stage renal disease (ESRD).

### Clinical Manifestations

Chronic kidney disease has a devastating effect on every system in the body (Fig. 62.5). Alterations in sodium and fluid balance result in hypertension, heart failure, and pulmonary edema. Altered potassium excretion can result in lethal arrhythmias. Impaired metabolic waste elimination results in uremia and GI symptoms such as nausea, vomiting, and anorexia and neurological symptoms such as a headache, lethargy, fatigue, confusion, and ultimately, without treatment, seizures and coma. Altered calcium and phosphorus levels result in bone breakdown and osteodystrophies or defective bone development. Decreased acid clearance and bicarbonate production result in metabolic acidosis. Endocrine and reproductive dysfunctions occur, such as infertility, amenorrhea, hyperparathyroidism, and thyroid abnormalities.

Decreased production of erythropoietin results in chronic anemia.

### Management

#### Medical Management

#### Diagnosis

The diagnosis of CKD is based on consistently elevated serum creatinine levels and decreased creatinine clearance, both of which are impacted by the GFR. Another key indicator is the persistent presence of protein/albumin in the urine. Urinalysis can also detect RBCs, WBCs, protein, casts, and glucose. See Table 62.4 for a listing of laboratory values in CKD. Imaging studies such as renal ultrasound, CT scans, and a renal biopsy can provide additional information on the status of kidney structure and function.

Chronic kidney disease can be staged based on GFR and protein in the urine, with six stages delineated by GFR and three stages delineated by albuminuria or the albumin-to-creatinine ratio (ACR). This staging provides guidance for the detection and management, including risk stratification for complications, of CKD (Table 62.5). For example, a patient with G6 and A3 has a very high risk for all-cause mortality.

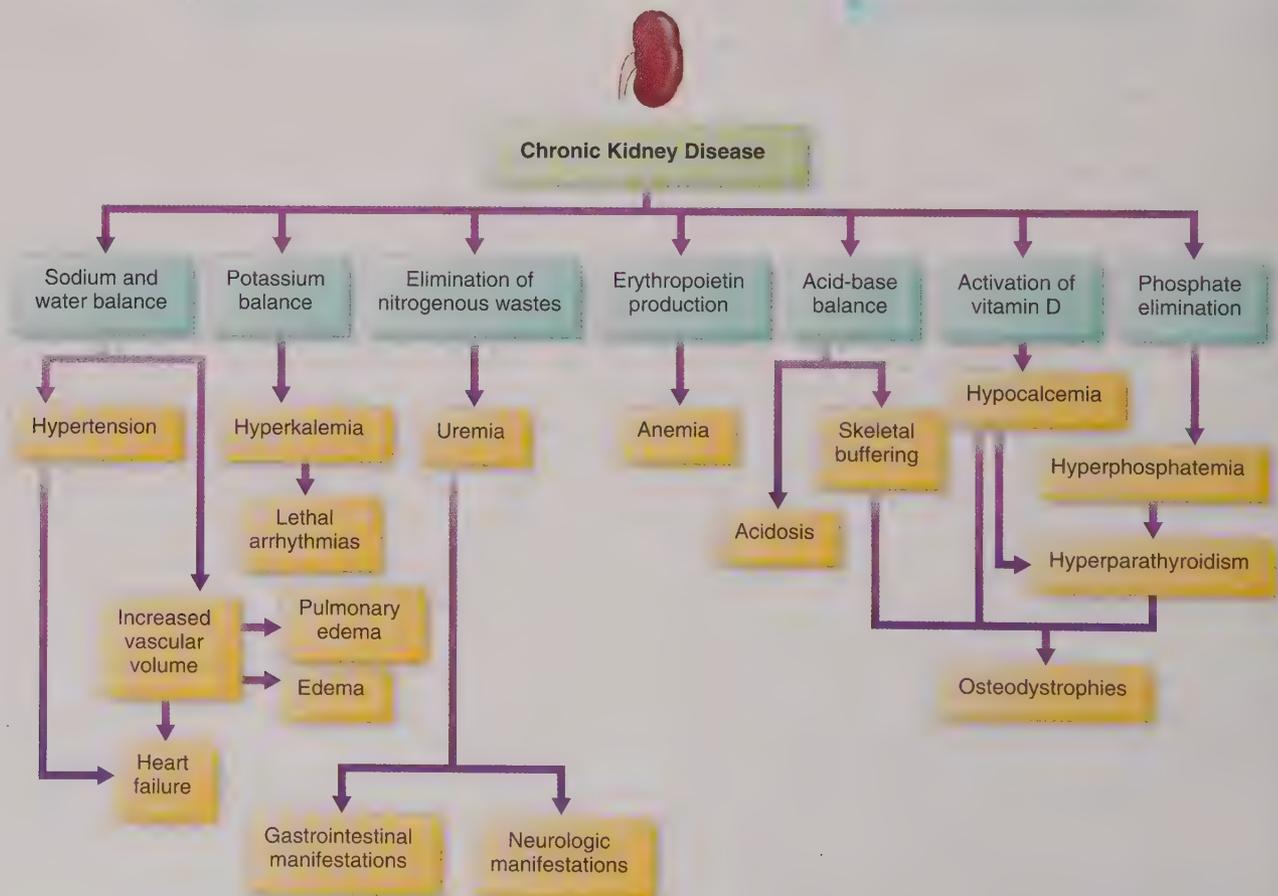

FIGURE 62.5 Clinical manifestations of chronic kidney disease.

**Table 62.4 Laboratory Values Related to Renal Failure**

Test	Normal Value	Value in Renal Failure
Creatinine	0.5–1.2 mg/dL	Increased
BUN	8–21 mg/dL	Increased
Serum sodium	135–145 mEq/L	Normal or decreased
Serum potassium	3.5–5.0 mEq/L	Increased
Serum phosphate	2.5–4.5 mg/dL	Increased
Serum calcium	8.2–10.2 mg/dL	Decreased
Serum CO <sub>2</sub>	23–29 mEq/L	Decreased
Arterial pH	7.35–7.45	Decreased
Hemoglobin	Male 14–17.3 g/dL Female 11.7–15.5 g/dL	Decreased
Hematocrit	Male 42–52% Female 36–48%	Decreased
Urine protein	6–8 g/dL	Increased
Creatinine clearance	88–137 mL/min	Decreased

BUN, Blood urea nitrogen.

**Table 62.5 Stages of Chronic Kidney Disease**

G Stages	A Stages
G1 = GFR >90 mL/min	A1 = ACR <30 mg/g
G2 = GFR 60–89 mL/min	A2 = ACR 30 to 299 mg/g
G3a = GFR 45–59 mL/min	A3 = ACR >300 mg/g
G3b = GFR 30–44 mL/min	
G4 = GFR 15–29 mL/min	
G5 = GFR <15 mL/min	

ACR, Albumin-to-creatinine ratio; GFR, glomerular filtration rate;

### Connection Check 62.12

The nurse understands that CKD is characterized by which of the following?

- A rapid decrease in urine output with a CKD-elevated BUN
- Progressive, irreversible destruction to the kidneys
- Abrupt increasing creatinine clearance with a decrease in urinary output
- Confusion and somnolence leading to coma and death

### Treatment

Once the patient has developed CKD, measures to remove the waste products should be immediately implemented. Removal of waste products is managed through renal replacement therapies (RRTs), which are discussed in detail later in the chapter. Secondary but essential goals are to support the remaining function of the kidneys, treat the patient's clinical manifestations, and prevent any complications. Preventive and maintenance therapies focus on managing and controlling hyperkalemia, hypertension, anemia, dyslipidemia, and renal osteodystrophies, which involves managing phosphate levels, hyperparathyroidism, and hypocalcemia. Medication and nutrition management are also key factors.

#### Hyperkalemia

Elevated potassium levels can be lethal and must be addressed immediately to avoid serious complications. Potassium can be cleared via dialysis or by managing diet—restricting foods high in potassium in the diet—and when acutely elevated, medication therapy may be necessary to reduce the serum potassium level. Acute hyperkalemia may require IV calcium gluconate to stabilize the cardiac membrane. Intravenous glucose and insulin, albuterol, or bicarbonate may be administered to stimulate the movement of potassium into the cell. Intravenous furosemide is administered to improve clearance through the kidneys.

Sodium polystyrene sulfonate (Kayexalate), a cation-exchange resin, is another treatment commonly used to lower elevated serum potassium levels. It binds with potassium in the GI tract to allow excretion in the stool. Diarrhea is expected with this treatment because the medication contains sorbitol, a sugar alcohol that exerts an osmotic laxative action that causes evacuation of the potassium from the bowel (see Safety Alert: Hyperkalemia).

#### Hypertension

Hypertension must be managed both before and after a diagnosis of renal failure. The target blood pressure should be around 130/80 mm Hg. Treatment measures for hypertension include weight loss for obese patients; lifestyle changes such as exercise, avoidance of alcohol, smoking cessation, and diet modification; and prescribed medication compliance. Medication therapy includes:

- Diuretics
- Beta-adrenergic blockers
- Calcium channel blockers
- ACE inhibitors
- Angiotensin-receptor blocker agents

#### Anemia

Anemia is caused by the decreased production of erythropoietin by the kidney. Guidelines recommend that hemoglobin levels should be 11 to 12 g/dL and hematocrit should be 33% to 36% for patients with CKD. Because of recombinant DNA technology, erythropoietin can be produced and administered intravenously or subcutaneously.

Improvements in hemoglobin levels can be noted in 2 to 3 weeks, which is reflected in improved cardiac performance and exercise tolerance and an enhanced quality of life. Hypertension can emerge as a complication of erythropoietin because it increases whole-blood viscosity.

Oral iron supplements may be needed if the ferritin concentrations fall below 100 ng/mL. Constipation is a side effect of oral iron supplements, requiring stool softeners. If iron levels are not increased with oral supplements, then parenteral iron injection may be used. Supplemental oral folic acid (1 mg daily) is also given because folic acid is removed with dialysis. Folic acid enhances the formation of RBCs.

Blood transfusions are an option but should be used only if the patient is actively bleeding and is symptomatic with dyspnea, excess fatigue, tachycardia, palpitations, or chest pains. Undesirable effects of transfusions include the suppression of erythropoiesis, which is stimulated in the face of hypoxia, and because each unit of blood contains about 250 mg of iron, there is a possibility of iron overload.

#### *Dyslipidemia*

Because of alterations in lipoprotein metabolism in CKD, dyslipidemia is another complication with CKD. Recommendations for patients with CKD include a goal of lowering low-density lipoproteins (LDLs) below 100 mg/dL (2.6 mmol/L) and maintaining a triglyceride level below 200 mg/dL (2.25 mmol/L). Statins are the most effective medications for lowering LDL cholesterol levels. Fibrates (fibric acid derivatives) are the most effective medications for lowering triglyceride levels. They can also increase high-density lipoproteins (HDLs).

#### *Renal Osteodystrophy*

Monitoring this condition is done through x-rays, bone scans, bone biopsy, and bone densitometry. Treatment options for osteodystrophies include managing phosphate and calcium levels. Phosphate management includes limiting dietary phosphorus, administering phosphate binders, and controlling hyperparathyroidism. Phosphorus intake is restricted to less than 1,000 mg per day. Phosphate binders are used to bind phosphate in the GI tract, which allows it to be excreted in the stool. Phosphate binders must be administered with each meal to be effective because most phosphorus is absorbed within 1 hour after eating. Constipation is a common complaint with phosphate binders, so stool softeners may need to be added to the medication regimen. Some phosphate binders contain aluminum. Because dementia and bone disease have been associated with excessive aluminum intake, preparations that contain aluminum should be used with extreme caution. Also, magnesium-containing antacids that can be used as phosphate binders should be avoided in CKD because magnesium is solely excreted via the kidneys.

**Hyperparathyroidism.** Secondary hyperparathyroidism occurs because of the excessive parathyroid stimulus due to decreased calcium levels in CKD. Calcimimetic agents

are used to control hyperparathyroidism by increasing the sensitivity of the calcium receptors in the parathyroid glands. As a result, the parathyroid glands detect calcium at lower serum levels and decrease PTH secretion. Parathyroid hormone and alkaline phosphatase levels should be monitored. If the renal osteodystrophy remains after treatments with pharmacological agents, the next option for decreasing the synthesis and secretion of PTH is subtotal parathyroidectomy. In severe cases, a total parathyroidectomy may need to be performed to control the condition.

**Hypocalcemia.** Hypocalcemia is present in CKD because of the inability of the GI tract to absorb calcium in the absence of activated vitamin D. Management of hypocalcemia includes vitamin D and calcium supplementation. Regular monitoring is essential because hypercalcemia may occur if hyperparathyroidism and the release of calcium from bone are not controlled. Hypercalcemia can cause increased cardiac irritability and mortality in patients with end-stage renal disease. If hypercalcemia exists, substances containing calcium should be avoided.

#### *Managing Medications*

Chronic kidney disease can cause delayed and decreased elimination of medications, leading to potentially toxic accumulation of medications in the circulatory system. Medication dosages may need to be adjusted according to the kidney's level of function. Agents that pose concerns regarding toxicity include digitalis preparations, antibiotics, and pain medications. Demerol is an example of a pain medication to be avoided in CKD. Demerol is contraindicated because it is metabolized to normeperidine in the liver, which the kidneys excrete. If serum levels of Demerol become elevated in the CKD patient, seizures can occur. Nonsteroidal anti-inflammatory drugs should also be avoided with CKD patients; NSAIDs block the synthesis of the renal prostaglandins that promote vasodilation, and this can worsen renal hypoperfusion. Acetaminophen can be substituted for NSAIDs in patients with renal failure. If more potent pain medications are required, oxycodone with acetaminophen and morphine sulfate may be considered.

Certain medications, such as aminoglycosides, penicillin, and tetracyclines, can be nephrotoxic, thus requiring adjustments to the frequency or dose for safety. Adjustments are based on trough and peak serum blood levels.

Medication administration times may need to be changed for patients on dialysis. Some water-soluble medications are filtered out in dialysis, resulting in a decreased therapeutic benefit of the medication for the patient. Medications typically prescribed in the morning may need to be given after dialysis. Also, antihypertensives or cardiac medications may need to be given after dialysis to avoid the hypotensive events that may occur because of fluid shifts during dialysis.

#### *Nutrition*

A dietician should be consulted for nutritional education and guidance. The recommendations for diet should be

individualized to meet the needs of the patient and the degree of renal failure. Dietary proteins are restricted in patients with CKD because urea nitrogen and creatinine are end products of protein metabolism. A diet that is low in protein (0.6–0.8 g/kg of body weight per day) and low in phosphorus and that is supplemented with amino acids can slow the progression of renal failure. Once the patient starts dialysis, an increase in protein intake may be allowed (1.2–1.3 g/kg of ideal body weight [IBW] per day) because protein loss is high in dialysis.

Sufficient calories from carbohydrates and fats are needed to minimize the catabolism of body protein and to maintain body weight. The required intake of carbohydrates and fats should be 30 to 35 kcal/kg of body weight per day. For individuals with malnutrition or inadequate caloric intake, commercially prepared products are available that are high in calories and low in protein, sodium, and potassium. Such preparations include Nepro, Microlipid, Sumacal, Suplena, and Polycose. Amino acid preparations may also be supplemented (Amin-Aid).

Water restrictions are based on urine output and insensible water losses. Insensible losses through sweat and respiration account for about 600 mL of water per day. Adding the previous day's urine output and the insensible water loss together gives the replacement amount for the next day for patients not receiving dialysis. Careful monitoring of all liquid intake is important, including items such as gelatin and ice cream that are liquid at room temperature. The fluid replacement must be distributed throughout the day to lessen the patient's feelings of thirst. Adjustments must be made to fluid intake to maintain weight gains of no more than 1 to 3 kg between dialysis treatments.

Sodium and potassium restrictions are important and depend on the ability of the kidneys to excrete these electrolytes. Sodium may be restricted to between 2 and 4 g depending on the degree of edema and hypertension. Patients and families are instructed to avoid high-sodium foods such as cured meats, pickled foods, canned soups and stews, frankfurters, cold cuts, soy sauce, and salad dressings. Salt substitutes should be avoided because of high potassium chloride content. Dietary restrictions for potassium range between 2 and 4 g (39 mg = 1 mEq). High-potassium foods that should be avoided include oranges, bananas, melons, tomatoes, prunes, raisins, deep green and yellow vegetables, beans, and legumes.

Phosphate should be limited to 1,000 mg per day. Foods that are high in phosphate include dairy products (milk, ice cream, cheese, and yogurt) and some puddings. Most foods that are high in phosphate are also high in calcium, so restricting phosphate also restricts calcium.

### **Surgical Management**

**Renal transplantation** is a surgical option for a patient in ESRD. Renal transplantation is not considered a cure but is thought to improve the quality of life. The need for dialysis is removed; dietary and fluid restrictions are not eliminated but are reduced. Patients do need to remain

compliant with a lifelong treatment plan that involves continued vigilant treatment for comorbidities such as hypertension, diabetes, and heart disease as well as lifelong immunosuppressive therapy.

Recipients who are in good health except for the primary kidney disease and are between the ages of 5 and 50 years have the best outcome and prognosis for transplant. The complications associated with the primary renal disease, such as retinopathy due to uncontrolled hypertension or diabetes, usually improve with the transplantation.

Although the science surrounding renal transplant is rapidly evolving, there are several absolute contraindications. Some of these relate to disease states that may hinder successful transplant over time, such as untreated or metastatic cancer, or refractory coronary artery or heart disease. Other contraindications are psychosocial issues such as persistent drug abuse or severe psychiatric disease that may hinder compliance with the very complicated lifelong treatment regimen.

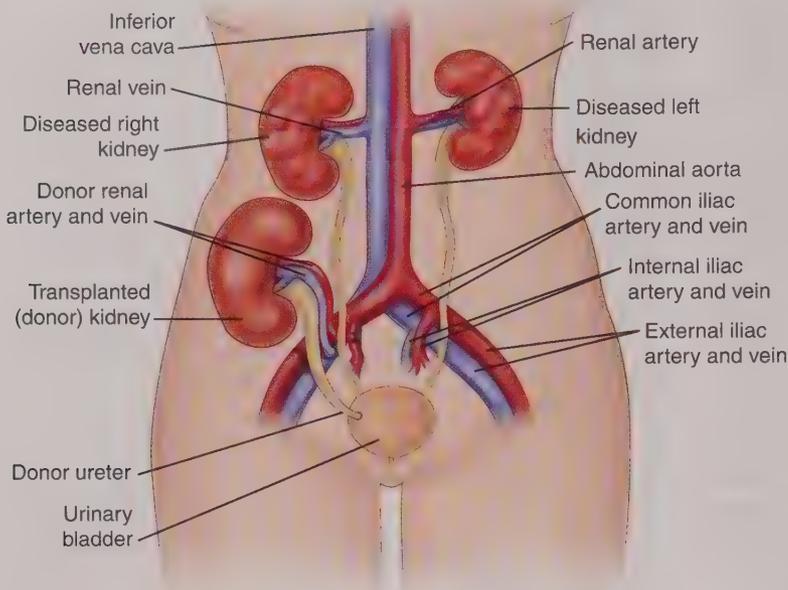

The transplantation procedure involves placing the donated kidney in the lower abdominal cavity (iliac fossa) of the recipient. The renal artery of the donor kidney is connected to the external iliac or hypogastric artery and the renal vein to the external iliac vein. The ureter is connected to one of the recipient's ureters or directly to the urinary bladder (Fig. 62.6).

There are three types of donors:

- Deceased or cadaveric donors
- Living related donors
- Living unrelated donors

The most common form of donation is cadaveric. Donors are matched to potential recipients via a national registry. Success is tied to close blood and antigen matching. An ideal deceased donor is young, between 10 and 39 years old, with no medical conditions known to affect the kidneys, such as hypertension; had normal kidney function; and had no infectious or malignant conditions that could be transmitted to the recipient through the act of organ donation. Unfortunately, the number of patients in need of a kidney transplant is increasing, so critical review and evaluation of the ideal donor are ongoing. An issue with cadaveric donation is the amount of "cold ischemia time." **Cold ischemia time** is the amount of time the kidney is separated from a blood supply, chilled, and transported for transplantation. Cold ischemia time is sometimes associated with a delay in the function of the transplanted kidney or poor overall transplantation results. Living donors are another option and are considered beneficial for several reasons: living related donors tend to have better compatibility, the surgery for both types of living donor types can be scheduled for a time most beneficial to all, and there is limited "cold ischemia time."

Treatment post-transplantation involves continued management of the existing comorbidities and the suppression of the immune system to minimize the risk of rejection. Rejection is minimized with immunosuppressive medications.

**FIGURE 62.6** Placement of the transplanted kidney. The donated kidney is placed in the lower abdominal cavity. The renal artery of the donor kidney is connected to the external iliac or hypogastric artery and the renal vein to the external iliac vein. The ureter is connected to one of the recipient's ureters or directly to the bladder.

## Complications

There is a risk of rejection even if immunosuppressive therapy is used. Hyperacute rejection occurs within minutes to hours after the graft; accelerated rejection occurs within 2 to 4 days. Both conditions result in graft failure and necessitate graft removal. Acute rejection, the most common and treatable form, occurs during the first 3 months after the transplant. The clinical manifestations of acute rejection may include fever, swelling, and tenderness over the graft site; decreased urine output; and a rise in the serum creatinine level. Increased doses of immunosuppressive medications are used to manage episodes of rejection. Chronic rejection is another primary cause of graft loss. The presenting manifestations associated with chronic rejection are progressive azotemia, proteinuria, and hypertension. These are evidence of progressive renal failure.

Other complications associated with renal transplantation include hypertension as a result of rejection, renal artery stenosis, and renal vasoconstriction. Some patients develop glomerular lesions and may have manifestations of nephrosis. Hypertension and altered blood lipids increase the risk of death from myocardial infarction and stroke following transplant.

Long-term immunosuppression is associated with complications such as viral, bacterial, and fungal infections of the blood, lungs and central nervous system (CNS). Tumors may appear with carcinoma in situ of the cervix, lymphomas, and skin cancers. The risk of congenital anomalies is increased in infants whose mothers have undergone immunosuppressive therapy. Corticosteroid use may lead to bone problems, GI disorders such as ulcer formation, and cataract formation.

## Nursing Management

### Assessment and Analysis

The clinical manifestations reflect the derangements of all body systems seen with CKD. They include hypertension, heart failure, and pulmonary edema because of alterations in sodium and fluid balance. Also present are GI symptoms such as nausea, vomiting, and anorexia and neurological symptoms such as a headache, lethargy, fatigue, and confusion due to impaired metabolic waste elimination. Altered calcium and phosphorus levels result in bone breakdown and osteodystrophies. Endocrine and reproductive dysfunctions occur, such as infertility, amenorrhea, hyperparathyroidism, and thyroid abnormalities. Anemia is a result of the decreased production of erythropoietin.

### Nursing Diagnoses

- **Excess fluid volume** related to renal failure and fluid retention
- **Disturbed thought processes** reflecting the effects of uremic toxins on the CNS
- **Fatigue** related to anemia, metabolic acidosis, and uremic toxins
- **Potential complications:** dysrhythmias arising from electrolyte imbalances

### Nursing Interventions

#### ■ Assessments

- Vital signs/SpO<sub>2</sub>  
*Hypertension may indicate fluid overload due to inadequate water removal.*  
*Oxygen saturation may be decreased in the presence of fluid overload/pulmonary edema.*

- Assess pulmonary, cardiac, and peripheral vascular systems.  
*Rales may be present on auscultation because of fluid retention. Peripheral edema and neck vein distention may be present because of fluid retention.*
- Monitor laboratory values.
  - Serum potassium  
*Hyperkalemia may be present in CKD because of decreased glomerular filtration.*
  - Serum sodium  
*Serum sodium may be increased or decreased depending on volume status.*
  - Serum calcium and serum phosphate  
*Calcium levels are decreased due to the loss of vitamin D activation. Phosphate and calcium levels are inversely related. Decreases in calcium levels stimulate the parathyroid gland to release parathyroid hormones, increasing phosphate. Phosphate is also increased due to inadequate clearance in the kidneys.*
  - Hemoglobin and hematocrit  
*Hemoglobin and hematocrit levels are decreased because of the decreased production of erythropoietin.*
  - Arterial pH  
*Metabolic acidosis may be present because of decreased hydrogen ion excretion and decreased bicarbonate production.*

### Post-transplant

- Vital signs/SpO<sub>2</sub>/temperature/pain  
*Hypotension may be present post-transplantation if there is excessive bleeding. Decreased oxygenation may be present if the patient develops atelectasis or pneumonia. Increased temperature may signal an infection. Increased or poorly managed pain may contribute to the patient's inability to do respiratory exercises to prevent pulmonary complications.*
- Incision  
*Assess for redness, warmth, or drainage that may indicate infection or acute rejection.*
- Renal function tests  
*Poor renal function may indicate rejection.*
- Monitor intake and output.  
*Urine output may be increased due to the improved clearance of BUN, which acts as an osmotic diuretic, and because of the IV fluids received in the operating room.*

### Actions

- Maintain cardiac monitor.  
*Cardiac monitoring is necessary to assess for ECG changes that might indicate hyperkalemia.*
- Weigh the patient at the same time each day in the morning before dialysis; use the same scale and record and maintain the same clothing with weights  
*The weight of the patient provides accurate information regarding fluid status. Weight gain/loss guides the dialysis treatment plan; it helps in identifying the amount of fluid to be removed.*

- Restrict fluids and sodium.  
*Fluid and sodium restrictions are necessary because of the kidney's inability to remove excess fluid, placing the patient at risk of volume overload.*
- Administer prescribed medications as directed.
  - Medication used to treat hyperkalemia  
*It is essential to maintain potassium within normal ranges to avoid potentially lethal cardiac dysrhythmias.*
  - Antihypertensives  
*Antihypertensives are necessary to control hypertension.*
  - Phosphate binders  
*Phosphate binders bind phosphate in the GI system, allowing for excretion in the stool.*
  - Calcium supplementation  
*Calcium supplementation is used when necessary to maintain normal calcium levels.*
  - Calcimimetic agents  
*Calcimimetic agents manage secondary hyperparathyroidism by increasing the parathyroid gland's sensitivity to calcium, thus decreasing the release of PTH.*
  - Synthetic erythropoietin  
*Synthetic erythropoietin replaces reduced erythropoietin levels that occur in CKD, helping maintain adequate hemoglobin and hematocrit levels.*
  - Folic acid and ferrous sulfate  
*Replacement may be necessary to support RBC production. They are water-soluble vitamins that are lost during dialysis.*
  - Stool softeners  
*Constipation is a side effect of many of the medications used in CKD, and so stool softeners help treat constipation.*
- Skin care  
*Edema decreases tissue perfusion and increases the risk of decubitus ulcers.*
- Proper positioning  
*Maintaining a semi-Fowler's position eases the work of breathing by facilitating the diaphragm to lower on inspiration.*
- Renal diet; adequate protein levels  
*Adequate caloric intake is necessary to avoid protein breakdown, which worsens the accumulation of nitrogenous wastes.*

### Post-transplant

- Administer medications as ordered.
  - Immunosuppressive medications  
*Immunosuppressive medications help prevent rejection.*
  - Pain medication  
*Adequate pain control allows the patient to participate in care, perform respiratory exercises, and ambulate as soon as possible to prevent respiratory complications.*

### Teaching

- Do not miss dialysis appointments.  
*Missing scheduled dialysis may result in acute and lethal fluid and electrolyte complications, especially hyperkalemia.*

- Dietary restrictions  
*Adequate protein and limited salt and fluid are necessary to support the caloric needs of the body and reduce the occurrence of volume overload.*
- Clinical manifestations of CKD and complications  
*The patient must know when to seek help in order to avoid the complications of CKD.*
- Avoid nephrotoxic substances such as NSAIDs, contrast media, nephrotoxic antibiotics, and alcohol.  
*Avoidance of nephrotoxic substances is essential to avoid the complications of CKD.*
- Daily weight  
*Weight is an excellent indicator of fluid volume status.*

### Post-transplant

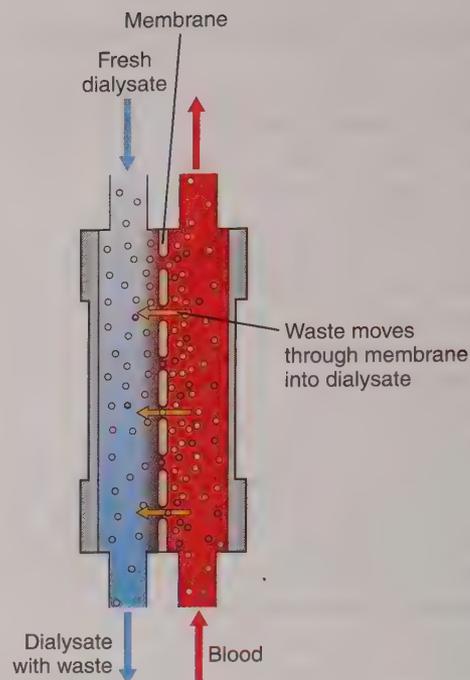

- Teach the patient and family the importance of taking immunosuppressive agents as prescribed.  
*Immunosuppressive medications preserve the life of the transplanted kidney. The medications will be taken for the remainder of the patient's life.*
- Teach the patient and family to avoid exposure to potentially infectious environments or persons as much as possible.  
*Teach the patient and family the importance of avoiding contact with potentially infectious environments or persons because of the risk of infection due to the lifetime of immunosuppressive therapy.*

### Evaluating Care Outcomes

Patients with CKD can be well managed with meticulous care and compliance with the treatment regimen. A well-managed patient maintains a regular dialysis schedule and is compliant with diet and medications, avoiding the complications associated with CKD.

## RENAL REPLACEMENT THERAPIES

Renal replacement therapies (RRTs) are artificial processes for removing waste and water from the body when the kidneys are no longer functioning adequately. Renal replacement therapy techniques include intermittent hemodialysis (HD), commonly referred to as hemodialysis; continuous hemofiltration and HD, also referred to as continuous renal replacement therapies (CRRTs); and peritoneal dialysis (PD). Hemodialysis and PD are processes in which blood is separated from a dialysis solution by a semipermeable membrane. Hemodialysis uses an artificial membrane; PD uses the peritoneal membrane. Solutes and water move across the membrane by diffusion (Fig. 62.7), or movement across a concentration gradient, supported by the addition of dialysate to the circuit, and by filtration, which is the movement of water driven by a hydrostatic pressure gradient. Continuous renal replacement therapy is a process where blood flows through a filter, and solute and fluid removal is accomplished via filtration, diffusion, or convection—the movement of solutes through the membrane via the force of fluid or water movement.

**FIGURE 62.7** Solute and water movement across the semipermeable membrane. Solutes and water move across the membrane, driven by diffusion, or movement across a concentration gradient, supported by the addition of dialysate to the circuit, and by filtration, which is the movement of water driven by a hydrostatic pressure gradient.

Dialysis is indicated for AKI or ESRD characterized by the following:

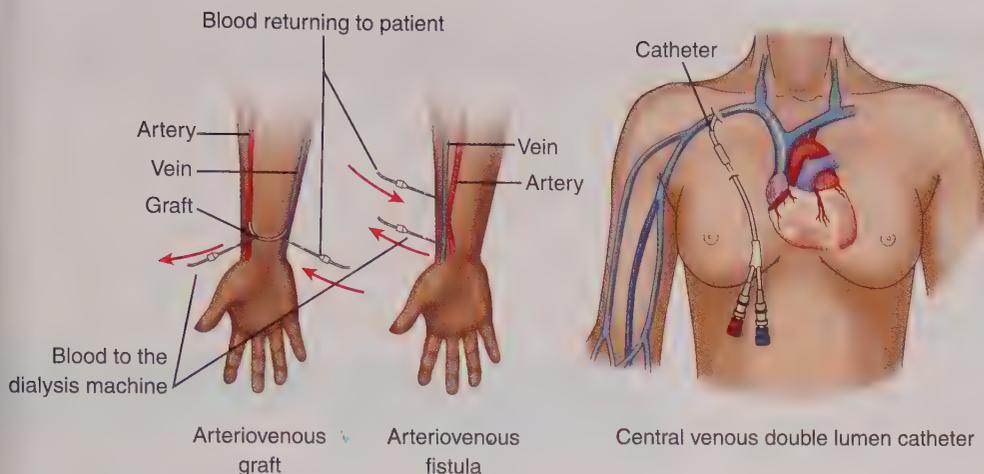

- Presence of severe fluid and electrolyte imbalances
- Elevated serum creatinine
- Elevated serum potassium levels
- Acidosis
- Presence of uremic manifestations
- Patients with GFR less than 10 mL/min

The most common forms of RRT for ESRD are intermittent HD and PD. Hemodialysis can be performed in outpatient centers, inpatient hospital settings, and sometimes in home settings. Peritoneal dialysis is generally performed in the home, but patients often receive PD while hospitalized or as outpatients. The morbidity and mortality of the two types of dialysis are comparable; however, the patient's condition, desire, and ability to manage dialysis at home; work situation; and proximity to a dialysis center may influence a decision to pursue either form. Continuous renal replacement therapies are typically indicated for acutely ill patients; these therapies manage acid-base balance, electrolyte levels, and fluid balance slowly and continuously in a hemodynamically unstable patient.

## Hemodialysis

### Vascular Access

There are generally three types of vascular access for HD (Fig. 62.8). Intravenous vascular access may be secured using a central venous double-lumen catheter in the subclavian

**FIGURE 62.8** Options for vascular access for hemodialysis. A central venous double-lumen catheter is typically used for short-term treatment. An AV fistula is a surgical anastomosis of an artery and vein. An AV graft is created by inserting a prosthetic graft between an artery and vein.

or internal jugular vein. This type of access is typically used for the short term, such as treating a patient with AKI with intermittent HD or when waiting to secure long-term access for HD via **arteriovenous (AV) fistula** or **arteriovenous (AV) graft**. An AV fistula is created by surgical anastomosis of an artery and vein, typically the radial artery and cephalic vein, in the nondominant arm. After the procedure, the fistula is allowed to mature to become suitable for dialysis. Maturing the AV fistula occurs when the low-pressure vein becomes accustomed to the higher pressures generated in the artery, which allows adequate blood flow for dialysis. The “matured” fistula appears large—bulging and tortuous under the skin. Maturation can require weeks to months, so advanced planning is needed, or, as noted previously, a central venous catheter may be used in the short term.

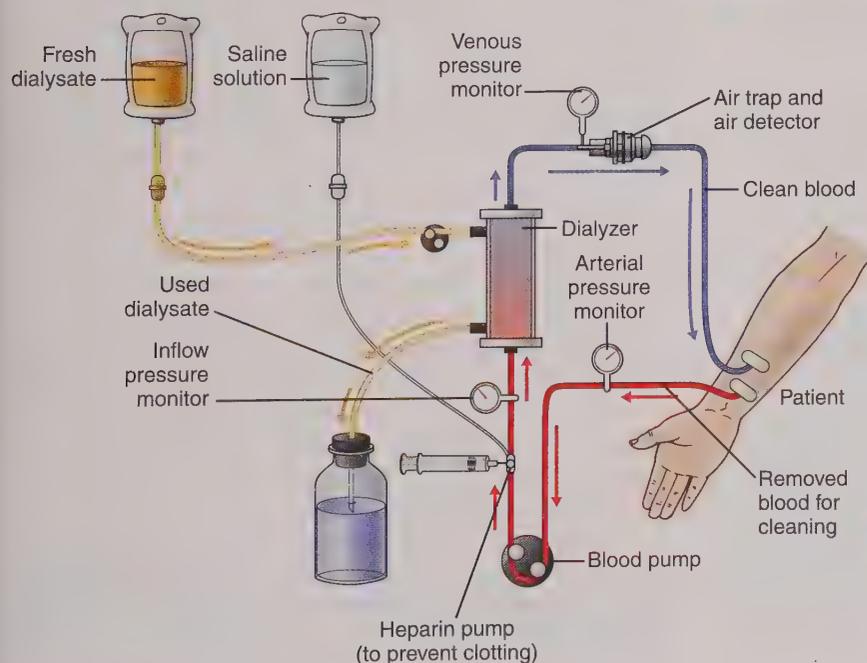

An AV graft, another option for dialysis, is created by inserting a prosthetic graft between an artery and vein, typically in the nondominant arm. Arteriovenous graft access can be used more quickly than the fistula but does

not last as long and is more prone to infection; thus, it is not the preferred option for access. On assessment, a functional AV fistula or graft has a palpable pulsation, a thrill, and a bruit on auscultation.

### Hemodialysis Process

Hemodialysis is a life-sustaining procedure for a patient with AKI or ESRD. Hemodialysis uses the processes of diffusion and filtration to remove waste products, electrolytes, and excess water from the body (Fig. 62.9). Patients generally undergo dialysis three times per week, 3 to 5 hours for each treatment. The exact duration and the number of sessions per week depend on the individual’s status—renal function, weight, serum electrolyte, BUN/creatinine levels, and general health of the patient. The process involves several steps:

1. Blood is pumped from the body through the vascular access device to a dialyzer.
2. In the dialyzer, the blood moves past an artificial semi-permeable membrane.

**FIGURE 62.9** Hemodialysis. Blood is removed from the body and pumped through a dialyzer. Dialysis fluid is pumped through the dialyzer in the opposite direction of the blood to provide a concentration gradient for the removal of wastes. Blood is then returned to the body.

3. A dialysate solution with similar solute concentration as normal extracellular fluid is warmed to body temperature and pumped along the other side of the membrane.
4. Solute molecule movement across the membrane is determined by a concentration gradient, from an area of higher to lower concentration via diffusion. Waste products such as urea and creatinine diffuse across the membrane into the dialysate.
5. Bicarbonate may be added to the dialysate to make corrections for acidosis if present.
6. Negative pressure is maintained on the dialysate side to allow excess fluid removal via hydrostatic pressure, a process known as filtration.
7. Heparin is added to the circuit to prevent clotting.
8. Saline may be added to help prevent clotting and facilitate flow through the dialyzer.
9. The “cleaned” blood is returned via the vascular access device.

### Complications

Systemic complications of HD can occur during or after dialysis and include:

- Hypotension due to the rapid removal of fluid from the vascular compartment or vasodilation. The patient may display light-headedness, nausea, vomiting, seizures, vision changes, and chest pain from cardiac ischemia. The treatment is to decrease the rate of fluid removal and to replace fluid intravenously with normal saline (0.9% saline solution).
- Muscle cramps, headache, nausea, dizziness, and malaise are common during and after dialysis as a result of the rapid removal of electrolytes and water. Treatment includes reducing the filtration rate or infusing a normal saline bolus.
- Bleeding may occur because of the altered platelet function associated with uremia and the use of heparin during the dialysis procedure.
- Systemic infection is a concern. Patients on chronic HD have a higher risk of developing hepatitis B, hepatitis C, cytomegalovirus, and HIV infections than the general population. Multiple blood transfusions, immune system depression, and underlying disease processes all contribute to the risk of infection.
- Dialysis-associated dementia is a progressive, potentially incurable neurological complication associated with long-term dialysis. It is thought to be due to aluminum, which is present in phosphate binders in the dialysate or the PO phosphate binders.
- Dialysis disequilibrium syndrome develops as a result of very rapid changes in the composition of the extracellular fluid. Urea, sodium, and other solutes are removed more rapidly from the blood than from the cerebrospinal fluid and the brain. The rapid shift of fluid and substances can create a high osmotic gradient in the brain, resulting in a shift of fluid

into the brain, causing cerebral edema. Clinical manifestations of dialysis disequilibrium syndrome include nausea, vomiting, confusion, restlessness, headaches, twitching and jerking, and seizures. Treatment includes slowing or decreasing the rate of dialysis and infusing hypertonic saline solution, albumin, or mannitol to draw fluid from the brain cell back into the systemic circulation. In order to avoid this syndrome, the first HD is usually done much slower and is less aggressive in removing fluids and solutes.

Localized AV fistula and graft complications can also occur. Infection and clotting or thrombosis are the most common shunt problems. Aneurysms may also occur. *Staphylococcus aureus* septicemia is commonly associated with contamination of the fistula. Infection and thrombosis can lead to systemic manifestations such as septicemia and embolization.

### Continuous Renal Replacement Therapy

Continuous renal replacement therapy is indicated for acutely ill patients with AKI or patients with severe fluid overload who are hemodynamically unstable. It is recommended in critically ill patients because it limits the risk of complications associated with the rapid rate of fluid and solute loss, such as the hypotension that complicates intermittent HD. Vascular access for CRRT is accomplished through the double-lumen catheter described for short-term HD or a single-lumen central venous line in combination with an arterial line. In CRRT, fluid and solute removal is slow and continuous and can be adjusted hourly depending on how the patient is tolerating the procedure. The mechanisms used for solute and fluid removal are similar to HD, diffusion via a concentration gradient and filtration via hydrostatic pressure. Continuous renal replacement therapy adds solute removal via convection, which is the movement of solutes through the membrane via the force of fluid or water movement.

Generally, the process for CRRT is as follows: Blood from the patient flows through a highly permeable hemofilter, which removes water and solutes, collectively termed *ultrafiltrate* or *filtrate*. In some forms of CRRT, dialysate is pumped countercurrently to the blood to aid in solute removal. The ultrafiltrate drains into a collection device. Blood continues through the filter and returns to the patient. As the blood returns to the patient, replacement fluid and electrolytes can be infused to replace volume and solutes as the patient requires to maintain stability. Replacement fluid may also be infused into the infusion port before the hemofilter to facilitate convection for greater clearance of solutes, which also aids in the prevention of clots in the filter. Anticoagulation is also used to prevent blood clotting during CRRT. Heparin may be infused as a bolus at the beginning of the dialysis or through the heparin infusion port before the hemofilter. There are several types of CRRT described in Table 62.6.

**Table 62.6** Types of Continuous Renal Replacement Therapy (CRRT)

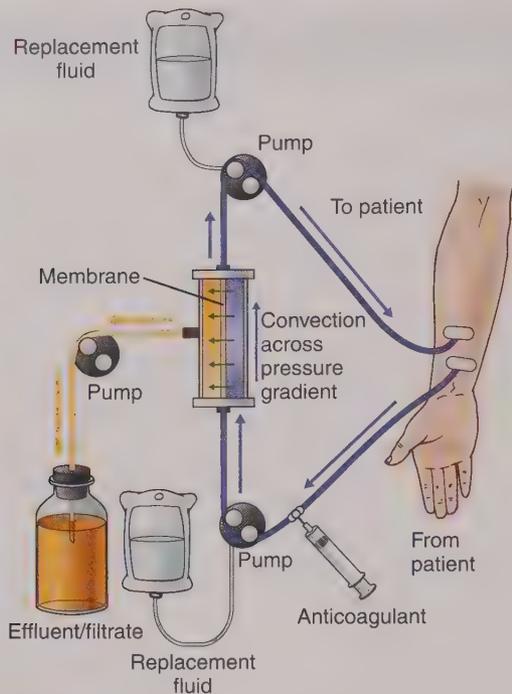

Type of CRRT	Vascular Access	Purpose	Requirements	Limitations
<b>Slow continuous ultrafiltration (SCUF)</b>	Double-lumen central venous catheter (venovenous [VV] or arterial/venous access)	Slow fluid removal via filtration	Requires a pump to generate pressure to drive blood through the circuit with VV access; does not use dialysate or replacement fluid	Low filtration rates; requires extensive monitoring
<b>Continuous arteriovenous hemofiltration (CAVH)</b>	Arterial and central venous access	Slow fluid and solute removal via convection and filtration	Does not require a pump—difference between mean arterial pressure and venous pressure drives blood through the filter; requires replacement fluids prior to filter; does not use dialysate; may use replacement fluids after the filter to aid in maintaining patient stability	Low solute removal due to lack of diffusion; unreliable blood flow in critically ill, hypotensive patients; increased risk of embolus; requires extensive monitoring
<b>Continuous arteriovenous hemofiltration with dialysis (CAVHD)</b>	Arterial and central venous access	Slow fluid and solute removal via diffusion and filtration	Does not require a pump—difference between mean arterial pressure and venous pressure drives blood through the filter; uses dialysate fluid to increase solute removal; may use replacement fluids after the filter to aid in maintaining patient stability	Unreliable blood flow in critically ill, hypotensive patients; increased risk of embolus; requires extensive monitoring
<b>Continuous venovenous hemofiltration (CVVH) (Fig. 62.10)</b>	Double-lumen central venous catheter	Slow fluid and solute removal via convection and filtration	Requires a pump to generate pressure to drive blood through the circuit; does not use dialysate; requires replacement fluid prior to the filter; may use replacement fluids after the filter to aid in maintaining patient stability	Low solute removal due to lack of diffusion; requires extensive monitoring
<b>Continuous venovenous hemofiltration with dialysis (CVVHD)</b>	Double-lumen central venous catheter	Slow fluid and solute removal via diffusion and filtration	Requires a pump to generate pressure to drive blood through the circuit; uses dialysate fluid to increase solute removal; may use replacement fluids after the filter to aid in maintaining patient stability	Requires extensive monitoring

## Peritoneal Dialysis

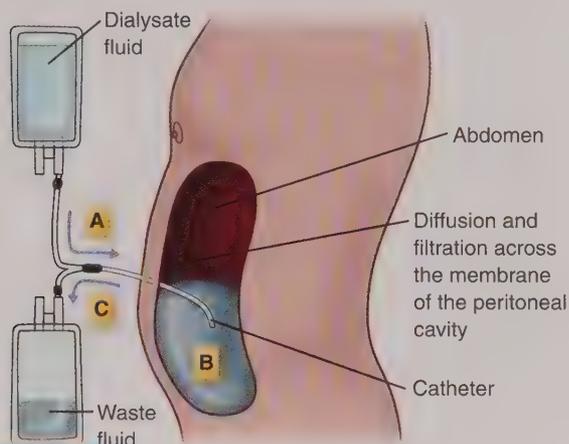

Peritoneal dialysis is another life-sustaining treatment for a patient with ESRD. It offers increased patient control and flexibility with the option of home treatment. Peritoneal dialysis requires a shorter training period for the patient and can be performed independently by the patient or a family member. Typically, PD involves fewer dietary restrictions and greater mobility for the patient. The clearance of metabolic wastes is slower but more continuous. It avoids rapid fluctuations in extracellular fluid composition and associated symptoms. Peritoneal dialysis is indicated for patients who desire more control, who have vascular access problems, or who respond poorly to HD with hemodynamic

instability. Older patients and ESRD patients with diabetes may be more easily managed with PD.

In PD, the highly vascular membrane of the peritoneal cavity is used as the dialyzing layer (Fig. 62.11). Fluid and solute removal occurs via diffusion and filtration. The PD process consists of fill, dwell, and drain phases. In the fill phase, room-temperature, sterile dialysate is instilled into the peritoneal cavity via a permanent indwelling PD catheter, typically made of silicone rubber tubing. The fluid remains in the abdomen for a predetermined “dwell time.” Metabolic waste products and excess electrolytes diffuse into the dialysate while it remains in the abdomen. Water diffusion is controlled using dextrose in the dialysate as an

**FIGURE 62.10** Continuous venovenous hemofiltration. Blood is pumped from the patient and flows through a highly permeable hemofilter that removes water and solutes. Blood continues through the filter and returns to the patient. As the blood returns to the patient, replacement fluid and electrolytes can be infused to replace volume and solutes as the patient requires to maintain stability.

**FIGURE 62.11** Peritoneal dialysis (PD). The PD process consists of the (A) fill, (B) dwell, and (C) drain phases.

osmotic agent. Gravity then drains the fluid out of the peritoneal cavity into a sterile bag.

There are several forms of PD: continuous, automated, and intermittent:

**Continuous ambulatory peritoneal dialysis (CAPD).** With CAPD, dialysate is infused into the abdomen four or five times a day with a dwell time of 4 to 6 hours. Patients may be ambulatory during the dwell time. With CAPD, it is not necessary to wake up and perform dialysis tasks during the night; patients typically sleep with the solution in the abdomen at night. Additionally, CAPD does not require any machines.

**Automated peritoneal dialysis.** Automated peritoneal dialysis uses a cycler to perform multiple overnight exchanges, specifically programmed to meet individual patient needs. A typical pattern calls for 30-minute cycles, 10 minutes for each phase, for 8 to 10 hours during the night. This method allows the patient to be dialysis-free during the day.

**Intermittent peritoneal dialysis.** The intermittent regimens typically consist of multiple short dwells utilizing automated technology. Intermittent peritoneal dialysis calls for 30 to 40 exchanges weekly. Typically, the patient has 30- to 60-minute exchanges, allowing approximately 15 minutes of drain time.

### Contraindications

Contraindications for PD include:

- History of multiple abdominal surgeries or chronic abdominal conditions such as pancreatitis or diverticulitis
- Recurrent abdominal wall or inguinal hernias
- Obesity with large abdominal wall
- Pre-existing back problems or vertebral disease
- Severe chronic obstructive pulmonary disease

### Complications

#### Peritonitis and Catheter Infection

Peritonitis can result from contamination of the dialysate or tubing or from bacteria in the intestine migrating into the peritoneal cavity. Peritonitis is usually caused by *S. aureus* or *Staphylococcus epidermidis*. The primary clinical manifestation of peritonitis is a cloudy peritoneal effluent with an increased WBC count. Antibiotics can be given orally, intravenously, or intraperitoneally. Repeated infections warrant removal of the PD catheter and a switch to the use of HD. Catheter site infection can also be caused by *S. aureus* or *S. epidermidis* (from skin flora) and is usually treated with antibiotics. Clinical manifestations of infections of the catheter exit site include redness at the site, tenderness, and drainage. If the infection is not treated properly, then subcutaneous tunnel infections usually result in abscess formation and may cause peritonitis, necessitating catheter removal.

#### Abdominal Pain

Abdominal pain and distention may be caused by intraperitoneal irritation from the low pH of the dialysate solution and generally subside in 1 to 2 weeks. Pain can also result from the tip of the catheter resting against the bladder, bowel, or peritoneum; accidental infusions of air; infusing the dialysate too rapidly; or infusing the dialysate at less than room temperature. Changing the catheter's position and attention to correctly infusing the solution may help solve these problems.

#### Hyperglycemia and Increased Triglyceride Levels

Glucose in the dialysate can be absorbed into the bloodstream, causing hyperglycemia. Serum triglyceride levels may also increase with PD because continuous absorption

of glucose results in increased insulin secretion, which stimulates the hepatic production of triglycerides. Dietary and insulin administration modifications may be necessary.

### Outflow Problems

Outflow problems occur because of mechanical interruptions in the flow of the dialysate or ultrafiltration. Interruptions may be caused by kinks in the catheter, an omentum (a fold of peritoneum) compressing the catheter, or migration of the catheter out of the peritoneal cavity. Catheter repositioning or replacement may be required. Constipation or a full colon may also cause these problems, requiring some form of cathartic.

### Respiratory Compromise

Atelectasis, pneumonia, and bronchitis may occur from a repeated upward displacement of the diaphragm, resulting in decreased lung expansion. The longer the dwell time, the higher the risk of developing pulmonary complications. Frequent repositioning, deep-breathing exercises, and elevating the head of the bed can help prevent respiratory complications.

### Protein Loss

The peritoneal membrane is permeable to plasma proteins, amino acids, and polypeptides, which may result in an excessive protein loss. A positive nitrogen balance can be maintained with adequate protein intake.

## Connection Check 62.13

The nurse understands that CRRT is indicated for which of the following patients?

- A. A hospitalized but hemodynamically stable patient
- B. A hospitalized, hemodynamically unstable patient
- C. A hospitalized ESRD patient being discharged home soon
- D. A hospitalized ESRD patient who is stable but in an intensive care setting

## Nursing Management

### Nursing Interventions

#### Assessments

##### Vital signs

*Blood pressure and heart rate are indicators of fluid volume status that are changing during the dialysis procedure. Hypotension may occur with aggressive fluid removal.*

##### Oxygenation/respiratory status

*Decreased oxygenation may occur with fluid volume overload, with decreased respiratory effort, or during dwell time in PD. Abnormal findings such as gallops, murmurs, rales, shortness of breath, and tachypnea can indicate fluid volume overload.*

##### Temperature

*Increased temperature is an indicator of infection. All forms of dialysis increase the risk of infection through the presence of multiple IV lines or a PD catheter.*

- Daily weight at the same time every day  
*Weight gain or loss is a good indicator of fluid volume status and helps guide dialysis treatment.*
- Filtrate appearance  
*Pink or bloody filtrate in any form of dialysis indicates bleeding. Cloudy filtrate in PD indicates infection.*
- Laboratory values
  - Coagulation studies; hemoglobin/hematocrit  
*Bleeding risk is higher with all forms of dialysis because of the need for heparinization.*
  - WBC count  
*Infection is a risk with all forms of dialysis.*
  - Electrolytes and renal studies  
*Dialysis produces changes in electrolytes and renal studies, which may require changes in the dialysis procedure or dialysate composition.*
- Nutritional intake  
*Sodium and water restriction may be necessary to optimize dialysis. Protein intake may need to be increased because of protein loss during dialysis.*
- Specific assessments by the type of dialysis
  - HD
    - Frequent assessment of bruit/thrill  
*A patent AV fistula or graft has a palpable pulsation, a thrill, and a bruit or whooshing sound on auscultation caused by the flow of blood. A normally functioning graft has a low-pitched bruit. A turbulent bruit is indicative of an increased force, mostly due to stenosis. Absence of thrill or bruit is indicative of a nonfunctional AV fistula or graft.*
    - Neurological assessment  
*The rapid shift of fluid and substances can create a high osmotic gradient in the brain, resulting in a shift of fluid into the brain causing cerebral edema (dialysis disequilibrium syndrome). Dialysis-related dementia, primarily caused by aluminum in the dialysate or phosphate binders, may occur.*
    - Systems assessment post-dialysis  
*Muscle cramps, headache, nausea, dizziness, and malaise are common during and after dialysis as a result of the rapid removal of electrolytes and water.*
  - CRRT
    - Frequent/hourly vital signs  
*Continuous renal replacement therapy is typically performed in critically ill patients who may become unstable during dialysis.*
    - Hourly assessment of the volume of filtrate  
*Increases of filtrate may require modifications of the procedure to maintain hemodynamic stability. A decrease in filtrate may indicate a clot or obstructed filter, necessitating a change in the CRRT tubing and filter.*
  - PD
    - Abdominal girth  
*Measure the abdominal girth and record in order to make comparisons for future assessments.*
    - Monitor outflow.  
*Decreased outflow may indicate a kinked or malpositioned catheter, which may require repositioning of the catheter; turning the patient to the side, or gentle abdominal massage.*

### Actions

- Perform dialysis as prescribed.
  - HD
    - Specially trained HD staff perform hemodialysis. *Specialized training is required because of the risk of complications with HD, one being hypotension caused by rapid fluid shifts.*
    - Avoid any procedures, blood draws, IV insertion, or blood pressure readings in the arm with the HD access. *Use of the extremity of the vascular access site for any procedures, blood pressure readings, or venipuncture can increase the risk of thrombus formation and infection.*
    - Hold medications that may be dialyzed out or cause complications during the procedure until after the HD session. *Some antibiotics or anticonvulsants may be lost in dialysis. Water-soluble vitamins are also lost during dialysis. Antihypertensives or vasoactive medications may cause hemodynamic instability during the procedure and should be held as ordered, especially if the patient is known to be hemodynamically unstable during dialysis.*
  - CRRT
    - Continuous renal replacement therapy requires intensive nursing support to perform and document hourly functions of fluid maintenance, including replacement and dialysate infusions if utilized; measuring of the filtrate; and monitoring of lines, circuits, and vital signs. *Fluctuations may require changes in the dialysis protocol, such as decreasing fluid removal, or changes in dialysate or replacement fluid.*
  - PD
    - Perform instill, dwell, and drain functions. *This process allows for the removal of water and solutes.*
    - Warm dialysate to body temperature. *Body-temperature dialysate helps prevent hypothermia and discomfort.*

### Teaching

- Teaching regarding disease process and dialysis *Teaching the patient and family regarding the importance of dialysis is essential. Compliance with dialysis, whatever form the patient is receiving, is life sustaining.*
- Assistance with social service and counseling services *Assist the patient and family in accessing social services and counseling. Patients undergoing dialysis of any form require extensive support services to assist with adaptation to their condition. The patient and family may need help coping with the loss of function of the kidney, the change in body image, and the thoughts regarding dependency on the dialysis machine.*
- Teach patient and family about troubleshooting for possible problems during PD. *Teach the patient and family the techniques of instillation, dwelling, and draining, such as warming dialysate; slowing instillation if necessary; increasing the height of bag to foster*

*instillation; checking the tubing for kinks and removing kinks to facilitate instillation and drainage; repositioning the patient for proper instillation, dwelling, and drainage; and checking abdominal dressings for dampness and changing if needed to prevent infection.*

### Evaluating Care Outcomes

Dialysis does not cure renal failure but is a life-sustaining treatment. Well-managed patients can lead close-to-normal lives—able to work, relax with friends and family, and eat with some limitations—as long as they remain compliant with the prescribed dialysis treatment regimen. Strong emotional support is necessary to adapt to the changes in lifestyle and body image.

## Making Connections

### CASE STUDY: WRAP-UP

Doris Flood's diagnosis of PKD is confirmed by IVP. Her blood pressure remains elevated at 178/102 mm Hg. Laboratory testing reveals a BUN of 30 mg/dL and creatinine of 2.5 mg/dL, indicating renal impairment is already occurring. Ms. Flood is complaining of abdominal pain and continued urinary frequency and burning during urination. She expresses extreme anxiety over this diagnosis.

Ms. Flood's provider orders antibiotics to treat the UTI. She is started on an ACE inhibitor, captopril, for her hypertension. Ms. Flood and her provider begin discussions on how to treat her renal insufficiency. A social worker is contacted to help her obtain the resources necessary to manage her medical condition adequately. The nurse talks with her about her anxiety and helps her explore options to deal with this new diagnosis.

### Case Study Questions

1. The nurse monitors for which clinical manifestation in Ms. Flood, who is newly diagnosed with PKD?
  - A. Hypotension related to fluid shifts
  - B. Bradycardia related to fluid overload
  - C. Hypertension related to decreased renal perfusion
  - D. Tachycardia related to fluid loss
2. The nurse includes which information in the teaching plan about the management of PKD?
  - A. "Your blood pressure will normalize when we successfully manage your PKD."
  - B. "Your UTI will not recur if you finish your antibiotic prescription."
  - C. "Staying on your antihypertensive medication is necessary to control your blood pressure."
  - D. "This disease is reversible if you closely follow your provider's orders."

3. The nurse providing care for Ms. Flood should include which activity in the plan of care?
  - A. Providing cranberry juice at meals to reduce the risk of UTIs
  - B. Frequent range-of-motion exercises to reduce stiffness due to inactivity
  - C. Encourage fluids to maintain adequate volume and perfusion to the kidneys
  - D. Restrict fluids to reduce the risk of fluid overload
4. The nurse caring for Ms. Flood incorporates which priority nursing diagnosis into the plan of care?
  - A. Pain related to irritation on urination secondary to UTI
  - B. Imbalanced nutrition related to excessive loss of protein in the urine
  - C. Decreased cardiac output related to dysrhythmias secondary to electrolyte imbalance
  - D. Impaired perfusion related to decreased circulating volume secondary to diuresis
5. Which statement by Ms. Flood indicates that teaching has been effective?
  - A. "I'm glad we can control this disease with medications."
  - B. "I'm glad we caught this early so I won't need dialysis forever."
  - C. "Getting a new kidney will help even if I develop the cysts again."
  - D. "I have a choice between hemodialysis and peritoneal dialysis."

antihypertensives to treat hypertension; edema is treated with sodium and fluid restriction, and inflammation/infection is treated with antibiotics.

Renal or kidney cancer is one of the most common cancers in the United States. Malignant tumors in the kidney are more frequent than benign tumors. Kidney tumors compress the underlying tissues, reducing circulation to the renal structures and damaging underlying tissues. This compression can lead to compromised renal functioning or renal failure. The typical treatment for renal cancer is radical nephrectomy.

The kidneys are vulnerable to injury and renal trauma because of the lack of bony structures to protect the area where they are located compared to other organs such as the heart, which the rib cage protects. The extent of the injury depends on the mechanism, the force, and the speed upon impact. Management is based on the extent of the injury. Treatment focuses on stabilizing the patient and surgically repairing any perforations or lacerations. Surgery may be required to control severe bleeding; however, if the kidneys are intact, rest and observation may be indicated.

Acute kidney injury (AKI) is a condition characterized by an acute, rapid loss of renal function. It is defined as rapid and progressive azotemia, an accumulation of nitrogenous waste products such as urea nitrogen and creatinine, and progressive increases in potassium. Prerenal causes of AKI are external to the genitourinary system that reduce renal blood flow and lead to decreased glomerular perfusion and filtration. Intrarenal causes of AKI involve direct damage to the renal system. Postrenal causes involve mechanical obstruction of the lower urinary tract. The goals of managing AKI are to eliminate the cause and prevent complications. Management is primarily supportive and involves ensuring adequate circulating volume, correcting fluid overload, and correcting biochemical abnormalities. Dialysis may need to be considered in the short term to allow recovery of the renal tissue while preventing possible life-threatening disorders.

Chronic kidney disease (CKD) is the progressive, irreversible loss of kidney function. Different from AKI, it has a longer, more insidious onset and is typically caused by a long-term disease or medical comorbidities. The diagnosis of CKD is consistent with elevated serum creatinine levels, decreased creatinine clearance determinations, and increased protein in the urine. It has profound effects on all body systems. Chronic kidney disease is managed through renal replacement therapies (RRTs) and supportive care to treat the patient's signs and symptoms and prevent any complications. Renal transplantation is a surgical option for a patient with ESRD. Renal transplantation is not considered a cure but is thought to improve the quality of life—the need for dialysis is removed, and dietary and fluid restrictions are not eliminated but are reduced.

Renal replacement therapies are artificial processes for removing waste and water from the body when the kidneys are no longer functioning. Renal replacement therapy techniques include intermittent HD, commonly referred to as

## CHAPTER SUMMARY

Polycystic kidney disease (PKD) is one of the most common genetic disorders. It appears as large, thin-walled, fluid-filled cysts on the kidneys. The cysts become large and compress the surrounding tissue, destroying the underlying renal tissue. The disease progresses to end-stage renal disease (ESRD) in about 50% of patients by age 60, requiring treatment consistent with ESRD—hemodialysis (HD) or peritoneal dialysis (PD). Other treatment goals for PKD include managing UTIs, pain, and hypertension.

Pyelonephritis is an inflammation of the renal parenchyma and urinary collecting system. Clinical manifestations include signs of infection, such as fever, chills, and nausea/vomiting. Antibiotics are typically used in the management of pyelonephritis.

Glomerulonephritis is an inflammation of the glomeruli of the kidney. There is an overall decrease in the glomerular filtration rate and an increase in permeability to larger-size proteins. Treatment is based on the cause of the disease and symptom management, such as diuretics and other

hemodialysis; continuous hemofiltration and HD, also referred to as continuous renal replacement therapies (CRRTs); and PD. Intermittent HD uses the processes of diffusion and filtration to remove waste products, electrolytes, and excess water from the body. Continuous renal replacement therapy is indicated for acutely ill patients in AKI or patients with severe fluid overload. It is recommended in

critically ill patients because it limits the risk of complications due to the rapid rate of fluid and solute loss, such as the hypotension that complicates intermittent HD. Peritoneal dialysis uses the highly vascular membrane of the peritoneal cavity as the dialyzing layer. Fluid and solute removal occurs via diffusion and filtration. It offers increased patient control and flexibility with the option of home treatment.

# Chapter 63

## Coordinating Care for Patients With Urinary Disorders

*Kristen Ann Farling and Joanne Walker*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of urinary disorders
2. Correlating clinical manifestations with pathophysiological processes of:
  - a. Urinary tract infections
  - b. Urolithiasis
  - c. Incontinence
  - d. Bladder cancer
3. Describing the diagnostic results used to confirm the diagnosis of urinary disorders
4. Discussing the medical management of:
  - a. Urinary tract infections
  - b. Urolithiasis
  - c. Incontinence
  - d. Bladder cancer
5. Developing a comprehensive plan of nursing care for patients with urinary disorders
6. Designing a teaching plan that includes pharmacological, dietary, and lifestyle considerations for patients with urinary disorders

### CONCEPTS

- Assessment
- Cellular Regulation
- Comfort
- Fluid and Electrolyte Balance
- Infection
- Medication
- Perioperative
- Safety
- Urinary Elimination

### ESSENTIAL TERMS

Adjuvant  
Calculus  
Clean intermittent catheterization (CIC)  
Cystitis  
Detrusor muscle  
Dysuria  
External urethral sphincter  
Functional incontinence  
Hematogenous  
Hematuria  
Immunotherapy  
Internal urethral sphincter  
Micturition  
Neoadjuvant  
Nephrolithiasis  
Overflow incontinence  
Pessary  
Precision medicine  
Pyelonephritis  
Reflex incontinence  
Stress incontinence  
Targeted therapy  
Ureterolithiasis  
Ureteropelvic  
Urge incontinence  
Urothelium

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Heather Tomlinson is a healthy 24-year-old sexually active female who presents with a 3-day history of urinary frequency, dysuria, and urgency. She denies fever, chills, or vomiting but has mild nausea. She is married and the mother of a 1-year-old daughter. Her family history is significant for heart disease and kidney stones. Physical examination reveals a well-nourished female in no distress. Mild suprapubic tenderness is noted but no costovertebral angle tenderness (tenderness on the back in the area over the kidneys). VSs: T 98.9°F (37.2°C), P 75 bpm, R 18, BP 118/78 mm Hg. Urinalysis reveals cloudy yellow urine, urine dip TNTC (too numerous to count) white blood cells, small amount of red blood cells, positive nitrites, and a large number of bacteria. A urine culture is submitted, and results are awaited...

## URINARY TRACT INFECTIONS

### Epidemiology

Urinary tract infections (UTIs) account for 8 million doctor visits and more than 100,000 hospital admissions each year. The annual cost of treating UTIs is estimated to be \$1 billion. Urinary tract infections occur more frequently in females than males. As men age, however, their risk for UTIs increases because of prostatic enlargement. More than 50% of females will have at least one UTI in their lifetime (see Evidence-Based Practice). The most common age groups for UTIs in women are those in the 18-to-30-year range (thought to be due to honeymoon cystitis and pregnancy) and older women. Sexual activity, diabetes, poor hygiene, estrogen deficiency, recent catheterizations, and foreign objects such as kidney or bladder stones increase the risk of developing a UTI. Conditions causing incomplete bladder emptying, such as pelvic organ prolapse, also increase the risk for UTI because of retained urine acting as a reservoir for bacteria. If the infection is isolated to the lower urinary tract or bladder, it is referred to as *cystitis*, and if it involves the upper urinary tract or kidneys, it is referred to as *pyelonephritis*.

### Evidence-Based Practice

#### Treatment and Prevention of Recurrent Lower Urinary Tract Infections in Women

A rapid review of the literature was conducted to evaluate the science addressing the treatment and prevention of

recurrent urinary tract infections (UTIs) in women, defined as more than two UTIs in 6 months or more than three UTIs in 1 year. After evaluation of original research, systematic reviews, meta-analyses, and practice guidelines, an algorithmic approach was developed. The algorithm proposes the use of prophylactic antibiotics after patient assessment for complicating factors and education regarding behavioral changes such as better control of glucose in diabetes, discontinuing the use of cleansers that disrupt normal flora, voiding before and after sexual activity, and avoiding sequential anal and vaginal intercourse.

Smith, A. L., Brown, J., Wyman, J. F., Berry, A., Newman, D. K., & Stapleton, A. E. (2018). Treatment and prevention of recurrent lower urinary tract infections in women: a rapid review with practice recommendations. *The Journal of Urology*, 200(6), 1174-1191.

### Connection Check 63.1

The nurse recognizes which patient is at greatest risk for a UTI?

- A. A 35-year-old sexually active male
- B. A 23-year-old sexually active female
- C. A 50-year-old sexually active female
- D. An 18-year-old sexually active male

### Pathophysiology

A UTI occurs when bacteria enter the sterile bladder, causing inflammation. The most common way for bacteria to gain entrance to the bladder is through the urethra. A **hematogenous**, or blood-borne, infection is less common. Females are at risk for developing a UTI because of their short urethra and its close proximity of the vagina and rectum. This proximity allows vaginal and fecal flora to migrate to the urethra, causing a UTI. Men are less likely to develop a UTI because of their long urethra that deters migration of bacteria to the bladder.

### Clinical Manifestations

Clinical manifestations of a UTI include bladder irritability or **dysuria** (painful urination), urinary frequency, urgency, urinating in small volumes, **gross hematuria** or **microhematuria**, and suprapubic pain. If systemic symptoms such as fever, nausea, vomiting, and flank pain are present, the infection has potentially migrated to the kidney and is classified as *pyelonephritis*.

### Management

#### Medical Management

#### Diagnosis

Diagnosis of a UTI is based on clinical manifestations and aided by urinalysis. A urine culture may be done when

necessary or in the case of a complicated UTI. A visual inspection of the urine specimen may reveal bloody and/or cloudy urine. Urinalysis demonstrates leukocytes, nitrites, hemoglobin, and bacteria. Leukocytes or white blood cells (WBCs) and red blood cells (RBCs) are present in the urine because of the inflammatory and infectious process associated with an infection. Nitrites are present because some bacteria convert nitrate to nitrite. Urine culture reveals greater than 100,000 bacteria. *Escherichia coli*, *Enterobacter*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* are common offenders. *E. coli*, a common intestinal bacterium, is responsible for 80% of all uncomplicated UTIs.

### Treatment

Treatment is primarily through medications. First-line treatment is antimicrobial therapy. The choice of antibiotic is dependent on urine culture sensitivities but, typically, an uncomplicated UTI—women who are not pregnant, do not have diabetes and are afebrile—can be treated empirically with a 3-day course of antibiotics. Trimethoprim/sulfamethoxazole (Bactrim DS) and ciprofloxacin (Cipro) are common antibiotics prescribed because of their efficacy in treating urogenital pathogens. A complicated UTI—diabetic, febrile, male gender—is typically treated with 7 to 10 days of antibiotics. In addition to antibiotics, bladder analgesics such as phenazopyridine (Pyridium) can be used to decrease dysuria, frequency, and urgency. Urinalysis and a urine culture can be obtained after completing antibiotics to verify the infection has been treated appropriately.

### Complications

Complications of a UTI include drug resistance or pyelonephritis and renal abscess. Drug resistance is possible when the patient does not complete antibiotics as prescribed. This resistance makes it difficult to find an appropriate antibiotic when/if the infection returns. Untreated or incomplete treatment of a UTI potentially allows for bacteria to migrate to the kidneys, causing pyelonephritis or renal abscess.

### Surgical Management

Surgical management of a UTI is reserved for patients with known risk factors for infections (bladder or kidney stones) or anatomical defects allowing for incomplete bladder emptying (pelvic organ prolapse in women or an enlarged prostate in men). An example of pelvic organ prolapse is a cystocele, which occurs when the walls between the bladder and vagina are weakened, allowing the bladder to descend into the vagina (Figure 63.1). This change in anatomy prevents the bladder from emptying completely, leading to UTIs. Surgical interventions such as colporrhaphy correct the defect in the vaginal wall, allowing the bladder to empty effectively, thus decreasing the risk of UTIs. Similarly, men with an enlarged prostate can also retain urine and develop UTIs (Figure 63.2). Surgical interventions for this condition, such as a transurethral resection of the prostate, remove excess prostatic tissue, allowing for complete bladder emptying.

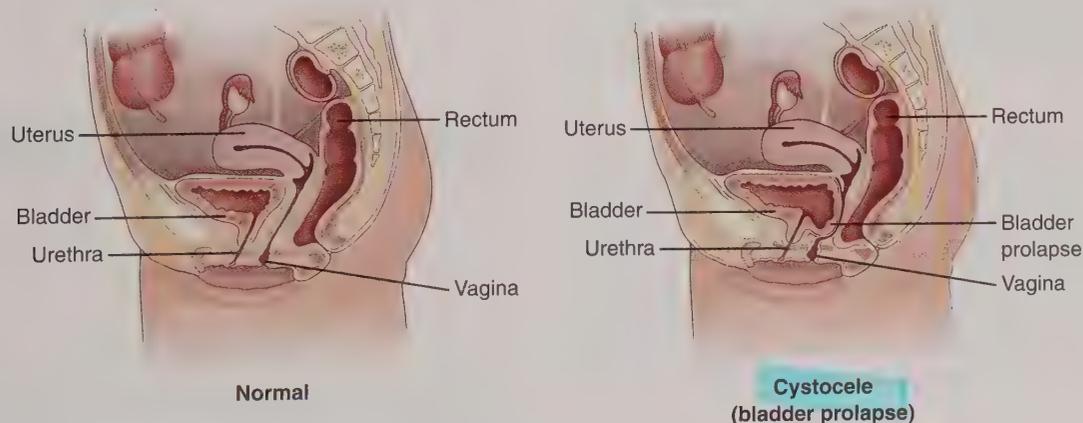

### Nursing Management

#### Assessment and Analysis

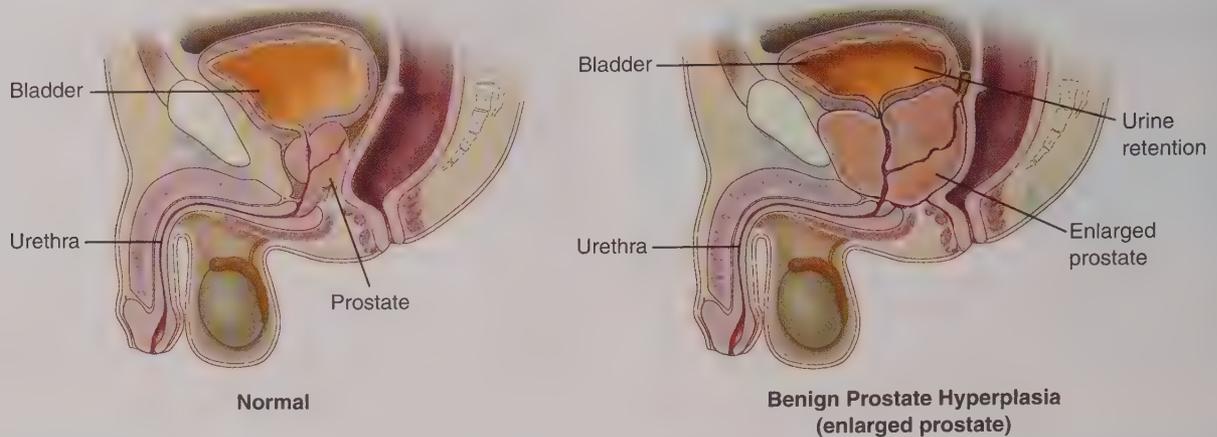

Most patients' physical examination is benign. When present, clinical manifestations of a UTI are due to the inflammatory process that occurs because of the infection. Assess the patient for the following:

- Fever
- Dysuria
- Urinary frequency
- Urinary urgency
- Gross hematuria
- Cloudy urine
- Malodorous urine

Physical examination findings of suprapubic tenderness, costovertebral tenderness, or fever may indicate pyelonephritis. Assess vital signs for temperature elevation, tachycardia, and low blood pressure, which can be indicative of an infection requiring hospitalization for fluid status monitoring and IV antibiotics.

**FIGURE 63.1** Cystocele (bladder prolapse). The walls between the bladder and vagina are weakened, allowing the bladder to descend into the vagina.

**FIGURE 63.2** Benign prostatic hyperplasia (enlarged prostate) can cause urinary retention, which increases the risk for urinary tract infection.

### Nursing Diagnoses

- **Altered urinary elimination** associated with irritation of bladder mucosa
- **Knowledge deficit** associated with the infection
- **Acute pain** associated with inflamed bladder mucosa

### Nursing Interventions

#### Assessments

- Vital signs  
*Elevated temperature, elevated heart rate, and decreased blood pressure may indicate upper urinary tract involvement and dehydration or a patient developing a systemic infection.*
- Urinary symptoms  
*Dysuria, urinary frequency, urgency, and gross hematuria are signs of a possible UTI.*
- Abdominal examination  
*Suprapubic tenderness can indicate lower tract infection, and costovertebral tenderness can indicate upper tract infection.*
- Urinalysis  
*The presence of hematuria, leukocytes, nitrates, and cloudy urine indicates infection.*
- Urine culture  
*Urine culture with greater than 100,000 bacteria indicates an active infection. Antibiotic use is dictated by urine culture sensitivities.*

#### Actions

- Administer antibiotics as ordered, dependent on urine culture sensitivities  
*Treatment with antibiotics, if indicated to clear the infection and avoid ascending infection such as pyelonephritis*
- Administer bladder analgesics such as phenazopyridine (Pyridium)  
*Phenazopyridine (Pyridium) decreases the irritative voiding symptoms associated with a UTI, such as dysuria, frequency, and urgency. Phenazopyridine (Pyridium) is used only short term (3 days) to avoid masking continued symptoms of a UTI.*

### Teaching

- Report elevated temperature, flank pain, nausea, and vomiting  
*Fever, flank pain, nausea, and vomiting despite antimicrobial therapy may indicate spread of infection, antibiotic resistance, and the need for either hospitalization or a change in antibiotics.*
- Increase fluid intake  
*Increase fluids to prevent dehydration and to flush urine of bacteria.*
- Signs and symptoms of a UTI  
*Early treatment of infection decreases morbidity.*
- UTI prevention  
*Wipe front to back and urinate before and after intercourse to prevent migration of bacteria to the bladder.*
- Medication education  
*Complete all antibiotics as prescribed. Untreated or incomplete treatment of a UTI may cause pyelonephritis or renal abscess or drug resistance. Educate patients that phenazopyridine (Pyridium) turns the urine an orange/red color.*

### Evaluating Care Outcomes

The health of the kidneys is protected by early and completed treatment. A well-managed patient has resolution of irritative lower urinary tract symptoms after completing antimicrobial therapy.

### CASE STUDY: EPISODE 2

Heather's urine culture results are positive for greater than 100,000 *E coli*, supporting the diagnosis of a UTI. The bacteria are shown to be sensitive to trimethoprim/sulfamethoxazole (Bactrim DS). She is prescribed a 7-day course of trimethoprim/sulfamethoxazole (Bactrim DS). Additionally, phenazopyridine (Pyridium) is prescribed to alleviate discomfort from dysuria. She is encouraged to increase her water intake...

## UROLITHIASIS

### Epidemiology

Urolithiasis is calcifications in the urinary system, commonly referred to as *kidney stones*. They can occur in the kidneys, ureter, and bladder, with renal stones being the most prevalent. **Nephrolithiasis** refers to a **calculus** in the kidney; **ureterolithiasis** refers to a calculus in the ureter. Urinary stones affect 12 per 10,000 persons in the United States, occur more frequently in males, and affect Caucasians more than African Americans. Stones appear more frequently in the southeastern United States and summer months, thought to be because of humidity, sweating, and decreased water consumption leading to **dehydration**. **Family history** increases one's risk of stones as do dietary habits such as increased sodium intake. Industrialized countries have a higher incidence of stones, thought to be due to high dietary protein intake. A person who develops urinary stones is at an increased risk of developing subsequent stones, with 10% of first-time stone formers developing another stone within 10 years.

### Connection Check 63.2

The nurse understands which population is at increased risk for developing urinary stones?

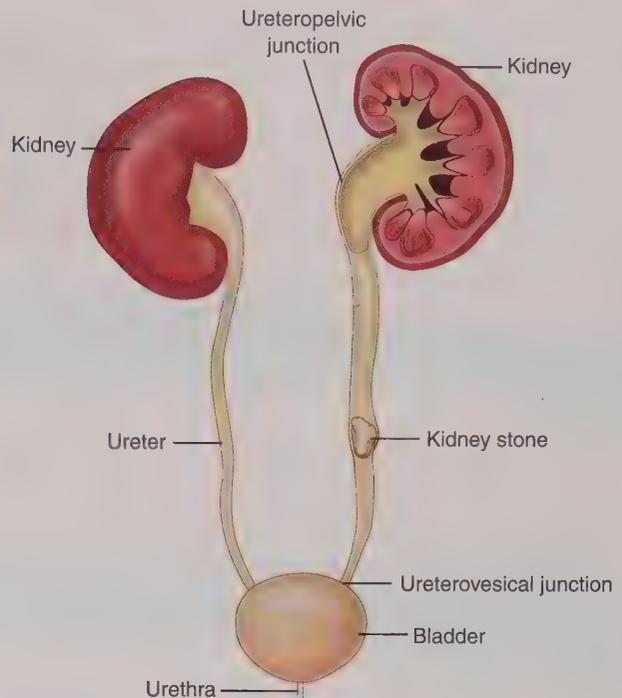

- Black females living in Florida
- White males living in Georgia
- Black males living in New York
- White females living in Oregon

### Pathophysiology

Urinary stones occur when microscopic crystals in the urinary tract aggregate together, causing a stone (calculus) to occur. Just as a small piece of sand can cause a pearl to develop in an oyster, tiny crystals in the urine can accumulate to form a stone. The majority of stones (80%) are calcium, and the remaining 20% are a combination of cystine, uric acid, and xanthine. Dehydration contributes to stone formation by allowing solutes to accumulate in the concentrated urine. Common places for a stone to obstruct include the **ureteropelvic junction** as the urine exits the kidney, the lower third of the ureter as it crosses the iliac vessels, and the **ureterovesical junction** as the urine flows into the bladder (Fig. 63.3).

### Clinical Manifestations

The major clinical manifestation of urinary stones is severe pain when the stone lodges in the ureter, causing distention and obstruction of urine flow. Pain associated with urinary stones is usually colicky, with concomitant nausea and vomiting. The location of the stone influences the location of the pain, with upper ureteral stones causing referred pain to the flank and lower ureteral stones causing lower abdominal, genital pain along with irritative voiding symptoms. Gross hematuria and microhematuria

**FIGURE 63.3** Kidney stone in the ureter.

can be present with any stone location and occur in 95% of patients.

### Management

#### Medical Management

##### Diagnosis

The diagnostic modality of choice for urinary stones is a noncontrast, stone survey computed tomography (CT) scan. A CT scan is a quick, noninvasive imaging modality with high sensitivity and specificity. In addition to identifying calculi, CT can assess for obstructive uropathy such as hydronephrosis. Hydronephrosis, or swelling of the kidneys, occurs when urine flow is blocked, allowing urine to accumulate in the kidney. A kidney ureter bladder (KUB) plain film or x-ray is quick and inexpensive but does not detect radiolucent stones such as uric acid stones. Ultrasound is recommended in children and pregnant females because of the lack of radiation exposure.

##### Treatment

Fifty percent of stones less than 5 mm pass spontaneously. For patients with small, less than 5-mm stones, minimal pain, and no hydronephrosis or infection, the opportunity to pass the stone on their own, a trial of passage, is the first-line treatment. Narcotics and/or nonsteroidal anti-inflammatory medicine along with antiemetics are used during this trial of passage. Alpha-adrenergic blockers such as tamsulosin (Flomax), doxazosin (Cardura), and terazosin (Hytrin) can be used to relax the musculature of the lower ureter and aid in stone passage. If the stone does not pass after 4 to 6 weeks or if the patient develops renal colic

(pain associated with the stone) unresponsive to narcotics, nausea/vomiting, or signs of a UTI, then surgical management is required.

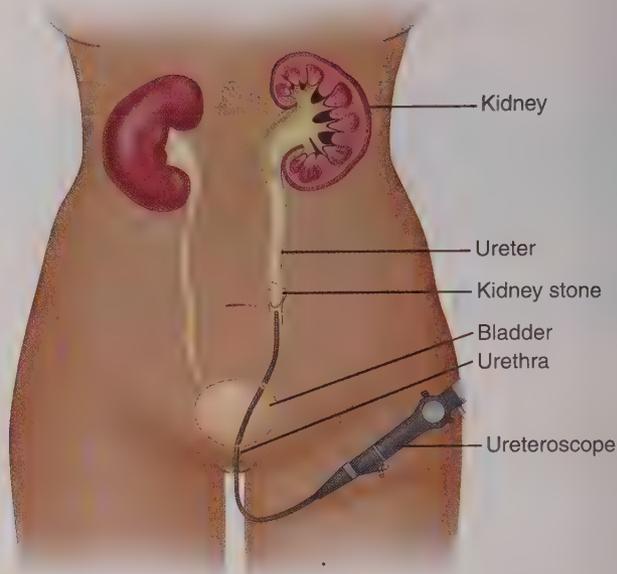

### Surgical Management

Surgical intervention is required when a stone is larger than 10 mm, causing severe obstruction and pain uncontrolled by narcotics and/or fever with infected urine. Surgery is varied and dependent on stone size, location, and urgency of treatment. Ureteroscopy, percutaneous nephrolithotomy, and extracorporeal shock wave lithotripsy are common surgical procedures for the management of stones.

Ureteroscopy is used for mid/distal ureteral stones. Under general anesthesia, a flexible scope is inserted through the urethra, bladder, and ureter to identify and remove the stone (Fig. 63.4).

For large stones greater than 2 cm and staghorn calculi, stones located in the renal pelvis and branching into the calyces, percutaneous nephrolithotomy is the treatment of choice. Under anesthesia, direct access is gained to the kidney percutaneously, allowing an instrument called a *nephroscope* to identify and remove the offending stone (Fig. 63.5).

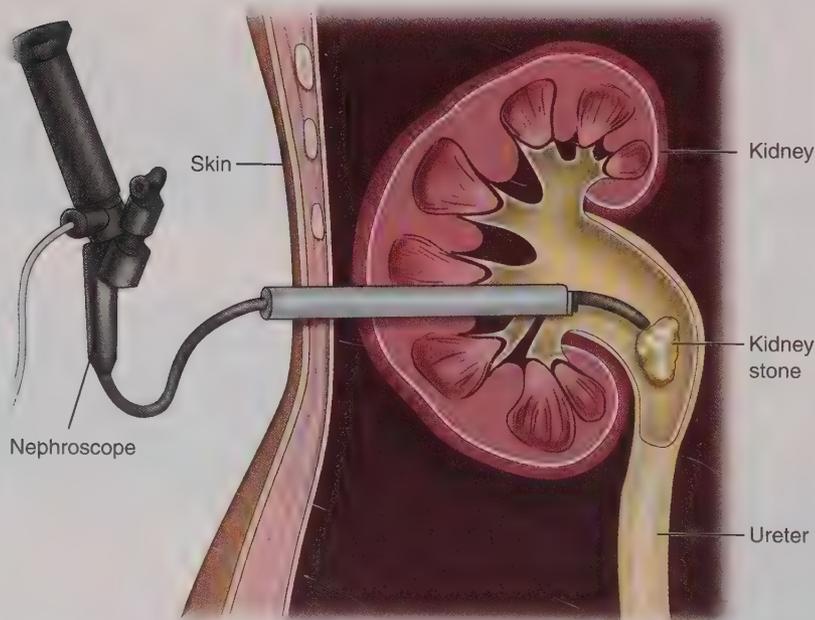

Extracorporeal shock-wave lithotripsy (ESWL) can be used for both renal and ureteral stones less than 2 cm. Extracorporeal shock-wave lithotripsy is a noninvasive procedure that utilizes shock waves to break up stones into small pieces, allowing the patient to pass stone fragments. Under conscious sedation and with the assistance of fluoroscopy, the offending stone is identified and fragmented with shock waves. Contraindications to ESWL include pregnant females and patients with uncorrected bleeding disorders (Fig. 63.6).

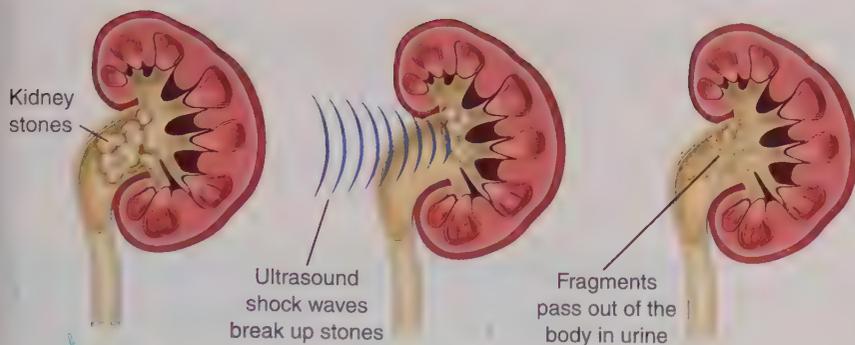

**FIGURE 63.4** Ureteroscopy: a flexible scope is inserted through the urethra, bladder, and ureter to identify and remove the stone.

### Complications

Untreated stones can lead to pyelonephritis, urosepsis, and irreversible renal damage. A rise in renal function indicators such as blood urea nitrogen and creatinine (BUN/Cr) indicates that aggressive treatment of the kidney stone is required to avoid these complications. A ureteral stent or nephrostomy tube may be necessary to allow drainage of urine from the obstructed kidney. A ureteral stent is a thin, flexible tube inserted into the ureter to facilitate urine drainage from the kidney. A nephrostomy tube is inserted through the skin into the kidney to allow urine drainage.

**FIGURE 63.5** Percutaneous nephrolithotomy: direct access is obtained to the kidney percutaneously, allowing a nephroscope to identify and remove the offending stone.

**FIGURE 63.6** Extracorporeal shock-wave lithotripsy (ESWL) to crush kidney stones.

**Safety Alert** If a trial of passage is prescribed, it is imperative that the patient either confirms passage of the stone with actual stone fragments collected while straining urine or that a KUB or CT scan confirms passage of the stone. A retained, asymptomatic ureteral stone can insidiously obstruct the flow of urine, resulting in potential loss of kidney function.

## Nursing Management

### Assessment and Analysis

The prominent clinical manifestation of urolithiasis is pain. It is due to the stone lodging in the ureter causing inflammation, distention, and blockage of urine flow. Renal colic is the severe, intermittent pain associated with a kidney/ureteral stone. Patients with renal colic have a difficult time finding a comfortable position because of the pain. Patients may be pacing, trying to alleviate the pain. This is in contrast to patients with other types of severe pain who sit or lie as still as possible because movement exacerbates the pain.

### Nursing Diagnoses

- **Acute pain** associated with inflammation and obstruction of the kidney
- **Altered elimination** associated with the obstruction
- **Risk for infection** associated with the obstructed stone

### Nursing Interventions

#### Assessments

- Vital signs  
*Increased heart rate and respiratory rate may be due to pain. Elevated temperature and low blood pressure can be caused by dehydration, infection and sepsis, and complications of untreated stones indicating a need for more aggressive therapy.*
- Pain or renal colic—severe, intermittent pain associated with a kidney/ureteral stone  
*Evaluation of pain helps determine the location of the stone and is necessary to evaluate effectiveness of the therapy. Renal stones cause flank pain and may radiate to the scrotum in men and the vulva in females. Midureteral stones can present with abdominal pain. Lower ureteral stones can present with*

*lower abdominal pain, referred pain to the genitalia, and irritative voiding symptoms.*

- Nausea and vomiting  
*Kidney obstruction can cause nausea and vomiting because of severe pain and irritation of the gastric nerve.*
- Urine pH  
*Acid stones are formed in acid urine.*
- Urine culture  
*A positive urine culture indicates the need for aggressive management with antibiotics, stone removal, and possible hospitalization.*
- Complete blood count and serum chemistries  
*Elevated WBC count may indicate antibiotics are required. Monitor BUN/Cr to assess renal function. The BUN may be elevated if dehydrated, and the Cr may be elevated in acute obstruction of the kidney with resulting renal damage.*
- Urine output/color  
*Minimal urine output should be between 30 and 50 mL/hr. Decreased urine output may indicate dehydration or an obstructed kidney. Gross hematuria may be present and, if present, ranges from iced-tea color to fruit punch. Aggressive stone removal is indicated for thick urine, “ketchup” consistency, or blood clots.*

#### Actions

- Administer analgesics such as hydromorphone (Dilaudid) or morphine sulfate (morphine) as ordered  
*Kidney stones can cause severe pain because of inflammation, irritation, distention, and blocked urine flow.*
- Administer antiemetics as ordered  
*Kidney stones can cause nausea and vomiting because of gastric nerve irritation.*
- Administer alpha blockers as ordered  
*Tamsulosin (Flomax), doxazosin (Cardura), or terazosin (Hytrin) helps dilate/relax the lower ureter and allows for ease of stone passage. A common side effect is light-headedness, and patients should be educated to rise slowly from a seated position to avoid orthostatic hypotension.*
- Maintain fluid status; encourage PO fluids or administer fluids IV as ordered.  
*Hydration to facilitate urine production and flow is paramount in kidney stone management. If the patient is unable to stay hydrated despite antiemetics, hospitalization for IV fluids may be required.*

- Strain urine  
*Collect stone and send for stone analysis. Stone analysis helps dictate patient education and prevention of future stones.*
- Insert Foley catheter if the patient is unable to void  
*Urine retained in the kidney or bladder puts the patient at risk for pyelonephritis, urosepsis, and irreversible renal damage.*

### ■ Teaching

- Trial of passage patients: Strain urine, call provider for fever, chills, nausea/vomiting, or pain uncontrolled by pain medicine
  - *Straining urine is important to confirm passage of the stone with actual stone fragments.*
  - *The symptoms may indicate obstruction and/or infection and the need for hospitalization.*
- Kidney stone prevention: hydration, low-sodium diet, increase dietary intake of citrate, decrease dietary intake of oxalate
  - *Hydration is paramount in the prevention of kidney stones. Encourage urine output of 2 L a day and monitor urine color. If urine is clear yellow, this shows adequate hydration, and if urine is amber, this indicates the need to increase fluids.*
  - *A low-sodium diet can prevent stones by decreasing the risk of dehydration associated with a high-sodium diet.*
  - *Increase dietary intake of citrate found in lemons and lemonade. Citrate prevents the formation of stones.*
  - *Avoid foods high in oxalate, such as rhubarb, chocolate, tea, coffee, and nuts. These foods can increase the risk of stones.*

### Connection Check 63.3

Which statement by the patient indicates teaching about tamsulosin (Flomax) has been effective?

- “Will this medicine help my nausea?”
- “So, this medicine will help me pass the stone by relaxing the muscles?”
- “I need to take this medicine so I don’t get an infection.”
- “This medicine is for my pain.”

### Evaluating Care Outcomes

The avoidance of kidney stone formation is accomplished by adequate hydration, following dietary restrictions, and careful monitoring. If a stone is present, kidney function can be preserved through careful assessment of urine and appropriate management with hydration. A well-managed patient is free from pain, is afebrile, and has adequate amounts of clear yellow urine.

## INCONTINENCE

### Epidemiology

Urinary incontinence is a growing public health problem that affects approximately 20 million Americans. While the percentage of our aging population increases, the incidence

of incontinence increases. It is estimated that 15% to 35% of people older than age 60 experience some urinary incontinence.

### Pathophysiology and Clinical Manifestations

Urinary incontinence is defined as the involuntary or uncontrolled loss of urine in any amount. To understand incontinence, it is first necessary to understand the components of the normal **micturition** (urination) cycle. It involves a complex interplay between the sympathetic and parasympathetic nervous systems. The parasympathetic nervous system provides motor stimulation to the bladder and mediates bladder contraction. The sympathetic nerves mediate bladder storage by stimulating contractions in the bladder neck and proximal urethra, blocking urine flow. While the bladder slowly fills with urine from the kidneys via the ureters, the stretching of the **detrusor muscle** (or bladder muscle) slowly increases. Stimulation from the sympathetic nervous system maintains closure of the **internal urethral sphincter** preventing contraction of the detrusor muscle, allowing the bladder to fill. When the detrusor muscle reaches a certain threshold of distention, sensory nerves on the bladder wall are stimulated. This sensation is perceived as fullness, and the signal is transmitted to the spinal cord, to S2–S4, the portion of the spinal cord known as the **sacral micturition center**, by way of the pelvic nerve. The message is also transmitted to the brain via the spinal cord. The brain then sends the message back through the spinal cord via parasympathetic fibers (sympathetic activity is inhibited) to initiate detrusor muscle contraction. At the same time, the internal urethral sphincter relaxes (an involuntary action) to initiate voiding, or emptying, of the bladder. If perceived as an appropriate time to void, the **external urethral sphincter** is voluntarily relaxed, allowing urine to flow into the urethra.

There must be intact neural pathways for normal bladder function. Injuries or lesions at the level of S2 to S4 or below generally result in an areflexic (flaccid) bladder, resulting in retention with overflow. Injuries above this level often result in a hyperreflexic bladder, resulting in uncontrolled spontaneous voiding. Types of incontinence include **stress incontinence**, **urge incontinence**, mixed (combination of stress and urge), **overflow incontinence**, **reflex incontinence** or **functional incontinence**. Types, causes or risk factors, and manifestations are outlined in Table 63.1.

### Management

#### Medical Management

The first step in the management of urinary incontinence is a realization on the part of the patient that incontinence is not a normal part of the aging process and that it is often treatable and always manageable. The nurse plays a key role in the management process throughout, beginning by

**Table 63.1** Types of Incontinence

Incontinence Type	Causes/Risk Factors	Manifestations
<b>Stress incontinence</b>	<ul style="list-style-type: none"> <li>• More common in women</li> <li>• Childbirth, which causes stretching and relaxing of pelvic floor muscles, ligaments, and urethra</li> <li>• Postmenopausal women</li> <li>• Smoking, obesity</li> </ul>	<ul style="list-style-type: none"> <li>• Urine leakage occurs when abdominal pressure increases: laughing, coughing, lifting, exercising</li> </ul>
<b>Urge incontinence</b>	<ul style="list-style-type: none"> <li>• Exposure to bladder irritants such as caffeine, artificial sweeteners, or nicotine</li> </ul>	<ul style="list-style-type: none"> <li>• Strong urge to urinate followed by uncontrolled leakage</li> </ul>
<b>Mixed (combination of stress and urge)</b>	<ul style="list-style-type: none"> <li>• Combination of previous</li> </ul>	<ul style="list-style-type: none"> <li>• Combination of above</li> </ul>
<b>Overflow</b>	<ul style="list-style-type: none"> <li>• Flaccid/enlarged bladder due to obstruction (e.g., enlarged prostate), spinal cord injury, stroke, diabetes, neurological diseases</li> </ul>	<ul style="list-style-type: none"> <li>• Frequent urination</li> </ul>
<b>Functional</b>	<ul style="list-style-type: none"> <li>• Inability to get to the toilet or communicate the need to do so</li> </ul>	<ul style="list-style-type: none"> <li>• Patient is continent but environmental factors lead to loss of urine in inappropriate areas</li> </ul>
<b>Reflex</b>	<ul style="list-style-type: none"> <li>• Disorders that affect the nervous impulse for voiding such as multiple sclerosis, brain tumors, or stroke</li> </ul>	<ul style="list-style-type: none"> <li>• Bladder muscle contracts on its own, urethral sphincters exhibit varying control</li> </ul>

encouraging the patient to seek help/evaluation and helping to reduce the self-imposed stigma that many patients feel.

### Diagnosis

Diagnosis starts with a thorough history. This history should include questions about medical, urological, voiding, neurological, and reproductive history. The patient should be questioned as to management routines and patterns of incontinence and voiding characteristics. A voiding diary may provide much useful information. A physical should include a thorough neurological assessment and examination of the genitalia.

### Laboratory Testing/Imaging Studies

Laboratory testing begins with urine culture and urinalysis, which may rule out infection and/or illness such as uncontrolled diabetes mellitus as factors. Blood tests associated with renal function, such as BUN/Cr, reveal the effects of bladder function on the upper urinary tracts.

Imaging studies may include plain x-rays or films of the kidneys, ureters, and bladder (KUB), IV pyelogram (an x-ray of the renal system with IV contrast solution to facilitate imaging), or a voiding cystourethrogram (VCUG). A VCUG uses contrast dye injected into the bladder to enable visualization of the voiding process. Ultrasound tests provide useful information about the urinary tract without exposing the patient to radiation. Urodynamic studies measure the transport, storage, and elimination functions of the urinary tract. An element of urodynamic testing is uroflowmetry, which tests the urinary flow rate in milliliters per second.

A cystometrogram (CMG) assesses the bladder's filling and storage function. It graphically represents bladder pressure compared with volume while the bladder is filled with liquid. Often, a CMG is coupled with a sphincter electromyogram. Electrical signals from the periurethral muscles are graphically recorded by placing electrode patches on the external area (perineal and perianal). A pressure-flow analysis combines data from the previous tests with measurement of the urine flow pattern.

### Treatment

The primary goal of treatment, when possible, is to prevent or stop urinary leakage. If this is not possible, containment with scrupulous skin care and odor control becomes the new objective. Another goal of equal importance is prevention or reduction of damage to the upper tracts or the kidneys, manifested by deteriorating renal function. Management is based on the type of incontinence and is done with medications, nonsurgical measures, or surgical measures if the medications or nonsurgical means have not worked. Medications indicated in the management of incontinence are noted in Table 63.2.

Nonpharmacological and nonsurgical measures include measures to strengthen the pelvic floor such as Kegel exercises. Kegel exercises consist of contracting and relaxing the pubococcygeus muscles that form part of the pelvic floor in an effort to improve muscle tone. Specifically, Kegel exercises are used for strengthening the external urinary sphincter, which is under voluntary control. Other nonsurgical means are treatments that alter the angle of the structures that affect bladder and urethral pressure such as a pessary. A pessary is a device that fits into the vagina to

**Table 63.2 Medications Used to Treat Incontinence**

Medication	Purpose
<b>Anticholinergics</b> Oxybutynin (Ditropan); tolterodine (Detrol); darifenacin (Enablex); trospium (Sanctura); salifenacin (Vesicare); and fesoterodine (Toviaz)	Used to calm an overactive bladder. Anticholinergics block nervous stimulation from the parasympathetic nervous system to help relax and control bladder muscle contractions
<b>Topical estrogen</b>	Used in stress incontinence in peri and postmenopausal women to help restore tone in the urethra and vaginal areas
<b>Tricyclic antidepressant</b> Imipramine (Tofranil)	Used to treat mixed-urge and stress incontinence; decreases bladder contractility and has an antispasmodic effect on the bladder
<b>Alpha-adrenergic blockers</b> Tamsulosin (Flomax), alfuzosin (Uroxatral)	Used in issues of urge or overflow in men - useful in enlarged prostate issues. Promote urethral relaxation, relaxes bladder neck and muscle fibers in the prostate
<b>Beta-3 adrenergic agonist</b> Mirabegron (Myrbetriq)	Used to treat frequent and/or urgent uncontrolled urination; relaxes bladder muscles

BPH, Benign prostatic hyperplasia.

support the bladder in an attempt to control incontinence and support bladder emptying (Fig. 63.7). **Clean intermittent catheterization (CIC)** is another technique used to manage incontinence. Clean intermittent catheterization involves the intermittent placement of a catheter through the urethra into the bladder. This is done to completely empty the bladder in an effort to prevent UTIs or kidney damage due to urinary retention. A CIC also helps establish voiding patterns and may eliminate the frequent feelings of needing to void.

### Surgical Management

Surgical interventions include procedures that tighten the pelvic floor and provide support to the urethra; a suburethral sling used for stress incontinence, or a procedure to increase

bladder capacity; augmentation cystoplasty. There are several types of suburethral slings; a bladder neck or pubo-vaginal sling with support at the bladder neck and proximal urethra and a midurethral sling with support at midurethral level. These slings prevent urethral descent and urine leakage during physical activity or stress when abdominal pressure increases. Severe stress incontinence after prostate cancer treatment in men can be treated with an artificial urinary sphincter. This is a surgically implanted device; a cuff, balloon and pump, which supports the function of the urinary sphincter by restricting flow from the bladder via the saline filled cuff around the urethra. When appropriate to void, the man squeezes the pump located in the scrotum, allowing the saline to flow from the cuff into the balloon, releasing the pressure to allow urination. See Table 63.3 for a listing of interventions based on incontinence type.

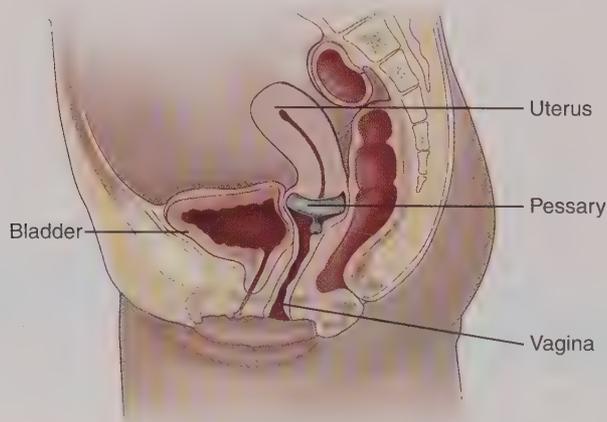

### Complications

Complications of urinary incontinence include skin changes associated with exposure to a moist environment. Poorly managed incontinence may also lead to renal disease secondary to retention and/or incomplete emptying, which results in backflow of infected urine.

### Connection Check 63.4

The patient with stress incontinence is prescribed Kegel exercises. The nurse tells the patient that Kegel exercises will help:

- Strengthen the detrusor muscle
- Strengthen the posterior urethral valves
- Strengthen the internal sphincter
- Strengthen the external sphincter

**FIGURE 63.7** Pessary: a device that fits into the vagina to support the bladder in an effort to control incontinence.

**Table 63.3 Interventions Based on Incontinence Type**

Type of Incontinence	Nonsurgical Measures	Surgical
<b>Stress</b>	<ul style="list-style-type: none"> <li>● Pelvic floor exercises, e.g., Kegel</li> <li>● Pessaries</li> </ul>	<ul style="list-style-type: none"> <li>● Suburethral sling</li> <li>● Artificial urinary sphincter</li> <li>● Collagen injection (periurethral) to strengthen the muscles around the urethra</li> </ul>
<b>Urge</b>	<ul style="list-style-type: none"> <li>● Eliminate bladder irritants such as nicotine or coffee</li> <li>● Prompted voiding— voiding at predetermined intervals</li> <li>● Fluid control; adequate intake without large volumes at one time, stop intake 2 hours before sleep</li> <li>● Clean intermittent catheterization (CIC) when antispasmodics are used in doses high enough to paralyze the detrusor muscle</li> <li>● Biofeedback</li> </ul>	<ul style="list-style-type: none"> <li>● Augmentation cystoplasty to increase bladder capacity</li> </ul>
<b>Reflex incontinence and dyssynergia</b> (incoordination of the detrusor muscles and the external urethral sphincter)	<ul style="list-style-type: none"> <li>● CIC</li> <li>● Reflex voiding (for men)—using a condom catheter and a leg bag to collect the urine—allowing the bladder to spasm and empty on its own</li> </ul>	<ul style="list-style-type: none"> <li>● Augmentation cystoplasty</li> </ul>
<b>Overflow incontinence (retention)</b>	<ul style="list-style-type: none"> <li>● CIC</li> <li>● Indwelling catheter</li> <li>● Double voiding—void and then wait 3-5 minutes and void again</li> <li>● Fluid control—adequate intake—spread out during waking hours—stopping 2 hours before bed</li> </ul>	<ul style="list-style-type: none"> <li>● Correction of underlying obstruction</li> </ul>
<b>Total or continual incontinence</b>	Containment devices and skin protection, such as diapers and skin barrier ointments	<ul style="list-style-type: none"> <li>● Correction of structural anomaly</li> <li>● Urinary diversion</li> </ul>
<b>Functional</b>	Nursing measures to alleviate functional aspects of leakage, such as timed toileting or mobility devices	<ul style="list-style-type: none"> <li>● As indicated by concomitant causes of incontinence</li> </ul>

## Nursing Management

### Assessment and Analysis

The clinical manifestations of incontinence vary depending on the causative factors. Some patients have stress incontinence associated with physical activity due to sphincter incompetence. Others have incontinence associated with urinary retention issues secondary to obstructions such as benign prostatic hypertrophy.

### Nursing Diagnoses

- **Alteration in urinary elimination** associated with lack of control
- **Knowledge deficit** associated with incontinence skin care and management
- **Alteration in body image perception** associated with incontinence or “wetting” episodes

## Nursing Interventions

### Assessments

- **Vital signs**  
*Increased temperature, rapid pulse, and decreased blood pressure may indicate infection with urinary retention as a possible etiological factor*
- **Assessment of what precipitates urinary incontinence**  
*Determining the cause, such as stress or urge incontinence, impacts treatment.*
- **Urinalysis**  
*White blood cells, nitrates, proteinuria, and hematuria may indicate infection.*
- **Urine culture**  
*A urine culture identifying specific bacteria identifies the presence of an infection and dictates antibiotic treatment.*

- Voiding diary  
*Determining incontinence patterns is essential to outlining management options.*

### ■ Actions

- Administer medications as ordered on the basis of incontinence assessment results
  - Anticholinergics/Antispasmodics  
*Block impulses from the parasympathetic nervous system to relax and control the bladder.*
  - Tricyclic antidepressants  
*Decreases bladder contractility and has an antispasmodic effect on the bladder*
  - Alpha-adrenergic blocking agents  
*Promote urethral relaxation; aid in issues of urinary retention*
  - Topical estrogen  
*Restore tone in urethra and vaginal areas*
  - Beta-3 Adrenergic Agonist  
*Relaxes bladder muscles*

### ■ Teaching

- Medications  
*Understanding the medications and side effects used in the treatment plan helps ensure compliance.*
- Technique for CIC  
*Clean intermittent catheterization is a fairly easy but awkward procedure. Adequate teaching with a return demonstration helps ensure effective technique at home.*
- Voiding diary  
*The voiding diary helps determine the type of incontinence and the effectiveness of therapy.*

### Evaluating Care Outcomes

The well-managed patient has been assessed for type of incontinence, and appropriate interventions have been implemented. The incontinence has been resolved or managed through containment and skin barrier products, and the patient is able to carry out normal activities of daily living. The patient is clean, odor-free with intact skin, and has a management plan in place that considers mobility, skin integrity, and maintenance of urological health.

## BLADDER CANCER

### Epidemiology

Bladder cancer is the fourth most common cancer among men and the eighth most common among women. The incidence of bladder cancer has increased by 50% from the mid-1950s to the mid-1990s. According to the American Cancer Society, in 2017 in the United States there were 79,030 new cases of bladder cancer and 16,780 deaths. Smoking is the most important risk factor for bladder cancer in the United States. Other risk factors include aromatic amine exposure from the rubber and chemical industries, polycyclic aromatic hydrocarbon exposure from the coal and aluminum industries, chronic infection

or inflammation from chronic catheter use, or incomplete bladder emptying. In some third-world countries, schistosomiasis, a parasitic infection, is the leading risk factor.

### Pathophysiology and Clinical Manifestations

Tumor formation in bladder cancer is attributed to genetic changes in target cells. Target cells are normal cells of the body that have undergone some alteration, synthesize abnormal proteins, and then undergo malignant changes. The process is thought to be caused by the activation of oncogenes (genes that when altered promote the uncontrolled proliferation of cancer cells) that act in one of two ways: by inactivation of tumor suppression genes or by activation of genes that cause cells to grow in a rapid, random manner.

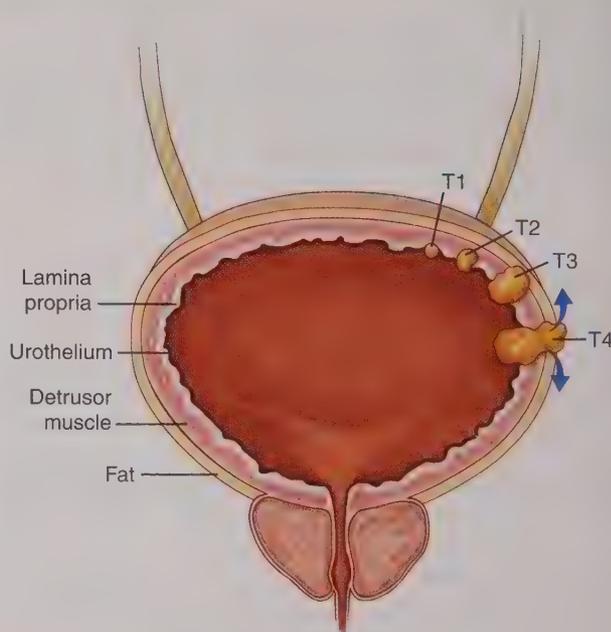

The tumor, nodes, metastasis (TNM) staging system is a widely used system for staging all types of cancer (Fig. 63.8). Bladder cancers are classified as non-muscle invasive cancer (T1), affecting the inner lining of the bladder (**urothelium**), or muscle invasive cancer (T2–T4), which means the cancer has extended through the urothelium and into the detrusor muscle. Painless hematuria is the most common presenting symptom of bladder cancer.

### Management

#### Medical Management

#### Diagnosis

Early detection and treatment increase survival rates. A thorough history and physical are essential first steps in reaching a diagnosis of bladder cancer. The history should

**FIGURE 63.8** The stages of bladder cancer. Superficial (T1) cancer affects the urothelium or lining of the bladder. Invasive (T2–T4) is when the cancer has extended through the urothelium and into the detrusor muscle.

include careful questioning associated with risk factors such as smoking and exposure to second-hand smoke. There are a number of tests that are helpful in determining a diagnosis of bladder cancer. Urine cytology is a screening test but has only 40% accuracy. Blood and urine tests may be done to look for tumor markers. Urine cultures are done to rule out infection as a cause of symptoms. Cystoscopy, or examination of the bladder with a scope, is used to make a definitive diagnosis. This is coupled with a biopsy of any lesions that are discovered during the examination. Imaging studies (CT, magnetic resonance imaging, positron emission tomography, ultrasound) may be used to determine whether there is spread of the cancer outside of the bladder.

## Treatment

Drug therapy for low-grade bladder cancers consists of topical therapy or installation of solutions into the bladder, intravesical therapy. This can be either intravesical immunotherapy or chemotherapy. Intravesical immunotherapy, such as bacille Calmette-Guérin (BCG), is aimed at “jump-starting” the body’s own immune defenses to battle the invasion of cancer. Intravesical chemotherapy instills medications given to kill actively growing cancer cells.

Although topical chemotherapy has long been a mainstay in the treatment of non-invasive bladder cancers, systemic immunotherapy is relatively new in the treatment of later-stage bladder cancer. In a healthy individual, “checkpoint” molecules keep the immune system from attacking the body’s normal cells. Cancer cells avoid being attacked by the immune system by using these checkpoint molecules. Systemic immunotherapy targets checkpoint molecules. Examples of drugs in this category are atezolizumab (Tecentriq), durvalumab (Imfinzi), avelumab (Bavencio), nivolumab (Opdivo) and pembrolizumab (Keytruda).

New advances in high-grade metastatic bladder cancer management and treatment may be classified under the broad title of precision medicine. Diagnostic testing may identify genetic changes in bladder cancer cells and allow more accurate/precise prediction of individual prognosis. Those individuals with cancers that are likely to recur are candidates for targeted therapy. Targeted drug therapy is directed at changes in cells that cause them to become cancer: examples include lapatinib (Tykerb) and erlotinib (Tarceva). This therapy may also target blood vessels that carry nutrition to the cancer cells using antiangiogenesis drugs. Examples of these drugs are bevacizumab (Avastin); sorafenib (Nexavar); cabozantinib (Cometriq); and pazopanib (Votrient). Gene therapy is another new treatment using lab-modified viruses that are instilled into the bladder and infect cancer cells.

**Safety Alert** Bacille Calmette-Guérin is a live, weakened bacterium. To ensure that others are not

infected by the bacteria, after voiding following treatment, the patient should pour 2 cups of bleach into the toilet and allow it to sit for 20 minutes before flushing.

## Surgical Management

The surgical interventions for low-grade bladder cancers consist of excision or removal of the tumor through fulguration or laser ablation. Fulguration destroys the tumor by using high-frequency electrical current, and laser ablation destroys tissue by irradiating it with a laser beam.

Prior to treatment, a biopsy is done to determine the depth of invasion. Intravesical chemotherapy may be given before surgical excision (neoadjuvant) or after surgical excision (adjuvant). Radiation is indicated postoperatively.

Muscle-invasive bladder cancers require more extensive and life-altering treatments. There are surgical, nonsurgical, and combined approaches. One approach, a “bladder preservation” procedure; excision of the tumor or partial cystectomy (partial bladder removal), may be combined with radiation and/or chemotherapy. Chemotherapy is indicated to downgrade tumors preoperatively or to help eradicate cancer that has spread beyond the bladder either grossly (visible to the eye) or microscopically through the lymphatic system. Radiation is indicated postoperatively in those patients who have solid tumor recurrence after cystectomy.

Another approach for surgical management of invasive bladder cancer, radical cystectomy, combined with neoadjuvant chemotherapy, is considered to be the definitive approach. It offers the best chance of cure or extension of the disease-free state. In male patients, the procedure is called a radical cystoprostatectomy and involves removal of the bladder, prostate, seminal vesicles, lower ureters, and in some cases, the urethra. In female patients, the procedure is called a radical cystectomy or anterior exenteration. Generally, the structures removed are the bladder, uterus, ovaries, fallopian tubes, anterior wall of the vagina, lower ureters, and often the urethra. These procedures also involve pelvic lymph node dissection in both male and female patients. There is controversy as to how extensive this dissection should be, and it varies from a wide, all-encompassing excision to excision of the sentinel lymph node.

This radical surgery requires reconstruction of the urinary tract. This may be accomplished in one of three ways, all of which use segments of the gastrointestinal tract to provide reconstruction for the removed portion of the urinary tract. The ileal conduit uses a short (15-cm) segment of ileum to provide a viaduct for the exit of urine from the body through a stoma on the abdomen. The orthotopic neobladder uses 20 to 30 cm of small intestine to create a bladder that is anatomically in the same position as the native bladder and uses the patient’s external sphincter for continence. The third option, a neobladder with catheterizable stoma and an internal pouch to collect urine, requires clean intermittent catheterization (CIC) and is the option most fraught with complications. Table 63.4 outlines options for urinary tract reconstruction.

**Table 63.4 Summary of Urinary Tract Reconstruction Options**

	<b>Ileal Conduit</b>	<b>Orthotopic Neobladder</b>	<b>Neobladder With Continent Catheterizable Stoma</b>
<b>Advantages</b>	<ul style="list-style-type: none"> <li>● Simplest “tried and true” procedure</li> <li>● Fewest complications</li> </ul>	<ul style="list-style-type: none"> <li>● No external pouch</li> <li>● Most closely resembles “normal” urination</li> </ul>	<ul style="list-style-type: none"> <li>● No external pouch</li> <li>● Stoma often placed in umbilicus, not visible</li> </ul>
<b>Disadvantages</b>	<ul style="list-style-type: none"> <li>● External pouch, stoma</li> <li>● Adhesives may cause skin irritation</li> <li>● Lifelong equipment (pouches, drainage bag) required</li> </ul>	<ul style="list-style-type: none"> <li>● May require intermittent catheterization</li> <li>● May require physical therapy for sphincter training</li> <li>● May not achieve continence</li> </ul>	<ul style="list-style-type: none"> <li>● Stoma may not be continent</li> <li>● Strictures at skin level may occur</li> <li>● Catheter required to empty the internal pouch at regular intervals</li> </ul>
<b>Bowel used</b>	● 10–15 cms of terminal ileum	● 30 cm of ileum	● Ileum and cecum, possibly appendix

### Connection Check 63.5

The nurse understands that non-muscle cancers affect only:

- Muscle and surrounding fat
- The urothelium, or inner lining of the bladder
- Structures adjacent to the bladder
- The lobes of the prostate

### Complications

Complications may be associated with the disease process or treatment. Disease process complications include bleeding from friable tumors in the bladder or pain caused by impingement of other organs by the tumor. Treatment-related complications include lasting side effects from chemotherapy, such as peripheral neuropathy, or hemorrhagic cystitis from radiation. Complications from surgery include bowel obstruction, fistula formation, hernia development in the surgical site, and complications/disadvantages specific to the type of reconstruction of the urinary tract (see Table 63.4).

### Nursing Management

#### Assessment and Analysis

The clinical manifestations noted in patients with bladder cancer are typically associated with treatment side effects and the emotional factors associated with the diagnosis. Fatigue and poor nutritional intake may be associated with chemotherapy or antibiotic side effects such as lowered hemoglobin and hematocrit, nausea, and oral thrush. Decreased appetite and a flat affect may be associated with depression secondary to poor prognosis and a change in body image. Painless hematuria, which may be gross or microscopic, is the most common presenting symptom of bladder cancer. The patient may have irritative voiding symptoms (frequency, urgency, nocturia), which may be due to the presence of the tumor in the bladder.

### Nursing Diagnoses

- **Knowledge deficit** associated with disease, diagnostics, and management options
- **Alteration in elimination pattern** associated with the effects of treatment on a continuum from irritative symptoms to reconstruction of the urinary tract

### Nursing Interventions

#### Assessments

- Vital signs  
*Increased pulse and decreased blood pressure may indicate blood loss postoperatively. Increased pulse, decreased blood pressure, and increased temperature may indicate infection.*
- Urinalysis  
*Hematuria may be present in bladder cancer.*

#### Actions

- Administer medications as ordered:
  - Intravesical immunotherapy  
*Immunotherapy is used to aid the body’s natural defense against tumor growth.*
  - Intravesical chemotherapy  
*Chemotherapy is used to destroy the tumor cells.*
  - Immunotherapy  
*Systemic immunotherapy targets checkpoint molecules to allow for destruction of cancer cells.*
  - Targeted therapy  
*Targeted drug therapy is directed at changes in cells that cause them to become cancer or target blood vessels that carry nutrition to the cancer cells*
- Continuous bladder irrigation (CBI)  
*Continuous bladder irrigation may be used after tumor excision or biopsy to clear blood and clots from the bladder and prevent obstruction.*
- Accurate intake and output  
*Accurate bladder intake and output recording is essential to determine whether clots have cut off the flow of urine. (If CBI is in place, true urine output = total fluid output minus amount of irrigant instilled.)*

## ■ Teaching

### ● Bladder cancer, treatment and outcome

*A cancer diagnosis is frightening. Increasing a patient's knowledge helps him or her feel a measure of control and increases compliance.*

## Evaluating Care Outcomes

The well-managed patient with bladder cancer has an effective pain management plan in place, is disease-free or symptom controlled, and is aware of the treatment course and options. Anxiety is at an acceptable level as self-reported or reported by significant others. There is an awareness of how to access support through peer and professional groups.

## Making Connections

### CASE STUDY: WRAP-UP

Heather understands the importance of completing her antibiotics as directed to prevent bacterial resistance. She is encouraged to increase her fluid intake to flush her urine and to call her provider for fever or flank pain or if her symptoms do not improve after completing the antibiotics. She is provided with education on how to prevent future UTIs, such as wiping front to back after using the toilet and urinating after sexual intercourse.

### Case Study Questions

- Which statement by Heather regarding new flank pain indicates teaching has been effective?
  - "I'll call the doctor for pain medicine if the flank pain comes back."
  - "Does new flank pain mean I might have an infection in my kidneys?"
  - "New flank pain means the infection has spread to my gallbladder."
  - "This pain may mean the infection could involve my reproductive system."
- Which action by Heather indicates the need for further teaching about her prescribed medicines?
  - Heather calls in a panic because her urine is an orange color.
  - Heather is scheduling her follow-up appointment even though her dysuria resolved with phenazopyridine (Pyridium).
  - Heather states her understanding that phenazopyridine (Pyridium) should be taken no more than 3 days.
  - She reports her symptoms have improved but continues to take her trimethoprim/sulfamethoxazole (Bactrim DS) as prescribed.

- The nurse recognizes Heather's urinalysis is suspicious for a UTI by the presence of the following: (*Select all that apply.*)
  - Ketones
  - White blood cells
  - Bacteria
  - Bilirubin
  - Protein
- Which statements are true regarding UTIs? (*Select all that apply.*)
  - Urinary tract infections are more common in women because of the close proximity of the urethra, vagina, and rectum.
  - Sexual intercourse does not increase the risk for UTIs.
  - It is more common for males to develop a UTI because of the length of the urethra.
  - Sexual intercourse increases the risk for a UTI.
  - Flank pain is a symptom of lower UTIs.
- The nurse understands which common signs indicate a lower UTI? (*Select all that apply.*)
  - Fever
  - Dysuria
  - Frequency
  - Hematuria
  - Nausea

## CHAPTER SUMMARY

Urinary tract infections occur more frequently in young women but can affect older men and women as well. Irritative voiding symptoms such as frequency, urgency, dysuria, and suprapubic pain are signs of a UTI, and diagnosis is made on the basis of urinalysis and urine culture results. Treatment of UTIs is based on urine culture sensitivities, and repeated urine cultures should be obtained after completion of antibiotics to verify that the infection has been eradicated.

Approximately 8% of Americans will develop a kidney stone in their lifetime. Kidney stones frequently occur in the southeastern United States, and risk factors for urolithiasis include poor fluid intake, diet high in sodium and protein, and family history. Patients with urolithiasis can develop severe pain, and the size and location of the stone helps dictate treatment options. If the patient has a concurrent UTI, surgical intervention may be required.

Urinary incontinence, defined as the involuntary or uncontrolled loss of urine in any amount, affects as many as 25 million Americans, both men and women. Incontinence is a symptom of other pathology. Careful assessment is necessary to determine the type of incontinence, eliminate the causative factors, and formulate the disease-specific treatment plan. In part because of our aging population

(baby boomers), incontinence is one of the fastest-growing public health problems.

Bladder cancer incidence has increased by 50% in the last 40 years. In the United States, cigarette smoking is the most important risk factor, which has implications for public

health education by nurses. Treatment for bladder cancers ranges from intravesical instillations of chemotherapeutic agents for superficial and low-grade cancers to bladder removal and urinary tract reconstruction for muscle-invasive or high-grade cancers.

## Promoting Health in Patients With Reproductive Disorders

### Chapter 64

## Assessment of Reproductive Function

*Valerie Bader*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Identifying key anatomical components of the reproductive system
2. Discussing the function of the reproductive system
3. Describing the procedure for completing a history and physical assessment of reproductive function
4. Correlating relevant diagnostic examinations to reproductive function
5. Explaining nursing considerations for diagnostic studies relevant to reproductive function
6. Discussing changes in reproductive function associated with aging

#### CONCEPTS

- Assessment
- Female Reproduction
- Inflammation
- Male Reproduction
- Pregnancy

#### ESSENTIAL TERMS

Androgens	Mons pubis
Breast	Oocyte
Cervix	Ovaries
Clitoris	Ovulation
Ejaculation	Parity
Epididymis	Penis
Estrogen	Perineum
Fallopian tubes	Progesterone
Fertile	Prostate gland
Follicle-stimulating hormone (FSH)	Scrotum
Gonad	Seminal vesicles
Gravida (G)	Sperm
Labia majora	Spermatogenesis
Labia minora	Testes
Luteinizing hormone (LH)	Testosterone
Menarche	Uterus
Menstruation	Vagina
	Vas deferens
	Vulva

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Cindy Stevenson is a 29-year-old gravida 1, para 1011. She is here today for her gynecological examination. Her last gynecological examination was 2 years ago after the birth of her child. Cindy states that she has not had a period in 3 months and complains of unusual fatigue. Last evening, she took a home pregnancy test that was negative. Cindy expresses relief that she is not pregnant and would like more information on long-term birth control options.

## FEMALE REPRODUCTIVE SYSTEM

The main goal of the reproductive system is to ensure species survival through the creation of life. To accomplish reproduction, the female reproductive system manages the following: (1) the secretion of sex hormones; (2) the production of ova (eggs); and (3) maintenance of an environment for fertilization, embryonic and fetal development, and expulsion of the fetus when it has physiologically matured and can survive extrauterine life.

### Anatomy of the Female Reproductive System

The anatomy of the female reproductive system includes both external female genitalia and internal reproductive organs. External female genitalia are collectively referred

to as the *vulva*, and includes two structures not directly involved in reproduction, the urethral meatus and the perineal body (the central tendon of the perineum that provides support to the pelvic floor). The internal female reproductive organs are directly responsible for reproduction and both produce and respond to female sex hormones.

### External Female Genitalia

The external female genitalia or **vulva** consists of the **mons pubis**, **labia majora**, **labia minora**, **clitoris**, **vestibule**, and the **perineum**: the area between the **vagina** and **anus** (Fig. 64.1). The mons pubis is located anterior to the vaginal opening and is composed of a firm pad of adipose tissue that protects the symphysis pubis during sexual intercourse. After puberty, the mons pubis is covered by coarse hair in the shape of an inverted triangle. The labia majora consist of two folds of dense adipose tissue that extend directly from the mons pubis. The labia majora provide a protective covering for the labia minora. They can vary in size and appearance depending on age and childbearing status. The labia majora are 7 to 8 cm in length, 2 to 3 cm in width, and 1 to 1.5 cm in thickness and are somewhat tapered in the posterior portion.

The labia minora consist of two smaller folds of connective tissue, covered by skin without hair follicles. The skin of the labia minora is rich in sebaceous glands, which lubricate the area, and nerve endings, which make this tissue very sensitive. The labia minora have a pink to reddish color and can vary greatly in appearance depending on age, race, and parity. Anteriorly, the labia minora converge to form the frenulum of the clitoris. Posteriorly, the labia minora meet to form the fourchette, which is a bandlike area of skin that may tear during vaginal childbirth, or trauma. The fourchette is directly anterior to the anus.

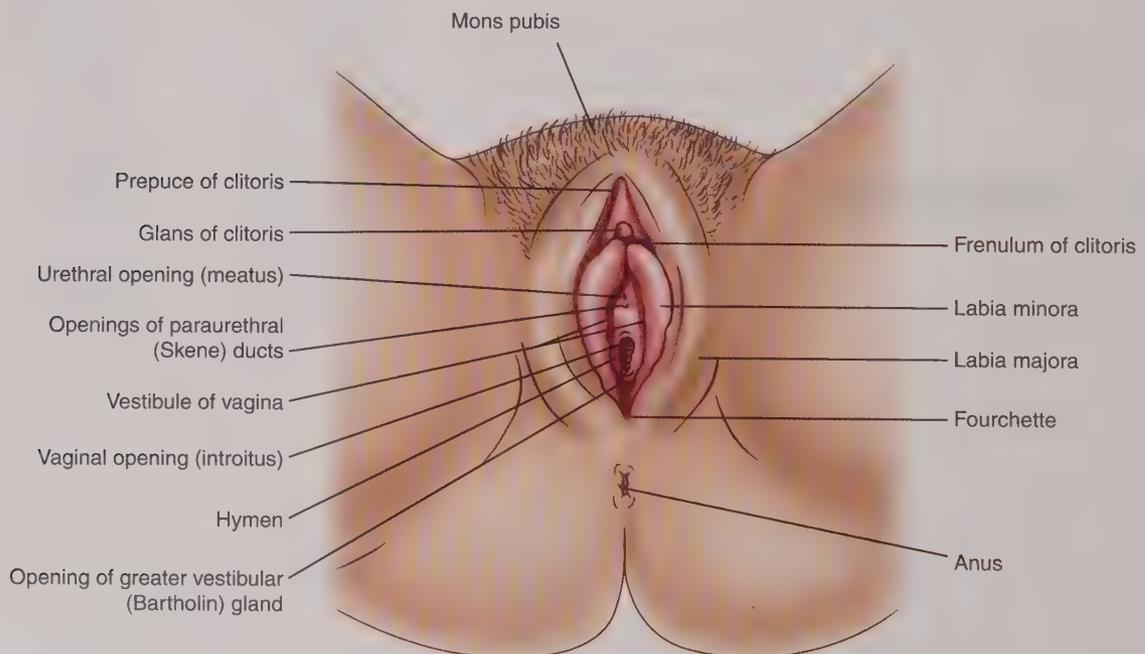

FIGURE 64.1 Female external genitalia.

The clitoris, at the anterior junction of the labia minora, consists of erectile tissue that extends through both sides of the labia minora. Together, the clitoris and labia minora are anatomically homologous structures to the male penis. The clitoris especially is very well innervated, which heightens sensitivity and erotic sensation. The clitoris, like the penis, enlarges with sexual stimulation. The area of skin that surrounds the hood of the clitoris is called the *glans clitoridis*. The glans clitoridis is the exposed portion of the clitoris. It is located at the anterior junction of the labia minora and together with the labia minora plays a vital role in sexual sensation.

The vaginal vestibule is located medially to the labia minora. It is composed of the external urethral orifice, vaginal introitus, hymen, if present, and Skene's and Bartholin's glands. The majority of the vestibule is occupied by the vaginal orifice called the *introitus*, the opening of the vagina, which may be covered by the hymen. The hymen is a thin membrane that can completely or partially cover the vaginal orifice if present. The vestibular bulbs consist of two elongated masses of erectile tissue on either side of the vaginal orifice. The vestibular bulbs become engorged with blood during sexual arousal, causing narrowing of the vaginal orifice during intercourse. This narrowing applies pressure on the penis during intercourse and thus increases stimulation of the penis. The vestibular bulbs are analogous to the corpus spongiosum of the penis.

The urethral orifice, or meatus, is posterior to the clitoris and anterior to the vaginal opening. This is the site of micturition, or voiding. On either side of the urethral meatus are the Skene's glands, also referred to as the *paraurethral glands*. These glands are mucus-secreting glands embedded in the urethral wall. The Skene's glands are anatomically homologous structures to the male prostate gland. The Bartholin's glands, or

greater vestibular glands, are located just inside the vaginal opening. The Bartholin's gland secretes mucus that helps to lubricate the vagina and introitus during intercourse.

### Connection Check 64.1

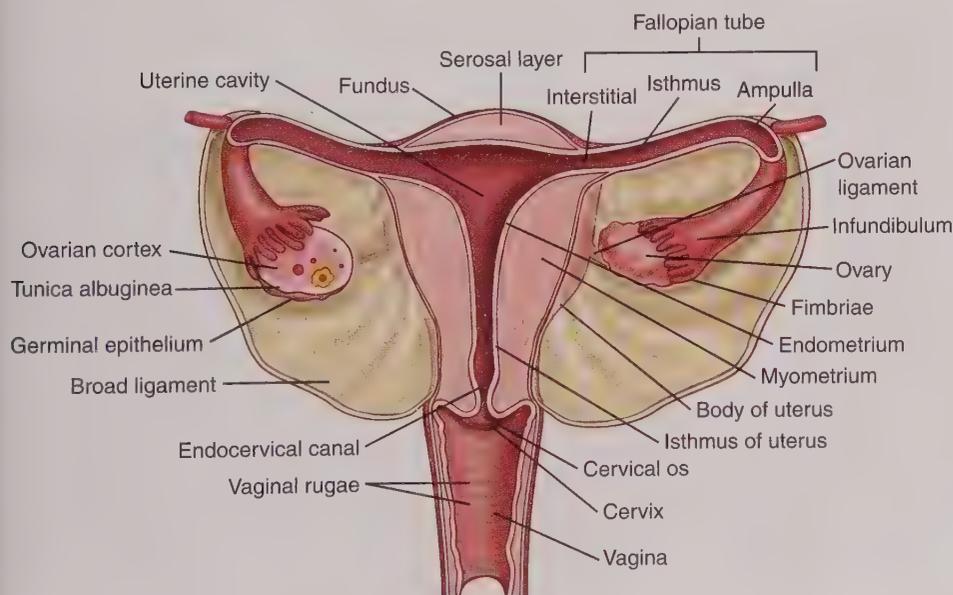

The patient asks the nurse in which part of her vulva do orgasms occur. The nurse understands the principal location of sexual pleasure for women is which of the following?

- Clitoris
- Hymen
- Vagina
- Introitus

### Internal Female Genitalia

The internal female genitalia consist of the vagina, cervix, uterus, fallopian tubes, and ovaries (Fig. 64.2). The **vagina** is a tube that serves as a passageway for menstrual flow, sexual intercourse, and childbirth. The entrance is marked by the introitus and extends to the uterine cervix. The walls of the vagina are approximately 7.5 cm anteriorly and 9 cm posteriorly and are lined with a mucous membrane called the *vaginal mucosa*. Vaginal mucosa is composed of stratified squamous epithelium and has a pink to reddish color with tiny palpable folds called *rugae*. The rugae unfold, and the cells of the vagina enlarge during pregnancy, both of which allow the vagina to expand dramatically during childbirth and accommodate the birth of the fetus. The vagina is directly adjacent to the bladder anteriorly, and the rectum posteriorly. Normal vaginal discharge is composed of mucoid cervical secretions, desquamated vaginal wall epithelium, and normal bacteria.

The uterine **cervix**, located in the deepest part of the vagina, contains a narrow opening into the uterus which is

**FIGURE 64.2** Internal female reproductive genitalia.

called an *os*. The cervix can be visualized by using both a speculum, which is inserted into the vagina, and a light source. On visual examination, a nulliparous (a woman who has not given birth) woman's cervix appears smooth with a small circular *os*, whereas the cervical *os* of a woman who has given birth appears more like a slit. The outer portion of the cervix, which protrudes into the upper vagina, is covered by stratified squamous epithelial tissue. The endocervical canal, to which the *os* opens, can be 2 to 4 cm in length and is lined with columnar epithelial tissue. The squamocolumnar junction is the area where the columnar epithelium of the endocervical canal, and the squamous epithelium of the external *os* meet. The cells of the squamocolumnar junction are sampled for the Papanicolaou (Pap) smear, because this area is where cervical cancer occurs.

The **uterus**, also called the *womb*, is shaped like an inverted pear. It is a thick-walled, hollow, muscular organ, located between the bladder and the rectum. The uterus is suspended in the pelvis by a series of ligaments and is usually positioned in an anteverted posture, tilting slightly anteriorly. The uterus is divided into three distinctive areas: the cervix; the lower uterine segment or isthmus; and the upper uterine segment, at the top of which is the dome-shaped fundus. The size of the uterus varies, depending on age and **parity** (viable pregnancies) but is approximately 7.3 cm in length, 4 cm in width, and 3.2 cm in height for nulliparous women. The uterus has several layers: the outermost layer of the uterine wall is called the serosal layer, the middle muscular layer is called the myometrium, and the inner layer that grows and sheds with each menstrual cycle is called the *endometrium*. The term **menstruation** refers to the shedding of the endometrial lining each month while a woman is fertile. The middle layer of the uterus, or myometrium, has muscle fibers arranged in three layers: each layer of cells is aligned at an angle to the other layers. When the uterine muscle contracts, arterioles that are perpendicular to the layers of muscle cells are closed off, and bleeding is controlled. This action prevents continuous haemorrhage during childbirth. The uterus is where the fertilized ovum, or zygote grows into an embryo, then a fetus. The uterus also provides a passageway for **sperm** to travel to the fallopian tubes, where fertilization may take place.

The **fallopian tubes** grow from both sides of the top of the uterus, an area referred to as the cornua. The fallopian tubes, or oviducts, extend to the ovaries and average 10 to 14 cm in length and 1 cm in diameter. Oviducts consist of four anatomical sections: the interstitium, isthmus, ampulla, and infundibulum. The interstitial portion of the fallopian tube is closest to the uterus, and the isthmus and ampulla are midsection. The infundibulum is most distal to the uterus and closest to the ovaries. Fimbriae are finger-like projections extending out from the infundibulum at the very end of the fallopian tube covering the ovary. The fimbriated end of the fallopian tube catches the **oocyte** (immature ovum) released by the ovary. The oocyte is

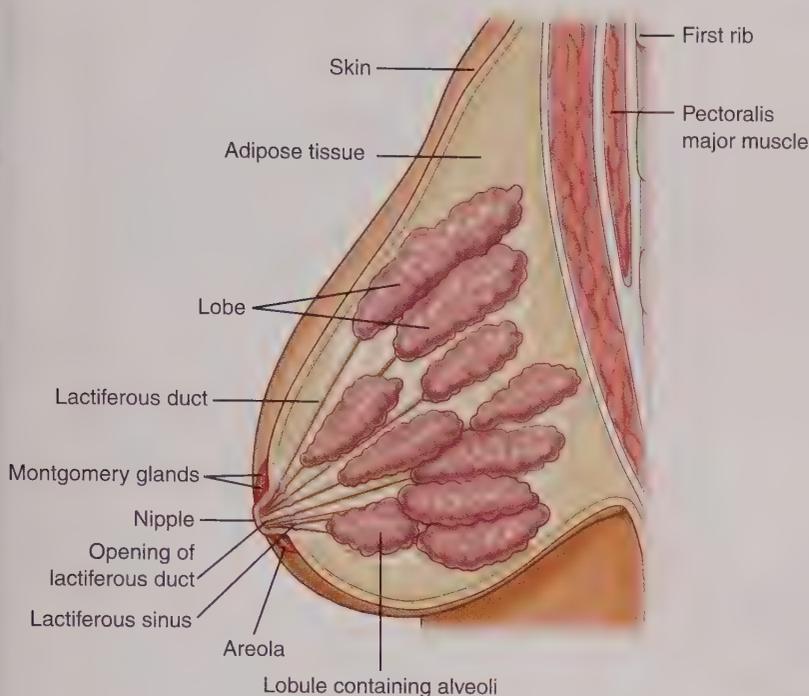

then swept toward the ampulla by the movement of ciliated columnar epithelium cells and muscular tubal contractions. The ampulla is the site of fertilization of the oocyte by the sperm. A pregnancy that implants outside the uterus, in the fallopian tube, causes severe pain and internal haemorrhage.

The **ovaries** are located on either side of the uterus in the upper pelvic cavity in an area called the *ovarian fossa*. They are suspended by the ovarian ligament anteriorly and the broad ligament posteriorly that runs between the pelvic sidewall and the uterus. Ovaries are shaped like a large almond and are grey in color: a normal ovary measures as large as 1.5-cm by 2.5-cm and 4-cm long. The ovaries are the female gonad; ovarian follicles, the site of oocyte or egg development, are located within the ovaries. The ovaries are the site where female sex hormones (**estrogen** and **progesterone**) are produced. At birth, a woman has over a million oocytes present in each ovary, of which approximately 300 mature and are released during the reproductive years.

### Breasts

Breast tissue consists of a series of glands, lobes, ducts, and fibrous and fatty tissue (Fig. 64.3). They are attached to the chest wall by the fascia covering the pectoralis major muscle and serratus anterior muscles. Cooper's ligaments connect the fascia of the two muscles and form support for the breasts that lie between the second and sixth rib and extend from the sternum to the midaxillary line. Fibrous and fatty tissue forms the majority of the breast's volume and provides support for the underlying ducts and lobes. The variations in breast size and shape can be attributed to the amount of dense fibrous and fatty tissue and are greatly affected by pregnancy, lactation, and age.

Each breast contains approximately 15 to 20 lobes of glandular tissue; mammary glands that produce milk after childbirth. Lobes connect to the nipple through extensive ducts. The ducts and lobes of the breast begin to proliferate during puberty in response to rising and falling estrogen and progesterone stimulation. They reach full maturity during pregnancy and lactation, with the development of more extensive lobes, secretory alveoli, and ducts. During lactation, the alveoli secrete milk under the stimulation of prolactin, a hormone that is released by the anterior pituitary gland. Milk flows through the ductal system to the lactiferous sinus directly under the nipple. The nipple is the most external structure of the breast and is surrounded by the areola and sebaceous-producing Montgomery's glands. Once the milk has reached the nipple, it is expelled through 15 to 20 tiny openings that allow milk to flow when the breast is suckled. Milk production can also occur outside of normal lactation, i.e., galactorrhea (Box 64.1). In menopause, many of the glandular components of the breast regress, leaving only the ducts and fatty tissue.

**FIGURE 64.3** Breast anatomy.

## Physiology of the Female Reproductive System

### The Menstrual Cycle

**Menarche** is characterized by the first episode of menstrual bleeding. The first menses is an indication that the female has reached puberty, which is preceded by increased production of progesterone and estrogen secreted by the ovaries. The age of onset of menses can vary but typically occurs between the ages of 12 and 13. Each month after menarche, **follicle stimulating hormone (FSH)** produced in the pituitary gland stimulates the ovary to develop a mature oocyte, and **luteinizing hormone** stimulates the release of the mature oocyte. If fertilization of the oocyte fails to occur, then the endometrial lining, which had thickened to support a fertilized egg, sheds in a process called *menstruation*. This

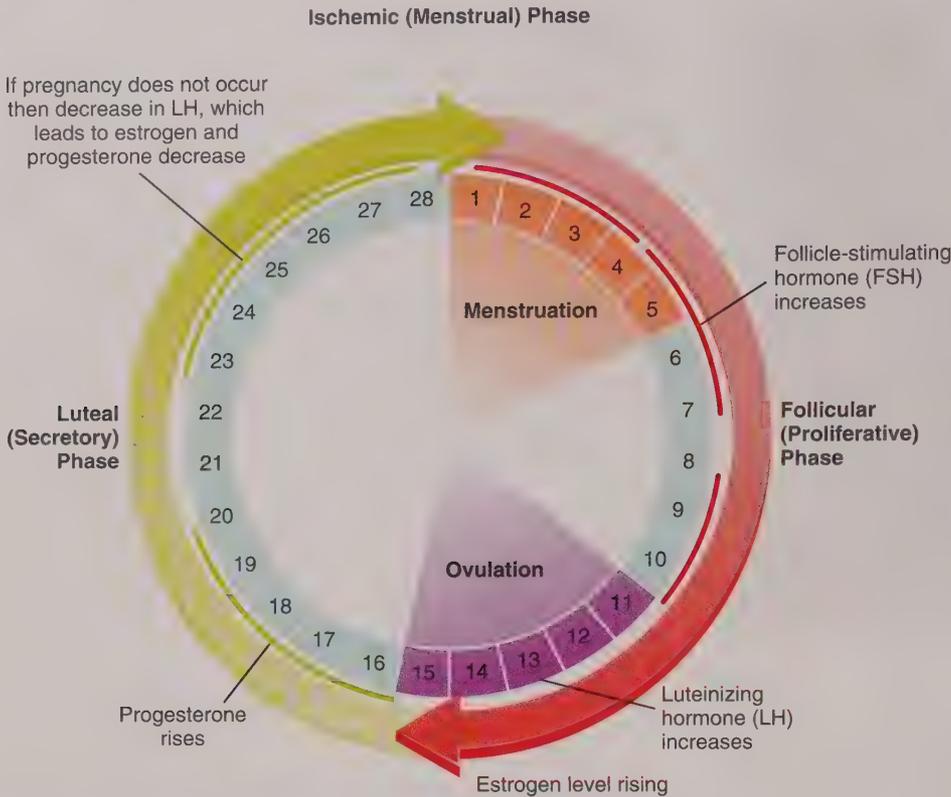

monthly cycle is controlled by hormonal secretions of FSH and **luteinizing hormone (LH)** from the anterior pituitary and the release of estrogen and progesterone from the ovaries.

The menstrual cycle can be divided into three distinct parts: the follicular or proliferative phase, the secretory or luteal phase, and the menstrual or ischemic phase (Fig. 64.4). The follicular phase is when the ovaries are the least hormonally active, resulting in low serum estrogen and progesterone concentrations. During the follicular phase, the level of FSH begins to increase, causing the maturation of the developing follicles, the site of oocyte development. One of these follicles will eventually become the dominant follicle, which is released during **ovulation**. The maturing follicles stimulate estrogen production, which in turn suppresses the release of FSH. This is an example of the negative feedback system controlled by the hypothalamus (Box 64.2). Follicle-stimulating hormone is required for the initial recruitment and maturation of the dominant follicle, but LH is needed for the completion of follicle maturation and, ultimately, the release of the oocyte, also known as *ovulation*.

Estrogen levels peak on the 12th day of the cycle, resulting in a surge of LH. This is the beginning of the luteal phase. During this time, the endometrial lining begins to thicken under the stimulatory effects of estrogen. Progesterone levels rise to maintain the endometrial lining. As a result of the LH surge, the ovary releases a mature follicle approximately 1 to 2 days after the surge. Once ovulation has occurred, LH levels continue to increase, along with a slight increase in serum FSH concentration. If fertilization does not occur, there are gradual decreases in LH, which lead to decreases in progesterone and estrogen production.

### Box 64.1 Galactorrhea

Galactorrhea is the production of milk from the breast that occurs outside of normal lactation. This can be a sign of underlying pathology and should be evaluated. Galactorrhea usually affects women of reproductive age but has also been seen in males and infants. There are several causes, which range from sexual stimulation of the breast, abnormalities in hormonal levels, and pituitary adenoma. Galactorrhea can resolve spontaneously, and in some cases the cause may not be known. The evaluation for galactorrhea usually includes a physical examination, serum hormone testing, and imaging if necessary.

**FIGURE 64.4** The menstrual cycle. The follicular phase: the ovaries are the least hormonally active, resulting in low serum estrogen and progesterone concentrations. The level of follicle-stimulating hormone (FSH) begins to increase, causing the maturation of the developing follicles. The maturing follicles stimulate estrogen production, suppressing the release of FSH. Luteal phase: Estrogen levels peak on the 12th day of the cycle, with a resultant surge of luteinizing hormone (LH). The endometrial lining begins to thicken under the stimulatory effects of estrogen. Progesterone levels rise to maintain the endometrial lining. One to two days after the LH surge, the ovary releases a mature follicle: ovulation. LH levels continue to increase along with a slight increase in serum FSH concentration. Ischemic phase: If fertilization does not occur, there are gradual decreases in LH, leading to decreases in progesterone and estrogen production leading to sloughing off of the endometrial lining; menstruation.

### Box 64.2 Hypothalamic-Pituitary-Gonadal Regulation of the Menstrual Cycle

Secretions of gonadal hormones are under the direct control of the hypothalamus. The hypothalamus secretes gonadotropin-releasing hormone (GnRH) that stimulates the anterior pituitary gland to secrete follicle-stimulating hormone (FSH) and luteinizing hormone (LH). Increasing levels of GnRH cause increases of FSH, which promotes proliferation and maturation of ovarian follicles. The maturing follicle then begins secreting estrogen. The rising level of estrogen suppresses the release of FSH in a negative feedback loop. At the same time, inhibin, an additional hormone, is also secreted by the maturing follicle. This hormone blocks the secretion of GnRH and FSH. As the cycle progresses, estrogen promotes proliferation or growth of the lining in preparation for implantation.

LH is primarily responsible for the completion of follicle maturation and ultimately ovulation. Once ovulation has occurred, the corpus luteum secretes progesterone that sustains endometria lining and the embryo until the placenta begins to produce progesterone.

Ultimately, the drop in estrogen and progesterone leads to sloughing off of the endometrial lining, known as *menstruation* or the *ischemic phase* (Fig. 64.5).

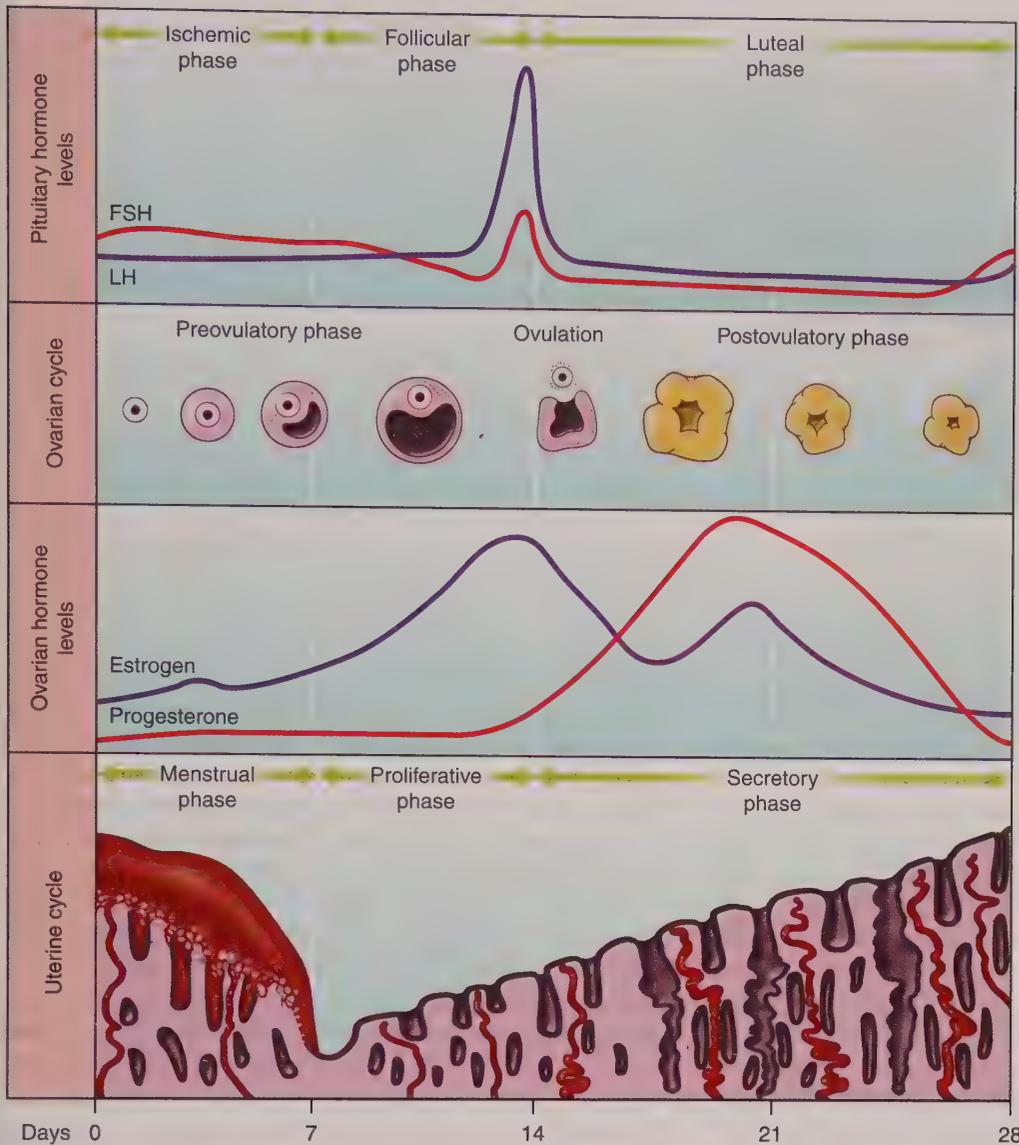

The average menstrual cycle occurs every 28 days. The onset of menses is considered day one of the menstrual

cycle. The normal cycle length varies considerably from female to female but should occur every 21 to 35 days, lasting 2 to 8 days in duration. The average blood loss ranges from 20 to 80 mL. Abnormalities in frequency, volume loss, and duration are discussed in Chapter 65.

### Ovulation

Ovarian follicles are the site of oocyte development. The immature oocyte lies within a primordial follicle surrounded by granulosa and theca cells. During follicle development, under the stimulation of estrogen, the granulosa and theca layer nourishes and protects the follicle until it reaches maturity. Ovulation, the release of a mature oocyte from the dominant follicle, occurs as a result of the LH surge. The area on the ovary where the follicle ruptures to release the egg transforms itself. Facilitated by LH, the follicle walls collapse inward, forming the corpus luteum. The fully developed corpus luteum continues to secrete estrogen as well as progesterone, which helps prepare the endometrium for implantation of the pre-embryonic morula (early-stage embryo). Should fertilization occur, the levels of both estrogen and progesterone increase under the direct stimulation of human chorionic gonadotrophic, a glycoprotein hormone secreted from the corpus luteum on the ovary during early pregnancy. The progesterone secreted by the corpus luteum continues to maintain the embryo until the placenta develops and begins to secrete progesterone.

Few primordial follicles reach maturity. The body reabsorbs the follicles that fail to reach maturity in a process called *atresia*. The lifetime allocation of follicles is present in the ovaries prior to birth. During intrauterine development,

**FIGURE 64.5** Hormonal control of the menstrual cycle.

the human ovarian reserve consists of several million follicles at approximately 5 months of gestational age. After birth, there is a decline in the follicular count from 4 million to 2 million. At the onset of menses, it is estimated that only 300,000 to 400,000 follicles remain. During the reproductive years of a normal female, approximately 500 mature follicles are released from the ovaries. Further decline in follicle count occurs as the female ages. When the finite store of ovarian follicles has been depleted, decreasing secretion of estrogen and progesterone causes the commencement of menopause. Menopause is discussed in Chapter 65.

### Connection Check 64.2

The nurse understands the luteal phase of the menstrual cycle is accompanied by what hormonal changes?

- Low levels of estrogen and progesterone
- Increased levels of progesterone and estrogen
- Increased levels of estrogen and LH
- Increased levels of FSH and estrogen

## MALE REPRODUCTIVE SYSTEM

The organs of the male reproductive system are specialized for the following functions:

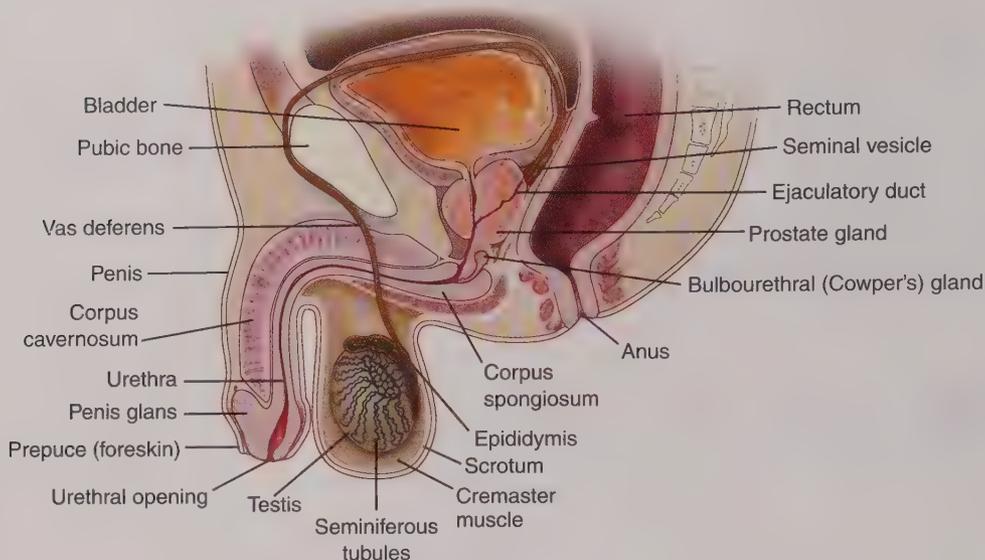

- To produce, maintain, and transport sperm and protective fluid, semen
- To discharge sperm within the female reproductive tract
- To produce and secrete male sex hormones

### Anatomy of the Male Reproductive System

The anatomy of the male reproductive systems includes both external and internal male genitalia (Fig. 64.6). They can be further delineated into primary reproductive organs, the testes, and secondary organs, the ducts, glands, and penis. There are also supportive components of the male reproductive system, the **scrotum** and spermatic cords.

#### External Male Genitalia

External male genitalia include the penis and scrotum. The **penis** (glans penis) is a long cylindrical structure with three

**FIGURE 64.6** The male reproductive system.

columns of erectile tissue, two corpora cavernosa and one corpus spongiosum, covered by a thin layer of skin. The primary functions of the penis are micturition and ejection of seminal fluid during sexual activity. The two corpora cavernosa run parallel to each other and are located on the dorsal side of the penis. The corpus spongiosum is located on the ventral side and houses the urethra. The prepuce is an area of loose skin (foreskin) that covers the tip of the glans in the uncircumcised male. The skin can be retracted to reveal a slit-like opening called the *meatus* of the urethra, where both urine and seminal fluid are released. The frenulum is a connective tissue membrane of foreskin extending from the urethra on the ventral side of the penis. It prevents excessive retraction of the foreskin. Sexual arousal causes the penis to become erect; the erection is a result of increased blood flow to the glans from a series of large venous sinuses. During intercourse, semen is forced through the ejaculatory duct in a process called **ejaculation**. Ejaculation occurs during orgasm, which provides a great sense of pleasure.

The **scrotum** is a loose protective pouch suspended between the penis and anus. The scrotum contains two lateral compartments that house the testes. After adolescence, the scrotum is sparsely covered with hair and has a darker pigmentation than the adjacent skin. The function of the scrotum is to protect and support the testes. The scrotal wall has tiny skin folds called rugae; below the rugae is an underlying muscle called the *cremaster muscle*. The cremaster muscle can cause minute fluctuations in the scrotal size. The changes in size allow for regulation of the temperature within a testis. The temperature must be approximately two degrees below body temperature to produce sperm. When the body's temperature is elevated, the muscles relax to lower the scrotum, moving farther from the body. Alternatively, when the body's core temperature is lower, the muscles contract, bringing the scrotum closer to maintain heat and sperm viability.

### Internal Male Genitalia

The internal male genitalia include the **testes**, urethra, **epididymis**, and **vas deferens**. The testes are a pair of male gonads that produce sperm and generate male sex hormones. The testes are homologous structures to the female ovaries. As mentioned previously, they are suspended in the scrotal sacs. Each testis is oval in shape and measures approximately 4 to 5 cm in length and 3 cm in width in the adult male. Each testis is enclosed in a firm, fibrous membrane called the *tunica albuginea*. Inside the testes are lobules that contain long, coiled seminiferous tubules, which is the site of **spermatogenesis**; the development of spermatozoa, the mature sperm cell. The Leydig, or interstitial cells that are responsible for secreting **androgens** can be found in the area between the seminiferous tubules. Androgens are male sex hormones, the primary one being **testosterone**. Testosterone is responsible for the development of primary and secondary sex characteristics in males. Testosterone in the embryonic stages causes undifferentiated gonads, ducts, and external genitalia to develop into the testes, scrotum, ducts, glands, and penis. Without the initial presence of testosterone, the genitalia develop in a female form. The testicular arteries (gonadal arteries) branch off the abdominal aorta. They are paired arteries that supply blood to the testes.

Sperm forms in the seminiferous tubules, then moves through a series of ducts—the epididymis, vas deferens, ejaculatory duct, and urethra—that ultimately transport the sperm outside the body. The epididymis is very long, measuring about 20 feet in length. It is a tightly coiled duct lying just outside each testis connecting the efferent ducts to the vas deferens, providing storage and a site of maturation of sperm. Sperm that has matured exits the epididymis through the vas deferens.

The vas deferens is a straight, fibromuscular tube connecting the left and right epididymis with the **seminal vesicles** to form the ejaculatory ducts. During ejaculation,

the smooth muscle in the vas deferens wall contracts, propelling sperm forward into the ejaculatory ducts. They pass through the prostate and empty into the urethra.

There are three glands in the male reproductive system: the seminal vesicles, prostate, and bulbourethral or Cowper's glands. Their primary function is to add fluid and provide nutrients to the sperm to increase viability. The seminal vesicles are two saclike glands located on the posterior base of the bladder. They are approximately 5 cm in length. The convoluted structure is attached to the vas deferens near the base of the urinary bladder. They produce a thick alkaline fluid that makes up 65% to 75% of the seminal fluid. This fluid contains proteins, enzymes, fructose, mucus, vitamin C, flavins, phosphorylcholine, and prostaglandins. High fructose concentrations provide nutrient energy for the spermatozoa as they travel through the female reproductive system.

The **prostate gland** is a walnut-sized gland that is located below the bladder surrounding the urethra and ejaculatory ducts. The prostate consists of five lobes enclosed by a fibrous capsule. It stores and secretes a thin, milky, slightly alkaline fluid that promotes sperm motility along with protecting the sperm from acidic fluids, which can be found in both the male urethra and the female vagina.

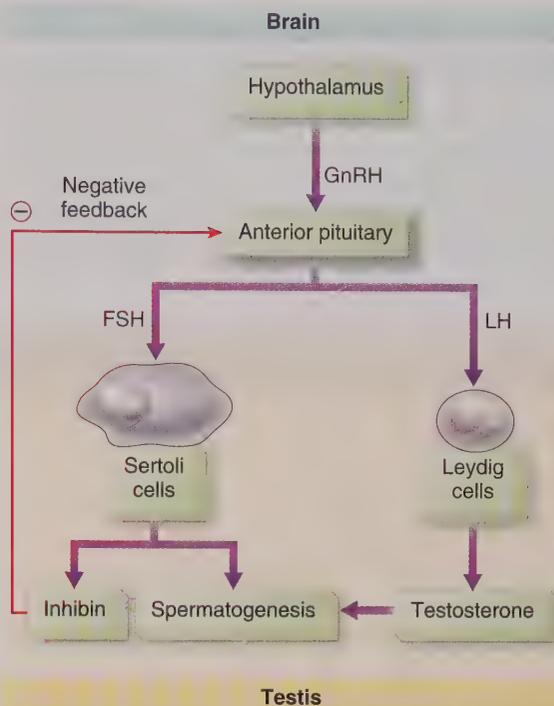

Bulbourethral, or Cowper's, glands are pea-sized glands posterior to the prostate on either side of the urethra. These glands are responsible for the secretion of a gelatinous seminal fluid called *pre-ejaculate*. This fluid helps to lubricate the urethra for spermatozoa to pass through and also flushes out any residual urine or foreign matter, which decreases sperm viability. The lubrication also aids with penetration during intercourse. The urethra, a tubular structure approximately 8-mm long, connects the bladder and ejaculatory ducts to the outside of the body.

## Physiology of the Male Reproductive System

### Spermatogenesis

Spermatogenesis is the process of sperm production. Spermatogenesis begins at puberty as a result of stimulation from the anterior pituitary's gonadotropic hormones, LH and FSH. Luteinizing hormone (LH), also called interstitial cell-stimulating hormone (ICSH), is the hormone responsible for the production of testosterone inside the Leydig, or interstitial, cells. Interstitial cell-stimulating hormone works synergistically with FSH to stimulate sperm production.

The testes contain primitive sex cells called *spermatogonia*. The spermatogonia are located in the seminiferous tubules. Inside the walls of the seminiferous tubules are Sertoli's cells ("nurse cells"). These cells form a protective envelope around the immature sperm cell. They are stimulated by FSH and secrete nutrients that aid in the process of meiosis and the development of mature sperm. As nutrients become depleted, the hormone inhibin is secreted from the Sertoli's cells, sending a signal to the anterior pituitary to slow the release of LH. As with female hormonal control, this is a negative feedback loop that helps control the production of sperm (Figure 64.7).

**FIGURE 64.7** Hormonal control of spermatogenesis. Luteinizing hormone (LH) facilitates the production of testosterone inside the Leydig cells. Sertoli's cells are stimulated by FSH and secrete nutrients that aid in the process of meiosis and the development of mature sperm. While nutrients become depleted, the hormone inhibin is secreted from the Sertoli's cells, sending a signal to the anterior pituitary to slow the release of LH.

### Connection Check 64.3

The negative feedback loop involved in spermatogenesis is facilitated by what hormone?

- ICSH
- LH
- FSH
- Inhibin hormone

### CASE STUDY: EPISODE 2

Cindy's reproductive history reveals she is a G2 P1011. She has not had a period for the last 3 months. In addition to her fatigue, she also complains of cold intolerance and a noticeable increase in weight. She could possibly be pregnant despite her negative home test. Laboratory testing to be done includes serum pregnancy tests along with prolactin, FSH, and LH. A laboratory sample for thyroid-stimulating hormone (TSH) is also sent to evaluate her fatigue, cold intolerance, and recent weight gain which may be signs of hypothyroidism. Speculum and bimanual examinations are done. A Pap smear is obtained along with cultures for gonorrhea and chlamydia. The remainder of her examination is unremarkable...

## ASSESSMENT OF MALE AND FEMALE REPRODUCTIVE SYSTEMS

The assessment starts with a complete history including allergies, current medications, past medical history, surgical history, psychological history, family history, and a detailed reproductive history. Table 64.1 outlines the complete, detailed reproductive history, and Table 64.2 lists drugs that

can affect reproduction. Transitional Care lists birth control options.

### Physical Examination of Female Genitalia

The physical examination of the female genitalia consists of external and internal assessments. External examination of female genitalia includes inspection of the mons pubis,

**Table 64.1 Reproductive History**

#### Health History

##### Female

##### General Reproductive History

- Do you have any sores or pain on your labia?
- Do you have any vaginal discharge? What is the color? Does it have a foul odor? Does it cause itching, pain, or burning?
- Do you have a history of ovarian cyst or fibroids?
- Have you had a Pap smear? If yes, have they all been normal?
- Family history of breast, ovarian, uterine, or cervical cancer

##### Menstrual History

- When was your last menstrual period (LMP), or are you menopausal?
- Age of first menses (menarche)
- Cycle frequency? (every 21-35 days within normal limits [WNL])
- How many days are your cycles? (2-8 days is WNL)
- How heavy is the flow? (pad/tampon count)
- Do you have premenstrual symptoms?
- Do you have painful periods?
- Do you have bleeding between your periods?

##### Pregnancy History

- Pregnancy history, including number of pregnancies, number of living children (see Box 64.3)

##### Sexual History

- Are you sexually active?
- Are you satisfied with your sex life?
- Do you have painful intercourse?
- Do you bleed after intercourse?
- What age did you begin your sexual experiences? Please be specific, oral vs. penetration.
- What is your sexual preference? Male, female, both, or other?
- How many partners have you had in the last 12 months? In the last two months?
- How many partners do you currently have?
- Assess contraceptive use
- Do you have a history of any sexually transmitted infections? HIV, hepatitis B, hepatitis C, herpes, syphilis, gonorrhea, chlamydia, *Trichomonas*, warts?
- Assess strategies to protect from sexually transmitted infections.

##### Male

##### General Reproductive History

- Any painful lesions, sores, or discharge from your penis?
- If discharge, what color is it? How long have you had it? Does it have an odor?
- Do you have any problems with your scrotum or testes?
- Have you noticed any lumps, bumps, or swelling of the scrotum?
- Have you ever been told you have a hernia?
- Family history of prostate cancer

##### Sexual History

- Are you sexually active?
- Are you satisfied with your sex life?
- Do you have painful intercourse?
- What age did you begin your sexual experiences? Please be specific, oral vs. penetration.
- What is your sexual preference? Male, female, both, or other?
- How many lifetime partners have you had?
- How many partners do you currently have?
- Contraceptive use? Do you use condoms?
- Do you have a history of any sexually transmitted infections? HIV, hepatitis B, hepatitis C, herpes, syphilis, gonorrhea, chlamydia, *Trichomonas*, warts?
- Assess strategies to protect from sexually transmitted infections.

## Box 64.3 Determining Pregnancy History

**Gravida (G)** = The total number of pregnancies regardless of duration.

**Parity (P)** = The numbers of past pregnancies that have gone to viability and have been delivered. Parity can be further delineated by using (TPAL): T = Full Term, P = Preterm, A = Abortions: spontaneous or induced, L = Living Children. An example = A woman who has one child born at 40 weeks and one spontaneous abortion is a G2 P1011.

Descriptive terms include:

- A nulliparous woman (nullip) has not given birth previously; also refers to a woman who has given birth to a baby unable to survive outside the womb
- A primigravida is in her first pregnancy.
- A primiparous woman (primip) has given birth once.
- A multigravida has been pregnant more than once.

labia majora and minora, inguinal area, and perineum. Careful attention is paid to areas of inflammation, lesions, asymmetry, and palpable masses.

A breast examination is also performed. Breast examination is first done with the patient in a seated position. A visual inspection is done to assess the breasts for symmetry; it is common for one breast to be larger on the dominant side. Skin color, texture, vascularity, abnormal skin lesions, and dimpling should all be assessed. The patient is then asked to place her arms at her side, above her head, leaning forward, and finally, placing her hands on her hips. These various maneuvers are used to detect abnormalities that can be a sign of abnormal pathology. Next, attention is focused on the clavicular and axillae areas, which are palpated for

lymph node enlargement. The patient is then asked to lie in the supine position with one arm behind her head. The breast should be palpated with a light, medium, and firm circular motion making sure to palpate all the layers of the breast down to the chest wall. Assess the nipple and areola for masses and discharge. If discharge is observed, document color, consistency, and whether discharge is bilateral or unilateral. Discharge can be a sign of underlying pathology and should be investigated. Use the moment to assess the patient's knowledge of self-breast examination. If the patient is knowledgeable, then reinforce the pertinent normal findings and timing of monthly breast examinations.

Internal examination is done manually (bimanual examination) and with the speculum. The speculum examination is done to visualize the vagina and cervix. The patient is supine, with her legs in the dorsal lithotomy position with her feet comfortably resting in the stirrups. Place a drape across the patient's lower abdomen to provide coverage. The drape should provide coverage but should not obscure the external genitalia. The patient should be informed of the examiner's actions at all times; each step should be announced before it is performed. The patient should also be informed that she may stop or pause the examination at any point.

The speculum should be warmed by lukewarm water or a heating pad and lubricated to provide comfort upon insertion. The labia minora are gently spread apart with the examiner's nondominant hand, and the speculum is inserted below the meatus to avoid stimulation of the urethra. Inform the patient that she may experience a little pressure as the speculum is advanced. Once the speculum is inside, assessment of the vaginal mucosa and vaginal secretions and cervix is completed.

The bimanual examination can provide very valuable information. The examiner places the two lubricated fingers of the dominant hand into the vagina until the cervix is

**Table 64.2 Drugs Affecting Reproduction**

### Women

- Steroids can hamper the pituitary's ability to produce follicle-stimulating hormone and luteinizing hormone.
- Antihypertensives such as Aldomet may raise prolactin levels, hampering ovulation.
- Medications targeting the central nervous system, such as antiseizure medications or tranquilizers, may negatively impact prolactin levels and ovulation.
- Thyroid medications may interfere with ovulation.

### Men

- Supplemental testosterone and anabolic steroids have a negative effect on sperm production.
- Alcohol may decrease testosterone production and increase estrogen production.
- Tetrahydrocannabinol, the main ingredient in marijuana, decreases sperm production.
- Long-term opiate use decreases testosterone production, decreasing quantity and quality of sperm.
- 5-Alpha-reductase inhibitors used to treat prostate enlargement decrease semen and sperm volume.
- Alpha blockers used to treat prostate enlargement can negatively impact ejaculation.
- Selective serotonin reuptake inhibitors (SSRIs) have a negative impact on the movement of sperm.

## Transitional Care

### Birth Control Options Method

### Advantages/Disadvantages

Birth control pills:

- Combination pills (progestin and estrogen combination)
  - Mainstay of birth control pills (99% effective)
  - Risk of blood clot formation
- Progestin only
  - Decreased risk of clot formation
  - Must be taken at the exact same time every day to be effective
  - No placebo pills—all pills are active

Vaginal ring (NuvaRing): A flexible plastic ring placed in the vagina that delivers estrogen and progestin; remains in place for 3-4 weeks and then is removed for a week to allow for menstruation

- Do not have to remember to take a pill every day
- Risk of blood clot formation

Diaphragm/Cervical cap: Dome-shaped rubber barrier method **used in combination with spermicide**; inserted into the vagina and covers the cervix

- 85% to 95% effective
- Eliminates blood clot risk of birth control pills
- Inserted prior to sexual activity; must remain in place 6 hours after sex

Intrauterine device (IUD):

- ParaGard: Surgically implanted device that continuously releases copper that lines the uterus, creating an environment toxic to sperm
  - 99% effective
  - Once implanted, may remain in place for approximately 5 years
- Mirena: Surgically implanted device that releases progestin
  - May cause pain and heavy bleeding for several months after insertion
  - Risk of serious side effects such as uterine perforation

Patch: Hormone (estrogen)-releasing patch that is placed on an arm, back, or buttocks that remains in place for a week; replaced once a week for 3 weeks then left off 1 week to allow for menstruation

- 99% effective
- Delivers 60% more estrogen than birth control pills, resulting in higher blood clot risk especially in women who smoke

Implant (Implanon, Norplant): A small rod (matchstick size) device inserted under the skin of the upper arm that releases progestin

- 99% to 100% effective
- Effective as long as 3 years
- May cause irregular bleeding

Injectables (Depo-Provera): Intramuscular injection of progestin given every 12 weeks

- 99% effective
- Requires an injection every 12 weeks

Condom

- Protects against sexually transmitted infection
- 98% effective when used correctly
- Oil-based lubricants such as Vaseline may create holes in the condom, eliminating its effectiveness

reached. The other hand is placed on the lower abdomen to aid in palpation during the examination. Uterine size, position, mobility, and tenderness can be assessed with this technique. Careful attention is given to the presence of cervical motion tenderness because this is a sign of pelvic inflammatory disease. Afterward, attention is turned to the

assessment of the adnexal area, the fallopian tubes and ovaries. They are assessed for the presence of a mass and tenderness. Normal ovaries are often not palpable.

A rectovaginal examination is not routinely performed. It is used to assess specific areas of concern such as pelvic pain, pelvic masses, and rectal symptoms. Stool guaiac testing, an

assessment for bleeding from the gastrointestinal tract, may also be done with this examination. The examination is accomplished by placing one finger in the vagina and the other in the rectum. The examiner must change gloves between the bimanual examination and rectal examination to avoid cross-contamination of the rectum and vagina.

### Physical Examination of Male Genitalia

Examination of the male external genitalia includes both inspection and palpation and can be performed with the patient in the lying or standing position. The general consensus is to perform the examination while the patient is standing. The examiner is seated directly in front of the patient. As with the female examination, the male should be given a verbal explanation of all aspects of the examination before it occurs. The male patient is also assured that he may stop or pause the examination at any time. With gloved hands, the examiner assesses the pubic hair, general appearance of the penis, and scrotum. Next, the penis is inspected for lesions, scars, or swelling. The presence or absence of foreskin is assessed. If foreskin is present, it is retracted to assess hygiene and inflammation. The glans is compressed to assess for drainage or discharge, paying careful attention to the color and odor of the discharge. Palpation of the penile shaft for tenderness and masses is done next. Visually inspecting the scrotum is done by lifting each scrotal sac and assessing all aspects of the skin. A visual scanning of the scrotum may reveal large scrotal masses, undescended testes, and the inguinal bulges of a hernia. Masses in the scrotum should be transilluminated in a dark room with a powerful light source. The results of the transillumination examination are quite informative because most benign masses easily allow light to pass through. Palpation of the scrotum and its contents may reveal the presence, size, position, and shape of the testicles. Visually assess the inguinal region for rashes, inflammation, or lesions. Ask the patient to bear down to assess for asymmetry or bulge. The right and left inguinal regions are palpated by using the index finger to check for lymphadenopathy (enlargement of the lymph nodes).

The internal examinations of the prostate and anus are done together. First, a visual inspection of the perineal and anal sphincter is done to assess for lesions, masses, or hemorrhoids. A digital rectal examination is done to assess the size of the prostate. It should be performed on all males older than 50 years and any male complaining of difficulty initiating urination or frequency.

### DIAGNOSTIC STUDIES

Diagnostic studies include imaging and surgical procedures to assess the male and female reproductive systems. They include mammography, ultrasound, magnetic resonance imaging (MRI), colposcopy, laparoscopy, hysteroscopy, dilation and curettage, endometrial biopsy, and hysterosalpingography.

Mammography is a screening tool used to detect tumors in the breast less than 5 mm in diameter in asymptomatic

women, which may not be palpable on clinical breast examination. The mammography uses x-ray films of the breast taken from various angles to detect abnormalities in breast tissue. Ultrasonography is a noninvasive imaging modality that uses high-frequency sound waves that pass through tissue. It records the pattern of the sound waves as they bounce off the organs. Waves are converted into images that assess structures' size, location, shape, contour, and position. It is usually the first-line testing to assess pelvic abnormality because it is inexpensive and readily available. It is valuable for screening for both men and women.

Magnetic resonance imaging is noninvasive imaging that uses a powerful magnet and radiofrequency to obtain cross-sectional images of body tissue. It is a screening tool used for both men and women. This modality is superior to computed tomography in producing images in any plane. It cannot be used to image bones, bone density, calcification, or calcium stones and therefore is used solely to visualize soft tissue.

Colposcopy is used to evaluate the mucosa of the cervix and/or vagina. It is most often used after there has been an abnormal Pap smear that revealed an underlying lesion or precancerous cells. Colposcopy provides direct visualization and magnification of the mucosal layer of the vagina or cervix with a colposcope, a low-power binocular microscope. During the procedure, a dilute solution of acetic acid is used to remove mucus and to enhance visualization of the columnar epithelium. In addition, Lugol's solution, an iodine-based solution, may be used to assess vaginal and cervical tissues. Normal vaginal tissue has a high glycogen content and stains brown with the application of Lugol's solution. Suspicious or abnormal tissue does not absorb the stain and may appear lighter in color. If abnormal areas are observed, endocervical biopsies are taken from the cervix.

Laparoscopy is an invasive procedure that allows direct visualization of the female anatomy by use of a fiber-optic scope inserted through a small incision on the abdominal wall. The abdomen is distended with CO<sub>2</sub> to increase visualization.

Hysteroscopy is an invasive surgical procedure that allows for direct visualization of the endometrial cavity via fiber-optic scope inserted through the cervix via the vagina. The hysteroscopy can be interventional as well as diagnostic, allowing resection of endometrial polyps and intracavitary fibroids.

Dilation and curettage (D&C) is an invasive surgical procedure that dilates the cervix to allow passage of a curette for endometrial sampling or removal of products of conception.

Endometrial biopsy can be done via D&C or noninvasively in the doctor's office. It provides a sampling of the endometrial lining. It is indicated if there is abnormal uterine bleeding or to assess for infection. Biopsies are also indicated in men to rule out cancers of the reproductive system.

Hysterosalpingography is an x-ray procedure used to assess the uterus and fallopian tubes. A small catheter is placed through the cervix. A contrast solution is then instilled via the catheter after which an x-ray of the pelvis is performed to assess the flow of the contrast through the uterus and fallopian tubes. See Table 64.3 for a description

**Table 64.3 Significance, Patient Preparation, and Nursing Implications of Diagnostic Studies of the Reproductive System**

Study	Significance of Abnormal Findings	Patient Preparation	Nursing Implications
<b>Mammography</b>	May show areas of concern for breast cancer that may require further imaging and biopsies	Instruct patient to avoid the use of cream, deodorant, and lotions.	Inform the patient that the results may not be available for a few days and that her provider will contact her with the results.
<b>Ultrasound</b>	May show tumors, abscess, thickened endometrial stripes, and congenital anomalies  Ultrasound may also be used to assess breast tissue and guide a biopsy if an abnormality is detected on a mammogram.  In men, ultrasound can detect tumors or abnormal tissue i.e. – in the scrotum.	A full bladder may be required for this test if assessing the female pelvis. Undress from the waist down. If a transvaginal approach is to be used, explain how the probe will be inserted in the vagina.	Inform the patient that results are usually available within hours of the testing; however, the practitioner will have to review them before a management decision is made.
<b>Magnetic resonance imaging</b>	May show anatomical anomalies, tumors, abscess, inflammation, atrophy, bleeding, or hemorrhage	Explain to the patient that this test requires that the patient lie still while the images are taken. It may also require administration of IV contrast.  Remove all jewelry.  Assess pregnancy status.	<ol style="list-style-type: none"> <li>1. Inquire about implanted metal in the body, which may prevent the patient from participating in the study.</li> <li>2. Assess for claustrophobia; provide supportive care.</li> <li>3. Confirm allergies before administering contrast.</li> </ol>
<b>Colposcopy</b>	May show precancerous cells, human papillomavirus-related changes of the cervix	Encourage the patient to empty her bladder. Patient should avoid placing anything in the vagina for at least 24 hours before the procedure. If the patient is menstruating, the procedure may need to be rescheduled because heavy bleeding makes visualization of the cervix and vaginal mucosa difficult.  Assess pregnancy status prior to the procedure.	<ol style="list-style-type: none"> <li>1. Informed consent must be signed before the procedure.</li> <li>2. Confirm patient's allergy; Lugol's solution is contraindicated in patients with an iodine or shellfish allergy.</li> <li>3. Recognize that the patient may be anxious regarding the procedure and may have additional questions before and after the procedure.</li> <li>4. Provide adequate pain medication after the procedure.</li> <li>5. Review postprocedure expectations along with signs and symptoms that require further evaluation.</li> </ol>
<b>Laparoscopy</b>	May show possible pathology, ovarian cyst, fibroids, endometriosis, tubal abscess	NPO the night before surgery. Prep the surgical site for the procedure. Confirm right site, right patient, and right procedure.  Assess pregnancy status prior to procedure.	<ol style="list-style-type: none"> <li>1. Ensure patient understands surgical procedure.</li> <li>2. Informed consent must be signed before the procedure.</li> <li>3. Ensure patient understands anesthesia and pain control methods.</li> <li>4. Discharge teaching should include at least 2 days of rest postoperatively. The risk of bloating and abdominal pain should be discussed with the patient as the result of the instillations of CO<sub>2</sub> into the abdomen.</li> </ol>

**Table 64.3 Significance, Patient Preparation, and Nursing Implications of Diagnostic Studies of the Reproductive System—cont'd**

Study	Significance of Abnormal Findings	Patient Preparation	Nursing Implications
<b>Hysteroscopy</b>	Uses direct visualization of the endometrial cavity; allows surgical removal of fibroids and polyps that are in the cavity	NPO the night before surgery. Prep the surgical site for the procedure. Confirm right site, right patient, and right procedure.  Assess pregnancy status prior to procedure.	<ol style="list-style-type: none"> <li>1. Ensure patient understands surgical procedure.</li> <li>2. Informed consent must be signed before the procedure.</li> <li>3. Discharge teaching should include at least 2 days of rest postoperatively.</li> <li>4. Nothing in vagina for 4 weeks after procedure.</li> </ol>
<b>Dilation and curettage</b>	Can assess for molar pregnancy (when what should have been fetal tissue becomes an abnormal growth in the uterus), endometrial cancer, and other abnormalities of the endometrial lining	NPO the night before surgery. Prep the surgical site for the procedure. Confirm right site, right patient, and right procedure.  Assess pregnancy status prior to procedure.	<ol style="list-style-type: none"> <li>1. Ensure patient understands surgical procedure.</li> <li>2. Informed consent must be obtained.</li> <li>3. Discuss normal postoperative bleeding (pad counts). The patient may experience cramping that should respond to NSAIDs.</li> </ol>
<b>Endometrial biopsy</b>	Assess for possible endometrial cancer or endometritis	Assess pregnancy status prior to procedure.	<ol style="list-style-type: none"> <li>1. Ensure patient understands procedure.</li> <li>2. Informed consent must be obtained.</li> <li>3. Explain that some cramping and vaginal bleeding may occur after the procedure; cramping should respond to NSAIDs.</li> </ol>
<b>Hysterosalpingogram</b>	May reveal blocked or dilated fallopian tubes or abnormalities in the uterine cavity	Assess pregnancy status prior to the procedure.	<ol style="list-style-type: none"> <li>1. Ensure patient understands procedure.</li> <li>2. Assess allergies to iodine and other contrast materials.</li> <li>3. Informed consent must be obtained.</li> <li>4. Explain that some cramping and vaginal bleeding may occur after the procedure; cramping should respond to NSAIDs.</li> </ol>

NPO, Nothing by mouth.

of the diagnostic studies, abnormal findings, and nursing implications for patient preparation.

## Laboratory Testing

Laboratory assessment includes the Pap test (cervical cytology), wet preparations (wet preps), and cervical, vaginal, rectal, and genital cultures. The Pap test is effective in detecting cancerous or precancerous cells in the cervix. The American Congress of Obstetricians and Gynecologists (ACOG) recommends women have cervical cytology done regularly starting at age 21. The Pap test should be done every 3 years between the ages of 21 and 29 provided that all results are within normal limits. Women ages 30 through 65 can be screened every 5 years with Pap and human papillomavirus (HPV) cotesting or a Pap test alone every 3 years. The decision to test for HPV should be made by the patient and her provider. The American

Cancer Society recommends discontinuing screening for cervical cancer in low-risk women at age 65. There are certain populations of women who may require earlier or more frequent screening, depending upon risk factors. An example of a high-risk population for cervical cancer is women with HIV. The Office on Women's Health from the U.S. Department of Health and Human Services recommends a Pap test twice annually the first year of diagnosis of HIV and annually thereafter. It is important to note that even if a cervical cancer screening is unwarranted, annual assessment of external and internal genitalia may be performed.

A wet prep refers to a microscopic examination of secretions obtained from the vagina during the speculum examination. The sample is placed on a slide, mixed with saline and covered with a slip, then visualized microscopically to detect common vaginal infections such as *Trichomonas*, *Candida*, and bacterial vaginosis.

Serum blood tests looking at hormone levels of FSH, LH, total estrogen, progesterone, and testosterone are important to determine normal functioning. Serum testosterone testing is used if there are complaints of decreased libido, erectile dysfunction, or impotence in men. Human chorionic gonadotropin, a hormone produced by the placenta, can be assessed to confirm pregnancy and help quantify gestational age.

Men have been advised to have a prostate-specific antigen (PSA) test done to screen for prostate cancer annually. Prostate cancer is one of the leading causes of mortality for men older than 50. Prostate-specific antigen is a protein produced by the prostate gland and may be considered a tumor marker. Increased levels of PSA have been associated with a 25% to 60% increase in prostate cancer risk. Recently, that recommendation for annual testing has come under review because of questions of accuracy. There have been instances of men with elevated PSA levels who do not have cancer, resulting in unnecessary biopsy and treatment. There are also instances of men who have normal PSA levels who do have prostate cancer, resulting in inadequate treatment. Routine testing should be done after conversations with the provider, taking into account age, patient history, and any other pertinent factors.

## AGE-RELATED CHANGES IN THE FEMALE AND MALE

Aging in the female is marked by several external and internal changes. Approximately four years before their last menstrual cycle, women begin to notice more irregularity in their menstrual cycles and decreased bleeding during menses. Some women with uterine fibroids or obesity actually experience increased bleeding. Twelve months after the final menstrual cycle, a woman is considered postmenopause. When a woman enters postmenopause she can no longer achieve a pregnancy. Also, during menopause, estrogen and progesterone decrease significantly, and FSH levels become elevated. The decrease in estrogen leads to the classic symptoms of perimenopause and menopause: hot flashes, bladder symptoms, decreased pelvic support, vaginal atrophy, shrinking of the labia minora and majora, and decreased clitoral size and sensitivity. Subsequently, some women experience an increased incidence of vulvovaginitis (infections of the vulva and vagina), urinary symptoms, dyspareunia (painful intercourse), and decreased libido. Cardiovascular disease risk increases after menopause and is the leading cause of death for women older than 50. This increased risk is associated with the decline in circulating estrogen as well as other risk factors such as hypertension (HTN), obesity, diabetes, and sedentary lifestyle. Bone loss also accelerates after menopause, leading to osteoporosis in some women.

The male reproductive ability remains throughout the lifespan, but normal sexual function requires a biopsychosocial process that relies on multiple factors to function properly. With advancing age, there is an increase in erectile dysfunction,

benign prostatic hyperplasia, prostate cancer, and other chronic illnesses that may cause sexual dysfunction. Additionally, psychosocial illness and its subsequent treatment may also play a role in decreased libido and erectile dysfunction. All complaints of erectile dysfunction and urinary abnormalities should be investigated because they may be a symptom of an underlying disorder or malignancy.

### Connection Check 64.4

Assessment of the male and female reproductive systems includes: (*Select all that apply.*)

- A. Reproductive history
- B. Electrocardiogram
- C. Abdominal CT scan
- D. Physical examination
- E. Laboratory markers such as PSA

## Making Connections

### CASE STUDY: WRAP-UP

Cindy's serum studies are unremarkable except for a slightly elevated TSH level. Her pregnancy test is negative. She restates her desire to get more information about long-term birth control (see Transitional Care). She is encouraged to follow up with her primary care provider regarding her slightly elevated TSH level because it may indicate hypothyroidism, which would account for her fatigue, cold intolerance, irregular menses, and weight gain. It could also affect her ability to get pregnant should she wish to. Cindy should also take medroxyprogesterone, 10 mg daily for five days to stimulate shedding of the endometrial lining. When the endometrial lining builds up without shedding, a cancer can develop. The menses following the medroxyprogesterone treatment will likely be very heavy, and Cindy should be forewarned about this.

#### Case Study Questions

- 1 The nurse includes which information in the teaching plan for Cindy? (*Select all that apply.*)
  - A. Follow up with your primary care provider if this fatigue and cold intolerance continues.
  - B. The use of condoms as a birth control method
  - C. The use of an at-home pregnancy test is a satisfactory way to confirm pregnancy.
  - D. Make an appointment with your primary care provider within 2 weeks.
  - E. The reason for the medroxyprogesterone treatment and what to expect.

2. Which statement by Cindy indicates teaching has been effective?
  - A. "I wish condoms were more effective. I don't like to take pills."
  - B. "I'll make an appointment to see my provider soon to follow up on the TSH levels."
  - C. "This thyroid problem won't affect me if I want to get pregnant."
  - D. "I'm feeling better. I don't need to see my doctor."
3. The nurse includes which of the following in the discussion about birth control?
  - A. Progestin-only birth control pills increase the risk for blood clots.
  - B. Intrauterine devices protect against sexually transmitted disease.
  - C. Condoms are very effective when used correctly.
  - D. Hormone releasing patch lowers blood clot risk.
4. Cindy begins to have very heavy bleeding with her periods. She is scheduled for a hysteroscopy for evaluation. Which statement by Cindy indicates teaching has been effective?
  - A. "I'll be able to resume normal activities the same day as the test."
  - B. "I'll have to abstain from sex for a few days after the test."
  - C. "I'm glad I will be able to eat and drink prior to this test."
  - D. "This is a test that can be done in the doctor's office."
5. Cindy understands the hysteroscopy is being done to evaluate her for which of the following?
  - A. The presence of fibroids
  - B. An HPV infection
  - C. A molar pregnancy
  - D. The presence of an abscess

pubis, labia majora, labia minora, clitoris, vestibule, and perineum. The internal female genitalia consist of the vagina, cervix, uterus, fallopian tubes, and ovaries.

The menstrual cycle can be divided into three distinct parts: the follicular or proliferative phase, the secretory or luteal phase, and lastly the menstrual or ischemic phase. It is regulated by the hypothalamic and pituitary glands and gonadal hormonal secretions of GnRH, FSH, estrogen, and progesterone.

While the female ages, her fertility declines, culminating in menopause, which is the cessation of menstruation. Along with the loss of fertility are several age-related changes that occur to the external and internal female anatomy. These changes can affect a woman's sexual health as well as result in alteration of body self-image. The nurse understands that it is important to recognize the various stages and phases of female reproductive health so that she may educate her patient regarding normal anatomy and physiology.

The organs of the male reproductive system are specialized for the following functions: to produce, maintain, and transport sperm and protective fluid, semen; to discharge sperm within the female reproductive tract; and to produce and secrete male sex hormones. The anatomy of the male reproductive systems includes both external and internal male genitalia. They can be further delineated into primary reproductive organs, the testes, and secondary organs, the ducts, glans, and penis. The internal male genitalia include the testes, urethra, epididymis, and vas deferens. External male genitalia include the penis and scrotum.

The assessment of male and female reproductive systems starts with a complete history including allergies, current medications, past medical history, surgical history, psychological history, family history, and a detailed reproductive history. The female physical examination includes an internal speculum and manual examination and breast examination. Examination of the male external genitalia includes both inspection and palpation. The internal examination of the prostate and anus is done to check for prostate enlargement.

Diagnostic studies include imaging and surgical procedures to assess the male and female reproductive systems. They include mammography, ultrasound, MRI, colposcopy, laparoscopy, hysteroscopy, dilation and curettage, and endometrial biopsy. Laboratory assessment includes the Pap smear, wet preparations (wet preps), and cultures. Serum blood tests looking at hormone levels of FSH, LH, total estrogen, progesterone, and testosterone are important to determine normal functioning. Men should have a PSA test done to screen for prostate cancer and testing for testosterone levels.

## CHAPTER SUMMARY

The anatomy of the female reproductive system includes both external and internal female genitalia. They can be further delineated into primary reproductive organs (ovaries) and secondary organs (uterus, fallopian tubes, and the breasts). The external female genitalia consist of the mons

## Coordinating Care for Female Patients With Reproductive and Breast Disorders

*Amy S. D. Lee*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of reproductive disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Breast cancer
  - b. Dysmenorrhea
  - c. Endometriosis
  - d. Menopause
  - e. Fibroids
  - f. Ovarian cancer
  - g. Uterine cancer
  - h. Cervical cancer
3. Describing the diagnostic results used to confirm the diagnoses of reproductive disorders
4. Discussing the medical management of:
  - a. Breast cancer
  - b. Dysmenorrhea
  - c. Endometriosis
  - d. Menopause
  - e. Fibroids
  - f. Ovarian cancer
  - g. Uterine cancer
  - h. Cervical cancer
5. Developing a comprehensive plan of nursing care for patients with reproductive disorders
6. Designing a teaching plan that includes pharmacological, dietary, and lifestyle considerations for patients with reproductive disorders

### CONCEPTS

- Assessment
- Cellular Regulation
- Comfort
- Female Reproduction
- Medication
- Nutrition

### ESSENTIAL TERMS

Aromatase inhibitor  
Breast cancer type 1 susceptibility protein (BRCA1)  
Breast cancer type 2 susceptibility protein (BRCA2)  
Breast conservation therapy  
CA 125  
Ductal carcinoma in situ (DCIS)  
Dysmenorrhea  
Dysplasia  
Endocrine therapy  
Endometriosis  
Hormone therapy (HT)  
Human papillomavirus (HPV)  
Invasive breast cancer  
Leiomyoma  
Lobular carcinoma in situ (LCIS)  
Mastectomy  
Menopause  
Menorrhagia  
Metastasis  
Prostaglandins  
Sentinel node  
Tamoxifen  
Vasomotor symptoms

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Karen Sims is a 43-year-old female patient who presents to her healthcare provider complaining of noticing a “knot” in her right breast recently in the shower. It is not painful and does not seem to change with position or palpation. She had a mammogram at age 40 that was normal, but she has not had one since. She takes combination oral contraceptive pills (OCs) for birth control and is otherwise in relatively good health. She is clearly worried about the knot in her breast and presents for evaluation...

## BREAST CANCER

### Epidemiology

Cancer of the breast almost exclusively occurs in women. Breast cancer affects tens of thousands of American women yearly, and although breast cancer survival rates have increased significantly, it remains the second most common cause of cancer-related deaths in women. The single greatest risk factor for breast cancer is a woman's age. While a woman ages, her risk of breast cancer increases. American women aged 80 to 85 are 15 times more likely than women aged 30 to 35 to develop breast cancer. Ethnicity modifies the effect of age, although ethnicity alone does not have consistent risk elevation. African American women younger than 50 have a higher risk of developing breast cancer, whereas those older than 50 have a lower risk than Caucasian women of the same age. Hispanic women in North America have a lower incidence of breast cancer than Caucasian women, whereas Asian women in North America have the same risk as Caucasian women. However, Asian women living in Asian countries have a very low risk of breast cancer. There currently exists no accepted explanation for these differences.

Women with higher numbers of ovulatory cycles in their lifetime also carry a higher risk of breast cancer. Those with early menarche and late menopause have a 30% to 50% increase in breast cancer risk. Lack of pregnancy and live childbirth before the age of 30 nearly doubles the breast cancer risk. Only pregnancies resulting in a live birth lower the breast cancer risk. Seventy percent to 80% of breast cancer simply occurs by chance and cannot be traced to any family member but family history, particularly in first-degree relatives, can be a risk factor for breast cancer. Five percent to 10% of breast cancers are caused by known genetic mutations (see Genetic Connections). Women with a family history not associated with a known genetic mutation have a lifetime risk below 30%. Fifteen percent to 20% of breast cancers are associated with a family history but are

likely also a result of environmental factors in the setting of genetic susceptibility. Benign, noncancerous breast disease that is proliferative; those with quickly growing cells such as hyperplasia, have an increased breast cancer risk of as much as 70%. Benign breast disease that is nonproliferative is not associated with any increased risk. Other factors associated with the risk of breast cancer include excessive alcohol use, inactivity, obesity, and the use of hormones.

## Genetic Connections

### Genetic Testing to Assess Breast Cancer Risk

Genetic testing provides an opportunity for women to learn whether they have a family history of breast cancer caused by an inherited gene mutation. The two gene mutations that have been currently identified are the BRCA1 and BRCA2. Genetic carriers of these mutations have a 50% to 85% lifetime risk of breast cancer and a 45% risk of ovarian cancer by age 70. Genetic testing for BRCA1 and BRCA2 can be done with a simple blood test. It has been widely publicized, but this testing is indicated only for certain people at high risk, including women with a:

- History of breast cancer before age 50
- History of triple negative breast cancer (hormone receptor–negative)
- History of ovarian cancer
- Personal or family history of bilateral breast cancer
- Family history of breast cancer diagnosed before age 45
- Family history of ovarian cancer

This test is not indicated in women with a low risk of gene mutation, such as women who are the only person in their family with breast cancer, no family history, or when the breast cancer diagnosed in the family occurred after age 50.

## Pathophysiology

Cancer is a condition in which the cells of the body grow and divide abnormally and uncontrollably. The cells can invade nearby tissues and spread to other areas through the bloodstream and lymphatic system. Breast cancer can be divided into a series of categories or stages associated with size, spread to lymph nodes, and distant spread of the breast tumor to other tissues called **metastasis** (Fig. 65.1). The first stage, stage 0, includes the in-situ lesion of **ductal carcinoma in situ (DCIS)**. Ductal lesions occur in and are limited to the lining of the milk ducts. **Lobular carcinoma in situ (LCIS)**, lobular lesions occurring in the lobules where milk is produced, were included in stage 0 in past staging models but are now not considered cancer. Both DCIS and LCIS place the patient at higher risk of developing

**invasive breast cancer.** Invasive lesions are those that spread to other areas or organ systems (see Evidence-Based Practice).

**Evidence-Based Practice**

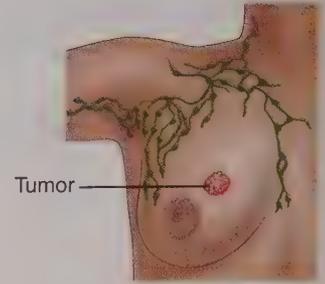

**Breast Cancer Staging**

In 2018, the American Joint Commission on Cancer (AJCC) updated the breast cancer staging guidelines. Early guidelines included tumor size (T), lymph node involvement (N), and distant spread or metastasis (M); the T, N, M characteristics. The updated guidelines include cancer characteristics such as tumor grading or how much the abnormal cells look like normal cells, hormone receptor (estrogen and progesterone) status, *HER2* status (a gene that can play a role in the development of breast cancer) which looks at the amount of *HER2* protein produced by the cancer cells, and a *oncotype DX* score; a genomic test that analyzes the gene activity that can affect how cancer is likely to develop and respond to treatment. Including these new factors is more complex but more accurately matches treatment. For instance, a tumor with stage 2 characteristics but hormone-positive cancer will have a different plan of treatment than a hormone receptor-negative tumor, thus the stage and treatment may change; downgraded in this example. The following table is not comprehensive but provides examples of staging.

Giuliano, A. E., Edge, S. B., & Hortobagyi, G. N. (2018). Eighth Edition of the AJCC Cancer Staging Manual: Breast Cancer. *Annals of surgical oncology*, 25(7), 1783-1785.

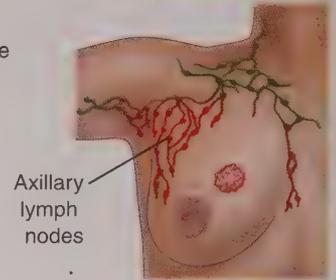

**Stage I**

Tumor 2 cm or less with no lymph node spread and no distant metastasis.

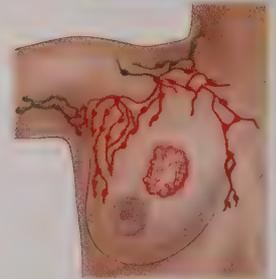

**Stage II**

Tumor may increase in size with possible spread to nearby lymph nodes; no distant metastasis.

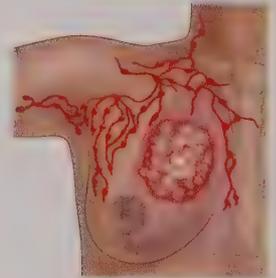

**Stage III**

Tumor may increase in size with possible spread to lymph nodes, chest wall, or skin; no distant metastasis.

**Stage IV**

Tumor of any size with direct extension to chest wall or skin and with distant metastasis.

**FIGURE 65.1** Four stages of breast cancer.

**Evidence-Based Practice**

Stage	Description	Lymph node	Metastasis	Hormone status
Stage 0	In situ lesions (DCIS)	No	No	
Stage IA	Tumor up to 2 cm	No	No	
Stage IB	No tumor in breast or tumor less than 2 cm	Yes – less than 2 mm	No	But if hormone receptor-positive staged and treated as IA
Stage IIA	No breast tumor	Yes – greater than 2 mm	No	
	Tumor less than 2 cm	Yes	No	
	Tumor 2-5 cm	No	No	But if HER2-, HR + staged and treated as IB

## Evidence-Based Practice—cont'd

Stage	Description	Lymph node	Metastasis	Hormone status
Stage IIB	Tumor 2-5 cm	Yes	No	But if HER2+, HR+ staged and treated as IB
Stage IIIA	Tumor greater than 5 cm	No	No	But if HR+, HER2+ staged and treated as IB
	Tumor any size	Yes – 4-8 lymph nodes	No	
Stage IIIB	Tumor >5cm	Yes	No	But if HR+, HER2+ staged and treated as IIA
	Tumor any size and spread to chest wall	Yes – 9 lymph nodes		
Stage IIIC	Inflammatory breast cancer	Yes	No	But if HR+, HER2+ or – staged and treated as IIIA
	Tumor any size and spread to chest wall	Yes – 10 or more lymph nodes		
Stage IV	Tumor of any size	Yes	Yes	

## Clinical Manifestations

Clinical manifestations vary depending on the type of breast cancer. Most commonly, the presence of a new mass or lump is noted. Cancerous masses are typically hard, irregular, and painless but may be soft or rounded and tender. There are sometimes changes in the shape of the breast or swelling. There may be skin changes such as peeling, flaking, pitting, dimpling, or redness. There may also be changes in the nipple such as inversion, thickening of the tissue, or drainage.

## CASE STUDY: EPISODE 2

Ms. Sims' breast examination reveals a palpable 2-cm mass in the right breast. The mass is not mobile and is nontender. There are no nodes felt in the axilla or adjacent areas. There is no nipple discharge. The patient is referred for diagnostic mammography and ultrasonography of the palpable mass...

## Management

## Medical and Surgical Management

## Diagnosis

Diagnostic tests for breast cancer include mammography, ultrasonography, magnetic resonance imaging (MRI) and, if necessary, biopsy. Patients may have breast cancer detected as part of routine screening mammography or mammography with MRI (currently recommended screening for high-risk women), or they may present with a specific complaint that leads to the discovery of the tumor through diagnostic imaging. Once mammography detects a suspicious area, ultrasonography may be used to further define the area.

Ultimately, the area will be recommended for biopsy if it is deemed suspicious on imaging. Biopsy results will be definitive for diagnosis. Table 65.1 outlines the different types of biopsy.

If the initial diagnostics indicate the tumor may be invasive, sentinel node biopsy may be indicated. This evaluation may help determine the extent or stage of the breast cancer. The **sentinel node(s)** is the first lymph node to which cancer cells travel if they are to spread. In breast cancer, these nodes are generally found in the axilla but may be more central if the cancer is in the center of the chest. Injecting a radioactive substance or blue dye near the tumor and tracking it to the first node determines the sentinel node(s). Research has demonstrated that if the sentinel lymph node(s) is found to be free of cancer, it may not be necessary to proceed with the removal of further nodes or an axillary lymph node dissection (which generally removes 20–40 nodes). If the sentinel nodes have cancer cells present, a more complete removal of the lymph nodes is necessary for evaluation, and axillary lymph node dissection may be completed.

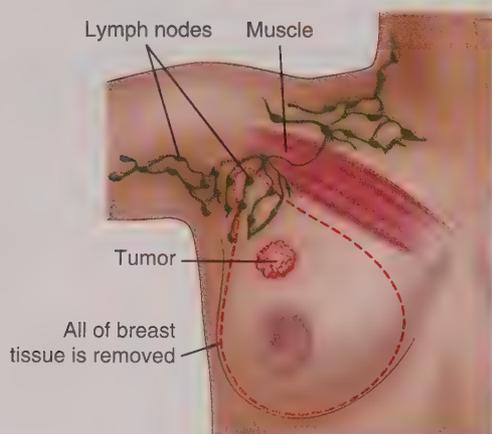

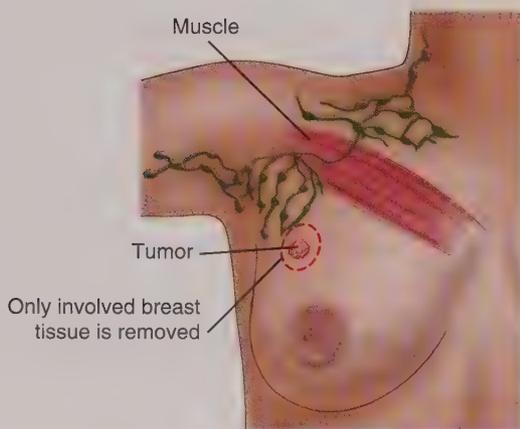

Once a diagnosis is made, laboratory data that may be obtained include a complete blood count (CBC) with platelets, liver function tests, and a chest x-ray. A baseline bone scan and liver scan may be obtained if the patient is found to have skeletal symptoms or abnormal liver function tests. Computed tomography (CT) of the abdomen and a bone scan may also be performed if the disease is clinically felt to be stage II or higher.

## Treatment

Medical and surgical management varies depending on the category or staging of the cancer. Treatment options include surgery, chemotherapy, and radiation. Surgery alternatives are **breast conservation therapy**, also referred to as *lumpectomy*, or total **mastectomy** (Figs. 65.2 and 65.3).

**Table 65.1** Types of Breast Biopsy

Biopsy Type	Description
<b>Fine-needle aspiration</b>	If the mass is palpable, the needle is guided to the mass through feel. If the mass is not palpable, the needle is guided to the mass through mammographic imaging, ultrasound, or magnetic resonance imaging (MRI). Once the needle is in the mass, a sample is suctioned out into a syringe. This is repeated several times. Local anesthesia may or may not be used.
<b>Core needle</b>	Similar to fine-needle aspiration except it uses a wider needle with a cutter that removes a larger sample. Local anesthesia may or may not be used.
<b>Vacuum-assisted</b>	Uses mammographic imaging, ultrasound, or MRI to locate the mass. A biopsy probe is introduced through a small skin incision. A vacuum device pulls tissue through the probe, where a rotating cutting device removes the sample and delivers it to a collection area. The probe can be repositioned to sample several areas. Sutures are not required. Done under local anesthesia.
<b>Surgical excision</b>	If the mass is palpable, an incision is made across the breast and the mass is accessed. If the mass is less than 2.5 cm, it is usually removed completely. If the mass is larger, a portion is removed for evaluation. If the mass is not palpable, it is first located through imaging and then “marked” by a hooked wire that is inserted into the mass and left to guide the surgeon to the mass. The surgical excision is the same as for a palpable mass. Sutures are required for closure of the incision. Local or general anesthesia may be used.

**FIGURE 65.2** Breast cancer surgery. A, Breast conservation or lumpectomy. B, Modified radical mastectomy.**FIGURE 65.3** Chest after mastectomy.

Chemotherapy options include adjuvant chemotherapy, which is administered after surgery to destroy any remaining cancer cells, or neoadjuvant chemotherapy, which is administered prior to the surgical procedure in an attempt to shrink the tumor. Table 65.2 describes treatment options available for breast cancer.

#### **Treatment for In Situ Lesions**

Lobular carcinoma in situ (LCIS) is not considered a precursor for invasive breast cancer and therefore has no recommended treatment. Care of the patient with LCIS is directed at risk-reduction strategies because these women are at an increased risk of developing invasive breast cancer. Ductal carcinoma in situ (DCIS) requires surgical treatment. Lesions thought to be large (more than 4 cm) require mastectomy. Even though lymph node dissection or sentinel

**Table 65.2 Breast Cancer Treatment Options**

Treatment	Description
<b>Breast conservation surgery (lumpectomy)</b>	Removes only the involved breast tissue and a minimal surrounding margin with the best possible cosmetic preservation of the breast. An option in early-stage disease or advanced disease that has been reduced by chemotherapy. Used in conjunction with postoperative radiation and chemotherapy.
<b>Modified radical mastectomy</b>	Removal of the entire breast tissue. An option in early-stage disease or more advanced disease that has been reduced by chemotherapy. Used in conjunction with chemotherapy and may or may not require postoperative radiation.
<b>Axillary lymph node staging</b>	Removal of axillary lymph nodes. Done with invasive breast cancer and some noninvasive. Recent advances allow for removal of only the first lymph node from the tumor (sentinel node). Other nodes are then removed only if the sentinel node is positive.
<b>Chemotherapy</b>	Drugs used to treat cancer. May be used prior to surgery or after.
<b>Radiation therapy</b>	Radiation directed at the tumor and surrounding tissue to treat cancer. Typically done after surgery for lumpectomy or inflammatory breast disease, for recurrence, or for palliation in advanced disease.

node evaluation is not usually indicated in DCIS, patients with large lesions may benefit from nodal assessment because of the risk of invasive disease. Lesions of intermediate size that can be removed with clear margins (no cancer shown in the margin of tissue around the tumor) can be considered for mastectomy or breast conservation therapy. Breast conservation therapy is done in conjunction with radiation therapy. After adequate counseling, the choice of treatment is largely left up to the patient. Patients with very small DCIS lesions may, on an individual basis, be offered excision of the lesion without radiation therapy. Tamoxifen (Nolvadex), antiestrogen therapy, has been shown to reduce the risk of local recurrence in women undergoing breast conservation therapy and therefore may be offered in these patients.

#### **Treatment for Early-Stage Invasive Cancers**

Cancers smaller than 1 cm with a clinically negative axilla are preferably treated with surgical excision. Patients with larger tumors that have significant comorbidities or no spread to the axillary nodes may also be referred for surgical excision. Multiple trials have demonstrated that mastectomy and breast conservation therapy are equivalent, and therefore the patient is offered both of these options. If mastectomy is chosen, immediate reconstruction may be considered.

Radiation therapy is recommended for patients undergoing breast conservation therapy. Radiation therapy is also recommended for those choosing mastectomy if four or more lymph nodes are found to be positive. It may also be selectively used in those stage II patients with one to three positive nodes. Patients with tumors at least 1 cm in size or with axillary node involvement are recommended to have cytotoxic (toxic to cells) adjuvant chemotherapy. If patients are found to have cancers that are hormone

receptor-positive, **endocrine therapy (aromatase inhibitor or tamoxifen)** is also recommended after completion of cytotoxic therapy. Postmenopausal patients with tumors between 1 and 2 cm without nodal involvement may be offered endocrine therapy alone, but all premenopausal patients should be offered chemotherapy.

#### **Treatment for Intermediate-Stage and Advanced-Stage Cancers (Operable)**

Preoperative neoadjuvant chemotherapy is usually the first line of treatment for intermediate-stage and advanced-stage operable cancers unless the patient has underlying comorbidities that preclude the use of chemotherapy. After chemotherapy, the tumor is reassessed to evaluate for the potential of breast conservation therapy as a result of tumor response to the chemotherapy. Preoperative chemotherapy has been shown to increase the success rate of breast-conserving surgery. Chemotherapy is recommended after surgical treatment in all patients. This is followed by or done concurrently with radiation therapy. If the tumor is hormone receptor-positive, endocrine therapy is offered for 5 to 10 years. Breast reconstruction may be done in those undergoing mastectomies, but it is often preferable for reconstruction to be delayed until after completion of radiation therapy.

#### **Treatment for Locally Advanced and Inoperable Cancers**

Patients with inoperable breast cancers may undergo neoadjuvant chemotherapy as initial treatment. If the tumor responds to chemotherapy and becomes operable, the next step is to undergo modified radical mastectomy. If the cancer responds dramatically, the patient can be offered breast conservation therapy. If the tumor does not respond to initial chemotherapy, the patient may be switched to another chemotherapy regimen before surgery is attempted. All

patients should be offered postoperative chemotherapy and radiation to the breast or chest wall. In these cases, immediate breast reconstruction is not encouraged.

#### Treatment for Local Recurrence and Systemic Metastases

If the recurrence of the tumor is confined to the breast alone, a course of curative therapy is begun. In patients who have undergone initial breast conservation therapy, a complete mastectomy is the next step. If the tumor is not initially operable, chemotherapy may be considered. When the patient has not previously undergone radiation, surgical excision is done followed by chemotherapy and radiation. If the patient has undergone an initial mastectomy, surgical excision can be attempted, although the disease is often too advanced for this option. In this situation, chemotherapy can be initiated followed by surgery once the disease is under control. If this patient has not previously had radiation, then radiation may follow. Patients who have metastases to one or more organ systems have quality and quantity of life as focuses of treatment, as current approaches do not appear to be curative. Therapeutic benefit has to be weighed against toxic effect.

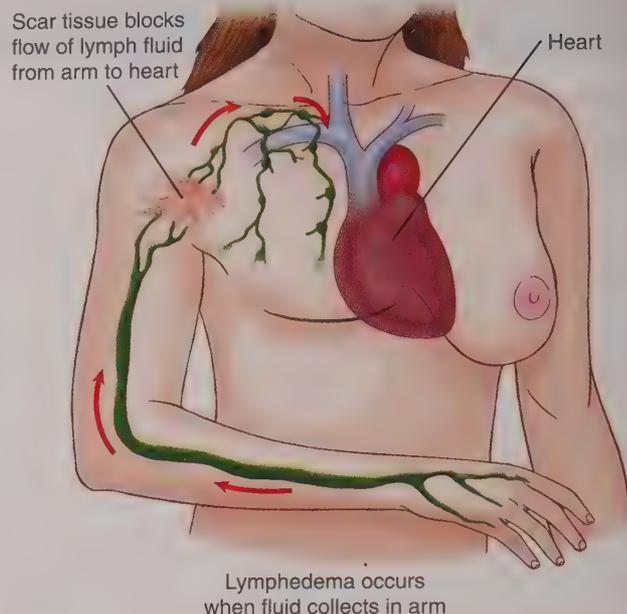

#### Complications

Treatment does sometimes have complications. Immediate postoperative complications are the same as those for any surgery. Wound infection and dehiscence are of initial concern as well as the usual immobility side effects of surgery such as pulmonary embolism and pneumonia. Once acute surgical recovery has occurred, complications of surgery stem from scarring and lymph node effects. The most common long-term complaints are shoulder immobility, pain, and lymphedema.

Lymphedema occurs because of the removal of the axillary lymph nodes and subsequent scarring, resulting in disruption of lymph drainage from the arm. The result is swelling of the arm. Sentinel lymph node evaluation and minimization of lymph node dissection have led to lowered incidences of lymphedema (Fig. 65.4).

Once chemotherapy has begun, the patient may experience a variety of side effects associated with the cytotoxic drugs. The most common chemotherapy side effects are hair loss, nausea, vomiting, mouth pain, diarrhea or constipation, peripheral neuropathy, rash, and nail changes. Decreased white blood cell count with possible subsequent fever and increased risk for infection is also a complication. Chemotherapy may also result in premature ovarian failure. In a young woman, this has significant implications for future estrogen-related health issues, including bone loss and loss of fertility. There is also a possible long-term risk of myelodysplastic syndrome (dysfunctional blood cells) and acute leukemia for some chemotherapeutic agents.

Finally, radiation therapy has some very predictable side effects. These include some redness with patchy desquamation (shedding of the outer skin layers) of the treated skin. The skin may also itch but usually does not have a “burning” sensation. Breast swelling and discoloration may continue for 6 months after treatment but usually resolves in 12 to

**FIGURE 65.4** Lymphedema. Scar tissue can prevent the flow of lymph fluid, resulting in edema in the affected extremity.

18 months. Pneumonitis, a nonproductive cough with a chest x-ray demonstrating an infiltrate in the radiated area, may develop in some patients 6 weeks to 6 months after treatment completion. Evidence also exists to show that significant radiation to the myocardium may lead to latent (15–20 years) cardiac morbidity and mortality. There is an increased risk of other cancers in women treated with radiation for breast cancer. However, the incidence of these malignancies is suggested to be clinically insignificant.

#### Nursing Management

##### Assessment and Analysis

Assessment of the breast cancer patient is dependent on the point in time of diagnosis and treatment. Initial clinical manifestations are associated with the presence of a tumor, noting a lump in the breast, or other signs such as skin and nipple changes. Later manifestations are associated with treatment. Due to the killing of all rapidly dividing cells, chemotherapy may result in hair loss, nausea, vomiting, mouth pain, diarrhea or constipation, peripheral neuropathy, rash, and nail changes as well as a decreased white blood cell count. Lymph node removal may result in lymphedema or swelling of the arm on the affected side due to blockages in lymph flow. Radiation causes skin changes such as irritation, redness, itchiness, or burning. Breast swelling may be present as well as nonproductive cough with lung infiltrate.

##### Nursing Diagnoses

- **Pain/Discomfort** associated with surgery, scarring, and radiation irritation of the skin
- **Risk for infection** associated with surgical procedure, lowered white blood cell count
- **Nutrition:** altered, less than body requirements associated with nausea/vomiting

- **Body image disturbance** associated with loss of breast, loss of hair

## Nursing Interventions

### ■ Assessments

- **Vital signs**  
*Elevated blood pressure and rapid pulse can be a sign of pain or anxiety. Elevated temperature and pulse are also indicative of infection.*
- **Pain**  
*Patients should verbalize their pain on a rating scale to help understand their pain level and to ensure adequate treatment.*
- **Daily weight**  
*Weights will give an idea of the nutritional status of the patient. Drastic weight loss indicates a nutritional deficit.*
- **Intake and output**  
*Intake and output allows evaluation for tolerance of oral liquids and foods and an evaluation of vomiting.*
- **Wound evaluation**  
*Good wound evaluation detects the early signs of infection such as redness, warmth, and increased or purulent drainage.*
- **Skin evaluation**  
*Inspect any radiated skin for radiation side effects such as irritation, redness, itchiness, or burning.*
- **Monitor complete blood count (CBC) and metabolic profile**  
*Due to its cytotoxic effects, chemotherapy may result in decreased white blood cell counts, decreased hemoglobin and hematocrit, and elevations in liver enzymes.*
- **Assess mood and nonverbal cues**  
*These patients are at great risk for psychological issues. Patients with depression are often withdrawn or offer other nonverbal cues that indicate pain, depression, and anxiety.*

### ■ Actions

- **Give chemotherapeutic drugs as ordered**  
*Chemotherapy is indicated for invasive breast cancer.*
- **Give pain medications as ordered**  
*Provides pain relief allowing the patient to more fully participate in activities of daily living*
- **Give antiemetics as ordered**  
*Help to relieve nausea and vomiting, promoting adequate nutritional intake*
- **Have the patient cough and deep breathe postoperatively**  
*Prevents atelectasis and pneumonia*
- **Keep the wound clean and dry**  
*Aids in wound healing and helps prevent infection*
- **Encourage verbalization**  
*It is important to actively involve patients in their care. Encouraging verbalization and communication is part of that process.*

### ■ Teaching

- **Explain the treatment course**  
*Patients will be less anxious if they are educated about what to expect, and what their planned treatment involves.*
- **Medications and treatment side effects**  
*Patients should understand the side effects of radiation and chemotherapy as well as potential treatment options.*

- **Wound care**  
*Teach the patient to keep the wound clean and dry. Report any signs of infection or dehiscence immediately.*
- **Nutritional counseling**  
*Help patients develop a nutrition plan to maintain adequate weight and hydration.*
- **Support groups**  
*Give patients a list of support groups and other resources to help them cope.*
- **Breast cancer screening with mammography:**
  - Women ages 40-44 may begin annual screening
  - Women ages 45-54 should have annual screening
  - Women ages  $\geq 55$  can maintain yearly or move to biannual; screening should continue as long as the woman is in good health.
  - Clinical breast examination is not recommended  
*The goal of screening is to detect breast cancer early*

## Evaluating Care Outcomes

With adequate treatment, many women are able to survive breast cancer today. Those with advanced-stage cancer are still able to achieve prolongation of their life while balancing quality of life. The patient undergoing treatment for breast cancer will have immediate needs associated with surgery, chemotherapy, and radiation. The well-managed patient should be able to manage any nausea and vomiting in a way that allows her to maintain adequate nutrition and weight. Her surgical sites should heal without infection. Scarring and lymphedema should be kept to a minimum through appropriate therapy. The psychological support provided throughout treatment helps to manage anxiety and depression.

### Connection Check 65.1

- Chemotherapy
- Radiation
- Mammogram
- Surgery

## DYSMENORRHEA

### Epidemiology

**Dysmenorrhea**, or difficult monthly menses, is one of the most common gynecological complaints among younger women. It is the leading cause of school and work absence in young women. The majority of dysmenorrhea is associated with normal menstrual cycles and has no associated pelvic pathology. This is considered primary or functional dysmenorrhea. Dysmenorrhea is less common in the first few years after menarche but becomes more commonplace as regular ovulatory cycles are established. The severity of symptoms tends to be worse in those with early menarche, longer menses, and heavier menses. Cigarette smoking may also increase dysmenorrhea, likely because of nicotine-related vasoconstriction. Only 10% of dysmenorrhea is found to correlate with pelvic pathology such as

endometriosis and is considered secondary dysmenorrhea. Endometriosis is discussed later in this chapter.

## Pathophysiology

In primary dysmenorrhea, a buildup of fatty acids in the phospholipids of the cell membranes occurs after ovulation. The high level of omega-6 fatty acids in the Western diet contributes to a high level of omega-6 fatty acids in the cell wall phospholipids. Just prior to menses, progesterone levels in the body begin to fall. During this time, the omega-6 fatty acids, especially arachidonic acid, are released, causing the release of **prostaglandins** and leukotrienes in the uterus. Prostaglandins and leukotrienes cause an inflammatory response in the uterus that results in several common complaints.

## Clinical Manifestations

Abdominal cramping is the most common symptom of dysmenorrhea. However, women may also complain of other symptoms including headache, nausea, and vomiting. Symptoms are acutely associated with the onset of menses, generally continue for 24 to 48 hours, and occur cyclically.

## Management

### Medical Management

Medications are the primary means of management for dysmenorrhea. The mainstay of treatment is non-steroidal anti-inflammatories (NSAIDs). NSAIDs result in the reduction of the production of prostaglandins. This causes decreased uterine contractions and therefore fewer symptoms. NSAIDs should be initiated 1 or 2 days prior to the onset of menses and continued until symptoms resolve (usually 1–2 days after menses start). Combined oral contraceptive pills (OCPs) that contain both estrogen and progesterone are also used to treat primary dysmenorrhea. Their action of limiting endometrial growth reduces the amount of endometrium available for prostaglandin and leukotriene production. Also, by prohibiting ovulation, they interfere with ovarian progesterone secretion. There are other pharmacological approaches that are similar to OCPs, but they are administered differently. They include transdermal patches (Ortho Evra patch), vaginal rings (Nuva-Ring), injections (Depo-Provera), and intrauterine (IUD) devices (Mirena). Typically, they are either a combination of both estrogen and progesterone or progesterone alone that inhibit ovulation and/or limit endometrial growth, thus decreasing the symptoms associated with dysmenorrhea.

Some nonpharmacological approaches such as herbal preparations, transcutaneous nerve stimulation (TENS), heat therapy, physical activity, and dietary supplementation with omega-3 fatty acids have been shown to improve the symptoms of primary dysmenorrhea.

### Surgical Management

Surgical treatment may be indicated if NSAIDs or other hormonal approaches have not been effective. If after

6 months of medical treatment no relief has been achieved, then laparoscopy is indicated to evaluate for endometriosis. Uterine anomalies should also be considered. If symptoms are suspicious for an anomaly, imaging and surgical management may be indicated.

## Nursing Management

### Assessment and Analysis

Dysmenorrhea is generally cyclic, timed to the menstrual cycle. The symptoms are associated with prostaglandins and leukotrienes released during menses that cause an inflammatory response in the uterus resulting in abdominal cramping. The symptoms sometimes also include headache, nausea, and vomiting.

### Nursing Diagnosis

- **Pain, acute** associated with cyclic dysmenorrhea

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Pain may result in increased blood pressure and pulse.*
- Pain  
*The pain of dysmenorrhea may be very mild or can be quite debilitating. Treatment options may change depending upon pain levels.*

#### ■ Actions

- Provide nonpharmacological interventions: heat, acupuncture, herbal preps, exercise, TENS, omega-3 supplementation as ordered  
*These interventions have been shown to result in relief of dysmenorrhea through localized relaxation, release of natural endorphins, increased pelvic blood supply, and production of less potent prostaglandins and leukotrienes.*
- Give NSAIDs as ordered  
*These medications are the first-line treatment in dysmenorrhea because they inhibit prostaglandin production.*
- Administer hormonal methods as ordered  
*Drugs such as oral contraceptives and other devices that contain a combination of estrogen and progesterone are effective in the treatment of dysmenorrhea through the limiting of endometrial growth, thereby allowing less production of prostaglandins and leukotrienes.*

#### ■ Teaching

- Counsel on possible nonpharmacological interventions  
*Patients need education on the possible relief demonstrated with these methods.*
- Educate on how to take prescribed medications  
*NSAIDs and hormonal therapy should be taken as prescribed for best results.*
- Maintain a menstrual calendar  
*Patients can chart symptoms and medication administration in relation to their menstrual cycles. This can aid in diagnosis, timing of treatment, and effectiveness of medications. Dysmenorrhea is usually cyclic and worse during the first 2 days of the cycle.*

## Evaluating Care Outcomes

Patients with dysmenorrhea can be managed with NSAIDs, hormonal suppression, or both. A well-managed patient has her pain well controlled with no interference in her everyday activities.

### Connection Check 65.2

Ms. Green is a 16-year-old who has missed 2 days of school each month this year because of painful menses. She has seen her healthcare provider for treatment. The school nurse is reinforcing the prescribed treatment of oral contraceptives and NSAIDs. The nurse teaches Ms. Green to do which of the following?

- Take her OCPs every other day
- Take the NSAIDs at the onset of symptoms and then as needed
- Start NSAIDs 2 days prior to menses and continue on schedule until symptoms resolve
- Stop the oral contraceptives if she has any vaginal bleeding

## ENDOMETRIOSIS

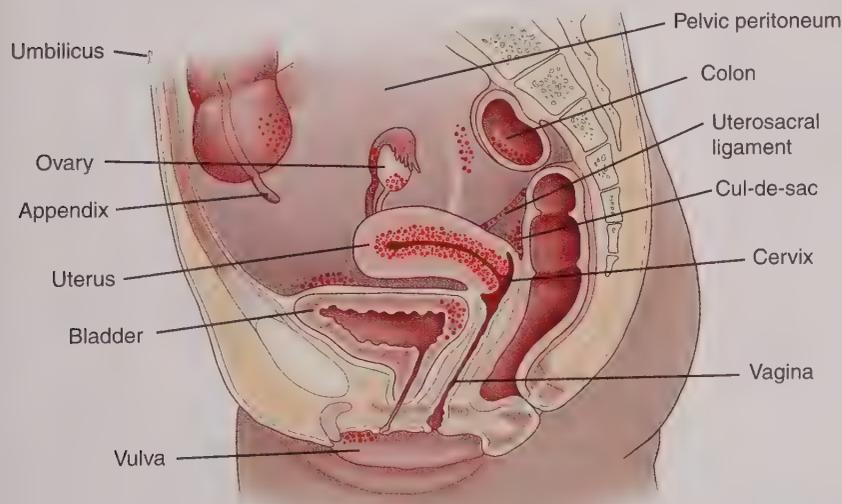

### Epidemiology

**Endometriosis** results when uterine endometrial glands exist and grow outside the uterine cavity or endometrium, often resulting in pain. Endometriosis is the most common cause of secondary dysmenorrhea. There is an apparent hereditary link to endometriosis. Patients with a first-degree relative with endometriosis are five- to tenfold more likely to have endometriosis. Monozygotic twins have a 75% concordance rate for endometriosis. Patients with bleeding disorders also demonstrate an increased risk for endometriosis.

### Pathophysiology

Endometriosis development depends on abnormal hormonal activity associated with the interaction of the enzyme aromatase, an enzyme involved in the synthesis of estrogen. Endometriosis tissues have an increased amount of aromatase in them that is not found in normal endometrium. The aromatase leads to a rise in the local production of estrogen. The increase in local estrogen results in prostaglandin activity that contributes to even higher aromatase levels and even more estrogen production. Also implicated is a deficiency in 17-B hydroxysteroid dehydrogenase type 2 in the tissue that inhibits the inactivation of estradiol (the most potent estrogen) to estrone (the least potent estrogen), further raising local estrogen levels in the tissues.

In endometriosis, endometrial tissue is found outside the uterus implanted on other body structures. The majority of endometriosis implants are found in the pelvis (Fig. 65.5). The ovaries are the most likely sites for implants. Other sites in the pelvis may include the pelvic peritoneum, the cul-de-sac: a pouch between the rectum and uterus, uterosacral ligaments, pelvic lymph nodes, cervix, uterus, vagina, vulva, colon, and appendix. Less likely but possible sites include the umbilicus, surgical scars, bladder, kidneys, lungs, and extremities. Many theories have been postulated to explain this phenomenon, such as the possibility of retrograde menstruation in which endometrial tissue is shed up into the pelvis out of the fallopian tubes during menstruation. The finding of endometriosis implants in premenarchal girls questions this theory. Other possible theories include deficient cell-mediated immunity leading to impaired removal of endometrial cells from aberrant locations, “multipotential” cells in other areas with the ability to transform into endometrial cells, and the spread of endometrial cells through the blood and lymph systems.

**FIGURE 65.5** Common sites of endometriosis implants.

## Clinical Manifestations

The overall accumulation of estrogen and prostaglandin in the endometriosis tissues results in inflammation and pain that can be both cyclic and acyclic. Typical symptoms include dysmenorrhea, excessive bleeding during menses, pain during intercourse, and infertility.

## Management

### Medical Management

#### Diagnosis

Diagnosis of endometriosis is through laparoscopy with biopsy of suspicious lesions. Oral contraceptives are the first line of treatment of endometriosis. If these fail, other pharmacological approaches should be used. Gonadotropin-releasing hormone (GnRH) agonists result in a systemic hypoestrogenic state that impairs the action of the endometriosis. Another pharmacological option is aromatase inhibitors that block local estrogen biosynthesis that occurs outside of the ovaries. They are generally administered in combination with a progestin, a combination oral contraceptive, or a GnRH analog. Aromatase inhibitors are still under investigation for the treatment of endometriosis and are typically reserved for severe, refractory pain.

**Safety Alert** All agents that lead to hypoestrogenism (such as GnRH agonists and aromatase inhibitors) can cause bone loss. Any patients receiving these agents should receive hormonal add-back therapy such as norethindrone acetate, the female hormone progestin, and counseled to maintain adequate dietary calcium and vitamin D intake as well as practice appropriate weight-bearing exercise.

### Surgical Management

The most common surgical treatment for endometriosis is laparoscopy. Patients are five times more likely to get relief from surgical management than medical management. Visible endometriosis implants can be excised, cauterized, or laser vaporized. It is common after surgery to follow up with pharmacological management to prevent further endometriosis recurrence. In extreme cases, it may be necessary to perform hysterectomy (removal of the uterus) with or without oophorectomy (removal of the ovaries). Removal of the ovaries has been associated with less recurrence of disease, but the risk associated with ovarian removal in young women (younger than age 40) associated with the loss of estrogen must be weighed carefully. This should also be considered very cautiously in young women who desire fertility.

### Complications

The location of the endometriosis implant will determine the complications associated with this process. The most

common complications are implants in the pelvis that lead to inflammation and scarring resulting in chronic pelvic pain and infertility. In the rare cases in which the implants are located in other areas, the results will be pain, inflammation, and scarring. Another complication, catamenial pneumothorax, is a condition in which endometrial implants on the lungs result in cyclic pneumothorax associated with the menstrual cycles.

### Nursing Management

#### Assessment and Analysis

The symptoms of debilitating chronic pain, excessive bleeding, and infertility are the result of the increased vicious cycle of increased aromatase, increased estrogen, and inflammation.

#### Nursing Diagnoses

- **Pain, chronic** associated with inflammation and scarring of endometrial implants
- **Risk for infertility** associated with hormone irregularities and tissue scarring

#### Nursing Interventions

##### Assessments

- Vital signs  
*Blood pressure and pulse may be elevated in the patient in pain.*
- Pain scale rating  
*Endometriosis may cause very little pain or may be completely debilitating. It is important to know how much pain the patient is experiencing to evaluate the extent of the disease and efficacy of treatment.*

##### Actions

- Administer medications as ordered: pain medications, GnRH agonists  
*Pain medications may be necessary in the patient with chronic pelvic pain. Gonadotropin-releasing hormone agonists lead to a hypoestrogenic state and decreased symptoms.*

##### Teaching

- Educate about the disease process  
*Understanding disease action is important in helping the patient manage her disease.*
- Educate about medication use  
*Any patient receiving a GnRH agonist should take adequate calcium and vitamin D for bone protection.*
- Maintain a menstrual calendar  
*While understanding that endometriosis is often acyclic, patients can chart symptoms in relation to their menstrual cycles to determine whether a pattern exists.*

#### Evaluating Care Outcomes

It is important that the diagnosis and treatment of endometriosis be made early. The mainstay of treatment is through pharmacological methods. The patient should have adequately controlled pain that allows her to continue to function normally in all of her daily activities.

Early intervention will optimally minimize infertility and chronic pelvic pain.

### Connection Check 65.3

The nurse is taking care of Ms. Davis, a 19-year-old with significant pelvic pain not associated with her menstrual cycles. After 6 months of oral contraceptive use and NSAIDs, she has had no relief. The nurse understands the next course of treatment indicated includes:

- A. Narcotics
- B. Laparoscopy
- C. Hysterectomy
- D. Oophorectomy

## MENOPAUSE

**Menopause** is considered to have occurred after 12 months of no vaginal bleeding, or amenorrhea. All women will eventually go through menopause while they age. The menopausal transition initiates with the irregularity of menses and ends after 12 months of amenorrhea. The time from the beginning of menstrual irregularity until after 12 months of amenorrhea is referred to as *perimenopause*. Once 12 months of amenorrhea has occurred, *postmenopause* is considered to have commenced. Menopause occurs on average at the age of 50 to 51.

### Pathophysiology

Menses is dependent on estrogen and progesterone production from the ovaries. Menopause occurs while the ovaries fail and their estrogen production declines. If the ovaries fail to produce estrogen through the process of ovulation, menses slowly become irregular and finally disappear completely while the uterine lining becomes thin and atrophic.

### Clinical Manifestations

The most common symptoms of menopause are **vasomotor symptoms** such as hot flashes (Box 65.1). Other potential clinical manifestations or complications include bone loss, osteoporosis, increased fracture risk, central weight gain leading to cardiovascular disease, dyslipidemia, and type 2 diabetes mellitus.

## Management

### Medical Management

#### Diagnosis

Diagnosis of menopause is typically based on symptoms as described above and menstrual evaluation. It is important to rule out other etiologies for amenorrhea such as hypothyroidism as it can result in many of the same symptoms as menopause. Other etiologies to consider are pregnancy,

## Box 65.1 Common Vasomotor Symptoms of Menopause

- Hot flashes
- Night sweats
- Joint pain
- Vaginal atrophy leading to vaginal dryness and painful intercourse and urinary dysfunction
- Sleep disturbance
- Anxiety
- Moodiness
- Depression
- Cognitive changes

hyperprolactinemia, other thyroid diseases, medication use, hypoglycemia, malignancies, and pheochromocytomas.

### Laboratory Tests

Laboratory tests include follicle-stimulating hormone (FSH) levels. In response to ovarian failure, the pituitary increases production of FSH in an attempt to make the ovaries respond and ovulate. Perimenopausal women and postmenopausal women demonstrate varying elevations of FSH. Women in the perimenopause period may have periodic elevations of FSH followed by periods of normal levels. Therefore, measurement of FSH can be misleading and should be evaluated with caution. Pregnancy testing, prolactin levels, a thyroid panel, CBC, and a metabolic panel are other laboratory tests that can assist in ruling out other etiologies of amenorrhea described above.

### Medications

Estrogen therapy is the most effective treatment for the symptoms of menopause but should be used with caution because its use is associated with varying increased risk of breast cancer and cardiovascular events. There appears to be an increased risk of breast cancer in women using estrogen and progesterone combined and less in women using estrogen alone. This is thought to be due to an increase in breast density that results in difficulty reading mammograms. This risk increases with prolonged use. Also, women who began estrogen and progesterone use in the first 10 years of menopause showed no significant increase in cardiovascular events, but this was not true for those who started **hormone therapy (HT)** once they were past the first 10 years of menopause.

With an understanding of these risks, recommendations for HT include treating women with significant vasomotor symptoms for the shortest duration required. The lowest possible effective dose should be initiated in recently menopausal women with moderate to severe symptoms who are in good cardiovascular health. Therapy should not generally extend beyond 4 to 5 years. In women with an intact uterus who require the addition of progestin to protect the uterus from hyperplasia (or overgrowth of the tissue that lines the uterus that can lead to cancer) that can occur with

the use of estrogen alone, it is best to minimize the dose and duration of that medical therapy. For the minority of women who continue to have severe symptoms, HT may be continued after trials of alternative therapies and a complete risk versus benefit evaluation.

Treatment for genitourinary atrophy includes the use of vaginal estrogen therapy. This can be used with little systemic effect and is the preferred method of treatment. Moderate to severe vaginal symptoms can be treated with local estrogen in the form of vaginal tablets, creams, or rings. Patients with mild atrophy may opt to try vaginal moisturizing agents and lubricants.

If the woman is not able to take estrogen or simply chooses not to, there are several off-label medications and treatments that are used. Selective serotonin reuptake inhibitors (SSRIs), selective norepinephrine reuptake inhibitors (SNRIs), clonidine, and gabapentin have all been shown to be somewhat effective. Selective serotonin reuptake inhibitors should be avoided in women with breast cancer on tamoxifen therapy because they reduce tamoxifen metabolism. Black cohosh is one of the most commonly used herbal treatments, but it has been shown to be ineffective in trials.

### Complications

Several overall health concerns result from the hypoestrogenic state of menopause. Bone loss leading to osteoporotic fracture is a direct result of declining systemic estrogen levels. Increased abdominal fat and weight gain associated with menopause may contribute to a higher risk of cardiovascular disease (CVD) due to insulin resistance, hyperlipidemia, and hypertension. Cardiovascular disease is the leading cause of death and disability in women worldwide. This risk increases significantly with age and menopause.

### Nursing Management

#### Assessment and Analysis

Assessment of the menopausal patient focuses on symptomatology due to decreased estrogen levels. The most common symptoms include hot flashes; vaginal atrophy-related symptoms such as vaginal dryness, painful intercourse, and urinary dysfunction; sleep disturbances; mood changes; joint pain; and memory decline.

#### Nursing Diagnoses

- **Fatigue** associated with sleep disturbances
- **Impaired memory** associated with estrogen loss
- **Sexual dysfunction** associated with vaginal atrophy

#### Nursing Interventions

##### Assessments

- Vital signs  
*Hypertension in the postmenopausal woman is a sign of CVD.*
- Menstrual calendar  
*Menopause is defined as occurring after 12 months of amenorrhea.*

- Weight  
*Postmenopausal weight gain may contribute to CVD, insulin resistance, hyperlipidemia, and hypertension.*
- Laboratory review  
*FSH will be elevated in menopause as the pituitary increases production of FSH to make the ovaries respond and ovulate. Prolactin, thyroid-stimulating hormone, CBC, and chemistry panel are frequently drawn to eliminate other etiologies for patient symptoms.*

##### Actions

- Administer estrogen and progesterone as ordered  
*Replacement of hormones no longer released because of menopause produces the most effective relief of symptoms.*
- Administer other therapies as ordered such as SSRIs, SNRIs, gabapentin, and clonidine if hormonal therapy is contraindicated  
*Some nonhormonal medications have been found to be effective in the relief of menopausal symptoms for reasons not completely understood. SSRIs are thought to be effective because they play a role in regulating body temperature.*
- Discuss alternative methods of relief  
*Cooling therapies may help with hot flashes; naps may assist with sleepless nights, as well as reassurance that symptoms are usually self-limiting.*

##### Teaching

- Educate on the pros and cons of HT  
*Hormone therapy is controversial and is recommended only for short-term use in symptomatic patients because of increased cancer and CVD risk.*
- Teach patients the etiology of symptoms  
*Patients may find comfort in knowing the majority of symptoms are short term.*
- Educate patients on alternative treatments for vaginal symptoms  
*Educate on lubricants or estrogen creams for the vagina to decrease symptom of painful intercourse.*
- Educate on the importance of adequate calcium and vitamin D intake as well as regular weight-bearing exercise  
*With the loss of estrogen, women are at increased risk for decreased bone density and fracture—calcium, vitamin D, and weight-bearing exercises help maintain bone health.*

#### Evaluating Care Outcomes

A well-managed menopausal patient has symptoms under control through the use of hormonal therapy if indicated or the use of SSRIs, SNRIs, clonidine, or gabapentin. This patient maintains a healthy diet and weight, exercises regularly and takes calcium and vitamin D supplementation. It is important that women begin these healthy behaviors at a young age and continue in menopause to protect their bone and cardiac health.

### Connection Check 65.4

The nurse takes a phone call from Ms. Case. Ms. Case is 50 years old and is complaining of a lack of menses, the inability to sleep, hot flashes, and fatigue. What condition is the nurse not concerned about?

- A. Endometriosis
- B. Pregnancy
- C. Hypothyroid
- D. Menopause

## FIBROIDS

### Epidemiology

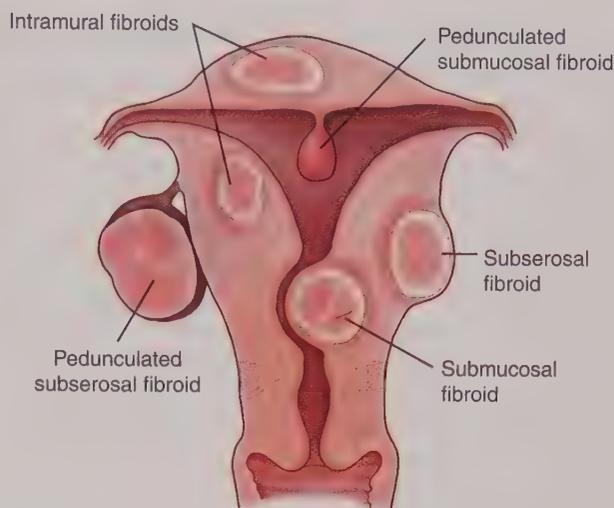

Fibroids are reported to occur in as many as 70% to 80% of women. They are more prevalent in African American women, occurring in as many as 75% of women of that race. They are more prevalent in white women than in Asians. They are also more common in women who have never been pregnant, those who started menstruating at an early age, and those who were older at the time of their first term pregnancy. Black women who have had children do not appreciate the same risk reduction as white women. Fibroids are more likely in obese women in general but also in nonobese women with polycystic ovarian syndrome. Diabetes mellitus and hypertension have also shown a correlation to a higher incidence of fibroids.

### Pathophysiology

Fibroids or uterine **leiomyomas** are the most common solid benign tumors of the female pelvis and are the leading cause of hysterectomy. The tumors originate from the muscular tissue of the uterus, but their etiology is not completely understood. They are defined by their location in the uterus. Submucous fibroids are found inside the uterus and distort the uterine cavity. Intramural fibroids are found within the muscle wall of the uterus but do not distort the cavity or extend to the subserosal surface. Fibroids that extend out of the outer, subserosal surface of the uterus are called *subserosal*. These may extend off the uterus completely in a pedunculated fashion (Fig. 65.6). Fibroids are dependent on the ovarian production of estrogen and progesterone for growth. Therefore, growth will generally occur in the reproductive years with a decline in growth once menopause has been achieved.

### Clinical Manifestations

Many fibroids are completely asymptomatic. The most common symptoms are vaginal bleeding and pelvic pressure. Women may experience heavy menses associated with an overall increase in uterine and endometrial size, or they may experience **menorrhagia** (prolonged irregular bleeding) associated with endometrial distortion from submucosal fibroids. This is the most common complaint because

**FIGURE 65.6** Fibroids. Submucosal, intramural, subserosal, and pedunculated subserosal that extend off of the uterus.

it often results in significant anemia. Significant pelvic pressure and bulk can result in dyspareunia (painful intercourse), dysuria, and difficult defecation.

### Management

#### Medical Management

##### Diagnosis

The diagnosis of fibroids is often suspected when a patient presents for menorrhagia or pressure symptoms. Pelvic mass may be felt on pelvic examination, but imaging is key in the diagnosis of fibroids. Transabdominal or transvaginal ultrasound is 90% to 100% sensitive in the detection of fibroids. Color Doppler studies help identify the vascularity of the fibroid.

Magnetic resonance imaging assists in the anatomical delineation, further identifying the site, size, and depth of muscular invasion of the fibroid. Any other reasons for pelvic mass and uterine bleeding should also be thoroughly evaluated to verify the diagnosis.

##### Treatment

Medical treatment of fibroids is primarily focused on hormone therapy (HT) for reduction of symptoms. Estrogen and progestin combination pills and progestin-only formulations are used for the control of bleeding and dysmenorrhea. Evidence suggests that their relief in fibroid patients tends to be short term. Also, there is some concern that hormonal use could stimulate fibroid growth and should be monitored closely if used. Tranexamic acid is an antifibrinolytic drug that can be taken for five days with the onset of menses to decrease overall blood loss. Gonadotropin-releasing hormone (GnRH) agonists induce a false menopause state that results in size reduction of the fibroids and decreased bleeding. The bone loss and menopausal symptoms associated with this type of drug lead to a suggestion of a limit of 6 months of use. The effect with a GnRH agonist is temporary, and the fibroids

will return to their previous size once the GnRH agonist is discontinued. Therefore, GnRH agonists are often used preoperatively to shrink fibroids prior to surgical management. Aromatase inhibitors, which block estrogen production, have also shown a decrease in the size of fibroids without as many side effects as the GnRH agonists. However, further research is needed to confirm these findings. Finally, antiprogestone agents are being studied for their effect on fibroids. Early data indicate a reduction in fibroid size with a benefit of amenorrhea. Side effects of concern include endometrial hyperplasia without atypia (cellular abnormality) and temporary elevations in liver enzymes. As with aromatase inhibitors, further study is required to confirm the positive impact of these drugs on fibroids.

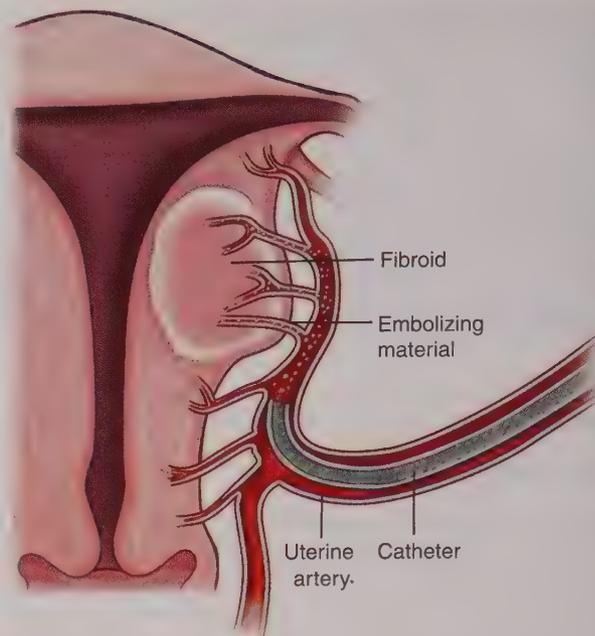

### Surgical Management

Surgical options are the primary tool utilized in the management of fibroids. Hysterectomy, or surgical removal of the uterus, is the most common treatment for fibroids. It is the only definitive treatment that ensures no recurrence and complete resolution. It is permanent and eliminates all future fertility as well. Hysterectomy may be performed via laparotomy, an open abdominal incision; transvaginally (removal of the uterus through the vagina); or laparoscopically, a procedure done through several small incisions that allow introduction of instruments and a camera, with or without robotic assistance. Vaginal and laparoscopic hysterectomies offer lower complications, shorter hospital stays, and quicker recovery.

If fertility is a priority, then myomectomy is an option. Myomectomy is a surgical procedure to remove the visible and accessible fibroids and then repair the uterus to its prefibroid state. Myomectomies are traditionally performed through laparotomy, but in certain patients with trained skilled surgeons, a myomectomy may be able to be performed laparoscopically. As with hysterectomy, laparoscopy generally results in less blood loss, decreased hospital stays, and quicker recovery.

Interventional radiologists may perform a procedure called a *uterine artery embolization* (UAE). In this procedure, the uterine arteries are accessed through the femoral arteries. An embolizing material is introduced into the uterine arteries, which results in devascularization (cutting off the blood supply) and subsequent degeneration of the fibroids (Fig. 65.7). Minor complications include vaginal discharge, fibroid expulsion, and hematoma. When compared with patients undergoing other surgical procedures, UAE patients had shorter hospital stays and a quicker recovery. Concerns do exist over the effect of UAE on premature ovarian failure. Also, there are few data demonstrating the safety of pregnancy after UAE. Therefore, the current recommendation is that women should not become pregnant after undergoing this procedure.

Another approach uses MRI-focused ultrasound therapy to penetrate and destroy the fibroid. Adverse effects include

**FIGURE 65.7** Uterine artery embolization. Embolizing material is infused into the uterine artery to cut off blood flow to the fibroid.

heavy menstrual bleeding, continued pain, nausea, and leg and buttock pain due to sono effect on the sciatic nerve. The sciatic nerve pain will eventually resolve. The procedure is costly and can treat only one fibroid at a time. Women wishing to conceive in the future are not advised to pursue this approach.

### Complications

In rare cases, fibroids may become so large as to cause pathologic compression on adjacent structures such as the ureters, resulting in compromised renal function. Patients may become so anemic that blood transfusion is required. The least common but most concerning issue is distinguishing the fibroid from a leiomyosarcoma, a dangerous malignant tumor that often appears similar to a benign fibroid on examination and imaging. Consideration must be given to this option when evaluating fibroids or uterine tumors.

### Nursing Management

#### Assessment and Analysis

Patients with fibroids present with symptoms such as heavy or prolonged vaginal bleeding due to increased uterine size from the fibroids or bleeding of a submucosal fibroid. They may also have pelvic pressure due to the bulk of the fibroids putting pressure on other organs in the pelvis.

#### Nursing Diagnoses

- **Risk for activity intolerance** due to anemia, vaginal bleeding, and pelvic pressure
- **Impaired urinary elimination** due to pressure from fibroids
- **Chronic pain** associated with pelvic pressure from fibroids

- **Acute pain** associated with the surgical procedure for fibroid treatment

### Nursing Interventions

#### ■ Assessments

- Vital signs  
*Hypotension and tachycardia will reflect symptomatic anemia. Pain may cause tachycardia.*
- Pain scale  
*Pain assessment can help evaluate fibroid development and the adequacy of pain management.*
- Pad count  
*Evaluating the number of pads used can help to quantify the actual amount of vaginal bleeding.*

#### ■ Actions

- Administer blood transfusion as ordered  
*The significantly anemic patient may acutely need blood to maintain intravascular volume and oxygen carrying capacity.*
- Administer nonsurgical methods of treatment if chosen  
*Gonadotropin-releasing hormone agonists induce a false menopause state that results in size reduction of the fibroids and decreased bleeding; estrogen and progesterone therapy are used for the control of bleeding and dysmenorrhea; and aromatase inhibitors block estrogen production, decreasing the size of fibroids.*
- Administer medications for pain relief as ordered  
*Pain medications may be necessary in the preoperative or postoperative patient. Degenerating fibroids can be quite painful.*

#### ■ Teaching

- Treatment options  
*The patient should make a well-informed choice about treatment on the basis of her age, health, and fertility desires.*

### Evaluating Care Outcomes

The well-managed patient should have controlled vaginal bleeding that does not result in anemia or interference with normal activity. This patient understands the risks and benefits of all treatment options and chooses the one that best meets her needs based on age, health, and fertility desires.

### Connection Check 65.5

Ms. Harris has large uterine fibroids that are causing her pain and heavy bleeding. The nurse is educating her on her treatment options. Which option is considered the only definitive treatment for fibroids?

- Uterine artery embolization
- Hysterectomy
- Lupron administration
- Myomectomy

## OVARIAN CANCER

### Epidemiology

Ovarian cancer is the fifth most common cancer found in women. Approximately 70% to 75% of the cases are not discovered until the late stages (stage III or IV) of the disease. As a result, ovarian cancer causes the most deaths of any gynecological malignancy. If diagnosed in stage I, the 5-year survival rate is more than 73%. However, if diagnosed in stage III or IV, the 5-year survival rate falls to 21% and less than 5%, respectively.

There appears to be a hormonal influence on the development of ovarian cancer. A history of breastfeeding, pregnancy, and oral contraceptive use bestows a protective effect as does the use of progesterone alone as hormone replacement therapy. Conversely, long-term hormone replacement with estrogen only or estrogen/progesterone combination increases the risk of ovarian cancer. Androgens (primarily male hormones such as testosterone) are suspected to have a negative effect on ovarian cancer. This is evidenced by the fact that obesity and polycystic ovarian syndrome, states that have higher circulating androgens, appear to carry a greater risk. Elevated gonadotropin levels (FSH/LH) found in menopause do not appear to cause malignant lesions but may promote the growth of an existing tumor. Other factors that may be implicated but not completely understood are age of first menses, age of menopause, infertility history, and the use of ovarian-stimulating drugs. Other women considered high risk for developing ovarian cancer are those with a family history, those with *BRCA1* or *BRCA2* gene mutations, or those with hereditary nonpolyposis colorectal cancer (HNPCC) syndrome. It is uncommon to find ovarian cancer in a woman younger than 40, but the incidence increases from that point forward. Most cases are diagnosed in women in their 70s.

### Pathophysiology

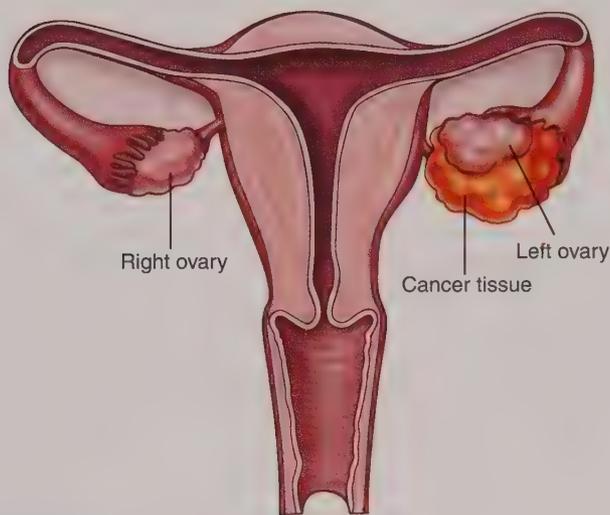

As with breast cancer, ovarian cancer is a condition where the cells of the body grow and divide abnormally and uncontrollably. The cells can invade nearby tissues and spread to other areas through the bloodstream and lymphatic system. Staging of ovarian cancer is established by the International Federation of Gynecology and Obstetrics (FIGO) and is based on operative findings. Table 65.3 outlines staging of ovarian cancer. Fig. 65.8 illustrates ovarian cancer.

### Clinical Manifestations

The symptoms experienced prior to diagnosis of ovarian cancer tend to be vague and nonspecific. Symptoms that should cause one to consider ovarian cancer are bloating, pelvic or abdominal pain, early satiety or problems with eating, and urinary urgency or frequency. In later-stage ovarian cancer, ascites or excessive fluid in the abdominal cavity is present. Often patients and providers alike dismiss the

**Table 65.3 Federation of Gynecology and Obstetrics Staging of Ovarian Cancer**

Stage	Description
<b>Stage I A, B, C</b>	Growth limited to one or both ovaries; staging increases if it extends to a surface tumor and there are malignant cells in ascites or peritoneal washings
<b>Stage II A, B, C</b>	Involves one or both ovaries with extension to the pelvis; staging increases as there is extension to the uterus, fallopian tubes, or to other pelvic tissues and there are malignant cells in ascites or peritoneal washings
<b>Stage III A, B, C</b>	Involves one or both ovaries with peritoneal metastasis limited to or beyond the pelvis and/or positive retroperitoneal or inguinal lymph nodes; staging increases as abnormal cells are noted on the abdominal peritoneal surfaces and there is abdominal metastasis increasing in size
<b>Stage IV</b>	Involves one or both ovaries and has distant metastasis

**FIGURE 65.8** Ovarian cancer.

symptoms as associated with common nonpathologic etiologies. As a result, most ovarian cancers are diagnosed in the advanced stages. It is important for both patients and healthcare providers to recognize the symptoms of ovarian cancer and be diligent in investigating the etiology.

## Management

### Medical and Surgical Management

#### Diagnosis

There are no recommended screening tests for ovarian cancer. If ovarian cancer is suspected, the biochemical marker **CA 125**, a blood test, may be ordered. CA 125 levels will rise in the presence of ovarian cancer, but there is no established expected rise, and many other conditions such as diverticulitis, endometriosis, cirrhosis of the liver, and uterine fibroids may also cause the levels to rise. CA 125 levels are normal in 50% of early ovarian cases as well.

Radiographical tests include pelvic ultrasonography or CT to visualize the ovaries. In women who are at particularly high risk for developing ovarian cancer (BRCA1/2 positive, family history, or HNPCC syndrome), CA 125 levels and pelvic ultrasounds may be used together for screening. However, this approach is not recommended in the general population because studies have shown that the overall benefit of earlier detection through these methods does not demonstrate a significant overall effect on mortality. It may actually lead to more invasive harm with minimal yield because of aggressive surgical intervention for ultimately benign lesions. Biopsy of an ovarian mass is not generally recommended because of the potential for spread during biopsy. Definitive diagnosis is made through surgical removal of a suspected mass followed by total specimen pathology.

Gene [BRCA] 1 or BRCA2 positive, family history, or HNPCC syndrome), CA 125 levels and pelvic ultrasounds may be used together for screening. However, this approach is not recommended in the general population because studies have shown that the overall benefit of earlier detection through these methods does not demonstrate a significant overall effect on mortality. It may actually lead to more invasive harm with minimal yield because of aggressive surgical intervention for ultimately benign lesions. Biopsy of an ovarian mass is not generally recommended because of the potential for spread during biopsy. Definitive diagnosis is made through surgical removal of a suspected mass followed by total specimen pathology.

#### Surgical Treatment

Surgical management of a suspected ovarian carcinoma traditionally consists of surgical staging and debulking of the tumor. The debulking procedure attempts to remove as much of the tumor bulk as possible. In addition to removal of the mass, the staging procedure includes peritoneal washings (saline solution is rinsed into the abdomen and pelvis and then removed and sent for cytology), peritoneal biopsies (removal of samples of the peritoneal enclosure of the abdomen for pathology), omentectomy (removal of samples of the omental tissue surrounding the bowels), and lymphadenectomy (removal of lymph nodes for pathology to determine spread). Most procedures also include removal of the uterus, both ovaries, and fallopian tubes. However, in rare situations in the woman wishing to retain her fertility with very early-stage malignancy, this may be deferred and only the involved ovary is removed.

#### Medications

Medical management with chemotherapy follows surgical debulking. Standard chemotherapy is typically administered through IV methods, but recent trials have shown intraperitoneal (IP) chemotherapy to be superior to IV administration. However, IP chemotherapy tends to carry a higher toxicity risk. Another more recent medical option is to give chemotherapy prior to surgery. This can complicate diagnosis of histological or cell type of the tumor because

chemotherapy tends to alter the composition of the tumor. This is important because histological subtype is an important factor to consider when determining which chemotherapeutic agent is most effective for treatment. For this reason, optimal initial debulking remains the standard of care in the majority of patients.

## Nursing Management

### Assessment and Analysis

Symptoms of ovarian cancer tend to be vague and nonspecific and are often not reported until the cancer is advanced. Even when reported, they are frequently dismissed as benign in etiology. The common symptoms due to the presence of the tumor are bloating, difficulty eating or early satiety, pelvic or abdominal pain, and urinary frequency or urgency.

### Nursing Diagnoses

- **Ineffective coping** associated with the cancer diagnosis
- **Acute pain** associated with surgery
- **Altered nutrition**, less than body requirements secondary to cancer and chemotherapy

### Nursing Interventions

#### Assessments

- Symptom assessment  
*Ovarian cancer should be considered when bloating, difficulty eating, abdominal pain, or urinary frequency or urgency is present.*
- Vital signs  
*Elevated blood pressure and pulse are signs of pain. Elevated temperature can indicate infection.*
- Abdominal girth  
*A manifestation of later-stage ovarian cancer is ascites.*
- Weight  
*Weight loss may be associated with nutritional deficits associated with cancer and chemotherapy, whereas weight gain can be an indicator of fluid retention.*
- Diagnostic tests; CA 125 levels and imaging  
*CA 125 levels may be elevated in ovarian cancer but should be evaluated with other indicators as CA 125 can be elevated in other conditions. Pelvic ultrasound or CT may visualize the tumor.*
- Chemotherapy side effects  
*The chemotherapy for ovarian cancer treatment is often toxic with many side effects. They include nausea, vomiting, diarrhea, and constipation. Hair loss is common as well as a decrease in white blood and red blood cells. It is important to evaluate for these side effects and treat them as able.*
- Psychological evaluation  
*Be aware of the potential of anxiety and depression associated with this diagnosis and offer support and counseling as necessary.*

#### Actions

- Give pain medications as ordered  
*Pain medications help the patient to maintain comfort and participate in activities of daily living.*

- Give chemotherapeutic agents as ordered  
*Adjunct therapy to surgery with ovarian cancer*
- Give antiemetics as ordered  
*Nausea and vomiting are common with chemotherapy. Antiemetics are very important in treatment as they help the patient maintain a nutritional balance.*

#### Teaching

- Educate all women on the symptoms of ovarian cancer  
*Symptoms are vague and nonspecific. It is extremely important that women recognize them early and providers investigate them thoroughly.*
- Discuss methods to ease chemotherapy side effects  
*Patients should use all prescribed methods and any complementary methods to combat the side effects of chemotherapy and ease the treatment of this disease. Poorly controlled side effects may delay or hamper treatment, cause nutritional deficiencies, and put the patient at risk for infection.*
- Provide information on support groups or counselors  
*This is a difficult disease with a poor prognosis. Patients can find help through support groups and counselors.*

### Evaluating Care Outcomes

Optimal management includes awareness of even the vaguest symptoms of ovarian cancer and immediately reporting them. It is imperative that women be taught the early symptoms. Once diagnosed, the patient will need support throughout the operative and chemotherapeutic phases of treatment, both physically and mentally. A well-managed patient undergoing chemotherapy is receiving adequate antiemetics to control nausea. Nutritionally, the patient is eating enough calories to maintain adequate weight for healing. Hair loss and body image are addressed through psychological support, and ultimately end-of-life issues may need to be addressed.

### Connection Check 65.6

A nurse working in a clinic has received phone calls from several patients. It is a priority for the nurse to suggest immediate follow-up for the female patient complaining of which of the following?

- Urinary frequency at night
- Chest discomfort after spicy meals
- Difficulty eating due to feeling full and bloated
- Pain with the onset of menses

#### Safety Alert Transgender Males and Gynecologic Care

It is important for transgender males to receive appropriate gynecologic care and recommended preventive screening exams (breast, pap, and pelvic exams). Transgender males continue at risk for gynecologic disorders but often delay seeking this care. Increased sensitivity and knowledge by the medical staff and nurses to the unique needs and concerns of this population can aid in providing these services.

## UTERINE CANCER

### Epidemiology

Uterine cancer, or endometrial cancer, is the most common gynecological cancer in the United States. There is a 2.6% lifetime risk for women living in developed nations. Uterine cancer primarily occurs in postmenopausal women, with the highest incidence between the ages of 55 and 65. The median age at diagnosis is 61. Most cases are sporadic and multifactorial in nature; 2% to 5% are associated with a hereditary gene alteration called hereditary nonpolyposis colorectal syndrome (HNPCC).

The greatest risk factors for the most common endometrial cancers (type I, endometrioid) are unopposed estrogen exposure and obesity. Unopposed estrogen exposure may be the result of estrogen therapy in the absence of progesterone replacement or therapeutic tamoxifen use. Endogenous sources of elevated estrogen levels that may result in endometrial cancers include obesity, cirrhosis, estrogen-producing tumors, and anovulation. A less common but more aggressive type of uterine malignancy (type II, serous/clear cell) is a malignancy with aging and genetic/molecular changes. Serous carcinomas occur more commonly in African Americans.

### Pathophysiology

As with other cancers, uterine cancer is a condition in which the cells of the body grow and divide abnormally and uncontrollably. The cells can invade nearby tissues and spread to other areas through the bloodstream and lymphatic system. Approximately 80% of endometrial carcinomas are endometrioid adenocarcinomas that consist of malignant glandular cells that look very much like the cells of the uterine lining. They are commonly early stage and grade and are associated with estrogen stimulation associated with obesity. Approximately 10% of endometrial carcinomas are serous and clear cell carcinomas. Associated with endometrial atrophy, they tend to be diagnosed in women 5 to 10 years older than those with endometrioid carcinomas. With early diagnosis, endometrioid carcinomas have an 88% overall survival rate. Serous carcinomas and clear cell carcinomas have a much poorer prognosis, with 18% to 27% overall survival rates for serous carcinomas and 42% overall survival rates for clear cell carcinomas. Uterine sarcomas, cancers that arise from muscle and support tissue of the uterus, account for 3% to 5% of all uterine cancers (Fig. 65.9). Metastatic or recurrent uterine cancer of any histology is considered incurable and in the advanced stage has a median survival of approximately 1 year. Table 65.4 outlines FIGO tumor staging for uterine cancer.

### Clinical Manifestations

The most common symptom of endometrial cancer is vaginal bleeding. Postmenopausal women with vaginal bleeding and premenopausal women with irregular or heavy bleeding who have risk factors or who have been unresponsive to

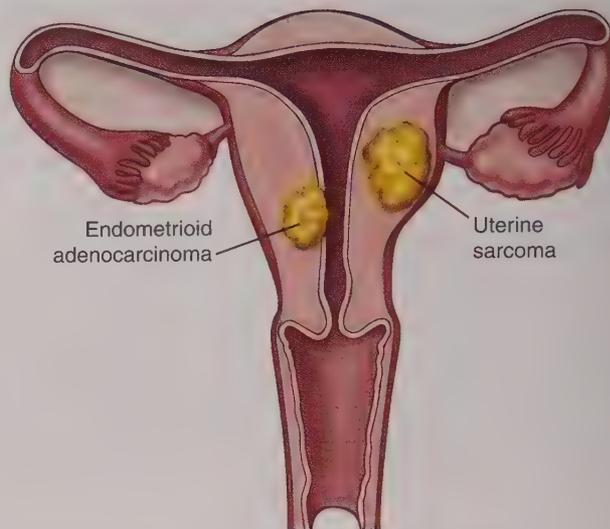

FIGURE 65.9 Uterine cancer.

**Table 65.4 Federation of Gynecology and Obstetrics Tumor Staging for Uterine Cancer**

Stage	Description
<b>Stage I A, B, C</b>	Endometrial cancer confined to the corpus, the main body of the uterus; staging increases as there is invasion of the myometrium
<b>Stage II A, B, C</b>	Endometrial cancer involves the corpus and the cervix but has not extended outside the uterus; staging increases as there is invasion of the cervical stroma
<b>Stage III A, B, C</b>	Endometrial cancer extends outside the uterus but is confined to the true pelvis; staging increases as there is invasion of the visceral peritoneum, fallopian tubes, vagina and there are metastases to pelvic and/or para-aortic lymph nodes
<b>Stage IV A, B</b>	Endometrial cancer involves the bladder or bowel mucosa or has metastasized to distant sites; staging increases with distant metastases

medical treatment should undergo evaluation for endometrial cancer.

## Management

### Medical and Surgical Management

#### Diagnosis

Diagnosis can be done through biopsy, pelvic ultrasound, and in some cases, surgical dilation and curettage (D & C: scraping the lining of the uterus for a tissue sample). Endometrial biopsy is 99% sensitive in detecting high-grade endometrial carcinomas. Pelvic ultrasound also aids in the detection of an abnormally thickened endometrium that may be associated

with the development of endometrial cancer. Patients with a negative endometrial biopsy and normal pelvic ultrasound who continue to have abnormal bleeding may be candidates for surgical D&C to ensure adequate uterine sampling.

### Treatment

The initial treatment is the surgical removal of the uterus, fallopian tubes, and ovaries. As in ovarian cancer, other procedures include obtaining abdominopelvic washings for cytology (saline solution is rinsed into the abdomen and pelvis and then removed) to check for cancer cells and performing pelvic and aortic lymphadenectomy (removal of lymph nodes for pathology to determine spread). Omentectomy (removal of samples of the omental tissue surrounding the bowels) and peritoneal biopsies may also be performed. The FIGO tumor staging then guides treatment. For example, early stage I disease can be treated with surgery that is often curative, not requiring further treatment.

Adjuvant therapy (additional therapy after surgery) is determined on the basis of staging or risk. Typically, radiation treatment is the choice of therapy. Chemotherapy is the first-line management for those with high risk or higher-stage disease, but response continues to be modest. Despite a good survival rate in early-stage patients, patients with advanced or recurrent endometrial cancer have an overall poor survival rate. Once primary chemotherapy has failed, there is no accepted second-line agent for treatment. Chemotherapy resistance is not uncommon and presents challenging treatment dilemmas. Metastatic and recurrent disease is considered incurable and has poor survival rates of only about 1 year. Optimal sequencing with chemotherapy and radiation continues to be investigated.

### Nursing Management

#### Assessment and Analysis

Identification of the patient at risk is critical in assessment of the patient when evaluating for uterine cancer. Patients with uterine cancers will often present with abnormal vaginal bleeding. The most common age at presentation is between 55 and 65. Once the possibility of uterine cancer is considered, pelvic ultrasound and endometrial biopsy are critical for further assessment.

#### Nursing Diagnoses

- **Acute pain** associated with the surgical staging procedure
- **Nausea** associated with chemotherapy
- **Ineffective coping** associated with the cancer diagnosis

#### Nursing Interventions

##### Assessments

- Vital signs  
*Blood pressure and pulse may be elevated in the patient in pain. Temperature elevations are a sign of infection.*
- Daily weight  
*Weight loss reflects fluid loss and nutritional deficits. Nausea and vomiting from chemotherapy treatment are*

*often implicated in weight loss. Weight gain may be reflective of fluid retention.*

- Intake and output  
*Intake and output allows for evaluation of the patient's fluid balances as well as nutritional deficits.*
- Pain scale  
*Pain scales allow patients to identify and adequately treat their pain.*
- Abnormal vaginal bleeding  
*Abnormal vaginal bleeding is the most common symptom in uterine cancer.*
- Patient age  
*Most uterine cancers occur between the ages of 55 and 65.*

##### Actions

- Administer pain medications as ordered  
*Pain medications are important to relieve the acute pain associated with surgical intervention as well as the chronic pain associated with the disease and its treatment. Adequate pain management allows the patient to participate in activities of daily living.*
- Administer chemotherapy as ordered  
*Chemotherapy after surgery is often indicated, but a positive response is limited.*
- Provide comfort measures for the chemotherapy patient  
*The patient undergoing chemotherapy may experience side effects of nausea, vomiting, or stomatitis. Assist these patients with comfort measures including antiemetics, mouth rinses with salt water or mouthwash, and complementary therapies.*

##### Teaching

- Educate about disease prevention  
*Obesity and unopposed estrogen are the most common risk factors for uterine cancer. Encourage patients to maintain a healthy weight and exercise regularly. Any patients on estrogen therapy who have an intact uterus should be on replacement progesterone as well. Patients on tamoxifen should be closely monitored for endometrial hyperplasia.*
- Discuss chemotherapy comfort measures  
*It is important that the patient undergoing chemotherapy also receive medications for nausea. Avoiding hot or spicy food, anti-inflammatories, and mouth wash preparations may help stomatitis. Complementary therapies may also be used to relieve the common side effects of chemotherapy.*
- Provide psychological support resources  
*Support groups, image centers, and counselors are all important resources to have readily available for the patient undergoing treatment for cancer.*

#### Evaluating Care Outcomes

Nutritional needs are paramount with a patient undergoing treatment for uterine cancer. The well-managed patient is able to maintain adequate weight and nutritional status while optimally achieving most of her normal daily functions. The majority of endometrial cancer is diagnosed in the early stage and frequently is cured with surgery alone. Education

regarding the need for routine long-term follow-up is important. Psychological support resources should be available and easily accessed.

### Connection Check 65.7

The nurse is most concerned about Ms. James, a 60-year-old female patient, when she calls complaining of which of the following?

- A. Vaginal itching
- B. A foul vaginal discharge
- C. Hot flashes at night
- D. Vaginal bleeding

## CERVICAL CANCER

### Epidemiology

Cervical cancer is the 13th most common cancer in women in the United States. It is in the top 10 cancers among black women, American Indian or Alaska Native, and Hispanic women. The highest incidence is in women 50 to 79 years of age and in Hispanic women. Approximately half of cervical cancer cases are diagnosed in the late stages of the disease. Diagnosis in later stages occurs more frequently in women older than 50, black women, and women who have not had a Pap smear for longer than 5 years.

Cervical cancer rates in the United States and other developed nations have declined significantly since the introduction of the Pap smear in the mid-20th century. The lowest users of Pap smears today are uninsured women, smokers, obese women, women older than the age of 65, Asians or Pacific Islanders, and recent immigrants. A majority of cervical cancer cases worldwide occur in underdeveloped countries. Approximately 85% of cervical cancer deaths occur in these countries.

Nearly 100% of cervical cancer tests are positive for infectious **human papillomavirus (HPV)**. Although women may be infected with HPV and never develop cervical cancer, it is almost always the cause of cervical cancer. Associated risk factors for HPV include early sexual activity, multiple sexual partners, low socioeconomic status, and immunosuppression. Other risk factors that are thought to be possible contributors are herpes simplex virus type 2, smoking, douching, poor nutrition, and oral contraceptive use.

**Safety Alert** It is important to counsel patients to avoid the modifiable risk factors for HPV. They

include early sexual activity, multiple sexual partners, smoking, douching, and poor nutrition. It is also important to encourage young women to get vaccinated against HPV. The Centers for Disease Control and Prevention (CDC) currently recommends vaccination for children aged 11 or 12. Two HPV vaccines are now available as prevention; however, they are ineffective against an existing virus.

### Pathophysiology

Cervical cancer is a slow-developing disease that begins with early cervical **dysplasia**, or abnormal cell maturation (low grade progressing to high grade), that only develops into invasive cancer if left untreated. Early detection of dysplasia allows for removal of the dysplastic cells and prevention of cervical cancer.

### Clinical Manifestations

There are no recognizable symptoms of cervical dysplasia. Most dysplasia is not even visible to the eye of the trained provider. Vaginal bleeding is the most common symptom of invasive cervical cancer. Sexually active women may experience postcoital bleeding. In women who are not sexually active, it is not uncommon to be completely asymptomatic until the disease is very advanced.

### Management

#### Medical and Surgical Management

#### Diagnosis

Almost all cervical cancers are preventable with adequate routine screening. The mainstay of cervical cancer screening is the Pap smear. Human papillomavirus testing is also frequently being used as an adjunct to the Pap smear. Screening guidelines include the following:

- Women should have their first Pap smear at age 21.
- Women between ages 21 and 30 with normal Pap smears should have Pap smears every 3 years. Human papillomavirus (HPV) testing is not indicated as a screening test in women in that age group but should be sent reflexively if atypical cells are detected on the Pap smear of any age group.
- A Pap smear with HPV cotesting is preferable in women between the ages of 30 and 65. If both Pap and HPV tests are negative, cotesting may be repeated every 5 years.
- Those with risk factors such as HIV, immunosuppression, diethylstilbestrol exposure, or a history of dysplasia or cervical cancer may need more frequent Pap smears.
- Women who have had a total hysterectomy for benign cause and with no history of cervical intraepithelial neoplasia (CIN 2; abnormal cells found on the cervix caused by HPV) in the preceding 20 years should not have any further Pap smears.
- Women older than 65 with no history of CIN 2 in the last 20 years and either three consecutive negative Pap smears or two consecutive cotests in the last 10 years with the last one done within 5 years may discontinue Pap smears.

If the Pap smear reveals dysplasia or atypical cells with the presence of HPV, the patient is referred for colposcopy and cervical biopsy. Colposcopy involves swabbing the

cervix with an acetic acid solution or a Lugol's solution and then looking at it with a lighted magnifying device that allows for abnormal areas to be easily identified. Once abnormal tissue is identified, a sample or biopsy of the tissue is obtained for pathology (Fig. 65.10). Cervical biopsy is diagnostic for dysplasia or cancer.

Radiological evaluation is an important step prior to treatment. Magnetic resonance imaging is accepted as the best measurement of tumor volume. Positron emission tomography scanning is helpful in identifying distant metastasis. If cervical cancer is diagnosed, FIGO staging is used but can be somewhat difficult because it may understage the patient. Its value is still under investigation, but tumor stage may be a prognostic indicator along with the patient's age, presence of anemia, and any other patient comorbidities.

### Surgical Treatment

Surgical management is used in the early stages of cervical cancer. Radical trachelectomy (removal of the uterine cervix only) is performed, particularly in women who desire to retain their fertility. In women without a desire for fertility, a radical hysterectomy with lymph node dissection is frequently performed. Those with recurrent cervical cancer are evaluated closely to determine the extent of the disease. If the cancer is truly confined to the pelvis, exenteration or removal of all pelvic organs can be curative. Patients must be thoroughly counseled about the surgery. The mortality rate is around 5%, and the morbidity rate is close to 70%. The patient is ultimately left with a colostomy and urinary diversion.

### Medical Treatment

Medical management in the form of chemoradiation is routine in women with higher-stage disease after radical

surgery. In chemoradiation, chemotherapy is administered at the same time as radiation because it is thought that chemotherapy makes the cancer cells more susceptible or sensitive to radiation. Radiation is generally achieved through localized brachytherapy (internal radiation placed directly into or next to the tumor) but may also be done through generalized pelvic radiation. Chemoradiation may also be used in those women with recurrent cervical cancer if they have not received radiation previously. If the patient has previously been radiated, the only choice of treatment is chemotherapy alone. Five-year survival rates depend on the stage at diagnosis. Those with localized disease have a 92% 5-year survival rate compared with 58% for those with regional disease and 17% for those with distant disease.

### Nursing Management

#### Assessment and Analysis

Cervical cancer usually exhibits no symptoms until it is very advanced; thus, assessment of the cervical cancer patient must focus on prevention, early diagnosis, and treatment. The importance of routine screening cannot be overstated.

#### Nursing Diagnoses

- **Ineffective health maintenance** associated with lack of Pap screening
- **Ineffective coping** associated with the cancer diagnosis
- **Acute pain** associated with the surgical procedure
- **Nausea** associated with chemoradiation administration

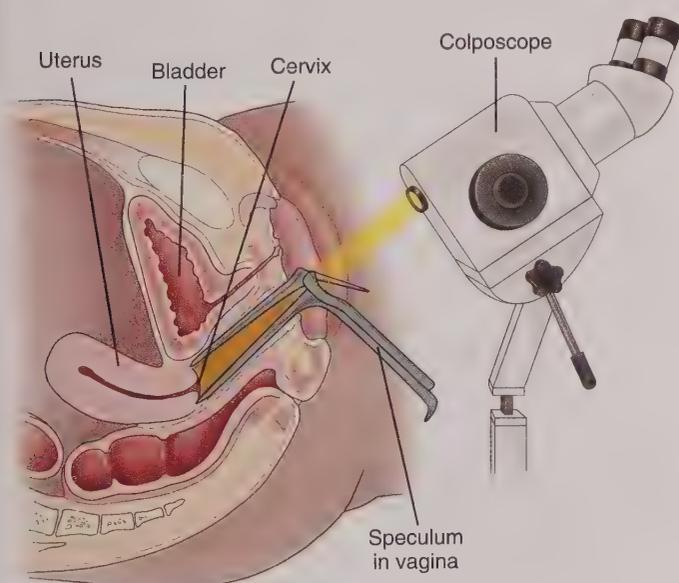

#### Nursing Interventions

##### Assessments

- Vital signs  
*Elevated blood pressure and pulse are symptoms of pain and anxiety.*
- Pap smear results  
*Pap smear is the screening tool to identify cervical cell change associated with dysplasia and cancer.*
- Intake and output  
*Patient intake and output can help reveal nutritional deficits or fluid retention.*
- Daily weights  
*Patient weight is also an indicator of nutritional status and fluid retention. If the patient is suffering nausea and vomiting, weight may be a valuable indicator of nutritional status.*
- Pain scale  
*Patients may use a pain scale to indicate their subjective level of pain and evaluate treatment.*

##### Actions

- Refer for colposcopy/biopsy  
*Abnormal Pap results require further investigation with colposcopy and biopsy.*
- Give pain medications as ordered  
*Patients with good pain relief will heal better and will be more able to participate in activities of daily living.*

**FIGURE 65.10** Colposcopy. The colposcope is inserted through a speculum into the vagina. The cervix is swabbed with an acetic acid solution allowing abnormal tissue to be identified and sampled for biopsy.

- Give antiemetics as ordered  
*A common side effect of surgery and chemoradiation is nausea/vomiting.*
- Give support/offer resources  
*Patients with a cancer diagnosis often have psychological concerns and feel comforted by support. Offer resources for support groups, counselors, or image centers.*

### ■ Teaching

- Educate on the need for routine screening  
*Educate all women to seek routine Pap screening and to follow up on any recommended interventions. Cervical cancer can be successfully treated if found early.*
- Provide information on support groups  
*Patients with a cancer diagnosis often have psychological concerns and may benefit from a support group or counselor.*

### Evaluating Care Outcomes

With screening and early intervention, cervical cancer is an almost completely preventable disease. Women must be properly educated and provided with the resources to seek screening and treatment. Once cancer is diagnosed, a well-managed patient has her pain under control and her nutritional needs maintained throughout surgery and chemoradiation to facilitate healing. Psychological support is vital for the woman enduring cervical cancer.

### Connection Check 65.8

A 25-year-old patient presents to the clinic for her annual gynecological examination. Her last Pap smear was at the age of 21. What should she have today?

- Breast examination, pelvic examination, and Pap smear
- Breast examination, pelvic examination, and Pap smear with HPV cotesting
- Breast examination, pelvic examination, and HPV testing
- Breast and pelvic examinations only

## Making Connections

### CASE STUDY: WRAP-UP

Ms. Sims's imaging suggests a lesion suspicious for malignancy. Biopsy of the mass confirms invasive cancer of the right breast. On the basis of imaging, clinical examination, and biopsy, it is felt to be a stage I breast cancer. Ms. Sims is referred to a breast surgeon, radiation oncologist, and medical oncologist for management and treatment.

Ms. Sims consults with her physicians. Because she is stage I, she is offered breast conservation versus mastectomy. After

careful consideration, she chooses breast conservation. Because her tumor is more than 2 cm, she requires 3 to 6 months of chemotherapy after surgery. Once chemotherapy is complete, she will undergo radiation therapy as recommended for all breast conservation patients. Stains of her tumor also reveal that her tumor is estrogen positive. She will take tamoxifen (Nolvadex) for 5 years. She will require life-long follow-up with mammograms.

### Case Study Questions

- The nurse at the breast center is educating Ms. Sims on her options. She explains that if she chooses breast conservation therapy, her next step in treatment after surgery will be which of the following?
  - Chemotherapy followed by radiation
  - Radiation followed by chemotherapy
  - Chemotherapy and physical therapy
  - Follow-up surgery 6 months later
- The nurse has received a set of orders for Ms. Sims. Which order should the nurse call the provider to verify prior to implementation?
  - Pain medication
  - Oral contraceptives
  - Tamoxifen
  - Stool softener
- The nurse taking care of Ms. Sims in the postoperative area should be most concerned about the surgical wound if the assessment includes which of the following?
  - Bloody drainage saturating the dressing
  - Serosanguineous drainage on the dressing
  - Redness under the surgical tape
  - Tenderness at the incision site
- The nurse in the postoperative area assesses Ms. Sims for pain. The pain assessment should include which of the following? (*Select all that apply.*)
  - Pain scale
  - Heart rate
  - Extremity pulse check
  - Blood pressure
  - Wound drainage
- Ms. Sims has begun radiation treatments. The nurse in the radiation center monitors Ms. Sims for what important side effect?
  - Swelling of the affected arm
  - Opening of the surgical wound
  - Infection of the surgical site
  - Redness, itching, and irritation of the radiated skin

## CHAPTER SUMMARY

With adequate treatment, many women are able to survive breast cancer today. Those with advanced-stage cancer are still able to achieve prolongation of their life while balancing quality of life. Treatment is generally a combination of surgery, chemotherapy, and radiation. The degree of each is determined by the stage of the cancer.

Dysmenorrhea is the most common gynecological complaint for young women and can greatly interfere with their lives each month. Ninety percent of cases of dysmenorrhea have no associated pelvic abnormalities. The majority of cases will easily respond to treatment with NSAIDs, hormonal suppression, or both. Women may also find relief in nonpharmacological approaches as well. After 6 months of failed treatment for dysmenorrhea, laparoscopy should be performed to evaluate for endometriosis.

Endometriosis occurs when endometrial tissue implants outside the uterus. The ovaries are the most common location for the implants, but they may also be found throughout the pelvis and even outside the pelvis. Biopsy through laparoscopy must be done to confirm a suspected diagnosis. Endometriosis is an estrogen-dependent disorder, and therefore treatment stems on control of estrogen levels in the body. First-line treatment is continuous oral contraceptives followed by medications such as GnRH agonists that decrease circulating estrogen. Surgical treatment first attempts to excise or cauterize the endometriosis but ultimately may result in hysterectomy. In the most extreme cases, hysterectomy must be accompanied by oophorectomy to achieve a beneficial result.

Although the actual average age of menopause is 50 to 51, symptoms may begin much earlier and may persist for several years. In a minority of women, symptoms may persist well into their 70s and may be detrimental to overall quality of life. It is important that patients receive care, education, and treatment to make symptoms manageable and controllable. Although HT is the most effective symptom relief medication, its controversial effect on breast cancer and cardiovascular health has led to recommendations that it be used only short term and only in women who are very symptomatic. Those with only vaginal symptoms may use vaginal estrogen therapy, which has little to no systemic

absorption. As women continue to age, the long-term issues of hypoestrogen begin to emerge such as poor bone health.

Patients with asymptomatic fibroids may be monitored and managed expectantly in the low-risk patient. The most common symptoms patients complain of are heavy vaginal bleeding and pelvic pressure. The most common and only definitive treatment to ensure no recurrence is hysterectomy. However, patients who desire to maintain fertility and preserve their uterus may opt for a procedure that just removes the fibroid, myomectomy.

Patients with ovarian cancer are frequently in the advanced stages by the time they are diagnosed. The prognosis is generally poor. Early detection is key in better outcomes for these patients. Unfortunately, no screening test currently exists for the general population. Women must be aware of the vague symptoms of ovarian cancer which include pelvic or abdominal pain, difficulty with urination, and difficulty eating and report them immediately to their provider. Providers must thoroughly investigate these complaints before deciding that they are attributable to other benign causes. If ovarian cancer is suspected and confirmed, the patient will undergo surgery and chemotherapy.

Uterine or endometrial cancers are the most common of all the gynecological cancers. The majority of endometrial cancer is diagnosed in the early stage and frequently is cured with surgery alone. Most patients present with vaginal bleeding that should be evaluated with pelvic ultrasound and endometrial biopsy. Once a diagnosis is made, FIGO recommends surgical removal of the uterus, ovaries, and fallopian tubes in addition to pelvic washings and lymphadenectomy. If the patient has a higher-risk or higher-stage malignancy, she will undergo both chemotherapy and radiation. Higher-risk and higher-stage cancers carry a poorer prognosis, whereas metastatic and recurrent cancers are considered noncurable, with an average of 1-year survival.

Cervical cancer is the 13th most common cancer in women in the United States. There are no recognizable symptoms, but vaginal bleeding is the most common complaint. Almost all cervical cancers are preventable with adequate routine Pap smear and HPV screening and early intervention if diagnosed. Treatment consists of surgical excision and, in advanced stages, chemoradiation.

# Chapter 66

## Coordinating Care for Male Patients With Reproductive and Breast Disorders

*Shari Lynn*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of male reproductive disorders
2. Correlating clinical manifestations to pathophysiological processes of:
  - a. Benign prostatic hyperplasia
  - b. Erectile dysfunction
  - c. Prostate cancer
  - d. Testicular cancer
  - e. Breast cancer
  - f. Testicular trauma
3. Describing the diagnostic results used to confirm the diagnosis of male reproductive disorders
4. Discussing the medical management of:
  - a. Benign prostatic hyperplasia
  - b. Erectile dysfunction
  - c. Prostate cancer
  - d. Testicular cancer
  - e. Breast cancer
  - f. Testicular trauma
5. Developing a comprehensive plan of nursing care for patients with male reproductive disorders
6. Designing a teaching plan that includes pharmacological, dietary, and lifestyle considerations for patients with male reproductive disorders

### CONCEPTS

- Assessment
- Cellular Regulation
- Male Reproduction
- Medication
- Perioperative
- Trauma
- Urinary Elimination

### ESSENTIAL TERMS

Benign prostatic hyperplasia (BPH)  
Bladder outlet obstruction (BOO)  
Brachytherapy  
Breast cancer type 1 susceptibility protein (BRCA1)  
Breast cancer type 2 susceptibility protein (BRCA2)  
Digital rectal examination (DRE)  
Ductal carcinoma in situ (DCIS)  
Erectile dysfunction (ED)  
Human epidermal growth factor receptor 2 (HER2)  
Lower urinary tract symptoms (LUTS)  
Medicated urethral system for erection (MUSE)  
Nocturia  
Paget's disease  
Phosphodiesterase type 5 (PDE-5) inhibitors  
Prostate-specific antigen (PSA)  
Transurethral incision of the prostate (TUIP or TIP)  
Transurethral microwave therapy (TUMT)  
Transurethral needle ablation (TUNA)  
Transurethral resection of the prostate (TURP)  
Watchful waiting

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Scott Andrews is a 65-year-old male patient who presents to his healthcare provider with a complaint of difficulty urinating. He complains of pain with urination and occasional blood-tinged urine. He states that he has an increased urgency to urinate and wakes up three to four times during the night to urinate. He also complains of occasional incontinence...

of BPH include an accumulation of the male hormone dihydrotestosterone (DHT) and a high intake of calories, protein, calcium, and polyunsaturated fats. When this gland does become enlarged, it pinches the urethra, interfering with the flow of urine from the bladder (Fig. 66.1).

### Connection Check 66.1

Which of the following is true of BPH?

- A. It is a form of metastatic cancer.
- B. Benign prostatic hyperplasia is not a form of cancer.
- C. Males as young as 25 years old are equally at risk.
- D. Benign prostatic hyperplasia is a precursor to testicular cancer.

## BENIGN PROSTATIC HYPERPLASIA

### Epidemiology

**Benign prostatic hyperplasia (BPH)**, an enlarged prostate, is noted in about 50% of men 51 to 60 years of age and 90% of men over the age of 80. It equally affects men of all races. BPH is not a form of cancer. A patient can have BPH and prostate cancer simultaneously or independently of each other.

### Pathophysiology

The prostate gland is a normal part of the male anatomy. It is about the size of a walnut and surrounds the urethra. Its primary function is to assist in controlling urine flow. It also mixes sperm with prostatic fluid and seminal fluid to be ejaculated during orgasm. Around the age of 25, the prostate begins to grow. This growth is not completely understood. One theory related to enlargement of the prostate is a change in the balance between estrogen, which is present in small amounts in males, and testosterone. Other theories implicated in the development

### Clinical Manifestations

The clinical manifestations of BPH are related to **lower urinary tract symptoms (LUTS)**. Those manifestations include difficulty starting the flow of urine even with straining, a weak stream of urine, multiple interruptions during urination, and dribbling once urination is complete. Symptoms related to changes in the bladder include urgency, frequency, the feeling that the bladder has not completely emptied after urination, and frequent awakening at night to urinate. As the bladder becomes more sensitive to the retention of urine, incontinence may result. The patient may experience bed-wetting and the inability to respond quickly enough to the need to urinate. A urethral obstruction or enlarged prostate that is left untreated may result in **bladder outlet obstruction (BOO)**, which includes acute urinary retention (AUR), bladder infection, bladder stones, and increasing pressure in the kidney, possibly resulting in hydronephrosis or postrenal acute kidney (AKI) injury or pyelonephritis (Table 66.1).

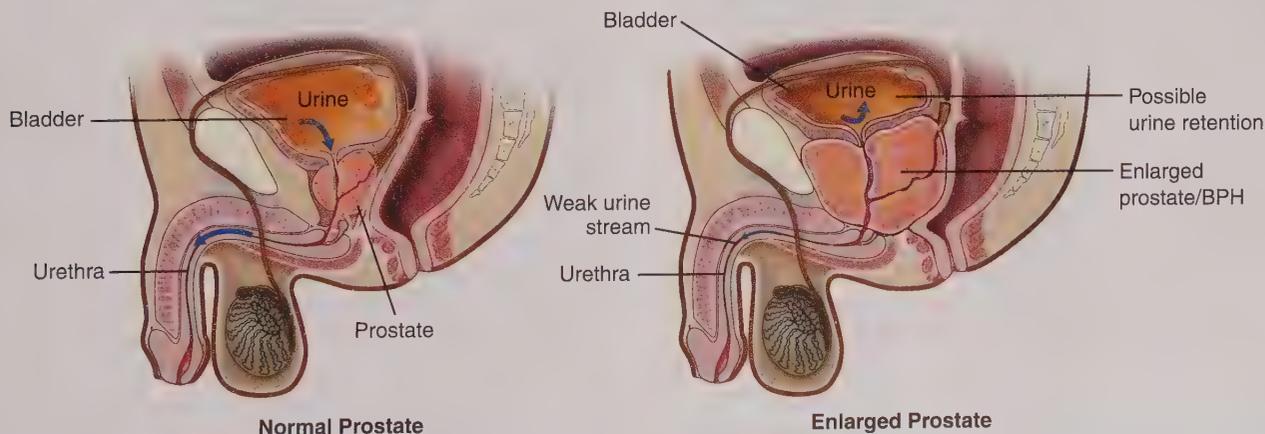

FIGURE 66.1 Normal and enlarged prostate.

**Table 66.1 Complications of Benign Prostatic Hyperplasia**

Clinical Manifestation/ Complication	Cause
<b>Acute urinary retention</b>	Blockage of urethra by enlarged prostate, obstructing urine flow
<b>Urinary tract infection (UTI)</b>	Secondary to urinary stasis
<b>Bladder stones</b>	Crystallization of mineral deposits in concentrated urine due to obstructed urine flow
<b>Bladder damage</b>	Stretching and weakening of the bladder wall muscles from incomplete emptying, resulting in the bladder no longer contracting properly
<b>Kidney damage</b>	Increased pressure in the kidney secondary to urinary retention and backflow of urine, causing hydronephrosis (swelling of urine-collecting structures in the kidney) and postrenal AKI  Pyelonephritis—UTI migrating from the bladder to the kidney

AKI, Acute kidney injury.

## Management

### Medical Management

#### Diagnosis

Diagnosis is made on the basis of the symptoms. It is confirmed with a **digital rectal examination (DRE)**. The enlarged prostate can be palpated on examination. A urinalysis is done to rule out the presence of an infection causing symptoms. In addition, the **prostate-specific antigen (PSA)** level is checked. This is a protein produced by the prostate gland and may be considered a tumor marker. An elevated PSA may be indicative of prostate cancer. However, raised PSA levels may also be due to infection, so it is important to note that PSA levels do not distinguish between cancer and BPH.

#### Treatment

The least invasive treatment for BPH is “**watchful waiting**,” or “active surveillance.” This approach is used in patients who have minimal symptoms and minimal enlargement of the prostate. Patients who opt for this treatment plan receive yearly provider examinations with evaluation using a DRE. It is advised during this watchful waiting or active surveillance period that the patient avoid tranquilizers and over-the-counter medications that contain decongestants because these medications can worsen obstructive symptoms. In addition, patients should avoid excess fluids in the

evening to decrease the chances of **nocturia** (waking up to void).

### Connection Check 66.2

The nurse realizes that which clinical manifestation is an expected finding of BPH?

- A. Increased urinary output
- B. Swelling of the penis and scrotum
- C. Frequent nocturia
- D. Tea-colored urine

### Medications

Pharmacological management may also be a treatment option for BPH. Many types of medications are currently being used to treat BPH. The two major classes of drugs are 5-alpha reductase inhibitors and alpha-adrenergic blockers. It is not possible to predict which medication will work best for any particular patient; however, these medications appear to improve symptoms in 35% to 40% of men taking them. Alpha blockers act on the alpha receptors in the prostate, causing the smooth muscles of the prostate to relax. Relaxation of these muscles decreases the constriction of the urethra. It may take 2 weeks to 4 months to notice symptom improvement. The patient needs to be aware of adverse effects, such as headache, nasal congestion, dizziness, drowsiness, postural hypotension, reflex tachycardia, and retrograde or delayed ejaculation.

The other class of medications is the 5-alpha reductase inhibitors, which act as antiandrogens. Testosterone affects prostate growth and development. 5-Alpha-reductase converts testosterone into DHT. Dihydrotestosterone stimulates the growth factors that encourage prostate hyperplasia while concurrently reducing the rate of cell death in the prostate. This imbalance results in enlargement of the prostate. The 5-alpha-reductase inhibitors prevent testosterone from being converted to DHT, which causes enlarged tissues to shrink, thus reducing obstruction of the urethra. Fortunately, this medication does not affect levels of circulating testosterone, which reduces the chance of **erectile dysfunction (ED)**, the inability to achieve or maintain an erection sufficient for sexual intercourse. It can take 3 to 6 months for these medications to take effect. It is reported that the use of these medications reduces AUR by 57% to 59% and reduces the need for surgical intervention by 36% to 55%. In addition, it has been reported that some men may experience a reduction in male-pattern baldness. Possible adverse effects include rash, breast enlargement, breast tenderness, reduced volume of ejaculate, decreased libido, and ED. Some men experience better results with the combination of the alpha blockers and the 5-alpha-reductase inhibitors. The combination has been shown to delay clinical progression by as much as 67%.

If the patient with BPH has an overactive bladder, an anticholinergic to relax bladder smooth muscle, such as oxybutynin, may be added.

### Alternative Therapies

If medication is not an effective treatment and the patient is not a surgical candidate, then obstruction of the urethra secondary to prostate enlargement and incontinence can be managed through intermittent catheterization of the bladder or the use of an indwelling catheter. The indwelling catheter can stay in place and be changed monthly or per protocol.

Other alternative therapies that have been used in treating BPH include saw palmetto (*Serenoa repens*), African plum (*Pygeum africanum*), Cernilton, and South African star grass (*Hypoxis rooperi* and some species of *Pinus* and *Picea*). Saw palmetto is reported to be used by approximately 2 million men in the United States. The long-term effects and safety of this herbal remedy are unclear. Some studies have shown that there were mild to moderate reductions in urinary symptoms. African plum has not been compared to pharmaceutical therapy but has been shown to reduce symptoms of BPH in comparison to placebo. South African star grass has been shown to improve urinary symptoms of BPH due to beta-sitosterols, substances that may bind to the prostate to reduce inflammation. The effectiveness and safety have not been studied over the long term. Cernilton (from ryegrass pollen, *Secale cereale*) has been shown to reduce urological symptoms; however, long-term effects have not been studied.

### Surgical Management

#### Transurethral Resection of the Prostate

If pharmacological treatment is not effective and the patient is a surgical candidate, there are other possible interventions. One of these is a **transurethral resection of the prostate (TURP)** (Fig. 66.2). This has been the most common surgery for BPH for many years and is usually used to treat smaller prostates. In this procedure, a lighted scope known as a resectoscope is passed into the urethra. A small

cutting tool is used to remove the entire inner prostate, leaving the outer layer. Symptoms are usually relieved quickly, resulting in a stronger flow of urine. A catheter may remain in place after surgery for 3 to 5 days to drain the bladder. Recovery from the TURP may include a risk of bleeding and infection. The patient is permitted only light activity immediately postoperatively.

#### Transurethral Incision of the Prostate

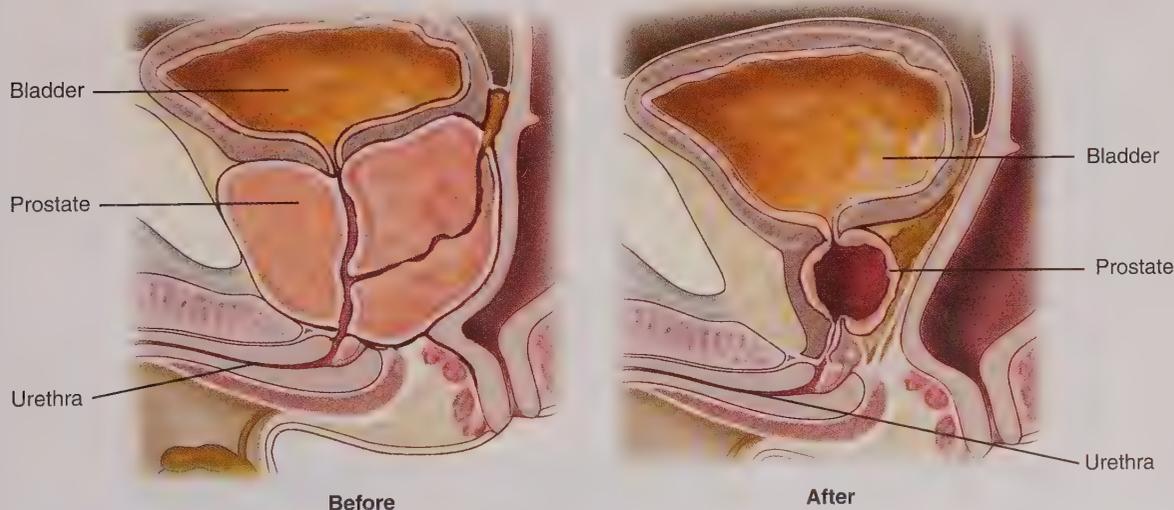

Another procedure is the **transurethral incision of the prostate (TUIP or TIP)**. This procedure is used for the patient with a small to moderately enlarged prostate. During the TUIP/TIP, instruments are inserted through the urethra as in the TURP, but the prostate is not removed. The surgeon makes two small incisions into the prostate, which relieves compression of the urethra and opens up the channel. The result is an easier passage of urine.

#### Open Prostatectomy

For the patient with a very large prostate who is experiencing complications such as bladder stones or bladder damage, the surgeon may perform an open prostatectomy. This procedure is performed approximately 200,000 times a year in the United States. During this procedure, an incision is made in the patient's lower abdomen to access and remove the prostate gland. This procedure carries a higher risk of complications such as incontinence, impotence, and retrograde ejaculation (ejaculation that does not result in semen exiting the body but reverses and deposits it in the bladder).

#### Laser Surgery

Another option is laser surgery for men with a smaller or moderately large prostate gland. This therapy uses high-energy lasers to annihilate and/or remove overgrown prostate tissue. Several laser procedures include ablation procedures that burn away prostate tissue and enucleation procedures that remove the prostate tissue that is restricting

**FIGURE 66.2** Changes in the prostate gland after a transurethral resection of the prostate (TURP). The entire inner prostate is removed, leaving just the outer layer, easing the flow of urine.

the flow of urine and prevent tissue regrowth. Laser surgery usually results in immediate symptom relief and has a lower risk of adverse effects than the TURP procedure. This may be used for men who are taking anticoagulants because there is usually less bleeding.

### Transurethral Microwave Therapy

A **transurethral microwave therapy (TUMT)** is a minimally invasive procedure in which an electrode is passed through the urethra into the area of the prostate. The electrode produces microwave energy that heats the inner portion of the prostate, destroying the tissue and causing the gland to shrink. Ease of urine flow is restored. Irritating adverse effects may last for weeks so symptom relief may take some time to occur. This procedure is usually reserved for small prostates.

### Transurethral Needle Ablation

**Transurethral needle ablation (TUNA)** is an outpatient procedure. A lighted cystoscope is passed through the urethra allowing visualization to place needles into the prostate. Once the needles are in place, radio waves pass through the needles to heat and destroy the prostate tissue that is constricting the urethra. This procedure results in scarring of the prostate tissue, causing it to shrink and open. Men who receive this procedure may not notice symptom relief immediately. It is a good choice if there is a concern about excess bleeding.

### Prostatic Stents

Prostatic stents may also be used. These stents are placed in the urethra to keep it open. Tissue growth on the metallic stent anchors it in place. If a plastic stent is used, it needs to be changed every 4 to 6 weeks. Stents are not usually considered a long-term treatment because of potential adverse effects of pain upon urination and urinary tract infections (UTIs). This is usually only an option for men who cannot take medication and are not surgical candidates.

## Water-Induced Thermotherapy and Transurethral Ethanol Ablation

Two of the more recent procedures are water-induced thermotherapy and transurethral ethanol ablation of the prostate. Water-induced thermotherapy is a 45-minute procedure done using topical anesthesia. Hot water is used to cause coagulation necrosis of the prostate tissue that is compressing the urethra. Transurethral ethanol ablation of the prostate involves the injection of ethanol into arterioles and venules. The ethanol creates a necrotic area secondary to thrombotic occlusion. This necrosis stops the hyperplastic overgrowth of prostatic tissue. Additional evaluation is needed for these two procedures. See Figure 66.3 for a flowchart of treatment options.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of BPH are caused by the obstruction of urine flow due to an enlarged prostate. They include difficulty starting the flow of urine, a weak urine stream, multiple interruptions during urination, and dribbling once urination is complete. Other symptoms include urgency, frequency, the feeling that the bladder has not completely emptied after urination, and nocturia.

#### Nursing Diagnoses

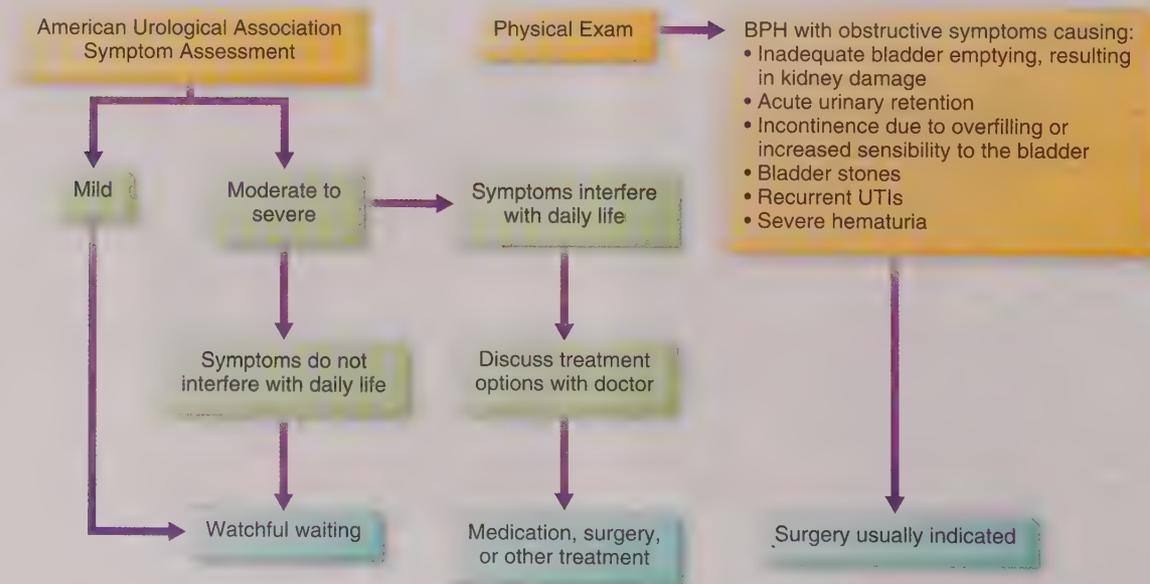

- **Disturbed sleep pattern** related to nocturia
- **Risk for infection** related to urinary stasis

#### Nursing Interventions

##### ■ Assessments

- Urinary symptoms

*Subjective data from the patient regarding the extent of urinary symptoms assist in diagnosis and aid in determining treatment options. Mild symptoms that do not interfere with*

**FIGURE 66.3** Treatment options for benign prostatic hyperplasia.

activities of daily living may require only watchful waiting. More severe symptoms that interfere with activities of daily living, such as nocturia and an inability to empty the bladder, may require more aggressive treatment.

- **Temperature**

*An increase in temperature may indicate a UTI secondary to urinary stasis.*

- **Focused abdominal examination**

*A distended abdomen may signify bladder distention, thus indicating the patient's inability to empty the bladder and risk for a UTI.*

- **Bladder scan**

*Use of a bladder scanner to check postvoid residual (PVR) to determine the ability of the patient to empty his bladder and discovering any urinary stasis that may lead to infection*

- **Urinalysis**

*The results will determine a possible infection from urinary stasis or related LUTS.*

### ■ **Actions**

- **Catheterization**

*To check for PVR and to relieve distended bladder, decreasing the risk of bladder damage*

- **Administer medication therapy: 5-alpha-reductase inhibitors and/or alpha-adrenergic blockers as ordered.**

*5-Alpha-reductase inhibitors limit the production of DHT, a substance that encourages prostate hyperplasia. Alpha-adrenergic blockers relax the smooth muscle of the prostate.*

### ■ **Teaching**

- **Watchful waiting**

*Explanation of the term "watchful waiting," including recognition of worsening symptoms, and when to seek further treatment help alleviate anxiety and ensure that the patient seeks treatment when necessary.*

- **Decrease liquid intake in the evening.**

*Decreased fluid intake in the evening may decrease nocturia.*

- **Medication therapy education**

*Understanding the possible adverse effects of medications and contraindications with other medications and food assists the patient in making choices about what medication therapy is best.*

- **Follow-up**

*Stressing the importance of follow-up with the provider results in better care of the patient as well as more prompt recognition of worsening symptoms and the need for possible further intervention.*

- **Information regarding surgical options**

*Printed information given to the patient allows the patient to make better-informed choices should surgery become a necessity.*

- **Care of surgical/invasive treatment sites**

*Care of any surgical sites using aseptic technique decreases the risk of infection and assists in healing.*

## Connection Check 66.3

A patient's orders include the placement of a catheter as a temporary treatment of his BPH. The nurse understands that rationales for this intervention is which of the following? (Select all that apply.)

- A. Exact monitoring of intake and output
- B. Retrieving a sterile sample for urinalysis
- C. To evaluate PVR volume
- D. To facilitate complete emptying of the bladder
- E. To avoid unnecessary surgical procedures

## Evaluating Care Outcomes

Patients with BPH are usually managed with watchful waiting and medication therapy. A well-managed patient understands the importance of compliance with the medication regimen, limiting fluid intake at night, and following up with the provider if symptoms worsen. This patient has less urinary retention, a strong urine stream, and decreased nocturia. With the proper interventions and education, the patient can live a normal life with BPH.

## ERECTILE DYSFUNCTION

### Epidemiology

According to the National Institutes of Health, there are an estimated 30,000,000 men in the United States who suffer from chronic erectile dysfunction. The incidence increases with age, affecting 61% of males 40 to 69 years of age and 77% of males over the age of 70. Erectile Dysfunction is projected to affect 32,000,000 males throughout the world by the year 2025. The most common causes of ED include cardiovascular disease, smoking, obesity, stroke, spinal cord injury, diseases of the neurological system, diabetes, liver disease, kidney disease, low levels of testosterone, prostate and/or rectal surgery, Peyronie's disease (curvature of the penis occurring during erection secondary to scar tissue), adverse effects of medication, and psychological issues. Substance abuse disorder is implicated in problems of ED in up to 25% of cases.

### Pathophysiology and Clinical Manifestations

Erectile dysfunction is the inability to achieve or maintain an erection sufficient for sexual intercourse. An erection occurs when the penis fills with blood, making it firm enough to penetrate the vagina. A normal erection typically occurs in response to sexual stimulation. There is an inhibition of the sympathetic nervous system and an activation of the parasympathetic nervous systems (PNS). In response to stimulation of the PNS, nitric oxide is released from the endothelial lining in the cavernosum blood vessels in the penis forming cyclic guanosine monophosphate (cGMP). This causes smooth muscle relaxation, allowing the arterial blood to rush into the corpus cavernosum, which compresses venous return, causing the penis to become tumescent or engorged with blood. In the older male, any number

of these actions may be compromised due to decreased perfusion of the penis, atherosclerosis of the arteries, decreased endothelial function, decreased production of nitric oxide and decreased androgen production.

### Connection Check 66.4

A patient is complaining of an inability to achieve an erection. The nurse realizes this may be related to a personal medical history of which condition?

- A. Crohn's disease
- B. Hepatitis C
- C. Migraines
- D. Diabetes

## Management

### Medical Management

#### Diagnosis

Diagnosis is made on the basis of patient complaint. A careful assessment may reveal causative factors, such as diabetes, cardiovascular disease, or low levels of testosterone. Erectile dysfunction is managed according to the cause of the problem.

#### Medications

Medication therapy is one of the first forms of medical management of ED. Medications include **phosphodiesterase type 5 (PDE-5) inhibitors** such as sildenafil (Viagra), vardenafil (Levitra), avanafil (Stendra) and tadalafil (Cialis). The PDE-5s inhibit the breakdown of the cGMP, the substance that causes smooth muscle relaxation, vasodilation, and increased blood flow that leads to an erection. This allows for an erection to develop. These medications do not have an effect on how long the erection lasts or the size of the erection. They do not work in the absence of sexual stimulation. These medications are not recommended in the patient who is taking nitrates for other cardiac issues or alpha blockers for BPH because these medications together can cause sudden hypotension. Some other adverse effects of these medications can include headache, facial flushing, effects in color vision, and nasal congestion. The medication chosen to treat an individual is related to the patient's sexual activity and personal choice. These medications come in pill form and are convenient to use.

Another treatment option is alprostadil pellets, known as **medicated urethral system for erection (MUSE)**. The pellets are placed in the urethra with the use of an applicator. Once the pellet is in place, the patient massages the penis for approximately 10 minutes, allowing the medication to coat the urethra and promote absorption. Alprostadil is a prostaglandin  $E_1$ , which causes increased blood flow to the penis through vasodilation. The male is encouraged to urinate before application of the pellet because this improves the action of the medication. Adverse effects include a burning sensation in the urethra and a risk for

hypotension. Effects of this medication on the fetus are not clear, so the patient must be counseled to use a barrier method of contraception so as not to risk pregnancy in his partner.

Another treatment for ED is intracavernosal injection, which requires the male to deliver the medication via injection directly into the corpus cavernosa of the penis. After injection of this medication, the male attains an erection in 5 to 20 minutes, which lasts 30 to 60 minutes. There is the rare chance of priapism, which is an erection lasting more than 3 hours. The challenge with this medication is the ability of the man to self-inject. An adverse effect related specifically to this form of medication is penile scarring from repeated injections. In addition, this medication is contraindicated in men who are taking anticoagulants because of the increased risk of bleeding. Also, because the man has now created an opening in the penis at the injection site, there is an increased risk of contracting a sexually transmitted infection or a blood-borne infection.

Another treatment option is a vacuum device. This option involves a cylinder placed over the penis using subatmospheric pressure to draw the penis into the tube, creating an erection. A constriction band is then put in place to keep the blood in the penis. It should be noted that the temperature of the penis will be cooler. Although some men may find it cumbersome to have to work the device, it does not have the adverse effects of medications.

### Surgical Management

If medication therapy or the vacuum device is not successful, there is the option of surgery to place an implant or penile prosthesis. An inflatable tube is placed in the penis with the inflation bulb in the scrotum. The male compresses the bulb to inflate the tube, creating an erection. There is a 90% success rate with the implant.

**Safety Alert** An erection lasting more than 3 hours, priapism is a rare occurrence with oral medication as well as intracavernosal injection but can occur with any of these treatment options. Priapism is a medical emergency, requiring immediate treatment by a physician or in the emergency department so as not to risk permanent impotence.

### Psychosocial Management

In addition to all methods, there is also psychosexual counseling for possible psychogenic issues that may be affecting the ability of the man to achieve an erection. Even if the reason for ED is organic, there is still a psychological aspect. Regardless of the intervention, men may still have anxiety regarding the success of the intervention, anxiety related to performance, and anxiety related to the response of their partners.

## Nursing Management

### Assessment and Analysis

Erectile dysfunction can present when there is neurological or vascular damage interfering with the coordination of the brain, nervous system, and hormonal activity required to cause the blood vessels in the penis to become engorged, causing an erection and allowing vaginal penetration.

### Nursing Diagnoses

- **Ineffective sexual patterns** related to altered body function or structure/surgical procedure
- **Risk for situational low self-esteem**

### Nursing Interventions

#### ■ Assessments

- Health history  
*Cardiovascular disease, diabetes, low testosterone levels, and trauma are health problems that may lead to ED.*
- Emotional state, performance anxiety  
*Unstable emotions, embarrassment, or performance anxiety may increase the problem of or be a causative factor of ED.*

#### ■ Actions

- Administer medications as ordered—PDE-5 inhibitors.  
*The PDE-5s inhibit the breakdown of cGMP, a substance leading to smooth muscle relaxation, vasodilation, and increased blood flow essential for the development of an erection.*
- Emotional support  
*Creating a nonjudgmental, relaxed atmosphere reduces patient anxiety and creates a relationship of trust.*

#### ■ Teaching

- Education regarding contributing factors  
*Teaching patients that smoking and obesity can contribute to ED may give the patient an incentive to stop smoking and/or control his diet.*
- Medications—PDE-5 inhibitors, alprostadil (pellets)  
*Do not take ED medications with nitrates because of the potential for a sudden drop in blood pressure. Recognize the risk of priapism and the need to treat it as a medical emergency to avoid permanent impotence.*
- Medications—intracavernosal injections  
*Ensure the patient understands the increased risk of infection and priapism.*
- Education regarding other options to treat ED  
*Patients should make the decision as to what option best meets their needs. They then need careful instruction on the use of a penile pellet implantation, a penile injection, or a vacuum device. This should be done in a compassionate and nonjudgmental way to help overcome fear and possible embarrassment.*

### Evaluating Care Outcomes

Patients with ED are often embarrassed regarding discussion of the subject. It is important to create an atmosphere that is professional and nonjudgmental, allowing the patient to feel comfortable discussing his concerns. A well-managed

patient is educated regarding treatment options and associated contraindications such as the concurrent use of alpha blockers and nitrates due to the dangers of sudden hypotension. Appropriate and educated use of medications or other modalities may allow normal, healthy sexual functioning.

### Connection Check 66.5

A patient is experiencing ED. He has a history of angina treated with nitroglycerin when necessary. His understanding of his possible medical treatment is indicated by which statement?

- “I guess I’m not bad enough yet to need Viagra.”
- “I understand Viagra can make my blood pressure higher.”
- “Can Viagra increase my chest pain?”
- “So I guess Viagra is out of the question because it might drop my blood pressure.”

## PROSTATE CANCER

### Epidemiology

Prostate cancer is globally one of the most commonly diagnosed cancers in men. Of males diagnosed with prostate cancer, 81% have localized prostate cancer, with a smaller percentage having regional or metastasized cancer. The 5-year survival rate for men who are diagnosed with local prostate cancer is 100% as opposed to 28.7% for those found to have distant metastatic cancer. African American males have a greater incidence of prostate cancer and have a greater chance of dying from the disease than Caucasian men. The lowest rates are found in American Indian and Alaska Native males. Most males diagnosed with prostate cancer are over 65 years of age; however, there has been an increase in the number of men under the age of 55 years.

Although the absolute cause of prostate cancer is not known, studies have related diagnosis to genetic and environmental factors. Risk factors include family history. Other risk factors are believed to be diets high in red meat and consumption of calcium as well as a high body mass index (BMI). There is evidence to show that a diet that consists of vegetables, vitamin E, lycopene, selenium, and antioxidants may play a protective role against the development of prostate cancer.

### Pathophysiology

Prostate cancer is a slow-growing cancer (Fig. 66.4). Tumors that develop in the prostate tend to develop on the periphery of the gland, which does not obstruct the flow of urine; hence, they go unnoticed until there is associated pain. Prostate cancer most commonly can metastasize to the lymph nodes, bone, rectum, and bladder. It may be curable when localized but responds to treatment even when widespread. In cases where the cancer has metastasized to the bone, patients may still experience an extended survival rate.

**FIGURE 66.4** Appearance of the normal prostate compared with prostate cancer.

## Clinical Manifestations

In the early stages, prostate cancer may not cause any signs or symptoms, but as it advances, symptoms may develop. They may vary on the basis of local or invasive disease. Infrequently, symptoms similar to the symptoms of BPH may develop, such as trouble urinating or a weak stream of urine. Table 66.2 lists the clinical manifestations of prostate cancer.

## Management

### Medical Management

#### Diagnosis

Diagnosis of prostate cancer is controversial. The American Cancer Society recommends that men have digital rectal examinations (DREs) beginning at the age of 50 on an

annual basis. The recommendation changes to age 45 for African American men and/or those with a family history of prostate cancer. Additionally, the prostate-specific antigen (PSA) test has been the gold standard for the detection of early prostate cancer for years. Prostate-specific antigen is a protein produced by the prostate gland and may be considered a tumor marker. Commonly, men were advised to get the PSA test on an annual basis. The critical cutoff point for PSA screening is 4 ng/mL; however, some studies suggest that this is too high. A man with a PSA of 4 to 10 ng/mL has a 20% to 25% chance of being diagnosed with prostate cancer. Men with a reading greater than 10 ng/mL increase their chances to approximately 60%. Levels of PSA are also affected by age. A PSA of 5 ng/mL may be considered a normal reading for a man who is 73 years old; however, a reading of 3.9 ng/mL may indicate a red flag in a man who is 50 years old. Because of these differing predictive values, this practice is now being questioned. Annual testing is resulting in overdiagnosis and overtreatment of prostate cancer as well as underdiagnosis. There have been many instances of men with elevated PSA levels who do not have cancer as well as those with normal readings who do have cancer. Some providers now look at serial PSAs from month to month as opposed to just one reading.

Guidelines for prostate cancer screening have been updated to include “informed decision making” (Box 66.1) before taking a routine screening test. Men who are of average risk for prostate cancer are advised to begin discussing prostate cancer with their healthcare provider by the age of 50 or by the age of 40 to 45 if they are African American or have a family history. For men who decide to go forward with screening, recommendations include a PSA with or without a DRE. A DRE may be suggested if PSA results are borderline. If the PSA is 4.0 ng/mL or greater, this should be followed by further evaluation. A PSA between 2.5 and 4.0 ng/mL should result in an individualized risk assessment, which includes race, family history, results of previous biopsies, and a DRE. For those men who have a PSA less than 2.5 ng/mL, the recommendation is continued testing every other year. Although these guidelines exist, it is important

**Table 66.2 Presenting Symptoms of Localized Prostate Cancer**

Local Disease	Locally Invasive Disease
● Asymptomatic	● Hematuria
● Elevated PSA	● Dysuria
● Weak urinary stream	● Perineal and suprapubic pain
● Hesitancy	● Erectile dysfunction
● Sensation of incomplete emptying of the bladder	● Incontinence
● Frequency	● Loin pain or anuria resulting from obstruction of the ureters
● Urgency	● Symptoms of renal failure
● Urge incontinence	● Hemospermia (blood in the semen)
● Urinary tract infection	● Rectal symptoms, including tenesmus (rectal pain or cramping, a sensation of incomplete defecation)

PSA, Prostate-specific antigen.

## Box 66.1 Important Discussion Points Regarding the Decision-Making Process of Prostate Screening and Treatment

- There is conflicting evidence that screening may reduce the risk of death.
- PSA and DRE can give a false-positive or a false-negative result.
- If prostate cancer is present, the PSA will detect it earlier than no screening at all.
- Abnormal screening results may result in biopsies, which are painful and can cause complications such as bleeding or infection.
- The treatment of prostate cancer can lead to complications such as erectile dysfunction, incontinence, and bowel problems, to name a few.
- Immediate treatment of prostate cancer is not always necessary.

DRE, Digital rectal examination; PSA, prostate-specific antigen

to note that there is no absolute value below which a man can be assured he does not have prostate cancer.

If abnormalities are found on the DRE and PSA, the next step is a prostatic biopsy. This involves taking a small tissue sample via needle from the prostate for analysis. This can be done in a provider's office with local anesthetic. If found to be positive, the tissue is staged using various scoring systems and staging methods. One of the scoring systems is the Gleason scoring system (Fig. 66.5). This system differentiates the diagnosis of prostate cancer into five different grades. In grade 1, the tissue is well differentiated and most likely results in the best prognosis. This patient has the greatest chance of a cure. A grade 5 classification is a poorly differentiated cancer with a poor prognosis. Tissue samples from two different sites are graded separately, and both scores are added together. The highest score possible on the Gleason scale is a 10 if each of the two sites tested is graded as a 5. An alternative scoring system

is the tumor, nodes, metastasis (TNM) classification used with other cancers. The score is based on T—the size and location of the tumor, N—spread to lymph nodes, and M—presence of metastasis (Table 66.3; Fig. 66.6).

### Connection Check 66.6

A patient does not understand how he can be diagnosed with late-stage prostate cancer because he has never had any difficulty urinating. What is the appropriate answer the nurse may provide?

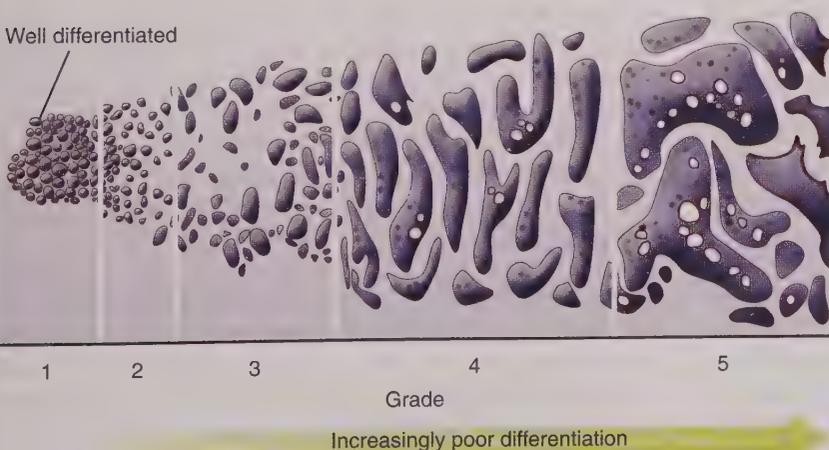

- Tumors of the prostate often develop near the edges of the prostate, so they do not interfere with urination.
- The tumor has already metastasized away from the urethra, so it does not interfere with urination.
- There is interference with urination only when there is an underlying urethral stricture.
- Tumors of the prostate do not interfere with urination in the early stages of the disease.

### Treatment

Treatment options for prostate cancer include radiation, cryotherapy, ablative hormone therapy, chemotherapy, and surgery.

#### Radiation

Radiation may be a nonsurgical option for those patients who would like to avoid surgery. Radiation may also be used after surgery if there is evidence that the cancer has metastasized. The two options for radiation treatment include the use of external-beam radiation that is aimed at the tumor or the surgical implantation of small radioactive pellets into the prostate called brachytherapy. The external-beam radiation involves high-energy radiation that precisely targets the prostate tumor. This can also include the associated lymph nodes. This therapy is time-consuming because treatments are repeated at least five times a week for 8 weeks. External-beam radiation therapy can also be delivered using the CyberKnife technology. CyberKnife is a robotic assisted

**FIGURE 66.5** Cell type appearance and grading with the Gleason scoring system. Scoring ranges from grade 1, where the tissue is well differentiated, to grade 5, reflecting poorly differentiated cancer and a poorer prognosis.

**Table 66.3 Stages of Prostate Cancer Using TNM Classification**

TNM Classification	Definition
<b>T1</b>	Incidental (impalpable and not detected by ultrasonography)
<b>T2</b>	Locally confined to the prostate
<b>T3</b>	Locally extensive
<b>T4</b>	Fixation onto or invasion of neighboring organs
<b>N0</b>	No regional lymph node metastasis
<b>N1</b>	Metastasis in single regional lymph node less than 2 cm in largest dimension
<b>N2</b>	Metastasis in single regional lymph node greater than 2 cm but less than 5 cm in largest dimension
<b>N3</b>	Metastasis in regional lymph node greater than 5 cm in largest dimension
<b>M0</b>	No distant metastasis
<b>M1</b>	Distant metastasis
<b>M1a</b>	Metastasis in nonregional lymph nodes
<b>M1b</b>	Metastasis in bone
<b>M1c</b>	Metastasis in other sites

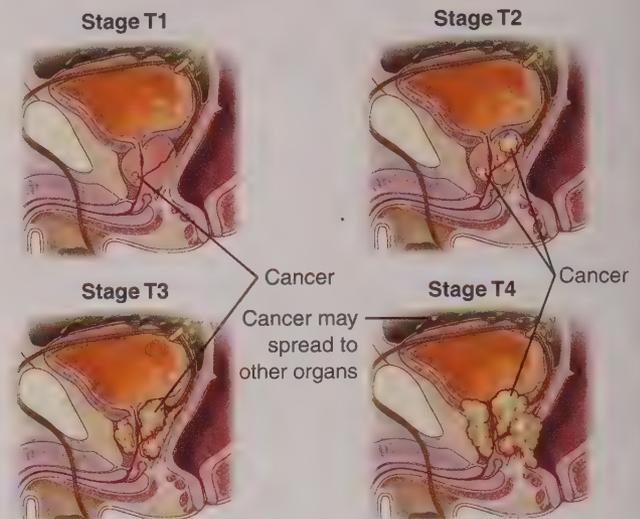

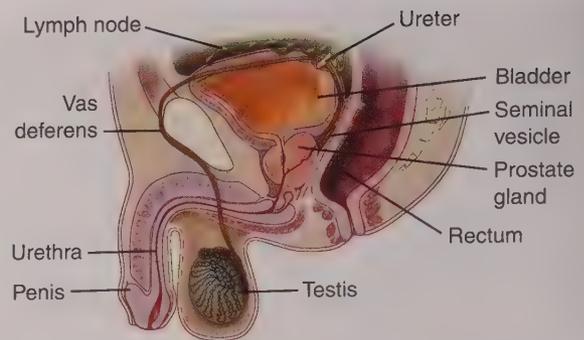

TNM, Tumor, nodes, metastasis.

system that allows the delivery of high doses of radiation with precise accuracy. Treatment may be completed with four or five sessions; it is much more efficient when compared with conventional external-beam radiation therapy.

**Brachytherapy** is a procedure that places radioactive seeds or pellets in the prostate through the perineum. In this way, the therapy can be targeted at a very precise area. The pellets are left in place permanently. They gradually lose reactivity over time. The patient is instructed to abstain from sex for 2 weeks, and at the end of the 2 weeks, he is instructed to wear a condom to protect his partner from radiation exposure. This method is more convenient for the patient because it is often outpatient surgery with a short recovery time. It is used with cancer that has not metastasized outside the prostate. Both external-beam radiation and brachytherapy may result in incontinence and/or impotence.

**Safety Alert** A man receiving brachytherapy should use a condom during sex to avoid exposing his partner to radiation.

**FIGURE 66.6** Tumor, nodes, metastasis (TNM) staging of prostate cancer. T1 = impalpable; T2 = locally confined to the prostate; T3 = locally extensive; T4 = fixation onto or invasion of neighboring organs.

### Cryotherapy and Ablative Hormone Therapy

Cryotherapy is another treatment for prostate cancer. Liquid nitrogen is delivered into the prostate through the perineum using metal probes to freeze the prostate. This is an early-stage treatment or is used when other treatments have failed. It is not used often because it has a low success rate; usually needs to be repeated; and may result in impotence, incontinence, and rectal complications.

Ablative hormone therapy is often used in men whose cancer has metastasized into the lymph nodes or bones. Ablative, meaning “suppression of,” refers to suppression of testosterone. Testosterone is an androgen that can promote the growth of tumors. Suppression of these hormones may lead to the slowing of tumor growth and provide symptom relief. This type of treatment is referred to as neoadjuvant therapy when it is used to shrink the prostate before radiation treatment.

### Chemotherapy

Chemotherapy is utilized in advanced prostate cancer. It is often used in men who no longer respond to ablative hormone therapy. This is known as hormone-refractory prostate cancer. Chemotherapy is given in pill form or intravenously and is given in cycles with a treatment period

followed by a rest period. These cycles vary from daily to weekly or every 3 to 4 months.

### Surgical Management

Surgical options include the radical prostatectomy. In this procedure, the patient's prostate and seminal vesicles are removed under general anesthesia. If deemed necessary, the surgeon may remove pelvic lymph nodes. There are various surgical techniques for performing the radical prostatectomy. In the open retropubic technique, the surgeon removes the prostate and lymph nodes through a single abdominal incision. A newer method is the laparoscopic technique in which the surgeon removes the prostate and lymph nodes through a few small abdominal incisions. A variation on this is the robot-assisted prostatectomy in which the surgeon directs the laparoscopic procedure from a console. An additional surgical procedure is the perineal approach, in which the incision is made between the scrotum and the anus. The choice of surgical approach is usually the surgeon's preference. Some surgeons feel that the perineal approach causes less pain; however, this technique does not allow access to the lymph nodes that drain the prostate. The radical prostatectomy almost always results in impotence, but a newer procedure, the nerve-sparing prostatectomy, attempts to keep the nerves intact that control erection.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of prostate cancer are typically not evident until the disease has been present for a long period of time. It is a slow-growing cancer developing on the periphery of the prostate gland, so it does not obstruct the flow of urine, which allows it to go unnoticed until there is associated pain. The pain is due to obstruction of urine flow and bladder distention resulting from compression of the urethra.

#### Nursing Diagnoses

- **Risk for infection** related to surgical intervention/ pharmacological intervention
- **Sexual dysfunction** related to the disease process/ surgical intervention

#### Nursing Interventions

##### Assessments

- Risk factors  
*African American men, men 55 or older, men with a family history of prostate cancer, and men with a diet low in fruits and vegetables are at higher risk for prostate cancer.*
- PSA levels  
*A PSA level of 4 ng/mL or greater requires further assessment.*
- DRE results  
*A large, palpable prostate on examination combined with a high PSA level requires further assessment.*
- Urinary symptoms  
*Obstruction of urine flow, a weak stream, and a distended bladder may indicate an enlarged prostate that requires further assessment—PSA and DRE.*

##### Actions

- Administer medication therapy as ordered:
  - Ablative hormone therapy  
*Ablative hormone therapy suppresses androgens, which promote tumor growth, thus slowing tumor growth.*
  - Chemotherapy  
*Targeted chemotherapy to destroy cancer cells once ablative hormone therapy is no longer effective*

##### Postop surgical care

- Aseptic wound care after prostatectomy  
*Reduces risk of infection and promotes healing*
- Manage bladder irrigation, if present.  
*Bladder irrigation helps remove blood clots to ensure the free flow of urine*
- Administer stool softeners.  
*To prevent straining during bowel movements*

##### Teaching

- Education regarding disease process  
*It is important the patient understands the disease and treatment process to improve compliance and potential positive outcome.*
- Brachytherapy  
*Keep the patient and significant other safe by explaining the importance of abstinence from sex for 2 weeks following the start of treatment and then condom use to protect the patient's partner from radiation.*
- Chemotherapy/radiation  
*Explain possible adverse effects of chemotherapy/radiation so that the patient may be better prepared as to what to expect.*
- Signs of infection  
*Teach the patient the signs and symptoms of possible postsurgical infection, such as fever, increasing pain, swelling, bleeding, nausea, vomiting; instruct the patient to contact the healthcare provider or go to the emergency department if symptoms are severe.*
- Prevention  
*Instruct the patient as to possible causes and preventions of prostate cancer. An increased prostate cancer risk is associated with a high consumption of calcium or the ingestion of greater than seven multivitamins a week. Prostate cancer prevention includes increased consumption of foods with selenium, such as oysters, tuna, whole-wheat bread, or sunflower seeds.*

##### Evaluating Care Outcomes

Prostate cancer responds well to treatment. It may be curable when localized but responds to treatment even when widespread. A well-managed patient demonstrates proactive behaviors such as regular screening, avoiding high consumption of calcium and high-dose multivitamins, and eating foods containing selenium. This patient articulates good understanding of the disease process and treatment options. The best outcomes include good response to treatment with normal sexual functioning, normal urination, and no incontinence.

## TESTICULAR CANCER

### Epidemiology

The incidence of testicular cancer diagnosis has increased over the last 20 years. This increase involves environmental and genetic factors. A male with a brother who has been diagnosed with testicular cancer is 8 to 10 times more likely to be diagnosed as well. A male whose father was diagnosed with testicular cancer has a four- to six-times-greater chance of being diagnosed. There is also an increased risk in males with Down's syndrome and testicular dysgenesis syndrome. The occurrence of testicular cancer is highest in Caucasian men and lowest among African American men. Cryptorchidism (undescended testicle) is one of the greatest risk factors for testicular cancer. Of men who receive a diagnosis of testicular cancer, the expected cure rate is 95%, and in patients with metastatic cancer, the expected cure rate is 80%.

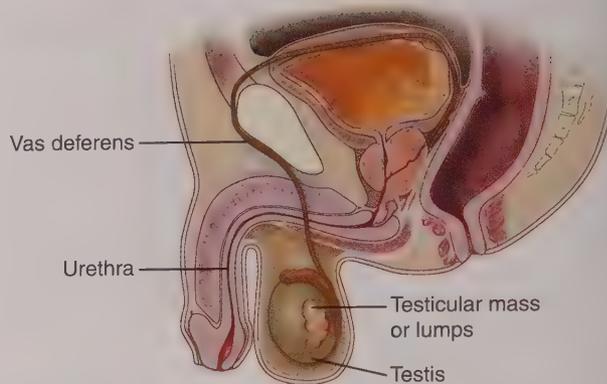

### Pathophysiology

Testicular cancer may be localized or metastasized to other locations. Testicular tumors usually spread through one of three routes. First, they may spread through the testicular wall into the blood supply or tubes that transport sperm, metastasizing into adjacent tissue. The second route is through the lymph nodes to the back of the abdomen. A tumor on the right side tends to spread to the right side of the abdomen. Tumors on the left side tend to spread to the back of the abdomen. Metastasis through the lymph nodes is the most common mode of transportation. The third mode of transportation involves the spread of cancer via the bloodstream to more distant organs, such as the brain, lung, and bone.

There are various types of testicular cancer. The most common types that account for the majority of testicular cancers are seminoma and nonseminoma, such as embryonal carcinoma, teratocarcinoma, and teratoma. Seminoma is a slow-growing cancer usually found in men in their 30s and 40s. Seminomas are usually in the testis but can spread to the lymph nodes. This type of cancer is very sensitive to radiation. A nonseminoma cancer generally occurs in men in their teens to 40s. It tends to grow and spread more quickly. It is not uncommon to have more than one type of testicular cancer in a given testicle (Fig. 66.7).

### Clinical Manifestations

Testicular cancer usually presents as a painless mass; however, some patients may complain of pain, swelling, or hardness in the scrotum. The patient may complain of discomfort ranging from acute testicular pain, dull abdominal pain, and dull ache in the scrotum to a heavy or firm feeling in the scrotum. The mass may also present with swelling and redness. Where there is metastasis, the patient may present with gastrointestinal symptoms; pain in the lumbar region of the back; gynecomastia

**FIGURE 66.7** Mass associated with testicular cancer.

(breast enlargement); and respiratory symptoms including dyspnea, cough, and hemoptysis.

### Management

#### Medical Management

#### Diagnosis

Diagnosis of testicular cancers is done through a combination of physical assessment, ultrasonography, and laboratory results. Physical assessment reveals a mass and swelling in the testicle or scrotum. There may be patient report of pain. Self-examination may be the first evidence of a lump, which is best done in a warm shower. The use of ultrasound is an important diagnostic tool to identify a mass as testicular cancer as opposed to an infection, collection of fluid, testicular torsion, or hernia. In a small percentage of patients, testicular cancer is not detected as the primary site until patients first present with symptoms such as pain in the abdomen, back, or bones; cough or difficulty breathing; and neck mass and/or swelling of breast tissue. Some testicular cancers produce tumor markers, which are proteins released by the tumors that can be detected by blood tests. Two of these common tumor markers are alpha-fetoprotein and human chorionic gonadotropin. Once the tumors are removed, these tumor marker laboratory values should decrease. If they do not, there may be other tumors present. If testicular cancer is in fact present, the tumor is classified through staging to assess the best treatment options. Staging is based on x-ray, computed tomography (CT) scans, microscopic examination, and on surgical findings. Testicular cancer staging is similar to prostate cancer staging using the TNM system (Table 66.4).

#### Treatment

Treatment typically depends on the type of tumor. For all types, it starts with the removal of the affected testicle, including the blood supply to that testicle, through an abdominal incision. Surgery for seminomas may be followed by radiation and/or chemotherapy. Nonseminomas that grow more quickly are not responsive to radiation. Treatment for them involves the removal of the affected testicle, including the blood supply, and removal of lymph nodes. Surgery is followed by chemotherapy.

**Table 66.4 Staging of Testicular Cancer**

Stage	Meaning
T0	No evidence of primary testicular cancer
T1	Tumor confined to the testicle
T2	Tumor invading outside the capsule of the testicle
T3	Tumor invading the tubes that transport sperm
T4	Tumor invading blood vessels that supply the testicles
T4B	Invades the scrotum
N0	No tumor in any lymph nodes
N1	Less than six nodes positive for cancer, no nodes greater than 2 cm
N2	More than six positive nodes, any node greater than 2 cm
N3	Masses, disease, and lymph nodes in the back
N+	Tumor has spread to multiple sites outside the lymph nodes

## Nursing Management

### Assessment and Analysis

The clinical manifestations of testicular cancer are due to the mass or lump present in the testes. The patient may complain of a heavy or full feeling in the scrotum, a dull ache in the scrotum, or abdominal pain.

### Nursing Diagnoses

- **Ineffective health maintenance** related to lack of knowledge regarding self-care secondary to the disease process/surgical intervention
- **Risk for infection** related to surgical intervention/pharmacological intervention

### Nursing Interventions

#### Assessments

- Physical assessment  
*Lumps, swelling, and redness in the scrotum are symptoms of testicular cancer that require further assessment.*
- Vital signs/temperature  
*Hypotension and tachycardia may reflect volume loss postoperatively. An increased temperature may be a sign of a postoperative infection.*

#### Actions

- Wound care  
*Maintaining aseptic technique while cleaning and dressing the surgical wound is essential in preventing infection.*
- Administer chemotherapeutic agents as ordered.  
*Chemotherapy is indicated to destroy cancer cells in both seminoma and nonseminoma testicular cancer.*

## Teaching

- Signs of infection  
*Teach the patient the signs and symptoms of possible postsurgical infection, such as fever, increasing pain, swelling, bleeding, nausea, and vomiting; instruct the patient to contact a healthcare provider or go to the emergency department if symptoms are severe.*
- Chemotherapy  
*Educate the patient as to the possible effects of chemotherapy, including the possibility of decreased testosterone production and increased risk of cardiovascular disease, such as angina and myocardial infarction.*
- Retroperitoneal lymph node resection  
*If retroperitoneal lymph node resection is performed, inform the patient that this procedure may result in nerve damage, affecting ejaculation.*
- Sperm storage  
*Encourage the patient to bank sperm before treatment should the patient wish to preserve potential fertility.*
- Follow-up  
*There is an increased risk for recurrence in the patient with testicular cancer, and the patient should be encouraged to see his primary care provider for a minimum of 10 years after treatment because 10 years is the most common time frame for recurrence.*

## Evaluating Care Outcomes

Testicular cancer has an excellent survival rate. The cure rate when testicular cancer is diagnosed early without metastasis is 90% to 100%, depending on the type of tumor and metastatic state. With adequate education and screening, testicular cancer can be diagnosed early, resulting in a successful treatment plan. Planning ahead and “banking” sperm will allow the possibility of a family in the future.

## Connection Check 66.7

A patient is diagnosed with testicular cancer. In educating the patient, the nurse realizes that the best treatment is which of the following?

- Watching and waiting to see if the cancer metastasizes
- Chemotherapy and then rechecks every 6 months
- Concentrated radiation to the testicle and lymph nodes
- Removal of the affected testicle

## MALE BREAST CANCER

### Epidemiology

Male breast cancer is a rare disease, 100 times less common than in females. Men have a breast cancer risk of 1/1,000. The American Cancer Society stated there were approximately 2,360 new cases of invasive breast cancer in men diagnosed in 2014. It is also estimated that male breast cancer would cause approximately 430 deaths. Male breast cancer is usually diagnosed later in life, with the mean age of diagnosis in the 60s. The rates of male breast cancer are

higher in North America, Europe, and Africa. There is a lower incidence in Asia.

There are many risk factors associated with male breast cancer. These risk factors include advanced age between 60 and 70 and a mutation in the **breast cancer type 2 susceptibility protein (BRCA2)** gene or **breast cancer type 1 susceptibility protein (BRCA1)** gene, with *BRCA2* being the more predominant cause. Other risk factors include a family history of breast cancer, excessive alcohol consumption, testicular disorders such as cryptorchidism or mumps orchitis (inflammation of the testes), working in a hot environment and/or working with gasoline, and previous exposure to radiation. Risk factors also include hormonal imbalance related to obesity, liver disease, Klinefelter's syndrome (a genetic condition resulting from an extra "X" chromosome, resulting in smaller-than-normal testicles and lower production of male sex hormones), and hormonal treatments such as estrogen treatment for prostate cancer or estrogen-related medications used in a sex-change procedure (Box 66.2).

## Pathophysiology

Men possess a small amount of breast tissue that cannot produce milk. It is nonfunctioning tissue that is located in

the area directly behind the nipple on the chest wall. Breast cancer in men is the uncontrolled growth of abnormal cells of that breast tissue. Because of this small amount of breast tissue, cancer spreads more easily to the nipple, skin, and muscle. Men are typically diagnosed with ductal carcinoma, the most commonly occurring form, which consists of infiltrating ductal carcinoma and ductal carcinoma in situ (DCIS). Other forms include inflammatory breast cancer, or Paget's disease of the nipple. Infiltrating ductal carcinoma occurs when abnormal cells spread beyond the lining of the ducts. **Ductal carcinoma in situ (DCIS)** occurs when abnormal cells are found in the lining of the duct in the breast. Inflammatory breast cancer occurs when cancer cells block lymph vessels in the skin, resulting in a breast that appears warm, swollen, and red. Lastly, **Paget's disease** of the nipple occurs when a tumor grows from ducts beneath the nipple and into the surface of the nipple. Lobular carcinoma, which can occur in women, is rare in men.

## Clinical Manifestations

Clinical manifestations of breast cancer in men are similar to those in females, but because of the smaller amount of breast tissue, it is easier to feel a developed mass. Symptoms include a swelling or lump in the breast area, a dimpling of the skin or nipple, erythema, discharge from the nipple, and/or inversion of the nipple. Inflammatory breast cancer results in red, warm, and swollen breast tissue.

## Management

### Medical and Surgical Management

#### Diagnosis

A physical examination that includes a clinical breast examination is completed, checking for lumps or unusual appearance or drainage. Ultrasonography and magnetic resonance imaging (MRI) can be used to visualize internal abnormalities. An estrogen and progesterone receptor test determines the amount of estrogen and progesterone receptors that exist in the cancer tissue. The results of this test give information on whether the cancer may respond to hormone therapy. The **human epidermal growth factor receptor 2 (HER2)** test measures the amount of HER2 growth factor that is present in the cancer tissue. This growth hormone signals cell growth. Cancer cells may produce this growth factor in excess, causing excessive growth of cancer cells. The results of this test determine if monoclonal antibody therapy may halt cancer growth. Additional tests, including sentinel lymph node biopsy, chest x-ray, CT scan, bone scan, and positron emission tomography (PET) scan, are used to determine if metastasis to other body parts has occurred. If breast cancer is found to be present, the tumor is classified through staging to assess the best treatment options. Table 66.5 lists tumor staging.

## Box 66.2 Nursing Care of Transgender Patients

There are barriers to the ability of transgender patients to receive healthcare. These barriers include feeling uncomfortable disclosing their identity to the healthcare provider; lack of resources and knowledge of providers; lack of financial resources and insurance; physical barriers, including hospital room assignments as they relate to gender; precision in electronic medical documentation; and accurate references in evaluating lab results. It is important for the provider to understand proper vocabulary, such as *transgender*, *trans-male*, *transfemale*, *transsexual*, and so forth. Attention to anatomy and physiology is important for proper treatment. Because hormonal therapy is undertaken by a large part of the transgender population, understanding the effects of these hormones on the body and possible interactions with medications prescribed for male reproductive disorders is vital in treating patients. For example, a biological male who is transitioning to a female and receiving estrogen with decreasing levels of testosterone will need to be monitored closely as treatment progresses. Estrogen may cause an increased risk of cardiovascular events, which may also be affected by medications administered for benign prostatic hyperplasia, prostate cancer, and/or testicular cancer. It is equally important to address the psychological needs of transgender patients as they move forward in attaining comprehensive healthcare.

**Table 66.5 Male Breast Cancer Staging**

Stage	Definition
<b>Stage 0 (carcinoma in situ)</b>	
● Ductal carcinoma in situ (DCIS)	● Abnormal cells present in lining of breast duct but without metastasis
● Paget's disease of the nipple	● Abnormal cells in nipple only
● Lobular carcinoma in situ (LCIS)	● Abnormal cells in lobules of breast
<b>Stage I</b>	Tumor of less than 2 cm in diameter with no lymph node involvement
<b>Stage II</b>	Tumor of up to 5 cm in diameter with or without lymph node involvement
<b>Stage III</b>	<ul style="list-style-type: none"> <li>● Tumor of greater than 5 cm in diameter</li> <li>● May involve proximal lymph nodes and lymph nodes above the collarbone</li> </ul>
<b>Stage IV</b>	Metastasis to other areas, such as bone, brain, liver, and/or lungs

## Treatment

Male breast cancer treatment correlates with the stage of cancer diagnosed. Treatment options include surgery, chemotherapy, hormone therapy, and radiation therapy. Surgical options include a lumpectomy or breast-conserving surgery or mastectomy. Lumpectomy is rarely used in men due to the small amount of tissue that enables easy cancer spread to the nipple, requiring removal of all breast tissue for successful treatment. Surgery usually involves a mastectomy. Depending on the stage of cancer, there are several options for mastectomy. A simple mastectomy involves the removal of the entire breast, including the nipple but not the lymph nodes. A modified radical mastectomy involves the removal of the breast and axillary lymph nodes. With a large, fast-growing, and spreading tumor, a radical mastectomy is indicated. This procedure involves the removal of the breast, axillary lymph nodes, the lining over the chest muscle, and possibly part of the chest muscle.

Chemotherapy can be used prior to or after surgery. Adjuvant chemotherapy (chemotherapy after surgery) is used as insurance against the possible presence of cancer cells not readily seen in an effort to lower the risk of a recurrence. Neoadjuvant chemotherapy is used prior to surgery to shrink the tumor to allow for more complete excision. Hormone therapy is used when the tumor is hormone receptor–positive, meaning the cancer grows in response to the hormone estrogen. Although estrogen is usually thought of as a female hormone, it is also present

at lower levels in men. Antiestrogen medications block estrogen from binding to estrogen receptors on breast cancer cells, slowing their growth. Hormonal therapy is not effective on tumors that are hormone receptor–negative.

Radiation may also be used to kill cancer cells or keep them from growing. Internal radiation or brachytherapy and external radiation are options. External radiation employs the use of an external beam to shrink or kill cancer cells or decrease symptoms. Internal radiation involves implanting radioactive substances concealed in seeds, catheters, wires, and needles directly into or near the cancer. Radiation is largely used when breast-conserving surgery is done, so, as noted previously, it is rarely used in men.

Targeted therapy uses medications or other substances to specifically attack cancer cells without attacking normal cells. An example of this form of treatment is monoclonal antibodies. These antibodies are created from a single type of immune cell. They attach to the substances on cancer cells. By attaching to the cells, antibodies kill cancer cells, stop them from growing, or keep them from spreading. The monoclonal antibodies are delivered through infusion.

## Connection Check 66.8

The nurse understands that neoadjuvant chemotherapy is utilized in which of the following ways?

- A. After surgery as insurance against reoccurrence of the tumor
- B. Prior to surgery to help facilitate complete excision of the tumor
- C. Prior to surgery as insurance against recurrence of the tumor
- D. After surgery to eliminate any obvious remaining tumor cells

## Nursing Management

### Assessment and Analysis

The clinical manifestations of breast cancer are due to the mass or lump present in the breast tissue. Symptoms include a swelling or lump in the breast area, a dimpling of the skin or nipple, erythema, discharge from the nipple, and/or inversion of the nipple. Clinical manifestations of inflammatory breast cancer are due to blockage of lymph vessels and include red, warm, and swollen breast tissue.

### Nursing Diagnoses

- **Ineffective health maintenance** related to lack of knowledge regarding self-care
- **Risk for infection** related to surgical intervention/ pharmacological intervention

### Nursing Interventions

#### ■ Assessments

- Physical assessment  
*A lump in the breast, dimpling or discharge from the nipple, nipple inversion, and redness may indicate the presence of a*

tumor. Red, warm, and swollen breast tissue may indicate inflammatory breast cancer.

### Postoperatively

- Vital signs  
*An increase in temperature may indicate an infection. A decrease in blood pressure may indicate bleeding or hypovolemia postoperatively. An increase in pulse may indicate bleeding, hypovolemia, pain, or anxiety.*
  - Incision  
*Check for bleeding, color, edema, and approximation of the suture line to determine the status of the wound. A clean, well-approximated incision with minimal to no serous sanguineous drainage indicates a healing wound.*
  - Pain  
*Request a pain scale rating to assess the need for pain medication, and determine the efficacy of treatment.*
- **Actions**
- Administer medications as ordered.  
*Depending on the tumor staging, chemotherapy may be given preoperatively to shrink the tumor to facilitate complete excision, or it may be given postoperatively to kill any possible remaining cancer cells.*
  - Change dressing.  
*Change dressing as ordered by the provider. Observe for redness, bleeding, odor, discharge, swelling, and approximation. Aseptic technique assists in preventing an infection.*
  - Empty drain at the surgical site.  
*Empty the drain; record the color and amount of drainage. Proper documentation allows the surgeon to determine when the drain can be removed.*
  - Administer pain medication per order.  
*Managing pain makes the patient more comfortable and allows better participation in essential postoperative activities, such as coughing and deep breathing and ambulation.*
- **Teaching**
- Care of suture site  
*Discuss dressing changes and proper cleaning techniques.*
  - Signs and symptoms of infection  
*Discuss signs of infection, such as fever, chills, nausea, vomiting, purulent discharge, or increased redness, so that the patient recognizes when it is necessary to call the provider.*
  - Breast self-examinations  
*Continue or start self-breast examinations to monitor for reoccurrence.*
  - Follow-up appointment with provider  
*Keep appointments with the surgeon to monitor the progress of healing.*
  - Provide emotional support and resources.  
*Creating a nonjudgmental, relaxed atmosphere reduces patient anxiety and creates a relationship of trust and acceptance; give the patient information on resources for support.*

## Connection Check 66.9

The nurse would question which order in a patient with receptor-negative male breast cancer after radical mastectomy?

- A. Administer antiestrogen therapy PO.
- B. Empty drain every 4 hours and prn.
- D. Administer pain medication every 4 hours prn.
- E. Instruct on proper self-breast examination.

## Evaluating Care Outcomes

A clean, dry wound without swelling, redness, drainage, or pain and with well-approximated wound edges indicates good surgical site healing. A well-managed patient knows what to expect regarding the care of the surgical site and signs of infection, as well as all resources available to help with emotional coping. The ability to articulate fears and anxieties regarding the cancer and the ability to return to the previous lifestyle and work indicate the beginning of emotional healing.

## TESTICULAR TRAUMA

### Epidemiology

Testicular trauma is an uncommon event even though the testicles are a vulnerable target. Approximately 85% of testicular trauma is from blunt trauma, whereas penetrating trauma accounts for 15%. Blunt trauma result from sports injuries, a kick to the groin, motor vehicle accidents, or falls and injury resulting from the straddling of an object. Sports injuries are the most common cause of injury. Penetrating trauma may be a result of stab wounds, gunshot wounds, animal bites, self-mutilation, or emasculation. Testicular injuries are more commonly found in males 25 to 40 years old.

### Pathophysiology

The testes are the male sex glands located behind the penis in the scrotum. They are essential in the production of sperm and testosterone. The testes are surrounded by connective tissue called the *tunica vaginalis* and are covered by a fibrous capsule called the *tunica albuginea*. When there is testicular rupture, the integrity of the tunica albuginea is altered, resulting in bleeding into the tunica vaginalis, referred to as a *hematocele*. Bleeding into the scrotal wall results in a scrotal hematoma.

### Categories of Injury

There are three basic categories related to testicular injury: blunt trauma, penetrating trauma, and degloving trauma. Blunt trauma refers to testes that receive an impact from an object of significant force. This trauma can be from a baseball injury or a kick to the groin. This kind of injury has also been seen in mountain bikers from the force of the bike seat or as a result of motorcycle accidents. Occasionally,

blunt trauma results in the dislocation of a testicle. In this case, the testicle has moved to a location other than its normal anatomical position. Dislocation can involve one or both testicles. Penetrating trauma to the testes may be secondary to stabbings or gunshot wounds.

Degloving injuries, also called *avulsion injuries*, occur when the skin of the scrotum is sheared off. This most typically occurs from accidents incurred while operating heavy machinery such as industrial or farming accidents. Degloving trauma is the least likely of the three trauma categories to occur.

### Connection Check 66.10

The emergency department nurse receives a report from a field provider regarding a patient being transported to the hospital after a groin injury sustained during a football game. The nurse prepares for which type of trauma?

- A. Blunt trauma
- B. Degloving trauma
- C. Penetrating trauma
- D. Retrograde trauma

## Management

### Medical and Surgical Management

Management starts with a thorough history and physical exam. Essential information includes the mechanism of injury. Scrotal ultrasound is helpful in determining the extent and nature of the injury. Blunt injuries occur most often and can often be treated conservatively if there is no rupture of the tunica albuginea. This treatment includes nonsteroidal anti-inflammatory drugs (NSAIDs), support of the scrotum, ice packs, and bedrest for 24 to 48 hours. If the injury has resulted in epididymitis (inflamed testicle) or a UTI, treatment involves antibiotics. Immediate surgical exploration may be necessary if Doppler studies or ultrasonography suggests internal trauma that may result in atrophy and necrosis. Initial management requires debridement and irrigation. Injury to the epididymis or vas deferens may be repaired using microsurgery. Removal of the testicle, orchiectomy, is rarely necessary unless there is irreparable damage to the testis.

If degloving is involved, the favored method of repair is primary closure using the remaining intact scrotal skin. If there is not sufficient skin for primary closure, the testis may be relocated to another body area, such as the subcutaneous tissue of the thigh, while allowing time for the tissue injury to heal. The temperature of the thigh is approximately 10° lower than the core body temperature, which promotes sperm production while allowing time for the damaged tissue to heal. Scrotal reconstruction can then begin in about 4 to 6 weeks. If neither of these options is possible, the testicles may remain

exposed and be treated with daily dressings until enough granulation tissue forms that can be combined with a split-thickness graft for coverage. Successful reimplantation if testicular amputation has occurred is possible using microvascular techniques to restore vascularization if treatment is received within 8 hours of amputation. With any testicular surgery, antibiotics are given preoperatively and postoperatively. The patient may have drains inserted intra-operatively to decompress the surgical site, facilitating drainage, and decreasing swelling and pressure. Bleeding and infection are major risks in this type of injury.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of testicular trauma are the result of either blunt or penetrating trauma. They are pain, swelling, bleeding, and infection. Degloving injury can result in significant loss of tissue and potential loss of testicular function.

#### Nursing Diagnoses

- **Risk for infection** related to surgical intervention/ pharmacological intervention
- **Anxiety** related to the threat to biological integrity

#### Nursing Interventions

##### ■ Assessments

- Physical assessment  
*Bleeding, swelling, or skin evulsion of the testicles indicate blunt, penetrating, or degloving testicular trauma.*
- Pain  
*A testicular injury typically results in intense pain. Assessing pain level and duration helps determine the extent of injury and the adequacy of treatment.*
- Temperature  
*An increased temperature is a sign of infection, which is especially important in penetrating or degloving injury.*
- Wound assessment  
*Assess for signs of wound infection, such as redness, warmth, or purulent drainage.*

##### ■ Actions

- Conservative treatment for minor trauma with NSAIDs, scrotal support, ice packs, and bedrest  
*Conservative treatment allows time for the swelling to decrease and the tissue to heal.*
- Wound care  
*Dress wound using aseptic technique to prevent infection.*
- Administer antibiotics as ordered.  
*Antibiotics may be ordered to prevent or treat infection.*
- Monitor drain output.  
*Excessive drainage may indicate bleeding, which may require repair. Discolored or malodorous drainage may indicate infection.*

- Compassion and support  
*Offer emotional support to help the patient emotionally deal with this injury.*

### ■ Teaching

- Care related to nonsurgical intervention  
*Teach the patient how to care for scrotal injury by explaining proper dosing of NSAIDs; the use of a scrotal sling or folded towels to elevate the scrotum; the use of ice packs, including the use of a towel between the skin and the ice pack; and the importance of rest to assist in recovery.*
- Postsurgical care  
*Teach the patient how to care for the surgical area, especially keeping it clean and dry to decrease the chance of infection.*
- Drains  
*Teach the patient and/or significant other how to manage the care of drains, should the patient be discharged with drains in place, to encourage independence.*
- Worsening symptoms  
*Teach patient to call the provider when signs and symptoms of a worsening condition occur, such as fever, redness, a heavy feeling in scrotal area, swelling, bleeding, nausea and vomiting, and increasing pain.*

### Evaluating Care Outcomes

A well-managed patient experiencing testicular trauma has pain under control and understands the necessary treatment to aid in recovery. The patient with minor trauma is resting, using ice and scrotal support to decrease swelling. The patient who required a surgical repair is healing well and free from infection.

## Making Connections

### CASE STUDY: WRAP-UP

After assessment of his symptoms and education, Scott agrees to a blood draw for PSA levels, a urinalysis, and a DRE. Based on the results of the DRE, a PSA of less than 2 ng/mL, and urinalysis within normal limits, Scott is told the best intervention at this time is “watchful waiting.” He is told that if his symptoms worsen, he may be prescribed medication therapy such as 5-alpha-reductase inhibitors or alpha-adrenergic blockers. The nurse provides patient education focusing on watchful waiting and the importance of future provider follow-up.

#### Case Study Questions

1. Scott’s initial complaint is of problems urinating. He is diagnosed with BPH. He understands BPH causes this symptom because the enlarged prostate exhibits which of the following?
  - A. Often swells when the patient has a full bladder
  - B. Obstruction to the flow of urine
  - C. Can easily be injured secondary to blunt trauma
  - D. Is sensitive to diets high in potassium
2. Scott has been told by his provider that the best approach for his diagnosis of BPH at this time is “watchful waiting.” The nurse explains that watchful waiting is appropriate because of which of the following?
  - A. He has minimal symptoms and minimal prostate enlargement.
  - B. He is too old to require surgical intervention.
  - C. The provider wants to monitor lymph node involvement.
  - D. His PSA levels were too high in combination with a negative DRE.
3. The nurse recognizes more teaching is necessary by which of the following statements?
  - A. “I guess I need to plan on yearly follow-ups.”
  - B. “I’ll call for an appointment if my symptoms get worse.”
  - C. “I’m glad I’ll be able to take my decongestants for my allergies.”
  - D. “I’m glad medications are not necessary at this point.”
4. If Scott is given a prescription for an alpha blocker such as Flomax, he will be educated as to how this medication works. This education will include which of the following statements?
  - A. The medication relaxes the muscles of the prostate, allowing easier urination.
  - B. The medication relieves discomfort associated with urination.
  - C. The medication lowers PSA levels.
  - D. The medication dilates the urethra, allowing easier urination.
5. Scott is told to report any additional pain, fever, nausea, and/or vomiting to his provider for which of the following reasons?
  - A. An enlarged prostate can cause a spike in fever.
  - B. Nausea and vomiting can be related to dilation of the prostate gland.
  - C. The combination of these symptoms with BPH may be a sign of cancer.
  - D. Urine stasis from lack of bladder emptying may cause a UTI.

## CHAPTER SUMMARY

Benign prostatic hyperplasia (BPH) affects 50% of men age 51 to 60 years of age and 90% of men over the age of 80. Frequent nocturia is a common complaint. Although “watchful waiting” is often the treatment with BPH, if left untreated, the patient may develop urinary retention, a urinary tract infection (UTI), bladder stones, bladder damage, and kidney damage. If severe urinary retention develops, catheterization may be indicated to fully empty the bladder. Patients need to be educated to be able to recognize worsening symptoms to avoid complications.

Erectile dysfunction is the inability to achieve or maintain an erection sufficient for sexual intercourse. Causative factors include diabetes, cardiovascular disease, or low levels of testosterone. There are several treatment options, but the most common is medication therapy in the form of PDE-5 inhibitors. Erectile dysfunction can be treated surgically with a penile implant as well as with other non-surgical options, such as medications injected into the penis or pellets inserted into the urethra that cause vasodilation that stimulates blood flow.

Prostate cancer is the cause of approximately 9% of cancer-related deaths in the male population. Regular screening should be done for patients at risk for prostate cancer because it is relatively symptomless in the early stages. Tumors develop on the edges of the prostate, so they do not interfere with urine flow initially. Although the prostate-specific antigen (PSA) test has always been the gold standard for the diagnosis of prostate cancer, it is now being questioned because annual testing is resulting in overdiagnosis and overtreatment of prostate cancer as well as underdiagnosis. Some providers now look at serial PSAs from month to month as opposed to just one reading. Patients need to be

educated as to what the results of the PSA mean for them in particular according to their age and other risk factors.

The prevalence of testicular cancer is low; the expected cure rate is 95%, and in patients with metastatic cancer, the expected cure rate is 80%. The disease is more prevalent in Caucasian males and less prevalent in African American males. The survival rate after a patient has been treated for testicular cancer is good. Treatment for all types starts with the removal of the affected testicle, including the blood supply to that testicle. Slow-growing testicular cancers are treated with radiation and/or chemotherapy following surgery. Faster-growing tumors do not respond to radiation and so are treated with chemotherapy and the removal of lymph nodes postoperatively.

Male breast cancer is a rare disease affecting less than 1% of the population and is usually diagnosed in men between the ages of 60 and 70. Breast cancer in men is the uncontrolled growth of abnormal cells of the breast tissue. Because there is a small amount of breast tissue in a man, cancer spreads more easily to the nipple, skin, and muscle. It is treated in the same way female breast cancer is treated, using chemotherapy, radiation, and surgery, depending on what stage the breast cancer is when diagnosed.

Testicular trauma, although the testes are seemingly in a vulnerable position, is an uncommon event. The three categories of testicular trauma include blunt trauma (e.g., from a kick to the groin), penetrating trauma (e.g., from a knife wound), and degloving trauma (e.g., from a heavy machinery accident). Degloving trauma is the least common. Most blunt testicular trauma requires treatment with NSAIDs, bedrest, ice, and scrotal support. For the more severe testicular traumas, secondary to penetration or degloving, surgery is required.

# Chapter 67

## Coordinating Care for Patients With Sexually Transmitted Infection

*Lynn McDonald*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of sexually transmitted infections
2. Correlating clinical manifestations with pathophysiological processes of:
  - a. Human papillomavirus (HPV)
  - b. Primary, secondary, and tertiary syphilis
  - c. Genital herpes
  - d. *Chlamydia trachomatis*
  - e. Gonorrhea
  - f. Pelvic inflammatory disease
3. Describing the diagnostic results used to confirm the diagnosis of sexually transmitted infections
4. Discussing the medical management of:
  - a. Human papillomavirus (HPV)
  - b. Primary, secondary, and tertiary syphilis
  - c. Genital herpes
  - d. *Chlamydia trachomatis*
  - e. Gonorrhea
  - f. Pelvic inflammatory disease
5. Developing a comprehensive plan of nursing care for patients with sexually transmitted infections
6. Designing a teaching plan that includes pharmacological, dietary, and lifestyle considerations for patients with sexually transmitted infections

### ESSENTIAL TERMS

Atypical  
Colposcopy  
Cytolysis  
Cytology  
Epididymitis  
Fitz-Hugh-Curtis syndrome  
Human papillomavirus 9-valent vaccine  
Incubation period  
Latent  
Lymphadenopathy  
Obligate intracellular bacterium  
Oncogenic  
Pathogenesis  
Prodromal  
Reiter's syndrome  
Salpingitis  
Subclinical  
Urethritis

### CONCEPTS

- Assessment
- Cellular Regulation
- Comfort
- Female Reproduction
- Infection
- Inflammation
- Male Reproduction
- Medication

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Keisha Pritchard is a 24-year-old female who presents to her OB/GYN healthcare provider for her annual checkup. Her medical history consists of sexual activity since 13 with a history of 11 partners, chlamydia (treated at a clinic 1 year ago), smoking (one-half pack a day), and drinking (every weekend while partying). She also states she does not use condoms because she does not like how they feel. She states she knows her current male partner is “clean” because she asked him. She attends school at a local college...

## INTRODUCTION

Sexually transmitted infections (STIs), also referred to as sexually transmitted diseases (STDs), are a worldwide epidemic. Sexually transmitted infections are contagious (viral, bacterial, or parasitic) and may cause physical, emotional, and psychological burdens with the capability of causing catastrophic sequelae. They are mainly transmitted from person to person by intimate contact but can be spread congenitally or via bloodborne pathogens. Sexually transmitted infections have also been linked to the acquisition and transmission of HIV. Common STIs, such as the human papillomavirus (HPV), *Chlamydia*, gonorrhea, pelvic inflammatory disease (PID), syphilis, and genital herpes, are discussed in this chapter.

## HUMAN PAPILLOMAVIRUS

### Epidemiology

Human papillomavirus is a very common STI of the anogenital tract. There are more than 100 known types of HPV, with 40 types linked to the lower genital tract of males and females. Human papillomavirus is well recognized as the precursor to cervical cancer. Additional evidence is being revealed as to its role in the development of cancers of the vulva, vagina, anus, penis, and some head and neck cancers. Infection with HPV, specifically HPV 6 and HPV 11, is also responsible for other diseases, such as juvenile respiratory papillomatosis and genital warts.

Globally, the incidence of HPV in females is highest in sub-Saharan Africa (24%), Latin America and the Caribbean (16%), Eastern Europe (14%), and South East Asia (14%). In the United States, the prevalence of any type of HPV in females is 39%, and 20.4% of females are infected with an **oncogenic** (implicated in the formation and development of cancerous tumors) type of HPV. Human papillomavirus is very common in women under 30, and approximately 75% to 80% of females will acquire HPV by the age of 50.

Human papillomavirus exposure is typically temporary and has little long-term significance. However, exposure to oncogenic HPV increases the risk for cervical cancer for women who are past the age of 30. Worldwide, cervical cancer is the fourth-leading cause of cancer in women and the second-leading cause in women aged 15 to 44 years. Because the prevalence of HPV in cervical cancer overwhelms the incidence in other cancers, this section focuses primarily on females and HPV and how HPV relates to cervical lesions and cancer.

### Connection Check 67.1

The nurse recognizes that which virus leads to an increased risk for cervical cancer?

- A. Cytomegalovirus
- B. Herpes simplex virus
- C. Human parvovirus
- D. Human papillomavirus

All HPV strains are transmitted by direct skin contact during vaginal, anal, and oral sexual intercourse; therefore, risk factors are related to sexual behavior. They include multiple sexual partners (within the year and lifetime), sexually active unmarried females, and onset of sexual intercourse at an early age. In addition to risk factors, there are several cofactors that aid in the **pathogenesis** (origin and development of disease) and progression of HPV. These are immunosuppressive conditions (e.g., HIV), chronic conditions requiring long-term immunosuppressive therapy (e.g., transplant recipients), oral contraceptives, smoking, and STIs, particularly herpes and chlamydia. These risk factors are associated with an increased risk for cervical cancer; however, not everyone exposed to high-risk HPV will develop cervical cancer.

### Pathophysiology

The different types of HPV are grouped into “low-risk,” “intermediate-risk,” and “high-risk” strains. “Low-risk” strains cause 90% of condyloma acuminata (condylomas), or genital warts. Low-risk strains are not commonly known to lead to cervical cancer. The estimated **incubation period** (exposure to infection time) is 3 weeks to 8 months. Genital warts may appear as soft, fleshy, flat, raised lesions that may resemble cauliflower in appearance and usually occur in clusters. Common sites are the penis, vulva, vagina, perineum, and anal region (Fig. 67.1).

Certain intermediate-risk and high-risk strains have been known to lead to cervical cancer. There are 14 different high-risk strains in total, and all are considered oncogenic. Specifically, the high-risk strains HPV 16 and HPV 18 are linked to 70% of squamous cell carcinomas of the cervix. The majority of patients who have oncogenic HPV usually have **subclinical** disease or are in the early stage of a disease that does not show symptoms.

**FIGURE 67.1** Condylomata acuminata, or genital warts, in the perianal region; they resemble cauliflower in appearance.

High-risk HPV is a double-stranded deoxyribonucleic acid (DNA) virus that invades the cells through microabrasions of the basal epithelium in the epithelial tissue of the cervix, making the host susceptible to attack. As HPV slowly replicates, it begins to occupy more of the basal membrane. In the beginning stages of infection, low-grade squamous intraepithelial lesion (LSIL), otherwise known as cervical intraepithelial neoplasia I (CIN I), occupies one-third of the epithelium. If the infection persists, it may develop into CIN II (two-thirds of the epithelium) or CIN III (the full thickness of the epithelium). Both CIN II and III can be referred to as *high-grade squamous intraepithelial lesions (HSILs)*. High-grade squamous intraepithelial lesions may take several years to develop (up to 20 years) depending on the host's immunity and ability to fight off infection.

## Clinical Manifestations

Typically, HPV infections cause no symptoms, hence the need for adequate screening. Females with nononcogenic HPV may experience symptoms of genital warts. Most patients who have genital warts claim they do not have other associated symptoms, but genital warts can be painful and bothersome. Some patients complain of itching, burning, and tenderness. Genital warts may also cause emotional distress.

## Management

### Medical Management

#### Diagnosis

The Papanicolaou (Pap) test remains the most cost-effective tool to screen females for cervical cancer. It is the first-line test to detect an abnormal growth in the cervix or vagina. In this test, cells are scraped from the surface and internal opening of the cervix. The cells are examined under a microscope to view for abnormalities (**cytology**). When used routinely at scheduled intervals, the Pap test has proven to be an effective tool to detect preinvasive cervical cancer.

Human papillomavirus DNA testing, an evaluation of cells scraped from the cervix, is used to detect high-risk oncogenic HPV. It can be used as a reflex check in females who are diagnosed with **atypical** (abnormal) cells on a Pap test. In females over 30 years, HPV testing is recommended as a routine addition to the Pap test as a co-test. Human papillomavirus testing should not be used in lieu of Pap testing. A **colposcopy** is a magnified examination of the cervix, vagina, and vulva. A colposcopy and biopsy may be indicated if the cytological specimen (Pap) is abnormal and if high-risk HPV DNA is detected. Current guidelines ([www.acog.org](http://www.acog.org)) suggest that cervical cancer screening should begin at 21 years of age because cervical carcinoma is relatively rare under the age of 20 years. Also, females under the age of 21 who are exposed to oncogenic HPV are highly likely to clear the infection.

### Medical Management of Nononcogenic HPV

Treatment is not recommended for HPV in the absence of genital warts or lesions. If genital warts are diagnosed, largely by way of visual inspection, treatment is done to remove the warts, but it is not clear if removal clears the HPV infection. Recommended treatments for genital warts include creams (imiquimod ([Aldara] 5% cream), gels (podofilox 0.5% solution or gel), or ointments (sinecatechins 15%) applied directly to the affected area. They work by modifying or enhancing the immune response to the wart or by breaking down the skin on the wart. Another option, cryotherapy, may be a first-line clinician therapy to treat genital warts. Cryotherapy destroys the wart through thermal-induced **cytolysis** (breakdown of cells). Surgical excision is also an option. The warts may be surgically removed at a single visit; however, recurrence is possible.

#### **Safety Alert** Special precautions about genital warts and pregnancy:

- The safe administration of the creams, gels, and ointments used to treat warts has not been established in pregnant females and therefore should be avoided.
- If the pelvic outlet is obstructed by genital warts, a cesarean section may be indicated.

### Medical Management of Oncogenic HPV

Providers take several factors into consideration in the management of cervical warts and lesions associated with high-risk oncogenic HPV strains: age, size, location and stage of the disease, pregnancy, probability of compliance, cost, skill level, and resource availability. Invasive procedures are one option but may be performed only after the HSIL has been diagnostically proven with colposcopy and biopsy. Once the lesion is confirmed as HSIL, the provider will decide which procedure is most appropriate for the patient. Table 67.1 lists the common procedures to manage HSIL.

**Table 67.1 Common Procedures and Definitions for Management of HSIL**

Procedure	Definition
<b>Loop electrosurgical excision procedure</b>	This procedure employs a wire loop that transmits a painless current to the affected abnormal cervical tissue.
<b>Ablation</b>	These procedures burn or freeze abnormal cervical tissue. The most common procedures are cryosurgery (freezing) and laser ablation (beam of light used to irradiate abnormal cells).
<b>Excision</b>	This procedure involves the resection of abnormal tissue. The most commonly done procedure with advanced cervical lesions is cold knife conization (CKC). This procedure involves biopsy of the cervix by obtaining a cone-shaped sample; CKC may be done to diagnose cancers of the cervix or uterus or to treat CIN.
<b>Laser conization</b>	This procedure utilizes a beam of light to excise abnormal cervical tissue.

CIN, Cervical intraepithelial neoplasia; HSIL, high-grade squamous intraepithelial lesion.

## Prophylaxis

Prophylactic HPV management in the form of a vaccine is recommended for females and males. The Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention (CDC) recommends routine vaccination with the **human papillomavirus 9-valent vaccine** (see Evidence-Based Practice: Human Papillomavirus Vaccination).

## Evidence-Based Practice

### Human Papillomavirus Vaccination

The Advisory Committee on Immunization Practices (ACIP) recommends vaccination for female and males with the human papillomavirus 9-valent (9vHPV) vaccine to prevent HPV-associated cancers and disorders, such as cervical, vulvar, vaginal, and other HPV-related malignancies; precancerous HPV-related lesions; and genital warts in females and genital warts and penile, anal, and HPV-associated oral pharyngeal cancers in males. Current ACIP guidelines for females and males include a two-dose vaccination between the ages of 9 and 14 and three doses between the ages of 15 and 26. Females can be vaccinated through the age of 26 years, and males can be vaccinated through 21 years. Special populations include children with a history of sexual abuse. This population should begin the vaccination series at 9 years old. Men who have sex with men (MSM) and transgender persons can be vaccinated up through 26 years old. The ACIP also recommends three doses of the vaccine for individuals with immunocompromising conditions such as HIV, B-lymphocyte antibody deficiencies, and

transplantation. The administration of the 9vHPV vaccine has been proven to significantly reduce the risk of cervical cancer in women by 90%.

Bernstein, H. H., Bocchini, J. A., & Committee on Infectious Diseases. (2017). Practical approaches to optimize adolescent immunization. *American Academy of Pediatrics*, 139(3), e20164187. doi:10.1542/peds.2016-4187

Practices.Meites, E., Kempe, A., & Markowitz, L. E. (2016). Use of a 2-dose schedule for human papillomavirus vaccination—Updated recommendations of the Advisory Committee on Immunization Practices. *Morbidity and Mortality Weekly Report*, 65(49), 1405–1408. doi:10.15585/mmwr.mm6549a5

### Nursing Management

#### Assessment and Analysis

Clinical manifestations are not clearly defined in HPV. Some patients have no symptoms; others complain of burning, itching, or pain associated with genital lesions or warts.

#### Nursing Diagnosis

- **Ineffective health maintenance** related to deficient knowledge regarding self-care, treatment prevention, and spread of disease

#### Nursing Interventions

##### ■ Assessments

- Pain  
*May be an indication of a worsening condition or complication*
- Presence of genital warts  
*Genital warts are a common manifestation of HPV.*

##### ■ Actions

- Administer mild analgesia prn as ordered after treatment to remove or manage HSIL.  
*Provides pain relief and comfort*

### ■ Teaching

- Educate the patient on prevention, manifestations, transmission of STIs, reducing the number of partners, and the use of barrier methods.

*Safe sex will help to decrease transmission of HPV to another person and thus the overall prevalence.*

- Encourage healthy practices (e.g., healthy diet, limit drinking, no smoking) and routine gynecological and primary care.

*Improve health outcomes and well-being*

- Encourage completion of the full series of HPV vaccinations.

*Vaccination will reduce the risk of the acquisition of HPV-related cancers and disease.*

- Instruct the patient to report any history of infection to partners.

*The partner may be at risk and/or may need to be treated.*

*Early treatment can reduce complications of infection.*

- Instruct the patient on the appropriate application of gels, creams, or ointments as indicated for genital warts.

*Proper application will maximize benefit and minimize adverse effects.*

- Call provider if experiencing worsening pain and/or vaginal discharge.

*May be an indication of a worsening condition or complication*

### Evaluating Care Outcomes

Many females and males are exposed to HPV; however, because of its slow progression and effective treatment modalities, patients do not have to succumb to complications related to that exposure. A well-managed patient receives the appropriate vaccinations, practices safe sex, limits partners, has good health habits (e.g., annual pelvic examinations), and is aware of when to contact the provider.

## SYPHILIS

### Epidemiology

Syphilis is complex chronic infection that has the ability to acutely or chronically infect every organ of the body in a very subtle manner. It is classified into four stages: primary, secondary, latent (early and late), and tertiary. The tertiary stage is also classified as cardiovascular and gummatous. Neurosyphilis (central nervous system [CNS]) has been classified at times as tertiary but can be present at any stage. The World Health Organization (WHO) estimated that more than 12 million persons are infected with syphilis annually. The CDC reported 88,042 new cases (all stages) and reported 27,814 primary and secondary syphilis cases in the United States in 2016. It is transmitted through genital and oral sexual intercourse and congenitally from mother to fetus. Populations most at risk are persons 25 to 29 years of age and homosexual men. The CDC reported a surge of 17.6% in primary and secondary syphilis and an increase of 27.6% in congenital syphilis. Females are screened routinely during antepartum visits. Similar to those of other

STIs, risk factors include unprotected sexual intercourse, multiple sexual partners, men who have sexual intercourse with men (MSM), transgender women, sex workers, incarcerated individuals, and individuals with a history of HIV (see Evidence-Based Practice: The Care of Transgender Men and Women). Infants are at increased risk when they have a mother who has been exposed to syphilis.

## Evidence-Based Practice

### The Care of Transgender Men and Women

The term *transgender* relates to a person who identifies with a sex that differs from the one assigned at birth. Transgender women (trans-women) identify as women but have male genitalia. Correspondingly, transgender men (trans-men) identify as men but have female genitalia. Gender expression differs from sexual orientation. Trans-male or trans-women may engage in sexual relations with either men, women, or both. Trans-women may not undergo genital affirmation surgery but can engage in oral, vaginal, and anal relations with a functioning penis. Trans-men who have a vagina and cervix will continue to be at risk for bacterial infections, human papillomavirus (HPV), and cervical cancer. Clinicians should assess and screen appropriately for asymptomatic and symptomatic sexually transmitted infections (STIs) and human immunodeficiency virus (HIV)-related risks in relation to the individual's anatomical features and sexual practices.

Luzzati, R., & Maurel, C. (2015). Transgender identity and sexually transmitted diseases including HIV. In C. Trombetta, G. Liguori, & M. Bertolotto (Eds.), *Management of gender dysphoria* (pp. 337–344). Milano, Italy: Springer. 20171217140706435997486

### Pathophysiology and Clinical Manifestations

Syphilis is an ulcerative genital disease caused by the anaerobic spirochete *Treponema pallidum*. This bacterium invades the mucous membranes and becomes systemic by entering the blood and lymphatic system. The CNS is invaded early in the disease. The incubation period is 1 week to 3 months. Primary syphilis initially manifests as a chancre. A chancre is a painless, hard lesion that can develop into a painless open lesion, located at the site of exposure. The most common sites are the vulva, vagina, anus, penis, rectum, lips, and oral pharynx (Fig. 67.2).

Chancre lesions will last 3 to 6 weeks with or without treatment. **Lymphadenopathy** (abnormally large lymph nodes, usually a result of a disease) often occurs in combination with the chancre or in secondary syphilis. If the patient

**FIGURE 67.2** Primary chancre of syphilis: a large ulceration on the penis.

with primary syphilis does not receive adequate treatment, the infection will travel systematically and progress to secondary syphilis.

Secondary syphilis is marked by a rash and/or mucous membrane lesions. These rashes or lesions may overlap the time period when the chancre is still healing or appear weeks later. A maculopapular rash may develop on the palms, soles, buttocks, and upper thighs (Fig. 67.3). These rashes may appear macular (flat discolored spot), papular (elevated, hard skin that does not contain pus), or pustular (skin that contains pus) or a combination of all. Lesions called *condylomata lata* (wart-like growths on the skin) may also develop at this time, along with mucous patches in the mouth. These lesions are considered infectious (Fig. 67.4).

Other symptoms may include fever or malaise, alopecia, joint pain, and headaches. The infection may involve the kidney and liver (nephritic syndrome, hepatitis), but this is rare. The primary and secondary periods are the most infectious stages.

Early **latent** (hidden) syphilis develops after the secondary symptoms reduce in intensity, typically 1 year after exposure. The late latent period is considered greater than 1 year after exposure. In the latent period, the risk of sexual transmission is low. Within the late latent period,

**FIGURE 67.3** Maculopapular rash on palms that occurs with secondary syphilis. This rash can appear macular, papular, and/or pustular on the palms, soles, or trunk.

**FIGURE 67.4** Secondary syphilis condylomata lata; wart-like growths in the perianal region.

three situations may occur: (1) the patient spontaneously resolves the infection, (2) the patient remains in a latent state, or (3) the patient progresses to late or tertiary syphilis. Late or tertiary syphilis may develop in one-third of patients with syphilis without treatment. There are three types of tertiary syphilis: neurosyphilis, cardiovascular syphilis, and gummatous syphilis (skin and subcutaneous tissues).

Neurosyphilis is an infection in which *T. pallidum* invades the CNS. Neurosyphilis can manifest in four forms: asymptomatic, general paresis, meningovascular, and a syndrome called *tabes dorsalis*. Asymptomatic is the most common form of neurosyphilis. In this form, there are cerebrospinal fluid (CSF) abnormalities without symptoms of nervous system damage. In general paresis neurosyphilis, there is a combination of psychiatric and neurological findings. Patients can present with decreased mental function or mood and personality changes. Meningovascular or syphilitic meningel infection may result in fibrosis or thickening of cerebral vessels, causing sudden-onset stroke, hemiplegia, or abnormal CSF findings. *Tabes dorsalis*, a late stage of neurosyphilis, involves a slow degeneration of the spinal cord leading to loss of sensation, loss of peripheral reflexes, progressive ataxia, and finally, paralysis.

Cardiovascular syphilis and gummatous syphilis are rare forms of tertiary syphilis. Cardiovascular syphilis damages the aortic musculature. Gummatous syphilis, composed of rubberlike lesions, occurs in the skin, bones, or internal organs. Both are rare because of the widespread use of penicillin but have an increased incidence in patients with HIV. See Table 67.2 for common manifestations of syphilis.

**Table 67.2 Common Manifestations of Syphilis**

Syphilis Stage	Details
<p><b>Primary</b></p> <p>Genital ulcer</p> <p>Chancre: firm, round, and painless</p>	<p>The first symptom occurs on average at 21 days or 10–90 days.</p> <p>The chancre lasts 3 to 6 weeks.</p> <p>Ulcers and chancres appear where syphilis enters the body.</p> <p>Without treatment, the infection progresses to secondary stage.</p>
<p><b>Secondary</b></p> <p>Skin rashes: lesions (including palms and soles), macular, papular, pustular</p> <p>Mucous patches: painless, silvery ulcerations of mucous membrane with surrounding erythema</p> <p>Condyloma lata: large, raised, gray or white lesions</p> <p>Generalized lymphadenopathy</p> <p>Fever (low-grade), malaise, anorexia, arthralgias, and myalgias</p> <p>Central nervous system: headache, meningitis, cranial neuropathies</p> <p>Other:</p> <p>Renal: glomerulonephritis, nephritic syndrome</p> <p>Liver: hepatitis</p> <p>Bone and joint: arthritis</p>	<p>A rash can appear when the primary chancre is healing or several weeks after the chancre has healed.</p> <p>Symptoms can go away with or without treatment.</p> <p>However, without treatment, the infection progresses to the latent or possibly tertiary stage.</p>
<p><b>Latent (hidden)</b></p> <p>No signs or symptoms</p>	<p>Early latent—infection occurred within the past 12 months.</p> <p>Late latent—infection occurred more than 12 months ago.</p> <p>Detected through serological tests</p> <p>Can continue in this stage for years</p>
<p><b>Tertiary</b></p> <p>Cardiovascular:</p> <p>Aortic regurgitation</p> <p>Aortic aneurysm</p> <p>Neurosyphilis:</p> <p>Seizures</p> <p>Hemiparesis or hemiplegia</p> <p>Impaired proprioception and vibratory sensation</p> <p>Visual changes</p> <p>Ataxia</p> <p>Urinary and fecal incontinence</p> <p>Cranial nerve involvement (II–VII)</p> <p>Stroke</p>	<p>This stage is rare.</p> <p>Early neurological manifestations may occur within the first few months or years of infection.</p> <p>Late neurological manifestations may occur 10–30 years after the infection was first acquired.</p> <p>Death can occur due to damage to internal organs.</p>

**Table 67.2 Common Manifestations of Syphilis—cont'd**

Syphilis Stage	Details
Optic atrophy	
General paresis	
Personality changes	
Hyperactive reflexes	
Decreased memory	
Slurred speech	
Gummata: rubbery nodules or ulcers of pink, fleshy tissue located in the skin, mucous membranes, bones, eyes, respiratory system or gastrointestinal system	
Tabes dorsalis: syphilitic myelopathy causing a loss of coordination of movement	

## Management

### Medical Management

#### Diagnosis

The diagnosis of syphilis is confirmed by serological (blood testing) and microscopic testing. The most commonly used serological procedure is done in two stages, the nontreponemal and treponemal-specific tests. Nontreponemal tests look for indirect markers of infection, such as biomarkers released as a result of cellular damage due to the spirochetes of syphilis. Examples include the rapid plasma reagin (RPR) and Venereal Disease Research Laboratory (VDRL) tests. Treponemal tests look for direct markers of infection, such as antibody production. Examples include fluorescent treponemal antibody absorption (FTA-ABS), *T pallidum* particle agglutination assay (TP-PA), and various enzyme immunoassays (EIAs). These nontreponemal and treponemal-specific tests cannot be used individually because they both have limitations that may produce false-positive results.

Darkfield microscopy is a quick traditional method of testing for primary and secondary syphilis. It may not be used as often if serological testing is available. Darkfield microscopy works by “brightening up” an object against a dark background. This form of microscopy can illuminate the slim bacterium *T pallidum* that is not readily visible utilizing other types of stains. In order to obtain a specimen for microscopy, the lesion is cleaned with saline-soaked gauze, and then a slide is pressed firmly on the exudates and viewed. The combination of serological testing and the examination of the CSF obtained through a lumbar puncture is the current method to definitively diagnose neurosyphilis.

#### Medications

The main medication used for all stages of syphilis is penicillin. Patients who are allergic to penicillin may use other

approved medications; however, these alternatives may not be as effective. They include ceftriaxone, tetracycline, and doxycycline. Patients who are allergic may undergo desensitization for treatment with penicillin. Desensitization is a procedure where, under close observation in the hospital, a penicillin dose is slowly administered after the administration of both methylprednisone (anti-inflammatory) and diphenhydramine (antihistamine) to counteract the potential reaction. Pregnant women with a penicillin allergy would go through desensitization because there are no alternatives to penicillin in the treatment of syphilis while pregnant.

### Connection Check 67.2

The nurse understands that which of the following are correct about syphilis? (*Select all that apply.*)

- A chancre is a common symptom in tertiary syphilis.
- Neurosyphilis invades the CNS and may occur at any stage of syphilis.
- The most infectious stages of syphilis are the primary and secondary stages.
- Latent infections are detected primarily by visual inspection.
- Penicillin G is the preferred treatment for all stages of syphilis.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of syphilis vary depending on the stage of the disease, as illustrated in Table 67.2. The initial manifestation is a chancre sore. Without treatment, the disease can progress into secondary and tertiary stages. The symptoms worsen as the disease progresses. In the second

stage, skin rashes may appear, along with fever and symptoms of malaise. In the tertiary stage, gummatous disease may produce extensive tissue damage and disfigurement. In addition, profound damage to the cardiac system or CNS may result in valvular problems, seizures, issues with mobility, and eventually paralysis.

### Nursing Diagnoses

- **Risk for loss of cognitive function** related to infection with syphilis
- **Situational low self-esteem** related to the clinical manifestations of syphilis
- **Impaired mobility** related to spinal cord damage

### Nursing Interventions

#### ■ Assessments

- Vital signs, particularly temperature  
*Increased temperature is a sign of infection. Monitoring temperature helps to evaluate the course of infection and response to treatment.*
- Presence of chancre  
*Initial manifestation of primary syphilis*
- Skin  
*The presence of a diffuse rash or mucous patches is indicative of secondary syphilis.*
- Neurological status  
*Neurological changes such as mood swings, confusion, seizures, and balance issues are indicative of neurosyphilis.*
- Serology tests  
*Positive tests are indicative of the presence of syphilis; the response to treatment may be monitored by decreasing markers of infection in the serology tests.*

#### ■ Actions

- Administer penicillin as ordered.  
*Penicillin is the most effective antibiotic in the treatment of syphilis.*

#### ■ Teaching

- Educate the patient on the importance of seeking and maintaining treatment.  
*Treatment is essential to avoid progression of the disease to secondary or tertiary stages.*
- Educate the patient on prevention, manifestations, transmission of STIs, reducing the number of partners, and barrier methods.  
*Safe sex can help decrease the transmission and occurrence of syphilis.*
- Instruct the patient to report any history of infection to sexual partners.  
*The partner may be at risk and/or may need to be treated. Early treatment can reduce untoward complications of infection.*

### Evaluating Care Outcomes

Even with the discovery of penicillin, syphilis continues to be a global health concern, particularly with the growing

epidemic of HIV/AIDS. Effective treatment for halting progression to the later stages is possible with early diagnosis and management. A well-managed patient is compliant with the treatment plan, practices safe sex, and is aware of when to contact the provider. Similar to other STIs, syphilis screening should be part of routine screening for those at risk because this infection may present asymptotically.

## GENITAL HERPES

### Epidemiology

Genital herpes is a common, chronic STI caused by herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2). National estimates reveal that the prevalence of HSV-1 is 47.8% and that of HSV-2 is 11.9% among individuals aged 14 to 49, with a total adolescent and adult population ratio of 1 to 5. The majority of genital herpes is caused by HSV-2. Globally, the prevalence of HSV-2–related genital herpes present in persons aged 15 to 49 is 417 million. Estimates reach over a billion within the same age range when including the cases of genital herpes caused by either HSV-1 or HSV-2.

Risk factors for genital herpes are similar to those for other STIs. They include a history of other STIs, early age of sexual intercourse, MSM practices, multiple partners, low socioeconomic status, and immune-compromised individuals. Herpes simplex virus 2 is more commonly diagnosed in females than males because the female genitalia are more susceptible to skin breaks. Genital herpes is more easily transmitted from males to females than from females to males.

### Pathophysiology

Genital herpes is a highly contagious infection caused by HSV. Entry can occur through minute breaks such as a scratch or abrasion through uninfected skin. The herpes simplex virus travels from the site of infection (skin or mucous membrane) via the lymphatic, blood, or ascending nerves to the sacral ganglion cells and remains latent until it becomes reactivated and travels down many different sensory nerve fibers. Herpes antibodies develop after the initial infection.

Generally, genital herpes is transmitted by direct skin-to-skin contact during the **prodromal** stage of infection (onset of the infection). Infection can occur through oral-to-oral, oral-to-genital, genital-to-genital, or anal contact. Transmission can also occur during childbirth when the child is passing through the birth canal. The virus may shed from persons with or without symptoms. The majority of patients are unaware they are infected; therefore, transmission to others may occur unknowingly. Others may not recognize the infection as herpetic and therefore may not take necessary precautions to prevent transmission to others.

## Clinical Manifestations

HSV outbreaks occur episodically. Between outbreaks, HSV lies dormant in the sacral area in the CNS. It becomes reactivated as a result of stressors or triggers. Triggers for the onset of these outbreaks can be due to physical factors (e.g., immunosuppression, ultraviolet radiation, fatigue, menses) and psychological factors (emotional and psychological stress). The frequency, severity, and duration of these episodes may vary from patient to patient. Females tend to have more severe symptoms than males. Outbreaks or episodes also tend to decrease over time. The primary or initial outbreak presents as one or several clear vesicles, or blisters, that erupt in the genital area. The vesicle then ruptures and forms a painful ulcer several days later. The ulcer may last up to 2 to 4 weeks if untreated (Fig. 67.5). Table 67.3 displays common symptoms observed in males and females.

### Psychosocial Impact of Genital Herpes

Genital herpes is a chronic condition that may affect quality of life. The frequency and severity of the pain can change the general well-being of an individual, especially when clustered with other symptoms. Psychosocially, genital herpes may have implications that can lead to depression, withdrawal from relationships, poor coping skills and self-confidence, shame, guilt, and perceived poor body image. Patients may feel or be stigmatized or stereotyped as one who is promiscuous and/or one who made a poor decision, making them unwilling to disclose the chronic infection to new sexual partners. At the same time, these individuals are concerned they may transmit the infection to others. This can lead to overall detrimental effects on quality of life.

**FIGURE 67.5** Genital herpetic ulcers. Clear vesicles, or blisters, in the genital area.

## Management

### Medical Management

#### Diagnosis

Diagnosis of HSV infection can begin clinically through visual inspection of the oral, genital, and anal areas. Cell culture and polymerase chain reaction (PCR) testing are the preferred methods for those who seek medical treatment for the HSV ulcers or lesions. In order to obtain a culture from an ulceration, the top layer is removed, and the sample is retrieved from the underside. Fluid from a ruptured vesicle can be collected and sent off in a culture medium. Results are most accurate within 24 to 48 hours from the time the vesicle or ulcer appears. Culture sensitivities are low; therefore, the PCR assay is the more sensitive test to

**Table 67.3** Manifestations of Genital Herpes

Common Site for Genital Herpes	Other Symptoms That May Occur With Vesicles	Prodromal Signs
<b>Females:</b>		
Cervix	● Fever	● Itching
Vulva/Perineum	● Headache	● Burning
Legs	● Dysuria	● Tingling or an abnormal sensation prior to presence of a vesicle or ulcer
Buttocks	● Myalgias—pain in the muscles	
Anus	● Burning and tingling	
<b>Males:</b>		
Penis	● Itching localized to groin area	● Itching
Prepuce (penile) (foreskin)	● Swollen lymph nodes in groin area	● Burning
Scrotum	● Flu-like symptoms	● Tingling or an abnormal sensation prior to presence of a vesicle or ulcer
Anus		
Buttocks		
Thighs		
Inside urethra		

detect HSV antibodies. Samples may be obtained from a vesicle or ulcers, skin or mucous membranes, or spinal fluid. Type-specific laboratory confirmation is necessary because the vesicles or ulcers may be missed or may resemble another type of infection. A surface protein, glycoprotein (GgG) is an accurate serology test that elicits type-specific antibody responses; HSV-specific glycoprotein G1 is used to diagnose HSV-1, and HSV-specific glycoprotein G2 is used to diagnose HSV-2. Immunoglobulin M (IgM) testing for HSV-1 or HSV-2 is not useful because it is not type-specific, and its antibodies may be detectable during recurrent genital or oral episodes. Both type-specific virology and type-specific serology testing should be available in the clinical setting for prognostic and counseling implications; however, routine serological testing of asymptomatic individuals is not recommended because it may heighten the risk of false-positive test results.

### Medications

Medication therapy consists of antiviral medications to suppress the infection and provide symptom relief. Antiviral medications can also help to decrease the duration and severity of the infection. Currently, there is no cure for genital herpes.

*Primary therapy* is used to treat all newly diagnosed outbreaks in a patient. Fever, malaise, and a headache may accompany the genital lesion outbreak. Treatment may help to lessen the severity and duration of symptoms. *Episodic therapy* is used to treat symptoms that occur intermittently. Episodic therapy is most effective when treatment begins in the prodromal stage or within the first 24 hours. *Suppressive therapy*, regular daily dosing with an antiviral, is used to reduce the incidence of outbreaks by 70% to 80%. Suppressive therapy may be encouraged for individuals who have six or more outbreaks in a year. Because the incidence of outbreaks tends to lessen with time, the provider should have frequent communication with the patient to determine the continued necessity of suppressive therapy.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of genital herpes are a result of HSV traveling down sensory pathways typically to the genital area in response to a physiological or psychological trigger or stress. As a result, a vesicle or painful blister appears that may last days to weeks. Prodromal symptoms such as itching or altered sensation may occur prior to the appearance of the blister, indicating the beginning of an outbreak. Along with the physical pain, psychological discomfort or embarrassment may result.

#### Nursing Diagnoses

- **Ineffective sexual pattern** related to abstinence from sexual activities until acute infection subsides; change in reproductive potential
- **Situational low self-esteem** related to expressions of shame or guilt

### Nursing Interventions

#### Assessments

- Skin of buttocks and genital area  
*The presence of clear vesicles or blisters indicates a herpes outbreak.*
- Frequency of outbreaks  
*Therapy is dictated by the frequency of outbreaks; six or more outbreaks in a year may indicate a need for suppressive therapy.*

#### Actions

- Administer antiviral medications as ordered.  
*Prompt initiation of medication in the prodromal stage helps decrease the severity and duration of the outbreak.*
- Refer patient to support groups for counseling if needed.  
*Group support is beneficial to expose the patient to others who have coped with infection and to help the patient validate and share feelings.  
Counseling is beneficial to help attain or nurture a healthy psychosocial makeup.*

#### Teaching

- Educate the patient on prevention, manifestations, transmission of STIs, reducing the number of partners, and barrier methods.  
*Safe sex can help decrease the transmission and occurrence of genital herpes.*
- Instruct the patient to report any history of infection to sexual partners.  
*The partner may be at risk and/or may need to be treated. It is important that the patient understand that genital herpes transmission is possible even when symptoms are not evident.*
- Start treatment as soon as prodromal symptoms occur.  
*Prompt treatment may decrease the severity and duration of an outbreak.*
- The importance of abstinence during symptomatic episodes  
*Abstinence during an acute outbreak can help reduce transmission to sexual partners.*
- Educate patient on means to help alleviate symptoms.
  - Warm salt baths prn  
*Assist with drying up the lesions and ease physical discomfort due to pain or itching from the vesicles or ulcers*
  - Ice to the affected area  
*May aid in relieving discomfort*
  - Loose-fitting clothing  
*Increased airflow may help ease discomfort and promote healing.*

### Evaluating Care Outcomes

Genital herpes is a non-life-threatening, incurable infection that can have physical and psychological consequences. A well-managed patient understands that effective management requires prompt treatment as soon as prodromal symptoms are evident. This patient understands that normal, healthy sexual relationships are possible with appropriate safe-sex practices, abstinence during acute outbreaks, and proper treatment with antivirals.

### Connection Check 67.3

Which statement is correct when providing discharge instructions to a patient with genital herpes?

- Genital herpes is an infection that is always symptomatic.
- Genital herpes is a mildly contagious infection.
- Genital herpes is an infection that can be cured by antivirals.
- A person can transmit HSV to others without displaying any symptoms.

## CHLAMYDIA TRACHOMATIS

### Epidemiology

*Chlamydia trachomatis* (chlamydia) is the most common sexually transmitted bacterial infection. It is a urogenital infection that primarily infects the urethra and cervix. It is transmitted through vaginal, anal, or oral sexual intercourse via bodily secretions. Transmission may occur during childbirth, from mother to child, and may lead to conditions such as conjunctivitis, pharyngitis, and pneumonia. Globally, the WHO reports there are more than 131 million cases annually. Although cases are felt to be underreported, the CDC estimated approximately 1.6 million new cases annually in the United States in 2016. The frequency and morbidity of *Chlamydia* infections are reported to be greater in females. Simultaneous *Chlamydia* infection often occurs with gonorrhea, but the incidence of chlamydia is greater.

Risk factors for *Chlamydia* include age, particularly 25 years or younger; low socioeconomic status; multiple sexual partners; history of STIs; unmarried status; immature cervix; and a diagnosis of mucopurulent inflammation of the cervix. Three groups at high risk are sexually active females under the age of 25, persons over the age of 25 who frequently engage in sexual intercourse with a new partner, and MSM. The CDC recommends that these groups be screened annually.

### Pathophysiology and Clinical Manifestations

*C trachomatis*, the bacteria that causes chlamydia, is an **obligate intracellular bacterium** that cannot grow outside a living cell; it needs the metabolism of the host to reproduce. The incubation period is between 7 and 21 days. Its cellular walls resemble gram-negative bacteria.

### Connection Check 67.4

The nurse recognizes that which patient is at the greatest risk for *C trachomatis*?

- An 18-year-old single female
- A 45-year-old married female
- A 60-year-old single female
- A 30-year-old married male

Most individuals who contract chlamydia have no symptoms; only 5% to 30% of females and 10% of males develop symptoms. Table 67.4 displays the female and male manifestations of chlamydia.

## Management

### Medical Management

#### Diagnosis

The diagnosis of chlamydia is made through a swab specimen taken from the vagina, cervix, penis, urethra, rectum, or other involved orifice. It is done utilizing a highly sensitive assay called the *nucleic acid amplification test (NAAT)*. To obtain a urethral specimen from a male, the swab is placed in the urethral meatus about 2 to 3 cm. Samples from females should be taken from the vagina or endocervix. If a urine sample is obtained, the most sensitive sample is obtained during the first void in the morning. Many reports describe the coexistence of *Chlamydia* infection with gonorrhea; therefore, patients should be routinely tested for both infections simultaneously. Individuals diagnosed with chlamydia should be rescreened in 3 months after completion of prescribed therapies because there is a high risk for reinfection.

#### Medications

Medication therapy consists of doxycycline or azithromycin as first-line treatment of *C trachomatis* for nonpregnant females, males, and HIV-infected individuals. Azithromycin is administered in one dose, in contrast to doxycycline,

**Table 67.4 Manifestations of Chlamydia**

#### Clinical Symptoms in Females

- Dysuria—painful urination
- Dyspareunia—painful sexual intercourse
- Lower abdominal pain
- Abnormal vaginal bleeding (postcoital/after sexual intercourse or intermenstrual/between menses)
- Vaginal discharge (clear or cloudy)
- Cervical abnormalities (friable, tender, inflamed)
- Proctitis (inflammation of the rectum or anus) or rectal discharge (clear or cloudy)

#### Clinical Symptoms in Males

- Dysuria
- Urethral discharge (clear or cloudy)
- Meatitis—inflammation of the urinary meatus
- Proctitis or rectal discharge (clear or cloudy)

Rectal infections may occur in both females and males: discharge, anal itching, soreness, bleeding and painful bowel movements

which is administered twice daily for 7 days. For this reason, azithromycin is the medication of choice for patients at risk of noncompliance with lengthy medication regimens; however, both medications are equally effective. If doxycycline is chosen, it is important to warn against excessive sun exposure. Erythromycin is an alternative medication used to treat pregnant females.

### Safety Expedited Partner Therapy Alert

Expedited partner therapy (EPT) is the clinical practice of providing a prescription to the partner of a patient diagnosed with chlamydia or gonorrhea without completing a physical exam on the partner. The purpose of EPT is to prevent reinfection, halt the spread of the disease, and lessen long-term sequelae to the female reproductive system. Quick partner treatment provides another strategy for partner notification. Providers advise their patients to inform their partners to get tested or treated. Expedited partner therapy increases the number of partners treated and decreases the likelihood of reinfection by 29%. Expedited partner therapy is available in most states and many countries throughout the world and shows promise as a public health initiative in decreasing chlamydia and gonococcal infections at a population level.

Centers for Disease Control and Prevention 2017

201801081142511773430229

## Complications

If left untreated in females, the *Chlamydia* infection may travel to the uterus and fallopian tubes and cause a condition called pelvic inflammatory disease (PID). This condition is addressed later in this chapter. In males, if the *Chlamydia* infection spreads, it may travel to the epididymis, causing **epididymitis** (inflammation of the epididymis), a rare condition, or prostate gland infection. Further complications in women include infertility, tubal abscesses, ectopic pregnancy, chronic pelvic pain, and **Fitz–Hugh–Curtis syndrome** (perihepatitis, or inflammation of the peritoneal covering of the liver). Other complications include **Reiter's syndrome**, also known as reactive arthritis. This is a rare autoimmune arthritic condition that causes **urethritis**, or inflammation in the urinary genital tract, and conjunctivitis, an inflammation of the mucous membranes lining the eyes.

## Nursing Management

### Assessment and Analysis

Both females and males may be asymptomatic for chlamydia; however, dysuria is a symptom that may occur. Females may experience lower abdominal pain and painful intercourse because of inflammation caused by the infection.

Males may present with inflammation and infection of the urinary meatus.

## Nursing Diagnosis

- **Risk of infection:** Risk factors: insufficient knowledge to avoid exposure to pathogens; unsafe sex practices

## Nursing Interventions

### Assessments

- Monitor vital signs, particularly temperature.  
*Increased temperature may signal infection. Monitoring temperature helps to evaluate the course of infection and response to treatment.*
- Monitor current signs/symptoms of STI.  
*Symptoms, when present, indicate active infection. Monitoring helps in the evaluation of response to treatment.*
- Urinary function  
*Dysuria in both males and females is a clinical manifestation of chlamydia.*
- Pain during intercourse  
*Painful intercourse may occur with a Chlamydia infection.*
- Unusual vaginal bleeding or discharge from urinary meatus  
*Bleeding or discharge is a manifestation of a Chlamydia infection.*

### Actions

- Administer antibiotics as ordered.  
*Antibiotics such as azithromycin, doxycycline, and erythromycin are the treatment of choice for chlamydia.*

### Teaching

- Educate the patient on prevention, manifestations, transmission of STIs, reducing the number of partners, and barrier methods.  
*Safe sex can help decrease the transmission and occurrence of chlamydia.*
- Instruct the patient to report any history of infection to sexual partners.  
*The partner may be at risk and/or may need to be treated. Early treatment can reduce untoward complications of infection.*
- Educate the patient on the importance of taking the entire prescribed therapy.  
*The patient may develop resistance to the antibiotic if the entire regimen is not completed.*
- Call the provider if experiencing worsening pain and/or vaginal discharge.  
*May be an indication of a worsening condition or complication*
- Encourage healthy practices (routine gynecological and primary care, healthy diet, no drinking or smoking).  
*Improve outcomes and well-being*
- Instruct the patient on the importance of getting retested for chlamydia in 3 months.  
*Reinfection is common.*

## Evaluating Care Outcomes

Successful management of the patient with chlamydia requires prompt diagnosis and treatment with appropriate antibiotics. A well-managed patient completes the entire prescribed therapy and understands that safe-sex practices are essential in limiting reoccurrence and transmission to sexual partners.

## NEISSERIA GONORRHOEAE

### Epidemiology

*Neisseria gonorrhoeae* (gonorrhea) is the second most common bacterial STI, after chlamydia. Like chlamydia, gonorrhea tends to be underdiagnosed and underreported. Globally, the WHO reports there are more than 78 million cases annually. The CDC reported a total of 468,514 gonorrhea cases in 2016. Although rates have decreased from those reported in the 1990s, the national rate increased to 145.8 cases per 100,000 population in 2016. The CDC reports an increase in incidence with younger persons, with the highest rates in males and females aged 20 to 24. The CDC also reports an increase in incidence in MSM and in populations in endemic areas of the United States where the infection is routinely seen.

Risk factors are similar to those of chlamydia: age, particularly under 25 years old; low socioeconomic status; multiple sexual partners; history of STIs, including PID; and unmarried status. The CDC suggests that high-risk groups be screened annually.

### Pathophysiology and Clinical Manifestations

Gonorrhea is transmitted through genital-to-genital, oral-to-genital, and anal-to-genital contact. Perinatal transmission (mother to infant) during delivery may also occur. It is caused by the bacterium *Neisseria gonorrhoeae*, also known as gonococcus, a gram-negative intracellular diplococcus. These gonococci attach to the surface of columnar mucosa epithelial cells. Local invasion occurs and attacks the mucosal surfaces of the genitourinary tract, eyes, throat, and rectum. The gonococci replicate and invade host immune cells, leading to dissemination and systemic infection. The incubation period for females is usually less than 10 days. For males, the incubation period is usually within a 14-day period. Approximately 50% of females and males experience clinical manifestations. See Table 67.5 for the female and male clinical manifestations of gonorrhea.

## Management

### Medical Management

#### Diagnosis

The diagnosis of gonorrhea is made through the NAAT assay. It is the most sensitive and specific test to detect gonorrhea in women. The test is costly, but the results are

**Table 67.5 Manifestations of Gonorrhea**

#### Clinical Manifestations in Females

- Vaginal discharge
- Intermenstrual bleeding
- Anorectal discomfort
- Dysuria
- Cervicitis—inflammation of the cervix

#### Clinical Manifestations in Males

- Dysuria (which occurs before purulent discharge)
- Copious purulent urethral discharge (gold standard manifestation for gonococcal urethritis)
- Rectal pain, bleeding, or purulent discharge

Rectal infections may occur in both females and males; manifestations include discharge, anal itching, soreness, bleeding, and painful bowel movements.

available rapidly. Samples can be obtained from the vagina, cervix, and urine. All samples from the male or female must be immediately placed into the proper medium and transported promptly to the laboratory. Diagnosis may also be made by culture. The results are extremely sensitive for males and females who are symptomatic but are less sensitive in those who are asymptomatic. In addition to detecting gonococci, the culture test has the added benefit of detecting antibiotic resistance. The culture test is less expensive than the NAAT, with a turnaround time of 48 hours. The collection procedure is similar to that for obtaining chlamydia cells.

Gram staining may be used to test the urethra in males. It is a highly sensitive and specific test and is considered positive if polymorphonuclear leukocytes with intracellular gram-negative diplococci are present (Fig. 67.6); however, stains demonstrate low sensitivity for males who are asymptomatic. Concomitant infection with chlamydia may occur; therefore, testing should be done for both.

### Connection Check 67.5

The nurse recognizes that which statements are true of gonorrhea? (Select all that apply.)

- A. Gonococci are viruses caused by *N gonorrhoeae*.
- B. Concomitant infection with chlamydia can occur; therefore, test for both.
- C. Gonorrhea remains localized to an expectant mother; therefore, there is a very low risk of vertical transmission to the infant.
- D. The NAAT is effective in the detection of genitourinary infection with *N gonorrhoeae*.
- E. A hallmark symptom in males with gonorrhea is copious purulent urethral discharge.

**FIGURE 67.6** Gram stain of urethral discharge from a male patient with gonorrhea shows gram-negative intracellular diplococci.

## Medications

Quinolone-resistant strains of gonorrhea have been detected worldwide. As a result, a classification of antimicrobial medications called *fluoroquinolones* should not be administered to patients to treat gonorrhea. Instead, the CDC recommends a dual treatment of two medications to treat gonorrhea (see Safety Alert). One is an antimicrobial classification of medications called *cephalosporins*. Ceftriaxone is a *cephalosporin*, administered intramuscularly or intravenously. The second medication is a semisynthetic macrolide antibiotic called azithromycin. Azithromycin is also used to treat several bacterial infections other than STIs. Infectious disease consultation should be considered for those individuals who experience treatment failure due to antibiotic resistance.

### Safety Antibiotic-Resistant Gonorrhea Alert

With the global increase in the incidence of gonorrhea has come the rise of antimicrobial-resistant cases. Over the years, certain gonorrhea strains have developed resistance to microbials such as penicillin, tetracycline, and fluoroquinolones. This led to extended-spectrum cephalosporins (cefixime or ceftriaxone) as a treatment option. However, many global countries reported cephalosporin resistance. The macrolide antibiotic azithromycin was administered to patients who could not tolerate cephalosporins. When used alone, some patients developed azithromycin resistance. The CDC identified the dual (two-medication) therapy for treatment (ceftriaxone and azithromycin) for gonorrhea with the aim of delaying the appearance of gonorrhea strains resistant to either medication. The combination of these two medications has been shown to be successful in the treatment of gonorrhea. New medications continue to be studied and evaluated for possible dual-therapy use in the future.

Centers for Disease Control and Prevention. (2015). *Gonococcal Isolate Surveillance Project (GISP)*. Retrieved from <https://www.cdc.gov/std/gisp>

## Complications

Complications in females include PID, pelvic abscesses, ectopic pregnancy, infertility, and Fitz-Hugh-Curtis syndrome. In males, epididymitis and, in rare cases, infertility may occur. Disseminated gonococcal infection may lead to systemic complications such as arthritis, tenosynovitis (common), and skin lesions. Rare complications include endocarditis and meningitis.

## Nursing Management

### Assessment and Analysis

The clinical manifestations of gonorrhea are similar to those of chlamydia. Unusual vaginal bleeding, dysuria, rectal pain, vaginal or urethral drainage in females and dysuria, rectal pain, gonococcal urethritis, and urethral discharge in males are caused by inflammation due to the infectious process.

### Nursing Diagnosis

- **Risk of infection:** Risk factors: insufficient knowledge to avoid exposure to pathogens; unsafe sex practices

### Nursing Interventions

#### ■ Assessments

- Monitor vital signs, particularly temperature. *Increased temperature may signal infection. Monitoring temperature helps to evaluate the course of infection and response to treatment.*
- Monitor current signs/symptoms of STI. *Symptoms indicate active infection. Monitoring helps in the evaluation of the response to treatment.*
- Urinary function *Dysuria in both males and females is a clinical manifestation of gonorrhea.*
- Rectal pain *Rectal pain is a common clinical manifestation of gonorrhea in both males and females.*
- Vaginal bleeding or discharge from the urinary meatus *Bleeding and discharge are manifestations of gonorrhea infections.*

#### ■ Actions

- Administer antibiotics as ordered. *Antibiotics such as ceftriaxone and azithromycin are the treatment of choice for gonorrhea.*

#### ■ Teaching

- Educate the patient on prevention, manifestations, transmission of STIs, reducing the number of partners, and barrier methods. *Safe sex can help decrease the transmission and occurrence of gonorrhea.*
- Instruct the patient to report any history of infection to sexual partners. *The partner may be at risk and/or may need to be treated. Early treatment can reduce untoward complications of infection.*

- Educate the patient on the importance of taking the entire prescribed therapy.  
*The patient may develop resistance to the antibiotic if the entire regimen is not completed.*
- Call the provider if experiencing worsening pain and/or vaginal discharge.  
*May be an indication of a worsening condition or complication*
- Encourage healthy practices (routine gynecological and primary care, healthy diet, no drinking or smoking).  
*Improve health outcomes and well-being*
- Instruct the patient on the importance of getting retested for gonorrhea in 3 months.  
*To check for reinfection*

### Evaluating Care Outcomes

Gonorrhea is a common bacterial infection, especially in high-risk groups. Many findings report that males and females continue to engage in risky sexual practices and therefore should be tested routinely. Partners of those infected should also be tested and treated accordingly. Successful management of the patient with gonorrhea requires prompt diagnosis and treatment with appropriate antibiotics. A well-managed patient completes the entire prescribed therapy and understands that safe-sex practices are essential in limiting reoccurrence and transmission to sexual partners.

### CASE STUDY: EPISODE 2

During her physical examination by her OB/GYN provider, Keisha complains of lower abdominal pain. On examination, the provider notes that Keisha has mucopurulent discharge coming from her cervix, along with uterine tenderness. The provider sends NAAT cervical swabs for gonorrhea and chlamydia and performs a Pap test and a wet prep that immediately show the presence of white blood cells (WBCs). Serology is sent for HIV, syphilis, and hepatitis. As part of his work-up, the provider sends Keisha for a transvaginal ultrasound...

## PELVIC INFLAMMATORY DISEASE

### Epidemiology

According to the National Health and Nutrition Examination Survey (NHANES), of U.S. women aged 18 to 44, 2.5 million have experienced a diagnosis of PID in their lifetime; however, the accurate number may be higher because of unreported cases. This leads to approximately 60,000 hospitalizations, 106,000 outpatient visits, and frequent emergency visits annually. Overall, the trend in the prevalence of PID has decreased within the United States and other resource-rich countries within the last decade.

The risk factors for PID are similar to those for other STIs and include unprotected sexual intercourse, sexual

intercourse at 25 years old or younger, oral contraceptive use, multiple sexual partners, and previous history of PID. Bacterial vaginosis, douching, sexual intercourse during menses, and intrauterine devices may contribute to the onset of PID by causing a disturbance in the cervical barrier that may aid in the movement of bacteria through the pelvic cavity.

### Pathophysiology

Pelvic inflammatory disease is an acute infection that originates from the vagina or cervix and ascends to the upper genital tract, infecting the uterus, fallopian tubes, and ovaries. Pelvic inflammatory disease is a polymicrobial infection caused by an STI such as chlamydia or gonorrhea or by other pathogenic microorganisms that comprise the normal vaginal flora (Fig. 67.7; see Evidence-Based Practice: Another Bacterial Infection Associated With PID).

### Evidence-Based Practice

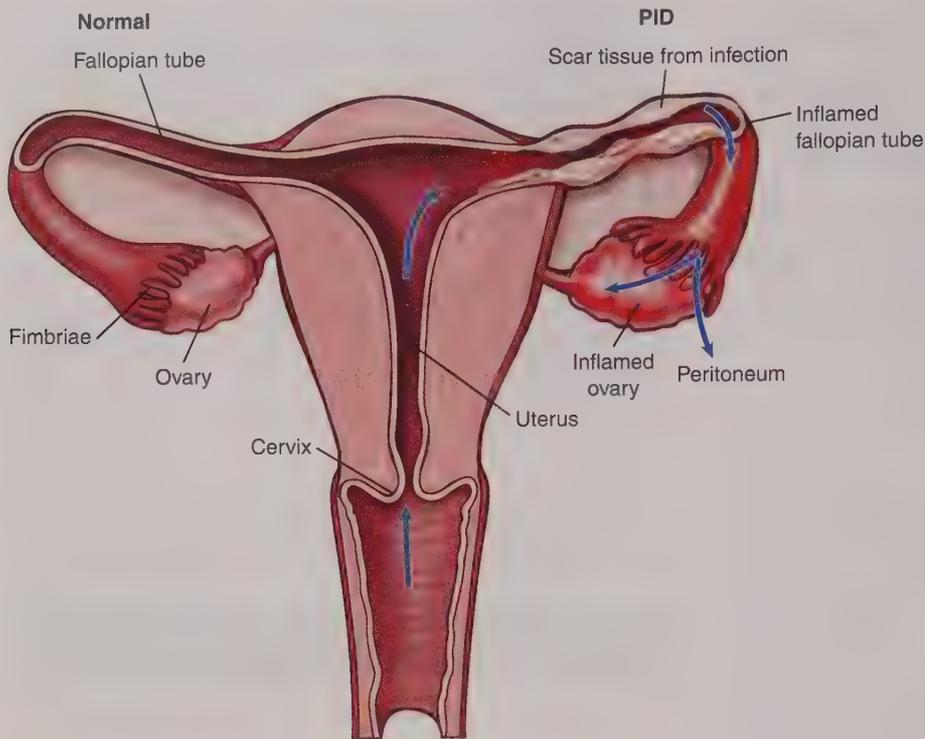

#### Another Bacterial Infection Associated With PID

There is growing evidence that *Mycoplasma genitalium*, a slow-growing sexually transmitted pathogenic bacterium, is associated with pelvic inflammatory disease (PID). This bacterial infection is seen in 0.4% of young adults. In males, *M genitalium* may cause urethritis (inflammation of the urethra) and is linked to nongonococcal urethritis (NGU) and nonchlamydial urethritis. Persistent and recurrent urethritis attaches itself to the epithelial cells. In women, *M genitalium* can be detected in the cervix and/or endometrium of women with PID. This infection in women is typically asymptomatic. *M genitalium* may cause PID and tubal infertility but not as often as chlamydia. There is no current diagnostic test approved by the U.S. Food and Drug Administration (FDA) available in the United States. However, with the advent of the nucleic acid amplification test (NAAT), more studies are being conducted to understand the pathogenicity (cause of disease) of this organism. Treatment is dependent on the symptoms associated with urethritis and cervicitis (inflammation of the cervix) or PID.

Centers for Disease Control and Prevention 2015 Sexually Transmitted Diseases Treatment Guidelines, 2015. Centers for Disease Control and Prevention. (2015). Sexually transmitted diseases treatment guidelines, 2015. *Morbidity and Mortality Weekly Report*, 64(3), 1–140. Retrieved from <http://www.cdc.gov> 20171217160447762587428

**FIGURE 67.7** Normal female anatomy (L) and female anatomy with pelvic inflammatory disease and its sequelae (R).

## Clinical Manifestations

Clinical manifestations of PID include:

- Lower abdominal pain
- Uterine tenderness
- Adnexal tenderness, which is pain in the ovaries or fallopian tubes noted during examination
- Cervical motion tenderness

## Management

### Medical Management

#### Diagnosis

Pelvic inflammatory disease is a challenge to diagnose due to the variety of symptoms and the subtle or lack of symptoms the patient may experience. Additionally, the clinical manifestations that present with a diagnosis of PID may have other causes, which should be ruled out. Diagnosis is primarily done through clinical observation of the presence of lower abdominal pain in combination with one or all of the clinical manifestations indicative of PID. Additional criteria that can reinforce a diagnosis of PID are the following:

- Oral temperature greater than 101°F (<math>38.3^{\circ}\text{C}</math>)
- Abnormal cervical or vaginal mucopurulent discharge or cervical friability
- Abundance of WBCs on saline microscopy of vaginal fluid
- Elevated C-reactive protein level
- Elevated erythrocyte sedimentation rate
- Laboratory-confirmed diagnosis of chlamydia or gonorrhea

Radiological imaging such as transvaginal ultrasound and magnetic resonance imaging (MRI) can be used as an aid in diagnosing PID if the clinical determination is uncertain. Other procedures used to diagnose PID are endometrial biopsy and laparoscopy. Doppler studies may be used if a pelvic infection is suspected. Laparoscopy, once viewed as the gold standard for diagnosis, detects limited symptoms of PID, such as **salpingitis** (inflammation of the fallopian tube). This procedure is difficult to justify given the variety of symptoms that can occur with PID in addition to salpingitis. Also, it can be costly and may promote increased procedural risks, such as infection, bleeding, and organ injury.

#### Treatment

Treatment of PID should be initiated as soon as the diagnosis is strongly suspected. Treatment may be done on an inpatient or outpatient basis. Inpatient hospitalization is considered for the following reasons:

- If the patient does not respond well to or tolerate oral antibiotics
- Pregnancy
- Severe illness
- Differential diagnoses such as tubo-ovarian abscess (TOA) or appendicitis
- Suspected ectopic pregnancy

Hospitalized patients should receive parenteral or IV antibiotic treatment for a minimal of 24 hours and should be changed to oral antibiotics when clinical symptoms improve. Outpatient treatment includes both a single intramuscular dose of ceftriaxone and oral antibiotics such as

metronidazole or doxycycline. It is important to educate patients to abstain from alcohol when taking metronidazole because of the potential of serious side effects. Both parenteral and oral regimens have comparable efficacies.

### Complications of PID

The complications of PID are chronic pelvic pain, infertility, and ectopic pregnancy. Occasionally, females with PID may be diagnosed with a TOA, an inflammatory mass involving the fallopian tubes, ovaries, and neighboring organs. A ruptured TOA can lead to peritonitis (inflammation of the peritoneum) or sepsis and is considered a surgical emergency. Ultrasound or computed tomography (CT) may be used to diagnose TOA. Patients with TOA should be hospitalized for at least 24 hours for treatment with parenteral antibiotics. After discharge, oral antibiotics are continued.

### Connection Check 67.6

The nurse recognizes that which of the following statements are true of PID? (Select all that apply.)

- A. Pelvic inflammatory disease is an acute infection that routinely descends from the upper genital tract to the cervix or vagina.
- B. If the patient is diagnosed with PID and is pregnant, inpatient admission should be considered.
- C. Symptoms such as lower abdominal pain and elevated blood pressure are specific criteria for PID.
- D. Laparoscopy is the only definitive test to diagnose PID.
- E. A tubo-ovarian abscess is a severe complication of PID.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of PID—lower abdominal pain, uterine and adnexal tenderness, and abnormal purulent vaginal discharge—are due to the inflammation occurring in the upper genital tract. Other manifestations are related to the inflammatory process, such as elevated temperature and increased C-reactive protein and sedimentation rates, both markers of inflammation.

#### Nursing Diagnoses

- **Acute pain** related to biological injury, inflammation, edema, congestion of the pelvic tissues
- **Anxiety** related to the disease/infectious process

#### Nursing Interventions

##### Assessments

- Pain  
*Lower abdominal pain with uterine or adnexal tenderness may be present because of the upper genital tract inflammation.*
- Unusual vaginal bleeding or discharge  
*Bleeding or discharge is due to irritation and inflammation in the genital tract.*
- Temperature  
*A fever may be due to the acute inflammatory process.*

- Sexual practices  
*Multiple partners and unprotected sex expose the patient to pathogens and thus increase the risk of STIs and PID.*
- Birth control  
*The presence of intrauterine devices disturbs the cervical barrier and allows for the movement of pathogens into the upper genital tract, as does douching.*
- Previous STI or PID  
*Repeated STIs or previous PID is a risk factor for PID.*

##### Actions

- Administer antibiotics as ordered.  
*Prompt antibiotic treatment is necessary to prevent long-term sequelae from PID.*

##### Teaching

- Educate the patient on prevention, manifestations, transmission of STIs, reducing the number of partners, and barrier methods.  
*Safe sex can help decrease the occurrence of PID.*
- Avoid douching, tub baths, tampon use, and sexual intercourse during active infection.  
*Avoid activities that may bring bacteria into the upper genital tract.*
- Educate the patient on the importance of taking the entire prescribed therapy.  
*The patient may develop resistance to the antibiotic if the entire regimen is not completed.*
- Call the provider if experiencing worsening pain and/or vaginal discharge.  
*May be an indication of a worsening condition or complication*

### Evaluating Care Outcomes

Safe-sex practices can help decrease the occurrence of STIs and PID. A well-managed patient receives early intervention that includes proper diagnosis, the establishment of an effective antibiotic regimen, and suitable follow-up and maintenance to avoid the potential complications of PID.

#### Safety Adolescents and STIs Alert

Young people 15 to 24 years old account for nearly half of the 20 million reported STI cases. Vulnerable adolescents engage in risky behavior for affection, social status, and sexual desire. They can be easily influenced by the media and/or peer pressure. Some adolescents possess a false sense of invincibility and denial because they do not see the deleterious and potentially life-long effects resulting from the infections. Engagement in these risky sexual behaviors can lead to unfavorable outcomes. Schools, youth-serving programs, family, the community, and online and mobile technologies should support and promote positive, healthy behavioral changes, preferably before the onset of sexual intercourse. Counselors and health professionals should be readily available to promote healthy communication

between adolescents and their parents. Educational content should be all-inclusive and developmentally appropriate to promote abstinence. It should discuss the myths and harmful effects of acquiring an STI, risk factors, and sexual and non-sexual strategies that can limit contraction and transmission.

## Making Connections

### CASE STUDY: WRAP-UP

On completion of Keisha's physical assessment and radiology test, the provider diagnoses her with PID. She is given an intramuscular shot of ceftriaxone and sent home with a prescription for oral doxycycline and metronidazole to be taken for 14 days. Keisha's nurse educates her about the medications and provides information on steps to make positive lifestyle changes related to drinking, smoking, and unhealthy sexual practices. Keisha is asked to return within 3 days to check the status of symptoms and to obtain the results of her test.

Keisha returns in 3 days as requested. She states that she is feeling much better, which is confirmed by a clinical examination by her provider. All results are negative except for chlamydia. Keisha is informed that the chlamydia can be treated with doxycycline, so no additional antibiotics are necessary. Keisha is very interested in making some lifestyle changes because the diagnosis of PID has really scared her. The nurse provides Keisha with community resources, the number to the local health department, and informative Web sites to assist her in making these modifications for better health. She is asked to return in 3 months to be retested for at-risk STIs.

#### Case Study Questions

- Keisha is diagnosed with chlamydia during her recent examination. The nurse is aware that this infection can transcend the upper genital tract and lead to which clinical manifestations if untreated?
  - Leg/calf tenderness, adnexal tenderness, pelvic tenderness
  - Heavy menses, abdominal pain, fatigue
  - Elevated C-reactive protein, positive rapid plasma reagin (RPR), elevated erythrocyte sedimentation rate (ESR)
  - Uterine tenderness, abdominal pain, cervical motion tenderness
- Keisha is diagnosed with PID. If left untreated, what complication is she at risk for developing?
  - Uterine prolapse
  - Polycystic ovary syndrome
  - Infertility
  - Endometriosis
- Keisha is prescribed metronidazole (Flagyl) as part of the medications she needs to take after discharge. When addressing this medication, what should the nurse explain?
  - "This medication should be taken only on an empty stomach."
  - "This medication should be refrigerated."
  - "When you take this medication, alcohol should be avoided."
  - "When you start feeling better, this medication can be discontinued."
- The nurse provides recommendations for which healthy lifestyle changes for Keisha? (*Select all that apply.*)
  - Avoid sexual intercourse while under the influence of drugs or alcohol.
  - Limit the number of sexual partners.
  - Utilize condoms if engaging in sexual activity.
  - Seek out reputable Web sites to become properly informed about STIs.
  - Abstain from sexual intercourse.
- Which statements by Keisha indicate that teaching has been effective? (*Select all that apply.*)
  - "I know I should eat well and limit sexual activity for a while."
  - "I can expect my symptoms to improve within 3 days."
  - "There is no point in telling my boyfriend; I can't give him PID!"
  - "I should call my provider if I experience a fever, increased abdominal pain, vaginal discharge, or nausea and vomiting."
  - "Because I was prescribed doxycycline, I know I should avoid prolonged exposure to sunlight."

## CHAPTER SUMMARY

Human papillomavirus (HPV) is a very common sexually transmitted infection (STI) of the anogenital tract. Risk factors are related to sexual behavior, including early onset of sexual activity, multiple partners, and unprotected sex. Females with nononcogenic HPV may experience symptoms of genital warts. Oncogenic HPV is the precursor to cervical cancer. The Papanicolaou (Pap) test is the most used tool to screen females for cervical cancer. Human papillomavirus DNA testing, an evaluation of cells scraped from the cervix, is used to detect high-risk oncogenic HPV and is routinely ordered in women 30 years and older.

Syphilis is classified into four stages: primary, secondary, latent (early and late), and tertiary. Syphilis is most infectious during the primary and secondary phases. Latent phases are

not contagious, but if not treated, severe complications can occur. The tertiary stage is a rare complication of syphilis developing 10 to 30 years after the initial infection. This stage may affect a multitude of organs, causing tissue damage and disfigurement, cardiovascular damage, and central nervous system (CNS) changes. However, neurosyphilis can occur at any stage. The risk factors are similar to those of other STIs and include early onset of sexual activity, multiple partners, and unprotected sex. The therapy for all stages of syphilis is penicillin.

Genital herpes is a common, chronic, and at-present, incurable STI caused by herpes simplex virus 1 (HSV-1) and herpes simplex virus 2 (HSV-2). The risk factors for genital herpes are similar to those of other STIs. The clinical manifestations include an outbreak of clear vesicles or blisters in the genital area that rupture and form a painful ulcer several days later. Medication therapy consists of antiviral medications used to suppress the infection and provide symptom relief.

*Chlamydia trachomatis* (chlamydia) is the most common sexually transmitted bacterial infection. The majority of individuals who contract chlamydia do not have symptoms.

The complications include infertility, tubal abscesses, ectopic pregnancy, chronic pelvic pain, and Fitz–Hugh–Curtis syndrome (perihepatitis, or inflammation of the peritoneal covering of the liver). Medication therapy consists of doxycycline or azithromycin as first-line treatment.

*Neisseria gonorrhoeae* (gonorrhea) is the second most common bacterial STI, after to chlamydia. They commonly occur together. The clinical manifestations include vaginal discharge, intermenstrual bleeding, anorectal discomfort, dysuria, and cervicitis—inflammation of the cervix. Medication therapy consists of a combination of ceftriaxone (injection) and azithromycin (orally).

Pelvic inflammatory disease (PID) is an acute infection that originates from the vagina or cervix and ascends to the upper genital tract—the uterus, fallopian tubes, and ovaries. The risk factors for PID are similar to those of other STIs. The clinical manifestations of PID include lower abdominal pain, uterine tenderness, and adnexal tenderness. The treatment of PID is IV or oral antibiotics, which should be initiated as soon as the diagnosis is strongly suspected. The complications of PID are chronic pelvic pain, infertility, and ectopic pregnancy.

## Promoting Health in Special Populations

### Chapter 68

## Managing Care for the Adult Patient With Obesity

*Alice Moore*

#### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Describing the epidemiology of obesity.
2. Describing the pathophysiology of obesity
3. Correlating clinical manifestations to pathophysiological processes of obesity
4. Describing the diagnostic results used to confirm the diagnosis of obesity
5. Discussing the medical management of obesity
6. Describing complications associated with morbid obesity
7. Developing a comprehensive plan of nursing care for patients with obesity
8. Developing a teaching plan for a patient with obesity

#### CONCEPTS

- Assessment
- Medication
- Metabolism
- Nutrition
- Perioperative

#### ESSENTIAL TERMS

Anastomosis  
Anorexigenic  
Bariatrics  
Basal metabolic rate  
Body mass index (BMI)  
Dumping syndrome  
Energy expenditure  
Leptin  
Obesogenic  
Satiety

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Lauren Wiley is a 34-year-old who was diagnosed with obesity 15 years ago. She has tried various dietary and exercise programs along with pharmaceutical options. Lauren describes that her weight is interfering with her ability to walk and participate in social activities with her family. She is currently 5 ft 6 in. tall and weighs 256 lb. She presents to her primary care provider to discuss a referral to a bariatric surgeon for weight loss...

## CLASSIFICATIONS OF BODY WEIGHT

The degree to which a person has excess adipose tissue is classified in terms of being overweight and obese. **Body mass index (BMI)** is routinely used to classify body weight and correlates with total body adiposity. Body mass index is calculated by weight in kilograms divided by height in meters squared.

$$\text{BMI (kg/m}^2\text{)} = \frac{\text{Weight (kilograms)}}{\text{Height (meters)}^2}$$

Table 68.1 lists body weight classifications based on the National Institutes of Health (NIH) criteria.

In addition to BMI, waist circumference and overall health risks are important in the management of patients who are overweight or obese. Increased waist circumference correlates with abdominal adiposity. Subcutaneous and intra-abdominal adiposity significantly increases morbidity. In adults with a BMI of 25 to 34.9 kg/m<sup>2</sup>, a waist circumference of greater than 102 cm (40 in.) in men and greater than 88 cm (35 in.) in women denotes an increased relative risk of obesity-related risk factors. The presence

**Table 68.1 Classification of Body Weight**

NIH Classification	BMI (kg/m <sup>2</sup> )
Underweight	Less than 18.5
Normal weight	18.5–24.9
Overweight	25.0–29.9
Obesity (class 1)	30.0–34.9
Obesity (class 2)	35.0–39.9
Extreme obesity (class 3)	Greater than 40.0

BMI, Body mass index; NIH, National Institutes of Health.

of obesity-related diseases, obesity-associated conditions, cardiovascular risks, and other risks increases the need for weight reduction in patients who are overweight and obese. Due to this growing prevalence of obesity, **bariatrics**, the medical specialty that focuses on the causes, prevention, and treatment of obesity, has expanded over the last decade.

### Connection Check 68.1

Using the NIH classification for BMI, the nurse identifies the patient with a BMI of 32 kg/m<sup>2</sup> as which category?

- Overweight
- Class 1 obesity
- Class 2 obesity
- Extreme obesity

## EPIDEMIOLOGY

### Prevalence

Obesity has reached epidemic levels in the United States. According to the Center for Disease Control and Prevention, in 2017, the obesity prevalence rates in all states revealed that more than 20% of adults are obese. States ranged from 20% or less of the state population in Colorado and Hawaii to 35% or more in seven other states (Alabama, Arkansas, Iowa, Louisiana, Mississippi, Oklahoma, and West Virginia). In 2015–2016, 39.8% of adult Americans, approximately 93.3 million people, were considered obese; this is an increase from the 2011–2013 percentage of 34.9%. It is estimated that in 2013, of those persons categorized as obese, 41%, or 33.7 million people, were categorized as class 2 obesity or higher. On the basis of current trends, it is projected that 42% of all American adults will be obese by 2030.

### Effects of Long-Term Obesity

Obesity increases mortality and significantly increases morbidity. Obesity and obesity-associated conditions significantly increase hospital length of stay and overall healthcare costs. Medicare and Medicaid finance 42% of the total medical costs attributed to obesity. In 2013, Medicaid paid nearly 11%, or \$8 billion, of the cost to treat conditions associated with severe obesity and predicted an increase of \$941 in annual per-capita medical expenditures for moderately obese adults and an increase of \$1,980 for severe obesity. Annual hospital costs are \$160 million higher in patients who are obese and undergo the most common nonbariatric surgical procedures compared with their normal-weight counterparts.

### Impact on Mortality

Obesity causes a marked decrease in life expectancy, and the all-cause mortality (death from any cause) risk increases in patients with a BMI of greater than 30 kg/m<sup>2</sup>. In the United States, the all-cause mortality rate is 20% higher in adults

with obesity compared to adults with normal weight. The effect of a high BMI on mortality also increases with age. Class 2 and class 3 obesity in adults aged 45 to 64 is associated with premature death of at least 7 years from all-cause mortality and 10 years from cardiovascular disease-specific mortality.

### Impact on Morbidity

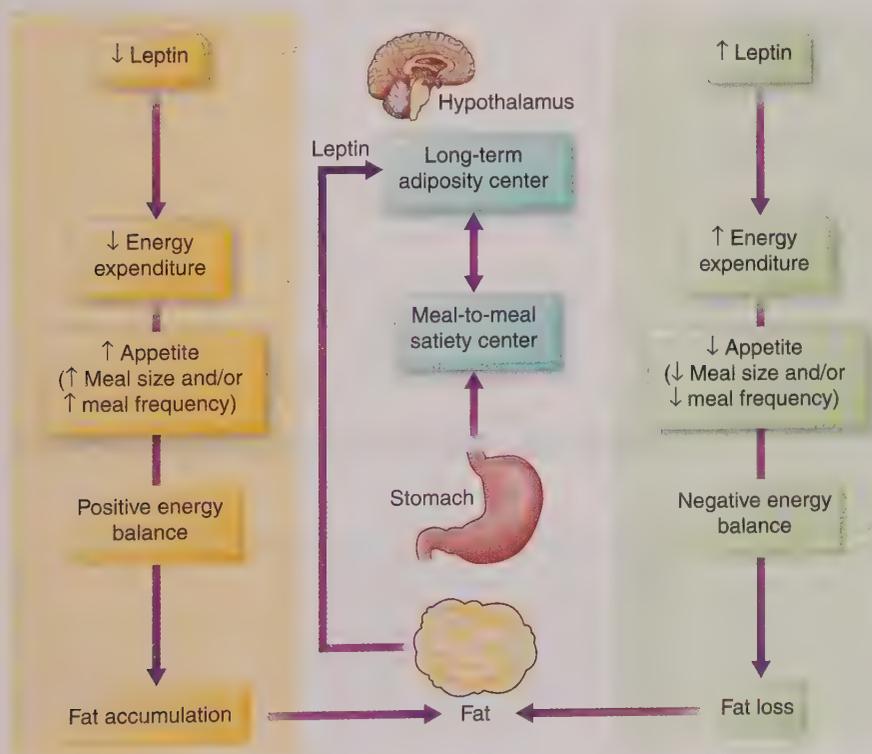

Obesity is linked to numerous chronic health conditions, and there is a strong association between obesity and its major comorbidities. Type 2 diabetes mellitus (DM) is the most prevalent, with the overlap between type 2 DM and obesity being about 50%. Heart disease is the second most prevalent and is associated with metabolic syndrome, which is defined as central obesity, high serum triglyceride levels, lower serum high-density lipoprotein, elevated total cholesterol levels, hypertension, and elevated fasting blood glucose. These top two are followed by other comorbidities such as airway obstruction, chronic kidney disease, nonalcoholic fatty liver disease, infertility issues, gastroesophageal reflux disease (GERD), cancer, increased medication prescription for pain relief, and psychiatric disorders.

Obesity also increases the risk of stroke and obstructive sleep apnea. Gastrointestinal conditions such as GERD, cholelithiasis, and nonalcoholic fatty liver disease are increased in patients with obesity. Osteoarthritis is increased in non-weight-bearing and weight-bearing joints, suggesting that the disease of obesity itself rather than solely mechanical trauma causes the increase in osteoarthritis. Increased BMI is associated with a decreased glomerular

filtration rate with progression to chronic kidney disease. Obesity increases the risk of cancer and also increases the likelihood of dying from cancer. Reproductive abnormalities are also seen. Obesity is associated with a decrease in psychosocial aspects of health, such as well-being and quality of life, and is related to an increase in social stigmatization and discrimination. Having a diagnosis of more than one comorbidity is highly associated with obesity and an increasing BMI category.

### PATHOPHYSIOLOGY

The regulation of body weight is a complex interplay between appetite and **energy expenditure**. The hypothalamus is signaled by hormones, metabolites, and neural pathways to regulate appetite. Figure 68.1 displays the complex mechanisms that contribute to appetite. The majority of energy expenditure is in the form of basal metabolism, or the amount of energy required to maintain vital organ function, also referred to as the **basal metabolic rate**. **Leptin**, a hormone produced by fat cells, plays a major role in body weight. Two major roles of this hormone are communicating **satiety** (the feeling of being satisfied with the amount of food eaten) to the hypothalamus and regulating energy expenditure or balance. In addition, energy expenditure comes from an increase in physical activity or exercise and the metabolic requirements of metabolizing and storing food, along with thermogenesis, which varies according to chronic caloric intake levels. Weight gain occurs when the intake of caloric nutrients exceeds energy expenditure.

**FIGURE 68.1** The complex mechanisms that contribute to appetite. The regulation of body weight is a complex interplay between appetite and energy expenditure. The hypothalamus is signaled by hormones, metabolites, and neural pathways to regulate appetite. Leptin communicates satiety to the hypothalamus and regulates energy expenditure or balance. The majority of energy expenditure is in the form of basal metabolism. Energy expenditures also come from an increase in physical activity or exercise and the metabolic requirements of metabolizing and storing food, along with thermogenesis. Weight gain occurs when the intake of caloric nutrients exceeds energy expenditure.

Obesity is a complex disease in which genetic, environmental, biochemical, and behavioral factors intertwine, and most patients with obesity have more than one factor contributing to their disease. Genetic factors are well documented and contribute to more than 50% of variations in BMI. People with relatives who are obese are more likely to develop obesity. Identical twins, regardless of whether they are raised together or apart, are likely to have similar BMIs. Specific genetic mutations have been found and have led to an increased understanding of obesity. Most of the genetic defects identified affect appetite, such as leptin and melanocortin-4 receptor mutations. Genetic polymorphisms have been linked to obesity in several populations. The discovery of these mutations has led to increased understanding of the powerful biological nature of appetite and has resulted in obesity being seen as a medical condition as opposed to a moral failing.

Environmental factors have a significant role in obesity. **Obesogenic** environments, those that cause obesity, coupled with genetic factors likely account for the majority of the increase in obesity. Increased availability and access to high-calorie, high-fat foods have led to increases in caloric consumption. Other environmental factors, such as automation, have led to a decrease in energy expenditure because the availability and preparation of food require much less activity.

### Connection Check 68.2

In correlating contributing factors with the pathophysiology of obesity, which factor is considered environmental?

- A. Increased appetite
- B. Automation
- C. Growth hormone deficiency
- D. Obese family members

Behavioral factors such as physical inactivity also promote obesity. In addition to an increase in energy expenditure from physical activity, increased muscle mass increases the basal metabolic rate and helps to increase energy expenditure. Binge eating and compulsive eating are also behavioral factors that promote obesity.

Biochemical alterations can be genetic or acquired. Medication therapy is one cause of acquired biochemical alteration. Many medications are obesogenic and increase appetite. The precise actions of these medications are not specifically understood, although these medications are frequently used to treat conditions in patients with obesity. Box 68.1 lists commonly prescribed obesogenic medications.

There are also many secondary causes of obesity. Cushing's disease (hypersecretion of cortisol), insulinoma (insulin-secreting tumor of the pancreas), hypothyroidism, polycystic ovarian syndrome, hypogonadism, pregnancy, and growth hormone deficiency are a few examples of secondary disorders.

## Box 68.1 Obesogenic Medications

- Hypoglycemic agents
- Antihypertensive medications
- Hormones
- Antihistamines
- Anticonvulsants
- Antipsychotics
- Antidepressants

### Connection Check 68.3

The nurse correlates which clinical manifestations with the pathophysiology of obesity? (*Select all that apply.*)

- A. Increased waist circumference
- B. Increased basal metabolic rate
- C. Binge eating
- D. Joint pain
- E. Yellowish skin

## MANAGEMENT

### Medical Management

Clinical practice guidelines on the identification, evaluation, and treatment of adults who are overweight or obese direct the management of obesity (Box 68.2; see Evidence-Based Practice: Clinical Practice Guidelines for Obesity Treatment).

## Evidence-Based Practice

### Clinical Practice Guidelines for Obesity Treatment

Clinical practice guidelines are important for the delivery of evidence-based care to patients. There are many myths about obesity and obesity management. Nurses should follow the “2013 AHA/ACC/TOS Guideline for the Management of Overweight and Obesity in Adults” when making recommendations to patients about obesity treatment.

Jensen, M. D., Ryan, D. H., Apovian, C. M., Ard, J. D., Comuzzie, A. G., Donato, K. A., . . . Obesity Society. (2014). 2013 AHA/ACC/TOS guideline for the management of overweight and obesity in adults: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines and The Obesity Society. *JAMA: Journal of the American College of Cardiology*, 63(25 pt. B), 2985–3023.

## Box 68.2 Healthy People 2020 Goal

Promote health and reduce chronic disease risk through the consumption of healthful diets and achievement and maintenance of healthy body weights.

## Laboratory Testing

Laboratory testing in obesity is aimed at the identification of secondary causes and comorbid risk factors, and specific tests are selected on the basis of the results of the history and physical examination. Because of the prevalence of concomitant disease, laboratory testing may include screening for diabetes mellitus, dyslipidemia, thyroid dysfunction, and fatty liver disease. Initial laboratory tests include fasting blood glucose or hemoglobin A1C, liver function tests, fasting lipoprotein panel, and thyroid-stimulating hormone (TSH). Elevations in TSH may point to primary hypothyroidism, whereas decreased TSH and decreased triiodothyronine and thyroxine may indicate secondary hypothyroidism. In patients with physical characteristics of Cushing's disease, 24-hour urine collection for urinary free cortisol excretion should be performed to assess for excessive cortisol secretion leading to weight gain.

## Diagnostic Testing

Diagnostic testing is seldom indicated to diagnose or treat obesity, and a thorough history and physical examination usually determine whether further diagnostic testing is necessary. Diagnostic tests are used to evaluate for comorbidities of obesity. An overnight sleep study is used to test for sleep apnea. A right upper quadrant ultrasound tests for fatty liver disease. Transvaginal ultrasonography is used to evaluate for ovarian cysts. An electrocardiogram (ECG) or echocardiogram may be used for patients with obesity who have a high risk of cardiovascular disease.

Accurate ECG lead placement is important in all patients, but particular attention is needed in performing a 12-lead ECG in patients with obesity. Patient size can obscure landmarks and result in improper lead placement. Electrocardiogram abnormalities, such as T-wave abnormalities, left axis deviation and low QRS voltage, can be seen in obesity in the absence of clinical symptoms.

It is important to note the impact of obesity on radiological testing. Computed tomography (CT), magnetic resonance imaging (MRI), fluoroscopy, and plain radiograph tables all have weight limits, typically 350 to 450 lb. A 2008 survey found that one-quarter of all U.S. emergency departments were unable to obtain CT imaging for patients greater than 350 lb, and two-thirds were not able to obtain MRI studies. More than 90% of emergency departments were unable to perform CT or MRI studies on patients greater than 450 lb. In addition, excess abdominal adiposity obscures organs and traditional landmarks, making the diagnosis of many conditions more difficult. Because of attenuation through excess adipose tissue in ultrasound, plain radiographs, and nuclear medicine, CT is the preferred imaging modality for patients with obesity. The utility of ultrasonography in the morbidly obese is severely limited.

## Connection Check 68.4

Which diagnostic result does the nurse assess in the patient with obesity to evaluate for concomitant Cushing's disease?

- A. Growth hormone
- B. Thyroid-stimulating hormone
- C. Urine cortisol excretion
- D. Hemoglobin A1C

## Treatment

### Weight-Loss Therapy

All adults with a BMI greater than or equal to 30 kg/m<sup>2</sup> should be assisted with developing weight-related goals and treatment. Those with a BMI greater than or equal to 25 kg/m<sup>2</sup> or with a high-risk waist circumference and greater than or equal to two other risk factors should also begin weight-loss therapy.

### Diet Therapy

Diet modification, increased physical activity, and behavior therapy are the mainstays of all weight-loss regimens. Diet therapy is developed and individualized between the health-care provider and the patient. A calorie reduction of 500 to 1,000 calories daily (kcal/day) results in a 1- to 2-lb (2.2- to 4.4-kg) weight loss weekly if the patient is currently maintaining a stable weight. Very low-calorie diets, those less than 800 kcal/day, are used only in limited circumstances and only under the supervision of a healthcare practitioner in a medical setting where frequent monitoring can be accomplished because of the potential risk for complications.

### Physical Activity

Physical activity is important for all adults. Long-term goals of 30 minutes of moderate-intensity exercise on most, if not all, days of the week are recommended. Increased physical activity in patients with obesity can increase daily energy expenditure and increase the basal metabolic rate by increasing lean body mass.

### Behavioral Therapy

Behavioral therapy combined with diet and physical activity is recommended. Self-monitoring via food logs, stimulus control, social support, and cognitive restructuring is encouraged. Patients with obesity can find Internet, as well as face-to-face, weight-loss programs that offer behavioral therapy. A psychological evaluation may be considered if there is a suspected eating disorder.

### Medications

Pharmacotherapy should be considered in patients with a BMI greater than or equal to 30 kg/m<sup>2</sup> or with a BMI greater than or equal to 27 kg/m<sup>2</sup> with one or more obesity-associated comorbidities whose weight-loss attempts have been unsuccessful in the past. It should be employed only in the presence of diet, exercise, and behavioral therapy and requires close observations by a healthcare provider. The

potential risks of medication treatment should be weighed against the benefits, and a thorough health examination should take place prior to starting any pharmacotherapy.

The majority of weight loss occurs within the first 6 months of starting a medication. Several medications currently available for the long-term treatment of obesity include orlistat; lorcaserin; phentermine-topiramate extended release; bupropion-naltrexone extended-release tablet; and liraglutide, a daily injectable.

Orlistat (Xenical, Alli) inhibits pancreatic lipase, thereby reducing dietary fat absorption. The prescription brand of orlistat (Xenical) is supplied in a 120-mg capsule and should be taken three times per day with any meal that contains fat. The over-the-counter version of orlistat (Alli) is supplied in a 60-mg capsule. Orlistat causes a modest increase in weight loss of 5 to 7 pounds over a year period. Persons who take the medication may also report the lowering of blood pressure and are less likely to develop type 2 diabetes. Common side effects of the medication include significant gastrointestinal symptoms, including increased flatus, loose and oily stools, abdominal cramping, and nausea. Rare cases of liver injury, a serious side effect, have been reported, and symptoms include dark urine, itching, light-colored stools, loss of appetite, or jaundice. Because of the mechanism of action, it may also decrease the absorption of fat-soluble vitamins (A, D, E, and K) and beta-carotene. Patients are instructed to take a multivitamin 2 hours before or after taking orlistat. It is contraindicated in patients with cholelithiasis, hepatic disease, pancreatic disease, or malabsorption syndrome.

Lorcaserin (Belviq) affects chemicals in the brain that help to regulate appetite and increase the feeling of fullness after eating so that less food is eaten. Lorcaserin is taken twice daily, and the expected weight loss is 3% to 5% of an individual's weight. Common side effects include headache, dizziness, nausea, fatigue, constipation, and dry mouth. Lorcaserin is contraindicated in patients with severe depression and cardiac or valvular disease.

Phentermine/topiramate-extended release (Qsymia) is a combination medication. Phentermine is approved by the U.S. Food and Drug Administration (FDA) to suppress appetite for up to 12 weeks. Topiramate is approved for the treatment of seizures and migraines, and weight loss was observed to be a side effect associated with decreased appetite and enhanced satiety. Phentermine/topiramate is taken once daily and produces the most weight loss, as much as 9% of initial weight. To minimize side effects, the combination of phentermine/topiramate contains lower dosages of each medication than if used alone. Common side effects include altered taste, numbness, tingling, insomnia, dizziness, and anxiety. Because phentermine/topiramate may cause birth defects, females must use a reliable form of birth control and receive pregnancy tests on a monthly basis during treatment.

Bupropion-naltrexone (Contrave) is a combination medication typically used as a second option in the treatment of obesity. It was approved by the FDA in September 2014 as an adjunct to diet and exercise in patients with a BMI of greater than 30 kg or greater than 27 kg in the presence of at least

one weight-related comorbidity. The initial dose is one tablet daily for 1 week, which is then increased to two tablets twice daily by week 4. It is approved for up to 12 weeks and results in the loss of approximately 5% to 6% of body weight. Common side effects are headache, insomnia, vomiting, dizziness, and dry mouth. It can raise blood pressure, and cardiovascular effects have not been yet established. It contains bupropion, an antidepressant, and the FDA recommends counseling in patients aged 18 to 24 for risks of suicidal ideations.

Liraglutide (Saxenda) is the only FDA-approved injectable medication for weight loss. It is an adjunct to a reduced-calorie diet and increased physical activity for chronic weight management in adults with a BMI of greater than 30 kg or greater than 27 kg with at least one weight-related comorbid condition. Dosing is done through daily injection, with the initial dosing titrated up by weekly increments to the target dose of 3 mg to reduce the gastrointestinal (GI) side effects of nausea and vomiting. The mechanism of action is via slowing gastric emptying. It is contraindicated in patients with medullary thyroid cancer (MTC). Common side effects of liraglutide include headache, nausea, diarrhea, and an increase in the resting heart rate.

Phendimetrazine (Bontril PDM), diethylpropion (Tenuate), benzphetamine (Regimex), and phentermine (Adipex-P, Lomaira) are available for short-term treatment of up to 12 weeks for obesity. They decrease appetite, also known as an **anorexigenic** effect. They may also increase satiety, and through these mechanisms, patients may experience weight loss. Because of their sympathomimetic effects, these medications should be used with caution in patients with hypertension and are contraindicated in patients with cardiovascular disease, hyperthyroidism, arrhythmias, agitation, insomnia, or glaucoma. Common side effects include insomnia, headache, dry mouth, and irritability. Because of the chronic nature of obesity, these medications are not strongly supported by treatment guidelines. Patients often develop tolerance within several weeks.

**Safety Alert** Patients with cardiovascular or heart valve disease should be monitored closely for adverse effects if prescribed lorcaserin or phentermine/topiramate for weight loss. Phendimetrazine, diethylpropion, benzphetamine, and phentermine are contraindicated in patients with cardiovascular disease because of their sympathomimetic effects.

### Connection Check 68.5

In administering orlistat to a patient for weight loss, the nurse recognizes which as the mechanism of action of this medication?

- Reducing fat absorption
- Suppressing appetite
- Increasing satiety
- Accelerating metabolic rate

## Surgical Management

### Bariatric Surgery

Diet, physical activity, behavioral therapy, and pharmacotherapy are ineffective in many patients with obesity. Bariatric surgery, a procedure intended to lead to weight loss, is an option for patients who have a BMI greater than or equal to 40 kg/m<sup>2</sup>. Patients with a BMI of 35 to 39.9 kg/m<sup>2</sup> with comorbidities or a significant reduction in quality of life should also be considered for surgery (see Evidence-Based Practice: Bariatric Surgery). In 2011, a total of 340,768 bariatric surgeries were performed worldwide. The American Society of Metabolic and Bariatric Surgery estimated that the number of surgeries in the United States grew from 158,000 in 2001 to 228,000 in 2017, with approximately 59.39% of these procedures being sleeve gastrectomy (Box 68.3).

## Evidence-Based Practice

### Bariatric Surgery

The Cochrane Collaboration performed a systematic review of 22 bariatric surgery studies in 2014. The review indicated that bariatric surgery results in greater weight loss than conventional treatment and that body mass index (BMI) was on average 6 kg/m<sup>2</sup> lower 2 years after surgery. In addition, patients had improvements in quality of life and management of diabetes mellitus.

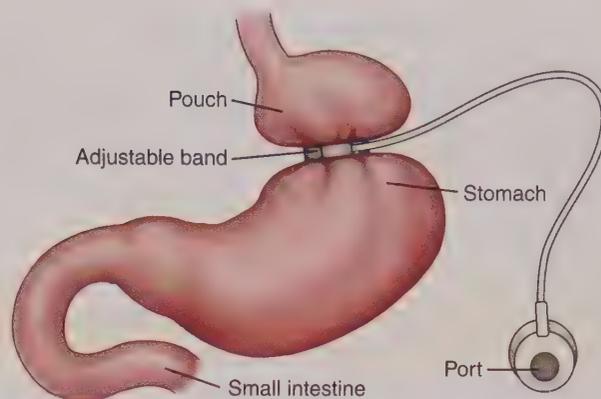

Colquitt, J. L., Pickett, K., Loveman, E., & Frampton, G. K. (2014). Surgery for weight loss in adults. *Cochrane Database of Systematic Reviews*, 8. doi:10.1002/14651858.CD003641.pub4

## Types

Bariatric surgical procedures include restrictive, malabsorptive, and combination techniques. Most procedures are performed openly or laparoscopically, dependent on the surgeon's expertise and the patient's history of abdominal surgery, degree of obesity, and other medical conditions. More than 90% of the procedures are performed laparoscopically.

### Restrictive Procedures

Restrictive procedures cause weight loss by reducing gastric capacity and include adjustable gastric banding (AGB), sleeve gastrectomy, and gastric plication. Laparoscopic AGB (Fig. 68.2) involves the placement of a silicone band

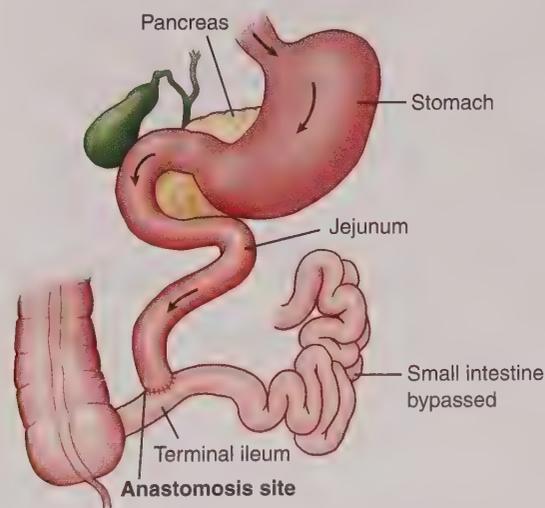

**FIGURE 68.2** Adjustable gastric banding (AGB). Laparoscopic AGB involves placement of a silicone band around the fundus of the stomach, causing a restriction in the amount of food intake.

around the fundus of the stomach, causing a restriction in the amount of food intake. The band can be adjusted by a healthcare provider to decrease or increase the amount of restriction by injecting saline through a subcutaneous port in the abdominal wall. During a sleeve gastrectomy, most of the greater curvature of the stomach is removed, creating a smaller, sleeve-like tube. The remaining stomach is approximately 25% of its original capacity. Gastric plication, a new procedure, is still considered investigational. This procedure involves infolding of the greater curvature of the stomach to create gastric restriction.

### Malabsorptive Procedures

Although malabsorptive procedures are no longer commonly performed and account for only 2% of the surgeries performed worldwide, there are many patients who had these procedures in the past and require regular follow-up care. These procedures induce weight loss through decreased nutrient absorption; jejunioleal bypass and biliopancreatic diversion are examples of these procedures. Jejunioleal bypass (Fig. 68.3) is

**FIGURE 68.3** Jejunioleal bypass procedure (JIB). A jejunioleal bypass is an end-to-end anastomosis of the jejunum to the terminal ileum, bypassing a large portion of the small intestine, causing malabsorption.

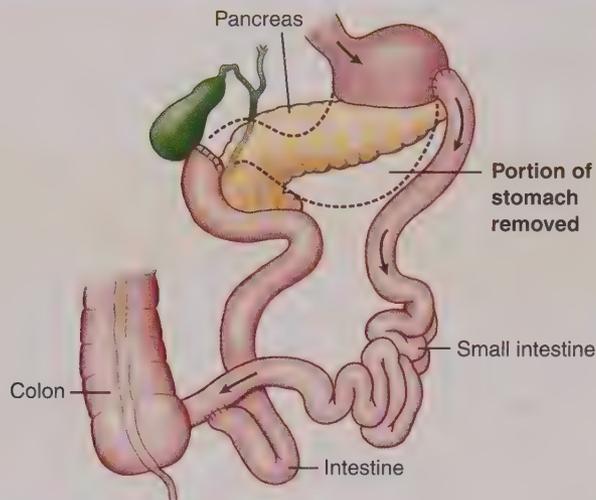

## Box 68.3 Health Disparities

Obesity is more prevalent among middle-aged, rural, economically and educationally disadvantaged, and racial/ethnic minority populations, yet these patients are unlikely to have bariatric surgery.

an end-to-end **anastomosis** (surgical connection between structures that were surgically removed) of the jejunum to the terminal ileum, bypassing a large portion of the small intestine, where the majority of nutrient absorption occurs. Biliopancreatic diversion (Fig. 68.4) involves a bypass of the majority of the small intestine and the removal of a large portion of the stomach, causing malabsorption.

### Combination Procedures

Combination approaches induce weight loss primarily through restriction but also create a component of

**FIGURE 68.4** Biliopancreatic diversion (BPD). Biliopancreatic diversion involves a bypass of the majority of the small intestine and removal of a large portion of the stomach, causing malabsorption.

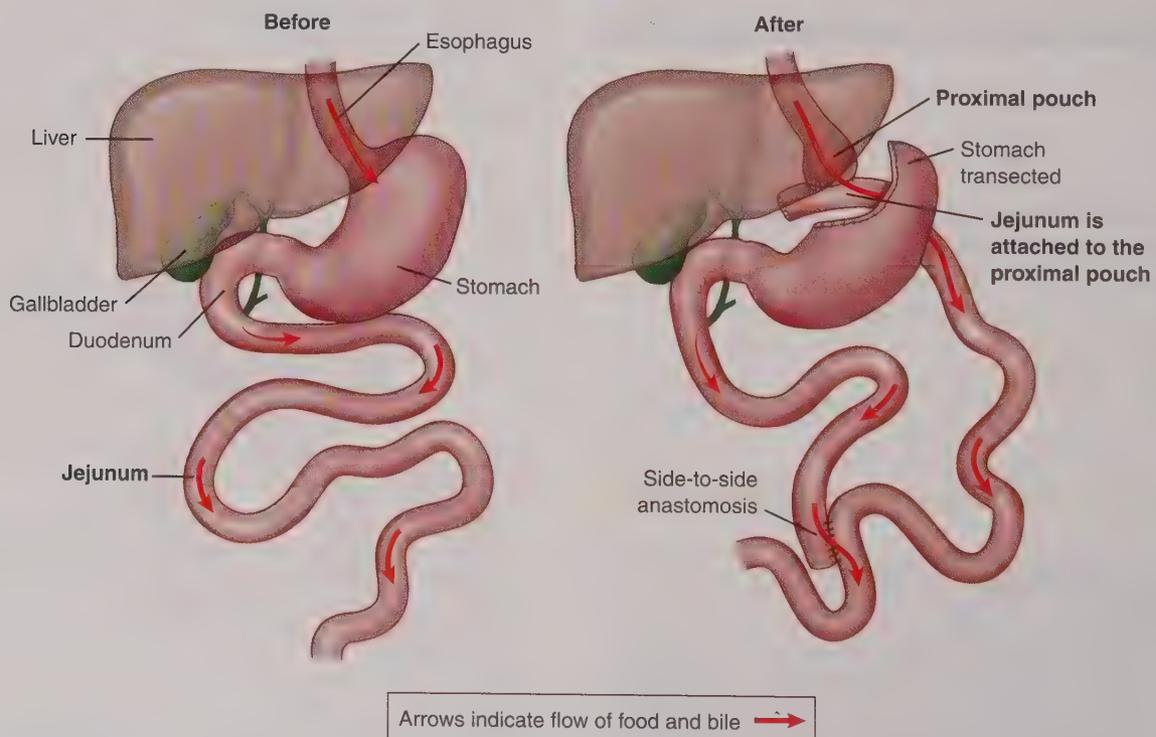

malabsorption. The Roux-en-Y gastric bypass (RYGB; Fig. 68.5) is a combination procedure that involves the creation of a restrictive 30-mL gastric pouch and bypass of a portion of the small intestine, causing mild malabsorption. The Roux-en-Y gastric bypass is the most commonly performed (46.6%) bariatric surgery worldwide.

### Complications

Recent data show that the 90-day mortality rate after bariatric surgery is 0.11%, and the 30-day mortality rate is 0.09%. Several other studies have shown a mortality rate consistently under 1%. With the improvement in surgical techniques, mortality rates have steadily declined and are significantly less than those for other commonly performed surgical procedures.

As with all surgeries, there are complications, and they vary depending on the type of surgery. Overall, short-term life-threatening complications of bariatric surgery include pulmonary embolism, infection, and anastomosis leak. Long-term complications and side effects include band slippage, obstruction, hernia, esophageal erosion, ulcers, acid reflux, vitamin deficiency, osteoporosis, anemia, and **dumping syndrome**. Dumping syndrome is the result of stomach contents being rapidly “dumped” into the small intestine and occurs because of this rapid delivery of large amounts of osmotically active solids and liquids into the duodenum. The following clinical manifestations are often observed with this syndrome:

- Nausea
- Vomiting
- Abdominal pain, cramps

**FIGURE 68.5** Roux-en-Y gastric bypass (RYGB). Roux-en-Y gastric bypass is a combination procedure that involves the creation of a restrictive 30-mL gastric pouch and bypass of a portion of the small intestine, causing mild malabsorption.

- Diarrhea
- Dizziness, light-headedness
- Bloating, belching
- Fatigue
- Heart palpitations, rapid heart rate

## CASE STUDY: EPISODE 2

Ms. Wiley is referred to a bariatric surgeon by her primary care provider. Other than her obesity, Ms. Wiley also has mild hypertension and chronic joint pain. She is referred to an information session on bariatric surgery, and after this session, she decides to have laparoscopic RYGB surgery. The surgery is planned for the following week...

### Connection Check 68.6

The nurse assesses for which clinical manifestations of dumping syndrome in the patient after bariatric surgery? (Select all that apply.)

- A. Nausea
- B. Increased urine output
- C. Hypoglycemia
- D. Diarrhea
- E. Abdominal cramping

## Nursing Management

### Assessment and Analysis

Patients with obesity undergoing bariatric surgery are at risk for complications. Because bariatric surgery is considered a major abdominal surgery, patients can be expected to remain hospitalized for 1 to 2 days. Patients undergoing bariatric surgery should be observed for complications related to both surgery and obesity. Complications specifically related to obesity and bariatric surgery in hospitalized patients include:

- Impaired breathing
- Increased risk of venous thromboembolism
- Increased risk of pressure injury
- Increased risk of skin infections
- Immobility
- Urinary and fecal incontinence
- Infection
- Increased risk of venous thromboembolism
- Anastomosis leak (a leak where dissected bowel is reattached together)
- Peritonitis
- Intestinal obstruction
- Atelectasis and pneumonia
- Dehydration
- Electrolyte imbalance related to vomiting
- Bleeding

**Safety Alert** Tachycardia, fever, hypotension, and abdominal pain should be reported immediately because they may be signs of anastomosis leak, a life-threatening complication associated with infection and sepsis.

### Nursing Diagnoses

- **Deficient fluid volume** related to malabsorption secondary to surgical procedure
- **Imbalanced nutrition: less than body requirements** related to poor nutrition prior to surgery and postoperative restriction
- **Impaired physical mobility** related to body habitus and postoperative pain
- **Acute pain** related to surgical incisions
- **Disturbed body image** related to obesity and failed attempts to lose weight
- **Anxiety** related to the surgical procedure

### Nursing Interventions

#### ■ Assessments

- Vital signs, using appropriately sized equipment  
*Body temperature, heart rate, respiratory rate, and blood pressure can point to early complications such as infection or bleeding. Elevated heart rate and decreased blood pressure may be secondary to hypovolemia, hemorrhage, or infection. Bariatric-sized blood pressure cuffs are essential to obtain proper readings in patients who are obese.*
- Oxygen saturation  
*Decreased ventilation due to obesity hypoventilation syndrome (OHS) and opioid analgesics can result in lower oxygen saturation.*
- Electrolytes  
*The patient is at risk for fluid and electrolyte disturbances, particularly with dumping syndrome.*
- Daily weight and intake and output  
*Dehydration and fluid overload are common in postoperative patients and can be identified through changes in weight and monitoring of intake and output.*
- Skin using a pressure-injury-prevention protocol  
*Increased weight and decreased mobility increase the risk of skin breakdown due to pressure as well as increased moisture.*
- Skinfolds (breast, groin, neck, abdomen, perianal) for irritation/fungal infections  
*Patients with obesity have increased skinfolds, which are prone to skin irritation and infection.*
- Incisions and drains  
*Signs of bleeding, anastomosis leak, and infection may be observed in incisional drainage and drains.*
- Pain  
*Postoperative pain not only decreases ventilation and mobility, but it can also be a sign of infection and other complications.*

### ■ Actions

- Obtain appropriately sized equipment for care (gowns, bed, chair, bedside commode, stretcher, wheelchairs, etc.).  
*Properly sized bariatric gowns are needed to provide patient dignity. A bariatric bed should be large enough to ensure the patient can turn and reposition. Skin should not be in contact with bed rails because this can lead to pressure injury. Bariatric chairs, bedside commodes, and wheelchairs/stretchers increase patient mobility, prevent injury, and allow safe patient transport.*
- Elevate head of bed 30 to 45 degrees if no contraindications  
*Obesity hypoventilation syndrome is worsened when patients are supine or prone. Elevating the head of the bed 30 to 45 degrees optimizes diaphragmatic excursion and minimizes the pressure of abdominal contents on the thoracic cavity.*
- Encourage use of incentive spirometer  
*Promotes increased lung expansion and decreases risk of atelectasis and pneumonia*
- Apply sequential compressive devices as ordered.  
*The risk for venous thromboembolism is increased in patients with obesity.*
- Encourage self-care and mobility as appropriate.  
*Early ambulation and mobility decrease the risk of venous thromboembolism and other complications associated with decreased mobility (atelectasis, pressure injury, constipation, etc.).*
- Turn patients with decreased mobility frequently, a minimum of every 2 hours, using additional staff as needed.  
*Skin injury is common in hospitalized patients who are obese and have decreased mobility, in part because of the difficulty in achieving rotational pressure relief for all body surfaces.*
- Use slide and transfer assistance devices as appropriate.  
*Proper equipment is essential for the safety of the patient and nursing staff when repositioning or transferring patients who are obese. Skin shearing and back injuries can be prevented.*
- Assist patient with skin care.  
*Patients with obesity commonly have difficulty with toileting and bathing, which, along with increased skinfolds, makes patients more prone to skin breakdown and infection.*
- Administer pain medication.  
*Pain management improves early ambulation and the use of the incentive spirometry. Intravenous patient-controlled analgesia is the suggested method of pain control in the first 24 to 48 hours after surgery or until the patient can transition to oral pain management.*
- Do not reposition a nasogastric tube (NGT); monitor the NGT for patency if applicable.  
*Repositioning or insertion of an NGT can perforate the new gastric staple or suture lines.*
- Introduce clear liquids as ordered.  
*Dehydration is common after bariatric surgery, so introducing and encouraging small sips of clear liquids as ordered decreases the risk of a fluid volume deficit.*

- Inform transportation and other departments of weight prior to transport.  
*Hospital equipment is often not properly sized for patients who are obese or overweight. In addition, some tests may not be able to be performed on certain equipment, and accommodations may need to be made before the patient arrives. Alerting staff early to bring proper equipment or prepare for the patient decreases patient embarrassment and decreases the risk of injury.*
- Collaborate with appropriate members of the health-care team: wound ostomy care nurse for skin assessment and specialty bed recommendation; physical therapy and occupational therapy; respiratory therapy; social services; clinical pharmacist; nutrition services.  
*Obesity is a complex disease, and proper care of this patient population requires a collaborative approach with other healthcare experts.*

### ■ Teaching

- Incentive spirometry, coughing, and deep-breathing exercises  
*Decrease risk of pneumonia and atelectasis*
- Sequential compression devices  
*Decrease risk of venous thromboembolism*
- Ambulation  
*Decreases risk of pneumonia, atelectasis, and venous thromboembolism*
- Postoperative lifting restrictions  
*Decrease hernia development or suture disruption*
- Postoperative and recovery activity  
*Exercise should begin in the immediate postoperative period to decrease the risk of operative complications and to begin lifelong healthy weight-management practices.*
- Postoperative dietary restrictions  
*Decrease risk of dehydration, suture disruption, and vomiting*
- Medication side effects  
*Pain medications may cause drowsiness and constipation. Patients should not drive, drink alcohol, or operate machinery while taking opioid pain medications. Patients should be taught about the increased risk of constipation as a side effect of opioid medications.*
- Care of wounds/drains  
*Wounds should be kept clean, dry, and covered. Jackson-Pratt drains should be emptied when they are half-full to decrease pull on the surgical site and should be kept clean to prevent infection.*
- Signs and symptoms to report to the healthcare provider  
*Shortness of breath, tachycardia, severe abdominal pain, fever, rigors, purulent discharge or redness at wounds, and hypotension can be indicative of life-threatening complications, such as pulmonary embolism, anastomosis leak, or infection, and need to be immediately reported to the healthcare provider.*
- Signs of dumping syndrome  
*Symptoms include nausea, vomiting, diarrhea, diaphoresis, tachycardia, salivation, fatigue, and dizziness, and this complication places the patient at risk of fluid and electrolyte disorders.*
- Available support groups  
*Patients who attend support groups are more likely to have better outcomes.*

## Connection Check 68.7

In which position does the nurse place the patient to minimize complications in the patient with OHS?

- A. Prone with hips elevated
- B. Head of bed elevated 30 to 45 degrees
- C. Side-lying with head flat
- D. Head of bed elevated 90 degrees

**Safety Alert** Never insert or reposition a nasogastric or orogastric tube on a patient who has had bariatric surgery because it can disrupt the suture line.

## Evaluating Care Outcomes

Obesity is a complex, multifactorial condition. Diet; exercise; and behavioral, pharmacological, and surgical interventions are available to treat the condition, and the primary expected outcome is weight loss. Community nursing interventions are crucial to decreasing the prevalence and reoccurrence of obesity. Prevention of complications related to obesity in hospitalized patients is important. The postoperative care of patients undergoing bariatric surgery is similar to that of patients undergoing other abdominal surgeries but has the added risks of pre-existing obesity. Nurses play a critical role in the follow-up of patients who have had postoperative bariatric surgery by monitoring for complications, supporting dietary and lifestyle changes, monitoring for nutritional deficiencies, and advocating for social support.

## Connection Check 68.8

Which statement by the patient being discharged after gastric bypass surgery indicates the need for further teaching?

- A. "I may need to take a multivitamin every day."
- B. "I may develop constipation while I am taking pain medications."
- C. "I should not lift anything heavy until cleared by the surgeon."
- D. "I should drink at least one cup of fluids with every meal."

## Making Connections

### CASE STUDY: WRAP-UP

Ms. Wiley undergoes gastric bypass surgery and has an uneventful postoperative course. On postoperative day 2, her bowel sounds return, the NGT is removed, and she is allowed sips of clear liquids. She is discharged to home the following day with instructions to monitor her temperature every 4 hours and to contact the surgeon if she has an elevated temperature, nausea and vomiting, or increased pain. She is to return to the bariatric surgeon for postoperative follow-up in 7 to 10 days.

## Case Study Questions

1. Ms. Wiley is 5 ft 6 in. tall and weighs 256 lb. The nurse calculates her BMI to be which value?
  - A. 19 kg/m<sup>2</sup>
  - B. 34 kg/m<sup>2</sup>
  - C. 41 kg/m<sup>2</sup>
  - D. 49 kg/m<sup>2</sup>
2. Ms. Wiley asks if she qualifies for bariatric surgery. What is the best response by the nurse?
  - A. "No. You are healthy and therefore do not qualify for bariatric surgery."
  - B. "Yes. You meet the BMI criteria, but I would not recommend bariatric surgery for someone so young. I know someone who died from it."
  - C. "No. You do not meet the BMI criteria for bariatric surgery."
  - D. "Yes. You meet the BMI criteria, but there are several other factors that determine whether someone should have bariatric surgery."
3. Ms. Wiley wants to know the key difference between the Roux-en-Y and adjustable gastric banding. Which explanation by the nurse is most accurate?
  - A. "Some surgeons just prefer one over the other."
  - B. "Roux-en-Y is a combination of a restrictive surgery and a malabsorptive surgery."
  - C. "Adjustable gastric banding is designed to be temporary."
  - D. "Roux-en-Y is a type of adjustable gastric banding."
4. The nurse is caring for Ms. Wiley in the presurgical suite. The patient asks, "Will you hold my hand? I am getting nervous. My mom told me this morning that I could die from this surgery." Which action by the nurse is best?
  - A. Patting the patient on the shoulder and covering her up
  - B. Asking her if she would like some alprazolam (Xanax) to calm her down
  - C. Holding her hand and listening to her concerns
  - D. Explaining that the percentage of people who die from bariatric surgery is small
5. The nurse is caring for Ms. Wiley in the post-anesthesia recovery unit. The patient is 2 hours post-gastric bypass surgery and has a nasogastric tube (NGT). The orders state that the NGT should be hooked up to low continuous suction. There is scant blood-tinged drainage coming from the tube. What action should the nurse take?
  - A. Call the surgeon right away.
  - B. Reposition the NGT.
  - C. Discontinue the NGT.
  - D. Document the findings.

## CHAPTER SUMMARY

On the basis of body mass index (BMI), patients are classified as underweight, normal weight, overweight, or obese (class 1, 2, or 3). Obesity occurs when energy expenditure is less than caloric intake. Obesity is a complex phenomenon involving genetic, behavioral, environmental, and biochemical processes. Obesity increases mortality and morbidity, such as diabetes, sleep apnea, hypertension, and gallbladder disease.

Diet, exercise, and behavioral treatment should be implemented in patients with a BMI greater than or equal to 30 kg/m<sup>2</sup> or greater than or equal to 25 kg/m<sup>2</sup> with risk factors. The pharmacological treatment of obesity is limited but should be considered in patients who have not been

successful with diet, exercise, and behavioral treatment who have a BMI greater than or equal to 30 kg/m<sup>2</sup> or a BMI greater than or equal to 27 kg/m<sup>2</sup> with other risk factors.

Bariatric surgery is considered in patients who have been unsuccessful with diet, exercise, and behavioral and pharmacological treatments and have a BMI of greater than or equal to 40 kg/m<sup>2</sup> or a BMI of greater than or equal to 35 kg/m<sup>2</sup> with additional comorbidities. There are three main types of bariatric surgery: restrictive, malabsorptive, and combination. Patients with obesity are at increased risk of respiratory, circulatory, and skin-related issues during hospitalizations. Complications vary depending on the type of bariatric surgery. Pulmonary embolism and infection are common complications that nursing interventions can significantly reduce.

## Substance Use Disorders in the Adult Population

*Wanda Edwards*

### LEARNING OUTCOMES

Content in this chapter is designed to support the learner in:

1. Describing the difference between physical dependence and substance use disorders and key features of both
2. Describing the essential features of mild, moderate, and severe substance use disorders
3. Describing the essential features of two substance-induced disorders, intoxication and withdrawal
4. Discussing the epidemiology of substance use disorders
5. Understanding how addictive substances affect the brain
6. Identifying common substances used by persons with a substance use disorder and general physical, behavioral, and psychosocial signs of common substance use disorders
7. Describing the clinical manifestations of specific substances commonly used by persons with a substance use disorder
8. Describing options for treating substance use disorders
9. Analyzing the nursing care priorities for the hospitalized patient with a history of one or more substance use disorders
10. Developing teaching strategies for adults with a diagnosis of substance use disorder

### CONCEPTS

- Addiction
- Assessment
- Communication
- Fluid and Electrolyte Balance
- Medication
- Nursing Roles
- Safety

### ESSENTIAL TERMS

Addiction  
Alcohol use disorder (AUD)  
Antagonist  
Behavioral therapy  
Blackouts  
Blood alcohol level (BAL)  
Cognitive-behavioral therapy  
Contingency management  
Craving  
Delirium tremens  
Detoxification  
Full agonist  
Intoxication  
Motivational interviewing  
Opioid  
Partial agonist  
Physical dependence  
Pleasure reward pathway  
Psychoactive drugs  
Screening, brief intervention, and referral to treatment (SBIRT)  
Substance use disorder (SUD)  
Tolerance  
Wernicke–Korsakoff’s syndrome  
Withdrawal

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

Ms. Mary Litfield is a 64-year-old widowed female who is admitted on Monday to the surgical service of a general hospital for resection of colon cancer. Her operation is very successful, but on Wednesday, when she is about to be transferred from the step-down unit to a regular surgical bed, there is a change in her condition. She becomes confused, anxious, and tremulous. Her pulse and blood pressure are elevated, and she seems to be responding to visual hallucinations. Her surgical team initially suspects pneumonia or a postoperative infection, but her temperature and white blood cell count are both normal, and her abdomen is soft. Radiographic examination of her chest and abdomen demonstrate no new problems, but abdominal ultrasonography reveals a fatty liver. Mary's nurse suspects alcohol withdrawal and calls her family to obtain more information. Mary's daughter tells the nurse that she has been worried about Mary's drinking. The death of her husband 2 years ago was very hard on her, but his life insurance provided enough money for her to take early retirement from her job as a high school English teacher. She has been spending a lot of time alone at home, not going out with her old friends, seems less interested in her two young grandchildren, and is sometimes irritable with them. Mary and her husband used to enjoy one or two cocktails together in the evenings, but her daughter expresses concern that her drinking may have increased...

## INTRODUCTION

Substances such as drugs, alcohol, and tobacco are abused for varied and complicated reasons. Substance abuse is the use of a substance in amounts that are harmful to the abuser or others, impacting individuals, families, and society. The individual who abuses substances may neglect important obligations or role responsibilities at home, school, or work. Ongoing interpersonal problems, such as the loss of friends or a marital separation, may occur. There may be family disintegration, loss of employment, failure in school, domestic violence, or child abuse. The individual who is abusing substances may expose him- or herself to dangerous situations, such as driving while intoxicated or having unprotected sex with a stranger. The substance use may continue even when the substance user is aware of actual and potential negative consequences. Society also pays a significant cost. The cost to the U.S. economy is estimated at hundreds of billions of dollars and includes increased

healthcare costs, crime-related costs, and costs associated with lost productivity.

## DIAGNOSTIC CRITERIA OF SUBSTANCE USE DISORDERS

In the *Diagnostic and Statistical Manual of Mental Disorders* (4th edition, Text Revision; *DSM-IV-TR*), “abuse” and “dependence” were defined as diagnoses. Dependence was considered a more severe form of substance abuse. In the fifth edition (*DSM-5*), the diagnosis of “**substance use disorder (SUD)**” replaces “abuse and dependence.” The *DSM-5* describes the essential feature of an SUD as “a cluster of cognitive, behavioral, and physiological symptoms indicating that the individual continues using the substance despite significant substance-related problems.” For a diagnosis of an SUD based on the *DSM-5*, the pattern of substance use must be problematic, must be associated with clinically significant manifestations, and at least 2 of 11 possible symptoms or criteria must be present (Table 69.1). The severity of an SUD is determined by the number of symptoms present: mild (two or three symptoms), moderate (four or five symptoms), or severe (six or more symptoms). In the *DSM-5*, the specific substance used is included as part of the diagnosis. If an individual uses alcohol and the use meets the criteria for an SUD, the diagnosis is **alcohol use disorder (AUD)**; an individual who uses marijuana has a diagnosis of cannabis use disorder if the marijuana use meets the criteria for an SUD.

**Tolerance, withdrawal, and craving**—three symptoms of **physical dependence**—are also clinical manifestations that may be evident with the diagnosis of an SUD. Dependence occurs because the body naturally adapts to regular exposure to a substance. The adaptation may lead to tolerance, withdrawal, or both. When tolerance develops, more of the substance is required to achieve the same effect. If a person who has an AUD has developed tolerance to alcohol, the person may be able to walk and talk with a **blood alcohol level (BAL)** that would seriously incapacitate the inexperienced drinker. Withdrawal is the occurrence of physical or emotional clinical manifestations if the substance is decreased or abruptly stopped.

Physical dependence may lead to craving (strong desire or persistent thoughts about the substance), which may be triggered by external or internal factors. External triggers include places, people, or things associated with the substance use patterns of the substance user. Internal triggers include emotional or physical symptoms of withdrawal.

Physical dependence is a separate condition from SUD. When medications with addictive properties are prescribed for an individual, it is not uncommon for the individual to develop physical dependence without engaging in the maladaptive behaviors that define an SUD. One example is a patient with cancer who is prescribed an opiate for pain; physical dependence may develop even when opiates are used as prescribed. Careful assessment and interprofessional team collaboration are essential for the accurate identification of clinical manifestations of physical dependence and for

**Table 69.1** Diagnosis of a Substance Use Disorder

Impaired Control	Social Impairment	Risky Use	Pharmacological Criteria
<b>Criteria 1–4</b>	<b>Criteria 5–7</b>	<b>Criteria 8–9</b>	<b>Criteria 10–11</b>
<ol style="list-style-type: none"> <li>1. Substance is often taken in larger amounts or over a longer period than was intended.</li> <li>2. There is a persistent desire or unsuccessful efforts to cut down or control substance use.</li> <li>3. A great deal of time is spent in activities necessary to obtain substance, use substance, or recover from its effects.</li> <li>4. Craving, or a strong desire or urge to use substance</li> </ol>	<ol style="list-style-type: none"> <li>5. Recurrent substance use resulting in a failure to fulfill major role obligations at work, school, or home</li> <li>6. The characteristic withdrawal syndrome for substance (refer to Criteria A and B of the criteria set for substance withdrawal in the <i>DSM-5</i>)</li> <li>b. Substance (or a closely related substance) is taken to relieve or avoid withdrawal symptoms.</li> </ol> </li> </ol>

*DSM-5, Diagnostic and Statistical Manual of Mental Disorders, 5th edition.*

A substance use disorder is a problematic pattern of substance use leading to clinically significant impairment or distress, as manifested by at least 2 of the 11 criteria listed in this chart, occurring within a 12-month time period.

The *DSM-5* criteria for Criterion A diagnosis of a substance use disorder fits into one of four broad categories: impaired control, social impairment, risky use, and pharmacological criteria.

Source: American Psychiatric Association. (2013). *Diagnostic and statistical manual of mental disorders* (5th ed.). Arlington, VA: Author, pp. 483–484.

determining the appropriate plan of action. If an individual on prescription pain medication develops tolerance to the prescribed medication, modification of the medication dose or frequency of dosing to adequately control pain may be required. The same individual may require further assessment to identify and address SUDs if symptoms are present that suggest the presence of an SUD.

### Connection Check 69.1

The patient with an SUD diagnosis may demonstrate which symptoms? (Select all that apply.)

- A. Failure to fulfill major role obligations at work, home, or school
- B. Recurrent use in situations in which it is physically hazardous
- C. Continued use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of the substance
- D. Withdrawal from the substance when the dose is decreased or stopped
- E. Successful attempts to cut down

## EPIDEMIOLOGY

### Prevalence

The development and manifestation of an SUD are influenced by genetic, psychosocial, and environmental factors. Common substances associated with hazardous or harmful use include alcohol, tobacco, and illicit drugs, including prescribed medications when used for nonmedical purposes (Table 69.2). In the United States, alcohol is the most commonly used drug; tobacco and marijuana are close seconds. Although tobacco and alcohol are legal, the patterns of use by individuals who use one or both of these substances frequently meet the criteria for a tobacco or alcohol use disorder. In 2016, 136.7 million people aged 12 and older in the United States (50% of the population) reported current use of alcohol. Among current alcohol users, 16.3 million (11.9%) met the criteria for heavy use, defined as five or more drinks on the same occasion on each of 5 or more days in the past 30 days. The rate of heavy drinking was highest among young adults aged 18 to 25 (57.1%). In 2016, the prevalence of any drinking; binge drinking, defined as drinking five or more alcoholic drinks on the same occasion on at least 1 day in the past 30 days; and heavy drinking

**Table 69.2 Commonly Used Addictive Substances**

<b>Substance Category and Generic and Brand or Chemical Name</b>	<b>Examples of Commercial and Street Names</b>	<b>How Used</b>
<b>TOBACCO</b>		
<b>Tobacco</b> Nicotine	Cigarettes E-cigarettes  Smokeless tobacco (chewing tobacco, snuff)	Smoked Vaped (inhalation of vapors produced by an electronic/battery-operated device) Chewed, sniffed
<b>CANNABINOIDS</b>		
<b>Cannabis/Hashish</b> Marijuana	Hashish: Hash, hash oil, hemp  Marijuana: Aunt Mary, BC bud, blunt (marijuana cigar), boom, chronic, dope, gangster, ganja, grass, hash, herb, hydro, indo, joint, kif, Mary Jane, mota, pot, reefer, sinsemilla, skunk, smoke, weed, yerba	Smoked, swallowed, vaped
<b>DEPRESSANTS</b>		
<b>Alcohol</b> Ethanol/alcohol	Booze, brew, juice, sauce, hooch	Swallowed
<b>Barbiturates</b> <i>Phenobarbital, Amytal, Nembutal, Seconal</i>	Barbs, reds, red birds, phennies, yellow jackets	Injected, swallowed, snorted
<b>Benzodiazepines</b> <i>Ativan, Halcion, Klonopin, Librium, Valium, Xanax</i> Flunitrazepam/ <i>Rohypnol</i>  Gamma-hydroxybutyric acid (GHB) Methaqualone/ <i>Quaalude</i>	<i>Ativan, Halcion, Klonopin, Librium, Valium, Xanax:</i> Candy, downers, sleeping pills  <i>Rohypnol:</i> Forget-me pill, Mexican Valium, R2, Roche, roofies, roofinol, rope, rophies  <i>Gamma-hydroxybutyrate:</i> G, Georgia home boy, liquid ecstasy  <i>Quaalude, Sopor, Parest:</i> Ludes, mandrex, quad, quay	Swallowed, injected
<b>HALLUCINOGENS</b>		
Phencyclidine (PCP and analogues) Ketamine/Ketalar	<i>Phencyclidine (PCP):</i> PCP, angel dust, supergrass, boat, peace pill, tic tac, zoom, Shermans, hog  <i>Ketamine:</i> Cat Valium, K, special K, vitamin K, kit kat	Injected, snorted, smoked, swallowed
<b>Other Hallucinogens</b> <i>Ayahuasca</i> (Combination of <i>Psychotria viridis</i> plant, which contains DMT, and <i>Banisteriopsis caapi</i> vine, which contains an MAO inhibitor)  <i>Lysergic acid diethylamide:</i> acid/LSD <i>Mescaline</i> <i>Psilocybin</i>	<i>Aya, Yagé, Hoasca</i>  <i>Lysergic acid diethylamide:</i> Acid, blotter, boomers, cubes, microdot, yellow sunshines  <i>Mescaline:</i> Buttons, cactus, mesc, peyote  <i>Psilocybin:</i> Magic mushrooms, mushrooms, shrooms	Brewed and ingested as tea  Swallowed, absorbed through mouth tissues, smoked

Table 69.2 Commonly Used Addictive Substances—cont'd

Substance Category and Generic and Brand or Chemical Name	Examples of Commercial and Street Names	How Used
<b>OPIOIDS AND MORPHINE DERIVATIVES</b>		
<b>Codeine</b>	<i>Empirin with Codeine, Fiorinal with Codeine, Robitussin-AC, Tylenol with Codeine:</i> Captain Cody, Cody, schoolboy; (with glutethimide) doors and fours, loads, pancakes and syrup	Injected, swallowed, smoked, snorted
<b>Fentanyl and fentanyl analogues</b> Actiq, Duragesic	<i>Actiq, Duragesic, Sublimaze:</i> Apache, China girl, dance fever, friend, jackpot, murder 8, TNT	
<b>Heroin</b> Diacetylmorphine	<i>Diacetylmorphine:</i> Brown sugar, dope, H, horse, junk, skag, skunk, smack, white horse	
<b>Morphine</b> Roxanol, Duramorph	<i>Roxanol, Duramorph:</i> M, Miss Emma, monkey, white stuff	
<b>Opium</b> Laudanum, paregoric	<i>Laudanum, paregoric:</i> Big O, black stuff, block, gum, hop	
<b>Oxycodone HCL</b> OxyContin	<i>OxyContin:</i> Oxy, OC, killer	
<b>Hydrocodone bitartrate</b> Acetaminophen/Vicodin	<i>Vicodin:</i> Vike, Watson-387	
<b>STIMULANTS</b>		
<b>Amphetamine</b> Biphetamine, Dexedrine	<i>Biphetamine, Dexedrine:</i> Bennies, black beauties, crosses, hearts, LA turnaround, speed, truck drivers, uppers	Injected, swallowed, smoked, snorted
<b>Cocaine</b>	<i>Cocaine hydrochloride:</i> Blow, bump, C, candy, Charlie, coke, crack, flake, rock, snow, toot	
<b>Methamphetamine</b> Desoxyn	<i>Desoxyn:</i> Chalk, crank, crystal, crystal meth, fire, glass, go fast, ice, meth, speed	
<b>Methylphenidate</b>	<i>Ritalin:</i> JIF, MPH, R-ball, Skippy, the smart drug, vitamin R	
<b>3,4-Methylenedioxymethamphetamine</b> MDMA	<i>MDMA:</i> Adam, clarity, ecstasy, Eve, lover's speed, Molly, peace, STP, X, XTC	
	<b>Note:</b> MDMA is a synthetic psychoactive drug with properties similar to those of both stimulant amphetamines and the hallucinogen mescaline.	

among college students (aged 18–22) was higher as compared to others in the same age group. There is wide variation in the prevalence of alcohol use among individual communities within the United States. In 2016, the prevalence of alcohol use was higher in the Northeast (36%) and Midwest (37%) and lower in the South (27%) and West (28%).

Although the legal drinking age is 21 in all states in the United States, there is a high prevalence of alcohol use among individuals between 12 and 20 years of age. In 2016 about 7.3 million young people (19.3%) under age 21 reported using alcohol during the past 30 days. Among current

underage users, approximately 4.5 million (12.1%) were binge drinkers, and 1.1 million (2.8%) were heavy drinkers. The rate of alcohol use among persons 12 to 20 was lower in 2017 compared to 2012. However, underage use of alcohol is still a significant public health issue.

The use of alcohol among women of childbearing age increases the risk of fetal alcohol spectrum disorders and other disorders associated with substance use among pregnant women. In the United States, 9.4% of pregnant women aged 15 to 44 reported current alcohol use, 2.3% reported binge drinking, and 0.4% reported heavy drinking.

Among nonpregnant women in the same age group, 55.4% reported alcohol use, 24.6% reported binge drinking, and 5.3% reported heavy drinking.

Although marijuana is legal now in some areas, it is the most commonly used illegal substance, with an estimated 24 million people (8.9% of the population) reporting use in 2016, up from 19.8 million users in 2013. It is estimated that 1 in 11 people who use marijuana develop a cannabis use disorder and that an estimated 1% of the American population meets the diagnostic criteria for a cannabis use disorder.

An estimated 4.6 million young adults and older were current users of illicit drugs other than marijuana in 2016. Nonmedical use of prescription medications accounted for the next highest number of illegal substances used (5.3 million persons, or 2.3% of the population). Individuals who used prescription psychotherapeutic medications for nonmedical purposes included 3.3 million misusers of pain relievers (1.4%), 2 million misusers of tranquilizers (0.7%), 1.7 million misusers of stimulants (0.6%), and 500,000 misusers of sedatives (0.2%). The prevalence of past-month illicit substance use in the United States in 2016 was 10.6% (Box 69.1).

Once on the decline, heroin use has increased over the past decade, and this rise is attributed largely to young people who are smoking or sniffing the drug rather than injecting it. The prevalence of opioid use, including heroin, in the United States in 2016 was 1.4% of the young adult and adult population.

Methamphetamine use has seen a dramatic increase over the last 25 years in the United States. Initially observed primarily in Hawaii and the western United States, methamphetamine abuse quickly spread eastward. In 2016, there were 700,000 users in the United States. Although cocaine

use has declined since its popularity soared in the 1980s and 1990s, the appeal of cocaine as a stimulant continues. In 2016, of the young adults and older adults in the U.S. population, 9% reported the use of cocaine during the past month.

Substance use is a factor in many preventable injuries and deaths. In the United States in 2015, 2,333 teens aged 16 to 19 were killed and 235,845 required emergency treatment for injuries suffered in motor vehicle crashes. In 2016, alcohol was a factor in 28% of all traffic deaths (10,497) in the United States; 15% involved a driver aged 15 to 20. There is a significant link between alcohol use and motor vehicle crashes, homicides, alcohol poisoning, falls, burns, drowning, and suicides. One in four patients admitted to medical and surgical services in general hospitals has an AUD.

Compared to 2013, drug-poisoning deaths in the United States increased among all age groups in 2016. There were 63,632 drug-poisoning deaths in 2016 compared to 43,982 in 2013. Natural and synthetic opioids such as oxycodone and hydrocodone were responsible for 14,487 poisoning deaths, and 15,469 drug-poisoning deaths involved heroin. Frequently, when drug poisoning is the cause of death, toxicology tests reveal the presence of more than one drug. In 2016, fentanyl or another synthetic opioid was involved in 50% of all overdose deaths in the United States, with fentanyl responsible for 19,413 deaths in 2016.

## Risk Factors

Multiple risk factors are associated with SUDs (Box 69.2). It is evident that no independent factor is sufficient to cause a SUD; rather, a complex interaction of multiple factors is responsible. Not everyone who has an opportunity to use an addictive substance does so, and not everyone who uses an addictive substance develops an SUD. Many individuals with biological, social, or environmental risk factors who use one or more substances do not develop an SUD.

## Genetics

Genetics influences the risk for SUDs. Research supports a genetic component for nicotine, alcohol, cocaine, opioid, and cannabis use disorders (see Genetic Connections:

### Box 69.1 Prescription Drug Abuse: A National Epidemic

- Prescription medications, such as those used to treat pain, attention deficit disorders, and anxiety, are being abused at a rate second only to marijuana among illicit drug users.
- In 2016, an estimated 11.8 million people reported misusing opioids in the past year. Among people who misused opioids, 11.5 million misused prescription pain relievers, and 948,000 used heroin.
- Among those who reported nonmedical use of a prescription medication, 5.3 million persons, or 2.3% of the U.S. population reported nonmedical use of prescription medication within the past 30 days.
- In 2016, drug-poisoning deaths were higher than in previous years. There were 63,632 drug-poisoning deaths in 2016 compared to 43,982 in 2013. Natural and synthetic opioids such as oxycodone and hydrocodone were responsible for 14,487 poisoning deaths, and 15,469 drug-poisoning deaths involved heroin.

### Box 69.2 Risk Factors for Substance Use Disorders

- Biology/genetics
- Ethnicity/gender/age
- Presence of other mental health disorders
- Early drug use
- Peer group pressure
- Childhood adverse events/history of sexual abuse
- Increased stress/crisis
- Home environment/family beliefs and attitudes
- Academic failure or poor social skills

Alcohol Use Disorders). Of course, an individual with the genetic predisposition for an AUD or another SUD cannot develop a disorder if the person does not drink alcohol or use drugs. The interaction of biology and environment truly determines whether an individual develops an SUD.

## Genetic Connections

### Alcohol Use Disorders

Rates of alcohol use disorders are substantially higher in the relatives of people with an alcohol use disorder than in relatives of people who do not have an alcohol use disorder, even in cases of people who have been adopted and not raised by their biological parent. It has been postulated that the genes a person is born with, in combination with environmental influences, account for about half of a person's vulnerability to substance use disorders (SUDs). With rapidly increasing access to online databases and data from genomic studies, including the Genome-Wide Association Studies catalog, genomic studies will quickly add to the understanding of the role of genetics in the development of SUDs.

### Ethnicity, Gender, Education, and Mental Health Disorders

A person's ethnicity, gender, and level of education and the presence of other mental health disorders are also associated with the risk of developing an SUD. Males are almost twice as likely as females to have an SUD. However, women are almost twice as likely as men to develop a sedative, hypnotic, or anxiolytic use disorder. In the United States, the prevalence of AUDs is significantly higher among men, Caucasians, Native Americans, younger and unmarried adults, and those with lower incomes.

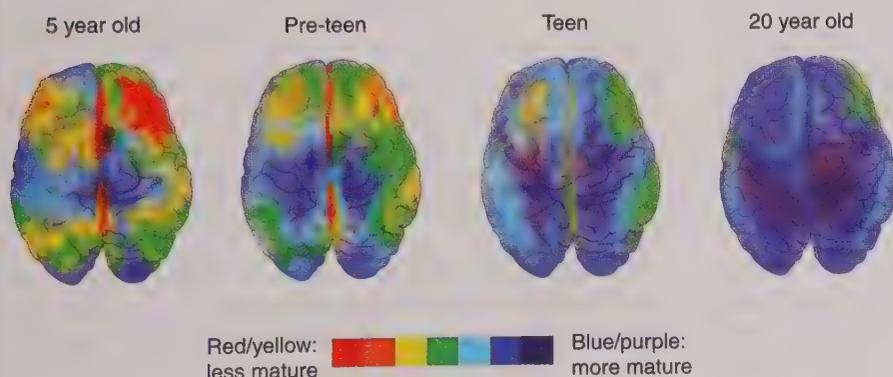

Education is identified as a factor associated with the nonmedical use of prescription stimulants. When compared to individuals in the same age group, nonmedical use of Adderall was higher among college students. Recently

reported statistics among college students in the United States demonstrate that the use of illicit drugs was highest for Caucasians (25.1%), followed by Hispanics (21.5%), then African Americans (19.7%) and Asians (9.4%). Looking at ethnicity as a risk factor for the use of illicit substances, the highest use rates were reported among persons of two or more races (17.4%) and Native Hawaiians or Other Pacific Islanders (14.0%), followed by American Indians or Alaska Natives (12.3%), African Americans (10.5%), Caucasians (9.5%), and Hispanics (8.8%). The lowest rate was reported among Asians (3.3%).

Individuals with other mental health disorders are at much higher risk than the general population of developing an SUD by approximately two to one. Associated mental health disorders include mood, anxiety, and personality disorders; eating disorders; attention deficit-hyperactivity disorder (ADHD); and conduct disorders in childhood.

### Age

A person's age at the initial use of an addictive substance is a strong risk factor for subsequent substance use problems. Often, initial substance use takes place in adolescence. When adolescent individuals first try an addictive substance, they might not be fully aware of the effect of the drug or the dangers and consequences of drug use. Adolescents' brains (Fig. 69.1) are still developing in the areas that govern decision making, judgment, and self-control, making them especially prone to risk-taking behaviors, including trying addictive substances. The likelihood of developing an AUD has been found to quadruple if drinking begins before the age of 15. The harmful effects of the drugs themselves on the developing brain may further increase the chances of future substance use problems. Once there has been an initial exposure to alcohol and other addictive substances, the likelihood of going on to use other drugs increases. Research has shown that teens who have an AUD and smoke marijuana are more likely to go on to use drugs such as cocaine and heroin. Stress is also strongly associated with the development of SUDs, with adverse events in childhood being a particularly significant risk factor. Adolescents are more likely to develop problems at times of change or increased stress, such as when there is a divorce, change in schools, or death in the family. Women are more likely than

**FIGURE 69.1** National Institute of Drug Abuse (NIDA) images of brain development in healthy children and teens (aged 5–20).

men to say their heavy drinking followed a crisis, such as miscarriage, divorce, or unemployment, or a recent departure of a child from the home. The use of alcohol is also increasing among adults aged 65 years or older.

The method of administration of a drug also increases its addictive potential. Smoking a drug or injecting it into a vein allows the drug to enter the brain within seconds. This intense, almost immediate “high” and the fact that the rush can fade in a few minutes may drive some individuals to repeated drug use in an attempt to recapture the initial pleasurable state.

### Psychosocial Risk Factors

Although there is no one reason why people decide to use drugs, one of the simplest reasons that people use drugs and alcohol is to *feel good*. Most addictive substances produce intense feelings of pleasure, making them highly desirable. Depending on the substance, the associated feelings can be those of power, increased self-confidence, increased energy, or a sense of creativity. For example, persons who use cocaine and other stimulants (such as methamphetamine) often experience an inflated sense of self and describe feeling energized and ready to take on anything. People who use heroin or marijuana often feel very relaxed and “mellow” after the initial euphoria.

Alcohol and other drugs are often portrayed as enhancing the enjoyment of social interactions. Many find that the shared activity of using drugs or drinking with others makes them feel part of a group, which is socially reinforcing. This can make stopping drinking or drugs all the more difficult. Not only does the substance user have to give up familiar activities, locations, and established socializing patterns on the path to recovery, but friendships with individuals who continue to use may also have to be relinquished.

Another reason people use drugs is to *feel better*. Not uncommonly, people who suffer from social anxiety, stress-related disorders, and depression begin abusing drugs in an attempt to lessen feelings of distress. Stress can play an important role in the initiation and maintenance of drug use and the relapse back to the use of drugs and alcohol. Significant associations are found between SUDs and co-occurring mental health illness, including mood, anxiety, and personality disorders. The term “self-medicating” refers to individuals who take drugs in an attempt to cope with genuinely difficult problems such as stress, trauma, and the symptoms of mental health disorders. It is important, however, to remember that these drugs are not prescribed medications, and they frequently exacerbate the very conditions they are being used to relieve.

Just as some individuals use drugs to *feel good* or *feel better*, others use them in an attempt to *be the best*. With increasing pressure on individuals to achieve more in the classroom, in the boardroom, or on the court, more individuals are using drugs to enhance their cognitive and athletic performance. College campuses across the nation have seen dramatic

increases in the numbers of students abusing stimulant drugs such as methylphenidate (Ritalin) and dextroamphetamine (Adderall) in an effort to achieve established goals, such as staying awake and focused during long hours of studying or working.

### Connection Check 69.2

The nurse recognizes that which patient(s) are at risk for developing problems with substance abuse? (*Select all that apply.*)

- A. The 14-year-old girl whose family has just moved and who is smoking and drinking after school with friends
- B. The 17-year-old senior in high school who has untreated ADHD and whose mother has an AUD
- C. The 32-year-old mother of two with a past history of binge drinking in college whose husband just left her
- D. The 52-year-old executive with severe back pain who typically drinks cocktails in the evenings after work
- E. The 64-year-old recently retired man who has an occasional drink in the evening after work

### HOW PSYCHOACTIVE DRUGS AFFECT THE BRAIN

To understand how an SUD can be considered a disease, the nurse must appreciate the intricate communication system going on inside the brain. To function normally, the brain must maintain a careful balance of neurotransmitters. These small molecules carry messages between nerve cells (neurons) to help regulate the body’s function and behavior. **Psychoactive drugs** are chemicals that, in one way or another, tap into this communication system and disrupt the way the neurons normally send, receive, and process information. There are at least two ways that drugs are able to do this: (1) by imitating the brain’s natural chemical messengers (neurotransmitters) and/or (2) by overstimulating the “reward circuit” of the brain.

Researchers have found that marijuana and heroin can activate neurons because they have a structure similar to that of a natural neurotransmitter and thus are able to “fool” the brain’s receptors, causing abnormal messages to be transmitted. Cocaine and methamphetamine disrupt the brain’s communication system in another way. These stimulant drugs can cause the nerve cells to either release abnormally large amounts of natural neurotransmitters or prevent the brain’s transporters from recycling these neurotransmitters, which is required to shut off the signal between neurons. Either way, a greatly amplified message is produced.

Fundamentally, all drugs of abuse, including nicotine and alcohol, stimulate a common reinforcement pathway, the **pleasure reward pathway**. Directly or indirectly, these drugs target the brain’s reward system by flooding the circuit with

dopamine. Dopamine is present in regions of the brain that control movement, emotion, motivation, and feelings of pleasure. The dopaminergic system normally responds to natural behaviors that are linked to survival, such as eating or spending time with loved ones. The overstimulation of the dopaminergic system, which produces euphoric effects, sets in motion a pattern that “teaches” people to repeat the behavior of abusing drugs. As a person continues to abuse drugs and alcohol, the brain starts to adapt to these chemical changes by producing less dopamine or by reducing the number of dopamine receptors in the reward circuit. As a result, dopamine’s impact on the reward circuit is lessened, reducing the abuser’s ability to enjoy the drugs and the things that previously brought pleasure. This conditioning leads individuals with an SUD to experience uncontrollable cravings when they see a place or person they associate with the drug experience (trigger) even when the drug itself is not available.

With ongoing exposure, the brain may become insensitive to the effects of drugs or alcohol. This, in turn, can cause the individual to require larger amounts of the drug (tolerance) to achieve the euphoria or “dopamine high.” Long-term use causes changes in other brain chemical systems and circuits as well. Glutamate is a neurotransmitter that influences the reward circuit and the ability to learn. Alteration of glutaminergic function by an SUD can impair cognitive function. Brain imaging studies of individuals with one or more SUDs show changes in areas of the brain that are critical to judgment, decision making, learning and memory, and behavior control. Together, these changes can cause a person with an SUD to seek out and take drugs compulsively despite adverse consequences.

### Connection Check 69.3

Which reaction in the brain results from drugs causing overwhelming surges of dopamine?

- Production of more of the neurotransmitter
- Increase in the number of receptors that can receive and transmit signals
- An increased ability to respond to pleasure
- A decreased ability to respond to pleasure

## SUBSTANCES AND CLINICAL MANIFESTATIONS

In virtually every practice setting, nurses encounter patients struggling with one or more SUDs. There are general physical, behavioral, and psychosocial signs the nurse should be alert to that may indicate a patient is abusing drugs and/or alcohol (Box 69.3). To provide safe and individualized care, it is helpful for the nurse to be aware of categories and names of substances commonly used by persons with SUDs, examples of commercial and street names, and methods and routes of use (see Table 69.2) and their clinical manifestations.

## Box 69.3 Physical, Behavioral, and Psychological Signs of Hazardous Substance Use

### Physical Signs

- Bloodshot eyes
- Pupils larger or smaller than usual
- Changes in appetite
- Sudden weight loss or gain
- Changes in sleep patterns
- Deterioration of physical appearance and personal grooming habits
- Unusual smells on breath, body, or clothing
- Tremors, slurred speech, or impaired coordination

### Behavioral Signs

- Poor performance or missed days at school or work
- Financial troubles; unexplained need for money; may borrow or steal to get money
- Secretive or suspicious behaviors
- Change in peer group, hangouts, favorite activities, or hobbies
- Frequently getting into trouble (fights, accidents, illegal activities)

### Psychological Signs

- Unexplained changes in personality or attitude
- Sudden mood swings, irritability, or angry outbursts
- Periods of unusual hyperactivity, agitation, or giddiness
- Lack of motivation; appears lethargic or “spaced out”
- Appears fearful, anxious, or paranoid for no apparent reason

### Connection Check 69.4

The nurse working in the pediatric clinic is performing substance abuse screenings on all children aged 12 to 18 as part of a community effort to identify at-risk teens. The nurse should consider which teen at greatest risk?

- The 13-year-old girl who has recently been irritable and moody
- The 14-year-old boy being treated for diagnosed ADHD with prescription stimulants
- The 15-year-old who recently entered high school and appears down, reports trouble sleeping, and has difficulty concentrating
- The 17-year-old cheerleader who quits the squad, suddenly changes her group of friends, and has been acting very secretive at home

## Alcohol

### Categories of Alcohol Use

Alcohol use can be defined by the pattern of use and amount consumed (e.g., binge or heavy) or by the number of symptoms and consequences associated with its use (e.g., mild,

moderate, or severe). The amount of alcohol consumed and the pattern of use are also indicators of an individual's risk (i.e., low, moderate, or high) of developing an AUD. According to guidelines developed by the National Institute on Alcohol Abuse and Alcoholism, persons at risk for developing an AUD are men who consume more than 4 drinks and women who consume more than 3 drinks on a single occasion or more than 14 drinks in a week for men and more than 7 for women. The guidelines for persons aged 65 and older are the same as the guidelines for women under 65. Heavy alcohol use is defined as five or more drinks on the same occasion on each of 5 or more days in the past 30 days. Binge drinking is defined as drinking five or more alcoholic drinks on the same occasion on at least 1 day in the past 30 days or a pattern of drinking that brings BALs to 80 mg/dL. This typically occurs after four drinks for women and five drinks for men are consumed within about 2 hours.

The category of “moderate” alcohol consumption is used for individuals whose alcohol use falls between abstinence (i.e., no use of alcohol) and heavy use. According to the Dietary Guidelines for Americans, moderate drinking is up to one drink per day for women and up to two drinks per day for men. In the United States, a standard drink is any drink that contains about 14 g of pure alcohol. Among individual alcohol users, the definition of one “standard” drink may vary. In Figure 69.2, examples are given of a “standard” drink based on the choice of alcoholic beverage—beer, malt liquor, table wine, or 80-proof spirits. Table 69.3 quantifies the number of standard drinks in common container sizes sold in the United States. According to Table 69.3, if an individual reports drinking one beer daily, clarification of the meaning of *beer* (beer or malt liquor) and the size of the container (12, 24, or 40 oz) is needed to more accurately estimate the number of “standard” drinks consumed daily.

### Effects

Alcohol is a central nervous system depressant that affects several areas of the brain (Fig. 69.3). When alcohol reaches the brain, it interferes with communication between nerve cells by interacting with the receptors on some cells.

**FIGURE 69.2** Examples of a “standard” drink based on the choice of alcoholic beverage, beer, malt liquor, table wine, or 80-proof spirits.

Alcohol enhances inhibitory nerve pathway activity at gamma-aminobutyric acid A (GABA<sub>A</sub>) receptors, which has the effect of making a person sluggish. Additionally, alcohol reduces excitatory neurotransmission at glutamate N-methyl-D-aspartate receptor (NMDA) receptors, serving to further enhance sluggishness. Although the entire brain is affected, the cerebellum, responsible for balance, coordination, and movement, and the frontal lobes, responsible for cognition, memory, thought, and learning, are most heavily affected by alcohol consumption.

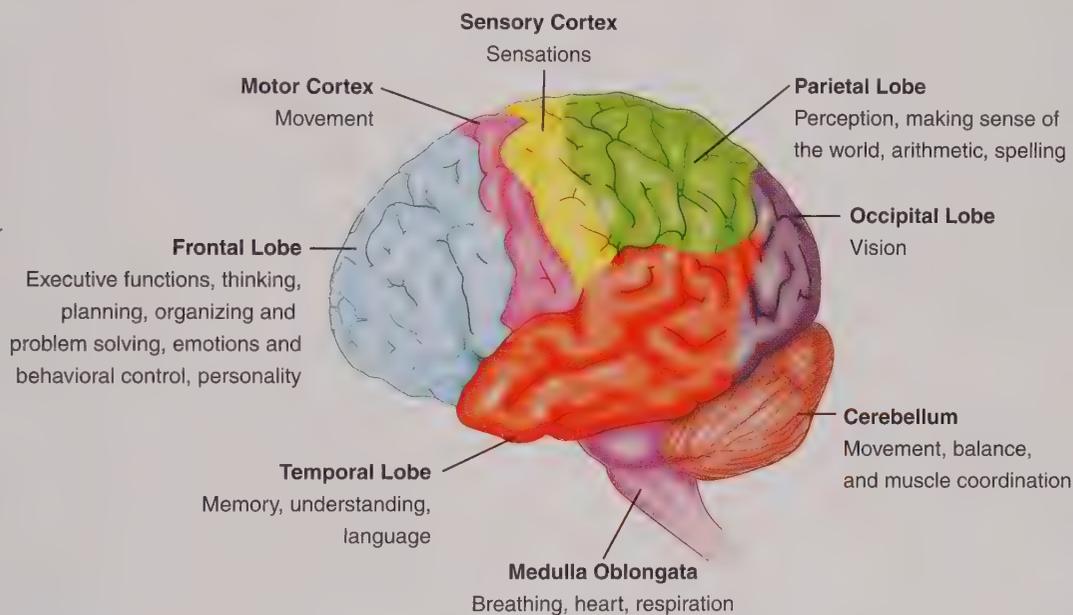

The short-term effects of alcohol vary on the basis of a number of factors, such as a person's size, the setting, the amount and time of consumption, hydration levels, and whether a heavy meal is being consumed. In general, though, in low doses, alcohol's effects include euphoria, mild stimulation, relaxation, and lowered inhibitions. In higher doses, alcohol causes drowsiness and symptoms of **intoxication**, such as slurred speech, decreased reaction time, further disinhibition, nausea/vomiting, emotional volatility, loss of coordination, visual distortions, impaired memory, nystagmus, unsteady gait, sexual dysfunction, and loss of consciousness. Both the quantity of alcohol ingested and the rate of the rise of the BAL determine the level of intoxication (Table 69.4). Changes in behavior and functional abilities are usually observable at BALs of 20 mg/dL or higher. Examples of behaviors and functional ability at BALs of 20 to 40 mg/dL are shown in Table 68.4 along with the equivalent blood alcohol concentration (BAC) in grams per deciliter (g/dL) and percentage of alcohol in the blood. The amount of ingested alcohol required to reach a specific BAL varies among individuals. Body weight, gender, and percentage of body fat influence the BAL. **Blackouts** are intervals of time for which the intoxicated person cannot recall key details of events. They are thought to be much more common in social drinkers than previously assumed and occur during a rapid rise in BAL, such as when a person drinks quickly or drinks on an empty stomach.

The long-term effects of alcohol abuse are associated with a wide range of physical and mental health disorders, including liver and heart disease, hypertension, risk for infectious diseases, nutritional deficiencies, depression, certain cancers, infertility, and AUD, to name a few (Box 69.4). Women who consume less alcohol and for a shorter period of time than men are at higher risk of developing alcohol-related health problems. Studies also report that women with an AUD are up to twice as likely as men to die from alcohol-related causes such as suicide, accidents, and illnesses. Alcohol has been implicated in more than 200 types of disease and injury, almost 75% of all rapes, and up to 70% of all incidents of domestic violence. Annually, 696,000 students between the ages of 18 and 24 are assaulted by another student who has been drinking; 97,000 students between the ages of 18 and 24 report experiencing alcohol-related sexual assault or date rape. In the United States, alcohol is the third-leading preventable cause of death. Nearly 88,000 people die annually from alcohol-related causes. In 2013, 10,076 fatalities were related to alcohol-impaired

**Table 69.3** Number of Standard Drinks in a Container (Bottle or Can)

Type of Beverage	Sample of Containers/Sizes Sold	Number of "Standard" Drinks in the Container
<b>Regular beer</b>	12 oz	0.8 "standard" drink
		A little less than the equivalent of 1 standard drink
<b>Malt liquor</b>	12 oz	1.4 standard drinks
	24 oz	2.8 standard drinks
	40 oz	4.7 standard drinks
<b>Table wine</b> 750 mL standard: Common bottle size for most distributed wine	750 mL = 25.36 oz	5 standard drinks
<b>80-proof spirits (whiskey, gin, rum, vodka tequila, etc.)</b>	Pint: 12.7 oz = 375 mL	8.5 standard drinks
	Fifth: 25.36 oz = 750 mL	16.9 standard drinks

**FIGURE 69.3** Schematic drawing of the human brain. Although all areas are affected, the cerebellum, responsible for balance, coordination, and movement, and the frontal lobes, responsible for cognition, memory, thought, and learning, are most heavily affected by alcohol consumption.

driving (30.8% of all driving fatalities). More than 10% of U.S. children live with a parent with issues related to alcohol consumption.

**Alcohol and Pregnancy**

Alcohol is a known teratogen, a substance that can harm the fetus. Fetal alcohol syndrome is a constellation of birth defects that includes poor growth, developmental delay, heart defects, and craniofacial abnormalities. When a woman drinks during pregnancy, alcohol crosses the placental barrier and enters the bloodstream of the fetus in levels that equal or exceed that of the mother. Newborns have been

known to go through alcohol withdrawal and to require benzodiazepines for treatment after delivery. Alcohol can also pass through breast milk to the baby.

**Age-Related Considerations**

As a person ages, blood flow, metabolism, and excretion all diminish. In the older adult population, where health may already be deteriorating, alcohol serves to cause new health concerns or exacerbate old ones. The change in physical health complicates alcohol absorption and metabolism, can interfere with medications, and can lead to falls and associated complications.

**Table 69.4 Comparison of Equivalent Measures of the Blood Alcohol Level, Blood Alcohol Concentration, and Percentage of Alcohol in Blood**

Blood Alcohol Level (BAL) (mg/dL)	Blood Alcohol Concentration (BAC) (g/dL)	Percentage of Alcohol (Weight/Volume) Parts Alcohol per 1,000 Parts Blood	Typical Effect	Effect on Driving
20	0.02	0.02% Two-tenths of 1% of the person's blood volume is alcohol	<ul style="list-style-type: none"> <li>● Some loss of judgment</li> <li>● Relaxation</li> <li>● Feels slightly warmer even in cold temperature</li> <li>● Mood euphoric</li> </ul>	<ul style="list-style-type: none"> <li>● Decline in visual functions (rapid tracking of a moving target)</li> <li>● Decline in ability to perform two tasks at the same time (divided attention)</li> </ul>
50	0.05	0.05%	<ul style="list-style-type: none"> <li>● Difficulty focusing eyes on an object</li> <li>● Judgment impaired</li> <li>● Usually good feeling</li> <li>● Less alert</li> <li>● Release of inhibition</li> </ul>	<ul style="list-style-type: none"> <li>● Reduced coordination</li> <li>● Reduced ability to track moving objects</li> <li>● Difficulty steering</li> <li>● Reduced response to emergency driving situations</li> </ul>

## Box 69.4 Manifestations of Chronic Alcohol Use

- Anxiety
- Bleeding disorders
- Cardiomyopathy
- Certain cancers
- Cirrhosis
- Delirium
- Depression
- Erectile dysfunction
- Gastrointestinal disorders
- Hypertension
- Insomnia
- Korsakoff's syndrome
- Nutritional deficiency
- Osteoporosis
- Recurrent falls
- Self-care deficient
- Spider angiomas
- Weight loss
- Wernicke's encephalopathy

### Nutritional Deficiencies

Because very heavy drinkers take in most of their calories through alcohol rather than food, a large percentage of persons with an AUD are found to have a deficiency in thiamine. Thiamine (vitamin B<sub>1</sub>) is vital for carbohydrate metabolism and for the proper functioning of neurotransmitters. Thiamine also plays a key role in protecting neurons from injury, and a thiamine deficiency is one of the main mechanisms of alcohol-related brain injury. Long-term thiamine depletion in the brain can lead to serious central nervous system (CNS) disorders, such as **Wernicke–Korsakoff's syndrome**. Wernicke–Korsakoff's syndrome is a neurocognitive disorder that consists of two separate syndromes; an acute, short-lived, severe condition called *Wernicke's encephalopathy* and a long-lasting and debilitating condition known as *Korsakoff's psychosis*. The clinical manifestations of Wernicke's encephalopathy include mental confusion, paralysis of the nerves that move the eyes (i.e., oculomotor disturbances), and difficulty with muscle coordination. Korsakoff's psychosis is a chronic and debilitating syndrome characterized by persistent learning and memory problems.

### Withdrawal Symptoms

Almost all people with an AUD who have been chronic heavy drinkers experience some level of withdrawal symptomatology if they suddenly stop drinking or significantly decrease the amount of alcohol consumed. The clinical presentation can range from mild tremors, anxiety, and discomfort to life-threatening seizures and **delirium tremens**—which can include confusion, hallucinations, autonomic instability, and death. When the depressant effect of alcohol is removed, every mechanism overreacts within hours of the last drink, resulting in alcohol withdrawal syndrome (AWS; Table 69.5).

**Table 69.5 Common Findings of Alcohol Withdrawal Syndrome**

Early to Mild AWS (6–12 Hours)	Moderate AWS (12–48 Hours)	Severe AWS (48–72 Hours)
● Fine tremor	● Increased tremor	● Tremors become uncontrollable shaking
● Mild diaphoresis	● Diaphoresis	● Diaphoresis becomes profuse
● Increased heart rate	● Tachycardia	● Hypertension, tachycardia, and tachypnea worsen, and hyperthermia may occur
● Increased blood pressure	● Blood pressure continues to increase	● Seizures may present
● Nausea/Vomiting	● Nausea and vomiting worsen	● Mental status worsens to extreme agitation, fluctuating disorientation, confusion, and hallucinations—alcohol withdrawal delirium tremens or DTs
● Anorexia	● Increasingly anxious, distressed, or agitated	
● Headache	● Marked insomnia	
● Anxiety	● May experience transient confusion or hallucinations	
● Irritability		
● Insomnia		
● May be demanding or aggressive in interactions		
● Sensitivity to light and sounds		

AWS, Alcohol withdrawal syndrome.

Many factors determine whether a person is considered as having a high risk for complicated withdrawal, including a previous history of significant withdrawal, multiple previous detoxifications, comorbid illnesses, and recent drinking at high levels.

### Treatment

Various treatments are available to help people with an AUD, and depending on the circumstances, AUD treatment may involve a brief intervention, an outpatient program or counseling, medications, or a residential inpatient stay. Specific treatment for alcohol withdrawal may be inpatient or outpatient. The majority of people with an AUD with mild to moderate withdrawal symptoms can be treated on an outpatient basis. Some need to be hospitalized in a facility that specializes in detoxification and can provide close monitoring of vital signs and assessment of withdrawal symptoms. Medically managed detoxification generally includes the use of benzodiazepines. Alcoholics Anonymous (AA) plays a major role in the treatment of AUDs nationwide and has been proven to be an extremely effective treatment approach. The AA 12-step program (Box 69.5), essential to so many people with an AUD for the day-by-day

## Box 69.5 The 12 Steps of Alcoholics Anonymous

1. We admitted we were powerless over alcohol—that our lives had become unmanageable.
2. Came to believe that a Power greater than ourselves could restore us to sanity.
3. Made a decision to turn our will and our lives over to the care of God *as we understood Him*.
4. Made a searching and fearless moral inventory of ourselves.
5. Admitted to God, to ourselves, and to another human being the exact nature of our wrongs.
6. Were entirely ready to have God remove all these defects of character.
7. Humbly asked Him to remove our shortcomings.
8. Made a list of all persons we had harmed, and became willing to make amends to them all.
9. Made direct amends to such people wherever possible, except when to do so would injure them or others.
10. Continued to take personal inventory and when we were wrong promptly admitted it.
11. Sought through prayer and meditation to improve our conscious contact with God, *as we understood Him*, praying only for knowledge of His will for us and the power to carry that out.
12. Having had a spiritual awakening as the result of these Steps, we tried to carry this message to alcoholics, and to practice these principles in all our affairs.

support they need, works best when combined with other forms of therapy such as psychotherapy and medical care.

Currently, there are only three medications that are approved by the U.S. Food and Drug Administration (FDA) for the treatment of AUD. Disulfiram (Antabuse) was the first medication approved for the treatment of AUD, and it works by causing a severe adverse reaction when someone taking the medication consumes alcohol. Naltrexone (ReVia and Depade) works by blocking in the brain the “high” that people experience when they drink or take drugs such as heroin or cocaine. Acamprosate (Campral) is the most recently approved medication treatment for AUD, and it works by reducing the physical distress and emotional discomfort people experience when they quit drinking.

### Connection Check 69.5

The nurse monitors for which clinical manifestations in the patient diagnosed with early alcohol withdrawal?

- A. Anxiety, stomach cramping, and aching muscles
- B. Restlessness, diaphoresis, and sensitivity to lights and sounds
- C. Autonomic hyperactivity, hallucinations, and global confusion
- D. Depression, hunger, and fatigue

## Sedative-Hypnotics

The sedative-hypnotics, sometimes referred to as *depressants*, are a diverse group of medications that are generally classified on the basis of their medical effects on the body. All reduce the activity of the CNS. Most do so by enhancing the actions of the neurotransmitter GABA and decreasing the activity of the reticular activating system in the brainstem, which in turn causes a reduction in the level of consciousness. Sedatives cause a mild depression of the CNS, decrease excitability and anxiety, and have a muscle-relaxing property sought by many abusers of drugs. Hypnotics, on the other hand, induce sleep. Increasing the dose of a sedative can cause a hypnotic effect, and increasing the dose even further can produce an anesthetic state, a deep depression of the CNS. This group of agents includes the benzodiazepines, barbiturates, and various agents not belonging to either of these categories. The use of alcohol, also a CNS depressant, with any of these medications potentiates the effects of the medication and can lead to an additive and dangerous reaction.

### Barbiturates

Barbiturates are defined as any of a group of barbituric acid derivatives used in medicine as sedatives and hypnotics. They have considerable medical value but can easily be misused. Initial use can cause loss of inhibition, euphoria, and behavioral stimulation. Chronic nonmedical use of barbiturates causes a cumulative toxic effect on the CNS. Delirium can develop with increased doses or when used in the presence of other medical or psychiatric conditions.

Barbiturates still enjoy some use as anticonvulsants and anesthetic agents but have been almost entirely replaced by the benzodiazepines as legitimate anxiolytics, medications used in the treatment of anxiety. Because of the potential for barbiturates to cause respiratory depression, they are much more dangerous in cases of overdose.

### Benzodiazepines

Benzodiazepines are minor tranquilizers, anxiolytics, or antianxiety agents often prescribed for short-term treatment of medical and mental health conditions, such as anxiety, acute stress reaction, and panic attacks. The primary action of the minor tranquilizers is on the limbic system, which serves as the intermediary between the hypothalamus and the cerebral cortex and appears to control emotion. Specific agents, including diazepam (Valium), lorazepam (Ativan), oxazepam (Serax), and chlordiazepoxide (Librium), are frequently employed to treat acute alcohol withdrawal. The more sedating benzodiazepines with intermediate half-lives, such as triazolam (Halcion), estazolam (ProSom), and temazepam (Restoril), are prescribed for short-term treatment of sleep disorders. Benzodiazepines are also used to treat anxiety disorders in the geriatric population but should be used with caution (see Geriatric/Gerontological Considerations: Benzodiazepines).

## Geriatric/Gerontological Considerations

### Benzodiazepines

- The biological half-life of benzodiazepines is significantly longer for older adults compared to younger adults.
- Starting doses must be much lower than those given to younger adults and should be adjusted to the individual to prevent oversedation.
- Susceptibility to the side effects of these medications, including dizziness, drowsiness, unsteady gait, and confusion, increases with age, putting older adults at greater risk for falls and accidents.

People of all ages tend to view these medications differently than “street drugs” and may not realize the potential for **addiction**, a complex condition leading to compulsive use of a substance despite its harmful effects. Findings in a previous survey indicated that 40% of teens believed that even if these medications are not prescribed by a provider, they are much safer to use than illegal drugs. Physical and psychological dependence can easily develop with repeated use and resemble dependence on alcohol and the barbiturates. Tolerance is common, and doses must be increased to obtain the desired results. Adverse effects of chronic benzodiazepine use can include a general deterioration in physical and mental health, cognitive impairment, behavioral problems, anxiety, depression, loss of sex drive, agoraphobia (extreme fear of entering open or crowded places, leaving own home, or being in places from which escape is difficult), social phobia, an altered perception of self and environment, and an inability to experience or express feelings. Chronic abusers may experience paradoxical effects such as aggression, violence, impulsivity, irritability, and suicidal behavior.

### Miscellaneous Agents

#### Flunitrazepam

Flunitrazepam (Rohypnol) is a highly potent, intermediate-acting benzodiazepine derivative that is prescribed outside the United States for the treatment of severe cases of insomnia and as a preanesthetic. Although this medication is neither manufactured nor approved for sale in the United States, it is legally prescribed in over 60 countries (including Mexico, Colombia, and some European countries) and is often smuggled into the United States. It is often referred to as the “date rape” drug due to its amnesia-inducing effects. Flunitrazepam’s effects include sedation, muscle relaxation, relief from anxiety, and prevention of convulsions. The effects of flunitrazepam are stronger than those of other benzodiazepines, appearing 15 to 20 minutes after administration and lasting approximately 4 to 6 hours. Some residual effects can be found for 12 hours or more. Flunitrazepam causes partial amnesia, and individuals are frequently unable to remember events that they experienced

while under the influence of the drug. It can also be used to boost the high of heroin and modulate the effects of cocaine. It also cannot be detected in a urinalysis.

Flunitrazepam is usually consumed orally, often combined with alcohol, or by crushing tablets and snorting the powder. As with the other CNS depressants, chronic use of Rohypnol can lead to psychological and physical dependence and produce a withdrawal syndrome when the medication is discontinued, necessitating a 3- to 5-day inpatient detoxification admission that follows accepted protocols for benzodiazepine withdrawal syndrome.

#### Methaqualone

Methaqualone (Quaalude) is a popular nonbarbiturate sedative-hypnotic that is commonly abused in the United States. At higher doses, excessive CNS depression results, much like that produced by barbiturates—drowsiness, dizziness, decreased alertness and concentration.

#### Gamma-Hydroxybutyric Acid

Gamma-hydroxybutyric acid (GHB; Xyrem) is a CNS depressant that was approved in 2002 by the FDA, with severe restrictions, for use in the treatment of the sleep disorder narcolepsy. Gamma-hydroxybutyric acid, often referred to as “liquid ecstasy,” is gaining popularity as a club drug and is used for its ability to produce euphoric and hallucinatory states. Some bodybuilders abuse GHB to aid in fat reduction and muscle building because of its anabolic effects. Like flunitrazepam, GHB is available in tasteless, colorless, and odorless forms; is frequently combined with alcohol; and has been used to commit sexual assaults because of its ability to sedate and incapacitate unsuspecting victims.

Gamma-hydroxybutyric acid is found naturally in the CNS. When ingested, GHB acts on at least two receptors, including the GABA<sub>B</sub> receptor and a specific GHB-binding site. Gamma-hydroxybutyric acid is rapidly absorbed after ingestion and takes 20 to 60 minutes, depending on the dose, to reach a maximal plasma concentration. Clinical effects become evident approximately 5 to 15 minutes after ingestion and can last up to several hours. Its effects include euphoria, disinhibition, enhanced sensuality, and feelings of kinship with others. Its relaxant properties cause the heart rate and respiration to slow and can interfere with blood circulation, motor coordination, balance, and speech. Other adverse effects may include nausea, vomiting, loss of reflexes, tremors, delusions, seizures, and amnesia. Taken in higher amounts, GHB can cause unconsciousness, seizures, severe respiratory depression, and coma. Gamma-hydroxybutyric acid can be addictive if used for prolonged periods. Chronic abusers who stop using GHB suddenly may experience withdrawal symptoms that include increased heart rate, hallucinations, sweating, insomnia, and seizures.

#### Withdrawal and Treatment

Discontinuing prolonged use of high doses of CNS depressants can lead to serious clinical manifestations of withdrawal, such as insomnia, nausea, vomiting, tremors, anxiety, restlessness, agitation, muscle spasms or twitching,

dizziness, orthostatic hypotension, sweating, irritability, fearfulness, depression, or psychosis. Because the medications work by slowing the brain's activity, when a person stops taking a CNS depressant, this activity can rebound to the point that seizures occur. Abrupt withdrawal from benzodiazepines likely precipitates an acute syndrome resembling alcohol withdrawal and can be quite complicated and prolonged depending on the amount the person was taking. Improved psychomotor and cognitive functioning, particularly in older adults, is usually seen after discontinuation of benzodiazepines.

The treatment for withdrawal is based on the severity of the symptoms and the patient's individual profile, including overall health status, comorbidities, and age. Detoxification requires a cautious and gradual reduction of these medications. After initial detoxification, the treatment for dependence on CNS depressants is much like that of other drugs and includes cognitive-behavioral therapies, psychoeducation, and comprehensive care in a supportive environment.

## Marijuana

The hemp plant *Cannabis sativa* is a potent substance that alters mood, perceptions, and sensations. The potency can vary significantly depending on the source and selection of plant materials. The psychoactive properties of marijuana are produced by delta-9-tetrahydrocannabinol (THC), the main active chemical found in cannabis. In 1974, the average THC content of illicit marijuana was less than 1%. The more recent use of hydroponic solution, however, has produced marijuana plants with THC concentrations ranging from 18% to 24% on average.

The THC binds to and overstimulates cannabinoid receptors found in areas of the brain responsible for movement, coordination, learning and memory, judgment, perception, and concentration. Marijuana enhances the senses and brings on feelings of relaxation and well-being. Marijuana is also used medicinally to relieve pain, reduce nausea and vomiting, and stimulate the appetite. Marijuana is usually smoked, and the effects of the drug can be felt within 10 minutes and can last from 1 to 3 hours.

Although marijuana was long thought to be a "benign" recreational drug, its use can have serious consequences. It can result in red eyes with dilated pupils, increased blood pressure and heart rate, impaired balance and coordination, difficulty concentrating and decreased memory, slowed reaction time, anxiety, paranoid thinking, and psychosis. Marijuana abuse has also been linked to low achievement, delinquent behavior, and poor family relationships.

Marijuana also contains known toxins and cancer-causing chemicals that are stored in fat cells for as long as several months. Smoking three to four cannabis cigarettes a day is associated with the same degree of acute and chronic bronchitis and the same degree of damage to the bronchial mucosa as smoking 20 or more tobacco cigarettes a day. The long-term use is implicated in respiratory disease, heart attack, stroke, stomach ulcers, and other health problems.

## Withdrawal and Treatment

Although it is not thought to produce physical dependence, marijuana use can produce a strong psychological dependence, and new research is revealing a marijuana withdrawal syndrome. The clinical presentation includes decreased appetite, nausea, weight loss, headaches, irritability, anxiety, anger, aggressive behavior, restlessness, depressed mood, sleep disturbances, strange dreams, and cravings. Generally, only mild and symptomatic pharmacological treatment is needed.

## Opiates/Opioids

Opiates are narcotic analgesics derived from the opium poppy plant grown in Asia and Central and South America. The term **opioid** refers to narcotic analgesics that are either semisynthetic or fully synthetic but can also refer to the entire family of both opiates and opioids. Morphine and codeine are both considered natural opiates. Semisynthetic opioids include hydrocodone (Vicodin), hydromorphone (Dilaudid), meperidine (Demerol), oxycodone (Percocet, Percodan, and OxyContin), and the highly addictive drug heroin. Synthetic opioids are fentanyl (Duragesic), propoxyphene (Darvon), pentazocine (Talwin), and methadone.

Opioids act by attaching to specific proteins called *opioid receptors* (mu receptors) that are found in the brain, spinal cord, gastrointestinal tract, and other organs in the body. Opiates can be classified as **full agonists**, **partial agonists**, or **antagonists** depending on their actions at the mu receptor. Full agonists bind to and activate receptors until all opioid receptors are occupied. Partial agonists behave like agonists but do not cause full receptor activation. Opioids such as Demerol and heroin are agonists; buprenorphine is a partial agonist. Antagonists bind to the same receptor but do not cause activity. They prevent the opiate "high" while simultaneously blocking the receptor to other agonists. Naloxone is an antagonist.

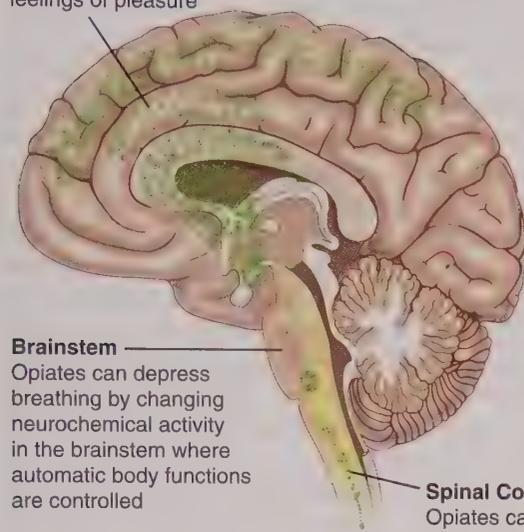

Opioids reduce the intensity of pain signals reaching the brain and affect the brain areas controlling emotion, which diminishes the effects of the painful stimulus (Fig. 69.4). They can produce drowsiness, mental confusion, nausea, and constipation, and depending on the amount taken, they can depress respiration. These drugs also produce feelings of euphoria, relaxation, and contentment, making them highly reinforcing psychologically. Consequently, there is a high potential for nonmedical use of opioids and the development of an opioid use disorder.

## Prescription Narcotics

These medications are commonly prescribed because they are extremely effective for the treatment of pain. Because of their common use, most abusers can get them from family and friends or directly from providers. In recent years, among young adults and older adults who used prescription opiates, 27% obtained them through a prescription from their healthcare provider. Other sources include from friends or relatives for free (26%), buying from friends or relatives (23%), or buying from a drug dealer (15%).

**Limbic System**

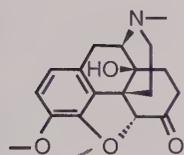

Opiates can change the limbic system which controls emotions and increases feelings of pleasure

**Brainstem**

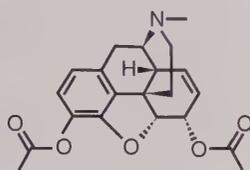

Opiates can depress breathing by changing neurochemical activity in the brainstem where automatic body functions are controlled

**Spinal Cord**

Opiates can block pain messages transmitted through the spinal cord from the body

Oxycontin (oxycodone)

Heroin

**FIGURE 69.4** Locations in the brain affected by opiates. The chemical structures of OxyContin and heroin are similar and bind to the same receptors in the brain.

In addition to nonmedical use, more people are being exposed to prescription opiates legitimately to treat pain due to an aging population (see Geriatric/Gerontological Considerations: Prescription Narcotics) and more sports-related injuries in the younger population. The consistent use of prescription narcotics can lead to physical dependence with characteristic withdrawal signs (Table 69.6). Tolerance may

**Table 69.6 Opioid Withdrawal Symptoms**

Initial	Cravings, anxiety, runny nose (rhinorrhea), yawning, excess tears (lacrimation), perspiration, and minor stomach cramps
12–72 hours	Hot and cold flashes, loss of appetite, nausea, vomiting, diarrhea, goose bumps, muscle twitching and aching muscles and bones, insomnia, increased blood pressure, fever, tachycardia
24–48 hours	Significant muscle and bone aches along with powerful muscle spasms that cause violent kicking motions (“kicking the habit”)

accompany the physical dependence, resulting in the need to take higher doses of the medication to get the same effect. When this occurs, it can be very difficult for a provider to know if the patient is developing a drug problem or has a real medical need for higher doses to control the symptoms. If the provider believes it to be a drug problem, the medication is discontinued, which can sometimes lead the dependent patient to seek out the opiates someplace else.

## Geriatric/Gerontological Considerations

### Prescription Narcotics

- Persons 65 or older comprise only 13% of the population yet account for more than one-third of total outpatient spending on prescription medications in the United States.
- Older persons are more likely to be prescribed long-term and multiple prescriptions.
- Some experience cognitive decline, which could lead to improper use of medications.
- Older adults on a fixed income may take another person’s remaining medication to save money.
- High rates of comorbid illnesses, age-related changes in medication metabolism, and the potential for medication interactions increase the risk of danger in geriatrics.
- The use of over-the-counter medicines, dietary supplements, and alcohol can compound any adverse health consequences resulting from prescription medication abuse.

### Heroin

Heroin is a highly addictive drug that is processed from morphine and usually appears as a white or brown powder or as a black, sticky substance. It is injected, snorted, or smoked and rapidly delivered to the brain. Short-term effects of heroin include a surge of euphoria (“rush”), dry mouth, a feeling of heaviness of the extremities, a warm flushing of the skin, and clouded thinking. This is followed by alternating wakeful and drowsy states.

Like other opioids, heroin depresses breathing, and overdoses can be fatal. Users who inject the drug are at particular risk for infectious diseases such as HIV/AIDS and hepatitis. Pulmonary complications may result from the poor health of the abuser as well as from heroin’s depressing effects on respiration. Injecting heroin can also contribute to valvular infections due to the possibility of introducing bacteria into the bloodstream. It can also lead to collapsed veins, cellulitis, and abscesses. Repeated IV injections can cause vascular sclerosis and lead the injectors to inject subcutaneously or intramuscularly. Resulting infections such as necrotizing fasciitis can lead to disfigurement or death.

## Treatment

Because of the withdrawal syndrome that develops when doses are significantly reduced or stopped, treatment for an opiate use disorder usually begins with medically assisted detoxification using buprenorphine (Suboxone, Buprenex) in tapered doses. Buprenorphine is also gaining popularity as an effective maintenance medication to prevent relapse. Buprenorphine, a partial agonist, produces less risk for overdose, fewer withdrawal effects when stopped, and a lower level of dependence than the more reinforcing agonist, methadone. Some chronic abusers, however, may not respond to buprenorphine and may require maintenance treatment with methadone. Methadone has been used effectively for more than 30 years to treat opiate use disorders. It is a full agonist; it binds with the opioid receptors but has a controlled-release effect that greatly reduces the addiction risk while reducing withdrawal symptoms and drug cravings. Naltrexone (ReVia, Vivitrol), an antagonist, blocks opioids from binding to their receptors and thus prevents substance users from feeling the effects of the drug.

In 2017, the FDA approved the NSS-2 Bridge device to treat opioid withdrawal. The NSS-2 Bridge is a tiny electrical nerve stimulator placed behind the patient's ear. A battery-powered chip emits electrical pulses to stimulate branches of certain cranial nerves, and these stimulations may provide relief from opioid withdrawal symptoms. The device is used during the acute physical withdrawal phase. In 2018 the FDA approved lofexidine (Lucemyra) for use in reducing symptoms associated with opioid withdrawal in adults. Lofexidine is a central alpha-2 adrenergic agonist indicated for the mitigation of opioid withdrawal symptoms to facilitate abrupt opioid discontinuation in adults.

In cases of life-threatening overdose, naloxone (Narcan), another antagonist, is used to counteract the effects of opiates. It reverses the respiratory depression but also has the effect of triggering immediate withdrawal. The best treatment outcomes for opiate use disorders are achieved when available medications are used in conjunction with behavioral and cognitive therapies.

## Stimulants

Stimulants are a class of psychoactive drugs that temporarily elevate mood, increase feelings of well-being, and increase energy and alertness. Some stimulant drugs are legal and widely used for legitimate medical purposes, and others are used as illicit drugs. All can be highly addictive. The therapeutic effect of stimulants is achieved by slow and steady increases of dopamine, which is similar to the natural production of the chemical by the brain. The doses prescribed by providers start low and increase gradually until a therapeutic effect is reached. When taken in doses and routes other than those prescribed, stimulants can increase brain dopamine in a rapid and highly amplified manner. Examples of stimulants include amphetamines, methylphenidate (Ritalin), cocaine, methamphetamine, and MDMA (3,4-methylenedioxymethamphetamine), better known as

“ecstasy” (see Table 69.2). Taken repeatedly or in high doses, stimulants can cause anxiety, hostility, paranoia, and even psychosis. Further, taking high doses of a stimulant may result in dangerously high body temperatures, irregular heartbeat, cardiovascular failure, or seizures.

## Amphetamines and Methylphenidate

Amphetamines, such as dextroamphetamine (Dexedrine, Adderall) and methylphenidate (Ritalin, Concerta), are stimulants generally prescribed by providers for a small number of medical problems, including ADHD, narcolepsy, and occasionally depression. For those who take these medications to improve properly diagnosed conditions, they can be transforming, greatly enhancing a person's quality of life. The dramatic increase in stimulant prescriptions over the last two decades has led to a greater availability and increased risk for diversion and nonmedical use. Like other addictive prescription medications, stimulants are frequently being used without a legitimate prescription or in doses higher or in ways other than prescribed (crushed or snorted).

## Cocaine

Cocaine is one of the most addictive recreational drugs available. Its use as a stimulant goes back thousands of years, with a documented history dating back to 500 A.D. Today, cocaine is a Schedule II drug, meaning that it has high potential for abuse but can be administered by a provider for legitimate medical purposes (e.g., as a local anesthetic for ear, eye, and throat surgeries).

## Effects

The mechanism of action of cocaine, like that of other substances of abuse, is related to its ability to modify the action of dopamine in the brain's “pleasure reward pathway.” Cocaine promotes dopamine transmission by binding to a protein called the *dopamine transporter*, which in turn inhibits the removal of dopamine and ultimately leads to increased activation of the dopaminergic reward pathway. This increased activation leads to the feelings of euphoria and the “high” associated with cocaine use. Cocaine provides a reward that the user learns to obtain in the most efficient manner possible. Unlike learning to obtain natural rewards, such as food, sex, or social cooperation, cocaine results in a pathological form of reward-seeking and ultimately takes precedence over adaptive social and personal behaviors. Cocaine administration results in an increase in dopamine that is markedly greater in terms of both amplitude and duration than what is physiologically induced by a novel, rewarding stimulus. Cocaine's reinforcing value impels repeated drug use. Studies have demonstrated that animals will work very hard for cocaine, such as pressing a bar 10,000 times after a single injection of the drug. These animals choose cocaine over food and water and take lethal doses if supply is not limited.

The increased energy and mental alertness and the feelings of exhilaration in acute cocaine intoxication can quickly turn to irritability, agitation, and restlessness. The euphoric

state is replaced in relatively short order by withdrawal, characterized by anxiety, paranoia, depression, and even suicidality. These contrasting mood states signal the brain to use more in an attempt to regain the “high.” Cravings for the drug are a cardinal feature of cocaine use disorders and are significant because of the potential to trigger use and relapse. Strong psychological dependence, tolerance, and varying degrees of physical dependence can ensue.

The complications associated with chronic use of cocaine are varied, and virtually every organ system is affected by chronic cocaine use because of the vasoconstriction and neuronal death that occurs. Cocaine abuse has been associated with cardiovascular, pulmonary, neurological, infectious, gastrointestinal, hematological, and obstetrical complications, as well as homeostatic disturbances. The method of administration strongly influences the pathophysiological processes that develop in persons using cocaine. Respiratory complications, usually associated with smoked cocaine, can range from exacerbation of asthma or wheezing to pulmonary edema, acute respiratory distress syndrome, bacterial pneumonia, pneumothorax, and eosinophilic pneumonitis or “crack lung.” Intranasal cocaine is often responsible for atrophy of the nasal mucosa, rhinitis, rhinorrhea, bleeding, loss of the sense of smell, and vasculitis. Necrosis and perforation of the nasal septum have occurred in more severe cases. Patients often present in the emergency department with chest pain or with depression or psychosis during a psychiatric evaluation. Significant morbidity, seizures, coma, and sudden death are all possible during periods of intoxication and withdrawal.

### Treatment

The current treatment for cocaine use disorders is primarily focused on the psychosocial models of cognitive-behavioral, motivational, and rewards therapy, typically combined with support groups and counseling. Pharmacological treatment for cocaine use disorders has proven challenging over the years, and to date, no medication with proven efficacy is available for the treatment of cocaine or stimulant use disorders. Dopamine agonists, GABA enhancers, adrenergic blockers, and stimulant medications have all shown some promise. More recently, a cocaine vaccine that would block the effects of cocaine has been studied and shows promise for relapse prevention when used in combination with more traditional psychotherapeutic models.

### Methamphetamine

Methamphetamine (MA) is a highly addictive psychostimulant that has proven to be a serious worldwide public health problem. Methamphetamine can be synthesized at home using a straightforward, one-step process of reduction of ephedrine or pseudoephedrine, making it easy and inexpensive to produce. There has been an expansive proliferation of “mom-and-pop” meth laboratories along with larger criminal “super-lab” organizations in Mexico, Canada, and the United States that has led some regions to have near epidemics of MA-use disorders. The most predominant

form of MA currently consumed, d-methamphetamine hydrochloride, commonly referred to by the street name “crystal” or “ice,” is also the most potent, with purity levels often above 80%. Methamphetamine’s high purity level, combined with the almost immediate onset of effects produced by inhalation or injection, can quickly lead to the development of an MA-use disorder.

### Effects

Methamphetamine acts on the brain’s reward pathway like no other substance or pleasure-generating activity, with a two-fold mechanism of action that causes an extreme surge in dopamine of almost 3.5 times the amount produced by cocaine and 12 times that produced by sex. In addition to blocking the reuptake of dopamine, like cocaine does, MA stimulates the release of dopamine and other catecholamines in the CNS, resulting in levels of dopamine that are about 1,200% more than the baseline level found in a normal brain. Methamphetamine also has a significantly greater elimination half-life (8–13 hours) than many other psychostimulants, such as cocaine (1–3 hours), leading to behavioral and psychological effects that last substantially longer than those of other drugs. It can take up to 2 days to eliminate a single dose. Additionally, MA also has relatively high lipid solubility, allowing more rapid transfer of the drug across the blood–brain barrier.

The acute effects of MA are like those of the other stimulants; however, methamphetamine has the ability to increase energy to the point that users feel “superhuman,” making it particularly appealing. The enhanced sexual experiences that many users report put individuals at increased risk for contracting sexually transmitted infections, including HIV. There is significant morbidity associated with acute and chronic MA abuse, including respiratory, cardiovascular, renal, and infectious complications. Many MA users rapidly lose their teeth, a condition known as “meth mouth” that is caused by a combination of dry mouth, poor oral hygiene, consumption of high-sugar beverages, and bruxism (tooth grinding). Additionally, MA exposure in utero has been associated with low birth weight and cognitive deficits in infants.

Unlike cocaine use, long-term MA exposure has been shown in numerous studies to result in extensive neural damage that is associated with cognitive impairments, including deficits in attention, memory, and executive function. This neurotoxicity may play a critical role in the individual’s inability to regulate and control the use of the drug. There is a strong psychological dependence associated with MA use, along with substantial evidence that heavy use can lead to progressive social and occupational deterioration. Mood and psychotic disorders are not uncommon and can persist months or years after use has ceased.

### Treatment

Multiple medication trials have been tried over the years to identify pharmacotherapy treatment for MA-use disorders, including experiments with selective serotonin reuptake

inhibitors, tricyclic antidepressants medications, monoamine oxidase inhibitors (MAOIs), the GABAergic medications gabapentin (Neurontin) and baclofen (Lioresal), and the anti-nausea medication ondansetron (Zofran), all with inconclusive or negative results. Second-generation atypical antipsychotics and agents that increase dopamine levels are being studied along with other, more diverse approaches. The treatment of MA complications is primarily supportive and needs an interprofessional approach. The effectiveness of psychotherapy and behavioral treatments has reliably demonstrated a clinical benefit with minimal potential for side effects.

### **Safety Methamphetamine and Women Alert**

- Methamphetamine can be appealing to women because of the potential for significant weight loss, increased energy, and mood-enhancing properties.
- Women have been found to transition from initiation of drug use to regular use of MA in less time than men who use.
- Women who use MA are often in abusive relationships and engage in antisocial behaviors, including drug trafficking, and report difficulty controlling violent tendencies.
- Depression and anxiety due to chronic use have been found to be more severe in women than in men.
- Women are now entering treatment settings with primary diagnoses of MA-use disorder in higher numbers than men.

### **MDMA (3,4-methylenedioxymethamphetamine)**

MDMA, or ecstasy, is a synthetic psychoactive drug that is similar to the stimulant MA and the hallucinogen mescaline. In 2014, the National Survey on Drug Use and Health reported that more than 17 million people aged 12 and older had used MDMA at least once, which is an increase from the 11 million reported 10 years earlier. In a 2016 annual survey of teen drug use by the National Institute of Drug Abuse (NIDA), 2.7% of 12th graders, 1.8% of 10th graders, and 1% of 8th graders reported using MDMA.

#### **Effects**

MDMA, usually taken orally as a capsule or tablet, produces feelings of emotional warmth, euphoria, and increased energy along with distortions in time, perception, and tactile experiences. As opposed to dopamine, serotonin is the neurotransmitter primarily affected by MDMA. The serotonin system plays an important role in regulating mood, aggression, sexual activity, sleep, and sensitivity to pain. MDMA binds to the serotonin transporter and thereby increases and prolongs the serotonin signal. It also causes excessive release of serotonin from the neurons. MDMA has similar effects on the neurotransmitter norepinephrine, which can cause the increases in blood pressure and pulse that are seen in ecstasy use.

Like other drugs of abuse, MDMA can be dangerous to overall health and even lethal at times. The increased blood pressure and pulse caused by MDMA increase the cardiovascular risks. In high doses, MDMA can interfere with the body's ability to regulate temperature, which can lead to sharp increases in hyperthermia and result in liver, kidney, and cardiovascular system failure or death. Ecstasy is often taken in combination with alcohol or other drugs, and ecstasy tablets can also contain other substances, such as ephedrine, dextromethorphan, ketamine, caffeine, and cocaine, making MDMA use potentially more dangerous.

#### **Treatment**

Although there are no current pharmacological treatments for MDMA-use disorders, behavioral interventions used in the treatment of other SUDs have been shown to be the most effective. Cognitive-behavioral interventions that help modify the patient's thinking, expectancies, and behaviors related to the drug use and increase coping skills are particularly helpful, especially in combination with drug abuse support groups such as Narcotics Anonymous (NA).

### **CASE STUDY: EPISODE 2**

Mary is given a diagnosis of delirium tremens, an AWS characterized by global confusion, autonomic hyperactivity, and hallucinations. The nurse assesses Mary's AWS using the CIWA-Ar, a tool that assesses the presence and severity of AWS (Fig. 69.5). On the basis of a total score of 20, she contacts the nurse practitioner working with Mary's team. Mary is given lorazepam (Ativan) 2 mg intramuscularly immediately and monitored every hour for 4 hours. After 4 hours, Mary is less confused and less tremulous. Monitoring of Mary's status is ongoing. The CIWA-Ar is repeated every 4 hours. Lorazepam 2 mg PO is ordered every 4 hours for a CIWA-Ar score between 10 and 19. Lorazepam is discontinued when the CIWA-Ar score is less than 10. Her stay in the hospital is prolonged by 3 days, 2 of which are spent in the step-down unit. Her vital signs stabilize, and she becomes more coherent.

On her final day in the hospital, the nurse who first spoke to her family goes to check on her. Mary acknowledges that she has been drinking more since retirement and the death of her husband. She is skeptical of the idea that her hospital complications have been caused by alcohol withdrawal because "nothing like that has ever happened to me before." She denies having a drinking problem and insists that she can abstain for as long as necessary if it is required. Mary's daughter comes to pick her up and asks the nurse to "do something" because she is worried about Mary's ability to recover from the surgery and do the necessary follow-up if her drinking continues. The nurse asks to meet with Mary and her daughter to discuss ongoing treatment, but Mary is packed up and leaves the hospital before the meeting can take place...

<b>Clinical Institute Withdrawal Assessment of Alcohol Scale, Revised (CIWA-AR)</b>	
Patient: _____ Date: _____ Time: _____ (24 hour clock, midnight = 00:00)	
Pulse or heart rate, taken for one minute: _____ Blood Pressure: _____	
<p><b>Nausea and Vomiting</b>—Ask “Do you feel sick to your stomach? Have you vomited?”</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 No nausea and no vomiting</li> <li>1 Mild nausea with no vomiting</li> <li>2</li> <li>3</li> <li>4 Intermittent nausea with dry heaves</li> <li>5</li> <li>6</li> <li>7 Constant nausea, frequent dry heaves, and vomiting</li> </ul>	<p><b>Tactile Disturbances</b>—Ask “Have you any itching, pins and needles sensations, any burning, any numbness, or do you feel bugs crawling on or under your skin?”</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 None</li> <li>1 Very mild itching, pins and needles, burning, or numbness</li> <li>2 Mild itching, pins and needles, burning, or numbness</li> <li>3 Moderate itching, pins and needles, burning, or numbness</li> <li>4 Moderately severe hallucinations</li> <li>5 Severe hallucinations</li> <li>6 Extremely severe hallucinations</li> <li>7 Continuous hallucinations</li> </ul>
<p><b>Tremor</b>—Arms extended and fingers spread apart</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 No tremor</li> <li>1 Not visible, but can be felt fingertip to fingertip</li> <li>2</li> <li>3</li> <li>4 Moderate, with patient’s arms extended</li> <li>5</li> <li>6</li> <li>7 Severe, even with arms not extended</li> </ul>	<p><b>Auditory Disturbances</b>—Ask “Are you more aware of sounds around you? Are they harsh? Do they frighten you? Are you hearing anything that is disturbing to you? Are you hearing things you know are not there?”</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 Not Present</li> <li>1 Very mild harshness or ability to frighten</li> <li>2 Mild harshness or ability to frighten</li> <li>3 Moderate harshness or ability to frighten</li> <li>4 Moderately severe hallucinations</li> <li>5 Severe hallucinations</li> <li>6 Extremely severe hallucinations</li> <li>7 Continuous hallucinations</li> </ul>
<p><b>Paroxysmal Sweats</b></p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 No sweat visible</li> <li>1 Barely perceptible sweating, palms moist</li> <li>2</li> <li>3</li> <li>4 Beads of sweat obvious on forehead</li> <li>5</li> <li>6</li> <li>7 Drenching sweats</li> </ul>	<p><b>Visual Disturbances</b>—Ask “Does the light appear to be too bright? Is its color different? Does it hurt your eyes? Are you seeing anything that is disturbing to you? Are you seeing things you know are not there?”</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 Not Present</li> <li>1 Very mild sensitivity</li> <li>2 Mild sensitivity</li> <li>3 Moderate sensitivity</li> <li>4 Moderately severe hallucinations</li> <li>5 Severe hallucinations</li> <li>6 Extremely severe hallucinations</li> <li>7 Continuous hallucinations</li> </ul>
<p><b>Anxiety</b>—Ask “Do you feel nervous?”</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 No anxiety, at ease</li> <li>1 Mildly anxious</li> <li>2</li> <li>3</li> <li>4 Moderately anxious, or guarded, so anxiety is inferred</li> <li>5</li> <li>6</li> <li>7 Equivalent to acute panic states as seen in severe delirium or acute schizophrenic reactions</li> </ul>	<p><b>Headache, fullness in head</b>—Ask “Does your head feel different? Does it feel like there is a band around your head?” Do not rate for dizziness or lightheadedness. Otherwise, rate severity.</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 Not Present</li> <li>1 Very mild</li> <li>2 Mild</li> <li>3 Moderate</li> <li>4 Moderately severe</li> <li>5 Severe</li> <li>6 Very severe</li> <li>7 Extremely severe</li> </ul>
<p><b>Agitation</b></p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 Normal activity</li> <li>1 Somewhat more than normal activity</li> <li>2</li> <li>3</li> <li>4 Moderately fidgety and restless</li> <li>5</li> <li>6</li> <li>7 Paces back and forth during most of the interview, or constantly thrashes about</li> </ul>	<p><b>Orientation and Clouding of Sensorium</b>—Ask “What day is this? Where are you? Who am I?”</p> <p>Observation:</p> <ul style="list-style-type: none"> <li>0 Oriented and can do serial additions</li> <li>1 Cannot do serial additions or is uncertain about date</li> <li>2 Disoriented for date by no more than 2 calendar days</li> <li>3 Disoriented for date by more than 2 calendar days</li> <li>4 Disoriented for place/or person</li> </ul>
Total CIWA-Ar Score _____ Rater’s Initials _____ Maximum Possible Score 67	
Patients scoring less than 10 do not usually need additional medication for withdrawal.	
The CIWA-Ar is <i>not</i> copyrighted and may be reproduced freely.

## MEDICAL MANAGEMENT: SCREENING AND INTERVENTIONS

Similar to other chronic, relapsing diseases, such as diabetes, asthma, or heart disease, SUDs can be successfully managed. Effective treatment approaches include screening to identify the problem and interventions that are tailored to each patient's drug use patterns and particular strengths, challenges, resources, and needs.

For those who receive substance abuse treatment, the hospital emergency department (ED) may serve as an initial entry point. Common presenting complaints are chest pain and injuries, whether from falls, violence, spousal and child abuse, or other accidents directly related to the substance abuse. The ED is an appropriate and convenient setting for immediate interventions and represents a unique access point for directing patients with SUDs to appropriate treatment programs. Screening and brief interventions are particularly suited to the ED and the hospital setting. Adults admitted to hospitals and/or EDs may be particularly receptive to an intervention because the adverse event is current. Although the stress and emotion of the crisis situation may interfere with learning, it can also make people more receptive to health advice and recommendations. Nurses are well placed to provide interventions in the clinical setting that capitalize on a "teachable moment" and a "window of opportunity." As with other chronic diseases, it is not uncommon for a person to relapse and begin abusing drugs again. Relapse, however, does not signal failure; rather, it indicates that treatment needs to be reinstated or adjusted or that alternative treatment is needed to help the individual regain control and recover.

Many people with an SUD deny having a problem and do not independently seek help. However, to be effective, treatment does not necessarily need to be voluntary. Sanctions or enticements from family, employers, or the criminal justice system can significantly increase treatment entry, retention rates, and the ultimate success of drug treatment interventions.

### Screening

Research has demonstrated that screening for substance use combined with brief interventions in primary care settings can be cost-effective, practical techniques to use with people at risk for and those with actual drinking problems. Screening, brief intervention, and referral to treatment (SBIRT) is an example of an evidence-based approach. Screening followed by 3 to 5 minutes of simple advice from a health-care professional helps many patients reduce their drinking. The Web site of the Substance Abuse and Mental Health Services Administration (SAMHSA) of the U.S. Department of Health and Human Services has information on SBIRT training and related resources.

Screening tools and approaches include:

- SBIRT
- CAGE questionnaire
- AUDIT-C

### Screening, Brief Intervention, and Referral to Treatment

Implementation of the **screening, brief intervention, and referral to treatment (SBIRT)** approach is designed for early identification of individuals with an SUD. The SBIRT approach is suited to identify individuals at risk for substance use disorders and to plan early interventions. The brief intervention focuses on increasing insight and awareness regarding substance use and motivation toward behavioral change. Emergency departments, trauma centers, primary health clinics, and other community healthcare venues provide opportunities for early intervention with at-risk substance users before more serious consequences occur. Screening quickly assesses the severity of substance use and identifies the appropriate level of treatment. Those individuals deemed to be at risk receive a brief intervention that focuses on raising their awareness of substance abuse and motivating them to change their behavior. Patients who need more extensive treatment receive referrals to specialty care. Research has demonstrated that SBIRT is effective and that approaching patients during the "teachable moment" of their hospital or primary care visit helps change drinking behavior (see Evidence-Based Practice).

## Evidence-Based Practice

### Substance Use Outcomes After SBIRT Implementation

This study used the screening, brief intervention, and referral treatment (SBIRT) to estimate changes in behaviors in patients with substance use disorders before and 6 months after the implementation of SBIRT. Using a pre/post design and previously collected performance-monitoring data, data from a sample of 17,575 patients were used to compare pre-SBIRT substance use and substance use 6 months after receiving SBIRT services. Results demonstrated a large and statistically significant decrease for most measures of substance use, including a 35.6% decrease in the prevalence of alcohol use, a 43.4% decrease in heavy drinking, and 75.8% decrease in illicit drug use. The findings of this study support the continued use of SBIRT to monitor substance use reduction in adults.

Aldridge, A., Linford, R., & Bray, J. (2017). Substance use outcomes of patients served by a large US implementation of screening, brief intervention and referral to treatment (SBIRT). *Addiction, 112*(s2), 43–53.

### CAGE Questionnaire

The CAGE questionnaire is a widely used tool for assessing alcohol use. One "yes" answer suggests the patient needs closer assessment; two "yes" answers is highly correlated with AUDs (Box 69.6).

## Box 69.6 CAGE Questionnaire

Two “yes” responses indicate that the possibility of alcoholism should be investigated further. The questionnaire asks the following questions:

1. Have you ever felt you needed to Cut down on your drinking?
2. Have people Annoyed you by criticizing your drinking?
3. Have you ever felt Guilty about drinking?
4. Have you ever felt you needed a drink first thing in the morning (Eye-opener) to steady your nerves or to get rid of a hangover?

### AUDIT-C

The AUDIT-C is a standardized, three-question tool that focuses on consumption and evaluates the severity of alcohol use. It is a short version of the original 10-question AUDIT questionnaire (Fig. 69.6).

AUDIT-C	
<b>Q1: How often did you have a drink containing alcohol in the past year?</b>	
Answer	Points
Never	0
Monthly or less	1
Two to four times a month	2
Two to three times a week	3
Four or more times a week	4
<b>Q2: How many drinks did you have on a typical day when you were drinking in the past year?</b>	
Answer	Points
None, I do not drink	0
1 or 2	0
3 or 4	1
5 or 6	2
7 to 9	3
10 or more	4
<b>Q3: How often did you have six or more drinks on one occasion in the past year?</b>	
Answer	Points
Never	0
Less than monthly	1
Monthly	2
Weekly	3
Daily or almost daily	4
The AUDIT-C is scored on a scale of 0-12 (scores of 0 reflect no alcohol use). In men, a score of 4 or more is considered positive; in women, a score of 3 or more is considered positive. Generally, the higher the AUDIT-C score, the more likely it is that the patient's drinking is affecting his/her health and safety.	

**FIGURE 69.6** The Alcohol Use Disorders Identification Test—Consumption (AUDIT-C).

Treatment approaches and individual programs continue to evolve and diversify. Approaches involve pharmacotherapy; detoxification and treatment of acute withdrawal symptoms; maintenance therapy; and relapse prevention that includes 12-step programs, behavioral therapy, motivational interviewing techniques, and counseling. Finally, there needs to be a comprehensive substance abuse treatment approach that treats not only the abuse disorder but also any comorbidities that complicate recovery. Table 69.7 provides an overview of disorders and complications associated with substance use and SUDs.

### Pharmacotherapy

Pharmacotherapy is used in conjunction with behavioral and supportive therapy. Medications can be used to help reestablish normal brain function, manage withdrawal symptoms, and prevent relapse and diminish cravings. As discussed earlier, there are medications proven to help treat opioid use disorders (buprenorphine, methadone, naloxone, lofexidine) and AUDs (disulfiram, naltrexone, acamprosate). Others are being developed to treat stimulant (cocaine, MA) and cannabis (marijuana) use disorders.

### Detoxification

**Detoxification** is the process by which the body clears itself of drugs. It is often accompanied by unpleasant and sometimes even fatal side effects caused by withdrawal. Easing withdrawal symptoms is important in the initiation of treatment. The process of detoxification is often managed with medications in an inpatient or outpatient setting that provides medical supervision and is sometimes referred to as “medically managed” or “medically assisted withdrawal.” Medically assisted detoxification can safely manage the acute physical symptoms of withdrawal but is only the first stage of SUD treatment. It is rarely sufficient by itself to help individuals with an SUD to achieve long-term recovery. Detoxification needs to be followed by a formal assessment and referral for subsequent SUD treatment.

### Maintenance and Relapse Prevention

#### 12-Step Meetings—Alcoholics Anonymous and Other 12-Step Programs

Alcoholics Anonymous and many other 12-step fellowships, such as Narcotics Anonymous, are international, nonprofessional organizations composed of individuals who all share a common problem of an AUD or another SUD. Members share their experiences, strengths, and hopes with each other in order to stay sober and help others to achieve sobriety. The 12-step model of Alcoholics Anonymous (see Box 69.5) promotes the achievement of sobriety and the maintenance of lifetime recovery by encouraging members to take proactive steps on a daily basis to monitor their mental, emotional, physical, and spiritual condition. Balance in life is stressed in order to “protect sobriety” and “prevent relapse.” Working with a sponsor and developing a sober network are critical to the success of this approach.

**Table 69.7 Common Disorders and Complications Associated With Substance Use or Substance Use Disorder**

Condition	Related to
Carcinoma—esophageal	Alcohol and tobacco alone or in combination
Carcinoma—liver, hepatocellular	Heavy alcohol for several years
Carcinoma—pancreas	Smoking associated with pancreatic cancer and delays healing
Cirrhosis—alcohol-induced Laënnec’s cirrhosis	Chronic alcoholism + malnutrition
Delirium	Alcohol poisoning Overdose of an opiate or another drug Drug-related physical syndromes
Depression	May be evident during or after substance use
Gout	Decreased clotting ability associated with alcoholic beverages, especially beer, contributes to increased production of uric acid
Hypertension	Heavy alcohol intake
Hypothermia	Alcohol use High risk of hypothermia related to dilation of blood vessels and poor judgment
Nutritional deficiencies, including thiamine deficiency	Alcohol
Wernicke–Korsakoff’s syndrome	Chronic alcohol use
Pancreatitis	Alcohol associated with 1 in 3 cases of pancreatitis
Poisoning, accidental or intentional	Alcohol, opioids
Pre- and postoperative complications	Alcohol, smoking
Traumatic injuries	Alcohol and other substances that impair alertness or judgment
Withdrawal	Related to decreasing or stopping alcohol, an opiate, or another substance with a history of a discontinuation syndrome, when there has been a pattern of regular use.

## Behavioral Therapy

**Behavioral therapy** helps patients engage in the treatment process, modify their attitudes and behaviors related to drug abuse, and increase healthy life skills. These treatments also enhance the effectiveness of medications and help people stay in treatment longer. The most commonly used behavioral treatment is **cognitive-behavioral therapy**, which seeks to help patients recognize, avoid, and cope with the situations in which they are most likely to abuse drugs or alcohol.

**Contingency management**, another form of behavioral therapy, uses motivational incentives (tokens, money, and privileges) to encourage abstinence from drugs. The three key principles of contingency management are identified as follows: (1) frequently monitor the behavior the individual is trying to achieve (abstinence); (2) provide tangible, immediate positive reinforcers each time the behavior occurs; and (3) when the behavior does not occur, withhold the positive reinforcers.

## Motivational Interviewing

**Motivational interviewing** capitalizes on the readiness of individuals to change behavior and enter treatment by combining personal feedback with an empathetic approach. The motivational interviewing approach uses open-ended questions, affirmations, reflective listening, and summaries. This approach attempts to meet the individual where the person is rather than where the person should be, finding out what is important to the individual and using that as motivation for change. A 15- to 20-minute session using the motivational interviewing has been quite effective.

## Individualized Counseling

Individualized drug counseling includes the content and structure of the patient’s recovery program and focuses on reducing or stopping illicit drug or alcohol use, as well as addressing related areas of impaired functioning, such as employment status, illegal activity, and family/social relations. Through an emphasis on short-term behavioral goals,

individualized counseling helps the patient develop coping strategies and tools to abstain from drug use and maintain abstinence. The addiction counselor encourages 12-step participation (at least one or two times per week) and makes referrals for needed supplemental medical, psychiatric, employment, and other services.

### Group Counseling

Many therapeutic settings use group therapy to capitalize on the social reinforcement offered by peer discussion and to help promote drug-free lifestyles. Research has demonstrated that when group therapy is offered in conjunction with individualized drug counseling or is formatted to reflect the principles of cognitive-behavioral therapy or contingency management, positive outcomes are achieved. Currently, researchers are testing conditions in which group therapy can be standardized and made more community-friendly.

### Internet

The Internet may offer a treatment-delivery alternative for persons who cannot easily access more traditional drug treatment services either because of limited financial resources or the availability of specific services. Many Web sites now exist that offer information and support for individuals, families, teachers, and communities. The National Institutes of Health published preliminary findings on Web-based treatment for rural women with alcohol problems and found that barriers to professional care were greatest in rural areas; these barriers include limited financial resources, a scarcity of gender-focused services, privacy issues, and stigma associated with alcohol abuse among women. Other barriers are the fact that any lay-led support groups in these areas, such as AA, tend to be frequented by men, and there are generally no childcare services offered. The Internet may prove to be a viable option for women who struggle with one or more SUDs.

### Comprehensive Substance Abuse Treatment Approach

The high rate of comorbidity between drug use disorders and other mental health disorders demonstrates the need for a comprehensive approach to interventions that identify, evaluate, and treat each disorder concurrently. Programs that utilize a comprehensive treatment approach are designed to help the patient learn to avoid relapse and include extensive substance abuse and psychiatric evaluations, individual and group therapy, behavioral therapy, pharmacotherapy, education, social services, promotion of 12-step programs, and treatment of any comorbid psychiatric illness. Often, these programs involve individual reflection about how problems with substance abuse first developed, the direct and indirect costs of substance abuse, the triggers for substance use, relapse prevention strategies, ways to enhance coping skills, and spiritual issues. They also assist the patient in exploring motivations to change, building skills to resist drug use, replacing drug-using activities with constructive and rewarding activities, improving problem-solving skills, and nurturing better interpersonal relationships.

Programs that use a more comprehensive treatment approach assess patients for the presence of HIV/AIDS, hepatitis B and C, tuberculosis, and other infectious diseases, as well as provide targeted risk-reduction counseling to help patients modify or change behaviors that place them at risk of contracting or spreading infectious diseases. Targeted counseling specifically focused on reducing infectious disease risk can help patients further reduce or avoid substance-related and other high-risk behaviors.

### Treatment Settings

Treatment for SUDs is delivered in many different settings. In the United States, there are thousands of specialized drug treatment facilities that provide counseling, behavioral therapy, medication, case management, and other types of services to persons with SUDs. Along with specialized drug treatment facilities, drug abuse and SUDs are treated in jails, providers' offices, and mental health clinics by a variety of professionals, including counselors, physicians, psychiatrists, psychologists, nurses, and social workers. Treatment is delivered in outpatient, inpatient, and residential settings. Although specific treatment approaches often are associated with particular treatment settings, a variety of therapeutic interventions or services can be included in any given setting.

#### Inpatient Hospital-Based Treatment

Hospital-based treatment takes place on a general hospital unit and serves those persons who, along with their SUD, have concurrent acute medical or psychiatric problems. The length of stay on these units is generally shorter than in freestanding SUD treatment centers. In many cases, individuals are referred to a longer outpatient or residential program from the hospital-based unit to continue with SUD treatment.

#### Freestanding Residential Substance Use Disorder Treatment Centers

A freestanding residential SUD treatment center is a stand-alone facility that specializes in the treatment of SUDs and dual diagnoses. Patients generally reside within the treatment facility 24 hours a day under the care of a team of addiction professionals. Although these SUD treatment programs may have other components of care, such as day treatment, partial hospitalization, or outpatient therapy, their main focus lies in providing 24-hour residential care for their patients. Freestanding SUD treatment programs are also capable of providing drug and alcohol detoxification, but not all SUD treatment programs offer this service in-house. The average length of stay for private insurance in these SUD treatment centers is approximately 21 days. A residential center that is federally funded may have a length of stay that is approximately 3 to 6 months.

#### Long-Term Drug Treatment Programs

Long-term SUD treatment programs are designed for people who have completed anywhere from 14 to 30 days of residential SUD treatment and, for a variety of reasons, require additional residential treatment. Reasons that

persons may need long-term treatment may be that they are still displaying drug-seeking behavior after completion of a 30-day SUD treatment program, they have experienced a relapse after a short-term stay in a SUD treatment center, or more time is needed in a structured setting to resolve outstanding clinical issues. The average length of stay in a long-term SUD treatment center is approximately 90 days. Originally designed to treat impaired professionals, the additional time in long-term SUD treatment proved so positive that many SUD treatment facilities began referring other patients. Today, it is not uncommon for all types of people to access long-term SUD treatment.

### **Outpatient Substance Use Disorder Treatment Programs**

Patients participating in outpatient SUD treatment programs generally reside at home and attend the program several evenings or days during the week. Outpatient services are provided to individuals at a variety of intensity levels (i.e., education classes, outpatient treatment, and intensive outpatient treatment). This type of treatment costs less than residential or inpatient treatment and often is more suitable for people with jobs or extensive social supports. This is often the first-line treatment for persons who are newer to treatment or who do not have insurance coverage for more intensive residential treatment. Outpatient programs provide therapeutic activities and interventions for patients to assist them in their recovery from substance abuse while they maintain residence and employment in the community. The focus of the programs is on SUD treatment and the provision of ancillary services. It should be noted that low-intensity programs may only offer drug education.

### **Opioid Treatment Programs**

Opioid treatment programs provide medication-assisted therapy with methadone and/or buprenorphine for the treatment of opiate use disorders and SUDs related to the nonmedical use of prescription painkillers. The extent of services offered varies from simple medication dispensing to comprehensive outpatient programs that provide opiate-replacement medication along with treatment for any comorbid psychiatric or medical issues, individual and group counseling, behavioral therapy, contingency management treatment, and other treatment approaches are also aspects of these opioid treatment programs.

### **Long-Term Residential Settings (Therapeutic Communities)**

Long-term residential treatment provides care 24 hours a day, generally in nonhospital settings. The best-known residential treatment model is the therapeutic community (TC), with planned lengths of stay between 6 and 12 months. Therapeutic communities differ from other treatment approaches principally in their use of the community treatment staff and those in recovery as a key agent of change. Substance use disorders are viewed in the context of an individual's social and psychological deficits, and treatment

focuses on developing personal accountability and responsibility as well as learning to live socially productive lives. Treatment is highly structured and can be confrontational at times, with activities designed to help residents examine damaging beliefs, self-concepts, and destructive patterns of behavior and adopt new, more harmonious, and constructive ways to interact with others. These are programs based in the community and may include faith-based programs connected with a church or religious organization. Patients live at these facilities, attend groups and various rehabilitative classes, and are often assigned work duties as part of the treatment. These programs offer “rehab from the ground up,” including job skills training, GED® programs, and other forms of assistance to prepare patients to be productive members of society. Research shows that TCs can be modified to treat individuals with special needs, including adolescents, women, homeless individuals, people with severe mental health disorders, and individuals in the criminal justice system.

### **Halfway Houses, Recovery Houses, and Transitional Houses**

Halfway houses, recovery houses, and transitional houses provide clean and sober living environments where groups of people reside together while recovering from SUDs. House managers are often in later stages of recovery and can mentor others to try to stay clean and sober. Patients can be in various stages of recovery. Facilities are shared (bedrooms, bathrooms, and kitchen). Each house varies in the amount of structure and rules, including a possible “blackout period” where the patient may not be able to leave the house unescorted. Recovery houses do not take health insurance, and they each set their own prices. Patients are required to attend AA/NA meetings and can also benefit from being involved with an outpatient treatment program.

### **Treatment Within the Criminal Justice System**

Research has found that combining criminal justice sanctions with drug treatment can be effective in decreasing drug abuse and related crime. It has also demonstrated that individuals under legal coercion tend to stay in treatment longer and do as well or better than those not under legal pressure. Often, drug abusers come into contact with the criminal justice system earlier than other health or social systems, presenting opportunities for intervention and treatment prior to, during, after, or in lieu of incarceration, which may ultimately interrupt and shorten a career of drug use. Unfortunately, only a small percentage of all inmates with SUDs receive any treatment during incarceration. Studies have indicated that if all inmates who needed treatment and aftercare services received such services and just over 10% remained substance- and crime-free and employed, the nation would break even in a year.

## **NURSING MANAGEMENT**

With an understanding of common risk factors associated with SUDs, clinical manifestations of commonly used addictive substances, symptoms of intoxication, and withdrawal

issues, nurses are prepared to identify at-risk individuals and use the information to individualize a plan of care. To ensure patient safety when caring for persons with a SUD, it is important to consider the primary diagnosis and any comorbid or co-occurring SUDs and psychiatric or other medical diagnoses.

Substance abuse causes, complicates, or coexists with other illnesses that may require admission to the hospital setting. The clinical manifestations of substance abuse are often subtle, caused by a comorbid condition or the substance abuse itself, and may not be recognized among the more obvious indicators of the admitting diagnoses. This is also complicated by denial on the part of the patient. The cornerstone of assessment for substance abuse problems is establishing rapport and taking a thorough history from the patient and from outside informants, including family, friends, and other providers. The nurse must communicate to the patient that there is no judgment, that information will be kept confidential, and that the nurse is there to help.

### Assessment and Analysis

Clinical manifestations observed in the patient with SUDs may be related to intoxication, withdrawal, and longer-term physiological and psychological changes associated with specific SUDs. In some cases, the toxic effect of the substance

directly damages body organs. Second, the route or method of administration may cause health problems (e.g., skin infections). Third, lifestyle factors associated with substance abuse cause illnesses (e.g., malnutrition and poor hygiene). Increased risk taking or impairment in judgment while under the influence of drugs or alcohol may result in injuries or life-threatening situations that require hospitalization. Whatever the reason for hospitalization, if a patient has participated in hazardous use of substances, there is a risk for withdrawal once use has ceased or dosages are decreased. Several opioid withdrawal scales are available for identifying and quantifying the severity of opioid withdrawal symptoms. Validated tools include:

- The Objective Opioid Withdrawal Scale (OOWS), which relies on clinical observation
- The Subjective Opioid Withdrawal Scale (SOWS), which records the patient's rating of opioid withdrawal on a 16-item scale
- The Clinical Opioid Withdrawal Scale (COWS), which includes 11 items and contains both objective and subjective signs and symptoms of opioid withdrawal

All nurses should have current, working knowledge of usual intoxication and withdrawal symptoms and other health conditions associated with hazardous use and SUDs (Table 69.8).

**Table 69.8 Common Indicators of Intoxication, Withdrawal, or Other Health Concerns Associated With Substance Use Disorders**

Intoxication	Withdrawal	Other
<ul style="list-style-type: none"> <li>• Drowsiness</li> <li>• Slurred speech</li> <li>• Impaired balance and coordination</li> <li>• Difficulty focusing</li> <li>• Decreased alertness and concentration</li> <li>• Mood lability</li> <li>• Strange, aggressive, or paranoid behavior</li> <li>• Constricted or dilated pupils</li> <li>• Changes in vital signs</li> </ul>	<ul style="list-style-type: none"> <li>• Changes in vital signs</li> <li>• Tremulousness</li> <li>• Nausea/vomiting</li> <li>• Headache</li> <li>• Poor appetite</li> <li>• Diarrhea</li> <li>• Diaphoresis</li> <li>• Complaints of muscle aches</li> <li>• Disturbed sleep</li> <li>• Sensitivity to light and sounds</li> <li>• Hallucinations</li> <li>• Confusion</li> <li>• Seizures</li> <li>• Anxiety</li> <li>• Depression/suicidality</li> <li>• Irritability/hostility</li> <li>• Cravings</li> <li>• Drug-seeking behavior</li> <li>• Manipulative behavior</li> </ul>	<ul style="list-style-type: none"> <li>• Malnutrition</li> <li>• Poor dentition</li> <li>• Track marks</li> <li>• Abscesses</li> <li>• Presence of infectious diseases</li> <li>• Abnormal laboratory values</li> <li>• Histories suggesting nonepileptic seizures, liver disease, gastric bleeding, or pancreatitis</li> <li>• History of motor vehicle accidents, falls, fires, or suicide attempts</li> <li>■ History of noncompliance</li> <li>• Drug-seeking behavior</li> <li>■ Homelessness</li> <li>■ Lack of social supports</li> <li>• History of legal, social, occupational problems</li> <li>• History of aggression</li> </ul>

## Nursing Diagnoses

- **Alteration in comfort:** Physical pain or discomfort related to craving or withdrawal from substances
- **Sensory perception alteration** related to withdrawal from substances
- **Potential for injury** related to withdrawal from substances
- **Alteration in nutrition less than body requirements** related to poor dietary intake secondary to drug or alcohol use and decreased appetite with accompanying N/V secondary to withdrawal
- **Sleep pattern disturbance** related to withdrawal from substances
- **Anxiety** related to the distress of withdrawal and absence of usual coping mechanism
- **Hopelessness** related to chronic nature of the disease and past failed attempts at recovery
- **Knowledge deficit** related to the withdrawal process and treatment, recovery planning, and relapse prevention

## Nursing Interventions

### ■ Assessments

- Vital signs  
*Increased pulse, blood pressure, and temperature may be signs of autonomic hyperactivity and indicate withdrawal. Vital signs are a useful index of the severity of substance withdrawal. Frequent monitoring is required to ensure safety, treat withdrawal symptoms, and promote comfort.*
  - Mental status examination  
*Withdrawal symptoms may be unpredictable. Changes from baseline may indicate increased severity of withdrawal or other physiological or psychiatric problems. Prompt response reduces the risk of worsening clinical manifestations. Comorbid psychiatric problems are common in persons who abuse substances. Diagnosis and treatment may aid in recovery from illicit substances. Patients withdrawing from substances may have impaired reality testing.*
  - Nutritional status  
*Albumin and total protein may be decreased; vitamin deficiencies may be present, reflecting malnutrition/malabsorption associated with drug and/or alcohol abuse.*
  - Blood alcohol/drug levels  
*Determine the substance used and the risk for substance withdrawal. The alcohol level may or may not be severely elevated depending on the amount consumed and the length of time between consumption and testing. These levels provide an indication of tolerance and the risk for complicated withdrawal. Numerous controlled/illicit substances may be identified in a polydrug screen that could also cause symptoms of withdrawal.*
  - Complete blood count (CBC)  
*Decreased hemoglobin/hematocrit may reflect such problems as iron-deficiency anemia or acute/chronic gastrointestinal*
- bleeding associated with chronic alcohol use. The white blood cell count may be increased with infections associated with drug and alcohol use.*
  - Glucose  
*Hyperglycemia/hypoglycemia may be present related to pancreatitis, malnutrition, or depletion of liver glycogen stores associated with drug and/or alcohol use.*
  - Serum electrolytes  
*Hypokalemia and hypomagnesemia are common with AUD.*
  - Liver function studies  
*Creatine kinase (CK), lactate dehydrogenase (LDH), aspartate aminotransferase (AST), alanine aminotransferase (ALT), and amylase may be elevated, reflecting liver or pancreatic damage associated with drug and/or alcohol abuse.*
  - Human immunodeficiency virus (HIV), hepatitis C virus (HCV), and tuberculosis (TB) testing as indicated  
*Infection with HIV, HCV, and TB is a possibility because of the risky lifestyle behaviors of individuals with an SUD. These disorders require treatment and may complicate or confound withdrawal.*
  - Electrocardiogram (ECG)  
*Dysrhythmias, cardiomyopathies, and/or ischemia may be present because of the direct effect of alcohol on the cardiac muscle and/or conduction system, as well as the effects of electrolyte imbalance.*
  - Chest x-ray  
*May reveal pneumonia or chronic lung disorders associated with tobacco use, which is often associated with drug and/or alcohol abuse*
  - Comprehensive medical, psychiatric, and substance use/abuse history and physical examination  
*Establishing an appropriate diagnosis and determining if acute intoxication/overdose is present are essential in determining the appropriate treatment. An estimated 15% to 20% of hospitalized patients are dependent on alcohol. To prevent AWS in hospitalized patients, nurses need to assess the pattern of alcohol use. Medical and psychiatric problems that may have been masked by substance use may reappear.*
  - CAGE questionnaire (see Box 69.6)  
*The CAGE questionnaire is a widely used tool for assessing alcohol use. One “yes” answer suggests the patient needs closer assessment; two “yes” answers is highly correlated with AUDs.*
  - AUDIT-C (see Fig. 69.6)  
*The AUDIT-C is a standardized, three-question tool that focuses on consumption and evaluates for the severity of alcohol use. The AUDIT-C is a short version of the original 10-question AUDIT questionnaire.*
  - CIWA-Ar (see Fig. 69.5).  
*The CIWA-Ar is a widely used standardized assessment tool that assesses the presence of 10 symptoms of ethyl alcohol (ETOH) withdrawal, such as tremor and hallucinations (visual, tactile, and other types of hallucinations are associated with alcohol withdrawal). The higher the score, the more severe the withdrawal. It allows the nurse to identify and assess the severity of symptoms in order to intervene and medicate appropriately.*

- SBIRT

*The SBIRT approach is designed for early identification of individuals with an SUD or risk for SUDs, early determination of the severity of identified SUDs, implementation of an appropriate level of brief intervention, and referral to the appropriate level of treatment.*

- **Actions**

- Establish and maintain airway.

*Required if the patient is acutely intoxicated or has overdosed. Excessive somnolence increases the risk of airway compromise. Additionally, with vomiting along with a decreased level of consciousness, there is also an increased risk of aspiration.*

- Provide adequate fluids and electrolytes.

*Abnormalities in fluid and electrolyte levels should be corrected. Intravenous fluid may be necessary in patients with more severe withdrawal because of excessive fluid loss through hyperthermia, sweating, and vomiting. Intravenous fluid should not be administered routinely in patients with less severe withdrawal because these patients may become overhydrated.*

- Administer medications to treat withdrawal symptoms and specific SUD as ordered.

- Opioid use disorder (OUD) treatment

- Lofexidine

*A central alpha-2 adrenergic agonist for use in reducing symptoms associated with opioid withdrawal in adults*

- Methadone

*A full agonist that binds with the opioid receptors but has a controlled-release effect that greatly reduces the addiction risk while reducing withdrawal symptoms and drug cravings*

- Buprenorphine

*A partial agonist, it has actions like agonists but does not cause full receptor activation. There is less risk for overdose, fewer withdrawal effects when stopped, and a lower level of dependence than with the more reinforcing agonist, methadone.*

- Naloxone

*An antagonist, it blocks opioids from binding to their receptors and thus prevents substance users from feeling the effects of the drug. It is also used to reverse the respiratory depression seen with acute overdose.*

- AUD treatment

- Disulfiram

*It works by causing a severe adverse reaction (nausea/vomiting) when someone taking the drug drinks alcohol.*

- Naltrexone

*Blocks the “high” that people experience when they drink or take drugs such as heroin or cocaine*

- Acamprosate

*This medication reduces the physical distress and emotional discomfort people experience when they quit drinking.*

- Multivitamins, folate, and thiamine

*Individuals with an AUD have poor nutrition and may be deficient in thiamine and folate. Thiamine is*

*essential for the metabolism of glucose. A patient who is deficient in thiamine is at risk for acute and chronic mental status changes associated with Wernicke–Korsakoff’s syndrome. Folate, crucial for the formation of red blood cells and protein metabolism, helps to treat or prevent anemia.*

- Promote adequate nutrition.

*Nutrition is especially important for the individual recovering from an SUD because these patients are likely to be nutritionally depleted because of poor diet or impaired absorption of nutrients.*

- Maintain a calm environment with appropriate lighting.

*Patients in withdrawal need a quiet environment with appropriate lighting. Excessive stimulation may exacerbate the effects of withdrawal.*

- Establish rapport by using a nonjudgmental, caring, and competent approach.

*Builds trust and minimizes resistance; demonstrates acceptance of patient as worthy human being and one deserving of care*

- Provide psychological support and instill hope that successful recovery is possible.

*Hopelessness is often present if the patient has made several attempts at rehabilitation and suffered relapses.*

- Consult social work, case management, or psychiatry to plan for longer-term treatment.

*Detoxification alone is insufficient for long-term recovery from substances. Ultimately, the goal is to prepare the person for entry into a rehabilitation program, with the hope of long-term abstinence.*

- **Teaching**

- Educate the patient on symptoms and treatment of withdrawal.

*Make the patient a partner in care; signs may be subtle and may need to rely on patient report of symptoms.*

- Disease process and general health education

*Patients need to have an appreciation of the physical, psychological, cognitive, and behavioral changes and conditions that are associated with drug use and SUDs.*

- Recovery planning and relapse prevention education

*Patients need to learn treatment options and ways to develop sober support systems that will facilitate long-term recovery. They need to learn ways to identify, avoid, and cope with triggers.*

- Educate the patient on basic concepts of 12 steps and how to locate meetings in his or her area after discharge.

*It is important to understand what the 12 steps are and what they can offer for recovery because they have helped millions achieve and maintain sobriety.*

- Stress management

*It is important that the patient increases his or her repertoire of effective coping mechanisms in order to better avoid destructive coping such as drug abuse.*

- Post-acute withdrawal syndrome (PAWS)

*The symptoms of PAWS may occur because the brain’s ability to react to stress has been weakened by long-term*

*substance use. Post-acute withdrawal syndrome can last from months to a year to several decades, with the symptoms entering into periods of relative remission between periods of instability. Patients need to be aware of the signs and symptoms of PAWS, understand that it is a normal part of recovery, and learn ways to cope in order to maintain sobriety.*

## Evaluating Care Outcomes

With prompt recognition and treatment, complications from acute withdrawal may be avoided, physiological status stabilized, and injury prevented, and the patient reports significantly decreased discomfort related to withdrawal. Expected outcomes include stable vital signs, mental status, fluid and electrolyte status, and weight. A well-managed patient with an SUD understands the disorder, actively states personal responsibility for recovery, and is compliant with the treatment program best suited to his or her individual needs.

## Making Connections

### CASE STUDY: WRAP-UP

At her daughter's urging, Mary abstains from alcohol for several weeks and makes a successful recovery from her surgery, but 2 months later, she is back in the hospital with a broken hip, sustained in a fall down her basement stairs. She spends a day in the ED waiting for a bed, and when she returns to the unit, she is already tremulous and hallucinating. The nurse makes the diagnoses of

- Potential for injury related to alcohol withdrawal
- Alteration in sensory perception (such as visual illusions or hallucinations) related to alcohol withdrawal

Mary is again assessed using the CIWA-Ar and is treated with lorazepam. The nurse monitors her vital signs at frequent intervals and uses the CIWA-Ar to assess withdrawal symptoms and response to the medication. She implements seizure and fall precautions. Mary has IV fluids running and is receiving a multivitamin, folic acid, and thiamine. The nurse is providing a calm, quiet, supportive environment, as well as reality orientation as needed. Mary begins to improve significantly on the second day. Her hip replacement surgery goes well, and she is beginning to bear weight again. The nurse now believes it to be a good time to start educating Mary about alcohol-related disorders and recovery planning. The nurse understands that simply treating the withdrawal is not enough and that Mary needs ongoing treatment to address her AUD. She asks the provider to get a substance use treatment referral from social work. Mary is visited by her daughter, son-in-law, and granddaughter and by an old friend of

hers who has been in recovery for many years. Mary attends an AA group that meets in the hospital and is expressing interest in starting substance abuse treatment after she is discharged.

## Case Study Questions

1. During Mary's first admission, prior to transferring her from the step-down unit, the nurse observes symptoms of AWS. On the basis of her length of time in the hospital and Mary's symptoms, the nurse knows Mary's symptoms indicate which stage of AWS?
  - A. Severe AWS
  - B. Moderate AWS
  - C. Mild AWS
  - D. Early AWS
2. During her first admission, which factor(s) place Mary at greatest risk of developing severe AWS? (*Select all that apply.*)
  - A. Diaphoresis
  - B. Age
  - C. Drinking history
  - D. Recent surgery
  - E. Pain
3. The nurse caring for Mary incorporates which nursing diagnosis into the plan of care? (*Select all that apply.*)
  - A. Alteration in comfort: discomfort related to withdrawal
  - B. Risk for injury related to withdrawal
  - C. Anxiety related to the distress of withdrawal
  - D. Imbalanced nutrition: less than body requirement
  - E. Dysfunctional family processes
4. The nurse includes which assessments for Mary related to the status of AWS? (*Select all that apply.*)
  - A. Vital signs
  - B. CIWA-Ar score
  - C. CAGE score
  - D. Mental status
  - E. Respiratory status
5. The nurse includes which of the following information in Mary's teaching plan? (*Select all that apply.*)
  - A. How to cope with triggers and cravings
  - B. Importance of good nutrition
  - C. Substance abuse treatment options
  - D. How much alcohol is acceptable to drink
  - E. Importance of building a support network

## CHAPTER SUMMARY

The United States has one of the highest levels of substance use disorders (SUDs) in the world. An SUD is defined as a maladaptive pattern of substance use that results in recurrent

and significant adverse consequences. The severity of SUDs is classified as mild, moderate, or severe. A severe SUD is characterized by compulsive drug seeking and use despite harmful consequences. A SUD is a chronic, relapsing brain disease that often results in individuals developing tolerance to drugs or alcohol over time and manifesting a withdrawal syndrome when use stops or decreases after prolonged heavy use.

People in all age groups from any background could be at risk for developing an SUD. As with many other diseases, genetics influences a person's risk of developing an SUD. Additionally, ethnicity, age of first use, gender, stress, and the presence of other mental health disorders are also strongly associated with the risk of developing SUDs.

Psychoactive drugs are chemicals that in one way or another tap into the brain's communication system and disrupt the way the neurons normally send, receive, and process information. As the person continues to abuse drugs or alcohol, the brain starts to adapt to these chemical changes by producing less dopamine or by reducing the number of dopamine receptors in the reward circuit. As a result, dopamine's impact on the reward circuit is lessened, reducing the abuser's ability to enjoy the drugs and the things that previously brought pleasure.

Nurses in virtually every practice setting encounter patients struggling with SUDs and need to be aware of commonly used substances and their clinical manifestations in order to provide optimal care for patients. There are physical, behavioral, and psychosocial signs that all nurses should be alert to that may indicate a patient is abusing drugs and/or alcohol. Any sudden or obvious changes in hygiene, sleep, energy, eating patterns, weight, health, behavior, performance, personality, or attitude can be a sign that a person is abusing substances.

Substance abuse causes, complicates, or coexists with other illnesses that require admission to general hospital units. Millions of ED visits each year are connected to substance use, including the nonmedical use of prescription medications, adverse reactions to drugs, or other drug-related consequences. Nonmedical use of prescription opioids and access to fentanyl has led to a dramatic increase in deaths from unintentional drug overdose. Although alcohol is legal, it is also a frequently abused drug. About

3 in every 10 adults in the United States consume sufficient alcohol to elevate their risk of physical and psychosocial problems, and 1 in 4 patients admitted to medical and surgical services in general hospitals has an alcohol use disorder (AUD). Many of these patients experience withdrawal from drugs or alcohol once they come into the hospital and no longer have access to the substance. Nurses need to be able to recognize symptoms of withdrawal so that treatment can be initiated and progression to more serious withdrawal can be prevented. Almost all people with an AUD who have been chronic heavy drinkers experience some level of withdrawal symptoms when they suddenly stop drinking or significantly decrease the amount of alcohol they drink. Alcohol withdrawal, in particular, can be very serious and can put patients at risk for serious harm if not adequately treated early on in the hospital stay. Early signs of alcohol withdrawal can present as anxiety and restlessness, sensitivity to light and sounds, autonomic hyperactivity, mild tremor, nausea, and headache. If there is not continued monitoring and appropriate pharmacotherapy initiated for moderate withdrawal symptoms, they can progress to life-threatening seizures and delirium tremens, which can include confusion, hallucinations, autonomic instability, and death. Aside from continued assessment of the patient and pharmacological treatment for symptoms of withdrawal, nursing care includes the provision of adequate nutrition and rest in a quiet, safe, and supportive environment.

Detoxification is rarely sufficient by itself to help individuals achieve long-term recovery, so it should be followed by a formal assessment and referral to subsequent SUD treatment. Treatment approaches that are tailored to each patient's substance use patterns and any co-occurring medical, psychiatric, and social problems can help individuals with an SUD stop drug and alcohol use, avoid relapse, and successfully recover their lives. Treatment for an SUD is delivered in many different settings, using a variety of behavioral and pharmacological approaches. Unfortunately, most people who require treatment for an SUD do not get the help they need. Nurses are in a unique position to intervene with these patients and can provide valuable education about relapse prevention and recovery planning, stress management, treatment options, and signs and symptoms of post-acute withdrawal symptoms.

# Chapter 70

## Emergency, Trauma, and Environmental Injuries

*Monica Filburn and Nancy Sullivan*

### LEARNING OUTCOMES

Content in this chapter is designed to support the learner in:

1. Stating the prevalence of trauma in our society
2. Identifying the roles of healthcare professionals on the emergency care team
3. Discussing the priorities of care in the field
4. Examining hospital emergency/trauma care priorities
5. Describing common mechanisms of injury
6. Defining major complications of trauma
7. Describing the prevalence of environmental emergencies
8. Explaining the pathophysiological processes of environmental emergencies
9. Correlating clinical manifestations with the pathophysiological processes of
  - a. Poisoning
  - b. Hypothermia
  - c. Hyperthermia
  - d. Snakebites
  - e. Spider bites
  - f. Drowning
10. Describing the diagnostic results used to confirm the diagnoses of selected emergencies
11. Discussing the medical management of selected emergencies
12. Developing a comprehensive plan of nursing care for patients with selected emergencies

### ESSENTIAL TERMS

Acceleration	Mild hypothermia
Active external rewarming	Moderate hypothermia
Antivenin	Motor vehicle collision (MVC)
Blunt trauma	Neurotoxic
Cavitation	Passive external rewarming
Compression	Penetrating trauma
Conduction	Primary survey
Convection	Profile
C-spine stabilization	Rapid fluid infuser
Deceleration	Rhabdomyolysis
Decontamination	Secondary survey
Envenomation	Severe hypothermia
Evaporation	Shearing
Exsanguination	Systemic
Fragmentation	loxoscelism
Golden period	Thermoregulation
Heat cramps	Trauma triad of death
Heat edema	Traumatic aneurysm
Heat exhaustion	Triage
Heat stress	Tumble
Heat stroke	Venom
Heat syncope	Yaw
Hemotoxic	
Hyperthermia	
Internal rewarming	
Mechanism of injury	

### CONCEPTS

- Assessment
- Fluid and Electrolyte Balance
- Medication
- Nursing Roles
- Oxygenation
- Perfusion
- pH Regulation
- Safety
- Thermoregulation
- Trauma

## Finding Connections

### CASE STUDY: EPISODE 1

Follow this patient throughout the chapter.

On a hot Saturday summer night, three male teenagers are at a friend's house for a house party. While they are leaving the house at approximately 1 a.m., a vehicle drives by and starts shooting at them and at the house. One male is shot in the head, another male is able to run away and call 911. The third is shot in the torso. On the arrival of emergency medical personnel at the scene, the team finds two victims. The first victim is found to be shot in the head and has no vital signs or signs of life. He is declared dead at the scene. The second victim is found to have two gunshot wounds. The EMS team quickly stabilizes, packages, and starts to transport the patient to the nearest trauma center.

Prehospital EMS consultation to the level I hospital emergency department (ED) and trauma center: 19-year-old male with a gunshot wound to the right shoulder and lower back. Vital signs: heart rate: 120 bpm; blood pressure: 120/60 mm Hg; respiratory rate: 24 breaths/minute; pulse oximetry: 90% on room air, 98% on 100% nonrebreather (NRB) mask; GCS: 15; IV: 18 g left antecubital; ETA: 2 minutes...

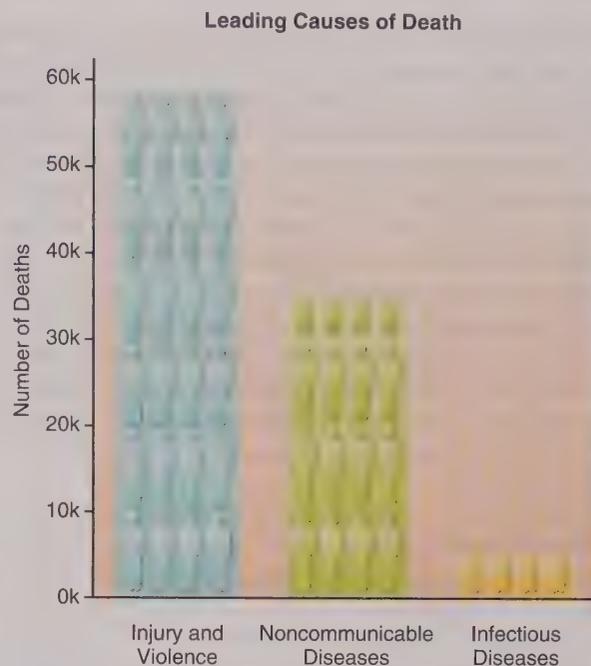

## EMERGENCY NURSING

Emergency nursing is a specialty practice in the nursing profession that requires the rapid assessment and treatment of patients, particularly during the initial phase of acute illness and trauma. Emergency nurses provide episodic care for individuals of all ages and cultures who may present with real or perceived alterations of health that require a primary evaluation and often a timely intervention. To provide quality patient care for people of all ages, emergency nurses must possess both general and specific knowledge about a wide variety of health topics ranging from sore throat to heart attack. Emergency nurses must tackle diverse tasks with professionalism, efficiency, and caring.

## TRAUMA

### Epidemiology of Trauma

In the United States, an unintentional injury is the third leading cause of death for all ages but is the leading cause of death for those aged 1 to 44 (Fig. 70.1). Falls are the leading cause of unintentional injury; **motor vehicle collisions (MVCs)** are the leading cause of death. Unintentional injury is also the leading cause for lost work years

**FIGURE 70.1** Unintentional injury is the leading cause of death for those aged 1 to 44 years in the United States.

because trauma affects mostly a younger population in its prime. Not only does trauma (fatal or nonfatal) affect the patients, it also affects their family, friends, and employers because they have to adjust to the changes brought about by the injury.

Age is a risk factor. The majority of deaths associated with motor vehicle trauma occur in individuals aged between 15 and 45 years. Patients older than 65 years of age have the greatest risk of dying from unintentional injury because of multiple factors such as comorbidities. Older adults also have a statistically higher occurrence of diaphragm laceration/rupture, heart laceration, hemo/pneumothorax, lung contusion/laceration, and rib and sternum fracture when compared with other age groups.

Gender is also a risk factor of trauma. Females are most likely to fall; however, males are at twice the risk for injury than females in motor vehicle-related collisions. There are a number of factors that affect this statistic such as higher risk-taking behavior, participation in more hazardous activities, occupation, and cultural norms. However, females sustain 80% of hip fractures. Females are also at greater risk for injury and death when the cause of injury is associated with intimate partner abuse. Males are much more likely to sustain and die from a penetrating injury than females.

Race and socioeconomic background are other risk factors of trauma. There are many reasons for this, although they are not completely understood. The higher the income, the lower the death rate, irrespective of the mechanism of injury or race. African Americans have the highest rate of homicide in the population. The pedestrian death rate is almost two times higher in African Americans than Caucasians. African American women have the highest rate of intimate partner violence injuries. The highest rate for

suicide is found in the Caucasian population, and Caucasian men have the greatest number of fatalities in MVCs. The second leading cause of death in the Hispanic population between the ages of 10 and 24 is homicide. In the Native American populations, unintentional injuries are the leading cause of death from ages 1 to 44. The economy affects trauma as well. The more depressed the economy, the fewer MVCs, but homicides and suicides are increased.

Geographical location and time of year are also risk factors. Urban areas have higher rates of homicide and suicides, whereas rural areas have greater rates of unintentional injuries. The weekends have the greatest rates of injuries and deaths, with the peak on Saturday. Of all months, July has the greatest number of injuries most likely as a result of summer activities.

Alcohol plays an important role in trauma. It influences cognitive function, coordination, balance, and judgment. Alcohol is implicated more in MVCs with teen drivers than in those with adult drivers. Of drivers between the ages of 15 and 20 years, 25% who died in an MVC had a blood alcohol level (BAL) of 0.08% or greater. Tobacco may not have an important role as a risk factor for trauma; however, it does affect morbidity and mortality. Smoking increases the morbidity and mortality associated with trauma secondary to the smoking-related health issues. Substance abuse is found in all socioeconomic and educational levels. There is no clear evidence that connects drug use and trauma, but it should be considered when thinking about causes and risk factors of trauma.

### Connection Check 70.1

As an emergency nurse in an inner-city ED, you are responsible for developing a trauma prevention program for your community. Who will be your priority patient population?

- 10- to 34-year-old African American males
- 10- to 34-year-old Caucasian females
- 75+-year-olds
- 10- to 34-year-old Hispanic males

### Emergency/Trauma Care Centers

Trauma care is ideally provided by professionals working in institutions designated as trauma centers. Trauma centers are hospitals specially equipped to provide comprehensive emergency care to patients suffering from a traumatic injury. They came into existence from the realization that traumatic injury is a disease process requiring specialized multidisciplinary treatment and resources. Trauma centers have been shown to improve outcomes for trauma patients. To be designated as a trauma center, certain criteria must be met. The hospital must maintain a specialty trained workforce that is prepared to provide a range of emergency care 24/7 and must also ensure access to the equipment that is needed to provide immediate lifesaving care to critically injured patients.

In the United States, hospitals are designated as level I, II, III, or IV trauma centers on the basis of the depth of the resources and available personnel (Box 70.1). Some states have five designated levels, in which case level V (level 5) is the lowest. The American College of Surgeons (ACS) outlines the criteria for each designation level and verifies the presence of the resources recommended for optimal care of trauma patients. The general differentiation is that higher level trauma centers have trauma surgeons and other specialists, such as neurosurgeons and orthopedic surgeons, available as well as highly sophisticated medical diagnostic

## Box 70.1 Levels of Trauma Centers (TCs)

### Level I

- Regional resource hospital that is central to the trauma care system
- Provides total care for every aspect of injury from prevention through rehabilitation
- Maintains resources and personnel for patient care, education, and research; usually in university-based teaching hospital
- Provides leadership in education, research, and system planning to all hospitals caring for injured patients in the region
- Meets minimum requirement for volume of trauma patients

### Level II

- Provides comprehensive trauma care, regardless of the severity of injury
- Might be most prevalent facility in a community and manages majority of trauma patients or supplements the activity of a level I trauma center (TC)
- Can be an academic institution or a public or private community facility located in an urban, suburban, or rural area
- Where no level I TC exists, is responsible for education and system leadership

### Level III

- Provides prompt assessment, resuscitation, emergency surgery, and stabilization and arranges transfer to a higher-level facility when necessary
- Maintains continuous general surgery coverage
- Has transfer agreements and standardization treatment protocols to plan for care of injured patients
- Provides back-up care for rural and/or community hospitals

### Level IV

- Rural facility that supplements care within the larger trauma system
- Provides initial evaluation and assessment of injured patients
- Must have 24-hour emergency coverage by a provider
- Has transfer agreements and a good working relationship with the nearest level I, II, or III TC

Source: Centers for Disease Control and Prevention. (2012, January 13). Guidelines for field triage of injured patients: Recommendations of the National Expert Panel on Field Triage, 2011. Retrieved from <http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6101a1.htm>

equipment. Lower-level trauma centers may be able to provide only initial care and stabilization and arrange for transfer of the injured patient to a higher level of care.

To maintain trauma center designation, the hospital must ensure that all staff members receive ongoing education in trauma and maintain their competency in trauma care. Life support equipment, blood and blood products, and diagnostic tools need to be maintained in the highest state of readiness so that they are available when the patient arrives.

## Prehospital Care

According to R. Adams Cowley, MD, the father of trauma medicine, there is a “**golden hour**,” now known as a “**golden period**” – the critical time between when an injury occurs, and definitive care is initiated. During this period, if bleeding is uncontrolled and there is inadequate tissue perfusion, damage occurs throughout the entire body. If bleeding and tissue oxygenation are not quickly controlled, the patient’s chances of survival drop. This critical period may be much less than an hour for some patients, while others have more time. It is the prehospital provider who is responsible for recognizing the urgency of the situation and transporting the patient as quickly as possible to a hospital that can provide definitive care.

### Priorities of Prehospital Care

#### Stabilization

At the scene, emergency medical providers such as emergency medical technicians (EMTs) or paramedics are the primary care providers. They use “field triage” to evaluate the severity of the injury. The initial assessment they perform drives decisions involving the management and transportation of the patient. The patient’s respiratory, circulatory, and neurological systems are all quickly assessed to identify life-threatening conditions that require urgent intervention and resuscitation. The goal is to minimize time spent on the scene.

There is a systematic method to rapidly assess patients presenting with traumatic injury. This process is guided by the mnemonic “**ABCD**”: airway (A); breathing (B); circulation (C); and disability (D). This sequence maximizes the ability of the body to oxygenate blood and deliver oxygen (O<sub>2</sub>) to the tissues. The first step is A for airway, which must be checked to make sure it is open and clear while maintaining C-spine stabilization. **C-spine stabilization** is when a patient is in a supine position with the spine in neutral alignment (no rotation or bending of the spine); this position protects the patient from spinal cord damage and minimizes further damage. If a patient is able to vocalize, there is likely a stable airway. Gaspings, gurgling, or no respirations at all often indicate a compromised airway in need of emergent definitive management. Step B is for breathing: ventilation and oxygenation, which can rapidly be assessed by auscultating for breath sounds in both lung fields and checking O<sub>2</sub> saturation via pulse oximetry. All

patients must be placed on O<sub>2</sub>. For patients who are found not breathing on their own, the prehospital provider must start assisting ventilation with a bag-valve mask device with supplemental O<sub>2</sub>. Step C is for circulation: checking perfusion and assessing for hemorrhage and circulatory system compromise or failure. During this stage of assessment, palpating pulses and measuring blood pressure can determine the adequacy of circulation. Management of circulatory compromise includes hemorrhage control. Direct pressure is the most effective way of stopping external hemorrhage. The patient may also need IV insertion to provide IV fluids while in transport. Step D is for disability: neurological function. The goal is to determine the patient’s level of consciousness.

#### Transport

If life-threatening conditions are identified, the patient should receive necessary emergency care described above, be rapidly “packaged” (the process of preparing a patient for transport) and transported to the nearest appropriate trauma facility. Important factors to be considered in determining appropriate transportation type and destination is the mechanism of injury and transportation time to the medical facility. If the transport time by ground is too long, air transportation may be necessary. If there is no air transportation or close trauma facility, the patient should be taken to the closest facility for stabilization then transported to a trauma center. Other special considerations such as age, pregnancy greater than 20 weeks, and bleeding disorders are also considered when determining the level of care necessary for the patient.

If in doubt, the EMS team may consult the trauma center and the closest facility to obtain guidance on the best initial treatment location of the patient. It is always recommended to notify the receiving hospital in advance so that the trauma team can assemble before the patient’s arrival.

### Connection Check 70.2

The nurse understands priority prehospital interventions include which of the following?

- Transporting the patient as quickly as possible to the nearest trauma center
- Treating all injuries found and then transporting the patient
- Notifying the local hospital of the transport of a trauma patient and transporting the patient quickly
- Assessing the patient using ABCs, treating life-threatening conditions, then transport to the hospital

## Hospital Care

### Hospital Personnel

Once the injured patient has been delivered to the trauma center, the aim of the trauma team is to provide safe and efficient evaluation and treatment. The team must identify all injuries and initiate definitive management of such injuries

in an expedient matter. The staff at trauma centers are specially trained to function smoothly in the most challenging and chaotic circumstances.

The response of hospital personnel depends on the type of trauma patient presenting. Many trauma centers designate a tiered response based on the severity of the injuries. The more seriously injured a patient, the more hospital resources are activated to respond. The core trauma team is composed of many people working around a single patient. It is vital that everyone on the team knows their role and has the skills, equipment, and support to safely care for the patient. Typical roles of the trauma team include the following: trauma team leader, airway provider, surgical provider, nurses, respiratory therapy, radiologist, clinical technician (a highly trained nursing assistant or EMT), clinical pharmacist, social work and/or pastoral care, and ancillary support staff (Fig. 70.2).

The team leader typically does not physically touch the patient but orchestrates the care of the patient through delegation and supervision of the other providers and staff in the room. The team leader establishes priorities for the patient's care and authorizes interventions based on the assessment of the patient and all diagnostic results. If there are several providers attempting to initiate orders or carry out procedures independently, the care of the patient can be uncoordinated and confusing for team members. The team

leader must be clear and in control of the situation; the captain of the team. The trauma room should be quiet so that all members of the team can hear the voice of the team leader.

The airway, surgical, and ED providers are responsible for establishing and maintaining an airway, ordering medications, and performing surgical procedures at the direction of the team leader. At least one of the providers is typically assigned to perform the **primary survey** (the first quick assessment and initial management of life-threatening injuries). Some overlap in roles is necessary between the general surgeons and ED providers to ensure that tasks continue simultaneously, and no time is lost.

In the management of a trauma patient, nursing is typically responsible for administration of all medications and IV fluids as well as setup of equipment for wound management and surgical procedures. The **rapid fluid infuser** is sometimes used to administer blood or boluses of fluid to the injured patient who has lost large volumes of blood. When it is in use, a nurse is dedicated to its management, ensuring empty fluid bags are replaced as necessary and fluid intake is closely monitored. During the patient's care, one nurse typically serves in the role of a scribe and is responsible for the full documentation of the trauma assessment and care. Records must include the details of the patient's care, such as time of arrival, personnel present at call, physical findings, and fluids and drugs administered. After the patient has been stabilized, nursing staff are responsible for providing updates to the family (Box 70.2).

Clinical technicians, EMTs, or paramedics may be delegated duties within their scope of practice, such as establishing IV access, performing chest compressions during cardiopulmonary resuscitation, preparing equipment,

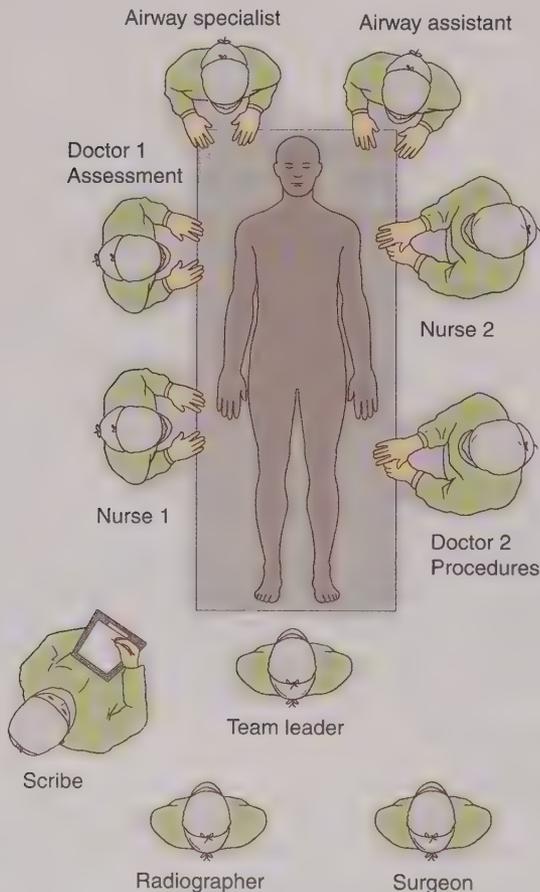

FIGURE 70.2 The trauma team.

### Box 70.2 Family Presence During Trauma Resuscitation

The concept of family presence during trauma resuscitation (FPTR) remains controversial. Healthcare workers have expressed concern that the witness of the resuscitation of a severely injured trauma patient may be inappropriate for the family, but studies support that family members who were present benefited from the experience. They gained better understanding of the situation. A recent study reported that this is especially true in pediatric trauma: the ability of the parent to support the child is extremely important to both the parent and child. FPTR is a growing trend and should be considered unless family behaviors interfere with resuscitative efforts. A designated nurse case manager, social worker or clergy should be assigned to the family during resuscitation to assure their own psychosocial needs and knowledge deficits are being met and addressed. If the family is not present, nursing staff is responsible for giving frequent updates to the family.

obtaining vital signs, and placing the patient on a cardiac monitor. Clinical pharmacists are excellent resources in the care of the trauma patient as they provide expert support in the pharmacological management of the patient. A radiologist is necessary to evaluate the many x-rays and scans typically performed in the trauma assessment. Social workers and ED nursing case management are helpful in serving as liaisons with the families who are often in need of support as their loved one is cared for by the team. Ancillary staff members in the room retrieve equipment and supplies and run blood samples to the laboratory.

### Connection Check 70.3

The nurse caring for a trauma patient understands which team member will establish priorities for the patient's care and authorize the interventions and procedures?

- A. Trauma surgeon
- B. Trauma team leader
- C. Anesthesiologist
- D. Radiologist

### Triage

**Triage** is the sorting of patients based on their need for treatment and the resources available to provide that treatment. The triage nurse must quickly identify patients who need to be seen immediately and those who can safely wait for treatment. This is based on a quick assessment often including vital signs, which allows the nurse to assign an acuity level. There are several different triage systems used in hospitals, but priorities are universal. As in the survey for prehospital providers, triage and acuity are based on the ABCD priorities: **A**irway with C-spine precautions, **B**reathing, **C**irculation with hemorrhage control, and **D**isability and resource management. The importance of rapid and accurate triage is necessary for optimal patient outcomes.

### Trauma Assessment

Trauma assessments are broken down into a primary survey and secondary survey. They should be performed on all trauma patients even if they do not appear to be seriously injured. In addition to gaining information on the patient's presenting condition, the initial assessment includes obtaining

limited subjective information about major injuries and mechanism of injury from the prehospital providers, patient, or family members. A more detailed report is received during the secondary survey.

### Primary Survey

The **primary survey** begins immediately on the patient's arrival to the hospital. The purpose of a rapid primary survey is to identify life-threatening conditions and simultaneously institute management of these conditions. Similar to the prehospital assessment, it follows the ABCDs with the addition of E. "E" stands for "exposure/environment" (Table 70.1). The primary survey starts with an **A**irway assessment. The airway needs to be inspected for injuries that may result in airway obstruction. If the patient is talking, there are likely no airway issues, but the airway requires frequent reassessment later. Once the airway has been quickly assessed, **B**reathing, or ventilation, needs to be quickly assessed because it can be affected by numerous thoracic injuries and can be life threatening. Ineffective breathing patterns may indicate life-threatening injuries.

Key components of the **C**irculatory assessment are pulses, heart rate, skin color, blood pressure, capillary refill, and any obvious signs of bleeding, internal or external. A **D**isability assessment is a brief neurological assessment that measures the patient's level of consciousness. This is done using the Glasgow Coma Scale (GCS) (Box 70.3). The GCS provides a quick assessment of neurological abilities or disabilities. The best GCS score is 15, which is found in a person with no deficits or injuries. The lowest GCS score a patient can receive is 3. This is a person who is nonresponsive or is intubated and heavily sedated. Pupils should also be assessed for size, shape, equality, and reaction to light as well as looking for lateralizing signs that may help locate an area of brain injury. Finally, **e**xposure means to completely undress the patient so that obvious and potential injuries, both front and back, can be quickly identified. Exposure also includes measures to prevent hypothermia. With a large trauma team, these assessments of the primary survey can be done simultaneously.

### Secondary Survey

The **secondary survey** is performed after the primary survey is complete and lifesaving interventions have been

**Table 70.1** ABCDE: The Primary Survey

Letter	Body System	Assessment
A	Airway	Airway with C-spine precautions which is especially important if airway is not patent
B	Breathing	Evaluate ventilation; apply high-flow O <sub>2</sub>
C	Circulation	Evaluate perfusion and bleeding; includes hemorrhage control
D	Disability	Evaluate neurological status and evaluate resources necessary for the care of the patient
E	Exposure/Environment	Complete assessment of the patient; prevent hypothermia

## Box 70.3 Glasgow Coma Scale

### Eye Opening Response

- 4 = Spontaneous
- 3 = To verbal stimuli
- 2 = To pain
- 1 = None

### Verbal Response

- 5 = Oriented
- 4 = Confused
- 3 = Inappropriate words
- 2 = Incoherent
- 1 = None

### Motor Response

- 6 = Obeys commands
- 5 = Localizes pain
- 4 = Withdraws from pain
- 3 = Flexion to pain; decorticate
- 2 = Extension to pain; decerebrate
- 1 = None

### Total Scores

15: Best score possible. Patient opens eyes spontaneously (E=4), is oriented (V=5), and obeys commands (M=6)

13–15: Minor brain injury

9–12: Moderate brain injury

8 or less: Severe brain injury

3: Worst score possible (cannot have a score lower than 3).

The patient is not opening eyes (E=1), is making no sounds (V=1), and is flaccid/not following any commands (M=1).

A patient who is intubated and heavily sedated may have a Glasgow Coma Scale score of 3 as well.

Adapted from Teasdale, G., & Jennett, B. (1974). Assessment of coma and impaired consciousness: A practical scale. *Lancet*, 2(7872), 81–84.

initiated. This survey identifies the other injuries that the primary survey did not assess along with pertinent information about the patient such as other comorbidities. It is during the secondary survey that pain should be assessed. At the start of the secondary survey, a complete set of vital signs should be obtained again. If they are abnormal, the team may need to return to the primary survey and re-assess. If vital signs remain normal, then a head-to-toe assessment should be completed, including the posterior surfaces. Also, it is during this time that the trauma team is gathering critical information about the event from the patient, prehospital providers, witnesses, and family. In an MVC, information about where the patient was in the car, the use or nonuse of safety devices, the speed, location and extent of car damage, and where the patient was found and in what condition helps to create a high index of suspicion for injuries. Additionally, determination of the sequence of events, such as whether the patient was able to get out of the vehicle independently or if the damage was so significant

that the patient had to be extricated by emergency personnel is important. Entrapment can result in greater injury and may prolong the transport time. This delay is important when considering the “golden period.” With penetrating trauma, knowing the weapon, type of gun, or length of the knife or other sharp object, how many shots were heard, how close the patient was to the weapon, and size of the assailant help develop a high index of suspicion of injuries.

### Intervention

Priority interventions include airway, breathing, circulation, disability, and environment.

### Airway

Airway priority interventions include (A) open airway; (B) provide oxygen; and (C) prepare for an advanced airway. If the airway is not patent, open and clear the airway using the jaw thrust (Fig. 70.3) maneuver and suction. The chin-lift (Fig. 70.4) maneuver is another option for opening the airway. If the patient’s tongue has fallen backward and obstructed the airway, both maneuvers allow the airway to become unobstructed but the jaw thrust maneuver is always used for trauma patients when spinal cord injury is suspected to prevent primary or further injury to the spinal cord (see Safety Alert). The jaw thrust is also very effective at creating a good seal with the face mask of a bag-mask

FIGURE 70.3 Jaw-thrust technique of opening airway.

FIGURE 70.4 Chin-lift technique of opening airway.

device. Care must be taken to not hyperextend the neck with either maneuver. If necessary, an oropharyngeal or nasopharyngeal airway can be placed. At this stage, preparations for endotracheal intubation or a surgical airway, cricothyroidotomy, should be implemented if indicated.

### **Safety Alert** Assessing airway in a trauma patient:

There is always a high index of suspicion for C-spine injury after trauma. It is essential to maintain C-spine precautions and use the jaw thrust maneuver when assessing airway and breathing and when placing a definitive airway, if necessary.

### **Provider Protection:**

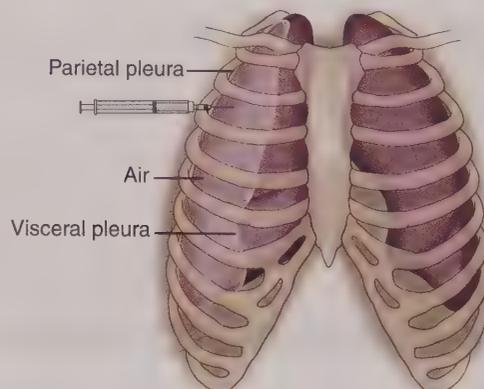

Always wear full protective gear to guard against splashes with body fluid. While exposing patients, be on the lookout for sharp objects that may be on them or in their clothing.

## Breathing

Breathing priority interventions include (A) providing oxygen and (B) diagnosing and treating life-threatening breathing injuries. All trauma patients should receive O<sub>2</sub> via face mask and placed on pulse oximetry to properly measure oxygenation changes. Chest x-rays should be done to check for life-threatening chest injuries along with appropriate laboratory studies, such as arterial blood gases. Any abnormal assessment findings should be acted on. For instance, patient respiratory distress, hemodynamic instability and/or decreased breath sounds on the injured side should raise the suspicion for a pneumothorax that should be confirmed by chest x-ray (CXR) and treated with chest tube placement. A pneumothorax occurs when air enters the pleural space between the visceral and parietal pleurae partially collapsing the lung. If the pneumothorax is evolving quickly or untreated, it may lead to a tension pneumothorax. A tension pneumothorax is caused when the air entering the pleural space cannot escape on expiration, increasing the intrathoracic pressure. This results in a fully collapsed lung and a mediastinal shift that compresses the heart, trachea, great vessels, and uninjured lung. Please refer to Chapter 27 for more in-depth details regarding pneumothorax. If tension pneumothorax occurs, it may be necessary to perform a needle thoracostomy (needle decompression); the insertion of a needle into the pleural space on the side of the pneumothorax. This procedure allows the air that has accumulated in the pleural space to escape (Fig. 70.5). This is followed by tube thoracostomy (chest tube) placement and again, confirmed by CXR.

## Circulation

Circulation priority interventions include (A) IV access; and (B) fluid resuscitation. Vascular access is essential. The patient needs one or two large-bore (18-gauge or larger) IV catheters to allow for fluid and medication administration.

**FIGURE 70.5** Needle thoracostomy: insertion of a needle into the pleural space, allowing the accumulated air to escape and prevent a pneumothorax from becoming a tension pneumothorax.

If venous access is difficult, the patient should be prepared for insertion of a central line. An intraosseous catheter, a catheter placed into the marrow cavity of a bone, is also an option for fluid or medication administration when peripheral blood vessels are inaccessible. As a last resort, a surgical cutdown may be performed. This is an emergency procedure that surgically exposes a vein, typically the saphenous vein, allowing placement of an IV catheter under direct visualization of the vessel.

Fluid resuscitation is dictated by the patient's condition. Typically, this starts with the judicious infusion use of warmed isotonic crystalloid solution. Blood products are indicated if there is excessive bleeding. If the patient is severely hypotensive or has suffered extensive blood loss, fluids may be placed in pressure bags or administered through a rapid infusion device that can infuse about 1,000 mL of warmed fluid per minute but recent evidence suggests a more judicious use of fluids (see Evidence-Based Practice: Fluid Resuscitation).

## Evidence-Based Practice

### Fluid Resuscitation

Previous fluid replacement strategies in severe trauma began with the rapid infusion of crystalloid solutions, but recent research suggests that a balanced resuscitation strategy for severe hemorrhagic shock may have better outcomes. First, minimization of crystalloids and the use of balanced crystalloids: normal saline and Ringer's lactate rather than just normal saline. Second, a 1:1:1 blood product ratio for infusions and last, permissive hypotension. Based on significant experiential evidence in the military population, an approach using limited resuscitation with crystalloids and a blood product ratio of equal amounts of packed red blood cells with fresh frozen plasma and platelets may have a positive impact on overall survival. Additionally, maintaining a mean arterial

pressure of 50 rather than 65 or greater results in less bleeding and reduces the risk of dislodging a clot that may have formed to stop bleeding.

Cantle, P. M., & Cotton, B. A. (2017). Balanced resuscitation in trauma management. *Surgical Clinics*, 97(5), 999-1014.

Self, W. H., Semler, M. W., Wanderer, J. P., Ehrenfeld, J. M., Byrne, D. W., Wang, L., . . . & Shaw, A. D. (2017). Saline versus balanced crystalloids for intravenous fluid therapy in the emergency department: study protocol for a cluster-randomized, multiple-crossover trial. *Trials*, 18(1), 178.

## Disability

Maintaining spinal immobilization is essential in trauma patients with a risk of spinal cord injury. Also, if during the primary survey the patient is found to have a decreased level of consciousness, there should be further investigation in the secondary survey, including a detailed neurological evaluation and imaging of the brain and spinal cord.

## Exposure/Environment

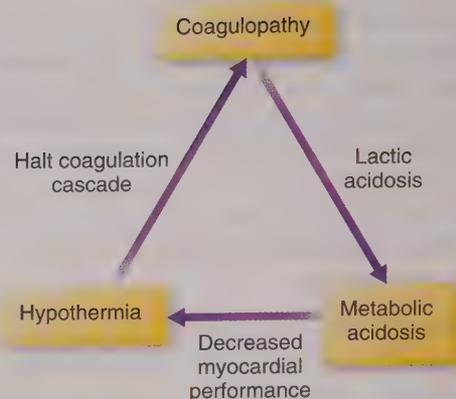

An environmental priority intervention is to control the environment to prevent hypothermia. Warming blankets, warmed fluids, and continual temperature monitoring are essential to help prevent the **trauma triad of death** (Box 70.4).

## Further Secondary Survey Interventions

During the secondary survey further laboratory, radiographical, ultrasound, and other diagnostic studies should be performed. A valuable diagnostic tool is a focused assessment with sonography for trauma (FAST). This is an ultrasound that looks for free fluid in the abdominal cavity, pericardium, or pelvis. If the FAST examination is positive, it typically indicates the presence of blood. The patient with a positive FAST requires emergency surgery to find the source of the bleeding and repair of the injury. Other

### Box 70.4 Trauma Triad of Death

The **trauma triad of death** is a term describing the lethal combination of hypothermia, metabolic acidosis, and coagulopathy (Fig. 70.6) in the trauma patient. Hypothermia, a preventable contributory factor, is caused by a number of factors, such as massive hemorrhage, sepsis, exposure, fluid resuscitation without warm fluid, and certain medications (muscle relaxers, sedatives, anesthetics, and/or opioids). Hypothermia causes peripheral vasoconstriction, which decreases oxygenation, causing hypoperfusion and lactic acidosis. This leads to reduced efficiency of the heart muscle, which then further reduces the O<sub>2</sub> delivery. Also, as the body temperature drops, coagulation is inhibited, resulting in bleeding (coagulopathy). Without interruption in the cycle, principally by preventing hypothermia, the consequential sequelae of the “trauma triad of death” may result in serious complications and death.

**FIGURE 70.6** Trauma triad of death. Hypothermia results in peripheral vasoconstriction, which decreases oxygenation, causing hypoperfusion and lactic acidosis as well as coagulopathy. The acidosis also results in decreased myocardial performance.

interventions include the insertion of a Foley catheter to monitor urine output and renal function. If blood is present at the urinary meatus, further evaluation is required before a Foley catheter is inserted because of the potential of injury to the urinary structures. Additionally, the insertion of a gastric tube to empty the stomach and prevent aspiration is essential especially for a patient where bag-valve mask ventilation has been used. Nasogastric tubes are not recommended in patients with significant facial trauma because of the potential presence of fractures that may result in intracranial insertion of the tube. Once the secondary survey has been completed, definitive interventions are performed, or initial surgical stabilization is performed if the patient is too ill to tolerate definitive procedures (see Evidence-Based Practice: Damage Control Surgery).

## Evidence-Based Practice

### Damage Control Surgery

Damage control surgery is indicated for a select group of trauma patients that present in physiological extremis or at the point of death and require immediate surgical control of hemorrhage and contamination. It is a concept that originated in the military many years ago and has been refined in more recent years due to conflicts in the Middle East and by trauma physicians in the civilian sector. It has demonstrated success in increasing survival rate in patients in severe hemorrhagic shock by 50%. It uses a staged surgical approach after initial resuscitation, avoiding long, complicated procedures on unstable patients and focusing instead on stabilizing potentially fatal problems at the initial operation. The philosophy of this type of management is to abbreviate surgical interventions before the development of irreversible physiological endpoints; avoiding or correcting the lethal triad of hypothermia,

acidosis, and coagulopathy before definitive surgical management. The stages are:

1. Stop hemorrhage, control contamination, perform temporary closure of wounds.
2. Correct physiologic abnormalities in the critical care setting through intensive monitoring, ensuring adequate fluid resuscitation, warming, and correcting coagulopathy.
3. Definitive operative management

Weber, D. G., & Bendinelli, C. (2017). Damage control surgery for emergency general surgery. In *Acute Care Surgery Handbook* (pp. 387-401). Springer: Cham.

### Connection Check 70.4

The nurse understands the purpose of damage control surgery is which of the following? Select all that apply.

- A. Control hemorrhage
- B. Prevent renal failure
- C. Prevent contamination
- D. Avoid further surgery
- E. Control hypoxia

### Mechanism of Injury

**Mechanism of injury** is defined as the transference of energy from an external force to the body of the patient. Understanding the type of mechanism of injury: blunt or penetrating, region of the body affected, and how severely the force was applied helps determine the extent of injury.

#### Blunt Trauma

**Blunt trauma** is when the energy transference does not cause disruption to the skin, making these injuries more difficult to see. Mechanisms of energy transference that cause blunt trauma injuries are deceleration and acceleration forces, compression, and shearing. **Deceleration** is when the body has been moving and comes to an abrupt stop. **Acceleration**

is a sudden increase in speed. Acceleration is often followed by deceleration. An example of deceleration is a motor vehicle traveling at 50 mph that hits a brick wall, causing the vehicle to come to a sudden stop. All passengers inside the vehicle come to a sudden stop, typically against a hard surface in the car. An example of acceleration is a pedestrian standing on the side of the road who is hit by a moving vehicle, causing the pedestrian to be thrown 20 feet. Deceleration forces are applied when the pedestrian hits the ground. **Compression** injuries are as they sound—organs or tissues compressed between two immovable surfaces such as bones or a steering wheel. **Shearing** occurs when skin or tissue slides in opposite but parallel directions. Although blunt trauma injuries may be more difficult to see on first assessment, they are frequently very severe and widespread. The most common forms of blunt trauma are MVCs, motorcycle crashes, pedestrians struck, bicycle injuries, sports (football) injuries, falls, and assaults.

#### Blunt Thoracic Trauma

Thoracic injuries can be some of the most life-threatening injuries. Many vital organs are located in the thoracic cavity: heart, lungs, and aorta. These injuries can cause airway disruptions, and/or serious circulatory alterations. Isolated blunt trauma thoracic injuries are not common and should generate a high suspicion for related abdominal injuries.

The primary mechanism of blunt trauma to the thoracic cavity is from compression causing the chest wall to be displaced inward with impact, such as when the chest hits the steering wheel during an MVC. Rapid deceleration is often the force involved with compression injuries. When the body stops moving forward after it hits an object, the internal organs still continue to move forward until they hit something (Fig. 70.7). The heart tends to hit the sternum, the lungs hit the ribs, and the aorta can be pressed up against the spine. It is these types of movements that often also cause shearing injuries.

#### Blunt Cardiac Injury

Blunt cardiac injury (BCI), one form of thoracic trauma, can be anything from a myocardial contusion to a cardiac rupture. The most common causes of BCIs are high-speed

The chest hits the steering wheel and the body stops moving

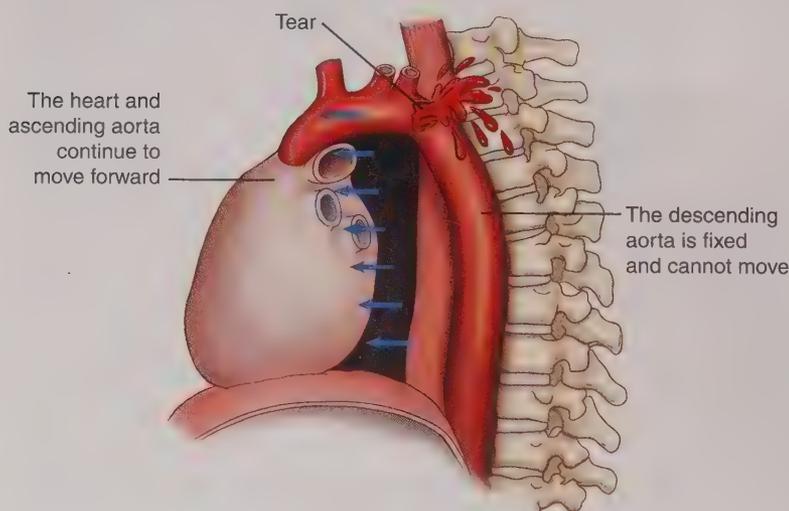

The internal organs continue to move forward until they hit something

**FIGURE 70.7** Rapid deceleration and compression injuries in motor vehicle crashes.

MVC impacts and falls from heights where there is a direct impact on the chest. Sternum fractures can result in right ventricular perforation, and fractured ribs can lacerate either the right or left ventricle. Blunt cardiac injuries can also happen due to deceleration and shearing forces. An example is injury to the descending aorta. Unlike the heart, aortic arch, and ascending aorta, the descending aorta is tightly restrained to the posterior thoracic wall and vertebral column. This predisposes the descending aorta to shearing injuries. When the body is rapidly decelerated, the heart and ascending aorta continue to move forward while the descending aorta cannot. This can cause a tear in the aorta at the junction of the aorta that can move freely and the section that is restrained (Fig. 70.8). This tear can be a complete transection of the aorta, causing immediate death due to **exsanguinations** (extreme loss of blood volume), or it can be a partial tear, a **traumatic aneurysm**. A traumatic aneurysm is caused by a partial or incomplete laceration of the layers of the aorta wall (Fig. 70.9). Both can cause ischemia and a hematoma that causes a weakened area in the aorta wall, allowing an aneurysm to form (see Chapter 31 for more information on aneurysms). This traumatic aneurysm can rupture anywhere from minutes to days from the time of injury.

Compression injury to the heart can occur when the heart is compressed between the sternum and spine or when a heavy object is crushing a person on the chest. When the heart becomes compressed, it can result in cardiac contusion and dysrhythmias. The most common dysrhythmia is sinus tachycardia, which may be caused by other reasons such as hypotension as well as cardiac contusion. Other dysrhythmias noted are premature ventricular contractions. Cardiac compression can also happen when a pneumothorax progresses to a tension pneumothorax compressing the heart, trachea, great vessels, and uninjured lung. Worst case, cardiac contusion can result in nonperfusing rhythms such as ventricular fibrillation or ventricular tachycardia and cardiac arrest. (Chapter 29 discusses dysrhythmias in detail.)

### Blunt Pulmonary Injuries

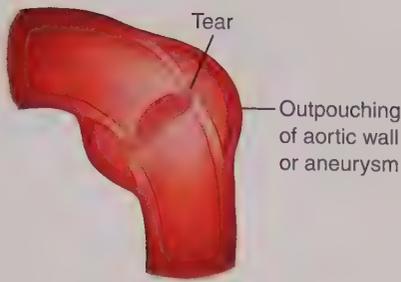

**Rib Fractures.** The most common thoracic traumatic injury is rib fracture. Rib fractures can be seen in many types of blunt trauma to the thorax: the steering wheel hitting the chest in an MVC, a baseball bat to the rib cage, a fall landing on the chest or side. The sternum and ribs resist energy forces better than other bones of the body and provide protection to the vital thoracic organs. If these bones are fractured, significant injuries to the underlying structures must be evaluated because of the force necessary to fracture these bones. Understanding which ribs are fractured can help identify associated intrathoracic injuries (Table 70.2). When a rib fracture produces a free-floating sternum or there is a fracture of two or more ribs in two or more places, a condition called *flail chest* results. Clinically, this condition can be identified by paradoxical motion of the flailed segment of chest wall during spontaneous respiration.

### Pneumothorax, Hemothorax, and Pulmonary Contusion.

Rib fractures and flail chests can cause pneumothorax or hemothorax when the sharp edges of the broken ribs perforate the chest wall, causing a loss of the negative intrapleural pressure. This can cause a partial or total lung collapse. Once a pneumothorax has developed, tension pneumothorax, as discussed previously, may occur. Traumatic hemothorax is caused by a laceration in the lung or intercostal vessel.

Pulmonary contusion is another possible injury caused by blunt thoracic trauma. Before impact, whether in an MVC or fall, a person instinctively takes a deep breath and holds it, closing the glottis and sealing off the lungs. As when a paper bag full of air is suddenly compressed, when the chest wall is suddenly compressed, the lungs can rupture; but more typically, they become contused. Pulmonary contusion leads to pulmonary edema with blood collecting in the alveoli, causing poor gas exchange, decreased lung compliance, and increased pulmonary vascular resistance.

**FIGURE 70.8** Sheared descending aorta: when the body rapidly decelerates and the heart and ascending aorta continue to move forward while the descending aorta cannot, causing a tear in the aorta.

**FIGURE 70.9** Traumatic aortic aneurysm caused by a partial or incomplete laceration of the layers of the aorta wall.

**Table 70.2 Injuries Associated With Rib Fractures**

Rib Fracture	Associated Injuries
Upper ribs (1–3)—protected by scapula, clavicle, humerus; these fractures indicate great energy was necessary to cause damage	<ul style="list-style-type: none"> <li>● Scapula, clavicle, sternal, humerus fractures</li> <li>● Head, neck, spinal cord injuries</li> <li>● Great vessel injuries</li> <li>● Lung injuries</li> <li>● Blunt cardiac injuries</li> </ul>
Middle ribs (4–9) most commonly injured	<ul style="list-style-type: none"> <li>● Pneumothorax</li> <li>● Hemothorax</li> <li>● Pulmonary contusion</li> <li>● Muscle injuries</li> <li>● Blood vessel injuries</li> </ul>
Lower ribs (10–12)	<ul style="list-style-type: none"> <li>● Liver, spleen, and intra-abdominal injuries</li> </ul>

### Blunt Abdominal Trauma

Abdominal organs are more vulnerable to injury than those in the thorax because of the lack of protection from the sternum and rib cage. They are separated into two categories by density: solid and hollow (Box 70.5). The solid organs are dense masses of very vascular tissue. The hollow organs are less dense because of the presence of a cavity that is filled with air or digestive matter. This is important to understand and differentiate when looking at potential for traumatic injuries. Like blunt thoracic trauma, blunt abdominal trauma injuries result from compression, shearing, and acceleration/deceleration. Blunt abdominal trauma may be associated with damage to the viscera (internal organs), which can result in massive blood loss or the spilling of intestinal contents into the peritoneal space, and peritonitis. The manifestation of these injuries is often subtle and requires a high index of suspicion during patient evaluation. Motor vehicle crashes are the leading cause of blunt abdominal injuries.

#### Compression Injuries

Compression injuries in the abdomen are caused by the vertebral column pressing the internal organs into an external structure, causing them to bruise or rupture. This external

## Box 70.5 Abdominal Organ Categories by Density

### Solid Abdominal Organs

- Liver
- Spleen
- Kidneys
- Pancreas
- Adrenal glands
- Ovaries

### Hollow Abdominal Organs

- Bladder
- Large intestines
- Small intestines
- Stomach
- Uterus

structure could be a steering wheel or dashboard in an MVC or the ground after a fall from a height. The sudden increase in pressure caused by compression frequently injures the solid organs. This overpressure within the abdomen can also cause the diaphragm to tear or be ruptured (Fig. 70.10). Diaphragm injuries can affect ventilation by allowing the abdomen organs and blood from an intra-abdominal hemorrhage to enter the thoracic cavity. This can result in compression of the lung or heart, and worst case from cardiac compression, cardiac tamponade.

#### Shearing Injuries

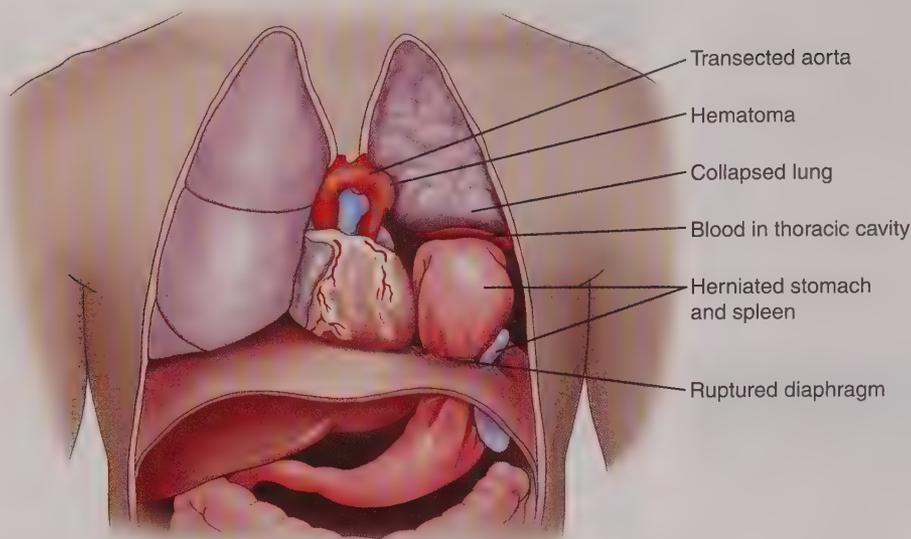

Rapid deceleration produces shearing forces, causing tears or ruptures in organs. When the body stops moving forward, the internal organs continue to move forward in the abdomen, causing tears at the point of attachment to the abdominal wall. Blood vessels that enter these organs may also be torn. The kidneys, spleen, and large and small intestines (mesenteric attachments) are known for being highly susceptible to shearing injuries.

Liver lacerations often occur during rapid deceleration events secondary to its impact with the ligamentum teres. This ligament divides the left part of the liver into medial and lateral sections. The liver is supported by the diaphragm and not by any fixed structure. When the body experiences a rapid deceleration, the liver keeps moving in a downward fashion onto the ligamentum teres. This movement onto the ligament can cause a tear in the liver.

Safety restraints such as seat belts provide significant protection but when not used correctly can cause injury. If the lap belt of a seat belt is not placed correctly, it can cause shearing injuries to the lower abdomen, such as rupture of the small bowel or colon.

#### Pelvic Fractures

Also, as a result of blunt abdominal trauma, pelvic fractures can be seen in MVCs, pedestrians struck, and falls.

**FIGURE 70.10** Diaphragmatic rupture allowing abdominal organs and blood from an intra-abdominal hemorrhage to enter the thoracic cavity; resulting in compression of the lung or heart and shearing injuries.

They can be stable or unstable fractures, with unstable being the most dangerous. Genitourinary injuries are noted in approximately 10% of those patients with pelvic fractures. These include bladder ruptures, ureteral transections, and urethral disruptions. In severe, unstable pelvic fractures, there can be circulatory disruption, both venous and arterial.

### Penetrating Trauma

**Penetrating trauma** is defined as injuries produced by a foreign object penetrating the tissue. Knives, guns, or ice picks are the most common cause of penetrating trauma. However, anything that penetrates the skin, such as glass from a broken windshield, can be a cause of trauma. Foreign objects that cause penetrating trauma are often classified according to the amount of energy they or their projectiles produce:

- Low-energy: knife or other sharp objects thrown by hand; also glass from an MVC or another falling object
- Medium-energy: handguns
- High-energy: military or hunting rifles

The energy created by the foreign object dissipates into the surrounding tissues, causing injury. The extent of the damage is affected by three main factors: the character of the wounding object, its velocity, and the characteristics of the tissues that it passes through. Penetrating injuries can be like an iceberg; the injury one sees on the skin may be minor compared to the significant injury beneath the surface.

### Gunshot Wound

Many bullets do not travel in a linear fashion once entering the body. Direction can change after contact with different density tissues or by hitting bone. Noting entrance and exit wounds can help determine the anatomical structures in the bullet's pathway. Also, to help estimate the damage that can be done by a bullet it is important to understand the type

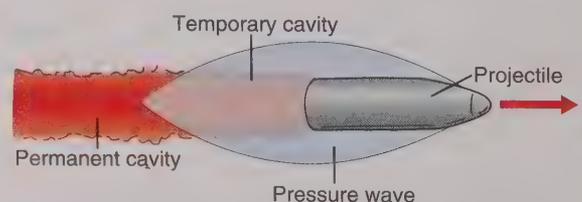

of bullet and the factors that affect its movement and action: cavitation, velocity, profile, tumble, yaw, and fragmentation.

#### Cavitation

**Cavitation** is associated with shock waves that compress the tissues and travel ahead and to the sides of the bullet—the energy exchange between the missile/bullet and the body tissue it is passing through. There can be a permanent cavitation caused by the track of the bullet and a temporary cavitation (Fig. 70.11) in which the wound cavity is temporarily stretched outward as a result of a pressure wave created in the tissue in the wake of the bullet. The elasticity in the tissue struck by the missile determines the size of the permanent cavity created. The permanent cavity in muscle is relatively small because muscle has more elasticity and can expand and return back to shape. An organ such as the liver has very little elasticity, and thus the permanent cavity created is much larger.

#### Velocity

**Velocity** is the speed of a traveling object and is the most significant determinant of its wounding capability. The velocity affects the extent of cavitation and tissue deformation. Low-velocity missiles have little disruptive effect on tissues; they have a small radius of distribution around the center tract of injury. These low-velocity missiles push the tissues aside along a path without creating a

**FIGURE 70.11** Cavitation injury; permanent or temporary cavitation caused by the track of the bullet where the wound cavity is stretched outward as a result of a pressure wave created in the wake of the bullet.

large cavitation. Most sidearms fall into this category. High-velocity missiles such as from a rifle create high cavitation and high-energy transference. Also, negative pressure behind a high-velocity missile can pull foreign matter into the wound, causing contamination.

### Profile

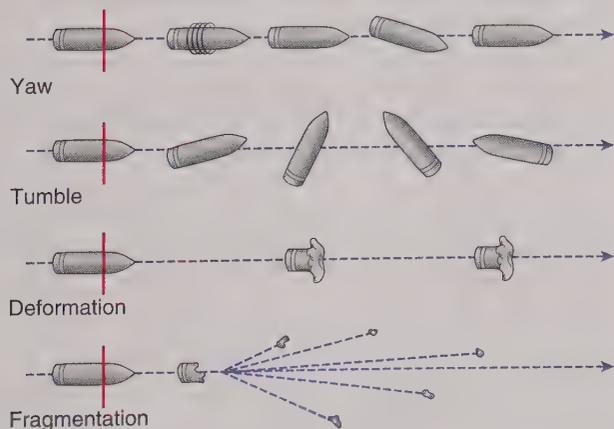

**Profile** describes the initial size of the projectile and changes, if any, at the time of impact. The bullet shape is specifically designed to be aerodynamic, with minimal drag through the air but more drag when it passes through body tissues. If it becomes deformed when it hits the skin, then it impacts a larger area, creates more drag, and has a much greater energy exchange, causing a larger cavitation and more injury. This is why hollow-point bullets (bullets that flatten and spread on impact) cause more damage.

### Tumble and Yaw

**Tumble** is when the bullet assumes a different angle once inside the body. This creates more drag inside the body than air. **Yaw**, also known as the wobble of the bullet, is the deviation of the tip of the bullet from the straight axis of flight as it comes out of the barrel. It should come out going straight but spinning. The higher the velocity, the longer it should take for the bullet to yaw. The longer it takes a bullet to yaw after entering tissue, the deeper the maximum injury.

### Fragmentation

**Fragmentation** is when the missile/bullet breaks up to produce multiple parts which causes more drag and energy exchange. There can be fragmentation upon leaving the weapon, such as shotgun pellets, and there can be fragmentation upon entering the body, which can be passive or active. Active fragmentation is when a bullet has an explosive that detonates inside the body, whereas passive fragmentation is when the bullet has a soft nose that contains small fragments that break off on impact. Fragmentation can happen when the bullet hits bone, creating not only bullet fragments but also bony fragments. Figure 70.12 illustrates tumble, yaw, hollow point, and fragmentation.

**FIGURE 70.12** Yaw, tumble, deformation (hollow-point bullet), fragmentation.

## Stabbing

Penetrating injuries caused by low-energy weapons are most often hand-driven such as a knife. Broken glass from a broken window shield in an MVC can cause penetrating trauma if it enters the body. Foreign bodies causing penetrating trauma can produce damage only with their sharp points or edges. Less cavitation occurs with low-energy injuries, and the injury pathway is much easier to determine by tracing the path of the weapon as it entered the body. As with gunshot wounds, stab wounds can have more extensive damage on the inside that is not visible upon external examination. The amount of damage done is based on the potential scope of movement of the inserted object, the length of the object, and the density of the tissue affected. Knowing the position of the patient and the attacker and the type of weapon used can help identify the projected path of injury. A single stab wound can penetrate several body cavities such as thoracic and abdominal cavities.

### Connection Check 70.5

A 30-year-old female driver who was in a front-end, high-speed MVC is admitted to the ED. She had a seat belt on, but the car did not have any air bags. There was severe front-end damage with spidering of the windshield in front of the driver's seat and a bent steering wheel. The nurse caring for this patient should anticipate and monitor for which injuries?

- Sternal/rib, T-spine, pelvic fracture injuries
- Head, cervical-spine (C-spine), sternal/rib, cardiac contusion, hollow abdominal organ injuries
- Head, C-spine, solid abdominal organ injuries
- Sternal/rib, collarbone fracture, pelvic fracture, facial fracture injuries

## Complications of Trauma

### Hemorrhage

Hemorrhage is a serious and common complication of trauma. It is the leading cause of preventable death after injury if not controlled. Obvious causes of hemorrhage include abdominal or chest trauma injuring organs or vessels. The major sources of abdominal bleeding in blunt trauma are injuries to the spleen or liver. Both organs are very vascular and prone to shearing and lacerations. Chest damage resulting in a massive hemothorax may cause not only blood loss (1,500 mL or one-third or more of the patient's blood in the intrapleural space) but also a tension pneumothorax due to airway compression. Vessel damage, especially damage to arteries, can result in exsanguination if not quickly controlled. Hemorrhage can also occur as a result of fractures (Table 70.3). Pelvic or femur fractures can be a source of major hemorrhage that needs to be controlled by stabilizing the fractures.

### Airway Compromise

Airway compromise can occur because of direct damage to the airway, injury to the surrounding tissue, or secondary issues such as a decreased level of consciousness. Direct injury

**Table 70.3** Approximate Blood Losses From Fractures

Bone	Blood Loss
Rib fracture	125 mL
Ulna or radius fracture	250–500 mL
Tibia or fibula fracture	500–1,000 mL
Femur fracture	1,500 mL
Pelvic fracture	1–3 L (retroperitoneal hematoma)

due to blunt or penetrating trauma or as a result of smoke inhalation may result in the loss of an effective airway, requiring the insertion of an artificial airway through intubation. Trauma to the surrounding tissue such as facial and neck trauma that results in excessive bleeding or swelling may also result in airway compromise requiring intubation to maintain a patent airway. A decrease in level of consciousness, administration of a sedative or pain medication, hypovolemia, or hypoxemia may result in the patient's inability to protect his or her airway or in an ineffective breathing pattern, again requiring the insertion of an artificial airway.

Additional potential causes of airway compromise are the presence of rib fractures and flat supine patient positioning. Both increase the work of breathing. Patients with rib fractures, especially in the geriatric population, may tire when breathing against rib fractures. Flat supine positioning to ensure C-spine immobilization increases the work of breathing and can also increase the risk of aspiration if vomiting were to occur.

### Sepsis

Sepsis is a potential complication in the critically injured trauma patient. The injuries themselves and the invasive interventions necessary to treat the injuries put the patient at risk for infection. The trauma itself is thought to be one cause of the initiation of a systemic inflammatory response. Recognizing the signs and symptoms of sepsis and treating it early can help prevent serious complications and death. See Chapter 14 for more information on shock and sepsis.

### Connection Check 70.6

The trauma nurse anticipates which of the following complications when treating an intoxicated homeless patient after he was hit by a car in the snow? The patient is in C-spine immobilization, has an open femur fracture, a pelvic fracture, abdominal tenderness, and a GCS of 12. (Select all that apply.)

- A. Decreased hemoglobin and hematocrit
- B. Decreased SpO<sub>2</sub>
- C. Tension pneumothorax
- D. Sepsis
- E. Decreased PaCO<sub>2</sub>

### Nursing Management

#### Assessment and Analysis

The clinical manifestations seen in a trauma patient are dictated by the mechanism of injury and area of the body impacted. Blunt trauma of the chest can result in compression, shearing, deceleration or acceleration injuries. Penetrating trauma to the abdomen can result excessive bleeding especially when a very vascular organ such as the liver is impacted.

#### Nursing Diagnoses

- Impaired tissue perfusion
- Ineffective breathing patterns
- Impaired gas exchange

#### Nursing Interventions

##### ■ Assessment

- Airway  
*Assess for possible airway obstruction that would impair ventilation.*
- Breathing  
*Assess for the ineffective breathing patterns that may indicate life-threatening injuries.*
- Circulation  
*Assess pulses, heart rate, skin color; blood pressure, capillary refill, and any obvious signs of bleeding; internal or external that would indicate ineffective perfusion.*
- Disability  
*Assess the GCS to determine the patient's level of consciousness and determine if further evaluation and treatment are necessary.*
- Expose  
*Completely undress the patient so that obvious and potential injuries, both front and back, can be quickly identified.*

##### ■ Actions

- Open airway using c-spine precautions  
*Assure patent airway*
- Provide oxygen  
*Optimize oxygenation*
- Prepare for an advanced airway  
*Assure patent airway and adequate oxygenation if patient cannot protect their own airway.*
- Establish IV access  
*Necessary for fluid and drug administration*
- Fluid resuscitation as ordered with warmed fluids  
*Maintain adequate circulating volume/prevent hypothermia.*
- Monitor temperature  
*Monitoring temperature is essential to prevent hypothermia.*
- Provide warming blankets  
*Prevent hypothermia.*

##### ■ Teaching

- Safe lifestyle skills  
*Avoid high-risk behaviors and/or potential situations that may result in unintentional injury.*

**CASE STUDY: EPISODE 2**

On arrival to the trauma bay, the patient is sitting up and yelling that he cannot breathe. VSs: HR: 130 bpm; BP: 100/55 mm Hg; RR: 30, SpO<sub>2</sub>, 98% on 100% NRB. There is a single gunshot wound to the right shoulder and a single gunshot wound to the right upper quadrant of the abdomen, no other wounds. On assessment, there are minimal breath sounds on the right, positive breath sounds on the left. The trachea is midline. The prehospital providers had performed a needle decompression to the right chest to release accumulated air due to a pneumothorax...

**POISONING**

The definition of a poison is any substance that is harmful to the body when ingested, inhaled, injected, or absorbed through the skin. Too much of any substance can be poisonous. If the person taking or giving a substance did not mean to cause harm, then it is an unintentional poisoning. Unintentional poisonings include the excessive use of drugs or chemicals for recreational purposes. It also includes the accidental exposure to drugs or chemicals for nonrecreational purposes such as a child ingesting cleaning fluid. If the substance is given or taken with the intention of causing harm, then it is an intentional poisoning. Intentional poisoning can be done with the aim to commit a crime or with the goal of committing suicide.

**Epidemiology**

Poisonings involve people of all ages across all socioeconomic, cultural, and religious boundaries. According to the Centers for Disease Control and Prevention (CDC), a total of 55,403 individuals died of drug-induced causes in the United States in 2015. In 2017, the CDC stated that an estimated 75,000 children (18-years of age and younger) are seen in emergency departments each year because of unintentional medication poisoning. The most common poison exposures are due to analgesics, cleaning substances, cosmetics, foreign bodies, plants, sedative-hypnotics and antipsychotics, and cough and cold preparations. Fatalities most commonly result from the ingestion of analgesics, sedative-hypnotics, antipsychotics, antidepressants, street drugs, cardiovascular medications, or alcohol.

From 2012 through 2014, the number of drug overdose deaths per year increased by 23% (from 38,329 to 47,056 in 2014). According to the 2015 statistics, this number continues to increase substantially. The most commonly used drugs resulting in overdose include ten drugs in three classes: opioids (heroin, oxycodone, methadone, hydrocodone, and fentanyl); benzodiazepines (alprazolam and diazepam); and stimulants (cocaine and methamphetamine). A new public

health epidemic emerging in the United States is the number of overdose deaths due to prescription painkillers. The number of overdose deaths from these medications is greater than the deaths from heroin and cocaine combined. This growing trend is resulting in a call to change the way prescribers address patients with pain-related issues. Opium-based prescription pain medication is discussed in detail in Chapter 69.

**Pathophysiology and Clinical Manifestations**

Common poisoning agents include:

- Salicylates
- Acetaminophen
- Sedatives/hypnotics; barbiturates, benzodiazepines
- Antidepressants
- Cardiovascular medications such as beta blockers
- Alcohol

Salicylates are a class of medications that include aspirin or aspirin-containing compounds such as Pepto-Bismol, Kaopectate, Maalox, and some topical creams. Risk factors for salicylate poisoning include accidental ingestion by young children, chronic exposure seen with adults older than age 70, dehydration, renal disease resulting in decreased renal clearance, and disorders or conditions associated with increased bleeding risk such as alcoholism, ulcers, use of anticoagulants, and concomitant use of other NSAIDs such as ibuprofen.

Acetaminophen toxicity is the result of either intentional or unintentional poisoning. Intentional poisonings are typically suicide attempts. They are seen more often in females 15 to 24 years old or older than 40. If females are older than 40, the effects of acetaminophen toxicity are more likely to be severe. Unintentional poisoning can occur when someone is unfamiliar with the appropriate dosing or unknowingly takes two or more medications that contain acetaminophen at the same time. Also, patients with chronic liver disease are predisposed to acetaminophen toxicity because of the impaired ability of the liver to metabolize the medication. Acetaminophen overdose can result in significant liver damage.

Sedatives-hypnotics: barbiturates and benzodiazepines are central nervous system (CNS) depressants. Most severe sedative-hypnotic poisonings are deliberate or suicidal in nature. Risk factors for toxicity include present or history of alcohol or drug abuse, emphysema, asthma, bronchitis or other chronic lung disease, mental depression, sleep apnea, kidney or liver disease, and elderly age. Antidepressant (tricyclic antidepressant [TCA]) medication toxicity is seen most frequently in the young. Overdose of serotonin reuptake inhibitors (SSRIs) antidepressants is also seen. SSRIs are generally safer than TCAs but in severe cases, serotonin toxicity can be fatal. Toxicity to cardiovascular medications such as beta blockers can be seen in children and adults. With young children, toxicity typically occurs through the accidental

exposure to adults' unsecured medications. With adults, toxicity is typically intentional.

Risk factors for alcohol toxicity are many. A small child can get a lethal dose of alcohol by drinking a very small amount. Young people, teenagers, or college students are more likely to binge drink. It occurs more frequently in males, but women are more vulnerable to the effects of alcohol. Small, thin people are also more vulnerable to the effects of alcohol because the body absorbs the alcohol more rapidly. Overall health plays a role. Chronic health conditions make a person more vulnerable to life-threatening

symptoms of alcohol toxicity. Conditions such as diabetes may cause a person to experience dangerously low blood sugar levels during and after ingesting alcohol. Finally, the combination of alcohol and medications greatly increases the risk for fatal alcohol overdose. It is important to note that a growing trend in the presentation of alcohol withdrawal in hospitalized patients is occurring. Patients who drink daily, no matter the amount, should be closely monitored for signs and symptoms of acute withdrawal. Table 70.4 outlines the pathophysiology and clinical manifestations of the poisoning agents.

**Table 70.4 Pathophysiology and Clinical Manifestations of the Poisoning Agents**

Poisoning Agent	Pathophysiology	Clinical Manifestation
<b>Salicylates</b>	<p><u>Salicylate Toxicity:</u></p> <p>Acid-base disturbances</p> <ul style="list-style-type: none"> <li>● Toxicity impairs cellular respiration, stimulating the respiratory centers in the medulla to increase O<sub>2</sub> consumption (hyperventilation) causing respiratory alkalosis.</li> <li>● Salicylate levels greater than 35 mg/dL cause increases in rate and depth of respirations.</li> <li>● Salicylates enter cells and poison mitochondria, causing a metabolic acidosis.</li> </ul> <p>Glucose metabolism</p> <p>With the increase in cellular metabolic activity, the patient may develop clinical hypoglycemia; glucose levels may be within normal range, but the intracellular glucose is depleted.</p> <p>Fluid and electrolytes</p> <ul style="list-style-type: none"> <li>● Dehydration with significant poisoning due to increased gastrointestinal (GI) tract losses (vomiting) and insensible fluid losses (hyperpnea and hyperthermia)</li> <li>● Decreased renal clearance secondary to dehydration</li> </ul> <p>Bleeding</p> <p>Impaired blood clotting and platelet dysfunction</p>	<ul style="list-style-type: none"> <li>● Presentation of toxicity is dependent on dose, acute vs. chronic ingestion, and the patient's age.</li> <li>● Adult patients with acute poisoning usually present with a mixed respiratory alkalosis and metabolic acidosis. Children present with metabolic acidosis.</li> <li>● <u>Early Symptoms (&lt; 30 mg/dL)</u> Nausea, vomiting, diaphoresis and tinnitus, vertigo, hyperventilation, tachycardia, abdominal pain, occasional hematemesis, and hyperactivity</li> <li>● <u>Toxicity Progression (30–70 mg/dL)</u> Agitation, delirium, hallucinations, convulsions, lethargy, and stupor may occur.</li> <li>● <u>Severe Toxicity (&gt; 70 mg/dL)</u> Hyperthermia (especially in young children) Rhabdomyolysis: muscle damage resulting in the release of myoglobin into the bloodstream to be excreted by the kidneys; this eventually causes damage to the kidney, acute renal failure. Respiratory failure may eventually develop.</li> </ul>
<b>Acetaminophen</b>	<p><u>Hepatotoxicity:</u></p> <ul style="list-style-type: none"> <li>● <i>Glutathione</i> is a naturally occurring antioxidant that is in all the cells of the body, with the highest concentration in the liver. It is critically important in the detoxification and elimination of free radicals. An acute overdose of acetaminophen depletes glutathione (GSH) stores in the liver. Loss of</li> </ul>	<p>Acetaminophen poisoning can cause gastroenteritis within hours and hepatotoxicity 1 to 3 days after ingestion.</p> <p><u>Acute Overdose:</u></p> <ul style="list-style-type: none"> <li>● Greater than 150 mg/kg (about 7.5 g in adults) within 24 hours</li> <li>● Phase I: 0–24 Hours: anorexia, nausea, and vomiting, diaphoresis</li> <li>● Phase II: 24–72 Hours: right upper quadrant abdominal pain</li> </ul>

**Table 70.4 Pathophysiology and Clinical Manifestations of the Poisoning Agents—cont'd**

Poisoning Agent	Pathophysiology	Clinical Manifestation
	glutathione causes <i>N</i> -acetyl-p-benzoquinone imine (NAPQI), the principal toxic metabolite of acetaminophen, to accumulate and cause hepatocellular necrosis and damage to other organs.	<ul style="list-style-type: none"> <li>● Phase III: 72–96 Hours: vomiting and symptoms of liver failure, potentially renal failure</li> <li>● Phase IV: 5 Days: resolution of hepatotoxicity or progresses into multisystem organ failure</li> </ul>
<b>Sedatives/hypnotics</b> Benzodiazepines Barbiturates	Sedative-hypnotics are CNS depressants. The main effect is respiratory depression, especially for patients with preexisting pulmonary conditions, which may increase with the ingestion of alcohol or other depressant medications. These medications concentrate in the adipose tissue of the body, taking it longer to be eliminated.	<ul style="list-style-type: none"> <li>● CNS depression</li> <li>● Slurred speech</li> <li>● Ataxia</li> <li>● Altered (most commonly depressed) mental status</li> <li>● Respiratory depression</li> </ul> <p><b>Severe Overdose – Progression of Symptoms</b></p> <ul style="list-style-type: none"> <li>● Stuporous</li> <li>● Comatose</li> <li>● Difficult or slow breathing</li> <li>● Severe nausea or vomiting</li> <li>● Slowed heart rate</li> <li>● Heart failure</li> <li>● Lung failure</li> </ul> <p>Skin changes such as ecchymosis or blisters, referred to as barbiturate blisters, are seen with barbiturate, carbon monoxide or benzodiazepines poisoning over pressure areas. The exact mechanism for the development of these blisters is not entirely understood; however, pressure, friction, and local hypoxia have been implicated as causes.</p>
<b>Antidepressants</b>	Tricyclic antidepressants are rapidly absorbed and distributed into tissues. In excessive amounts, they can produce neurotoxicity. Anticholinergic side effects are also seen due to the altered levels of the neurotransmitter acetylcholine at the neuromuscular junction due to inhibition of reuptake or blocking at the receptor sites.  Acetylcholine dilates blood vessels; decreases heart rate; constricts bronchioles; increases the production of mucus in the respiratory tract; produces contractions or cramping of the intestines; stimulates the production of saliva, sweat, and tears; and constricts the pupil of the eye. Anticholinergic side effects therefore are the opposite of acetylcholine.	<p><b>Anticholinergic effects:</b></p> <ul style="list-style-type: none"> <li>● “Red as a beet”—Cutaneous vasodilation occurs as a means to dissipate heat (flushed face).</li> <li>● “Dry as a bone” (anhidrosis)—dry skin</li> <li>● “Hot as a hare” (anhidrotic hyperthermia)—Interference with normal heat dissipation mechanisms (i.e., sweating) frequently leads to hyperthermia.</li> <li>● “Blind as a bat” (nonreactive mydriasis)—Anticholinergic medications generally produce pupillary dilation and ineffective accommodation that frequently manifests as blurry vision.</li> <li>● “Mad as a hatter” (delirium; hallucinations)</li> <li>● Urinary retention</li> <li>● Dry mouth and eyes</li> <li>● Tachycardia</li> <li>● Delayed gastric emptying</li> <li>● Anti-<math>\alpha</math>-adrenergic effects: <ul style="list-style-type: none"> <li>● Hypotension</li> </ul> </li> <li>● Cardiac effects: <ul style="list-style-type: none"> <li>● QTc prolongation</li> <li>● QRS widening</li> <li>● Ventricular tachycardia—torsade des pointes</li> </ul> </li> </ul>

**Table 70.4 Pathophysiology and Clinical Manifestations of the Poisoning Agents—cont'd**

Poisoning Agent	Pathophysiology	Clinical Manifestation
		<ul style="list-style-type: none"> <li>● Central nervous system:               <ul style="list-style-type: none"> <li>● Restlessness</li> <li>● Delirium and coma</li> <li>● Seizures</li> </ul> </li> <li>● Noncardiogenic pulmonary edema</li> </ul> <p><b>SSRI Toxicity:</b> altered mental status, tremors, agitation, fever, diarrhea, coma, hyper or hypotension, or muscle rigidity. Muscle rigidity can lead to rhabdomyolysis which can cause renal failure</p>
<p><b>Cardiovascular medications</b> Beta blockers</p>	Beta blockers—cardiovascular class of medications that affects the heart by controlling the rate or intensity of cardiac contraction, blood vessel diameter, or blood volume	<p><b>Beta Blocker Toxicity:</b></p> <ul style="list-style-type: none"> <li>● Bradycardia</li> <li>● Hypotension (due to decreased cardiac output, which may impair myocardial perfusion)</li> <li>● Arrhythmias</li> <li>● Hypothermia</li> <li>● Hypoglycemia</li> <li>● Seizures</li> <li>● Decreased systemic vascular resistance (SVR)</li> <li>● Cardiogenic shock</li> </ul> <p>Symptoms may be seen as early as 20 minutes after ingestion, but it is more common to see them within 1–2 hours.</p>
<b>Alcohol</b>	<ul style="list-style-type: none"> <li>● Alcohol (ethanol) is absorbed into the blood system and the fluids surrounding various tissues and inside of the cells. The concentration of alcohol in blood and tissue depends on the amount of total body water because alcohol is soluble in water.</li> <li>● The liver metabolizes and eliminates alcohol in the body.</li> <li>● The mean rate of alcohol elimination is 100 mg/kg/hr for a 70-kg person.</li> <li>● Alcohol toxicity occurs when someone drinks so much alcohol that the liver cannot metabolize it fast enough, causing dangerously high blood alcohol levels.</li> </ul>	<p>Common symptoms of alcohol intoxication include:</p> <ul style="list-style-type: none"> <li>● Slurred speech</li> <li>● Euphoria</li> <li>● Impaired balance</li> <li>● Loss of muscle coordination (ataxia)</li> <li>● Flushed face</li> <li>● Vomiting</li> <li>● Red eyes</li> <li>● Reduced inhibition</li> <li>● Erratic behavior</li> </ul>

SSRI, Selective serotonin reuptake inhibitor.

## Management

### Medical Management

#### Diagnosis and Treatment

Diagnosis and treatment vary depending on the specific medication or substance ingested or exposed to and the levels that remain in the body. Table 70.5 details the diagnostics and treatment for common poisoning agents.

### Decontamination

The definition of **decontamination** is the process of removing or neutralizing a substance to decrease absorption. Regardless of the poison, decontamination is the first step in treating the patient. The most common form is gastrointestinal (GI) decontamination (Table 70.6). Other types of decontamination include flushing the exposed body area or eyes with water to remove or neutralize the substance. Once

**Table 70.5** Diagnostics and Treatments for Common Poisoning Agents

Agent	Diagnostics	Treatment
<b>Salicylates</b>	<ul style="list-style-type: none"> <li>● Serum salicylate level—greater than 100 mg/dL for acute toxicity or greater than 60 mg/dL with chronic overdose</li> <li>● Urine pH—excretion of salicylates increases when urine pH increases</li> <li>● ABGs—to determine acidosis (salicylates more toxic if pH is low)</li> <li>● Arterial lactate—increases in the face of metabolic acidosis—lactate levels are good prognostic indicators</li> <li>● Electrolytes—may be abnormal because of excessive vomiting, diarrhea, and insensible fluid losses</li> <li>● Glucose—increased metabolic activity produces hypoglycemia</li> <li>● PT/aPTT and CBC—may have alterations because of bleeding and platelet malfunction</li> </ul>	<p><b>IV Fluids</b></p> <p>To correct volume and electrolyte abnormalities</p> <p><b>Medications</b></p> <ul style="list-style-type: none"> <li>● Activated charcoal (see Table 70.6)—binds residual aspirin in the gastrointestinal tract if bowel sounds present; repeat dose every 4 hours until charcoal appears in the stool</li> <li>● Sodium bicarbonate to increase urine pH (alkalize urine), causing alkaline diuresis to occur; making the pH of the urine more alkaline increases clearance of an acid-type medication (e.g., salicylates)</li> </ul> <p><b>Hemodialysis</b></p> <p>Indications: coma, renal, hepatic, pulmonary failure, pulmonary edema, severe acid-base disturbances</p> <p><b>Evaluation and Ongoing Monitoring</b></p> <ul style="list-style-type: none"> <li>● Repeat laboratory tests and salicylate levels until the level peaks</li> <li>● Monitor urine pH every 2 hours to maintain pH at 7.5–8.5 during alkalization therapy</li> <li>● Treatment to remove salicylates can result in hypokalemia; therefore potassium must be carefully monitored during treatment.</li> </ul>
<b>Acetaminophen</b>	<ul style="list-style-type: none"> <li>● Serum acetaminophen levels to determine severity of toxicity</li> <li>● Liver function tests (AST—aspartate aminotransferase, <i>ALT</i>—alanine aminotransferase, albumin, bilirubin, alkaline phosphatase) to determine extent of injury to the liver</li> <li>● PT/aPTT—clotting abnormalities may occur as a result of liver damage</li> </ul>	<p><b>Medications</b></p> <ul style="list-style-type: none"> <li>● Activated charcoal (see Table 70.6) to decrease absorption</li> <li>● <i>N</i>-acetylcysteine, an amino acid, is given by mouth or IV to prevent or minimize hepatotoxicity</li> </ul> <p><b>Evaluation and Ongoing Monitoring</b></p> <ul style="list-style-type: none"> <li>● Acetaminophen levels</li> <li>● Liver function tests</li> </ul>
<b>Sedatives/hypnotics</b> Benzodiazepines Barbiturates	<ul style="list-style-type: none"> <li>● Medication levels</li> <li>● Serum glucose to rule out hypoglycemia</li> <li>● Serum and urine drug screen</li> <li>● ABGs—to assess level of respiratory depression</li> </ul>	<p><b>Medications</b></p> <ul style="list-style-type: none"> <li>● Flumazenil is the antidote for benzodiazepines, but its risk for withdrawal symptoms such as seizures may outweigh its benefits</li> <li>● Activated charcoal (see Table 70.6)</li> </ul> <p><b>Hemodialysis</b> for severe cases</p> <p><b>Supportive Care</b></p> <ul style="list-style-type: none"> <li>● Rapid airway, breathing, and circulation assessment</li> <li>● Endotracheal intubation if respiratory depression severe</li> <li>● Oxygen</li> <li>● IV access</li> <li>● Cardiac monitoring</li> <li>● End tidal CO<sub>2</sub> (i.e., capnography)</li> </ul>

Practice	Contraindications/Precautions	Comments
<b>Whole bowel irrigation</b>	<p>with an altered level of consciousness or a weak gag reflex to prevent aspiration.</p> <ul style="list-style-type: none"> <li>● Precaution in paediatric patients</li> <li>● Contraindicated in patients with known GI disease or at risk for ileus, perforation, or obstruction</li> </ul>	May cause nausea, vomiting, abdominal cramping, electrolyte imbalance
<b>Irrigation (ocular)</b>		<ul style="list-style-type: none"> <li>● Alkali exposures require longer irrigation of the eye.</li> <li>● Eye pH should return to neutral before discontinuation of irrigation.</li> </ul>
<b>Irrigation (dermal exposures)</b>	<p>Remove all contaminated clothing</p> <p>Wear PPE</p> <p>Thoroughly wash the whole body including hair and nails</p>	

GI, Gastrointestinal; NG, nasogastric; OG, orogastric; PPE, personal protective equipment.

commonly used, syrup of ipecac, is discouraged by poison control centers in out-of-hospital situations.

### Nursing Management

#### Assessment and Analysis

The general appearance and clinical manifestations seen with poisoning are related to the specific substance, type and amount of exposure, and complicating comorbidities. For example, level of consciousness changes manifested as drowsiness, sedation, euphoria, impaired memory and judgment, changes in speech patterns, ataxia, or depression may be present with barbiturates or alcohol poisoning because of CNS depression. Tachypnea, crackles on auscultation, and respiratory distress may be seen with salicylate poisonings because of the body's attempt to compensate for the decrease in cellular respiration and the increased O<sub>2</sub> consumption, which causes respiratory alkalosis. Tachycardia and/or hypotension may be present in any type of poisoning that results in excessive vomiting, diarrhea, or blood loss due to bleeding, such as salicylate overdose. It should be evaluated in relation to other presenting symptoms such as a prolonged QTs or cardiac dysrhythmias, which may be seen with overdose of tricyclics and cardiovascular medications.

### Nursing Diagnoses

- Risk for ineffective airway clearance
- Ineffective breathing patterns
- Impaired gas exchange
- Risk for aspiration

### Nursing Interventions

#### ■ Assessment

- Vital signs  
*Hypotension and tachycardia may be present in many types of poisonings as a result of volume loss from vomiting and diarrhea; an overdose of beta blockers that affects the heart by controlling the rate or intensity of cardiac contraction, blood vessel diameter, or blood volume may result in hypotension and bradycardia.*
- Pulse oximetry  
*Many common poisoning agents result in a decreased level of consciousness, potentially resulting in respiratory depression and hypoxia.*
- Neurological assessment  
*Many types of poisoning cause a decreased level of consciousness, confusion, delirium, or seizures.*
- Continuous cardiac monitoring  
*Antidepressants and cardiovascular medications such as beta blockers can cause dangerous dysrhythmias and*

*bradycardia. Alkalinization therapy for salicylate poisoning may deplete potassium, increasing the potential for cardiac dysrhythmias.*

- **Laboratory assessment**
  - **Toxicology screen - serum and urine**  
*A tox screen is essential in determining the type and amount of poison in the patient.*
  - **Arterial blood gases**  
*Salicylate levels greater than 35 mg/dL cause increases in rate and depth of respirations, resulting in respiratory alkalosis. Salicylates enter cells disrupting mitochondrial function, causing a metabolic acidosis.*
  - **Potassium**  
*Alkalinization therapy for salicylate poisoning may deplete potassium.*
  - **Serum glucose**  
*Hypoglycemia must be ruled out as a cause of decreased level of consciousness; with the increase in cellular metabolic activity with salicylate poisoning, the patient may develop clinical hypoglycemia.*
  - **Urine pH**  
*Making the pH of the urine more alkaline increases the clearance of acid-type medications such as salicylates.*
  - **Complete blood count/Clotting studies**  
*Salicylate poisoning impairs blood clotting and platelet dysfunction and may result in bleeding.*
  - **Liver function tests**  
*Acetaminophen overdoses lead to impaired liver function, resulting in elevated liver enzymes.*
  - **Repeat urine and serum medication levels**  
*Necessary to assess level of medication or alcohol in the system and assess adequacy of treatment*

### ■ Actions

- **Airway management, including supplemental O<sub>2</sub> and preparations for intubation**  
*Airway compromise may be present because of the decreased level of consciousness.*
- **Establish IV access**  
*Necessary to facilitate fluid and medication administration for the treatment of the overdose*
- **ECG**  
*To assess for cardiac conduction abnormalities due to poisoning or potassium depletion*
- **Administer medications as ordered**
  - **IV fluids with thiamine**  
*Alcoholics are prone to thiamine depletion, making them susceptible to Wernicke-Korsakoff's syndrome, which may cause seizures.*
  - **Benzodiazepines**  
*For tricyclic- or alcohol withdrawal-induced seizures*
  - **Flumazenil**  
*Flumazenil is the antidote for benzodiazepine overdose.*
  - **Sodium bicarbonate**  
*To increase urine pH (alkalize urine) causing alkaline diuresis, increasing clearance of acid-type medications such as salicylates*

- **N-acetylcysteine**  
*An amino acid is given by mouth or IV to prevent or minimize hepatotoxicity with acetaminophen toxicity.*
  - **Activated charcoal**  
*Decontamination agent that works by binding with the poison, preventing or slowing absorption into the system*
  - **Glucagon**  
*Administered for beta blocker toxicity; enhances myocardial contractility and heart rate*
  - **Prepare for decontamination through GI, ocular, or dermal irrigation or flushing**  
*To enhance elimination of the poison, which helps reverse the effects of the overdose*
- ### ■ Teaching
- **Careful use of over-the-counter (OTC) medications—read the labels, be aware of maximum daily doses**  
*Misuse or overuse of OTC medications such as acetaminophen may be dangerous; many OTC products contain aspirin.*
  - **Review early signs of toxicity or overdose with patients/family**  
*Facilitate early identification and prompt treatment in the event of overdose*
  - **Review dangers of alcohol and/or sedative abuse as well as dangers of abrupt withdrawal**  
*Alcohol and sedative abuse has serious and long-term consequences. Abrupt withdrawal is life threatening and may result in seizures.*
  - **Precaution in the use of aspirin with children suffering a viral disorder**  
*Aspirin has been linked with Reye's syndrome in children. Reye's syndrome is a disorder resulting in sometimes fatal neurological and hepatic changes.*

### Evaluating Care Outcomes

Poisoning may be managed with prompt recognition and treatment. A well-managed patient is discharged with adequate respiratory effort and is hemodynamically stable, understanding the cause and future risk of poisoning. If poisoning was intentional, the patient is discharged to a psychiatric facility for treatment in hopes of preventing further suicide attempts.

### Connection Check 70.7

The nurse is caring for a patient coming into the ED unconscious after taking an overdose of an unknown substance approximately 1 hour ago. Which of the following actions should the nurse take first?

- A. Initiate gastric lavage
- B. Insert two large-bore IVs
- C. Assess vital signs with pulse oximetry
- D. Insert nasogastric tube

## INJURIES RELATED TO THERMOREGULATION

The human body strives to maintain normal body temperature at 98.6°F (37.1°C) regardless of environmental factors. **Thermoregulation** is a physiological response that occurs in the anterior (cooling) and posterior (heating) hypothalamus. The hypothalamus responds to temperature information sent to the brain from peripheral and central thermoreceptors in the skin, limb muscles, and spinal cord.

The body's response to cool environments is to minimize heat loss through cutaneous vasoconstriction, increasing heat production by shivering, mobilization of carbohydrate reserves, and elevation of the basal metabolic rate. Heat is dissipated through **convection** (being exposed to cool air or water), **conduction** (loss of heat to cold object), or **evaporation** (sweating). In response to overheating, the body initiates cutaneous vasodilation to shunt blood to the skin

surface, increasing heat loss through convection and conduction. The body also activates the sweat glands causing perspiration, which helps cool the body. Fig. 70.13 illustrates the maintenance of temperature homeostasis. Sweating is the body's primary cooling mechanism, but it may also cause a loss of sodium, potassium, and body fluids. It is important to assess for dehydration and replace fluid and electrolytes.

## Hypothermia

### Epidemiology

The incidence of hypothermia is increasing in the United States. Between 2003 and 2013, there were greater than 13,400 hypothermia deaths, with annual rates ranging from 0.3 to 0.5 per 100,000 persons. A report from the CDC in 2015, indicated that this statistic may be increasing. The growing trend is a combination of colder more drastic

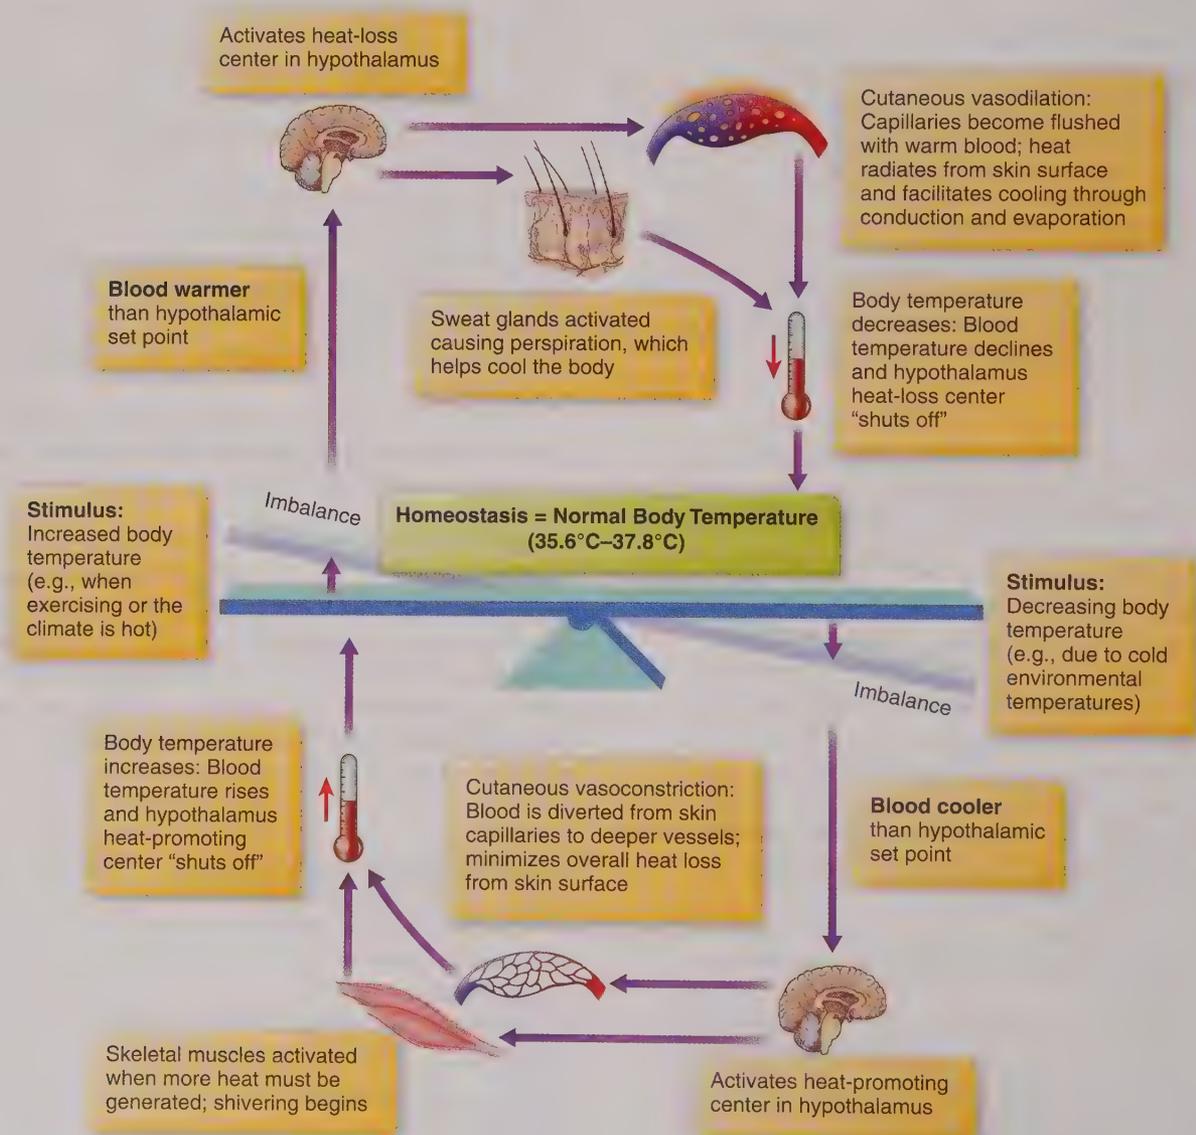

FIGURE 70.13 Thermoregulation.

winters with cold spells and the increasing number of homeless populations. Risk factors for hypothermia include the following:

- In older adults
  - Ability to regulate body temperature and to sense cold may lessen with age.
  - More likely to have medical conditions that will affect temperature regulation
  - May not be able to communicate when they are cold or may not be mobile enough to get to a warm location
- The very young
  - Children lose heat faster than adults because of a larger percentage of body surface area for their weight.
  - Children will lose more heat through the head (largest body surface area in young children).
  - Children may not have the judgment to dress properly in cold weather or to get out of the cold when they should.
  - Infants have less efficient mechanisms for generating heat, putting them at risk for hypothermia.
- Psychiatric problems/Diminished capacity
  - Condition(s) interferes with judgment (i.e., may not dress appropriately for the weather or understand the risk of cold weather)
  - People with dementia may wander from home or get lost easily, making them more likely to be stranded outside in cold or wet weather.
- Alcohol and drug use
  - Alcohol may make your body feel warm inside, but it causes your blood vessels to dilate, or expand, resulting in more rapid heat loss from the surface of your skin.
  - Using alcohol or recreational drugs can affect your judgment about the need to get inside or wear warm clothes in cold weather conditions.
  - If a person is intoxicated and passes out in cold weather, the risk of hypothermia is high.
- Certain medical conditions
  - Some medical conditions affect the body's ability to regulate body temperature such as hypothyroidism, poor nutrition, stroke, severe arthritis, Parkinson's disease, trauma, spinal cord injuries, and burns.
  - Some medical conditions affect sensation in the body's extremities, such as peripheral neuropathy with diabetes, dehydration, or any condition that limits activity or restrains the normal flow of blood.
- Medications
  - Some medications can change the body's ability to regulate, such as certain antidepressants, antipsychotics, and sedatives.

### **Pathophysiology and Clinical Manifestations**

**Mild hypothermia** is when the body's core temperature drops to 89.6°F to 95°F (32°C to 35°C). The human body tries to compensate for decreases in body temperature by stimulating the sympathetic nervous system to shiver and increase heart rate, blood pressure, respirations, and promote

peripheral vasoconstriction. Tachypnea causes a decrease in carbon dioxide (CO<sub>2</sub>) levels, resulting in a respiratory alkalosis. Hyperglycemia may be present because of a decrease in glucose use by the cells and a decrease in insulin secretion due to an increase in corticosteroid levels. Cold diuresis develops as a result of peripheral vasoconstriction, hyperglycemia, and decreased renal tubular absorption. Other symptoms, including mild confusion, ataxia, and diminished fine motor movements, may also be present in patients with mild hypothermia because of the shifts in metabolic state.

**Moderate hypothermia** is when the body's core temperature drops to 82.4°F to 89.6°F (28°C to 32°C). As the body's temperature continues to lower, shivering becomes more violent and eventually stops. There is deterioration in the patient's mental status (agitation, hallucinations) that, if left untreated, progress to coma. Pupils dilate, and movements become less coordinated as a result of CNS depression. Blood shunts away from the skin surface to preserve heat as part of the body's compensatory mechanism. Compensatory mechanisms begin to fail, resulting in bradycardia, hypoventilation, and hypoxemia. Myocardial irritability begins to develop with increasing bradycardia and decrease in spontaneous depolarization of the pacemaker cells. This change in cell excitability increases the risk for dysrhythmias such as atrial fibrillation, ventricular fibrillation, and ventricular tachycardia. The metabolic rate slows and respiratory and lactic acidosis develops. In addition, patients develop hypokalemia because potassium shifts into the cell.

**Severe hypothermia** is when the body's core temperature is lower than 82.4°F (28°C). At this temperature, the body begins to shut down. When the patient reaches this point, compensatory mechanisms that cause vasoconstriction and shunting of blood away from the skin to vital organs in an effort to retain heat completely fail. There is a massive dilation of vessels moving blood back to the surface of the skin, causing further cooling and also resulting in further deterioration of cardiovascular, respiratory, and neurological functions. Compromised cardiovascular functions include decreased cardiac output, arterial pressure, and basal metabolic rate (20% of basal metabolic rate), resulting in severe cerebral hypoperfusion. Patients become severely hypotensive, myocardial irritability worsens, and muscle rigidity develops. Eventually, the body completely shuts down and the patient dies.

Frostbite is another complication associated with cold weather exposure (see Box 70.6).

### **Management**

#### **Medical Management**

#### **Diagnosis**

When treating the patient with hypothermia, it is essential to assess the following:

- Mechanism of exposure
  - Ambient temperature
  - Enclosed or open space; was the person in a protected area out in the open
  - Did the exposure include water?
- Time of exposure

## Box 70.6 Frostbite

In response to cold temperatures, the vessels in the skin constrict allowing less warm blood to flow to the affected areas causing freezing of the tissues. Hands, feet, and the face are the areas most typically affected. There are four stages or grades of frostbite:

### Stage 1: Frostnip

- Superficial skin surface damage
- Initial symptom is numbness with an area of pallor and edema
- Damage is not permanent

### Stage 2:

- Clear blisters are evident with hardened skin
- Over time the affected area becomes black, dries, and peels
- There is typically no tissue loss

### Stage 3:

- Tissues below the superficial skin layers freeze
- Blood blisters and a blue-grey discoloration appears
- Pain is persistent and blackened eschar develops

### Stage 4:

- Tissue damage extends to muscle and bone
- Involves complete tissue necrosis and permanent damage

### Treatment

- Prevention is the best treatment
- Move to warm environment, remove wet clothing and place affected tissue in warm water or, if water not available, use body heat for warming—place fingers under the arms. Do not rewarm in the prehospital environment if there is a possibility of refreezing before arriving at the hospital for definitive care. That can exacerbate tissue damage. Avoid walking on frost-bitten feet as that can cause more tissue damage.
- Most effective treatment is immersion in warm water. Successful rewarming is evident when the tissue is red and soft to the touch. This process is painful so analgesia may be necessary. More severe frostbite may require thrombolysis due to clot formation in affected tissue. Very severe tissue damage may require amputation.

- Length of time since the incident
- Predisposing factors such as mental status, alcohol, drugs
- Past medical history that may predispose the patient to hypothermia.

Laboratory and diagnostic tests are detailed in Table 70.7.

### Treatment

Treatment priorities are the same as for any trauma patient: focus on the ABCs. Ensure an adequate airway and effective ventilation, insert an IV line, and start IV fluids. The specific treatment varies depending on the degree of hypothermia. **Passive external rewarming** can be used for mild hypothermia. **Active external rewarming** is used for mild to moderate hypothermia, and **internal rewarming** is used for moderate to severe hypothermia. See Table 70.8 for a description of rewarming techniques.

### Safety Alert Complications in Rewarming the Patient With Hypothermia

- Rewarming the core at a prescribed rate is important to prevent significant complications. Rewarming too rapidly can cause hyperkalemia as potassium shifts out of the cells and a condition known as “afterdrop.” Afterdrop is defined as a precipitous reduction in core temperature due to redistribution of body heat to improperly warmed peripheral tissues, with rapid shunting of cold blood from the periphery to the core as the direct result of vasodilation. This causes a bolus of cold, hyperkalemic, acidotic blood to return from the periphery to the heart, which results in a biochemical injury that leads to severe hypotension and dysrhythmias.
- Limit invasive procedures and overall movement of the patient when severely hypothermic because of a greater susceptibility to dysrhythmias.
- If cardiac arrest is suspected:
  - Hypotension and bradycardia are expected when core temperature is low. The patient may appear pulseless and lifeless. A longer than usual attempt should be made to determine pulselessness; 45 to 60 seconds. If there is no pulse, cardiopulmonary resuscitation should be initiated. Resuscitation medications and defibrillation are not effective until the patient’s temperature is above 86°F (30°C). Defibrillation should be attempted one time, but if ineffective, further attempts are deferred until temperature reaches higher than 86°F (30°C). Advanced cardiac life-support medications such as antiarrhythmics, vasopressors, and inotropes are ineffective at low body temperatures so are usually not given. Conversely, very mild hypothermia is recommended after cardiac arrest to slow the metabolic rate and decrease cerebral injury (see Evidence-Based Practice: Therapeutic Hypothermia).

## Evidence-Based Practice

### Therapeutic Hypothermia

In 2015, the American Heart Association recommended therapeutic hypothermia, targeted temperature management between 89.6°F (32°C) and 96.8°F (36°C), for patients who have had a return of spontaneous circulation (ROSC) after cardiac arrest but are still demonstrating a decreased level of consciousness. Reducing body temperature will reduce cerebral metabolic rate, reducing the risk of anoxic brain injury. Hypothermia induction may begin as soon as the patient has ROSC and should continue for at least 24 hours.

Neumar, R. W., Shuŝter, M., Callaway, C. W., Gent, L. M., Atkins, D. L., Bhanji, F., . . . Hazinski, M. F. (2015). Part 1: Executive summary 2015 American Heart Association guidelines update for cardiopulmonary resuscitation and emergency cardiovascular care. *Circulation*, 132(18 Suppl. 2), S315–S367.

**Table 70.7 Laboratory and Diagnostic Tests**

Laboratory Test	Rationale
<b>Arterial blood gas</b>	Assess for metabolic acidosis, respiratory alkalosis, or both
<b>Electrolytes</b>	Abnormalities in blood chemistries may indicate the degree of hypothermia and necessary treatment
<b>Glucose</b>	Depending on the level of hypothermia, may see an increase or decrease in blood glucose
<b>CBC</b> Hemoglobin, hematocrit	Cold diuresis and subsequent loss of fluid causes hemoconcentration of the blood
<b>Coagulation studies (PT/aPTT)</b>	Hypothermia inhibits the coagulation cascade
<b>Other diagnostics</b>	
<b>ECG</b>	Hypothermia causes heart to become irritable, resulting in changes to ECG, changes to electrical conduction
<b>Chest radiograph</b>	Assess for aspiration pneumonia, vascular congestion, pulmonary edema
<b>Head CT</b>	Rule out significant injury causing changes in LOC different from hypothermia
<b>Serum and urine toxicology</b>	Rule out drugs or alcohol involvement
<b>Pregnancy test</b>	Should be completed on women of childbearing years to determine pregnancy status

CBC, Complete blood cell count; CT, computed tomography; ECG, electrocardiogram; LOC, level of consciousness; PT/aPTT, partial thromboplastin time/activated partial thromboplastin time.

**Table 70.8 Rewarming Strategies**

Category	Strategies
<b>Passive external rewarming</b>	Used for mild hypothermia and focuses on preventing further heat loss: Move to a warmer environment Remove all wet clothing and dry the patient Cover the patient with warmed blankets and wrap the head to prevent heat loss
<b>Active external rewarming</b>	Used for mild to moderate hypothermia: External heat sources such as heat lamps and forced warm air blankets
<b>Active internal rewarming</b>	Used for moderate to severe hypothermia: <u>Least invasive</u> Warmed humidified O <sub>2</sub> —increases core temperature and reduces heat loss due to evaporation Warmed IV fluids O <sub>2</sub> and fluids should be warmed to 40°C–42°C <u>More invasive rewarming methods</u> Peritoneal, bladder, and thoracic lavage with warmed fluids Open thoracotomy (surgical opening into thorax) followed by thoracic lavage and cardiac massage in cardiopulmonary arrest. Cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO)—blood is circulated extracorporeally (outside of the body), oxygenated, warmed and returned to the body; allows the heart to warm and provides adequate cardiac output. This is the preferred method of rewarming for the cardiac arrest patient because it reduces the risk of intractable cardiorespiratory failure while providing adequate circulation and oxygenation

## Nursing Management

### Assessment and Analysis

The clinical manifestations are directly related to the severity of the hypothermia. Shivering is the body's first compensatory mechanism in an attempt to raise the body's temperature. Muscle groups around the vital organs begin to shake in small movements in an attempt to create warmth by expending energy. Other compensatory mechanisms are activated as core body temperature decreases, such as vasoconstriction to shunt blood away from the skin to vital organs. As compensatory mechanisms fail, massive vasodilation occurs, resulting in profound changes in neurological, respiratory, and cardiovascular status.

### Nursing Diagnoses

- Ineffective airway clearance
- Impaired gas exchange
- Deficient fluid volume
- Hypothermia
- Impaired skin integrity

### Nursing Interventions

#### ■ Assessment

- Vital signs including temperature (rectal temperature or automatic continuous temperature probe should be used) and pulse oximetry  
*Initial temperature to determine degree of hypothermia, then ongoing vital sign monitoring to assess effectiveness of treatment. Initial vital signs reflect tachycardia and hypertension resulting from stimulation of the sympathetic nervous system in an attempt to compensate for the hypothermia. Hypotension and bradycardia may eventually occur because of massive dilation.*
- Neurological status  
*Profound hypothermia produces a deterioration in neurological status.*
- Laboratory values
  - Arterial blood gases  
*Blood gases may reflect a metabolic acidosis secondary to decreased flow and shunting and/or respiratory alkalosis due to tachypnea.*
  - Potassium  
*Hypokalemia occurs initially because of cellular shifts. Later during rewarming, hyperkalemia may occur.*
  - Glucose  
*Monitor glucose because of the risk for hyperglycemia and hypoglycemia.*

#### ■ Actions

- Administer O<sub>2</sub>; prepare to intubate with severe respiratory depression  
*Airway compromise may be present because of a decreased level of consciousness.*
- Continuous cardiac monitoring  
*Myocardial irritability develops with a decrease in spontaneous depolarization of the pacemaker cells. This change in cell excitability increases the risk for dysrhythmias such as atrial fibrillation, ventricular fibrillation, and ventricular tachycardia.*

- Establish IV access  
*Necessary for administration of warm fluids and medications*
- Prepare for appropriate rewarming technique
  - Remove from cold environment
  - Remove wet clothing
  - Dry patient
  - Warm blankets
  - Heat lamp
  - Warmed IV fluids
  - Peritoneal, bladder, and thoracic lavage with warmed fluids
  - Cardiopulmonary bypass/extracorporeal membrane oxygenation (ECMO)  
*Warming techniques increase in complexity and invasiveness as hypothermia worsens.*

#### ■ Teaching

- Signs and symptoms of early hypothermia  
*With knowledge, the patient may be able to avoid more severe or profound hypothermia.*
- The risk of overindulgence in alcohol or recreational drugs and hypothermia  
*Alcohol may make a person's body feel warm inside, but it causes blood vessels to dilate, resulting in more rapid heat loss from the surface of the skin. Using alcohol or recreational drugs can affect judgment about the need to get inside or wear warm clothes in cold weather conditions. If a person is intoxicated and passes out in cold weather, the risk of hypothermia is high.*

### Evaluating Care Outcomes

Managing a patient with hypothermia varies according to the degree of hypothermia. Successful treatment requires prompt assessment, continuous monitoring, and careful rewarming. A well-managed patient is discharged with a normal temperature, dysrhythmia free, and an understanding of how to avoid future occurrences.

## Connection Check 70.8

The nurse should monitor for which clinical manifestations in the patient diagnosed with mild hypothermia? (Select all that apply.)

- A. Ataxia
- B. Shivering
- C. Cardiac dysrhythmias
- D. Oliguria
- E. Hypoglycemia

## Hyperthermia

### Epidemiology

**Hyperthermia** is considered a body temperature of more than 103°F (39.4°C) and occurs when the body produces or absorbs more heat than it can dissipate. Hyperthermia is a medical emergency and requires immediate treatment to prevent disability or death. Data from a 2009/2010 Nationwide

Emergency Department sample demonstrated there were approximately 4,100 ED visits each year associated with heat stroke and heat-related illnesses. Heatstroke and deaths from excessive heat exposure are more common during summers with prolonged heat waves. Morbidity and mortality from heatstroke are associated with the duration of the temperature elevation. Delayed therapy is associated with a higher mortality rate of 80% from heatstroke. Mortality is highest among the elderly population, patients with preexisting disease, those confined to a bed, and those who are socially isolated.

Risk factors for hyperthermia include:

- Very young, less than 5 years of age
  - Produce proportionally more metabolic heat
  - Core body temperature rises faster in response to dehydration
  - Smaller organ system that is not as efficient in dissipating heat
- Older adults, older than 65 years of age
  - More commonly have a chronic illness that interferes with normal thermoregulation such as chronic lung or heart disease
  - More likely to be taking medication that alters the body's response to heat:
    - Phenothiazines, which depress the hypothalamus (temperature regulation center in the body)
    - Anticholinergic medications, which inhibit sweating
    - Diuretics, which cause or exacerbate dehydration
    - TCAs and amphetamines, which stimulate the hypothalamus and increase muscle activity
    - Beta blockers or calcium channel blockers, which decrease the body's cardiovascular response to heat
- Patients with an illness that causes a fever
- Patients that have diabetes, peripheral vascular disease, or uncontrolled hypertension
- Patients who have taken drugs or alcohol
- Athletes exercising strenuously in hot climates
- Obese people who generate more heat during activity and dissipate heat more slowly

### Pathophysiology and Clinical Manifestations

The hypothalamus in the brain helps the body maintain a normal temperature by balancing heat production and heat loss. During hot weather or in a hot environment, the body works to regulate its internal temperature by producing sweat, which cools the body as it evaporates. A humid environment reduces evaporation of sweat and decreases cooling. When the sweat does not evaporate effectively, or the person is not sweating at all, there is likelihood for a heat-related illness. **Heat cramps** are painful, involuntary muscle spasms of the arms, legs, or abdomen that occur because of sweating profusely during strenuous activity. It is postulated that the loss of sodium, magnesium, or calcium is responsible for the muscle cramps. The cramps generally last 1 to 3 minutes. The muscles are tender and hard, and the patient may have some involuntary twitching. The skin is moist and cool. Generally, the patient's vital signs are within normal limits, and the temperature is either normal

or slightly elevated. **Heat edema** occurs when exposure to a hot environment causes swelling of the feet, ankles, and hands. **Heat stress** occurs when your body can no longer regulate your temperature and you become too hot.

**Heat syncope** occurs when standing still for an extended period or when moving too quickly from sitting to standing while in the heat. This occurs in response to a sudden drop in perfusion to the brain as the body tries to cool itself by diverting blood flow to the skin through peripheral dilation. As a result of peripheral dilation and gravity, blood pools in the legs and the blood pressure drops. As a response to the pooling in the lower extremities, the patient experiences dizziness, vertigo, tunnel vision, weakness, and nausea before finally losing consciousness.

**Heat exhaustion** occurs when a person performs strenuous activity in a hot environment for an extended time without drinking enough fluid to replace sodium and water lost from profuse sweating. Symptoms include fatigue, weakness, dizziness, headache, nausea, vomiting, and muscle cramps. A patient with heat exhaustion may have some confusion but does not have significant neurological impairment. Patients may also be tachycardic, hypotensive, and tachypneic. The patient's temperature is usually higher than 100.4°F (38°C) and lower than 104°F (40°C).

**Heat stroke** is a medical emergency. The body's thermoregulatory mechanism has failed, and the body temperature rises uncontrollably. Immediate intervention is necessary to prevent organ damage and death. Classic heatstroke develops over several days during a heat wave and typically affects elderly, sedentary people with preexisting conditions. Patients usually present with red, dry skin; the patient has stopped sweating altogether. However, moist skin does not rule out the presence of heatstroke. Exertional heatstroke generally occurs in younger healthy people who are participating in strenuous physical activity. They have signs and symptoms of heat exhaustion but also have CNS dysfunction, which may appear as confusion, irrational behavior, delirium, seizures, or coma. Core temperature is greater than 104°F (40°C) in heatstroke. Without immediate intervention, pulmonary edema, dysrhythmias, and **rhabdomyolysis**, a condition in which skeletal muscle cells break down, releasing oxygen-carrying myoglobin potentially precipitating renal failure, may occur. Eventually, hypovolemic and cardiogenic shock and multiorgan failure occur.

### Management

#### Medical Management

Treatment is dependent upon the category of heat-related illness. It is vital to reduce the patient's core temperature as quickly as possible to decrease the probability of serious complications. All interventions start with removal to a cooler environment and hydration. Heat stress or heat edema may require nothing more than removing to a cooler environment. The patient with heat syncope requires safety maneuvers to help prevent injury from falling. After being gently helped to the floor, the patient should be placed in the recovery position until full recovery of consciousness.

Heat cramping requires rehydration with oral fluids containing electrolytes to correct the fluid and electrolyte loss.

Cooling interventions for the patient with heat exhaustion include moving the patient to a cool environment, having the patient lie down and elevate his or her feet, removal of extra clothing, and encouraging the patient to drink cool, nonalcoholic beverages. For this purpose, sports drinks, water, and fruit juices are best. Additional cooling interventions include the application of a cool cloth or towel to the skin or encouraging the individual to shower, bathe, or sponge off with cool water. In the hospital, cooling blankets, ice packs, or fans are interventions utilized to cool the patients. Fluid replacement with IV 0.9% normal saline solutions may be necessary if vital signs are abnormal or the patient is unable to tolerate oral fluid replacement. Patients should rest for at least 24 hours before resuming normal activity.

Immediate emergency intervention is required if the victim is exhibiting signs of heatstroke. Reducing the patient's temperature (to approximately 102.2°F [39°C]) is the number one priority because the duration of elevated temperature is the primary determinant of outcome. Particular attention to airway, breathing, and circulation is essential in resuscitating the patient adequately. The heatstroke patient requires intensive hemodynamic monitoring as well as monitoring a continuous core temperature. This patient also requires administration of IV fluids. Avoid aggressive fluid resuscitation in these patients because it puts the patient at risk for pulmonary edema due to fluid overload. A Foley catheter is essential for accurate measurement of intake and output. Cooling methods include ice packs to the axilla and groin, cooling blankets or fans, and submersion in tepid water if the patient's condition allows. Along with immediate active cooling, take the necessary steps to stop excessive heat production. Treat agitation and shivering with benzodiazepines.

## Nursing Management

### Assessment and Analysis

The clinical manifestations of hyperthermia are consistent with the degree of increased temperature. Patients with early stage or mild hyperthermia such as heat stress or heat syncope sweat profusely. Patients with heat exhaustion manifest some mild symptoms of CNS dysfunction such as confusion, but patients with heat stroke manifest severe symptoms of CNS dysfunction such as delirium and seizures. Severe heatstroke results in dysrhythmias and cardiac and/or respiratory failure.

### Nursing Diagnoses

- Ineffective airway clearance
- Impaired gas exchange
- Deficient fluid volume

### Nursing Interventions

#### ■ Assessment

- Vital signs with temperature  
*Continual monitoring of temperature is essential to determine the severity of hyperthermia and effectiveness of the*

*intervention. Hypotension and tachycardia may be present because of fluid loss.*

- Neurological status  
*Signs of CNS dysfunction such as confusion occur with heatstroke.*
- Skin assessment  
*Patients sweat profusely during early stages of hyperthermia; the skin becomes flushed and dry in later stages.*

#### ■ Actions

- Move the patient into a cool environment  
*Removing the patient from the heat source reduces the impact of radiant heat.*
- Encourage intake of oral fluids such as cool nonalcoholic beverages, fruit juices, or sports drinks  
*Replaces circulating volume*
- Administer IV fluids as necessary  
*Replace circulating volume when fluid by mouth is not adequate or possible because of CNS dysfunction*
- Active cooling methods
  - Sponge bath
  - Ice packs in the axilla/groin
  - Cooling blanket/fans
  - Submerge in tepid water if condition allows  
*Reduce body temperature through convection and conduction*

#### ■ Teaching

- Avoid hyperthermia
  - Avoid excessive activity in high-heat environments
  - Drink plenty of fluids in the heat and while exercising
  - Know the signs and symptoms of hyperthermia  
*Prevention of hyperthermia is safer than treating hyperthermia.*

### Evaluating Care Outcomes

The best treatment of hyperthermia is prevention. Evaluating heat risk in the environment, modulating activity as necessary in a hot environment, and drinking plenty of fluids are first steps at prevention. A well-managed patient is discharged alert and oriented, safe from injury or falls, and hemodynamically stable with a normal temperature and an understanding of how to avoid future occurrences of hyperthermia.

## Connection Check 70.9

The nurse is caring for patient who came into the ED with a temperature of 105°F (40.6°C). This patient was found at home in an apartment without air conditioning; the current heat wave has temperatures higher than 100°F (37.8°C) for the last 3 days. Which of the following actions should the nurse plan to take first?

- A. Apply cooling blankets
- B. Obtain laboratory specimens
- C. Establish IV access
- D. Administer Tylenol

## SNAKEBITES

### Epidemiology

Snakebites are a significant problem worldwide. They account for approximately 125,000 deaths per year worldwide, although they are less common in the United States than in other parts of the world. In the United States, approximately 5,000 snakebites per year are reported to the American Association of Poison Control Centers, with a fatality rate of reported cases of 0.06%. These deaths are often in the age extremes—children and elderly—and in those who do not receive **antivenin** or its administration is delayed. Reporting snakebites is not mandatory, so many snakebites may go unreported, and not everyone seeks treatment for snakebites. About 25% of bites are believed to be dry bites, bites in which there is no envenomation, the injection of venom into the victim.

The largest group of venomous snakes in North America is the Viperid subfamily Crotalinae, also known as pit vipers. This has three genera with more than 30 species of rattlesnakes, water moccasins/cottonmouths, and copperheads. This group of snakes causes 95% of the snakebites in the United States, followed by coral snakes and a small number of imported exotic snakes.

Snakebites tend to occur during the warmer months (April through October) when snakes are more active. The peak months are July and August, when more people are outside and active as well. Warmer, more southern states such as Georgia, Louisiana, North Carolina, Florida, Texas, California, and Arizona have the largest number of reported snakebites.

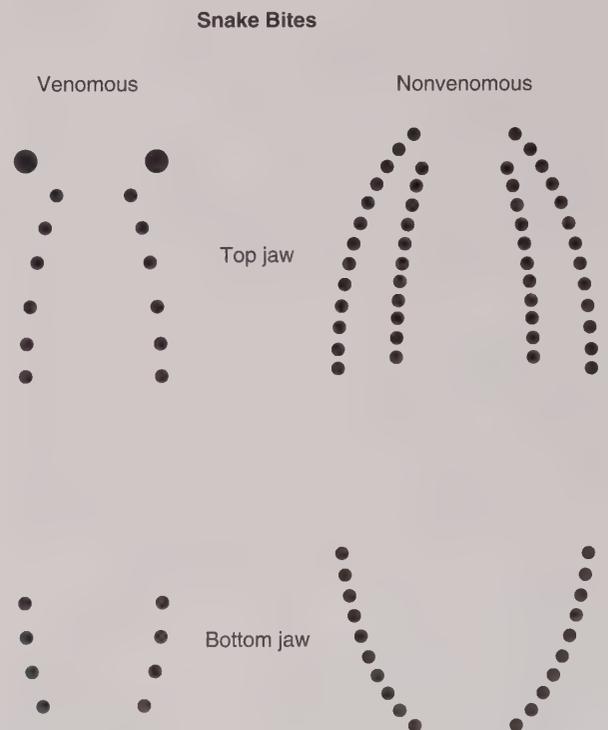

Snakes are often found in tall grass and leaf piles, lying under logs or rocks, in rock/log piles, or basking on warm rocks. When snakes are surprised, they may bite. The majority (98%) of snakebites are on the extremities. Of the extremities bitten, most bites occur on the hands or arms. These are bites associated with attempting to handle or kill the snake. Even a dead snake is dangerous. The bite reflex in a recently killed snake remains intact even if the snake has been decapitated. Of those who have been bitten by a snake in the United States, about 77% are male and 70% are adults older than 20 years old.

### Pathophysiology and Clinical Manifestations

When a venomous snake bites and injects venom through its fangs, the process is called **envenomation**. **Venom** differs from species to species but is typically a complex mixture of enzymes and proteins designed to immobilize and digest prey. Immobilization occurs because of the **neurotoxic** properties of venom, blocking the transmission of acetylcholine at the neuromuscular junction, causing weakness or paralysis. Venom can also be **hemotoxic**, causing the destruction of red blood cells. The venom of Crotalinae results in increased capillary permeability allowing the shift of fluid, red blood cells, and albumin into the site of envenomation. These are local effects that are seen at the site of

injury. Clinical manifestations include local swelling and ecchymosis. At the site of the bite, fang marks, teeth marks, and/or scratches are visible (Fig. 70.14). With envenomation, there is edema and erythema at the site and the surrounding tissues, which occurs usually within 30 to 60 minutes. Ecchymosis may appear around the bite site within 3 to 6 hours in moderate or severe envenomation. Within 8 hours, serous and/or hemorrhagic bullae usually appear at the bite site. The edema is usually limited to dermal and subcutaneous tissues. Rarely, severe envenomation may cause compartment syndrome, substantial amounts of serous fluid within the subcutaneous tissue causing compression of the muscle, nerves, and blood vessels. With rattlesnake bites, necrosis (or cell/tissue death) around the bite site is common. The necrosis is caused by the enzymes/toxins within the rattlesnake venom that cause hemolysis and the decreased perfusion to the involved tissue due to the increase in capillary membrane permeability. Most soft tissue venom effects peak within 2 to 4 days.

There are systemic effects that occur while the venom is circulated through the vascular system. Systemic effects include damage at the cellular level, weakening vascular walls, causing muscle breakdown, and initiating the coagulation cascade. This results in excessive clotting abnormalities similar to disseminated intravascular coagulation (DIC) discussed in Chapter 14. The toxic systemic effects can be seen in the lungs, kidneys, myocardium, peritoneum, and CNS. In severe Crotalinae bites, specifically rattlesnake, it is common to see significant thrombocytopenia (greatly decreased platelet count). The thrombocytopenia may be asymptomatic

**FIGURE 70.14** Bite mark differences between venomous and nonvenomous snakes.

or symptomatic with spontaneous bleeding. Other coagulopathies may occur leading to a DIC-like syndrome causing more bleeding. Most often, patients hemorrhage from the bite site, mucous membranes, and venipuncture sites. They may develop epistaxis (bloody nose), hematemesis (bloody emesis), hematuria (blood in urine), gingival bleeding, or hematochezia (blood in stool). Later, hypovolemia occurs while blood loss continues, and fluids pool in the microcirculation as a result of the increased capillary permeability. Severe hypotension, rhabdomyolysis, hemolysis, nephrotoxic venom effects, or DIC-like syndrome may cause renal failure in severe envenomation snakebites. Decreasing circulating blood volume contributes to cardiac failure. The end result is shock, lactic acidosis and, in severe cases, multisystem organ failure.

Clinical manifestations from coral snake bites differ in several significant ways. Coral snakes leave smaller wounds due to having shorter fangs and smaller mouths. Coral snake envenomation may resemble dry bites as a result of minimal swelling and pain. Neurological manifestations of the neurotoxic effects may be delayed for 12 hours. These symptoms are often cranial-nerve palsies that cause ptosis, dysphagia, diplopia, dyspnea, dysarthria, blurred vision, and respiratory paralysis. Other symptoms may include increased salivation, weakness, lethargy, drowsiness, euphoria, and tremors. These bites may eventually result in respiratory failure secondary to systemic neuromuscular blockade.

### Connection Check 70.10

The nurse is caring for a patient bitten by a rattlesnake 3 hours before admission to the ED. The nurse correlates which of the following clinical manifestations with a venomous snakebite? (*Select all that apply.*)

- A. Edema at the site
- B. Bleeding at the site
- C. Excessive diuresis
- D. Dysrhythmias
- E. Numbness at the site

## Management

### Medical Management

#### Diagnosis

Laboratory tests include those used to assess for evidence of coagulopathies, renal failure, and rhabdomyolysis. The following diagnostic tests should be performed at regular intervals as determined by the patient's status:

- Complete blood count—to evaluate hemoglobin, hematocrit, and platelet values
- Urinalysis—testing for blood, myoglobin, and protein in the urine
- Coagulation studies—evaluate the presence of clotting abnormalities and DIC

- Renal studies—elevated blood urea nitrogen (BUN) and creatinine indicate renal failure
- Electrolytes—potassium may be elevated in renal failure
- Serum creatine kinase (CK)—increases because of muscle breakdown; will be elevated in rhabdomyolysis

Diagnostic studies for a coral snake envenomation are aimed toward detection of respiratory failure and may include blood gas measurement, capnography, pulmonary function testing, and continuous pulse oximetry.

#### Treatment

Medical treatment is dependent on the type of snake involved. Medical treatment for a Crotalinae bite is based on the symptoms and the severity of envenomation. Patients who do not show immediate signs of envenomation should be observed for 12 hours. If the patient does not develop any local or systemic signs after 12 hours, discharge home is indicated.

For severe envenomation, antivenin administration is the recommended treatment. Prior to administration, consultation with a medical toxicologist through the poison control center should be performed. The antivenin provided to patients with severe Crotalinae envenomation is called Crotalidae Polyvalent Immune Fab (Ovine) (FabAV). When FabAV is infused to a patient with a Crotalinae bite, the Fab fragments bind the venom in the intravascular space to allow excretion through the kidneys. Antivenin is most effective when given within 4 to 6 hours after envenomation. The tissue swelling and ecchymosis around the bite site should be evaluated to determine the appropriate dose. The adequacy of the dose is based on improvement of vital signs—a decrease in tachycardia and tachypnea and an increase in blood pressure, partial or complete reversal of the coagulopathies, and improvement of systemic findings such as diarrhea, vomiting, pain, altered mental status, or oral paresthesias.

The patient should be closely monitored while receiving antivenin because reactions may occur. If the patient experiences signs of acute hypersensitivity, the antivenin infusion should be stopped immediately. Epinephrine (1:1,000 [1 mg/mL] 0.3 to 0.5 mg intramuscularly), diphenhydramine, inhaled albuterol, and IV corticosteroids should be available to treat the anaphylactic reaction. The antivenin may be restarted at a lower infusion rate after the acute hypersensitivity has been treated. This patient should be continually monitored in an intensive care setting over 24 hours after the antivenin administration to observe for signs of immediate or recurrent toxicity. For coagulopathies, do not transfuse platelets or fresh frozen plasma (FFP) because the Crotalinae venom inactivates them. The only time a patient with a Crotalinae bite should receive platelets or FFP is when there is significant bleeding uncontrolled by high-dose antivenin administration.

A bite from a coral snake involves serial detailed neurological examinations for at least 12 hours. If the patient has clinical evidence for ventilatory failure, then prompt endotracheal intubation is warranted. Antivenin specific for coral snake is again the recommended treatment. This antivenin

is not as readily available, so consultation with a medical toxicologist or poison control center may be necessary to locate available antivenin or for advice regarding alternative clinical treatment. The poison control number should be readily available.

Do not apply a tourniquet, ice, or alcohol to the affected extremity. Previously, these treatments were recommended, but they have been found to have minimal effect. Additionally, the tourniquet can damage tissue, blood vessels, nerves, and tendons. The wound care is the same for all snakes. The wound should be cleansed, and the patient should receive tetanus prophylaxis if the immunization is outdated or unknown. It is not recommended to provide antibiotics for snakebites unless the wound is heavily contaminated.

## Nursing Management

### Assessment and Analysis

A Crotalinae bite with envenomation produces swelling, pain, blistering, and ecchymosis due to proteins in venom breaking down muscle and blood vessels and triggering the clotting cascade. Later clinical manifestations include signs of ventilatory decompensation, rhabdomyolysis, compartment syndrome, and signs of coagulopathies such as bleeding from the wound, IV sites, and mucous membranes. The clinical manifestations associated with a coral snake bite are due to the neurotoxic effects of the venom. Muscular weakness, ptosis, and dysphagia are common signs. Later manifestations include respiratory failure.

### Nursing Diagnoses

- Impaired gas exchange
- Deficient fluid volume
- Impaired mobility

### Nursing Interventions

#### Assessments

- Vital signs  
*Tachycardia, hypotension, and tachypnea may be present because of fluid volume loss due to bleeding and increased capillary permeability causing leakage into the tissues. Worsening vital signs indicate either worsening of systemic reaction (before antivenin), anaphylaxis reaction to antivenin, or needing a higher dose of antivenin. The adequacy of the antivenin dose is also based on improvement of vital signs.*
- Pulse oximetry  
*Decreased O<sub>2</sub> saturation and increases in respiratory distress may indicate a venomous coral snake bite.*
- Skin assessment  
*A venomous bite produces edema, bleeding, ecchymosis, and pain at the site; a venomous coral snake does not produce significant inflammation in the localized tissue.*
- Laboratory assessment
  - Renal studies  
*Blood urea nitrogen and creatinine are elevated in renal failure which is a risk with rhabdomyolysis.*
  - Coagulation studies  
*Coagulation studies will be prolonged.*

- Urinalysis  
*Urinalysis reveals myoglobin, indicating the presence of rhabdomyolysis.*
- Electrolytes, specifically potassium  
*Potassium may become elevated with decreased renal function.*

#### Actions

- Continuous cardiac monitoring  
*Dysrhythmias may be present with elevated potassium in renal failure.*
- Administer IV fluids as ordered  
*IV fluids help maintain intravascular volume, preventing hypotension. The treatment of rhabdomyolysis involves administration of large volumes of IV fluids to flush the kidneys and maintain urine output.*
- Administer antivenin as ordered  
*Antivenin is the recommended treatment to counteract the neurotoxic and hemotoxic effects of venom.*
- Keep affected extremity immobilized in a functional position below the level of the heart  
*Reduces blood flow to the heart and the spread of the venom*
- Remove tight clothing and jewelry from affected extremity  
*These objects could act as a tourniquet if swelling is present*
- Keep patient calm  
*Enables identification of symptoms as related to the snakebite and not the autonomic manifestations of nausea, vomiting, tachycardia, diaphoresis, and diarrhea caused by the terror of a snake bite*

#### Teaching

- Discharge instructions: return to the ED immediately if they develop swelling, redness, increase in pain, epistaxis, fever, dark or bloody urine, shortness of breath, vomiting, diaphoresis, any change in mental status, or any other symptoms besides mild pain at the site.  
*These signs may indicate inadequate treatment with antivenin, requiring repeated dosing.*
- Avoid handling snakes, including dead snakes. When possible, avoid tall grass, piles of wood, piles of rock, and other snake hiding places. While outdoors in the warmer months when snakes are most active, people should wear long pants and thick or leather boots and be aware of where they are placing their feet and hands at all times.  
*Snakebite prevention: snakes have bite reflex even after death.*

### Evaluating Care Outcomes

Careful, ongoing assessment, prompt treatment with antivenin, and IV fluids as dictated by patient presentation are necessary for successful management of a snakebite. A well-managed patient remains calm and is discharged with stable vital signs and the knowledge of when to return to the hospital if conditions change.

## SPIDER BITES

### Epidemiology

There are no national or international registries for spider bites, nor is there mandatory reporting; therefore, global epidemiological information is somewhat difficult to obtain. However, according to the data collected by the American Association of Poison Control Centers, almost half of all spider bites within the United States are reportedly caused by black widow or brown recluse spiders, each causing nearly 2,500 envenomations each year. These data are based mostly on self-report and are not 100% reliable because these bites are often misdiagnosed. Ulcerating or necrotic wounds, which are assumed to be a result of a spider bite, can be caused by a myriad of other insect-induced, infectious, or physical sources.

### Pathophysiology and Clinical Manifestations

Most spider bites are not dangerous to humans and produce only mild, local erythema. However, there are a few species of spiders in the United States that are known to produce more serious reactions, namely the brown recluse (*Loxosceles*), the black widow (*Latrodectus*), and the hobo spider (*Tegenaria agrestis*). These spiders have been associated with significant disease and have been known to cause death, though rarely and more commonly in small children or the elderly.

The brown recluse spider (*Loxosceles*) is found mostly in the southwestern United States and is known for its characteristic violin pattern on its back. Brown recluse spider venom contains multiple enzymes that make it hemotoxic. Its bite sometimes progresses to extensive local necrosis but rarely to hemolytic reactions. The exact mechanism of this reaction has not been conclusively determined. The typical course progresses from an initially painless bite to painful blistering that occurs within 2 to 8 hours of the bite and then progresses to more serious ulceration within 72 hours. Approximately 20% of the time, necrosis eventually forms. The bite then slowly heals over the course of several weeks to months. **Systemic loxoscelism**; arthralgias, fever, rash, and vomiting followed by hemolytic anemia, thrombocytopenia, DIC, acute renal failure, and very rarely coma, is uncommon. If it does occur, it presents within 72 hours of the bite.

The black widow spider (*Latrodectus*) is found throughout North America but is more common in the southwestern United States. The spider, identified by a red color on the underside of its abdomen, releases a neurotoxic venom with its bite. This neurotoxin causes massive presynaptic release of neurotransmitters, thereby causing diffuse muscle pains, spasms and rigidity, and extreme stomach pain. Associated symptoms also include arthralgias, fever, hypertension, vomiting, and hyperreflexia. This resulting condition, latrodecism, usually resolves in 3 to 7 days. It rarely results in death.

The hobo spider, most commonly found in the Pacific Northwest, is large and brown with distinct yellow markings on its abdomen. A bite from the hobo spider can result in

extensive dermal necrosis and permanent scarring. It is characterized by a completely painless initial bite, progressing to painful induration and erythema within 30 minutes, then multiple small blisters within 15 to 35 hours, and then finally progressing to serous exudate encrusting a cratered wound within 72 hours. These lesions generally heal spontaneously. Systemic symptoms include severe headache, vomiting, weakness, fatigue, and vision impairment within 10 hours of the bite.

### Management

#### Medical Management

Once a person has been bitten, serious sequelae can usually be prevented if the spider species is identified early and the person receives the appropriate medical treatment quickly, especially if a venomous spider bite is suspected. In general, bites can be treated with oral or IV analgesics and antihistamines and antibiotic treatment for secondary wound infections. A tetanus vaccine is suggested for prophylaxis because spider bites can become infected with tetanus spores. Occasionally, systemic symptoms result, and further monitoring in the hospital setting is warranted.

#### Treatment for a Brown Recluse Bite

Recommended laboratory tests include complete blood count, serum glucose, platelet count, BUN and creatinine levels, partial thromboplastin time/activated partial thromboplastin time (PT/aPTT), fibrinogen, renal function tests, and urinalysis. These studies are aimed at identifying signs of hemolysis and intravascular coagulation. Treatment may include oral corticosteroids, dapsone, colchicine, or hyperbaric oxygenation, all of which work to reduce the effects of the dermonecrosis—necrosis of the skin caused by the venom. Antibiotics may be indicated if signs of infection exist. Some recommend early excision of the bite site. An antivenin is under investigation but is not universally available.

#### Treatment for a Black Widow Bite

Laboratory tests may include complete blood count, blood glucose, CK, and urinalysis and often identify leukocytosis, elevated CK levels, and proteinuria. Treatment includes opioids or muscle relaxants. Calcium gluconate 10% IV may relieve muscle rigidity. Antivenin is available but is often only used to treat those who do not respond promptly to the other treatments first. If warranted, the antivenin has high therapeutic efficacy and has little risks.

#### Treatment for a Hobo Bite

Treatment is symptomatic and includes excision of the necrotic tissue as indicated.

### Nursing Management

#### Assessment and Analysis

The clinical manifestations of spider bites are unique to the type of spider. The venom of the brown recluse and hobo spiders contains enzymes that are hemotoxic and result in local tissue necrosis. The black widow venom is neurotoxic and causes diffuse pain as a result.

## Nursing Diagnoses

- Impaired skin integrity
- Pain
- Ineffective airway clearance

## Nursing Interventions

### ■ Assessments

- Vital signs  
*The black widow spider bite may result in hypertension.*
- Pain assessment  
*Spider bites can result in severe pain at the site.*
- Skin assessment; color, size, and drainage  
*These characteristics may help identify the type of spider involved.*

### ■ Actions

- Cleanse wound thoroughly  
*Minimizes risk of infection*
- Apply cold compresses and elevate the affected extremity  
*Minimizes swelling*
- Administer medications as ordered
  - Antivenin if available  
*Antivenin counteracts the neurotoxic and hemotoxic effects of venom spider bites.*
  - Pain medication  
*Spider bites can be very painful.*
  - Antibiotics  
*To treat infection if necessary*
  - Tetanus  
*For prophylaxis because spider bites can become infected with tetanus spores*

### ■ Teaching

- Wound care  
*Keeping the wound clean and reporting any changes or worsening immediately to the provider*

## Evaluating Care Outcomes

Successful treatment of a spider bite requires prompt intervention, administration of antivenin if available, and symptom management. A well-managed patient is discharged home hemodynamically stable with pain under control and clear wound care instructions.

## Connection Check 70.11

The nurse is caring for a patient who presents 4 hours after a spider bite to the hand. The hand is slightly swollen, and there are areas of redness and painful blistering. The nurse correlates these symptoms with what type of spider bite?

- Brown recluse
- Black widow
- Hobo spider
- Tarantula

## DROWNING

### Epidemiology

Drowning accounts for more than one-half million deaths worldwide. It is difficult to get an accurate number of drowning and near-drowning victims because of differences in terminology and reporting requirements. The outcome of drowning is either death or survival. The term “drowned” typically means that the victim died as a result of drowning. A victim survives drowning if he or she is successfully resuscitated from cardiac or respiratory arrest and is discharged from the hospital. It is also termed *survival from drowning* if the victim dies from other causes in which the death is not directly due to the drowning. Drowning is classified as witnessed when the episode is observed or unwitnessed when the victim is found in the water.

Risk factors for drowning include but are not limited to:

- Alcohol use
- Assault
- Drug abuse
- Head trauma
- Hypothermia
- Severe weather
- Water sport accidents
- Younger age (0–5 years)
- Inability to swim
- Open water swimming in severe currents, riptides, waves, and cold water temperatures

### Pathophysiology and Clinical Manifestations

The pathophysiology of drowning starts with submersion in water and the victim’s automatic or voluntary response of holding his/her breath. There is a depletion of oxygen and a buildup of CO<sub>2</sub>. As the victim remains under water, he or she starts to breathe in water without any gas exchange occurring, further decreasing oxygenation. The respiratory and circulatory systems collapse. Neurologically, the victim ultimately suffers seizures, coma, and death. Fig. 70.15 illustrates the pathophysiology associated with the drowning process.

#### Cardiovascular System

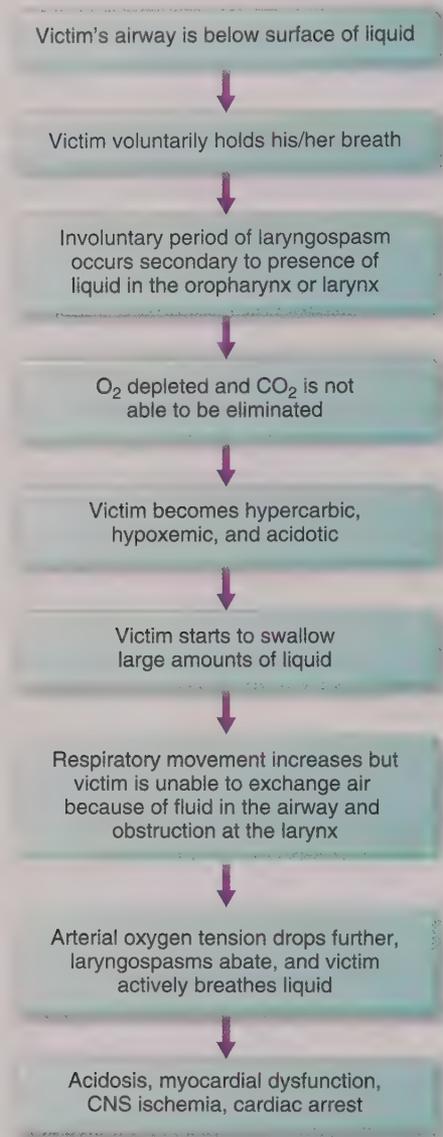

Initially, the victim is hypertensive and tachycardic with activation of the sympathetic nervous system. While hypoxia, acidosis, and hypothermia worsen, the victim becomes bradycardic, pulmonary hypertension develops, and there is a decreased cardiac output. Atrial fibrillation and other arrhythmias may occur, ultimately progressing to asystole.

#### Respiratory System

Because of impaired or nonexistent ventilation, hypoxia, hypercarbia, and acidemia occur.

#### Neurological System

Development of hypoxia from drowning causes CNS dysfunction. It begins within 5 minutes of inadequate

**FIGURE 70.15** Drowning process.

oxygenation. This is the leading cause of morbidity and mortality in drowning victims. The clinical manifestation ranges from confusion and disorientation to coma, seizures, and death.

### Complications

If the victim survives, approximately 70% will develop acute respiratory failure. This develops due to aspirated fluid, increased capillary permeability, and neurogenic pulmonary edema. Decrease in lung compliance is the result of surfactant washout and dysfunction resulting in atelectasis, ventilation-perfusion mismatch, and intrapulmonary shunting.

## Management

### Medical Management

#### Diagnostic and Laboratory Tests

- Arterial blood gases are done to assess respiratory status.

- Chest x-ray may reveal the presence of infiltrates or aspiration.

Examination should focus on the respiratory, cardiovascular, and neurological systems. Dyspnea, wheeze, and crackles suggest aspiration, while the level of consciousness may have prognostic relevance. Examine for signs of trauma or other medical conditions.

### Treatment

The initial priorities in a drowning victim are to restore oxygenation, ventilation, and perfusion. Ventilatory support with supplemental O<sub>2</sub> is required. Further support with noninvasive ventilation or intubation may be required depending on the severity of the respiratory failure and the patient's level of consciousness. Intensive care management is directed at treating hypoxia, maintaining cardiovascular stability, neuroprotection, and prevention and/or management of infection likely present due to aspirated fluid. Hypothermia is common in drowning victims. Medications and defibrillation are not likely to be successful if the patient's core temperature is lower than 86°F (30°C). Slow, active rewarming should be instituted as soon as possible to facilitate resuscitation priorities. Ultimately, prevention and/or treatment of multiorgan failure may be necessary.

## Nursing Management

### Assessment and Analysis

The clinical manifestations of drowning are directly related to the amount of time the victim has been submerged underwater. Respiratory effects range from respiratory distress to respiratory failure and apnea. Cardiovascular effects range from hypertension and tachycardia secondary to the initiation of the sympathetic nervous system to cardiovascular collapse secondary to lack of oxygen. Neurovascular effects may be as minimal as slight confusion to no response, again secondary to lack of oxygen.

### Nursing Diagnoses

- Impaired gas exchange
- Hypothermia
- Decreased level of consciousness

### Nursing Interventions

#### ■ Assessment

- Vital signs  
*Initial vital signs indicate hypertension and tachycardia; later, because of hypoxia, acidosis, and hypothermia, bradycardia and hypotension result.*
- Arterial blood gases  
*Blood gases indicate respiratory and metabolic acidosis due to the inability to clear CO<sub>2</sub> and inadequate oxygenation.*
- Neurological assessment  
*Neurological assessment varies depending upon the amount of time the patient was submerged and hypoxic; the more hypoxia, the more profound the neurological deterioration.*

### ■ Actions

- Administer 100% nonrebreather mask  
*Administer O<sub>2</sub> to maintain adequate saturation to support vital bodily functions.*
- Prepare for intubation  
*Intubation may be necessary if the patient's respiratory and/or neurological status has deteriorated to the point the victim cannot protect the airway.*
- Continuous cardiac monitoring  
*Continuous monitoring allows for early detection of bradycardia or dysrhythmias.*
- Insert IV  
*An IV is necessary for the administration of IV fluids to support cardiovascular status and administration of medications.*
- Anticipate cardiopulmonary resuscitation (CPR)  
*In severe and prolonged drowning, cardiopulmonary arrest is likely, necessitating CPR.*

### ■ Teaching

- Water safety—careful observation of children, use of life preservers, limit alcohol, learn to swim  
*The best treatment of drowning is prevention.*

### Evaluating Care Outcomes

Successful intervention is possible if submersion time is minimal. The longer underwater, the more dire the outcome. A well-managed patient is one who is discharged with minimal to no respiratory, circulatory, or neurological sequelae. This patient understands the hazards of water and takes the necessary safety precautions for himself/herself and family. The best cure is prevention.

## Making Connections

### CASE STUDY: WRAP-UP

The 19-year-old gunshot patient is still complaining of shortness of breath. A needle decompression was done in the field to release air because of the pneumothorax, preventing a tension pneumothorax. Initial assessment confirms minimal breath sounds on the right, requiring a right-sided chest tube with positive air and blood return in the chest tube. The patient's breathing becomes less shallow and labored. A second IV is placed, laboratory tests are drawn, and warm fluids are hung. On further assessment, patient has a wound to the right lower back, which is tender to palpation. Current VSs HR: 135 bpm; BP: 90/50 mm Hg; RR: 22 breaths/minute; O<sub>2</sub> 99% with 100% NRB mask in place, temperature 97.7°F (36.5°C). A FAST examination is performed and is positive. The operating room (OR) is alerted and the patient is prepared to go to the OR STAT. In the OR, the bleeding is controlled. The patient is moved to the ICU, where he begins to stabilize.

### Case Study Questions

1. After receiving the report from the field provider about the patient, the trauma nurse anticipates and prepares for which initial interventions? (*Select all that apply.*)
  - A. Chest tube placement
  - B. Rapid fluid infuser
  - C. Open chest massage
  - D. Intubation
  - E. Magnetic resonance imaging
2. The nurse recognizes this patient is at risk for developing which complications? (*Select all that apply.*)
  - A. Infection
  - B. Airway compromise
  - C. Hypovolemia
  - D. Rhabdomyolysis
  - E. Seizures
3. What symptom should prompt a quick intervention from the nurse in this case?
  - A. Hypertensive
  - B. Hypothermic
  - C. Anxious
  - D. Tachycardic
4. In addition to the trauma surgeon and nurse, what other members of the team are essential at the bedside in this patient's care? (*Select all that apply.*)
  - A. Airway provider
  - B. Radiology
  - C. Clinical technician
  - D. Laboratory technician
  - E. Pharmacist
5. The nurse is responsible for which of the following functions as part of the trauma team? (*Select all that apply.*)
  - A. Documentation
  - B. Medication administration
  - C. Airway management
  - D. Management of rapid fluid infuser
  - E. Central line insertion

## CHAPTER SUMMARY

In the United States, unintentional injury is the fifth leading cause of death for all ages. Trauma centers are hospitals specially equipped to provide comprehensive emergency care to patients suffering from a traumatic injury. A designated trauma center must maintain a specialty-trained workforce that is prepared to provide a range of emergency care 24/7 and must also ensure access to the equipment that is needed to provide

immediate life-saving care. Roles in a trauma team include a trauma team leader, nurses, airway provider, surgical provider, respiratory therapy, radiologist, and clinical technician, pharmacist, social work and/or pastoral care, and support staff.

The prehospital provider is responsible for recognizing the urgency of the trauma situation, providing initial care based on the ABCs, and transporting the patient as quickly as possible to a hospital. Once at the hospital, the patient undergoes a primary survey based on the ABCDEs, emergency treatment is provided as necessary, and then a more thorough secondary assessment is performed.

It is important to understand the mechanism of injury because that may help determine the scope and extent of injuries. Mechanisms of injury may be characterized as blunt or penetrating injuries. In blunt trauma, there is no penetration of the skin. Mechanisms of energy transference that often cause blunt trauma injuries are deceleration and acceleration forces, compression, and shearing. Penetrating trauma is defined as injuries produced by a foreign object penetrating the tissue. The energy created by the foreign object dissipates into the surrounding tissues, causing injury.

A poison is any substance that is harmful to your body when ingested, inhaled, injected, or absorbed through the skin. Prompt recognition and treatment are essential. Common clinical manifestations include respiratory depression, excessive vomiting, diarrhea, bradycardia, hypotension, and arrhythmias, depending on the poison. Definitive treatment is specific for each poison, but decontamination—removing or neutralizing a substance to decrease absorption—is an important component of care for all.

Thermoregulation is a physiological response the body uses to maintain normal body temperature. If body

temperature is not maintained, hypothermia or hyperthermia may result. Hypothermia may result in symptoms such as shivering and increased heart rate and blood pressure to myocardial irritability and bradycardia when hypothermia worsens. Depending on the level of hypothermia, treatment involves passive external rewarming, active external rewarming, or active internal rewarming. Depending on the level, hyperthermia results in symptoms such as swelling of the feet, ankles, and hands to fatigue, weakness, dizziness, headache, nausea, vomiting, and muscle cramps. Cooling interventions include moving the patient to a cool environment, removal of extra clothing, applying cool cloths, applying ice packs, and encouraging the patient to drink cool, nonalcoholic beverages.

When a venomous snake bites and injects venom through its fangs, the process is called *envenomation*. Venom immobilizes prey and can be neurotoxic, hemotoxic, and can disrupt fluid balance. Treatment with antivenin is important if available; otherwise, treatment is based on patient symptoms.

Most spider bites are not dangerous to humans, but serious reactions are produced by the bite of the brown recluse, the black widow, and the hobo spider. The effects can be treated if identified early. Spider bites can be treated with antivenin if available, analgesics and antihistamines, and antibiotic treatment for secondary wound infections.

Drowning is a process resulting in primary respiratory impairment from submersion/immersion in water. Oxygenation and removal of CO<sub>2</sub> is impaired, resulting in acidosis, neurological impairment, and myocardial dysfunction. The initial priorities in a drowning victim are to restore oxygenation, ventilation, and perfusion.

## Disasters, Mass Casualty Incidents, and Complex Emergencies

*Dianne Whyne*

### LEARNING OUTCOMES

Content in this chapter is designed to assist in:

1. Providing a broad overview of the existing knowledge related to disasters, mass casualty incidents, and complex emergencies.
2. Describing the difference between disasters, mass casualty incidents, and complex emergencies.
3. Describing the many types of disasters and their impact.
4. Identifying current concepts in disaster response.
5. Discussing the hospital response to a disaster including triage, personal protective equipment, decontamination, surge planning, evacuation, sheltering in place and mental health.
6. Describing essential nursing tasks in response to a disaster or mass casualty incident.
7. Listing the essential elements of a personal preparedness plan.

### CONCEPTS

- Assessment
- Healthcare System
- Safety
- Trauma

### ESSENTIAL TERMS

Acute radiation syndrome (ARS)  
Aftershock  
Alpha radiation  
Beta radiation  
Bioterrorism  
Blast front  
Blast wind  
Biocontainment unit (BCU)  
Chemical, biological, radiological, nuclear, and explosive (CBRNE) weapons  
Complex Emergency (CE)  
Contamination  
Cyclones  
Decontamination  
Dirty bomb  
Disaster  
Ebola Virus Disease (EVD)  
Emergency Management Assistance Compact (EMAC)  
Emerging Infectious Diseases (EID)  
Epicenter  
Epidemic  
Fault line  
Federal Emergency Management Agency (FEMA)  
Foreshocks  
Gamma radiation  
Hazard vulnerability analysis (HVA)  
Hurricanes  
Improvised explosive device (IED)  
Incident Command System (ICS)  
Internally contaminated  
Ionizing radiation  
Irradiation  
JumpSTART  
Mass casualty incident (MCI)  
Mass shooting  
Pandemic  
Personal protective equipment (PPE)  
Primary blast injury  
Radiation  
Sort, Assess, Lifesaving interventions, Treatment and/or Transport (SALT) Triage  
Secondary blast injuries  
Shelter in Place (SIP)  
Simple Triage and Rapid Treatment (START)  
Surge capacity  
Terrorism  
Tertiary blast injuries  
Tornado Alley  
Tornadoes  
Triage  
Typhoon  
Typhoon  
Weapon of mass destruction (WMD)

## Finding Connections

### CASE STUDY: EPISODE 1

Follow the scenario throughout the chapter.

The spring of 2011 saw three record-breaking and deadly tornado outbreaks in the United States. In mid-April, a severe storm produced 179 confirmed tornadoes across 16 southern states. Two weeks later, an even larger outbreak spawned at least 336 tornadoes across 21 states. In all, more than 300 people died from tornadoes during the month of April 2011.

Late Sunday afternoon, May 22, 2011, a supercell thunderstorm tracked from extreme southeast Kansas into far southwest Missouri. The National Weather Service issued a tornado warning (Box 71.1) at 5:17 p.m. Central Time Zone that included the city of Joplin, Missouri. Joplin is a city of more than 50,000 with a population density near 1,500 people per square mile. The area's major industries include agriculture, education, health and social services, manufacturing, and retail trade. Two hospitals, Mercy/St. John's Regional Medical Center and the Freeman Health System, provide medical care to the region and serve as the city's emergency medical service (EMS) providers. Joplin is home to Missouri Southern State University, Ozark Christian College, and Messenger College. The Joplin area is located within "Tornado Alley," a part of the central United States that experiences a high frequency of tornadoes each year. Meteorically, this region is ideally situated for the formation of supercell thunderstorms that produce tornadoes rated Enhanced Fujita (EF) scale-2 or higher.

Joplin city residents were given a 24-minute notice of the impending tornado. Twenty-five tornado sirens sounded, and weather alert boxes appeared in the corners of local TV stations. As the EF scale-5 tornado touched down in Joplin, it had maximum winds in excess of 200 mph and was three-fourths to 1-mile wide with a damage path 6-miles long (the entire tornado path was 22.1-miles long and up to 1-mile wide). The tornado's eye was 300-yards wide. This tornado resulted in 161 fatalities and approximately 1,371 injuries. Of the fatalities, 54% died in their homes, 32% died in nonresidential areas, and 14% died in vehicles or out-of-doors. The tornado destroyed 4,380 homes and damaged an additional 3,884 homes, not including 400 businesses and 8 schools. Eighteen thousand vehicles were destroyed, and 4,500 jobs were displaced.

At St. John's Regional Medical Center, a 9-story building, there were 183 patients—patients watching television, visiting with friends, or eating their dinner. There were also 25 patients in the emergency department (ED) and approximately 100 staff members on duty. The announcement over the hospital speakers warned of a potential tornado, and "Plan Gray" was activated.

Plan Gray is the Tornado Emergency Operations Plan. No one panicked, as such calls are routine in Joplin; "Condition Gray" is practiced several times per year. On the inpatient units, patients who were able to walk were placed in hardback chairs or wheelchairs and lined up in the halls; others were rolled into the hallways on their beds, and for those too sick to move, blankets and pillows were placed over them. Staff also pulled shades over windows to shield patients from flying debris. Because the storm was not expected to hit them, hospital visitors watched the storm on TV while they continued their visits. The storm came up quickly and passed over St. John's Hospital in 45 seconds. The hospital sustained a direct hit at approximately 5:41 p.m. At the hospital, just prior to the hit, an employee ran down a corridor shouting, "Take cover! We're gonna get hit!" Seconds later, the air turned cold, the lights flickered and died, and glass exploded from the hospital's windows.

Within seconds, this community of 50,000 was devastated and broken. The tornado flattened whole neighborhoods, splintered homes, debarked trees, and flipped over cars and trucks. Some homes were completely swept away. Immediately following the tornado, emergency responders were deployed to the city to undertake search and rescue efforts. The governor declared a "state of emergency" for the Joplin area shortly after the tornado hit and ordered Missouri National Guard troops into the city...

## OVERVIEW OF DISASTERS

Throughout recorded history, disasters have been an integral part of our existence, causing immeasurable amounts of pain and suffering. The term "**disaster**" is used commonly to describe many different events. The 2013 Boston Marathon bombing that killed three people and injured more than 260 others, including 16 who lost limbs, was called a disaster. The 2014 Ebola outbreak that caused more than 28,000 cases worldwide and more than 11,000 deaths was called a public health disaster. The October 2017 mass shooting at an outdoor concert in Las Vegas where a gunman sprayed gunfire on a crowd of 22,000 concert goers,

### Box 71.1 Tornado Warning vs Tornado Watch

- A **Tornado Watch** is issued when, although a tornado has not been seen, conditions are very favorable for one to occur at any moment
- A **Tornado Warning** is issued when a tornado has actually been sighted or picked up on radar

killing 58 people and injuring almost 500 was called the worst U.S. mass shooting and a disaster. In September of 2017 a major earthquake that registered a magnitude of 7.1 struck the area around Mexico City, killing 370 people and collapsing more than 40 buildings. That event was called a disaster.

There is no one definition of a disaster. The definition adopted by the World Health Organization (WHO) terms a disaster as “a serious disruption of the functioning of a community or a society causing widespread human, material, economic or environmental losses which exceed the ability of the affected community or society to cope using its own resources.” The U.S. **Federal Emergency Management Agency (FEMA)** describes a disaster as “an occurrence of a natural catastrophe, technological accident, or human event that has resulted in severe property damage, deaths, and/or multiple injuries.” The U.S. Stafford Act defines a major disaster as “any natural catastrophe (including any hurricane, tornado, storm, high water, wind driven water, tidal wave, tsunami, earthquake, volcanic eruption, landslide, mudslide, snowstorm, or drought), regardless of cause, or any fire, flood, or explosion, in any part of the United States, which in the determination of the President, causes damage of sufficient severity and magnitude to warrant major disaster assistance to supplement the efforts and available resources of states or local governments, and disaster relief organizations to alleviate the damage, loss, hardship, or suffering caused.” When the President declares that a major disaster or emergency exists, an array of federal programs are activated to assist in response and recovery efforts. The United Nations defines disasters as “a serious disruption of the functioning of society, causing widespread human, material, or environmental losses which exceed the ability of affected society to cope using only its own resources.” Dr. Kathleen J. Tierney, sociologist and internationally known expert on disasters, puts the matter in a different perspective. She defines disasters as “many people trying to do quickly what they do not ordinarily do, in an environment with which they are not familiar.” A simpler definition yet is that “a disaster occurs when needs exceed resources following an event.”

In general, most disaster events are defined by three main characteristics: (1) an event of destructive magnitude; (2) that kills, injures, or causes human suffering to a significant number of people or the environment; and (3) that requires the need for external assistance. A disaster is a large-scale destructive event that disrupts the infrastructure and normal functioning of a community or society. Disasters can be natural or man-made. This chapter will define and describe types of disasters, complex emergencies, and mass casualty events as well as disaster response.

### Complex Emergency

The WHO defines a **complex emergency (CE)** as “situations of disrupted livelihoods and threats to life produced by warfare, civil disturbance and large-scale movements of

people, in which any emergency response has to be conducted in a difficult political and security environment.” Such “complex emergencies” are characterized by the WHO as involving:

- extensive violence and loss of life
- displacements of populations
- widespread damage to societies and economies
- the need for large-scale, multifaceted humanitarian assistance
- the hindrance or prevention of humanitarian assistance by political and military constraints
- significant security risks for humanitarian relief workers in some areas

According to the United Nations, those suffering the consequences of complex emergencies are primarily civilians (50%-90%) and especially vulnerable populations that include children, women, the elderly, and the disabled. Over the last few decades, complex emergencies have generally become more complex and longer-lasting.

### Mass Casualty Incident

A **mass casualty incident (MCI)** refers to any large-scale event in which emergency medical resources such as supplies, medical/rescue personnel, or equipment are overwhelmed by the number and severity of casualties, thus requiring prioritization of medical care by triage. All MCIs are disasters, but not all disasters are MCIs. The term *casualty* includes all persons who are ill, injured, missing, or dead as the result of the incident. The term *incident* is defined as an event that requires scene or casualty management. This may look different in different locales. In a large city with multiple hospitals, hundreds of casualties may be handled locally without any outside assistance. In a rural setting, 10 casualties may overwhelm the single local hospital. A simple definition of an MCI is “when the healthcare needs exceed the healthcare resources.” The goal of the response to any MCI is to “do the greatest good for the greatest number of people.” Regardless of whether a situation is classified as a disaster, a mass casualty incident, or a complex emergency, an effective triage method is needed to optimize overall patient outcomes. This is done through the process called *disaster triage*.

### Disaster Triage

**Triage** is the process of placing the right patient in the right place at the right time to receive the right level of care. On a daily basis, most EDs in the United States use some form of daily triage to identify those patients who are more critically ill or injured and cannot tolerate a delay in receiving care. The goal of daily triage is to identify and treat the most seriously ill or injured first.

In a disaster situation, there is a paradigm shift in the triage philosophy. Simply stated, the goal of disaster triage is to ensure “doing the most good for the greatest number

of people rather than doing everything possible to save every life.” This may mean delaying care to selected patients who have little hope of survival or would consume too many resources. In most instances, disaster triage is used only in the most catastrophic situations.

During a disaster event, prehospital personnel arriving at the scene usually establish a casualty collection area. Patients brought to this area are triaged and maybe tagged with a corresponding colored triage tag, provided with basic field care for stabilization, and transported to the most appropriate facility for care. At the hospital, secondary triage is typically performed by Emergency Department (ED) personnel, and then patients are assigned to a treatment area for care.

There are different triage models that can be used to sort patients. At present, no one model is universally accepted as the standard. Two commonly used models are **Simple Triage and Rapid Treatment (START)** and **Sort, Assess, Lifesaving Interventions, Treatment, and/or Transport (SALT)**.

### Simple Triage and Rapid Treatment

**Simple Triage and Rapid Treatment (START)** is one of the most popular triage systems in use in the United States. It uses physiological parameters and is designed to be completed in 60 seconds or less. It is based on three observations: (1) respirations; (2) perfusion (or pulse); and (3) mental status. The mnemonic “RPM” is used as a memory aid. Simple Triage and Rapid Treatment begins by directing all patients who are ambulatory to move to a safe area. These patients are tagged “green,” or “minor.” These patients are capable of ambulating and understanding directions and have adequate perfusion to follow commands and stay upright. Triage then continues for the remainder of the patients. Patients with no spontaneous respirations receive airway repositioning. If they remain apneic, they are tagged “deceased” by using a black label and receive no further care or interventions. If repositioning the airway initiates respirations, that patient is tagged red or “immediate.” Patients with respirations greater than 30 breaths per minute or capillary refill longer than 2 seconds (or who lack a radial pulse) or who are unable to follow simple directions are also tagged “immediate” by using a red triage tag. The remaining patients are tagged “delayed” and are given a yellow tag. The START triage model allows for only two interventions during the triage process: (1) direct pressure to control bleeding and (2) basic airway-opening maneuvers. Disaster triage is not a static activity; the patient’s condition may change or there may be a change in available resources. Patients not moved or transferred to a definitive area for care are retriaged on a constant basis.

**JumpSTART** is a Pediatric Mass Casualty Incident Triage tool. It is an objective triage model designed for triaging infants and young children. It takes into consideration the developmental and physiological differences of

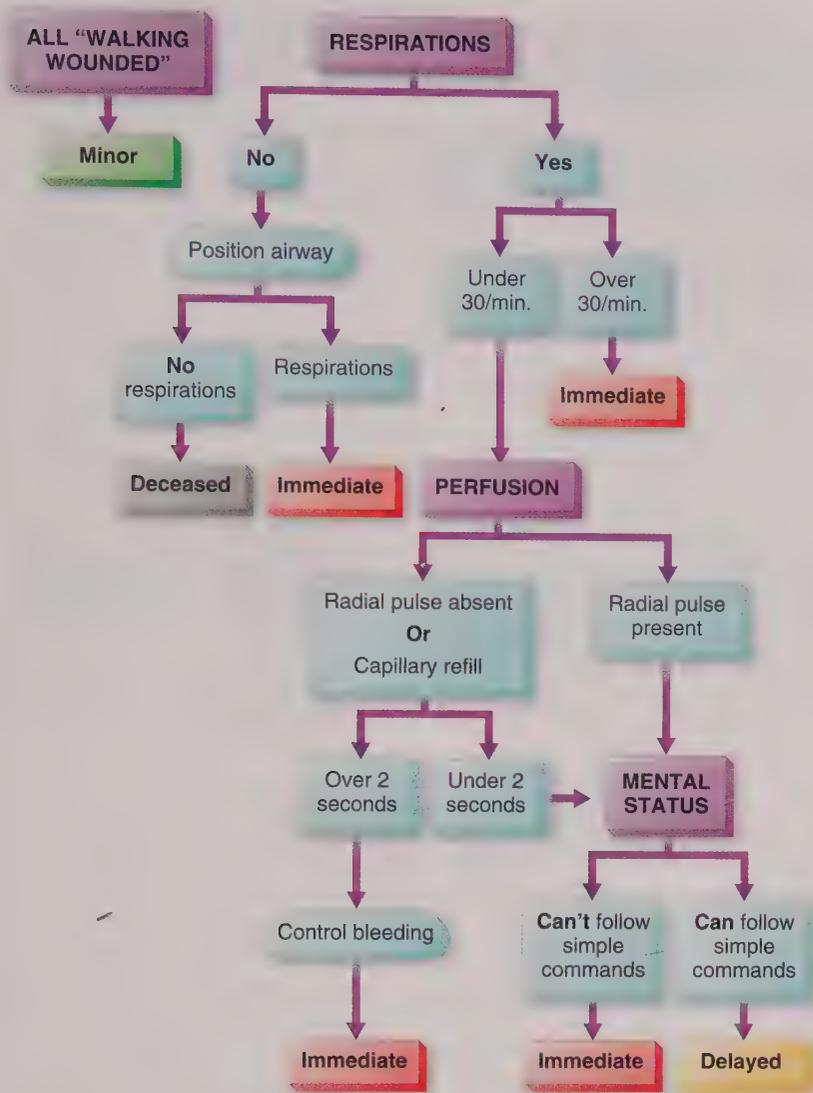

children by using breathing as the cornerstone for triage decisions (Fig. 71.1).

### Sort, Assess, Lifesaving Interventions, Treatment, and/or Transport Triage

In response to the lack of scientific data regarding the efficacy of mass casualty triage systems, the Centers for Disease Control and Prevention (CDC) formed an interdisciplinary advisory committee to review existing disaster triage models. The advisory committee developed the **Sort, Assess, Lifesaving Interventions, Treatment, and/or Transport (SALT)** model by combining the best features of the existing systems (Fig 71.2). The SALT model can be used to triage both adults and children and is endorsed by several national organizations, including the American College of Emergency Physicians, the American College of Surgeons Committee on Trauma, the American Trauma Society, and the National Association of EMS Physicians.

The first step in the SALT model is to address the “walking wounded.” Those who are able to walk are prioritized last; those who cannot follow a command or have an obvious life threat are prioritized first; and those who can follow a command but are unable to walk are prioritized second. The next step is to make lifesaving interventions before assigning a patient to a triage category. Lifesaving interventions include control of major hemorrhage, opening the airway and providing two breaths for child casualties, decompression of a tension pneumothorax, and the use of auto injector antidotes. Finally, triage categories are assigned (delayed, immediate, or expectant) based on breathing, peripheral pulses, respiratory distress, and hemorrhage control. The SALT system of triage is different from the other systems in that there is a grey or “Expectant” category. This category means that the patient may have a life-threatening injury, but current resources are not available to meet the need. As resources become available, this “Expectant” category of patients should be re-evaluated frequently. It is a different method of triage in that there are two phases; a global sorting based on the ability to follow commands and walk, and a triage category assignment based on response to lifesaving interventions. Regardless of the system used, the primary goal of disaster triage is to maximize the number of survivors.

Many casualties will present to the hospital within the first 2 hours of the event. Patients usually arrive at the hospital in two waves. Wave 1 arrives in approximately 15 to 30 minutes. These patients are the walking wounded who were able to self-extricate themselves from the scene and make it to the hospital on their own. Past disasters have shown that 80% to 85% of all disaster casualties will bypass the EMS system and arrive at the hospital on their own. Wave 2 will follow in 30 to 45 minutes. This second group needed assistance for extrication from the scene and were transported by EMS. They are usually more seriously injured than the patients in the first wave.

**FIGURE 71.1** Adult Simple Triage and Rapid Treatment (START) triage algorithm.

### Connection Check 71.1

Which of the following statements best explains the relationship between an MCI and a disaster?

- All disasters are mass casualty events.
- All mass casualty events are disasters.
- Mass casualty events are natural disasters.
- Mass casualty events are man-made disasters.

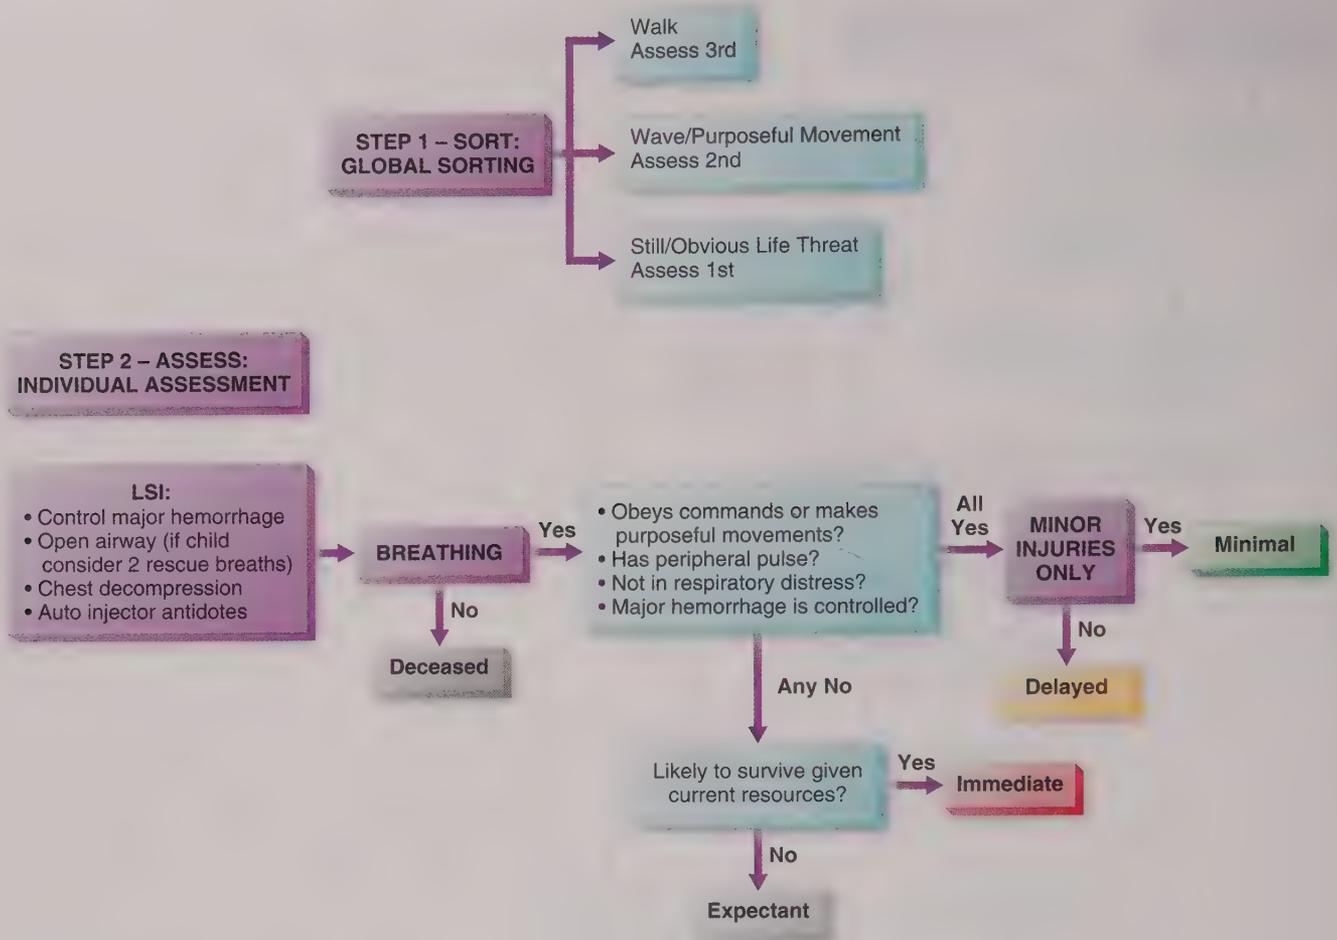

### Types of Disasters

Disasters are commonly categorized by their origin: natural events, nuclear/radiological events, bioterrorism/emerging infectious diseases, chemical incidents, and explosive/blast incidents. All disasters are unique because of the nature of the affected community in terms of preparedness, affluence, political structure, and baseline health system preparedness.

### Terrorism

**Terrorism** is a particular type of disaster that may or may not produce an MCI. No one definition of terrorism has gained universal acceptance. Title 22 of the United States Code defines terrorism as “premeditated, politically motivated violence perpetrated against noncombatant targets by subnational groups or clandestine agents, usually intended to influence an audience.” FEMA defines terrorism as “the use of force or violence against persons or property in violation of the criminal laws of the United States for the purpose of intimidation, coercion, or ransom.”

Terrorism is often motivated by religious, political, or other ideological beliefs. Terrorists use threats to (1) create fear among the public; (2) try to convince citizens that their government is powerless to prevent terrorism; and (3) get immediate publicity for their causes. Terrorism differs from other forms of military action in that noncombatants are usually deliberately targeted by the terrorists. Acts of terrorism can include threats of terrorism, assassinations,

**FIGURE 71.2** Sort, Assess, Lifesaving interventions, Treatment and/or Transport (SALT) triage algorithm.

kidnappings, hijackings, bomb scares, bombings, cyberattacks (computer-based), and the use of **chemical, biological, radiological, nuclear, and explosive (CBRNE)** weapons also known as weapons of mass destruction.

A **weapon of mass destruction (WMD)** is defined as “any weapon or device that is intended, or has the capability, to cause death or serious bodily injury to a significant number of people through the release, dissemination, or impact of (1) a toxin or poisonous chemical or their precursors; (2) a disease organism; (3) radiation or radioactivity; or (4) an explosive device.” The term “weapon of mass effect” has recently appeared in the literature, and many consider it to be a more appropriate description, considering the large numbers of injuries and deaths that can occur. A WMD may be used by a terrorist(s) to produce an MCI.

### Connection Check 71.2

Which of the following factors contributes the most to positive patient outcomes in a mass casualty disaster?

- On-site patient treatment
- Disaster triage
- Transport of all victims to the closest hospital
- Availability of patient air transportation

### Natural Disasters

Natural disasters are numerous and widespread and are part of the human experience. They often result in significant losses, including physical destruction of dwellings, social and economic disruption, human pain, suffering, and injury including loss of life. Some natural disasters are predictable, but most are unpredictable, unpreventable, and uncontrollable. They can be classified as acute or slow in their onset. Natural disasters with a slow onset include blizzards, drought, famine, and pest infestations. Those with an acute onset include floods, earthquakes, tsunamis, tornadoes, volcanic eruptions, and hurricanes. The severity of damage caused by natural disasters is directly associated with the population density in the disaster area, local building codes, community preparedness, and the public communication system. Recovery following a natural disaster is largely dependent on the public’s access to information, the speed of disaster relief services, and the political and economic climate of the area. Table 71.1 lists common natural disasters and the resultant possible injuries and medical issues.

### Earthquakes

Earthquakes are defined as a sudden rapid shaking of the ground caused by the shifting of the tectonic plates that

**Table 71.1 Natural Disasters, Human Impacts, and Medical Issues**

Natural Disaster	Potential Injuries and Medical Issues
<b>Earthquake</b>	Skull fractures, spinal cord injuries, hypothermia, wound infections, exacerbation of pulmonary diseases such as asthma, and crush injuries
<b>Tsunami</b>	Drowning, blunt force trauma, crush injuries, impalements, penetrating trauma, closed head injury, eye injuries, pulmonary injury from aspiration of contaminated water, orthopedic injuries
<b>Tornado</b>	Blunt injuries (rapid movement of victims through the air who then strike a stationary object); penetrating ballistics (wind-driven projectiles striking people); crush injuries (from collapse of structures); traumatic injuries to the head, thorax, and abdomen; eye injuries; closed and open brain injuries
<b>Cyclone/Hurricane/ Typhoon</b>	Drowning, electrocution, lacerations, punctures from flying debris, blunt trauma or bone fractures from falling trees and other debris, heart attacks and other stress-related disorders, disrupted wildlife (bites from animals, insects, and snakes), injuries from improper use of chain saws or other power equipment when responding to the event
<b>Blizzard</b>	Orthopedic injuries; acute myocardial infarction; carbon monoxide poisoning; cold exposure; hypothermia; frostbite; frostnip; motor vehicle accidents; head, chest, and abdominal injuries from snowmobile accidents; injuries from the use of power equipment for clearing debris, fallen trees, and snow
<b>Heat wave</b>	Heatstroke, sunstroke, heat cramps, heat exhaustion, fatigue

form the Earth's crust. Where the edges of these tectonic plates meet is referred to as a major **fault line**. The San Andreas Fault in California is an example of a fault line. In the United States, the greatest seismic activity is along the Pacific Coast from Alaska to California. Miles underground, as the Earth's plates move, stressed areas develop and rupture, resulting in the release of tremendous amounts of energy and ground motion. The point of rupture is known as the **epicenter**. The Richter Scale (Table 71.2) is a logarithmic scale that estimates the total energy released by an earthquake. A change of 1 unit on the scale corresponds to a 10-fold change in ground motion and a 32-fold change in radiated energy. Measurements on the scale below a magnitude of 2.0 are not usually felt, and measurements above a magnitude of 5.0 usually cause damage (Box 71.2). Earthquakes can cause buildings and bridges to collapse, disruption of gas service, communication failures, and electric line failures.

A major earthquake can be preceded by less severe preliminary tremors called **foreshocks**. Smaller tremors after the main earthquake are called **aftershocks**. Earthquakes can sometimes trigger landslides, avalanches, flash floods, fires, and huge destructive ocean waves called tsunamis. Table 71.3 lists the world's earthquakes with greater than 1,000 dead since 2001.

### Tsunami

A **tsunami** is a Japanese word meaning "harbor wave." A tsunami is a tremendously powerful ocean wave that is the result of an underwater earthquake, landslide, or volcano. Tsunami are not a single wave but rather a series of waves spaced minutes to more than 1 hour apart. These waves can travel across the ocean at speeds up to 500 miles per hour

depending on the location and the source of the event. A tsunami is relatively unnoticeable until the wave reaches shallow water; then it can come crashing ashore at heights up to 50 feet or more. Historically, tsunami have been reported in all the oceans, but the Pacific Ocean is the most common location. Tsunami can cause buildings to collapse, disruption of utilities, loss of coastal marine systems, and injuries/deaths to coastal populations.

**Table 71.2 Richter Scale**

Description	Magnitude (Richter Scale)	Number per Year
<b>Great earthquake</b>	Over 8.0	1-2
<b>Major earthquake</b>	7.0-7.9	18
<b>Destructive earthquake</b>	6.0-6.9	120
<b>Damaging earthquake</b>	5.0-5.9	800
<b>Minor earthquake</b>	4.0-4.9	6,200
<b>Smaller usually felt</b>	3.0-3.9	49,000
<b>Detected but not felt</b>	2.0-2.9	300,000

## Box 71.2 Earthquake in Nepal (2015)

On April 25, 2015, a magnitude 7.8 earthquake struck Nepal. It was the worst to strike the region in more than 80 years. The area suffered a second 7.3 magnitude quake just 17 days later, on May 12, causing further damage and hardship for those who had survived the initial disaster. Nepal, well known for its rich cultural heritage and extreme tourism, is one of the poorest countries in southeast Asia. The damage done by the quake put a strain on the country's citizens that has lasted many years. Approximately 8 million people were affected. The death toll was around 8,900 with 22,000 suffering injuries. Deaths were also reported in neighboring Tibet and India. Approximately 1.1 million children needed urgent assistance, and 2.8 million people needed humanitarian assistance. Homes and historic temples crumbled, roads damaged and communications made sporadic. The quake triggered an avalanche that killed 19 climbers on Mt. Everest and stranded hundreds at base camp. Entire villages were destroyed without a single home left standing. Water systems in hillside villages were wrecked. Terraced farms and cattle were wiped out by the quake or subsequent landslides, destroying people's entire livelihoods. More than 800,000 homes were destroyed, and 298,000 homes were damaged. The quakes' strongest impact was in remote rural areas that made the response extremely challenging.

**Table 71.3 World's Earthquakes With 1,000 or More Dead Since 2001**

Date	Region	Magnitude	Fatalities
2015	Nepal	7.3	8,900
2011	Japan	9.0	28,000
2010	Haiti	7.0	222,570
2009	Indonesia	7.5	1,117
2008	China	7.9	87,587
2006	Indonesia	6.3	5,749
2005	Pakistan	7.6	86,000
2005	Indonesia	8.6	1,313
2004	Sumatra	9.1	227,898
2003	Iran	6.6	31,000
2003	Algeria	6.8	2,286
2002	Afghanistan	6.1	1,000
2001	India	7.7	20,023

## Tornadoes

**Tornadoes** are spawned by severe thunderstorms. There are approximately 1,000 tornadoes each year in the United States. Although most tornadoes remain aloft, those that touch the ground can cause significant damage. The United States has the most severe tornadoes on Earth because of our weather patterns and terrain. Although a tornado is inherently dangerous, it becomes a serious risk only when it threatens a populated area (Fig. 71.3).

Tornadoes can occur in all regions of the United States, but the majority occurs in what has been termed "**Tornado Alley**." Tornado Alley is a colloquial and popular media term that refers to the area between the Rocky and Appalachian Mountains. Although no U.S. state is entirely free of tornadoes, they are most frequent in the "Plains States." In this area, the cold, dry air from Canada and the Rocky Mountains meets the warm, moist air from the Gulf of Mexico and the hot, dry air from the Sonoran Desert. These combine and produce atmospheric instability and intense thunderstorms. Tornadoes can have a wind velocity of more than 250 miles per hour, and the winds can generate sufficient force to destroy even massive buildings. Tornado severity is rated using the Fujita Scale seen in Table 71.4.

## CASE STUDY: EPISODE 2

In 45 seconds, the tornado all but destroyed St. John's Hospital. Patients and visitors were screaming. Everyone in the hospital thought they were going to die. The wind roared with such force that it twisted the top floors of the hospital by several inches. Water pipes burst, the ceiling tiles caved in, and wires were hanging in the air. There were no lights; both power generators were gone from their foundations. Intravenous lines were ripped from patients' arms, and the IV poles became projectiles. All emergency lights and exit signs were ripped from their mounts and were useless, and the exit stairwells were blocked by debris. X-ray machines, respirators, and computer monitors crashed through the air. Doors were ripped off their hinges. The winds were so powerful that items from the hospital such as medications, medical records, and radiographs were found in neighboring counties. Fortunately, most people inside the hospital and the ED were uninjured.

In the town, survivors told harrowing stories of riding out the 200-mph winds in walk-in coolers in restaurants and convenience stores. Some hid in bathtubs and closets, others ran for their lives as the tornado bore down on them. Heavy objects including concrete bumpers and large trucks were tossed up to one-eighth mile.

It was a storm more ferocious than the citizens of Joplin had ever seen. At its height, it plowed a path of destruction three-quarters of a mile wide and kicked debris more than 20,000 feet into the air...

FIGURE 71.3 Tornado.

Table 71.4 Fujita Tornado Scale

Scale Value	Wind Speed Range and Description of Damage
F0	40–72 mph: Light damage. Some damage to chimneys; tree branches broken off, shallow-rooted trees pushed over, sign boards damaged.
F1	73–112 mph: Moderate damage. The lower limit is the beginning of hurricane wind speed. Roof surfaces peeled off, mobile homes pushed off foundations or overturned, moving autos pushed off roads.
F2	113–157 mph: Considerable damage. Roofs torn off houses, mobile homes demolished, boxcars pushed over, large trees snapped off or uprooted, light object missiles generated.
F3	158–206 mph: Severe damage. Roofs and some walls torn off well-constructed houses, trains overturned, most trees in a forest uprooted, heavy cars lifted off ground and thrown.
F4	207–260 mph: Devastating damage. Well-constructed houses leveled, structures with weak foundations blown off some distance, cars thrown, large missiles generated.
F5	261–318 mph: Incredible damage. Strong frame houses lifted off foundations and carried considerable distances, car-sized missiles fly through the air in excess of 100 yards, and trees debarked.

### Hurricanes, Cyclones, and Typhoons

Hurricanes, cyclones, and typhoons are all the same weather phenomena. The only difference is the location where the storm occurs. All are storm systems that can produce extremely powerful winds, torrential rain, high

waves, and damaging storm surges, as well as spawn tornadoes. These storm systems develop over large bodies of warm water and eventually may move over land. They are among the most devastating naturally occurring hazards and are capable of producing large-scale devastation in human populations. Hurricanes are classified according to their intensity using the Saffir-Simpson Scale (Table 71.5 and Box 71.3).

### Winter Storms and Blizzards

Winter storms and blizzards are severe, dangerous weather events. Winter storms consisting of extreme cold and heavy snowfall and ice can affect every state except Hawaii. States where cold weather is rare are more severely disrupted by winter storms than states that experience severe winter weather more frequently. Severe winter storms can isolate and disrupt families; shut down schools, businesses, and transportation; and destroy large components of agriculture. Heavily populated areas are particularly impacted when severe storms disrupt communication and electricity as a result of downed power and phone lines. In a severe storm, snow and ice removal from roads can be difficult when the snow and ice accumulate faster than equipment can clear it.

### Heat Waves

Heat waves are characterized as extreme summer temperatures with a combination of very high temperatures and very high humidity levels. When these persist over several days and nighttime temperatures do not drop significantly, it is called a *heat wave*. As a result of the heat wave, mortality and morbidity rise. There have been more than 20 serious heat emergencies in the world since 1901, including the deadly 2003 heat wave in Europe that killed more than 35,000, with 15,000 dead in France alone.

### Connection Check 71.3

Which of the following is an example of a natural disaster?

- A. The 1984 Bhopal, India, methyl isocyanate release
- B. The March 20, 1995, sarin incident in Japan
- C. The 2007 Virginia Tech campus shootings
- D. The 2011 earthquake in Japan

### Nuclear/Radiological Events

Exposures to radiation may be accidental or deliberate in origin. An accidental exposure occurred in March 2011 following the Japan earthquake and tsunami. The earthquake and tsunami damaged the Fukushima nuclear power plant, resulting in accidental radiation exposure to hundreds of civilians.

### Radiation

Radiation is a form of energy that is present all around us. People are exposed to small amounts of radiation every day. The exposure can be from naturally occurring sources such

**Table 71.5 Saffir-Simpson Hurricane Scale**

Intensity	Winds (mph)	Storm Surge	Damage Caused
<b>Category 1</b> <b>Minimal</b>	74–95	4–5 ft above normal	Minimal damage to building structures. Damage primarily to unanchored mobile homes, shrubbery, and trees; some coastal road flooding and minor pier damage
<b>Category 2</b> <b>Extensive</b>	96–110	6–8 ft above normal	Some roofing material, door, and window damage; considerable damage to vegetation, mobile homes, and piers; small craft in unprotected anchorages break moorings
<b>Category 3</b> <b>Extensive</b>	111–130	9–12 ft above normal	Structural damage to small residences and utility buildings with a minor amount of curtain wall failure; mobile homes are destroyed; flooding near the coast destroys smaller structures with larger structures damaged by floating debris
<b>Category 4</b> <b>Extreme</b>	131–155	13–18 ft above normal.	More extensive curtain wall failures with some complete roof structure failures on small residences; major beach erosion; major damage to lower floors of structures near the shore
<b>Category 5</b> <b>Catastrophic</b>	Greater than 155	More than 18 ft above normal	Complete roof failure on many residences and industrial buildings; some complete building failures with small utility buildings blown over or away; major damage to lower floors of structures located more than 15 ft above sea level and within 500 yd of the shoreline

*Curtain wall*, Nonstructural outer covering of buildings designed to keep weather out and occupants in

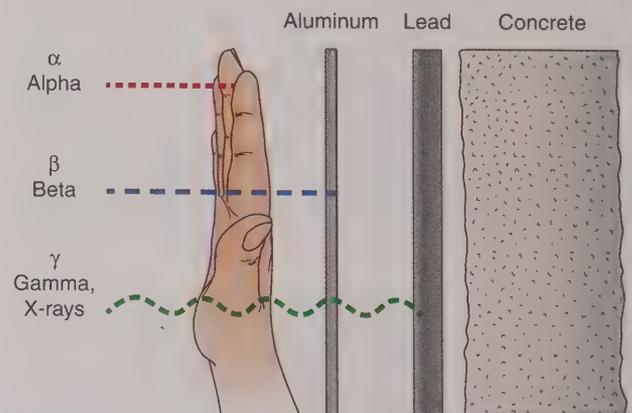

### Box 71.3 Hurricane Maria

Hurricane Maria made its first landfall on the Caribbean island nation of Dominica on September 18, 2017 as a Category 5 storm with winds topping 160 mph - the strongest hurricane on record to make landfall there. With devastating force and 155mph winds the storm hit the U.S. territory of Puerto Rico as a Category 4 hurricane on September 20, 2017. Puerto Rico had not yet fully recovered from Hurricane Irma, which pummeled the island with high winds just two weeks earlier. On Puerto Rico widespread property destruction took place with many structures leveled. The hurricane completely destroyed the island's power grid, leaving all 3.4 million residents without electricity. All communication networks were crippled across the island. Ninety-five percent of cell networks were down. Approximately 80 percent of the territory's agriculture was lost due to the hurricane, with agricultural losses estimated at \$780 million. Seven months after the hurricane, the island's healthcare system was still slowly recovering and facing many challenges. Maria caused an estimated \$90 billion in damage in Puerto Rico, Florida, and the U.S. Virgin Islands.

as cosmic rays from the sun or from man-made sources such as televisions, microwave ovens, or certain diagnostic tests such as x-ray examinations. Exposures such as these present no health risk to humans. In contrast, **ionizing radiation** can damage our DNA and cause health effects when humans are exposed to sufficiently high doses. There are three basic types of ionizing radiation: alpha, beta, and gamma (Fig. 71.4).

**Alpha radiation** is a stream of positively charged particles that travel only about an inch in the air. They have no penetration power past the keratinized layer of the skin and can be stopped by thin clothing or a sheet of notebook paper. However, if ingested, inhaled, or introduced into an open wound, alpha radiation can be very damaging because of the energy transfer to the “delicate” cells of the lungs or internal organs.

**Beta radiation** is a stream of electrons that can be stopped by a few millimeters of aluminum but can penetrate up to a centimeter into human tissue. Large quantities of beta particles impinging on the skin can damage the basal layer of the skin and cause what are commonly referred to as *radiation burns*. As with alpha particles, if the radioactive atoms that emit beta particles are ingested or inhaled, they can cause biological damage.

**FIGURE 71.4** Radiation penetration.

**Gamma radiation** is similar to x-rays as it can penetrate the whole body, but unlike x-rays they are more radioactive and can kill cells. Because of its high penetrability, gamma radiation can deliver radiation doses to the internal organs as well as the skin, resulting in damage.

### Means of Exposure

**Irradiation** is the act of “exposing” something or someone to radiation. A person is irradiated when he or she is “exposed” to ionizing radiation from a source outside the body (Fig. 71.5). There is no transfer of radioactive material from the environment to the body, and the person poses no radiological hazard to anyone else. Being exposed to external radiation does not make a person radioactive.

**Contamination** occurs when people have radioactive material on or in them. A person is externally contaminated when material that contains radioactive atoms is deposited on the skin, clothing, or anywhere it is not desired. A person externally contaminated with radioactive materials will be irradiated until the source of radiation (the radioactive material) is removed from the body, clothing, or wound. Decontamination is typically performed to remove external contamination.

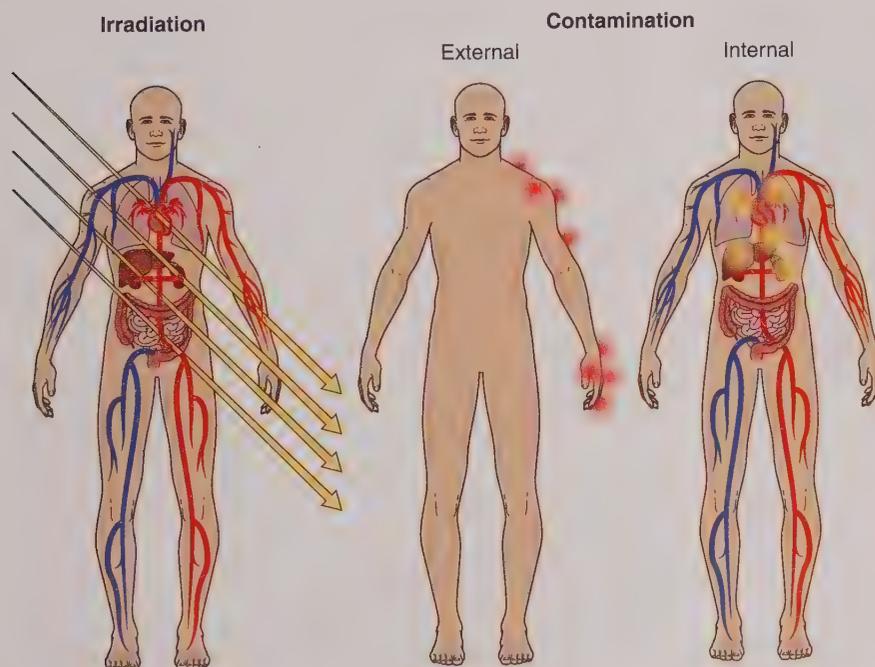

A person is **internally contaminated** if radioactive material is breathed, swallowed, or absorbed through wounds. Treatment for internal contamination includes gastric lavage, cathartics, blocking the uptake to the thyroid by administering potassium iodide, excision of the wound to minimize absorption, dilution, altering the chemistry of the substance, chelation (binding of ions and molecules to render a harmful agent inactive or facilitate excretion), or bronchoalveolar lavage.

**Radiation Effects.** Radiation can affect the body in a number of ways. The adverse health effects of exposure may

not be apparent for many years and can range from mild to serious. Mild effects include skin reddening, and serious effects include cancer and death, depending on the amount of radiation absorbed by the body, the type of radiation, the route of exposure, and the length of time a person was exposed. Exposure to very large doses of radiation may cause death within a few hours or days. Exposure to lower doses of radiation may lead to an increased risk of developing cancer or to other adverse health effects later in life.

If there is a radiation emergency in the United States, local authorities monitor the levels of radiation and determine what protective actions people should take. The appropriate action will depend on the situation. If the radiation emergency involves the release of large amounts of radioactive materials, officials may advise people to “shelter in place,” which means to stay in their home or office, or they may be advised to move to another more safe location. It is often less risky to stay inside than to try to evacuate.

There are two types of radiation injury: local radiation injury and acute radiation syndrome. Most radiation injuries are “local” injuries frequently involving only the hands. An acute local injury may occur separately or may coexist with acute radiation syndrome. Local radiation injury patients present with a skin lesion without a history of chemical or thermal burn, an insect bite, or a history of skin disease or allergy. The patient may give a history of possible radiation exposure (such as from a radiography source, x-ray device, or accelerator) or a history of finding and handling an unknown metallic object. Local injuries to the skin, especially the hands, evolve very slowly over time, and symptoms may not manifest for days to weeks after the exposure. The nurse may note the presence of any of the following: erythema, blistering, dry or wet desquamation, epilation, or ulceration.

**FIGURE 71.5** Illustration of radiation exposure. Irradiation: There is no transfer of radioactive material from the environment to the body. External contamination: Radioactive material is deposited on clothing or skin. Internal contamination: Radioactive material is breathed, swallowed, or ingested internally.

Conventional wound management is usually ineffective in these cases.

**Acute radiation syndrome (ARS)** is an acute illness caused by irradiation of the whole body (or a significant portion of it). It follows a somewhat predictable course and is characterized by signs and symptoms that are manifestations of cellular deficiencies and the reactions of various cells, tissues, and organ systems to ionizing radiation. The initial clinical manifestations are nonspecific and may be indistinguishable from those of other illnesses. They include nausea, vomiting, anorexia, diarrhea, fever, and possible mild skin erythema. These symptoms will start within minutes to days after the exposure, will last for minutes to several days, and may come and go. The person usually looks and feels healthy for a short time, after which he or she will become sick again with loss of appetite, fatigue, fever, nausea, vomiting, diarrhea, and possibly even seizures and coma. This seriously ill stage may last from a few hours to several months followed by recovery or death. Each phase of the illness varies in length relative to the radiation dose received. Early onset of anorexia, nausea, vomiting, and malaise is an indication of a high dose of exposure.

People with ARS also typically have some skin damage. This damage may become evident within a few hours after exposure and includes swelling, itching, and redness of the skin (like a bad sunburn). There also can be hair loss. As with other symptoms, the skin may heal for a short time, but this is followed by the return of swelling, itching, and redness days or weeks later. Complete healing of the skin may take from several weeks to a few years depending on the radiation dose the person's skin received. The medical management of ARS is focused mainly on support and recovery of the hematological system. Two major aims are to prevent neutropenia and sepsis.

The chance of survival for people with ARS decreases with increasing radiation doses. Most people who do not recover from ARS will die within several months of exposure. The cause of death in most cases is the destruction of the bone marrow, which results in infections and internal bleeding. For survivors, the recovery process may last from several weeks to 2 years. Many survivors of the Hiroshima and Nagasaki atomic bombs in the 1940s and many of the firefighters who first responded after the Chernobyl Nuclear Power Plant accident in 1986 became ill with ARS.

### **Safety Principles for minimizing exposure Alert to radiation**

- Stay as far away from the source as is practical
- Use appropriate shielding
- Limit exposure time

## **Infectious Disease Disaster**

Infectious disease disasters are events that involve the dissemination of a biological agent or disease that results in

mass casualties. The occurrence of **emerging infectious diseases (EID)** or reemerging infectious diseases in human history is not new. The great plague and the influenza pandemics are well-known historical examples. Humans are in a delicate balance with the microbial coinhabitants of the earth. There will always be emerging pathogens that may cause the next big infectious disease disaster. Emerging infections can be considered an MCI if large numbers of people are affected. Recent examples include Ebola and the Zika virus.

### **Ebola Virus Disease**

**Ebola virus disease (EVD)** is a rare and deadly disease caused by the Ebola virus. It was first discovered in 1976 near the Ebola River in what is now the Democratic Republic of Congo. Since then, the virus has been infecting people from time to time, leading to outbreaks in several African countries. The Ebola virus spreads to people through direct contact with the body fluids of a person who is sick with or has died from EVD. The virus can also spread to people through direct contact with the blood, body fluids, and tissues of infected fruit bats or primates. Symptoms may appear anywhere from 2 to 21 days after contact with the virus, with an average of 8 to 10 days.

The 2014–2016 Ebola outbreak in West Africa began in a rural setting of southeastern Guinea, spread to urban areas and across borders within weeks to become a global **epidemic**. From 2014 through 2016 there were 28,652 cases of Ebola and 11,325 Ebola deaths. The 2014–2016 Ebola outbreak is a dramatic illustration of the threat of EID. It is also an example of an evolving public health crisis of international concern. The U.S. government took a number of steps to address the 2014–2016 EVD outbreak. One of them resulted in the construction of several **biocontainment units (BCUs)** or Ebola treatment centers across the US.

### **Zika Virus**

Zika virus is a mosquito-borne flavivirus that was first identified in Uganda in 1947. Zika primarily spreads through infected mosquitoes, but it can also be transmitted through sexual intercourse and can be passed from a pregnant woman to her fetus. Zika virus infection during pregnancy is a cause of congenital brain abnormalities, including microcephaly, and it can also be a trigger of Guillain-Barré syndrome.

Zika virus outbreaks occurred in Africa, Southeast Asia, and the Pacific Islands prior to 2015. In 2015 and 2016 there was a Zika epidemic in the Americas. The outbreak began in April 2015 in Brazil and spread to other countries in South America, Central America, North America, and the Caribbean. In January 2016, the WHO called Zika a Public Health Emergency of International Concern. By November 2016, the WHO declared that the Zika virus was no longer a global emergency while noting that the virus still represents “a highly significant and a long-term problem.”

### **Bioterrorism**

**Bioterrorism** (also known as *biological terrorism*) is the intentional use of a biological agent or derivative to inflict harm or death onto a civilian population. Biological warfare

differs from bioterrorism in that the target of the attack is military personnel.

Bioterrorism and biological warfare are ancient in its origins, dating back to at least 1346 when Tartar invaders laid siege to the city of Kaffa on the Black Sea. Plague broke out among the invaders. Using catapults designed to throw boulders and fireballs over the walls, the Tartar invaders launched the plague-infected corpses of their dead men into the city. The bodies were quickly dumped into the sea, but the damage was done. Hoping to escape the quickly spreading disease, four ships departed from Kaffa and sailed to Italy. When the ships reached Italy, many sailors onboard were sick, causing the plague to quickly spread throughout Europe. By the time the **pandemic** played itself out 3 years later, between 25% and 35% of Europe's population had fallen victim to the disease.

Bioterrorism has the potential to result in high morbidity and mortality. Organisms and toxins that can be used as biological weapons have been categorized by the CDC into three categories. Agents classified as Category A are easily disseminated or transmitted. They can result in high mortality rates, have the potential for a major public health impact, may cause public panic and social disruption, and may require special action by public health officials. Category B and C agents, although still concerning, are less easily disseminated and result in lower morbidity and mortality rates. A renewed sense of appreciation of the potential of biological weapons came following the anthrax-contaminated letters sent in the United States in late 2001.

### Chemical Incidents

Today there are nearly 100,000 known commercial chemicals, and worldwide chemical production is estimated at 400 million tons per year. The CDC divides chemicals into categories by the effects they can have on people exposed to them. Some of these chemicals can cause death by interfering with the nervous system; some inhibit breathing and lead to asphyxiation. Others have caustic effects on contact. Chemical injuries also may accompany and complicate the treatment of conventional injuries in trauma patients. Additionally, exposure can complicate or trigger existing illnesses such as asthma. As a result, treatment of exposure can be complicated. Also, depending on what chemical is encountered, healthcare providers may need to wear different **personal protective equipment (PPE)**, for example, a simple mask and gloves versus a special chemical protection suit and breathing apparatus.

A chemical incident usually involves the release of a vapor or liquid. The type and volume of the agent released is important in determining the type and volume of injuries. An outdoor vapor cloud release is quickly dissipated by the wind and may result in a small number of casualties at the release site. An agent dispersed indoors does not dissipate as easily and can lead to a greater number of casualties. Temperature, humidity, and the type of terrain can also affect the dispersal and the number of casualties. Incidents involving chemicals can be nonintentional/accidental or

intentional. Nonintentional chemical incidents leading to an MCI can occur during the manufacture, storage, or transport of chemical agents (Box 71.4). An intentional chemical disaster is defined as the intentional release or spill of toxic chemicals to harm people and/or the environment (Box 71.5). Some of these compounds can be potential WMDs if used by terrorists.

The early detection of a chemical event is critical, but not all chemical events are immediately apparent. Clues to the detection of a chemical event are (1) a rapid onset of symptoms in patients; (2) large numbers of patients presenting with common symptoms; (3) low-lying clouds or vapors; (4) dying animals or insects; (5) unexplained odors; and (6) concentrations of dead, dying, or sick people at the scene.

### Explosions and Blast Events

Explosions occur when a solid or liquid material is rapidly transformed into a gas, and energy is released. The gas expands outward in a high-pressure blast wave that exceeds the speed of sound. Air is highly compressed on the leading edge of the wave, creating a shock or **blast front**. The body of the wave and the associated mass outward movement of ambient air, the **blast wind**, follows the front. Explosive events can occur as a result of an intentional or unintentional incident. Blast trauma from explosives varies greatly depending on the environment (indoors or outdoors), the structural characteristics of the building or vehicle, the presence of reflecting surfaces, and the distance from the blast. **Primary blast injury** is a result of barotrauma, unique to explosions, which causes damage to air-filled organs—the lungs (hemothorax, pneumothorax), gastrointestinal tract (bowel perforation), and auditory system (tympanic membrane rupture). **Secondary blast injuries** refer to trauma caused by projectiles carried by the blast pressure wave

### Box 71.4 Nonintentional Release in Bhopal, India

A nonintentional chemical event occurred on the evening of December 2–3, 1984, at the Union Carbide plant in Bhopal, India (population 900,000). Approximately 27 tons of methyl isocyanate were accidentally released into the atmosphere. The atmospheric conditions resulted in a gas cloud that moved slowly and relatively close to the ground. The cloud quickly covered the homes of a large number of residents. The release is estimated to have killed at least 3,500 people immediately, and thousands more are said to have since died or been injured as a result of the toxic cloud. An Indian government affidavit in 2006 stated the leak caused 558,125 injuries. They included 38,478 temporary partial injuries and approximately 3,900 severely and permanently disabling injuries. Many pets, farm animals, and livestock near the scene were also killed. This release has been called the world's single most catastrophic chemical event to date.

## Box 71.5 Intentional Release in Matsumoto, Japan

An intentional chemical release occurred on March 20, 1995, in Matsumoto, Japan, a city of 200,000 situated at the foot of the Japanese Alps in the heart of Japan. At the peak of the morning rush hour, the chemical agent sarin was released on five different subway trains scheduled to arrive within 4 minutes of each other at the Kasumigaseki Train Station. Entering the trains carrying packets of sarin and umbrellas with sharpened tips, the perpetrators placed the plastic containers of sarin on the floor and then punctured them several times with the sharpened tip of an umbrella. The men then quickly exited the trains and the stations.

Sarin is a volatile nerve agent, which means that it can easily and quickly evaporate from a liquid into a vapor and spread into the environment. People can be exposed to the vapor even if they do not come in contact with the liquid form of sarin. With the punctured packets left on the floor, the sarin was allowed to leak out into the train cars and evaporate. The sarin affected passengers, subway workers, and anyone in the immediate vicinity. Those affected by the sarin experienced a variety of symptoms including bleeding from the nose and mouth, seizures, difficulty breathing, loss of consciousness, nausea and vomiting, and vision problems. Witnesses said that “the subway entrances resembled battlefields.” In many cases, the injured simply lay on the ground, many with breathing difficulties. Several of those affected were exposed to sarin only by helping those who had been directly exposed.

Following the event, 4,930 people were seen at Tokyo’s hospitals, and of that number, 1,100 were admitted to the hospitals. There were 12 deaths as a result of the attack. The initial report to the hospitals was that there had been a “gas explosion,” and hospitals prepared to receive patients with burns and carbon monoxide poisoning. St. Luke’s Hospital, closest to the scene, received more than 600 patients within the first 24 hours; of these, 5 patients were in critical condition, 3 were in cardiac arrest, and 2 were unconscious. Because it was not identified initially as a chemical event, no personal protective equipment was worn by the rescuers or the hospital personnel, and no decontamination occurred. This resulted in 10% of the prehospital workers and 23% of the hospital staff experiencing some symptoms (cross-contamination) of sarin exposure.

penetrating any body part. **Tertiary blast injuries** are caused by the individual being propelled by the blast wave and thrown into an object or when a structure collapses and causes injury. Other injuries, quaternary injuries, include exacerbations or complications of preexisting illnesses or injuries as a result of the blast such as burns.

Today’s terrorists and insurgents are deploying unique devices and using various delivery tactics for explosives. One

common weapon is the **dirty bomb**. A dirty bomb is any explosive device that intentionally releases a secondary agent. The secondary agent can be any hazardous (chemical, radiological) or infectious (biological) agent. **Improvised explosive devices (IEDs)** are conventional explosive devices deployed in an unconventional fashion such as a suicide bombing.

## Mass Shooting Events/Active Shooters

**Mass shootings** are man-made disasters. The agreed-upon definition of an active shooter by U.S. government agencies—including the White House, U.S. Department of Justice/FBI, U.S. Department of Education, and U.S. Department of Homeland Security/Federal Emergency Management Agency—is “an individual actively engaged in killing or attempting to kill people in a confined and populated area.” In most cases, active shooters use firearms, and there is no pattern or method to their selection of victims.

Active shooter situations are unpredictable and evolve quickly. Typically, the immediate deployment of law enforcement is required to stop the shooting and mitigate harm to victims. Active shooters usually will continue to move throughout buildings or areas until stopped by law enforcement, suicide, or other intervention.

The definition above does not include shootings tied to gang disputes or robberies that went awry, and it does not include shootings that took place in private homes. In an active shooter event, the people who are killed come from every race, religion and socioeconomic background. Their ages range from the unborn to the elderly. Shootings occur without warning in the most mundane places. Most of the victims are chosen not for what they have done but simply for where they happen to be. Mass shootings in America appear to be getting deadlier and happening more frequently (Box 71.6). Some have said “it feels like they’ve taken hold like a virus.”

## Connection Check 71.4

Several patients present to the triage nurse in an ED. They are complaining of skin redness, itching, vomiting, and diarrhea. What does the nurse suspect the patients have been exposed to?

- A. Radiation
- B. Chemical agents
- C. Influenza
- D. Biotoxin agent

## CURRENT CONCEPTS IN DISASTER PREPAREDNESS AND RESPONSE

The first response to a disaster is the responsibility of the local government’s emergency services, supplemented by neighboring communities and volunteer agencies. If

## Box 71.6 Mass Shooting Events

### Recent Deadly Shootings

**February 14, 2018** – Parkland, Florida – gunfire at a High School – 17 people killed, 12 injured

**November 5, 2017** – Sutherland Springs, Texas – gunfire at a small church – 26 people killed, 20 wounded.

**October 1, 2017** – Las Vegas, Nevada – gunfire into a crowd of 22,000 at a concert – 58 people killed and 546 injured.

**June 12, 2016** – Orlando, Florida – gunfire inside a nightclub, – 49 people killed and 58 injured.

**December 2, 2015** – San Bernardino, California – gunfire at an employee gathering – 14 killed, 22 injured.

**December 14, 2012** – Newtown, Connecticut – gunfire at an Elementary School – 26 killed (20 children, ages six and seven), 2 injured.

overwhelmed, the local government can turn to the state for assistance. The state responds with state resources such as the National Guard and other state agencies. The state's governor, not the U.S. president, is primarily responsible for the health and welfare of the respective citizens. The governor possesses broad police powers that include the legal authority to order evacuations, commandeer private property, require quarantine, and take other actions to protect public safety. If needed, a state can request outside assistance from other states through the **Emergency Management Assistance Compact (EMAC)**. If they are available, the assisting states can provide resources such as National Guard or medical personnel.

If the disaster event is clearly more than the state and local governments can handle alone, the governor of the affected state may request federal assistance. Federal resources can be mobilized through FEMA. The agency can assist with search and rescue, electrical power, food, water, shelter, and other basic human needs. If FEMA assistance is needed, the agency will evaluate the request and recommend an action to the White House based on the disaster, the local community, and the state's ability to recover. The president can either approve or deny the request. This decision process can take a few hours or several weeks, depending on the nature of the disaster. A governor's request for a major disaster declaration could mean an infusion of federal funds into the state, but the governor of the state must also commit significant state funds and resources to the recovery efforts. If a Presidential Major Disaster Declaration is declared, funding comes from the president's Disaster Relief Fund, which is managed by FEMA, and from disaster aid programs of other participating federal agencies. A Presidential Major Disaster Declaration puts into motion long-term federal recovery programs, some of which are matched by state programs, and is designed to help disaster victims, businesses, and public entities.

## National Response Framework

In recent years, the United States has faced an unprecedented series of disasters and emergencies. In October 2011, the first-ever National Preparedness Goal was released. The national goal is “to have a secure and resilient Nation with the capabilities required across the whole community to prevent, protect against, mitigate, respond to, and recover from the threats and hazards that pose the greatest risk to the nation.” This goal recognizes the reality that the entire community including the public and private sectors, faith-based and nonprofit organizations, and the general public must continue to work together to build a more prepared and resilient nation. Our national response structures have evolved and improved to meet this goal. The National Response Framework, written in 2008 and revised in 2016, is the disaster plan for the nation. This document establishes a comprehensive, national, all-hazards approach to domestic incident response, from the smallest incident to the largest catastrophe. The framework identifies the key response principles as well as the roles and structures that support the plan. Additionally, it describes special circumstances in which the federal government exercises a larger role in a disaster response, including incidents in which federal interests are involved and catastrophic incidents in which a state requires significant support. The response plan lays the groundwork for first responders, decision makers, and supporting entities to provide a unified national response.

### Assessing Risk and Vulnerability

The first step in disaster planning is the development of a **hazard vulnerability analysis (HVA)** and risk assessment. The HVA is an assessment of the risks and consequences of a disaster or critical event occurring in the community. A list of all potential hazards and threats in the region is compiled. The list may be quite lengthy and will vary depending on the location. Factors that should be considered when developing the list include historical records, input from local emergency managers and healthcare providers, and the presence of high-risk local industries, rail lines, stadiums, and airports. Communities should pay special attention to targets of high value to terrorists, including historical monuments. Each hazard is then given a ranking of low, medium, or high probability of occurrence.

Next, the potential consequences of the event are evaluated and rated as high, medium, or low consequence. Things to consider include potential injuries, loss of life, disruption of services, loss of community trust, and business continuity issues. The data can then be put into a matrix that defines the probable events and consequences as high, medium, or low. Disaster planners will then use this grid for planning purposes.

### Disaster Phases

Disasters do not just appear one day and go away the next. Rather, they have an occurrence cycle. This cycle entails a series of management phases that include strategies to

mitigate hazards and prepare for, respond to, and recover from disasters and their effects (Fig. 71.6).

### Mitigation

Mitigation includes activities that eliminate or reduce the chance of occurrence or the effects of an event if it occurs. Disaster mitigation programs have shown that communities can do a lot to prevent major emergencies or disasters from affecting them negatively. If communities cannot prevent disasters, they can at least reduce the damaging impact, for example, requiring roof reinforcements to reduce damage from hurricane winds or passing legislation that prevents new construction in floodplains.

### Preparedness

Preparedness, the next phase, is planning how to respond when an emergency or disaster occurs. This step builds an organization's capacity to manage the effects of an event should it occur. These activities help to save lives and minimize damage by preparing people to respond appropriately. Examples include disaster drills, evacuation plans, and fire drills.

### Response

Response covers the period during and immediately following a disaster. During this phase, emergency responders and public officials provide emergency assistance to victims of the event and try to reduce the likelihood of further damage.

### Recovery

Recovery begins almost concurrently with response activities and is directed at restoring essential services and resuming normal operations. This phase may require a large amount of time, money, and resources.

**FIGURE 71.6** Disaster cycle. Mitigation: activities that eliminate or reduce the chance of occurrence or the effects of an event if it occurs. Preparedness: planning how to respond when an emergency or disaster occurs. Response: emergency assistance to victims of the event. Recovery: activities directed at restoring essential services and resuming normal operations.

### Incident Command System

The initial challenges met by those responding to a disaster are “how to rapidly gain control of the chaos at the scene,” be it in the field or in the hospital ED. The second challenge is how to rapidly organize the personnel resources into a hierarchy of command. This process is referred to as establishing command and control. The **incident command system (ICS)** is an organizational tool that is used to provide the management infrastructure to support any disaster response. The structure is the same regardless of the nature of the disaster. Fig. 71.7 illustrates the hierarchical structure of the ICS.

The ICS is modular and can be expanded or contracted according to the changing needs of the disaster response. The structure is built around five major management activities/functions required in a disaster setting regardless of size or type. The functions are command, operations, planning, logistics, and finance/administration. For some terrorist incidents, a sixth role, intelligence gathering, may be added. Each function is headed by a section chief, and the overall response is led by an incident commander. The ideal span of control is three people, and the maximum is seven persons. Additional functions that aid in the response include liaison, public information, and safety/security. Table 71.6 explains the ICS's roles and responsibilities.

### Connection Check 71.5

An ICS is set up at the scene of a disaster. Who has the responsibility for keeping ahead of the disaster by evaluating the status of the resources and determining future resource needs?

- Incident commander
- Planning chief
- Operations chief
- Logistics chief

### Incident Command System Organizational Structure

**FIGURE 71.7** Disaster incident command organization.

**Table 71.6 The Incident Command System**

Role	Responsibilities
<b>Incident commander</b>	Responsible for all aspects of the response. This person has the overall authority and responsibility for the entire operation; develops the incident objectives and manages all incident operations. Four section chiefs report to the incident commander. Each section chief is part of the general staff and supervises a team of responders.
<b>Operations chief</b>	Responsible for all tactical operations, including decontamination, rescue/extrication, triage, treatment, transportation, communication, and medical control.
<b>Planning chief</b>	Responsible for continuously evaluating the response and “keeping ahead of the disaster”; maintains resource status, evaluates future resource needs and personnel, maintains all incident records, develops the strategy and action plans with the incident commander for the other section chiefs to implement.
<b>Logistics section chief</b>	Responsible for obtaining and providing services and resources, obtaining equipment needed, and staff support.
<b>Finance/Administration chief</b>	Responsible for documenting all financial costs of the incident including the cost of recovery for services and supplies.
<b>Public information officer</b>	A member of the command staff who is responsible for advising the incident commander on all public information matters relating to the management of the incident. This person also manages the media, public inquiries, warnings, rumor monitoring, and other functions required to gather, verify, coordinate, and disseminate accurate, accessible, and timely information related to the incident.
<b>Safety/Security officer</b>	A member of the command staff who is responsible for monitoring and assessing personnel hazards and unsafe situations.
<b>Liaison officer</b>	A command staff position who acts as the on-scene contact point for assisting agencies.

## HOSPITAL RESPONSE TO A DISASTER

Disasters come in all shapes and sizes, and hospitals need to be prepared to respond to virtually any type of event. Some disasters impact a small number of people, produce a few critically injured patients, and put intense demands on the hospital for a short period of time. Others may involve a large number of casualties over the course of several weeks. For disasters such as hurricanes and floods, hospitals are likely to receive advanced warning and are able to activate their disaster plan before the event. For disasters such as earthquakes, tsunamis, chemical plant explosions, industrial accidents, building collapses, and acts of terrorism, there is no advanced warning system. Regardless of the warning, all disaster scenarios carry with them the possibility of many injured patients.

The overall response to a disaster used to focus just on rescuing victims at the scene of the disaster and delivering these victims to the hospital. It was assumed hospitals would always be there, ready to receive all victims. However, the events of September 11, 2001, the anthrax incidents in 2001, and the 2002/2003 SARS cases changed the rules that defined hospital disaster preparedness and response. Following Hurricane Katrina in 2005 and the 2009 H1N1 pandemic, the rules changed again. Currently, disaster preparedness in hospitals is shifting yet again to include internal workplace violence concerns, active shooters, and strategies surrounding Emerging Infectious Diseases. Hospitals need to be accessible, prepared, and functioning at

maximum capacity so that they are ready to respond to both external and internal events.

### Hospital Preparedness

Hospital preparedness for an MCI is a daunting task. Unique issues must be considered with each type of event. For example, a hospital response to a new highly infectious influenza virus is entirely different from the response to a chemical explosion. It is these differences that hold challenging implications for hospitals. Effectively planning an emergency response requires hospitals to address many details such as staff safety and availability of PPE, decontamination equipment and processes, surge capacity, evacuation plans, addressing mental health or psychosocial issues, debriefing plans, and maintaining readiness. Box 71.7 lists the many important details in hospital preparedness.

### Personal Protective Equipment

Personal protective equipment (PPE) is a means of protecting staff from hazardous materials (Fig. 71.8). At the first notice of an event, the hospital emergency planner or safety officer should evaluate the potential hazardous exposure of employees and provide the appropriate PPE. The selection of the appropriate PPE is a complex process and is based on a hazard assessment that (1) identifies the hazards or suspected hazards; (2) identifies the routes of entry of the potential hazard (inhalation, skin absorption, ingestion, and eye or skin contact); and (3) defines the performance of the

## Box 71.7 Hospital Preparedness

Disaster plans should address the following:

- Staff safety/personal protective equipment
- Decontamination equipment and processes
- Surge capacity
- Mental health
- Lockdown procedures
- Mass fatality management
- Evacuation
- Altered standards of care
- Allocation of scarce resources
- Mass employee medication prophylaxis
- Internal utility failure
- Workplace violence including active shooters
- Bomb threats
- Civil unrest

PPE materials in providing a barrier to these hazards. The potential exposure of hospital staff is usually a result of proximity to or contact with a patient whose skin and/or clothing may be contaminated with a hazardous substance.

### Level A PPE

Level A is the highest level of respiratory, eye, mucous membrane, and skin protection. This level provides protection against gas, vapor, liquid, and oxygen-deficient atmospheres. It includes a totally encapsulating chemical protective suit, often called a “moon suit,” with a self-contained breathing apparatus (SCBA), gloves, and boots. This level should be selected when the hazards are unknown or unquantifiable or when the greatest level of protection is required. It provides full protection against liquids and vapors. Generally, this level is not appropriate for hospital staff.

### Level B PPE

Level B provides the greatest level of respiratory protection but a lower level of skin protection than Level A. It differs from Level A in that the suit is not fully encapsulated and airtight, but it provides splash protection against liquids.

This level should be selected when the highest level of respiratory protection is necessary, but a lesser level of skin protection is needed. Level B consists of an SCBA, nonencapsulated chemical-resistant garments, gloves, and boots.

### Level C PPE

Level C provides the same skin protection as Level B but a lesser level of respiratory protection than Levels A and B. Level C consists of a nonencapsulated chemical-resistant suit (splash protection), air-purifying respirator (APR), gloves, and boots. Level C is used when the type of airborne exposure is known to be guarded against adequately by an APR.

### Level D PPE

Level D PPE consists of a surgical gown, mask, and gloves. It provides no additional protection for respiratory or splash hazards, only minimal protection for nuisance contamination.

### Decontamination

**Decontamination** is the reduction or removal of contaminating material from a person or equipment by water and mechanical processes. All hospitals must have the capability to provide some form of patient decontamination. Eliminating contaminants from a patient’s skin and clothing is important because it reduces the risk for further absorption or inhalation and helps to prevent others from becoming secondarily exposed or contaminated. During the decontamination procedure, the patient must be monitored for signs of decomposition. Antidotes or other medications may need to be given.

There are three goals for patient decontamination. First, hospitals must not allow contaminated patients to enter the facility. Hospital security staff needs to lock down the entrances and exits in order to protect patients and staff. Ideally, when medically appropriate, patients should be decontaminated at the incident scene. However, complete on-incident scene decontamination may not be possible because of the medical condition of the patient as well as weather conditions and equipment availability. This may

**FIGURE 71.8** Levels of personal protective equipment. Level A provides the highest level of respiratory, eye, mucous membrane, and skin protection. Level B provides the highest level of respiratory protection but a lower level of skin protection. Level C provides the same skin protection as Level B but a lower level of respiratory protection. Level D protects from nuisance exposure with mask, gown, and gloves.

require that decontamination sites and triage station be set up immediately outside the hospital ED. If needed, decontamination is carried out prior to triage. This arrangement is essential for security and safety reasons. Second, hospitals should decontaminate patients as rapidly as possible. This means the decontamination equipment must be easily deployable and the staff trained to set it up. Third, hospitals must plan to protect the decontamination team from secondary exposure and injury. This includes having enough decontamination suits, respirators, boots, and gloves on hand to sustain the facility for at least 24 hours with a cadre of staff rotating through the process.

Patient decontamination includes the following procedures:

- Remove the patient's clothing. In general, removing and bagging a patient's clothing eliminates 60% to 90% of the contaminants.
- Wet the patient's skin and wash with soap and water for 5 to 10 minutes. Gentle cleaning of the skin with soap and a soft cloth removes any remaining contaminants.
- Pay special attention to hair, face, hands, and other areas that were exposed but were not covered by clothing.
- Follow washing by a copious rinsing of the patient with tepid water.

Additional elements of decontamination include:

- Determining the level of PPE required for staff to wear.
- Controlling access to the decontamination site as well as the hospital.
- Having a container ready to receive contaminated clothing, valuables, and contaminated supplies.
- Ensuring screens are available for patient privacy.
- Ensuring a collection system for water runoff is available if needed.

The degree of decontamination performed depends on the situation. Anyone suspected of being acutely exposed to or contaminated by a toxic material—whether it is chemical, biological, or radiological—should be provided adequate decontamination.

### Surge Capacity

**Surge capacity** has been defined as the ability of a health-care system to “expand rapidly and to obtain adequate staff, beds, supplies, and equipment to provide sufficient care to meet the immediate needs of an influx of patients following a large-scale incident or disaster. Hospitals should have surge capacity plans in order to diffuse this imbalance of supply and demand.

### Hospital Evacuations

In the traditional approach to disasters, hospitals are viewed as sources of medical care for victims. However, it is important to remember that hospitals also are vulnerable to disasters and may need to close or evacuate depending on the circumstances. Evacuations may be necessary due to fire or damage from a natural disaster such as a hurricane, earthquake or flood. The decision to evacuate a hospital should

be based on the ability of the hospital to meet the medical needs of the patients. Hospitals should have in place plans for either a full or partial evacuation and those plans should be consistent with regulatory requirements. A full evacuation of a hospital should generally be considered a last resort. There are two types of hospital evacuations: “advanced warning events” and “no advanced warning events.”

### Advanced Warning Events

Hurricanes are the most common example of an advanced warning event. For example, several New Orleans hospitals evacuated their patients prior to Hurricane Katrina in 2005, and in September of 2017 at least 35 hospitals in Florida, Georgia, and South Carolina either closed entirely or ordered partial or complete evacuations ahead of Hurricane Irma.

With advanced warning events, the hospital incident commander has time prior to the event to make a decision but must remember there is a limited opportunity to evacuate. As the event draws nearer, the opportunity for a safe evacuation diminishes. Evacuation requires consideration of two factors: (1) the nature of the event, including its expected arrival time, magnitude, area of impact, and duration; and (2) the anticipated effects on both the hospital and the community. Once notified of an impending disaster, the hospital incident commander may decide to (1) preemptively evacuate the hospital while the hospital structure and surrounding environment are not yet compromised or (2) **shelter in place (SIP)**. Sheltering in place is defined as “the need to take immediate shelter in a current location. Shelter in place (SIP) is a rapid and effective way to protect the hospital occupants from an external or internal threat. External threats include: civil unrest or a chemical release. Internal threats include infrastructure damage from an earthquake, flood, or tornado. Since SIP plans will differ depending on the type of event it is important to have plans that are flexible and scalable. Plans should also define what happens to those persons “locked out” when the hospital is “locked down.” If the decision is made to shelter in place, as soon as possible after the event, the building's integrity, including the availability of critical utilities (water, sewer, electricity, and heating systems) requires assessment. The utilities must be assessed to determine whether the hospital can continue to provide safe, appropriate medical care or if a postevent evacuation may still be necessary. For example, following Hurricane Katrina, some New Orleans hospitals that did not evacuate prior to the event lost city water, lost all power, or were unable to ensure the safety of patients and staff in the midst of civil unrest. In this case, it was not the hurricane or the subsequent flood that caused the incident commander to order the evacuation, rather it was the damage to city infrastructures and the conditions in the surrounding community.

### No Advanced Warning Events

No advanced warning events include earthquakes, building fires, tornadoes, and explosions. Decisions must often be made very quickly in the midst of the disaster or immediately afterward.

## Evacuation

Regardless of the warning, successful hospital evacuation requires the symphonic coordination of personnel, transportation, communication and the tracking of patients and materials. Additional considerations during an evacuation include:

- *Sequences of the evacuation:* The most medically fragile and resource-intensive patients are usually evacuated first, as soon as appropriate transportation and staff are available. However, in cases in which all patients are in immediate danger and evacuation must be conducted as quickly as possible, some suggest that the most mobile patients should be evacuated first.
- *Urgency of the evacuation:* It is important to distinguish between an orderly and planned evacuation, in which there is time to move patients in a manner that maximizes safety for all, and a “drop-everything-and-go” evacuation, in which patients and staff are in immediate danger and must exit the unit and/or hospital as quickly as possible. Optimal procedures for safely moving patients may be abandoned in favor of the fastest possible egress.
- *Extent of the evacuation:* A hospital evacuation will be planned differently depending on whether the entire area/community is being evacuated or just one hospital. If just one hospital is being evacuated (e.g., because of a fire), patients can be more easily dispersed among nearby hospitals. In most metro areas, the transport would be for a distance of less than 10 miles, and ambulances could cycle back and forth moving patients.
- *Condition of hospital infrastructure:* Although unlikely to be a problem during an “orderly and planned” evacuation, egress from a hospital may be severely constrained during a “drop-everything-and-go” evacuation. Stairwells or exits may be obscured by smoke or unavailable because of fire. Stairwells may be dark if backup power has failed. Elevators can also be out of service, lengthening the time required to move all patients out of the hospital.
- *Types of patients:* Highly complex patients—especially intensive care unit and other specialty-care patients—may be difficult to place in the surrounding community.
- *Road conditions:* In a disaster where a community and more than one hospital are affected, evacuating transport destinations may be far away. Traffic-choked highways and the lack of refueling stations preventing ambulances from quickly cycling back for repeated evacuation trips could slow the evacuation process.
- *Transportation resources:* Transportation resources include not only the vehicles but also the staff, equipment, and supplies that must accompany the patient in the vehicle.

If a hospital is either fully or partially evacuated, plans should be in place for repopulation of the facility. These

plans should identify safety and operational considerations as well as regulatory agency requirements.

## Mental Health Considerations

For every person physically injured in a disaster, there are an estimated 4 to 20 psychological victims. The psychological casualties following a disaster may include those who cared for the victims of the disaster, including prehospital workers, ED staff, social workers, and pastoral care staff. In the aftermath of the September 11, 2001, attacks, the Psychiatric Department at St. Vincent’s Medical Center, just one of many healthcare facilities in the area, provided counseling to more than 7,000 patients and received more than 10,000 calls to its help line during the first 2 weeks. Hospitals need to make provisions to accommodate and manage these acute mental health needs.

## Debriefing

A postevent disaster debriefing should be held within 24 hours of the disaster response. This debriefing should include all participants in the disaster response. The purpose of the debriefing is to critically analyze all aspects of the response and to identify strengths and areas that need to be improved. Additionally, this debriefing allows hospital leadership to begin to identify staff who may need assistance recovering from the disaster response.

## Maintaining Readiness

Hospitals and other healthcare organizations must be prepared to handle a large influx of patients with any level of acuity from any disaster event. Disaster drills or disaster exercises are an integral element of preparedness and should be conducted twice yearly. A *disaster drill* or exercise is a controlled, scenario-driven experience designed to demonstrate and evaluate an organization’s capability to execute its Emergency Operations Plan (EOP). The goal during an exercise is to assess disaster processes and staff performance when systems are stressed during a simulated emergency. During the exercise, performance should be critiqued to identify deficiencies and opportunities for improvement facilitating modifications/improvements of the EOP. Disaster drills and exercises should test every aspect of the EOP including:

- Setting up the incident command center
- Receiving casualties
- Triage
- Testing communications systems, both internal and external, with response to agencies, including other healthcare organizations
- Evacuating and transporting patients
- Requesting and receiving emergency supplies
- Staff roles and responsibilities
- Utility management
- Safety and security
- Resources and assets, including the following equipment: decontamination, PPE, transportation, communication, and emergency supplies

**Safety Alert** To maximize the effectiveness of the drill, inject as much “reality” into the exercise as possible such as volunteer moulaged patients (using makeup to simulate injuries), donning PPE, and testing communication devices and messaging. It is also essential to ensure safety for all participants during the drill. To do this, two key elements must be in place:

1. All communications during the drill should start and end with “This is a drill.”
2. A safety officer with the sole responsibility to monitor and respond to any unsafe situations should be identified.

### Connection Check 71.6

Which of the following contributes to a successful hospital disaster response?

- A. Aggressive resuscitation efforts for patients without a pulse
- B. Immediate response for patients as soon as they arrive at the ED
- C. Appropriate PPE to protect staff from contamination
- D. Decontamination area located within the ED

## NURSE’S ROLE DURING A DISASTER

In the United States, nurses constitute the largest sector of the healthcare workforce and are on the front lines of any disaster response. When a disaster strikes, nurses must be ready and able to respond quickly and competently to the array of sudden new demands for care.

Nursing plays a role in all aspects of disaster preparedness, response, and recovery. Nursing plays a major role in mass casualty triage, helping to ensure patients get the most appropriate level of care. This includes differentiating as quickly and as accurately as possible between physiological victims of the event and the “worried well” and manage each appropriately. Nursing also plays a role in putting disaster response plans into action, evacuation, and decontamination when necessary. Obviously, nursing plays a major role in treatment: patient stabilization, medication administration including antidotes or prophylaxis where necessary, and routine or emergency care as part of the healthcare team, as dictated by the patient’s condition. Nursing also provides supportive care and mental health support to victims of the disaster.

A great distracter to a nurse’s participation in a disaster response is worrying about family and significant others. Staff members whose roles are considered essential must feel comfortable that their family members know what to do in the event of a disaster. Box 71.8 lists some essential elements to be considered in developing a personal/family disaster plan. Comprehensive family disaster planning information is available from the American Red Cross and FEMA.

### Connection Check 71.7

Which of the following items is an essential component of your personal disaster plan?

- A. Water
- B. Fresh fruit
- C. Reading material
- D. Hazard flares

## Box 71.8 Personal/Family Disaster Planning

### Disaster Supply Kit

1. Water for 3 to 5 days (remember water for pets also); a normal person needs 2 quarts of water per day
2. Cans of food
3. Food items such as nuts, dried fruit, and other packaged snacks
4. Blanket, small pillow
5. Inflatable bed (may be used as a float if needed)
6. Closable waterproof plastic bags
7. Backpack for carrying items
8. Battery-operated radio (change the batteries every 6 months)
9. Medications to sustain 14 days
10. Personal hygiene items
11. Extra eyeglasses
12. Manual can opener
13. Flashlight with extra batteries
14. Face masks to protect from dust
15. Traffic flares
16. Duct tape and scissors
17. Whistle
18. Plastic sheeting
19. Work gloves
20. One complete change of cloths
21. Heavy duty plastic garbage bags and ties—for personal sanitation uses—and toilet paper
22. Compass
23. Waterproof matches
24. Waterproof markers (used to write a young child’s name, address, phone number, and next of kin number on children’s feet)
25. Over-the-counter medications for diarrhea, headache, nausea, and vomiting
26. Basic first aid kit
27. Cell phone charger
28. Water purifier kit
29. Sunscreen and insect repellent
30. Cash

*Continued*

## Box 71.8 Personal/Family Disaster Planning—cont'd

### Home

1. Draw a floor plan of your home. Mark two escape routes from each room.
2. Make sure everyone in the household knows how to shut off water, gas, and electricity at the main switches.
3. Post emergency phone numbers by the telephones. Teach children how and when to call 911.
4. Identify two meeting places: The first should be near your home in case of fire; the second should be away from your neighborhood in case you cannot return home.
5. Keep car gas tank filled.

### Documents\*

1. Birth certificates
2. Immunization records

3. Homeowners insurance policy with contact information
4. Health records
5. Driver license copy
6. Complete list of medications
7. Copies of health insurance cards
8. All emergency phone numbers for family
9. List of all credit card numbers

### Other

1. Consider ways to help neighbors who may need special assistance, such as the elderly or the disabled
2. Make arrangements for pets. Most pets are not allowed in public shelters
3. Identify an out-of-state family member or friend so all your family members have a single point of contact.

\* Consider laminating all documents so they are waterproof

## Making Connections

### CASE STUDY: WRAP-UP

The response within St. John's Hospital went well. When the tornado warning was issued for Joplin, the hospital activated "Code Gray," its tornado response plan. Staff members simply did what they had to do. Patients were moved into safe areas if possible, and the staff braced for the impact. Very shortly after the tornado passed over the hospital, officials decided that the hospital was unsafe and they needed to quickly evacuate their 183 patients. Because elevators were not operating, patients were carried down up to 10 flights of stairs without overhead lighting or air-conditioning. Staff and visitors carried fragile patients down blackened hallways guided by the dim lights of their cell phones. Patients were carried on backboards, canvas slings, doors, wheelchairs, wooden chairs, sheets, and even sagging mattresses. The hospital did attempt to discharge as many patients as possible, but there was nowhere for these patients to go because of the destruction in the surrounding community and the road conditions.

In moving the patients out of the hospital, the first challenge was knowing where and how to start. The patients needed to get to facilities that could handle their medical conditions.

The roads surrounding the hospital were mostly covered with debris, and the heliport was unusable. Plus, landlines and cell phone towers were destroyed, making communication difficult. Fortunately, the city's other hospital was close and had suffered little damage from the tornado, so it was able to accept patients. Ten hospitals in Missouri also accepted patients from St. John's, as did hospitals in nearby Arkansas, Kansas, and Oklahoma.

The hospital staff loaded patients on pickup trucks and did whatever they could to get them to safety. Dozens of ambulances

from towns as far as 100 miles away came to offer assistance. Strangers rushed to the hospital in convoys of pickup trucks to help evacuate patients. Within 90 minutes, all the patients were evacuated, and by 2 a.m., the situation at the hospital was largely under control.

Tragically, in Joplin, despite a 24-minute advanced tornado warning, 160 people died and more than 1,000 were injured. There were a number of people who did all the right things, took shelter in the best available place, but still found themselves in situations that weren't survivable; however, given the scale of destruction in Joplin, it is a wonder that more people were not killed or injured. The tornado offers many important lessons about disaster preparedness. The National Weather Service final report had several observations and recommendations.

First, tornado warning communications should be improved to convey a sense of urgency for extreme events. This will compel people to take immediate lifesaving action. Since the first tornado forecast was made in 1948, tornado warning lead times have been increasing and now average 13 minutes; however, societal response to a tornado warning is highly complex and involves a number of factors, such as risk perception and overall credibility of the warning. There is a 70% false tornado alarm rate. Because of this "tornado warning fatigue," the vast majority of Joplin's residents either ignored or were slow to react to the first warning sirens and did not immediately take protective action. To help improve communication, partnerships should be established with technology to develop global positioning system-based warning communications, including the use of text messaging, smart phone applications, and social media. For instance, the City of Joplin used both traditional mechanisms and social media (e.g., Facebook, Twitter, and YouTube) to communicate emergency information to the public.

Second, preparedness is key. Participation in the National Level Exercise 2011 helped to prepare federal, state, regional, local, and private sector personnel to respond effectively. Finally, volunteer effort is essential. It was key in the rapid evacuation of Mercy/St. John's Hospital. Also, on the lighter side, volunteer organizations established a mass shelter for thousands (1,308) of animals made homeless by the tornado.

### Case Study Questions

- What aids communication of a potential tornado?
  - Frequent tornado warnings
  - Communication only when the tornado is visible
  - Social media, text messaging, phone apps
  - Loud sirens
- What is the average number of minutes of warning time forecasters can give before a tornado strikes?
  - 90 minutes
  - 60 minutes
  - No advanced warning is possible.
  - 13 minutes
- What is the difference between a tornado watch and a tornado warning?
  - A tornado watch means that a tornado has been spotted. A tornado warning means conditions are good for a tornado to form.
  - A tornado watch defines an area where tornadoes are possible in the next several hours. A tornado warning means that a tornado has been spotted or that Doppler radar shows a thunderstorm circulation that can spawn a tornado.
  - A tornado watch defines an area where tornadoes are possible in the next 48 hours. A tornado warning means a tornado has been spotted.
  - A tornado watch and a tornado warning mean the same thing. They mean conditions are good for a tornado to form.
- What is the average number of tornadoes in the United States each year?
  - 500
  - 5,000
  - 10,000
  - 1,000
- Which of the following actions at St. John's Hospital helped the most in the smooth response to the Tornado?
  - Preparedness due to frequent practice
  - Quickly moving patients in darkened hallways
  - Quickly moving patients in available transportation
  - Volunteerism from the community

## CHAPTER SUMMARY

No country or community is immune to disasters. The last part of the 20th century and the first few years of the 21st century have witnessed an increase in both natural and man-made disasters. A disaster is defined as "a serious disruption of the functioning of a community or a society causing widespread human, material, economic or environmental losses which exceed the ability of the affected community or society to cope using its own resources." A mass casualty incident is any large-scale event in which emergency medical resources such as supplies, medical/rescue personnel, or equipment are overwhelmed by the number and severity of casualties, thus requiring prioritization of medical care by triage. All disasters are not mass casualty events, but all mass casualty events are disasters.

Disasters are commonly categorized by their origin: natural events, nuclear and radiological events, bioterrorism/emerging infection incidents, chemical incidents, and explosive/blast event incidents. Natural disasters can be classified as acute or slow in their onset. Natural disasters with a slow onset include blizzards, drought, famine, and pest infestation. Those with an acute onset include floods, earthquakes, tsunamis, tornadoes, volcanic eruptions, and hurricanes. Exposure to radiation, infection, and chemicals produce different clinical manifestations. Patients with radiation exposure, for example, present with loss of appetite, fatigue, fever, nausea, vomiting, diarrhea, and possibly even seizures and coma. They also have some skin damage that includes swelling, itching, redness of the skin (like a bad sunburn), and hair loss.

The National Response Framework is the disaster plan for the nation. This document establishes a comprehensive, national, all-hazards approach to domestic incident response, from the smallest incident to the largest catastrophe. The framework identifies the key response principles as well as the roles and structures to support the plan.

The incident command system (ICS) is an organizational tool that is used to provide the management infrastructure to support the disaster response. The ICS's roles include:

- Incident commander responsible for all aspects of the response
- Chief of operations responsible for all tactical operations
- Planning chief responsible for continuously evaluating the response and "keeping ahead of the disaster"
- Logistics section chief responsible for obtaining and providing services and resources, obtaining equipment needed, and staff support
- Finance/administration chief responsible for documenting all financial costs of the incident

During the last three decades, the field of disaster management has evolved into a respected profession, and nursing personnel working in these emergencies have proven to be key agents in both the response and recovery phases of disasters. When a disaster strikes, nurses must be ready and

able to respond quickly and competently to an array of sudden, new demands such as triaging casualties, assisting with lifesaving care, administering medications, participating or coordinating decontamination or evacuation, and helping ensure positive patient outcomes across a wide range of injuries and conditions. Staff members whose roles are considered essential must also develop a personal/family disaster plan to be certain that their family members know what to do in the event of a disaster.

Since September 11, 2001, much has changed in our world and the nation. We have become more aware of the devastation that can be caused by disasters, no matter the cause. Each individual, family, and community needs to take steps to prepare for a possible disaster. In every community there are several organizations that lead the way to prepare for and recover from a disaster should one strike. An important part of personal disaster preparedness is becoming involved your community disaster organizations.
